E.Kampar and O.Neilands

The principal methods for the determination of the degree of charge transfer are examined and experimental data on the intermolecular distribution of electron density in charge-transfer complexes and radical-ion salts of the $\pi-\pi$ are surveyed. The relation between the degree of charge transfer and the ionisation potential of the donor, the half-wave potential in the anodic oxidation of the donor, and the electron affinity and the polarographic reduction potential of the acceptor, which largely determine the degree of charge transfer in donor-acceptor systems of the $\pi-\pi$ type, is discussed.
The bibliography includes 104 references.

## I. INTRODUCTION

The interaction of a π-electron donor with a π-electron acceptor is accompanied by an intermolecular redistribution of electron density. All the properties of the system as a whole depend on the effectiveness of this process, which is characterised by the degree of charge transfer (CT). Weak $\pi-\pi$ complexes exhibit semiconducting and photoconducting properties.[1-3] Systems with a degree of CT within the limits 0.4–0.7 frequently behave as organic metals, while a further increase of the degree of CT again leads to a semiconductur.[6-13] The degree of CT should therefore be regarded as one of the most important characteristics of the donor–acceptor system.

The main textbooks and reviews on donor–acceptor interaction[14-19] include only fragmentary data on the determination of CT in systems of the $\pi-\pi$ type. Theoretical ideas concerning the laws governing the variation of the degree of CT are considered in the present review for the first time and the experimental data on systems of the $\pi-\pi$ type which have accumulated are also discussed.

## II. DEGREE OF CHARGE TRANSFER AND METHODS FOR ITS DETERMINATION

According to Mulliken,[15] the behaviour of a donor–acceptor system can be described by the following wave function:

$$(D, A) \quad (D^+ - A^-)$$

where $\psi_0$ is the wave function of a hypothetical structure in which only the van der Waals interaction obtains and $\psi_1$ the wave function of a hypothetical "dative" structure in which one electron has been transferred from the donor to the acceptor and there is a semipolar bond between the donor and the acceptor, but it need not necessarily be of the localised interatomic type. An increase of the fraction of electron density transferred from the donor to the acceptor corresponds to an increase of the coefficient $b$. The quantitative characteristic of this process is the resulting charge or degree of CT ($\delta$). The degree of CT is expressed[15] as $\delta = b^2 + abS_{01}$, where $S_{01}$ is the overlap integral of the wave functions $\psi_0$ and $\psi_1$. Some workers define the degree of CT as $b^2$ or $b^2/(a^2 + b^2)$,[14] which leads to results in agreement with Mulliken's approach[15] only for very low values of $\delta$.

Thus Mulliken's approach is based on the idea of a partial charge transfer: the real system is assumed to be, as it were, made up of two extreme structures. An analogous interpretation follows from the calculation for the intermolecular complex as a "supermolecule" by the LCAO-MO method.[20-29] As a consequence of the formation of molecular orbitals delocalised over the entire supermolecule, an intermolecular charge distribution takes place and partial resultant charges arise on both the donor and the acceptor. In the determination of this resultant charge, the same difficulties arise as in the determination of atomic charges in calculations for the usual molecules.

A different model is frequently used to describe the properties of crystalline donor–acceptor systems. According to this model, the donor–acceptor system represents a mixture of real donor–acceptor pairs with zero and total charge transfer. The degree of CT or the amount of ionic character is defined as the ratio of the number of pairs with total charge transfer to the total number of donor–acceptor pairs.[6] Although this model differs fundamentally from the previous ones, as regards numerical values it apparently yields the same results as Mulliken's model.

The method of dipole moments, nuclear quadrupole resonance (NQR), X-ray electronic spectroscopy (XES), infrared spectroscopy (IR), Raman spectroscopy (RS), and quantum-chemical calculations are usually employed to determine the degree of CT.[6,14,16,20] The method dipole moments is one of the main ones and has been considered in detail.[16] The dipole moment is a general characteristic of the complex, characterising the charge distribution over the complex as a whole. The experimenqally determined dipole moment of the complex is ususally regarded as the vector sum of the dipole moments of the donor, the acceptor, and the donor–acceptor bond (with a specified geometry of the complex). However, the formation of the complex may be accompanied by a change in the dipole moments of the components and can be also complicated by the formation of complexes of different geometry; this greatly hinders a correct estimation of the dipole moment of the donor–acceptor bond in the study of complexes with a slight degree of CT. The application of the method of dipole moments to the study of weak $\pi-\pi$ complexes is therefore coupled with considerable difficulties.[16,30]

In contrast to the dipole moment method, the NQR method[20] yields information about the local distribution of valence

electrons at the sites where nuclei with a quadrupole moment are located, which must be regarded as a major advantage of the NQR method. However, an exact interpretation of the experimental resonance frequency shifts is not always possible, since the quadrupole interaction constants depend not only on the distribution of valence electrons but also on the contribution by the remaining electrons of the atom involved in resonance, on the degree of hybridisation, on the influence of the crystal field, and on the thermal movement of the molecules. For low degrees of CT, the last effects in fact predominate; analysis of the experimental data obtained in a study of weak $\pi-\pi$ complexes by the NQR method has shown[31] that the influence of the CT on the resonance frequency shift can be fully swamped by the crystal field effects. It is therefore virtually impossible to obtain the quantitative characteristics of the degree of CT for weak complexes by the NQR method.[32]

X-Ray electronic spectroscopy is based on the parallel variation of the effective charges of the atoms investigated and of the shift of their lines in the X-ray electronic spectrum or on the characteristic change in band shape.[33] The principles of the method have been considered in fair detail by Poleshchuk and Maksyutin[20] and Ikemoto et al.[33] One must note that information about the redistribution of valence electrons on complex formation is obtained in this instance from the change in the ionisation potential of the inner electrons, whose ionisation is accompanied by an appreciable reorganisation of the electron shell. Since the decrease of the energy of the ion as a consequence of the reorganisation of the electron shell can exceed by an order of magnitude the change in the ionisation potential due to the redistribution of valence electrons, the interpretation of the experimental data may prove to be very difficult. In practice, this problem is solved by means of a preliminary study of a series of related complexes in which the degree of CT is known beforehand. However, it is clear that the XES method is relatively unsuitable for the study of complexes with an insignificant degree of CT and complications can also arise in the investigation of donor–acceptor systems with a considerable charge transfer.

The IR and Raman spectroscopic methods have not so far found extensive applications in the determination of the degree of CT. IR spectroscopy is used in the study of $\pi-\pi$ complexes as a rule only for the qualitative investigation of the characteristics of the structure of the complex, i.e. it helps to establish whether the intermolecular associated species investigated is a true charge transfer complex (CTC) or a radical-ion salt, whether proton transfer takes place, etc.[14–17,34–40] This is due to the fact that the changes observed in the IR spectra on passing from a weak complex to a radical-ion salt are much more significant than the differences between the spectra of the isolated components and the weak complex or between the spectra of two different weak complexes. However, even the formation of weak $\pi-\pi$ complexes leads to the observation of a number of changes in the spectra,[40] which carry information about the electronic structure of the CTC. Since IR spectroscopy as a method for the determination of the degree of CT has not yet attracted the attention of investigators which it deserves, we believe it necessary to consider in somewhat greater detail the characteristic features of the IR spectra of the CTC.

On formation of the CTC, the following changes may be observed in the IR spectra: the appearance of "forbidden" vibrations of the donor and acceptor and of new vibrations of the donor–acceptor bond and also a spectral shift and a change in the integral intensities of the allowed vibrations of the donor and acceptor.

The appearance of forbidden vibrations of the components in the IR spectrum of the complex is not frequently observed.[41] One of the instances thoroughly investigated in this respect is the CTC of tetracyanoethylene.[42–45] A band appears in the IR spectrum of the hexamethylbenzene–tetracyanoethylene CTC at 1561–1565 $cm^{-1}$, which is due to the $A_{1g}\nu(C=C)$ vibrations of tetracyanoethylene. The study of polarised IR spectra of the CTC single crystal showed that these vibrations are active when the electric field vector of the polarised radiation is directed at right angles to the planes of the donor (D) and acceptor (A) molecules along the alternating DADA stack.[42,45]

This conclusion is satisfactorily consistent with the Ferguson–Person–Friedriech model,[46] which envisages a delocalisation effect on the oscillation of the charge in the direction of charge transfer during vibrations in the plane of the donor or acceptor molecules. In the case of the 2:1 hexamethylbenzene–tetracyanoethylene CTC, two new bands appear in the IR spectrum (at 1567 and 1295 $cm^{-1}$), polarised at right angles to the planes of the donor and acceptor molecules. The latter band refers in all probability to the fully symmetrical vibrations of the $C(CH_3)$ group of hexamethylbenzene. In the spectra of the hexamethylbenzene–hexacyanobenzene, phenanthrene–hexacyanobenzene, and 1,3,5-trimethoxybenzene–hexacyanobenzene complexes, a new band appears at 1300 $cm^{-1}$ and is apparently due to the $A_{1g}\nu(C-C)$ vibrations of hexacyanobenzene, which are manifested in the Raman spectra at 1310 $cm^{-1}$.[47]

Notation: $\nu$ are the frequencies of the vibrations of the corresponding groups in the "free" donor or acceptor; $\Delta\nu$ are the shifts on complex formation. BQ = 1,4-benzoquinone, TCNE = tetracyanoethylene, TCNQD = 7,7,8,8-tetracyanoquinodimethane, TNB = *sym*-trinitrobenzene, and CA = *p*-chloranil.

* Vibrations of the functional groups of the donor; in all the remaining cases the vibrations are those of the corresponding groups of the acceptor.

Few studies have been devoted to the intermolecular D–A vibrations[41] despite the fact that they might yield information about both the strength of the D–A bond and about the degree of CT. This is apparently due to the difficulty of the experimental measurement of absorption bands in the region of 100 $cm^{-1}$ and of the interpretation of the results. For example, a band has been observed at 115 $cm^{-1}$ in the spectrum of the mesitylene–tetracyanoethylene CTC in solution in the donor and was assigned to intermolecular vibrations.[48] Later doubts arose about the correctness of this assignment, since intramolecular vibrations of the acceptor are manifested in this region of the spectrum.[41] More extensive studies on tetracyanoethylene complexes have been carried out by Rossi and Haselbach,[49] who concluded that intermolecular vibrations are indeed observed in the range 80–100 $cm^{-1}$. Both the forbidden vibrations and the D–A vibrations carry information about the degree of CT, but the use of this information for the determination of the degree of CT has not so far been reliably achieved.

Spectral shifts of the allowed absorption bands of the CTC components are almost always observed on formation of crystalline CTC. The magnitude of the shift of the vibrational bands does not then ususally exceed 5–10 $cm^{-1}$ (Table 1) and amounts to more than 20 $cm^{-1}$ only on formation of radical-ion salts.[60]

It is noteworthy that the spectral shift on complex formation has been used by some workers for a kind of classification of donor–acceptor systems. For example, it has been suggested[61] that all the CTC derived from *p*-benzoquinone can be divided into three types depending on the shift of the $\nu$(CO) and $\nu$(CC) stretching vibration bands.

Theoretical ideas about the influence of complex formation on IR spectra have been developed on the basis of several models.[14,15,41,62] At present there is no generally accepted theory taking into account the influence of both the "classical" forces and the CT forces on the spectroscopic parameters of the complex. According to Mulliken's theory,[15] intermolecular charge transfer should be accompanied both by a shift of the allowed bands in the IR spectrum and by a change of their integral intensity. If the band shifts are insignificant, then the relation between $\Delta\nu$ and the degree of CT ($\delta$) is described by the equation:[15,58]

$$\delta = \frac{2\Delta\nu}{\nu_0}\left[1 - \frac{\nu_1^2}{\nu_0^2}\right]^{-1} , \qquad (1)$$

where $\nu_0$ and $\nu_1$ correspond to the positions of the band investigated in the spectra of the "free" component and its radical-ion respectively. It has been shown experimentally that in the case of the TCNQD complexes [there is a shift of the $\nu$(CN) band], for example, Eqn.(1) assumes the following form:[58,59]

$$\delta = 43.5 \cdot \Delta\nu/\nu_0 . \qquad (2)$$

A corresponding equation has been obtained in another study[60] from the experimental band shifts in the spectra of CTC and radical-ion salts with a comparatively high degre of CT known beforehand:

$$\delta = \Delta\nu/44 . \qquad (3)$$

Eqns.(2) and (3) lead to close results, although the degree of CT obtained from Eqn.(2) is lower by 12%. This suggests that the approximation in the form of Eqn.(1) is fairly well-founded and the equation can be used to calculate the degree of CT in other donor–acceptor systems, for example, in a tetracyanoethylene complex.[63] Using the literature data,[64–69] it is possible to obtain equations for the calculation of the degree of CT from the shift of the CO vibration bands in the spectra of the CTC of *p*-benzoquinone and 2,3-dibromo-5,6-dicyano-*p*-benzoquinone:

$$\delta = 11.2 \cdot \Delta\nu/\nu_0 ,$$
$$\delta = 16.6 \cdot \Delta\nu/\nu_0 .$$

The influence of complex formation on the integral intensities of the stretching vibration bands is in the general case more complex.[15] The band intensity is determined by the so-called "$M_{0,1}$ term" which depends both on the change of the dipole moment $\mu_N$ and on the "delocalisation" moment $M_d$, i.e. on the vibronic interactions:

$$M_{0,1} = \partial\mu_N/\partial Q_i + M_d .$$

The quantity $M_d$ may differ from zero if the following parameters change as a consequence of the vibrations investigated: the intermolecular donor–acceptor distance, the ionisation potential, the electron affinity, or the overlap integral $S_{01}$. If the vibrations investigated do not entail such changes, then $M_d = 0$. The term $M_{0,1}$ may be expressed by the dependence on the dipole moments of hypothetical "without bond" and "dative" structures:[15,57]

$$\delta = \frac{A_N^{1/2} - A_0^{1/2}}{A_1^{1/2} - A_0^{1/2}} , \qquad (4)$$

where $A_N$, $A_0$, and $A_1$ are the integral intensities of the stretching vibrations studied in the spectra of the complex, the hypothetical structure "without bond", and the "dative" structure respectively. If one studies, for example, the stretching vibrations of the acceptor, then $A_0$ and $A_1$ should be approximately equal to the integral intensities of the bands due to the given vibrations in the spectra of the "free" acceptor and its radical-anion respectively.[57–59]

It has been suggested[57–59] that Eqn.(4) can be almost always used in the study of the asymmetric vibrations of functional groups in the plane of the donor or acceptor in complexes of the $\pi-\pi$ type, since this should entail virtually no changes in the ionisation potential, the electron affinity, the donor–acceptor distance, and $S_{01}$. The validity of this hypothesis has been confirmed by the results of a study of single crystals of donor–acceptor systems using polarised infrared radiation.[45,55] It was established that the allowed stretching vibrations remain polarised in most cases virtually only in the plane of the component molecules of the CTC; consequently the contribution of the delocalisation moment is indeed insignificant. The stretching vibrations of the CO and CN groups in the CTC of quinones and tetracyanoethylene respectively belong to the above type.[45,55] On the other hand, certain vibrations involving the entire electronic system of the acceptor are polarised also along the DADA stack—for example, the CC vibrations in the 1,4-chloranil molecule (band at 1245 $cm^{-1}$).[45]

A change in the intensities of the bands due to allowed vibrations of the CTC components has been noted in a number of studies and has been used to investigate the CTC of $\sigma$-acceptors.[41] On the other hand, in the case of $\pi-\pi$ complexes the change in the intensities of the allowed vibration bands of the components has so far been used only in a few instances,[56–58,61] although it has been noted in a series of studies that this change is associated with CT from the donor to the acceptor.[45,47,55] It has been established[57] that the change in the integral intensities of the stretching vibration bands of the cyano-groups in the TCNQD spectrum is a more sensitive parameter than the spectral shift and an expression has also been obtained for the calculation of the degree of CT:

$$\delta = \frac{A_N^{1/2} - A_0^{1/2}}{2.8} . \qquad (5)$$

Eqn.(5) has been used to determine the degree of CT in both two-component donor–acceptor systems and in three-com-

ponent donor–acceptor–solvent systems.[57–59] The influence of the universal intermolecular interactions on the spectroscopic properties of the acceptor has been taken into account by studying under the same conditions a model compound which does not form CTC. The data thus obtained agree well with the results secured by other methods.

Among the methods for the determination of the degree of CT, mention should also be made of X-ray diffraction analysis (XDA) and electronic absorption spectra (EAS). The use of the XDA method is based on the characteristic changes in the geometry of the acceptor or donor when a neutral compound is converted into its radical-ion.[70–72] The EAS method is based on the measurement of the integral intensities of the CT bands in the ultraviolet absorption spectra:[14,73–75]

$$b^2 = \frac{f}{1.085 \times 10^{11} h\nu_{CT} R_{DA}^2},$$

where $f$ is the oscillator strength of the electronic transition, $h\nu_{CT}$ the CT energy ($cm^{-1}$), and $R_{DA}$ the intermolecular distance (cm). This equation has been used to determine the degree of CT[14,15,73–75] from the electronic spectra of various complexes in solutions and in the crystalline state (it is essential to take into account the change in $f$ on passing to the crystalline state). The EAS method apparently yields reliable results in the study of CTC with a low degree of CT, for which the energy of the local transitions in the CTC components differs sufficiently from the CT energy.

Electronic spectroscopy can be used to determine the degree of CT from the shfit of the CT band maxima on changing the solvent.[76]

Apart from the methods for the determination of the degree of CT mentioned above, others are also used,[77,78] among which mention should be made of the elastic scattering of neutrons[79] and the measurement of the temperature dependence of the magnetic susceptibility.[80]

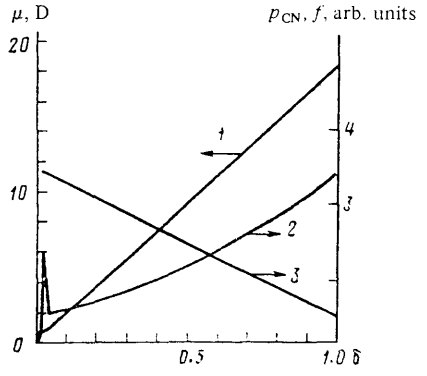

**Figure 1.** The calculated dependence of the dipole moment μ (line *1*), the oscillator strength $f$ (line *2*), and the CN bond order $P_{CN}$ (line *3*) on the degree of CT for model 7,7,8,8-tetracyanoquinodimethane complexes.[21]

The accuracy and reliability of the above methods are fairly difficult to estimate. Nevertheless, the results of calculations for the model complexes of 7,7,8,8-tetracyanoquinodimethane by the LCAO-MO method in the CNDO/S valence approximation give rise to the possibility of such analysis.[21] Fig.1 shows that the results of the calculation confirm the extremely high sensitivity of the dipole moment method. One should note that the $z$ component of the dipole moment (the selected geometry of the complex is characterised by the fact that the donor has been displaced relative to the acceptor along the $C_{2v}$ axis) is directly proportional to the degree of CT throughout the region. The overall dipole moment of the complex may differ from zero also in the absence of CT; one must therefore assume that the dipole moment method can be used with a high degree of accuracy for the study of complexes in which the degree of CT exceeds 0.03. Fig.1 shows that the EAS method based on the measurement of the integral intensities is probably comparatively unreliable. Its application is justified only in those cases where it is known that the transition accompanied by charge transfer does not interact with electronic transitions of another type.

One must assume that IR spectroscopy is a reliable method for the determination of the degree of CT, since, throughout the entire range of variation of the degree of CT, an approximately linear relation is observed between the degree of CT and the order of the bonds formed by the cyano-groups of the acceptor (Fig.1). However, one must note that this method can be used successfully only in those cases where the degree of CT exceeds 0.03, since the bond order hardly changes when δ varies in the range 0.01–0.03.

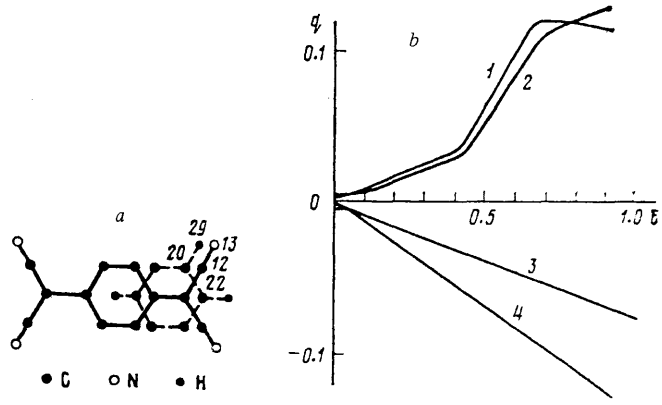

Figure 2. The selected geometry of the complex (*a*) and the dependence of the effective charges $q$ on the individual donor atoms [1) C(20); 2) H(29)] and acceptor atoms [3) N(13); 4) C(7)] (*b*) on the degree of CT for model 7,7,8,8-tetracyanoquinodimethane complexes (calculation by the LCAO-MO method).[21]

Extremely interesting results have been obtained by comparing the degree of CT with changes in charge density on individual atoms of the charge-transfer complex. It was found that the relation between the characteristics investigated is not described in all cases by a simple linear equation (Fig.2). One should also note that in the region of weak CTC ($\delta < 0.05$) the changes in charge density are insignificant and may even prove to be the opposite to those expected [for example, the charge density on the C(22) atom of the donor increases slightly with decrease of δ]. It is therefore clear that all the methods for the determination of the degree of CT based on the measurement of parameters depending on the charge density on individual atoms can be used only for $\delta \geq 0.03–0.05$. The possibility of a non-linear relation between δ and $q$ makes it necessary, in its turn, to treat

the results obtained by these methods with a certain amount of caution at least in those cases where the experimental determination of the above relation has not been carried out for a sufficiently large number of examples in which the degree of CT was known beforehand.

Thus, one must conclude that the dipole moment and IR spectroscopic (and also RS) mrthods are the simplest and most reliable, but apparently there is as yet no reliable method for the determination of the degree of CT for $\delta \leqslant 0.03$.

## III. THEORETICAL IDEAS CONCERNING THE DEPENDENCE OF THE DEGREE OF CHARGE TRANSFER ON THE CHARACTERISTICS OF THE SYSTEM COMPONENTS

Mulliken's theory[15] yields several simple approximate equations describing the dependence of the degree of CT on the difference between the ionisation potential of the donor $I_D$ and the electron affinity of the acceptor $EA$. Among them, mention should be made of the equation

$$\delta^{1/2} \simeq b \simeq \frac{CS_{01}}{I_D - EA - E_c} , \qquad (6)$$

where $C$ is a constant for the CTC of the given type and $E_C$ the energy of the Coulombic interaction of the oppositely charged species in the excited state of the $(D^+, A^-)$ complex ($E_C \cong 3$–$3.3$ eV).

The following expression can also be obtained from Mulliken's theory:[15]

$$\left[\frac{1-\delta}{\delta}\right]^{1/2} \simeq -\frac{1}{\beta_0}(I_D - EA) + \frac{E_c}{\beta_0} , \qquad (7)$$

according to which the comparatively simple function of $\delta$ is approximately linearly related to the difference $I_D - EA$.

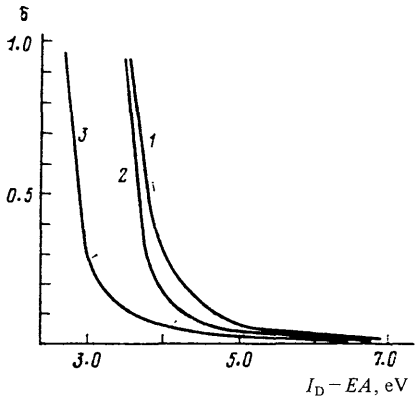

Figure 3. Dependence of the degree of CT on the difference between the ionisation potential of the donor and the electron affinity of the acceptor according to Mulliken's theory [1) $c^2S_{01} = 0.1$, $E_C = 3.2$ eV; 2) $c^2S_{01} = 0.16$, $E_C = 3.2$ eV] and the molecular orbital method in the CNDO/S valence approximation (curve 3).[21]

Although the above equations describe fairly satisfactorily the behaviour of a real system only for a comparatively small degree of charge transfer, they can be used successfully for a preliminary study of the dependence of the degree of CT on the characteristics of the CTC components (Fig.3).

Fig.3 also illustrates a relation obtained in calculations for model complexes,[21] which is represented by a function of the difference between the energies of the frontier molecular orbitals of the complex. Evidently Eqn.(6) and calculations by the LCAO-MO method predict the existence of a range of critical values of the difference $I_D - EA$, in which a comparatively sharp transition from the CTC to the radical-ion state should be observed.

Initially examination of this relation for mixed DADA stacks in the crystalline state[81–83] led to somewhat different results, according to which there exists not a critical region but a critical value of the difference $I_D - EA$ for which an abrupt transition to the radical-ion state should be observed. However, it has been shown[6,84] that a sharp increase of the degree of CT also in the crystalline state takes place likewise over a specific range of values of the above difference (Fig.4). It has been noted[6] that this range is in fact of greatest practical interest.

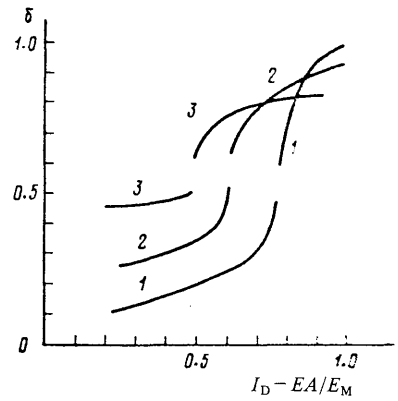

Figure 4. Characteristic form of the dependences of $\delta$ on $I_D - EA/E_M$ for different ratios $\beta/\gamma$ ($\beta$ and $\gamma$ are the resonance and Coulombic integrals respectively): 1) 0.1; 2) 0.3; 3) 0.5.[6]

In crystals consisting of individual alternating stacks of D and A, the degree of CT is also not always unity.[6,83] For the majority of the complexes considered, the state of the system is described by the expression $E(\delta) = E_M(\delta) + (I_D - EA)\delta$, where $E_M$ is the Madelung energy. Other conditions being equal, this should lead to approxomately the same dependence of $\delta$ on the difference $I_D - EA$ as that illustrated in Fig.4.

## IV. EXPERIMENTAL DATA

The majority of the experimental determinations of the degree of CT available at present for donor–acceptor systems of the $\pi$–$\pi$ type both in solutions and in the crystalline state are listed in Table 2. It follows from these data (Fig.5) that the experimental results agree satisfactorily with the theoretical predictions (Fig.3). The fairly considerable scatter of the experimental points is due to the experimental errors in the determination of $I_D$ and $EA$ and also to the approximate nature of the equations (which do not take into account the changes in $S_{01}$, $E_C$, and $E_M$ on passing from one donor–acceptor system to another). Despite this, it is seen

from Fig. 5 that the transition from weak CTC to a state with almost total CT does not take place abruptly but in a certain transition region in the range $3.8 \leqslant I_D - EA \leqslant 4.3$ eV. The region $3.5 \leqslant I_D - EA \leqslant 4.1$ eV corresponds to donor-acceptor systems with the properties of quasi-one-dimensional metals, since these systems are characterised by a considerable but not complete CT.

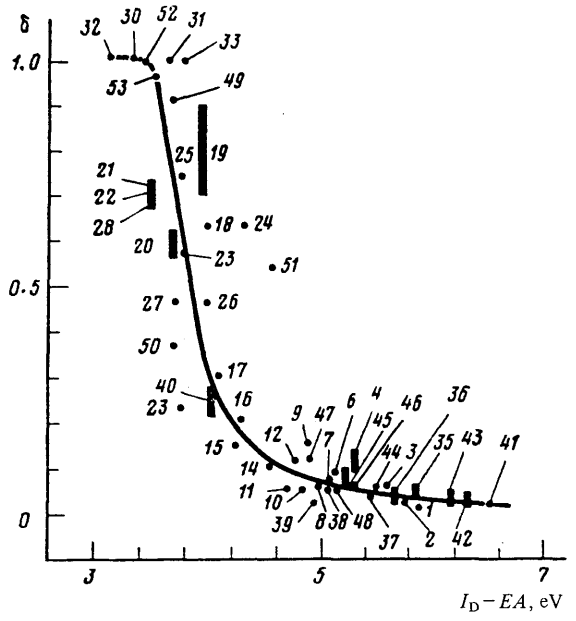

**Figure 5.** Dependence of the experimental values of δ on the difference $I_D - EA$. The ionisation potentials were taken from Refs. 94–97 and the electron affinities from Ref. 98; the numbering of the points corresponds to the numbering of the complexes in Table 2.

Apparently not only electrophysical characteristics but also the crystal structure is controlled in a definite manner by the degree of CT. It has been noted[99] that, on passing from one range of degrers of CT to another, a change in the method of packing is also observed. Indeed, donor–acceptor systems with $0.3 < \delta < 0.7$ consisting of mixed stacks are virtually unknown (according to Kistenmacher,[100] the dibenzotetrathiafulvalene–TCNQD complex is a system of this kind); systems with $\delta < 0.2$ consisting of individual stacks of the donor and acceptor species have not been observed either. All the foregoing findings suggest that the determination of fairly exact relations between the degree of CT and the characteristics of the system components, on the one hand, and between the degree of CT and chemical, spectroscopic, and photo- and electro-physical characteristics of the donor–acceptor systems, on the other, constitutes a branch of the field under consideration whose development will permit the purposeful synthesis of donor–acceptor systems in the future.

The possibility of refining relations of the type $\delta = f(I_D - EA)$ depends in the first place on the accuracy of the determination of $I_D$ and $EA$. Only the ionisation potential can be determined with adequate accuracy at the present time but usually this applies only to the vertical and not the

**Table 2.** The degree of charge transfer in π–π complexes and radical-ion salts.

Notation. IRS = Infrared spectroscopy, RS = Raman spectroscopy, RRS = resonance Raman spectroscopy, XES = X-ray electronic spectroscopy, ENS = elastic neutron scattering, and DM = determination of dipole moments; TFTCNQD = tetrafluoro-7,7,8,8-tetracyanoquinodimethane. Conditions in the measurements: I) solution of the donor; II) solution; III) crystalline state; IV) crystalline state at a pressure of 4.6 kbar.

adiabatic ionisation potentials, which would have to be used in the analysis of rules governing the variation of $\delta$. The latest studies in this field have shown[101] that only in the case of aromatic hydrocarbons is the discrepancy between the vertical and adiabatic ionisation potentials small ($\leqslant$0.1 eV). On the other hand, in the case of donors such as tetrathiafulvalenes the discrepancy is considerable (from 0.35 to 0.52 depending on the substituents). As regards electron affinity, the accuracy of its determination is undoubtedly inferior to that of the determination of $I_D$, which, together with the errors in the determination of the values of $\delta$, can lead to an additional distortion of the experimental relation.

Taking into account the factors above, the experimental relation (Fig.5) must be regarded as very satisfactory. One should also note that, in determining this relation, no account was taken of the structural characteristics of the donor and the acceptor which could alter quantities such as both $S_{01}$ and $E_C$ and $E_M$. It may be that some information about the changes in $E_C$ and $E_M$ is contained in an implicit form in characteristics of the donor and acceptor such as the half-wave potential for the anodic oxidation ($E^{ox}_{1/2}$) and the half-wave potential for the polarographic reduction ($E^{red}_{1/2}$), because they contain information about the solvation energies ($E_C$ and $E_M$ depend on the ionic radius and the charge density). Since the quantities $E_{1/2}$ characterise in addition adiabatic processes, the determination of the correlation between $\delta$ and $E^{ox}_{1/2} - E^{red}_{1/2}$ is of undoubted interest.

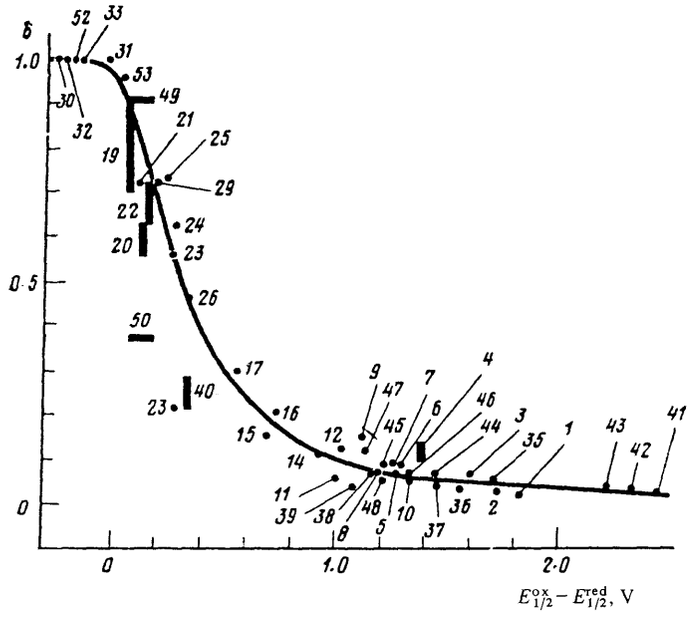

Figure 6. Dependence of the experimental values of $\delta$ on the difference $E^{ox}_{1/2} - E^{red}_{1/2}$. Ther electrochemical characteristics of the components were taken from Refs.10, 98, and 102–104; the numbering of the points corresponds to the numbering of the complexes in Table 2.

It follows from Fig.6 that such a correlation does obtain and that in the region of high degrees of CT it is more pronounced than the relation between $\delta$ and $I_D - EA$. With its aid, it is possible to predict fairly accurately the degree of CT solely from two characteristics of the donor and acceptor which can be comparatively readily determined, namely $E^{ox}_{1/2}$ and $E^{red}_{1/2}$.

It is noteworthy that some scatter in the experimental points is nevertheeless observed. This may indicate the need to take into account also more refined characteristics of the donor–acceptor system, for example, the changes in overlap integrals, etc.

## V. CONCLUSION

The synthesis and investigation of organic complexes and radical-ions with unusual electrophysical characteristics have developed vigorously in recent times. Theoretical ideas permitting the choice of the initial components of the complex for the synthesis of systems having particular properties with a definite reliability have therefore assumed special importance. We believe that the road to these theoretical ideas leads via the determination of a relation between characteristics of the components such as the ionisation potential (the anodic oxidation half-wave potential) and electron affinity (the polarographic reduction half-wave potential) and a characteristic of the complex such as the degree of charge transfer. Here many theoretical and practical problems remain, although the relations obtained already permit a purposeful selection of the components of the complex at a specific level. There is no doubt that, as more accurate methods for the determination of the degree of charge transfer develop and as more extensive experimental data accumulate, relations of the property of the component–property of the complex type will be to a considerable degree refined.

# Phosphorus Acid Hydrazides

V.M.Ovrutskii and L.D.Protsenko

The review is devoted to the methods of synthesis, chemical reactions, and physicochemical properties of phosphorus acid hydrazides, among which biologically active substances have been discovered.
The bibliography includes 106 references.

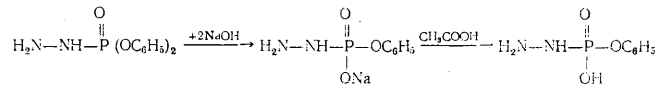
## I. INTRODUCTION

The studies in the field of phosphorus acid hydrazides, which began to attract the attention of investigators as early as the end of the past century, have developed particularly vigorously during the last two decades. The presence of two nucleophilic nitrogen atoms together with the nucleophilic phosphorus atom in phosphorus acid hydrazides have led to extensive synthetic possibilities of these compounds. Substances with properties useful in practice have been discovered among phosphorus acid hydrazides. The hydrazides of phosphorothioic acid esters exhibit a pesticidal activity.[1-3] The dihydrazides of halogenophenol esters of phosphorothioic acid and the sulphonyl hydrazides of phosphorothioic acid have been used as bactericides and fungicides.[4,5] Certain hydrazides of phosphoramidothioic acid have been shown to exhibit a weak acaricidal and fungicidal activity.[6] Among phosphorus acid hydrazides, substances with insecticidal activity have been found.[7] The hydrazides of diarylphosphinic acids and esters of methylphosphonic and methylphosphonothioic acid have been synthesised as potential biologically active substances with cytostatic, insecticidal, and pesticidal properties.[8-10]

It has been shown that the hydrochlorides of *O*-aryl-*NN*-di(2-chloroethyl)phosphoramidohydrazidates have a pronounced antitumour activity[11,12] and act selectively in the absence of inhibition of blood generation. Some of the compounds mentioned have shown a high antitumour activity not inferior to that of chlorobutyne.[13,14] Thus the need to search for substances with antitumour activity among phosphorus acid hydrazides by the structural modelling of "carriers" of cytotoxic groups in order to increase the selectivity of the antitumour activity of the compounds has been demonstrated.

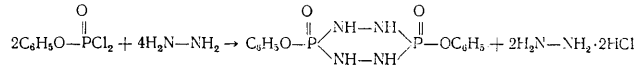
Hitherto there have been no reviews of phosphorus acid hydrazides. Bearing in mind that phosphorus acid hydrazides are of both theoretical and practical interest for research, we thought it useful to write the present review of literature data concerning the methods of synthesis and chemical and physicochemical properties of the given class of organophosphorus compounds. The review covers the literature up to the beginning of 1983.



## II. METHODS OF SYNTHESIS

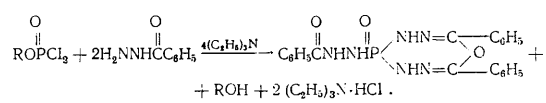
### 1. Hydrazides of Phosphoric Acid

Among all the known phosphorus hydrazides, the largest group comprises the hydrazides of phosphoric acid. These include the hydrazides of phosphoric acid monoesters and diesters, phosphoramidate esters, phosphorodiamidic acids, the dihydrazides of phosphoric esters and phosphoramidic acids, and phosphoric trihydrazides.



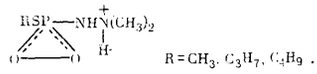
#### *(a) The Hydrazides and Dihydrazides of Phosphoric Acid Monoesters*

One of the methods of synthesis of the hydrazides of monoaryl and monoalkyl phosphate esters involves the partial hydrolysis of the hydrazide of the corresponding phosphoric acid diesters on heating with concentrated solutions of sodium hydroxide or ammonia,[15,16] for example:



The catalytic hydrogenation of diphenyl phosphorohydrazidate in the presence of platinum dioxide also results in the formation of monophenyl phosphorohydrazidate.[17]

Phenyl phosphorodihydrazidate has been obtained by treating phosphoryl chloride with a calculated amount of phenol and then with hydrazine hydrate in alcoholic solution.[16] *o*-Biphenylyl and *p*-cumenylphenyl phosphorodihydrazidates have been synthesised similarly.[18] The reaction of phenyl phosphorodichloridate with anhydrous hydrazine in ethereal solution also affords only the dihydrazide when hydrazine is used in excess.[16] On reaction with two moles of hydrazine in an aqueous medium, the above acid dichloride gives rise to 3,6-dioxo-3,6-diphenoxy-1,2,4,5,3,6-tetra-azadiphosphane:[19,20]



A study of the reaction of alkyl (and aryl) phosphorodichloridates with benzoylhydrazine in the presence of triethylamine showed that its product is 3-benzoylhydrazido--3-oxo-6,8-diphenyl-3-phospha-7-oxa-1,2,4,5-tetra-aza-cyclo-octa-5,8-diene:[21]

Interesting data have been obtained in a study of the reaction between *S*-alkyl phosphorodichloridothioates and 1,1-dimethylhydrazine.[22] *S*-Alkyl-2,2-dimethylphosphorohydrazidates were isolated in 26–40% yield and were found to exhibit unusual acid–base properties. Their basic

properties proved to be very weak ($pK_a < 2$) and so were their acid properties. The $pK_a$ in water were 5.22 ± 0.05 for R = $CH_3$ and $C_3H_7$. On the basis of these properties and IR and $^1H$ NMR spectroscopic data, it has been suggested that the above compounds exist in the form of the dipolar ions:

R = $CH_3$, $C_3H_7$, $C_5H_9$ .

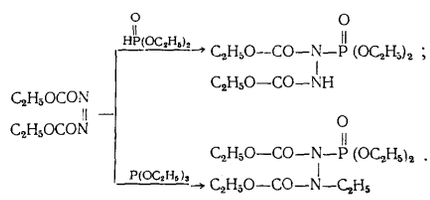
*(b) Hydrazides and Substituted Hydrazides of Phosphoric Acid Diesters*

The most widely used method of synthesis of the hydrazides of phosphoric acid diesters involves the reaction of the corresponding chlorides of phosphoric acid diesters with hydrazine, hydrazine hydrate, or substituted hydrazines. The reaction can also be carried out in the presence of water, using sodium carbonate to bind the hydrogen chloride evolved. Diaryl phosphorohydrazidates have been obtained in this way: [16,23,24]

The phosphorylation of hydrazine, *NN*-dimethylhydrazine, phenylhydrazine, and acetylhydrazine by alkyl 2-chlorophenyl phosphorochloridates has been studied and it has been established that, when the reaction is carried out in benzene solution and the reactants are in molar proportions of 1 : 2, then the monohydrazides of the mixed phosphoric acid diesters are produced. [25]

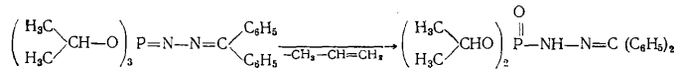
It is of interest that the nature of the hydrazine hardly influences the rate of reaction, since the basicity of substituted hydrazines changes insignificantly, in contrast to the amines.

The reaction of hydrazine with 2-chlorophenyl ethyl phosphorochloridate yielded, together with the monohydrazide, also the *NN*-bishydrazide as a side product. The amount of the bishydrazide increases when anhydrous hydrazine is used.



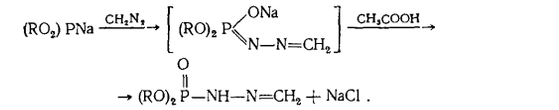
1-Alkyl-substituted hydrazides of phosphorus acids have been described for the first time by Shanduk et al., [23] in particular diaryl phosphoro(1-ethylhydrazidates) $(C_6H_5O)_2$.
O
‖
.$PN(C_2H_5)NH_2$. The 1-substitution of the resulting hydrazide has been confirmed by its ability to form the corresponding hydrazones with *p*-nitrobenzaldehyde.

Dialkyl phosphorohydrazidates can be obtained by the Todd–Atherton reaction by treating dialkyl phosphites with two moles of hydrazine and carbon tetrachloride: [16,26]



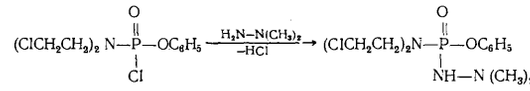
A modification of the Todd–Atherton method, based on the use of anhydrous potassium carbonate as the base in the presence of the phase transfer catalyst $(C_2H_5)_3\overset{+}{N}CH_2C_6H_5Cl^-$ in the reactions of dialkyl phosphites with hydrazine hydrate and carbon tetrachloride. [27]

Dialkyl or trialkyl phosphites react with azo-compounds to form the corresponding dialkyl phosphorohydrazidates: [28]

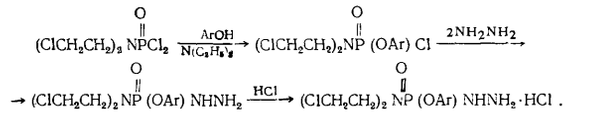


Dialkyl phosphorohydrazidates can be obtained also by reducing dialkyl azophosphoric acids with various reductants. [29]

The thermal decomposition of trialkoxyphosphazines at 170–180 °C is accompanied by the elimination of propene and the formation of di-isopropyl phosphoro(2-diphenylmethylenehydrazidate): [30]



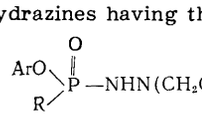
The salts of dialkyl phosphorous acids react with diazomethane to form dialkyl phosphoro(2-methylenehydrazidates): [31]



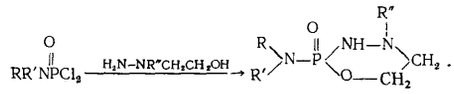
A communication about the synthesis of diethyl phosphoro(diphenylhydrazidates), which have been little investigated, has been published recently. [32]

*(c) Hydrazides of Phosphoramidate Esters*

There are comparatively few literature data on the hydrazides of phosphoramidate esters. Phenyl phosphoro[di(2-chloroethyl)amido](2,2-dimethylhydrazidate), formed when phenyl phosphoro[di(2-chloroethyl)amido]chloridate reacts with dimethylhydrazine, has been described: [33]



A method of synthesis of the hydrochlorides of aryl phosphoro[*NN*-di(2-chloroethyl)amido]hydrazidates, consisting in the reaction of aryl phosphoro[*NN*-di(2-chloroethyl)amido]-chloridates with hydrazine in a mixture of anhydrous benzene and methanol and subsequent bubbling of a benzene solution with hydrogen chloride, has been developed: [34]



It has been established that the reaction between aryl phosphoro[*NN*-di(2-chloroethyl)amido]chloridates and phenylhydrazine proceeds in benzene in the presence of triethylamine with formation of the corresponding phenylhydrazides. [34]

The reaction between substituted phosphoromonochloridates and di(2-chloroethyl)hydrazine has been investigated and phosphorylated hydrazines having the formula

where R is a tetra-acetylglucose residue, were synthesised for the first time. [35]

Cyclic hydrazides of phosphoramidate esters, formed from phosphoramidic dichlorides and the corresponding substituted hydrazines, are known: [36]

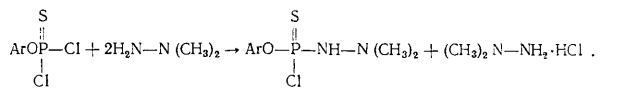
*(d) Hydrazides and Dihydrazides of Phosphoramidic Acids*

A preparative method for the synthesis of phosphorodiamidic hydrazides involves the interaction of the corresponding phosphorodiamidic chlorides with hydrazine hydrate in solution in benzene, dioxan, or tetrahydrofuran at 60 °C:[24,37]

There are comparatively few literature data on phosphoramidic dihydrazides. The synthesis of phosphoramidic dihydrazides from the corresponding phosphoramidic dichlorides and phenylhydrazine has been described.[38]

*(e) Phosphoric Trihydrazides*

Phosphoryl trihydrazides can be obtained by treating phosphoryl chloride with six moles of hydrazine:[16]

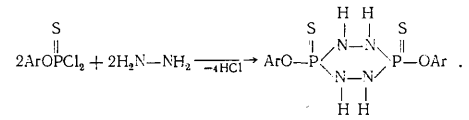


Phosphoryl chloride reacts analogously with six moles of arylhydrazines (phenyl- or 4-methylphenyl-hydrazine) in solution in ether or chloroform. The corresponding phosphoric tris(*N*-arylhydrazides) were isolated in these reactions.[39,40]

## 2. Hydrazides of Phosphorothioic Acid

Among the hydrazides of phosphorothioic acid, the dihydrazides of phosphorothioic esters and hydrazides of phosphorothioic diesters have been most thoroughly investigated.

*(a) The Hydrazides and Dihydrazides of Phosphorothioic Esters*

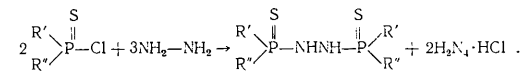


The reaction of *N*-mono- or *NN*-di-substituted hydrazines (*N*-phenyl or *NN*-dimethylhydrazines) with aryl phosphorodichloridothioates, involving the selective substitution of only one chlorine atom and the formation of the corresponding aryl phosphorochloridohydrazidothioates, has been described:[41]

When unsubstituted hydrazine was used under the conditions of this reaction (room temperature or a temperature below 0 °C, two moles of the corresponding hydrazine), the required monohydrazide could not be obtained.

Analysis of the literature data concerning the effect of hydrazines on aryl (and alkyl) phosphorodichloridothioates shows that the nature of the products formed under these conditions depends on the electronic and steric effects, the basicity of the nucleophiles, the reaction temperature, the reactant ratio, and the order in which the reactants are added.

Thus data have been published[41,42] on the synthesis of aryl phosphorodihydrazidothioates by treating one mole of the corresponding phosphorodichloridothioate ester with four moles of hydrazine hydrate, phenylhydrazine, or 1,1-dimethylhydrazine. Phenyl phosphorodihydrazidothioate has been obtained similarly.[16] On the other hand, the formation of a cyclic product, namely 3,6-diphenoxy-3,6-dithiono-1,2,4,5,3,6-tetra-azadiphosphene by the reaction of phenyl phosphorodichloridothioate with two or three moles of hydrazine has been demonstrated:[43]

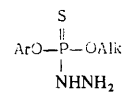


*(b) Hydrazides and Substituted Hydrazides of Phosphorothioic Diesters*

Diaryl (or dialkyl) phosphorochloridothioates, hydrazine, or a substituted hydrazine are used to synthesise the hydrazides of phosphorothioic diesters:

In certain cases the above reaction leads to the formation of secondary hydrazides:

The reaction may be controlled by the polar effects of the groups R′ and R″. Thus the reaction of diaryl phosphorochloridothioates with hydrazine hydrate always affords a high yield of primary hydrazides for an equimolar reactant ratio.[42,44]

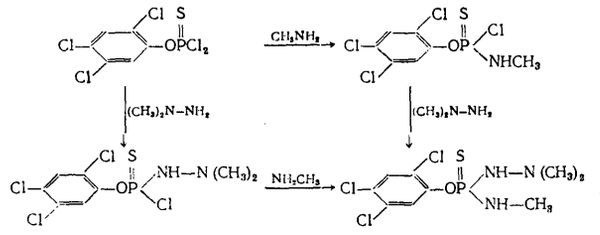


The formation of primary hydrazides from diaryl phosphorochloridothioates and hydrazine hydrate has been established also when the latter was used in excess.[23]

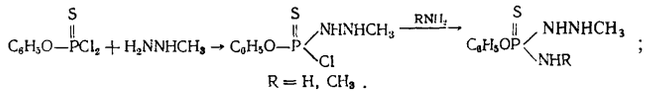
Dialkyl phosphorochloridothioates give rise to not only primary but also secondary hydrazides. The maximum yield of the latter of the type $[(R'O)(R''O)P(S)NH]_2$ is attained when anhydrous hydrazine is added to the corresponding acid monochloride in molar proportions of 3 : 2.

The most convenient method of synthesis of dialkyl phosphorohydrazidothioates is based on the reaction of dialkyl phosphorochloridothioates with two moles of hydrazine hydrate or a substituted hydrazine.[45–47]

The reaction leading to the synthesis of secondary hydrazides becomes more effective with increase of the electron-donating capacity of the substituents R′ and R″. It has been established that, when the sum of the constants ($\Sigma\sigma^*$) of the polar substituents R′ and R″ is greater than +4 (in the presence of aryl substituents), the above reaction does not occur. When $\Sigma\sigma^* = +1$, which happens for the secondary hydrazine $[(CH_3O)_2P(S)NH]_2$, the formation reaction leading to secondary hydrazides proceeds more rapidly and incorporates two bimolecular $S_N$ reactions. In the first of these the corresponding dialkyl phosphorochloridothioates and hydrazine react to form a primary hydrazide. In the second reaction the above intermediate primary hydrazide is phosphorylated with formation of a secondary hydrazide.[47]



Mixed diesters of phosphorohydrazidothioic acid, formed from the corresponding phosphorochloridothioates and hydrazine hydrate and having the structure

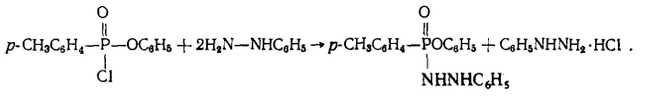


are known.[1,25]

*(c) Hydrazides of Phosphoramidothioic Acid Esters*

Phenyl phosphoramidohydrazidothioates can be obtained by the reaction of 2,4,5-trichlorophenyl phosphorochloridohydrazidothioate or phosphorochlorido(1,1-dimethylhydrazido)thioate with the corresponding amine or by the reaction of, for example, 2,4,5-trichlorophenyl phosphoro(*N*-methylamido)chloridothioate with the corresponding hydrazine.[41,47]

The first method of synthesis of phosphoramidohydrazidothioates has also been described[48] in connection with the synthesis of the following phenyl phosphoramidohydrazidothioates:

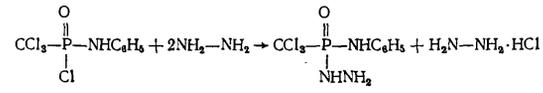


A series of phosphoramidohydrazidothioates have been synthesised by treating alkyl phosphoramidochloridothioates with dimethylhydrazine in boiling benzene in the presence of triethylamine.[6]

## 3. Hydrazides of Phosphonic and Phosphonothioic Acids

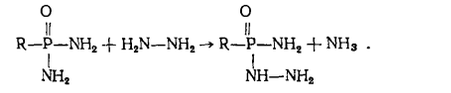
*(a) Hydrazides of Phosphonic and Phosphonothioic Acid Esters*

The hydrazides of phosphonic and phosphonothioic acid esters are usually formed when the chlorides of the corresponding acid esters react with hydrazine or a substituted hydrazine. Thus phenyl *p*-tolylphosphonochloridate reacts with phenylhydrazine to form the corresponding phenylhydrazide:[49]



When methyl phosphonochloridate and methylphosphonochloridothioate are added to an excess of hydrazine or hydrazine hydrate, the hydrazides of the above acid esters are formed. When the order in which the reactants are mixed was altered, bisphosphorylated hydrazines were isolated.[9]

The phosphorylation of hydrazine by 2-chlorophenyl methylphosphonochloridate or methylphosphonochloridothioate in proportions of 2 : 1 led to the formation of the corresponding monohydrazide.[25] Aryl methylphosphonochloridates and methylphosphonochloridothioates also react with hydrazine hydrate to form monohydrazides, but, in order to facilitate their isolation, it is necessary to treat the reaction mixture with potassium carbonate.[10]

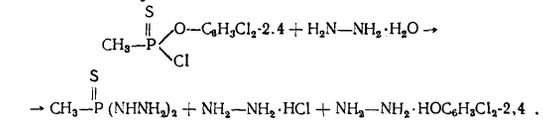


*(b) The Hydrazides of Phosphonamidic Acids*

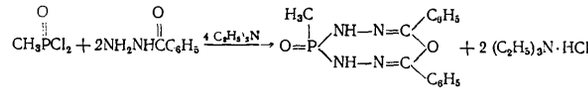
The usual method of synthesis of phosphonamidic acid hydrazides involves the interaction of phosphonamidochloridates with hydrazine or its derivatives, for example:[50]

Solutions of strong inorganic bases can also be used to remove the hydrogen chloride formed.

It is of interest that treatment of phosphonic diamides with hydrazine also leads to the formation of phosphonamidic hydrazides:[51]

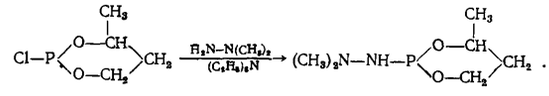


*(c) Dihydrazides of Phosphonic and Phosphonothioic Acids*



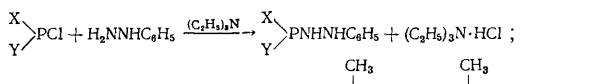
One of the methods of synthesis of the dihydrazides of phosphonic or phosphonothioic acids involves the treatment of the dichlorides of the corresponding acids with hydrazine, for example:[51]

A novel method of synthesis of methylphosphonothioic dihydrazides has also been described.[52] It was found that the interaction of hydrazine hydrate with 2,4-dichlorophenyl methylphosphonochloridate entails the hydrazinolysis of not only the acid chloride but also of the labile ester linkage with formation of a dihydrazide:



The reaction of methylphosphonic dichloride with two moles of benzoyl hydrazide and four moles of triethylamine in solution in toluene takes place in an unusual manner. The formation of 3-methyl-3-oxo-6,8-diphenyl-3-phospha-7-oxa-1,2,4,5-tetra-azacyclo-octa-5,8-diene was demonstrated in this instance:[53]

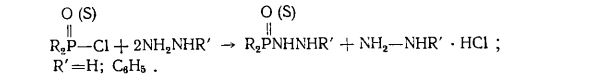
The reaction proved to be general for the synthesis of 3-alkyl(aryl)-3-oxo-6,8-diphenyl-3-phospha-7-oxa-1,2,4,5-tetra-aza-cyclo-octa-5,8-dienes.



## 4. The Hydrazides of Phosphorous Acid

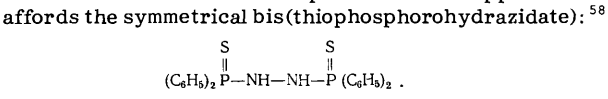
The first representative of the hydrazides of phosphorous acid was described by Nifant'ev in 1964.[54] It was obtained by the reaction of 1,3-butylene phosphorochloridite with 1,1-dimethylhydrazine in the presence of triethylamine:

The methods of synthesis of the hydrazides of phosphorous acid were investigated in detail in later studies.[55,56] It was



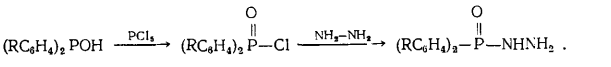
found that the hydrazides can be obtained from the corresponding acid chlorides and phenylhydrazine in the presence of triethylamine as the hydrogen chloride acceptor:

X = Y = $OC_2H_5$; $OC_3H_7$; $OC_4H_9$; —O $(CH_2)_2$O—; —OCHCH$_3$O—; —OCH $(CH_2)_2$O— .

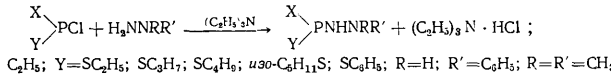


### 5. The Hydrazides of Phosphinic, Phosphinothioic, Phosphinous, and Phosphinothious Acids

The hydrazides of phosphinic and phosphinothioic acids have been synthesised by the reaction of the corresponding acid chlorides with two moles of hydrazine or a substituted hydrazine in an inert solvent: [57]

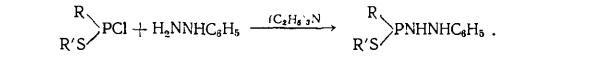


R′=H; $C_6H_5$ .



Diphenylphosphinothioic acid hydrazide has been synthesised by adding the chloride of the above acid to hydrazine hydrate. The addition of the components in the opposite order affords the symmetrical bis(thiophosphorohydrazidate): [58]

The hydrazides of diarylphosphinic acids containing both identical and different aromatic substituents at the phosphorus atom have been described. [23] They have been synthesised in accordance with the following schemes:



The hydrazides of phosphinous acids, obtained from the corresponding acid chlorides and phenylhydrazine or 1,1-dimethylhydrazine in the presence of triethylamine, are known: [56]

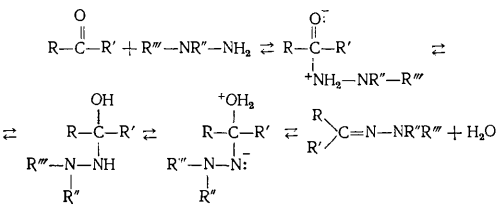
X=$CH_3$, $C_2H_5$; Y=$SC_2H_5$; $SC_3H_7$; $SC_4H_9$; *изо*-$C_6H_{11}S$; $SC_6H_5$; R=H; R′=$C_6H_5$; R=R′=$CH_2$.

2-Phenylhydrazides of alkylphosphinothious acids are formed analogous to the phenylhydrazides of dialkyl phosphorous acids: [59]

The properties characteristic of compounds with a tervalent phosphorus atom are also typical for the hydrazides of phosphinous and phosphinothious acids: they readily combine with elemental sulphur and with copper monohalide salts.

## III. CHEMICAL AND PHYSICOCHEMICAL PROPERTIES

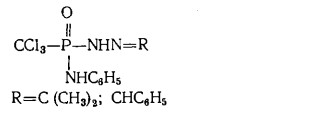
Extensive data characterising the chemical properties of phosphorus acid hydrazides have now accumulated. The presence of nitrogen atoms together with the nucleophilic phosphorus atom leads to the manifestation of amphoteric properties by the above compounds.



*N*-Unsubstituted hydrazides of phosphorus acids exhibit properties characteristic of other hydrazine derivatives by virtue of the presence of the free amino-group. Firstly, they undergo numerous reactions with electrophiles (aldehydes and ketones, diketones, β-ketoesters, monosaccharides, Schiff bases, carboxylic acids, carboxylic acid chlorides, alkyl chlorocarbonates, chlorides of alkane(arene)-sulphonic acids, phosphorus acid chlorides, picryl chloride, isocyanates, and isothiocyanates). Secondly, they react with nucleophiles (ethanol, phosphoric acids, water, caustic alkalies, and inorganic acids). In addition oxidation reactions are characteristic of phosphorus acid hydrazides.

### 1. Reactions with Electrophiles

#### *(a) Interaction with Aldehydes and Ketones*



Analysis of the literature data on the interaction of phosphorus acid hydrazides with aldehydes and ketones shows that they can involve both $NNH_2$ and NNH groups.

If the nucleophilic centre of the attacking nucleophile is a nitrogen atom linked to two hydrogen atoms, the reactions with aldehydes and ketones proceed in accordance with the following scheme:

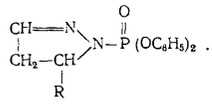
Ultimately the carbonyl group is substituted by the C=NNR″R‴ group, while the intermediate stages involve the highly mobile tautomeric equilibria shown in the scheme above. Acid catalysts accelerate the first stage as a result of the formation of conjugate acids, which polarises the carbonyl group still further. [60,61]

The aldehyde and ketone hydrazones derived from trichloromethylphosphono(*N*-phenylamidic) hydrazides have been described. [50]

The hydrazones derived from phosphoramidates, synthesised from both aliphatic and aromatic aldehydes and ketones, have been described. [24,62]

The following compounds have been used [24] to synthesise the hydrazones: formaldehyde, acetone, ethyl methyl ketone, methyl propyl ketone, acetaldehyde, propioaldehyde, acetophenone, 3,4-dichlorobenzaldehyde, 2-nitrobenzaldehyde, 4-dimethylaminobenzaldehyde, 4-chlorobenzaldehyde, etc.

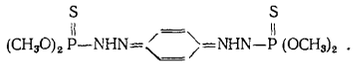
The reactions of the hydrochlorides of aryl phosphoro[*NN*-di(2-chloroethyl)amido]hydrazidates with formaldehyde, benzaldehyde, and acetophenone have been investigated. [62,63] The reactions were carried out with heating in an alcoholic medium, without isolating the phosphoramidohydrazidate base, with formation of aryl phosphoro[*NN*-di(2-chloroethyl)-amido][2-alkylidene(arylalkylidene)hydrazidates].



Kitaev and co-workers [64,65] established that the arylhydrazones can exist in aqueous-methanolic solutions in three tautomeric forms.

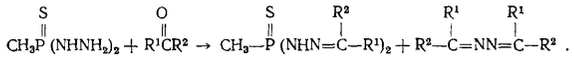
Ovrutskii et al. [66] used polarography at a dropping mercury electrode for the first time to investigate the tautomeric transformations of aryl phosphoro[*NN*-di(2-chloroethyl)-amido](2-methylene, benzylidene-, and methylbenzylidene-hydrazidates). The investigation showed that the half-wave potentials of the hydrazo-group in these phosphoroalkylidene-(arylalkylidene)hydrazidates differ little and remain constant

when the solutions of the test compounds are kept for a long time. This factor as well as the finding that half-wave potentials ranging from −0.6 to −0.96 V correspond to the azo-forms of the aldehyde and ketone arylhydrazones, while half-wave potentials ranging from −1.34 to −1.56 V have been obtained for the hydrazones derived from the above phosphorohydrazidates at pH 5.8 and 9.2, suggest that these hydrazones do not undergo reversible transformations under the polarographic conditions and do not have the structure of the azo-form but are in fact true hydrazones.



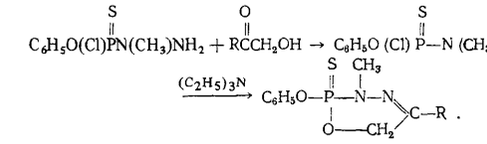
The influence of various substituents in the aromatic ring on the polarographic reduction has been estimated quantitatively. The quantities $\rho^*$ at pH 5.8 and 9.2 are 0.25 and 0.20 respectively ($r = 0.99$; $S = \pm 0.2$). The constant $\rho^*$ for the reduction of the C=N group at pH 5.8 and 9.2 is virtually invariant, which indicates the absence of changes in the mechanism of reduction at a dropping mercury electrode.

It is of interest that, when unsaturated aldehydes and ketones (acrolein and crotonaldehyde) are used in the reaction with diphenyl phosphorohydrazidate, five-membered heterocycles, namely pyrazolines, are formed:[56,67]

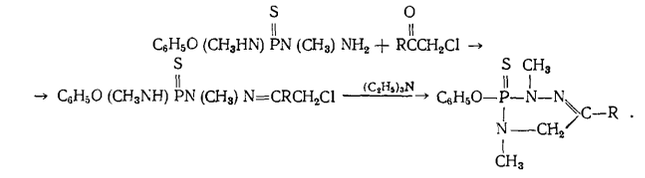


Diphenyl phosphoro(2-dimethylmethylenehydrazido)thioate has been obtained by the reaction of diphenyl phosphorohydrazidothioate with acetone.[25]

The reaction of dialkyl phosphorohydrazidothioates with aldehydes and ketones lead to the formation of the corresponding hydrazones derived from the phosphorothioic acids,[47,68] while the reactions with benzoquinone afford the compound

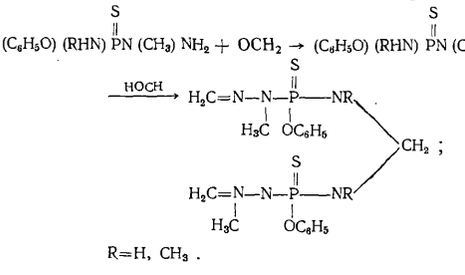


Grapov and co-workers[69] were the first to investigate the reactions of the dihydrazides of phosphorothioic acids with aldehydes and ketones and established that methylphosphonothioic dihydrazide reacts with benzaldehyde, *p*-chlorobenzaldehyde, *o*-, *m*-, and *p*-nitrobenzaldehydes, and *p*-dimethylaminobenzaldehydes to form the corresponding dihydrazones derived from methylphosphonothioic acids. Aldazans were isolated as side products. The reactions with acetone and acetophenone yielded the dihydrazones:



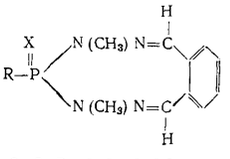
At the same time the reaction of methylphosphonothioic dihydrazide with benzophenone led to the isolation of only tetraphenylketazine.

The bisbenzylidenehydrazones derived from methylphosphonothioic acid have also been synthesised by the reaction of benzaldehyde and its substituted derivatives with methylphosphonothioic dihydrazide in the presence of acetic acid in an alcoholic medium as the catalyst.[52]

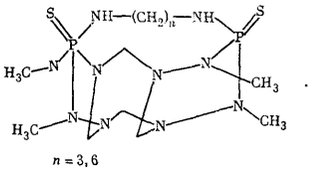


Interesting data have been obtained in the study of the reactions of asymmetric *N*-methylhydrazides of phosphorus acid with aldehydes and ketones.[48] Thus phenyl phosphorochlorido(1-methylhydrazido)thioate reacts with aldehydes and ketones to form hydrazones, which are converted in the presence of triethylamine into the corresponding 3-methyl-2-phenoxy-2-thiono-1,3,4,2-oxadiazaphosphorines:

1,3-Dimethyl-2-phenoxy-2-thiono-1,3,4,2-triazaphosphorines have been obtained by treating phenyl phosphoro(*N*-methylamido)(1-methylhydrazido)thioate with various ketones in the presence of triethylamine:

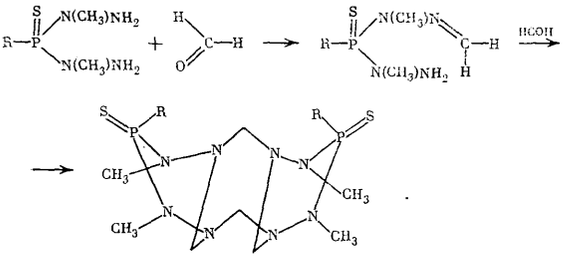


Treatment of phenyl phosphoro(*N*-alkylamido)(1-methylhydrazido)thioates with an excess of formaldehyde results in a reaction in accordance with the following mechanism:



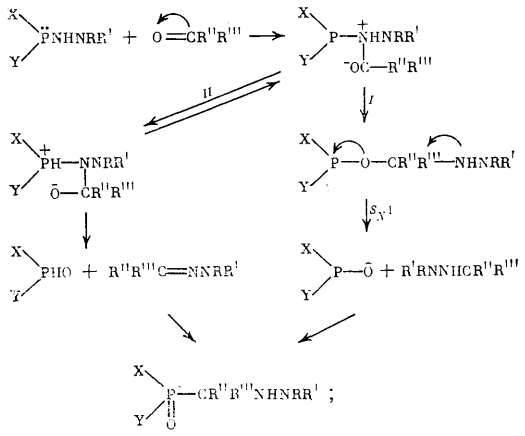
R=H, $CH_3$.

Di(1-methylhydrazides) of phosphoric, phosphonic, phosphorothioic, and phosphonothioic acids react with phthalic dialdehyde to form the dihydrazones:



X=O; S; R=$C_6H_5$; $C_6H_5O$.

The tetra(1-methylhydrazides) $(H_2NCH_3N)_2\overset{S}{\overset{\|}{P}}NH(CH_2)_nNH\overset{S}{\overset{\|}{P}}.(NCH_3NH_2)_2$ react with formaldehyde to form the compounds

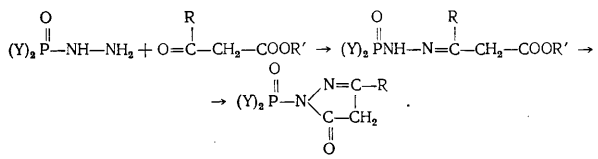


$n = 3, 6$

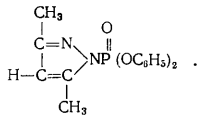
Treatment of the asymmetric phosphorodi(1-methylhydrazido)-thioate with one mole of formaldehyde leads to the corresponding perhydro-1,2,4,5-tetra-azaphosphorines, which react with formaldehyde to form tetracyclic compounds:

The structure of these compounds has been demonstrated by $^{1}H$ and $^{31}P$ NMR, IR and UV spectroscopy, and mass spectrometry.

The interaction of phosphorus acid hydrazides containing the NNH group with aldehydes and ketones has been investigated.[56,70] The reaction of dialkyl phosphoro(2-phenylhydrazidites) and *S*-alkyl alkylphosphono(2-phenylhydrazido)thioites with aldehydes and ketones yielded α-hydrazinophosphinates [and phosphonates?]. A reaction mechanism involving the formation of a four-membered ring as a result of the attack by the nucleophilic nitrogen atom on the electrophilic carbon atom of the carbonyl group, similar to that of the Staudinger–Wittig reaction, has been proposed:



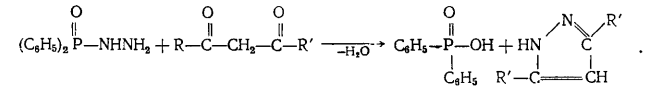
*I*: X=Y=$OC_2H_5$; $OC_3H_7$; $OC_4H_9$; —O $(CH_2)_2$ O—;
—OCH($CH_3$) $(CH_2)_2$ O—; —OCH($CH_3$) $(CH_2)_2$ O—; R=H; R′=$C_6H_5$;
*II*: X=$CH_3$; $C_2H_5$; Y=$SC_2H_5$; $SC_4H_9$; $SC_3H_7$;
neo-$C_5H_{11}$S; R=H; R′=$C_6H_5$; R=R′=$CH_3$; R″=$C_3H_7$; R‴=H; R″=$C_4H_9$; R‴=$C_2H_5$.



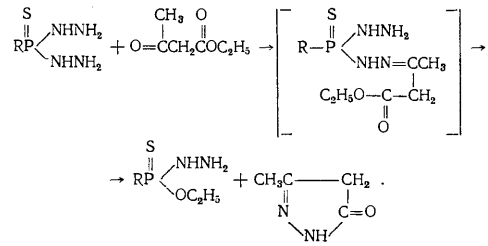
It is suggested that the initial intermediate can rearrange, as in case I, to produce an α-hydrazinophosphinite, which then rapidly decomposes via an $S_N1$ mechanism to form the final product. There is also a possibility of a proton shift (case II) with formation of a phosphonobetaine and the subsequent final stage of the Staudinger–Wittig reaction.

### *(b) Interaction with β-Ketoesters and α- and β-Diketones*

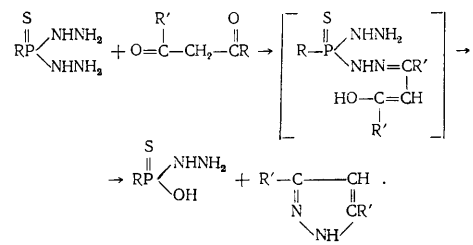
Ketoesters react with diphenylphosphinic hydrazide and diphenyl phosphorohydrazidate to form the corresponding hydrazones, which split off the alcohol on heating in solution to form phosphorylated pyrazolones:[56,67,71]



The use of acetylacetone instead of acetoacetic ester in the above reaction leads to the formation of 1-diphenoxyphosphoryl-3,5-dimethylpyrazole.[67]

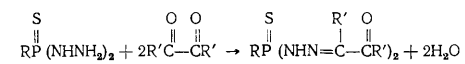


According to the data of Jahns et al.,[72] the reaction of diphenylphosphinic hydrazide with acetylacetone in equimolar proportions yielded 3,5-dimethyloxopyrazolyl diphenylphosphinate. Its structure was demonstrated by a specific synthesis from 3,5-dimethylpyrazole and diphenylphosphinic acid. After the reactions with benzoylacetone and dibenzoylmethane, only the corresponding hydrazones were isolated.

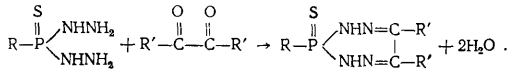


The reaction of diphenylphosphinic hydrazide with acetylacetone in proportions of 2 : 1 gave a 50% yield of an adduct from which diphenylphosphinic acid and 3,5-dimethylpyrazole were isolated after hydrolysis:

The reactions of the dihydrazides of various phosphorothioic acids with β-ketoesters and α-diketones have been studied in fair detail.[69] The reactions of phosphorodihydrazidothioic acids and phosphonothioic dihydrazides with acetoacetic ester proceed on heating in alcohol with dissociation of the P—N bond and the formation of 3-methylpyrazolone and ethyl phosphorohydrazidate and phosphonohydrazidothioate respectively:



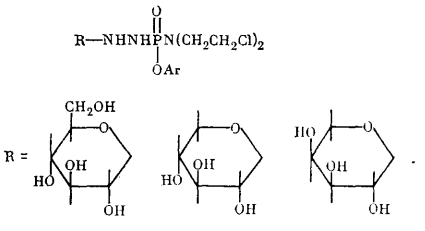
Methyl(phenyl)phosphonothioic dihydrazides and phosphorodihydrazidothioic acids react with acetylacetone and dibenzoylmethane to form respectively 3,5-dimethylpyrazole and 3,5-diphenylpyrazole. In addition, a hydrazidoacid is apparently formed, but its stability is low and the authors were unable to isolate it in a pure form:



The interaction of dihydrazides of methylphosphonothioic and a number of other phosphorus thioacids with α-diketones (diacetyl and dibenzoyl) proceeds in different ways depending on the reactant ratio.

The reaction of one mole of methylphosphonothioic dihydrazide or phosphorodihydrazidothioic acid with two moles of α-diketone in alcohol at 50–60 °C affords a high yield of phosphonothioic di(2-acetylalkylidenehydrazide) or (2-benzoylbenzylidenehydrazide) (or the corresponding phosphorothioate):

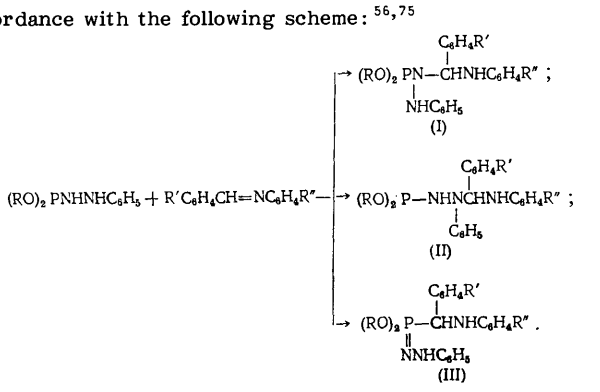
The dihydrazides of methyl- and phenyl-phosphonothioic acids and ethyl and phenyl phosphorodihydrazidothioates react with α-diketones or glyoxal in proportions of 1 : 1 to give 3-thiono-3,1,2,4,5-phosphatetra-azacyclohepta-5,7-



dienes:

Thus the structure of the products of the reactions of phosphorus acid hydrazides with β-ketoesters and diketones depends on the nature of the substituents in the carbonyl and hydrazone residues and on the nature of the initial reactants. The hydrazone cyclisation reactions with formation of a pyrazoline ring take place at the instant of the formation of the hydrazones or on heating the latter in solution and take place either with the dissociation of the P–N bond or with its retention.

*(c) Interaction with Monosaccharides*



The interaction of phosphorus acid hydrazides with monosaccharides has been investigated in recent years.[73] The corresponding [*O*-aryl-*NN*-di(2-chloroethyl)amidophosphoryl]-hydrazo-derivatives of D-glucose, D-xylose, and L-arabinose having the following formulae were obtained:

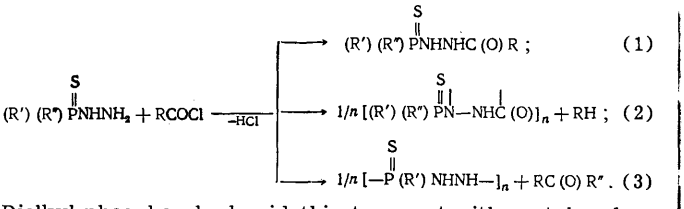
The IR spectra of these derivatives were investigated and it was established that the shift of the band characteristic of the OH group can be accounted for by the formation of an intramolecular hydrogen bond characteristic of the ring ($\nu$ = 3420–3380 cm$^{-1}$). The hypothesis of a cyclic structure of monosaccharides is also confirmed by the data characteristic of the antisymmetric vibrations of the pyranose ring ($\nu$ = 930–920 cm$^{-1}$). It has been shown that the products of the interaction of phosphorus acid hydrazides with D-glucose and D-xylose show deformation vibrations due to the equatorial position of the C–H bond relative to the pyranose ring ($\nu$ = 840–835 cm$^{-1}$), while in the case of the products of the interaction of phosphorus acids with L-arabinose, deformation vibrations of the C–H bond corresponding to the axial position of the hydrogen atom ($\nu$ = 900 cm$^{-1}$) were found. The bands in the range 1680–1600 cm$^{-1}$, characteristic of the hydrazone C=N group, are missing from the spectra of all the compounds.[74] The data obtained permit the conclusion that in the free crystalline states the compound synthesised do not exist as the true hydrazones (derivatives of the acyclic forms) but are in fact derivatives of the cyclic pyranose forms.

*(d) Interaction with Schiff Bases*

The reactions of the 2-phenylhydrazides of phosphonous acids with Schiff bases have been investigated. The reaction can involve both the NH groups of the phenylhydrazide and the phosphorus atom, i.e. can proceed with or without the transfer of the reaction centre and can give adducts in accordance with the following scheme:[56,75]

The properties of the products isolated from the reaction mixture (they do not combine with elemental sulphur and their hydrolysis gives rise to a phenylhydrazine salt) correspond to the structure of the product of the addition of the Schiff base to the phosphorus atom (structure III).

Ethylene phosphoro(1-phenylhydrazidites) react with Schiff bases to form the corresponding ethylene (α-anilino)-benzyl-*N*-anilinophosphazines.



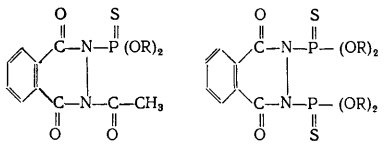
*(e) Interaction with Carboxylic Acids*

The interaction of diethyl, dibutyl, ethylene, and propylene phosphoro(2-phenylhydrazidites) with carboxylic acids (acetic, propionic, and butyric) is of the type of a double decomposition reaction with formation of carboxylic acid hydrazides and the corresponding phosphorus acids.[76]

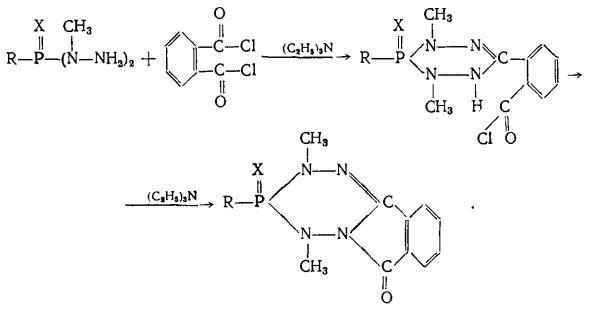
The reactions of dialkyl and alkylene phosphoro(2-phenylhydrazidites) with acrylic or methacrylic acid proceeds with formation of phosphorous acid and probably with the initial formation of the hydrazide of an unsaturated acid, which cyclises to the corresponding pyrazolidinone or pyrazolone. 1-Phenyl-5-pyrazolidinone, 1-phenyl-5-pyrazolone, 4-methyl-1-phenyl-5-pyrazolidinone, and 4-methyl-1-phenyl-5-pyrazolone were obtained.

*(f) Interaction with Carboxylic Acid Chlorides, Alkyl Chlorocarbonates, Alkane(arene)sulphonic Acid Chlorides, and Phosphorus Acid Chlorides*

The monohydrazides of phosphorus acids readily react with carboxylic acid chlorides to form acyl derivatives. The pathway followed in the reactions of phosphoric (phosphorothioic) hydrazide derivatives with acyl chlorides, benzoyl chloride, and ethyl chlorocarbonate depends on the structure of the derivatives of the phosphorus acid hydrazides and also on the electrophile:[47]

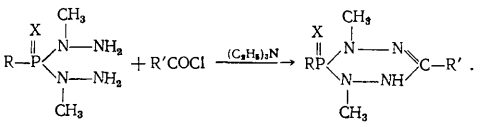


Dialkyl phosphorohydrazidothioates react with acetyl and benzoyl chlorides to form *N*-thiophosphoryl-*N'*-acylhydrazides [via reaction (1)].

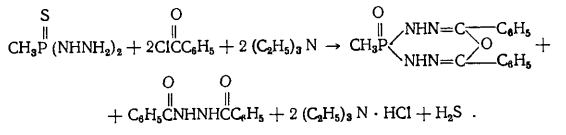


The reaction of phosphorodi(*N*-methylamidic) hydrazide with acetyl chloride leads to the formation of *NN*-dimethylacetamide and a condensed phosphorohydrazidate system [via reaction (3)].

*NNN'*-Triacyl-*N*-thiophosphoryl hydrazides and *NNN'*-triacetyl-*N*-dialkoxythiophosphoryl hydrazides have also been described.[47]

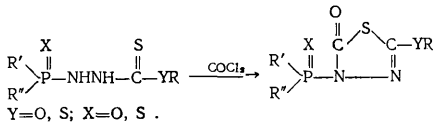


When phthaloyl chloride was allowed to react with *N*-acetyl-*N*-dialkoxythiophosphoryl hydrazides and *NN'*-bis(dialkoxythiophosphoryl) hydrazides, 3-acetyl-2-dialkoxythiophosphoryl-1,4-phthalazinediones and 2,3-bis(dialkoxythiophosphoryl)-1,4-phthalazinediones were obtained.[47]

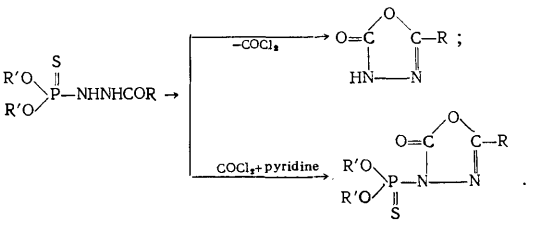


The di(1-methyl)hydrazides of phosphorus acids react with phthaloyl chlorides in the presence of triethylamine via the mechanism[48]

The interaction of di(1-methyl)hydrazides of phosphorus acids with formyl, acetyl, and benzoyl chlorides has been investigated. The reaction proceeds via the mechanism[48]

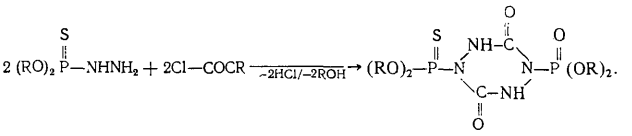


The acylation of methylphosphonothioic dihydrazide[69] with 2 moles of benzoyl chloride leads to the formation of 3-phospha-7-oxa-1,2,4,5-tetra-azacyclo-octa-5,8-diene:

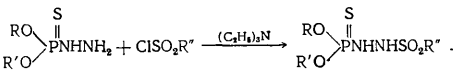


Sulphur is evolved in this reaction in the form of hydrogen sulphide.

The reactions of *N*-alkoxy(alkylthio)thiocarbonyl hydrazides of dialkyl phosphoric (phosphorothioic, phosphonothioic) acids with phosgene yielded the corresponding phosphorylated thiadiazoles:[77]

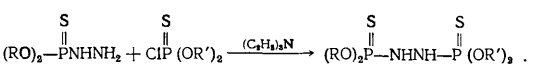


When dialkyl phosphorohydrazidothioates are treated with phosgene, the P—N bond is retained or broken depending on the reaction conditions. When the reaction is carried out in pyridine, phosphorylated oxadiazoles are formed. If the reaction proceeds in the presence of phosgene alone, the P—N bond is broken with formation of the phosphorothioic acid residue and oxadiazoles:



The reactions of phosphorus acid hydrazides with alkyl chlorocarbonates yielded aryl phosphoro[*NN*-di(2-chloroethyl)amido[(2-ethoxycarbonylhydrazidates),[62] diphenyl phosphoro(2-ethoxycarbonylhydrazidates),[78] and phosphorodi(*NN*-alkylphenylamidic) 2-methoxy(ethoxy)carbonylhydrazides.[79]

When dialkyl phosphorohydrazidothioates are treated with ethyl chlorocarbonate in the presence of alkaline reagents and in an inert organic solvent, 1,4-di(alkoxythiophosphoryl)-3,6-dioxo-1,2,4,5-tetrazines are formed in accordance with the mechanism[47,68]

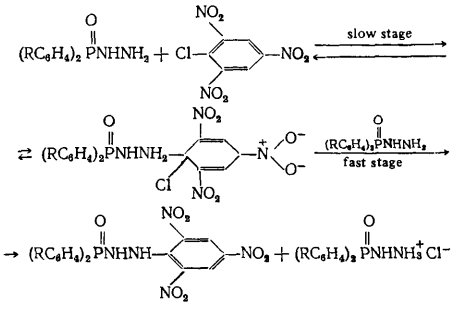


The reactions of phosphorohydrazidothioate esters with alkane (arene)sulphonyl chlorides take place in organic solvents in the presence of triethylamine with formation of 2-sulphonylhydrazides:[80,81]

The syntheses of phosphoramido(2-sulphonylhydrazido)-thioic acid and phosphorodi(*NN*-dialkylamido)thioic 2-sulphonylhydrazides,[5,82] aryl phosphoro[*NN*-di(2-chloroethyl)amido[(2-methanesulphonylhydrazidates),[62] aryl phosphoro[*NN*-di(2-chloroethylamido](2-*p*-toluenesulphonylhydrazidates),[63] phosphorodi(*NN*-alkylphenylamidic)-2-toluene-*p*-sulphonylhydrazides,[71] and phosphorodi[β-alkane-(arene)sulphonylhydrazido]thioic acids[83] have also been achieved.

The reaction of diphenyl phosphorohydrazidate with diphenyl phosphorochloridate leads to the formation of *NN'*-bis(diphenoxyphosphoryl)hydrazide.[16]

Bis(1,2-thiophosphoryl)hydrazides with various substituents at both phosphorus atoms have been obtained in the presence of triethylamine:[47,84,85]

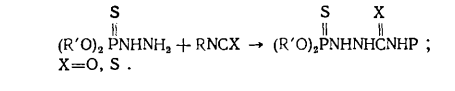


The formation of bis(1,2-dialkoxythiophosphoryl)hydrazide by the reaction of dialkyl phosphorohydrazidothioate with dialkyl phosphorochloridothioate has been described.[8,16,50]

### *(g) Interaction with Picryl Chloride*

Diarylphosphinic hydrazides have been synthesised, the kinetics of their reactions with picryl chloride have been investigated, and a mechanism has been proposed for this

reaction:[8]



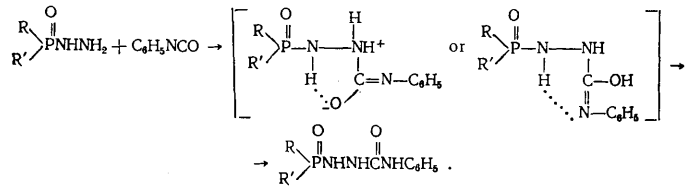
The reaction kinetics are described by a second-order equation, which is demonstrated by the linear time variation of the reciprocal of the current concentration. The reaction investigated obeys the Arrhenius equation. The activation energy $E_a$, the frequency factor $\lg A$, and the activation entropy have been calculated. It has been shown that the reactivity of diphenylphosphonic acid in the reaction with picryl chloride increases after the introduction of electron-donating substituents and diminishes in the presence of electron-accepting substituents.

*(h) Interaction with Isocyanates and Isothiocyanates*

Numerous studies have been made on the mechanism and kinetics of the reactions of phosphorus acid hydrazides with isocyanates and isothiocyanates.[47,86–94]

The interaction of dialkyl phosphorohydrazidothioates with isocyanates and isothiocyanates was first described by Tolkmith[47,86] and takes place in accordance with the mechanism presented below with formation of the corresponding semicarbazides and thiosemicarbazides:

Diphenylphosphinylthiosemicarbazides[87] and 4-acetyl-1-diphenylphosphinylthiosemicarbazides[88] are known.



β-Phosphorylated semicarbazides and thiosemicarbazides are formed on interaction of aryl methylphosphonohydrazidates and methylphosphonohydrazidothioates and ethylphosphono(*NN*-diethylamido)thioic hydrazide with alkyl and aryl isocyanates and alkyl and aryl isothiocyanates.[89]

Phosphonohydrazidic acids react more readily with isocyanates than phosphonohydrazidothioic acids. In the former case the reactions proceed in the absence of a catalyst, while in the latter catalytic amounts of triethylamine are required. In the series of isothiocyanates only aryl isothiocyanates combine with phosphonohydrazidic and phosphonohydrazidothioic acid; methyl isothiocyanate does not react with these hydrazides.

Chlorophenyl isocyanate and phenyl isothiocyanate add to methyl phosphorodihydrazidothioate with formation of bis-(semicarbazido)- and bis(thiosemicarbazido)-methylphosphonothioates.[69] The β-structure of the compounds obtained has been demonstrated by IR and $^1$H NMR spectroscopy.[69,89]

Analysis of a series of studies on the mechanisms and kinetics of the reactions of phosphorus acid hydrazides with isocyanates and isothiocyanates[90–94] permits the following conclusions.

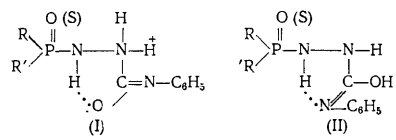
Since the reactions of diarylphosphinic hydrazides and diaryl phosphorohydrazidates with phenyl isocyanate[90] are nucleophilic addition reactions, it follows that, by analogy with the reactions of carboxylic acid hydrazides with isocyanates,[95,96] one can postulate that they proceed via a multistage addition mechanism with formation of a tetrahedral intermediate:

The decomposition of the intermediate is facilitated by the formation of a hydrogen bond between the hydrogen atom of the imino-group of the hydrazide and the electronegative oxygen or nitrogen atom of the isocyanate. The substitution of the hydrogen atom of the imino-group by the ethyl group rules out the formation of an intramolecular hydrogen bond, which decreases the rate constants for the reactions of diarylphosphinic 1-ethylhydrazides and phosphoro(1-ethylhydrazidates) with isocyanates.

The kinetics of the reactions of diarylphosphinic hydrazides and diaryl phosphorohydrazidates,[90] diaryl phosphorohydrazidothioates,[91] and diaryl phosphoro(1-ethylhydrazido)-thioates[92] with phenyl isocyanate in benzene have been investigated at different temperatures. The rate constants calculated from a second-order equation remain satisfactorily invariant during the process at different concentrations of the initial reactants in the presence of the reaction products.

The reactions of phosphorus acid hydrazide with phenyl isocyanate proceed with low activation energies and high negative activation entropies. The high negative activation entropies ($\Delta S^{\neq} = -49.5$–$57.4$) in the above reactions show that the approach of the electrophile to the molecule of a hydrazide having a tetrahedral configuration is sterically more hindered than the approach to the planar molecule of a carbonyl-containing hydrazide ($\Delta S^{\neq}$ for the reaction of benzoyl hydrazide with phenyl isocyanate is −41.8 cal mol$^{-1}$ K$^{-1}$).[95] The reactivities of the phosphorus acid hydrazides investigated vary in parallel with the basicity constants of the hydrazides.

The kinetics of the reactions of phosphorus acid hydrazides and 1-ethyl hydrazides with phenyl isothiocyanate in benzene have also been investigated. The reaction takes place quantitatively with formation of phosphorus acid thiosemicarbazides. The kinetics of these reactions are described by a second-order equation and the rate constants calculated from these equations remain satisfactorily invariant throughout the process.[93]



In the study of the kinetics of the reactions of phosphorus acid hydrazides with phenyl isocyanate,[97] questions concerning the influence of solvents on the rate and mechanism of this reaction were considered. The catalytic activity of dimethylformamide, dioxan, and pyridine in the reactions of diphenylphosphinic acid [hydrazide?] with phenyl isocyanate and picryl chloride shows that the solvation of the initial or transition state, involving the more acidic hydrogen atom of the imino-group in the initial hydrazide, is of decisive importance.

*(i) The α-Effect in Reactions with Electrophiles*

The α-effect is manifested as a positive deviation of the point corresponding to α-nucleophiles from the Brønsted straight line for compounds with the usual reactivity. Quantitatively the α-effect is defined as the ratio of the rate constants in the reactions of the α-nucleophile and a primary aromatic amine of equal basicity.

Hydrazine and its derivatives exhibit an enhanced reactivity in reactions with carbonyl- and sulphonyl-containing compounds.[94,98] Under the influence of the substituents in the aromatic rings of phosphorus acid hydrazides, the α-effect in the reaction changes.[8,90–94] However, the sequence in which the α-effect varies under the influence of such substituents is different in different series. In the reactions of diarylphosphinic hydrazides with phenyl isocyanate and picryl chloride,[8,90] electron-donating substituents reduce the α-effect, while electron-donating accepting substituents increase it. On the other hand, in the reactions of diaryl phosphorohydrazidates, diaryl phosphorohydrazidothioates,[90,92] and diaryl phosphoro(1-ethylhydrazido)thioates[94] with phenyl isocyanate, the substituents in the aromatic ring exert the opposite influence. The α-effect is linearly related to the basicity constants of the hydrazides.

Several possible causes of the manifestation of the α-effect have now been established but none, considered separately, can fully account for the nature of the phenomenon under consideration. On the assumption that the α-effect is to a large extent determined by the structure of the transition state, the enhanced reactivity of phosphorus acid hydrazides can be explained by their ability to form the cyclic complex (I) and (II) via a hydrogen bond between the oxygen or nitrogen atom of phenyl isocyanate and the hydrogen atom of the imino-group and also via a new bond between the carbon atom and the amino-group of the nucleophile.

(I) (II)

The transition states are distinguished by high stability as a consequence of the aromatic character and the presence of $4n + 2$ electrons. In addition a cyclic transition state promotes a more complete shift of the electron pair from the nucleophilic centre, facilitating thereby the formation of a new C–N bond.

In the reactions of phosphorus acid hydrazides with phenyl isothiocyanate, an appreciable decrease of the α-effect is observed compared with phenyl isocyanate, which can be explained by the lower capacity of the sulphur atom for the formation of a hydrogen bond in the transition state, which reduces the possibility of the formation of the cyclic complexes (I) and (II).[99]

Thus the extent to which the α-effect is manifested depends on the nature of both the nucleophile and the substrate and depends on the reaction mechanism. The reactions of phosphorus acid hydrazides involving the formation of cyclic atomatic complexes are energetically more favourable and are characterised by a higher α-effect.

## 2. Reactions with Nucleophiles

### *(a) Interaction with Ethanol and Diaryl Phosphoric acids*

In order to discover the possible phosphorylating properties of phosphorodi(*NN*-alkylarylamidic) hydrazides, a study was made of their interaction with various nucleophiles in the presence of iodine:[79] ethanol, diphenyl phosphoric acid, and phosphorodi(*N*-phenylamidic) acid. The synthesis was carried out in accordance with the following scheme:

$$(C_6H_5NR)_2\overset{O}{\overset{\|}{P}}NHNH_2 + HX \xrightarrow{I_2} (C_6H_5NR)_2\overset{O}{\overset{\|}{P}}X +$$

$$+ (C_6H_5NR)_2\overset{O}{\overset{\|}{P}}OP(O)(NHC_6H_5)(RNC_6H_5) + (C_6H_5NR)_2\overset{O}{\overset{\|}{P}}OP(O)(RNC_6H_5)_2 ;$$

R=CH$_3$, X=OC$_2$H$_5$; R=CH$_3$, X=OP(O)(OC$_6$H$_5$)$_2$;

R=CH$_3$, X=OP(O)(NHC$_6$H$_5$)$_2$ .

Phosphorodi(*NN*-cyclohexylphenylamidic)hydrazides are phosphorylating agents and give rise to the corresponding pyrophosphates on reaction with phosphorodi(*N*-arylamidic) acids:[79]

$$(RNH_2)_2\overset{O}{\overset{\|}{P}}NHNH_2 + (R'NH)_2\overset{O}{\overset{\|}{P}}OH \xrightarrow{I_2} (RNH)_2\overset{O}{\overset{\|}{P}}OP(O)(NHR')_2 .$$

### *(b) Interaction with Water, Caustic Alkalies, Hydrogen Chloride, and Nitric Acid*

It is known that in the presence of moisture one ester linkage in diaryl phosphorohydrazides is hydrolysed:[16]

$$(C_6H_5O)_2\overset{O}{\overset{\|}{P}}NHNH_2 + H_2O \rightarrow H[PO_2(OC_6H_5)(NHNH_2)] + C_6H_5OH .$$

Diaryl phosphorohydrazidates are stable only in the absolutely dry state.

In the reactions of diaryl phosphorohydrazidates and *OO'*-diaryl phosphorohydrazidothioates with caustic alkalies, the hydrolysis of one or two ester linkages, depending on reaction conditions, is observed, with formation of the mono- and di-sodium (potassium) salts of phosphorus acid hydrazides. The ester linkage is also hydrolysed in the hydrolysis of phenyl phosphorodihydrazidate and *O*-phenyl phosphorodihydrazidothioate[16,42] with formation of a salt. When sodium (potassium) salts of phosphorus acid hydrazides are treated with hydrochloric and acetic acids, the corresponding acids are produced.[16]

*N*-Substituted phosphorus acid hydrazides react with hydrochloric acid to form several products:[100]

$$(CH_3)_3C\overset{O}{\overset{\|}{P}}(OCH_3)NC(CH_3)_3NHC(CH_3)_3 \xrightarrow[15\ min]{6M\,HCl} (CH_3)_3C\overset{O}{\overset{\|}{P}}(OCH_3)NHNHC(CH_3)_3 \xrightarrow{\Delta}$$

$$\rightarrow (CH_3)_3C\overset{O}{\overset{\|}{P}}(OH)_2 + (CH_3)_3CNHNHC(CH_3)_3 \cdot HCl + (CH_3)_3CNHNH_2 \cdot HCl .$$

*t*-Butylhydrazine hydrochloride is formed from 1,2-di-t-butylhydrazine as a result of the dissociation of the C–N bond. On further hydrolysis, trimethylmethanol, chloromethane, and methanol were isolated.

On interaction with dry hydrogen chloride, phosphorus acid hydrazides form hydrochloride salts of the following type:[25,34,101]

$$(C_2H_5O)(o\text{-}ClC_6H_4O)\overset{X}{\overset{\|}{P}}NHNH_2 \cdot HCl ;$$

$$(ClCH_2CH_2)_2\overset{O}{\overset{\|}{P}}(OAr)NHNH_2 \cdot HCl ;$$

X=O; S .

On treatment with sodium nitrite in solution in hydrochloric acid, phosphorodi[*N*-cyclohexyl(benzyl)amidic] hydrazides are converted into phosphorodi(*N*-cyclohexylamidic) and phosphorodi(*N*-benzylamidic) azides.[24] The structure of the azides has been demonstrated by IR spectroscopy: $\nu_{max}$(NH) = 3368, 3260, and 3220 cm$^{-1}$; $\nu(N_3)$ = 2150–2140 cm$^{-1}$; $\nu$(P=O) = 1210–1205 cm$^{-1}$.

### 3. Oxidation Reactions

The oxidation of phosphorodi(*NN*-alkylarylamidic) 2-methoxy(ethoxy)carbonylhydrazides with lead tetra-acetate leads to the formation of the corresponding azo-derivatives:[79]

$$(C_6H_5NR)_2\overset{\overset{O}{\|}}{P}NHNHR' + Pb(OAc)_4 \rightarrow (C_6H_5NR)_2\overset{\overset{O}{\|}}{P}N{=}NR + Pb(OAc)_2 + AcOH\ ;$$
$$R{=}CH_3,\ C_2H_5;\ R'{=}COOC_2H_5,\ C_6H_5\ .$$

The relation is carried out in a 20 : 1 mixture of absolute chloroform and glacial acetic acid at 0 °C. Phosphorodi(*NN*-methylphenylamidic) 2-toluene-*p*-sulphonylhydrazide decomposes vigorously under the conditions of this reaction.

Bromosuccinimide, mercury(II) oxide, and nitrogen dioxide are weak oxidants. The oxidation with bromosuccinimide is carried out in absolute chloroform at −5 °C in accordance with the following scheme:

$$(C_6H_5O)_2\overset{\overset{O}{\|}}{P}NHNHCOOC_2H_5 + \begin{matrix}CH_2{-}CO\\ \\ CH_2{-}CO\end{matrix}\!\!>\!NBr \rightarrow (C_6H_5O)_2\overset{\overset{O}{\|}}{P}N{=}NCOOC_2H_5\ .$$

*N*-Unsubstituted hydrazides of phosphorus diesters are oxidised by iodine in aqueous solutions in the presence of tertiary amines with liberation of nitrogen and the formation of phosphoric acid diesters.[102]

### 4. Acid–Base Properties

The presence of nitrogen atoms together with the nucleophilic phosphorus atom results in the manifestation of amphoteric properties by phosphorus acid hydrazides. In connection with the investigation of the acid–base properties of phosphorus acid hydrazides, studies were made of the basic ($pK_{a_1}$) and acid ($pK_{a_2}$) ionisation constants of diarylphosphinic hydrazides and diarylphosphorohydrazidates[90,93] and the basic ionisation constants ($pK_{a_1}$) of *OO'*-diaryl phosphorothioates and *OO'*-diaryl phosphoro(1-ethylhydrazido)thioates have been determined.[91,92] Analysis of the data obtained showed that the ionisation constants of phosphorus acid hydrazides are satisfactorily correlated with $\Sigma\sigma^{ph}$;

$$pK_{a_1} = 2.57-0.37\sum\sigma^{ph}\ (r = 0.992;\ S = 0.0222)\ \ [90]$$
$$pK_{a_2} = 12.78-0.54\sum\sigma^{ph}\ (r = 0.99,\ S = 0.006)\ .$$

Comparison of the constants ρ in the equation shows that the secondary amino-group is more sensitive to structural changes in the diphenylphosphinic hydrazide molecule than the primary amino-group, which is more remote from the substituents. The same behaviour has been observed for the hydrazides of aromatic carboxylic acids.[103,104]

The acid–base properties of the hydrochlorides of aryl phosphoro[*NN*-di(2-chloroethyl)amido]hydrazidates, whose ionisation constants are satisfactorily linearly related to the Hammett $\sigma^0$ constants and Taft $\sigma^*$ constants, have been investigated:[105]

$$pK_a = 3.20-1.04\sigma^0\ \rho = -1.04\ (r = 0.99;\ S = 0.028)\ .$$

The constant ρ = −1.04 for aryl phosphoro[*NN*-di(2-chloroethyl)amido]hydrazidates compared with ρ = −0.37 for diarylphosphinic hydrazides indicates a greater sensitivity of phosphorohydrazidates to structural changes than that of the phosphinic acid derivatives.

### 5. Polarography of Phosphorus Acid Hydrazides

The polarographic behaviour of aryl phosphoro[*NN*-di(2-chloroethyl)amido]hydrazidates has been investigated.[105] The study of the half-wave potentials of phosphorus acid hydrazides containing the di(2-chloroethyl)amino-group showed that these quantities are in the range from −1.30 to −1.45 V. Satisfactory results have been obtained in alkaline media at pH 9.2, in agreement with literature data for the polarographic activity of the chloroethylamino-group.[106] The influence of various substituents in the *para*-position in the aromatic ring on the polarographic reduction has been estimated. The constant $\rho^* = 0.23$ ($r = 0.99$; $S = \pm 0.025$). The positive value of $\rho^*$ shows that the primary reaction at the electrode involves nucleophilic attack on the electron of the bond being reduced and the comparatively low value of $\rho^*$ indicates a weak influence of the substituents on the electrochemical reaction.

The replacement of the hydrogen atom in the hydrazide group by the toluene-*p*-sulphonyl group changes the direction of the oxidation-reduction process, the sign of the constant $\rho^*$ for which alternates.[63]

### 6. Spectroscopic Properties

The most varied physicochemical methods have been used to study the structure of phosphorus acid hydrazides: IR, UV, and $^1H$ NMR spectroscopy;[24,34,48,56,69,70,73,75,89] the present Section deals with problems in the IR spectroscopic study of the influence of electron-donating and electron-accepting substituents in the aromatic ring on the shift of the bands due to the NH and P=O groups.[90–92]

The complex behaviour of the spectroscopic characteristics of the stretching vibrations of the NH groups in phosphorus acid hydrazides is due to the presence of the imino- and amino-groups at different distances from the P=O group in the aromatic ring and interacting with one another. The influence of substituents on the stretching vibrations of the imino-group (NH) is dominant and is transmitted more effectively by virtue of the considerable amount of double bond character of the P–N bond. The influence of the substituent on the amino-group is transmitted via more extensive molecular systems, incorporating the N–N unit, where the transmission of the electronic influence takes place solely via the *I* effect.

Studies of the IR spectra of diaryl phosphorohydrazidates and *OO'*-diaryl phosphorohydrazidothioates and of the influence of electron-donating and electron-accepting substituents in the aromatic ring on the NH and P=O band shift have been reported.[90–92]

The IR absorption spectra of diaryl phosphorohydrazidates show the following frequencues: ν(P=O) = 1191–1213 $cm^{-1}$, ν(NH) = 3368–3321 and 3227–3204 $cm^{-1}$; the frequencies in the spectra of *OO'*-diaryl phosphorohydrazidothioates are as follows: ν(P=S) = 660–652 $cm^{-1}$ and ν(NH) = 3350–3330 and 3195–3138 $cm^{-1}$.

The NH and P=O stretching vibration frequencies of diaryl phosphorohydrazidates are satisfactorily correlated with the constants $\sigma^{ph}$ and can be expressed by the following equations:

$$\nu(NH) = 3222+45\sum\sigma^{ph}\ (r = 0.868;\ S \pm 4.889)\ ;$$
$$\nu(NH') = 3327-63\sum\sigma^{ph}\ (r = 0.945;\ S \pm 3.958)\ ;$$
$$\nu(P{=}O) = 1206+51\sum\sigma^{ph}\ (r = 0.987;\ S \pm 1.526)\ .$$

The stretching vibration frequencies in *OO'*-diaryl phosphorohydrazidothioates change slightly under the influence

of substituents of different electronic nature. A tendency is observed towards a linear relation between the logarithms of the reaction rate constants and the NH and P=S stretching vibration frequencies.

# Computer Modelling of Dense Polymer Systems

P.G.Khalatur, S.G.Pletneva, and G.N.Marchenko

The application of the Monte Carlo method and the methods of molecular and Brownian dynamics to the study of the structures and dynamic properties of dense polymer systems with a strong intermolecular interaction is examined. The methodological problems arising in the computer modelling of polymers are discussed. Data obtained in numerical experiments on computers for solutions of macromolecules in a low-molecular-weight solvent, semidilute polymer solutions, liquid and amorphous polymers, as well as partly ordered systems (liquid and rotation crystals) are surveyed. The results of the computer experiments are compared with the conclusions arising from modern analytical theory. The limitations of the numerical methods and the prospects for their further development are considered.
The bibliography includes 195 references.

## I. INTRODUCTION

In connection with the progress in computer technology, methods involving the computer simulation of the mathematical models of various physical systems have come to be widely used in recent years. Such models include primarily those of many non-ordered systems with a strong interaction between species: molecular liquids, liquid metals, dense gases and plasma, polymer solutions and melts, liquid crystals, etc.

Three principal computer simulations methods are used in the solution of a whole series of problems in the physics and chemistry of polymers: the Monte Carlo method (MC) and the methods of molecular dynamics (MD) and Brownian dynamics (BD). In the MC method the required properties are obtained by averaging over an *ensemble* of configurations of the system generated on a computer with the aid of a suitable algorithm. The most detailed information (both equilibrium and dynamic) is provided by the MD method, which consists of the numerical integration of the equations of motion formulated in classical mechanics for all the particles of the system under specified initial conditions. The BD method yields a more detailed picture; in this method the influence of the medium (solvent) is taken into account as the overall effect of the forces of viscous friction and random forces.

In the vast majority of studies on the computer modelling of polymers (starting with that of Wall et al.),[1] the influence of volume (long-range) interactions on the conformation of an isolated macromolecule has been investigated by the MC method. The real macromolecule is usually represented in such calculations by a broken line executing random movements on a regular lattice of a specified type (cubic, tetrahedral, etc.). The surrounding solvent is not then taken into account explicitly on the assumption that its role reduces wholly to an effective renormalisation of the interaction potentials of the units of the macromolecule. There exist reviews of early studies in this field.[2-4]

The increase of the power of computers made it possible to formulate computer experiments with more complex models. On the one hand, it became possible to specify in greater detail the models of macromolecules themselves, including the calculations of data concerning chemical structure, inhibiting potentials, etc. Studies have been made on the modelling of a whole series of synthetic polymers,[5-9] polypeptides,[10] polynucleotides,[11] and polysaccharides (for example amylose[12] and cellulose derivatives).[13] On the other hand, the MC and MD methods have come to be used in the study of condensed polymer systems with direct allowance for the influence of the molecules of the medium and of the interaction between molecules. Such investigations are analysed in this review.

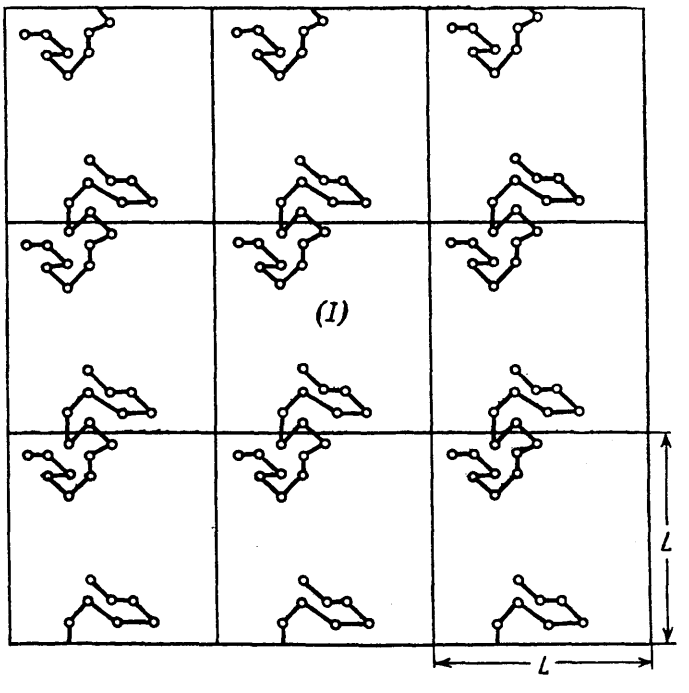

Figure 1. Planar projection of the computational cell (I) with periodic conditions on the boundaries. The cell contains one chain; the solvent particles are not shown.

## II. DILUTE SOLUTIONS

### 1. Methodological Problems

In the computer modelling of dilute polymer solutions (macromolecule + dense low-molecular-weight liquid) all the particles (species) are placed in a cell which usually has the form of a cube with a specified edge $L$ (Fig.1). In order to eliminate surface effects, periodic boundary conditions are introduced: the main cell is surrounded on all sides by similar cells. Free exchange of particles between the cells through the walls is possible. In addition, in dynamic methods a particle which enters the main cell from a neighbouring cell has the same momentum as the particle crossing the wall. We may note that the periodic conditions can be introduced in a different way by placing the molecules not in a cube but on the surface of a hypersphere with a specified radius and number of dimensions exceeding by unity that of the system being modelled.[14]

It is noteworthy that, among polymer systems, dilute solutions are the most inconvenient objects for computer modelling. The point is that, although the polymer molecule is of principal interest, nevertheless most computational effort is expended not on its investigation but on following the movement of solvent molecules, because the number of the latter in the cell is usually much greater than the number of polymer units. Indeed, in order to eliminate the interaction of the chains, it is necessary that the length of the edge of the cell should exceed the maximum size of the macromolecular chain. Consequently, in modelling even an extremely short chain, for example, one made up of 20 units with a contour having a length of ~20, the computational cell must contain ~$10^4$ solvent species when the density of the liquid, $\rho \cong 1$. Such systems lie at the limit of the capacity of the majority of modern computers. Furthermore, as in a physical experiment, the smallness of the observed effects is characteristic of the study of dilute solutions by computer methods. Before proceeding to the discussion of specific results, it is necessary to deal with certain new procedures for increasing the effectiveness of the calculations and also to examine the specific features which arise in the mathematical modelling of polymer systems.

We shall consider a system of $N$ interacting particles with a specified pair potential $f(r_{ij})$, where $\mathbf{r} = (\mathbf{r}_1,...,\mathbf{r}_N)$ are the radius-vectors of the particles which determine the configuration of the system and its potential energy:

$$U(\mathbf{r}) = \frac{1}{2}\sum_i^N \sum_j^N f(r_{ij}).$$

In the classical Metropolis scheme[15,16] the transitions between the configurations take place as follows. After a random selection of a particle $i$ and its displacement in a random direction ($\mathbf{r}_i \to \mathbf{r}_i'$) over a distance $\leq\delta$, the transition to the new configuration ($\mathbf{r} \to \mathbf{r}'$) takes place with the probablilty

$$p = \min\{1, q(\mathbf{r}, \mathbf{r}')\}, \qquad (1)$$

where $q(\mathbf{r},\mathbf{r}') = \exp[(U - U')/kT]$, $U$ and $U'$ being the corresponding potential energies. The system remains in the old state $\mathbf{r}$ with the probability $1 - p$. The formulation (1) means that $p$ is equal to the smallest of the numbers in braces. The random selection process and the subsequent attempt to shift the particle (step) are repeated in the MC method a large number of times, $s$ (~$10^3$–$10^5$ steps per particle); the required characteristic is averaged over all the $s$ steps. The resulting estimate at $s \to \infty$ tends to the true mean over the canonical *ensemble*.

In order to accelerate the convergence of the computational procedure, it has been suggested[17,18] that the Metropolis scheme be modified in such a way that the selected particle moves with a higher probability in the direction of the instantaneous force acting on it from the sides of all the remaining particles. In this algorithm, called the "force bias method", the new configuration is achieved with a probability

$$p = \min\left\{1, q(\mathbf{r}, \mathbf{r}') \cdot \frac{T(\mathbf{r}', \mathbf{r})}{T(\mathbf{r}, \mathbf{r}')}\right\} \qquad (2)$$

where $q$ is specified by Eqn.(1) and the quantity $T(\mathbf{r}, \mathbf{r}')$, linked to the transition $\mathbf{r} \to \mathbf{r}'$, is determined from the formula

$$T(\mathbf{r}, \mathbf{r}') = \begin{cases} C \cdot \exp(\lambda \Delta\mathbf{r} \cdot \mathbf{F}_i/kT) & \text{when } \Delta r \leqslant \delta \\ 0 & \text{when } \Delta r > \delta \end{cases} \qquad (3)$$

For the reverse transition, the quantity $T(\mathbf{r}', \mathbf{r})$ has an analogous form. In Eqn.(3), $\Delta\mathbf{r} = \mathbf{r}_i' - \mathbf{r}_i$ is the shift of the $i$th particle within the limits of the specified region $\delta$, $\mathbf{F}_i = -\partial U(\mathbf{r})/\partial \mathbf{r}_i$ the force acting on the particle in the configuration $\mathbf{r}$, $\lambda$ a parameter, and $C$ the normalising constant, which cancels out in Eqn.(2). It is seen from Eqns. (2) and (3) that the particles are displaced predominantly in the direction of the force $\mathbf{F}$. For $\lambda = 0$, the scheme described reduces to the Metropolis scheme. The parameters $\lambda$ and $\delta$ are chosen in such a way that the mean square shift of the particles is maximised.

A MC algorithm, formally similar to the method of Brownian dynamics, has been proposed[19–21] and Rossky et al.[19] called it SMART. If an $N$-unit chain is immersed in a viscous medium, then the movement of any $i$th particle (unit) can be described by the Langevin equation[22]

$$m_i \frac{d^2\mathbf{r}_i}{dt^2} = -m_i\gamma_i \frac{d\mathbf{r}_i}{dt} + \mathbf{F}_i + \mathbf{R}_i, \quad i = 1, 2, \ldots, N, \qquad (4)$$

where $m_i$ and $\gamma_i$ are respectively the mass and the coefficient of friction, $\mathbf{F}_i$ is the force acting on the $i$th particle from the side of all the remaining particles of the chain, and $\mathbf{R}_i$ is a random force reflecting the random jolts by other molecules of the medium. In a real situation, Eqn.(4) should include the hydrodynamic forces, but one can consider a highly viscous medium ($\gamma \gg 1$) where they are absent. In this case the inertial term on the left-hand side of Eqn.(4) can also be rejected. The following algorithm of motion, formulated in the finite difference form

$$\mathbf{r}_i' = \mathbf{r}_i + \Delta t D_i \mathbf{F}_i/kT + \mathbf{X}_i, \quad i = 1, 2, \ldots, N, \qquad (5)$$

is then obtained. Here $|\mathbf{r}_i' - \mathbf{r}_i|$ is the distance traversed by the $i$th particle during the period $\Delta t$, $D_i = kT/m_i\gamma_i$ the diffusion coefficient of the particle, and $\mathbf{X}_i$ the random shift corresponding to the force $\mathbf{R}_i$ and having the normalised Gaussian distribution

$$W(X_{i\alpha}) = (4\pi a_i)^{-1/2} \cdot \exp(-X_{i\alpha}^2/4a_i), \quad \alpha = x, y, z, \qquad (6)$$

where $a_i = \Delta t D_i$ is the specified parameter.

In Brownian dynamics the equation of motion (5) describes a sequence of unconditional transitions between states. In the MC method the new position $\mathbf{r}'$ in Eqn.(5) is adopted or rejected with a probability defined by Eqn.(2), where

$$T(\mathbf{r}, \mathbf{r}') = (4\pi a_i)^{-3/2} \cdot \exp\{-[(\mathbf{r}_i' - \mathbf{r}_i) - a_i \mathbf{F}_i/kT]^2/4a_i\}, \qquad (7)$$

and $T(\mathbf{r}', \mathbf{r})$ is formulated analogously. Compared with the standard scheme,[15] the "force bias" and SMART algorithms ensure an increase of the probability of the transition defined by Eqn.(1) by a factor of ~2–3.

Finally mention should be made of a fundamentally new approach to the MC modelling of chains based on the functional integration technique. In contrast to the usual treatment of the "chain–set of discrete force centres (units)" system, it has been suggested[23] that the macromolecule be described by a continuous line specified by a Fourier series in functional space. For a random selection of the series coefficients, the line changes its shape (i.e. it undergoes "conformational rearrangements") and the transitions between states evolve in accordance with the usual MC scheme.

In the study of polymers by the MD method, the problem of the way in which the valence bonds are described becomes important. Here there are alternatives: (1) the bonds can be modelled by any smooth function (for example, a quadratic function) and (2) the bonds can be regarded as absolutely rigid bounded formations, i.e. they are modelled by a $\delta$-function. In the former case the standard difference schemes of computational mathematics are suitable for the integration of the equations of motion $m_i d^2\mathbf{r}_i/dt^2 = \mathbf{F}_i$,[24] which make it possible to find the coordinates and momenta of the particles at finite time intervals $\Delta t$. However, owing to the great "rigidity" of the valence potentials, high-frequency oscillations are characteristic of the chain particles which can be taken into account only for a very small integration step $\Delta t$. This shortens the length of the trajectory susceptible to calculations. For this reason, the exclusion from the calculation of the corresponding degrees of freedom when chemical bonds are treated as geometrical bounded regions gives rise to a considerable computational effect.

Within the framework of this method of modelling, special procedures, correcting the bond length at each step, are used. One of the correction procedures has been proposed by Balabaev[25] and another, the widely used procedure SHAKE, has been put forward by Ryckaert et al.[26] An improved version of the algorithm SHAKE, which the author called RATTLE, has been proposed.[27] The specific features of the mathematical modelling of polymers by the MD method consist precisely in the presence of such correction procedures. Without any changes, they also enter into the BD method, which is based on the numerical integration of the Langevin equation. The algorithms used at present for calculations by the BD method (including those taking into account hydrodynamic interactions[29] and the random force delay effects)[30] have been published.[28–30] Both dynamic methods yield a phase trajectory from which the equilibrium characteristics (as time averages) and the time variations are determined.

In conclusion of this Section, we shall make two general remarks: about the relation between the computer methods and about their correspondence to a real experiment. As already stated, the physical principles on which the MC and MD modelling is based differ radically. In the former case these are the probability principles of statistical mechanics and in the latter they are the extremely deterministic foundations of classical Newtonian mechanics. The BD method, in which stochastic and determined descriptions are combined, occupies an intermediate position in this sense.

The question of the equivalence of the equilibrium properties obtained by averaging with respect to the *ensemble* and time along the dynamic trajectory is actually identical with the familiar ergodic problem. If there exists a thermodynamic limit $(N, V)_{N, V \to \infty} = \text{const}$. (where $V$ is the volume), then there is no doubt about the validity of the different types of averaging. Systems made up of a finite number $N$ of particles require a more careful analysis. We may note that such a problem can be solved within the framework of the computer calculations themselves. It is found that the results of the averaging by both methods differ by a quantity of the order of $1/N$.

Another part of the problem of the relation between the computer methods reduces to the dynamic interpretation of the Monte Carlo process. This treatment is based on the fact that the Metropolis scheme (or its modifications) reproduces the evolution process in which the system passes step by step from one state to another and the consecutive states are highly correlated. Naturally, such evolution self-models a kind of artificial (stochastic) kinetics, but it does not reflect the real alternation of the states of the system in real time, as happens in molecular dynamics. Nevertheless, it is possible to define conditions for which the MC method yields the correct description of the kinetic behaviour. It has been recently demonstrated rigorously[31] that, within the limits of a small step ($\delta \to 0$), in the usual MC calculation the configuration relaxation is described by the same kinetic relations as in the modelling by the BD method at the limit corresponding to a high friction, where $\gamma \gg 1$ and the non-inertial movement of the particles follows the Langevin equation (5). The Monte Carlo time scale (i.e. the number of steps per particle) and the real time $t$ are then linearly related: $s/N \cong Tt/\gamma\delta^2$, which is valid in practice for a fairly large step $\delta$. Therefore, having followed by the two methods the evolution of any one function of the coordinates, it is possible to correlate the time scales and thereby establish a relation between the results of the statistical and dynamic modelling.

Thus the computer simulation methods, based on different physical principles, have a most important advantage—they are closed, i.e. there is a possibility of a mutual test within the very results obtained for the same model.

The principal problems in the computer experiment arise in connection with the formulation of the model of the test object. This concept includes primarily the set of rules describing the interaction of the particles with one another or with external fields. The way in which the valence forces, i.e. the chemical combination of atoms, are taken into account is one of the examples of such rules. Since different kinds of valence and non-valence potentials, which constitute merely an approximation to the true interaction, are used for this purpose, this in fact defines a measure of the correspondence between the physical and computer experiments. Naturally, initially it is possible to solve the converse problem, where the potentials are at first calibrated against the available experimental data and are only then used to obtain more detailed information about the system. On the other hand, since numerical experiments for the specified model yield rigorous results within the limits of statistical error, they can be adopted as a standard to test the theories relevant to an analogous model and the approximations on which the analytical treatment is based. We believe that this precise formulation of the problem is methodologically justified. However, in both cases one must remember (and this is the principal limitation) that any modern computer can operate only with an immeasurably smaller number of particles than in real systems, where $N \cong 10^{23}$. The "record" calculations, familiar to the authors, on the most powerful multiprocessor or vector computers (of the PS-3000 or CRAY type) are restricted to models comprising $N \cong 10^6$ particles and times $t \sim 10^{-6}$ s†, which are very small on the macroscopic scale. As a rule, calculations are in fact performed for $N \cong 10^2$–$10^3$ and a time interval $T \lesssim 10^{-9}$ s.

---

†The symbol ~ is used in Russian to imply "proportional to", "of the order of", or even "approximately equal". No attempt has been made in the translation to elucidate its specific meaning in each use (Ed. of Translation).

Although small systems, such as molecular clusters or isolated macromolecules, are of independent interest, in the usual practice employed in computer calculations the interpretation of macroscopic properties on the basis of the modelling of a set of a small number of particles is an extremely non-trivial problem. The greatest difficulties are associated with the study of systems near phase transition points where large-scale low-frequency fluctuations arise. An extensive literature[16,24] has been devoted to the analysis of such problems, which we are unable to consider in detail here. We shall only note that, when periodic boundary conditions are used for the extrapolation to the thermodynamic limit, it is essential that the linear size of the cell $L(L \sim N^{1/d}$ in a $d$-dimensional space) should exceed significantly the correlation radius of the density fluctuations. If the calculation is not performed near a phase transition point, then for the usual short-range potentials this requirement is normally satisfied for $N \sim 10^2-10^3$ and the error due to the finite size is of the order of $1/N \sim 1/L^d$.

## 2. Equilibrium Properties

Since macromolecular compounds cannot be transferred to the gas phase, the question of the influence of the solvent on their conformation and movement is fundamental. It is important also from the methodological point of view. In fact the justification of the computer experiments in which the solvent is not considered explicitly and is taken into account either via the potential of the average force of interaction of the units or as a continuous viscous medium generating random jolts actually depends on the solution of this kind of problem.

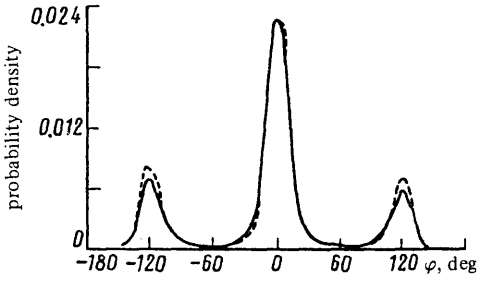

**Figure 2.** Distribution function with respect to torsional angles $\phi$ of the central C–C bond for n-butane at 218 K.[32] Continuous line—gas; dashed line—solution in $CCL_4$; the angle $\phi = 0$ corresponds to the *trans*-conformation.

A system comprising one n-butane molecule and 127 carbon tetrachloride molecules with an overall density of 1.61 g cm$^{-3}$ has been investigated by the MC method.[32] The interaction of the particles was described by the Lennard-Jones potential and the hindrance to the internal rotations around its central C–C bond in butane was described by a three-barrier cosinusoidal potential $V(\phi)$. The transitions between the configurations evolved in conformity with the Metropolis scheme.[15] Analysis of the distribution with respect to the angles of internal rotation showed (Fig. 2) that these distributions are virtually identical for both dissolved and isolated (present in a rarefied gas) butane molecules. In both cases the most probable values of $\phi$ are 0° and ±120°. The fractions of the *trans*-isomers also proved to be similar: 0.61 and 0.65. Consequently one may say that, within the limits of the accuracy of the calculation, the solvent does not exert an appreciable influence on the conformation of n-butane. Robertus et al.,[33] who modelled a dilute solution of n-butane by the MD method, arrived at the same conclusion.

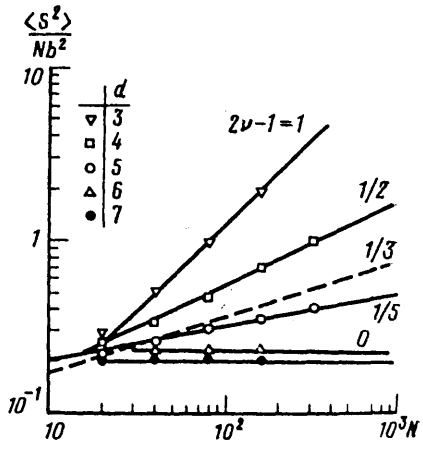

**Figure 3.** Dependence of the mean square radius of inertia of a charged chain on the number of units for spaces with different numbers of dimensions $d$.[47] Symbols—MC calculations; continuous lines—calculation based on the Flory theory; dashed line—calculation by the RG method for $d = 5$.

Naturally the calculations for n-butane do not reflect quite adequately the properties of long chains. Computer experiments on the modelling of chains with a large number of units are therefore of special interest. We may note the studies [34–41] in which the MD method has been used. In the first investigations of this kind[34,39] a nine-unit chain ($N = 9$), placed in a cell which also contained $N_S = 855$ solvent molecules, was studied. The interaction between any two particles in the system was described by the Lennard-Jones potential

$$f(r_{ij}) = 4\varepsilon[(\sigma/r_{ij})^{12} - (\sigma/r_{ij})^{6}], \qquad (8)$$

where $r_{ij}$ is the distance between the particles $i$ and $j$ and $\varepsilon$ and $\sigma$ are parameters. We may recall that reduced units are employed in the MD method: the lengths are expressed in units of $\sigma$, the rates in units of $(\varepsilon/m)^{1/2}$, and the time in units of $\tau = \sigma(m/\varepsilon)^{1/2}$, where $m$ is the mass (the mass was assumed to be the same for all the particles[34,39]). The chain considered in the above studies[34,39] contained bonds with a rigorously fixed length but the angles between the bonds and the angles of internal rotation were not restricted. The number-average density of the system was $\rho = (N + N_S)L^3 = 0.85$. As a result of averaging with respect to a trajectory whose length was 142$\tau$, the mean square of the distance between the ends of the chain $\langle R^2\rangle$ and the mean square radius of inertia $\langle S^2\rangle$ were found. In addition, the static structure factor $s(Q)$ was calculated for $|Q| \leq 40/\sigma$. For comparison, all the calculations were repeated for the same chain but without taking into account the solvent. It was found that in both cases the average

dimensions of the chains are similar. The functions $s(Q)$ are also virtually identical. Small differences were observed in the region of small $Q \leqslant 1.5/\sigma$ corresponding to units remote from one another. The characteristics of the average form of the polymer coil (i.e. the relations between the orthogonal components of the radius of inertia) also do not exhibit appreciable differences.

Rapaport,[36] who investigated by the MD method freely jointed chains comprising 5, 10, and 20 units immersed in a solvent with $\rho = 0.2$ or 0.3, arrived at analogous conclusions. It was shown that the quantities $\langle R^2 \rangle$ and $\langle S^2 \rangle$ agree satisfactorily with the results of a previous calculation,[42] where the solvent was altogether disregarded.

We may also note a study[41] of the MD modelling of a dense system ($\rho = 0.85$) comprising 246 solvent particles and one ten unit chain with fixed skeletal angles and bonds and with hindered rotation. Calculations taking into account the strong attraction between all the system particles showed that the quantities $\langle R^2 \rangle$ and $\langle S^2 \rangle$ are somewhat greater than in the case of a purely repulsive potential. In our view, this effect is due to the decreased overall pressure in the system.

Since the calculations described refer nevertheless to comparatively short chains, it is doubtful if they fully reproduce the properties of polymers in which the chain length is usually very large. However, this is not so. The use of the MC method in combination with the procedures of the renormalisation group (RG) theory[43] has shown[44] that asymptotic behaviour is attained fairly rapidly for flexible chains with strong volume interactions. Even for $N = 8$–16, freely jointed non-intersecting chains satisfy the relation

$$\langle R^2 \rangle \propto N^{2\nu} \qquad (9)$$

where the critical index $\nu = 0.589 \pm 0.003$, which actually agrees with the limiting value (the best calculation carried out hitherto by the field theory method[45] for $N \to \infty$ yielded $\nu = 0.588 \pm 0.001$; the most reliable experimental result is $\nu = 0.586 \pm 0.004$, which has been obtained[46] for polystyrene with $M_w \leqslant 5.6 \times 10^7$). A criterion of asymptotic behaviour is the inequality $N \gg (b/\sigma)^6$, where $b$ is the chain length and $\sigma$ the effective rigid chain diameter. For the chains considered in numerical experiments,[34–42] this condition apparently holds, since in all cases $b/\sigma \cong 1$. For this reason, even what are at first sight very short chains should correctly reflect the equilibrium properties of high-molecular-weight polymers.

Thus computer simulation methods have shown that, in dilute solution a low-molecular-weight neutral solvent has only a weak influence on the conformation of a flexible polymer chain for the usual densities and pressures. The interactions of the chain units themselves play a more significant role. The approaches in which the solvent is excluded from explicit consideration in the computer modelling of the equilibrium properties of polymers and the solvent is only considered via the appropriate selection of the interaction potentials between units are therefore fully justified. If the effective potentials are such that the repulsive forces predominate in the interaction and the macromolecule swells, increasing thereby its volume relative to the θ-dimension $R_\theta (R_\theta \sim bN^{1/2})$, it is natural to assume that a thermodynamically effective solvent is modelled. On the other hand, if the coil is compressed relative to $R_\theta$ owing to the strong attraction of the units and passes to a globular state, then one models a solvent whose quality is inferior to that of a θ-solvent. Naturally in such a study the effective potentials have the significance of the potentials of the average interaction force, i.e. they determine the change in the free energy and not in the potential energy of the interaction.

Special problems arise in the computer modelling of polyelectrolytes, in which there are long-range electrostatic interactions within the chain. Charged flexible chains containing $N \leqslant 321$ units have been investigated by the MC method in spaces with $d = 3$–7 dimensions.[47] A non-shielded Coulombic potential has been used to describe the electrostatic forces. It was found that the index $\nu$ in Eqn.(9) is $\nu = 3/d$. This result is extremely unexpected, because it is in full agreement with the conclusions of the classical Flory theory[48] but shows a sharp discrepancy with the RG treatment,[43] which predicts that $\nu = 2/(d-2)$ for $4 < d \leqslant 6$. This can be seen from Fig.3, where the result of the computer calculation of $\langle S^2 \rangle$ is compared with the RG relation for a five-dimensional space. It may be that in the case of a long-range potential the chain length is insufficient for the complete realisation of the volume effects even with $N \cong 10^2$.

## 3. Dynamic Properties

In the study of dynamic properties, one usually calculates the diffusion coefficients and various autocorrelation time functions (AF) of the type $C(A, t) = \langle A(0).A(t) \rangle$ characterising under stationary conditions the correlation between the values of the function $A$ considered at time intervals $t$.

The translational diffusion coefficient $D$ is obtained by integrating the AF for the velocity $C(\mathbf{v}, t)$ by the Green–Kubo formula[22]

$$D = (1/3) \int_0^\infty \langle \mathbf{v}(0) \cdot \mathbf{v}(t) \rangle dt,$$

or by the Einstein formula

$$\lim [\langle \Delta r^2 \cdot (t) \rangle]_{t \to \infty} = 6tD + B,$$

where

$$\langle \Delta r^2(t) \rangle = \langle [\mathbf{r}(t) - \mathbf{r}(0)]^2 \rangle$$

is the mean square displacement of the particle during time $t$ and $B$ a coefficient which determines whether the diffusion is more intense or weaker than a Markov process and the angular brackets denote averaging with respect to time and all the particles. The averaging range of $T$ should significantly exceed the relaxation time $t_0$ of the process considered because the error in the calculation of the normalised AF of the type $\langle A(0).A(t) \rangle / \langle A^2 \rangle$ for a given $t$ is $(2t_0/NT)^{1/2}[1 - \langle A(0).A(t) \rangle / \langle A^2 \rangle]$.

We shall now turn to small-scale and high-frequency movements (corresponding to times $\leqslant 10^{-0}$ s (error in Russian, Ed.) for real systems); information about such systems can be derived, for example, by the dielectric relaxation, polarised luminescence, NMR, EPR, etc. methods. This problem has been studied by the MD method.[37,38,49]

For a better understanding of the polymer effects, we shall consider primarily the simplest "molecule" of anisotropic shape made up of rigidly linked particles ("dumb-bell"), which moves in a liquid made up of non-bonded species. The mean square displacement of the centre of gravity of the dumb-bell is a linear function of $t$ with the exception of a short initial section—the inertial region, where $\langle \Delta r^2(t) \rangle \sim t^2$. As for a homogeneous system, the boundary between the inertial and diffusion regions is determined by the time $t \sim \gamma/m$, where $\gamma$ is the coefficient of friction of the moving particle. The rotation of the dumb-bell is also described by diffusional laws. This means that the rotational AF bond vectors b are given by the expression

$$\langle P_l[\cos \theta(t)] \rangle = \exp[-l(l+1)D_R t],$$

where

$$\cos \theta(t) = \mathbf{b}(0) \cdot \mathbf{b}(t)$$

is the cosine of the angle of rotation of b during the time $t$, $P_l$ is the $l$th Legendre polynomial, and $D_R$ the coefficient of rotational diffusion. We may note that the foregoing is valid for a bond length $b \gtrsim \sigma$, where the contribution of inertial movements to the relaxation of the AF is small. Otherwise a single characteristic time is insufficient for the description of the orientational AF.

There is a strong relation between the translational and rotational movements of an anisotropic particle in a liquid.[50] This feature can be manifested in spectroscopic experiments. In a dense medium the particle rotates faster the more rapid its translational movement. This correlation can be accounted for by the presence of a local structure in the liquid. For a constant density of the system, the coefficient $D$ for a dumb-bell increases linearly with temperature, which means that the local viscosity of the medium is determined primarily by the free volume.

Overall, analysis of the MD calculations permits the conclusion that the movement of an anisotropic particle in a solvent can by correctly described as the movement of a Brownian particle in a continuous viscous medium. The accuracy of such description increases with increased difference between the masses, dimensions, and shape anisotropies of the given molecule and the molecule of the medium. It must be specially emphasised that the translational movement of a particle and its rotation are, as it were, made up of a large number of small jumps and not of several large jumps. The diffusing particle interacts strongly with its environment under these conditions and its movement is a collective process. This idea was put forward by Frenkel'.[51] The MD method made it possible to elucidate certain fine details of molecular movements in dense media.

The study by the MD method of flexible chains in media made up of particles whose interaction is described by the Lennard-Jones potential [Eqn.(8)] has shown[49] that, for short times $t \lesssim 0.2\tau$, the units move as in the gas phase, while in the range $0.3 < t/\tau < 4$, so long as the displacement $\Delta r$ remains small compared with the characteristic chain dimension, we have $\langle \Delta r^2(t) \rangle \sim t^{\alpha}$, where $\alpha < 1$. A more detailed study[37] gave $\alpha \cong 1/2$. The manifestation of this unusual motion regime, which is absent for the free particles, is due to the inhibiting effects of skeletal bonds. The presence of branches induces additional inhibition: $\langle \Delta r^2(t) \rangle \sim t^{1/2}/k$, where $k$ is the functionality of the given monomer.[38] We may recall that the $\langle \Delta r^2(t) \rangle \sim t^{1/2}$ relation is predicted by the Kargin–Slonimskii–Rowse model of Gaussian subchains.[43] Naturally, for large values of $t$, the general diffusion law always holds, although the shift of the monomers is influenced by the chain length: $\langle \Delta r^2(t) \rangle t/N$.

A characteristic feature of the chains with rigid bonds is the increased velocity of the terminal chains compared with the internal chains (the difference is 10–10%).[52] This "hot end" effect is due to the differences in the number of degrees of freedom.

The relaxation of the spatial orientations of the bond vectors of a chain immersed in a solvent has been investigated.[37] Comparison of the results of the MD calculation with the analytical predictions of the viscoelastic Herst–Harris model showed that the relaxation of the mean cosine of the angle of rotation of the bonds [i.e. the orientational AF of the type $\langle \cos \theta(t) \rangle$] takes place in a real chain in virtually the same way as the relaxation of the equivalent quasi-elastic elements in the Herst–Harris model. A rigid chain bond then corresponds to an elastic element of the model and the mean angle between the elements of the viscoelastic model is close to the mean angle between the bonds. In addition, the relation between the mean cosines and mean squares of the cosines of the angles of rotation of the chain bond vectors is similar to the same relation for the individual dumb-bells diffusing in a viscous medium. In other words, the characteristic time of the orientational AF obeys with satisfactory accuracy the expression $t_1/t_l = l(l+1)/2$. However, the orientational AF of the bonds in the macromolecule do not reduce to a simple exponential relation with a single characteristic time $t_l$ and require for their description a fairly broad spectrum of relaxation times. The same conclusion has been reached also in modelling an individual chain by the BD method.[53] This fact is due to the interrelation between different movements in the macromolecule and reflects its chain structure and is not associated with the presence or absence of a solvent.

The general results of the MD calculations can be formulated as follows. The characteristics of the local movements of polymer chains in a low-molecular-weight solvent are close to those manifested in the movement in a continuous viscous liquid. The solvent behaves as a continuous homogeneous medium in relation to the dissolved macromolecule even when the dimensions of the solvent molecule and the chain are comparable. Consequently the MD method confirms the *a priori* postulates which are used in modelling the dynamics of polymers by the BD method, where the medium is regarded at the very beginning as a dense continuum and is not taken into account explicitly but only via the effective coefficient of friction $\gamma$ in the Langevin equation. Assuming that the chain units move like Brownian particles, it is natural to specify the parameter $\gamma$ on the basis of preliminary MD calculations. Because of this, there is no need in the BD method to solve the equations of motion for an enormous number of solvent molecules and it is therefore possible to increase significantly the observation time. This is the main advantage of the BD method. It is used, for example, in the study of the conformational *trans–gauche* transitions in polymers with barriers to internal rotation.[53,54] It has been established that the conformational rearrangements occur mainly owing to weakly correlated single barrier $T \rightleftharpoons G$ transitions and their rate is described by the relation $K \exp(-E^*/kT)$, which is close to the Arrhenius relation, where the activations energy $E^*$ differs little from the height of the potential barriers separating the rotational isomers $T$ and $G$. Cooperative transitions of the type GTT $\rightleftharpoons$ TTG and TTT $\rightleftharpoons$ GTG are observed much more rarely.

We shall now consider the movement of the chain as a whole. The autocorrelation function for the velocity of the centre of gravity of the coil has a complex form: after the rapid decrease to zero (during a time $t \cong 0.2\tau$ for $N = 9$), a region of negative values is observed.[39] This phenomenon is apparently associated with the small number of chain units and can be explained by the fact that the diffusing molecule, having collided with the shell of surrounding particles of the medium, undergoes a kind of "backward reflection". This is possible only when the local environment ("cell") around the molecule considered is retained during a certain period.

It is of interest to compare the AF for the dimensions of an isolated chain and a chain immersed in the solvent. Evidently in a viscous medium the relaxation processes are retarded. Indeed the relaxation times $R^2$ and $S^2$ of nine-unit chains suspended in a solvent exceed by more than an order of magnitude the corresponding values for an isolated chain.[39] The vector R connecting the terminal units relaxes most slowly, owing to the necessity for the reorientation of the entire chain. According to Grivtsov

and Mazo,[55] the distance $|\mathbf{R}|$ is an aperiodic function of time, undergoing individual relatively large fluctuations. On the other hand, regular pulsations, whose period increases in direct proportion to $N$, are characteristic of an isolated chain. An increase of temperature accelerates the decrease of AF. For $t = 10\varepsilon/k$, the AF for a freely jointed chain made up of nine units decrease to zero over a short period $t \lesssim \tau$ corresponding to approximately one vibration period of a pair of particles.[35]

The influence of attraction in a dilute solution has been investigated[41] and it has been shown that allowance for the attraction between all the system particles retards the decrease of the AF for dimensions.

An important question is the study of the dependence on the molecular weight of the characteristic times for the AF describing the relaxation of the polymer coil. The standard approach to the solution of this problem for an isolated chain (without hydrodynamic interaction) consists in using the MC method with its dynamic interpretation. However, in this case it must be emphasised that such calculations based on lattice models yield results which are determined to a large extent by the chosen mechanism of the movement of the chains and frequently lead to various kind of artefacts, including a very marked dependence of the maximum relaxation time of the coils $t_m$ on $N$: the non-lattice models are therefore preferable.

Using the MC method and the principles of dynamic scaling,[57] it has been shown,[56] in relation to non-intersecting annular molecules, that, as for the equilibrium properties, the asymptotic dependence of $t_m$ on $N$ is attained extremely rapidly (for $N \gtrsim 40$) and the exponent $\alpha$ in the relation

$$t_m \sim N^{\alpha} \qquad (10)$$

is close to 2.2. The same conclusion has been reached in modelling non-lattice non-intersecting chains ($N$ = 5–63) with the aid of the SMART algorithm.[20] It follows from Eqns.(9) and (10) that the formula $\alpha = 2\nu + 1$ holds with satisfactory accuracy. It is known that for Gaussian chains $\alpha = 2$.[43] In addition we may note that the above calculation[56] failed to reveal an appreciable difference in the dynamic behaviour of simple rings and their topological isomers—three-loop knots; for the same $N$, the times $t_m$ are almost identical.

The role of hydrodynamic interactions can be followed in the MD modelling of solutions or in the study of an individual chain on the basis of the corresponding algorithms based on Brownian dynamics. Calculations by the MD method of the autocorrelation functions for the dimensions of chain ($N \leq 20$) surrounded by the solvent have shown[36] that, for overall system densities $\rho \leq 0.3$, the AF are described by a simple exponential relation $\exp(-t/t_m)$ and the times $t_m$ satisfy Eqn.(10) for $\alpha = 2.2$. $t_m$ increases with increase in $\rho$.

A fairly unexpected result has been obtained[58] in the modelling by the BD method of hydrodynamic interactions. It was found that the ratio of the chain size $R$ to the hydrodynamic radius of the chain $R_H$ depend both on the coefficient of friction of the unit and on the number of units; on the other hand, in the theory $R/R_H$ = const.[43] It may be that the dependence of $R/R_H$ on $N$ can be accounted for by the insufficient length of the chains investigated ($N \leq 56$).

## III. SEMIDILUTE SOLUTIONS

### 1. Scaling and Computer Simulation

In a dilute solution the polymer coils are separated and only rarely come into contact, while their dimensions at $T > \theta$ are specified by Eqn.(9). The region of a "semidilute solution" $\rho^* \ll \rho \ll 1$, where $\rho^* \sim N/\langle R^2\rangle^{3/2}$ is the critical value of the average density of the polymer units $\rho$ at which the coils begin to overlap, can be determined from general considerations. It follows from Eqn.(9) that $\rho^* \sim N^{-4/5}$, i.e. for high values of $N$ the quantity $\rho^*$ is very small. In a semidilute solution the local density of the units should therefore undergo strong fluctuations. According to modern theoretical ideas,[43] the principal parameter of such a system is the correlation radius of the density fluctuations $\xi$—the correlation length, i.e. the distance $r$ over which the local density of the units $\rho(r)$ differs from the average value of $\rho$. The quantity $\xi$ thereby characterises the dimensions of the regions of inhomogeneity in the solution.

The use of the parameter $\xi$ constitutes the basis of an elegant and extremely clear phenomenological description—the so-called blob model. The idea is that, having increased the scale of the study, one passes from the usual formulation of properties in terms of the collective interactions of polymer units to the formulation of the same properties in terms of the interaction of blobs. A blob is defined as a section of the chain (subchain) made up of $N_\xi$ units with the average dimension $\xi$. In other words, the increase in scale consists in the replacement of the repeating unit whose size is $\sim\sigma$ by a subchain (blob) with the dimension $\xi$. Since the chains retain their individual properties for scales $r < \xi$, for sections made up of $N_\xi$ units, one can write, by analogy with Eqn.(9), $\xi \sim N_\xi^{\nu}$. On the other hand, for scales $r > \xi$, all correlations vanish by definition. Therefore a chain, which can be imagined to be divided into $n = N/N_\xi$ blobs, has overall the following Gaussian dimensions: $R \sim \xi n^{1/2} \sim N^{1/2}$.

The above data make it possible to express important characterstics such as $\langle R^2\rangle$ and $\Pi$ (osmotic pressure) in terms of $\xi$ or $\rho$. When $T > \theta$, we have in the general case for a $d$-dimensional space

$$\langle R^2\rangle \sim N\xi^{(2\nu-1)/\nu} \sim N\rho^{(2\nu-1)/(1-\nu d)}, \qquad (11)$$

$$\Pi/kT \sim \xi^{-d} \sim \rho^{\nu d/(\nu d-1)}, \qquad (12)$$

where $\nu$ enters into Eqn.(9) [or is formulated approximately as $\nu = 3/(d+2)$] and account is taken of the fact that $\xi$ is a decreasing function of the average density:

$$\xi \sim \rho^{\nu/(1-\nu d)} \qquad (13)$$

The above treatment is based on the extremely general hypothesis that in the region of strong fluctuations the thermodynamic and correlation functions are generalised homogeneous functions of their arguments. This hypothesis constitutes the essential feature of the so-called similarity or scaling hypothesis. According to this hypothesis, the transformation of the linear scale $\mathbf{r} \to \lambda\mathbf{r}$ (or, in terms of dynamic scaling, the frequency scale) with an arbitrary similarity parameter $\lambda$ leads to the situation where the fluctuating physical quantities $A(\mathbf{r})$ should also vary in a similar manner $[A(\lambda\mathbf{r}) \to \lambda^{\Delta}A.A(\mathbf{r})]$ with a similarity exponent $\Delta_A$. On the basis of the phenomenological scaling concept, it is easy to establish a relation between the critical exponents $\Delta_A$, provided that some of

them are already known. An example is provided by the power relations (11)–(13) formulated in terms of a single power exponent $\nu$. However, the calculation of the parameters themselves is a problem for microscopic theory.

One such approach, which takes into account the cooperative interactions in the system, is known as the theory of the mean (or self-consistent) field. The entire classical Flory theory of polymer solutions is based on this approximation.[48] In it, a uniform distribution of the densities throughout the system is assumed, i.e. it is assumed that the local density $\rho(r)$ coincides with the average value of $\rho$ over any distance. In this treatment $\langle R^2 \rangle$ is independent of $\rho$ and formulae (12) and (13) assume the forms $\Pi \sim \rho^2$ and $\xi \sim \rho^{-1/2}$.

The Flory theory proved to be extremely constructive, but, with increase of the experimental accuracy, data conflicting with it began to accumulate. This led to the appearance at the beginning of the 1970's of an alternative approach based on the fundamental postulate of the mathematical isomorphism of two systems: the polymer solution in the region of strong fluctuations and a magnetic material in an external field $H$ near the critical temperature $T_c$. It has been demonstrated rigorously[43] that there is an unambiguous correspondence between the "magnetic" and "polymeric" variables: $H \leftrightarrow \rho$ and $T/(T - T_c) \leftrightarrow N$ (or $N_\xi$). The field theory methods, which have been satisfactorily developed for magnetic materials, make it possible to calculate the critical indices at $|T - T_c| \to 0$ (or in polymer terms, $1/N \to 0$) and, by virtue of the analogy indicated between polymers and magnetic materials, these indices are automatically transferred to the polymer theory. In many cases they can be measured experimentally. This is in fact the aim of the computer experiment, whose evident advantage is the possibility of excluding the influence of extraneous factors such as the inhomogeneity of the chemical structure of the specimen and its polydispersity, the association of the macromolecules, etc. In the main, one solves problems designed to discover a measure of the deviation from the classical Flory theory, to refine the limits of applicability of the scaling relations (11)–(13) to the practically important region of the parameters $N$ and $\rho$, and to test the phenomenological relations between various critical indices resulting from their independent calculation.

The equilibrium properties of semidilute solutions are usually studied on a computer by the MC method. Two characteristic features of the modelling of such systems have been noted. On the one hand, there is the general problem of the modelling of long chains coupled with the need to incorporate a large number of geometrical conditions imposed by the skeletal angles and bonds. Generally speaking, for fixed geometrical parameters, it is not possible to consider the independent movements of an individual chain unit while the remaining chains are stationary, as is done in the Metropolis scheme for a system of "dissociated particles", where only one particle selected at random migrates at each step. For chains with rigid bonds, this type of movement can be organised in three artificial ways. If the chain is modelled by a broken line on a cubic lattice, there is a possibility of jumps of elementary sections in the form of "corners" (fragments made up of two bonds) or "collars" (fragments made up of three bonds); this is the model of Verdier and Stockmayer.[59] In the "slithering snake" algorithm[60] the terminal unit is "torn off" at each step and is reattached in a random manner to the opposite end of the chain. This algorithm is equally applicable to lattice and continuous models. Finally, if the skeletal angles are not fixed, then any internal unit $i$ can be caused to pass to a new state by rotating it by random angle around an imaginary axis connecting the neighbouring $i - 1$ and $i + 1$ units (the Baumgärtner model).[61] In all cases the possibility of the transition between successive configurations is defined by Eqn.(1).

Naturally, the use of smooth potentials (and not $\delta$-functions) for the description of the chain structure makes it possible to abandon artificial mechanisms of motion. The calculations, mentioned above, by means of the SMART algorithm[19–21] lead precisely to this type of model. In addition, without any *a priori* ideas about the mechanism of motion, it is possible to model by the MC method also chains with rigorously fixed bonds (angles), provided that one resorts to correcting algorithms (of the type of SHAKE), which are used in molecular dynamics. However, it is so far not clear whether such schemes have advantages over traditional schemes.[59–61].

On the other hand, by virtue of the fact that in the modelling of semidilute solutions without an explicit allowance for solvent molecules the average density of the test substance in the system is fairly low ($\rho \ll 1$), it becomes possible to use computational methods based on the generation of an *ensemble* of statistically independent configurations, where the chains in each configuration are built up from the beginning to the end by the successive increase in the number of units.[2–4] Polymer solutions constitute an extremely rare example of physical systems for which interesting problems, susceptible to solution by the method of independent samples, exist. Naturally, for $\rho \cong 1$, this method is generally useless. However, in those cases where it can be applied, it is virtually the optimum method.

## 2. Monodisperse Systems: Concentration Relations

*The correlation length.* Having specified around each chain unit a sphere with a radius $r$ and having found the number of units $N(r)$ in a volume $V = 4/3\pi r^3$, it is possible to calculate the local density $\rho(r) = \langle N(r) \rangle / V$ after averaging with respect to all the units of the system and with respect to all the configurations generated. For low values of $r$, the internal density of units makes an overwhelming contribution to $\rho(r)$; in essence, it determines the quantity $\xi$, which is a result of the numerical solution of the equation $\rho(r) = \rho$, which is satisfied by the condition $r = \xi$.

The concentration variation of $\xi$ has been studied by the MC method for continuous chains with free internal rotation,[62,63] for lattice chains,[64] and for a solution of polyethylene.[65] It has been shown that, for small values of $\rho$, the quantity $\xi$ is comparable to $\langle R^2 \rangle^{1/2}$ and is naturally independent of $\rho$. If $\rho > \rho^*$, then $\xi$ diminishes with increase of $\rho$, which indicates a weakening of the density fluctuations. It has been established[62,63] that for chains in a volume ($d = 3$) and on a plane ($d = 2$), the calculated data are described satisfactorily by Eqn.(13). Thus, for a system of 40-unit chains in the region $0.05 \leqslant \rho < 0.37$, the exponent $x_d$, which defines the dependence of $\xi$ on $\rho$ in Eqn.(13), was found to be $-0.65 \pm 0.04$ for $d = 3$ and $-1.17 \pm 0.09$ for $d = 2$. For chains on a cubic lattice, the quantity $x_3 = -0.71$ has been obtained.[64]

An important result of the study of Khalatur et al.[65] is the demonstration that $\xi$ is independent of $N$ for $\rho > \rho^*$. This conclusion also follows from de Gennes' theoretical study.[43] When $\rho \to 1$, the quantity $\xi$ approaches the size of the chain unit. It has been established[65] that, for polyethylene chains at a density equivalent to ~0.7 of that of the pure liquid, we have $\xi \cong 0.6$ nm.

These data can be correlated as a result of an experiment[66] where a decrease of $\xi$ from 10 to ~1 nm has been observed in neutron scattering by deuteriated polystyrene for $\rho = 0.01-0.15$. The second value is close to the length of Kuhn's segment, which is 1.7 nm for polystyrene.

A semidilute solution in contact with an impermeable wall has been investigated[67] by the MC method and the distribution of the densities of units $\rho(z)$ in the direction of the normal $z$ to the wall has been calculated. The quantity $\xi$ was found from the condition $\rho(z) = \rho$. Analysis confirmed the power relation (13) and the corresponding exponent was found to be $x_3 = -0.74 \pm 0.15$, which in fact does not differ from the values quoted above. Thus the concentration variations of $\xi$ are virtually the same for different ways of determining it. In all cases the values of $x_d$ found agree well with the theoretical values.[43] In fact, if the fairly accurate approximation $\nu = 3/(d + 2)$ is adopted for the index $\nu$, then we have from Eqn.(13) $x_3 = -3/4$ and $x_2 = -3/2$; in the Flory theory $x_2 = -1/2$.

The correlation length can also be estimated by calculating the intrachain contribution to the static structure factor. Such calculations have been performed by the MC method[68] for 201-unit chains on a lattice. It was found that, for $\rho = 0.344$, the quantity $\xi \cong 10$ when expressed in units of the length of the step in a tetrahedral lattice $b = 3^{1/2}$ and the average number of units in the blob has been estimated as $N_\xi \cong 16$.

Thus computer experiments confirmed the possibility of describing a semidilute polymer solution on the basis of the blob model. It is also significant that the comparatively short chains considered, consisting of several tens or hundreds of statistical segments, correspond to the range of molecular weights of practical importance.

*Average dimensions.* The dependence of $\langle R^2 \rangle$ on $\rho$ was first investigated[69] by the MC method for continuous chains consisting of 15 and 20 units. It was found that, with increase of $\rho$, the coils swollen in an effective solvent contract. Analogous conclusions have been reached in a large number of subsequent publications. Sariban et al.[70] also modelled a system under the conditions of a thermodynamically poor solvent at $T < \theta$. For this purpose, they attributed an attraction energy $\varepsilon = -0.5\ kT$ to pairs of units which have approached one another, which led to the contraction of the coils in a dilute solution relative to $\theta$-dimensions. For such a system, the opposite tendency was observed with an increase in $\rho$: compressed coils became uncoiled and their dimensions approached $\langle R_\theta^2 \rangle$.

A computer study of the functional relation between $\langle R^2 \rangle$ and $N$ showed that,[68] for sufficiently long chains ($N \sim 200$) in an effective solvent, the linear relation $\langle R^2 \rangle \sim N$, corresponding to Gaussian chains and agreeing with Eqn.(11), holds already for $\rho = 0.2$. The same results have also been obtained[71] for a two-dimensional system.

A critical analysis of computer studies of the concentration variation of chain dimensions has been carried out.[72-74] Such a relation can be usefully considered using the scaling variable $X = \rho N^{d\nu-1} \sim \rho/\rho^*$, which provides a measure of the overlap of the coils. It has been noted[73,74] that in the majority of the determinations of the power exponent in Eqn.(11) systems made up of insufficiently long chains have been used. This yielded results differing from the theoretical values. Indeed, for Eqn.(11) to hold it is necessary that the marked inequality $\rho \gg \rho^*$ should obtain. In terms of the variable $X$, this is equivalent to $X \gg 1$. However, since the range of variation of $\rho$ is always limited, the condition $X \gg 1$ is attained only for very long chains whose computer simulation is difficult for technical reasons. The authors[75] therefore proposed another approach. It follows from scaling considerations that in a general form the quantity $\langle R^2 \rangle$ should satisfy the relation

$$\langle R^2 \rangle \sim N^{2\nu} \cdot Y^{(2\nu-1)/(1-\nu d)},$$

where $Y = \rho/\tau\rho^*$ and $\tau = (T - \theta)/\theta$ is the relative difference between the temperature and the $\theta$ point. Clearly, for a fixed value of $Y$, an improvement in the quality of the solvent (i.e. an increase of $\tau$ leads to an increase of the ratio $\rho/\rho^* \sim X$. Consequently, by intensifying the volume interactions, it is possible to achieve the condition $X \gg 1$ without increasing $N$. In a computer experiment, it is sufficient for this purpose to impart a statistical weight $\omega > 1$ to the units in contact. The corresponding calculations[75] led to the conclusion that, even for comparatively short chains ($N = 40-61$) with $\omega = 0.9$, the power exponent in Eqn.(11) is $-0.212 \pm 0.050$, which is close to the theoretical value of $-1/4$ for three-dimensional systems.[43]

The lattice model of a polyelectrolyte solution has been studied[76,77] by the MC method. An individual non-intersecting chain made up of $N = 16$ or 64 units, some of which carried a unit charge, was placed in a cell with mobile counterions. Each counterion also had a unit charge and was regarded as an occupied lattice site. The interaction between the charges was described by a non-shielded Coulombic potential. Using the local jump method,[59] the authors investigated the dependence of the chain size on the fraction of charged units $p_e$ and the average density of units, which was varied by altering the volume of the computational cell for fixed values of the remaining parameters. The calculation showed that the chain swells with increase in $p_e$. Consequently the environment made up of counterions, arising around the chains, cannot compensate for their electrostatic repulsion. This effect is most pronounced in a dilute solution (i.e. at a low ionic strength), where the total electrostatic energy is positive and the form of the polyion is close to being rod-like. The decrease in cell size modelled the increase in ionic strength. When the Debye radius is less than the chain radius $R$, the total electrostatic energy becomes negative and the polyion assumes the form of a coil. Under these conditions, the role of electrostatic interactions is insignificant compared with the "usual" volume interactions.

*Interaction of coils and osmotic pressure.* In dilute solution, the virial expansion

$$\Pi/kT = C/N + A_2C^2 + \ldots \qquad (14)$$

where $C = \pi\sigma^3\rho/6$ and $A_i$ is the $i$th virial coefficient, holds for $\Pi$. On the other hand, one can write for an arbitrary concentration[22]

$$\frac{\Pi V}{mkT} = 1 - \frac{1}{6kT} \cdot \frac{mN^2}{V} \int_0^\infty 4\pi r^2 g(r) \frac{\partial f(r)}{\partial r} r\,dr, \qquad (15)$$

where $m$ is the number of chains in the system, $g(r)$ is the "intermolecular component" of the radial distribution function of the unit, and $f(r)$ is the interunit potential.

The temperature variation of $A_2$ has been investigated[78,79] for lattice chains and the inversion of the sign of $A_2$ (the $\theta$ point corresponds to the equality $A_2 = 0$) was considered. It was found that the critical energy for a single contact between units $\varepsilon_0 \sim 1/T$, for which $A_2(\varepsilon_0) = 0$, depends on the chain length and differs for each $N$ from the value of $\varepsilon_0$ at which the swelling of the coils ceases.[80] The quantity $\varepsilon_0$ approaches its limiting value $\varepsilon_0^\infty$ as $\varepsilon_0(N) = \varepsilon_0^\infty(1 - N^{\theta-1})$.[80,81] Thus, in the case of finite chains one should speak of a $\theta$ region rather than of a $\theta$ point. We emphasise that the concept of the $\theta$ region was first introduced precisely on the basis of the analysis of the results of a computer calculation[82] and Khokhlov subsequently achieved a rigorous physical justification of this concept.[83]

The quantities $\Pi$ and $A_2$ are linked directly to the pair correlation function for the interaction of coils $G(h)$, which determines the probability of finding them at a distance $h$ from one another. The function $G(h)$ was calculated by the MC method.[84-86] The fundamental result of the studies of Khalatur and co-workers[85-87] has been the demonstration of the fact that, in an effective solvent, the probability of encountering conformations with a marked overlapping of the coils is significantly different from zero even on extrapolation to $N \to \infty$. On the other hand, the classical Flory–Krigbaum theory[48] predicts a zero probability of such states for chains with an excluded volume. An explanation of the results of the computer experiments and of the deficiencies of the Flory–Krigbaum theory has been given on the basis of simple scaling considerations.[85,86] These conclusions were later confirmed more rigorously using the renormalisation group method.[88] Sharp differences from the Flory–Krigbaum theory are also observed for the $\theta$ region.[4,89]

The concentration variation of $\Pi$ has been investigated for an athermal system[90-93] also taking into account the interunit attraction.[94] We may note that, when the units are modelled by rigid spheres with a diameter $\sigma$, then Eqn.(15) transforms into the simple expression

$$\Pi V/mkT = 1 + 4NCg(\sigma),$$

where $g(\sigma)$ is the value of $g(r)$ at the point of contact for $r = \sigma$ and the product $C.g(\sigma)$ gives the average number of contacts referred to one unit.

Calculations for non-lattice chains with $N \leq 40$ showed[93,94] that the relation $\Pi \sim \rho^x$, where $x = 2.44$, holds in an effective solvent. From Eqn.(12) with $d = 3$, we have $x_3 = 9/4$. On the other hand, in the Flory–Huggins theory[48] $\Pi \sim \rho^2$. The difference is due to the fact that the Flory–Huggins theory[48] neglects the important correlation effects arising due to the chain-to-chain binding. For the osmotic isothermal compressibility, it was found[94] that $\rho^2\beta_T \sim \rho^{-0.3}$, while in the case where correlations were not taken into account we have $\rho^2\beta_T = \text{const}$.

The possibility of describing the relation $\Pi(\rho)$ on the basis of the integral equations of the theory of liquids (the Percus–Yevick and hyperchain approximations) has been considered.[95] It was found that in the region $\rho > \rho^*$ these approximations give an unduly low pressure compared with the computer calculations. Two-dimensional systems have also been simulated.[92,93] $\Pi \sim \rho^{3.07}$ has been obtained[93] for an athermal system. It follows from Eqn.(12) that $\Pi \sim \rho^3$. In addition, in the same study it was discovered that $\Pi \sim \xi^{-d}$.

Thus the computer simulation of semidilute solutions of flexible chains in an effective solvent generally confirms the validity of the scaling method and yields critical indices close to those obtained in modern theories. On the other hand, a systematic deviation from classical ideas has been observed.[48]

### 3. Polydisperse Systems

Real polymer systems almost always exhibit a particular degree of polydispersity. The role of this factor has been analysed using scaling relations.[96] The behaviour of a flexible chain made up of $N_1$ units surrounded by units having the same chemical composition but made up of shorter chains with $N_2$ units has been considered. It was established that, when $N_2 \lesssim N_1^{1/2}$, then, in an effective solvent with an overall density $\rho > \rho^*$, the size of long chains $R_{1,2}$ in a mixture with short chains should increase compared with the size $R_1$ of the same chains at the same density but in the absence of short chains. The relative swelling coefficient

$$\beta = \langle R^2_{1,2}\rangle / \langle R_1^2\rangle$$

depends both on the ratio of $N_1$ and $N_2$ and on the density $\rho$.

Continuous non-intersecting chains with free internal rotation have been studied[97] by the MC method. In the first place the concentration variation of $\langle R_1^2\rangle$ was obtained for a monodisperse solution of 61-unit chains. Some of these chains (50%) were then replaced by shorter chains with $N_2 = 5$. The density was then defined as $\rho = (m_1N_1 + m_2N_2)/V$, where $V$ is the volume of the computational cell and $m_1$ and $m_2$ are the numbers of chains of different kinds in the cell. In a monodisperse system, the quantity $\langle R_1^2\rangle$ also decreases with increase of $\rho$. The contraction of the coils has been observed also in a two component system made up of chains of two kinds. However, the decrease of $\langle R^2_{1,2}\rangle$ begins later than that of $\langle R_1^2\rangle$ (for $\rho/\rho^* \gtrsim 2$). It has been shown that, for the same density, $\langle R^2_{1,2}\rangle > \langle R_1^2\rangle$. Consequently the relative swelling coefficient $\beta > 1$. In other words, the replacement of some of the long chains by short chains entails the swelling of the longer chains, which is equivalent to an improvement in the quality of the solvent for them. Naturally, with increase of $\rho$, the absolute size of the coils in an effective solvent always diminishes, although the ratio $\beta$ increases in proportion to $\rho$. According to Pletneva et al.,[97] such an increase continues for the system investigated up to $\rho \cong 0.2$, after which $\beta$ virtually ceases to vary.

The computer modelling of a polydisperse system has also been carried out using the SMART algorithm.[98] A mixture of flexible chains with $N_1 = 70$ and $N_2 = 5$ (the cell with $\rho = 0.3$ contained ten 5-unit chains and one 70-unit chain) and it was found that the quantity $\langle R^2\rangle$ for a "trial" 70-unit chain in a medium made up of short chains increases by a factor of 1.1 compared with the homogeneous system, which is close to the results of Pletneva et al.[97] The concentration variation of $\beta$ has not been investigated.[98]

It is noteworthy that the results of computer calculations considered above[97,98] agree qualitatively with the experimental data[99] for neutron scattering by mixtures of polydimethylsiloxanes.

## IV. POLYMERIC LIQUIDS

### 1. Conformational Structure of Macromolecules

In the computer study of macroscopically isotropic (liquid, amorphous) polymers two questions are usually considered: (1) in what way does the local structure of a polymeric liquid made up of macromolecules with a large number of chemical bonds differ from the structure of a simple low-molecular-weight liquid and (2) how the chain conformation in the block differs from that in a dilute solution.

In most investigations of this field by the Monte Carlo method calculations have been made of the dimensions of the macromolecules represented by the simplest general models on lattices or in continuous space. Summarising the results obtained, one may say that, regardless of the model employed, the dimensions of flexible non-interacting chains in a block with a density $\rho \gtrsim 0.6$ are close to the $\theta$ dimensions. The dependence of $\langle R^2\rangle$ on the molecular weight is the same as for immaterial Gaussian chains, i.e. $\nu = 1/2$ in Eqn.(9). These conclusions confirm the so-called "Flory theorem".[48] This type of behaviour is a consequence of the fact that, for $\rho \cong 1$, the local density of the units hardly differs from the average value for the systems: the density fluctuations are therefore small and the treatment within the framework of the approximation of an average molecular field becomes valid.

Since the end of the 1970's, numerical experimental methods have been used vigorously in the study of more complex systems: liquid n-alkanes and polyethylene. An undoubted advantage of such systems is the possibility of a direct comparison of the calculated results with experimental data. On the other hand, the combination of computer methods, physical experimental methods, and analytical theory leads to the best understanding of the problem under consideration.

The MC method has been used[100–105] for the modelling of hydrocarbon chains in the melt. For each molecule of the system, account was taken of the chemical structure and of the hindrance and interdependence of the internal rotations. The interaction of chemically non-bonded groups was described by the Lennard-Jones potential [Eqn.(8)], whose parameters were selected on the basis of experimental data. Chains containing between 8 and 30 carbon atoms were studied;[100,101] longer chains (up to $C_{101}$) were examined in other studies.[102–105] The calculations showed that, for a density $\rho \gtrsim 0.7$ (relative to the density of the pure liquid), the chain sizes reach a constant value and depend only on the temperature and chain length but not on $\rho$. The mean square radii of inertia $\langle S^2 \rangle$ found for the melt are compared in Fig.4 with the corresponding values measured experimentally by the small-angle neutron scattering method.[106–108] In all cases an entirely satisfactory agreement between the results is observed. On the other hand, the values of $\langle S^2 \rangle$ for the chains in the block are close to the values of $\langle S_\theta^2 \rangle$ calculated analytically by the method of generating matrices for isolated chains without volume interactions. Consequently hydrocarbon chains in the melt are coiled up to form statistical coils. It is important to note that two series of independent calculations, i.e. those of Vacatello et al.[100] and Avitabile and Tuzi,[101] on the one hand, and those of Khalatur and co-workers,[102–105] on the other, carried out by means of different algorithms and on different computers, yielded virtually identical results.

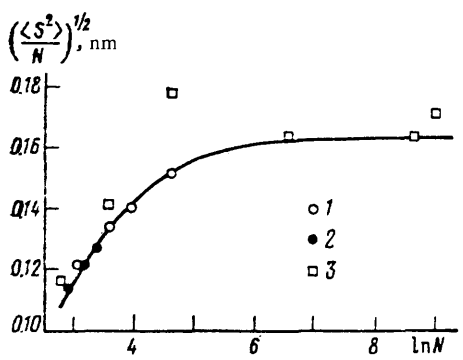

**Figure 4.** Dependence of $\langle S^2 \rangle$ for polyethylene chains in the melt on the number of carbon atoms $N$: 1) and 2) results of MC calculations from Refs.102–105 and 101 respectively; 3) experiment;[106–108] continuous curve—analytical calculation.

The problem of the mechanism of the transitions between the *trans*($T$)- and *gauche*($G$)-rotational isomers occupies an important place in the computer modelling of polymers. Naturally, for the solution of this problem it is necessary to consider realistic models. In this respect, the polyethylene oligomers are again the most convenient. The results of the molecular-dynamic calculations for liquid n-butane and n-decane[109–111] can be summarised as follows.

For liquid n-butane near the boiling point (292 K), a slightly increased fraction of the *gauche*-isomers ($p_G$) with respect to the C–C bonds is observed as compared with the gas phase: $p_G = 0.46$ in the liquid and $p_G = 0.34$ in the gas. The average $T \rightleftharpoons G$ transition time is ~10 ps. Modelling of liquid n-decane (27 molecules at 481 K) over 19 ps showed[111] that the average time interval $\Delta t$ between conformational transitions is ~2.1 ps. The fractions of the *gauche*-isomers with respect to different C–C bonds and the times $\Delta t$ are listed in Table 1. The relaxation of the chain as a whole takes 2–4 ps. This period is sufficient for the occurence of ~15 *trans–gauche* transitions. It has been shown[111] that the local conformation of n-decane is almost fully determined by intramolecular interactions.

More detailed calculations of the rotational-isomeric composition have been performed for liquid polyethylene oligomers by the MC method.[103,104] Not only the contents of the individual $T$- and $G$-isomers but also the contents of the various combinations of the *TT*, *GG*, *TG*, *TTT*, etc. types have been determined. We may note that it is only comparatively recently that we have learnt to extract such data from infrared and Raman spectra. Comparison of the results of computer modelling[103,104] for liquid $C_{21}$, $C_{51}$, and $C_{101}$ hydrocarbons with infrared spectroscopic data and the results of analytical calculation for unperturbed chains has shown a good quantitative agreement in all cases. This demonstrates that the local conformational structure of flexible chains in the block also differs little from the structure of a Gaussian coil.

The factors enumerated above constitute the most convincing evidence for the validity of the "Flory theorum" which has been produced by computer experiments.

## 2. Correlation in Liquid Polymers

We have already spoken of the correlation radius for density fluctuations; according to the results of the MC calculation,[65] $\xi < 1$ nm for liquid hydrocarbons. Calculations of the radial distribution functions[100] also show that $g(r) \cong 1$ at $r \gtrsim 0.7$ nm. The first $g(r)$ maximum in a hydrocarbon liquid, corresponding to the first coordination sphere, has been found at 0.4 nm, which agrees well with experimental X-ray diffraction data. In addition, the correlation function for the orientations of intermolecular pairs of C–C bonds has been determined[100] and it has been found that the orientational correlation disappears completely already at distances greater than 0.5 nm. An analogous result has been obtained[112] by the MD method for polyethylene having a density of 774 kg $m^{-3}$. At $r \lesssim 0.5$ nm, a weak tendency towards a perpendicular arrangement of segments has been observed. It has been established that even at $\rho > 0.5$ and even more so in the block state the polymer coils overlap almost completely.[87,113]

The question of the interpenetration of the coils on a plane has not been fully elucidated as yet. The available results of computer calculations are not unambiguous. Baumgärtner's data[114] indicate a tendency of two-dimensional coils towards segregation, which agrees with the hypothesis put forward by de Gennes.[43] However, this conclusion conflicts with other computer experiments[67,115] and theoretical studies[85,86] within the framework of the scaling method.

The relaxation behaviour of hydrocarbons in the melt has been investigated by the MD method.[109–111] Calculations[111] of the autocorrelation functions for the coil sizes in liquid n-decane have shown (Fig.5) that the AF for $S^2$ and $R^2$ decrease to zero over a period of ~1.5$\tau$ (2–3 ps). Consequently, despite the high viscosity of the medium, the coil sizes relax fairly rapidly. When the strong attraction of

the units is taken into account in the calculation, the rate of decrease of the AF diminishes[116] but to a much lesser extent than for a chain in a dilute solution. It is of interest to note that the AF calculated[111] by the MD method could be reproduced almost quantitatively by the method of Brownian dynamics for an individual chain with an appropriate choice of the coefficients of friction for the methylene group.[28] This result is also illustrated in Fig. 5. Naturally, the simulation of a dense system by a single macromolecule in the BD method is not suitable for the investigation of phenomena associated with topological effects arising owing to the intertwining of the chains in the liquid polymer. Such phenomena include the diffusion of the chains, which will be considered in the next Section of this review.

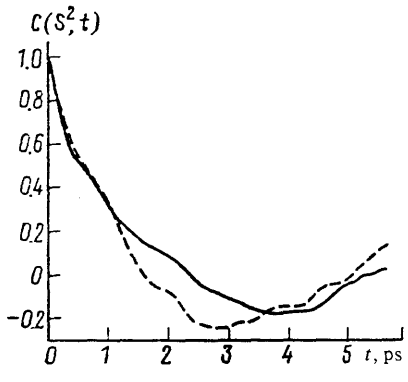

Figure 5. The autocorrelation function of the square of the radius with inertia of the n-decane chain.[111] Continuous curve—MD calculation for the melt; dashed curve—calculation by the method of Brownian dynamics for an individual chain.

Table 1. The fractions of the *gauche*-isomers relative to C–C bonds and the *trans-gauche* conformational transition times in liquid n-decane at 481 K.[111]

| No. of the C–C bond in the chain | $p_G$ | $\Delta t$, ps |
|---|---|---|
| 2 and 8 | 0.45 | 1.9 |
| 3 and 7 | 0.36 | 2.1 |
| 4 and 6 | 0.34 | 2.4 |
| 5 | 0.44 | 1.7 |

Naturally, in contrast to low-molecular-weight liquids, in liquid polymers there are correlations of a special kind due to the strong (chemical) bonds between neighbouring units in the chain. The role of these correlations can be traced by calculating the Van Hove spatial-temporal correlation function $G(r, t)$ (its Fourier transform defines the differential coherent scattering cross-section).[22] This function can be conveniently divided into two parts:

$$G(r, t) = G_d(r, t) + G_s(r, t),$$

where $G_d(r, t)$ is the density of the probability of observing any other species at time $t$ and a distance $r$ from the given species, while $G_s(r, t)$ is the density of the probability of observing the same species. We may note that $G_d(r, t)$ describes the evolution of the radial distribution function in time and $G_d(r, 0) \equiv g(r)$. The calculations of $G_d$ and $G_s$ were performed by the MD method for a system made up of 20 flexible 16-unit chains at $\rho = 0.8$.[117] The interaction of the units was described by the repulsive component of the potential defined by Eqn. (8). Fig. 6 presents the functions $g(r)$ and $G_d(r, t)$ at different times. The high first peak (with a height of ~11) on the $g(r)$ curve at $r = 1$ corresponds to the closest (bound) monomers in the chain separated by bonds of different lengths. The subsequent maxima correspond to different coordination shells. In the region $r > 4$ the oscillations in the $g(r)$ have almost completely decayed, which is also characteristic of simple low-molecular-weight liquids.[22] Thus the principal specific features of the equilibrium structure of a liquid polymer consist in the presence of an intense "valence" peak on the $g(r)$ curve.

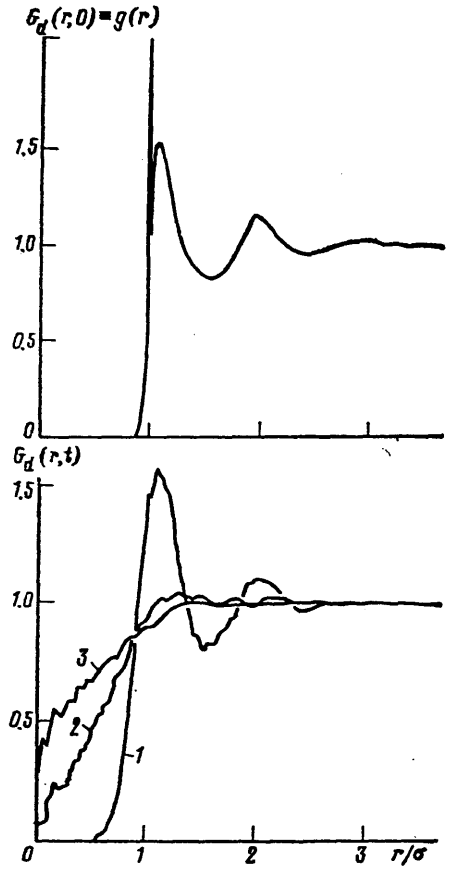

Figure 6. Radial distribution function of the density of the particles and the Van Hove function for a polymeric liquid at different times t: 1) $0.2\tau$; 2) $\tau$; 3) $2\tau$.

It might have been expected that many bonds in the chains should influence strongly the dynamics of the decomposition of the pair density correlations. However, Fig. 6 showed that, even for $t > 0.2\tau$, a barely perceptible trace remains of the "valence" peak on the $G_d(r, t)$ curve. With increase of $t$, other peaks spread and gradually disappear. Nevertheless, even at $t \cong \tau$, the short-range order cell, made up of particles in the first coordination sphere, is appreciable.

The region of forbidden volume persists for an even longer period for low values of $r$. However, during a period $t > 4\tau$, the initial $G_d(r, t)$ structure decomposes to a large extent and at $t \gg \tau$ we have $G_d(r, t) = 1$ for all distances, i.e. any relative positions of the particles are equally probable. The autocorrelation function $G_s(r, t)$, describing the self-diffusion of the particles, then obeys the Gaussian law.

### 3. Reptational Movement

De Gennes[118] proposed a heuristic model, which has been called the "reptation model", for the description of the diffusion of flexible chains in dense media. The movement of the chain can be clearly represented using the concept of an effective tube: it is assumed that at any instant each chain is, as it were, enclosed in a "tube" made up of the steric hindrance generated by other chains in the system. The macromolecule diffuses within this tube as a result of local conformational rearrangements—"defects", which migrate preferentially along the chain contour. Such low-scale (in fact one-dimensional) movement is the basis of the reptation model.

One of the maximum characteristic times of the process is $t_R \sim N^3$, during which the chain moves along the tube over a distance of the order of its contour length. At $t \sim t_R$ the movement of the chains is described by the relation $\langle \Delta r^2 \rangle \sim (t/N)^{1/2}$. For times much shorter than $t_R (t \leq t_R/N)$, when the average displacement of any unit $\langle \Delta r^2 \rangle^{1/2}$ is comparable to the effective tube diameter $d_T$, a special "local reptation" regime should be observed, in which $\langle \Delta r^2 \rangle \sim t^{1/4}$. Finally, for very short times $t$, the movement of the unit is controlled solely by the intrachain bonds and not by intermolecular interactions, which corresponds to the usual Rouse model, i.e. $\langle \Delta r^2 \rangle \sim t^{1/2}$.

The experimental observation of reptations in liquid polymers is extremely difficult. For this reason, there are as yet no direct unambiguous data confirming or disproving the postulated reptation mechanism. In a series of recent studies,[68,98,119–123] an attempt has been made to observe reptation by the dynamic MC method.[59,61] However, in the modelling of melts this could not be done. In our view, the failure can be accounted for by two causes. Firstly, in the above studies insufficiently dense systems ($\rho < 0.7$) were considered. Since $\langle \Delta r^2 \rangle^{1/2}$ should be close to $d_T$ for the manifestation of reptational movement, it follows that, when account is taken of the estimate $d_T \cong (\sigma\rho)^{-1/2}$ ($\sigma$ is the diameter of the monomer), it becomes clear that for low $\rho$, it is difficult to reproduce the required regime in a numerical experiment. Secondly, in modelling polymers by the dynamic MC method, the movement of the macromolecule is achieved as a result of successive rearrangements of short sections of the chains. It is then found that, for chains with volume interactions and rigid bonds, the rate of migration of units along the chain contour is very low. The reptation mechanism is therefore hardly realised. This has been confirmed by the results of a study[121] where the reptational movement has been observed only after assuming the overlapping of the monomers within the same chain. For this reason, one cannot regard as satisfactory also the calculations[122] for an individual macromolecule without exchange interactions, moving within a regular network of obstacles modelled by a regular cubic lattice. Furthermore, the appearance of reptational movement in a medium with regular obstacles is in general doubtful.

It has been reported[68,98,119,120] that it has been possible to observe a transition from the Rouse regime ($\langle \Delta r^2 \rangle \sim t^{1/2}$) to the reptational regime ($\langle \Delta r^2 \rangle \sim t^{1/4}$) after the movement of all the chains in the melt has been "frozen" with the exception of one trial chain. We should like to draw attention to the lack of justification of this conclusion. In fact, in the random appearance of a "frozen network" there is an extremely high probability that a mobile chain is incorporated in a cell closed on all sides (and not in a tube open at two ends), which naturally causes a sharp retardation of the movement.

The reptation of chains in the melt has also been investigated by the MD method.[117] This method is free from the above disadvantage characteristic of the MC method and it therefore provides a more objective description of the dynamic behaviour. The mean squares of the displacements of the units $\langle \Delta r^2 \rangle$ and the orthogonal components of the movement along the chain contour (the tangential component $\Delta r_\parallel$) and across the contour (the normal component $\Delta r_\perp$) have been considered[117] for a dense system of 20 flexible chains ($N = 16$, $\rho = 0.8$). Clearly

$$\langle \Delta r^2 \rangle = \langle \Delta r_\parallel^2 \rangle + 2\langle \Delta r_\perp^2 \rangle$$

and the ratio

$$Q = \langle \Delta r_\parallel^2 \rangle / \langle \Delta r_\perp^2 \rangle$$

is therefore always unity for isotropic movement. In order to make a comparison with the melt, an individual chain has also been considered.[117] The calculation showed that, owing to the presence of rigid bonds, the movement of the units of an individual chain in the tangential direction is suppressed and the normal component predominates, so that always $Q \leq 1$. An analogous behaviour is characteristic also of chains in the melt for short times $t \leq \tau$. The dynamic properties are then determined solely by the chain structure of the macromolecules and not by their interaction. However, for $t \geq 1.2\tau$, where each unit in the melt has sufficient time to traverse a fairly long distance $\sim d_T$, the obstacles offered by the surrounding chains, which arise during the movement in the transverse direction, force the units to migrate predominantly along the chain contour, as a result of which $Q > 1$. This picture can be readily traced in Fig. 7. Naturally, for very long times, the movement must be isotropic.

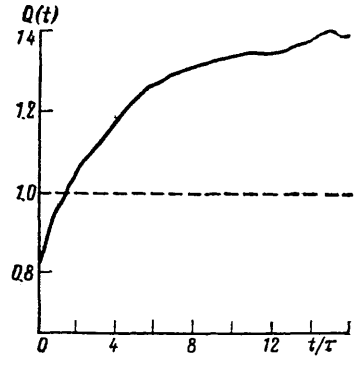

**Figure 7.** Time variation of the function $Q(t)$ defining the ratio of the shifts of the polymer chains along and across the chain contour. The calculation was performed by the method of molecular dynamics for a dense polymeric liquid.[117]

Thus a dynamic numerical experiment has shown that in a polymeric liquid there exists a preferential type of movement of the chain units along the chain contour. This

movement is solely determined by a specific interchain interaction and can be identified with local reptations in the melt. From the general standpoint, this situation is fairly unusual: in a system having an isotropic structure, there exists a local anisotropy in the movement of the particles.

## V. PARTLY ORDERED SYSTEMS

### 1. Liquid Crystal Polymers

The fields involving the practical application of polymeric liquid crystals have expanded sharply in recent years and new prospects have arisen for their further application. These factors stimulated theoretical studies of the conditions governing the appearance and physical properties of liquid crystal systems.

The possibility of transition to a liquid crystal phase is associated with the rigidity of the polymer chain, characterised by the statistical Kuhn segment $A$, rather than by its great length. If $A \gg \sigma$ ($\sigma$ is the chain diameter), then, under certain conditions, orientational ordering may take place. Polybenzamide, poly-(benzyl glutamate), and cellulose esters are typical examples of mesogenic macromolecules for which $A \gg \sigma$.

There exist two main approaches to the theoretical description of the orientational ordering of macromolecules: the Onsager method,[124] in which the virial expansion of the free energy of a rarefied gas comprising rigid rods is employed, and the Flory method,[125] based on the lattice model of the polymer. The present development of the Onsager theory has been described by Khokhlov and Semenov.[126]

Unfortunately, an analytical treatment can be rarely continued until numerical results are obtained, which applies particularly to the most interesting semirigid chains, for which $L$ is frequently comparable to $A$. The computer simulation of such systems is therefore evidently essential.

*Equilibrium properties.* The question of the conditions governing the transition to the liquid crystal state and the conformational changes in the orientational ordering of semirigid chains was first solved by the MC method.[127] Chains with free internal rotation, consisting of $N$ rigid units with a single diameter $\sigma$ connected by bonds of unit length at a specified angle $\alpha$, were considered. The angle $\alpha$ was chosen so that the local asymmetry parameter $A/\sigma$ was 57.7 and the criterial Flory parameter $f$ was 0.074, which reproduced the value of $f$ for the nitrocellulose chain.[13] The results of the calculation for 40-unit chains are presented in Fig.8, which illustrates the dependence of the quantity $\langle R^2 \rangle$ and the orientational order parameter $\eta = [(3 < \cos^2\gamma) - 1]/2$ ($\gamma$ is the angle between the vector R connecting the ends of the chain and the director of the specimen) on the number-average density $\rho$. Evidently, for low values of $\rho$, the parameter $\eta \cong 0$, i.e. the system is isotropic. Appreciable changes in $\eta$ and $\langle R^2 \rangle$ begin only at $\rho \geqslant 0.1$, where these quantities exhibit a rapid increase. The increase in $\eta$ shows that the system passes to a liquid crystal state (of the nematic type). The transition is accompanied by an increase in the length and rigidity of the chains. For $\rho \to 1$, it was found that $\langle R^2 \rangle \to L^2$. This effect constitutes a fundamental difference between the behaviour of semirigid and flexible chains. For comparison, Fig.8 illustrates the concentration variation of $\langle R^2 \rangle$ calculated for the same system of 40-unit chains but exhibiting a high flexibility ($\alpha = 90°$ and $A/\sigma = 1$). In this case the picture is completely reversed: with increase in $\rho$, the order parameter does not change and is close to zero, while $\langle R^2 \rangle$ tends to $\langle R_0^2 \rangle$. It has been shown[127] that the order effects, observed in the system of semirigid macromolecules, depend only slightly on the attractive forces. As for low-molecular-weight liquid crystal systems, the repulsive component of the interaction potential plays the main role.

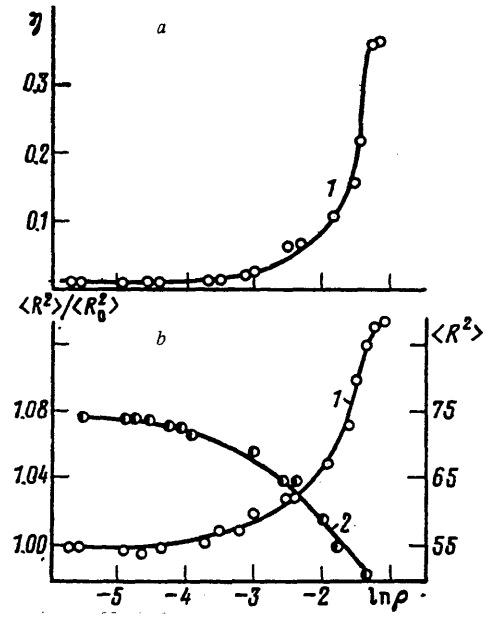

**Figure 8.** Dependence of the order parameter (*a*) and average chain dimensions (b) on the density: 1) system of semirigid chains (the quantity $\langle R^2 \rangle$ is expressed relative to the size of an isolated chain); 2) system of flexible chains.[127]

The results of the computer experiment[127] can be compared with theoretical predictions.[126] For the model considered by Pletneva et al.,[127] the ratio $L/A = 0.67$ and the critical density at the transition point $\rho_c$, estimated from the maximum in the derivative $d\eta/d\rho$, was found to be 0.23 (under these conditions, $\eta_c = 0.37$). The theory[126] yielded $\rho_c = 0.26$ and $\eta_c = 0.41$ for the same $L/A$ ratio. The agreement with the computer calculation is clearly extremely good. We may note that the Flory theory[125] yields a low critical density for the model investigated.[127]

The theoretical study[124,126] was based on the second virial approximation and its applicability is therefore restricted to the range of comparatively low polymer concentrations. On the other hand, the lattice model[125] describes the ordering in concentrated systems. Nevertheless, MC calculations[128] for the two-dimensional lattice model with $\rho = 0.952$ revealed significant deviations from the Flory theory. Recently the same workers[129] carried out an analogous calculation for a three-dimensional system of chains ($N = 20$) on a cubic lattice (441 chains with $\rho = 0.952$). The rigidity of the chain was regulated by the parameter $\Delta\epsilon$, which determines the extent to which the forward step on the lattice (the *trans*-isomer) is preferred to the sideways step (the *gauche*-isomer). Approximately $3.5 \times 10^9$ configurations were generated for each $\Delta\epsilon$ using the "quasi-reptation" algorithm.[60]

The results of the calculation of $\eta$ and of the average fraction of the *gauche*-bonds $p_G$ are presented in Fig. 9. These values can also be found within the framework of the lattice theory,[125] according to which the critical transition temperature $kT/\Delta\varepsilon_c = 0.56$ for $N = 20$ in the absence of unoccupied sites on the lattice. Calculation by the MC methods has shown that, with decrease of $kT/\Delta\varepsilon_c$ (i.e. with increase of the rigidity of the chains), there is a sharp transition at the point $kT/\Delta\varepsilon_c = 0.64$: the chains are almost completely uncoiled and ordered. Evidently, in the three-dimensional case there is a satisfactory correlation between the critical values of $kT/\Delta\varepsilon_c$ obtained theoretically[125] and in the computer experiment. On the other hand, the computer calculation reveals the phenomenon of hysteresis: the reverse transition from the ordered to the disordered states takes place at a different point $kT/\Delta\varepsilon'_c = 0.68$. The description of this behaviour is outside the framework of the theory.[125]

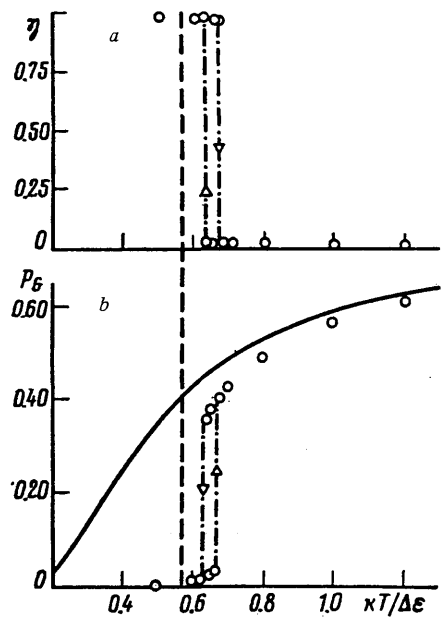

Figure 9. Dependence of the order parameters (*a*) and the average fraction of *gauche*-bonds (*b*) on the reduced temperature for the lattice model of a liquid crystal. Symbols—calculation by the Monte Carlo method (the arrows indicate the direction of the forward and reverse transitions); continuous curve—calculation based on the Flory theory; the dashed line indicates the critical transition temperature in the Flory theory.[125]

It must be emphasised that, in the examples described above, the rigid chains were ordered without any involvement of the attraction forces, solely as a result of packing effects. In a number of instances packing effects can cause the orientational ordering of flexible chain polymers. For this purpose, it is sufficient to restrict the mobility of the chains in space. Computer experiments have shown[130–132] that flexible chains "tied" by one end to an impermeable surface (for example, as a result of the strong adsorption of the terminal polar group or chemical "grafting") are capable of orientational ordering solely as a result of the steric hindrance, which depends on the degree of surface coverage. Another possibility for the transition of flexible chains to an ordered state is associated either with the presence of external orienting fields or with the anisotropy of the intermolecular interaction forces.[133]

*Dynamic properties.* There have been few studies on the modelling of partly ordered polymer systems by the MC method. Pershin and Skopinov[134] examined a two-dimensional system of rigid five-centre molecules and observed a tendency towards the formation of short-lived associated species (clusters) in which the degree of local order was higher than the average for the system. The association of molecules following their mutual approach is caused, according to the authors, by potential barriers preventing the shear displacement and stabilising a parallel configuration.

The dynamics of the behaviour of molecules having the form of infinitely rigid rods has been studied.[135] Although the cross-sectional area of the rods was assumed to be zero, they could not cross each other. Depending on the reduced density $\rho^* = NL^3/V$ (where $N$ is the number of rods with a length $L$ in a volume $V$), the AF for the rates of self-diffusion coefficients

$$D = (D_{\parallel} + 2 \cdot D_{\perp})/3,$$

where $D_{\parallel}$ and $D_{\perp}$ are diffusion coefficients in the longitudinal and transverse directions, were calculated. It was shown that, during the period between two collisions, the movement is free and not diffusional. For low values of $\rho^*$, the transport properties are described satisfactorily by the kinetic Enskog theory.[22] However, for $\rho^* \geqslant 8$, this treatment ceases to be valid. It was found for this range of densities that the rotational diffusion coefficient of the rod decreases as $(\rho^*)^{-2}$ or as $L^{-6}$, in conformity with the theory of Doi and Edwards.[136]

Table 2. The diffusion coefficient of rods and its longitudinal and transverse components for different reduced densities.[135]

| $\rho^*$ | $D$ | $D_{\parallel}$ | $D_{\perp}$ | $\rho^*$ | $D$ | $D_{\parallel}$ | $D_{\perp}$ |
|---|---|---|---|---|---|---|---|
| 1 | 2.40 | 2.59 | 2.30 | 16 | 0.24 | 0.50 | 0.11 |
| 2 | 1.16 | 1.37 | 1.05 | 24 | 0.21 | 0.49 | 0.073 |
| 4 | 0.61 | 0.82 | 0.51 | 32 | 0.20 | 0.50 | 0.049 |
| 6 | 0.44 | 0.60 | 0.36 | 40 | 0.23 | 0.64 | 0.031 |
| 8 | 0.34 | 0.53 | 0.25 | 48 | 0.34 | 0.97 | 0.025 |

In the study of translational motion, a fairly unexpected result was obtained. It was found that, in a sufficiently dense system, an increase of $\rho^*$ entails not a decrease of $D$ and $D_{\parallel}$, as seemingly should have been the case, but in fact their increase (Table 2). Such behaviour is associated with the fact that in a system of infinitely thin rods a change in the component of the velocity along the rod axis can occur only after a change in the rate of rotation as a result of the collision. However, for a high density and for long times, the maximum contribution to the corresponding component of the AF for the velocity $C(\mathbf{v}_{\parallel}, t)$ comes only from the rods for which the rotational component of the movement is minimal. Although the fraction of such particles in the

system may be small, nevertheless they play an increasingly significant role with increase in $\rho^*$. Therefore, the higher the value of $\rho^*$, the greater the extent to which $D$ and $D_\parallel$ are determined by particles with the maximum longitudinal velocity component.

### 2. The Effect of Orienting Fields

Luk'yanov et al.[137] investigated by the MD method the influence of the orienting field on flexible six-unit chains in a dense system. Each bond was acted upon by an orienting quadrupolar potential $U = -K\cos^2\gamma$, where $\gamma$ is the angle between the bond vector b and the direction of the field. It was shown that the degree of order in the system increases with increase in $K$ and that the order parameter $\eta$ is close to unity for $K \cong 10\ kT$.

Calculations of the orientation AF for the vectors b indicated an anisotropy of the relaxation properties, which is manifested in the different rates of decrease of the AF components: along the field ($C_\gamma$) and in the transverse direction ($C_\beta$). It was found that the corresponding characteristic times behave differently with increased $K$: $t_\gamma$ increases while $t_\beta$ falls. This is associated with the operation of two mechanisms of the orientational mobility: (1) rapid rotational-vibrational movements of b in the potential well generated by the field and (2) transitions across the potential barrier separating two equilibrium positions of b (parallel and antiparallel to the field). For the relaxation of $C_\gamma$, transitions precisely through this barrier are necessary, their frequency decreasing with increase of $K$. On the other hand, the relaxation of $C_\beta$ does not require that a barrier be overcome; vibrations at the bottom of the potential well are sufficient for this purpose and their frequency increases with increasing steepness of the potential.

The molecular dynamics of liquid alkanes has been studied in the field of external compressing and displacing forces.[138] Their intramolecular vibrational and rotational movements were considered and it was established that the external forces cause only a reorientation of the molecules but do not alter their distribution with respect to conformational states. The authors concluded that, in real experiments designed to study double refraction in a flow (the Maxwell dynamo-optical effect), the conformational composition of short hydrocarbon chains should not change appreciably compared with the static system in the absence of shear stresses.

The deformation of polyethylene chains stretched by pulling on the ends has been investigated by the MC method.[139] The "isoenergetic mechanism" of the increase in length, according to which the initial increase in length is due to a redistribution of the conformers in the chain and the change in the conformational composition begins only after numerous repetitions of the stretching process (~0.6), was confirmed.

### 3. The Rotational-Crystalline State

In a rotational crystal there is a possibility of the rotation of the molecules about their long axes, whereas the axes themselves retain an ordered arrangement. This state is characteristic of normal paraffins. Computer modelling of a rotational system has been carried out by the MD method.[140] A system comprising $C_{10}H_{22}$ molecules, in which the extreme H atoms were kept near the opposite ends of the chain (prism 1.3 nm high) by a harmonic potential, was considered. The chains bounding the cell along the $x$ and $y$ axes were stationary and 17 internal chains migrated in accordance with Newton's equations. The interaction of the C and H atoms was described by the atom–atom potentials. At the end of the initial relaxation period, numerical experiments

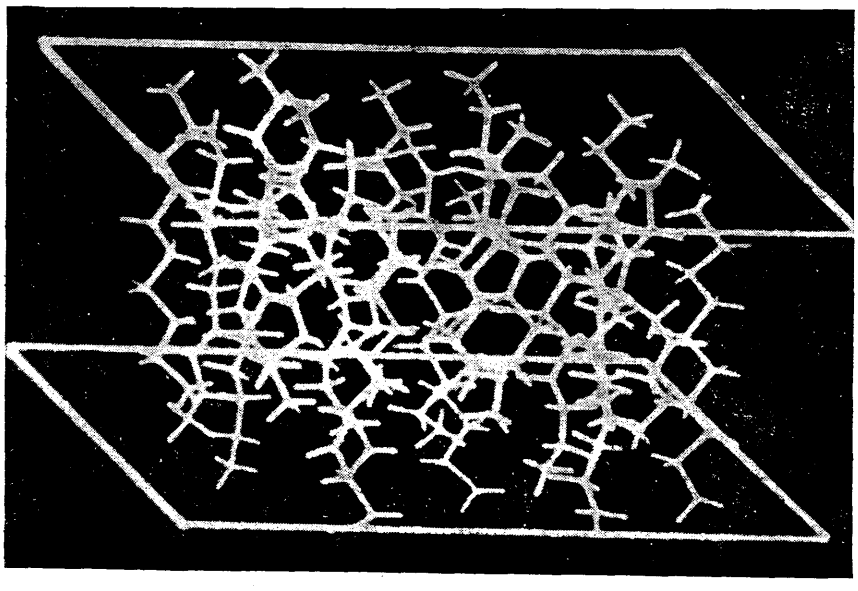

Figure 10. A film frame demonstrating the dynamics of the change in the configuration of a rotational hydrocarbon crystal.[40] The ends of the chains are held outside two opposite planes by a harmonic potential. The stationary chains bounding the cell are not shown; only the bonds between the C and H atoms are represented but not the atoms themselves.

were carried out at time intervals of ~7 ps (which corresponds to approximately three characteristic time units $\tau$). The calculation showed that the rotational-crystalline state, in which the internal paraffin chains in the cell rotate, obtains at temperatures in the range 205–269 K. At 205 K the amplitude of the torsional vibrations of the torsional C–C angles via the equilibrium position reaches 60°, while at 269 K it reaches 120°.

Balabaev et al.[140] filmed a graphical computer display on which the configurations of a rotational crystal were shown in succession. In a literal sense, the film makes it possible to see and analyse all the details of the movements of atoms in the system (Fig.10). Visualisation of information of this kind is a powerful means for a clear description of complex molecular models in the course of a dynamic computer experiment.

---o0o---

The examples of the use of the computer experiment method examined in this review by no means exhaust the numerous problems which are solved with its aid in the chemistry and physics of polymers. One may mention in addition computer studies of chemical macromolecular reactions[141] and gel formation phenomena,[142,143] the structures and mechanical properties of polymer networks,[144,145] the mechanisms of the breakdown of solid polymers,[146] crystallisation kinetics,[147] and topological effects in polymers.[148,149] The first attempts have been made to model non-equilibrium systems[150,151] and complex macromolecular objects of biological origin, for example, biological membranes.[130–132,152–157] The computer experiment frequently constitutes the only source of unique information. Vigorous studies have been initiated recently on the mathematical modelling of biopolymers: polypeptides and globular proteins in the course of their functioning[10,11,158–183] and also polynucleotides.[184–189]

Further progress in the chemistry of simulation modelling of molecular systems is probably to be expected not so much in the development of the numerical methods themselves as in the solution of strictly engineering problems in the construction of multiprocessor special purpose computers. An ideal procedure for the study of a system of $N$ interacting particles would involve the use of a computing device having the same number of $N$ microprocessors working in parallel, each of which would carry out calculations for only one particle. Calculations on specialised computers of this kind have already been reported in the literature.[190,191] Considerable advances have been achieved using computers with a vector processor.[192,193] Definite hopes for a qualitative improvement of the effectiveness of the numerical modelling of many systems are nowadays associated also with the prospect for the creation of a computer on the basis of the so-called reversible cellular automatic device.[194,195]

# The Specific Features of the Interaction of Ionising Radiation with a Molecular Medium and the Role of Tracks in Radiation Chemistry

I.G.Kaplan and A.M.Miterev

The interactions of charged particles with a molecular medium are surveyed and the highly excited molecular states arising under these conditions are discussed. The processes involving the absorption of energy in a condensed phase and the role of collective excitations are considered in detail. The relation between the structure of the track and the characteristics of the radiation-chemical reactions in the tracks of particles of different kinds is analysed.
The bibliography includes 170 references.

## I. INTRODUCTION

When charged particles pass through a substance, their interaction with the atoms and molecules of the medium results in energy transfer to the medium. This energy is consumed mainly in the excitation and ionisation of the medium. The energy of slow, heavy particles is converted into the kinetic energy of the movement of the atoms of the medium. In solids, when the transmitted kinetic energy is sufficiently large, atoms can be dislodged from their equilibrium positions. As a result, regions with a damaged structure are formed in the irradiated medium in which molecular excited states, positive and negative ions, and secondary electrons dislodged from atoms and ions are localised. All these defects are concentrated along the trajectory of the primary particle and form a track in the given substance. Since the effect of hard electromagnetic radiation on matter involves the dislodgement of fast Compton electrons and photoelectrons, the tracks of X-rays and $\gamma$-rays reduce to the tracks of fast electrons distributed throughout the specimen.

The tracks of $\alpha$-particles and the electrons dislodged by X-rays were first observed visually in the Wilson cloud chamber. Subsequently bubble and spark chambers were developed. Detectors based on the determination of the change in the structure of the specimen by treating the latter with appropriate chemical reagents have come to be widely used for the detection of tracks. They include primarily photoemulsions and also different types of solid detectors.[1]

Experimental observations of tracks yield in the first place information about the charged particle itself (mass and charge) and play an important role in the identification

of unknown elementary particles. As regards the characteristics of the track of the particle, they make it possible to measure only the ionisation density in gases along the track and to find specific energy losses. However, such information is quite inadequate to explain the changes which occur in the molecular medium on passage of ionising radiation. The microstructure of the short-lived regions of primary excitations and ionisations along the particle track is of decisive importance for the final chemical reactions. In order to achieve agreement between the theoretical model of the radiolysis of water and experimental data, it was necessary to take into account the non-uniform distribution of the active intermediate species in the electron tracks.[2,3]

The spectrum of the states arising on exposure of the medium to ionising radiation is much more complex than in the case where the medium is irradiated with light. The former includes states in the region of the continuous spectrum corresponding to the ionisation of electrons from the inner shells of the molecules with subsequent cascade of ionisations owing to the "shake-up" and Auger effects, the collective states of the plasmon type, and the so-called "superexcited" states.[4] All these states are short-lived, decomposing after $10^{-16}$–$10^{-12}$ s into active intermediates which initiate the chain of radiation-chemical reactions.

Since the instantaneous picture of the primary distribution of excitations on ionisation cannot be measured directly, it is investigated by numerical experiment on a computer. The passage of ionising radiation through matter is modelled with the aid of the statistical test method (the Monte Carlo method). In order to model the passage of radiation, it is necessary to know the excitation and ionisation cross-sections of the molecules.

Computer modelling makes it possible to find the spatial and energy distribution of the dislodged electrons and the densities of the ions and excited states generated at different distances from the axis of the particle track. The spatial-energy structure of the tract is a characteristic of the radiation which contains much more information than the usually employed characteristic—the linear energy loss (LEL). Knowing the structure of the track, it is possible to identify the characteristics of the primary radiation-chemical reactions in the tracks of particles of different kinds.[5] The evolution of ideas about the role of tracks in radiation chemistry can be traced in the relevant reviews.[6,7]

In the present review we have endeavoured to deal with the entire set of questions associated with the primary stage of radiolysis and its influence on the subsequent chemical reactions. The consecutive pattern of the physicochemical processes arising in the medium on irradiation is examined: from the initial physical stage of the radiolysis, in the discussion of which much attention has been devoted to the specific features of the condensed phase which are not usually taken into account, to the subsequent physicochemical stage. Much space has been devoted to the discussion of the relation between the structure of the track and the character of the radiation-chemical reactions occurring in it.

## II. INTERACTIONS OF CHARGED PARTICLES WITH ATOMS AND MOLECULES

Since numerous books and reviews (see, for example, Refs. 8–13) have been devoted to the interactions of charged particles with an atomic-molecular medium, we shall confine ourselves in the present review to a brief discussion of the question and shall quote a series of formulae used in calculations of the degradation of the energy of the charged particles in the medium.

Fairly simple analytical expressions for the inelastic scattering cross-sections are valid in the case of fast particles, whose velocity is high compared with the velocities of atomic electrons [the energy of the particle $E \gg (M/m)E_b^a$, where M is the mass of the particle, $m$ the mass of the electron, and $E_b^a$ the binding energy of the electron in the atom]. For a sufficiently high transmitted energy $\varepsilon \gg I_n$ (where $I_n$ is the potential of ionisation from the $n$th electron shell), the dislodged electron can be regarded as free and the scattering cross-section is defined by the familiar Rutherford formula

$$d\sigma = (2\pi Z^2 e^4/mv^2\varepsilon^2)\,d\varepsilon, \qquad (1)$$

where $Z$ and $v$ are the charge and velocity of the arriving particle. Such collisions have come to be referred to as short-range or knockout collisions. For energy transfers leading to the excitation of an atom or molecule to the $n$th quantum state from the initial zero-point state with a transition energy $\hbar\omega_{0n}$ (such collisions are referred to as long-range or glancing collisions), the cross-section is estimated from the Bethe formula[9]

$$d\sigma_{0n}(q) = (4\pi Z^2 e^4 f_{0n}(q)/mv^2\hbar\omega_{0n}q)\,dq \qquad (2)$$

where $\hbar q$ is the absolute magnitude of the transmitted momentum and $f_{0n}(q)$ the generalised oscillator strength introduced by Bethe.[9] The generalised oscillator strengths as well as semiempirical formulae for the ionisation cross-sections and total non-elastic scattering cross-sections may be found in a series of publications.[12–17]

For polyatomic molecules, the ionisation cross-section can be represented by an additive quantity. For the $H_2O$ molecule, the experimental ionisation cross-sections in the electron energy range from 0.1 to 20 keV have been expressed[18] in the form $\sigma_i(H_2O) = \sigma_i(H_2) + \frac{1}{2}\sigma_i(O_2)$. The differences between such additive cross-sections and the experimental cross-sections are insignificant over the entire calculated range. It has been shown[19] that the ionisation cross-section of a molecule can be quite accurately represented by the sum of the ionisation cross-sections of the chemical bonds. Having analysed the experimental data for the ionisation cross-sections of 40 hydrocarbon molecules of different kinds, Grosse and Bothe[19] calculated the effective ionisation cross-sections of the C–H, $\pi$(C–C), $\sigma$(C–C), C–O, and other bonds. The values obtained make it possible to represent approximately the ionisation cross-section of an arbitrary molecule with the given chemical bonds to within 2%. Such additivity had been observed earlier in another study.[20]

In the investigation of the effect of charged particles on matter, it becomes necessary not only to estimate the cross-sections but also to find the probabilities of the excitation or ionisation of a species as a function of its distance from the axis of the track (the impact parameter) $\rho$. For this purpose, one uses a quasi-classical approach, according to which it is assumed that the charged particle moves along a definite trajectory, is structureless, and can be regarded as merely the source of a variable electromagnetic field. This approach is most legitimate for heavy charged particles.

The trajectory of a heavy charged particle in a substance is to a large extent linear, since, with the exception of the knock out collisions, the interaction with the atoms of the medium hardly causes a curvature in its path. For long-range collisions, one can find in this instance the dependence of the probability of the excitation of the $n$th quantum state of the atom (molecule) on the impact parameter $\rho$. The expansion of the Coulombic interaction operator into a multipolar series and the restriction of the latter to the dipolar term lead to the following expression for the probability of the transition of the system to the $n$th quantum state in terms

of the first-order perturbation theory:[21]

$$W_{0n}(\rho) = (Z^2e^4/\hbar^2)\left|\int_{-\infty}^{\infty} \frac{x_{0n}vt + y_{0n}\rho}{[(vt)^2+\rho^2]^{3/2}} \exp(i\omega_{0n}t)\,dt\right|^2, \quad (3)$$

where

$$x_{0n} = \sum_{i=1}^{N} \langle\psi_n|x_i|\psi_0\rangle; \quad y_{0n} = \sum_{i=1}^{N} \langle\psi_n|y_i|\psi_0\rangle, \quad (4)$$

$\psi_n$ and $\psi_0$ are the wave functions of the $N$-electron system, and the $x$ axis is directed along the trajectory of the incoming particle. The integrand decreases in inverse proportion to the cube of the distance from the axis of the tract and the interaction is therefore significant only in the region of distances of closest approach.

It can be shown that the effective collision is $\tau \cong 2\rho/v$. The collision is regarded as adiabatic if the collision time is much greater than the period of the quantum transition $2\pi/\omega_{0n}$, i.e. the inequality

$$\omega_{0n}\rho/\pi v \gg 1 \quad (5)$$

holds. In this case the integrand in Eqn.(3) oscillates repeatedly during the period of the collision and the integral is close to zero. Consequently atoms are not excited in an adiabatic collision.

The condition specified by inequality (5) is too strong: the "much greater than" sign should be replaced by the "greater than" sign, i.e. for excitation it is sufficient that the effective collision time should be less than the quantum transition time. To demonstrate this rigorously, it is necessary to calculate integral (3). After representing the exponential function in the integrand by a cosine and a sine using Euler's formula and integrating by parts, we obtain

$$W_{0n}(\rho) = \frac{4Z^2e^4\omega_{0n}^2}{\hbar^2v^4}[|x_{0n}|^2K_0^2(\eta) + |y_{0n}|^2K_1^2(\eta)] \quad (6)$$

where $\eta = \omega_{0n}\rho/v$ and $K_0(\eta)$ and $K_1(\eta)$ are modified Bessel functions (Macdonald functions[22]). For $\eta = \pi$, the functions $K_0^2(\eta)$ and $K_1^2(\eta)$ are almost zero (see the graph on p.196 of Ref.22). After setting $\eta = \pi$, we find the effective size of the region of direct excitations:

$$b_{\text{eff}} = \pi v/\omega_{0n}. \quad (7)$$

Thus the excitation has an appreciable probability for $\rho \leq b_{\text{eff}}$.

According to Eqn.(2), the excitation cross-section is proportional to the oscillator strength of the quantum transition. The latter is non-zero only for transitions without a change in the total electron spin. Since the ground state of the molecules is of the singlet type [only the $O_2$ ($S = 1$) and NO ($S = 1/2$) molecules are exceptions], a fast charged particle excites only singlet states on interaction with a molecule. As in irradiation by light, the triplet states are then populated via radiationless intersystem crossing transitions S → T.[23,24] Further, we may note that in the calculations of the cross-sections described above no account was taken of the terms due to electron exchange. When these terms are taken into account, the probability of the excitation of triplet states is not zero. The excitation cross-section for a triplet state has been shown[25] to be proportional to $E^{-3}$, i.e. it decreases very rapidly with increase of the electron energy (while the excitation cross-section for singlet states is proportional to $E^{-1}\ln E$). The excitation of triplet states is therefore effective only for low electron energies. Ochkur's formula[25] has been modified by Rudge[26] and calculations of the excitation of triplet states by the Ochkur–Rudge formula can be found in two communications.[27,28]

Molecules in triplet states exhibit an enhanced reactivity and are longer-lived and it is therefore important to estimate the relative probability of triplet excitations. One of the authors of this review showed[29] that, when a substance is irradiated by a stream of charged particles, at least two additional mechanisms for the population of triplet states appear compared with irradiation by light. In the first place, there is the generation of triplet states on recombination of a positive ion with a thermalised electron. As a consequence of the high statistical weight of the triplet state, the probability of the formation of a molecule in this state is three times greater than in the singlet state.[30] The second possibility arises because slow electrons with $E < 100$ eV, which effectively excite triplet states, predominate in the spectrum of secondary electrons. In this respect the most favourable conditions are created on irradiation with heavy ions, since, having as a rule low velocities, the latter generate low-energy secondary electrons. As a result, the role of triplet states in radiation-chemical processes should be much greater than in photochemistry.[29] Experimental evidence for this, based on the measurement of the relative phosphorescence and fluorescence yields, has been published.[31]

Any electron whose energy is less than the lowest electronic excitation level of the medium is referred to as a "subexcitation electron". It is not able to transfer its energy for the excitation of electrons, but its energy is sufficient to excite molecular vibrations and rotations. Furthermore, subexcitation electrons can lose energy in elastic collisions and also in processes involving their capture by a molecule or a positive ion. The behaviour of subexcitation electrons therefore depends on the process which predominates in the given medium (see Section VI below).

## III. THE NATURE OF THE HIGHLY EXCITED MOLECULAR STATES ARISING ON EXPOSURE TO IONISING RADIATION

In contrast to photochemistry, in radiation chemistry the energy of the radiation is so high that the transfer to molecules of energy greatly exceeding their ionisation potential becomes possible. This results in the formation of both discrete high-energy states in the autoionisation region of the spectrum (the so-called "superexcited" states—see below) and states in the region of continuous spectrum which arise owing to the ionisation of electrons in the inner shells of the molecule and are accompanied by the appearance of the corresponding vacancies ("holes"). An ion with a vacancy in an inner shell must be regarded as in a highly excited state with energy equal to the reorganisation energy of the electron shell of the molecule on formation of the vacancy. This energy can be either transmitted to one or several electrons of the molecule with a subsequent ionisation or transfer to unoccupied orbitals (the Auger effect[32–34]—see Fig.1) or can be radiated in the form of an X-ray quantum.

Repeated ionisation is characteristic of molecules consisting of light atoms on dislodgement of an electron from an inner shell, whereas fluorescence begins to be manifested appreciably only for elements with an atomic number $Z_a > 30$. The ratio of the probabilities of the Auger effect and X-ray fluorescence is $W_a/W_r \cong 10^6/Z_a^4$.[32] Table 1 lists the probabilities $W_a$ and $W_r$, the width of the levels $\Delta E$, and the yields of the fluorescence associated with the $K$–$LL$ transition for a series of atoms. For light elements (and also for their chemical compounds), the probability of emission is very low, while for heavy elements the opposite behaviour is observed. Thus the $K$-fluorescence yield is 0.96 for thallium ($Z_a = 81$).[32]

Although processes involving the dislodgement of an electron from inner shells take place much more rarely than those where an electron is dislodged from outer shells (the degradation spectrum is displaced towards low-energy electrons), their role is very important owing to the high probability of the subsequent repeated ionisation. The yield of ionisation from the $K$ shells of light elements has been estimated[35] as $g_K \cong 10^{-2}$ per 100 eV of the absorbed energy, i.e. the absorption by the medium of an electron having an energy of 1 MeV results in the formation of approximately $10^2$ ions with a hole in the $K$ shell. For comparison, we may point out that the average number of ions formed under these conditions is approximately $3 \times 10^4$, since approximately 30 eV is consumed in the formation of a pair of ions. However, the abstraction of a $K$ electron causes a cascade of subsequent ionisations.

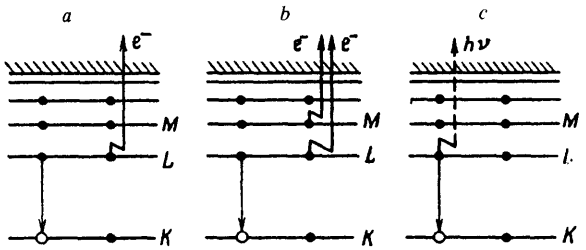

**Figure 1.** The possible forms of the evolution of the state with a vacancy in the $K$ shell: *a*) $KLL$–Auger effect; *b*) double $KLIM$–Auger effect; c) emission of the $K_\alpha$ X-ray line. In processes *a* and *b* the electron can pass to an unoccupied orbital instead of undergoing a transition to the continuous spectrum.

**Table 1.** The probabilities of the radiative and Auger–$KLL$ transitions for different atoms.[32]

| Atom | $Z_a$ | $10^{-14} W_a$, $s^{-1}$ | $10^{-14} W_r$, $s^{-1}$ | $\Delta E$, eV | $W_r/(W_a+W_r)$ |
|---|---|---|---|---|---|
| Ne | 10 | 7.40 | 0.063 | 0.98 | 0.0085 |
| Mg | 12 | 8.07 | 0.130 | 1.07 | 0.016 |
| Ar | 18 | 11.29 | 0.83 | 1.59 | 0.068 |
| Ni | 28 | 12.23 | 4.85 | 2.24 | 0.284 |
| Kr | 36 | 13.46 | 14.39 | 3.65 | 0.517 |

There are two physical mechanisms leading to ionisation on formation of a vacancy in an inner electron shell. One of these is due to the "shake-up" of the electron shell on dislodgement of an inner electron. On dislodgement of an inner electron the sharp change in the electromagnetic field in which the outer electrons move leads to additional ionisation (for a more detailed description of the "shake-up" mechanism, see the review of Matveev and Parilis[33]). The other mechanism is due to the Auger effect,[32] where an electron is transferred from one of the higher orbitals to an unoccupied inner orbital and the energy evolved is transferred to one or several outer electrons (see Figs. 1*a* and 1c). This process can be regarded as internal conversion of the quantum of electromagnetic radiation emitted on transition of an electron from an upper to a lower level. The Auger effect occurs after the formation of a vacancy over a period of $10^{-15}$–$10^{-11}$ s (depending on the extent to which the transitions are allowed), while the "shake-up" of the electron shell accompanies the formation of a vacancy and takes place over a period of $10^{-16}$–$10^{-15}$ s. Both mechanisms contribute to the formation of multicharged ions.

**Table 2.** The relative yields of ions with different numbers of charges on irradiation of neon with X-rays.[36]

| Ion | $Ne^+$ | $Ne^{2+}$ | $Ne^{3+}$ | $Ne^{4+}$ | $Ne^{5+}$ |
|---|---|---|---|---|---|
| Yield, % | 6.5±0.7 | 68.5±2.0 | 22±2 | 2.8±0.5 | 0.3 |

The probability of repeated ionisation on dislodgement of an electron from the $K$ shell is very high. For example, it is almost 99% for neon ($Z_a = 10$). When an $L$ electron is dislodged, the probability of ionisation diminishes to 13%.[36] Table 2 lists the relative yields of Ne ions with different numbers of charges on irradiation of the gas with X-rays ($K_\alpha$ Al line with $E = 1256$ eV). The overall yield of multicharged ions is 93.5% (its value less than 99% is due to the ionisation from $L$ and higher shells). A similar distribution is to be expected also for light molecules. For heavier elements, the probability of the formation of ions with the number of charges $n \geq 4$ becomes greater than for doubly charged ions.[37]

The repeated ionisation of molecules on dislodgement of electrons from inner shells can lead to their decomposition into several positively charged fragments and can ultimately give rise to a sequence of reactions different from that in photochemistry. According to estimates,[38] this effect should increase in the ultra-relativistic range of energies of the incoming particles. It is also noteworthy that, among states with an internal vacancy, highly excited states of an ion, which are not populated on irradiation with light, are in fact populated (for example, there is a possibility of the formation of $N_2^+$ in the $C^2\Sigma^+$ state[39]).

The excitation of atoms to discrete states with energies higher than the first ionisation potential $I_1$ generally leads to autoionisation, which can be explained by the fact that in the case of atoms autoionisation takes place over a period of $10^{-14}$–$10^{-11}$ s, while the duration of emission, which is the only competing process, is $10^{-9}$–$10^{-6}$ s. Emission from autoionisation states takes place only in rare instances. Thus the autoionisation peaks for the O atom at $\lambda = 878$–$879$ and 791–793 Å are characterised by an ionisation efficiency $\eta(E) < 1$. Prohibitions owing to selection rules lead to lifespans of these states $\tau = 10^{-8}$ s, which makes possible their radiative decay.[40] For atoms, this is exceptional, but the situation is different for molecules.

Platzman[4] drew attention to the fact that, according to experiments on the irradiation of molecular gases by vacuum ultraviolet light, the probability of the ionisation of certain gases $\eta(E) < 1$ when $E > I_1$ (for $E$ exceeding $I_1$ by 10 eV and more). These results were confirmed by experiments[41] on mixtures incorporating a noble gas and various molecules. An isotope effect is then observed. The replacement of hydrogen by deuterium led to an increased probability of

ionisation. Hence Platzman concluded that there is an effective competition between autoionisation and predissociation. Platzman used the term "superexcited states" for discrete states with $E > I_1$ in which predissociation takes place (see the relevant reviews[7,42]). Subsequently we shall use the abbreviation SES for such states.

As a consequence of vibronic interactions, there is a possibility of yet another non-ionisation channel leading to the decomposition of SES—radiationless relaxation via the conversion of the electronic energy into the vibrational energy of molecules and, in the case of a condensed phase, into the thermal energy of the medium. For fluorescent molecules, there is a possibility of fluorescence from the lowest excited state (in conformity with Kasha's empirical rule,[43] the molecular fluorescence originates from the lowest excited level regardless of the wavelength of the exciting light).

The SES formation and decomposition reactions can be represented schematically as follows:

$$\mathrm{ABC} \xrightarrow{h\nu > I_1} \begin{cases} \longrightarrow \mathrm{ABC^+} + \mathrm{e^-} & \text{(direct ionisation);} \quad (8a) \\ \longrightarrow \mathrm{ABC^{**}} & \text{(formation of SES);} \quad (8b) \end{cases}$$

$$\mathrm{ABC^{**}} \begin{cases} \longrightarrow \mathrm{ABC^+} + \mathrm{e^-} & \text{(autoionisation);} \quad (9a) \\ \longrightarrow \mathrm{AB^*} + \mathrm{C^*} & \text{(predissociation);} \quad (9b) \\ \longrightarrow \mathrm{ABC} + \Delta E'_{vib} + h\nu_1 & \text{(radiative relaxation);} \quad (9c) \\ \longrightarrow \mathrm{ABC} + \Delta E_{vib} & \text{(radiationless relaxation).} \quad (9d) \end{cases}$$

In the optical approximation for small molecules, the radiation yield of SES is estimated as being within the limits $g_{SES} \cong 0.6$–$1$.[44] Analogous estimates have been made also by Bednar.[35]

The important role of SES in radiation chemistry consists in the fact that their decomposition involves the formation of highly excited products (radicals). Such "hot" radicals can enter into endothermic reactions. In his first fundamental study, Platzman[4] already pointed out the possibility of a reaction with direct formation of the molecular product:

$$\mathrm{H^* + H_2O \rightarrow H_2 + OH.} \quad (10)$$

A series of data indicate that molecular hydrogen is formed by an analogous pathway in the radiolysis of hydrocarbons.[42]

Three possible pathways leading to the formation of SES can be considered: (1) the excitation of an electron in an inner shell to an unoccupied orbital; (2) the formation of a Rydberg state, these are a sequence of hydrogen-like levels converging to the ionisation potential $I \geq I_1$; (3) excitation of two valance electrons.

Owing to their short lifespan, the states of the first type decompose via the Auger mechanism and cannot be classified as SES, since the latter are neutral. Hydrogen-like excited states, referred to as the Rydberg states, are much longer-lived. At any rate, this is the case when $I$ is not very large, i.e. a hole is formed in the valence shell (although deeper valence levels can also be involved). The interaction of the electronic and vibrational movements leads to predissociation. In the Rydberg state the electron is sufficiently remote from the positive ion and moves more slowly, which ensures the exchange of the electronic and vibrational energies.

A special case of SES consists of highly excited vibrational Rydberg states converging to $I_1$. The vibrational quanta added to the electronic energy (which is less than the ionisation potential) cause the transition of the electron to the state with $E > I_1$. Most of the autoionisation thresholds for $E$ which exceed $I_1$ by several electron-volts, have a vibronic, Rydberg origin.[40] In these states predissociation competes with autoionisation as a result of which $\eta(E)$ becomes less than unity. Such a possibility of the appearance of SES was first pointed out in a review by one of the present authors[7] and also by Nishikawa and Watanabe.[45] The role of Rydberg states in radiation chemistry has been discussed in two communications.[46,47]

The energy levels of the Rydberg states are described by the "hydrogen-like" formula

$$E_n = e^2/2a_0(n-\delta_R)^2, \quad (11)$$

where $n$ is the principal quantum number, $\delta_R$ the Rydberg shift of the level, and $a_0$ the Bohr radius. Eqn.(11) is valid for molecules for low values of $n$, when the distance between the electronic levels greatly exceeds the distance between the rotational and vibrational levels. With increase of $n$, the adiabatic approximation ceases to be valid. The interaction of the Rydberg electronic states with the rotational-vibrational movement leads to a marked broadening of the lines and the Rydberg spectrum becomes almost continuous. As a result, the lifespans of the molecular Rydberg states are smaller by many orders of magnitude than those of the atomic states. Thus the width of the Rydberg level in the $H_2$ molecule is 1–5 $cm^{-1}$ for autoionisation, where $n = 8$–$11$,[48] which corresponds to $\tau = \hbar/\Delta E \cong 10^{-12}$ s, i.e. is of the order of magnitude of the vibrational period.

The lifespan of the Rydberg states increases significantly when they are characterised by a large angular momentum $l$. Fano[49] showed that, when the energy of the incoming electron exceeds by several electron-volts the ionisation potential, then the formation and subsequent decomposition of the intermediate negative complex can result in the appearance of Rydberg states with a high orbital momentum $l$.[50] Owing to the appearance of a centrifugal barrier, the lifespan of such states increases greatly both relative to the autoionisation and predissociation states and relative to the radiative transition times. Evidently the nature of the Rydberg states where $\tau = 10^{-5}$–$10^{-4}$ s, which had been observed[51,52] for $N_2$, $O_2$, $CO_2$, $NH_3$, etc., is apparently the same. It must be emphasised that these long lifetimes have been recorded in a rarefied gas, while in a condensed phase the situation may be different.

The interaction of Rydberg levels with the vibrational-rotation motion in diatomic molecules has been investigated by Golubkov and Ivanov.[53] Rydberg states with a hole in an inner shell have not so far been considered theoretically. The behaviour of Rydberg states in a condensed phase likewise still remains virtually uninvestigated. In this case the demoninator in Eqn.(11) for the energy should include the dielectric constant of the medium $\varepsilon(\omega)$, since the radius of the Rydberg state can reach hundreds of Ångstroms and for this reason there may be numerous molecules between the positive ionic residue and the electron. It is still not clear to what extent the lifespan of the Rydberg states would decrease under these conditions.

The measurement of the intensity of the luminescence of the decomposition products as a function of the energy of the ionising radiation is an effective method for the identification of SES. A series of such measurements have been made.[54,55] Thus, after irradiating hydrocarbons with electrons, it has been shown that, when $E > I_1$, lines of the Balmer series for the H atoms appear, i.e. H* is formed. For $CH_4$, the threshold corresponding to the appearance of the Balmer lines is 21.8 eV, which greatly exceeds the ionisation potential $I_1 = 12.51$ eV. The intensity of the lines then diminishes consistently with increasing number of the lines $n$, which indicates the Rydberg nature of the SES formed on excitation of the inner valence electrons from non-bonding orbitals.

Experimental data demonstrating unambiguously the formation of SES on two-electron excitation have been published.[55] Measurements of the probabilities of the absorption of energy and ionisation showed that $\eta(E) < 1$ is observed for $CH_4$ in the range of energies from 27 to 80 eV. Since the highest ionisation potential of the valence electrons is 21.3 eV and the next potential corresponds to the ionisation of the K shell and is in the region of 290 eV, the formation of SES in the given instance corresponds to the excitation of two or more electrons.

Thus, among the three possible pathways dealing with the formation of SES the last two are actually realised.

## IV. ENERGY LOSSES OF A CHARGED PARTICLES IN A CONDENSED MEDIUM. COLLECTIVE STATES.

### 1. Ionisation Energy Losses by a Charged Species

Over most of the path traversed by fast charged species, the energy losses in the excitation and ionisation of the electrons of the medium make the main contribution to the retardation of such a species; these energy losses have come to be referred to as ionisation losses. Numerous publications have been devoted to the determination of the ionisation losses (see, for example, the relevant monographs[8-10, 56-58]). Among the various methods for the calculation of ionisation losses, the commonest is the Bethe–Bloch method, according to which the medium is considered to be an *ensemble* of independent atoms (molecules). The average ionisation losses per unit length of the path traversed were formulated thus:

$$S_e = -(\mathrm{d}E/\mathrm{d}x)_e = n_0 \sum_n \hbar\omega_{0n}\sigma_{0n}, \qquad (12)$$

where $n_0$ is the density of the species constituting the medium and the summation includes integration with respect to continuous states. Using for $\sigma_{0n}$ the formulae obtained within the framework of the Bethe theory for $S_e$, it is possible to obtain the following expression ($v/c \ll 1$) [10]

$$S_e = (4\pi Z^2 e^4 n_0 Z_a/mv^2) \ln (2mv^2/\bar{I}_a), \qquad (13)$$

where $\bar{I}_a$ denotes the average excitation potential of the atoms of the medium, introduced in accordance with the relation

$$Z_a \ln \bar{I}_a = \sum_n f_{0n} \ln (\hbar\omega_{0n}). \qquad (14)$$

The quantity $\bar{I}_a$ is best determined experimentally, although methods have been developed for its calculation (see the relevant review[59]). Formulae for $S_e$ taking into account the relativistic effects have been published.[8,56]

For molecular media and high energies of the charged species, the values of $S_e$ can be calculated according to the Bragg rule by means of an additive scheme. $Z_a$ and $\bar{I}_a$ in Eqns.(13) and (14) are then replaced by $N_m$ and $\bar{I}_m$ in conformity with the expressions

$$N_m = \sum_a n_a Z_a; \quad N_m \ln \bar{I}_m = \sum_a n_a \ln \bar{I}_a, \qquad (15)$$

where $n_a$ is the number of atoms of type $a$ in the molecule.

For velocities of the charged particles slightly exceeding the velocities of the valence electrons, the Bragg rule does not hold. For protons, appreciable discrepancies appear already for energies below 150 keV.[60] In calculations of $S_e$ in such cases, it is essential to introduce corrections for the effect of the binding of electrons (for details, see Starodubtsev[56] and Ahlen[59]).

In a condensed medium, for high velocities of the charged particles, the excitation condition (7) is fulfilled when the impact parameter $\rho$ has values significantly exceeding the average distance between the molecules. As a consequence of the polarisation of the medium by the moving charged particle, the interaction of the latter with distant molecules is weakened. As a result, the real energy losses become smaller than the values calculated by Eqn.(13) as the simple sum of the energy losses in individual collision steps.

One way of taking into account the influence of the macroscopic properties of the medium on the retardation of the charged particles is to introduce the dielectric constant of the medium $\varepsilon(\omega)$ into the differential cross-section for the inelastic interaction.[14,61] In the general case the linear response of the system to the electric field of the charge is defined in terms of the dielectric constant, which depends on the frequency and the wave vector $\varepsilon(\mathbf{q}, \omega)$. The quantity $\varepsilon(\mathbf{q}, \omega)$ is an extension (to fields which vary in space) of the dynamic dielectric constant $\varepsilon(\omega)$. The probability, referred to unit time, of the transfer of the momentum $\mathbf{q}$ and the energy $\hbar\omega$ (in terms of the Born approximation) from the charged particle to the electrons of the system is defined by the imaginary component of the reciprocal of the dielectric constant:[62]

$$W(q, \omega) = \frac{8\pi Z^2 e^2}{\hbar q^2} \operatorname{Im}\left[\frac{1}{\varepsilon(q, \omega)}\right] = \frac{8\pi Z^2 e^2}{\hbar q^2} \cdot \frac{\varepsilon_2(q, \omega)}{\varepsilon_1^2(q, \omega) + \varepsilon_2^2(q, \omega)}, \qquad (16)$$

where $\varepsilon_1(\mathbf{q}, \omega)$ and $\varepsilon_2(\mathbf{q}, \omega)$ are the real and imaginary components of the dielectric constant.

Eqn.(16) is used as the initial expression in the macroscopic consideration of the energy losses by the particle in its interaction with the electron gas. In recent years this expression has come to be used also for the calculation of the energy losses in molecular liquids (particularly in water[63]). However, the calculation of the energy losses by Eqn.(16) is extremely difficult because the explicit form of the function $\varepsilon(\mathbf{q}, \omega)$ is as a rule unknown (the electron gas is an exception).

### 2. Excitation of Collective States of the Plasmon Type in a Molecular Medium

In the condensed phase, broad, intense maxima in the range 15–25 eV appear in the energy loss spectra of fast electrons apart from the absorption maxima and energies close to the electronic transition energies in isolated molecules (Fig.2). These maxima have come to be referred to as the excitation of collective states of the plasmon type. The plasmon states are delocalised, i.e. they characterise the states of the entire assembly and not of individual molecules and their lifespan is short.

A theory of plasmon states has been devised by Bohm and Pines for free electrons in metals[64] and is fully consistent with experimental data for inelastic energy losses by fast electrons in metallic films. Although the possibility of collective excitations of the plasmon type in molecular media was pointed out by Fano as early as 1960,[65] this question remained controversial for a long time (see the relevant discussion in a number of communications[7,47,66]). In 1974 Brandt and Ritchie (quoted by Kutcher and Green[66]) formulated the criteria which must be satisfied by the dielectric function of the medium in the vicinity of the plasmon absorption point, while Heller et al.[67] showed that the criteria of Brandt and Ritchie are satisfied for a broad absorption peak in water with a maximum at 21.4 eV. Subsequently absorptions of the plasmon type were observed also in other molecular liquids[68] and in solid films.[83]

We shall deal briefly with the nature of the plasmon vibrations. Plasmons are defined as the quanta associated with the vibrations of the electron density of plasma. They can be regarded as coherent periodic deviations of the electron density at each point from its average value:

$$\Delta n(\mathbf{r}, t) = n(\mathbf{r}, t) - \bar{n} = \Delta n_{max} \exp[i(\omega t - \mathbf{qr})].$$

These vibrations are longitudinal, i.e. the direction of their propagation **q** coincides with the electric field strength vector **E**.

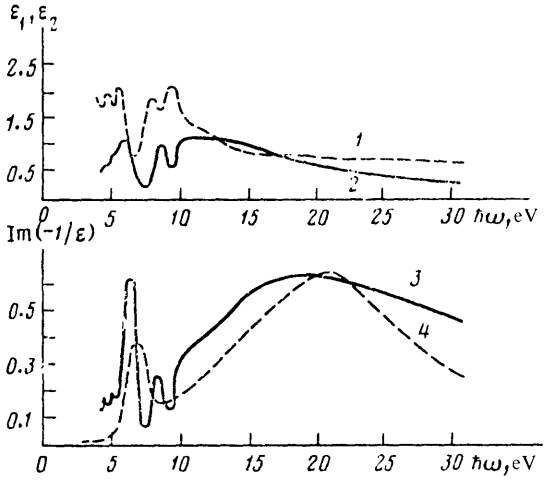

**Figure 2.** The form of the dielectric constant functions $\varepsilon_1(\omega)$ (curve *1*) and $\varepsilon_2(\omega)$ (curve *2*) and the energy loss function $\mathrm{Im}[-1/\varepsilon(\omega)]$ (curves *3* and *4*) in polystyrene; curve *3*—calculation based on $\varepsilon_1$ and $\varepsilon_2$ (Voltz[61]); curve *4*—experimental spectrum of the energy losses by electrons.[82]

According to Maxwell's equations, in the medium we have[61]

$$\mathrm{rot}\,\mathbf{H} = \frac{1}{c}\frac{\partial \mathbf{D}}{\partial t} + \frac{4\pi}{c}\mathbf{j} = i\omega\varepsilon(\omega)\mathbf{E} = 0. \qquad (17)$$

The magnetic field **H** = 0, since fields arising from the time variation of the electric induction vector **D** and the current **j** cancel out. An equation for the intrinsic frequencies of the plasmon vibrations follows from Eqn.(17):

$$\varepsilon(\omega) = 0. \qquad (18)$$

In the case of bound electrons, for example, in a molecular medium, the collective vibrations are not manifested in a pure form, being always combined with intramolecular transitions. The electron density vibrations can be represented in this case as a longitudinal polarisation wave, which leads to the vibrations of the dipole moment of the molecule. Such a wave is illustrated schematically in Fig.3 for non-polar molecules.

The passage of a fast particle with a velocity $v$ and a charge $e$ through the medium is equivalent to the current $\mathbf{j} = e\mathbf{v}\delta(x - vt)$. This entails the polarisation of the medium. The electric field $\mathbf{E}_{pol}$ arising as a result of this polarisation interacts with the moving particle, as a consequence of which the latter loses energy. By solving the Maxwell equations in the given medium, it is possible to find $\mathbf{E}_{pol}$ and to obtain an expression for the probability of the energy loss $\hbar\omega$ along the path of length $l$ for a single scattering of the particle in the solid angle $d^2\Omega$ owing to a deviation by an angle $\theta$:[69]

$$\frac{\partial^2 W}{\partial(\hbar\omega)\partial^2\Omega} = \frac{l}{(e\pi a_0 q)^2}\,\mathrm{Im}\left[-\frac{1}{\varepsilon(\mathbf{q}, \omega)}\right] \qquad (19)$$

where the momentum $q$ transmitted to the medium depends on the scattering angle and can be found from the laws of the conservation of the energy and momentum of the particle.

As in Eqn.(16), the principal dependence on the transmitted energy in Eqn.(19) consists in the factor $\mathrm{Im}[-1/\varepsilon(\mathbf{q}, \omega)]$. The maxima in the losses occur both in the region of the maxima in $\varepsilon_2(\mathbf{q}, \omega)$, which corresponds to allowed transitions in isolated molecules, and in the region of the zero values of the denominator, i.e. in the region corresponding to the solutions of Eqn.(18), which denotes the excitation of collective states; in order to find the frequencies, it is necessary to know the explicit form of the function $\varepsilon(\omega)$.

The medium with bound electrons can be represented by a set of oscillators, each of which is characterised by three parameters: the intrinsic frequency of the oscillator $\omega_i$, the oscillator strength $f_i$, and the decay constant $\gamma_i$ (a quantity which is equal to the reciprocal of the lifespan of the state). The following expression is valid for the dielectric constant of the medium in terms of the approximation $q \to 0$:[61,70]

$$\varepsilon(\omega) = 1 + \sum_i f_i\omega_p^2(\omega_i^2 - \omega^2 - i\gamma_i\omega)^{-1} \qquad (20)$$

where $\omega_p$ is the frequency of the plasma vibrations in the free electron system, which depends on the electron density $n_e$:

$$\omega_p = (4\pi n_e e^2/m)^{1/2}. \qquad (21)$$

Since the region $\hbar\omega < 30$ eV is important for the collective vibrations, the electrons in the inner atomic shells can be disregarded. The quantity $n_e$ is therefore determined by the density of the valence electrons and in the summation with respect to $i$ in Eqn.(20) it is necessary to consider oscillators corresponding to the transitions of valence electrons alone. An approximate expression for the frequency $\omega_p$ in molecular liquids has been published:[68]

$$\hbar\omega_p,\ \mathrm{eV} = 28.8\,(N_v\rho/M)^{1/2} \qquad (22)$$

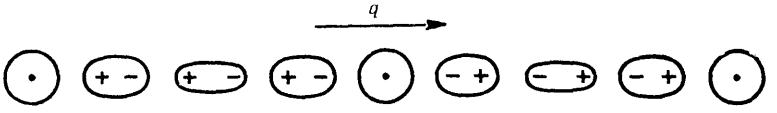

**Figure 3.** Schematic representation of the longitudinal polarisation wave in a condensed medium consisting of non-polar molecules.

where $N_v$ is the number of valence electrons per molecule, $M$ the molecular weight, and $\rho$ the density of the medium (g cm$^{-3}$); for water, $\hbar\omega_p \cong 19.2$ eV.

The intrinsic frequencies of the vibrations of the medium must satisfy Eqn.(18). It is very difficult to calculate these frequencies from Eqn.(20). We shall consider several special cases.

For free electrons in a metal, $f_0 = 1$, $\omega_0 = 0$, and all the $f_i = 0$ ($i \neq 0$);

$$\varepsilon(\omega) = 1 - \omega_p^2(\omega^2 - i\gamma_0\omega)^{-1}. \quad (23)$$

If the decay is slight, resonance is manifested at $\omega_2 = \omega_p$, i.e. free plasmons are excited.

In many molecules the maximum oscillator strength corresponds to one of the transitions. Suppose that it is $f_1$; in this case, one can put approximately

$$\varepsilon(\omega) = 1 + f_1\omega_p^2(\omega_1^2 - \omega^2 - i\gamma_1\omega)^{-1}. \quad (24)$$

For a weak decay, the energy loss function has only one maximum corresponding to $\varepsilon(\omega) = 0$:

$$\omega_r = (f_1\omega_p^2 + \omega_1^2)^{1/2}. \quad (25)$$

For low densities (gas phase), $\omega_p = 0$ and the maximum of the absorption function corresponds to $\omega_r = \omega_1$, i.e. as for an isolated molecule. In the opposite case, at very high densities, subject to the condition

$$f_1\omega_p^2 \gg \omega_1^2, \quad (26)$$

the quantity $\mathrm{Im}[-1/\varepsilon(\omega)]$ is a maximum for $\omega_r = f_1^{1/2}\omega_p$, i.e. corresponds to the longitudinal collective vibrations of free electrons. Peaks of the energy loss function between these two limiting cases cannot be fully assigned either to collective vibrations or to one-electron transitions. The latter situation is typical for molecular liquids.

The value of $\varepsilon_1(\omega)$, $\varepsilon_2(\omega)$, and the function $\mathrm{Im}[-1/\varepsilon(\omega)]$ in liquid water are presented in Fig.4. The $\varepsilon_2(\omega)$ peaks on the graph correspond to intramolecular transitions. The $\hbar\omega_1 = 13.5$ eV transition has the maximum oscillator strength $f_1 = 0.43$. The peak of the energy loss function $\mathrm{Im}[-1/\varepsilon(\omega)]$ at 21 eV is of plasmon origin, i.e. it corresponds to the longitudinal vibrations of the assembly of molecules. However, these are not the plasma vibrations of free electrons, since condition (26) is not explicitly fulfilled in this instance. Indeed, according to Eqn.(22), $\hbar\omega_p \cong 19.2$ eV for water. For the $\hbar\omega_1 = 13.5$ eV peak with $f_1 = 0.43$, we obtain $f_1(\hbar\omega_p)^2 = 159$ eV$^2$, while $(\hbar\omega_1)^2 = 182$ eV$^2$. Nevertheless, an appreciable change in the positions of the maximum indicates a relatively high contribution of the collective effects.

The theoretical determination of the energy loss function $\mathrm{Im}[-1/\varepsilon(\mathbf{q}, \omega)]$ is very difficult. In the region $q \to 0$ one can use optical data. For the electron gas, the expression for the dielectric constant has been obtained by Lindhard.[64] A semiempirical expression defining $\varepsilon(q, \omega)$ for water has been proposed.[71]

There are several ways in which collective excitations can break down. In the electron gas the breakdown takes place as a consequence of the interaction of the electrons with one another. The Coulombic interaction of electrons is strongly shielded by the electron cloud and is manifested only over short distances. As a result of such short-range interaction, the vibration energy of the plasmon is converted into the kinetic energy of the movement of individual electrons, i.e. it is distributed over the entire electron gas.[72]

In atomic-molecular media, the decay of plasmon states is due to the interaction of plasmons with electrons and also with the lattice vibrations or with impurities. The electron–plasmon interaction is of the long-range type. When a plasmon is absorbed, the momentum $\mathbf{q}$ is transferred to the electron; as a result, the collective excitation is converted into a one-particle excitation. This process is identical with the absorption of a photon having the same energy. Wölff[73] (see also Nazierea and Pines[74]) showed that the lifespan of the plasmon can be expressed in this case in terms of optical constants: the absorption coefficient $\kappa$ and the refractive index $n$:

$$1/\tau = n\kappa\omega. \quad (27)$$

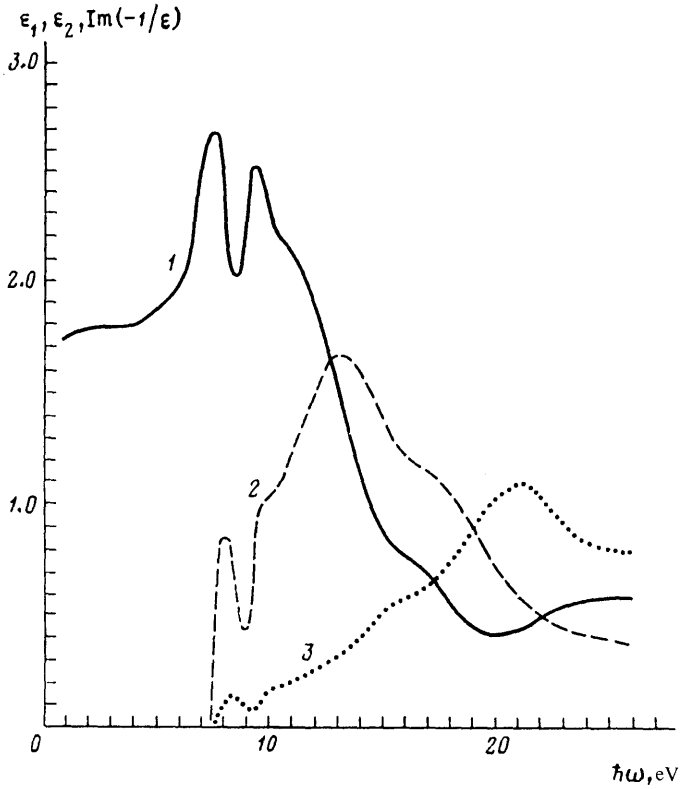

**Figure 4.** The form of the dielectric constant functions $\varepsilon_1(\omega)$ (curve *1*) and $\varepsilon_2(\omega)$ (curve *2*) and the energy loss function $\mathrm{Im}[-1/\varepsilon(\omega)]$ (curve *3*) in liquid water.[67]

For water in the region of the energy of the plasmon state, $\hbar\omega_r = 21.4$ eV, $n = 0.76$, and $\kappa = 0.36$.[67] Calculation by Eqn.(27) leads to $\tau \cong 1.1 \times 10^{-16}$ s. The lifespan of the plasmon state can be estimated also from the uncertainty relation. It follows from the spectrum of the energy losses in water that the half-width of the excited level with the energy $\hbar\omega_r = 21.4$ eV is $\Delta\hbar\omega_r/2 \cong 3.4$ eV. We therefore obtain $\tau = 1/\Delta\omega_r \cong 10^{-16}$ s, which agrees well with the calculation by Eqn.(27).

## V. THE LOCALISATION AND DELOCALISATION OF ENERGY LOSSES

The question of the degree of localisation of the absorbed energy arises from the study of the processes involving the absorption of the energy of the ionising radiation. There

are two possible causes of the delocalisation of its energy. The first is associated with the quantum-mechanical nature of the microparticle and the second with the possibility of collective excitations. We shall consider both causes in greater detail.

The quantum-mechanical nature of micro-objects is reflected by the uncertainty principle. The limitations imposed by the uncertainty principle were not previously taken into account in the study of the interaction of a stream of particles with matter. This was justified[75] by the fact that, during a period of $10^{-16}$ s, there is sufficient time for the localisation of the excitation as regards the molecules. However, this justification cannot be regarded as correct. It has been emphasised[47] that, since the subsequent localisation is stochastic, the initial delocalisation precludes in principle the determination of the site of the absorption of energy more precisely than is allowed by the uncertainty principle.

If a microparticle with the energy $E$ transmits the energy $\Delta E$ to the medium, then at the instant of the transfer the energy of the particle is defined to within $\Delta E$. This uncertainty $\Delta E$ in the energy is associated with the uncertainty $\Delta x$ in the position of the particle during the energy transfer process. This type of relation has been found for ultrarelativistic[75] and non-relativistic[47] particles. It has been shown[76] that in the general case the uncertainty as regards the coordinates of the particle during the transfer of its energy $\Delta E$ satisfies the inequality

$$\Delta x \geqslant \hbar v_x/\Delta E. \qquad (28)$$

The uncertainty in the site of the absorption of energy is the same.

The greater the energy transferred, the lower the degree of delocalisation. When inner 1s electrons are dislodged, the energy losses are in fact localised. Indeed, even for ultrarelativistic particles ($v = c$), $\Delta x = 0.66$ nm for the transfer of the energy $\Delta E = 300$ eV (i.e. an energy greater than the ionisation potential of the $K$ shell of the carbon atom) according to Eqn.(28), while in the transfer of $\Delta E = 500$ eV (an energy of the order of magnitude of the ionisation potential of the $K$ shell of the oxygen atom) we obtain $\Delta x = 0.40$ nm.

**Table 3.** The degrees of delocalisation in the transfer to the medium of the energy $\Delta E = 15$ eV by an electron having an energy $E_e$.[76]

| $E_e$, eV | $10^3$ | $10^4$ | $10^5$ | $10^6$ | $10^7$ | $10^8$ | $10^9$ |
|---|---|---|---|---|---|---|---|
| $10^{-8}v$, cm s$^{-1}$ | 5.93 | 18.7 | 58.5 | 164 | 282 | 300 | 300 |
| $\Delta x$, nm | 0.26 | 0.82 | 2.56 | 7.2 | 12.3 | 13.1 | 13.1 |

However, for small losses, which accompany the majority of inelastic scattering steps, the degree of delocalisation can be very considerable. In ionisation most of the dislodged electrons have low energies. The quantity $\Delta E = 15$ eV can be adopted as the most probable energy loss. The results of the calculation of $\Delta x$ for $\Delta E = 15$ eV and different energies of the incoming electron are presented in Table 3. Evidently, for relativistic electrons, the degree of delocalisation of the ionisation step is not less than 13.1 nm, i.e. is very considerable. In the excitation of an electronic state with an energy of 7.5 eV, the degrees of delocalisation are greater by a factor of 2 than those quoted in Table 3.

Thus the delocalisation region can embrace several tens of molecules of average size. Although subsequently the energy is localised at one of the molecules, it is random and the coordinates of the ionisation or excitation points cannot therefore be determined with an accuracy greater than to within $\Delta x$.

According to inequality (28), the degree of delocalisation depends on the velocity of the particle. For this reason, the values of $\Delta x$ quoted in Table 3 for heavy particles correspond to correspondingly large energies, amounting to $E = (M/m)E_e$. Thus the proton has the velocity $v = c$ for $E \geqslant 2$ GeV.

The second cause of the delocalisation of energy losses is the collective character of the excited states, which can obtain even in the excitation of the electronic states of a single molecule. The simplest example is the excitation of $\pi$-electronic states, which are delocalised along the molecule. A fast electron, exciting such a molecule, transmits energy to the entire assembly of $\pi$ electrons. As a result, the site of the excitation energy transfer is delocalised along the molecule, which can be fairly long, for example, in the case of a polymer.

The excited electronic states in molecular crystals are also collective owing to periodic symmetry. These are the thoroughly investigated exciton states.[77] The energy of the exciton state is close to the energy of the discrete electronic states of isolated molecules (4–8 eV), but in these states the excitation embraces a greater number of molecules. Under these conditions, the excitation migrates effectively in the crystal over distances up to 100 nm.[77,78] Thus owing to effective migration the excitation of one of the units of the polymer chain spread rapidly along the chain.[79] The high efficiency of such energy migration has been confirmed experimentally:[80] the saturation of the phosphorescence of luminescent additives in polystyrene on $\beta$-irradiation has been observed for a 1 : 1 ratio of the concentration of phosphor species and macromolecules, i.e. in the presence of one phosphor species per macromolecule.

Thus the excitations of discrete electronic states ($\Delta E_n < I_1$) in polymer molecules and molecular crystals are known to be delocalised. Collective excited states occur not only in crystals but also in liquids and polymer films when fast charged particles pass through them (see Section IV). The energy of such states as a rule exceeds the first ionisation potential and amounts to 15–25 eV.

It has been shown[76] that the linear size of the collective excitation region is determined by the expression

$$b_{pl} = \pi v/\omega_r = \pi\hbar v/\Delta E_r, \qquad (29)$$

where $\omega_r$ is the resonance frequency calculated by Eqn.(25). The maximum size of the region corresponds to $v = c$ and is $b_{pl}^{max} = \pi\hbar c/\Delta E_r$. For water, $\Delta E_r = \hbar\omega_r = 21.4$ eV,[66] which yields $b_{pl}^{max}(H_2O) = 29$ nm.

Thus, in the initial period of approximately $10^{-16}$ s, the energy transferred by the fast charged particle is delocalised both as a consequence of the quantum-mechanical uncertainty principle and as a consequence of cooperative effects.

As a result of the delocalisation along the direction of motion, caused by the uncertainty principle, the coordinates of the excitation and ionisation points can be determined with an accuracy to within a quantity not exceeding $\Delta x$, specified by Eqn.(28). For relativistic electrons, $\Delta x$ is fairly large and includes several tens of molecules. Thus $\Delta x = 26$ nm for the excitation of the $\Delta E = 7.5$ eV level. This factor is especially important for biological systems characterised by a marked non-uniformity as regards their sensitivity to radiation. The size of the target in radiobiology should not be

less than 10–25 nm (the spread being determined by the value of $\Delta E$ leading to the biological effect).

As shown above, the linear size of the collective excitation region of the plasmon type can reach 30 nm. Since the oscillator strengths are concentrated in the region of the peak maximum in the presence of collective peaks, the plasmon absorption is fairly considerable. It follows from the form of the energy loss function in water[66] that the plasmon absorption leads to a decrease of the fraction of the oscillator strength corresponding to transition to discrete excited states compared with their distribution in water vapour. Since the collective excitation of the plasmon type is dissipated mainly via energy transfer to a single molecule with subsequent ionisation, the "pumping" of energy from discrete excitation levels to collective excitation levels should entail an increase of the contribution of ionisation in the liquid phase compared with the gas phase. At the same time the dissipation of collective excitations can serve, as emphasised by Voltz,[81] as an additional source of superexcited states (see Section III). In the case of SES there is competition between predissociation and autoionisation. For the excitation of the SES in the course of the dissipation of the collective excitation, it is essential that the energy liberated in this process should be located in the region of the formation of the SES for the given type of molecules.

In conclusion we shall consider the consequences of the delocalisation of the excited electronic states in long molecules and of the effective migration of the electronic excitation along a polymer chain.[79] This should result in the preferential rupture of the weaker chemical bonds and also chemical bonds in the vicinity of an impurity or chain defects, since the excitation energy is localised at precisely these sites. Track effects arising from the energy transmitted to the electrons of the medium should not be manifested in such a polymer matrix, because the energy absorbed is rapidly dissipated throughout the electronic subsystem. Here there is a clear analogy with metals, where the electron gas dissipates the absorbed energy throughout the bulk of the metal without the formation of linearly extended tracks.

## VI. THE STRUCTURE OF THE TRACKS OF CHARGED PARTICLES

### 1. Tracks of Fast Electrons

Owing to its interaction with atoms and molecules on passing through the medium, a fast electron loses energy not continuously but in individual portions. The probability of such an energy loss step depends on the type of the excited state and energy of the electron (see Section II). It follows from the spectra of the energy losses arising when fast electrons pass through thin films that the most probable energy loss is 15–30 eV.[6] The transferred energy is used in the formation of ions and secondary electrons and also in the excitation of the molecules of the medium. The ions and excited molecules formed are localised in the vicinity of the trajectory of the primary electron and constitute its track.

The distance traversed by the primary electron between the energy transfer steps is referred to as the free path $l$. The mean $\bar{l} = (n\sigma_{tot})^{-1}$, where $\sigma_{tot}$ is the overall inelastic scattering cross-section and $n$ the density of the molecules of the medium. For a fast electron, up to $E > 10$ keV, $\bar{l}$ greatly exceeds the size of the region where the energy transmitted to the medium is localised. For example, for a relativistic electron in water, we have $\bar{l} = 200$–$300$ nm. Consequently a fast electron forms a series of non-overlapping microregions along its path, consisting of excited and ionised molecules.

The evolution of ideas about the structure of the fast electron track has been considered in a review[6] and in another publication.[7] Mozumder and Magee [84,85] introduced a classification of the energy structures of the track. According to this publication, the energy of the fast electron is consumed in the formation of "spurs" with energies of 6–100 eV, the so-called "blobs" with energies in the range 100–500 eV,† and "short tracks" with energies in the range 500–5000 eV.

The probability that an energy of 20 eV is localised in the spurs is highest.[85] Such spurs contain, as a rule, one ion pair (with a probability of approximately 0.5).[87] The average number of ion pairs in the spur is approximately 1.78 according to Magee and Chatterjee[87] for an average energy in the spur of approximately 30 eV. The maximum energy of the short track (5 keV) is determined from the condition for the overlap of the spurs. Short tracks consist of cylindrical regions with an enhanced concentration of excitations and ionisations and an energy distribution which can be found from the Rutherford formula [Eqn.(1)].

A numerical computer experiment with the aid of the Monte Carlo method is used to find the degradation spectrum and the energy structure of the fast electron track.[88–90] The degradation spectrum and a series of other energy characteristics of the track of a monochromatic electron beam with $E = 10$ keV in water have been found.[89,90] The authors used quantities employed for the gas phase as the interaction cross-sections, i.e. the specific features of the condensed phase were disregarded.

In a condensed phase it is difficult to separate the interaction of an electron with an isolated molecule. For this reason, instead of the molecular excitation cross-section $\sigma_k(E)$, one usually employs in this case the reciprocal of the free path $l^{-1} = n\sigma_k(E)$ in relation to the excitation in the $k$th state and the cross-section itself is expressed as a function of the energy losses $\mathrm{Im}[-1/\varepsilon(\mathbf{q}, \omega)]$ (see Section IV).

The tracks of an electron with $E_0 = 1$ and 10 keV in water have been modelled.[71,91,92] However, since the dependence of the dielectric constant function $\varepsilon(\mathbf{q}, \omega)$ on $\mathbf{q}$ is unknown, it was modelled using data for the gas phase. The role of the phase state in primary radiolytic processes has been investigated in a study[91] where the overall radiation ionisation and excitation yields and the degradation spectrum of the electrons in water and water vapour were found.# The evolution of the track of a fast electron in water for times up to $10^{-7}$ s has been investigated[92] by the computer modelling method.

For a more detailed investigation of the influence of the structure of the track on radiation-chemical reactions, it is necessary to know not only the energy characteristics of the track but also the spatial distribution of the secondary electrons and the excitation and ionisation steps throughout the bulk of the track. The Monte Carlo method is also

---

† The upper limit to the energy of the blob is extremely arbitrary. In a recent study by Magee and Chatterjee[86] the upper limit was assumed to be 1600 eV.

# In a communication by the authors of this review and V.Ya.Sukhonosov, a comparative study of the primary stage of the radiolysis of water in the gas and liquid phases is described: for a brief description of the results, see Ref. 170.

convenient for the determination of this distribution. Studies of this kind have been carried out.[91–95]

The so-called "stochastic" approach, in which an instantaneous picture of the spatial distribution of the excitation and ionisation steps is fixed, has been used in investigations[93,94] of electron tracks. In this case the tracks constitute a set of points in space where inelastic scattering steps have taken place. Having at one's disposal sets of such tracks, it is possible to calculate the spectrum of the absorbed energy in the sensitive regions of the irradiated medium[93] and to calculate their line shapes and the decay of the electronic spin echo signals.[94,95]

When the velocity of the electron exceeds the velocity of light in the medium, an additional source of energy losses, namely the Vavilov–Cherenkov radiation, appears. The contribution of this radiation to radioluminescence has been fairly clearly identified in a series of investigations[96–99] and its role in photoradiation processes has been analysed.[100,101] It has been shown that the number of quanta of such radiation generated on irradiation in the accelerators employed in radiation chemistry is comparable to the light flux from the lamps employed in photochemical experiments. Thus, when photosensitive media are irradiated in accelerators, internal photoradiation processes are inevitable. Since the yield of the Vavilov–Cherenkov radiation is much lower on irradiation with a $^{60}$Co source, the irradiation of photosensitive media in an accelerator should be more effective for the same dose.

## 2. Energy Losses by Pre-excitation Electrons

Since the energy of these electrons is insufficient for the excitation of the electronic states, their energy is consumed in the excitation of vibrational and rotational states and also in inelastic collisions. In polar liquids there is an additional energy loss in dipole relaxation. In the condensed phase the energy losses are determined by the dependence of the dielectric constant of the medium on the frequency and are expressed in terms of the energy loss function $\mathrm{Im}[-1/\varepsilon(\omega)]$ [see Eqn.(16)].

In the range of energies from 5 to 0.5 eV, the resonance process involving the formation of negative molecular ions by the capture of an electron with subsequent ionisation or dissociative ionisation has large cross-sections.[102,103] According to Schulz,[104] such resonances or short-lived states of the negative ion can be divided into two groups. These are in the first place potential shape resonances which arise following the capture of an electron by the potential well formed in the electronic ground state of the molecule as a result of the centrifugal or polarisation forces. The life-span of such states is $10^{-15}$–$10^{-10}$ s. The Feshbach resonances, whose appearance is associated with the excitation of one of the electrons of the molecule, belong to the second group. This results in the formation of a state which is energetically more favourable for the addition of an excess electron. A Rydberg state may be frequently an excited state of this kind.[105] The decomposition of the negative ion formed is as a rule accompanied by the excitation of the molecular vibration. The characteristic energy loss peaks for electrons with energies in the range 0.5–3 eV when they pass through thin films have been interpreted in terms of a resonance energy loss mechanism which involves the formation of an intermediate negative ion.[106–108]

An important characteristic in the study of the pre-excitation electron retardation processes is the thermalisation distance $l_{th}$. It is essential to know this quantity in determining the size of the spur and the yield of the free ions. The first estimates of the thermalisation distance and time ($t_{th}$) for slow electrons were made by Samuel and Magee[109] who used for this purpose the classical method based on the random movement of the electron in the Coulombic field of the parent ion. Assuming that the electron traverses identical distances $l$ between collisions in the course of the retardation process and that it loses the same energy $\Delta\varepsilon$ in each collision, the authors obtained $t_{th} \cong 2.83 \times 10^{-14}$ s and $l_{th} = 1.2$–$1.8$ nm for an electron with an energy of 15 eV. Since the electron cannot overcome the attraction of the parent ion for such a low value of $l_{th}$, it is captured by the ion after approximately $10^{-13}$ s, which results in the formation of a neutral molecule in an excited state which is capable of dissociation. However, the experimental yield of the free ions showed that some of the electrons are removed to considerable distances from the ion in the thermalisation process and do not recombine.

The retardation of slow electrons in a condensed medium has been studied theoretically by Frohlich and Platzman[110] taking into account the dielectric properties of the medium. Within the framework of classical electrodynamics, they obtained an expression for the rate of energy loss by an electron moving along a linear trajectory at a velocity $v$. This expression in fact represents the non-relativistic analogue of the Fermi formula:[111]

$$-\frac{dE}{dt} = \frac{2e^2}{\pi v^2}\int_0^\infty \omega\,\mathrm{Im}\left[-\frac{1}{\varepsilon(\omega)}\right] xK_0(x)K_1(x)\,d\omega, \qquad (30)$$

where $x = \omega b_{\min}/v$ and $b_{\min}$ is the minimum impact parameter, which is assumed equal to either the intermolecular distance $d$ or to the de Broglie wavelength of the electron $\lambda$ when $\lambda < d$. Since the form of the function $\mathrm{Im}[-1/\varepsilon(\omega)]$ was not known over a wide range of $\omega$, the authors[110] confined themselves to the calculation by Eqn.(30) of the energy losses only in dipole relaxation and obtained $-dE/dt \cong 10^{13}$ eV s$^{-1}$ for water, which is independent of the electron energy in the experimental range from 1 to 10 eV. This value of energy losses was shown by the authors to be comparable to the energy losses in the excitation of vibrations.

The contributions of various mechanisms to the energy losses have been analysed.[112,113] According to the results of Magee and Helman,[112] the main contribution to the overall energy losses comes from the energy consumed in dipole relaxation (provided that such losses occur). They amount to approximately $1.5 \times 10^{13}$ eV s$^{-1}$ for water, while the energy lost in vibrations in the infrared range amounts to only approximately $10^{12}$ eV s$^{-1}$. The opposite result was obtained by Byakov and Grishkin,[114] who showed that the main contribution to the retardation of the pre-excitation electron comes from the resonance losses in the excitation of retarded longitudinal vibrations of the water molecules. An approximate analytical formulation of the function $\mathrm{Im}[-1/\varepsilon(\omega)]$ was used[114] in the calculation of the energy losses by Eqn.(30). A more accurate calculation by Eqn.(30), carried out by Garin and Byakov[115] using the experimental optical properties of water, confirmed the general conclusion drawn in the previous study.[114]

According to the results of Garin and Byakov,[115] the resonance losses resulting from intramolecular vibration in the infrared range make the main contribution to the retardation of the excitation electrons in polar liquids. The contribution of the losses in dipole relaxation proved to be smaller by an order of magnitude. This conclusion is more valid for non-polar liquids, where the main channel for these losses is not the relaxation of permanent dipole moments (the latter are zero) but the dipole moments induced in the molecules of the medium by the passing electron. As a result, the electron retardation time in the majority of liquids is

determined by the resonance absorption in the infrared range. Liquids made up of molecules with a high symmetry, which have no active vibrations in the infrared range, for example the molecules of methane or neopentane, may constitute exceptions.

According to Garin and Byakov,[115] the rate of energy loss by an electron having $E = 7.5$ eV in Debye relaxation is $(-dE/dt)_D \cong 10^{12}$ eV $s^{-1}$ and the overall rate of resonance losses is $(-dE/dt)_r \cong 4 \times 10^{13}$ eV $s^{-1}$. The maxima in the region of molecular librations ($\bar{\nu} \cong 700$ $cm^{-1}$) and the intramolecular stretching vibations ($\bar{\nu} \cong 3400$ $cm^{-1}$) make the main contribution to the resonance losses. As a consequence of the increase by a factor of approximately 2 of the reduced masses in stretching vibrations in $D_2O$, the rate of energy loss should be lower by a factor of 2 and the retardation time and the path traversed should therefore be greater by a factor of 2. This conclusion agrees with the results of recent measurements.[116]

The energy barriers had been calculated earlier[117] by Eqn.(30) taking into account the experimental values of $\mathrm{Im}[-1/\varepsilon(\omega)]$. The data obtained in the above studies[115,117] for the overall energy losses by slow electrons agree. However, Raitsimring et al.[117] failed to analyse the contribution of the individual mechanisms to the retardation of slow electrons. On the other hand, they calculated the total thermalisation distances for water, ice, and benzene.

Calculation by Eqn.(30) makes it possible to estimate the energy losses in the course of the linear movement of an electron. The curvature of the trajectory has been taken into account with the aid of the Monte Carlo method[112,113] and analytically.[118] Mention should also be made of the fact that Eqn.(30) does not allow for the energy losses in close collisions of an electron with molecules, including the formation of an intermediate negative ion. The contribution of close collision processes to the energy losses has been estimated by Magee.[113] For water, the contribution of these processes to the rate of energy loss by an electron with $E = 1$ eV amounted to approximately $5 \times 10^{13}$ eV $s^{-1}$, while in paraffinic hydrocarbons it amounted to approximately $7 \times 10^{13}$ eV $s^{-1}$. Consequently, among all the mechanisms responsible for the retardation of slow electrons, it is difficult to isolate one which would be of decisive importance over the entire thermalisation distance.

Even when account is taken of the energy losses in close collisions, Eqn.(30) does not allow an adequate determination of the thermalisation distance. Electrons with an energy below the vibration excitation threshold are subjected to fairly effective elastic scattering. In the calculation of energy losses via elastic scattering one can as a rule neglect the energy transferred to effect the collision in view of its low value. On the other hand, the contribution of the elastic scattering to the thermalisation distance is comparable and perhaps even greater than the contribution of the inelastic collisions.

Thus it proved difficult to obtain direct information about the thermalisation distance by direct procedures. In a number of studies, for example those in Refs.119–121, the effective thermalisation distances were therefore determined from the distribution functions for electron pairs with respect to distances. These functions were found from the yields of the free ions either in the absence of a field or for low electron field strengths. However, the values obtained in this way are unreliable because the yield of the free ions is only weakly sensitive to the changes in the thermalisation distances.

After the development of a method for the investigation of photoemission phenomena at the metal–solution boundary,[122–124] the direct experimental determination of the thermalisation distances of free electrons became possible (see the studies quoted above and also Refs.116 and 125–127). The path traversed by an electron with $E \cong 3$ eV proved to be approximately 5 nm in $H_2O$ and approximately 10 nm in $D_2O$.[116] For comparison, we may note that the ionisation path of an electron with $E = 100$ eV in water is approximately 1.5 nm, i.e. is much shorter than the thermalisation distance). In a review by one of the present authors[47] it was stated in the discussion of the form of the function $l(E)$ obtained by Raitsimring et al.[125] that it was essential to explain the absence of the dependence of $l$ on $E$ for $E < 2$ eV. In a recently published study[116] a monotonic decrease of $l(E)$ as the electron was retarded was obtained for $D_2O$, while for $H_2O$ there is a plateau in the energy range $E = 1$–$2$ eV. However, it has been correctly stated[116] that, owing to the lack of data for the energy distribution of photoelectrons on excitation of the cathode, it is premature to carry out a detailed interpretation of the results.

After the electron has been thermalised, it can either recombine with a positive ion (not necessarily the parent ion) or it can be captured by a trap. The traps can be not only molecules with a positive electron affinity but also structural defects in the medium or polarisation wells formed when an electron interacts with the surrounding molecules. Such a captured electron has come to be referred to as solvated (hydrated in water). Since very numerous monographs and reviews have been devoted to the solvated electron,[128–130] we shall not deal with these questions. We may note that the theory of the solvated electron is still far from complete.[131]

Numerous studies have also been devoted to the behaviour of the excess electrons induced by irradiation in non-polar solutions and solid matrices (see the relevant reviews[132–134]). It has been established that the excess electrons exist in the medium in two states: localised and quasi-free. Their ratio depends on the nature of the molecules, especially on their symmetry: the higher the symmetry (for example, in neopentane) the greater the fraction of electrons in the quasi-free state.[135]

### 3. The Structure of the Tracks of Heavy Ions

Among the entire multiplicity of interactions of heavy ions in a medium, the most effective over a large part of the path traversed are, as in the case of fast electrons, the inelastic interactions with the electrons of the medium (electron retardation). Only at the end of the path does the role of elastic interactions with the atoms of the medium and the electron capture and loss processes (charge transfer) increase. The role of the latter processes becomes more pronounced with increasing mass of the ions.

The process in which the energy of the ion is transferred to the electrons of the medium is independent of the mass of the ion and its probability is proportional to the ratio $Z^2/v^2$. The size ($\Delta x$, $b_{\mathrm{eff}}$) of the region where the energy transferred to the medium in glancing collisions is localised is fully determined by the velocity of the charged particle. Hence it follows that a heavy ion generally speaking generates the same track structures as a fast electron having the same velocity $v$. The specific features of the transfer of the energy of the ion and of its distribution in the medium are manifested by the following factors.

A heavy ion is capable of dislodging an electron with a maximum energy $\varepsilon_{\max} \cong 2mv^2$ on ionisation, while in the case of a fast electron having the same velocity $\varepsilon_{\max} = \frac{1}{2}mv^2$. Consequently in head-on collisions, where the energy transferred $\Delta E \cong \varepsilon_{\max}$, this fraction of the energy is distributed

over larger distances from the site of the primary ionisation than in the collision of electrons having the same velocity.

Since the energy losses and the change in the momentum of the primary heavy ion in individual collisions with electrons of the medium constitute small fractions of the energy and moment of the ion ($\Delta E_{max}/E_0 \cong 4m/M < 2 \times 10^{-3}$), the electron retardation has only a weak influence on the curvature of the trajectory of the ion. For this reason, in the part of the track where ionisation losses predominate, the trajectory of the heavy ion can be regarded as linear.

The strength of the interaction of the ion with the medium is proportional to the square of its charge $Z^2$. The increase of the charge leads to an increase in the energy transferred to the medium in individual energy loss steps and also in the average energy loss per unit length of the path and of the number of electrons. On the other hand, an increase in $Z$ entails a diminution of the mean free path (because $\sigma_i \propto Z^2$). For this reason, the overlap of the track structures as the ion is retarded occurs earlier for ions with higher values of $Z$.

The proton and α-particle have the constant charge $Z$, equal to the nuclear charge $Z_a$, over most of their path so long as their velocity is sufficiently high. In multicharged ions (for example, in fission fragments) $Z$ is as a rule smaller than the nuclear charge. As a consequence of the charge transfer processes, when a beam of ions has passed through a sufficiently thick layer of the given substance, the ions show a distribution of charges. This distribution is characterised by an average quantity—the effective charge $Z_{eff}$, which is adopted as $Z$ in the calculations of ionisation energy losses. When the velocity of the ion $v \ll Z_a^{3/4} v_0$, the expression

$$Z_{eff} = \eta Z_a^{1/4} v/v_0,$$

where $v_0 = e^2/\hbar$ is the velocity of the electron in the first Bohr orbital and $\eta$ a constant which depends on $Z_a$ and the properties of the medium,[136] is valid for $Z_{eff}$. If $Z$ is now replaced by $Z_{eff}$ in Eqn.(13), then the dependence on the velocity of the ion in the multiplier of the logarithm disappears and it remains only in the logarithmic term. As a result, as the multicharged ion is retarded, its ionisation losses diminish in accordance with a logarithmic law. It will be shown below that this feature is manifested in the specific characteristics of the structure of the track of a multicharged ion.

At high velocities the track of a heavy ion can be regarded as consisting of individual track structures resembling the track structures of a fast electron. However, in radiation chemistry one deals with ions whose initial velocity does not as a rule exceed 10 MeV per nucleon. For initial energies of this kind, the velocity of the ions is less than $4 \times 10^9$ cm $s^{-1}$; the spurs overlap over most of the lengths of the track giving rise to a region of continuous ionisation along the paths traversed. The inner part of this region, which is characterised by an increase in the density of ionisations and excitations, has come to be referred to as the core. For low velocities of the ion, the radius of the core has been assumed[137] to be 1 nm. This value was chosen on the basis of the condition for the retardation of secondary electrons with an energy of 100 eV.

Part of the energy of the secondary electron is absorbed in the core of the track. Only high-energy δ electrons are capable of moving outside the limits of the core and of forming individual track structures. When the tracks of electrons overlap, a continuous shell surrounding the core, narrowing towards the end of the track, is produced.[138]

The distribution of ionisation excitation steps effected by secondary electrons has been studied in many investigations. The Monte Carlo method proved to be the most effective for detailed study.[139-141] The spatial distribution of the ionisation steps and the change of the energy distribution of the δ electrons as a function of the distance from the axis of the track and along the track have been investigated.[140] The data obtained can be used to compare the structures of the tracks of ions of different kinds with specific energies ranging from 82 to 420 keV per nucleon. Table 4 presents the results for the tracks of the α-particle and the multicharged $^{127}I$ ion in water. Evidently the geometrical dimensions of the tracks of ions having identical velocities are equal. However, the qualitative structure of the core and the dependence of the characteristics of the track of a multicharged ion on the linear energy transfer (LET) are different from those in the track of the α-particle (or the proton).

**Table 4.** Characteristics of the tracks of α-particles and the multicharged $^{127}I$ ion in water*.

| Characteristic of track | $10^{-8}v$, cm $s^{-1}$ | | | | |
|---|---|---|---|---|---|
| | 9 | 7 | 6 | 5 | 4 |

| $10^{-19}\bar{n}_i$, $cm^{-3}$ | 0.27 | 0.54 | 1.0 | 3.8 | 7.4 |
| | 9.7 | 14.0 | 23.8 | 58.7 | 94 |
| $r_{max}$, nm | 25.0 | 20.0 | 15.0 | 8.0 | 6.0 |

*The values of each parameter for the α-particle and the multicharged ion are given in the upper and lower rows respectively; $N_i$ and $N_\delta$ are the number of ions and δ electrons formed by the particle over 1 nm of the length of the track respectively, $\bar{n}_i^c$ is the average concentration of ions in the core of the track, $\bar{n}_i$ the average concentration of ions in the track, $r_{max}$ the maximum radius of the track, and $v_i$ the velocity of the ion.

As already mentioned above, owing to the effective neutralisation of the charge as the multicharged ion is retarded, its LET falls in the range of energies where ionisation losses predominate. Nevertheless, in view of the fact that the radius of the track contracts faster than the rate at which LET diminishes on retardation of a multicharged ion, the average concentration and yield of the primary ions in the track of such an ion behave in the same way as in the track of the α-particle, i.e. they increase with decrease in the energy of the ion. This increase continues up to energies at which the losses in elastic collisions become comparable to ionisation losses (i.e. up to $v \cong 4 \times 10^6$ m $s^{-1}$).

As a result of the primary effects, the multicharged ion ionises virtually all the molecules contained in a cylinder 0.7 nm in diameter (see the relevant estimates[138]). Most of

the energy of the secondary electrons is also localised in the core of the track. As a consequence of this, the number of ionisation steps in the core of the track of a multicharged ion exceeds the number of molecules. Thus almost every molecule in the core undergoes repeated ionisation and excitation processes and hence dissociates into fragments. For this reason, the region adjoining the axis of the track of a multicharged ion (with a radius of 1 nm) consists of a cylindrical ion core filled mainly by fragment ions. It has been shown[142] that at the end of the physical stage of the inhibition process the core of the track of the multicharged ion consists of a low-temperature, non-isothermal, spatially unlimited non-ideal plasma (an analogous conclusion was reached later by Ritchie and Claussen[143]). The individual components of such a plasma chain exist in local quasi-equilibrium states (for further details, see Miterev[142]). The processes in such tracks proceed under significantly non-equilibrium conditions where it is impossible to introduce a single temperature for all the degrees of freedom of this molecule. As a result, the usual ideas concerning the reaction rate constant lose their significance. In describing the processes in the track of multicharged ions, one must employ the methods of plasma chemistry.[144]

## VII. CHARACTERISTICS OF THE RADIATION-CHEMICAL REACTIONS IN THE TRACKS OF PARTICLES OF DIFFERENT KINDS

### 1. The Influence of the Phase States and the Role of the LET in Radiolysis

In a gas the track structures contain as a rule a small number of active species which are separated by large distances from one another. As a consequence of diffusion, the initial non-uniformity in the distribution of active species rapidly smoothes out and at the beginning of chemical reactions the intermediate species are distributed almost homogeneously throughout the volume. For this reason, the role of tracks in the gas phase is negligible. Only when the gas is acted upon by multicharged ions such as fission fragments can spatial non-uniformity influence the chemical reactions.[145,146]

The spatial non-uniformity in the distribution of the reactions in a liquid is more marked owing to the greater density of this medium. On the other hand, diffusion processes in liquids are slower. Furthermore, the phase state of the medium has an effect on the redistribution of the primary active species (increasing the number of ionised states in the liquid—see Section V) and also on the subsequent relaxation processes and the decomposition of the excited and ionised states.[147] The role of the reverse processes involving the recombination of electrons with the parent ion becomes more pronounced on passing from a gas to a liquid and the degree of decomposition of molecules into radicals as a consequence of the so-called cage effect diminishes.[148]

The differences between the kinetics of the gas- and liquid-phase reactions, which depend on many factors, preclude the differentiation in a pure form of the role of tracks by altering the density of the medium. The most fruitful procedure apparently involves the study of the dependence of the radiation effect on the structure of the track for constant physical and chemical properties of the medium.

One of the characteristics of radiation (and its ionising capacity) is the linear energy transfer. Quantitatively LET is equal to the average energy transferred to the medium when the ionised particle traverses a unit length of its path. For fast particles, the LET is virtually equal to the ionisation losses. It has come to be assumed that the higher the LET the higher the density of the chemically active species in the track and the greater the probability of the reactions of the active species with one another rather than with the molecules of the solute.[149-151] Thus the increase in the yield of molecular hydrogen and the decreased yield of electrons stabilised in the free radicals with increase of the LET in the radiolysis of water are well known.[152,153] The study of the radiolysis of some organic substances also produced data indicating an increase with increasing LET of the yield of molecular products, whose formation can be explained by the recombination of chemically active species, for example, radicals in the tracks.[154]

Calculations for the radiolysis of liquids are carried out by solving the equations of the diffusion-dependent kinetics of radiation-chemical reactions in tracks.[155-158] The use of ideas about the track structures with spherical or cylindrical formations and the application of the equations for diffusion-dependent kinetics explained many experimental facts observed in the radiolysis of aqueous solutions,[156,159,160] in particular, the dependence of the yield of products on the LET. As a result of this factor, LET came to be regarded as a universal characteristic of the quality of the radiation on the assumption that the concentration of the active species in the track depends directly on the LET without taking into account the type of the charged particle.

However, many experimental results obtained in the study of the dependence of the yields of the radiolysis products of organic liquids on the LET failed to find a new theoretical justification within the framework of the existing ideas about the relation between the structure of the track and the LET. Among such experimental facts, one may specify the following: a sharp increase in the yield of low-molecular-weight radiolysis products for high values of LET;[161,162] an increase in the yield of a series of products of the radiolysis of methanol (for example, ethylene glycol[163]), whose formation is attributed to the recombination of radicals in the tracks, with decrease in the LET; the difference between the yields of hydrogen $G(H_2)$ in the radiolysis of benzene by protons and $\alpha$-particles having identical values of the LET.[164]

In order to explain all these experimental results, it was necessary to resort to the concept of the detailed structure of the track and its dependence on the type of the charged particle.[5]

### 2. The Influence of the Structure of the Track on Radiation-Chemical Processes in Liquids

The role of the structure of the track has been traced most clearly in relation to the radiolysis of liquids by heavy ions. Precisely in this case it is possible to vary within wide limits the geometrical dimensions of the tracks and the concentrations of the active species in them. The influence of the structure of the tracks of ions has been investigated by Burns[164,165] and also by Kaplan and Miterev.[5]

Using detailed ideas about the structure of the tracks of ions, it is possible to account for the dependence of the yields of products on the LET in the following way.[5] Low values of LET are characteristic of the radiolysis of liquids on irradiation by high-energy protons. The track of the proton consists in this case of a core and branches—the tracks of $\delta$ electrons, and the higher the energy of the proton the greater the proportion of its energy removed outside the limits of the core by $\delta$ electrons. The core itself is ultimately transformed into individual non-overlapping spurs, i.e. the track of the proton resembles that of

the electron with the exception of certain features (see Section VI). As a result, the character of the radiolysis approaches that of the radiolysis by fast electrons.

As the proton is retarded, its LET and the number of δ electrons increase, while the size of the track actually diminishes, because the maximum energy of δ electrons falls. This results in a sharp increase of both the local and average concentrations in the vicinity of the axis of the track. This tends to increase the yields of the products of the recombination of the active species with increasing LET, i.e. there is a direct correspondence between the density of the active species in the track and the LET. An analogous picture has been observed in the tract of the α-particle.

High values of LET (in excess of 1 keV $min^{-1}$) are observed when a liquid is acted upon by multicharged ions, such as fission fragments. As already mentioned in the previous Section, the structure of the tracks of such ions has a number of characteristic features. The first of these is associated with the fact that the average concentration of active species increases with increasing LET. For this reason, the yields of many radiolysis products initially increase with decrease in the LET of the fragment, reach a maximum, and then (when in the course of further retardation of the fragment the energy losses in elastic collisions become significant) they dimish. The experimental results for the radiolysis of methanol by fission fragments having different energies can be accounted for in precisely this way.[163]

The second characteristic feature of the structure of the track of a multicharged ion is a high concentration of fragment ions in the core of the track manifested by the fact that mainly low-molecular-weight radiolysis products are formed in the core of the track, while the yields of products with a more complex structure diminish. The high yields of $H_2$, CO, and $CH_4$ in the radiolysis of liquid hydrocarbons by multicharged ions are associated with this fact.[161,163,164]

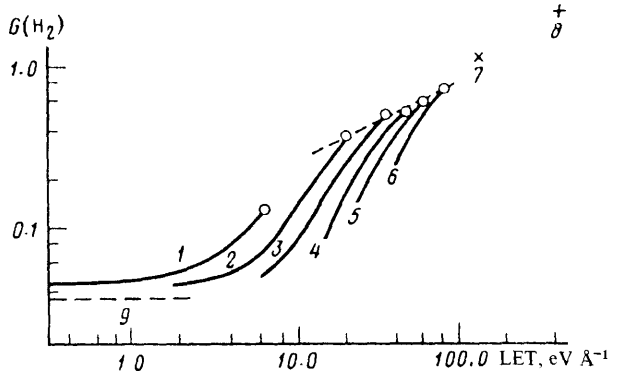

**Figure 5.** Dependence of the differential yield of molecular hydrogen $G(H_2)$ on the LET in benzene for different ions: 1) $^1H$; 2) $^4He$; 3) $^7Li$; 4) $^9Be$; 5) $^{11}B$; 6) $^{12}C$; 7) $^{20}Ne$; 8) fission fragments; 9) fast electrons.[166]

The intermediate values of the LET correspond to the radiolysis of liquids irradiated by different ions. As a result, it has been found that two and more ions can have the same values of the LET (see, for example, La Verne and Schluer[166]). With the exception of the range of low energies, the LET is determined by the ionisation losses $S_e$ [see Eqn. (13)]. If the ionic charges $Z$ are different, then the equality of the $S_e$ (up to the Bragg peak) holds for different velocities of these ions. An ion with a high value of $Z$ has a high velocity $v$ and for this reason the core of its track ($r_c \propto v$) and the region adjoining the core (formed by the tracks of δ electrons) have large dimensions. As a result, the local and average concentrations of the active species in the track of such an ion are reduced.

Thus the higher the charge on the ion the greater the volume of its track in which the linear losses are distributed, i.e. the lower the local concentrations of the active species. As a consequence of this, the radiolysis seen in the track of an ion with a high $Z$ corresponds in essence to a process which is observed for lower LET in the tracks of ions with a lower charge. This behaviour is in fact observed in the measurement of the yield of $H_2$ in the radiolysis of benzene by various ions[164,166] (Fig. 5).

Thus an important conclusion follows from the analysis of the influence of the structure of the tracks on radiation-chemical processes: there is no direct correspondence between the LET and the local and average concentrations of the active species in the tracks. For this reason, the LET cannot serve as a universal characteristic of the quality of the radiation regardless of the particular species involved.

Attempts have been made to introduce instead of the LET another characteristic of the quality of the radiation, for example, the ratio $Z^2/v^2$.[167,168] However, a complete description in terms of $Z^2/v^2$ could not be achieved,[169] which can be readily explained. The factor $Z^2/v^2$ is an approximation to the LET and all the remarks referring to the use of the LET as a universal characteristic of radiation fully apply also to this parameter.

The dependences of the differential yield $G(H_2)$ on the average density of the absorbed energy in the core of the track have been compared for different ions[166] and it was found that, for the same density, the values of $G(H_2)$ depend significantly on the type of ion and hence also on the distribution of the energy (and the primary species) outside the limits of the core, i.e. they depend on the complete structure of the track.

Apparently the attempts to introduce a universal parameter characterising the radiation-chemical effect of radiation have been unsuccessful. Such a characteristic may be only the spatial distribution of active species in the track. The form of the latter throughout most of the paths of the particles is determined both by the charge $Z$ and by the velocity $v$ of the particles and not solely by their ratio. These two parameters must in fact be used as the characteristics of charged particles. For a comparative estimate of the radiation effects of various types of radiation, certain characteristics averaged over the volume of the track, such as the average energy density in the track, the average concentration of active species in the track, etc., are also useful.

The foregoing has a direct bearing on the dosimetry of the ionising radiation using liquid systems. Since the radiation effect in such systems generally speaking depends on the structure of the track of the charged particles, the determination of the dependence of the readings of liquid type dosimeters on the LET is meaningful only when a single type of radiation is used. Furthermore, the application of a dosimeter calibrated against one type of radiation in the measurement of absorbed doses of other types of radiation requires the introduction of corrections for the specific features of the track effects.

---o0o---

In conclusion we may note that, in view of the multiplicity and complexity of the active primary species and intermediates formed in the radiolysis of even a thoroughly investigated

medium such as water, there is as yet no firmly established mechanism of the radiolysis in both the primary and subsequent stages. In the first place, the lack of reliable data on the cross-sections of the interactions of slow electrons with molecular media precludes the determination of a detailed spatial distribution of the primary active species in the electron tracks. The types of reactions of the primary active species in the condensed medium, namely ions, superexcited molecular states (for example, Rydberg states), and also plasmon excitations in non-metallic media, have not as yet been firmly established. The solution of these problems would make it possible to carry out calculations for the radiolytic process up to the evaluation of the radiation yields of the final products.

# The Application of High Resolution Nuclear Magnetic Resonance in the Study of Fast Non-equilibrium Reactions

S.I.Selivanov and B.A.Ershov

Literature data concerning the use of high resolution NMR in the study of the mechanisms of fast non-equilibrium chemical reactions are examined and surveyed. Attention is concentrated on the methods and techniques of flow experiments in which stationary and pulsed Fourier-transform NMR is used. The possibilities and prospects for the development of these methods are analysed.
The bibliography includes 139 references.

## I. INTRODUCTION

The greatest advances in the study of fast reactions by high resolution NMR have been made in the investigation of equilibrium processes with the aid of the dynamic magnetic resonance methods,[1-4] the saturation transfer effect,[5-8] and two-dimensional NMR.[9,10] On the other hand, the study of non-equilibrium processes, including irreversible chemical reactions, has been limited to very slow reactions with characteristic times $t_{1/2}$ in excess of 100 s.[11-14] This limitation was associated primarily with the lack of special methods for the measurement and treatment of high resolution NMR spectra for non-equilibrium reaction mixtures. At the same time there is no doubt about the likely usefulness of the application of NMR in the determination of the structures of relatively unstable intermediates in fast† chemical reactions and the determination of independent kinetic information.

The increase of the working frequency of spectrometers and the introduction of pulsed methods of recording[15] greatly increased the sensitivity and speed of NMR spectroscopy, which extended its functional possibilities for the study of rapid non-equilibrium chemical reactions in solution. The application of NMR in this field makes it possible to obtain qualitative and quantitative information about the composition of a non-equilibrium reaction mixture 0.05 s after the start of the reaction and hence permits an expansion by 3–4 orders of magnitude of the range in which it can be employed.

The large amount of information derivable from NMR spectra is one of the main factors responsible for the vigorous development of NMR methods for the rapid recording of short-lived intermediates in non-equilibrium chemical reactions. At the same time, the relatively low sensitivity of NMR prevents its being a competitor, in the determination of kinetic information, of the UV, IR, and EPR spectroscopic methods widely used for such purposes.[16-18] However, here too there has been definite progress as a result of the improvement of the methods of the kinetic NMR measurements and the development of fundamentally new methods for the determination of kinetic data.

The aim of the present review is the analysis of the methods and characteristics of the employment of NMR in the study of fast non-equilibrium reactions in solution. Two main factors are considered: the method whereby the initial non-equilibrium state of the specimen is established in the measuring cell of the NMR spectrometer and the actual NMR recording of the attainment of equilibrium in the test system. The first studies of the use of NMR in the investigation of fast irreversible reactions dealt with the effects of chemically induced nuclear polarisation (CINP),[19] electrolysis,[20] and radiolysis.[21] In order to generate the initial non-equilibrium state, appropriate exciting devices were used. However, among the special methods for the investigation of fast reactions in solution,[22] flow methods, in which equilibrium is perturbed as a result of the chemical reactions, have come to be most widely employed.[23] In most investigations the recording of the attainment of equilibrium is to some extent associated with the measurement of a high-resolution NMR spectrum in a flowing liquid. We shall therefore deal with the characteristic features of the use of an NMR spectrometer as the detecting device in flow methods for the study of fast reactions.

## II. FLOW METHODS AND NUCLEAR MAGNETIC RESONANCE IN A FLOWING LIQUID

The flow methods for the study of fast chemical reactions in solution are based on the rapid and effective mixing of the initial reactants at the mixing point and the recording of the changes in the NMR parameters as a function of time at the point where the receiving coil of the spectrometer sensor is located.

In virtually all the known studies two commonest and simplest methods have been used in one form or another, namely the continuous and stopped flow methods. The choice of one of them is associated primarily with the amount of the solution of the initial reactants available and the speed with which the observation can be made. The first of the methods is based on the establishment of a stationary composition of the reaction mixture at the recording point as a result of the uniform flow of the specimen through the spectrometer sensor and makes it possible to record the spectrum under the usual conditions. The NMR spectrum obtained in this way corresponds to the time necessary for the transport of reaction mixture after the start of the

†In $^1$H NMR, the term "fast" reaction should be understood as implying reactions occurring at room temperature with half-lives $t_{1/2} < 30$ s.

reaction ($\tau_{tr}$), which is unambiguously defined by two parameters of the flow system—the flow rate of the reaction mixture $v$ and the distance between the mixing and recording points $l$:

$$\tau_{tr} = \frac{l}{v} \quad . \tag{1}$$

When the stopped flow method is used, the amount of reactants consumed is much smaller. In this case, a selected section of the spectrum "varying" with time is rapidly scanned after the rapid arrest of the flow of the reaction mixture.

The theoretical principles of NMR in a flowing liquid, which have been described in a monograph,[24] reduce to the following: the flow of the specimen in the sensor along the y axis does not entail any frequency distortions in the NMR spectrum and is expressed by a decrease of the effective (observed) spin–lattice ($T_1^*$) and spin–spin ($T_2^*$) relaxation times. As early as 1951, an increase of the amplitude of the NMR signal was noted[25] under the conditions of a uniform movement of the liquid compared with a stationary specimen. This effect was explained[26] by the acceleration of the spin–lattice relaxation of the volume-average magnetisation of the nuclei, which takes place as a result of the flow into the sensor of the liquid with a uniform magnetisation. It was concluded that the signal amplitude in the flow sensor corresponds to the effective spin–lattice relaxation time $T_1^*$, which is related to the natural time $T_1$ by the expression

$$\frac{1}{T_1^*} = \frac{1}{T_1} + \frac{1}{\tau} \, , \tag{2}$$

where $\tau$ is the time during which a proportion 1/e of the depolarised nuclei is replaced by polarised nuclei as a result of the flow of liquid in the resonance zone (e is the base of natural logarithms).

At the same time an analogous decrease of the effective spin–spin relaxation time $T_2^*$ was observed:

$$\frac{1}{T_2^*} = \frac{1}{T_2} + \frac{1}{\tau} \quad . \tag{3}$$

This entails a broadening of the spectral lines. Owing to this broadening, Bloom and Shoolery[27] were unable to increase the sensitivity of high-resolution NMR spectrometers with the aid of a flow sensor and a varying working substance. Their attempt was based on the possibility of using higher powers of the microwave frequency field $H_1$ by reducing $T_1^*$ and $T_2^*$ in the flowing liquid while maintaining the value of the saturation factor $z$:

$$z = 1 + (\gamma H_1)^2 T_1^* T_2^* \, .$$

Another feature of the use of flow NMR which is of practical importance is the difficulty of ensuring the necessary equilibrium magnetisation of the liquid. Whereas for a usual specimen the equilibrium magnetisation $M_0$ is attained by placing it for a time in the field of the spectrometer magnet $H_0$, for a flowing specimen it can be achieved as a result of its being passed beforehand through a special polariser, since the time during which the specimen flows through the sensor is insufficient for the establishment of the equilibrium magnetisation. The polariser is usually placed in the space between the poles of the spectrometer magnet and, when no free space is available for this purpose, the flowing specimen is polarised with the aid of an additional polarising magnet having a field strength $H_0^{pol}$.[24]

The initial parameters in the calculation of the geometry of the polarisation coils are the spin–lattice relaxation time of the $i$th transition investigated ($T_1^i$) and the flow rate of the specimen. For a multispin system, the residence time of the flowing specimen in the polariser $t_p$ is chosen from the condition

$$t_p \geqslant 5 T_1^{max} \, , \tag{4}$$

where $T_1^{max}$ is the maximum spin–lattice relaxation time among all the values of $T_1^i$. When condition (4) holds, the Boltzmann distribution in the flow system is established to the extent of 98% and the phenomenon of nuclear magnetic resonance can be observed in it. Depending on the ratio of the reaction half-life and the value of $5T_1^{max}$, the preliminary magnetisation of the reaction mixture can be achieved both before and after mixing the initial reactants. For very short spin–lattice relaxation times, the role of the polariser can therefore be fulfilled by the section between the mixing and recording points located within the gap of the spectrometer magnet.

If the condition $H_0^{pol} > H_0$ holds when a second polarising magnet is used to polarise the flowing specimen, then an increase of the sensitivity of the spectrometer is achieved together with the magnetisation of the specimen. For sufficiently short times taken for the transport of the test specimen from the polarising magnet to the spectrometer magnet, the effective equilibrium magnetisation $M_0^{eff}(t)$ remains greater than the value of $M_0$ which can be attained in the uniform spectrometer field $H_0$. The disadvantage of this method of increasing sensitivity is that the amplification factor $K$ depends on the relaxation times of different nuclei $T_1^i$:[24]

$$K = \frac{M_0^{eff}(t)}{M_0} = \frac{M_0^{tot} \exp(-t/T_1^i)}{M_0} = K_0 \exp(-t/T_1^i) \, ,$$

which should distort the true ratio of the signal intensities in the NMR spectrum of the reaction mixture. However, since there is no need for a high uniformity of the field of the more powerful polarising magnet, these methods for the polarisation of the flowing specimen can be preferable in some cases.

Another approach to the establishment of the preliminary magnetisation in the flowing specimen consists in the artificial shortening of the spin–relaxation time of the nuclei with the aid of paramagnetic additives. However, this entails the simultaneous shortening of the corresponding spin–spin relaxation times, which leads to the broadening of the spectral lines to hundreds of gauss.[28] This disadvantage has been eliminated in a recently proposed method.[29] Owing to the interaction of the flowing liquid with the free radicals adsorbed on the solid substrate, the time necesssary for the polarisation of the specimen in the field of the spectrometer magnet is shortened in zone $A$ (Fig.1) by several orders of magnitude. It becomes comparable to the residence time of the flowing specimen in zone $A$. In the region $B$, the influence of paramagnetic centres on the width of the lines is to a large extent weakened owing to the effective filtration of the adsorbent on a glass filter. The necessary conditions for the use of free radicals in this procedure are their chemical inertness, the ease of filtration of the adsorbent, and the constancy of the concentrations in zone $A$. According to the authors,[29] the use of paramagnetic relaxants leads to the prospect that $^{13}C$ NMR experiments, which have longer spin–lattice relaxation times, may become possible.

The overall requirements which must be met by the method and technique of any flow experiments are well known.[22] These are primarily the necessity for the rapid and effective mixing of the reactants, the establishment of the laminar flow of the reaction mixture in the continuous flow method, and the rapid arrest of the flow in the stopped flow method. The main characteristic of the efficiency of the apparatus in

flow measurements is the experimental dead time $\tau_0$—the minimum time after the start of the reaction necessary to record any physical quantity. For the continuous and stopped flow methods, it includes the reactant mixing time $\tau_{mix}$ and the time required for transport to the recording point $\tau_{tr}$, while for the stopped flow method there is in addition the time necessary to stop the flow ($\tau_{st}$).

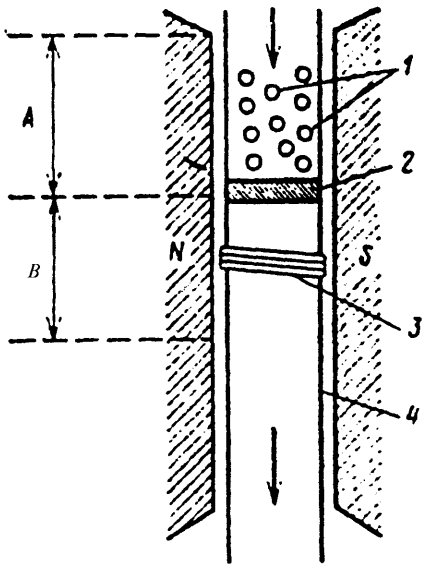

**Figure 1.** Artificial reduction of the magnetisation time of a flowing specimen by introducing stable paramagnetic centres into the recording channel in NMR flow experiments:[29] *1*) free radicals adsorbed on a solid substrate; *2*) glass filter; *3*) receiving coil; *4*) recording channel; *A*) preliminary polarisation region; *B*) recording region.

The mixing chambers developed previously for the UV, IR, and EPR methods[17,30,31] makes it possible to mix almost completely two solutions of the reactants over a period of ~$10^{-3}$ s; the flow of the reaction mixture can be arrested with the aid of a removable syringe and electromagnetic valves over a period of $(1-5) \times 10^{-3}$ s.[32] These values are much shorter than those which are really necessary when an NMR spectrometer is used as the recording device, for which the dead time is limited by the transport time, amounting usually to $(50-100) \times 10^{-3}$ s. The principal elements of the flow technique—the mixing chamber and the syringe system for the injection of reactants and the arrest of the flow—have been almost wholly taken from analogous studies employing IR, UV, and EPR spectroscopy.[33,34]

When NMR is used in the continuous flow method, the dead time can be shortened mainly by reducing the transport time $\tau_{tr}$, which can be achieved, according to Eqn.(1), either by increasing the flow rate or by reducing the distance between the mixing and recording points. However, the increase of flow rate entails the shortening of the residence time of the spin state in the region of the receiving coil and, according to Eqn.(3), the broadening of the spectral lines. The decrease of the distance between the reactant mixing point and the spectrum recording point is therefore the most suitable procedure for shortening the dead time. In the stopped flow method the use of high rates of transport (under the conditions of an effective arrest of the flow) does not introduce additional distortions into the NMR spectrum and the experimental dead time can be reduced to several milliseconds.[35]

Since there are two fundamentally different methods of recording NMR spectra—stationary and pulsed, it is useful to divide all the published communications concerning the application of NMR in the study of fast irreversible reactions into two groups and to consider for each examples of the practical employment of the continuous and stopped flow methods. Special mention should be made of the difference between the speeds at which information can be secured by the above two methods of NMR measurements. Thus usually 4–5 min is required to record a spectrum 10 p.p.m. wide in the stationary regime of the operation of the NMR spectrometer, while the counting of the free induction signals in the same spectral region under a pulsed regime takes only 4 s. From the point of view of speed, the continuous flow method is more suitable for stationary NMR spectroscopy despite the considerable consumption of the initial reactants, while the stopped flow method is more suitable for pulsed Fourier-transform NMR.

## III. STATIONARY NUCLEAR MAGNETIC RESONANCE

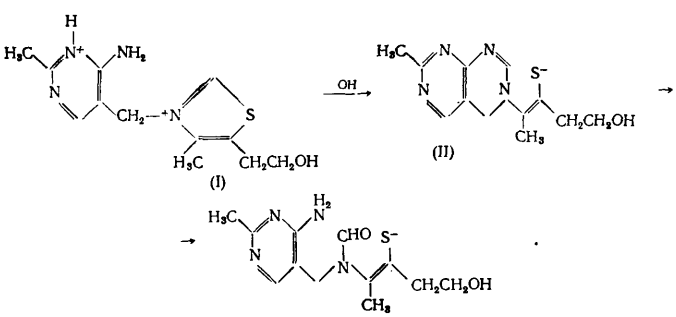
When stationary NMR is used, the following conditions governing the passage of resonance lines must be maintained:[36]

$$\frac{d\nu}{dt} \ll (\Delta\nu_{1/2})^2,$$

where $\Delta\nu_{1/2}$ is the spectral line half-width. The time taken to record a single NMR signal should then be ~2–3 s, which determines the minimum possible scanning period in the stopped flow method. An increase in the rate of scanning distorts the signal both due to transient processes and as a result of the progressive saturation of the spin system.[37] The stopped flow method is therefore convenient for the study of the kinetics of chemical reactions whose half-life is more than 5–10 s. Since only a very narrow section of the overall NMR spectrum of the reaction mixture is recorded in this instance, the stopped flow method yields very little information from the standpoint of the determination of the structure of the intermediates. Even for comparatively slow reactions ($t_{1/2} > 5$ s) one therefore as a rule records initially the total spectrum of the reaction mixture with the aid of the continuous flow method in which the signal intensities are independent of time. The structure of the intermediates and the reaction pathways are inferred from the interpretation of the resulting spectrum and the process kinetics are then studied by the stopped flow method.

The kinetic data for the lifespans of the shortest-lived intermediates ($t_{1/2} \cong 0.1-1$ s) can be obtained only by the continuous flow method involving the variation of two independent parameters which determine the transport time in Eqn.(1). For intermediate values of $t_{1/2}$, the time variation of the concentration is found from data obtained by both methods.

### 1. The Continuous Flow Method



The possibility of using high resolution NMR in the study of fast irreversible reactions by the continuous flow method was first reported by Schaumberg,[38] who was not only the first to propose the preliminary magnetisation of the initial

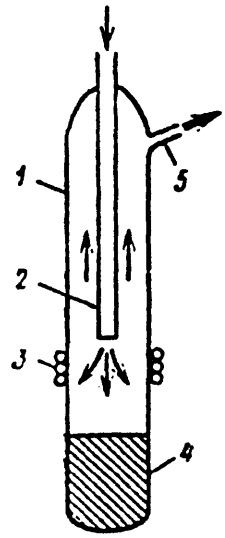
reactants in the gap of the spectrometer magnet but also initiated a series of the most promising directions in the development of the technique and methods of NMR flow experiments, many of which have now been successfully realised. For example, the idea of using the saturation transfer effect[39] in the study of the mechanisms for irreversible chemical reactions whose half-life is comparable to the spin–lattice relaxation time is due to him. This method is based on the transfer in the course of reaction of the magnetisation defect of one or several nuclear spins; this magnetisation defect arises as a result of the inversion or saturation of the equilibrium magnetisation in the spin system of one of the reactants directed before mixing.

The experimental realisation of this method with the aid of a stationary spectrometer in the broad-band version as a method of inverting the magnetisation of one of the reactants has been achieved by Fife et al.[40], who used the rapid adiabatic passage through the resonance conditions by the specimen[41] in the non-uniform section of the magnetic field whose strength was $0.7H_0$. This method, called "electronic isotope substitution", might have permitted, in its selective version, the selective observation at any stage of the given reaction of the transformations occurring in a non-equilibrium reaction mixture. However, the creation of selective magnetisation defects in a flowing liquid must take place in the uniform section of a magnetic field $H_0$ and, owing to the finite residence time of the spin system in this region, in the continuous flow method this entails the overcoming of a series of technical problems,[24] which restricts the application of this method to stationary NMR. On the other hand, Fourier-transform NMR methods, which have appeared in recent years and which are based on multipulse trains,[42,43] are more convenient for the generation of a microwave frequency label in the spin system of one of the reactants and for the recording of its transfer in the course of an irreversible chemical reaction.[44–46]

The wide-scale experimental employment of NMR in a flowing liquid for the investigation of fast irreversible reactions began in connection with the discovery of the phenomenon of chemically induced nuclear polarisation (CINP) and the possibility of investigating radical reactions by NMR.[47] In 1967 Bargon et al.[19] first recorded in a flowing liquid the polarised signals of benzene—the diamagnetic product of a radical reaction initiated by photolysis. This so-called "Bargon" tube[46] played a major role in these experiments,[19,48,49] making it much simpler to carry them out because its use shortens the transport time (as a consequence of the use of a thin capilliary) and simplifies the removal of the spent reaction mixture (Fig. 2). The radical reaction is initiated outside the spectrometer magnet and the polarised products are then transferred via a connecting tube to the NMR sensor in order to record the spectrum.

A simpler modification of the Bargon tube has been used[51] to detect the unstable thiol form (II) formed in the reaction of the thiazole (I) with KOH:

A vacuum pump ensured the removal of the spent reaction mixture from the rotating tube at a flow rate of 3 ml $min^{-1}$. The authors[51] obtained the complete NMR spectra of the reaction mixture, corresponding to its composition 5 s after mixing the reactants.



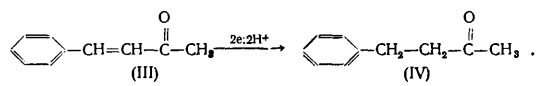


**Figure 2.** Bargon tube:[50] *1*) rotating bulb; *2*) capillary for the rapid injection of the reaction mixture into the recording region; *3*) receiving coil of spectrometer; *4*) Teflon insert for the optimisation of the recording volume; *5*) aperture for the removal of the reaction mixture.

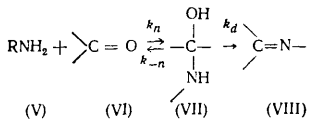
An analogous technique has been used[20] in the study of the electrochemical reduction of the unsaturated ketone (III):

The NMR spectra of the electrolysis product (IV) were measured at a flow rate of 0.4 ml $min^{-1}$ and a current in the range 0–5 mA.



Lawler and Halfon[52] used a second additional magnet for the preliminary polarisation of the nuclei in the test system and investigated the dependence of the CINP effect on the field strength of this magnet in the photolysis of di-t-butyl ketone; the maximum flow rate did not exceed 4 ml $min^{-1}$.

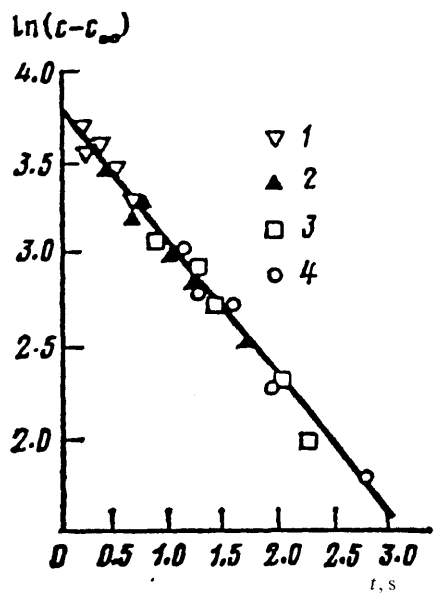
The experimental dead time achieved with the aid of the Bargon tube was several seconds, which was quite sufficient for the solution of the problems formulated in the above investigations. A further shortening of the dead time within the framework of the given technique is difficult owing to the necessity for the effective preliminary polarisation of the n;uclei and the difficulty of ensuring the rotation of the specimen at high flow rates.[53] These disadvantages have been eliminated in a study,[54] where, by abandoning the rotation of the specimen, it was possible to raise the flow rate of the reaction mixture to 60 ml $min^{-1}$#.[55] The equilibrium magnetisation was attained with the initial

#A further increase of the flow rate led to excessive (more than 5 Hz) broadening of the lines in the NMR spectrum.[54]

reactants flowing through two polarisation coils placed between the sensor and the pole tips of the spectrometer magnet; the reactants were mixed in a Teflon mixer, which was fixed over the inlet opening to the sensor and was rigidly connected to the recording channel. Two pairs of tangentially disposed inlet openings ($d_{in}$ = 0.36 mm) into the high pressure mixing chamber ensured the rapid and effective mixing of the reactants. In order to reduce the time required for the transport from the sensor, the device ensuring the rotation of the specimen under the standard conditions of the operation of the spectrometer was removed and the mixing chamber was thereby brought as close as possible to the recording point; in addition, the diameter of the recording channel outside the region of the receiving coils was reduced to 2.5 mm.

With the aid of this technique, Fife, Cocivera, and co-workers carried out and published about 30 studies, some of which have been discussed in a review.[56] The studies[57-63] of the mechanisms of the reactions involving the nucleophilic addition of nitrogen-containing bases (V) to the carbonyl group (VI) are based on the measurement of strong-field NMR spectra of the signals due to the methyl protons of the aminocarbinol fragment (VII):

(V) (VI) (VII) (VIII)



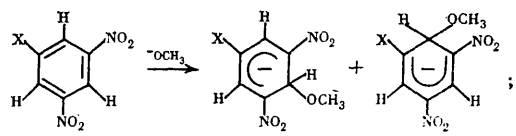


**Figure 3.** Dependence of $\ln(c - c_\infty)$ on $t$, where $c$ is the concentration of compound (X); distance between the mixing and recording points (cm):[65] *1*) 4; *2*) 5; 3) 6; 4) 7.

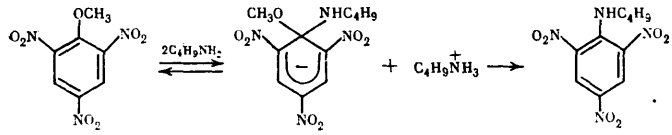
The authors were able to observe individual signals due to form (VII) only in the study of the interacton of acetaldehyde with hydroxylamine.[61] Owing to the reversibility of the first stage, in the remaining cases the spectrum showed the signals of the corresponding protons of the initial form (VI) and the intermediate form (VII) averaged by the rapid exchange (VI) ⇌ (VII). A standard approach, based on the determination of the half-width of the line averaged by the rapid exchange and of its position in the spectrum, was used to estimate the rate constants for the forward and reverse reactions ($k_n$ and $k_{-n}$) in these cases.

Thus the application of the continuous flow method extended the applicability of dynamic NMR in the study of the reversible stages of non-equilibrium reactions. The additional broadening of the lines associated with the movement of the reaction mixture [see Eqn.(3)] in these experiments was taken into account by introducing into the reaction mixture inert line form standards—t-butyl-alcohol[58] or methyl alcohol.[57] The position of the line of the standard molecule in the spectrum served simultaneously as the reference point for the reckoning of the chemical shift. The absorption lines of the solvents $H_2O$, $CH_3OH$, and DMSO were used as stabilisation signals. In the study of Cocivera and Effio,[57] the mixing chamber with six inlet openings was placed within the tube (5 mm) in the immediate vicinity of the receiving coil of the spectrometer sensor, which made it possible to reduce by a factor of 3 the transport time without increasing the flow rate of the reaction mixture.

Other studies by the same investigators[55,64,65] were devoted to the nucleophilic aromatic substitution reactions. The method is based on the direct recording of the thermodynamically unstable product (X) and the experimental determination of its lifespan as a function of the structural characteristics of the substrate (IX):



(IX) (X) (XI)

X = CN, $CF_3$, $COOCH_3$, $COOCH_2CH_3$, $COOCH(CH_3)_2$, $COOC(CH_3)_3$.

Fife et al.[65] demonstrated the possibility of using the continuous flow method to determine the kinetic parameters of fast reactions by varying the flow rate or the distance between the mixing and recording points. Such measurements yield a set of overlapping results for different experiments (Fig. 3) and ensure the determination of reliable kinetic data.

Yet another important methodological feature of the studies by this group of workers was the involvement in NMR flow measurements of the procedure for the study of the irreversible reactions in which the reaction mixture is cooled.[66-71] This makes it possible, on the one hand, to move the system to the range of reaction rates convenient for study and to detect in the reaction mixture the intermediates which are absent at room temperature and, on the other hand, it permits a wider employment of the more economical stopped flow method. The separate temperature control of the recording region and of the initial reactants has been employed in a number of studies.[61-66] The recording channel was cooled by means of a standard gas thermostatic control system, while the initial reactants were cooled by passing them through a liquid thermostat.[66-74] The temperature of the reaction mixture was measured before and after the experiment with the aid of methanol as the NMR temperature standard. Such a cooling system permits a reduction of the temperature to −40 °C and a qualitative study of the composition of the reaction mixture under these conditions Thus the interaction of 2,4,6-trinitroanisole (XII) with n-butylamine has been investigated:[66-68]

(XII) (XIII)

At −40 °C the maximum concentration of the intermediate (XIII) is observed 1 s after the start of the reaction (Fig. 4).

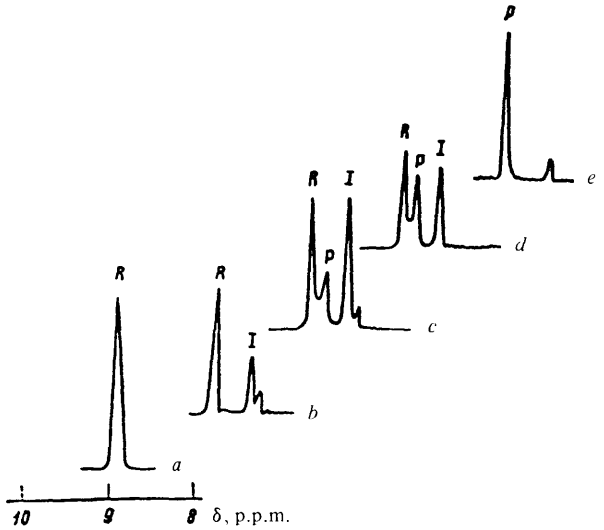


**Figure 4.** Section of the $^1$H NMR spectrum of a mixture of 2,4,6-trinitroanisole (XII) with n-butylamine at −40 °C obtained by the continuous flow method before (*a*) and at different times after mixing the reactants [*b*) 0.44 s; *c*) 0.98 s; *d*) 1.5 s; *e*) 30 s];[67] *R*, *I* and *P* are the absorption signals of the ring protons of the initial reactant, the intermediate, and the reaction product respectively.

The main disadvantage of the cooling method considered is the separate thermostatic control and the separate measurement of the temperatures of the initial reactants and of the recording region and also the existence under these conditions of a non-thermostatted section, including the mixing chamber. The above disadvantages§ can lead to considerable errors in the determination of the exact reaction temperature and to technical difficulties in its measurement during the flow experiment. Ultimately an appreciable scatter and poor reproducibility of the kinetic parameters of the reaction are observed.

§ Account should also be taken of the contribution to the error of the kinetic results introduced by the temperature gradient along the length of the recording channel, which is characteristic of the usual procedure for NMR measurements over a wide range of temperatures. The temperature drop along the length of the recording section of the reaction mixture can reach several degrees.[75]

It is known that the best results can be obtained when the entire measuring cell and the components of the flow system are simultaneously temperature-controlled in a liquid thermostat.[76] However, in the case of NMR the measuring cell is the sensor whose standard design precludes this procedure for the thermostatting of the flowing specimen. The above problem has been solved with the aid of a closed liquid thermostatic system[77,78] for the entire flow apparatus, which made it possible not only to improve greatly the quality of the thermostatic control of the flowing specimen and the accuracy of the determination of the temperature in the course of the reaction but also to eliminate the need for the employment of secondary NMR temperature standards.[79,80]

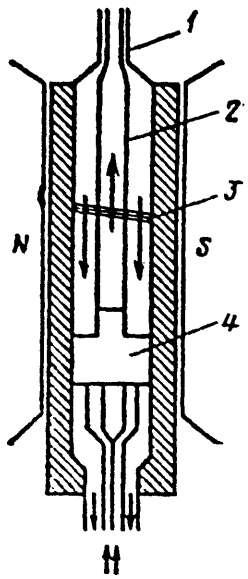

**Figure 5.** Liquid type thermostatic system in NMR flow experiments:[79] *1*) external circuit of the cryostat; *2*) recording channel; *3*) receiving coil of spectrometer; *4*) mixing chamber.

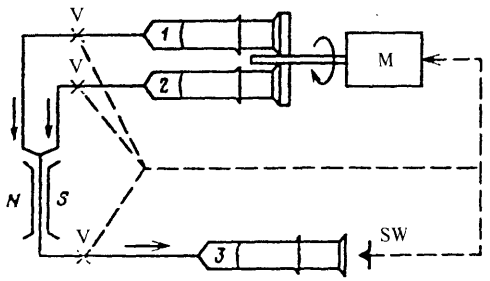
In the working regime two opposed streams are generated in the region of the receiving coil (Fig. 5): the stream of the reaction mixture within tube *2* which is 5 mm in diameter and the stream of the thermostatting liquid in the cylinder with an annular cross-section formed by the coaxially arranged glass tubes 12 and 5 mm in diameter. The mixing chamber *4*, located within the NMR sensor in direct vicinity to the receiving coil *3*, consists of a truncated cylinder and does not interfere with the circulation of the thermostatting stream. The disposition of all the elements of the flow system, including the initial reactants, within the outer circuit *1* of the cryostat ensures a high accuracy of the thermostatic control of the reaction mixture (±0.1 °C) in the temperature range from −40° to +60 °C. The influence of the absorption signals of the thermostatting liquid ($H_2O$, $CH_3OH$) on the spectrum of the reaction mixture is weakened owing to its incomplete magnetisation in the magnet gap[24] and the broadening associated with the decrease of its effective spin–lattice relaxation time $T_2^*$ [see Eqn. (3)]. This influence can be fully eliminated, for example, by introducing

paramagnetic additives.[28] The liquid thermostatic system for the flow apparatus was used in the study of the mechanism of the reactions of 1,3-diketones with hydrazines[81-83] and demonstrated the high reproducibility of the results of the kinetic measurements.

### 2. The Stopped Flow Method

The determination of data on the structures of the intermediates in irreversible chemical reactions by the continuous flow method is the first stage in the study of their mechanisms. The next stage consists of the study of the kinetics of the interconversions of the intermediates. If their half-lives are not less than 5 s, then kinetic data can be obtained with the aid of the stopped flow method by the rapid scanning of the selected section of the spectrum immediately after arresting the flow of the reaction mixture.

In order to achieve the rapid arrest of the flow in the stopped flow method, one usually employs a system with a third receiving syringe (Fig. 6). A microswitch ensures the disconnection of the reversible motor which moves the plungers of the supplying syringes. The time taken to arrest the flow by this method is usually ~1 s and permits the first recording to be made 2–3 s after the start of the reaction. The position of the microswitch can be varied within specific intervals within the limits of the amplitude of the movement of the plunger of the receiving syringe, which enables one to carry out repeated kinetic measurements under identical conditions.



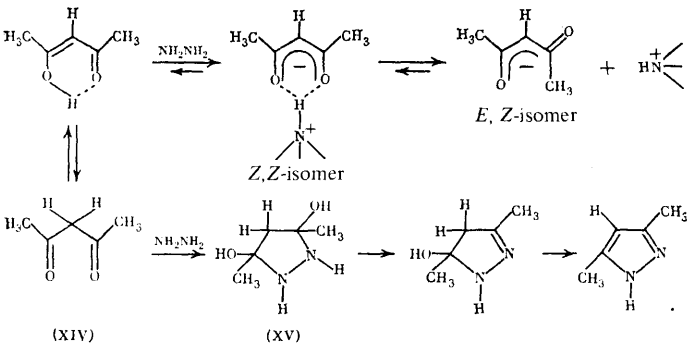


**Figure 6.** Schematic illustration of the apparatus for the stopped flow method: *1*) and *2*) supplying syringes; *3*) receiving syringe; SW = microswitch; V = electromagnetic valves; M = reversible motor.

The concentrations are usually determined from the integral[81-83] or peak[57-63] intensities of the corresponding signals in the NMR spectra. In carrying out the measurements, one must take into account the possibility of a synchronous increase of the intensities of all the signals during the reaction owing to the time variation of the dielectric constant of the reaction mixture.¶ The influence of this effect can be eliminated either by adding an inert signal intensity standard to the reaction mixture[58] or by calculating the relative signal intensities of all the components of the reaction mixture at each instant.[82,83]

The technique used in the cooling and thermostatting of the reaction mixture in the stopped flow method does not differ fundamentally in any way from that described for the continuous flow method.[67,79] The factors limiting the low-temperature measurements may be only the high freezing point of the solvent and the poor solubility of the individual components of the reaction mixture. The low temperature in the stopped flow method has been used[82] to demonstrate the higher reactivity of the keto-form of acetylacetone (XIV) compared with the enolic form in the reaction with hydrazine:

In methanol at −70 °C the attainment of the keto–enol equilibrium for acetylacetone is greatly retarded and the rapid formation of the dihydroxypyrazolidine intermediate (XV) from the keto-form can be observed immediately after mixing with hydrazine, while the enol form participates in the establishment of equilibrium between the hydrazinium salt having the *Z*, *Z*-configuration and the free anion with the *E*, *Z*-configuration.

The examples of the use of stationary NMR spectroscopy for the study of irreversible reactions discussed above show that the dead time of 0.05 s attained in the continuous flow regime[70] is apparently close to the limit for this method of measurement and further development of these procedures will take place to an increasing extent as a result of the wide-scale application of low-temperature measurements. This will permit the measurement of the NMR spectra of unstable intermediates in rapid non-equilibrium reactions which are inaccessible to investigation at room temperature even by the stopped flow method and will lead to the wider use of the more economical stopped flow method for kinetic measurements.

## IV. PULSED FOURIER-TRANSFORM NUCLEAR MAGNETIC RESONANCE

The main advantage of the pulsed Fourier-transform NMR is the simultaneous interaction of the microwave frequency pulse with all the spins of the non-equivalent nuclei, which makes it possible to accumulate in the study of rapid non-equilibrium reactions the free induction signals (FIS) at each point on the kinetic plot and hence to reduce the concentrations of the initial reactants in measurements involving the $^{1}H$ nuclei and also leads to the prospect of being able to employ $^{31}P$, $^{27}Al$, $^{13}C$, etc. NMR in the study of the compositions of non-equilibrium reaction mixtures.

¶This leads to the breakdown of the orthogonality of the polarisation of the microwave frequency fields of the receiving and transmitting coils which entails the leakage of the power of the transmitter to the input device of the receiver and a change in the regime governing its operation and hence to an identical distortion of the absolute intensities of all the signals in the spectrum.

The principal limitation in the wide-scale use of pulsed NMR in the study of rapid reactions is determined by the data access time, which for a spectral width of 8 p.p.m. is ~4 s and actually determines the minimum time interval between the recordings of the spectra in kinetic measurements. The artificial decrease of this interval by reducing the number of memory cells leads to the corresponding impairment of the quality of the spectra[15] but does allow one to reduce the scanning period in the stopped flow method to 0.1–0.2 s.[84]

### 1. The Continuous Flow Method

A characteristic feature of the pulsed regime in the operation of spectrometers is the difficulty, in principle, of obtaining the FIS from the flowing liquid.[85] After the application of the microwave frequency pulse, the signal is weakened owing to the continuous removal at a rate $v$ of the "excited" volume of the reaction mixture from the receiving coil. The increase of the rate of decay of the transverse component of the magnetisation ($M_{xy}$) in the time region corresponds to the widening of the absorption signals in the spectral region. In the present case this broadening is a complex function of the flow rate $v$, because the intensity of the recorded FIS diminishes as $1/l^2$ with the distance $l$ between the receiving coil and the excited volume.[24]

This problem can apparently be partly solved by employing a sensor with the receiving and transmitting coils separated by a specific distance which depends on the rate $v$. In order to eliminate completely the influence of the flow of the specimen on the line width, it is necessary to remove the receiving circuit during the recording of the FIS along the $y$ axis at a rate $v$ in the same direction, which presents significant difficulties.

Virtually no studies involving the use of Fourier-transform spectrometers in the continuous flow method have been described in the literature. In order to maintain a high concentration of a cell suspension in a state of equilibrium in studies of unstable biological objects by $^{31}$P NMR, the suspension was supplied continuously into the measuring region. In the accumulation of the FIS the access time was in this case reduced artificially to 0.2 s, which made it possible to avoid the distortion of the spectrum for a flow rate of the specimen of 5–10 ml min$^{-1}$.

One should also note the publications which appeared recently concerning the use of a flow-type Fourier-transform NMR spectrometer as the detecting device in liquid chromatography.[88–92] In terms of the technical and methodological problems solved in the above studies, they are closely related to the problems considered in this Section.

The conditions in the recording of $^1$H NMR spectra in quantitative measurements with the aid of a flow-type Fourier-transform spectrometer operating under accumulation conditions have been examined.[88] It has been found that, in order to eliminate the influence of various apparatus distortions in quantitative NMR flow measurements, it is best to introduce an intensity standard. It can be introduced either into the solvent before the mixing of the reactants or into the reaction mixture via the mixing chamber immediately before the recording.

The effect of the nuclear relaxation time $T_1$ on the measured signal intensity ratios in the spectrum was examined in the same study. It is inconvenient to eliminate this effect by increasing the arrest time between the pulses owing to the increase of the overall duration of the experiment. The requirement for the complete restoration of the Boltzmann equilibrium in the spin system is therefore not usually met. The use of the Bloch equation for the description of the equilibrium component of the magnetisation after a series of pulses,[93] which is a complex function of the spin–lattice relaxation time $T_1$, greatly simplified the analysis of the expression for the spectral density. It was concluded[88] that, in NMR flow measurements with pulsed recording of the composition of the reaction mixture, the accuracy of the quantitative measurements increases with decrease of the recording volume and with increase of the flow rate. Fig.7 illustrates the dependence of the effective spin–lattice relaxation times $T_1^*$ on the residence time $\tau$ of the spins in the recording region [see Eqn.(2)]. Evidently the lower the value of $\tau$, the smaller the difference between the values of $T_1^*$ for nuclear spins with different natural spin–lattice relaxation times $T_1^i$. The decrease of the effective spin–lattice relaxation times $T_1^*$ with the simultaneous equalisation for different nuclei in a flowing specimen has been used recently to increase the relative sensitivity of the recording of slowly relaxing quaternary carbon atoms in $^{13}$C NMR spectra.[94]

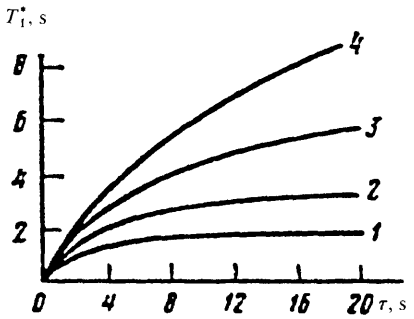

**Figure 7.** Dependence of $T_1^*$ on the residence time of the spin system in the recording region; natural spin–lattice relaxation times $T_1$(s):[88] *1*) 2; *2*) 4; *3*) 8; *4*) 16.

Thus the continuous flow method in the pulsed mode of operation of the spectrometer has no advantages over other NMR methods for the investigation of non-equilibrium reactions as regards the decrease of the experimental dead time, because it can be used only for very low flow rates of the reaction mixture ($\leq$1 ml min$^{-1}$) for which the distortions in the NMR spectrum due to the movement of the specimen can be neglected.

### 2. The Stopped Flow Method

An example of the employment of the pulsed Fourier-transform NMR for detection in the stopped flow method is provided by the studies of Grimaldy, Sykes, and co-workers who justified theoretically as early as 1972 [95] and later demonstrated in practice[96] the advantages of the pulsed methods for the study of rapid reactions compared with stationary NMR spectroscopy.[97,98] The simple application of the Fourier-transform NMR proposed by these workers consists in the successive recording of the NMR spectra of the non-equilibrium reaction mixture investigated within the limits of the inequality

$$n(\mathrm{AT} + \mathrm{TT} + \mathrm{PD}) \leqslant t_{1/2} \qquad (5)$$

where $n$ is the number of spectra recorded during the reaction time, AT the data access time, TT the time required for the Fourier transformation or for the transfer of the FIS to the memory device, and PD the delay period needed to restore the Boltzmann equilibrium ($AT + PD \geq 5T_1$). It follows from Eqn.(5) that, in order to increase $n$, it is necessary to reduce the times AT, TT, and PD. This is associated with additional distortions in the NMR spectrum. The PD time can be reduced to zero and for very short spin–lattice relaxation times ($T_1 \leq 0.1$ s) this does not introduce appreciable distortions into the final spectrum. The TT time can be reduced to 0.1 s by employing high-speed computers. The situation is different as regards the AT time, whose reduction to 0.1 s entails a broadening of the spectral lines to 5–10 Hz.[97]

Thus the method examined makes it possible to investigate reactions with half-lives up to 0.5 s and to reduce the dead time in experiments of this kind to 0.1 s. The method has been applied in a number of studies.[99–103] In an investigation of the kinetics of the base-catalysed deuterium exchange reaction between [$D_4$] methanol and the nitromethane anion (XVI), i.e.

$$CH_3NO_2 + [OCD_3]^- \xrightarrow{\text{fast}} [CH_2NO_2]^-,$$
$$[CH_2NO_2]^- + 2CD_3OD \xrightarrow{\text{slow}} [CD_2NO_2]^- + 2CD_3OH,$$
(XVI)

its slow second stage was recorded using pulsed NMR;[100] the microwave frequency pulses were repeated at 1.1 s intervals (Fig. 8). In order to increase the speed of recording, a spectral width of 1.2 kHz was used; time taken to transfer each FIS to the disc memory was 0.03 s.

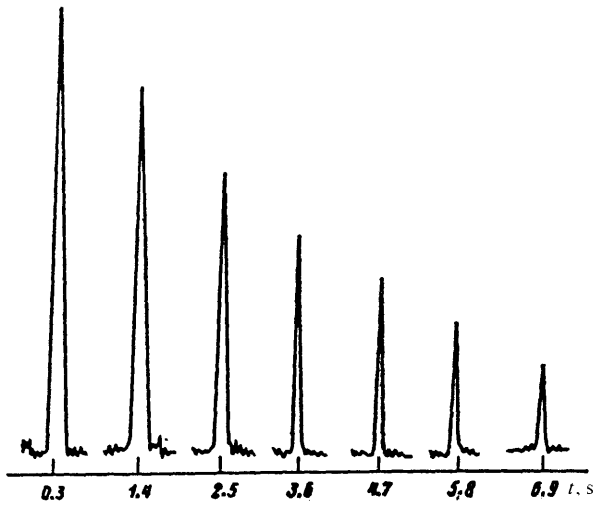

**Figure 8.** Decrease of the intensity of the signal of the nitromethane anion (XVI) ($\delta$ = 5.74 p.p.m.) during deuterium exchange with [$D_4$]methanol at 295 K.[100]

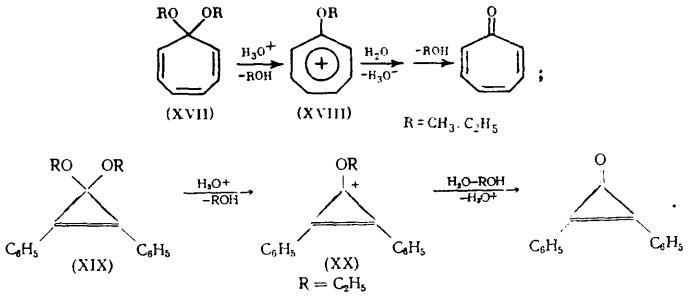
Another example of the effective use of this technique is provided by a study[102] of the hydrolysis of aluminium(III) by the method involving the $^{27}Al$ NMR of the reaction mixture; a single line is then present in the spectrum, which greatly facilitates the task of increasing the speed of recording such a spectrum. This enabled the authors[102] not only to obtain 20 points on the kinetic curve during 30 s but also to accumulate 20 FIS per second for each point.



The question of the possibility of accumulating FIS in kinetic measurements has been examined in two investigations[95,105] and it has been concluded that the accumulation of several FIS at a single time point is legitimate only in the study of reactions proceeding in accordance with a first-order kinetic equation For reactions of higher order, the data must be accessed without accumulation. This problem plays a significant role in the employment of Fourier-transform $^{13}C$ NMR for kinetic measurements.[106–109] The difficulty of the quantitative analysis based on $^{13}C$ NMR spectra is associated with the influence of the spin–lattice relaxation time $T_1$ and the nuclear Overhauser effect on the peak intensities of the lines. In order to eliminate these influences on the recorded $^{13}C$ NMR spectrum of the non-equilibrium reaction mixture, it has been suggested[109] that longer delays be employed between the microwave pulses and that specific relaxation additives be introduced to shorten the time $T_1$, while in another study[108] the possibility of using special pulse trains for the same purpose has been discussed. However, as a rule, these procedures reduce the signal to noise ratio. For this reason, the differences between the spin–lattice relaxation times and Overhauser coefficients for individual atoms are usually ignored and the changes in signal intensities during the reaction are estimated with the aid of an intensity standard introduced into the reaction mixture.[106]

The technique used to mix the reactants in pulsed NMR flow methods differs little from that in the analogous devices employed in stationary NMR.[110,111] The synchronisation of the instant at which the microwave frequency pulse is triggered and the instant when the reaction mixture is transferred from the mixing chamber to the recording point requires special attention in the stopped flow method. A modern pulse Fourier-transform NMR spectrometer, which is equipped with a minicomputer, makes it possible to achieve readily not only the synchronisation of the start of the experiment but also one can program the entire experimental procedure.[13,84,99–104,110,112,113]

In order to shorten the dead time and to achieve the rapid arrest of the flow of the reaction mixture, various piston devices have been used.[84,99–103,110,113] In the first instant, local inhomogeneities in the composition of the reaction mixture can arise in the region of the receiving coil and can lead to additional broadening of the spectral lines in the first spectrum. Provision must be made for delays of 0.1 to 0.2 s to eliminate this effect before the first pulse of the kinetic series.

We believe that in many respects the apparatus and experimental methods proposed by McGarrity and co-workers[84,110] are optimal. By combining the mixing and recording points into one and using a novel mixing device, the authors[84] were able to achieve a reduction of the dead time to 0.04 s with effective stirring of the initial reactants directly in the rotating tube (Fig. 9). The preliminary polarisation of the initial reactants, one of which is in the tube and the other in the supplying capillary, is achieved naturally in the gap of the NMR spectrometer magnet. The problem of the temperature control of the recording region is solved simultaneously, which makes it possible to increase appreciably the accuracy of the kinetic measurements in conjunction with high reproducibility of the experimental conditions. To demonstrate the possibilities of this method, the authors repeated the study of the reaction of methylamine with trinitroanisole, which had been carried out earlier with the aid of stationary NMR in a flowing liquid.[67] The results and conclusions reached in this comparative investigation agreed fully with the available data, but the amount of initial

reactants consumed for this purpose was smaller by 2–3 orders of magnitude. Another example of the employment of this technique† is the direct detection of the unstable oxocarbonium ions (XVIII) and (XX) formed in the acid hydrolysis of the corresponding ketals (XVII) and (XIX):

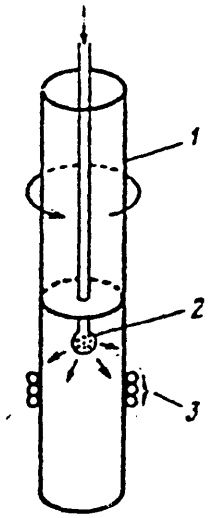


**Figure 9.** Apparatus for the rapid mixing of the initial reactants proposed by McGarrity et al.[84]: *1*) rotating bulb 5 mm in diameter; *2*) mixing device; *3*) recording region.

The tropylium ion (XVIII) proved to be sufficiently stable to detect it in an aqueous medium. On the other hand, the measurement of the $^1H$ NMR spectrum of the less stable intermediate (XX) required the use of the 1:1 $D_2O$–$(CD_3)_2CO$ mixed solvent; the lifespan of the intermediate in the reaction mixture was then 0.4 s.

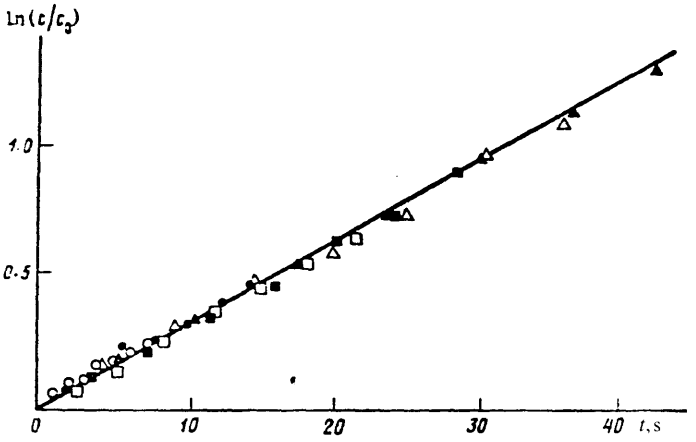
The possibilities of the "rapid injection" method in securing quantitative kinetic information have been demonstrated[84] in the determination of the rate of hydrolysis of trimethyloxonium tetrafluoroborate (XXI):

$$\underset{\text{(XXI)}}{(CH_3)_3O^+BF_4^-} + 2H_2O \xrightarrow{k} CH_3OH + (CH_3)_2O + H_3O^+ + BF_4^- .$$

The kinetic relation (6) was obtained[84] on the basis of six kinetic experiments in each of which eight spectra were measured (Fig. 10):

$$\ln\left(\frac{[XXI]_t}{([XXI]+[CH_3OH])_t}\cdot\frac{([XXI]+[CH_3OH])_{t_0}}{[XXI]_{t_0}}\right) = -k(t-t_0) . \quad (6)$$

The instant when the first spectrum was recorded in each of the six kinetic experiments was adopted as the initial time $t_0$ in Eqn.(6). If the instant of mixing of the reactants were adopted as $t_0$, then, although the slope of each of the kinetic curves would be unaltered, the scatter of the points around the resulting straight line would depend on the efficiency of the mixing of the reactants in each experiment. As a result of the above choice of the time $t_0$ and the adjustment for consistency of the integral intensities of all the components of the reaction mixture at each instant, the error of the determination of the hydrolysis rate constant was less than 1%. Thus the above example shows that NMR can be used successfully for exact kinetic measurements.



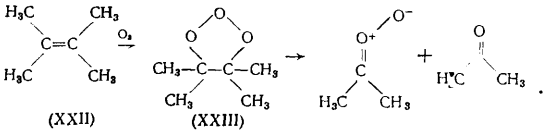


**Figure 10.** Kinetics of the hydrolysis of compound (XXI) in the 16:1 $D_2O$–[$D_3$]nitromethane mixed solvent at 23.4 °C; the points obtained in each of six independent measurements are designated by different symbols.[84]

The stability of the unstable intermediates in the reaction of tetramethylethylene (XXII) with ozone in [$D_2$]dichloromethane has been investigated by the rapid injection method:[110]

The use of low temperatures with a simultaneous reduction of the dead time of the kinetic measurements to 0.02 s and of the data access time to 0.1 s enabled the authors[110] to obtain half-reaction times of 4,4,5,5-tetramethyl-1,2,3-trioxolan (XXIII) in the temperature range from −80° to −100 °C and to estimate the thermodynamic parameters of its decomposition reaction. Even at −80 °C, where the half-reaction time is only 0.15 s, 11 spectra of the reaction mixture can be obtained for the construction of the kinetic curve. The error of the determination of $t_{1/2}$ does not then exceed 10%. The decrease of the temperature to −100 °C and the corresponding increase of $t_{1/2}$ to 3.2 s make it possible to increase the data access time and 25 virtually undistorted

†The technique of the NMR flow measurements was called by the authors the "rapid injection" method.[84]

NMR spectra of the reaction mixture can be obtained during the kinetic experiment (the error of the determination of $t_{1/2}$ at −100 °C is less than 2%).

The above study[110] was carried out on a spectrometer with a working frequency of 360 MHz and a superconducting magnet, which enabled the authors to reduce greatly the concentration of the initial reactants and to obtain qualitative $^1$H NMR spectra of 0.005 M solutions of the reaction mixture without the accumulation of the FIS.

Another promising aspect of studies of the kinetics of fast reactions by Fourier-transform NMR is the development of a dynamic resonance theory for non-equilibrium processes. In 1979 a group of investigators under the leadership of Ernst solved the problem of the influence of fast (comparable to the data time) non-equilibrium changes occurring in the spin system and the behaviour of the magnetisation vector.[113] They examined in a general form the non-normalised density operator $\sigma_j = [A_j]\rho_j$, where $\rho_j$ is the normalised density operator and $[A_j]$ the concentration of the molecules $A_j$, which depends on time under the conditions of an irreversible chemical reaction. Consequently the equation of motion for $\sigma_j$ is

$$\frac{d\sigma_j}{dt} = [A_j]\frac{d\rho_j}{dt} + \frac{d[A_j]}{dt}\rho_j .$$

Its solution for the line shape function $S_t$ has been obtained[113] for the simplest case of a first-order reaction. Analysis of the expression for $S_t$ permits the conclusion that the occurrence of rapid irreversible processes in the spin system does not lead to new spectral transitions compared with the equilibrium case. However, these processes are responsible for the broadening of the absorption lines of the initial reactants; the spectral lines of the product are not broadened, but they do undergo a phase distortion.

The fact that the amplitude and phase changes in the spectrum of the non-equilibrium mixture are analytically related to the reaction rate constant $k$ virtually leads to a new application of pulsed Fourier-transform NMR—the study by the method involving the total line shape analysis of the kinetics of irreversible chemical reactions whose half-lives are comparable to the data access time.

An an example, Fig. 11 illustrates the theoretical variation of the spectrum for the simplest case of a single-stage transition in a one–spin system $A \overset{k}{\rightarrow} B$ as a function of the rate constant $k$. The greatest changes in the spectrum of a non-equilibrium reaction mixture take place for comparable values of $k$ and of the difference between the chemical shifts of the initial reactant and the final product, while the character of the phase distortions of the line shape for the product is determined by the relative positions of the absorption signals for the initial and final states. Consequently the sign of the phase distortions of the NMR signal of the product is a criterion of the region in which the corresponding signal of the initial reactant is located relative to it.

Fig. 12 presents the theoretical spectra for a one-stage reaction of a two-spin system, $AB \overset{k}{\rightarrow} CD$, for different values of the rate constant $k$. These spectra were constructed subject to the following condition: as a result of the reaction, A is converted into C and B is converted into D; $\nu_A > \nu_C$ and $\nu_B < \nu_D$ and the phase distortions therefore have the opposite signs.

To demonstrate the possibilities of this new kinetic method, its authors selected the base hydrolysis of methyl formate (XXIV):

$$\underset{\text{(XXIV)}}{HCOOCH_3} + Na^+OD^- \xrightarrow[D_2O]{k_2} HCOO^-Na^+ + CH_3OD .$$

In the presence of an excess of NaOD, this reaction proceeds in accordance with a pseudofirstorder equation and the second-order reaction rate constant $k_2$ can be obtained from the expression $k_1 = k_2[O\bar{D}]$. The kinetic isotope effect, obtained from a comparison of the experimental and theoretical spectra of the reaction mixture (a mixture of a 0.15 M solution of lithium formate and a 0.63 M solution of NaOD) in $H_2O$ and $D_2O$, is

$$k_2(H_2O)/k_2(D_2O) = 0.64 \pm 0.08 .$$

This value is comparable to the familiar literature data (0.75).[114] The dead time in these measurements was $(3-5) \times 10^{-3}$ s and the number of repetitions of the experiments in order to accumulate the FIS ranged from

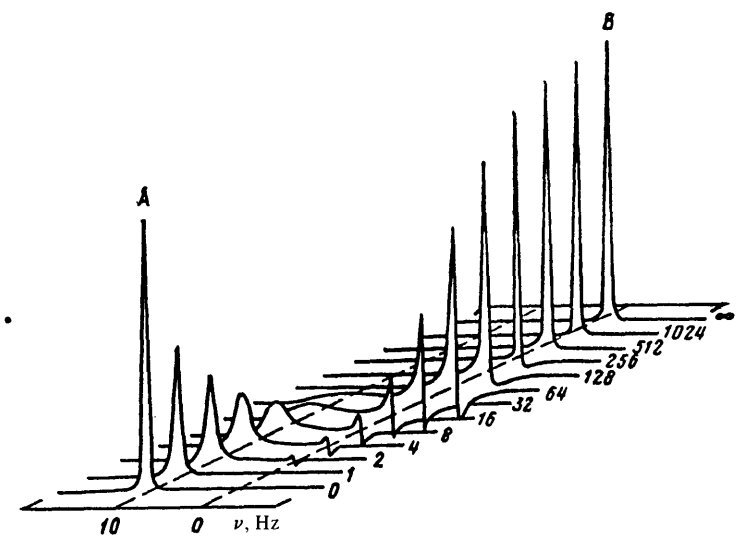

**Figure 11.** Theoretical dependence of the line shape for a single-stage reaction of a one-spin system for different rate constants $k$;[113] the numerals opposite each spectrum denote the values of $k$ (Hz) ($\nu_A - \nu_B = 10$ Hz).

40 to 100. In order to reduce $\tau_0$, the volume of the recording medium was artificially diminished and in the determination of the temperature of the reaction mixture a correction, taking into account the temperature rise (it did not exceed 3 °C when the accuracy of the thermostatic control of the recording region was to within 1 °C), was applied.

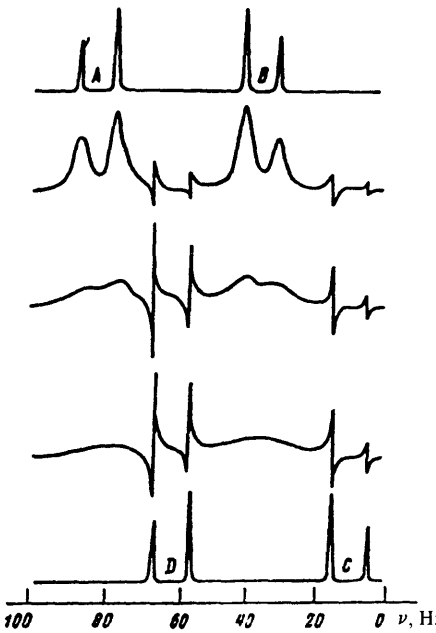

Figure 12. Theoretical variation of the line shape for a single-stage reaction of a two-spin system for different rate constants $k$(Hz):[113] *1*) 0; *2*) 10; *3*) 30; *4*) 50; *5*) ∞ ($\nu_A$ = 80 Hz, $\nu_B$ = 35 Hz, $\nu_C$ = 10 Hz, $\nu_D$ = 60 Hz, $J_{AB}$ = 10 Hz, $J_{CD}$ = 10 Hz).

The use of the method involving the total analysis of the line shape in order to obtain kinetic data for non-equilibrium chemical reactions[113] is so far limited to first-order reactions for which it is possible to obtain explicit analytical relations between the line shape in the NMR spectrum and the rate constant $k$. For higher-order reactions, numerical integration is required, which greatly complicates the construction and interpretation of the theoretical spectra.

The Fourier-transform NMR has been used for the first time[44–46] to study non-equilibrium chemical reactions with the aid of the saturation transfer effect, which has been applied previously only in the study of equilibrium reactions.[5,39] This selective magnetisation defect, which the authors[44–46] called the "microwave frequency label", is generated with the aid of a homonuclear decoupler by saturating the signals of specific atoms in the initial reactant directly before measuring the $^1$H NMR spectrum of the reaction mixture. The method involving the microwave probing of chemical reactions under specific conditions[46] makes it possible to trace, by employing NMR spectra, the path followed by the labelled atom in the course of the reversible reaction from the initial reactant to the product. The transfer of the label can be recorded by comparing the signal of intensities in the NMR spectra obtained with saturation and in the absence of saturation of specific signals from the initial reactant.

Fig. 13 illustrates the $^1$H NMR spectra of the reaction mixture of allyltriethylstannane (XXV) and bromotrichloromethane obtained under different conditions in the course of the photochemical reaction

$$(C_2H_5)_3Sn\overset{1}{C}H_2—\overset{2}{C}H=\overset{3}{C}H_2 + BrCCl_3 \xrightarrow{h\nu}$$

(XXV)

$$\xrightarrow{h\nu} CCl_3\overset{1'}{C}H_2—\overset{2'}{C}H=\overset{3'}{C}H_2 + (C_2H_5)_3SnBr\,.$$

(XXVI)

[the numerals 1, 2, 3, and 1′, 2′, and 3′ denote isotypical groups of atoms the reactant (XXV) and the product (XXVI), whose signals are indicated in the NMR spectra in Fig. 13*a*].

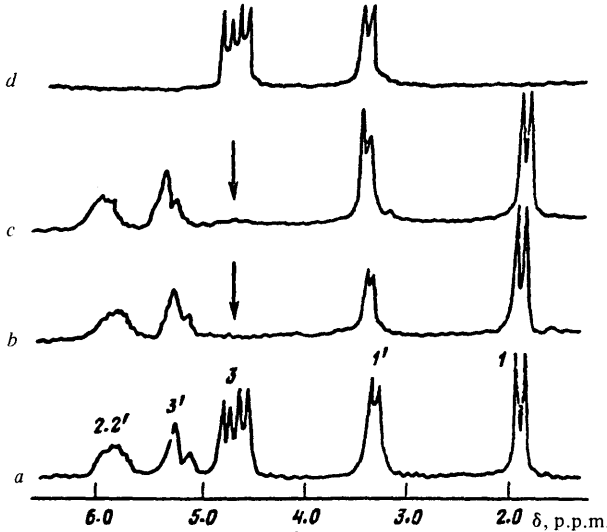

Figure 13. A section of the $^1$H NMR spectrum obtained in the course of the photochemical reaction of compound (XXV) with bromotrichloromethane in [$D_{12}$]cyclohexane under different conditions: *a*) reaction mixture without microwave frequency saturation of signals (the numerals denote the line assignment); *b*) and *c*) with saturation of the signals in the 3-position in compound (XXV) (the arrow indicates the position of the saturating field); spectra *b* and *c* were obtained with and without irradiation of the specimen by light respectively;[44] *d*) as for spectrum *b* but obtained with the aid of a selective pulse train[46] (evolution time ~1 s).

The fact that the saturation of signal 3 from the initial reactant (XXV) leads to a decrease (by 30–40%) of the intensity of signal 1′ from the product (XXVI) (Fig. 13*b*) compared with the intensity of this signal in the spectrum obtained without irradiating the specimen with light (Fig. 13*c*), while saturation of signal 1 from the reactant (XXV) entails a decrease of the intensity of signal 3′ from the product (XXVI) demonstrates unambiguously the occurrence of the 3 → 1′ and 1 → 3′ transitions in this reaction.[44,45]

The main deficiency of this method for the recording of the microwave frequency label is that the saturation transfer effect is observed against the background of the signal from the part of the product whose magnetisation has already returned to the state of equilibrium. In order to eliminate this disadvantage, an effective method involving the artificial isolation of the signals due to labelled atoms in the NMR spectrum of the reaction mixture has been proposed.[46]

This is achieved by the selective separation of the magnetisation vectors of the "labelled" and all the remaining atoms of the initial reactant during the preparatory period of the pulse train containing two in-phase microwave frequency pulses (broad-band and selective). Fig. 13*d* illustrates the spectrum of the reaction mixture obtained as a result of the effect of such a pulse sequence in the case of the selective isolation of signals associated with the generation of a microwave frequency label in the atomic group 3 of the initial reactant (XXV). The spectrum consists of only two signals (3 and 1'), which demonstrates the occurrence of the corresponding reaction transition.[46]

In connection with the employment of Fourier-transform NMR in the study of non-equilibrium reactions, it is essential to examine also the problems associated with the use for this purpose of NMR involving "rare" nuclei. Despite the difficulties due to the low sensitivity of these methods, $^{13}C$,[80,106,115–117] $^{31}P$,[86,87,118] and even $^{15}N$ [119] NMR has been used in recent years to obtain qualitative information about the structure of unstable intermediates in a whole series of chemical and biochemical reactions. Such investigations merit attention, because they provide an idea about the character of the experimental difficulties arising when they are carried out. In assessing the methodological advantages of these studies, it is necessary to take into account the fact that the very concept of a "fast reaction" has a different significance for each of the above nuclei#. In the determination of the experimental dead time $\tau_0$ in the stopped flow method, it is therefore necessary to take into account in addition the total FIS accumulation time in order to obtain an acceptable signal to noise ratio, which is to a first approximation§ inversely proportional to the square of the natural abundance of the isotope employed.

The frequent repetition of the entire procedure for the generation of the FIS in the non-equilibrium reaction mixture and for the accumulation of such signals must be regarded as the simplest and most effective method whereby the dead time in such experiments can be reduced,[113,120] which naturally requires an appropriate increase in the amount of the initial reactants. It is even more difficult to extract quantitative (or semiquantitative) kinetic information from NMR involving "rare" nuclei, because here one must take into account the influence of the relaxation effects on the peak intensities of the NMR signals. These problems have been discussed in detail in a number of studies[106,108,109,121] of the use of $^{13}C$ NMR for the recording of CINP effects. To save time, it is recommended that an external computer be used in kinetic measurements either for the simple storage of FIS corresponding to different time points on the same kinetic relation[101,110] or for their summation at a single time point for each of the frequently repeated kinetic experiments.[113,120]

#According to the definition given by Caldin,[22] the term "fast reaction" in relation to a given method of measurement should be understood as one which cannot be investigated under normal conditions and by means of a standard experimental technique.

§Here no account is taken of other parameters of the spin system and the NMR spectrometer which determine the resulting signal to noise ratio.

## V. CONCLUSION

The examples of the use of high-resolution NMR in the study of the mechanisms of fast irreversible reactions examined above indicate a vigorous development of mainly the flow methods and methods for the recording of CINP effects in which a non-equilibrium initial state is generated respectively as a result of the rapid mixing of the initial reactants and a photochemical reaction. The simple apparatus developed for these purposes, based on the use of NMR in a flowing liquid, makes it possible to obtain not only the spectral NMR characteristics of the relatively unstable intermediates with lifespans up to 0.02 s [110] but also quantitative data concerning the kinetics of their reactions. The relative error of the kinetic measurements can be reduced to 1% [84] and the chemical shift[14] or the spin–spin interaction constant[96] can serve as a time-dependent physical quantity together with the integral (or peak) signal intensity. Although kinetic data obtained with the aid of NMR are less accurate than the analogous results of the kinetic studies using the more sensitive UV, IR, and EPR spectroscopic methods, they can prove extremely useful in those cases where the intermediates do not contain chromophoric groups or unpaired electrons.

A characteristic feature of the development of NMR methods for the study of fast reactions is at the present time the tendency towards a wider employment of the stopped flow method with pulsed Fourier-transform recording of the spectra. This can be explained both by the economy of the method from the standpoint of the consumption of the reactants and the possibility of programming the experiment and by the increased sensitivity owing to the accumulation of the FIS, which permit, on the one hand, studies involving $^1H$ nuclei in more dilute solutions and, on the other, the use on a wider scale of measurements involving the $^{13}C$, $^{31}P$, $^{27}Al$, $^{15}N$, etc., nuclei. Fig. 14 presents the dead times $\tau_0$ attained with the aid of various $^1H$ NMR methods. It is noteworthy that $\tau_0 \cong (3-5) \times 10^{-3}$ s has been obtained by the Fourier-transform NMR under stopped flow conditions, such times being characteristic of the flow technique involving UV and IR spectroscopic analysis of the composition of the non-equilibrium reaction mixture, while the scope of the continuous flow method with stationary recording of the spectrum has been virtually exhausted and is restricted to $\tau_0 \cong 0.05$ s.

Another trend involves the use of methods with rapid NMR measurements at low temperatures. This permits a considerable extension of the range of irreversible reactions susceptible to study. Thus a decrease of the temperature of the reaction mixture to −90 °C expands the NMR time scale by approximately 8 orders of magnitude: by 4 orders of magnitude owing to the rapid measurement and by a further 4 orders of magnitude as a result of the decrease of temperature. The technical difficulties which arise in the development of the low-temperature NMR flow technique are associated primarily with the requirement for the effective temperature control of the measuring channel taking into account the possibility of the self-heating of the reaction mixture in the course of an exothermic reaction or heating due to the pulsed irradiation in the sensor of the Fourier-transform spectrometer.[77] These problems have been solved most successfully in the "rapid injection" method,[84,110] which permits kinetic measurements at temperatures up to −100 °C.

A study[122] involving the use of the NMR spectrometer as the recording device in a non-isothermal method[123] for the investigation of fast reactions is of interest from the standpoint of the employment of low temperatures and the economy in the consumption of the initial reactants. This method

consists in recording the changes in the NMR parameters of a non-equilibrium reaction mixture in the course of a linear temperature variation.[124] Analysis of this relation permits the calculation of the activation energy for first- or second-order reactions tending to equilibrium on the basis of a single kinetic experiment.

The extension of methods for the study of fast equilibrium reactions such as the total line shape analysis (TLSA) and the saturation transfer effect (STE) to the non-equilibrium case leads to new possibilities for the measurement of kinetic parameters and the study of mechanisms of irreversible reactions with half-lives comparable respectively to the data access time of the Fourier-transform spectrometer and the spin–lattice relaxation time of a selectively polarised nucleus.[45,46] The microwave frequency probing method has already found a practical application in the study of the mechanism of photochemical reactions.[44–46] However, its unique possibilities in meeting specific requirements[46] can be used in the study of a wider range of organic reactions.

The creation in the system of a non-equilibrium initial state with subsequent observation of its transition to the initial or new equilibrium state constitutes a general method for the investigation of both equilibrium and non-equilibrium chemical reactions.[125] For this reason, experimental methods and techniques for the NMR recording of fast irreversible transitions induced by chemical reactions, which have been examined in this review, can be useful in the study of both irreversible and irreversible chemical reactions in combination with other familiar methods for disturbing the equilibrium such as temperature,[126] or pressure jump[22] methods etc. The absence of NMR studies of this kind is associated in many respects with experimental difficulties in the creation of a sharp temperature or pressure drop in the standard NMR sensor. Nevertheless, it is to be expected that in the immediate future these relaxation methods will develop, for example, on the basis of sensors with wide temperature and pressure ranges, which have already been devised (for the solution of other problems).[127–131]

The problem of the low sensitivity of NMR involving "rare" nuclei, which prevents their wide-scale employment in the study of non-equilibrium reactions, has been partly solved with the aid of multipulse methods for the transfer of polarisation between atoms coupled by the spin–spin interaction which have been developed in recent years.[132] These methods for the artificial increase of the sensitivity and the corresponding shortening of the accumulation time of the NMR spectra involving "rare" nuclei have already found applications in the study of non-equilibrium biochemical reactions associated with the metabolism of living organisms.[133] The possibility of obtaining high-quality $^{31}P$,[135–137] $^{13}C$,[117,138] and $^{19}F$ [139] NMR spectra in soft tissues in the course of several minutes with the aid of surface coils[134] has given rise to wide possibilities for medical diagnostics with the aid of NMR and studies in this field merit separate consideration.

# Quantitative Estimation of the Electronic Effects of Substituents in Five-membered Nitrogen-containing Aromatic Heterocycles

V.A. Lopyrev, L.I. Larina, and T.I. Vakul'skaya

Data, characterising quantitatively the effect of substituents on the reactivity and physicochemical properties of five-membered nitrogen-containing heterocyclic compounds, which have accumulated in the literature during the last 15 years, are compiled in the review and discussed. The possibility of applying the Hammett and Jaffe equations in the determination of the direction of transmission of the electronic effects of substituents is analysed and the likely usefulness of this approach to the study of electronic influences by taking into account separately the inductive and resonance constants is demonstrated.
The bibliography includes 215 references.

## I. INTRODUCTION

The current advances in theoretical organic chemistry are in many respects associated with the vigorous use of the principle of the linearity of free energies (LFE) in studies of a wide variety of reactions and physicochemical properties.

The Hammett equation makes it possible to obtain quantitative estimates of reaction rate and equilibrium constants and to predict many important physicochemical characteristics. It is used widely in the study of the relation between structure and biological activity. The greatest advances on these lines have been achieved in hydrocarbon systems.

During the last decade, the Hammett equation, which was initially proposed for simple aromatic systems, has undergone a series of modifications based on the separate allowance for the inductive and resonance effects of substituents and proved to be applicable to various heterocyclic compounds.[1-9] The application of correlation analysis to heterocycles is usually considered in terms of the following aspects:

(1) The heterocycle functions as a substituent and one estimates its influence on the reaction centre of the molecule.

(2) The heteroatom in heterocyclic compounds is regarded as a substituent introduced into the aromatic ring. Here one estimates its influence on the properties of the system.

(3) The heteroatom in the heterocyclic system behaves as the reaction centre.

(4) The heterocycle is regarded as a single system in which the substituent and the reaction centre interact.

Since the first three aspects have been dealt with in fair detail in other reviews,[5-7] we concentrated attention on the transmission properties of heterocyclic systems. Since the comprehensive review of Mamaev and Shkurko on the transmission of the effects of substituents in azines has been published recently,[9] we confined ourselves to the consideration of nitrogen-containing five-membered heterocycles and their condensed derivatives.

## II. PYRROLES, INDOLES, AND CARBAZOLES

The $pK_a$ for a large series of substituted pyrroles have been determined[10] by the method involving transmetallation in dimethyl sulphoxide and it was shown that the NH acidity of such derivatives is satisfactorily correlated with the inductive constants of the substituents:

$$pK_a = (23.4 \pm 0.1) - (17.4 \pm 0.5)\sum\sigma_I, \quad r = 0.994,\ S_0 = 0.37,\ n = 17. \qquad (1)$$

An equation was fitted in the same study to the available literature data for the acidity of the substituted pyrroles in water:

$$pK_a = (16.6 \pm 0.6) - (10.5 \pm 0.9)\sum\sigma_I, \quad r = 0.97,\ S_0 = 1.0,\ n = 11. \qquad (2)$$

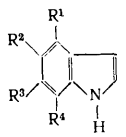
The difference between the reaction constants in Eqns.(1) and (2) is due to the employment of different solvents in which the $pK_a$ scales differ significantly. Furthermore, the formation of complexes between pyrroles and dimethylformamide (DMF) was investigated in the same study by IR spectroscopy. The $\Delta\nu$ in the infrared spectra of the complexes are proportional to the square of the energy of the N–H...O hydrogen bond and are therefore a measure of the relative acidities of these compounds. The relative acidities determined in this way are also satisfactorily correlated with $\sigma_I$. The data described enabled the authors[10] to conclude that the influence of substituents on the NH acidity of pyrrole is determined mainly by the inductive effect. The complex formation method for the estimation of the NH acidities of a series of pyrroles in which the substituent is separated from the ring by the methylene bridge has also been used by Janda et al.[11] A satisfactory linear relation between the relative acidities and the inductive constants of substituents was obtained for a series of 2(5)-substituted pyrroles. These results have been partly surveyed in a review.[12]

However, the vibration frequencies of the free NH groups in 2-ethoxycarbonylpyrroles vary linearly with the $\sigma_p$ constants.[13] The study of the acidities of pyrrole-2-carboxylic and pyrrole-3-carboxylic acids[14,15] showed that the influence of the substituents is transmitted through the pyrrole ring via the same mechanism as for the phenylene fragment but with a somewhat higher intensity.

In a study of 2-phenylpyrroles containing different substituents in the *para*-position in the benzene ring[16] and of their *N*-vinyl derivatives,[17] it was observed that the $\delta(^{13}C)$

parameter for both the pyrrole ring and the β-atom of the vinyl group varies linearly with $\sigma_p$. It has been concluded[16] that the degree of conjugation of the phenylene fragment with the pyrrole ring is significantly greater than in the corresponding furan derivatives.

It has been shown that the $^1H$ and $^{13}C$ chemical shifts of the vinyl group in 2-alkyl- and 2,3-dialkyl-1-vinylpyrroles vary linearly with the steric constants of the subsituents.[18]



The ionisation energies, determined from the photoelectron spectra for two series of substituted pyrroles [5-R-3-ethoxycarbonyl-2,4-dimethylpyrroles (the α-series) and 4-R-2-ethoxycarbonyl-3,5-dimethylpyrroles (the β-series)][19] are linearly related to the $\sigma_m$, $\sigma_p$, and $\sigma_p^+$ constants ($r = 0.90$ to 0.97), the best correlation being obtained when $\sigma_p$ constants are used. It is of interest that the ionisation potentials for the α- and β-series of substituted pyrroles[19] are satisfactorily correlated ($r = 0.97-0.99$) with the $pK_a$ of 4-substituted[14,15] and 5-substituted[15] pyrrole -2-carboxylic acids.

A linear correlation between $E_{1/2}$ and the constant $\sigma_p^+$ has been noted in a study[20] of the electrochemical oxidation of 3,4,5-triphenyl-2-(4-R-phenyl)-, 3,4-diphenyl-2,5-di-(4-R-phenyl)-, 5-(4′-biphenylyl)-3,4-diphenyl-2-(4-R-phenyl)-, and 5-(2-naphthyl)-3,4-diphenyl-2-(4-R-phenyl)-pyrroles in DMF.

The theoretical reactivity indices have been calculated for a series of 2-monosubstituted pyrroles by the CNDO/2 method.[21] The correlations between the theoretical and experimental reactivity indices has led to the conclusion that the electronic effects of substituents are transmitted in different ways from the 2-position (correlation with $\sigma_p^+$ constants) and the 3-position (correlation with $\sigma_m^+$ constants) in the pyrrole ring.

There exist data showing that the rate constant for the decolorisation of benzene solutions of 2-aryl-3,4,5-tetraphenylpyrrolyl and 2-aryl-5-biphenylyl-3,4-diphenylpyrrolyl radicals are correlated with the overall σ constants.[22]

A quantitative estimation of the influence of the electronic effects of substituents on the acidity of indoles has been reported in only one communication:[23]

$$pK_a = 2.56 \sum\sigma - 2.55 \qquad r = 0.996, \; n = 9 \qquad (3)$$

The $\sigma_m$ constants for the $R^1$ and $R^4$ substituents and the $\sigma_p$ constants for the $R^2$ and $R^3$ substituents were used in the correlation in Eqn.(3).

The question of the electronic effects of the substituents in indole systems has been considered mainly from the standpoint of the determination of the path followed in the transition of these effects to the reaction centre. Jaffe[2] suggested that the equation

$$\lg K/K_0 = \rho_1\sigma_m + \rho_2\sigma_p \qquad (4)$$

be used to determine the direction of the transmission of the effects of substituents via carbon–carbon or nitrogen–carbon bonds. Having fitted this equation to the constants for the hydrolysis of indole-2-carboxylic acid esters and the ionisation constants of these acids, Jaffe failed to observe significant differences between $\rho_1$ and $\rho_2$. On this basis, he concluded that the transmission of the effects of substituents via the =CH– and –NH– groups is approximately the same.[2]

The study of the acidities of 5- and 6-substituted indole-3-carboxylic acids in aqueous ethanol showed[24] that the $pK_a$ are satisfactorily correlated with the $\sigma_m$ constants for the 5-substituted acids and the $\sigma_p$ constants for the 6-substituted acids. Hence it was concluded that the electronic effects of the substituents are transmitted mainly via the hydrocarbon chain and not via the "pyrrole" nitrogen atom. However, the same data were treated in terms of Eqn.(25) and the results ($\rho_1 = 0.31$ and $\rho_2 = 0.42$) indicate the approximately equal contributions of the methylidyne groups and the "pyrrole" nitrogen atom to the transmission of the electronic effects. Eqn.(4) was also used to analyse the rate constants for the reactions of indole-2-carboxylic and indole-3-carboxylic acids with diphenyldiazomethane[25] and fairly high correlation coefficients were observed (0.980 and 0.997 respectively).

Thus the conclusions reached on the basis of the Jaffe equation are to a considerable degree contradictory and, as will be shown below, the application of Eqn.(4) and other multiparameter relations for the estimation of the paths followed in the transmission of the electronic effects of substituents in heterocyclic systems, inccluding condensed heterocycles, is unjustified without the analysis of the relation between the arguments.

Somewhat later the question of the transmission of the influences of substituents through the indole ring was examined by Bowden and Parkin.[26] The authors investigated the ionisation of indole-2-carboxylic acids containing substituents in various positions in the ring and concluded that, in contrast to benzene compounds, the $pK_a$ for these acids cannot be expressed by any one correlation equation using different constants σ and the same value of ρ for all the positions in the indole ring. The correlation is satisfactory when the constants $\sigma_D$ are calculated for each position of the substituent within the framework of Dewar's theory or $\rho_1$ and $\rho_2$ are fitted in the Jaffe equation (4). The authors therefore suggest that independent constants be fitted for each position of the substituent. However, this procedure cannot be regarded as promising.

The equilibrium constants for the formation of enzyme–indole complexes are correlated with the Hammett σ constants and, when the reaction centre in indoles is the nitrogen atom, the constants $\sigma_p$ are used for 5-substituted derivatives and $\sigma_m$ for the 4- and 6-substituted derivatives.[27]

The basicities of a series of carbazoles have been determined by the method of standard indicators in 20% ethanol[28] and it was shown that they are related to the σ constants by the expression

$$pK_{BH^+} = (-5.18 \pm 0.95) - (5.01 \pm 0.26)\sigma, \; r = 0.993, \; n = 6$$

The $\sigma_m$ and $\sigma_p$ constants were used respectively for the substituents in the 2- and 3-positions.

In a study of the mechanism of the acid hydrolysis of 3,6-disubstituted 9-(1-alkoxyethyl)carbazoles[29] and 9-alkenylcarbazoles,[30] it was observed that the reaction rate constants are correlated more effectively with the Hammett constants than with the Brown $\sigma^+$ constants, which indicates the absence of a direct polar conjugation of the substituents in the carbazole ring with the carbonium centre in the transition state. The amount of double bond character between the carbazole ring and the reaction centre in the transition state is then smaller in the hydrolysis of 9-vinylcarbazoles than in the hydrolysis of 9-(1-alkoxyethyl)carbazoles ($\rho = -2.24$ and $-3.52$ respectively).

The results of a study of the reactivities of 6-substituted 3-aminocarbazoles have been published.[31] The authors determined the basicity constants for the above compounds and the rate constants for their reactions with picryl chloride and *p*-nitrobenzenesulphonyl bromide. Correlations were noted between the experimental data and the $\sigma^0$ constants ($r = 0.962-0.999$). The reactivities of carbazoles have been compared with those of the analogous substituted diphenylamine derivatives and it was noted that the reactivities of carbazoles are somewhat higher, while their sensitivity

to the electronic influences of the substituents is lower than that of diphenylamines. In this approach no account is taken of the specific features of the carbazole ring as a single aromatic system, which undoubtedly reduces the value of the conclusions reached in the above study.

A thorough investigation of the transmision of the effects of substituents through the carbazole ring in 3-substituted 9-methylcarbazoles has been undertaken by $^{13}C$ NMR.[32] The authors of this study carried out one-parameter correlations between the chemical shift of the carbon atoms in the carbazole ring and the Brown $\sigma_p$ and $\sigma_p^+$ constants as well as two-parameter correlations taking into account the $\sigma_I$ and $\sigma_R^0$ constants. The results led to the conclusion that there is a direct polar conjugation within the limits of a single phenylene fragment. An attempt was also made to estimate the direction of the transmission of the effects of substituents on the basis of the satisfactory correlations $\Delta\delta[C(6)]-\sigma_p$ and $\Delta\delta[C(7)]-\sigma_m$ ($r = 0.964$ and 0.941 respectively). The "dominant" diphenylamine direction (i.e. via the nitrogen atom) proposed by the authors[32] apparently does not altogether correspond to reality, because, as will be shown below, it is not legitimate to employ one-parameter correlations for the determination of the paths followed in the transmission of the effects of substituents in heterocyclic systems.

## III. PYRAZOLES AND INDAZOLES

A limited amount of data concerning the application of the LFE principle to pyrazoles and indazoles is available in the literature. The study of the basicities of 90 derivatives of pyrazole has shown[33] that the $pK_{BH^+}$ are correlated with the Hammett $\sigma_m$ constants. In a study of the electrochemical oxidation of pentacyanoferrate(II) complexes of pyrazole and indazole, an excellent correlation was observed ($r = 0.99$) between the oxidation potentials and the $pK_{BH^+}$ for the ligand.[34] Although direct correlations with the parameters of the substituents are not quoted, presumably (bearing in mind the study of Elguero et al.[33]) the oxidation potentials of the pentacyanoferrate(II) complexes of pyrazole also depend linearly on the $\sigma_m$ constants).

The equilibrium NH acidities of pyrazole derivatives (3,5-dimethylpyrazole, pyrazole, 4-chloro-3,5-dimethylpyrazole, and 4-bromopyrazole) are satisfactorily correlated with the sum of the $\sigma_m$ constants of the substituents regardless of their positions in the heterocycle.[35] However, the authors themselves recognised that one cannot infer that the relations obtained are general on the basis of the four available points.

In the course of the study of the kinetics of the hydrolysis of *N*-acylazoles, it has been shown that the rate constants for the hydrolysis of 4-substituted *N*-acylpyrazoles are correlated with the $\sigma_p$ parameters.[36] The reliability of this relation is difficult to assess, since the results of a statistical treatment are not quoted.

A study of the polarographic reduction of 3-aryl-1,2-dimethylpyrazolium perchlorates[37] has shown that the half-wave potentials for the two-electron transfer are satisfactorily correlated with the Hammett $\sigma$ constants of the substituents in the 1-position. Unfortunately, correlation equations are not quoted in the above study and the relations are presented in the form of a graphical plot without a due statistical treatment.

The $^{13}C$ NMR spectra of 3-substituted indazoles have been investigated[39] but no correlation has been observed between the chemical shifts and the parameters $\sigma_m$, $\sigma_p$, $\sigma_I$, and $\sigma_R$. When the parameters of Swain and Lupton[40] ($\mathcal{F}$, $\mathcal{R}$) were used, a correlation was observed only for $\delta[C(5)]$,[39] but the large errors in the coefficients of the correlation equation and the unsuccessful selection of the points preclude the estimation of the influence of the electronic effects of the substituents.

## IV. IMIDAZOLES

The influence of substituents on the acid–base properties of the imidazoles has been studied in fair detail.[41–52] The main contribution in this field is due to Charton,[7,41] who showed that the $pK_{BH^+}$ of substituted imidazoles are better correlated with the $\sigma_m$ or $\sigma_I$ constants than with the $\sigma p$ constants. For certain series, the data have been treated in terms of a two-parameter correlation equation using the $\sigma_I$ and $\sigma_R$ constants.[43] These data led to the conclusion that the employment of two-parameter correlations does not improve the regression parameters.[41] However, this conclusion cannot be regarded as reliable because both the number and the selected sets of points in the series do not satisfy the recommended requirements for two-parameter correlations.[48,53]

The basicities of 2-phenyl-substituted 4,5-diphenylimidazoles in acetonitrile have been investigated[47] and it was found that the correlation between the basicity constants and the $\sigma_p$ constants is excellent, while the correlation with the $\sigma^+$ constants is much worse. The same data have been treated in terms of a two-parameter equation using the $\sigma_I$ and $\sigma_R^+$ constants and in terms of the Yukawa–Tsumo equation:[47]

$$pK_{BH^+} = 12.72 + 1.974(\sigma^0 + 0.269\Delta\sigma_R^+),\ R = 0.998\ n = 6\ .$$

A decrease of the basicity of the imidazole ring was noted after the introduction of aryl substituents in the 1-position.[49] When the substituents are in the aromatic ring, satisfactory correlations are obtained when $\sigma$ constants are used ($r = 0.958$), electron-accepting substituents ($NO_2$ and $COCH_3$) deviating from the linear relation, which the authors explained by their polar conjugation with the reaction centre.

In a study of the basicity of nitroimidazoles, an attempt was made to introduce special $\sigma$ constants for compounds of this class.[50] However, it is not possible to assess the reliability and the results of the above study because the correlation equations themselves are not quoted.

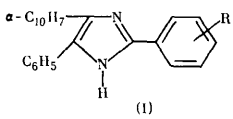
The acid properties of imidazoles have been investigated.[34, 43,51] The equilibrium NH acidities of imidazoles and their derivatives[35] are satisfactorily described, like the acidities of pyrazoles, by a linear relation between the $pK_a$ and the sum of the $\sigma_m$ constants of the substituents regardless of the positions which they occupy in the heterocycle:

$$pK_a = 18.9 - 9.5\sum\sigma_m,\ S = 0.25,\ r = 0.9991,\ n = 5\ .$$

The authors believe that, since there are no $\pi$-acceptor groups other than the phenyl group among the substituents investigated, it is diffiult to judge to what extent the relation found is general.

The acidity constants of 4(5)-substituted imidazoles are described by the equation[43]

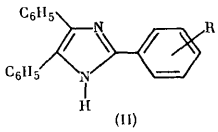
$$pK_a = 13.90 - 6.72\sigma_I - 2.77\sigma_R,\quad R = 0.988,\ n = 5\ .$$



The limited set of substituents in this series (H, $C_6H_5$, CHO, $CONH_2$, $NO_2$) and the lack of electron-donating substituents lower the value of the above equation.

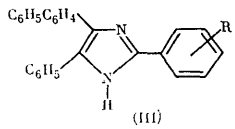
The acid dissociation constants of nitroimidazole have been determined recently[51] and it has been shown that the $pK_a$ for 2-substituted 4(5)-nitroimidazoles vary linearly with the $\sigma_m$ constants:

$$pK_a = 9.1625 - 8.8845\sigma_m.$$



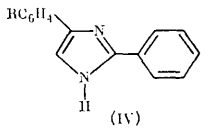
Similar relations have not been observed for 5(4)-substituted 4(5)-nitroimidazoles.[51]

The influence of the substituent in the arylene fragment on the acid properties in the series of imidazole derivatives (I)–(IV) has been investigated: [52]



$\Delta\nu = 34\sigma + 221$, $r = 0.97$, $n = 7$ ;

(I)



$\Delta\nu = 22\sigma + 215$, $r = 0.98$, $n = 10$ ;

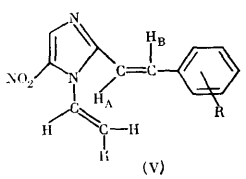
(II)

$\Delta\nu = 15\sigma + 217$, $r = 0.96$, $n = 6$ ;

(III)

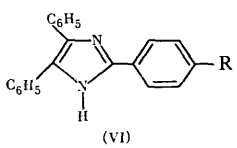
$\Delta\nu = 10\sigma + 210$, $n = 4$ .

(IV)



The authors explained the different sensitivities to electronic influences in the (I)–(IV) series by the effect of the direct polar conjugation between the substituents in the 2- and 4-positions in the imidazole ring. A deficiency of this treatment is that the differences between the steric effects of bulky subsituents in the 4- and 5-positions in the imidazole ring are excluded from consideration.

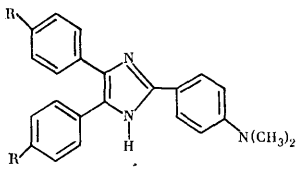
The heteroanalogues of triarylimidazoles have been investigated as inhibitors of the radical polymerisation of methyl methacrylate. [54] A linear relation has been observed between the logarithm of the inhibition factor and the Hammett $\sigma^+$ constants.



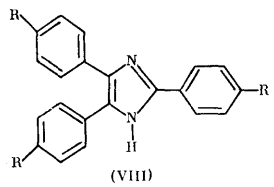
In a study of the photoelectron spectra of methylimidazole, it has been observed that the ionisation energies vary linearly with the basicity constants. [55] Since it is known that the latter are in their turn linearly related to the constants, [7,41] presumably their ionisation energies should also be correlated with these constants.

One-parameter correlations of the chemical shifts $\delta(^1H_A)$ with the $\sigma_R^0$ constants and two-parameter correlations of the chemical shifts with the $\sigma_I$ and $\sigma_R$ constants have been published for a series of substituted 5-nitro-2-styryl-1-vinylimidazoles (V). [56]

A correlation has been noted between the half-wave oxidation potentials of 2,4,5-triarylimidazoles (VI)–(VIII), [57,58] 2,4-diaryl-5-heterylimidazoles (IX), [59] and 4,5-diaryl-2-heterylimidazoles [59,50] and various constants. It is noteworthy that the potentials $E_{1/2}$ for the anions of the series (VI) depend on the $\sigma_p$ constants. [57]



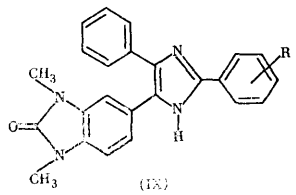
(V)



(VI)

R = $N(CH_3)_2$, $OCH_3$, $CH_3$, H, Cl, $NO_2$

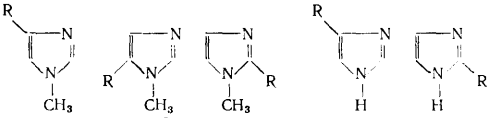
(VII)



R = $N(CH_3)_2$, $OCH_3$, $CH_3$, H, Cl

(VIII)

R = $N(CH_3)_2$, $OCH_3$, $C_6H_5$, H, Cl

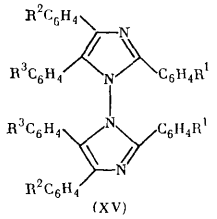


In the series (VI), 2-(*p*-nitrophenyl)-4,5-diphenylimidazole deviates from the correlation, which can be accounted for by the polar conjugation of the nitro-group with the reaction centre in the anion. The reaction constants for the series (VI) and (VII) are approximately equal ($\rho = 0.295$ and 0.284 respectively) and are smaller almost by a factor of 2 than for the series (VIII) ($\rho = 0.580$). [57] Unfortunately a statistical treatment of the correlations is not presented in the given communication. The $\sigma^+$ and $\sigma$ constants were used by Shishkin et al. [58] and Blokhin et al., [59] on the one hand, and Rozin et al., [60] on the other, respectively in the statistical treatment of the results of the polarographic oxidation of the structurally similar compounds (IX):

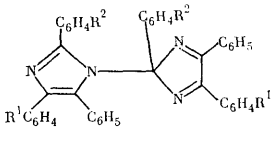
(IX)

The relatively low reaction constants show, according to the authors, that the half-wave potential is determined mainly by the dimethylbenzimdazolone substituent. [59] However, this conclusion is inconsistent with other data. [57] Satisfactory correlations have been obtained ($r = 0.949$) between the rate constants for the quaternisation of 1-arylimidazoles and the Hammett $\sigma$ constants of the substituents in the aryl fragment, although a low sensitivity of this reaction to electronic effects was noted. [49] A satisfactory correlation of the reaction rate constants for the azo-coupling of 2-substituted imidazoles and *p*-diazobenzenesulphonic acid with both $\sigma_m$ and $\sigma_p$ constants has been noted, [44] but, in view of the limited set of the substituents, the above relations cannot be treated as entirely reliable.

The influence of the electronic parameters of substituents on the solvolysis of *N*-acylimidazoles has been examined in several communications. [61–63] The rate constants for the acid [61] and base [62] hydrolysis of aroylimidazoles depend on the $\sigma$ constants of the substituents in the aroyl fragment. The rate constants for the solvolysis of 1-(1-methyl-2-imidazolyl)-ethyl *p*-nitrobenzoates have been measured and it has been shown that they are linearly related to the $\sigma_m^+$ constants for the 4-substituted derivatives and to the $\sigma_p^+$ constants for the 5-substituted derivatives. [63] The base-catalysed isotope exchange involving the substituted imidazoles (X)–(XIV) has been investigated. [64]



(X) (XI) (XII) (XIII) (XIV)



The set of substituents is the same in each case: $NO_2$, F, H, $CH_3$, and $CF_3$. The authors showed that the isotope exchange proceeds via two different mechanisms involving the intermediate formation of substrate anions or cations.

In the above study a significant difference between the transmission of the effects of substituents from the C(4) and C(5) positions to the C(2) position was noted for the first time and, what is particularly interesting, a difference was observed between the electronic conductivities on the pathway from the C(5) position to the C(2) position and in the opposite direction. Unfortunately, the correlation coefficients and other parameters of the statistical treatment are not quoted in this excellent investigation.

The influence of substituents on the thermal dissociation of the dimers (XV) and (XVI) has been studied in fair detail.[65–73]

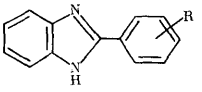
(XV)

(XVI)

It has been reported that the constant for the equilibrium between compound (XV) and the corresponding free radical does not obey the Hammett equation,[65] but subsequently these results were disproved.[73] The activation energy for the dissociation of the majority of the dimers investigated is in the range 17–23 kcal mole$^{-1}$.[69] The rate constants for the dissociation of the dimers (XV) and (XVI) are well correlated with the $\sigma$ constants.[66–73] The isokinetic temperature has been calculated on the basis of these correlations.[66] However, it cannot be regarded as reliable, because the measurements were performed over a narrow temperature range. It has also been shown that the nature of the solvent influences the reaction constants.[72,73]

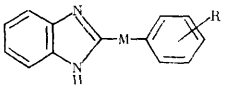
## V. BENZIMIDAZOLES

The question of the influence of the electronic effects of substituents in the 2-position on the basicities of benzimidazoles has been widely disucssed in the literature.[7,23,41,47,74–78] It has been suggested that this interaction has the character of direct polar conjugation.[74] However, more detailed investigations[7,23,41,75] have shown that better relations are obtained when the $\sigma_m$ constants are used. It is noteworthy that, despite the large number of publications devoted to the study of the influence of substituents on acid–base properties, conclusions have been reached in many instances on the basis of clearly inadequate statistical data. The study of Rabiger and Joullii,[76] who investigated the basicities of two series of 5(6)- and 4(7)-halogenobenzimidazoles (four compounds in each series) is instructive in this respect. Both the character of the substituent and the number of compounds preclude any serious generalisations. Nevertheless, on the basis of correlations between the basicity indices of 4(7)-substituted benzimidazoles and the $\sigma_m$ constants, the authors concluded that the tautomeric equilibrium has shifted, the 4-R-tautomer predominating. However, this conflicts with the available experimental data.[79] The basicity constants of 2-arylbenzimidazoles containing substituents in the aryl fragments are correlated more effectively with the Hammett $\sigma$ constants than with the $\sigma^+$ constants.[47]



It is of interest that the more pronounced are the electron-accepting properties of the substituent in the 2-position in the benzimidazole ring, the more sensitive is the given series to the electronic effects of the substituents in the phenylene fragment of the molecule.[23] Data based on the two-parameter correlations of the basicity indices and the electronic parameters of the substituents have been published.[42,77,78] The satisfactory ($r$ = 0.993–0.999) correlations between the $pK_{BH^+}$ for the 5(6)-substituted benzimidazole in both one-parameter ($\sigma_m$, $\Sigma\sigma$) and two-parameter ($\sigma_I\sigma_R$, $\sigma_I\sigma_R^0$, $\mathcal{F}\mathcal{R}$) equations[23,77,78] are striking. This is evidence that the thermodynamic stabilities of the 5- and 6-tautomers are similar.

The percentage contribution of the resonance component to the overall transmission of electron effects from the 5(6)-position to the "pyridine" nitrogen atom has been calculated.[78] Regardless of the set of parameters employed ($\sigma_I\sigma_R^0$ or $\mathcal{F}\mathcal{R}$), the percentage of the resonance component is almost the same (37 ± 2% in the former case and 33 ± 2% in the latter). One should therefore consider the numerous instances of the satisfactory correlations between the acid–base properties of the same compounds and $\sigma_m$ constants.[23,41,75]

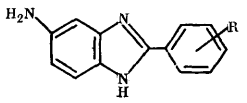


The $\sigma_m$ constant, the nature of which is complex, takes into account the inductive and resonance effects of the substituents with rigorously defined contributions by each. For example, according to Swain and Lupton,[40] the contribution of $\mathcal{R}$ to $\sigma_m$ is 22%. From the foregoing follows the important conclusion that, despite the satisfactory one-parameter correlations with $\sigma_m$ constants,[23,41,75] in the transmission of the effects of substituents in benzimidazoles from the 5(6)-position to the nitrogen atoms in the 1- and 3-positions, the contribution of the resonance component is different from that for the benzene series.[78] Admittedly, the set of substituents employed[38] does not meet the requirements of the "minimum set"[48,53] necessary for a sufficiently reliable separation of the effect into the inductive and resonance components and the above conclusions therefore require further tests on a larger series of compounds.

The acidities of benzimidazole derivative have been investigated.[78,80–87] Data have been published on the acidities of a series of 5(6)-substituted 2-phenyl- and 2-pyridyl-benzimidazoles together with the results of their correlation with the $\sigma_p$ constants.[80–82] The acidities of 4(7)-substituted 2-pyridylbenzimidazoles are correlated with the Taft $\sigma^*$ constants.[82]

The conductivities of certain bridging groups in benzimidazole systems have been studied.[83,84] 2-Arylbenzimidazoles (XVII), whose acidities have been measured potentiometrically, have been used as the standard series. The introduction of the –CH=CH– (XVIII), –S– (XIX), or –$CH_2$– (XX) bridge between the arylene and benzimidazole fragment weakens the electronic influence of the substituent approximately by a factor of two:

(XVII), $\rho_{st}$ = 1.25



(XVII), $\rho/\rho_{st}$ = 0.60
(XIX), $\rho/\rho_{st}$ = 0.46
(XX), $\rho/\rho_{st}$ = 0.46

The virtually identical conductivities of bridging groups of such different nature are surprising. Compounds of the (XVII)–(XX) series exhibit a spasmolytic activity and for this reason the electronic structures and the hydrophobic properties have been analysed within the framework of the partition coefficient model[88] in order to derive structure–activity relations.[85] It was found that the spasmolytic activity of these compounds is determined predominantly by their hydrophobic properties and is described by a parabolic relation with the hydrophobic constant taken from Leo et al.[88]

1-Methyl-5-R-benzimidazole-2-aldoximes exhibit acidity owing to the presence of the oxime group and their $pK_a$ depend linearly on $\sigma_m$ [86] The results of two-parameter correlations of the $\Delta pK_a$ for the 5-substituted benzimidazoles with the $\sigma_I \sigma_R^0$ constants ($r = 0.989$) and the Swain and Lupton parameters $\mathcal{F}\mathcal{R}$ ($r = 0.992$) have shown, as for the correlation of the $pK_{BH^+}$, that the percentage contribution of the resonance component is virtually identical regardless of the parameters selected.[78] On this basis, one may conclude that the substituent in the 5(6)-position influences both the acid and basic properties via a special mechanism, which differs from that characteristic of the benzene series. Naturally this conclusion requires additional tests on a wider series of compound.

The transmission factor $\gamma$ has been calculated for the series of 2-aryl-substituted 5(6)-aminobenzimidazoles (XXI) from the ionisation constants of the ammonium groups (the reaction state), from the stretching vibration frequencies $\nu$ of the amino-group (the ground state), and from the wavenumbers in the electronic absorption spectra (the excited state).[89]

(XXI)

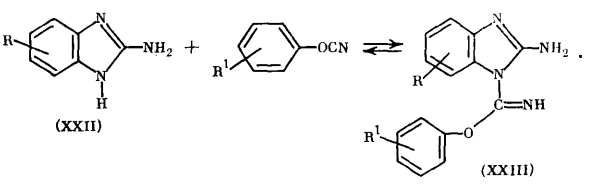
Analysis of the correlation of the above physicochemical quantities with the Hammett $\sigma$ constants led to the conclusion that the conductivity of the system (XXI) and the excited state is higher than that in the reaction of static states. However, this conclusion is doubtful, since quantities measured in terms of different scales were used in comparing the conductivites. It is noteworthy that, in order to explain the differences between the conductivities of the system (XXI) and the structurally analogous 5(6)-amino-2-(X-phenyl)-benzotriazoles,[89] the authors also used erroneous ideas, assuming that the electronic influences of the substituents in benzimidazoles are transmitted preferentially via the "imine" nitrogen atom.

It has been shown[90] for 2-substituted benzimidazoles that the intramolecular interaction between the substituent and the acidity centre is described quantitatively by the function $pK_a = f(\sigma_m)$ with a correlation coefficient of 0.998.

The differences between the conductivities with respect to the electronic effects of the substituents in the benzene and benzimidazole series were mentioned as early as 1966 in a study,[87] where a correlation was observed between the $pK_a$ for the 5- and 6-substituted benzimidazole and the "mixed" constants $\sigma = \frac{1}{2}(\sigma_m + \sigma_p)$ and $\sigma = \frac{1}{2}(\sigma_m + \sigma_o)$ for the 4- and 7-substituted derivatives.

The electronic influence of substituents and the chemical shifts of the protons of the *N*-methyl group in the $^1H$ NMR spectra of 5-substituted 2-chloro-1-methylbenzimidazoles have been studied.[91] The $^1H$ chemical shifts vary linearly with $\sigma_p$; in the case of solutions in deuteriochloroform the correlations are significantly between when the $\sigma_p^-$ constant is used for the $NO_2$ group, while for solutions in trifluoroacetic acid it is better to employ $\sigma_p$. This difference can be accounted for by the direct polar conjugation of the nitro-group with the indicator centre, while in trifluoroacetic acid the "pyridine" nitrogen atom is protonated.[91] It is of interest that a linear relation between $\delta[^1H(CH_3)]$ and $\sigma_m$ has not been observed for 6-substituted 2-chloro-1-methylbenzimidazoles.[91]

Two-parameter Jaffe and Dewar–Grisdale correlations have led to the hypothesis that the substituents in the 5-position in 1,3-dimethyl-2-benzimidazolones influence the vibration frequency of the carbonyl group and the chemical shifts of the protons in the methyl group mainly via the field effect.[92,93]



The kinetics of nucleophilic substitution in 2-chlorobenzimidazoles and their salts have been studied.[94–97] 5(6)-Substituted 2-chlorobenzimidazoles react with piperidine, the rate constants for this reaction depending linearly on the "mixed" $\sigma = \frac{1}{2}(\sigma_m + \sigma_p)$ constant.[94] The rate constants for the same reactions of 4(7)-derivatives of 2-chlorobenzimidazoles are correlated with $\frac{1}{2}(\sigma_m + \sigma_o)$.

The study of the kinetics of the substitution of chlorine by piperidine and the methoxide anion in 5- and 6-derivatives of 2-chloro-1-methylbenzimidazole,[95] where the Jaffe equation [Eqn.(4)] was fitted to the reaction rate constants, led the authors to the conclusion that the electronic spectra of the substituents are transmitted from the benzene ring to C(2) position mainly via the "pyridine" nitrogen atom, but the contribution of the "pyrrole" nitrogen atom to the transmission of the electronic influences is also considerable. As will be shown below, the authors lack adequate grounds for this conclusion.

An analogous study has been made for 4- and 7-derivatives of 2-chloro-1-methylbenzimidazole[96] and it was established that, together with the electronic factors, the reaction rate constants are influenced also by the steric effects of the substituents.

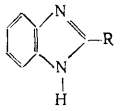
The rate constants for the nucleophilic substitution of chlorine in the perchlorates of 5-substituted 2-chloro-1,3-dimethylbenzimidazolium derivatives by thiophenol are correlated with the "mixed" $\sigma = \frac{1}{2}(\sigma_m + \sigma_p)$ constants.[97] The substitution of the chlorine atom in an acid medium in the perchlorates of 5- and 6-derivatives of 2-chloro-1-methylbenzimidazolium derivatives was investigated in the same study in their reactions with thiophenol. Statistical treatment of the results in terms of the Jaffe equation (4) led the authors to the conclusion that the effects of the substituents are transmitted from the benzene ring via the "pyrrole" nitrogen atom to the extent of 39.3%.[97] This conclusion cannot be regarded as sufficiently well-founded (see below). It is of interest to note that the $\sigma_p^-$ constant is used in these correlations for the $NO_2$ group in the 2-chloro-1-methyl-5-nitrobenzimidazolium cation, while in the correlations of the chemical shifts of the protons in the $N-CH_3$ group the $\sigma_p$ constants are employed[91] (see above). The kinetic measurements were performed in aqueous methanol and the $^1H$ NMR spectra were recorded in trifluoroacetic acid and the differences between the solvating capacities of these solvents in relation to the $-\overset{+}{N}H=$ group was in fact the reasons for the necessity to employ different $\sigma$ constants.

In the study of the kinetics of the addition of substituted 2-aminobenzimidazoles (XXII) to aryl isocyanates, it was observed that the rate constants for the consumption of compound (XXII) ($k_2^V$) and the formation of compound (XXIII) ($k_2^E$) vary linearly with the $\sigma$ constants of the substituents R [98] and that the best correlations are obtained when the $\sigma_p$ constants are used for electron-donating substituents and $\sigma_m$ constants for electron-accepting substituents.

(XXII) (XXIII)

The reaction mechanism proposed by the authors, which involves the formation of a six-membered transition state, is confirmed by the negative values of $\rho$ in the regression equations, indicating the acceleration of the reaction by electron-donating substituents:

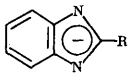
$$\lg k_2^V = -1.66\sigma + 2.07 \quad (r = 0.995),$$
$$\lg k_2^E = -1.22\sigma + 2.04 \quad (r = 0.999).$$



The $^{13}C$ NMR spectra of 5(6)-substituted benzimidazoles have been studied comparatively recently,[99] and it has been shown that the $\delta$[C(2)] are very satisfactorily correlated both with the $\sigma_p$ constants and the "naphthalene" constants $\sigma_6$. In the same study it was noted that the $\delta$[C(8)] vary linearly with the constants $\sigma_p$ and $\sigma_p^+$.

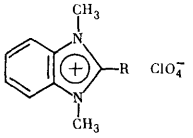
In order to infer the character of the transmission of the electronic influence of substituents in the opposite directions in benzimidazole derivatives, the correlation of the C[5(6)] chemical shifts in 2-substituted benzimidazoles and the C(2) shifts in their 5(6)-isomers was traced:[100–102]

$$\delta[C(5(6))] = (0.80 \pm 0.06)\delta[C(2)] + 8.19,$$
$$r = 0.981,\ S = 0.37,\ n = 7.$$



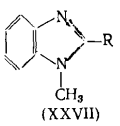
The high correlation coefficient in this equation indicates that the electronic effects of substituents in benzimidazole systems are transmitted in opposite directions via the same mechanism. However, the value of $\rho$ shows that the intensity of the transmission of the effects of substituents from the 2-position to the 5(6)-position is weaker by approximately 20% than in the opposite direction. This non-equivalence is apparently caused by the different environments of the C(2) and C[5(6)] atoms.

The transmission of the electronic influences of substituents in 2-substituted benzimidazoles (XXIV), their anions (XXV),[100,103] 2-substituted 1,3-dimethylbenzimidazolium perchlorates (XXVI),[104] 2-substituted 1-methylbenzimidazoles (XXVII),[105] and 2-substituted 5(6)-nitrogenzimidazoles (XXVIII)[101] has been investigated by $^1H$ and $^{13}C$ NMR:



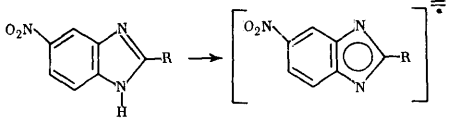
(XXIV)

R = $N(CH_3)_2$, $NH_2$, $OCH_3$, $CH_3$, $C_2H_5$, $SCH_3$, $C_6H_5$, H, Cl, $COOCH_3$, $COCH_3$, $CF_3$, $NO_2$



(XXV)

R = H, $CH_2OH$, Cl, $COOCH_3$, $COCH_3$, $C_3F_7$, $CF_3$, $NO_2$



(XXVI)

R = $N(CH_3)_2$, $NH_2$, $CH_3$, $C_2H_5$, $SCH_3$, $C_6H_5$, H, Cl, $COCH_3$, $CF_3$

(XXVII)

R = $NH_2$, $OC_2H_5$, $OCH_3$, $CH_3$, $C_2H_5$, H, Cl, $CF_3$, $COOCH_3$, $COCH_3$, CN, $SO_2CH_3$, $NO_2$

(XXVIII) (XXIX)

R = $N(CH_3)_2$, $NH_2$, $OCH_3$, $OC_2H_5$, $CH_3$, $C_2H_5$, H, Cl, $COCH_3$, $CF_3$, CN

In the above studies the chemical shifts of the protons and $^{13}C$ carbon nuclei of the benzimidazole ring were subjected to a regression analysis using two-parameter correlation equations and various sets of substituent constants ($\sigma_I\sigma_R$, $\sigma_I\sigma_R^0$, $\mathcal{FR}$, etc.) and it has been shown that the electronic influences of substituents are transmitted via the benzimidazole ring of the neutral molecule[100,101,105] and the cation[104] in accordance with the same mechanism. Under these conditions, the resonance mechanism plays a more important role in the transmission of the effects of substituents in the 4- and 7-positions in the benzimidazole ring in all the series investigated than in the 5- and 6-positions. The introduction into the correlation equation of a third semiempirical parameter Q, which takes into account magnetic shielding together with the electronic factors,[106] appreciably improves the correlation coefficients. Nevertheless, it is difficult to infer the contributions of a particular effect owing to the linear relation ($r > 0.9$) between the resonance and Q constants.[100,105] The attempts to replace $\sigma_I$ in correlation equations by the constant $\iota$ [107,108] resulted in the impairment of the correlation coefficients.[100,105]

It is of interest that, in contrast to the neutral molecules (XXIV), in the benzimidazole anions (XXV) the electronic effects of substituents are transmitted exclusively via the resonance mechanism.[100] It may be that this effect is associated with the presence of a delocalised negative charge on the molecule, which can increase the polarisability as a whole.

Attempts have been made with the aid of Eqn.(4) to establish the direction of the transmission of the electronic effects of substituents in certain condensed heterocyclic systems.[24,95–97,109,110] Formal analysis of the results of the two-parameter correlation of the $^{13}C$ NMR shifts of 2-substituted 1-methylbenzimidazoles (XXVII) in terms of Eqn.(4) led to the unexpected conclusion that the electronic effects of the substituents are transmitted from the 2-position to the 5-position mainly via the "pyrrole" nitrogen atom, while the transmission to the 6-position is via the "pyridine" nitrogen atom.[105] However, this conclusion is not reliable, because a linear relation between the parameters $\sigma_m$ and $\sigma_p$ is observed for the series of compounds investigated (with a partial correlation coefficient $r_{12} = 0.959$). According to Jaffe, $r_{12} < 0.9$ serves as a criterion of the applicability of Eqn.(4).[2] By varying the set of points, it is possible to reduce $r_{12}$ only to 0.896,[104] but this leads to a series of substituents which do not satisfy the "minimum set" requirements.[48,53] Thus, it is not possible to reach correct conclusions in terms of Eqn.(4) about the involvement of the "pyridine" and "pyrrole" nitrogen atoms in the transmission of the effects of substituents.

Unfortunately the partial correlation coefficients have not been analysed in the above investigations,[95–97,109] etc., where it was concluded on the basis of Eqn.(4) that the effects of substituents are predominantly transmitted via the "pyridine" nitrogen atom in benzazoles, although such partial coefficients are greater than 0.9, which throws doubt on the validity of the conclusions reached. However, these erroneous ideas have found their way into certain reviews[3] and monographs.[1] Thus the question of the role of a particular heteroatom in the transmission of the electronic influences of substituents remains open.

It is therefore useful to consider a study[111] in which data obtained by studying the transmission pathways of the electronic effects in benzothiazoles with the aid of Eqn.(4) have been analysed. It was shown that the use of this equation can lead to mutually exclusive results: ranging from the insulating influence of the sulphur atom in the transmission of electronic effects to its greater activity compared with the nitrogen atom. However, the relation between the arguments in Eqn.(4) is not analysed in the above study either and yet such analysis would throw light on the causes of the above contradiction. It is noteworthy

that the partial correlation coefficients for all the set of substituents employed by the authors of the communcations quoted by Attanasi et al.[111] are high and likewise preclude a reliable conclusion about the involvement of nitrogen or sulphur atoms in the transmission of the electronic effects of substituents.

In 2-substituted 1-methylbenzimidazoles (XXVII) the substituent is in the *ortho*-position relative to the N–$CH_3$ group. The simple Hammett equation is not applicable to the *ortho*-derivatives,[112] but Charton has shown that two-parameter correlation equations with the constants $\sigma_I$ and $\sigma_R$ in general describe satisfactorily the electronic effects of substituents for *ortho*-derivatives and an additional parameter taking into account the size of the substituent is necessary only in a few instances.[113] The results of the two-parameter correlation of the $\delta(NCH_3)$ in the series (XXVII) with different sets of substituent constants ($\sigma_I\sigma_R$, $\sigma_I\sigma_R^0$, $\iota\sigma_R$, $\mathcal{FR}$) show that the electronic influences of substituens are transmitted to the methyl group via the "pyrrole" nitrogen atom with approximately equal contributions by the inductive and resonance components.[105]

The electronic effects of substituents in the neutral molecules of 2-substituted 5(6)-nitrobenzimidazoles (XXVIII) and in their radical-dianions (XXIX), generated electrochemically, are transmitted to the nitrogen atoms of the nitro-group by the same mechanism according to $^{15}N$ NMR and EPR data with approximately equal contributions by the inductive and resonance components.[101]

In connection with the above data, it is of interest to compare the conductivities of the benzimidazole ring in 5(6)-nitrobenzimidazoles with the conductivities of the benzene ring in *para*- and *meta*-substituted nitrobenzenes. For this purpose, the results of the regression analysis of the $^{15}N$ chemical shifts of the nitro-group in the above compounds were compared.[101,114] Since Craik et al.[114] do not quote the contributions of the inductive and resonance components, an additional statistical treatment of the $\delta(^{15}N)$ for *para*- and *meta*-nitrobenzenes was carried out in terms of the two-parameter equation using the $\sigma_I\sigma_R$ and $\sigma_I\sigma_R^0$ constants. The results proved to be extremely unexpected. Regardless of the set of the inductive and resonance constants the electronic influences of the substituents in both the *para*- and *meta*-positions are transmitted to the nitrogen atom of the nitro-group with approximately the same contribution of the resonance component (approximately 20%). Thus the nitro-group is apparently more strongly conjugated with the benzimidazole fragment in compound (XXVIII) than with the benzene ring in the *para*- and *meta*-derivatives of nitrobenzene.

The electronic influence of substituents on the HFS constants of the protons in the 4-, 6-, and 7-positions in the radical-dianions (XXIX) is not exerted in the same way, their effects on the H(4) and H(7) HFS constants being exerted to a greater extent via the resonance mechanism regardless of the sets of the inductive and resonance parameters of the substituents employed.[101] It has been shown that allowance for the radical-stabilising factor $\sigma^{\cdot}$ [115] improves the correlation coefficients, while the contribution of $\sigma^{\cdot}$ to the transmission of the effects of substituents for H(6) and heterocyclic nitrogen atoms is ~30%.[101]

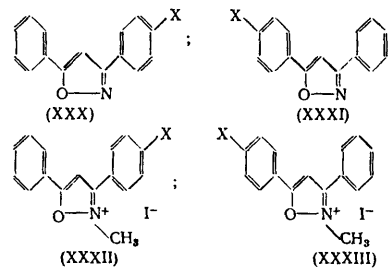
The $pK_a$ for the 2-substituted 5(6) nitrobenzimidazoles (XXVIII), determined by potentiometric titration, depend mainly on the inductive effects of the substituents.[116] The correlation analysis of the polarographic data for these compounds has shown that the influence of substituents on the $E'_{1/2}$ is exerted via both the inductive and resonance mechanisms with approximately equal contributions by each, while the effect on $E''_{1/2}$ is mainly via the resonance mechanism (85 ± 5%) regardless of the set of parameters of the substituents ($\sigma_I\sigma_R$, $\sigma_I\sigma_R^0$, $\sigma_I\sigma_R^+$, $\mathcal{FR}$). The quantities $E_{1/2}$ are in their turn satisfactorily correlated ($r = 0.987$) with the energies of the LUMO calculated theoretically.[116]

The results of two-parameter correlations of the dipole moments of 2-substitued 5(6)-nitrobenzimidazoles, calculated by the MINDO/3 method using various sets of parameters of the substituents, have shown that the inductive and resonance effects make approximately equal contributions to the overall influence of the substituent.[117,118]

## VI. AZOLES WITH TWO DIFFERENT HETEROATOMS

The acid ionisation of 2-substituted thiazole-4- and thiazole-5-carboxylic acids and the alkaline hydrolysis of their esters have been studied[119] and it has been noted that the $pK_a$ and the rate constants for the hydrolysis of 2-substituted thiazole-4-carboxylic acids are correlated with the $\sigma_m$ constants, while in the case of the 2-substituted thiazole-5-carboxylic acids the correlation is with the $\sigma_p$ constants. The acidities of 2-arylthioazole-4-carboxylic acids in aqueous ethanol solution with different alcohol contents were investigated later.[120] With increase of the content of ethanol in the system, the reaction constant increases somewhat, which can be accounted for by the increased planarity of the arylene and thiazole rings.

It has been noted that the enthalpy of ionisation of alkylthioazoles varies linearly with the constant $\sigma^*$.[121]



The basicities of 2- and 5-substituted thiazoles have been studied in greater detail by Forlani et al.[122] The authors used the $\sigma_m$ constants for the correlation and concluded that the substituent in the 2-position interacts with the nitrogen atom via the resonance and inductive mechanisms, with the latter predominating. The reaction constants for 2- and 5-substituted thiazoles ($\rho = -9.9$ and $-6.0$ respectively) are comparable to those for other nitrogen-containing heteroarylenes. It is of interest that 2-amino- and 2-dimethylaminothiazoles deviate from the overall correlation, which may be due to the fact that their protonation involves the endocyclic nitrogen atom. The influence of substituents on the acid–base properties of 2-aminothiazoles has also been studied in other investigations.[123,124] Since the reaction constants for two different series—5-substituted 2-amino and 2-dimethylamino-thiazoles—are similar, the authors concluded that the amine–imine tautomerism does not occur in 2-aminothiazoles.[124] The legitimacy of the use of the $\sigma_m$ constants in these series has been confirmed by the results of two-parameter correlations ($\rho_I/\rho_R \cong 0.5$), the endocyclic nitrogen atom proving to be the protonation centre.

The basicity constants of isoxazoles are also correlated with the $\sigma_m$ constants.[125] The dipole moments of 4-substituted 3,5-dimethylidoxazoles are also satisfactorily correlated with the $\sigma_m$ constants.[126]

The influence of substituents on the $^1H$, $^{13}C$, and $^{14}N$ chemical shifts for the substituted oxazoles has been studied[127] and linear relations have been observed between the corresponding $\delta(^{13}C)$ for 4,5-disubstituted oxazoles and the *ortho*-disubstituted benzenes. The possibility of calculating $\delta(^{13}C)$ from the three parameters $\Delta[C(2)]$, $\Delta[C(4)]$, and $\Delta[C(5)]$ characterising the contributions of substituents to the shielding of the C(2), C(4), and C(5) carbon atoms has been demonstrated.

The 3,5-diarylisoxazoles (XXX) and (XXXI) and their quaternary salts (XXXII) and (XXXIII) have been studied by $^1H$ [128–131] and $^{13}C$ [132,133] NMR. Both the one-parameter correlations of $\delta[H(4)]$, $\delta[C(4)]$, and $\delta[C(5)]$ with the $\sigma^+$ constants and the two-parameter correlations using $\sigma_I\sigma_R$ for neutral molecules[132] and $\sigma_I\sigma_R^*$ for quaternary salts[133]

proved to be excellent. It was shown that the sensitivity to the influence of substituents is smaller by a factor of three in the series (XXXIII) than in the series (XXXII) for both $\delta$[H(4)] and $\delta$[C(4)] [128,133] and that the mechanisms of the transmission of the electronic effects in these series is apparently unaltered. However, compared with the neutral molecules of compounds (XXX) and (XXXI), an increased sensitivity of $\delta$[C(4)] to the electronic influence of the substituent has been observed only in the series (XXXII).[133]

In a series of investigations Noyce and co-workers[134–136] studied the solvolysis of ring-substituted 1-thiazolylethyl chlorides.[134–136] The solvolysis rate constants for the substituted 1-(5-thiazolyl)ethyl chlorides are extremely satisfactorily correlated with the $\sigma_p^+$ constants.[134,135] On the basis of two-parameter correlations between the solvolysis rate constants and $\sigma_I\sigma_R$ or , the authors concluded that the resonance effects predominate over the inductive effects in the above reaction of substituted 1-(4-thiazolyl)-ethyl chlorides.[136]

Nucleophilic substitution in 2-chlorothiazoles has been studied.[137–139] The rate constants for the substitution of chlorine in 4- and 5-substituted 2-chlorothiazoles on treatment with thiophenol in acid and alkaline media are correlated with the Hammett $\sigma$ constants,[137,138] the $\sigma_m$ and $\sigma_p$ constants corresponding to the substituent in the 4- and 5-positions respectively. In an acid medium, the rate-determining stage of the reaction is protonation of the thiazole ring.[138] Somewhat later the interaction of 4-substituted 2-chlorothiazoles with the methoxide and thiophenoxide anions was investigated, using $\sigma$ constants, as in previous studies.[139]

The polarographic reduction of 2-amino-4-aryl-5-phenylisothiazoles has been investigated.[140] The substitutents in the phenylene fragment influence the polarographically active azo-group via the thiazole ring, although the absolute value of the reaction constant is low (0.12). In the polarographic reduction of 4-arylisoxazoles, the half-wave potentials are correlated with the $\sigma$ constants of the substituents in the aryl fragment.[141,142]

The study of the influence of substituents on the reaction constants and the physicochemical characteristic of condensed azoles with two different heteroatoms has involved mainly benzothiazole and benzoxazole derivatives. The ionisation constants of 5- and 6-substituted benzothiazolecarboxylic acids[143] and benzoisoxazole-3-carboxylic acid[144] are correlated with the Hammett $\sigma$ constants. The $\sigma_m$ and $\sigma_p$ constants correspond respectively to the substituents in the 5- and 6-positions.[143,144] From this, the authors[143] concluded that the sulphur atom has an insulating effect; the electronic influences of the substituents are transmitted from the benzene ring to the 2-position mainly via the nitrogen atom.

The dissociation constants of 2-benzoxazolines in 2-benzoxazolinethiones have been measured in solution in aqueous acetone.[145] The correlation of the $pK_a$ based on the Hammett and Jaffe equations led to the conclusions that the the compounds exist in the benzoxazoline and the benzoxazolinethione forms and not in the lactim and thiolactim forms respectively.

The basicities of 2-aryl-substituted benzoxazoles and benzothiazoles have been measured in acetonitrile[47] and it has been shown that the basicity constants of the above compounds are correlated best with the $\sigma^+$ constants, while for the corresponding imidazoles and benzimidazoles the best correlation is observed with the $\sigma$ constants.[47] The conductivities with respect to the electronic effects in 2-arylbenzoxazoles and 2-arylbenzothiazoles have been compared with those in 2-arylimidazoles and 2-arylbenzimidazoles on the basis of two-parameter correlation equations. The transmission of the resonance effects of substituents in the aryl fragment to the imidazole and benzimidazole rings is more intense than the transmission of the influences to the oxazole and thiazole rings, which can be accounted for, according to the authors, by the smaller involvement of the oxygen and sulphur atoms in the conduction of the effects of substituents.[47]

The basicities of a series of carbocyanine dyes based on benzothiazoles have been measured and a satisfactory correlation between the basicity constants and the $\sigma_p$ constants has been demonstrated.[146,147] The influence of substituents in the polymethine chain on the absorption spectra of such dyes has been studied with the aid of two-parameter correlations, which led to the observation that the effects of substituents are transmitted mainly via a resonance mechanism.[148,149]

The relation between the $^1H$ or $^{13}C$ chemical shifts and the electronic effects of substituents in various benzoazoles has been studied in a number of investigations.[150–154] The relation between $\delta[^1H(2)]$ and the effects of substituents in benzothiazoles in positions ranging from 4 to 7 was first reported by Taddei et al.[150] Later a linear relation was observed between the chemical shifts of the protons in the methyl group in the 5- and 6-positions in 2-methylbenzothiazoles, 2-methylbenzoxazoles, and 2-methylbenzoselenazoles and the $\sigma$ constants.[151,152] The influence of substituents in benzothiazoles was studied in greater details in two investigations.[153,154] It was shown that the C(4) and C(5) chemical shifts in 2-substituted benzothiazoles are linearly related to the $\sigma_p$ constants ($r$ = 0.9945 and 0.9862 respectively).[153] Three-parameter correlation equations relating $\delta(^{13}C)$ and the parameters $\mathcal{F}$, $\mathcal{R}$, and $\mathcal{Q}$ are quoted in the same communication. Unfortunately these results do not allow the separate estimation of the influences of the inductive and resonance components on the chemical shifts, since $\mathcal{R}$ and $\mathcal{Q}$ are linearly related and the results of two-parameter correlations are not presented. It has been established with the aid of the Jaffe equation (4) [154] that the electronic effects of substituents are transmitted to the benzene and thiazole ring mainly via the nitrogen atom. Shegal et al.[154] arrived at an analogous conclusion. Since the partial correlation coefficients between the arguments are not quoted in the above studies, this conclusion requires additional confirmation. It has also been observed[154] that the intensity of the transmission of the electronic effects of substituents from the 2-position to the 6-position in the benzothiazole ring is weaker by 1/3 than in the opposite direction.

The frequencies of the symmetrical and antisymmetrical stretching vibrations of the amino-group have been measured for twelve 6-substituted 2-aminobenzothiazoles.[156] Having interpreted the results in terms of Eqn.(4) the authors also concluded that the electronic effects of substituents are transmitted to the amino-group preferentially via the nitrogen atom. The transmission factor for benzothiazole, which

is in the range 0.33–0.37, indicating a weaker transmission of the effects of substituents by the benzothiazole ring compared than by the phenylene ring, was determined in the same study.

The investigation of the IR spectra of 2-subsituted benzothiazoles showed that the intensity of the C=N stretching vibrations is linearly related to $(\sigma_R^0)^2$.[157]

A linear relation has been observed between the two-electron reduction potentials of 2-aminobenzothiazoles in the presence of various metal ions and the sum of the Hammett constants.[158] The positive value of $\rho$ indicates a nucleophilic mechanism of the electrochemical reaction. The authors believe that the $\diagdown$C=NH double bond of the imino-tautomer is reduced, although it is known that 2-aminobenzothiazoles exist in the amino-form.[159,160]

Nucleophilic substitution in 4–7-substituted 2-halogenobenzothiazoles has been studied.[109,161–165] The rate constants for the nucleophilic substitution of the halogen by sodium methoxide or piperidine in 5- and 6-substituted 2-halogenobenzothiazoles are correlated with the usual Hammett $\sigma$ constants.[109,161] On the other hand, special $\sigma_4$ constants were introduced for 4-substituted 2-halogenobenzothiazoles and were subsequently employed for the correlation of the rate constants for the oxidation of 4-substituted 2-mercaptomethylbenzothiazoles.[162] The rate constants for the hydrolysis of 2-aryl-6-isothiocyanatobenzothiazoles are linearly related to the $\sigma$ constants of the substituents.[166] The reaction constant for this series ($\rho$ = 0.50) is virtually identical with the reaction constant ($\rho$ = 1.51) determined for the addition of glycine to 2-aryl-6-isothiocyanatobenzothiazoles.[166] The half-wave potentials for the reduction of these compounds also depend on the $\sigma$ constants.[167]

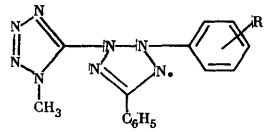
The base-catalysed hydrogen exchange in the 2-position in benzazoles has been studied in a series of investigations.[111,168,169] The rate constants for the proton exchange are satisfactorily correlated with Hammett $\sigma$ constants,[168] while in the case of 6-substituted derivatives it is necessary to employ two-parameter correlations based on the Jaffe equation.[111] The earlier studies,[109,165] in which it was claimed that the electronic effects of substituents in benzothiazoles are transmitted from the phenylene ring to the 2-position exclusively via the "aza" group were examined critically in two investigations.[111,169] Attanasi et al.[111] acknowledged the appreciable role of the sulphur atom in the transmission of the electronic effects of substituents, but their conclusions are based on the results involving the use of the two-parameter Jaffe equation (4) without the analysis of the correlations between the arguments (see above).

## VII. AZOLES WITH THREE AND MORE HETEROATOMS

A detailed analysis of the transmission of the influences of substituents in the series of 1,2,4-triazoles has been carried out in a study[170] where the concept of the limited applicability of one-parameter correlation equations to heterocyclic compounds was developed. Data published previously[171,172] on the quantitative allowance for the influence of substituents in the triazole ring on the physicochemical properties and reaction rates were treated in terms of the two-parameters equation using the $\sigma_I$ and $\sigma_R$ constants. The results show that the inductive effects predominate over the resonance effects.[170] However, it is extremely difficult to make correct estimates owing to the lack of knowledge about the absolute errors in the coefficients of the arguments.

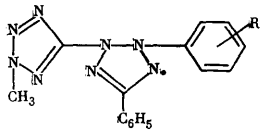
The acidities of C-substituted 1,2,4-triazoles have been studied in relation to five different series[170,172–174] in which the influence of substituents on the acidity constants was taken into account mainly in terms of the inductive mechanism. However, the resonance influence of the substituent cannot be neglected either except in those cases where the system ceases to be aromatic.[170,174]

The data on the correlations of the acid–base properties of substituted tetrazoles and the electronic parameters of the the substituents published after 1978 have been described in a series of studies[43,175–183] and have been surveyed in a review.[184] On the basis of the effective correlations of the $pK_a$ for several series of 5-substituted tetrazoles and various $\sigma$ constants, the authors[177,178] concluded that the compounds indicated exist in a single tautomeric form (1-H). The correlations of the $pK_{BH^+}$ and the $\sigma$ constants for a different series of tetrazole derivatives, taking into account the correlation of the charge density on the nitrogen atoms and the $\sigma_p$ constants,[180] established that the tetrazole ring is protonated at the nitrogen atom in the 4-position.[176,181–183] These investigations were continuned in subsequent years in relation to aryltetrazoles and tetrazolylacetic acid.[185–187] Excellent correlations have been found between their $\Delta pK_a$ and the Swain and Lupton parameters for both *meta*- and *para*-derivatives.[185] The $pK_{BH^+}$–$\sigma$ correlations observed[186] confirmed the earlier hypothesis concerning the protonation centre of the tetrazole ring.



It has been shown for 5-R-tetrazoles that the influence of substituents on the acidity and basicity of these compounds is manifested in the same way; a satisfactory linear relation has been observed between their $pK_a$ and $pK_{BH^+}$,[188] which permits a quantitative estimation of the acid–base properties of 5-substituted tetrazoles.

The influence of substituents on the position of the long-wavelength maximum in the electronic spectra of 1-methyl-3-nitro- and 1-methyl-5-nitro-1,2,4-triazoles.[170,189] The electronic and infrared spectra of 5-aryltetrazoles have been investigated by a group of Polish workers,[190,191] who correlated different frequencies in the spectra of these compounds with the $\sigma$ constants, but the correlation coefficients obtained are as a rule low.



The chemical shifts of the protons in the $^1H$ NMR spectra of 3(5)-substituted 1,2,4-triazoles are linearly related to the $\sigma_p$ constants.[192] It was demonstrated later that the correlations of the inductive and resonance components to the overall transmission of the effects of substituents are approximately the same.[170] Attempts have been made to estimate the influence of substituents on the chemical shifts of the protons in the methyl group in 3-substituted 1-methyl-5-nitrotriazoles,[173,193] but the correct analysis of these relations was complicated by the powerful shielding effects. The influence of substituents in the benzene ring on the H(5) chemical shifts in 4(5)-aryl-1,2,3-triazoles and 1-amino-4-aryl-1,2,3-triazoles has been studied.[194] It is noteworthy that the reaction constants for the above series of compounds are virtually identical (0.35 and 0.36 respectively). What is in essence the converse problem has been solved in a study[195] where the influence of the tetrazolyl group on the chemical shifts of the protons in the phenylene ring was investigated and the Swain and Lupton constants were calculated for the 5-tetrazolyl fragment.

A linear dependence of the spin–spin coupling constants $j'$[C(5)H] and the $\delta$[C(5)] chemical shift for the 1-substituted tetrazoles on the $\sigma_I$ constants has been observed by $^1H$ and $^{13}C$ NMR.[196]

The satisfactory correlations between the nitrogen HFS constants in the EPR spectra of the radicals (XXXIV) and (XXXV) indicate that the variation of the parameters of the isotropic HFS by the N(3) atom is determined by the electronic influence of the substituents, while the geometry of the radicals does not change significantly.[197]

(XXXIV)

(XXXV)

The influence of the solvent on the transmission of the electronic effects of substituents in *para*-substituted 4-aryl-1,2,4-selenodiazoles has been investigated with the aid of the Swain and Lupton parameters.[198] It was then shown by $^1$H NMR that the nature of the solvent does not have a significant influence on the ratio of the contributions of the inductive and resonance components in the overall transmission of the substituent effects.

The ionisation potentials of 3,5-diphenyl-1,2,4-oxadiazoles substituted in the 3- or 5-phenyl rings are linearly related to the $\sigma^+$ constants.[199] In later studies, the authors showed that only the intensity of the peaks due to the aroyl ions in the mass spectra of 5-amino-3-aroyl-1,2,4-oxadiazoles is correlated with the $\sigma^+$ constants albeit with a low correlation coefficients.[200]

In relation to the nucleophilic substitution of the nitro-group in 3-substituted 1-methyl-5-nitro-1,2,4-oxadiazoles 5-substituted 1-methyl-3-nitro-1,2-triazoles, it has been observed that the intensity of the transmission of conjugation effects from the 5- to the 3-position is approximately three times greater than in the opposite direction, while the inductive influence of substituents is transmitted to virtually identical extents in both directions.[170,201]

Alkylation of substituted 5-aryltetrazoles and their potassium salts by dimethyl sulphate[202,203] or ethyl bromoacetate[204] showed that the ratio of the 1- and 2-isomers in the reaction product is correlated with the $\sigma$ constants of the substituents in the benzene ring. Electron-accepting substituents inhibit the reaction and increase the fraction of the 2-isomer. An analogous behaviour has been observed in the alkylation of 5-aryltetrazoles by methyl iodide under the conditions of phase-transfer catalysis.[205] However, similar correlations have not been observed in the alkylation by dimethyl sulphate in a two-phase system. These data led to the conclusion that the alkylation of tetrazoles by methyl iodide takes place in the organic phase, while the alkylation by dimethyl sulphate takes place in both the organic and aqueous phases.

The rate constants for the substitution of the hydrogen in the methyl group by deuterium in 5-methyl-1-(R-phenol)-tetrazoles are correlated with the substituent constants $\sigma^0$ ($\rho = 3.0$).[206,207]

The half-wave potentials for the reduction of 1-amino-4-(X-aryl)-1,2,3-triazoles, 1-H-4-(X-aryl)-1,2,3-triazoles,[208] and 1-(X-aryl)-5-mercaptotetrazoles[209] are correlated with the $\sigma$ constants.

Much less information is available about the transmision of the effects of substituents in condensed azoles with three heteroatoms. It has been shown that the $pK_a$ for benzotriazoles are correlated with the Hammett $\sigma$ constants.[23] The half-wave potentials for the reduction of 1-aryl-2-aryl-5-isothiocyanatobenzotriazoles are also linearly related to the $\sigma$ constants, the 2-substituted isomers being reduced more readily and their reaction constants being lower.[167]

Benzothio- and benzoseleno-diazoles have been investigated thoroughly.[210] An approximate correlation has been obtained for these compounds between the positions of the maxima in the electronic absorption spectra and the $\sigma$ constants. Their electrochemical reduction potentials are also correlated with these constants. The replacement of selenium by sulphur increases somewhat the influence of the substituent and the authors believe that the inductive effect plays a decisive role. The intensity of the influence of the substituent is almost independent of its position in the molecule.[210]

The rate constants for the thermal decomposition of benzo-1,2,3-thiadiazole-1,1-diozide, containing substituents in the aromatic ring, are linearly related to the $\sigma$ constants.[211] The attempt by the above authors to estimate the direction of transmission of the effects of substituents with the aid of the Jaffe equation cannot be regarded as successful, in our view, because the relation between the arguments was not analysed.

---o0o---

The studies quoted in this review are not equivalent as regards their importance. Some of them have been carried out for a series of compounds with a limited set of substituents which we believe reduces the reliability of the results and sometimes leads to clearly erroneous conclusions, as happened, for example, in the study of Rabiger and Joullie.[76] On the other hand, an inadequate statistical treatment can also result in unjustified conclusions.[95,97,111,157,165,212]

In many cases it has been possible to apply the Hammett equation in its original form to various heterocycles. However, arbitrarily selected constants ($\sigma_m$, $\sigma_p$, $\sigma^0$, $\sigma^+$, $\sigma^-$, etc.) were then used without any justification. In other investigations, several different types of constants were compared and the authors inferred their applicability to a specific type of heterocycles on the basis of the correlation coefficient. However, in all cases it is implied that the relative contributions of the inductive and resonance mechanisms to the overall effect of the substituent on the reaction or indicator centre is the same as in benzene derivatives. Where it was not possible to select the type of constants for the benzene series for a quantitative description of the process, special sets of $\sigma$ constants characteristic of the given type of heterocycles only were introduced.[50,162,213] This procedure, involving the specification of a new set of $\sigma$ parameters for each type of heterocycle and for each relative disposition of the substituents and the reaction centre, rules out the possibility of comparing the reactivies of different classes of compounds, is extremely laborious, and vitiates the practical significance of such correlations.

The approach which takes into account separately the influence of the inductive and resonance effects of substituents on the reaction centre with the aid of many-parameter equations is more promising. It has made it possible to discover the specific features of the transmission of the electronic influences of substituents via the benzothiazole,[154] 1,2,4-triazole,[170] and benzimidazole [100-104,214,215] rings.

# The Present State of the Problem of Silicenium Ions

V.D.Nefedov, T.A.Kochina, and E.N.Sinotova

The present state of the problem of the existence and chemical behaviour of silicenium ions in the gas and condensed phases is examined and the principles of a new (nuclear-chemical) method for the generation of free silicenium ions, its characteristic features, and its advantages are described.
The bibliography includes 144 references.

## I. INTRODUCTION

The question of the possibility of the existence and the properties, reactivity, and role in the corresponding chemical processes of the silicon, germanium, and other analogues of carbenium ions is one of the most interesting in modern chemistry. The problem of the preparation and investigation of the properties of the silicon analogues of such ions is the most urgent at the present time.

Since silicon is less electronegative than carbon (their electronegativities are 1.8 and 2.6 respectively[1]), it was to be expected that silicenium ions would be formed at least as readily as carbenium ions and this is indeed the case in the gas phase.[1,2] The results of mass-spectrometric studies indicate the preferred formation, on energy grounds, of silicenium ions compared with carbenium ions.[2-4] However, many attempts to obtain silicenium ions in solution failed.[5-7]

Before proceeding to the consideration of various aspects of the problem of silicenium ions, it is essential to note that, apart from the great similarity in the chemical behaviour of silicon and carbon compounds, there exist also differences which can be accounted for in the first place by the presence of unoccupied $d$ orbitals in silicon. The results of numerous investigations have shown that in its chemical behaviour silicon tends to expand its coordination (there is a transition from the $sp^3$ state to the $sp^3d$ or $sp^3d^2$ state) and not to contract it, as happens in the case of carbon (transitions from the $sp^3$ state to the $sp^2$ and $sp$ states).

It was believed for a long time that, in contrast to carbon, silicon is incapable of forming multiple $p_\pi-p_\pi$ bonds. However, since 1967 communications began to be published[8-10] in which the formation of unstable silicon compounds with Si=Si bonds was reported. In 1981-82 the first stable compounds with Si=C and Si=Si bonds were obtained.[11-13] In addition the $p_\pi-d_\pi$ bond, which is unknown for carbon, exists in silicon compounds.[14,15] It arises as a result of a shift of the $\pi$ electrons in a neighbouring X atom (where X is a halogen, an aryl group, oxygen, nitrogen, etc.) to the unoccupied $d$ orbitals of silicon. As a result of such $p_\pi-d_\pi$ bonding, the Si-X bond has a partial double bond character. The smaller length of the Si-X bond compared with the value calculated from the covalent radii, the widening of the valence angle in excess of the usual tetrahedral value, the reduction of the electron-donating capacity of the X atom on formation of a hydrogen bond, etc. are usually regarded as evidence for the $p_\pi-d_\pi$ interaction.[15]

Two aspects must be distinguished in the study of the problem of silicenium ions. The first concerns the possibility of the existence of silicenium ions in crystals and solutions as independent species. The second aspect involves the possibility of the appearance and existence of these ions as intermediate species. The problem of silicenium ions will in fact be considered below in terms of these two main features.

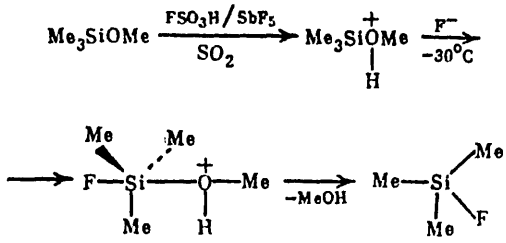
## II. SILICENIUM IONS IN CONDENSED PHASES

### 1. Silicenium Ions as Independent Species in Solutions and Crystals

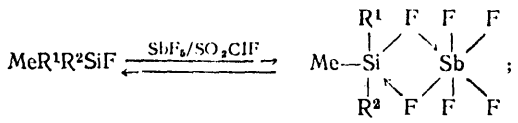
When attempts were made to demonstrate the existence of silicenium ions, organosilicon compounds which should have given rise to the corresponding ions under suitable conditions, by analogy with carbon compounds, were considered in the first place. Many investigators tried to show that the silicenium ion $Ph_3Si^+$, analogous to the stable ion $Ph_3C^+$, can exist. However, it has been demonstrated by a conductimetric method that there is no appreciable ionisation of $Ph_3SiCl$ in pyridine, in a mixture of nitrobenzene with $AlBr_3$, or in liquid sulphur dioxide, although it is well known that all these solvents induce the ionisation of $Ph_3CCl$:[16]

$$Ph_3CCl \rightarrow Ph_3C^+ + Cl^-.$$

Another attempt consisted in the study of the properties of the silicon analogue of chlorotris(*p*-dimethylaminophenyl)-methane, which is an ionic compound. It was established by means of a number of methods (conductimetry, IR and UV spectroscopy, and X-ray diffraction) that



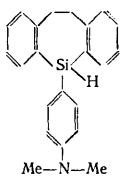
is a covalent compound.[17,18]



A number of studies were designed to compare and investigate the properties of silicon perchlorates.[19,20] It was demonstrated that the silicon perchlorates $R_3SiClO_4$ (where R = Me, Et, n-Pr, *p*-$MeC_6H_4$, or Ph) have a covalent structure, in contrast to the intensely coloured triarylmethyl perchlorates.

An attempt has been made[21,22] to obtain classical silicenium ions in the $FSO_3H/SbF_5/SO_2$ superacids whose nucleophilic properties are extremely weak. In this medium secondary and tertiary carbenium ions are stable and can be generated from organic compounds of different classes. The behaviour of alkoxysilanes and siloxanes in the above medium was studied at a low temperature by NMR and it was shown that

the oxygen atom is protonated, this being followed by a substitution reaction which leads to fluorosilane. $R_3Si^+$ ions were not detected. The formation of fluorosilanes can be accounted for by the appearance of a pentacovalent intermediate:



The behaviour of the fluorosilanes $Me_3SiF$ in the $SbF_5/SO_2$. .ClF medium, in which stable carbenium ions can be detected, has also been studied.[23] However, in this case too the silicenium ions $R_3Si^+$ were not detected as independent species. The authors suggested that an involved complex having the following structure may be formed:[23]

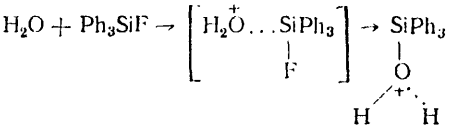
$R^1 = R^2 = Me$; $R^1 = Me$, $R^2 = F$; $R^1 = R^2 = F$.

Corey and co-workers[24,25] reported the synthesis of silicenium ions from a compound which they synthesised, i.e.

by abstracting a hydride ion from the latter. However, later these results were disproved.[26,27]

The cause of the failure of the above investigations has apparently been the fact that the authors began with the hypothesis that there is a complete analogy between the properties of carbon and silicon, which is not always justified. For example, it is known that carbenium ions are readily stabilised as a result of the resonance $2p-2p$ transition between the carbenium atom and the ligand atoms linked to it. However, a simple interaction is much weaker in silicenium ions, where the silicon atom is linked to the elements of the Second Period (a resonance $2p-3p$ transition).[28] Calculations have shown that a more effective stabilisation can be achieved as a result of the resonance $3p-3p$ interaction in structures of the type $(RX)_3Si^+$ or $(R_2X)_3Si^+$, where X = S, P, or elements of the Third Period.[29,30] These ideas have been confirmed experimentally by Lambert and Schultz,[31] who attempted to obtain substituted silicenium ions by abstracting a hydride ion from tris(2-propylthio)silane in accordance with the mechanism

$$(iso\text{-}PrS)_3SiH + Ph_3C^+ClO_4^- \rightarrow Ph_3CH + (iso\text{-}PrS)_3Si^+ClO_4^-.$$

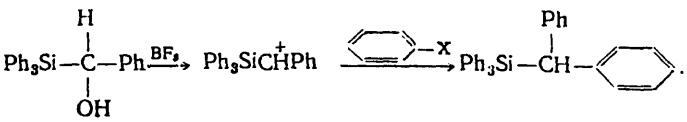


These investigations (conductrimetry, IR and UV spectroscopy, and NMR) led to results which agreed with the hypothesis of the formation of silicenium ions in this reaction.

The set of studies examined, including the last, indicate the lack of a final solution of the problem concerning the possibility of the existence of silicenium ions as independent species and the necessity for its further investigation.

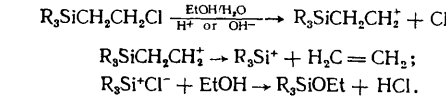
## 2. Silicenium Ions as Intermediate Species in Reactions of Organosilicon Compounds

Apart from the existence of silicenium ions as independent species, their involvement as intermediates in reactions has been frequently postulated. One of the first experiments designed to demonstrate the possibility of the formation of silicenium ions as reaction intermediates has been a kinetic study of the solvolysis of fluorotriphenylsilane.[32] The authors of this investigation observed a marked dependence of the rate of reaction on the nucleophilic properties of the medium. Thus $Ph_3SiF$ reacts ten times faster in the presence of $OH^-$ ions than in a neutral medium (acetone–water), while the rate of hydrolysis of $Ph_3CF$, which is the carbon analogue of the above compound, is independent of the pH of the medium. In addition, *p*-methyl substituents, introduced into fluorotriphenylsilane, decreased the rate of reaction by a factor of five, while their introduction into fluorotriphenylmethane increased the rate of reaction. This shows that a positive charge does not arise on the silicon atom in the transition state.

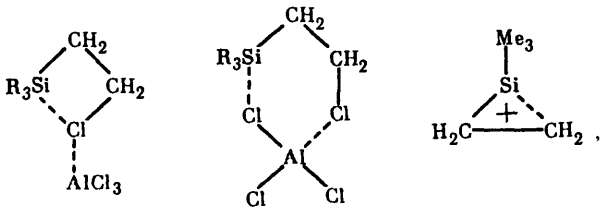


Bearing in mind the foregoing, Swain et al.[32] put forward a mechanism involving the formation of an intermediate pentacovalent silicon complex:

The rearrangement of organosilicon compounds with functional α-groups under the influence of Lewis acids is of interest from the standpoint of the possibility of the formation of silicenium ions as intermediates.[33–35] One of the proposed mechanisms is the Wagner–Meerwein mechanism:



The formation of stable silicon-containing carbenium ions has indeed been demonstrated for these reactions both by direct observation and with the aid of the Friedel–Crafts reaction:[34]



On the other hand, silicenium ions were never detected in these systems.

The hydrolysis of β-halogenoalkylsilanes has been investigated[36] and an ionic mechanism has been proposed for the reaction:

However, in this case too the formation of silicenium ions was not confirmed. The ionic mechanism has been criticised.[37,38] Other explanations of the formation of the observed products were based on the hypothesis that the reaction proceeds via a mechanism involving the appearance of complexes incorporating four-membered (A) or six-membered (B) rings[33] or via a stage in which a non-classical carbenium ion (C) is formed:[38]

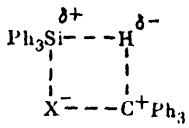
(A) (B) (C)

The formation of the latter has been confirmed by the fact that the reactivity of compounds with functional β-groups is much higher than might have been expected as a consequence of the inductive effect of the $Me_3SiCH_2$ group.[39] This means that the C–X bond is cleaved under the influence of precisely the $R_3Si$ group, in agreement with the structure of the non-classical carbenium ion.[38] Despite this, one cannot rule out the possibility that the above rearrangement proceeds via a mechanism involving the formation of silicenium ions, because such ions have been detected in a similar rearrangement in the gas phase.[40]

An ionic mechanism has also been proposed for the disproportionation of halogenosilanes under the influence of Lewis acids:[41–43]

$$R_2SiHCl + AlCl_3 \rightarrow [R_2SiH]^+ + [AlCl_4]^-;$$
$$R_2SiHCl + [R_2SiH]^+[AlCl_4]^- \rightarrow R_2SiH_2 + [R_2SiCl]^+[AlCl_4]^-;$$
$$[R_2SiCl]^+ + [AlCl_4]^- \rightarrow R_2SiCl_2 + AlCl_3.$$

However, no evidence in support of the proposed mechanism was obtained in this case either.



Reactions accompanied by racemisation are of special interest in the study of the possibility of the appearance of silicenium ions as intermediates. In the case of carbon compounds racemisation as a rule indicates the formation of a carbenium ion with the $sp^2$ structure as an intermediate form. However, the reactions are highly stereospecific for silicon compounds (>95%). Even in the presence of substituents such as aryl, vinyl, and allyl[44] a high stereospecificity was observed, indicating the absence of silicenium ions with the classical structure in the reactions of organosilicon compounds. In contrast to this, the analogous carbon compounds racemise very rapidly under solvolysis conditions as a result of the formation of the corresponding carbenium ions. However, one should note that in many cases optically active halogenosilanes do racemise.[45–54]

We shall consider the racemisation of halogenosilanes induced by certain solvents.[48,49] Conductrimetric measurements indicate the absence of any appreciable ionisation. The hypothesis of the formation of an ion pair has been put forward as an explanation, but it proved inconsistent with the absence of conductivity in the reaction medium. Further investigations showed that, among solvents capable of inducing the racemisation of chlorosilanes, there are some with a low dielectric constant, for example ethers ($\varepsilon < 15$), and also polar aprotic solvents.[54] The latter are especially interesting because they behave as effective ligands for elements with unoccupied *d* orbitals, since they form coordinate bonds readily. Analogous results have been obtained for optically active germanium compounds.[55,56] It has been suggested that the racemisation proceeds via a mechanism involving the formation of penta- and hexacoordinate intermediate silicon compounds. This hypothesis has been confirmed by the finding that bulky substituents at the silicon atoms retard the racemisation. The rate of racemisation involving the formation of the $R_3Si^+$ cation should have increased with increasing bulk of the substituents. This has been explained by the fact that, with increase of the bulk of substituents, their mutual repulsion should also increase, which facilitates the formation of the $R_3Si^+$ cation and hinders the formation of penta- and hexacoordinate intermediate compounds.

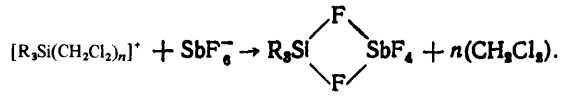
In order to demonstrate the possibility of the formation of silicenium ions as intermediate species, the hydride transfer reaction has also been investigated.[57–59] The ability of carbenium ions to act as acceptors of hydride ions was used for this purpose.[60] Formally, when a hydride ion is abstracted from silane by a carbenium ion, a silicenium ion, which is an analogue of the carbenium ion, should be formally produced:

$$Ph_3C^+ + HSiR_3 \rightarrow Ph_3CH + R_3Si^+.$$

However, the appearance of silicenium ions has not been demonstrated for numerous silanes.[57–59,60] On this basis, a mechanism postulating the formation of a complex with a four-membered ring has been proposed for the hydride transfer reactions:[61]

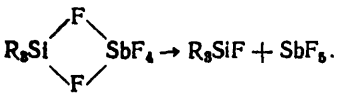
Reactions of this type include the hydrogenation of olefins or the hydrogenolysis of alcohols by silanes in an acid medium.[62,63] Like those examined above, these reactions proceed via the formation of carbenium ions, which then abstract a hydride ion from the silane. However, the formation of silicenium ions in these reactions was also not demonstrated. The absence of silicenium ions as kinetically independent species can apparently be accounted for by the presence in the silicon atom of occupied *d* orbitals, which are responsible for the tendency of organosilicon compounds, including silanes,[64] to associate with nucleophiles with expansion of the outer electron shell.[1]

However, in a study of the kinetics of the hydride transfer from a silane to a carbenium ion in the reaction



it has been observed[65] that the rate of appearance of the silane $R_3SiH$ is higher than the rate of formation of the fluorosilane $R_3SiF$, which conflicts with the four-centre synchronous mechanism. In addition, it had been shown earlier that the stereochemical course of the reaction depends on the solvent.[58] This shows that the four-centre mechanism may not be the only one possible and does not rule out the possibility of the formation of an intermediate in which the positive charge is localised on the silicon atom.[66] It has been suggested[65] that the reaction proceeds with participation of silicenium ions and involves at least three stages.

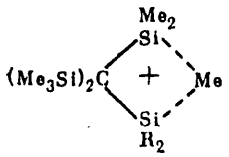
The first stage is the hydride transfer leading to the formation of a positively charged silicon intermediate:



$$Ph_3C^+ + HSiR_3 \xrightarrow{n(CH_2Cl_2)} Ph_3CH + [R_3Si(CH_2Cl_2)_n]^+.$$

The second stage involves the formation of an uncharged

intermediate:



The third stage involves the decomposition of the uncharged intermediate with formation of the final products:

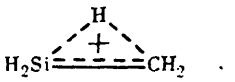
The reactions of organosilicon compounds containing the bulky tris(trimethylsilyl)methyl groups $(Me_3Si)_3C$ have been investigated.[67-70] The presence of these groups gives rise to steric hindrance in the nucleophilic attack on the silicon atom and hence makes it possible to observe reactions of an unusual type.

Thus, when the organosilicon iodides $(Me_3Si)_3CSiR_2I$ react with silver and mercury salts and also with halogens in methanol, the bridged silicenium cation (I)

(I)

is formed according to the authors.[67-70] The cation can also be attacked by nucleophiles, which is accompanied by the formation of rearrangement products of the type $(Me_3Si)_2C(SiR_2Me)(SiMe_2X)$.

A kinetic study of the solvolysis of the silicon perchlorate $(Me_3Si)_3CSiMe_2OClO_3$ has been carried out[71] in the presence of the salts NaOMe, LiCl, $LiNO_3$, and $NaClO_4$. The results of the kinetic investigations of the solvolysis were consistent with an $S_N1$ mechanism. It was suggested that the reaction also proceeds via the formation of the bridged silicenium cation (I).



Thus the results of studies of the behaviour of organosilicon compounds in condensed phases are contradictory and, in contrast to carbon compounds, they can be partly interpreted without resorting to the idea that classical silicenium ions are formed as stable species or as reaction intermediates. This is apparently associated with the characteristics of the electronic structure of silicon distinguishing it from carbon (the presence of unoccupied *d* orbitals, the greater size of the silicon atom, its lower electronegativity, etc.) and its high nucleophilicity caused by these features.

## III. SILICENIUM IONS IN THE GAS PHASE

### 1. Energy Relations in the Formation of Silicenium Ions

Whereas all attempts to demonstrate the existence of silicenium ions in the condensed phase have been unsuccessful, the formation of these species is a common phenomenon in rarefied gases, where they arise from organosilicon compounds under the influence of electron impact. Furthermore, the results of studies of the energetic conditions in the formation of tervalent silicenium ions have shown that their stability in the gas phase is greater than that of the analogous carbenium ions. Thus the heat of formation of the $H_3Si^+$ ion is 890 kJ $mol^{-1}$, while the heat of formation of the methyl cation $H_3C^+$ is 1090 kJ $mol^{-1}$.[72] The heat of formation of the $H_3Si^+$ ion has also been published[4] as 970 kJ $mol^{-1}$, which is somewhat greater than the value quoted in the above study[72] but is lower than the heat of formation of the methyl cation. The situation is analogous also as regards substituted silicenium ions. Thus the heat of formation of the trimethylsilicenium ion is 580 kJ $mol^{-1}$,[1] 590 kJ $mol^{-1}$,[3] or 610 kJ $mol^{-1}$ [4] according to the data of different investigators; evidently all these data are in good agreement. On the other hand, the lowest of the known heats of formation of the trimethylcarbenium ion is 680 kJ $mol^{-1}$,[73] i.e. is much higher than that of the trimethylsilicenium ion.

It has been shown[74] that the principal ion formed when methylsilane is bombarded by electrons having an energy of ~100 eV is the methylsilyl cation $MeSiH_2^+$. In the mass spectrum of deuteriated methylsilane $MeSiD_3$, the peak at *m/e* 47, corresponding to the $MeSiD_2^+$ ion, is 10 times higher than the peak at *m/e* 48, corresponding to the $D_3SiCH_2^+$ ion. In addition, non-empirical calculations have shown[75] that the heat of formation of the methylsilyl cation $MeSiH_2^+$ is higher by 190 kJ $mol^{-1}$ than that of the silylmethyl cation $H_3SiCH_2^+$ and by 170 kJ $mol^{-1}$ than that of the non-classical bridged ion

Thus the available theoretical and experimental data agree with one another.

The heats of formation of certain other tervalent silicenium ions have also been determined.[76,77] Thermodynamic calculations using the bond dissociation energies[76] as well as data for the vertical ionisation potentials of the radicals $RSiH_2^{\bullet}$ [76] and $RCH_2^{\bullet}$ [78] have shown that the silylcarbenium ions $H_3SiCH_2CH_2^+$ isomerise exothermically to the ethylsilicenium ions $EtSiH_2^+$ ($\Delta H = -120$ kJ $mol^{-1}$).[77]

Naturally the available information about the heats of formation of various silicenium ions is as yet insufficient, but analysis of the existing data already indicates that the energetic conditions in the formation of silicenium ions in the gas phase are more favourable than in the formation of the analogous carbenium ions.

### 2. Ion–Molecule Reactions of Silicenium Ions

In the general case ion–molecule reactions are understood as interactions of ions with neutral molecules accompanied by a change in either the elemental composition or in the charge or energy state of the species involved in such a process. Depending on the ratio of the time of the interaction (collision) between the ion and the molecule and the characteristic time of the transitions between the states of the colliding species, the mechanisms of ion–molecule reactions are divided into two types: direct reactions[79-86] and reactions proceeding via a mechanism involving the formation of a long-lived complex.[87,88]

Ion–molecule reactions proceed via the direct mechanism when the kinetic energy of the relative movement of the partners exceeds the energy of their polarisation attraction: $E_k > \alpha e^2/2r^4$ (here $\alpha e^2/2r^4$ is the energy of the polarisation interaction of the ion and the molecule over a distance *r*, equal to the sum of the radii of the ion and the molecule, and $E_k$ is the kinetic energy of the relative movement of the ion and the molecule). The simplest model describing the direct mechanism is that of the direct stripping mechanism proposed by Henglein.[86] According to this model, the

transfer of energy from the species to the reactant ion takes place over a very short period. The possibility of the transfer of momentum to the residual species is then ruled out and its velocities before and after collision differ little. In such reactions, it is possible to predict the energy distribution of the products. Thus, when a hydride ion is transferred from the silane molecule to the reactant ion, the kinetic energy of the movement of the product ion is equal to the thermal energy (like the energy of the silane molecules) and the neutral product formed is characterised by the same kinetic energy as the reactant ion (i.e. a considerable energy).

The second type of ion–molecule reactions includes those involving the formation of a long-lived complex.[87,88] The reactions proceed via this mechanism when the energy of the polarisation interaction exceeds the kinetic energy of the relative movements of the ion and the molecule, i.e. subject to the condition $E_K < \alpha e^2/2r^4$; this condition is a criterion of the stability of the complex. The capture of the ion by the polarisation orbital of the molecule, which leads to the mutual approach of the colliding species to distances of the order of atomic dimensions, proceeds via this mechanism for certain parameters of the ion–molecule collision process. For such distances, the kinetic energy of the colliding species can be consumed in the excitation of internal degrees of freedom, which entails the formation of a long-lived complex whose decomposition yields the final products.[87,88]

Numerous mass-spectrometric studies of ion–molecule reactions of silicenium ions have been published recently. These include the investigations of ion–molecules reactions in pure silane,[89–91] in methylsilane,[92,93] in mixtures of silane with organic compounds,[77,94–100] the studies of ion–molecule reactions of carbenium ions with alkylsilanes,[101–103] the study of the intramolecular and intermolecular rearrangements of organosilicon compounds,[40,104–110] and also the study of the ion–molecule reactions of trimethylsilicenium ions with organic and organosilicon compounds.[111–114]

*(a) Ion–molecule reactions in silane and its substituted derivatives.* Studies of the reactions in methane, whose main products are the ions $CH_5^+$ [115] and $C_2H_5^+$,[116] are known to have played a major role in the development of our knowledge about ion–molecule reactions:

$$CH_4^+ + CH_4 \rightarrow CH_5^+ + Me; \quad (1)$$

$$CH_3^+ + CH_4 \rightarrow C_2H_5^+ + H_2. \quad (2)$$

In the study of reactions occurring in silane, it is therefore of interest to compare the latter with processes characteristic of methane. Table 1 presents certain data for methane and silane which are of interest for the investigation of the gas-phase ion–molecule reactions of these compounds.

It is seen from Table 1 that, in contrast to methane, silane is not stable in relation to decomposition into its constituent elements. The ionisation of silane requires less energy than the ionisation of methane and much less energy must be expended on the formation of the $SiH_2^+$ and $SiH_3^+$ ions from silane than on the formation of the $CH_2^+$ and $CH_3^+$ ions from methane. The dipole moment of the Si–H bond has the opposite direction and should be much greater than the dipole moment of the C–H bond.

It has been shown[122] that the peak corresponding to the $H_5Si^+$ ion, which is analogous to the $H_5C^+$ ion in the case of methane, is absent from the mass spectra of monosilane (at pressures from $10^{-5}$ to $10^{-1}$ mmHg). Consequently a reaction analogous to reaction (1), in which the $H_5Si^+$ ion might have been formed, does not occur in the case of silane.[122] On the other hand, the absence of the $SiH_4^+$ ion can be readily accounted for with the aid of the data in Table 1. Using the ionisation potentials of the molecules and the appearance potentials of the ions (Table 1), it can be shown that the enthalpies of reactions (3) and (4) are only 60 and 20 kJ mol$^{-1}$ respectively:

$$SiH_4^+ \rightarrow SiH_3^+ + H; \quad (3)$$

$$SiH_4^+ \rightarrow SiH_2^+ + H_2. \quad (4)$$

**Table 1.** Some properties of methane and silane.

| Parameter | $CH_4$ | $SiH_4$ |
|---|---|---|
| $\Delta H_f^0$, kJ mol$^{-1}$ | −70 [117] | 30 [117] |
| $D(H_3E-H)$, kJ mol$^{-1}$ | 430 [117] | 350–400 [118] |
| $Ip(EH_4)$, kJ mol$^{-1}$ | 1220 [117] | 1130 [119] |
| $Ap(EH_3^+/EH_4)$, kJ mol$^{-1}$ | 1380 [117] | 1190 [118] |
| $Ap(EH_2^+/EH_4)$, kJ mol$^{-1}$ | 1470 [117] | 1150 [118] |
| $\mu$, D | +0.4 [121] | −1.6 [120] |

Notation: $\Delta H_f^0$ is the standard enthalpy of formation, $D(H_3E-H)$ the dissociation energy of the $H_3E-H$ bond, $Ip$ the ionisation potential, $Ap$ the appearance potential, and $\mu$ the dipole moment.
Note. The numbers in square brackets denote references (Ed.of Translation).

The enthalpies of the corresponding processes involving methane are 150 and 240 kJ mol$^{-1}$. Hence it follows that the $SiH_4^+$ ion, formed from the silane molecule, cannot be stable, bearing in mind the Franck–Condon principle, relative to the $SiH_3^+$ and $SiH_2^+$ ion and its peak is therefore absent from the mass spectrum of silane.

The principal ion in the system considered is $SiH_3^+$,[89–91] which is the product and reactant ion simultaneously:

$$SiH^+ + SiH_4 \rightarrow SiH_2 + SiH_3^+;$$
$$SiH_2^+ + SiH_4 \rightarrow SiH_3 + SiH_3^+;$$
$$SiH_3^+ + SiH_4 \rightarrow SiH_4 + SiH_3^+.$$

It is noteworthy that the $H_3Si^+$ ion was believed for a long time to be insufficiently active,[90] since a sharp rise was observed along the initial section of the curve relating the intensities of the peaks of this ion in the mass spectrum to the pressure (Fig.1). This finding showed that the rate of reaction of the $SiH_3^+$ ion in the region of low pressures is much lower than the rate of its formation. However, further investigation of the behaviour of this ion demonstrated that it is extremely active.[91] The point is that the main reaction of this ion involves the transfer to the hydride ion from silane, which results in the appearance of the same silyl cation. In order to elucidate the mechanism of this hydride transfer, the kinetic energy of the product ion was analysed using the deuteriated silane $SiD_4$ as the substrate.[91] The results of the analysis showed that the hydride ion transfer reaction proceeds mainly via the direct stripping mechanism.

However, there are also processes proceeding via a mechanism involving the formation of a long-lived complex, which is indicated by the presence of isotopically mixed

products:[91]

$$SiH_3^+ + SiD_4 \rightarrow [Si_2H_3D_4]^+ \begin{cases} \rightarrow SiD_3^+ + SiH_3D; \\ \rightarrow SiD_2H^+ + SiH_2D_2; \\ \rightarrow SiDH_2^+ + SiHD_3; \\ \rightarrow SiH_3^+ + SiD_4. \end{cases}$$

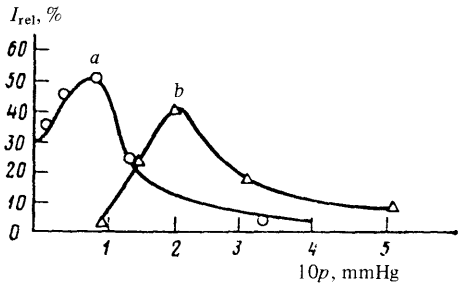


**Figure 1.** Dependence of the peak intensities of the $SiH_3^+$ (*a*) and $Si_2H_7^+$ (*b*) ions on pressure.[90]

Mass-spectrometric studies of the processes occurring in ionised methylsilane have been carried out in order to elucidate the role of the substituent (the methyl group).[92,93] One of the main ions (24%) formed on bombardment of methylsilane is $MeSiH_2^+$.[93] A characteristic reaction of this ion in methylsilane involves the abstraction of a hydride ion, as for unsubstituted silicenium ions. When the deuteriated methylsilane $MeSiD_3$ was used, it was shown that a hydride ion is abstracted from a Si–H bond and not from a C–H bond:[93]

$$MeSiH_2^+ + MeSiD_3 \rightarrow MeSiH_2D + MeSiD_2^+.$$

This is apparently due to the fact that the hydrogen in the Si–H bond is of the hydride type, while that in the C–H bond is of the proton type. The isotope distribution in the product ions shows that, as for silane, hydride transfer takes place mainly via the stripping mechanism; however, for low collision energies, processes involving the formation of a long-lived complex also take place.[93,123]

A mass-spectrometric study of $MeSiD_3$ showed that the hydrogen atoms in the methyl group are not involved in the hydrogen redistribution between the interacting species in the complex.[93]

Thus the C–H bonds are not involved in the hydride transfer reaction in silanes which proceed both via the direct mechanism and via the mechanism in which a long-lived complex is produced.

(*b*) *Ion–molecule reactions in silane–hydrocarbon mixtures.* Mass-spectrometric study of an ionised silane–hydrocarbon mixture is of great interest, because it becomes possible to follow simultaneously the ion–molecule reactions of silicenium and carbenium ions and to compare their chemical behaviour.

Processes in a silane–methane mixture have been investigated mass-spectrometrically in a number of studies.[94–96] The dominant processes in this system are the formation reactions of the $H_3Si^+$ ion via the mechanisms

$$CH_n^+ + SiH_4 \rightarrow CH_{n+1} + SiH_3^+, \text{ where } n = 0, 1, 2, 3; \quad (5)$$

$$CH_m^+ + SiH_4 \rightarrow CH_{m-1} + H_2 + SiH_3^+, \text{ where } m = 4, 5. \quad (6)$$

It has been shown[123] that the $C_2H_5^+$ ion, which is the main product of the ion–molecule reactions in methane, also reacts with silane to form exclusively the $SiH_3^+$ ion.

The possibility of the formation of the $SiH_3^+$ ion via proton transfer to the silane, postulated initially by some workers,[124] i.e.

$$CH_4^+ + SiH_4 \rightarrow [SiH_5^+]^* + CH_3 \rightarrow SiH_3^+ + H_2;$$
$$CH_5^+ + SiH_4 \rightarrow [SiH_5^+]^* + CH_4 \rightarrow SiH_3^+ + H_2.$$

is ruled out because the $SiH_5^+$ ion has not been detected even at a pressure of 0.5 mmHg.[96] If these processes did take place, one might have detected the $SiH_5$ ion stabilised by collisions at high pressure. The absence of the above proton transfer has been confirmed also by experiments carried out with fully deuteriated methane $CD_4$.[95] Within the limits of experimental error, the only silicenium ions in the mass spectrum are the $SiH_3^+$ ions.

We shall consider the reactions occurring in the silane–ethylene mixture. The main reactions in this case are also those involving the transfer of a hydride ion from silane to the attacking cation, which results in the formation of the $SiH_3^+$ ion:[7,97,125]

$$SiH_4 + C_2H_2^+ \rightarrow SiH_3^+ + C_2H_3;$$
$$SiH_4 + C_2H_3^+ \rightarrow SiH_3^+ + C_2H_4;$$
$$SiH_4 + C_2H_4^+ \rightarrow SiH_3^+ + Et.$$

In its turn, the silyl cation interacts with ethylene to form the complex $SiC_2H_7^+$, which is stabilised by collisions at high pressure. In the absence of stabilisation, this complex decomposes into the initial reactants or reaction products. Thus the interaction of the silyl cation with ethylene can be represented by means of the following schemes:

$$SiH_3^+ + C_2H_4 \rightarrow [SiC_2H_7^+]^* \rightarrow SiH_3^+ + C_2H_4;$$
$$[SiC_2H_7^+]^* \begin{cases} \rightarrow SiC_2H_5^+ + H_2; \\ \rightarrow SiCH_3^+ + CH_4; \\ \rightarrow SiC_2H_3^+ + 2H_2; \end{cases}$$
$$[SiC_2H_7^+]^* + C_2H_4 \rightarrow [SiC_2H_7^+] + C_2H_4^*.$$

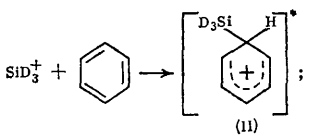
A study[77] has shown that the majority of the collisions between the $SiH_3^+$ ion and the $C_2H_4$ molecule lead to the initial reactants. This can probably be accounted for by the fact that there exists a potential barrier separating the $H_3SiCH_2.CH_2^+$ ions formed initially from the more stable isomeric form $EtSiH_2^+$. The majority of the $H_3SiCH_2CH_2^+$ ions decompose rapidly into the reactants and only a small proportion isomerise to the $EtSiH_2^+$ ions. These ions and their dissociation products are in fact detected mass-spectrometrically. The maximum energy transmitted by the complex $EtSiH_2^+$ to the ethylene molecule on stabilisation by collision has been determined as 0.6–0.8 eV.[77] This is in good agreement with the results of a study[126] where it has been reported that the ethylene molecule is capable of accepting an excitation energy up to 1.3 eV without decomposition on collision within the excited species.

We shall now consider the ion–molecule reactions in the silane–benzene mixture.[99,100] The main product ions in this system as as follows; $C_6H_6^+$ (*m/e* 78), $SiC_6H_7^+$ (*m/e* 107), and $SiC_6H_9^+$ (*m/e* 109). It has been shown that the $SiC_6H_9^+$ ion is a long-lived complex with a lifespan of $10^{-5}$ s. At a high pressure this complex is stabilised by collisions, while in

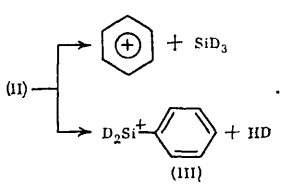
the absence of stabilisation it decomposes into the reaction products $C_6H_6^+$ and $SiC_6H_7^+$. One can therefore put forward the following mechanism of the interaction of the silyl cation with benzene:

$$SiH_3^+ + C_6H_6 \rightarrow [SiC_6H_9^+]^*;$$

$$[SiC_6H_9^+]^* \begin{cases} \rightarrow C_6H_6^+ + SiH_3; \\ \rightarrow SiC_6H_7^+ + H_2; \end{cases}$$



$$[SiC_6H_9^+]^* + C_6H_6 \rightarrow [SiC_6H_9^+] + C_6H_6^*.$$



With increase of the kinetic energy of the reactant ion, the yield of the energy-enriched complex $SiC_6H_9^+$ falls sharply, while the relative yield of the product $SiC_6H_7^+$ falls much more slowly and the yield of the $C_6H_6^+$ ion increases sharply, reaching 70%. The unimolecular decomposition of the long-lived complex $[SiC_6H_9^+]^*$ also involves the formation of other ionic products in insignificant yields ($C_6H_7^+$, $SiC_4H_5^+$, and $SiC_4H_7^+$). Among these product ions, the $C_6H_7^+$ ion which is believed[100] to be formed on proton transfer from the silyl cation to benzene via the mechanism

$$SiH_3^+ + C_6H_6 \rightarrow C_6H_7^+ + SiH_2.$$

is of greatest interest. Analogous processes have been observed in the interaction of methyl cations with certain aromatic hydrocarbons, for example, with toluene.[127]

Experiments using fully deuteriated silane have shown[100] that the $SiD_3^+$ ion in the $SiC_6H_9^+$ complex retains its individuality and there is virtually no exchange of the hydrogen and deuterium ions in the complex. This permits the conclusion that the short-lived complex is an ion with a structure analogous to that of the σ-complex (II) and not an ion of the troplyium type. The interaction of the silyl cation $SiD_3^+$ with benzene can then be formulated schematically in the following manner:

The structure of the benzyl type (III) had already been proposed earlier in a study of the ionisation of phenylsilane by electron impact.[128]

The interaction of the methyl, ethyl, and butyl cations with methylsilanes having the general formula $Me_nSiH_{4-n}$, where $n$ = 0, 1, 2, 3, or 4, has been reported.[101-103] The characteristic reactions of the above carbenium ions with methylsilanes are reactions involving hydride transfer from the silane to the attacking ion with formation of a tervalent silicenium ion $Me_nSi^+H_{3-n}$ and also processes involving the abstraction of the methyl anion from the silane and its transfer to the carbenium ion with formation of the $Me_{n-1}Si^+H_{4-n}$ ion.

The probabilities that the hydride ion or the methyl anion are split off are not the same for different carbenium ions.[103] The probabilities that the methyl and ethyl cations are split off are almost the same. In the case of the propyl cations the transfer of the methyl anion begins only in the presence of three methyl groups, while for the butyl cations four methyl groups are needed in the silane molecule.

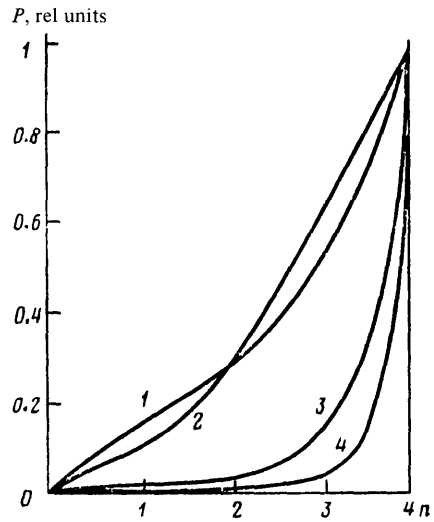


**Figure 2.** Dependence of the relative probability $P$ of the transfer of the methyl anion on the number of methyl groups $n$ in the methylsilane for different carbenium ions: *1*) $CH_3^+$; *2*) $C_2H_5^+$; *3*) $C_3H_7^+$; *4*) $C_4H_9^+$.[103]

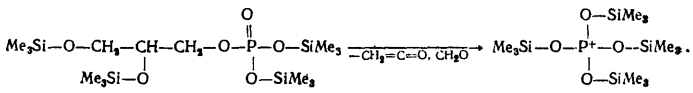

Fig. 2 illustrates the relative probabilities of the transfer of the $CH_3^-$ ion from the silane $Me_nSiH_{4-n}$ by various cations. The observed differences in the behaviour of the cations have been explained[103] by the fact that the propyl and butyl cations have the iso-structure. This hypothesis is consistent with the report[129] that the ionisation of neopentane by electron impact involves mainly the formation of the $Me_3C^+$ cation. Otherwise the propyl and butyl cations would have behaved in the same way as the ethyl cation.

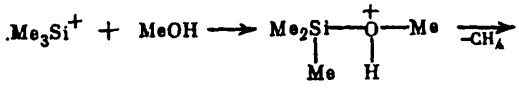
The reactions of the methyl and ethyl cations with ethylsilanes of the type $Et_nSiH_{4-n}$, where $n$ = 0, 1, 2, 3, or 4, were investigated and it was shown that the transfer of an alkyl anion is not observed in methylsilane systems only.[102,103]

The studies considered have shown that it is possible to obtain three silicenium ions in a rarefied gaseous phase from the corresponding silanes with the aid of electron impact and by the interaction of various carbenium ions with silanes.

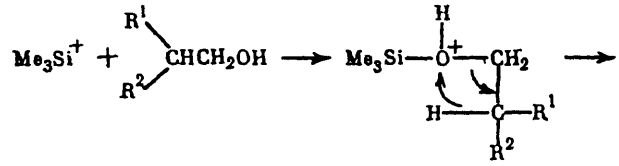
(c) *The ion–molecule reactions of trimethylsilicenium ions.* The next stage in the study of silicenium ions involved the investigation of the reactions of trimethylsilicenium ions with organic and organosilicon compounds belonging to various classes. An important step in this research consisted of studies devoted to questions concerning the rearrangement of the silicenium ions themselves.[40,104-110] The majority of such rearrangements can be accounted for by the localisation of the positive charge on the silicon atom and by the subsequent formation of a bond between

silicon and the electronegative centre, usually the oxygen atom:[104–110]

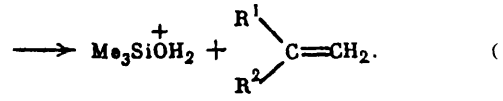


Apart from the peaks of the ions arising as a result of the intermolecular rearrangements, the presence of the (M + 73)† peak is characteristic of the spectra of all trimethylsilyl derivatives of organic compounds.[104–110] It has therefore been postulated[104–110] that an ion of this kind is formed as a result of the ion–molecule interaction of the trimethylsilicenium ion with the electronegative centre of the substrate molecule. These studies initiated the research into the ion–molecule reactions of trimethylsilicenium ions.

The interaction of trimethylsilicenium ions with a series of organic compounds containing various functional groups (indenamine, naphthaline, quinoline, octadec-1-ene) has been studied.[111,112] The main peak in the mass spectra of these compounds was that corresponding to the (M + 73) ion.

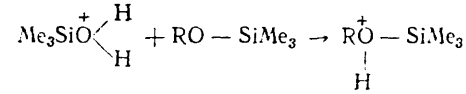


The investigations[111,112] established that trimethylsilicenium ions are extremely reactive species with very pronounced electrophilic properties owing to the presence of the positive charge, the unoccupied molecular *p* orbital, and the unoccupied *d* orbital. Despite the high reactivity of silicenium ions, a characteristic feature of the latter is the formation of the quasi-molecular (M + 73) complexes[111,112] and not fragment ions of the kind observed in the case of the carbenium ions. Thus the interaction of trimethylsilicenium ions with higher alcohols leads to the formation of quasi-molecular ions in 75% yield.[111] When trimethylcarbenium ions react with these alcohols, the total ionic current consists of the ionic currents of a multiplicity of fragment and quasi-molecular ions, the contribution of the quasi-molecular ion being insignificant.[130]



The investigation by the ion–cyclotron resonance method of the interaction of trimethylsilicenium ions with the alcohols ROH, where R = Me, Et, n-Pr, t-Bu, and other alkyl groups, has been reported.[113,114] It has been shown that the interaction of the silicenium ion with an alcohol molecule entails the formation of the adduct $\overset{+}{R}OH-SiMe_3$, which can then decompose further with loss of methane in the case of methanol and with loss of an alkene in the case of the remaining alcohols in accordance with the mechanism#

(7a)



(7b)

The elimination of methane in accordance with the mechanism (7a) is insignificant for higher alcohols. The explanation is apparently the stability of the alkene, which renders the process involving the elimination of the alkene rather than the methane more favourable.

It has been shown[112] that steric effects play an important role in the ion–molecule reactions in the gas phase. The (M + 73) peak was almost absent from the spectra of compounds containing a secondary siloxy-group with bulky substituents. Instead their mass spectra contained an intense (M + 1) peak. The formation of this ion can be accounted for by the interaction of the trimethylsilicenium ion with the water (atmospheric moisture) present in the system; this entails the appearance of a protonated silanol $Me_3Si\overset{+}{O}H_2$, which reacts further with a substrate molecule as a Brønsted acid, giving rise to the (M + 1) ion:

This mechanism has been confirmed by experiments using deuteriated water. In this case the (M + 1) peak shifts by unity. In addition, a peak corresponding to the protonated silanol (*m/e* 91) was present in the spectrum.

Thus, under conditions where the interaction of the fairly large trimethylsilicenium ion with electronegative atoms is hindered, the process involving the formation of the (M + 1) ion, i.e. the protonation of the substrate molecules, becomes energetically more favourable. In those cases where there is no steric hindrance in the molecule, the main reaction of the trimethylsilicenium ion is the formation of the (M + 73) quasi-molecular ion.

It follows from the analysis of data examined that, in contrast to the condensed phase, in the gas phase silicenium ions are formed readily and the relative intensities of their peaks in the mass spectra exceed by 1–2 orders of magnitude the intensities of the carbenium ions formed under analogous conditions, which agrees with the lower formation energies of the silicenium ions.

Like carbenium ions, silicenium ions have fairly pronounced electrophilic properties. The results of studies of the gas-phase ion–molecule reactions of ions of both types have demonstrated a considerable analogy in the character of their interactions and of the products formed. At the same time, by virtue of the difference between the electronic structures and properties of the carbon and silicon atoms, some differences have also been observed in the behaviour of these ions.

---

†The mass of 73 corresponds to that of the trimethylsilicenium ion.

#A radiochemical study of the gas-phase reactions of dimethylsilicenium ions with methanol at a vapour pressure of the latter of 30 mmHg and that of a noble gas diluent of ~300 mmHg have shown that the only product is dimethylmethoxysilane, which is formed as a result of the proton transfer from the long-lived complex to the alcohol molecule or to the diluent gas species.[131]

## IV. A NUCLEAR-CHEMICAL METHOD FOR THE GENERATION OF SILICENIUM IONS AND THE STUDY OF THEIR REACTIONS

The traditional physicochemical methods proved to be unsuitable for the generation of silicenium ions in either condensed or gas phases. The mass-spectrometric and ion-cyclotron resonance spectroscopic methods make it possible to obtain these ions and to investigate their reactions but only in the rarefied gas phase. A method which permits the investigation of silicenium ions in the gas phase over a wide range of pressures and also in the liquid and solid phases has recently become available. It is based on a combination of nuclear and chemical processes: the β-decomposition of the tritium atoms forming part of the composition of the silane molecule takes place initially and this is followed by chemical changes leading to the formation of silicenium ions.

In order to understand the essential feature of the method, it is necessary to consider the β-transformation of tritium. The β-decomposition process is known to involve the transformation of a neutron into a proton in the nucleus[132] via the mechanism

$$n \rightarrow p + e^- + \tilde{\nu},$$

where n and p are the neutron and proton respectively, $e^-$ is the nuclear electron (β-particle), and $\tilde{\nu}$ is the antineutrino. This transformation leads to the appearance of the nucleus of a new element with a charge greater by unity. Since the number of electrons in the atom remains unchanged in this process, the charge state of the resulting daughter element has increased by unity. Thus the β-decomposition of tritium can be represented schematically as follows:

$$T \rightarrow H^+ + e^- + \tilde{\nu}.$$

Since the β-particle is emitted over a period which is insignificant compared with the period of electronic vibrations, a sudden change under these conditions of the electric field of the nucleus can lead to the so-called "shaking" of the electron shell, which entails the excitation of the daughter ion.[133] In conformity with the sudden perturbation theory, this process should lead to the additional ionisation of some of the daughter ions.[134] However, for tritium, both the experimental data and calculations have shown that only 2.5% of all the transitions lead to the formation of doubly charged ions, i.e. ions with an excitation energy exceeding the second ionisation potential of helium. This is associated with a very marked intensification of the electrostatic interaction of the electron with the nucleus as a result of the doubling of the charge of the latter. Furthermore, the usual mechanism of the formation of multiply charged ions as a consequence of Auger processes does not obtain in the case of hydrogen (tritium).

The fact that the radioactive recoil energy,[133] which can also be responsible for the excitation of the ions formed, is insignificant is likewise characteristic of β-decomposition. Thus more than 90% of all the β-transformations of tritium are accompanied by a recoil energy less than 2 eV.

Thus, as a result of the β-decomposition of tritium, the yield of singly charged helium ions is a maximum compared with the yields of the ions of other elements and reaches ~97%; most of the singly charged ions (~70%) are then in the ground electronic levels or levels close to them.[134]

We shall now consider the processes occurring on decomposition of the tritium forming part of the composition of molecular systems, because these processes constitute the basis of the generation of reactive species, in particular carbenium ions.[135,136]

The first stage in the chemical changes in the β-decomposition processes of tritium atoms forming part of hydrocarbons is the appearance of primary molecular ions $RHe^+$. The results of theoretical and experimental studies[137–141] have shown that, as for atomic systems, most of the molecular ions formed are in the ground energy state or states close to it.

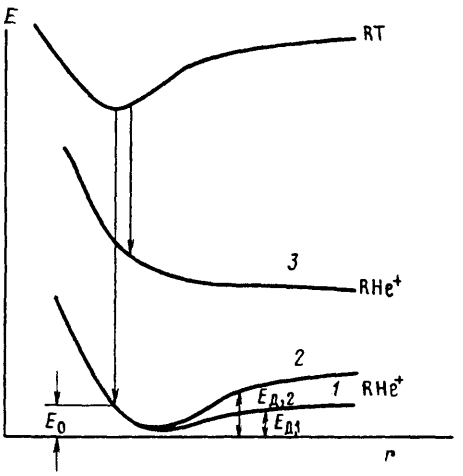


**Figure 3.** Potential energy curves for the RT molecule and the $RHe^+$ ion: *1*) and *2*) the ground state; *3*) the excited state.[140]

The configuration of the nuclei in the resulting molecular ion, which is characteristic of the initial molecular system, does not in general correspond to the minimum on the potential energy surface of this ion. According to the Franck–Condon principle, this means that the so-called vertical transitions on the potential energy diagram, associated with the change in the chemical nature and electronic state of the atoms, lead to the appearance of molecular ions in various vibrational levels. The potential energy curves for the initial molecule and the daughter ion are illustrated schematically in Fig. 3. Evidently, there can be two types of potential energy curves for the daughter ions in the ground states. In the first case the excitation energy $E_0$ is higher than the dissociation energy of the $RHe^+$ ion (curve *1*), while in the second case $E_0$ is lower than the dissociation energy of the $RHe^+$ ion (curve *2*). The first case leads to the decomposition of the primary molecular ion $RHe^+ \rightarrow R^+ + He^0$, while the second involves the retention of the $RHe^+$ ion.

Apart from the transitions leading to the ground states of the daughter ions, there can also be transitions resulting in excited states (curve *3*). In this case the potential energy curve has no minimum, which corresponds to a repulsion state. Such transitions inevitably lead to the dissociation of $RHe^+$ with formation of the $R^+$ ion. It has been shown[139,142,143] that the ions $R^+$ in the ground state do not undergo subsequent fragmentation.

The sequence of the processes developing in the β-decomposition of tritium forming part of hydrocarbons (for methane as an example) and their time characteristics have been

represented schematically as follows:

$$T_3C{:}T \xrightarrow[\sim 10^{-21}\,s]{\beta\,(a)} [T_3C{:}He^+,\beta] \xrightarrow[\sim 10^{-18}\,s]{(b)} \underset{(A)}{[T_3C{\cdot}He^+]} \xrightarrow[\sim 10^{-16}\,s]{(c)} \underset{(B)}{\rightarrow}$$

$$\rightarrow [T_3C{\cdot}He^+{\cdot}] \xrightarrow[\sim 10^{-15}\,s]{(d)} \underset{(C)}{[T_2C^+He{:}]} \xrightarrow[\sim 10^{-13}\,s]{(e)} \underset{(D)}{T_3C^+} + \underset{(E)}{He^0}.$$

Stage (*a*) is the transformation of the tritium nucleus into the helium nucleus, whereupon the β-particle is within the limits of the helium atom. In stage (*b*) the β-particle lies outside the limits of the molecular system, which entails the appearance of a positively charged molecular ion (B) in which the charge is localised on the helium atom. Stage (*c*) corresponds to the intra-atomic transition of the residual electron left over from the tritium atom to the energy level of the helium atom corresponding to its second ionisation potential. Stage (*d*) is the interatomic transition of an electron from the carbon atom to the helium atom—to the energy level corresponding to the first ionisation potential of this atom. The electron transfer from the hydrocarbon group to the helium atom is caused by the fact that the first ionisation potential of helium greatly exceeds (by ~15 eV) the ionisation potentials of the hydrocarbon groups. In the resulting molecular ion (D) the neutral helium atom and the charged $R_3C^+$ fragment become isolated. Stage (*e*) involves their separation in space, which leads to the formation of free carbenium ions. The yields of the carbenium ions obtained in this way are ~80%.[137,144]

Table 2. The probabilities *P* of the appearance of the daughter species in the ground state in the β-decomposition of a tritium atom in certain compounds.[138]

| Process | *P* |
|---|---|
| $T \xrightarrow{\beta^-} He^+$ | 0.70 |
| $HT \xrightarrow{\beta^-} HHe^+$ | 0.59 |
| $CH_3T \xrightarrow{\beta^-} CH_3He^+$ | 0.61 |
| $NH_2T \xrightarrow{\beta^-} NH_2He^+$ | 0.61 |
| $OHT \xrightarrow{\beta^-} OHHe^+$ | 0.62 |

Quantum-chemical calculations[138] have shown that the nature of the initial parent form in the β-decomposition of tritium atoms does not have a significant influence on the probability of the appearance of the daughter species in the ground energy state (Table 2). It is therefore to be expected that the β-decomposition processes involving the tritium atom in the corresponding compounds of the elements in the Third Period lead to the formation of primary molecular ions whose yield in the ground energy state is close to the yield of the ions indicated in Table 2. Thus, when the tritium forming part of the composition of organosilicon compounds, in particular the substituted silanes $R_{4-n}SiT_n$, decomposes, silicenium ions in the ground energy state are formed in fairly large yields in accordance with the scheme

$$R_{4-n}SiT_n \xrightarrow{\beta} R_{4-n}Si^+T_{n-1} + He^0.$$

Thus a possibility is created for extending the nuclear-chemical method for the generation of free carbenium ions to the preparation of their silicon analogues (silicenium ions). This method of generation of silicenium ions has a number of characteristic features.

1. The silicenium ions generated by the nuclear-chemical method are formed in a free state, i.e. without a counterion and a solvation shell. The β-particle emitted on decomposition cannot serve as a counterion, because it is removed to a distance over which the interaction energy between the ion and the electron is low. The absence of a solvation shell is explained by the fact that the initial molecular system lacked such a shell and the time required for its creation after the formation of the ion exceeds by several orders of magnitude the time of the ion–molecule interactions. Such a state of the ions formed ensures their enhanced reactivity.

2. The method makes it possible to obtain, in principle, silicenium ions with the required composition and structure and with a specific localisation of the charge, because organosilicon compounds having the corresponding structure and containing tritium in the specified position can be used as the sources of such ions.

3. The rate of generation of the silicenium ions (E) is independent of external conditions (temperature, pressure, the state of aggregation, etc.), because the formation of these ions is based on radioactive decomposition processes:

$$\frac{dN(R_{4-n}Si^+T_{n-1})}{dt} = n\lambda K N(R_{4-n}SiT_n),$$

where $N(R_{4-n}Si^+T_{n-1})$ is the number of silicenium ions formed, $N(R_{4-n}SiT_n)$ the number of silane molecules, $\lambda$ the decomposition constant of tritium, *n* the number of tritium atoms in the silane, and *K* a coefficient taking into account the yield of silicenium ions.

4. The given method makes it possible to generate silicenium ions and to investigate their reactions in the gas, liquid, and solid phases, since the β-decomposition processes are independent of the state of aggregation of the substance in the molecules of which tritium decomposes.

Dimethylsilicenium ions were obtained for the first time with the aid of the nuclear-chemical method via the process

$$Me_2SiT_2 \xrightarrow{\beta} [Me_2SiTHe]^+ \rightarrow Me_2SiT^+ + He^0$$

and their reactions with t-butoxydimethylsilane, pentadimethyldisiloxane, and methanol were investigated by Nefedov et al.[131] The reactions of the dimethylsilicenium ions with the compounds enumerated above are indicated schematically below:

$$\left[\begin{matrix} Me_2HSi^{\delta+}\ldots OR \\ | \\ Me_2TSi \end{matrix}\right] \rightarrow Me_2HSi^+ + Me_2TSiOR$$

$$\uparrow$$

$$Me_2TSi^+ + Me_2HSiOR \rightarrow \left[\begin{matrix} Me_2HSi\overset{+}{O}R \\ \vdots \\ Me_2TSi \end{matrix}\right]^* \rightarrow \left[\begin{matrix} Me_2HSiO\ldots R^{\delta+} \\ | \\ Me_2TSi \end{matrix}\right] \rightarrow Me_2HSiOSiTMe_2 + R^+;$$

$$Me_2TSi^+ + MeOH \rightarrow \left[\begin{matrix} Me\overset{+}{O}H \\ \vdots \\ Me_2TSi \end{matrix}\right]^* \xrightarrow{MeOH} Me_2TSiOMe + Me\overset{+}{O}H_2;$$

$R = Me_3C,\ Me_3Si.$

Further studies in this field should probably be directed to the extension of the nuclear-chemical method to the generation of other silicenium ions and to the study of their reactions with compounds of different classes in the gas and condensed phases.

--o0o--

In conclusion one must state that the problem of the preparation of silicenium ions and of the investigation of their properties and reactions still remains in the stage of

development. One of the directions of this development involves the use of the nuclear-chemical method. The above discussion of the essential features of this method and of its characteristic features permits the conclusion that the method is unique, because it allows one to generate silicenium ions of different composition and structure in any substances in the gas, liquid, and solid states. The development of this method will make it possible to investigate the behaviour of silicenium ions in reactions with compounds of different classes both in the gas phase, over a wide range of pressures, and in the condensed phases.

# Chalcogeniron Carbonyl Clusters

N.S.Nametkin (deceased), V.D. Tyurin (deceased), and M.A.Kukina

The literature data and the methods of synthesis, structure, and physicochemical properties of chalcogeniron carbonyl clusters and their derivatives are surveyed and described systematically.
The bibliography includes 163 references.

III. Structure and physical research methods 444
IV. Chemical properties 446

## I. INTRODUCTION

Iron clusters are particularly abundant among transition metal carbonyl complexes with sulphur-containing ligands.[1] Typical representatives of chalcogeniron carbonyl clusters are dichalcogendiiron hexacarbonyl $(\mu\text{-}X)_2Fe_2(CO)_6$ (I) and dichalcogentriiron nonacarbonyl $(\mu_3\text{-}X)_2Fe_3(CO)_9$ (II), where X = S, Se, or Te [for brevity, the formulae used subsequently will be $X_2Fe_2(CO)_6$ and $X_2Fe_3(CO)_9$].

The chemistry of these clusters has so far developed extensively, but some of their features have not been adequately explained. The study of the methods of synthesis and the properties of clusters (I) and (II) under comparable conditions involves considerable experimental difficulties. Very few thoroughly developed methods of synthesis of the above cluster compounds are so far available. Their chemical properties have likewise not been studied systematically.

Chalcogeniron carbonyl complexes, which are the compounds of a large number of cluster derivatives, in particular the cubane systems $[S_4Fe_4(SR_4)]^{n-}$, themselves possess a series of unique properties, which are considered in the present review. For example, sulphur-containing iron clusters enter into the composition of polynuclear enzymes (ferredoxins)—a new class of biocatalysts which play an exceptional role in vitally important processes such as the fixation of molecular nitrogen. The chemical modelling of the catalytic properties of cluster enzymes will make it possible to create fundamentally new effective catalysts of many industrial processes.

The aim of the present review is a critical consideration of the methods of synthesis and the structure of chalcogeniron carbonyl clusters together with the discussion of their physicochemical properties. Although more than 150 communications have been published on this subject, so far no attempt has been made to survey them and to give a systematic account. We believe that a review of the methods of synthesis and chemical properties of chalcogeniron carbonyl clusters is extremely urgently required in connection with the vigorous development of a new scientific discipline—the chemistry of cluster compounds.[2]

## II. METHODS OF SYNTHESIS

As already mentioned, there are as yet very few thoroughly developed methods of synthesis of chalcogeniron carbonyl clusters. The majority of these clusters have been obtained non-specifically. The interaction of aqueous alcoholic solutions of alkali metal tetracarbonylferrate salts with sulphurous acid (or selenous and tellurous acid respectively) must be regarded as the most general method whereby such compounds can be obtained. This method synthesis is so far the most convenient and the one most frequently used for preparative purposes. A survey of the methods of synthesis shows that molecules with different chemical properties can serve as sources for the preparation of the same chalcogeniron carbonyl clusters. Thus for sulphur these are compounds exhibiting differences from the standpoint of the formal valence of sulphur, such as $S_8$, $H_2S$, $SO_2$, $CS_2$, RSH, etc. These compounds will be considered below in greater detail as sources of sulphur.

Analysis of the literature data (see the Table below) has shown that the most effective methods of synthesis of iron carbonyl clusters involve the reaction of elemental sulphur $S_8$ [3] or hydrogen sulphide[4] with dodecacarbonyltriangulotriiron (DDCI) $Fe_3(CO)_{12}$. A novel method of synthesis of clusters of types (I) and (II), where X = S, based on the interaction of elemental sulphur with the triethylammonium salt of undecacarbonyltriiron hydride (TSUTH) $[(C_2H_5)_3NH]^+[HFe_3(CO)_{11}]^-$ is noteworthy.[3] Satisfactory results have also been obtained in the synthesis of the compound $S_2Fe_3(CO)_9$ from DDCI and 3-chloropropenyl sulphide[5] or by the reaction of $(C_6H_5)_3CSH$ with DDCI.[6] The reaction conditions and the method used to isolate the products apparently play a significant role in the synthesis of chalcogeniron carbonyl clusters.

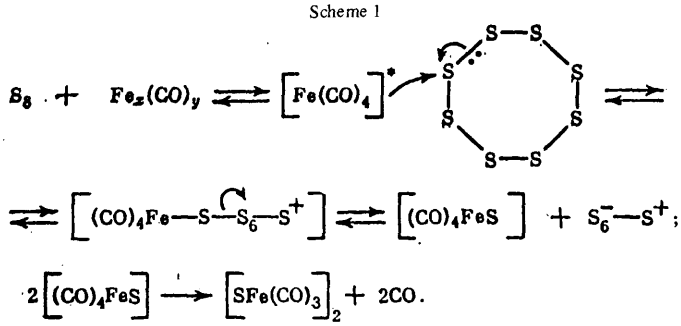
We shall consider initially the method of synthesis of chalcogeniron carbonyl clusters in which a mixture of compounds (I) and (II) is formed.

### 1. Interaction of Elemental Sulphur and Hydrogen Sulphide with Iron Carbonyls

The compounds $X_2Fe_2(CO)_6$ and $X_2Fe_3(CO)_9$ where X = S, Se, or Te) can be regarded as the products of the substitution of the bridging carbonyl groups in $Fe_2(CO)_9$ and $Fe_3(CO)_{12}$ by chalcogens.[7]

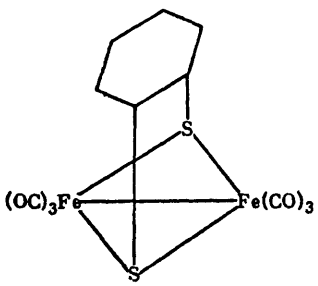
Until recently, there has been no information in the literature about the direct interaction of sulphur, selenium, and tellurium with iron carbonyls. It has been reported only that iron pentacarbonyl (IPC) does not react with elemental sulphur in the cold in solutions in carbon tetrachloride and xylene.[8] It has been shown[9-11] that elemental sulphur reacts with iron pentacarbonyl, iron nonacarbonyl (INC), and iron dodecacarbonyl in solution in benzene in

the course of 1–2 h at 80 °C to form very small amounts (2–5%) of the sulphur-containing clusters $S_2Fe_2(CO)_6$ and $S_2Fe_3(CO)_9$ in proportions of 1 : 3.



The reaction of elemental sulphur with iron carbonyls has been studied in greater detail by Mavlonov,[3] who examined the influence of the composition of the iron carbonyl, the reaction time, the reaction temperature, the reactant ratio, and the nature of the solvent and activating agents on the yield and ratio of compounds of types (I) and (II) and described the conditions for the chromatographic separation of these clusters.

The increase in reactivity of iron carbonyls in the sequence $Fe(CO)_5 < Fe_2(CO)_9 < Fe_3(CO)_{12}$ in the reaction with elemental sulphur agrees well with the hypothesis that the reactivity of iron carbonyls depends not only on the rate of formation and the amount of the coordination-unsaturated intermediate $[Fe(CO)_4]^*$ but also on the nuclearity of the cluster.[12–15]



On the basis of available data on the interaction of sulphur compounds with iron carbonyls,[16–19] the reaction presumably proceeds via Scheme 1.

In certain cases where large amounts of the starting materials were used [0.075 mole of $S_8$ and 0.1 mole of $Fe_3(CO)_{12}$], it was possible to isolate in addition a further two substances in very small amounts.[3] One of these compounds is dithiodiiron heptacarbonyl $S_2Fe_2(CO)_7$ (III). It is a pale-orange crystalline substance with a melting point of 81–82 °C, which is readily soluble in organic solvents and is relatively stable in the solid state, while in solutions it is quantitatively converted on standing into $S_2Fe_2(CO)_6$ with evolution of CO.

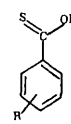
Scheme 1

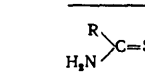
The structure of cluster (III) has been confirmed by elemental analysis, infrared spectroscopy, mass spectrometry, and X-ray diffraction.[20] The interaction of $Fe_3(CO)_{12}$ with a methanolic solution of NaOH and subsequent acidification of the solution in the presence of $Na_2SO_3$ yielded the cluster $SFe_3(CO)_{10}$ (IV).[21] At the same time the reaction of $S_8$ with an excess of cyclohexene or hex-1-ene in the presence of $Fe_3(CO)_{12}$ resulted in the formation,[22] apart from compound (IV), also of $S_2Fe_2(CO)_6$, $S_2Fe_3(CO)_9$, and the dithiolandiiron hexacarbonyl cluster having the structure

When cyclohexene is used, sulphur atoms are inserted in the double bond with formation of cyclic polysulphides. The structure of cluster (IV) has been studied by X-ray diffraction.[22]

The second compound formed together with compound (III) is apparently a polynuclear high-molecular-weight cluster $[S_xFe_y(CO)_z]$ (V), which is soluble only in polar organic solvents and is generated on heating compounds (I) or (II). The formation of a polynuclear cluster has also been noted in the interaction of elemental sulphur with dicobalt octacarbonyl.[23–25]

The methods of synthesis of clusters of types (I) and (II).





| Initial compounds | | Reaction conditions | Product (yield, %) | Refs. |
|---|---|---|---|---|
| sulphur compound | iron carbonyl | | | |
| $S_8$ | $Fe(CO)_5$ | $CCl_4$; $(CH_3)_2C_6H_4$; in the cold | — | [8] |

A mixture of clusters of types (I) and (II) in proportions of 2:1 has been isolated in 90% yield on passing an excess of hydrogen sulphide through a benzene solution of DDCI (52–54 °C, 2 h):[4]

$$H_2S + Fe_3(CO)_{12} \rightarrow S_2Fe_2(CO)_6 + S_2Fe_3(CO)_9.$$

It has been shown that TSUTH, which is an intermediate in the synthesis of DDCI, can be used successfully to obtain sulphur-containing compounds of types (I) and (II) [yield 33%, $C_6H_6$, 6 h, 60 °C, ratio (I):(II) = 1:3].[3] This method can be of preparative value in view of the availability of IPC and the possibility of regenerating triethylamine whose reactivity is relatively low in the substitution of CO groups in the clusters obtained.

It is noteworthy that, when iron carbonyls react with elemental sulphur or hydrogen sulphide and also when TSUTH reacts with sulphur, the initial reaction product is, according to thin-layer chromatographic (TLC) data, dithiodiiron hexacarbonyl, which is subsequently converted into a compound of type (II):[3]

$$S_2Fe_2(CO)_6 \xrightarrow{Fe_2(CO)_{12}} S_2Fe_3(CO)_9.$$

In earlier studies it was reported that the reaction of DDCI with 2-mercaptobenzothiazole, thiosemicarbazide, thioacetamide, or parathioformaldehyde leads to the formation of the compound $(H_2C)S_2Fe_3(CO)_{10}$ [26] in a low yield. Later it was demonstrated that in reality this compound is dithiotriiron nonacarbonyl $S_2Fe_3(CO)_9$.[27]

Spongy iron and matte, granulated iron, and certain natural ores are used as the iron-containing raw material in the industrial preparation of IPC.[28] The iron matte consists of an alloy of iron (in the form of filings) and iron pyrite $FeS_2$ in proportions of 3:1. The alloy contains ~92% of iron and 8% of sulphur. A number of studies have been devoted to the influence of sulphur compounds on the formation of iron, molybdenum, and nickel compounds.[29–31]

In the development of preparative methods for the synthesis of IPC from the metal in the absence of solvents, it has been established that small amounts of sulphur or selenium have a favourable effect on the reaction.[29] A systematic investigation has therefore been made of the influence of added sulphur, selenium, and tellurium on the formation of IPC[7] and it was suggested that these elements act as catalysts, forming intermediate clusters such as $S_2Fe_3(CO)_9$, which subsequently decompose under the influence of carbon monoxide to form IPC and sulphur. It was shown that the formation of nickel carbonyl is appreciably accelerated under the influence of hydrogen sulphide.[31] The first intermediate formed in this process is nickel γ-sulphide, which is reformed in subsequent transformations together with segregation of $Ni(CO)_4$, and catalyses the reaction at very minute concentrations.

An interesting phenomenon, the activation of the formation of iron, molybdenum, and nickel carbonyls by friction in the presence of sulphur-containing substances, has been described.[31] According to the authors, friction causes the breakdown of the crystal lattices of iron and the metal sulphide and the reaction proceeds via the disproportionation of the carbonyl sulphide formed:

$$\text{iron} + \text{sulphur} \rightarrow \text{iron sulphide} \xrightarrow{CO} \rightarrow S_2Fe_3(CO)_9 \xrightarrow{\text{disproportionation}} \begin{cases} \rightarrow Fe(CO)_5 \\ \rightarrow \text{iron sulphide} \end{cases}.$$

The mechanism of iron carbonyl formation via a stage involving the appearance of the intermediate $S_2Fe_3(CO)_9$, which was described previously,[29] does not operate solely in a high-pressure reactor but also under the conditions of mechanical treatment.

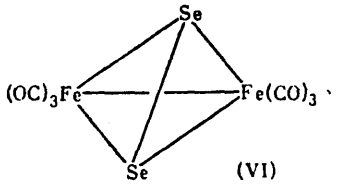
Analysis of the literature data on the synthesis of IPC under various conditions from iron and carbon monoxide in the presence of small amounts of elemental sulphur has shown that in certain cases dithiotriiron nonacarbonyl, which is a catalyst of this reaction, is formed.[29–31]

Thus, as shown above, the interaction of elemental sulphur and hydrogen sulphide with iron carbonyls and TSUTH leads to the formation of a mixture of clusters (I) and (II) in satisfactory yields.

## 2. The Synthesis from Tetracarbonylferrates

Chalcogeniron carbonyls of type (II) were first obtained[32] by the interaction of aqueous alcoholic solutions of alkali metal tetracarbonylferrate salts with sulphurous acid (and similarly with selenous and tellurous acids):

$$3[Fe(CO)_4]^{2-} + 2XO_3^{2-} + 10H^+ \rightarrow X_2Fe_3(CO)_9 + CO_2 + 2CO + 5H_2O.$$



The reactions with $[Fe_2(CO)_8]^{2-}$ and $[Fe_3(CO)_{11}]^{2-}$ take place in the same way and in this case $Fe_3(CO)_{12}$ is formed as well. It is noteworthy that, as established subsequently, a mixture of compounds (I) and (II) is formed in all cases.[27–31,33]

Under analogous conditions, when the tetracarbonylferrate ion is acidified with hydrochloric acid, it reacts with sodium polysulphide to form a mixed precipitate of $S_2Fe_2(CO)_6$ and $S_2Fe_3(CO)_9$ [32] (these compounds can be separated by subliming the first *in vacuo* at 40 °C):

$$5[Fe(CO)_4]^{2-} + S_5^{2-} + 2H^+ \rightarrow S_2Fe_2(CO)_6 + S_2Fe_3(CO)_9 + H_2S + 5CO.$$

The cluster $Se_2Fe_2(CO)_6$ (VI) has also been obtained by treating with KOH a solution of $Fe(CO)_5$ in methanol at 0 °C in an atmosphere of $N_2$ with subsequent addition of selenium and then a solution of $Na_2Se.9H_2O$ in water, the reaction mixture being stirred for 1 h and then acidified with a 15% HCl solution.[32] The properties of cluster (VI) have been recently described in detail.[34]

The cluster $Se_2Fe_3(CO)_9$ (VII) has been synthesised analogously[32] and its structure has been determined[35] by X-ray diffraction:

(VI)

The clusters $Te_2Fe_3(CO)_9$ (VIII)[32,36] and $Te_2Fe_2(CO)_6$ (IX) have been obtained by adding $K_2TeO_3$ to a solution of $Fe(CO)_5$ and KOH in aqueous methanol with subsequent acidification of the reaction mixture with HCl. Under analogous conditions, IPC reacts with compounds (IX) to form $Te_2Fe_3(CO)_{10}$ (X), which the authors suggest[36] is an intermediate in the formation of compound (VIII). The reaction of $Fe(CO)_5$ with compound (IX) in the presence of $(CH_3)_3NO$ affords compound (VIII):

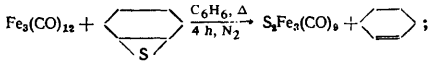
$$Te_2Fe_2(CO)_6 + Fe(CO)_5 + 2(CH_3)_3NO \rightarrow Te_2Fe_3(CO)_9 + 2CO_2 + 2(CH_3)_3N.$$

The structure of cluster (VIII) has been established by X-ray diffraction.[37]

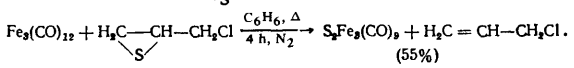
Iron clusters containing two different chalcogen atoms in one molecule were first obtained from the tetracarbonylferrate ion.[38] Despite certain difficulties in the isolation of these substances (repeated thin-layer chromatography), the reaction is of practical interest, since it leads to the formation in one stage of clusters which are otherwise difficult to obtain:

$$[Fe(CO)_4]^{2-} + XO_3^{2-} + YO_3^{2-} + H^+ \rightarrow X_2Fe_3(CO)_9 + XYFe_3(CO)_9 + Y_2Fe_3(CO)_9 + CO_2 + CO + H_2O;$$
$$X \text{ и } Y = S, Se, Te;\ X \neq Y.$$

The compounds $XYFe_3(CO)_9$ are solid crystalline substances whose external appearance and properties are very similar to clusters of type (II), which are already known. They do not dissolve in water but do dissolve in organic solvents, namely aliphatic and aromatic hydrocarbons, ether, carbon tetrachloride, chloroform, and especially $CS_2$; they are stable in the solid state in air, while in solution they are also stable in an inert atmosphere but in air they decompose to form brown amorphous insoluble deposits.[38]

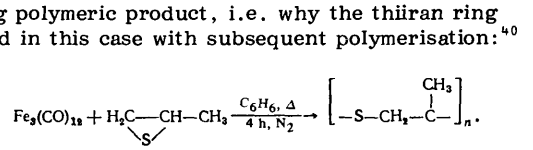


The formation of a cluster of type (II) in satisfactory yield by the reaction of the tetracarbonylferrate ion with sulphoxylic acid has been mentioned.[39]



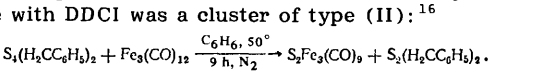
Thus the synthesis of a mixture of chalcogeniron carbonyl clusters (I) and (II) from aqueous alcoholic solutions of alkali metal tetracarbonylferrate salts and the corresponding acids must be regarded as the most general method of their synthesis.

We shall now consider the reactions of various organosulphur compounds with iron carbonyls which lead to the formation of the compound $S_2Fe_3(CO)_9$ as a side product.

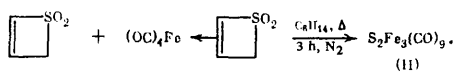


*(a) Reactions of cyclohexene sulphide and 3-chloropropene sulphide with DDCI.* The reaction of DDCI with cyclohexene or 3-chloropropene sulphide in boiling benzene involves the cleavage of the carbon–sulphur bond and the formation of a substance which was initially believed to be an isomer of $S_2Fe_3(CO)_9$.[5]

The decomposition of the thiiran ring with elimination of the sulphur atom and the formation of alkenes is a characteristic property of thiirans.[40] The method of synthesis of $S_2Fe_3(CO)_9$ from cyclohexene and 3-chloropropene sulphides is based on the desulphurisation of thiirans:[5]

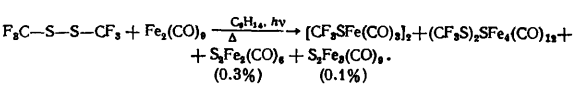


The conditions governing the elimination of sulphur in such cases are much milder compared with thermal desulphurisation, which indicates the preliminary coordination of DDCI or its decomposition products to the sulphur atom. At the same time it is not clear why the main product of the reaction of methylthiiran with $Fe_3(CO)_{12}$ is the corresponding polymeric product, i.e. why the thiiran ring is opened in this case with subsequent polymerisation:[40]



*(b) The reaction of sulphur dioxide, polysulphides, and thiacyclobutene sulphone with iron carbonyls.* The interaction of INC with sulphur dioxide in the absence of irradiation leads to $Fe_2(CO)_8SO_2$; a small amount of $S_2Fe_3(CO)_9$ was isolated together with the above product.[41] The reaction was carried out by passing $SO_2$ through petroleum ether containing a suspension of $Fe_2(CO)_9$ or in liquid $SO_2$ at −10° or −20 °C. However, Field and Newlands[42] did not detect $S_2Fe_3(CO)_9$ in the reaction product (−10 °C, inert atmosphere, 2 h); the reaction mixture contained $Fe_2(CO)_8SO_2$ and $Fe(CO)_5$. Analogous products have been isolated using DDCI.

One of the products of the interaction of bibenzyl tetrasulphide with DDCI was a cluster of type (II):[16]



A suspension of 1,1-dioxothiacyclobuteneiron tetracarbonyl, obtained from thiocyclobutene sulphone and $Fe_2(CO)_9$, gives rise to cluster (II) in 19% yield on refluxing with thiacyclobutene sulphone in hexane[43] (Scheme 2). It is of interest to note that not even traces of $Fe_2(CO)_8SO_2$ and a compound of type (I) were detected in the reaction products.

Scheme 2

(II)

*(c) The reactions of thiols and disulphides with iron carbonyls.* It is well known that dialkyl sulphides, dialkyl disulphides, primary aliphatic thiols, and the corresponding aryl derivatives react with iron carbonyls to form bis(alkyl-, arylthioiron tricarbonyls) (bis-ATITC) having the general formula $[RSFe(CO)_3]_2$ (XI).[44–46] Only two cases where the sulphur atom was eliminated from disulphides and thiols have been described. Thus very small amounts of clusters of types (I) and (II) have been isolated on treating bis(trifluoromethyl) disulphide with $Fe_2(CO)_9$. The main product was the corresponding bis(trifluoromethylthioiron tricarbonyl).[47] Compounds (I) and (II) were not formed when $Fe(CO)_5$ was used:

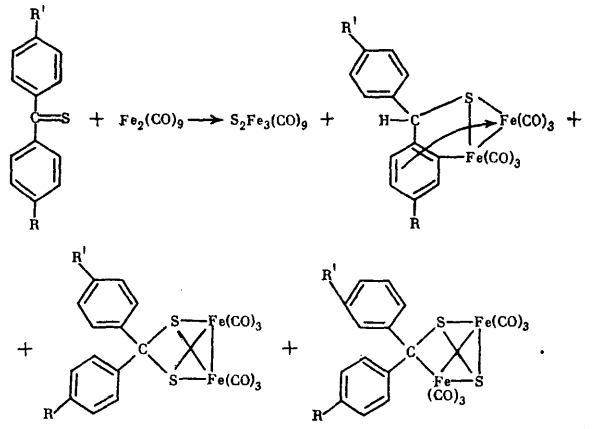
A higher yield (10%) of compound (II) was achieved in the reaction of $Fe_3(CO)_{12}$ with secondary and tertiary aliphatic thiols:[48,49]

$$t\text{-}C_4H_9SH + Fe_3(CO)_{12} \xrightarrow[12\ h]{C_6H_6,\ \Delta} [t\text{-}C_4H_9SFe(CO)_3]_2 + (t\text{-}C_4H_9S)_3Fe_3(CO)_9 + (t\text{-}C_4H_9S)_2SFe_4(CO)_{12} + S_2Fe_3(CO)_9.$$

(35%) (5%) (5%) (10%)

Winter and co-workers[6,50–53] carried out a series of studies on the deprotonation and substitution reactions with trinuclear iron clusters $(RS)(H)Fe_3(CO)_9$ (XII) and $(\mu_3\text{-}X)(\mu_3\text{-}S)Fe_3(CO)_9$ (XIII), where X = PR, AsR, or SO. The compound $S_2Fe_3(CO)_9$ has been obtained in a high yield (57%) by the reaction of $Fe_3(CO)_{12}$ with RSH, where R = $C(C_6H_5)_3$ (toluene, 80 °C, 4 h) together with clusters (XII).[6]

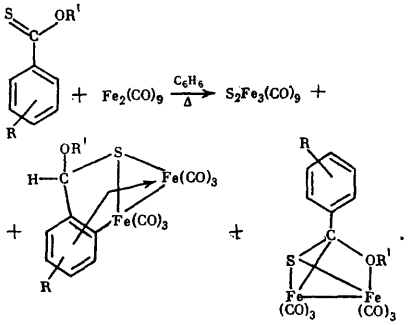
On decomposition, bis(fluorocarbonyl)disulphane also acts as a source of elemental sulphur and gives rise to a cluster of type (II) on interaction with $Fe(CO)_5$:[54]



$$F\text{–}\overset{O}{\overset{\|}{C}}\text{–}S\text{–}S\text{–}\overset{O}{\overset{\|}{C}}\text{–}F + Fe(CO)_5 \xrightarrow[14\ h,\ Ar]{C_6H_6,\ 78\text{–}80^\circ} S_2Fe_3(CO)_9.$$

(26.7%)

A compound of type (II) has been detected when industrial pipes through which a mixture of carbon monoxide and methane had been passed for a long time under a high pressure were disassembled.[55] This cluster might have been formed with participation of sulphur compounds behaving as donors of atomic sulphur and present in the gas mixture as an impurity, via a stage involving the preliminary formation of iron carbonyls.

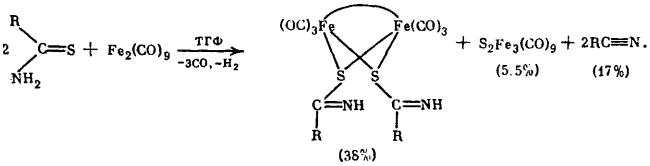


*(d) Reactions of thiobenzophenones with INC.* A cluster of type (II) has been obtained as a side product in 5.4–18.3% yield by the reaction of various thiobenzophenones with $Fe_2(CO)_9$ in benzene at room temperature together with clusters of the type $(C_6H_5)_2CS_2.Fe_2(CO)_6$ (Scheme 3).[56,57] The main compounds were the corresponding *ortho*-metallated complexes formed in most cases in high yields.

Scheme 3

*(e) Reactions of thioesters with INC.* In contrast to the reaction described above, treatment of various *o*-alkyl- and *o*-aryl-thioesters in benzene at room temperature leads mainly to the formation of mixed isomeric diiron hexacarbonyl clusters containing oxygen and sulphur as electron-donating ligands (Scheme 4). Insignificant amounts of the *ortho*-metallated product and a compound of type (II) have been isolated (0.7–7.5%).[51,58,59]

Scheme 4



*(f) Reactions of thiourea and thioamides with INC.* Under analogous conditions, substituted thiourea and a series of thioamides react with $Fe_2(CO)_9$ to produce iron tetracarbonyl clusters containing sulphur as the ligand, diiron hexacarbonyl clusters with mixed ligands, and traces (0.1–2.5%) of cluster (II):[17,60–62]

$$RNHCR' + Fe_2(CO)_9 \xrightarrow[\Delta]{C_6H_6} S_2Fe_3(CO)_9 + RNHCR' + [RNHCR']_3 + (RNCR')_2Fe_3(CO)_6.$$

Compound (II) is formed in 5.5% yield on treatment of $Fe_2(CO)_9$ with *p*-methoxythiobenzamide in tetrahydrofuran (THF) at room temperature for 24 h.[17] It is of interest to note that compound (II) is formed via a stage involving the formation of the diiron hexacarbonyl cluster (38%) with subsequent substitution of part of the ligand by the iron tricarbonyl fragment and the isolation of *p*-methoxybenzonitrile (yield 17%, Scheme 5):[60,61]

Scheme 5

*(g) Reactions of thionoadamantanes with INC.* The main product of the interaction of thionoadamantane with $Fe_2(CO)_9$ is the complex $C_{16}H_{14}S_2Fe_2O_6$ (71.5%) which is sensitive to air and differs from the product of the reaction of thiobenzophenone, containing both bridging and terminal carbonyl groups and two sulphur atoms attached to the same carbon atom.

At the same time in the reactions of thiocamphenilone with the complexes mentioned above, compound (II) was isolated as a side product (1.9%), while the reaction of thiofenchone gives rise to a mixture of compounds (I) and (II) (4.6 and 15.7% respectively)[61] [Ref.62? (Ed. of Translation)].

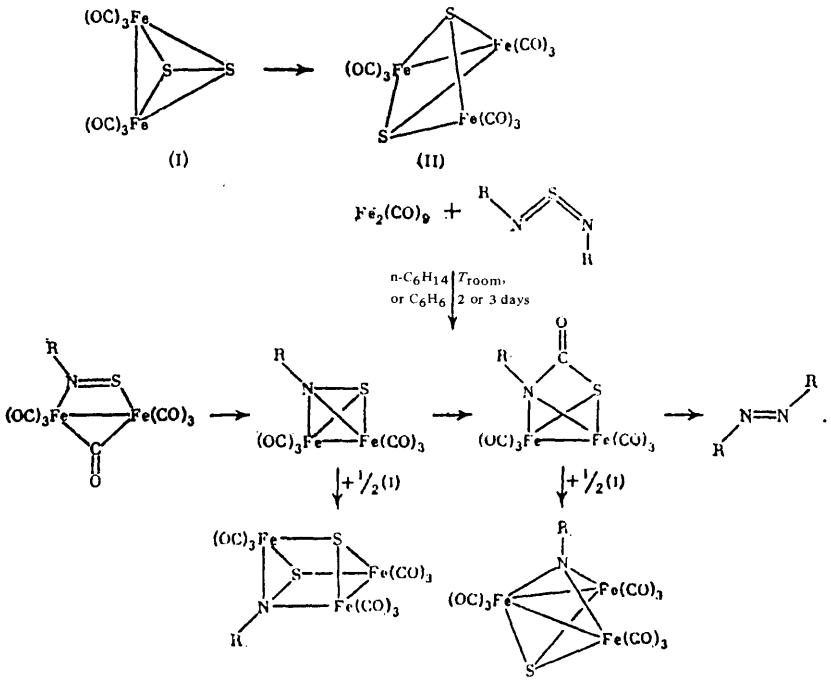
In addition traces of compound (II) have been isolated in the reaction of 2-thiono-1,3-dioxolanchromium pentacarbonyl with $Fe(CO)_5$ on irradiation in THF[63] and on interaction of diphenylthionocyclopropene with $Fe_2(CO)_9$ in THF.[64] Later the formation of ligands of a new type on treatment of diphenylthionocyclopropene with the carbonyl $Fe_2(CO)_9$ and the study of the crystal structures of carbene complexes with a cluster skeleton, namely $Fe_3S_2$, $C_3(C_6H_5)_2Fe_3S_2(CO)_8$, and the dithiodiketone derivative

$C_6(C_6H_5)_4S_2Fe_2(CO)_6$ were described.[65] When the sulphur diimide R–N=S=N–R [R = t-$C_4H_9$ or 4-$(CH_3)C_6H_4$] was treated with $Fe_2(CO)_9$, very small amounts of clusters (I) and (II) were isolated and analysed by a highly sensitive liquid chromatographic technique[66] together with dinuclear and trinuclear iron carbonyl clusters (Scheme 6).[67,68]

*(h) Reactions of carbon disulphide with DDCI.* The compound $S_2Fe_3(CO)_9$ was obtained together with the main product $(CS)SF_4(CO)_{12}$ and two unidentified complexes in the reaction of carbon disulphide with $Fe_3(CO)_{12}$ (in hexane at 80 °C, 10 atm, CO : Ar = 1 : 1, 7.5 h).[69] Only the overall yield of the four compounds is quoted (4%). In addition, the compound $S_2Fe_3(CO)_9$ was isolated in 8% yield together with the octacarbonyl cluster $(C_3H_2S_2)Fe_3(CO)_8S_2$ (43%) as the main product in the reaction of a 1,3-dithiole2-thione with $Fe_2(CO)_9$.[70]

The cluster $S_2Fe_3(CO)_9$ was also obtained as a side product in the reaction of $C_6H_5P(S)Cl_2$ with DDCI in the presence of magnesium in THF together with the mixed-ligand trinuclear cluster $(\mu_3\text{-}S)(\mu_3\text{-}PC_6H_5)Fe_3(CO)_9$ (17%) and the already known $(\mu_3\text{-}PC_6H_5)_2Fe_3(CO)_9$.[71]

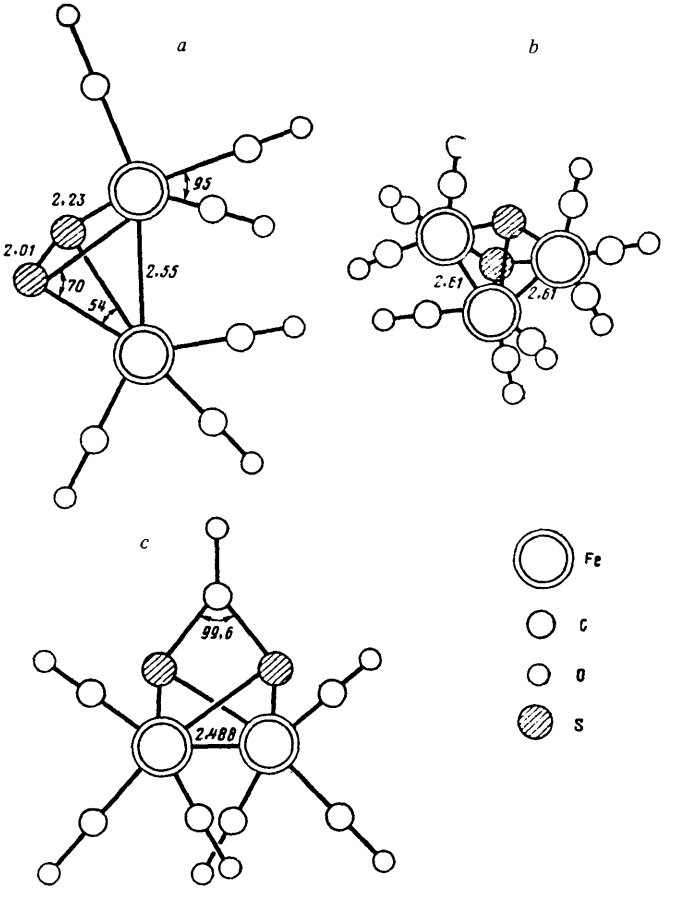
The formation of hydrothiocarbonylferrate cluster anions $H_{2-n}Fe_3(CO)_9S^{n-}$ ($n$ = 1,2) has been reported.[72] Such anions, $HFe_3(CO)_9S^-$ or $Fe_3(CO)_9S^{2-}$, are formed when the hydride clusters $HFe_3(CO)_9(SR)$ are heated in polar solvents.[73,74]



Thus it is seen from the foregoing that the trinuclear cluster $S_2Fe_3(CO)_9$ is a permanent side product in the interaction of iron carbonyls with various organosulphur compounds; it has been shown[3] that, according to TLC data, the initial product is dithiodiiron hexacarbonyl $S_2Fe_2(CO)_6$, which is subsequently converted into a compound of type (II). Methods for the separation of mixtures of compounds (I) and (II) are described in the same communication.[3] It has been found that cluster (II) is fully decomposed and cluster (I) is quantitatively isolated in column chromatography using alumina and n-hexane as the eluent. Refluxing of alcoholic solutions of a mixture of compounds (I) and (II) also decomposes fully compound (II), while cluster (I) is isolated in 72% yield (methanol) and 92% yield (isopropyl alcohol). On the other hand, refluxing of benzene solutions leads to the formation of only the trinuclear cluster (II) in 92% yield. The above results are important not only for the separation of a particular cluster in a pure form but also for the selection of conditions for reactions involving these compounds.

The principal methods of synthesis of the compounds $S_2Fe_2(CO)_9$ and $S_2Fe_3(CO)_9$ are surveyed in the Table. Analysis of the tabulated literature data shows that three methods are the most promising for the synthesis of a mixture of clusters (I) and (II): (1) from elemental sulphur and DDCI (in THF);[3] (2) from hydrogen sulphide and DDCI (in benzene);[4] (3) from elemental sulphur and TSUTH (in benzene).[3] The interaction of $H_2C\text{–}\underset{\underset{S}{\diagup}}{CH}\text{–}CH_2Cl$[5] or $(C_6H_5)_3CSH$[6] with DDCI must be regarded as the most effective method of synthesis of the trinuclear cluster (II).

## III. STRUCTURE AND PHYSICAL RESEARCH METHODS



The structures of the compounds $S_2Fe_2(CO)_6$,[75] $S_2Fe_2(CO)_7$,[20] $S_2Fe_3(CO)_9$,[76] $SFe_3(CO)_{10}$,[22] $Se_2Fe_3(CO)_9$,[35] and $Te_2Fe_3(CO)_9$[37] were established by X-ray diffraction. Fig. *a* illustrates the structure of a sulphur-containing cluster of type (I). Evidently the –S–S– ligand is a bridge linking symmetrically two iron atoms; the iron–iron distance corresponds

Scheme 6

to the formation of a metal–metal bond. Fig.*b* shows that the sulphur-containing cluster of type (II) contains a triangle of iron atoms: the lengths of the two Fe–Fe bonds are on average 2.6 Å, while the third side of the triangle is 3.37 Å long. Subsequently it was established that, on passing to the analogous clusters containing selenium[35] and tellurium,[37] all the metal–metal bonds become so much longer that in the structure of the $Te_2Fe_3(CO)_9$ cluster the three $Fe(CO)_3$ fragments are in essence linked to one another only via $\mu_3$-tellurium bridges.

It has been shown by X-ray diffraction that the structure of the cluster $[\mu\text{-S–C(O)–S–}]Fe_2(CO)_6$ corresponds to the insertion of CO in the S–S bond (Fig.*c*).[20] It has also been demonstrated with the aid of the same method that the $\mu_3$-bridging sulphide and CO ligands in the cluster $(\mu_3\text{-S})(\mu_3\text{-CO})Fe_3(CO)_9$ "build-up" the triangle of Fe atoms to a trigonal bipyramid (the number of valence electrons associated with the three Fe atoms is 48).[22]

The structures of the $(\mu\text{-S})_2Fe_2(CO)_6$ (*a*), $(\mu_3\text{-S})_2Fe_3(CO)_9$ (*b*), and $[\mu\text{-S–C(O)–S–}]Fe_2(CO)_6$ (*c*) clusters.

The relation between the number of atoms, the number of bonding electron pairs (skeletal electrons) and the geometrical structure of cluster compounds has been examined[77,78] and the different types of geometrical structures of cluster compounds have been classified as a function of the number of atoms in the cluster, and simple rules have been formulated for the calculation of the number of bonding electron pairs in cluster compounds of different types. Such calculation makes it possible to explain the known structures and to predict the unknown structures of the known compounds as well as the existence of new compounds and methods for their synthesis. In particular, certain possible transformations of geometrical structures of one type into those of another type in reactions accompanied by a change in the number of skeletal electrons of a given cluster have been examined and the interaction of compound (II) with $L_3M(CO)_3$ has been described, but has not so far been confirmed experimentally:

$$S_2Fe_3(CO)_9 + L_3M(CO)_3 \rightarrow (OC)_3MS_2Fe_3(CO)_9 + 3L;$$
$$L = CO, RCN;\ M = Cr, Mo, W.$$

The results of quantum-chemical calculations by the self-consistent field method (SCF–$X_\alpha$–SW) have been compared[79,80] with data obtained from the photoelectron spectra of the $S_2Fe_2(CO)_6$ molecule and it has been established that the Fe–Fe bond is best described in terms of a simple "bent" bond, while the orbital corresponding to it has the character of the highest occupied molecular orbital (HOMO).

The infrared and Raman spectra of $S_2Fe_2(CO)_6$ and the $(CH_3S)_2Fe_2(CO)_6$ isomers have shown[81] that the Fe–Fe bond stretching vibrations are at 191 $cm^{-1}$; the force constant of this bond is 1.3 mdyn $A^{-1}$ and is close to the value expected for a single Fe–Fe bond. Study of the infrared spectra in the CO group stretching region, in hexane solutions of a series of dinuclear bridged carbonyl complexes of the type $Y_2Co_2(CO)_6$, where Y = CO, P, As, or CR, and $X_2Fe_2(CO)_6$, where X = S, SR, Se, PRR′, Br, or I, both with normal and enriched in $^{13}CO$, established that the difference between the force constants for the axial and equatorial CO groups (the latter are in the *trans*-position relative to the bridging ligand) characterises the $\pi$ interaction of the metal with the bridging group.[82]

The dimeric character of the clusters $[XFe(CO)_3]_2$, where X = S, Se, $SC_2H_5$, $SeC_2H_5$, or $SC_6H_5$, has been demonstrated by their diamagnetism and also by the results of cryoscopic studies of these compounds (in benzene). The dipole moments of type (I) clusters considered, with X = S, Se, or $SC_2H_5$, in benzene and of a compound of type (I), with X = $SC_2H_5$, dissolved in cyclohexane are respectively 1.63 ± 0.1, 2.20 ± 0.07, 2.69 ± 0.05, and 2.66 ± 0.04 D,[83] which also indicates their dimeric character. The authors proposed for them non-planar bridged structures analogous to those which were later established by X-ray diffraction (Fig.*a*).

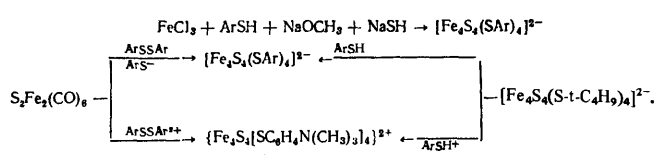
The $^{13}C$ NMR spectra have been investigated in a series of studies[84–87](including the observation of satellites due to the $^{57}Fe$ nucleus) for a series of clusters: $S_2Fe_2(CO)_6$ and the *syn*- and *anti*-isomers of $(CH_3S)_2Fe_2(CO)_6$ and $Fe_3(CO)_{12}$. The information obtained indicates the retention in solution of the structures established for these compounds in the crystal state. On varying the experimental temperature, intramolecular dynamic processes were discovered but their nature has not been accurately established.

The electronic structure of the dinuclear clusters (I) and their analogues containing metal–metal bonds has been studied[88] with the aid of He(I) and He(II) photoelectron spectra.

The Mössbauer spectra of the compounds $S_2Fe_3(CO)_9$, $Se_2Fe_3(CO)_9$, and $R_3PS_2Fe_3(CO)_8$ have been investigated by $\gamma$-nuclear resonance.[89–92] The mass spectra of $X_2Fe_2(CO)_6$ (X = S or Se) and $X_2Fe_3(CO)_9$ (X = S, Se, or Te) have been

published.[93] The data obtained have been compared with the results of thermogravimetric analysis of thermal decarbonylation, of the same clusters in the temperature range 25–600 °C. After decarbonylation, the residues were subjected to X-ray diffraction and magnetic investigations.[93]

The mass spectrum of compound (II) contains the molecular ion as well as ions formed as a result of the successive elimination of the nine CO groups. The maximum peak is that of the $S_2Fe_3^+$ ion, which subsequently decomposes with formation of $S_2Fe_2^+$ and $Fe_2^+$.[94] Mass spectrometric studies on the negative ions formed from $X_2Fe_3(CO)_9$ (X = S, Se, or Te) have been reported.[95] The peak of the $X_2Fe_3(CO)_7^-$ ion proved to be the most intense and a weak molecular peak due to $Te_2Fe_3(CO)_8^-$ was also observed.



Study of the oxidation-reduction reactions of the cluster $Cp_3Fe_3(CO)_2(S)(SR)$ by the cyclic voltamperometric method revealed the presence of two waves on the voltage–current plots corresponding to two reversible oxidation-reduction processes.[96,97] The voltage–current plot for $S_2Fe_3(CO)_9$ showed only one wave, whose potential was more negative than for $Cp_3Fe_3(CO)_2(S)(SR)$. The smaller chemical shift in the $^{57}Fe$ Mössbauer spectra of the cluster $Cp_3Fe_3(CO)_2(S)(SR)$ compared with $S_2Fe_3(CO)_9$ shows that the CO groups in the former cluster are more powerful π-acceptor ligands than the terminal CO groups in the latter cluster.[97]

## IV. CHEMICAL PROPERTIES

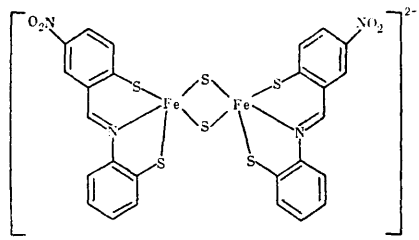
The advance achieved nowadays in the chemistry and physics of cluster compounds have brought to the fore the task of investigating their reactivities and their unique properties, which in many respects have altered traditional ideas about the reactivity of coordination and organometallic compounds.

### 1. The Conversion of Type (I) Clusters into Cubane Clusters

Considerable advances have been made in the synthesis and study of clusters having the general formula $[Fe_4S_4(SR)_4]^{n-}$, where R is an alkyl or aryl group. The structures of these synthetic analogues of proteins, established by X-ray diffraction, and their spectroscopic and magnetic properties are very similar to those of clusters found in the so-called "proteins with a high potential" (PHP) and in oxidised ferredoxin.[98] The synthesis of cubane clusters of the $Fe_4S_4$ type from a carbonyl-containing compound of type (I) has been described.[99] The preparation of the corresponding cluster and the specific syntheses from known compounds proceed in accordance with the following scheme:

The reaction mixture containing $S_2Fe_2(CO)_6$, $C_6H_5SSC_6H_5$, and $C_6H_5S^-$ in molar proportions of 1 : 1 : 2 yields $[Fe_4S_4(SC_6H_5)_4]^{2-}$ as the only product, which was isolated and identified in the form of the tetraphenylarsonium salt (65% yield):

$$S_2Fe_2(CO)_6 + C_6H_5SSC_6H_5 + C_6H_5SH + (C_6H_5)_4AsCl \xrightarrow[1\ h,\ CH_3OH,\ \Delta]{CH_3ONa,\ N_2} [(C_6H_5)_4As]_2\{Fe_4S_4(SC_6H_5)_4\} + CO + NaCl.$$



The cationic tetramer was obtained in the following way:

$$S_2Fe_2(CO)_6 + (n\text{-}(CH_3)_3NC_6H_4S)_2(PF_6)_2 + [n\text{-}(CH_3)_3NC_6H_4SH]PF_6^+ + CH_3ONa \xrightarrow[N_2,\ 1\ h,\ \Delta]{CH_3OH\text{–}CH_3CN} \{Fe_4S_4[SC_6H_4N(CH_3)_3\text{-}n]_4\}^{3+} + CO + NaPF_6.$$

According to the authors,[99] the carbonyl groups in compound (I) are initially fully substituted by the thiyl fragment with formation of the $Fe_2S_2$ cluster, which is followed by thermal or catalytic dimerisation:

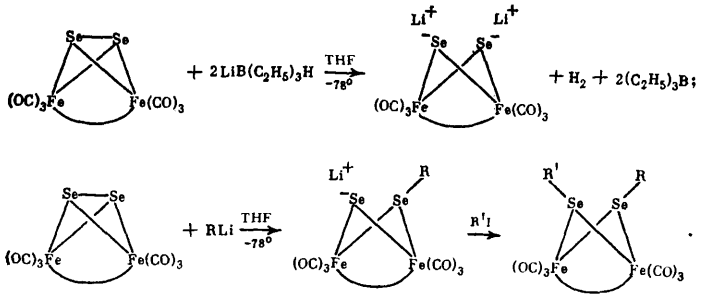
$$S_2Fe_2(CO)_6 + RSSR + 2RS^- \rightarrow [S_2Fe_2(SR)_4]^{2-} + 6CO;$$
$$2[S_2Fe_2(SR)_4]^{2-} \rightarrow [S_3Fe_4(SR)_4]^{2-} + RSSR + 2RS^-.$$

The interaction of 2,2-bis{benzo[*d*]thiazoline}-4,4-dinitrodiphenyl disulphide with compound (I) in the presence of sodium methoxide was investigated in the same study.[99] The corresponding anionic cluster, free from carbonyl groups, was identified in the form of the tetraphenylarsonium salt. The authors suggest that the cluster contains pentacoordinate iron(III). An analogous cluster has been obtained by the reaction of $FeCl_3$, NaSH, and a base with thiazoline disulphide.

### 2. Reduction Reactions of Type (I) Clusters

Treatment with reducing agents such as KH, metallic sodium, and the RLi–LiBr (R = $CH_3$ or $C_4H_9$) system leads to the cleavage of the S–S bond in compound (I).[100,101] The authors suggest the initial formation of both the monoanion (A) and the corresponding dianion (B), which subsequently readily enters into condensation reactions, for example, in accordance with the following scheme:

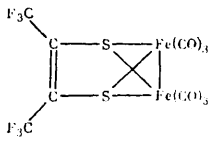
$$S_2Fe_2(CO)_6 + CH_3Li/LiBr \xrightarrow[-78^\circ]{(C_2H_5)_2O,\ N_2} \underset{(A)}{[(CH_3S)_2Fe_2(CO)_6]^-} \xrightarrow[12\ h]{CH_3I} \underset{(82\%)}{(CH_3S)_2Fe_2(CO)_6};$$
$$S_2Fe_2(CO)_6 + KH \xrightarrow[4\ h]{THF,\ N_2} \underset{(B)}{[S_2Fe_2(CO)_6]^{2-}} \xrightarrow{CH_3I} \underset{(53\%)}{(CH_3S)_2Fe_2(CO)_6}.$$



This leads to a way of synthesising various asymmetric bis(alkylthio)diiron hexacarbonyl clusters from the monoanion (A). The dianion (B) is of considerable interest for the synthesis of already known iron sulphide clusters containing both acyclic and cyclic groups.[101] An improved method of synthesis of the dianion (B) for compound (I) into THF by treatment with $LiB(C_2H_5)_3H$ has been proposed.[102]

The reactions of the dianion (B) with organic halides and with tin, germanium, silicon, and nickel halides have also been reported.[102] The protonation of the dianion (B) by treatment with $CF_3COOH$ leads to the formation of the bridged thiol cluster $(HS)_2Fe_2(CO)_6$ in a quantitative yield. Its synthesis and some of its properties have been described in detail in two communications.[103,104] This thiol cluster has been used to synthesise the $S_2Fe_2(CO)_6$ clusters in the study of the chemistry of these compounds.[105]

It has been found[34] that the reactivity of diselenodiiron carbonyl $Se_2Fe_2(CO)_8$ (VI) is the same as that of the usual organic diselenides RSeSeR. Thus the reaction with two molar equivalents of $LiB(C_2H_5)_3H$ converts compound (VI) into the dianion $(LiSe)_2Fe_2(CO)_6^{2-}$. Organolithium reagents



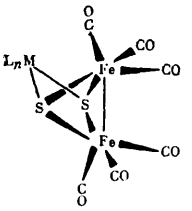
cleave the Se–Se bond in compound (VI), affording (μ-LiSe).(μ-RSe)$Fe_2(CO)_6$ [34] by analogy with the sulphur-containing cluster (Scheme 7).[101]

Scheme 7

### 3. Interaction of Compounds of Type (I) with Activated Acetylenes

The photochemical effect of activated acetylenes (hexafluorobut-2-yne or dimethyl or diethyl acetylenedicarboxylate) on dithiodiiron hexacarbonyl $S_2Fe_2(CO)_6$ in THF leads to their insertion in the cluster not in the Fe–Fe bond, as happens for $(RS)_2Fe_2(CO)_6$,[106] but in the S–S bond[107] with formation of a dithiolene cluster of the type

whose structure has been demonstrated by specific synthesis.[107]

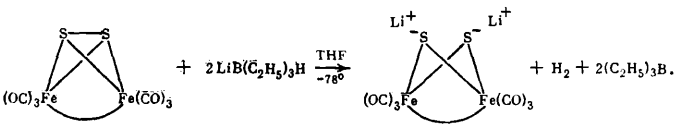


### 4. Reactions Involving Addition to Type (I) Clusters

It has been shown recently[108] that lithium alkyls also add to $S_2Fe_2(CO)_6$ at the S–S bond.

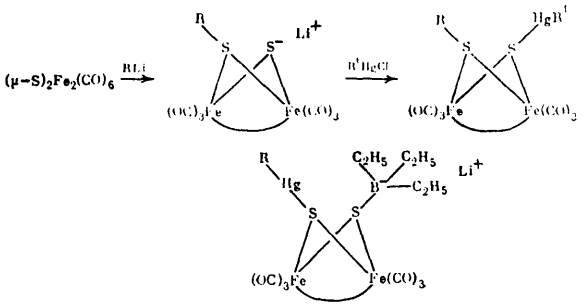
An unexpected intramolecular nucleophilic substitution in the anionic complex of $Fe_2(CO)_6$ with an organosulphur ligand has been observed.[109] It can be regarded as a new method of synthesis of complexes of $Fe_2(CO)_6$ with dithioformic acid esters. Later the same workers[110] discovered the formation of an exocluster sulphonium group from the product of the deprotonation of the diiron hexacarbonyl complex of thioformic acid ester.[111]

### 5. Reactions of Type (I) Compounds with Metal Complexes



The reactions of dithiodiiron hexacarbonyl can only involve the S–S bond, which constitutes a feature of this compound similar to that of organic disulphides. The reaction of compounds (I) with metal complexes in the zerovalent state, such as $[(C_6H_5)_3P]_4Pt$, $[(C_6H_5)_3P]_3Pd(CO)$, and $[(C_6H_5)_2PCH_2CH_2P(C_6H_5)_2]Ni(CO)_2$ entails the insertion of Ni, Pt, and Pd in the S–S bond, and under mild conditions (benzene, 20 °C, 2.5–24 h) the products are the coloured crystalline complexes $QM(S)_2Fe_2(CO)_6$ where Q = $(C_6H_5)_2PCH_2CH_2P(C_6H_5)_2$ or $[(PC_6H_5)_3]_2$ and M = Ni, Pd, or Pt, which are stable in air.[112]

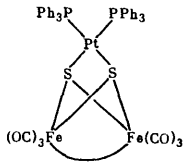
Analogous products have been obtained by the reaction of the dianion (B) with the corresponding metal chlorides.[112]



The transfer of the alkyl group from the boron atom to the sulphur atom in the reactions of lithium hydrotriethylborate derivatives of the bis(μ-thiolato)-bis(tricarbonylferrate) dianion with mercury and alkylmercury chlorides has been described.[113] The reactions of $(\mu\text{-LiS})_2Fe(CO)_6$, obtained by the interaction of $S_2Fe_2(CO)_6$ and $LiB(C_2H_5)_3H$ with $HgCl_2$ in THF in accordance with Scheme 8, in methyl, ethyl, or propyl alcohol, or in THF give rise to the product of the previously unknown transfer of the alkyl group from the boron atom to the sulphur atom: $(\mu\text{-SC}_2H_5)$. $(\mu\text{-SHgC}_2H_5)Fe_2(CO)_6$.

Scheme 8

The formation of elemental mercury in this reaction led the authors[112] to the hypothesis that RHgCl acts as an oxidant, oxidising the intermediate complex [shown in Scheme 9] and leading to the transfer of the ethyl group from boron to sulphur, yielding ultimately the observed product, for which four isomers are possible according to $^1H$ and $^{13}C$ NMR spectra (Scheme 9).[113]



Scheme 9

An interesting comparison of the reactivities of the carbonyl dianion $[S_2Fe_2(CO)_6]^{2-}$ and the anion of Roussin's red salt $[S_2Fe_2(NO)_4]^{2-}$ has been made in a report,[114] which describes also certain chemical properties of Roussin's red salt, in particular its reactions with monofunctional electrophiles RX[R = $CH_3$, $C_2H_5$, $CH_2=CHCH_2$, $C_6H_5CH_2$, $CH_3Sn$, $(C_6H_5)_3Sn$, $(C_6H_5)_3Pb$, $C_6H_5Hg$, or $CpFe(CO)_2$; X = halogen], resulting in the formation of the related nitrosyl complexes $(RS)_2Fe_2(NO)_4$ and NaX.

The synthesis and the structure of the bridged platinum derivative of Roussin's red salt (Scheme 10) are described in the subsequent communication by the same authors.[115]

Scheme 10

$$+ 4NO \longrightarrow (Ph_2P)_2PtS_2Fe_2(NO)_4 + 6CO.$$

The same derivative has been synthesised by the reaction of $Na_2[Fe_2(S)_2(NO)_4]$ with *cis*-$[(C_6H_5)_3P]PtCl_2$ in THF.[115]

## 6. The Insertion of Group IVB Elements in Type (I) Clusters

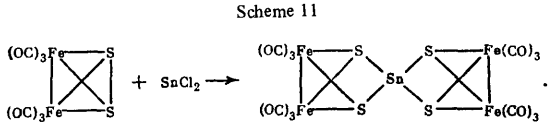
Group IVB elements can be inserted into a cluster (I) both in the S–S and Fe–Fe bonds. The compounds formed may be of definite interest, because fragments capable of entering into numerous reactions remain in both cases.

It has been shown[116] that the reaction of compound (I) with the triethylamine complex of trichlorosilane (pentane, 1 h, 40 °C) results in the formation of bis(hexacarbonyldithiodiiron)silicon (73%):

$$S_2Fe_2(CO)_6 + HSiCl_3\cdot(C_2H_5)_3N \rightarrow Si[S_2Fe_2(CO)_6]_2.$$

When methanolic solutions of compound (I) and the triethylamine complex of trichlorogermane are mixed, a brown-red precipitate of bis(dithiodiiron)germanium is formed instantly at room temperature (82%):[116,117]

$$S_2Fe_2(CO)_6 + HGeCl_3\cdot(C_2H_5)_3N \rightarrow Ge[S_2Fe_2(CO)_6]_2.$$



The structure of this cluster has been established.[118]

The reaction involving the dissociation of the S–S bond in compound (I) after preliminary treatment with various reducing agents (with formation of the corresponding dianions) has also been achieved and a complex containing the $(CH_3)_2Sn$ fragment has been obtained.[101] In contrast to the triethylammonium salts of trihalogenogermanes(silanes), the corresponding $HSnCl_3$ salt does not react with dithiodiiron hexacarbonyl.[3] At the same time refluxing of a solution of a type (I) cluster in absolute ethanol with the tribromostannane–amine complex leads to the formation of a product containing two molecules of the amine complex and one molecule cluster (I) (according to the results of elemental analysis and the infrared spectra):

$$S_2Fe_2(CO)_6 + (C_2H_5)_3N\cdot HSnBr_3 \rightarrow S_2Fe_2(CO)_6\cdot 2(C_2H_5)_3N\cdot HSnBr_3.$$

Treatment of compound (I) with tin dichloride in solution in methanol, ethanol, and a methanol–ethyl acetate mixture (4 h, 65 °C) gives rise to a compound in which the $SnCl_2$ : (I) ratio is 1 : 2 (on the basis of the results of elemental analysis) (Scheme 11).[3]

Scheme 11

## 7. Reactions of Compound (I) with Diazomethane

When compound (I) was allowed to react with diazomethane in ether at temperatures ranging from −40° to 20 °C, a brown deposit consisting of fractions having different molecular weights was obtained.[119] Treatment of the deposit with pentane and subsequent chromatography on $Al_2O_3$ or silica gel led to the isolation of various methylene-, bismethylene-, methyl-, and trismethylene-dithiodiiron hexacarbonyl clusters with the main high-molecular-weight $[H_2C = S_2Fe_2(CO)_6]_x$ fraction, which is insoluble in the usual organic solvents.[119]

## 8. The Effect of Halogens on Compounds (I) and (II)

The first data concerning the effects of the halogens on sulphur cluster complexes have been published by Hieber and Kaiser.[120] The reactions of dinuclear carbonyliron mercaptides $(C_2H_5S)_2Fe_2(CO)_6$ with halogens leads to compounds of the type $[C_2H_5SFe(CO)_3X]_2$ (X = Br or I). The phosphine-substituted compounds $[Fe(CO)_2LX]_2$ [L = $P(C_6H_5)_3$; X = S, $SC_2H_5$, or $SC_6H_5$] react with iodine to form the periodides $[Fe(CO)_2LXI_{0.5}]^+_2I_3$, while salts of a trinuclear cation of the type $[Fe_3(CO)_4L_2X_2Hal_4]^+Hal^-$ are formed when the unsubstituted compounds $[Fe(CO)_3LX]_2$ react with chlorine, bromine, or iodine (Hal). Compounds of the last two types are isolated from aqueous mediums as salts, for example, $[Fe(CO)_2LXHal_{0.5}]^+_2[PF_6]^-$.[120]

The reactions of the trinuclear dithiotriiron carbonyl of type (II) with the halogens lead to the formation of a trinuclear cluster cation under the same conditions: $[Fe_3(CO)_6\cdot S_2Hal_4]^+Hal^-$.[120]

## 9. Reactions Involving the Substitution of Ligands in Compounds (I)

We shall consider initially the reactions leading to the cleavage of the S–S bond in compounds (I) and in the same reactions involving compounds (II).

For the carbonylthio-clusters considered, there exist two examples of the complete substitution of carbonyl groups. The first concerns the preparation of synthetic analogues of iron- and sulphur-containing proteins (ferredoxins)[99] and the second the reaction of compounds (II) with bis(trifluoromethyl)dithioethane.[121]

The reaction of compound (II) with $S_2C_2(CF_3)_2$ affords a high yield of $S_2Fe_3[S_2C_2(CF_3)_2]_4$,[121] which has also been synthesised from $(CF_3)_2C_2S_2Fe_2(CO)_6$ and sulphur.[122] This is a novel method of synthesis of trinuclear clusters not containing carbonyl fragments.

Certain carbonyl groups in metal carbonyls are known to be readily substituted by phosphines, arsines, and stibines, but for the majority of metal carbonyls the removal of all the carbonyl groups presents considerable difficulties; this can be achieved only in reactions with triphenylphosphine.[7,45,123,126]

The interaction of the sulphur-containing cluster (I) with triphenylphosphine at room temperature has been described. It leads to the formation of a disubstituted cluster whose molecular weight has been determined:[127]

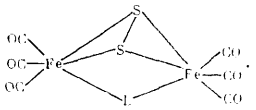
$$S_2Fe_2(CO)_6 + 2P(C_6H_5)_3 \xrightarrow[20°]{C_7H_{16}} [(H_5C_6)_3P]_2S_2Fe_2(CO)_4] + 2CO.$$

The reactions of $X_2Fe_2(CO)_6$, where X = S or Se, with a ligand L lead to various products, whose formation depends on the nature of both L and X.

When the less reactive $Se_2Fe_2(CO)_6$ is treated with $As(C_6H_5)_3$ or $P(OC_6H_5)_3$, mainly the monosubstituted product (A) and to a lesser extent the disubstituted compound (B) are formed; polynuclear complexes were not detected.[127]

$$Se_2Fe_2(CO)_6 + L \rightarrow \underset{(A)}{LSe_2Fe_2(CO)_5} + CO;$$

$$LSe_2Fe_2(CO)_5 + L \rightarrow \underset{(B)}{L_2Se_2Fe_2(CO)_4} + CO;$$



$$L = As(C_6H_5)_3,\ P(OC_6H_5)_3.$$

It is important to note that the interaction of compound (I) with $P(C_6H_5)_3$ leads initially to the formation of the compound $(C_6H_5)_3PS_2Fe_2(CO)_6$, which, however, has not been isolated.[127] It has been characterised only by infrared spectroscopy, together with $(C_6H_5)_3PS_2Fe_2(CO)_5$. The difficulty of isolating this cluster is probably associated with its instability and high reactivity. The main reaction products are the corresponding mono- and di-substituted derivatives (I) and (II).

The same workers[127] have shown that, when $P(OC_6H_5)_3$ is used, the unstable compound $(C_6H_5O)_3PS_2Fe_2(CO)_5$ is formed as an intermediate. The reaction mixture also contains mono- and di-substituted derivatives of compounds (I) and (II). It has been suggested that the trinuclear clusters are formed via a stage in which an intermediate complex is produced on interaction of compound (I) with the mono-derivative or the adduct.[127]

The greater difference between the reactivities of $As(C_6H_5)_3$ and $P(n\text{-}C_4H_9)_3$ in their reactions with compound (I) shows that the preliminary dissociation of the initial complex is unlikely and that the ligand is coordinated to compound (I) with formation of an adduct:

$$S_2Fe_2(CO)_6 + L \rightarrow LS_2Fe_2(CO)_6;$$
$$L = P(C_6H_5)_3,\ P(n\text{-}C_4H_9)_3;$$

A structure in which the ligand is formally coordinated to two iron atoms, forming a labile three-centre donor–acceptor bond, has been proposed for the adduct.

The dinuclear chalcogeniron carbonyl clusters $L_2(CH_3S)_2 \cdot Fe_2(CO)_4$, formed in the reactions of compounds (I) with a proton[128] and $HgCl_2$,[129] as well as the salt-like complexes with the halogens, namely $[Fe(CO)LL'(SR)]_2$ (L' = CO, phosphine, or phosphite), frequently have a similar structure.[130] An additional piece of evidence for the formation of adducts in the above systems is, according to the authors,[131] the oxidative addition of $(CF_3)_2C_2S_2$ or $NOPF_6$ to compounds (I), leading to the formation of the cationic complex $[Fe_2(SR)_3(CO)_6]^+$, in which the SR group is inserted in the Fe–Fe bond. The structure of this compound has been established by X-ray diffraction.[132]

Monosubstituted derivatives of compound (I) are readily generated from the adduct as a result of the migration of the ligand to one of the iron atoms with the simultaneous elimination of a CO group in accordance with the equation

$$LX_2Fe_2(CO)_6 \rightarrow LX_2Fe_2(CO)_5 + CO.$$

The subsequent attack by the iron atom on a second molecule of L leads to the formation of a disubstituted derivative of compound (I).[130]

The stability of the substitution products depends on the nature of the ligand,[45] apparently owing to the formation, on successive substitution, of a system having an exess electron density of the iron atoms, which promotes the mutual repulsion of the latter. An analogous influence of the nature of the cations on the stability of compounds with an Fe–Fe bond has been demonstrated in another study.[133]

The kinetics of CO substitution in $X_2Fe_2(CO)_6$ clusters (where X = S or Se) by ligands such as $As(C_6H_5)_3$, $P(OC_2H_5)_3$, $P(OC_6H_5)_3$, or $P(C_6H_5)_3$ has been investigated by infrared and ultraviolet spectroscopy.[134] A possible mechanism of the reactions of compounds (I) with L has been proposed, according to which the rate-determining reaction stage involves the formation of the associated species $X_2Fe_2(CO)_6L$, which subsequently loses a CO group with formation of a monosubstituted product or again reacts with a molecule of compound (I), giving rise to a trinuclear derivative via an intermediate of the type $X_2Fe_2(CO)_6L\ldots X_2Fe_2(CO)_6$:

$$X_2Fe_2(CO)_6 \underset{-L}{\overset{+L}{\rightleftarrows}} X_2Fe_2(CO)_6L \begin{cases} \xrightarrow{+L} \text{products;} \\ \xrightarrow{-CO} X_2Fe_2(CO)_5L \xrightarrow{+L} X_2Fe_2(CO)_4L_2; \\ \xrightarrow{+X_2Fe_2CO_6} [X_2Fe_2(CO)_6L\ldots X_2Fe_2(CO)_6] \rightarrow X_2Fe_3\text{-derivatives.} \end{cases}$$

The proposed structure of the "secondary" adduct is extremely doubtful, although it does not conflict with the possibility of the coordination of compound (I) to the initial adduct at the S–S bond.[134]

The adduct can react via different mechanisms, serving as the starting compound for the preparation of polynuclear clusters. It has been noted[134] that the yield of these clusters is a maximum when the concentrations of compound (I) and of L are a maximum.

The rate constants for the above reactions indicate the high sensitivity of compound (I) to the nature of the attacking ligand L, which can be explained, according to the authors,[134] by the ease of their coordination to the Fe atom.

## 10. Ligand Substitution Reactions Involving Compounds (II)

Numerous studies involving the substitution of the CO groups in the compounds $X_2Fe_3(CO)_9$ (X = S, Se, or Te) with phosphines, phosphites, and arsines have been carried out[126,135–140] and it has been shown[135] that, for X = S or Se, a mixture of mono- and di-substituted derivatives of compound (II) is formed:

$$X_2Fe_3(CO)_9 + L \rightarrow LX_2Fe_3(CO)_8 + CO;$$
$$LX_2Fe_3(CO)_8 + L \rightarrow L_2X_2Fe_3(CO)_7 + CO;$$
$$L = As(C_6H_5)_3,\ P(OC_6H_5)_3,\ P(n\text{-}C_4H_9)_3.$$

$Te_2Fe_3(CO)_9$, behaves differently in the reactions considered. It is characterised by the formation in the first stage of the corresponding adduct with subsequent elimination of a CO group:[135]

$$Te_2Fe_3(CO)_9 + L \rightarrow LTe_2Fe_3(CO)_9;$$
$$LTe_2Fe_3(CO)_9 \rightarrow LTe_2Fe_3(CO)_8 + CO.$$

The synthesis and properties of heterometallic cluster compounds obtained from $Te_2Fe_3(CO)_9$ have been described recently.[141]

The reactivity of the mixed cluster $XYFe_3(CO)_9$ (X and Y = S, Se, or Te; $X \neq Y$) in the reaction involving the displacement of a CO group by a triphenylarsine and triphenylphosphine corresponds to the reactivity of $X_2Fe_3(CO)_9$.[138]

The complexes $LXYFe_3(CO)_8$ and $L_2XYFe_3(CO)_7$ have more than one isomer. The ligand L in the monosubstituted complexes is probably coordinated to the Fe atom adjoining the chalcogen atoms, while in the disubstituted complexes two L molecules are coordinated to two iron atoms owing to steric hindrance. However, it cannot be ruled out that the existence of two and more isomers is a result of the ligand exchange between the iron atoms in the cluster.[138]

The synthesis of derivatives of compound (II) by the substitution of one, two, or three CO groups by triphenylphosphine and nitrogen-containing ligands (phenanthroline, $\alpha,\alpha'$-bipyridyl, acetonitrile, triethylamine, pyridine, and piperidine) has been described.[140] The character of the

infrared spectra of the compounds obtained in the carbonyl region depends on the strength of the $d_\pi$ bonds between the ligand and the metal.

### 11. The Reactions of Compounds (I) and (II) with Transition Metal Carbonyls

The rapid rearrangements of the adduct $X_2Fe_2(CO)_6 \cdot L \ldots X_2Fe_2(CO)_6$ lead to the formation of $X_2Fe_3(CO)_9$ or $LX_2Fe_3(CO)_8$ with loss of L or CO respectively. In this case the adduct behaves as a ligand containing a sulphur atom as the nucleophilic fragment. A similar behaviour of the $AsCo_3(CO)_9$ [84] and $SFeCo_2(CO)_9$ [142,143] clusters, in which the As and S atoms manifest the character of Lewis bases in reactions with $Fe(CO)_5$ and $M(CO)_6$ (M = Cr, Mo, or W), has been reported:

$$SFeCo_2(CO)_9 + M(CO)_6 \rightarrow (OC)_5MSFeCo_2(CO)_9 + CO;$$
$$SFeCo_2(CO)_9 + Fe(CO)_5 \rightarrow (OC)_4FeSFeCo_2(CO)_9 + CO;$$
$$AsCo_3(CO)_9 + M(CO)_6 \rightarrow (OC)_5MAsCo_3(CO)_9 + CO.$$

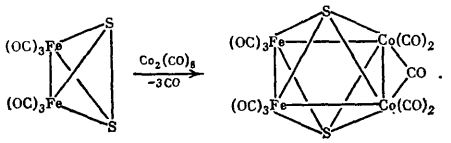
In the adduct the ligand weakens the S–S bond by increasing the electron density in the $X_2Fe_2$ fragment. Steric and electronic factors influence the electron-donating character of the adduct. For example, tributyl phosphite, which is a powerful ligand donor, ensures a high yield of the trinuclear cluster. The above mechanism makes it possible to interpret the difference between the reactions involving the direct substitution of the CO groups in compound (II) and the formation of $LX_2Fe_3(CO)_8$ from the adduct. On the basis of $^{13}C$ NMR spectra, the authors[143] concluded that the substituted trinuclear clusters synthesised by the two different methods are identical.

It has been shown[144] that heating of a mixture of $(PHR)_2 \cdot Fe_2(CO)_6$ with $Fe_3(CO)_{12}$ leads to the formation of $(PR)_2 \cdot Fe_3(CO)_9$ together with the clusters $(PR)_2Fe_4(CO)_{11}$ and $(PR)_2Fe_4(CO)_{12}$.

The structure of the cluster $(\mu_3\text{-}S)(\mu_3\text{-}PR)Fe_3(CO)_9$ (where $R = p\text{-}CH_3OC_6H_4$), obtained by the reaction of $Fe_3(CO)_{12}$ with the Lawesson reagent cyclo-$[p\text{-}CH_3OC_6H_4P(S)S]_2$, has been determined recently.[145,146]

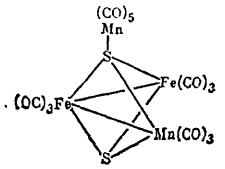
Treatment of compound (I) with $Fe_3(CO)_{12}$ or $(C_2H_5)_3N \cdot H_2Fe_3(CO)_{11}$ leads to the formation of a compound of type (II):[3]

$$S_2Fe_2(CO)_6 + Fe_3(CO)_{12} \rightarrow S_2Fe_3(CO)_9 + CO.$$



The presence of insignificant amounts of dithiodiiron heptacarbonyl $S_2Fe_2(CO)_7$ in the reaction mixture and the instability of this cluster, which is quantitatively converted into compound (I) in solution, suggests that the above dinuclear cluster can be an intermediate in the formation of the trinuclear cluster (II).[3] The reaction apparently proceeds via a stage involving the formation of compound (I) with subsequent insertion of the $Fe(CO)_3$ fragment in the S–S bond.

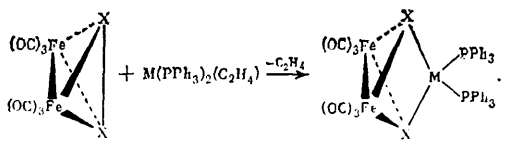
Dicobalt octacarbonyl does not react with compound (II), while the sulphur-containing cluster (I) reacts under mild conditions to give a relatively high yield (56%) of $SFeCo_2(CO)_9$,[147] whose structure has been established by X-ray diffraction:[148]



$$S_2Fe_2(CO)_6 + Co_2(CO)_8 \xrightarrow[\Delta]{C_6H_{14},N_2} SFeCo_2(CO)_9 + Fe(CO)_5 + S.$$

Vahrenkamp and Wucherer[149] were the first to synthesise a tetranuclear cluster from two initial dinuclear complexes of type (I). As expected, the substitution by cobalt carbonyl under mild conditions leads to the formation of the new tetranuclear cluster $S_2Fe_2Co_2(CO)_{11}$ (Scheme 12).

Scheme 12



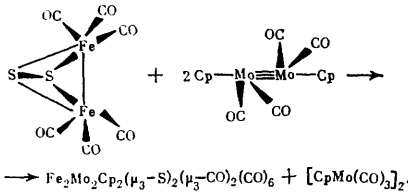
The photoinduced reaction of $S_2Fe_2(CO)_6$ with $Mn_2(CO)_{10}$ in solution in THF gives rise to a cluster having the composition $S_2Fe_2Mn_2(CO)_{14}$.[150] The composition and structure of this cluster, established by elemental analysis, mass spectrometry, Mössbauer spectroscopy, and X-ray diffraction, can be represented by $Fe_2Mn(CO)_9 \cdot (\mu_3\text{-}S)(\mu_4\text{-}S)Mn(CO)_5$, where the $Fe_2Mn$ system contains one Fe–Fe bond and one Fe–Mn bond.[150]

### 12. Oxidative Addition of Metal Complexes

New heterometallic chalcogenide clusters $X_2Fe_2(CO)_6M(PPh_3)_2$ (where X = S, Se, or Te; M = Pt or Pd), characterised by means of elemental analysis, molecular weight measurements, and infrared and NMR spectroscopic data (Scheme 13), have been obtained in quantitative yields by the oxidative addition of $M(PPh_3)_2(C_2H_4)$ to $X_2Fe_2(CO)_6$:[151]

Scheme 13

This reaction has been used to obtain heteronuclear clusters.[152] It formally involves the homolytic cleavage of the X–X bond in the initial $\mu\text{-}X_2$ complexes and leads to a new way of obtaining mixed metallic clusters.[152,153]



### 13. The Interaction of Compounds (I) with Transition Metal π-Complexes

The interaction of $S_2Fe_2(CO)_6$ with $[(\eta\text{-}C_5H_5)Ni(CO)]_2$ in heptane led to the synthesis in 15% yield of the first iron-nickel cluster in which the sulphur atom at the apex (centre) is symmetrically linked to three metal atoms: $(\eta\text{-}C_5H_5)_2Ni_2Fe(CO)_3S$. Its structure has been confirmed by X-ray diffraction.[154]

The interaction of $S_2Fe_2(CO)_6$ with $(C_5H_5)_2Mo_2(CO)_4$ in toluene at 0 °C has been described.[155] It leads to the formation of the red crystalline dimer $[(C_5H_5Mo(CO)_3]_2$

and red-brown crystals of a new iron–molybdenum sulphur-containing cluster of the "butterfly" type having the composition $Fe_2Mo_2(\eta^5\text{-}C_5H_5)_2(\mu_3\text{-}S)_2(\mu_3\text{-}CO)_2(CO)_6$ and characterised by infrared spectroscopy (Scheme 14):

Scheme 14

$\longrightarrow Fe_2Mo_2Cp_2(\mu_3\text{-}S)_2(\mu_3\text{-}CO)_2(CO)_6 + [CpMo(CO)_3]_2.$

The structure of this cluster has been demonstrated by X-ray diffraction.[155]

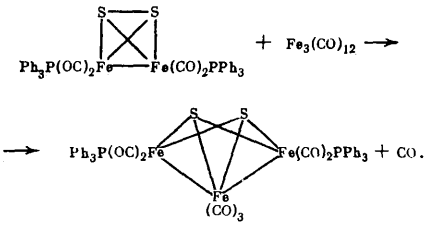
The reaction of compound (I) with $R_2Mo_2(CO)_4$, where R = Cp, Cp', or $\eta^5\text{-}CH_3C_5H_4$, leading to new isomeric iron–molybdenum sulphur-containing clusters, has been investigated:[156]

$$S_2Fe_2(CO)_6 + 2\,R_2Mo_2(CO)_4 \rightarrow Cp_2Mo_2(CO)_6 + \\ + R_2Mo_2Fe_2(\mu_3\text{-}S)_2(CO)_6(\mu\text{-}CO)_2 + R_2Mo_2Fe_2(\mu_3\text{-}S)_2(CO)_6(\mu\text{-}CO)_2.$$

The $Cp'_2Mo_2Fe_2(\mu_3\text{-}S)_2(CO)_6(\mu\text{-}CO)_2$ cluster has been analysed by X-ray diffraction.[156]

A new heterotetrametallic cluster $(\eta^5\text{-}C_2H_5)_2Cr_2Fe_2(\mu_3\text{-}CO)_2\cdot(\mu_3\text{-}S)_2(CO)_6$, whose structure has been demonstrated by X-ray diffraction, has been obtained by refluxing $S_2Fe_2(CO)_6$ with $[(\eta^5\text{-}C_5H_5)Cr(CO)_3]_2$ for 30 min in a hexane–toluene mixture.[157]

## 14. Catalytic Properties of Clusters (I) and (II)



It has been established[3] that cluster (I) and (II) exhibit catalytic activity in the conversion of thiols into disulphides:[158,159]

$$2\,RSH \xrightarrow{\text{(I) or (II)}} RSSR + H_2.$$

This reaction has served as the basis for a new method of eliminating mercaptans from hydrocarbon mixtures.[160] Cluster (II) has a greater catalytic activity in this reaction than cluster (I).

In order to elucidate the causes of the different behaviour of clusters (I) and (II) in the conversion of thiols into disulphides, triphenylphosphine-substituted compounds (I) and (II) were used and their relative activities in the above process were tested. It was found that the monoderivatives of compounds (I) and (II) differ insignificantly in their activities from the corresponding unsubstituted clusters. On the other hand, bis(triphenylphosphine)-substituted clusters (I) virtually lose their ability to convert thiols into disulphides. Steric factors associated with the presence of the bulky triphenylphosphine ligand, which prevents the coordination of the thiol, apparently exert an appreciable influence on the rate of reaction in this case. A different type of behaviour has been observed using a disubstituted derivative of the trinuclear clusters (II) obtained by the reaction of $Fe_3(CO)_{12}$ with a disubstituted derivative of compound (I):

Scheme 15

The activity of the latter cluster is comparable to that of the unsubstituted cluster (II). Bearing in mind the data concerning the interaction of the dinuclear cluster (I) with iron carbonyls and Group IVB elements, obtained by Mavlonov,[3] the $Fe(CO)_3$ cluster is presumably inserted in the S–S bond in this case also.

---o0o---

The data described above permit the conclusion that the abundance of the reactions of clusters (I) and (II) compared with the mononuclear complexes can apparently be accounted for by the presence of several active centres at the Fe atoms. The activity of tetra- and poly-nuclear clusters is probably still greater.

---o0o---

During the preparation of the manuscript for the press, a number of studies concerning the synthesis and properties of chalcogeniron carbonyl clusters were published.[161–163]

# Leukotrienes—Natural Biologically Active Metabolites of Polyunsaturated Acids

R.P.Evstigneeva and G.I.Myagkova

The review deals with the biosynthesis, chemical synthesis, and biological role of leukotrienes—low-molecular-weight bioregulators belonging to the class of eicosanoids—and discusses the prospects for their further investigation and practical application.
The bibliography includes 223 references.

## I. INTRODUCTION

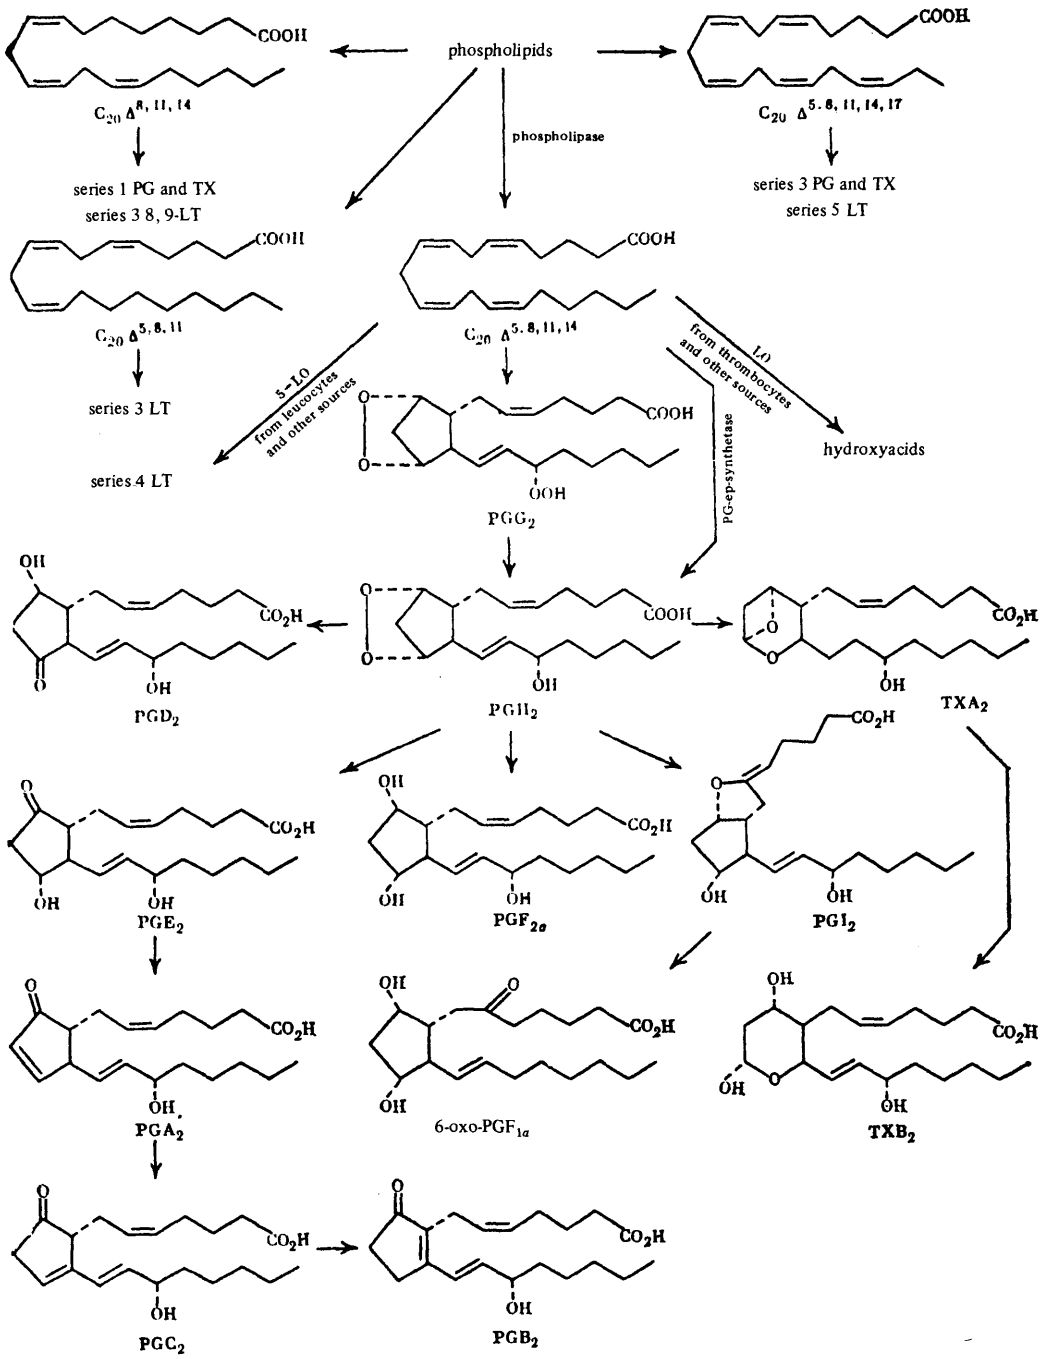
Polyunsaturated aliphatic acids occupy an important place among natural biologically active compounds. The $C_{20}$ polyenoic acids, namely 5Z, 8Z, 11Z-eicosatrienoic, 8Z, 11Z, 14Z-eicosatrienoic (dihomo-γ-linolenic), 5Z, 8Z, 11Z, 14Z-eicosatetraenoic (arachidonic), and 5Z, 8Z, 11Z, 14Z, 17Z-eicosapentaenoic (timnodonic), synthesised in the living organism from polyenoic acids with a smaller number of carbon atoms such as linoleic, linolenic, etc., are especially important. It has been shown during the last twenty years that polyunsaturated acids are not only structural components of cell membrane lipids, lipoprotein complexes in the brain and spinal cord, the heart, liver, and other organs, but are also precursors of a whole series of their biologically active metabolites—prostaglandins (PG), thromboxanes (TX), leukotrienes (LT), and others, combined under the common name eicosanoids.

The formation of these metabolites in the living cell is based on the enzymic oxidation of polyenoic acids with subsequent conversion into the final compounds. Two pathways leading to the enzymic oxidative transformation of polyenoic acids have now been extensively investigated, especially in relation to arachidonic acid: the cyclo-oxygenase pathway, in which cyclic metabolites of polyenoic acids (prostaglandins and thromboxanes) are formed under the influence of polyenzyme complexes, and the lipoxygenase pathway involving the operation of lipoxygenases and leading to the formation of non-cyclic hydroxyeicosapolyenoic acids and leukotrienes (Scheme 1).[1-9]

Prostaglandins have already been fairly thoroughly investigated and are known as intracellular bioregulators of many physiologically important processes, possessing a wide spectrum of activity on the cardiovascular, respiratory, reproductive, and other systems.[1,2]

Considerable advances have been made in the determination of the structure and in the investigation of the functions of thromboxanes, which are closely related to blood generation processes. Prostacyclin, which is a metabolite of arachidonic acid, has a relaxing effect on the smooth musculature of blood vessels and prevents the clotting processes.[1,2]

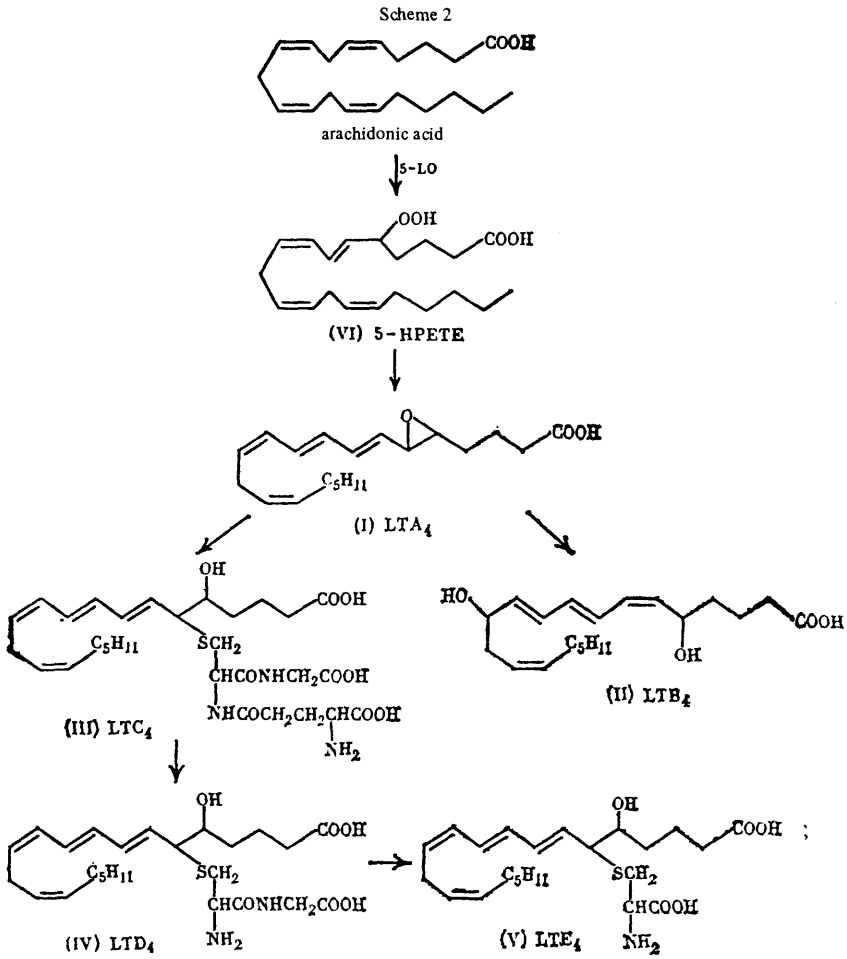
Among the acyclic eicosapolyenoic metabolites of arachidonic acid, leukotrienes, whose name was taken from the original source where they were discovered (leukocytes), have attracted special attention. In 1979 the structures of a series of compounds of this class, which are lipid-peptide derivatives exhibiting a high biological activity, were first elucidated. A relation was demonstrated between leukotrienes and the immune and inflammatory processes in the organism, namely its hypersensitivity (various allergic reactions). For this reason, the synthesis and study of the structures and biological activities of leukotrienes, their analogues, and the antagonists and inhibitors of their biosynthesis[2] is of great theoretical and practical interest not only for the recognition of the pathological phenomena in the organism due to the action of leukotrienes, but also for pharmacological purposes, involving the search for effective anti-inflammatory and antiallergic medicinal drugs.[3-9]



The enormous interest aroused among specialists in various branches of knowledge by the new class of biologically active compounds (leukotrienes) has made it extremely timely to write a review giving a systematic account of data concerning leukotrienes available at the present time.

### 1. The History of the Discovery of Leukotrienes

The lipoxygenase pathway leading to the oxidation of polyenoic acids in leukocytes leads to the formation of leukotrienes (LT)—a new class of biologically active natural metabolites[1-9] (Scheme 2). However, the elucidation of the metabolic pathway leading to the transformation of arachidonic acid into leukotrienes† was preceded by a long history of the discovery and determination of their structure covering a period of 40–80 years.[7,8]



†Leukocytes, the white blood corpuscles, are colourless cells having a nucleus and capable of passing through the walls of blood vessels. They contain proteolytic enzymes and can capture and digest foreign bodies (phagocytosis), performing protective functions in the organism. In terms of their structure, we distinghish granular leukocytes or granulocytes (neutrophils, eosinophils, and basophils) and non-granular leukocytes or agranulocytes (lymphocytes and monocytes).

A substance isolated from guinea-pig lung tissue on treatment of the latter with cobra venom was described in 1938.[10] A related substance, isolated from the lungs in anaphylactic shock was obtained later.[11]# As a result of its ability to cause a slow contraction of the smooth muscles, this substance has been called the "slow reacting substance of anaphylaxis" (SRS-A)§ to distinguish it from the "slow reacting substance" (SRS) obtained on non-immunological stimulation.

During the ten years following 1950 other sources from which SRS could be isolated were found—various tissues and cell preparations such as the lungs of several species of animals,[13] including human lungs affected by bronchial asthma, cats' paws,[14] the isolated mastocytoma cells¶ from the rat,[15] human leukocytes,[16] and the peritoneal fluid from rats.[17] The possibility of stimulating the isolation of SRS by means of the A23187 calcium ionophore[18] and L-cysteine at a high concentration[19] was demonstrated subsequently.

A23187

#Anaphylaxis (from the Greek ana = against and phylaxis = protection) is a special state with enhanced sensitivity—the hypersensitivity of the organism to the parenteral reintroduction of a foreign non-poisonous protein (for example the blood serum of another animal). The first introduction of a foreign protein (antigen) does not have a pathological effect on the organism but antibodies specific to the given protein introduced into the organism are generated in the latter. If the same protein is reintroduced parenterally after 3 to 4 weeks (when the state of enhanced sensitivity to the given protein has been established, it can persist throughout the life of the organism), severe pathological disorders take place in the organism—anaphylytic shock, which is manifested by a drop of blood pressure, a disorder in cardiac activity, etc. Antigens are substances with characteristic chemical groups which are recognised by the organism as foreign. In response to their introduction into the organism, glycoprotein substances, called antibodies, are generated. They are capable of a specific reaction with antigens.

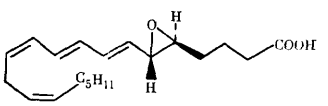
§SRS-A = slow reacting substance-A (A = anaphylaxis).

¶The mastocytoma cells are tumour mast cells in the connective tissue of vessels characterised by an abundance of basophilic granules.

All the SRS described exhibit an analogous type of biological activity, namely a capacity to cause a strong and prolonged contraction of various types of smooth muscle (the guinea-pig trachaea and human bronchi).[7,8]

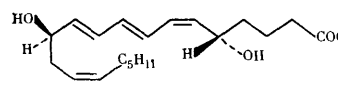
During the same years, a growing amount of information confirmed the important functions of the SRS in the enhanced sensitivity reactions of the organism. During the next 20 years many research groups attempted to determine the chemical structure of SRS-A, but major successes were not achieved.

Very promising publications about SRS-A appeared in 1960–1970. On the basis of the results of hydrogenation and oxygenation experiments and also physicochemical properties, it was shown that the SRS is an unsaturated aliphatic acid.[20] A number of investigations[18,21–26] confirmed that arachidonic acid is the initial compound in the synthesis of SRS-A. It has been shown[27] that arachidonic acid stimulates the secretion of SRS from basophilic† leukaemic# rat cells and that 5,8,11,14-eicosatetraynoic acid (an inhibitor of the cyclo-oxygenase component of prostaglandin synthesase as well as lipoxygenase) inhibits the secretion of mediators. It is also extremely important that arachidonic acid, labelled with $^{14}C$ and $^{3}H$, has been incorporated in SRS-A. Consequently it has been shown that SRS-A is a hitherto undescribed product of the metabolism of arachidonic acid.[24]



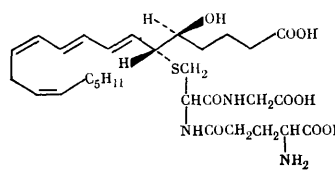
The UV spectrum of the SRS had the characteristic $\lambda_{max}$ = 280 nm, which corresponds to the presence of a ternary conjugated bond system of a non-aromatic chromopore.[28,29] The positions of the double bonds were determined in two ways. Firstly, by the reductive ozonolysis of the SRS biosynthesised from tritium-labelled arachidonic acid with formation of [$^{3}H$]-1-hexanol, which confirms the presence of the $\Delta^{14}$-double bond of the precursor.[30] Secondly, a simple enzymic method involving the use of soya bean lipoxygenase was applied.[31] This enzyme is known to be specific to oxidation at the C(6) atom in aliphatic acids containing the 1*Z*, 4*Z*-diene system, characteristic of linoleic and arachidonic acids, and the accompanying isomerisation of the alkene bond.[32]

The presence of sulphur in the SRS molecules was first mentioned in connection with the study of the mass spectra[33] and was later confirmed by the incoporation of radioactive sulphur on treatment of sensitive guinea-pig lungs with methionine or radioactive sodium sulphate.[34] The fact[35] that cysteine stimulates the formation of the SRS shows that SRS and SRS-A are derivatives of this sulphur-containing aminoacid.[36] The deactivation of SRS-A as a result of treatment with cyanogen bromide confirms the presence of the sulphide bond.[37] The loss of biological activity as a result of brief treatment of SRS-A with acylating and esterifying agents demonstrated the presence of the functional amino- and carboxy-groups.[37]



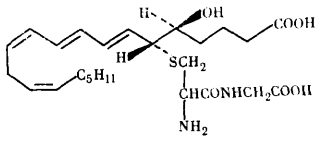
Simultaneously with the study of the structure and role of various slow reacting substances, other groups of investigators discovered that arachidonic acid is metabolised in peritoneal (abdominal) rabbit polymorphonuclear leukocytes.[30–40] Thus, during the last decade there has been a considerable increase in the amount of information available about the biochemical functions of arachidonic acid, which was also assisted by the discovery of prostaglandin endoperoxides, prostaglandins, thromboxanes, prostacyclin,[1–3] and later leukotrienes.[4,8] It was found that the formation of leukotrienes in the living organism is closely related to the appearance of hypersensitive reactions accompanied, as shown previously,[4] by the formation of SRS. This finding as well as structural similarity justified the assignment of SRS to the family of leukotrienes. This was greatly assisted by the major advances in the purification of the SRS, mainly as a result of the application of high-pressure liquid chromatography (HPLC). Morris et al.[28] purified very thoroughly a SRS-A specimen from the guinea-pig lung in a state of anaphylaxis and obtained its UV spectrum, demonstrating the presence of the characteristic absorption bands of leukotrienes. Thus much time and effort by the investigators in many scientific laboratories were needed before Samuelsson, Borgeat, Hammarström, and Murphy[4] reported at the International Congress on Prostaglandins in Washington the completion of studies on the characterisation of the leukotrienes isolated from mouse mastocytoma (tumour) cells and rabbit polymorphonuclear leukocytes (granular). It was also shown that SRS is a set of several leukotrienes, each of which is a $C_{20}$ polyenoic acid with a characteristic system of conjugated double bonds and substituents in various positions in the molecule, among which aminoacids and di- and tri-peptides were found in addition to the epoxy- and hydroxy-groups.[4–10]

## 2. The Nomenclature and Terminology of Leukotrienes

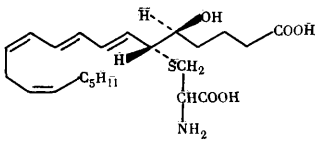


This new class of biologically active natural products was first described in a series of communications[4–8] and represents a set of oxygen-containing aliphatic polyenoic $C_{20}$ acids with various substituents. The compounds were called leukotrienes (LT), since they were first discovered in leukocytes and their structure is characterised by a system of three conjugated double bonds—a conjugated "triene". Owing to the structural differences between the substituents at the 5- and 12-carbon atoms, leukotrienes are divided into groups A, B, C, D, and E. Since leukotrienes are metabolites of 5*Z*, 8*Z*, 11*Z*-eicosatrienoic, 5*Z*, 8*Z*, 11*Z*, 14*Z*-eicosatetraenoic (arachidonic), and 5*Z*, 8*Z*, 11*Z*, 14*Z*, 17*Z*-eicosapentaenoic acids, a digital index (indication of the series) was introduced into the designation of the LT: 3, 4, and 5 respectively, defining the number of double bonds in the leukotriene molecule. The nomenclature and terminology are illustrated in relation to leukotrienes derived from arachidonic acid, since these have been most thoroughly investigated:

5(*S*), 6(*R*)-epoxy-7*E*, 9*E*, 11*Z*, 14*Z*-eicosatetraenoic acid (I)



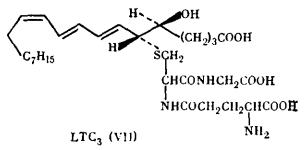
5(*S*), 12(*R*)-dihydroxy-6*Z*, 14*Z*, 8*E*, 10*E*-eicosatetraenoic acid (II)



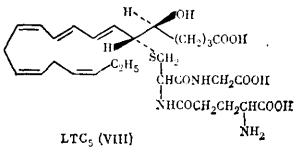
6(*R*)-*S*-glutathionyl-5(*S*)-hydroxy-7*E*, 9*E*, 11*Z*, 14*Z*-eicosatetraenoic acid (III)

†Basophilic cells are a variety of granulocytes (granular leukocytes).

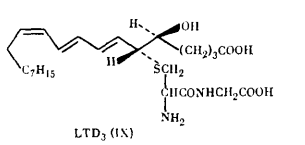
#Leukaemic cells are growing immature forms of leukocytes characteristic of malignant diseases of the blood generation system combined under the common name leukaemia.



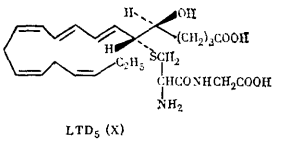
6(*R*)-*S*-cysteinylglycyl-5(*S*)-hydroxy-7*E*, 9*E*, 11*Z*, 14*Z*-eicosatetraenoic acid (IV)



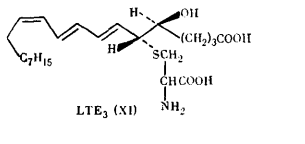
6(*R*)-*S*-cysteinyl-5(*S*)-hydroxy-7*E*, 9*E*, 11*Z*, 14*Z*-eicosatetraenoic acid (V)



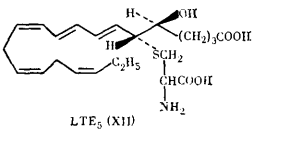
The following metabolites of 5,8,11- and 5,8,11,14,17-eicosapolyenoic acids are known at the present time:[41-44] $LTC_3$—6(*R*)-*S*-glutathionyl-5(*S*)-hydroxy-7*E*, 9*E*, 11*Z*-eicosatrienoic acid (VII); $LTC_5$—6(*R*)-*S*-glutathionyl-5(*S*)-hydroxy-7*E*, 9*E*, 11*Z*, 14*Z*, 17*Z*-eicosapentaenoic acid (VIII); $LTD_3$—6(*R*)-*S*-cysteinylglycyl-5(*S*)-hydroxy-7*E*, 9*E*, 11*Z*-eicosatrienoic acid (IX); $LTD_5$—6(*R*)-*S*-cysteinylglycyl-5(*S*)-hydroxy-7*E*, 9*E*, 11*Z*, 14*Z*, 17*Z*-eicosapentaenoic acid (X); $LTE_3$—6(*R*)-*S*-cysteinyl-5(*S*)-hydroxy-7*E*, 9*E*, 11*Z*-eicosatrienoic acid (XI); $LTE_5$—6(*R*)-*S*-cysteinyl-5(*S*)-hydroxy-7*E*, 9*E*, 11*Z*, 14*Z*, 17*Z*-eicosapentaenoic acid (XII):



$LTC_3$ (VII)



$LTC_5$ (VIII)



$LTD_3$ (IX)

$LTD_5$ (X)

$LTE_3$ (XI)

$LTE_5$ (XII)

In order to understand the above literature information, it is necessary to note the following points:[8,45] (1) The first component of SRS, characterised as a leukotriene has been the cysteinyl derivative of 5-hydroxy-7,9,11,14-eicosatetraenoic acid designated as LTC. At the present time this compound is referred to as $LTE_4$. (2) The initial studies on the purification of leukotrienes led to the preparation of two isomers relative to the C(11) atom involved in the double bond in the glutathione derivative of 5-hydroxy-7,9,11,14-eicosatetraenoic acid. The principal component was designated by LTC-1 [46] and the minor component by LTC-2. These compounds are referred to nowadays as $LTC_4$ and 11*E*-$LTC_4$ respectively.[45]

In 1983 studies were published demonstrating the conversion of 8*Z*, 11*Z*, 14*Z*-eicosatrienoic (dihomo-γ-linolenic) acid on incubation with A23187 ionophore, which stimulated the mastocytoma cells, into series 3 leukotrienes.[47,48] This led to the isolation of 8,9-$LTC_3$, exhibiting a spasmogenic activity comparable to that of $LTC_3$.[49] It has been suggested that the stoichiometry of 8,9-$LTC_3$ is analogous to that of the metabolites of polyenoic acids when the latter undergo the lipoxygenase oxidation at C(5).

## II. BIOSYNTHESIS AND DETERMINATION OF THE STRUCTURE OF LEUKOTRIENES

The metabolism of arachidonic acid under the influence of lipoxygenase was observed in peritoneal rabbit polymorphonuclear leukocytes. Borgeat et al.[38] incubated arachidonic acid with rabbit leukocytes of the above type and isolated 5(*S*)-hydroxy-6,8,11,14-eicosatetraenoic acid (5-HETE) (XIII) (Scheme 3). Similarly, 8*Z*, 11*Z*, 14*Z*-eicosatetraenoic (dihomo-γ-linolenic) acid is converted into 8(*S*)-hydroxy-9,11,14-eicosatrienoic acid.[48] Another arachidonic acid metabolite, whose structure was determined as 5(*S*),12(*R*)-dihydroxy-6,8,10,14-eicosatetraenoic acid, referred to subsequently as leukotriene $B_4$, was later isolated from rabbit polymorphonuclear leukocytes.[8,50] This was the first arachidonic acid metabilite isolated which contained three conjugated double bonds.[39]

The presence and positions of the two hydroxy-groups at C(5) and C(12) in compound (II) as well as the four double bonds at the 6-, 8-, 10-, and 14-carbon atoms were demonstrated by gas chromatography and mass-spectrometric analysis for a series of derivatives of compound (II).[39,51]

In the study of the metabolism of arachidonic acid in mammalian polymorphonuclear leukocytes,[39,52] the structures of four minor arachidonic acid metabolites were described in addition to $LTB_4$ (Scheme 3). These compounds were 5,6-dihydroxy-7,9,11,14-eicosatetraenoic acids, epimeric at C(6) (XIV, a and b), and two geometrical isomers of leukotriene $B_4$—epimeric at C(12) (XIV, C and D).[52] Although these four compounds probably do not themselves exhibit biological activity, their importance in subsequent studies of the mechanism of the formation of leukotrienes was nevertheless demonstrated.

Experiments showed[40] that, when mammalian polymorphonuclear leukocytes with polymorphic nuclei are incubated with arachidonic acid, the unstable compound (I) is formed, reacting readily with weak nucleophiles—water, ethanol, methanol, etc. Further studies demonstrated that this compound is very labile at low pH but is much more stable in an alkaline medium; its half-life is short (3 min, pH 7.4, $T$ = 37 °C). Other experiments permitted the conclusion that $LTB_4$ is formed in the enzymic hydrolysis of compound (I), while four other dihydroxy acids, namely (XIV, a and b) and (XIV, c and d), are formed from the same compound but as a result of non-enzymic hydrolysis[8,53] via the corresponding intermediates (Scheme 3).

These data suggested that the unstable intermediate 5,6-epoxy-7,9,11,14-eicosatetraenoic acid, subsequently called leukotriene $A_4$($LTA_4$), is formed from 5-hydroperoxy-6,8,11,14-eicosatetraenoic acid (5-HPETE), which is produced by the lipoxygenase oxidation of arachidonic acid.[40]

Corey et al.[54] published a method of chemical synthesis of 5(*S*)-hydroperoxy-6,11,11,14-eicosatetraenoic acid and of its enzymic synthesis by the incubation of arachidonic acid with lipoxygenase isolated from the potato.

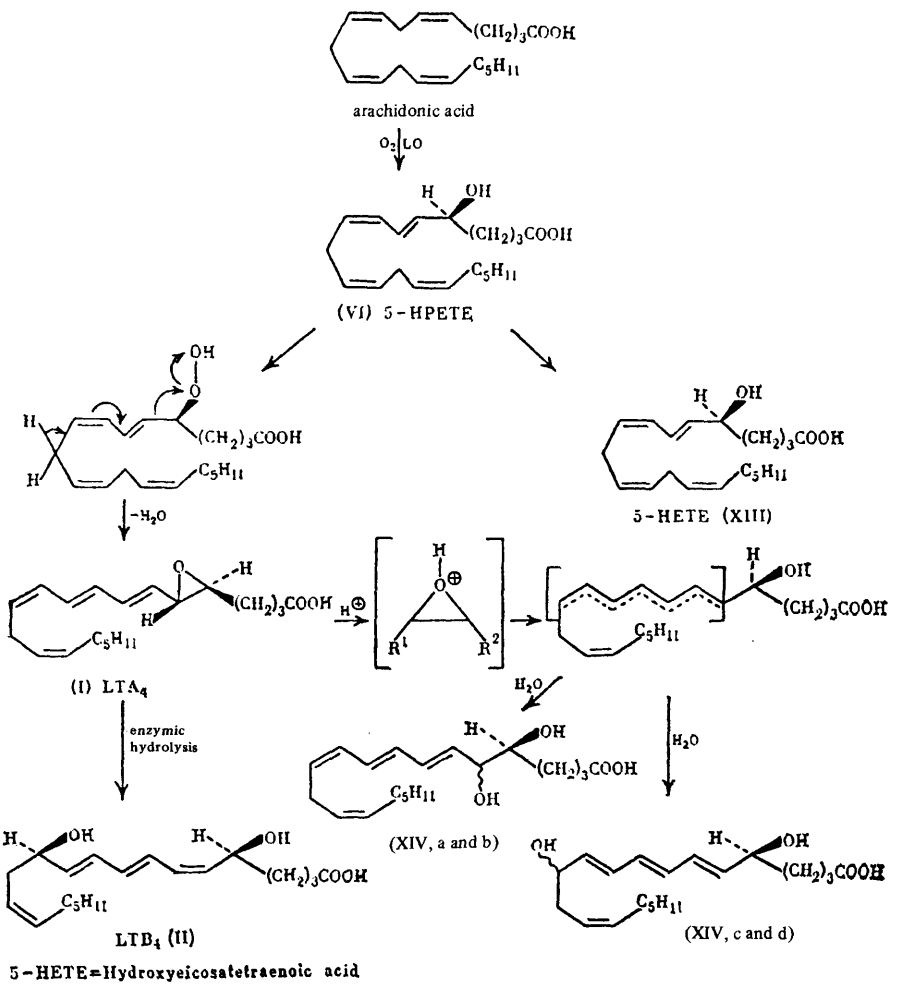
The epoxide (I) was isolated from human polymorphonuclear leukocytes.[55] It has also been shown that, under the influence of neutrophils,§ compound (I) ($LTA_4$) is capable of being transformed into $LTB_4$.[53]

The geometry of the double bonds and the configuration of the epoxy-group in $LTA_4$ have been confirmed by specific chemical synthesis of this compound and by the study of the products of its degradation.[56,57] The discovery of the leukotrienes $D_4$ and $C_4$ was associated with the efforts made

§ Neutrophils are a variety of granulocytes (granular leukocytes) (see above).

to establish the structure of the slow reacting substance of anaphylaxis (SRS-A).[3-8] Simultaneously with these investigations by Borgeat and Samuelsson,[30,38,39] some other investigators joined the research into the slow reacting substance. Thus a highly pure SRS-A specimen was obtained by the HELC method from the lung of the guinea-pig in a state of anaphylaxis whose UV spectrum showed clearly the characteristic features of the leukotrienes.[28] Many experimenters have pointed out the special role of arachidonic acid in the synthesis of SRS-A.[18-24,58-60]

It has been shown that many thiols and especially cysteine stimulate the formation of SRS and SRS-A.[30,36] These studies have confirmed that SRS and SRS-A may be suphonated compounds and thus can behave as conjugate compounds in relation to cysteine and leukotrienes $A_4$, which readily react with nucleophiles: thiols and alcohols. In their studies on this hypothesis, Murphy et al.[30] obtained SRS from mouse mastocytoma cells by incubating the latter with arachidonic acid, L-cysteine, and the A23187 ionophore.



Chemical analyses of the SRS specimen and also of the product of its degradation led to the conclusion that this compound is a derivative of leukotriene $A_4$.

Subsequently the substituent at C(6) in the SRS isolated from mastocytoma mouse cells was identified[61,62] as glutathione ($\gamma$-glutamylcysteinylglycine) and the structure and stereochemistry of the molecule were established by comparing the physicochemical and biological properties of the SRS specimens with a synthetic preparation of known structure.[57] Thus the SRS from the mouse mastocytoma cells was identifed for the first time as 6(*R*)-*S*-glutathionyl-5(*S*)-hydroxy-7*E*, 9*E*, 11*Z*, 14*Z*-eicosatetraenoic acid, which was called leukotriene $C_4$ (Scheme 4).

The role of $LTA_4$ as an intermediate in the metabolism of arachidonic acid has been confirmed by its conversion into $LTC_4$ both by mouse mastocytoma cells and by human polymorphonuclear leukocytes with polymorphic nuclei.[63] However, alternative structures of $LTC_4$ have also been proposed. The possibility of the presence in $LTC_4$ of the 5-hydroperoxy- or peroxyester group has been indicated.[64] Japanese investigators concluded in 1980 that the aminoacid chain is linked to C(6) in $LTC_4$ via a sulpho-group and assumed that this linkage is preferable.[65] The uncertainty concerning the structure of $LTC_4$ was eliminated by the study of the mass spectra and also by chemical synthesis, which confirmed that the natural $LTC_4$ is not a sulphone[66-68] but contains the sulphide bond at C(6).

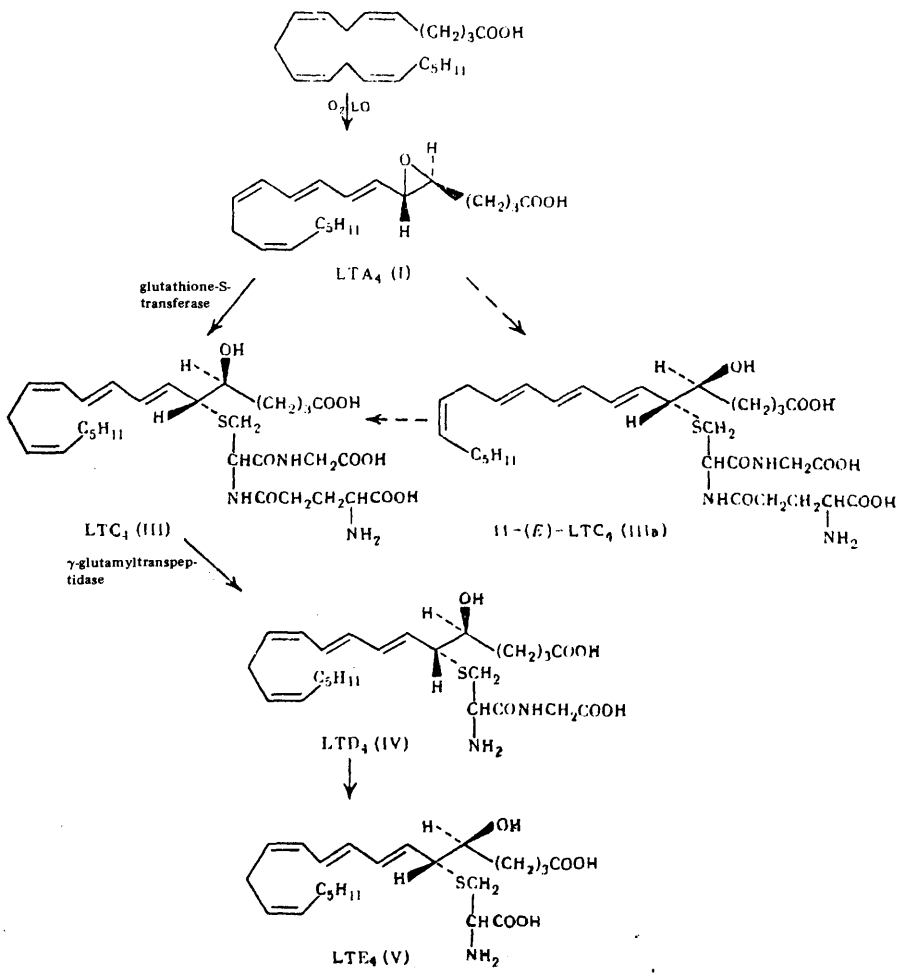
In 1980 two groups of investigators[69-71] published data concerning the determination of the structure of the SRS

Scheme 3

from basophilic leukaemic cells in the rate, which was identified as 6(*R*)-cysteinylglycyl-5(*S*)-hydroxy-7,9,11,14-eicosatetraenoic acid, called $LTD_4$.

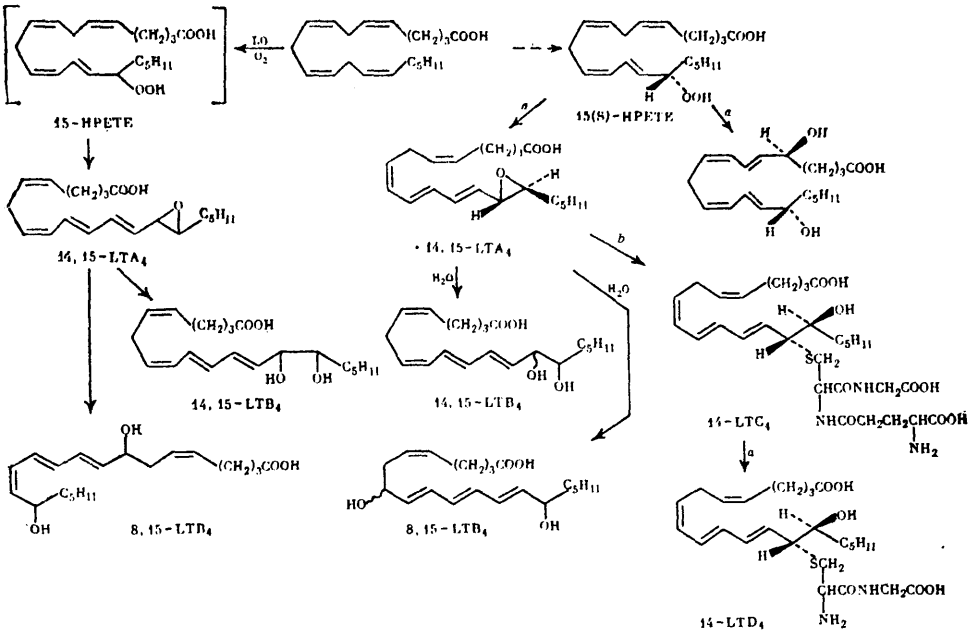
The structure of the SRS from basophilic laukaemic cells of the rat has also been determined by Orning et al.[71], who showed that $LTD_4$ can be obtained by treating $LTC_4$ with γ-glutamyl transpeptidase. This finding shows that $LTC_4$ is an intermediate in the biosynthesis of $LTD_4$ and justifies the assumption that the stereochemistry of the $LTD_4$ molecule is identical with that of $LTC_4$.[71]

It has been shown[70,72] that the SRS-A liberated when sensitive guinea-pig lungs were acted upon immunologically was identical with the SRS secreted by basophilic laukaemic cells of the rat (RBL-I) and was identified as $LTD_4$.[73] The 6-cysteinyl derivative of $LTA_4$ has been found in the SRS-A isolated from peritoneal rat cells.[74] The chemical structure and stereochemistry of this compound have been confirmed by chemical synthesis,[75] which showed it to be 6(*R*)-cysteinyl-5(*S*)-hydroxy-7*E*, 9*E*, 11*Z*, 14*Z*-eicosatetraenoic acid, which has been referred to as $LTE_4$.



The conversion of $LTA_4$ into $LTC_4$, $LTD_4$, and $LTE_4$ has been frequently confirmed by experiment.[76-80] The bioconversion of $LTC_4$ into $LTD_4$ has also been observed[63] as the enzyme-catalysed removal of the γ-glutamyl residue from $LTC_4$ in the biosynthesis of $LTD_4$.[71] $LTE_4$ has been obtained from $LTD_4$ using the aminopeptidase component of a specific arylsulphatase.[76]

Since leukotrienes are transformed in the $LTC_4 \rightarrow LTD_4 \rightarrow LTE_4$ metabolic cascade, it is not surprising that the composition of any SRS depends on the source, material, and methods used in its isolation. It has been suggested that the term leukotriene be used for an individual compound and the term SRS be applied to the description of material obtained biologically in which the relative amounts of the leukotrienes present are unknown.



The products obtained from 5-HPETE derived from arachidonic acid are not all confined to leukotrienes (Scheme I). Incubation of arachidonic acid with human leukocytes gives gise to a whole series of metabolites[81-86] which are positional isomers of natural leukotrienes (Scheme 5). Incubation of arachidonic acid with cytochrome P-450 [87] and with the fluid from adrenal cortex[88] leads to product of its oxidation at C(9) and at C(9) and C(15) respectively, which exhibit a high biological activity and are of great interest.[89]

Leukotrienes derives from 4*Z*, 8*Z*, 11*Z*-eicosatrienoic acid and 5*Z*, 8*Z*, 11*Z*, 14*Z*, 17*Z*-eicosapentaenoic acid have also been described in the literature.[41-45] Data have been published concerning the 8,9-$LTC_3$, whose biosynthesis has been achieved by incubating 8*Z*, 11*Z*, 14*Z*-eicosatrienoic (dihomo-γ-linolenic) acid.[47,48]

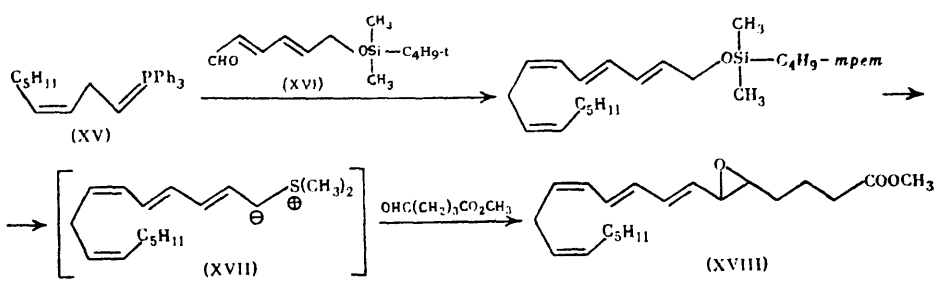
## III. CHEMICAL SYNTHESIS OF LEUKOTRIENES

The first total synthesis of leukotriene $A_4$ was carried out by Corey and published in 1979.[56,90] The syntheses of virtually all the known leukotrienes, their isomers, and their analogues, including isotopically labelled compounds, have now been achieved.

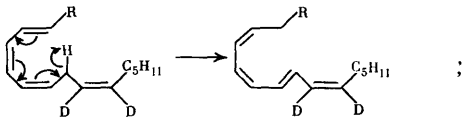
The synthetic studies have been concerned mainly with series 4 leukotrienes ($LTA_4$, $LTC_4$, $LTD_4$, $LTE_4$, $LTF_4$, and $LTB_4$), i.e. leukotrienes whose precursor is arachidonic acid.

The synthesis of the leukotrienes which have been developed are based on the Wittig reaction, whereby one can condense the key fragments in the synthesis—the "carboxyl-containing" fragment from the C(1) atom in the leukotriene molecule and the "hydrocarbon" fragment ranging up to the C(20) atom. The length of the hydrocarbon chain, the degree of unsaturation, and the functional substituents at the 5- and 6-carbon atoms can be varied in each of these fragments for $LTA_4$, $LTC_4$, $LTD_4$, etc. and at C(12) for $LTB_4$.



### 1. The Synthesis of Leukotriene $A_4$, Its Isomers, and Its Analogues

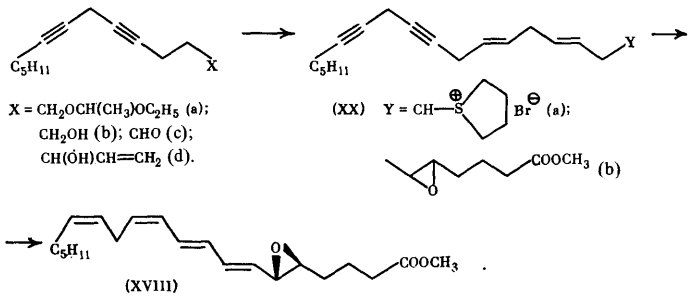
The earliest of the known syntheses is that of (±)-$LTA_4$ [56,90,91] involving the Wittig interaction of the monoene fragment (XV) and the diene fragment (XVI) with susequent addition of the hydrocarbon chain in the sulphonium ylide (XVII) and the introduction of the epoxy- and carboxy-groups (Scheme 6).



The methyl ester of $LTA_4$ (XVIII) has been obtained in the form of a 1 : 1 mixture of the *cis*-epoxide and the natural *trans*-epoxide.

Rokach et al.[92] have also used the sulphonium ylide (XVII) in the synthesis of the methyl ester of (±)-$LTA_4$ and succeeded in resolving the mixture of the *cis*- and *trans*-epoxides. The same group of investigators[92] attempted to synthesise 9Z-$LTA_4$ because the geometry of the $\Delta^{9,10}$-double bond in the natural leukotriene was unknown at the time. However, the immediate tetraene (XIXa) underwent the 1,7-hydrogen migration at 18–25 °C, affording the isomer

Scheme 6



(XIX):

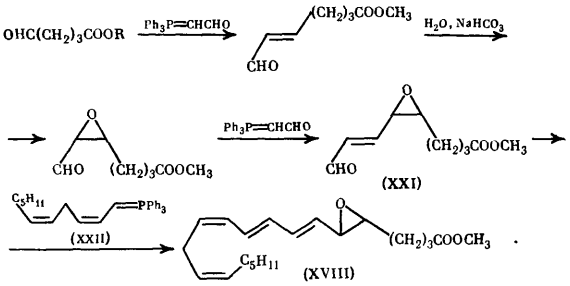
(XIXa) (XIX)

R = $COOCH_3$, $CH_2OH$ .

The methyl ester of (±)-$LTA_4$ was also synthesised by the selective reduction of the diyne (XXb) obtained from the salt (XXa):[93,94]

X = $CH_2OCH(CH_3)OC_2H_5$ (a); $CH_2OH$ (b); CHO (c); $CH(OH)CH{=}CH_2$ (d).

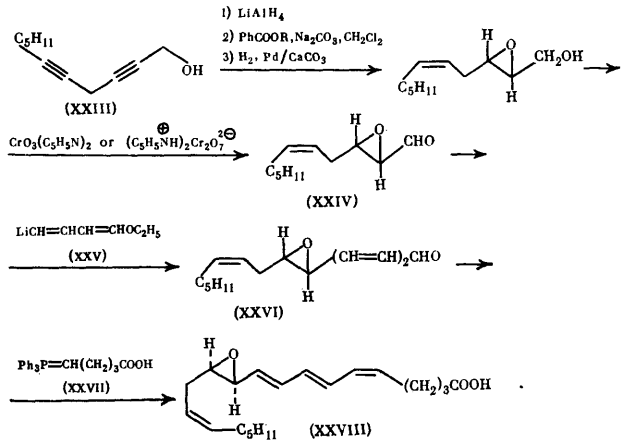
(XX) Y = $CH{-}S^{\oplus}Br^{\ominus}$ (a);



(b)

(XVIII)

Subsequently investigators used in the synthesis of $LTA_4$ schemes providing for the Wittig condensation of the hydrocarbon and carboxyl-containing fragments in the last stages of the synthesis after the preliminary introduction of the necessary functional groups into each fragment. The epoxyaldehyde (XXI), obtained by a series of stages from 4-formylbutyrate, has been used as the key synthone for the introduction of the carboxyl-containing unit[95,96] (Scheme 7). The undecadiene ylides (XXII),[95,96] prepared from phosphonium salts, are employed as the hydrocarbon fragment. The Z-configuration of the double bonds in compound (XXII) is due to the stereospecific hydrogenation of the corresponding acetylenic precursors. The interaction of compounds (XXI) and (XXII) yields the methyl ester of (±)-$LTA_4$ [95] (Scheme 7).



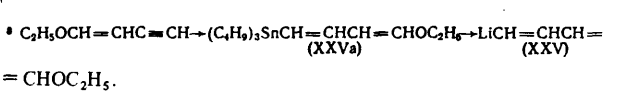
Scheme 7

Gleasson et al.[95] identified the methyl ester of (±)-$LTA_4$ which they synthesised as a 2:1 mixture of the natural 9*E*-compound and the isomeric 9*Z*-compound. The 1,7-hydrogen shift, noted by Rokach et al.[92] (see above), occurred also in the formation of 9*Z*-$LTA_4$.[96]

The triene component (XXVI) has been used as the hydrocarbon fragment in the syntheses of the 11,12-epoxides (XXVIII), which are analogues of the $LTA_4$ (Scheme 8), but, in contrast to the syntheses discussed above, this compound is not an ylide but an aldehyde (Scheme 8).[97] The initial undeca-2,5-diyn-1-ol (XXIII), obtained from acetylene and its derivatives, was converted into the aldehyde (XXIV) via a series of stages.

Scheme 8

The length of the epoxyaldehyde (XXIV) is increased using 4-ethoxy-1-lithio-butadiene (XXV) as the four-carbon component.¶ The conversion of carbonyl compounds into conjugated dienes with the aid of compound (XXV) has been suggested[98] and has been used by other workers to generate an analogous system of multiple bonds in carboxyl-containing components in the synthesis of the 7-*cis*-isomers of $LTA_4$ and $LTD_4$.[99] Subsequently the aldehyde (XXVI) is condensed with the ylide (XXVII) to form the 11,12-epoxy-analogue of $LTA_4$ (XXVIII).



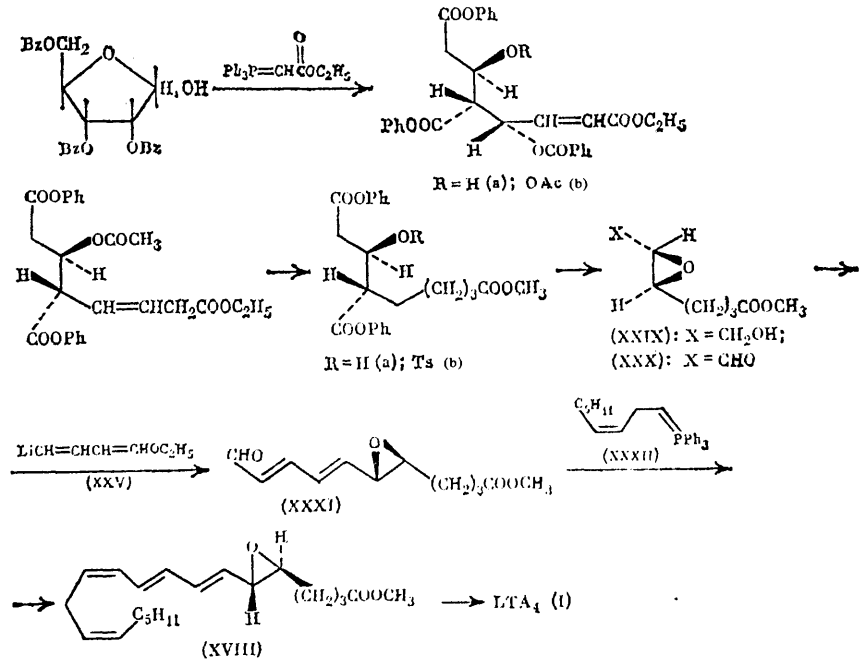
None of these syntheses described previously allowed the selective formation of the natural enantiomer of $LTA_4$. In order to solve this problem, the methyl ester of 5(*S*),6(*R*)-epoxy-6-formylhexanoic acid (XXX), which is synthesised from carbohydrates[100–105] or from carbohydrate derivatives[103,104] containing chiral centres in the molecule, has been suggested as the key compound. Corey et al.[100] (Scheme 9) described the synthesis of the aldehyde (XXX) from 2,3,5-tribenzoyl-D-ribose with its subsequent conversion by the Wollenberg method,[98,99] using 4-ethoxy-1-lithiobutadiene, into the 7*E*, 9*E*-C(1)-C(14) fragment (XXXI), whose interaction with the phosphorane (XXXII), obtained from acetylene,[56,90,92,99–106] gives rise to the enantiomerically individual methyl ester of 5(*S*),6(*S*)-$LTA_4$. The stereochemistry of this compound has been confirmed by its enzymic conversion into the natural $LTB_4$.[53]

The 5(*S*),6(*R*)-epoxyester (XXX) has also been converted into a mixture of the methyl esters of 9*Z*-$LTA_4$ and $LTA_4$.[100] The 11*E*-isomer of $LTA_4$ has been prepared from the 5(*S*),6(*R*)-epoxyester (XXX) by the *trans*-olefination method via the Wittig reaction[45,101] analogously to Scheme 9.

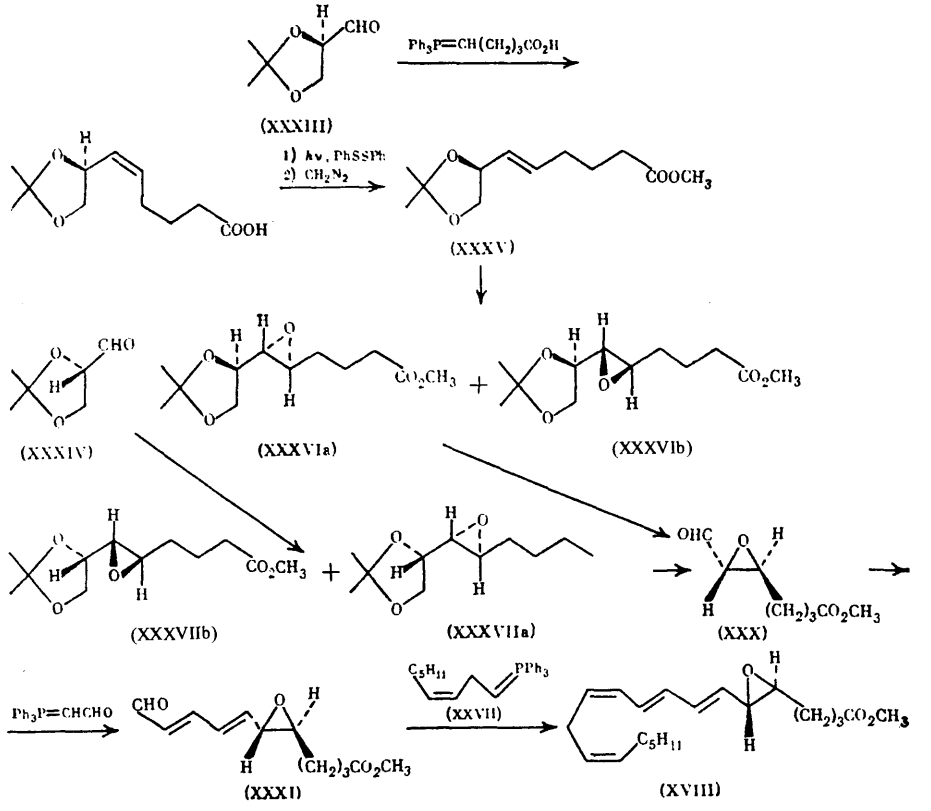
It has been suggested that D-glyceraldehyde acetonide (XXXIII), obtained from D-mannose and L-glyceraldehyde acetonide (XXIV), which was derived in its turn from L-arabinose, be used as the asymmetric precursor in the synthesis of the 5(*S*),6(*R*)-epoxyester (XXX) [105] (Scheme 10).

---

¶



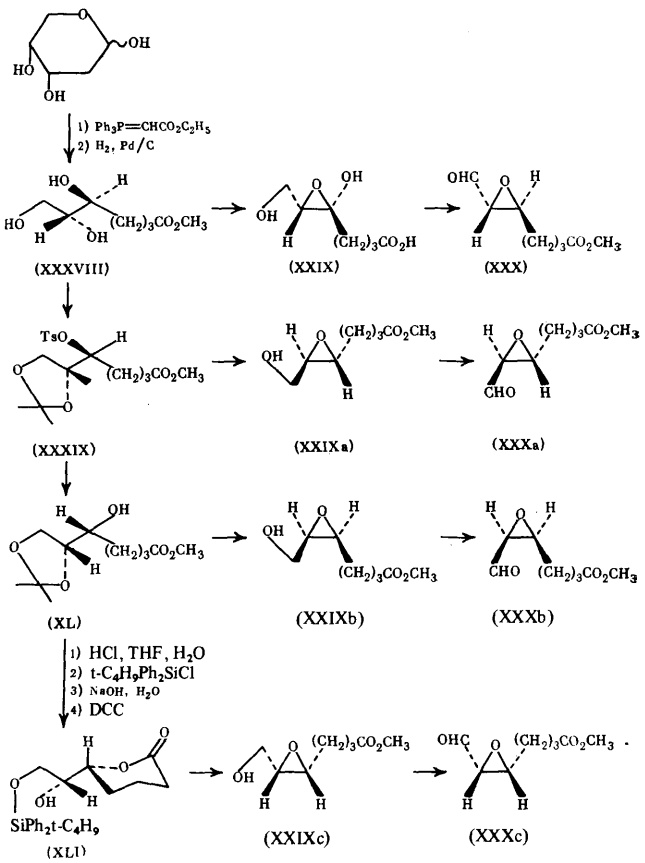
(XXVa) (XXV)



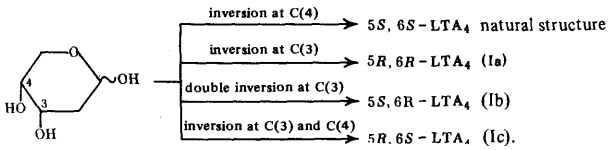
$= CHOC_2H_5$.

The hydrostannylation of 1-ethoxybut-1-en-3-yne yields vinyl stannate (XXVa), whose *trans*-metallation with n-butyllithium yields 4-ethoxy-1-lithiobutadiene (XXV).[98]

Scheme 9



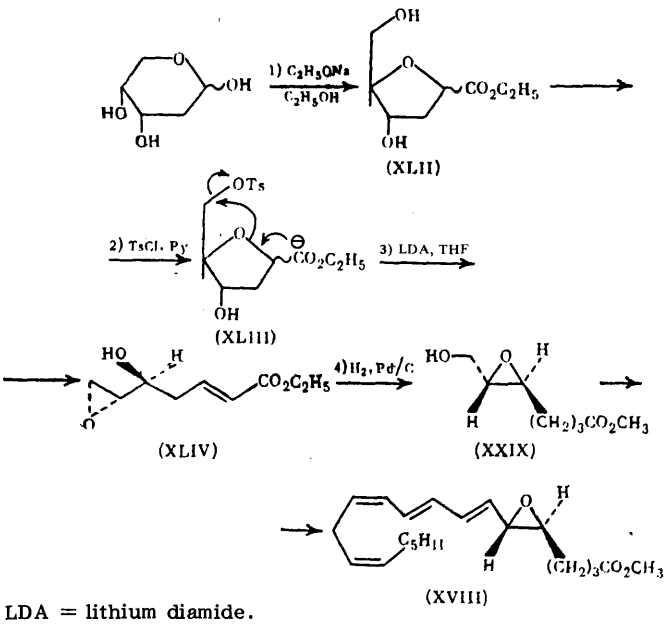
Scheme 10



The conversion of the acetonide (XXXIII) into the ester (XXXV) with subsequent epoxidation of the double bond yields a 1:2 mixture of the epoxyesters (XXXVIa) and (XXXVIb) with the preferential formation of the isomer (XXXVIb) having the unnatural stereochemistry of the substituents at the C(5) and C(6) atoms. The epoxide (XXXVIIa) is formed preferentially from L-glyceraldehyde acetonide (XXXIV). The hydrolytic cleavage of both diastereoisomers, (XXXVIa) and (XXXVIIa), leads to the 5(*S*),6(*R*)-formyl ester (XXX), which is converted by three consecutive Wittig reactions into the methyl ester 5(*S*),6(*S*)-$LTA_4$. The 5(*S*),6(*S*)-stereoisomer (XXXb) is synthesised from the acetonides (XXXVIb) and (XXXVIIb).[105]

Using D-2-deoxyribose, Rokach et al.[106] later developed new stereospecific methods of synthesis of the 5(*S*),6(*R*)-, 5(*R*),6(*S*)-, 5(*S*),6(*S*)-, and 5(*R*),6(*R*)-stereoisomers of the aldehydoepoxyester (XXX) and on this basis obtained the natural $LTA_4$: the 5(*S*),6(*S*)-epimer and the 5-epi,6-epi-5(*R*),6(*R*)-, 6-epi,5(*S*),6(*R*)-, and 5-epi-5(*R*),6(*S*)-isomers of $LTA_4$ [compounds (Ia), (Ib), and (Ic) respectively] in the form of their methyl esters (XVIII), (XVIIIa), (XVIIIb), and (XVIIIc) respectively. In these studies, the authors took into account the disadvantage of using D-ribose in such syntheses,[100,102] consisting in the fact that the hydroxy-group at the C(2) atom had to be removed by reductive elimination, which entailed additional complications as regards the protection of the hydroxy-group at the C(4) atom, and developed the syntheses from D-2-deoxyribose.

Scheme 11

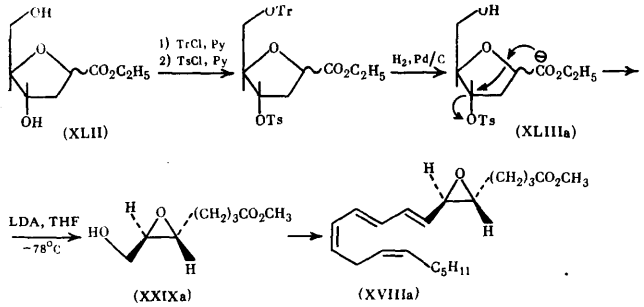


The main strategy used in these syntheses involved the appropriate manipulations of the chiral centres at the C(3) and C(4) atoms in D-2-deoxy-D-ribose in such a way that these two centres become chiral centres at the C(5) and C(6) atoms in the leukotrienes (I), (Ia), (Ib), and (Ic) synthesised, which can be represented schematically in the following way:

2-Deoxy-D-ribose is converted by a series of consecutive chemical reactions[106] into the triol (XXXVIII), the acetals (XXXIX) and (XL), and the lactone (XLI). Each compound obtained is a precursor of the diastereoisomeric epoxy-alcohols (XXIX), (XXIXa), and (XXIXb), (XXIXc), which are then oxidised[97] to the 5(*S*),6(*R*)-, 5(*R*),6(*S*)-, 5(*S*),6(*S*)-, and 5(*R*),6(*R*)-epoxyaldehydes [(XXX), (XXXa), (XXXb), and (XXXc) respectively] (Scheme 11).

The diastereoisomeric aldehydes (XXX), (XXXa), (XXXb), and (XXXc) obtained in this way by means of three consecutive Wittig olefination reactions,[105,106] as described above, are converted into the ethyl esters of $LTA_4$ (XVIII), 5-epi,6-epi-$LTA_4$ (XVIIIa), 6-epi-$LTA_4$ (XVIIIb), and 5-epi-$LTA_4$ (XVIIIc) respectively.[106]

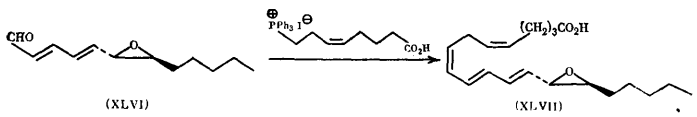
Another method in which 2-deoxy-D-ribose is used to synthesise the epoxyesters (XXIX), (XXIXa) and (XXIXc) has been proposed.[107] It is based on the conversion of 2-deoxy-D-ribose into the *C*-glycoside (XLII)[108,109] with subsequent initiation of the intramolecular reaction of the tosylate (XLIII), leading to the formation of the epoxy-compound (XLIV), which is readily converted into the primary alcohol (XXIX) from which the methyl ester of $LTA_4$ is obtained after a series of known stages:



LDA = lithium diamide.

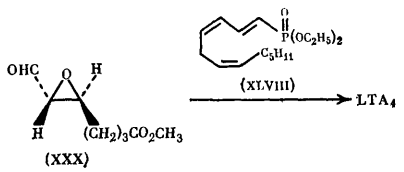
14,15-dehydro-$LTA_4$ has also been obtained from the hydroxyester (XXIX).[66,110]

The use of the tosylate (XLIIIa) leads to the inversion of the configuration at C(5) in the glycoside and the formation of the hydroxyester (XXIXa), which is converted further



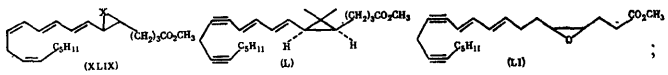
into the ester of 5-epi,6-epi-LTA$_4$:

The synthesis of the hydroxyester (XXIXc), a precursor of the ester of 5-epi-LTA$_4$, involves the inversion of the configuration of the secondary hydroxy-group of the *C*-glycoside (XLII) and the tosylation of the primary hydroxy-group in compound (XLV), as shown in Scheme 12.



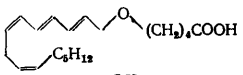
Simultaneously with the studies by Rokach and co-workers,[106,107] Mariotti and Bentick[111] proposed a somewhat modified synthesis of the epoxyalcohol (XXIX) also on the basis of 2-deoxy-D-ribose.

2-Deoxy-D-ribose has been used successfully in the synthesis of the epoxyaldehyde (XLVI),[112] from which 14(*S*),15(*S*)-epoxy-5*Z*, 8*Z*, 10*E*, 12*E*-eicosatetraenoic acid 14,15-LTA$_4$ (XLVII) was obtained by a standard method:[107,112]



The methyl ester of 5(*S*),6(*S*)-epoxy-7-hydroxyheptanoic acid (XXIX) and its 5(*S*),6(*R*)-diastereoisomer (XXIXb), which are precursors of LTA$_4$ and 6-epi-LTA$_4$, have also been synthesised from 2,3-*O*-isopropylidene-D-erythrose[113] and 5(*S*),6(*S*)-epoxyaldehyde (XXXb) has been obtained from bis-isopropylidene-D-(+)-mannose.[114]

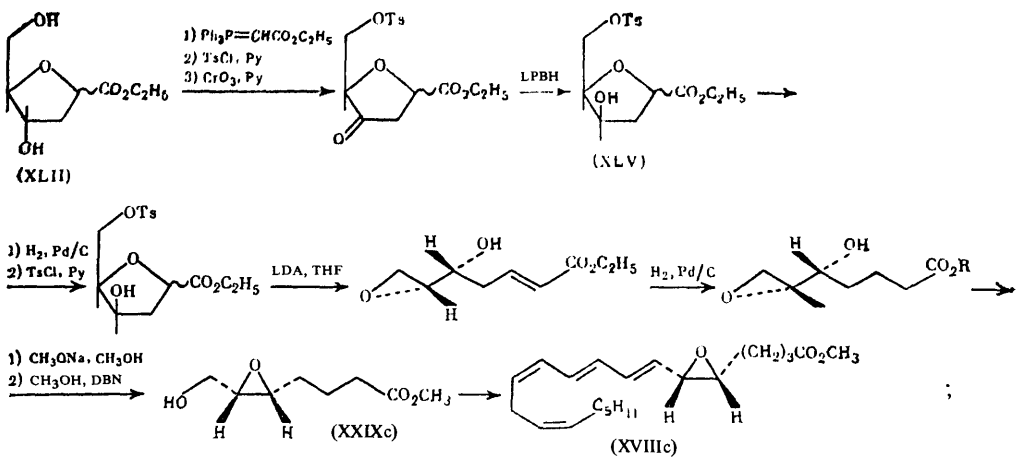
A synthesis of LTA$_4$ in which the phosphonates (XLVIII) were used instead of the phosphonium salts as the C(13) to C(20) fragment was published in 1982:[115]



The diacetylene analogue (XLVIII) was used in the synthesis of the methyl ester of (±)-LTA$_4$.[116] A phosphonate, whose structure resembled that of compound (XLVIII), has also been used to synthesise the methyl ester of 5,6-methanoleukotriene A$_4$ (XLIXa) [117,118] (a stable biologically active analogue of LTA$_4$), bisdehydrodimethylmethanoleukotriene A$_4$ (L),[119,120] and a bisdehydro-analogue of LTA$_4$ (LI):[120,121]

X = $CH_2$ (a); S (b); N (c).

A thio-analogue of LTA$_4$ (XLIXb) has been prepared by the same methods.[120] An aza-analogue of LTA$_4$ (XLIXc) has been synthesised[123] using 5-epi,6-epi-LTA$_4$.[106] The acetylenic analogues of LTA$_4$ serve as the initial compounds for the synthesis of tritium-labelled leukotrienes.[123,124]

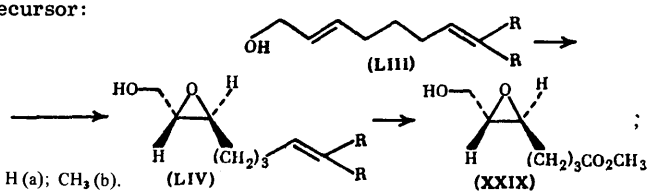


6-Oxa-8*E*, 10*E*, 12*Z*, 15*Z*-eicosatetraenoic acid, secoleukotriene A$_4$ (LII), whose synthesis has been published recently,[125,126] is also an analogue of LTA$_4$.

(LII)

The syntheses of LTA$_4$ using initial chiral compounds (carbohydrates and their derivatives) [100–114] involve many stages and require a large number of protecting operations and the removal of various groups to ensure the inversion of substituents at the initial chiral centres to give the configuration characteristic of the leukotriene structure. The stereospecific oxidation of achiral alcohols by a reagent comprising diethyl L-(+)-tartrate, t-butyl hydroperoxide,

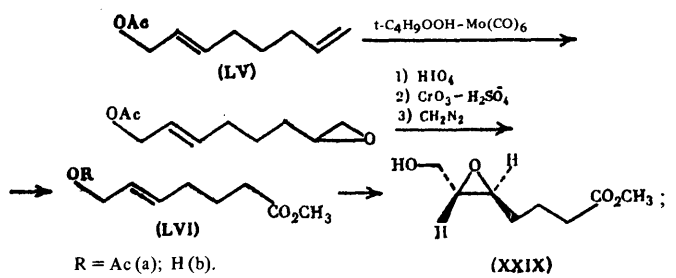
Scheme 12



LPBH = lithium perhydro-9B-boraphenylallyl hydride;
DBN = 1,5-diazabyclo[4,3,0]non-5-ene.

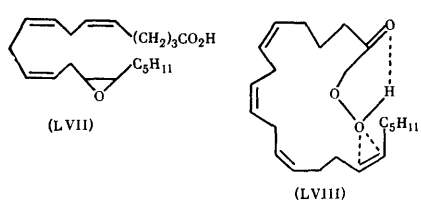
and tetraisopropoxytitanium, proposed by Katsuki and co-workers,[127,128] has been a major advance in the methology of the synthesis of leukotrienes.

However, there is evidence that methyl 7-hydroxy-5-heptenoate



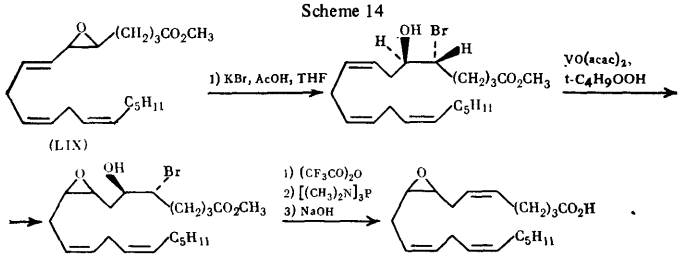
is epoxidised under these conditions with low yields.[103,127,128] At the same time, two research groups developed the selective epoxidation of the diene alcohols (LIIIa) [128] and (LIIIb).[103] The oxidative cleavage of the alkene structure of the epoxide (LIV) with subsequent esterification gives rise to the 5(*S*),6(*S*)-epoxyalcohol (XXIX) as the $LTA_4$ precursor:

R = H (a); $CH_3$ (b).



The epoxide (XXIX) has been synthesised[120,129] from 1-acetoxy-2*E*,7-octadiene (LV) by the chiral epoxidation of methyl 7-hydroxy-5*E*-heptenoate (LVIa) or its acetate (LVIb) using the Sharpless–Katsuki method (Scheme 13):

Scheme 13

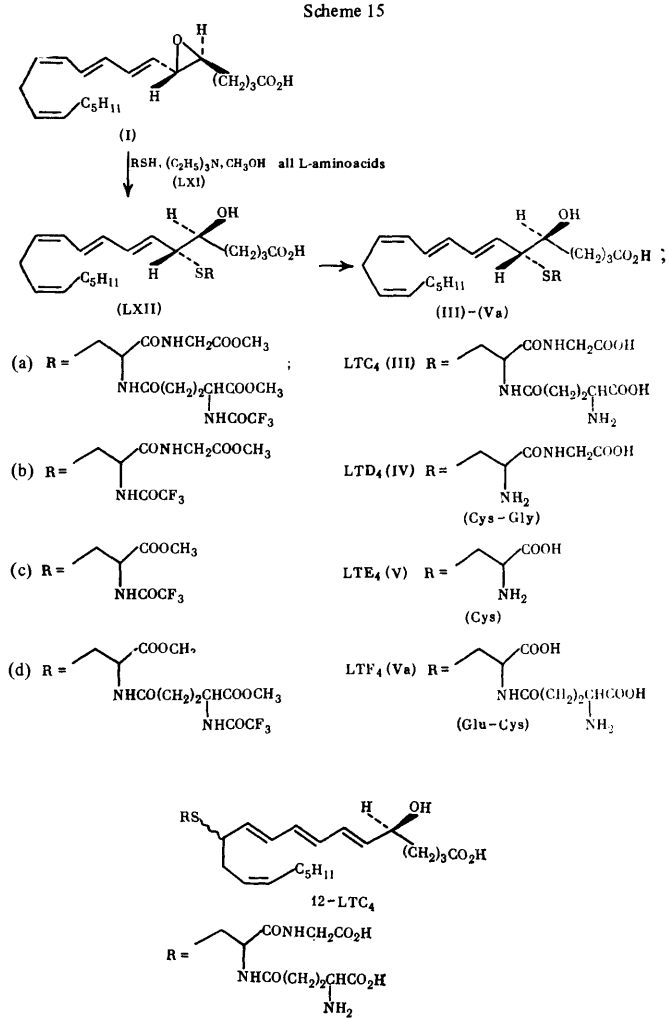


R = Ac (a); H (b).

This method[127,128] has been used also in the synthesis of 8,9-$LTA_3$.[47,130] Corey and co-workers[131–133] achieved the selective epoxidation of the double bond nearest to ($\Delta^{5,6}$) and most remote from ($\Delta^{14,15}$) the carboxy group in arachidonic acid. The 14,15-epoxide (LVII) has been synthesised by the novel intramolecular transfer of oxygen in peroxyarachidonic acid, which isomerises preferentially via the intermediate (LVIII):

8,8-Epoxyarachidonic acid (LIX) has been synthesised from the methyl ester of the 5,6-epoxyacid (LX),[87,134] (Scheme 14):

Scheme 14



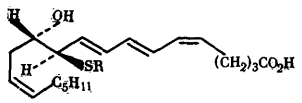
Compound (LX) has also been isolated from natural sources.[87]

A biospecific synthesis of the methyl ester of $LTA_4$ from 5-HPETE (VI) is known.[46,135–137] Other natural epoxides have also been obtained by biospecific synthesis.[112,136]

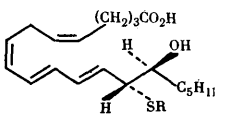
## 2. The Syntheses of the Leukotrienes $C_4$, $D_4$, $E_4$, and $F_4$, Their Isomers, and Their Analogues

The syntheses of $LTC_4$,[92–97,100–105,111,124,128–132,136–142] $LTD_4$,[92–105,114,124,130–142] $LTE_4$,[93,94,100,103,105,124,140–143] $LTF_4$,[94,143] their isomers, and their analogues[93,96,102,111,124,139–144] are based on the introduction in the 6-position in the $LTA_4$ molecule of the thio-derivatives (LXI), whose role is assumed by the corresponding protective aminoacids and peptides in $LTA_4$ [100,105] (Scheme 15).

Scheme 15

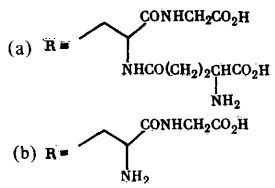


The removal of protecting groups from compounds (LXII, a–d), depends on the nature of the peptide substituent. There are data concerning the addition of glutathione in the unprotected form.[57,61,62,119–121,135] Hydroquinone, which is an essential component in the hydrolysis of the $LTE_4$ esters, leads to the partial isomerisation of the double bond in the 11-position in leukotrienes.[75] The use of an excess of lithium perchlorate when it is necessary to alter the direction of the $LTC_4$ formation reaction leads to the synthesis of 12-glutathionylleukotrienes (12-$LTC_4$),[102] which exhibit an extremely low biological activity and apparently do not make a significant contribution to the biological role of the members



of the family of leukotrienes. This finding is important for the elucidation of the structure of the SRS components.[145]

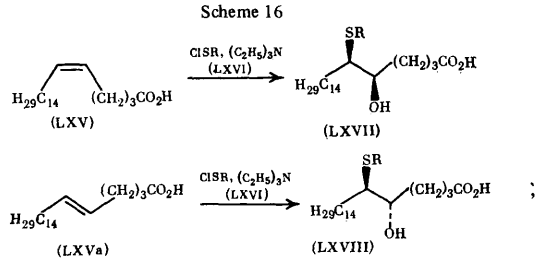
The recently isolated $LTF_4$ (Va) has been synthesised by means of Scheme 15 described above from $LTA_4$ and protected glutamylcysteine.[134] The compound has been obtained in a mixture with its 5(*R*),6(*S*)-diastereoisomer and proved to be 200 times less active in its effect on human bronchi than $LTD_4$.[143] The 5(*R*),6(*S*)-diastereoisomers of $LTC_4$, $LTD_4$, and $LTE_4$ were synthesised in the same investigation.[143] Their biological activities proved to be lower by two orders of magnitude than that of the natural product. Other $LTC_4$, $LTD_4$, and $LTE_4$ diastereoisomers have also been synthesised.[61,111,114]



11-Glutathionyl- [11-$LTC_4$ or (LXIIIa)], 11-cysteinylglycyl- [11-$LTD_4$ or (LXIIIb)], 14-glutathionyl-$LTC_4$ [14-$LTC_4$ or (LXIVa)], and 14-cysteinylglycyl-leukotrienes [14-$LTD_4$ or (LXIVb)] have been synthesised from 11,12- and 14,15-epoxy-analogues of $LTA_4$ and protected peptides. These leukotrienes are positional analogues of the natural $LTC_4$ and $LTD_4$.[97]

(LXIII)

(LXIV)

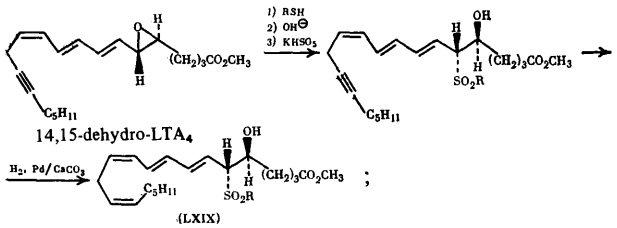


The 7-*cis*-isomer of $LTD_4$, whose activity amounted to one-tenth of that of the natural $LTD_4$, has been obtained by the same method.[99]

It has been suggested that the *S*-trimethylsilyl derivatives [R-S-Si$(CH_3)_3$] of the *N*-trifluoroacetylglutathione and *N*-trifluoroacetyl-L-cysteine esters be used in the synthesis of $LTC_4$ and $LTE_4$.[92]

The stereoisomers of fully saturated octahydro-analogues of the leukotrienes $C_4$ [(LXViia) and (LXVIIIa)], $D_4$ [(LXVIIb) and (LXVIIIb)], and $E_4$ [(LXVIIc) and (LXVIIIc)] have been synthesised[139,140] by the stereoselective interaction of sulphenyl halides (LXVI) with the 5*E*- and 5*Z*-eicosenoic acids (LXVa) and (LXVb) (Scheme 16):

Scheme 16

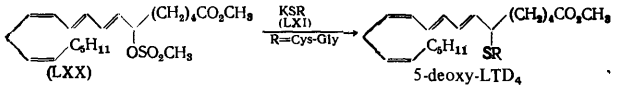


(a) R = glutathione; (b) R = Cys–Gly; (c) R = Cys.

9*Z*- and 9*Z*, 11*E*-$LTC_4$ have been synthesised from $LTA_4$ isomers with known stereochemistry.[138]

The 11*E*-isomer of $LTC_4$, isolated previously from mastocytoma cells,[30] has been synthesised from 11*E*-$LTA_4$ and glutathione.[68,101]

The uncertainty of the state of oxidation of the thio-bond in the natural $LTC_4$ in the determination of its structure (LXVII) made it essential to synthesise the $LTC_4$ sulphone (LXIX):



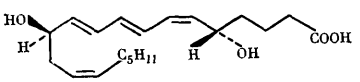
14,15-dehydro-$LTA_4$

(LXIX)

R = glutathione.

Comparison of the physicochemical and biological properties of the sulphone (LXIX) with those of the natural $LTC_4$ confirmed the presence of the sulphide linkage in the latter.[66,67]

The study of the molecular binding of leukotrienes and the determination of the structure of the possible receptor led to the problem of the synthesis of 5-deoxy-$LTD_4$,[142–147] which was achieved by the interaction of the methane-sulphonate (LXX)[102] with the potassium thiolate derived from the methyl ester of *N*-trifluoroacetyl-L-cysteinylglycine (LXI):[142]



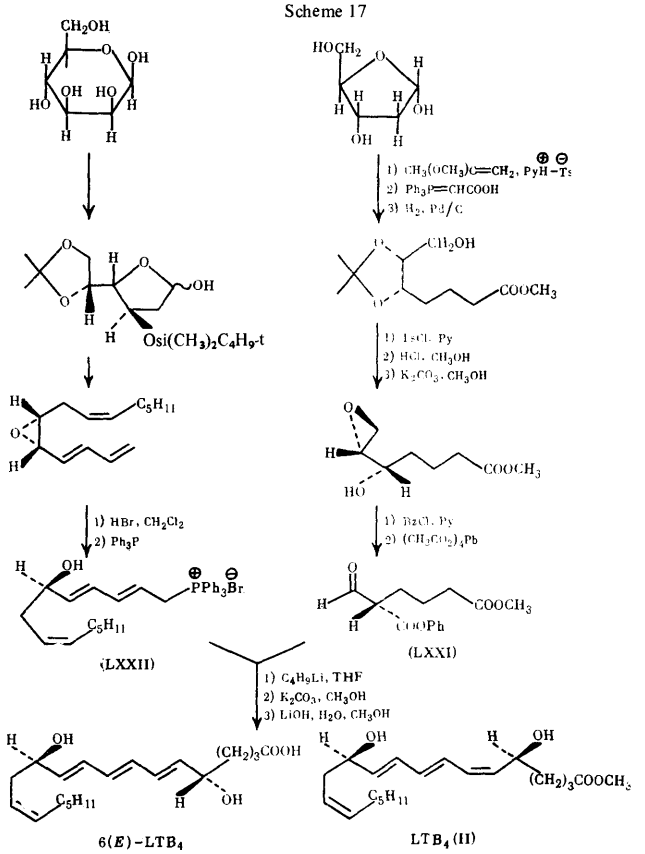
(LXX) 5-deoxy-$LTD_4$

All the diastereoisomers of 5-deoxy-$LTD_4$ synthesised exhibited only 1% of the activity of the natural $LTD_4$, which indicates the importance of the hydroxy-group at C(5) for the manifestation of the biological activity of $LTD_4$.

### 3. The Synthesis of Leukotriene $B_4$ and its Isomers and Analogues

Leukotriene $B_4$, namely 5(*S*),12(*R*)-dihydroxy-6*Z*, 8*E*, 10*E*, 14*Z*-eicosatetraenoic acid, is a chemotactic and chemokinetic† factor, which plays an important role in inflammatory processes and is a metabolite of arachidonic acid in its lipoxygenase oxidation, namely in the stage involving the enzymic hydrolysis of $LTA_4$ (Scheme 3).

$LTB_4$ (II)



The synthesis of $LTB_4$ is based on the same principles as the synthesis of $LTA_4$, but the characteristic features of the structure, namely the presence of hydroxy-groups at C(5) and C(12) in the hydrocarbon chain, introduced definite differences into the construction of the $LTB_4$ molecule. The synthesis is carried out by the Wittig condensation of two fragments—the hydrocarbon fragment [up to C(20)] and the carboxyl-containing fragment [from C(1)].[51,148–169] The aldehyde functional group, which is essential for the Wittig reaction, is located in the carboxy-fragment, while the hydrocarbon component is constructed in such a way that, before the Wittig condensation, it contains either the hydroxy-group at the C(12) carbon atom or groups which are readily converted to such a hydroxy-group, as well as three double bonds.

---

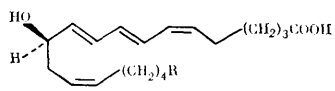
†Chemotaxis is the motor response of freely migrating cells of multicellular organisms under the influence of a unilateral chemical irritant.

The synthesis of natural $LTB_4$ was first proposed by Corey and was important in the determination of the structure of this compound[51,114,148] (Scheme 17). The chiral aldehyde (LXXI), the C(1)–C(6) fragment of the $LTB_4$ molecule, was obtained from 2-deoxyribose in several stages. The phosphonium salt (LXXII) [the C(7)–C(20) fragment] was synthesised from D(+)-mannose, as described previously.[114] The Wittig reaction of compound (LXXI) and (LXXII) followed by hydrolysis afforded $LTB_4$ with an admixture of 6*E*-$LTB_4$. The synthetic $LTB_4$ specimen is identical with the natural product and has the 6*Z*, 8*E*, 10*E*, 14*Z*-configuration of the double bonds.

Scheme 17

In order to confirm the structure of the natural $LTB_4$,[148–153] its 6*E*, 8*Z*- and 6*E*, 10*Z*-isomers, which possess no biological activity, were synthesised.[149] For this purpose, the stereospecific syntheses of the biologically active 5(*S*),12(*S*)-stereoisomer of 6*E*, 8*Z*-$LTB_4$,[143,149–152] and the 5(*S*),12(*R*)- and 5(*S*),12(*S*)-stereoisomers of 6*E*-$LTB_4$ [152–158] were carried out.

After the determination of the structure, more convenient methods of synthesising the natural $LTB_4$ were sought. A synthesis of $LTB_4$ from the epoxyphosphonium salt (LXIII) [97,106,149] and the aldehydoester (LXXI) [122] in accordance with Scheme 18 has been proposed.[150]

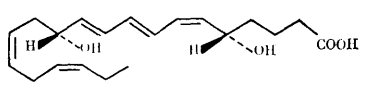


A stereospecific synthesis of $LTB_4$ from 2-deoxy-D-ribose, used previously by the same workers in the synthesis of series 4 leukotrienes ranging from $LTA_4$ to $LTF_4$ and their isomers,[155] was proposed in 1982.[154]

In another synthesis of $LTB_4$ and its 12(*S*)-epimer (IIa) (Scheme 20), the authors[156] used L- and D-arabinose respectively as the initial compounds to generate the chiral centre at C(12). L-Arabinose is converted by a standard method[157,158] in six stages to the aldehyde (LXXIV), which is then transformed by means of a series of reactions into $LTB_4$. The 12(*S*)-isomer of $LTB_4$ was obtained analogously from D-arabinose.

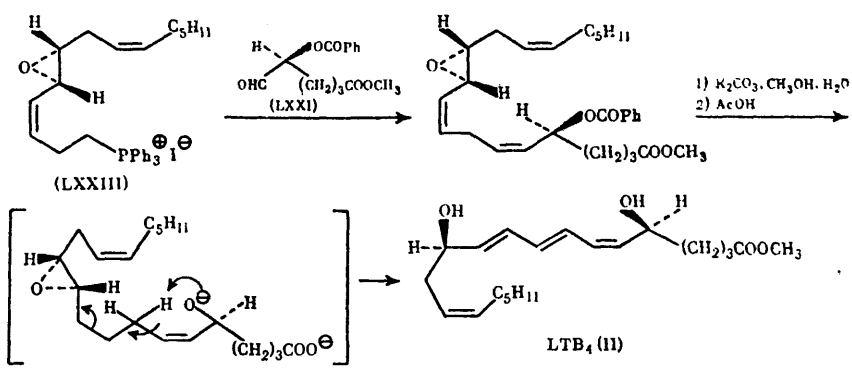
Enantiomeric epoxidation[127,128] greatly simplified the synthesis of the natural $LTB_4$.[159]

In 1983 it was suggested[160] that the optically active aldehydes (LXXI) [148,151,152,154] and (LXXV) [156] be synthesised from cinnamaldehyde rather than from carbohydrates.



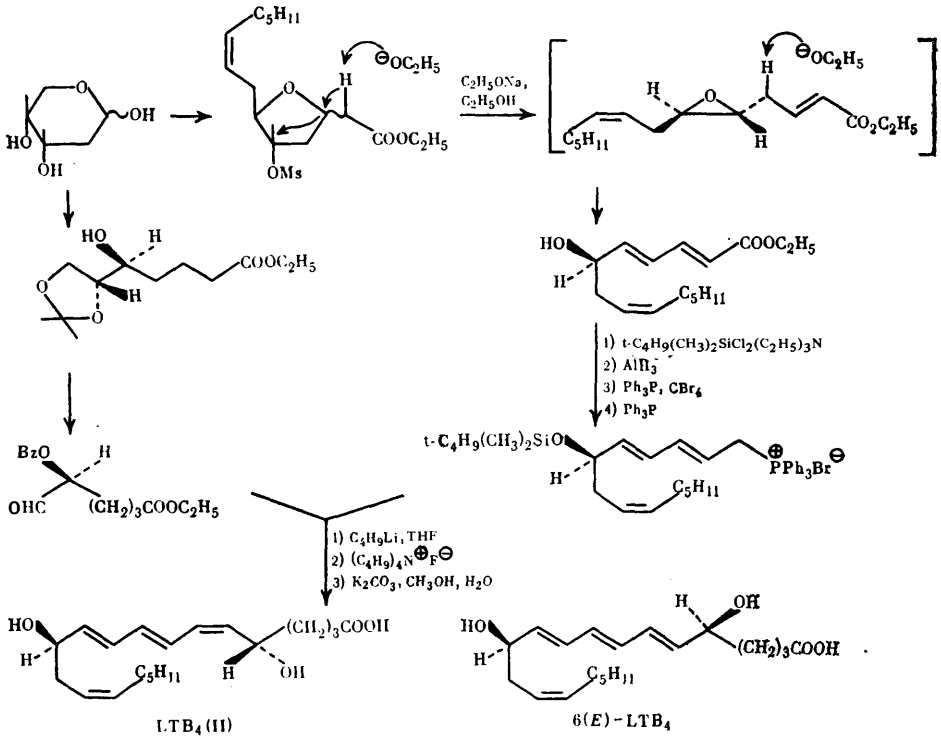
Two $LTB_4$ metabolites have been isolated and identified comparatively recently: ω-carboxy-$LTB_4$ (LXXVIa) [161–167] and ω-hydroxy-$LTB_4$ (LXXVIb),[161–167] which were synthesised[163] via a scheme developed previously:[154–156]

(LXXVI)



R = COOH; $CH_2OH$

$LTB_5$ (LXXVII), previously obtained by biosynthesis,[169] was synthesised in 1983:[168]



$LTB_5$ (LXXVII)

## IV. THE SYNTHESES OF OTHER OXYGEN-CONTAINING ACYCLIC ARACHIDONIC ACID METABOLITES

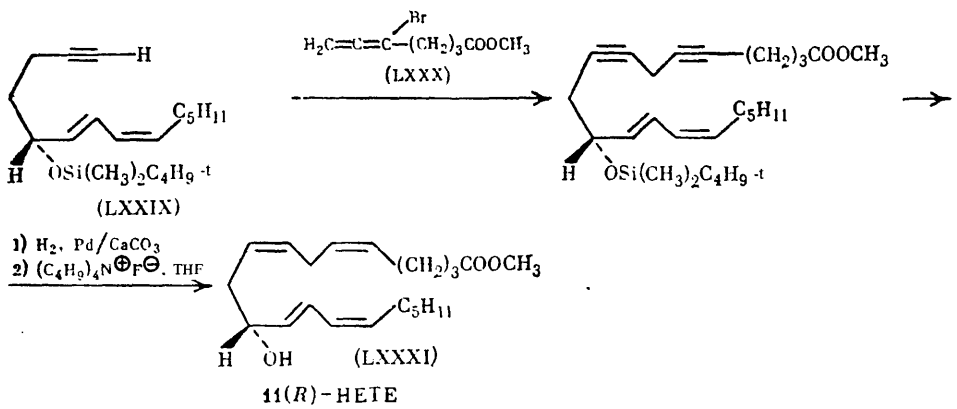
The initial compounds arising in the enzymic oxidation of arachidonic acids are the hydroperoxyeicosatetraenoic acids (VI) and the hydroxyeicosatetraenoic acids (XIII), which were designated in the literature by the abbreviations 5-TPETE and 5-HETE# [8,137,170–180] (Scheme 3) respectively. These biologically active compounds have been discovered in the human and animal organisms. Extremely little is known about the biological role of HETE in cell functions or about their biological precursors (HPETE). However, the fact that their formation from arachidonic acid is not inhibited by aspirin and indomethacin, in contrast to the prostaglandin endoperoxides ($PGG_2$ and $PGH_2$), and their high content in certain tissues (for example, human epidermic tissues in persons suffering from the skin disease psoriasis) makes them extremely interesting for comprehensive study.[8,176]

#Apart from 5-HETE, 11-, 12-, and 15-HETE are known for arachidonic acid,[8,171–175] and their corresponding HPETE precursors.[8,171]

The total synthesis of 12(*S*)-hydroxy-5*Z*, 8*Z*, 14*Z*, 10*E*-eocosatetraenoic acid (LXXVIIIb), which has been called "Samuelsson's HETE" was first achieved in 1978 [104] in accordance with Scheme 21:

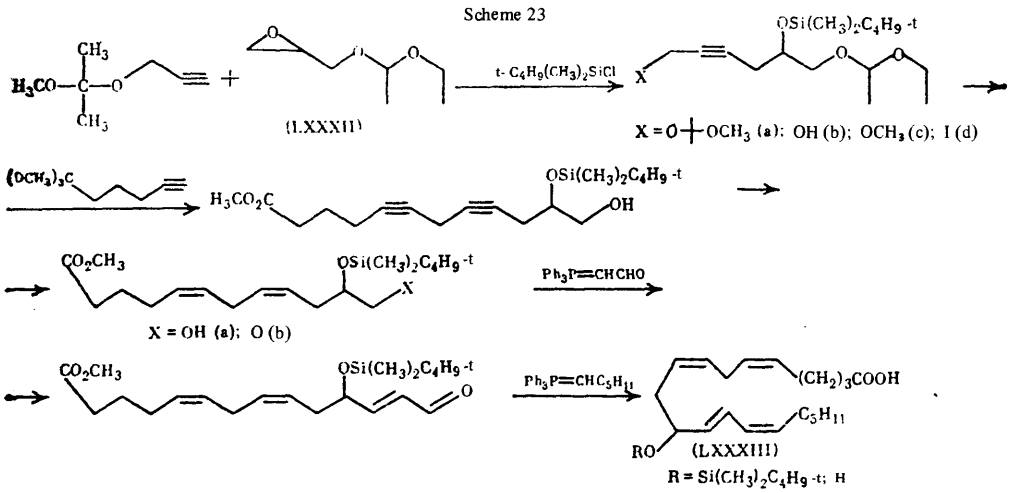
Scheme 21

(LXXVIII) (a) R = $CH_3$; (b) R = H



The oxidation of arachidonic acid by oxygen[177,178] leads as a rule to a random mixture of HPETE and HETE which is extremely difficult to use for comparative purposes.[179] However, it has been suggested[54] that (±)-5-HETE and (±)-5-HPETE be synthesised by selective substitution at the C(5) atom in the arachidonic acid molecule. (±)-5-HETE has been prepared by other investigators[181] in accordance with an analogous idea involving the introduction of the phenylseleno-group into arachidonic acid.

The (*S*)-enantiomer of 5-HETE discovered in natural sources, which is an important biological mediator functioning as a chemotactic agent for human leukocytes (eosinophils and neutrophils), and its (*R*)-enantiomer have been obtained by the chromatographic separation of the diastereoisomeric urethanes.[54,182] 5-(*S*)-HETE (VI) is a stronger chemotactic factor than 8-, 9-, 11-, 12-, and 15-HETE and its importance is comparable to that of the peptide derivatives involving the C(5) carbon atom.[182]



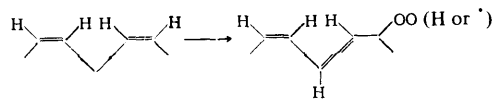
The synthesis of 5(*S*)-HETE (VIa) and 5(*R*)-HETE (VIb) via a scheme developed using the Wittig reaction[106,154,184] has been published.[183]

The methyl ester of 11(*R*)-HETE (LXXXI) has been synthesised[185] by a novel reaction of allene bromide (LXXX) with silyl derivatives of a terminal acetylenic diene (LXXIX) (Scheme 22). The same workers[171] achieved the synthesis of 11-, 12-, and 15-HETE from 11,12- and 14,15-epoxyarachidonic acids.

Scheme 22

Scheme 23

An alternative synthesis of 11(*R*,*S*)-HETE (LXXXIII) has been achieved[186] using the glycidol derivatives (LXXXII) (Scheme 23).

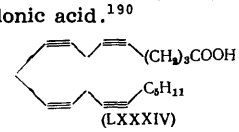


The 11(*R*)- and 11(*S*)-isomers of HETE have been synthesised by a new method involving the resolution of the initial mixture of diastereoisomeric acetoxyaldehydes with the aid of ephedrine.[187]

The syntheses of HPETE, which are precursors of HETE, have been described in a number of studies.[97,102,182]

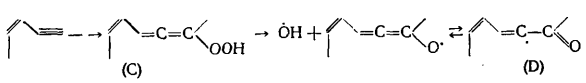
## V. THE SYNTHESES OF INHIBITORS OF THE ENZYMIC OXIDATION OF ARACHIDONIC ACID

Four oxidative pathways leading to the biosynthesis of biologically active eicosanoids from arachidonic acid under the influence of lipoxygenase are known.[188] Among them the pathway leading to the formation of leukotrienes [the 5-lipoxygenase (5-LO) pathway] is of special interest.[188,189] The biosynthesis of prostaglandins (PG) and thromboxanes (TX) via the lipoxygenase reaction of arachidonic acid involving C(11), catalysed by the enzyme cyclo-oxygenase (CO), has been studied to a considerable extent.[190]



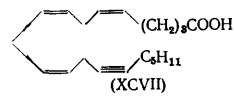
Both pathways involve the initial oxidation of the lipoxygenase type in which the 1*Z*, 4*Z*-pentadiene unit (A) is converted into the 1-oxygenated 2*E*, 4*Z*-pentadiene fragment (B):[171,188,191,192]

(A) (B)



Studies using various lipoxygenase, namely 5-LO from mammalian leukocytes,[8,180,192] potato tubers,[8,180,192] and other sources,[8] 12-LO from thrombocytes,[192] 15-LO from soya beans,[8,171,189,193] and others,[8] justify the hypothesis that the transformation A → B may be specific to the lipoxygenase catalysis.[192,194,195]

It has been found that aspirin, indomethacin, and a number of other non-steroid anti-inflammatory agents inhibit the biosynthesis of prostaglandins by blocking the initial stage of the lipoxygenase reaction of arachidonic acid at C(11), catalysed by cyclo-oxygenase.[8,189–191,196] The mechanism of the action of these empirically discovered and therapeutically important inhibitors of the prostaglandin biosynthesis is obscure but it has been demonstrated convincingly that they block the action of 11-LO but are ineffective as inhibitors of other biological oxidation pathways, including the 5-LO pathway.[189–191] 5,8,11,14-Eicosatetraynoic acid (LXXXIV), which has been synthesised by the author of this review,[197,198] inhibits the 11-, 12-, and 5-lipoxygenase reactions of arachidonic acid.[190]

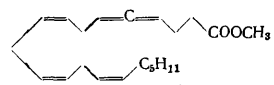


(LXXXIV)

It has been suggested[189,199] that monodehydroarachidonic acid should bind more strongly and more selectively to lipoxygenase, preventing the oxidation of natural arachidonic acid. The lipoxygenation of the acetylenic linkage gives rise to the olefinic hydroperoxide (C) and the dissociation of the O–O bond leads to the formation of the radicals OH• and (D),[189] which evidently results in the deactivation of lipoxygenase:

(C) (D)

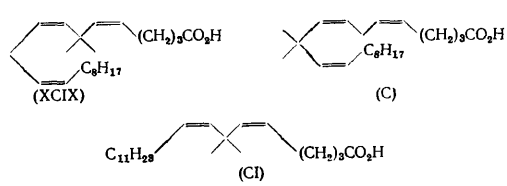
To confirm this hypothesis, Corey and Kang[199] synthesised 5,6-, 8,9-, and 11,12-dehydroarachidonic acids (DHA) [compounds (LXXXV), (LXXXVI), and (LXXXVII) respectively] and investigated them in lipoxygenase oxidation processes.[188,189] A fundamentally new method for the formation of the C–C bond in the construction of the *Z*-RCH=CHCH$_2$C≡R structure by the reaction of the iodo-olefins (LXXXIXb), (XCI), (XCII), and (XCb), obtained from the butylstannanes (LXXXVIII),[199,200] (LXXXIXa),[201] and (XCa),[201] with the iodoallenes (XCIII) and (XCIV),[185] (XCV),[202] and (XCVI) respectively, has been proposed in the syntheses of DHA (Scheme 24).[199] The synthesised DHA specimens were identical with those synthesised previously[122,188] using acetylenic compounds and the Wittig reaction.



(XCVII)

Like 5,8,11,14-eicosatetraynoic acid, 5,6-dehydroarachidonic acid was synthesised by the authors of this review[197,203] from acetylenic derivatives by nucleophilic substitution at the terminal acetylenic carbon atom—a method proposed by Osbond and Wickens[204] and subsequently modified and improved by other workers.[205,206]

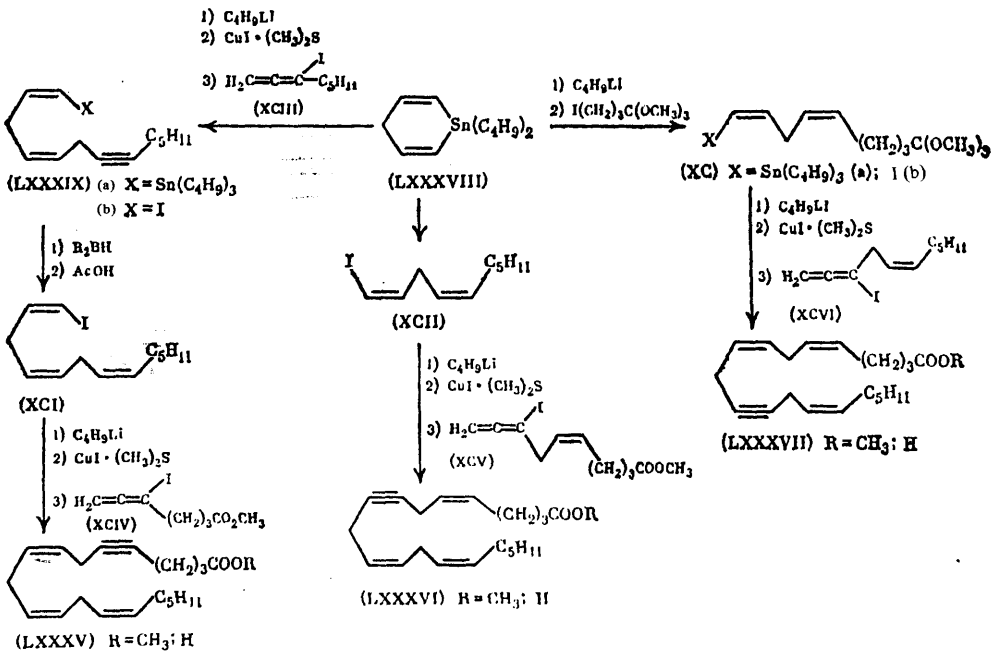
14,15-Dehydroarachidonic acid (14,15-DHA) (XCVII) was synthesised by arachidonic acid via the opening of the epoxy-ring[131] and the formation of a triple bond via a reaction involving ketobromides.[189]



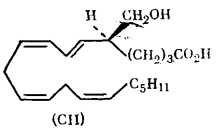
It has been shown[188,189,190] that 4,6-DHA and 14,15-DHA inhibit irreversibly only soya bean 5-LO and 15-LO respectively. A most effective inhibitor of the biosynthesis of prostaglandins is 11,12-DHA. 14,15-DHA can inhibit the formation of prostaglandins but at much higher concentrations than 11,12-DHA. 5,6-DHA and 8,9-DHA are not only inhibitors of the biosynthesis of prostaglandins but at higher concentrations can actually behave as substrates.

4,5-Dehydroarachidonic acid (4,5-DHA) (XCVIII), which is an irreversible and more selective inhibitor of the 5-LO from basophilic leukaemic rat cells,[207–209] the mechanism of the action of which on the enzyme is apparently different from that of 5,6-DHA, has been synthesised from 5,6-epoxyarachidonate (LIX).[131]

(XCVIII)



5-LO is inhibited by 7,7- and 10,10-dimethyl-5*Z*, 8*Z*, 11*Z*-eicosatrienoic acids (XCIX) and (C),[176] and also by 7,7-dimethyl-5*Z*, 8*Z*-eicosadienoic acid (CI),[191] which are derivatives of 5,8,11-eicosatrienoic acid—the substrate in the biosynthesis of series 3 luekotrienes.[8,41,122] The inhibitors (XCIX), (C), and (CI) have been synthesised from acetylenic compounds by means of the Wittig reaction.[176]



(XCIX) (C) (CI)

5,6-Methanolaukotriene $A_4$, the "carbo-analogue of $LTA_4$", (XLIXa),[117,118,210] the thio-analogue of $LTA_4$ (XLIXb),[122] and 5-hydroxymethyleicosatetraenoic acid (CII),[118] which are synthetic analogues of the selective inhibitors of the

Scheme 24

biosynthesis of leukotrienes, possess the properties of the latter.

(CII)

## VI. THE BIOLOGICAL ROLES UF LEUKOTRIENES

The leukotrienes $C_4$, $D_4$, $F_4$, and $B_4$ are of considerable interest as a new class of natural physiologically active bioregulators.[6,8,59,111,138,144,192,210–222] Leukotrienes have been identified both in leukocytes and in a series of other sources, which indicates their wide distribution.[6,8,144,211,212]

Purified SRS-A, isolated from natural sources, and the synthetic $LTC_4$, $LTD_4$, and $LTE_4$ are as a rule tested for their ability to contract the smooth muscle tissue in guinea-pig intestines in the presence of histamine antagonists.[8] The studies of the action of leukotrienes on the guinea-pig aorta,[118] bronchi,[99] and trachaea[92] and human bronchi *in vitro*[8,211,212] have shown that $LTC_4$ and $LTD_4$ increase microvascular permeability and are powerful spasmogenic agents in relation to bronchi, acting on the smooth muscle tissue in peripheral air pathways.[8,94,96,183,212] $LTC_4$ and $LTD_4$ make the main contribution to the biological activity of SRS-A.[192] The leukotriene $F_4$ is 282 times less active than $LTD_4$.[143] $LTD_4$ contributes more than 90% of the biological hypersensitivity of human lungs. Leukotriene $D_4$ is 1000 times more active than $LTC_4$.[143,213] Since leukotrienes are secreted in the course of immunological action, it is extremely probable that cells serving as receptors of immunoglobulins E (or G in guinea-pigs) serve as sources of leukotrienes.[6] It has been suggested that SRS is liberated together with other mediators (histamine and chemotactic factors).[6,8]

The study of the action of $LTD_4$ as a function of concentration in the presence and absence of selective inhibitors of the biosynthesis of leukotrienes[8] has confirmed the existence of two separate receptors in peripheral airways. The study of the effects of $LTC_4$ and $LTD_4$ on pulmonary mechanics and the arterial blood pressure[93,213] has shown that both leukotrienes can contract human bronchi[23,214] (1000 times more actively than histamine)[8,213] and has confirmed the fact that $LTC_4$ and $LTD_4$ act as mediators in the bronchial spasm in bronchial asthma[93,138] and other instant hypersensitive responses.[211] The discovery of the biological activity of $LTC_4$ and $LTD_4$, which is comparable to the activity of histamine, explained why the attempts to alleviate the symptoms of bronchial asthma by antihistamine preparations were unsuccessful.[8] The fact that their precursor, arachidonic acid, can be converted into both prostaglandins and leukotrienes, explained the unfavourable effect of non-steroid anti-inflammatory agents on asthmatic symptoms in aspirin-sensitive patients.[211,212] Thus the arachidonic acid balance, disturbed by cyclo-oxygenase inhibitors, increases the concentration of leukotrienes with a corresponding increase of the intensity of the bronchial spasm. It has been possible to account for the successful treatment with corticosteroids in asthma therapy. These substances block the action of phospholipase $A_2$, which is involved in the cleavage of phospholipids and the secretion of arachidonic acid, which ultimately reduces the degree of biosynthesis of leukotrienes.[8] Studies on the possibility of the contraction of smooth muscles by a series of $LTC_4$ and $LTD_4$ analogues made it possible to formulate a structural requirement which must be met by compounds in order that they can manifest such biological activity.[8] Positional isomers with peptide substituents at sites other than C(6) exhibit a weak ability to contract smooth muscles.[23,93,94,102,104,146,213,214] It has been shown that the 5(*S*),6(*R*)-configuration of the substituents must be maintained.[102,215] Diastereoisomers are less active by two orders of magnitude. The fully saturated analogues of $LTC_4$, $LTD_4$, and $LTE_4$ are in essence inactive.[140] The change in the geometry of the

double bond from 11*Z* to 11*E* results in a significant loss of activity.[75,212] The biological activity of the 7-*cis*-isomer of $LTD_4$ amounts to only 1/10 of the activity of the natural $LTC_4$.[99] The results obtained in the study of 38 analogues of leukotrienes have shown[146,147] that their hydrophobic component and their stereochemical features influence the manifestation of their activity. Analogues lacking the natural structure of the hydrophobic component of the leukotriene molecule are much less active. The terminal amino-group in the peptide side chain, the carboxy-group of glycine, and the C(5)-hydroxy-group[114] are extremely important for the manifestation of the maximum biological activity. On the other hand, the carboxy-group at C(1) is not an important component. Changes in the aminoacid residue present in $LTD_4$ entail some loss of biological activity. These results have led to the conclusion that the receptor for $LTD_4$ as regards its binding and the generation of the response[114] must consist of a broad hydrophobic binding site, adjoining a multicomponent active section, which should bind the non-ionised C(1)-carboxy-group, the C(5)-hydroxy-group, and the peptide functional group containing a non-protonated amino-group.[114]

Leukotriene $B_4$ induces the contraction of various preparations of the smooth muscle of the guinea-pig.[8,144,211-216] The duodenum is the organ most sensitive to the action of $LTB_4$, but the greater stability of the parenchymal§ component of the lung renders this tissue more suitable for biological tests. Leukotriene $B_4$ is closely associated with inflammatory processes and behaves as a chemotactic[146,154,156] and chemokinetic factor for neutrophil and eosinophil, which arise in large amounts (at a concentration of $3 \times 10^{-9}$ M) in inflammatory states.[162-166,212] This activity is greater by 2–3 orders of magnitude than the activity of mono-HETE. An increase of the content of $LTB_4$ has been observed in the synovial fluid of patients suffering from inflammatory diseases.[212,217] In combination with vasodilators of the type of $PGE_2$, leukotriene $B_4$ increases vascular permeability.[212,218] Prostaglandins synergise this effect, increasing the blood flow.[165,211,212] The release of lysozyme by the products of the metabolism of arachidonic acid[211,212,219] and apparently $LTB_4$ has been described. Even low concentrations of hydroxyeicosatetraenoic acids increase the content of cyclic guanosine monophosphate (c-GMP),[220] which is believed to promote, in its turn, the release of lysozyme[211] in phagocytotic processes. A change in the geometry of the double bonds of the conjugated triene[51,149,153] and of the configuration of the C(12)-hydroxy-group[156] in the natural structure lead to an appreciable decrease of the biological activity of $LTB_4$.[154,156] The unique lipoprotein nature of leukotrienes and their close relation with a whole series of pathological states underlying many diseases[8,211,212] [bronchial asthma, Quincke's (angioneurotic) oedema, vasomotor rhinitis, rheumatoid arthritis, psoriasis, etc.] and their role as long-acting regulators of nerve excitability by allergic reactions[211,212] have given rise to the question how molecules of these compounds function in the organism and how they are deactivated biochemically.[144] The answers to these questions can apparently be provided by a detailed study of the biological role of leukotrienes. Analogues and antogonists of leukotrienes, the inhibitors of their biosynthesis, the synthesis and study of the properties of which accelerate the search for effective antiallergic preparations, are of great interest for this purpose.

§ Parenchyma consists of a set of cellular elements of the organ which effects its specific functions. It can be made up of various types of tissue: blood generating tissue (spleen), epithelium (glands), nerve cells (nerve ganglia), etc.

# Characteristic Features of the Chemical Properties of Fluorine-containing Unsaturated Compounds†

N.P.Gambaryan and E.M.Rokhlin

The review deals with the results obtained in the study of the chemical properties of organofluorine and saturated compounds containing the C = C, C = O, C = N, C = C = C, C = C = O, C = C = N, etc. groups. The characteristics of the reactions of fluoro-olefins and related compounds with nucleophiles as well as the methods of synthesis and the properties of fluorocarbanions (including mesomeric fluorocarbanions) are examined. The electronically amphoteric character of the C = C bond in fluorine-containing unsaturated compounds, ensuring the possibility of interaction with strong electrophiles, and the synthetic possibilities resulting from these reactions are demonstrated. The analogy between the chemical properties of polyfluoro-substituted carbonyl compounds, their derivatives, heterocumulenes, and nitro- and nitroso-compounds is discussed. The influence of fluorine atoms is manifested by the markedly electrophilic properties of these compounds and in many cases also by the singular stability of the unusual structures formed as a result of their reactions.
The bibliography includes 180 references.

## I. INTRODUCTION

The establishment of the organic chemistry of fluorine as a separate branch of science dates back to the beginning and middle 1940's.[2] The development of this field was initially dictated by immediate practical needs (the necessity for the creation of materials resistant to the action of uranium hexafluoride). Since then organofluorine compounds are being increasingly used in a wide variety of fields, so that "it is at present difficult to name a branch of engineering which could do without materials containing fluorine".[2]

The possibilities in the application of fluorine compounds are determined by the characteristic features of this element. Fluorine is the most electronegative element in the Periodic System. The dissociation energy of its molecules is extremely low (the same as that for iodine) and the strength of its bonds with many elements is, on the other hand, high. As a result of this, the majority of substances, even the inert gases, can interact with fluorine.

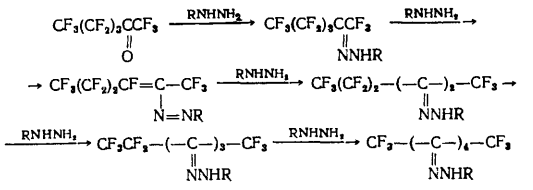
Perfluorocarbon chains are exceptionally stable both thermally and chemically owing to the great strength of the carbon–fluorine bond (on average about 110 kcal $mol^{-1}$) and also the very favourable ratio of the carbon–carbon bond length to the size of the fluorine atom. The van der Waals radius of fluorine is smaller than the C–C bond length and for this reason the accumulation of fluorine atoms in perfluorocarbons does not lead to the extension and weakening of this bond (as in perchlorocarbons); on the contrary, fluorine atoms give rise to close packing, reliably protecting the carbon chain from external influences and in particular rendering it resistant to oxidation.

All these factors led to an abundance of compounds of a wide variety of classes in which all the hydrogen atoms have been replaced by fluorine. Organofluorine chemistry, which is, as it were, a copy of organic chemistry, has been created. However, this copy is so unusual and the results have so far been so unexpected that they have enriched organic chemistry and have greatly extended its theoretical ideas.

Since the creation of the Institute of Organoelemental Compounds of the USSR Academy of Sciences (INEOS) in 1954, the Laboratory of Organofluorine Compounds, headed by Ivan Lyudvigovich Knunyants, was organised in it. In the present review an attempt is made to survey some of the most interesting and important results obtained by the members of this laboratory during the one-third of a century of its existence. Many of these results have been described in a series of other reviews.[2–26] In describing the relevant data, we shall as a rule refer to these reviews and the original papers will be quoted only in the case of the latest investigations.

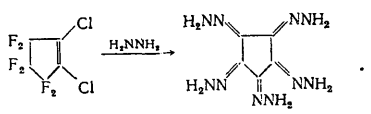
The principal direction taken by the studies in the above laboratory involves the investigation of the characteristic features of various multiple bonds in organofluorine compounds such as fluoro-olefins, including those with functional group substituents (the C=C bond), carbonyl compounds and their derivatives (the C=O, C=N, etc. bonds), nitro- and nitroso-compounds (the $N\overset{O}{\underset{O}{<}}$ and N=O groups), and cumulenes and heterocumulenes (the C=C=C, C=C=O, C=C=N, N=C=O, etc. groups). The present review is mainly devoted to these studies.

However, apart from the investigations of the multiple bonds, other branches of organofluorine chemistry also occupy an important place in the studies carried out in the Laboratory. Frequently these investigations are genetically related to the main field of study. Thus, numerous reactions of fluorine-containing unsaturated compounds, leading to the formation of carbocyclic and heterocyclic systems, including those with small rings, have been discovered. The study of the properties of these cyclic systems, which are frequently unusual, is of considerable interest.[2,3,13,16,27–31]



Fluorocarbanions, which are of very great synthetic importance# (see below), are formed as intermediates in various reactions of fluoro-olefins and related compounds in the presence of the $F^-$ anion.

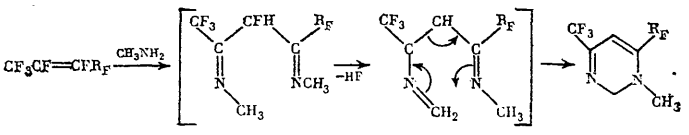
†The article has been written to commemorate the 80th birthday of the founder of the Soviet school of organofluorine chemists Academician I.L.Knunyants (cf.Rokhlin and Gambaryan[1]).



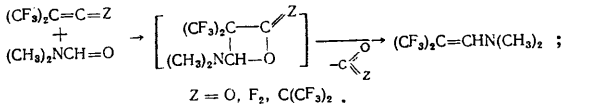
#Another important property of the $F^-$ anion, namely its high basicity, was discovered by Knunyants and co-workers as early as the middle 1940's;[32] this property is nowadays used widely for synthetic purposes.[2,33–35]

The study of the reactivities of fluoroketones yielded functional-group derivatives of 2,2-diphenylhexafluoropropane and aryl- or alkyl-bis(fluoroalkyl) carbinols. Compounds of these types have been the objects of two major series of investigations associated with the development of methods of synthesis of monomers for polycondensation polymers with valuable properties,[36,37] and fluorine-containing epoxides—intermediates in many syntheses of organofluorine substances.[2]

Knunyants introduced the bold idea of an analogy between the $CF_2$ and C=O groups,[5] which proved fruitful as regards syntheses. In particular, a rearrangement of fluoroalkyl azides, resembling the Curtius rearrangement of acyl azides, was discovered.[5] Like keten, a terminal fluoro-olefin is capable of undergoing reactions of the Wittig–Staudinger type.[13] Perfluoromonocarbonyl compounds behave similarly to polycarbonyl compounds, forming osazones and polyhydrazones,[38,39] for example:



In the series of alicyclic compounds it has actually been possible to obtain "perhydrazones",[39,40] for example:



These interesting reactions demonstrate the possibility of "livening" the perfluorocarbon chain. They are based on the ability of hydrazones of α-fluoro-substituted carbonyl compounds to be dehydrofluorinated with formation of unsaturated azo-compounds which then react with the next mole of hydrazine.

Such dehydrofluorination is apparently possible also for α-fluoroketone methylimines. This explains the unexpected result of the interaction of certain internal perfluoro-olefins with methylamine, which leads to dihydropyrimidines.[41] The intermediate heptafluoroacetylacetone diimine (cf. Kurykin et al.[42]) is dehydrofluorinated to a 1,3,5-heterotriene, which is converted into a substituted dihydropyrimidine as a result of intramolecular [4 + 2]-cycloaddition:

An analogy has also been observed in the reactions of fluorine-containing unsaturated compounds with dimethylformamide, leading to the products of the cleavage of the unstable oxetans formed initially. Bis(trifluoromethyl)keten,[20] perfluoroisobutene,[22] and perfluorotetramethylallene[43] give rise to hexafluoroisobutenyldimethylamine under these conditions:

Z = O, $F_2$, $C(CF_3)_2$ .

In the latter case the hexafluoroisobutenylidene group $C=C(CF_3)_2$ acts as an analogue of the carbonyl group.

Much attention has been devoted to the methods for the introduction of fluorine into an organic molecule. In particular, this applies to the discovery of the opening of the epoxide rings under the influence of HF, first discovered by Knunyants and co-workers,[32]§ and the coupled addition to olefins in hydrogen fluoride.[19] A number of studies have been devoted to the fluorination of organic compounds.[46–48] A convenient synthesis of the anticancer preparation 5-fluorouracil by the direct fluorination of the readily available uracil has been developed and introduced into practise.[46]

A method for the partial introduction of fluorine into organic molecules under mild conditions by means of anodic oxidation in the presence of the fluoride anion at low potentials is of special interest.[14,23] The method for the electrochemical trifluoromethylation of organic compounds (for example, of olefins, derivatives of αβ-unsaturated carboxylic acids, and aromatic compounds) with the aid of the $CF_3$ radical generated in the anodic oxidation of trifluoroacetic acid is also interesting.[49]

Studies on the synthesis and properties of chemically inert organic perfluoro-compounds, with an anomalously high capacity for dissolving various gases, in particular $O_2$ and $CO_2$, are very important. Such compounds are attracting increasing attention because various preparations for biomedical purposes, including artificial blood substitutes, can be obtained on their basis.[50]

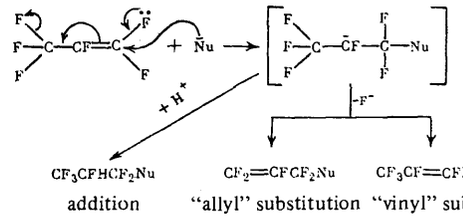
However, as already stated, the principal research carried out at the Laboratory was devoted to the investigation of the reactions of multiple bonds in organofluorine compounds, particular emphasis being laid on the study of the C=C bond.

## II. FLUORO-OLEFINS AND RELATED COMPOUNDS

The comparatively readily available fluoro-olefins can be regarded as "key" compounds in the organic chemistry of fluorine. An enormous range of the most varied organofluorine compounds can be obtained from them; in addition, the study of the reactivity of fluoro-olefins and related compounds made it possible to elucidate many important theoretical questions relevant to organofluorine chemistry (and organic chemistry in general).

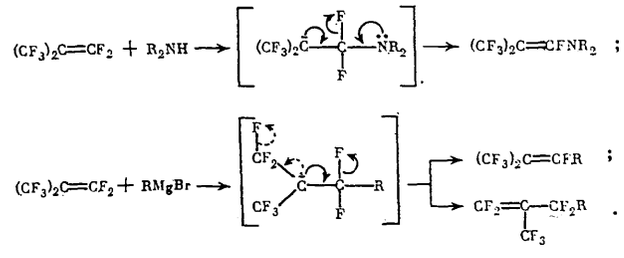
The unusual chemical properties of perfluoro-olefins are caused by the high electronegativity of the fluorine atom and the ability of its electrons to effect various types of conjugation in the molecule. In contrast to the usual hydrogen-containing olefins, perfluoro-olefins react very readily with nucleophiles.[45,51]

Soon after the first communications on the addition of nucleophiles to fluoroethylenes,[52,53] the studies by Knunyants and co-workers, devoted to the interaction of various fluoro-olefins with nucleophiles, were published.[54–56] Perfluoroisobutene proved to be especially active in these reactions. Studies of its chemical properties, which have continued to this day, demonstrated the truly inexhaustible synthetic possibilities arising from the use of this fluoro-olefin.[22] Other branched perfluoro-olefins, in particular perfluoropropene dimers and trimers, for example, $(CF_3)_2C = CFC_2F_5$ and $CF_3CF = C[CF(CF_3)_2]_2$,[57–67] have attracted much attention recently. Their interaction with nucleophiles lead to ways of synthesising potential monomers, fluorine-containing surfactants, and other products of practical value.



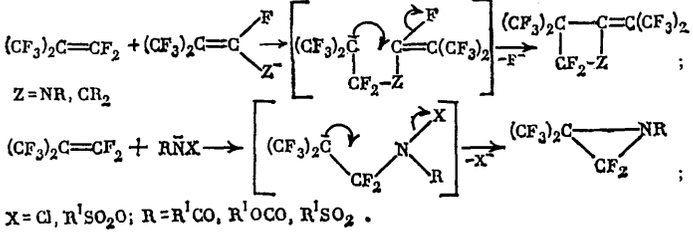
---

§ This reaction has found extensive applications, for example, in the synthesis of fluorine-containing steroids.[44,45]



In the study of the reactivity of the C=C bond "depleted" in electrons owing to the influence of the fluorine atoms and the perfluoroalkyl groups, a wide range of other fluorine-containing compounds with a C=C bond were also investigated, namely, 1,3-dienes,[6,68–71] allenes,[2,43,72–74] derivatives of αβ-unsaturated carboxylic[5,11,24,75–79] and phosphonic[78,80] acids, and alkyl polyfluoroalkenyl ethers.[6,7,60,63,81–83] The most varied nucleophiles, including unusual ones, have been involved in reactions which yielded interesting and sometimes unexpected results.

The first investigations already revealed the occurrence of "vinyl" substitution in perfluoropropene and perfluoroisobutene.[56] This reaction was surprising from the standpoint of the "usual" organic chemistry, but it was found to be common in the chemistry of organofluorine compounds.



Subsequently it was shown (to a large extent as a result of the work of Knunyants and his school) that, in the reactions of fluoro-olefins with nucleophiles, the direction of attack depends on the conjugation in the fluoro-olefin molecule and the final result depends on the realisation of various possibilities for the stabilisation of the intermediate carbanions:[2,3,22,51]

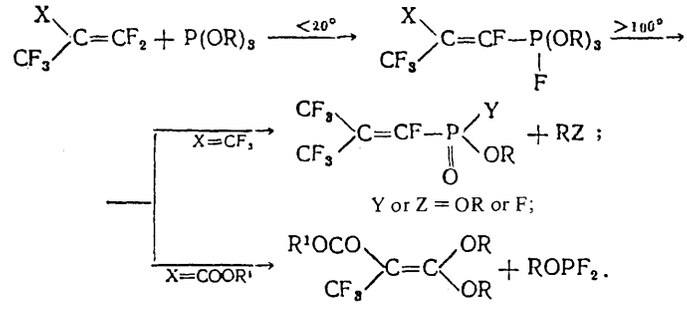
These possibilities are determined both by the structure of the initial fluoro-olefin and by the nature of the nucleophile. In particular, the contribution of the "allyl" substitution increases in the absence of an unshared electron pair in the substituent obtained from the nucleophile:[22]

Instances of the stabilisation of the intermediate carbanions by intramolecular cyclisation are of special interest,[13,22,60,77,84–87] for example:

The anions $RCO\bar{N}X$, formed in the Hofmann and Lossen rearrangements, were "captured" with the aid of a reaction of this type for the first time.[22]

The intense electron-accepting effect of the trifluoromethyl groups in perfluoroisobutene and related compounds leads to the possibility of obtaining geminal compounds as a result of "double vinyl substitution",[22,56,88,89] for example:

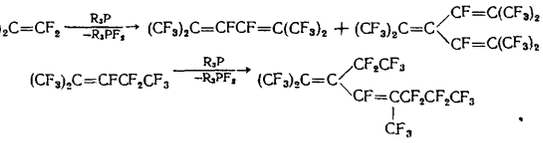
$$(CF_3)_2C{=}CF_2 \xrightarrow{R_2NH} (CF_3)_2C{=}C(NR_2)_2 .$$



Novel methods of synthesising fluorine-containing cumulenes and heterocumulenes are also based on the substitution of both fluorine atoms in the $=CF_2$ group,[13,22,77,90] for example:

$$(CF_3)_2C{=}CF_2 + H_2NR \xrightarrow[-(CF_3)_3CH]{(CF_3)_2C=CF_2} (CF_3)_2C{=}C{=}NR ;$$

$$(CF_3)_2C{=}CF_2 + CH_2(COOR)_2 \xrightarrow[-2Et_3\overset{+}{N}H\bar{B}F_4]{2Et_3N\cdot BF_3} (CF_3)_2C{=}C{=}C(COOR)_2$$

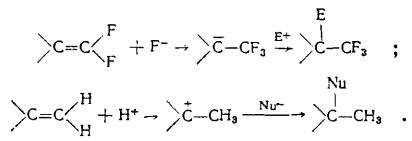


It is of interest that perfluoroisobutene itself plays the role of the dehydrofluorinating agent in the first of the above reactions; as in many other instances,[11,22,91–96] in the second reaction an unusual reagent, namely the triethylamine–boron trifluoride adduct,¶ has been used successfully for the smooth elimination of HF.

The reaction of the highly electrophilic fluoro-olefins with trialkyl phosphites yielded stable adducts—phosphoranes with a P–F bond, which are cleaved only on heating. Depending on the structure of the "fluoro-olefin" component of the phosphorane, its cleavage proceeds either in the direction of the Arbuzov reaction or follows an unusual pathway with formation of a compound of tervalent phosphorus and a fluorine-containing keten acetal:[11]

In the latter case the nucleophile ($RO^-$) attacks the highly electrophilic β-carbon atom of the "acrylic" system, which ultimately leads to the cleavage of the C–P bond.

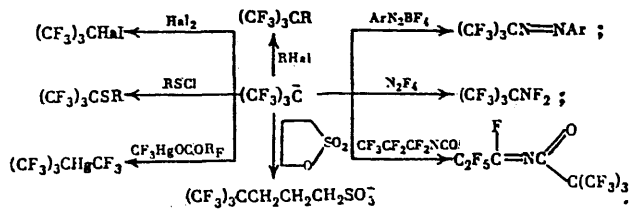
When perfluoro-olefins were acted upon by tertiary phosphines, interesting reactions were observed, including the defluorodimerisation and defluorotrimerisation reactions,[15,22,98] for example:



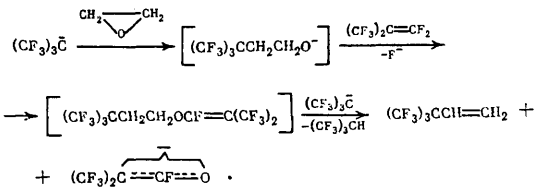
These reactions probably involve the intermediate formation of phosphorus ylides of the type $(CF_3)_2C=C=PR_3$ and $(CF_3)_2CFC(C_2F_5)=PR_3$ (cf. Stepanov and co-workers[65,67]).

¶ The dehydrofluorinating effect of the $Et_3N.BF_3$ adduct has been used to develop a new and apparently most convenient method of synthesis of derivatives of perfluoromethacrylic acid (potential monomers).[11] Other dehydrofluorinating agents are as a rule unsuitable in this case. The same adduct can sometimes be employed also to eliminate an alkyl fluoride, for example, in the conversion of trialkoxyhexafluoroisopropylidenephosphoranes $(CF_3)_2C=P(OR)_3$ into the "phosphorus analogues" of perfluoromethacrylates—the pentafluoroisopropenylphosphonates $CF_2=C(CF_3)PO(OR)_2$.[97]

Since the electron can play the role of a kind of "nucleophile", electrophilic fluoro-olefins undergo electrochemical reduction comparatively readily.[87,99-101] The study of the polarographic behaviour of fluoro-olefins† [87,100,101] showed that the reduction potential decreases with increase of the number of electron-accepting perfluoroalkyl groups at the C=C bond. A correlation was observed between the reduction potential of the fluoro-olefin and the energy of the lowest unoccupied molecular orbital (calculation by the MNDO method).[100,101]

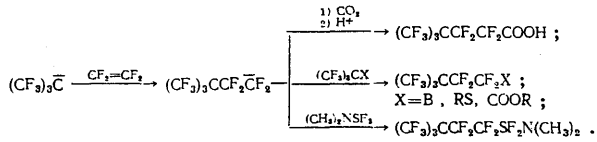


When the $F^-$ anion is used as the nucleophile, the corresponding fluorocarbanions are obtained from perfluoro-olefins. Reactions involving the intermediate formation of fluorocarbanions occupy a notable place in the chemistry of fluoro-olefins.[33,35,102,103] As frequently happens in organofluorine chemistry, a "reverse analogy" obtains here between the reactions of the fluoro-olefins in the presence of the $F^-$ anion and the reactions of non-fluorinated olefins in the presence of the $H^+$ cation (or a Lewis acid):[104]

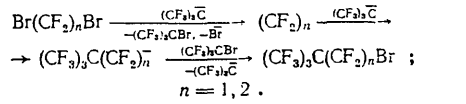


The main contribution made by the Laboratory of Organofluorine Compounds at the Institute of Organoelemental Compounds to this important field involved the study of the reactivity of highly branched fluorocarbanions (in particular the perfluoro-t-butyl anion[12,22] and the perfluoro-t-hexyl anion[57,105-107]), the development of the "nucleophilic mercuration" of fluoro-olefins,[12,22] the development of the chemistry of mesomeric fluorocarbanions,[7,24] the discovery of new sources of the weakly solvated $F^-$ anion containing carbonium counterions,[108] the detection of fluorocarbanions by NMR,[12,109] and the involvement of fluorocarbanions in new types of reactions—azocoupling,[12,107] difluoroamination,[12] sulphenylation,[22] coupled addition to fluoro-olefins,[22,110] reactions with geminal and vicinal dihalogenopolyfluoroalkanes,[22,106,111] etc.

The reactions of branched fluorocarbanions are extremely varied—see, for example, Scheme 1.[12,112,113] Together with subsequent reactions of the products, these reactions lead to extensive possibilities for the synthesis of organofluorine compounds, including potential monomers and surfactants.



Scheme 1



Interesting reactions take place between the carbanions $(CF_3)_2\bar{C}CF_2R_F$ ($R_F$ = F or $CF_3$) and epoxides.[12,24,105] Under certain conditions, the fluoro-olefin can play in this case the role of not only the dehydrofluorinating agent but also of a kind of dehydrating agent, for example:

The reaction involving the coupled addition of the perfluoro-t-butyl anion and electrophiles to fluoro-olefins has been discovered recently.[22,110] It leads to ways of synthesising various functional-group substituted organofluorine compounds, for example:

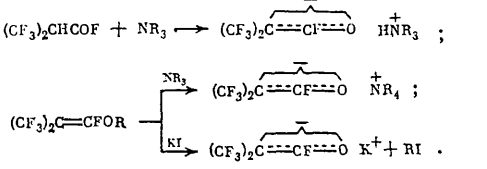
The coupled addition of the anion $(CF_3)_3C^-$ and bromine to tetrafluoroethylene also takes place in the intermediate stages of the reaction of the perfluoro-t-butyl anion with 1,2-dibromotetrafluoroethane, which leads to the substitution of one of the bromine atoms by the $(CF_3)_3C$ residue.[22] The reaction begins with the halogenophilic attack by the tertiary carbanion on the bromine atom of the vicinal dibromo-compound and is completed by a similar attack by the primary carbanion on the bromine atom in perfluoro-t-butyl bromide (or the initial vicinal dibromo-compound). Analogous reactions have been observed also in the reaction with a geminal dibromo-compound—dibromodifluoromethane.[22,106] Tetrafluoroethylene and difluorocarbene are formed respectively as intermediates in the reactions involving the vicinal and geminal dibromo-compounds:

Similar elimination–addition reactions have been observed also on treatment with other nucleophiles of organofluorine compounds containing halogen atoms other than fluorine in the vicinal positions. When the $F^-$ anion is used, the formal result of such a reaction is the substitution of one of the halogen atoms by fluorine, which is accompanied in certain cases by a rearrangement,[111] for example

The reactions of fluorocarbanions with sulphur lead to fluorine-containing sulphides, disulphides, trisulphides, dithiacyclobutanes and trithiacyclopentanes.[12] In particular, a convenient method of synthesising the hexafluorothioacetone dimer has been discovered:#

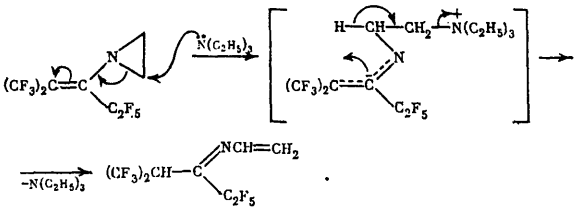
New effective sources of the fluoride anion, namely α-fluoroalkylamines, in which this anion is stabilised by organic cations, were found in subsequent years.[22,108,115] This extends the synthetic possibilities in the chemistry of fluorine-containing anions. Thus the benzoylation of the perfluoro-t-butyl anion has been achieved only when hexamethylguanidinium was used as the counterion:[22]

†The preparative reduction at the cathode via the intermediate formation of mesomeric fluorocarbanions is described below.

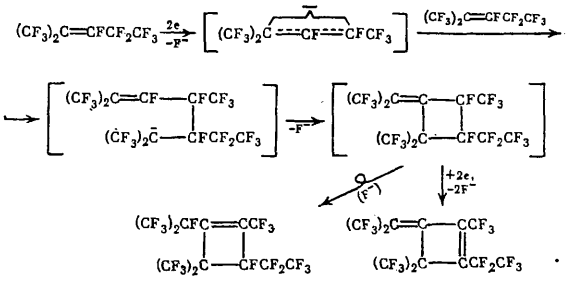


#Subsequently this method was improved.[114]

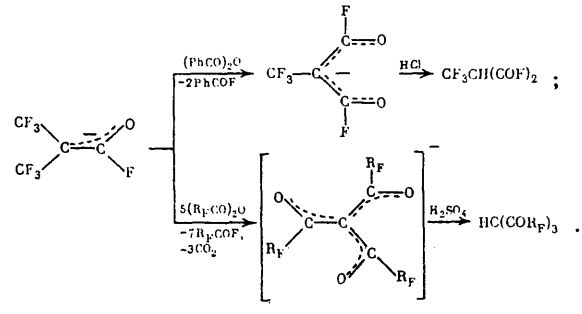
Other fluorine-containing unsaturated compounds react with the fluoride anion like fluoro-olefins (frequently even more readily). Perfluoromethylacryloyl fluoride,[11,24] bis-(trifluoromethyl)keten,[24,76,116] its *N*-benzenesulphonylimine,[91] fluorine-containing allenes,[72,74] and pentafluoroisopropenylphosphonate esters[80] give rise under these conditions to the corresponding stable mesomeric carbanions, for example:



The chemistry of mesomeric fluorocarbanions of this type has been investigated on a fairly wide scale.[2,3,7,24,64] They can be generated not only by the method described above but also from the corresponding CH acids§ and sometimes by the dealkylation of alkyl polyfluoroalkenyl ethers,[2,3,7,24,64,118] for example:

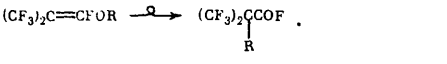


Hexafluoroisopropylidenetrimethoxyphosphorane is dealkylated similarly, forming the anion

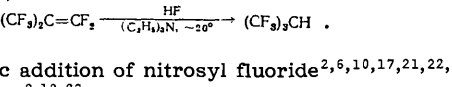


1-Perfluoroalkenylaziridines sometimes behave similarly to alkyl perfluoroalkenyl ethers, manifesting "alkylating" properties in relation to tertiary amines. This is in fact the explanation of the rearrangement of 3-(1-aziridinyl)-perfluoro-2-methylpent-2-ene to 2-hydroperfluoro-2-methyl-3-pentanone *N*-vinylimine:[62]

An unusual method of generating mesomeric fluorocarbanions involves the cathodic reduction of fluoro-olefins.[66,87,99] For example, in contrast to the effect of a tertiary phosphine (see above), the preparative electrochemical reduction of the perfluoropropene dimer leads to perfluorinated substituted cyclobutenes as a result of "cathodic dimerisation" involving defluorination and cyclisation. It has been suggested that a mesomeric fluorocarbanion is then formed as an intermediate as a result of the transfer of two electrons to the initial fluoro-olefin and the elimination of the $F^-$ anion:



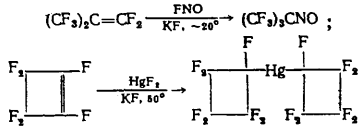
The stable salts formed by the mesomeric fluorocarbanions into a wide variety of reactions—halogenation, alkylation, and partial hydrolysis of the $CF_3$ groups.[2,7,24] On treatment with carboxylic acid anhydrides, the trifluoromethyl groups are converted into fluorocarbonyl or perfluoroacyl groups, which makes it possible to synthesise various di- and tricarbonyl compounds,[24,119] for example:



Fluorine-containing α-phosphonate anions enter into the Wittig–Horner reaction with carbonyl compounds:[80]

Mesomeric fluorocarbanions are formed as intermediates in the rearrangement of alkyl polyfluoroalkenyl ethers to the fluoride of α-alkyl-substituted carboxylic fluoroacids in the presence of catalytic amounts of a tertiary amine:[7,24]

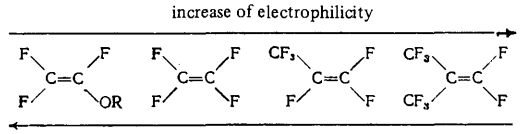
Certain reactions of perfluoro-olefins with the intermediate formation of fluorocarbanions constitute characteristic examples of the inversion of the addition mechanism, where reagents usually regard it as electrophiles react via a nucleophilic mechanism. Thus, hydrogen fluoride readily adds to perfluoroisobutene in the presence of bases[6,10,12,22] (cf. Brice et al.[120]):



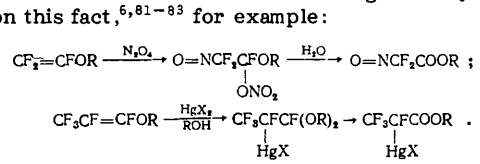
The nucleophilic addition of nitrosyl fluoride[2,6,10,17,21,22,121] or mercury fluoride[2,12,22] to electrophilic fluoro-olefins in the presence of the $F^-$ anion belongs to reactions of the same type,¶ for example:

§Not only mesomeric but also perfluoroalkylcarbanions can be obtained by the heterolysis of the C–H bond. Thus it has been shown for the first time in relation to monohydroperfluoroisobutane $(CF_3)_3CH$ that the proton mobility of the hydrogen atom in monohydroperfluoroalkanes can find a synthetic application.[12,24,117] The intramolecular sulphenylation of β-hydroperfluoroisobutylsulphenyl chloride led to a perfluorinated thiiran:[31]

¶The inversion of the mechanisms takes place also in other cases. Thus, it has been found unexpectedly that highly electrophilic fluorine-containing unsaturated compounds very readily undergo the Prilezhaev epoxidation in ethereal solvents[11,24,122] and are halogenated in acetonitrile.[22,78] Evidently in this case even the use of weakly basic solvents is sufficient to shift the reaction from the usual electrophilic mechanism to a "nucleophilic track".

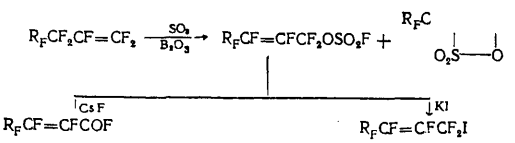


However, the interaction of nitrosyl fluoride with polyfluoroethylenes is catalysed by boron trifluoride in contrast to the analogous reactions of perfluoropropene and perfluoroisobutene:[6]

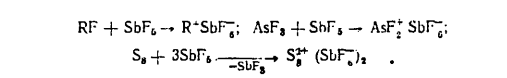


This example shows that reactions via the electrophilic mechanism usual for olefins are possible also in the case of fluoro-olefins.[2,10,21] Such reactions have been little investigated in the first stage of the study of the reactivity of fluoro-olefins, where attention was concentrated on the interaction with nucleophiles. At the same time, despite their low reactivity (or more correctly precisely because of it), fluoro-olefins have advantages in reactions with strong electrophiles over the usual non-fluorinated olefins because the replacement of hydrogen atoms by fluorine atoms as a rule prevents undesirable side processes—oxidation, polymerisation, etc.

The wide-scale study of the reactions of fluoro-olefins with nucleophiles and electrophiles made it possible to generalise the results obtained and to formulate the thesis of the electronically amphoteric character of the double bond in these compounds.[2,4,6] The order in which the electrophilic properties of fluoro-olefins are enhanced and the nucleophilic properties are correspondingly diminished can be accounted for by the electron-accepting effect of the fluorine atoms and the trifluoromethyl groups and also by the electron-donating mesomeric effect of fluorine atoms (and, in the case of alkyl polyfluoroalkenyl ethers, also the oxygen atoms) in the vinyl position acting in the opposite direction:

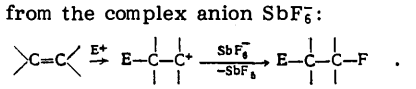


The reactions with electrophiles are more characteristic of the first members of this series than the last. Such reactions are achieved particularly readily for fluoro-olefins containing electron-donating substituents. The use of alkyl polyfluoroalkenyl ethers for the synthesis of a wide variety of derivatives of fluorine-containing carboxylic acids is based on this fact,[6,81-83] for example:

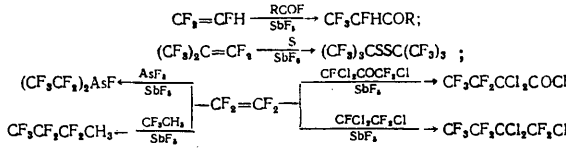


Under fairly severe conditions, strong electrophiles also react with very weak nucleophilic perfluoro-olefins. A typical example is provided by the interaction with sulphur dioxide, which leads to the corresponding cyclic adducts—β-sultones and pyrosultones; these compounds exhibit a varied reactivity and their reactions lead to a wide variety of sulphur-containing organofluorine compounds.[2,123]

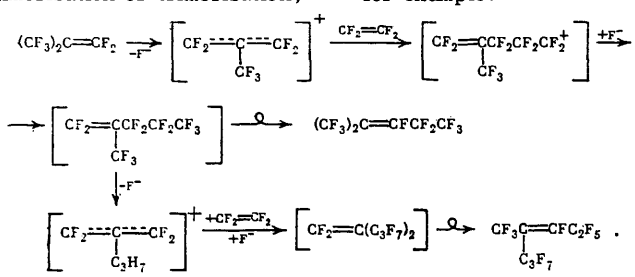
It has been shown recently[124-126] that another reaction, substitutional sulphotrioxidation, takes place together with cycloaddition in the presence of Lewis acids. The perfluoroallyl fluorosulphates formed have been used successfully in the synthesis of various fluorine-containing unsaturated compounds—iodides, derivatives of carboxylic acids, dienes, organomercury compounds, etc.[79,127-129], for example:



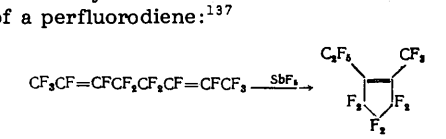
The use of antimony pentafluoride as the Lewis acid makes it possible to obtain fluorosulphates not only from terminal but also from internal fluoro-olefins.[130]



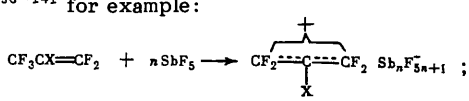
In general the reactions of fluoro-olefins in the presence of antimony pentafluoride are of great interest. Antimony pentafluoride is a very strong Lewis acid, exhibiting in addition oxidative properties, which is capable of generating cationoid species from various reagents,[2,131] for example:



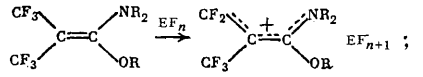
Highly electrophilic cationoid species attack the molecule of a fluoro-olefin and the resulting carbonium ions abstract a fluoride anion from the complex anion $SbF_6^-$:



Such reactions have led to extensive synthetic possibilities,[2,68,132-136] for example:

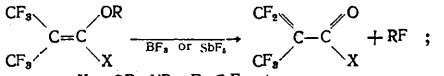


Reactive cationoid species (carbonium ions) can be formed not only from an acyl halide, a halogenoalkane, or a halogenoketone but also from a fluoro-olefin on treatment with $SbF_5$ as a result of the elimination of the fluoride anion from the allyl position. The resulting fluorine-substituted allyl cations can react with another molecule of the fluoro-olefin, which entails dimerisation and, in the case of different olefins, mixed dimerisation or trimerisation,[68,136] for example:

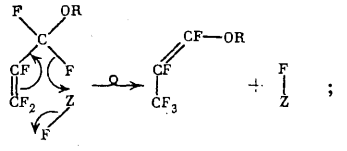


Intramolecular cyclisation has been observed similarly in the case of a perfluorodiene:[137]

Fluorine-containing polyhalogenoallyl cations proved to be so stable in a number of instances that they could be detected by NMR,[138-141] for example:



The mesomeric carbonium ion intermediate can be isolated in the form of a salt in the reaction of a Lewis acid with a fluoro-olefin having electron-donating substituents:[11]



$EF_n = BF_3, SbF_5$ .

Such cations are evidently formed as intermediates in the electrophilic elimination of alkyl fluorides from alkyl polyfluoroalkenyl ethers on treatment with Lewis acids. This reaction is used to synthesise αβ-unsaturated fluorocarbonyl compounds,[2,11,142] for example:

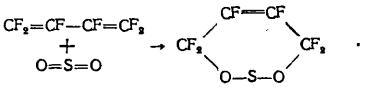
X = OR, $NR_2$, F, $C_2F_5$, etc.

The rearrangement of perfluoroallyl ethers to perfluoropropenyl ethers is also catalysed by fluorine-containing Lewis acids.[143] A synchronous cyclic mechanism has been proposed for this reaction:

R = Alk, Ph; ZF = $BF_3$, RCOF .

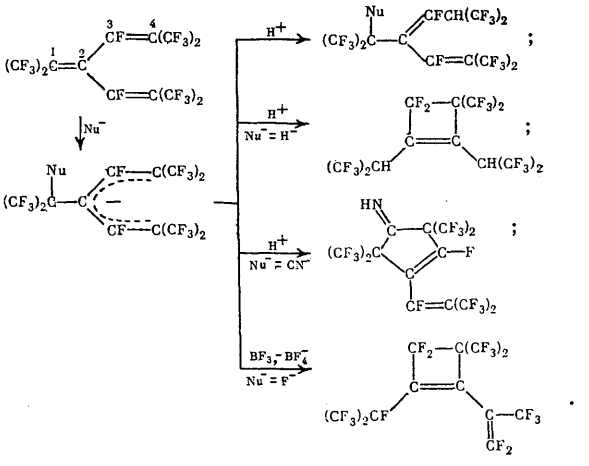
The driving force in this and similar rearrangements is the energy gain resulting from the formation of compounds with a more conjugated bond system.

Apart from Lewis acids, hydrogen fluoride can also be used as the catalyst for the generation of the cationoid species and as a source of $F^-$ anions. The coupled addition of various reagents in HF to olefins, including fluoro-olefins, is of considerable synthetic value:[19]



Fluoronitration, fluorohydroxymethylation, fluoroaminomethylation, fluorohydroxylation, etc. products have been obtained in this way.

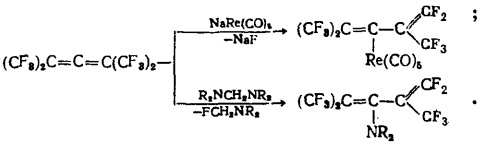
The coupled electrophilic addition of a halogen and the fluorosulphonic acid residue to fluoro-olefins proved to be a convenient method of synthesis of halogenopolyfluoroalkyl fluorosulphates,[144] for example:



The compounds obtained are of interest as intermediates in the synthesis of derivatives of carboxylic chloro- and bromoperfluoroacids.

Interesting data have been obtained in the study of the reactivity of fluorine-containing dienes. In the reactions of perfluorobuta-1,3-diene with nucleophiles, π,π-conjugation is usually not observed in the diene molecule.[6]† However, the photochemical or thermal reactions of perfluorobuta-1,3-diene with substituted styrenes or phenylacetylene afford mixtures of cyclic [2 + 2]- and [4 + 2]-adducts apparently as a result of a stepwise biradical reaction.[69,70] The 1,2- and 1,4-cycloaddition products are also formed as a result of the photochemical reaction with sulphur dioxide;[71] however, in the latter case sulphur dioxide reacts in a completely unusual manner, serving as the source of the –O–S–O fragment and not –O–S(=O)–; a new type of heterocyclic compound was thereby obtained—a seven-membered cyclic ester of sulphoxylic acid:

The interaction of the cross-conjugated perfluorotriene with nucleophiles involves 1,4-addition, the attack by the nucleophilic species being directed to the C(1) atom.[146] In certain cases the carbanionic intermediate is stabilised by cyclisation:[147,148]

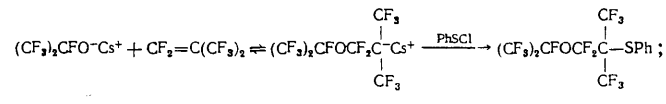


The cumulated perfluorodiene (perfluorotetramethylallene) proved to be extremely reactive. It readily combines with nucleophiles:[2]

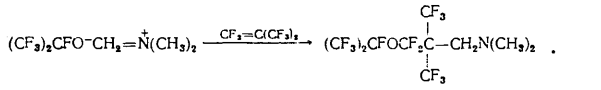
HX=$H_2O$, ROH, $RNH_2$ etc.

It is of interest that the 1,2-diene system of this compound cannot as a rule be converted into the conjugated 1,3-diene system.[2] The reactions with trialkyl phosphites, the anions of metal carbonyls, and tetraalkylmethylenediamines are exceptions,[149,150] for example:

## III. POLYFLUOROCARBONYL COMPOUNDS AND THEIR ANALOGUES

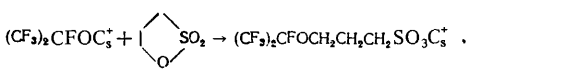


An extensive cycle of studies carried out at the Laboratory of Organofluorine Compounds of the Institute of Organoelemental Compounds has been devoted to the investigation of the influence of fluorine-containing groups on the reactivity of heteroatomic multiple bonds. These studies have made a decisive contribution to the investigation of the chemical properties of fluorine-containing ketones, ketens, and their derivatives, as well as analogues of carbonyl compounds such as aliphatic fluoronitroso- and fluoronitro-compounds.



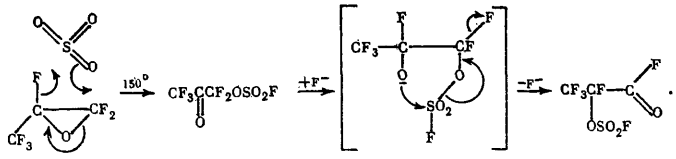
† Perfluorodimethylbuta-2,3-diene behaves analogously.[145]

The introduction of perfluoroalkyl groups enhances the electrophilic properties and diminishes the nucleophilic properties of the multiple bonds. Furthermore, perfluoroalkyl groups increase the stability of the corresponding compounds and a wide variety of derivatives obtained on their basis, so that structures which are unstable or do not exist at all in the "usual" organic chemistry become entirely stable. The most striking example is provided by the stable enol of pentafluoroacetone[25,151] (see below). Geminal diols, hydroxyamines, and diamines are all compounds whose existence conflicts with the El'tekov–Erlenmeyer rule, being stable in the series of organofluorine compounds.[18] Furthermore, unusual structures such as those of the "enols" of *N*-fluoroamides,[152] *N*-fluoroazoxy-compounds,[17] and many others are entirely stable.

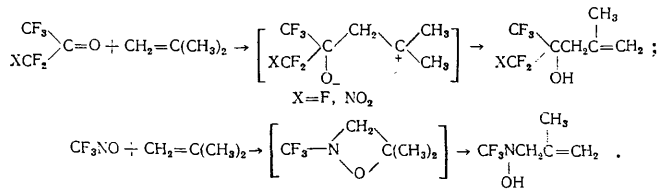


All these findings impart a considerable variety of fluorocarbonyl compounds and their analogues, which entails not only a radical change in their reactivity in the usual reactions but also the appearance of the possibility of reactions which are completely atypical of non-fluorinated compounds. In this Section we shall consider mainly reactions of the latter type.

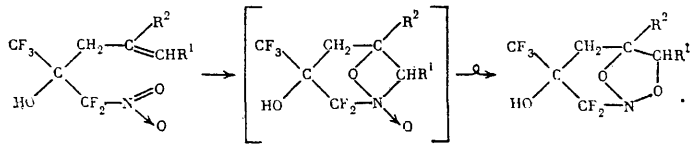
In contrast to the non-fluorinated ketones, perfluoroketones and their derivatives yield relatively stable adducts with alkali metal fluorides[16,33,35,153] or with α-fluoroalkylamines.[108] The α-fluoroalkoxides formed can in principle add to fluoro-olefins, but this reaction is reversible and the equilibrium is displaced towards the initial reactants. Nevertheless, the formation of the adduct, a perfluoroalkoxycarbanion, has been detected by reactions with electrophiles such as halogens, sulphenyl halides, or the methyleneimmonium cation:[22,108]



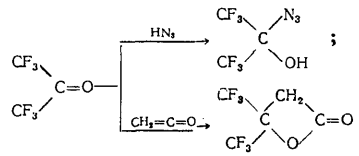
On reaction with propane sultone (1,2-oxathiolan 2,2-dioxide), α-fluoroalkoxides give rise to perfluoroalkoxy-substituted sulphonates, which are of interest for the synthesis of surfactants:[113]



The rearrangement of the fluorosulphate derived from hydroxypentafluoroacetone into α-formylperfluoroethyl fluorosulphate under the influence of the $F^-$ anion has been accounted for by the intermediate formation of a α-fluoroalkoxide and its intramolecular acylation:[2,154]

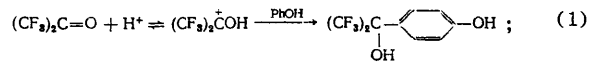


A certain analogy in the reactivities of ketones, ketens, and nitroso- and nitro-compounds is most conveniently traced in relation to stable polyfluoro-compounds, because aliphatic ketens and nitroso-compounds without fluorine are unstable.

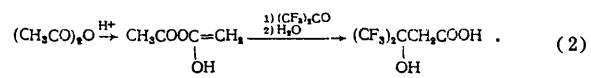


Perfluoroketones,[18,155] bis(trifluoromethyl)keten,[20] and perfluoronitrosoalkanes[17] react with a weak nucleophile such as isobutene in the cold and, in contrast to the non-fluorinated analogues, without catalysts:

The nitro-group reacts similarly with an olefinic double bond but the cyclic adduct formed initially isomerises in this case to a derivative of 1,3,2-dioxazolidine:[156]

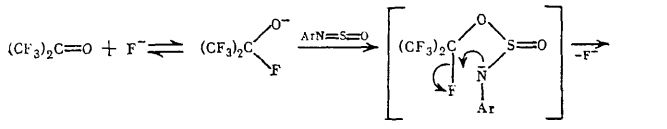


Hydrazoic acid and a keten readily interact with perfluoroketones in the absence of a catalyst[18] whereas their reactions with non-fluorinated ketones take place only in the presence of acids (protic or aprotic):[18]

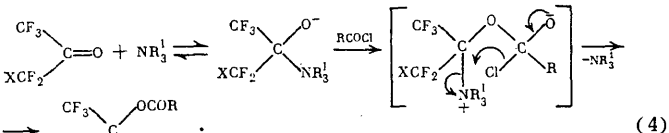


Thus it has been found that increase of electrophilic reactivity and a decrease of nucleophilic reactivity entail the "inversion" of the reaction mechanism: electrophilic addition (for non-fluorinated ketones) is transformed into nucleophilic addition (for perfluoroketones). It is of interest to note that trifluoroacetone reacts with keten only in the presence of $BF_3$ and the reaction proceeds with difficulty compared with the reaction involving acetone. Evidently the presence of one trifluoromethyl group is insufficient to convert the ketone from a nucleophile into an electrophile.[18]

Despite the highly electrophilic properties of perfluorocarbonyl compounds, they are frequently incapable of reacting with very weak nucleophiles. In such cases success has been achieved with the aid of acid catalysis; the catalyst then activates either the fluoroketone [Eqn.(1)] or the attacking agent [Eqn.(2)], for example:[18]

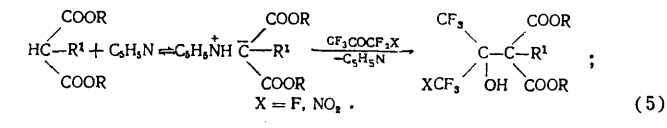


(1)



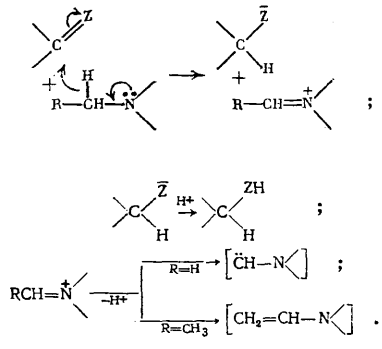
(2)

In view of the reduced basicity of fluoroketones and their derivatives, electrophilic addition of type (1) is difficult.[18]



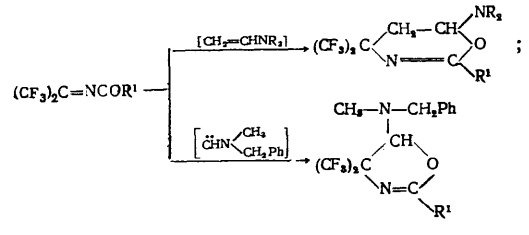
The use of basic catalysts in reactions with electrophiles proved to be no less successful. As in acid catalysis, the basic catalyst can activate either the fluorocarbonyl compound, by converting it into a nucleophilic α-substituted alkoxide [Eqns.(3) and (4)] [157–159] (cf. Zeifman et al.[160]), or the attacking agent, by converting it into a nucleophilic conjugate base [Eqn.(5)]:[18]

(3)

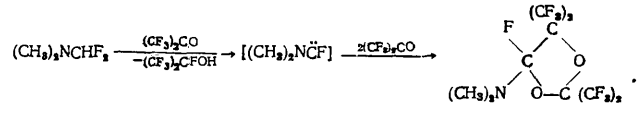


(4)

(5)

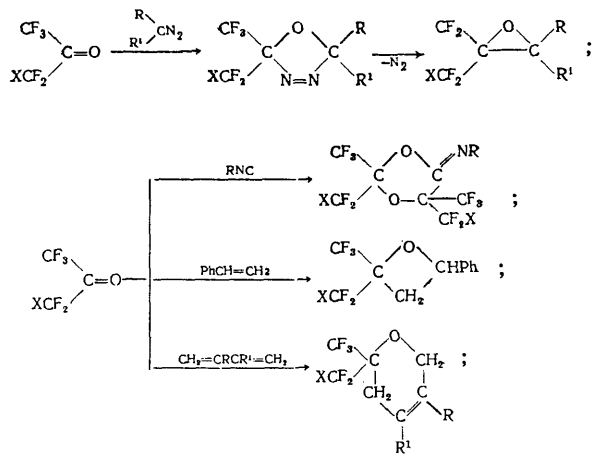


The very high electrophilicity of the C=O groups in fluoroketones[18] and in derivatives of carboxylic fluoroacids,[2,161] of C=N groups in hexafluoroacetone acylimines,[162,163] and of the C=C bond in perfluorotetramethylallene[2] is manifested in oxidation-reduction reactions with tertiary amines. The first stage of these reactions yields an immonium cation, which can be subsequently transformed into an aminocarbene or a vinylamine:

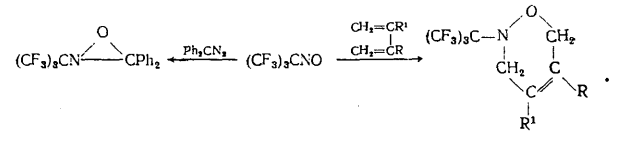


The intermediate formed reacts subsequently with the initial electrophilic fluorine-containing unsaturated compound, for example:

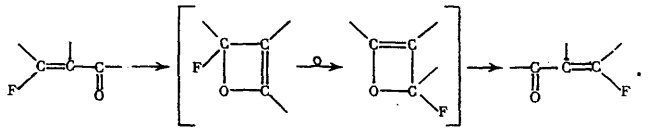
$$[CH_2{=}CHNR_2] + R_FCOX \rightarrow R_FCOCH{=}CHNR_2 .$$



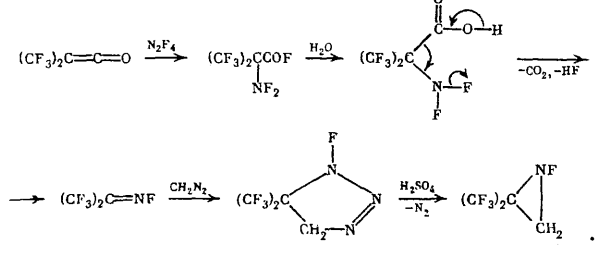
Hexafluoroacetone acylimines give rise to cyclic adducts under these conditions:

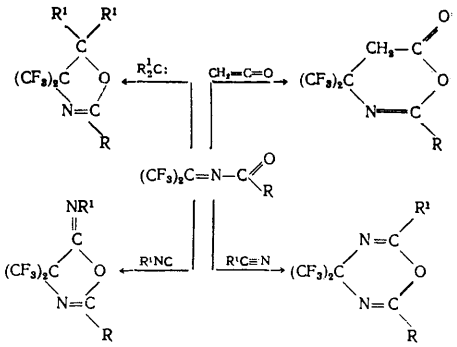


The aminocarbene obtained as a result of the dehydrofluorination of the αα-difluoroalkylamine by the perfluoroketone also undergoes cycloaddition to the initial ketone to form a 1:2 adduct:[115]

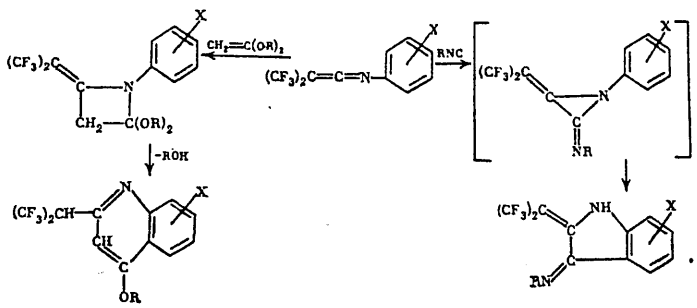


Cycloaddition reactions are in general very characteristic of fluorine-containing ketones[18,164] and ketens,[20] trifluoropyruvate esters,[165] and fluoronitrosoalkanes,[17] for example:

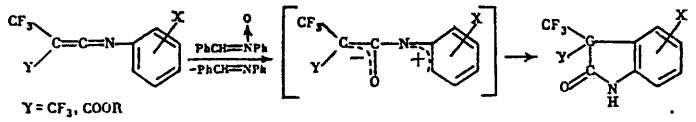




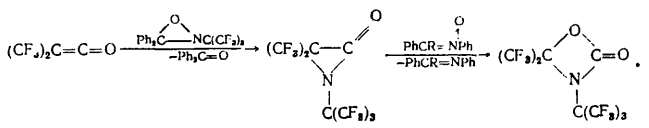
The carbonyl group can also add intramolecularly to the C=C double bond in certain fluorine-containing αβ-unsaturated carbonyl compounds. This entails a kind of rearrangement as a result of which the oxygen and fluorine atoms change places:[11,166]



Fluoroketone imines also enter into cycloaddition reactions with dienes and diazo-compounds.[16,167] Imines with electron-accepting substituents both at the carbon atom and at the nitrogen atom are particularly active. For example, hexafluoroacetone *N*-fluoroimine, which is readily obtained from bis(trifluoromethyl)keten, reacts with diazomethane at −50 °C:[152]

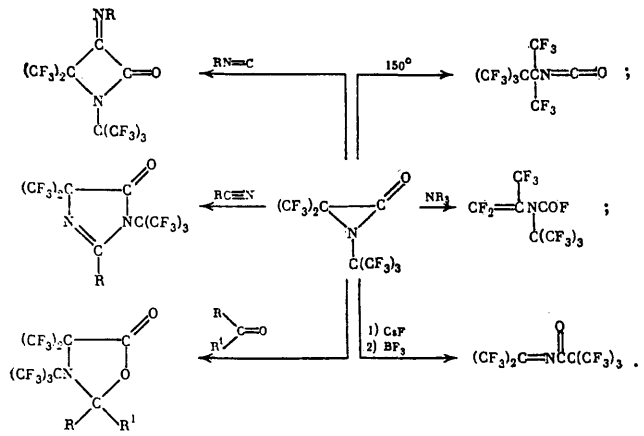


Fluoroketone *N*-acylimines are very reactive, typically undergoing 1,4-dipolar cycloaddition reactions with diazomethane, carbenes, isonitriles, and compounds containing the C=C, C≡C, C=O, and C≡N multiple bonds:[16,168]

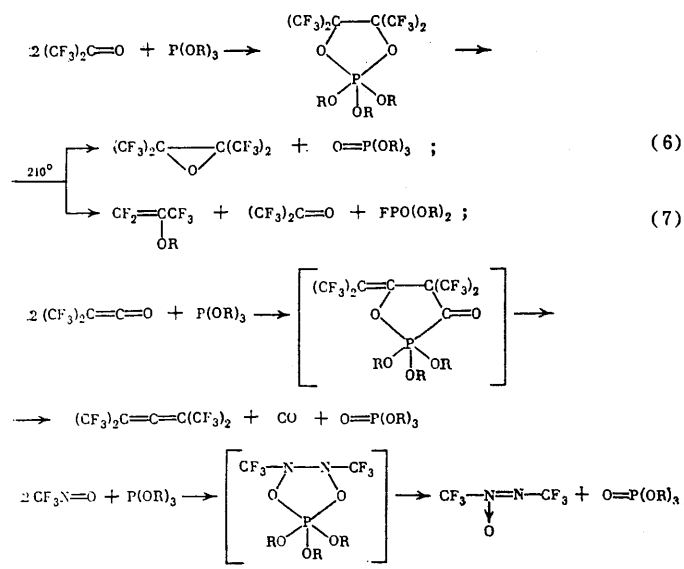


Cycloaddition reactions involving the aromatic ring have been discovered for bis(trifluoromethyl)keten *N*-arylimines. These reactions resemble structurally the Diels–Alder reactions, i.e. keten *N*-arylimines formally behave in this instance like 1,4-dipolar compounds. However, a two-stage mechanism rather than a synchronous mechanism is more likely for reactions of this type, where one of the double bonds of the 1,3-diene forms part of an aromatic ring: betaines or small rings are formed initially, being subsequently stabilised as a result of the reaction with the aromatic ring,[13,169] for example:

The unusual reaction of keten *N*-arylimines with nitrones, which in this instance play the role of oxygen sources, belongs to the class of reactions of this type:[13,169,170]



Nitrones react as oxidants also with the uniquely stable perfluoro-α-lactam, which is obtained by the epimination of bis(trifluoromethyl)keten:[27]

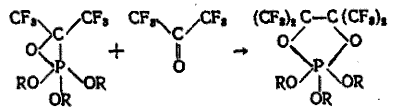


Any of the bonds of the three-membered ring can be ruptured in the cycloaddition reactions with perfluoro-α-lactam, four- or five-membered heterocycles with two heteroatoms being formed. On treatment with nucleophiles ($NR_3$, CsF) or after prolonged heating, perfluoro-α-lactam rearranges to linear isomers: a perfluoroalkyl isocyanate, an unsaturated carbamoyl fluoride, and a ketone acylimine; similar rearrangements of non-fluorinated α-lactams are unknown[28,29] (Scheme 2).

Scheme 2

The analogy between the properties of fluorine-containing ketones, ketens, and nitroso-compounds is manifested particularly strikingly in the isotypical nature of the reactions with phosphite esters. Thus it has been shown that triethyl phosphite reacts in the cold with perfluoroketones,[18] bis(trifluoromethyl)keten,[20] and trifluoronitrosomethane,[17] forming "pinacolisation" products, which decompose in the last two cases already under the conditions of the synthesis (Scheme 3).

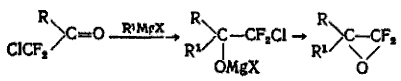
Scheme 3



The cyclic phosphorane formed from hexafluoroacetone decomposes only on heating and the reaction proceeds via two pathways [Eqns.(6) and (7)]; the second decomposition pathway [Eqn.(7)] is analogous to the formation of oxime ethers from secondary perfluoronitrosoalkanes:[17]

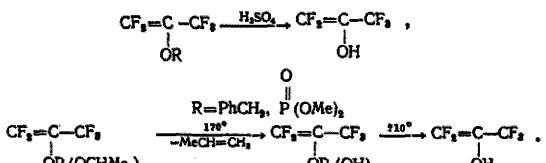
$$(CF_3)_2CFNO + P(OR)_3 \rightarrow (CF_3)_2C{=}NOR + FPO(OR)_2 .$$

A complete analogy has been observed between the Allen reactions of α-chloroperfluoronitrosoalkanes and the Perkow reactions of α-chlorofluoroketones.[17]



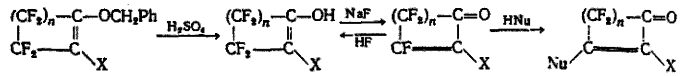
The first step in all these reactions involves the attack by the phosphite on the electrophilic carbon or nitrogen atom.[17,18] The strained three-membered cyclic phosphorane formed then either isomerises or combines with the next molecule of the unsaturated electrophile with rupture of the

C–P and not the P–O bond[18] (as in the decomposition of the four-membered cyclic intermediates in the Wittig reaction), for example:



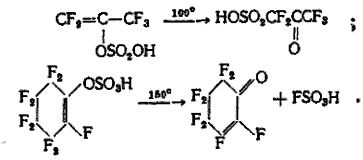
In the reaction with phosphites, two molecules of the fluorine-containing ketone or keten therefore combine with one another via the formation of a C–C bond, in contrast to the reaction with isonitriles, in which a C–O bond is formed.[8,18]

The trifluoromethyl groups in hexafluoroacetone and its derivatives are inert and do not react.# Although this restricts the synthetic possibilities of perfluoroketones, it is nevertheless convenient in the sense that the reactions of carbonyl groups are not complicated by the involvement of the other reaction centres of the molecule.[18] However, the replacement of one or several fluorine atoms by chlorine appreciably "activates" the fluoroalkyl groups, so that chlorofluoroketones are able to enter into the Perkow reaction.[25] It has been found that the chlorine atoms also readily undergo intramolecular nucleophilic substitution in the alkoxides of tertiary polyfluorocarbinols.§ This resulted in the formation of a wide range of polyfluorinated epoxides:[2]



An outstanding investigation by Knunyants, Dyatkin, and Bekker and co-workers was devoted to metastable enols. It is known[25] that pentafluoroacetone $HCF_2COCF_3$ does not enolise because of its low acidity (the greater thermodynamic stability of the keto-form of pentafluoroacetone compared with the enolic form has been confirmed by a non-empirical calculation by the SCF method[172]). However, it has been found that the corresponding enol (pentafluoro-2-propenol) is entirely stable and can be obtained by the acid hydrolysis of benzyl pentafluoroisopropenyl ether or dimethyl pentafluoroisopropenyl phosphate or by the thermolysis of diisopropyl pentafluoroisopropenyl phosphate:[25,151,173]

The first representative of the sterically unhindered metastable enols was synthesised in this way. The exceptionally high kinetic stability of this compound can be accounted for by the optimum combination of its properties. Pentafluoro-2-propenol manifests, on the one hand, a relatively low kinetic acidity as a consequence of the destabilisation of the corresponding anion due to the mesomeric electron-donating effect of the vinyl fluorine atoms and, on the other hand, it exhibits a low proton affinity owing to the electron-accepting effect of the fluorine-containing group.[25,174] Certain other aliphatic polyfluoroenols, for example, 3-chlorotetrafluoro-2-propenol $CF_2 = C(OH)CF_2Cl$ or nonafluoropent-2-en-3-ol $CF_3CF = C(OH)C_2F_5$ also proved to be entirely stable.[25,174]



Alicyclic fluorine-containing enols have been likewise synthesised.[25,175] Their most characteristic feature is their ready dehydrofluorination by weak bases and subsequent "vinyl" substitution of the β-fluorine atom:[25,173,175,176]

X = H, F; $n = 1-3$; Nu = RO, $R_2N$.

It is of interest that the dehydrofluorination is reversible, thus confirming experimentally the hypothesis of the 1,4-addition of hydrogen halides to αβ-unsaturated carbonyl compounds.[173,177]

A general property of the aliphatic and alicyclic enols obtained is their ability to give rise to *O*-derivatives as a result of the substitution of the mobile hydrogen atom by an alkyl, acyl, or sulpho-group. Pentafluoropropenyl sulphate isomerises to a sulphoketone on heating, while an alicyclic sulphate eliminates fluorosulphonic acid:[25,176]

Pentafluoro-2-propenol gives rise also to other O-derivatives, namely $CF_2 = C(CF_3)OX$ (X = Li, $R_3Si$, $R_3Ge$, $R_3Sn$, or $R_2P$) or the *C*-derivatives $XCF_2COCF_3$ (X = halogen, NO, ArN = N, or RHg).[25,178] When mercuripentafluoroacetone is treated with acids, the initial enol is regenerated; the transfer of the reaction centre in the protodemercuration of α-mercuricarbonyl compounds, suggested previously, has thus been confirmed.[25,178]

The metastable pentafluoro-2-propenol isomerises wholly to pentafluoroacetone on prolonged heating at 180 °C and also in the presence of weak bases.[25,173]¶ In contrast to this, α-hydrohexafluoroisobutyraldehyde $(CF_3)_2CHCHO$ is involved in a tautomeric equilibrium with the corresponding enol, whose content increases (up to 100%) with increase of the basicity of the solvent.[7] The presence of the electron-accepting trifluoromethyl groups greatly increases, as was to be expected, the tendency towards enolisation in this instance.

However, it has been found that in the case of bis-(perfluoroacyl)methanes, the introduction of perfluoroalkyl or perfluoroacyl groups has the opposite effect, causing a sharp suppression of the enolisation, so that the compounds $(R_FCO)_2CHCF_3$ exists wholly in the diketone form, while the compound $(C_3F_7CO)_3CH$ exists to the extent of 90% in the triketone form.[119] Evidently the bulky groups prevent the formation of the planar chelate ring of the cis-enol.

---

#On the other hand, the mobility of the allyl fluorine atoms in bis(trifluoromethyl)keten and in *N*-perfluoropropyldiphenylketen imine are responsible for the ready isomerisation of these heterocumulenes to 1,3-heterodienes.[13]

§Analogous intermolecular reactions are also known.[171]

¶The metastable enethiol $(CF_3)_2C = C(SH)C_2F_5$ isomerises analogously to the thioketone $(CF_3)_2CHC(=S)C_2F_5$.[179] However, the isomerisation of the corresponding sulphenyl chloride $(CF_3)_2C = C(SCl)C_2F_5$ to the α-chlorothioketone $(CF_3)_2CClC(=S)C_2F_5$ is reversible;[180] a new type of cationotropic tautomerism (chlorotropism) was observed in this instance.

It is of interest that a fairly considerable energy barrier to the enolisation of the metastable diketone form has been observed for heptafluoroacetylacetone $(CF_3CO)_2CHF$. At equilibrium, this β-diketone is 90% enolised[42] in contrast to the wholly enolised hexafluoroacetylacetone $(CF_3CO)_2CH_2$.

--o0o--

We believe that the foregoing data provide an idea about the extent to which the presence of perfluoroalkyl groups alters the chemical properties of organic compounds. "When one views the path traversed by fluorine chemistry, one sees that many features which previously outraged the chemist's imagination have become commonplace; however, the unusual characteristics of this field of chemistry are so pronounced that it still yields new phenomena and facts, which, on the one hand, expand theoretical ideas in chemistry and, on the other, lead to important practical results. Both these aspects are a source of enormous satisfaction to the investigator".[2]

# Coupled Chemical Diffusion of Ions and Electrons in Non-stoichiometric Crystals

V.N.Chebotin (deceased)

The theory of the coupled chemical diffusion of ions and electrons in solids under the influence of the gradient of the degree of deviation from the stoichiometric composition is described consistently on the basis of the phenomenological and statistical-thermodynamic approaches. Within the framework of the model of non-interacting defects, the behaviour of crystals with the following types of disorder is examined: Frenkel', structural, Schottky, Wagner, impurity, and electronic disorder. Account has been taken of the influence of the degeneracy of the electrons. The main principles of the experimental methods for the determination of the coupled chemical diffusion coefficient are described and the experimental data are compared with the theory.
The bibliography includes 85 references.

## I. INTRODUCTION

Studies of diffusion processes in solids have already had a history extending over a century. Nevertheless, the theory of these processes is still far from being perfect. Perhaps the only exception is that of the simplest type of diffusion, namely self-diffusion, characterising the rate of migration of species in chemically homogeneous substances. Considerable advances in this field have been achieved as a result of the employment of radioactive tracers which are chemically indistinguishable from the principal atoms of the material investigated.

However, when a more complex phenomenon is tackled, namely the diffusion of impurity atoms in a chemically homogeneous substance (heterodiffusion), considerable difficulties arise owing to the need to take into account the correlation factors as a consequence of the different mobilities of the main and impurity atoms, the formation of different kinds of associated species, etc. Finally, the picture becomes very greatly complicated when one considers diffusion in variable-composition chemical compounds (chemical diffusion), otherwise referred to as non-stoichiometric compounds. In non-stoichiometric ionic compounds of the type $M_{1+\delta}X_r$, where $r$ is an integer and $\delta$ the degree of deviation from stoichiometry, the excess content of cations and ions leads to the appearance of excess quasi-free electrons in the conductivity band or of electron holes in the valence band. When a gradient of the deviation from stoichiometry exists in a compound of this kind, the chemical potential gradients of both the metallic and non-metallic components, M and X, under the influence of which the cations and anions diffuse towards one another, are also present under these conditions. The local electroneutrality of the specimen is maintained by the equivalent flux of electrons. Such a process is usually referred to as chemical diffusion but this term requires revision. Strictly speaking, the term "chemical" refers to any diffusion in the field of chemical potentials, including the mutual diffusion of the components of non-ideal solutions. In a narrower sense the phenomena considered in this review will therefore be referred to as the coupled chemical diffusion (CCD) of ions and electrons in a chemical field, due to the deviations of the composition from stoichiometry (DCS), and in the electric field arising owing to the difference between the mobilities of species of different kinds.

The most important characteristic of CCD is the coupled chemical diffusion coefficient $D$, which is determined by the combination of the coefficients of the random diffusion of the cations and anions, the mobilities of the electron carriers, and the non-stoichiometry parameters. All these quantities are related to the defect structure of the crystal in different ways. For this reason, comparison of the CCD coefficient in the DCS field with other transport characteristics makes it possible to construct models of the disorder in crystalline bodies at the atomic level, which is one of the most important tasks of the modern solid state chemistry.

Chemical diffusion plays an important and in many cases also a decisive role in real processes accompanied by solid-phase chemical reactions: processes involving the formation of complex compounds from simpler compounds (the oxidation of metals and the solid-phase synthesis of materials) and the decomposition of complex compounds into simpler ones (the isolation of metals from ores, the purification of materials, etc.) and processes in which matter and electricity are transported in the elements of control systems (solid electrolytes and electrodes in microionics and electrochromic materials in optics) and in power plants (electrolysers and galvanic cells, thermoelectric converters, the electrodes of MHD generators, etc.).

A distinctive feature of the CCD in the DCS field relative to, for example, the self-diffusion of labelled atoms is the extremely high effective diffusion coefficients. Thus, whereas at 1000 K the self-diffusion coefficients are in the range $10^{-15}$–$10^{-8}$ $cm^2\ s^{-1}$ for the majority of crystalline bodies, reaching $10^{-5}$ $cm^2\ s^{-1}$ only in structurally disordered crystals (superionic conductors), the coupled chemical diffusion coefficient (CCDC) of ions, for example, in silver chalcogenides, is $10^{-1}$ $cm^2\ s^{-1}$. Such high values of the CCDC ensure an intense transport of matter for an insignificant driving force, i.e. for a small gradient of the degree of DCS.

The present review is devoted mainly to a consistent description of the theory of the CCD in the DCS field on the basis of ideas described in a monograph.[2] The methods for the measurement of the calculated quantities are also examined and the measured transport parameters of a series

of non-stoichiometric compounds are briefly discussed. The author did not attempt to give a detailed survey of the experimental studies and confined himself to the most reliable data. A more complete bibliography can be found, for example, in a number of other reviews.[3-6]

## II. PHENOMENOLOGICAL EQUATIONS

### 1. General Expressions

For the non-correlated diffusion in solids, where the movement of carriers of different kinds is independent, the flux of charged species of type $k$ in the chemical (concentration) and electrical field is defined by the Wagner equation[7]

$$J_k = -\frac{\varkappa_k}{q_k^2}(\nabla\mu_k + q_k\nabla\varphi) \ . \qquad (1)$$

Here the flux is measured as the number of species passing per unit time through a unit surface in a coordinate system rigidly linked to crystal lattice sites. The symbol $\varkappa_k$ denotes the partial specific electrical conductance of such species, $q_k$ is their charge, and $\nabla\mu_k$ and $\nabla\phi$ are respectively the chemical potential and electrostatic potential gradients. The following expression is equivalent to the above equation:

$$J_k = -\frac{N_k D_k}{kT}(\nabla\mu_k + q_k\nabla\varphi) \ , \qquad (2)$$

where $N_k$ is the concentration (number of $k$ species per unit volume) and $D_k$ the "random" diffusion coefficient of the $k$ species linked to their electrical conductivity $\varkappa_k$ by the Nernst–Einstein relation:[2]

$$kT\varkappa_k = q_k^2 N_k D_k \ . \qquad (3)$$

In contrast to Eqn.(1), Eqn.(2) contains no charge in the denominator and is applicable not only to charged but also to neutral species (atoms, molecules, and defects) with $q_k = 0$.

By virtue of their phenomenological character, Eqns.(1) to (3) are equally valid for two different methods of describing the structure of defective crystals and the set of current carriers present in them.[2,13] In the first case the systems of structural elements, where the mobile carriers are assumed to be atoms or ions, may be adopted as a basis. The corresponding random diffusion coefficients of ions and electrons are referred to as macroscopic.[13] Eqn.(2) is applicable both in the absence of correlation (for example, for the direct intersite transport mechanism and probably in structurally disordered phases), where the values of $D_k$ for atoms and ions are identical with their self-diffusion coefficients $D^*$ measured with the aid of radioactive isotopes, and in the presence of a correlation effect. In the latter case, the quantity $D_k$ in Eqn.(2) is linked to the self-diffusion coefficient by the Heyven relation[8] $D_k = f_k D_k$, where $f_k$ is the correlation factor. In the second case, which is preferable in the statistical description of transport, the mobile carriers are assumed to be the atomic and ionic or electronic defects in the crystal lattice differing in their nature and also in their charge and energy state. The corresponding diffusion coefficients are referred to as microscopic.[2,13]

### 2. Neutral Species

Neutral species diffuse only under the influence of their chemical potential gradient $\nabla\mu_k$ and their diffusion is independent of the electric field. Assuming that, for the known composition of the specimen, the chemical potential of the species $\mu_k$ is a single-valued function of the concentration $N_k$, we can express $\nabla\mu_k$ in the form

$$\nabla\mu_k = \frac{d\mu_k}{dN_k}\nabla N_k = kT\frac{d\ln a_k}{dN_k}\nabla N_k \ ,$$

where $a_k$ is the thermodynamic activity of the $k$ component. Then Eqn.(2) assumes the form of Fick's first equation $J_k = -D_k\nabla N_k$ with an individual chemical diffusion coefficient (ICDC) of species of type $k$:[2]

$$\tilde{D}_k = F_k D_k \ , \qquad (4)$$

where the multiplier

$$F_k = \frac{N_k}{kT}\frac{d\mu_k}{dN_k} = \frac{d\ln a_k}{d\ln N_k} \qquad (5)$$

represents the so-called thermodynamic chemical diffusion factor. In the case of substitutional solid solutions, where $\Sigma N_k = \text{const}$. and $d\ln N_k$ can be replaced by $d\ln c_k$, where

$$c_k = N_k / \sum_k N_k$$

is the atomic fraction of atoms of type $k$ in the corresponding sublattice, Eqn.(5) becomes identical with Darken's equation.[9]

Eqns.(4) and (5) belong to the set of principal equations of the modern theory of chemical diffusion and the calculation of thermodynamic factors is the central task in the latter.

### 3. Ions and Electrons. The General Case

The coupled diffusion of ions and electrons takes place as a rule in an electric field, which is determined both by an external source and by the charge of the moving species. The field accelerates the movement of the less mobile charge carriers and retards that of the more mobile ones. Accordingly, in the general case the role of the electric field in transport processes is just as important as the role of chemical fields. Nevertheless, for further consideration, it is convenient to introduce the concept of the individual chemical diffusion coefficient of charged species of type $k$, defined by the same equations (4) and (5) as for neutral species. The definition of the diffusion coefficient $\tilde{D}_k$, as the ratio of the flux of species of type $k$ to the chemical potential gradient multiplied by $N_k/kT$ subject to the condition that the electric field gradient is zero, follows from Eqn.(2).

In the general case of the coupled diffusion of electrons and several ions of the $k$ type, their fluxes are linked by the condition

$$-eJ_e + \sum_k q_k J_k = I,$$

where $I$ is the electric current density in the specimen. This makes it possible to eliminate the electric field strength from Eqn.(1) for the electron flux:

$$J_e = \frac{-\sigma}{e(\varkappa+\sigma)}\left[I + \sum_k \varkappa_k\left(\frac{\nabla\mu_k}{q_k} + \frac{\nabla\mu_e}{e}\right)\right] \ , \qquad (6)$$

where $\sigma = \varkappa_e$ is the electronic conductivity and $\varkappa = \sum_k \varkappa_k$ the overall ionic conductivity.

Eqn.(6) is phenomenological in character and is therefore applicable to systems containing mobile ions with any effective charges $q_k$, including arbitrarily selected charges. This factor is extremely important because the true ionic charges in solids are frequently unknown. In the calculation of the transport characteristics of the system within the framework of the phenomenological approach, it is more

convenient to choose classical ions as the moving species with the nominal charges $q_k = \pm z_k e$ determined by the valences of the corresponding elements $z_k$. In this case, it follows from the electro-neutrality condition for the crystals $eN_e = \sum_k q_k N_k$ that the valence electrons at a concentration $N_e$, in excess relative to the stoichiometric composition $\left(\sum_k q_k N_k = 0\right)$, participate in the transport regardless of whether these electrons exist in a quasi-free state or are localised at some donor or acceptor centres.

It is convenient to select the concentration of the excess (of deficient) electrons as a measure of the DCS. For example, in the case of a binary crystal $MX_r$ the quantity

$$N_e = z_1 N_1 - z_2 N_2$$

($z_1$ and $z_2$ are the valences of the metal M and the non-metal X) determines the difference between the concentrations of the cations and anions measured in terms of the number of elementary charges per unit volume (equivalent concentration multiplied by the Avogadro number). For the specified overall composition of the specimen, the chemical potential of both its components can be unambiguously related to $N_e$. In the absence of an electric current in the specimen, the expression for the electron flux [Eqn.(6)] can therefore be represented in the form of Fick's first equation $J_e = -\tilde{D}\nabla N_e$ with an effective CCDC:

$$\tilde{D} = t_i \tilde{D}_e + t_e \tilde{D}_i \ , \qquad (7)$$

where

$$t_i = \sum_k t_k = \varkappa/(\varkappa+\sigma)$$

is the overall transport number of the ions, $t_e = \sigma/(\varkappa+\sigma)$ the transport number of the electrons, and $\tilde{D}_e$ and $\tilde{D}_i$ are defined by the expressions

$$\tilde{D}_e = \frac{\sigma}{e^2}\frac{d\mu_e}{dN_e}; \qquad \tilde{D}_i = \sum_k \frac{\varkappa_k}{q_k e}\frac{d\mu_k}{dN_e} \ ,$$

where $\mu_e$ is the chemical potential of the electrons.

The physical significance of these quantities becomes apparent on further transformation. We shall represent the electronic conductivity by the sum of the conductivity due to the movement of $n$- and $p$-type carriers (conductivity electrons and holes): $\sigma = \sigma_n + \sigma_p$. With the aid of the Nernst–Einstein equation, we express the partial conductivities $\sigma_n$ and $\sigma_p$ in terms of the diffusion coefficients of the conductivity electrons and holes:

$$kT\sigma = e^2(nD_n + pD_p),$$

where $n$ and $p$ are their volume concentrations. The partial conductivities $\varkappa_k$ of ions of the $k$th type can also be expressed in terms of their diffusion coefficients:

$$kT\varkappa_k = q_k^2 N_k D_k.$$

Taking into account the evident relation $\mu_e = \mu_n = -\mu_p$, where $\mu_n$ and $\mu_p$ are the chemical potentials of the conductivity electrons and holes, and also the definitions specified by Eqns.(4) and (5), we obtain the equations

$$\tilde{D}_e = \frac{dn}{dN_e}\tilde{D}_n - \frac{dp}{dN_e}\tilde{D}_p; \quad \tilde{D}_i = \sum_k \frac{q_k}{e}\frac{dN_k}{dN_e}\tilde{D}_k \ . \qquad (8)$$

Hence it is seen that $\tilde{D}_e$ is the effective CDC of the electrons averaged with respect to $n$- and $p$-type carriers. The weighting factors $dn/dN_e$ and $-dp/dN_e$ of the ICDC of the electron carriers $\tilde{D}_n$ and $\tilde{D}_p$ in Eqn.(8) determine the contributions of the conductivity electrons and holes to the overall DCS gradient. The coefficients $(q_k/e)dN_k/dN_e$ of the ICDC of the ions $\tilde{D}_k$ have an analogous significance, so that $\tilde{D}_i$ is the effective CDC of the ions averaged with respect to all the ionic species.

An equation similar to Eqn.(7) was first derived[10] for the coupled diffusion of cations and anionic vacancies in a structurally disordered solid electrolyte. Since Grafov and Ukshe[10] used the relations of the thermodynamics of ideal solutions, their equation contained the usual diffusion coefficients of the corresponding species $D_k$ instead of the individual chemical diffusion coefficients $\tilde{D}_k$. A more rigorous derivation of Eqn.(7) taking into account thermodynamic factors was achieved by the author of the present review for the coupled diffusion of two arbitrary kinds of charged species.[1]

A remarkable feature of Eqn.(7) is the close relation between the electrical ($t$) and diffusional ($\tilde{D}$) characteristics of the ions and electrons due to the self-consistent character of the electrochemical fields in the diffusion zone. In the general case, this relation precludes the separation in Eqn.(7) of the individual terms due to the electrical and chemical fields. Such a separation becomes possible only in the limiting cases at $t \to 0$ or $t_e \to 0$, which are considered below.

Eqn.(7) can be conveniently used in the statistical calculation of the CCDC when the thermodynamic factors of the ions and electrons are determined by specific microscopic models of the disorder in the crystal. On the other hand, in the phenomenological approach, these factors remain undefined, because the chemical potentials of the ions and electrons are not susceptible to direct measurement separately. For this reason, within the framework of the phenomenological theory, it is useful to resort to the chemical potentials of the neutral components $A_k$ corresponding to the $k$ ions with the aid of the evident relation

$$\mu_{A_k} = \mu_k + \frac{q_k}{e}\mu_e \ .$$

Under these conditions, a simple and at the same time general formula for the effective CCDC follows from Eqn.(6):

$$\tilde{D} = \sum_k \frac{q_k dN_k}{e\, dN_e}\tilde{D}_{ke} \ . \qquad (9)$$

As in Eqn.(8), the summation for $\tilde{D}_i$ is carried out in this case over all types of ions. The partial quantities $\tilde{D}_{ke}$ have the significance of the CCDC for ions of the $k$ type and electrons and are expressed either in terms of the partial conductivities of the $k$ ions and electrons:

$$\tilde{D}_{ke} = \frac{\varkappa_k \sigma}{q_k^2(\varkappa_k+\sigma)}\frac{d\mu_{A_k}}{dN_k} \ , \qquad (10)$$

or in terms of the transport number of electrons and the macroscopic diffusion coefficients of the $k$ ions:

$$\tilde{D}_{ke} = t_e D_k \frac{d\ln a_{A_k}}{d\ln N_k} \ . \qquad (11)$$

## 4. Ions of One Kind

In the simplest case where mobile ions of only one kind are present and the concentrations of all the remaining ions are constant, the electroneutrality condition is $eN_e = q_k \Delta N_k$, where $\Delta N_k$ is the excess content of the mobile ions relative to the stoichiometric composition. In this case Eqn.(9) assumes the simple form $\tilde{D} = D_{ke}$, which has two important corollaries.

Firstly, for mobile ions of one kind the CCDC is expressed, according to Eqn.(10), in terms of quantities susceptible to direct determination from independent experiments, which leads to the possibility of a rigorous comparison of the phenomenological theory with experiment. The derivation of Eqn.(10) for the case under consideration is due to Yokota,[11] who used it to calculate the transfer of charge in non-stoichiometric compounds of the type of silver sulphide in which the charge carriers are electrons and cations.

Secondly, when mobile ions of only one kind are present, Eqn.(11) for the CCDC of ions and electrons differs from Eqns.(4) and (5) for the ICDC of neutral atoms $A_K$ only by the multiplier $t_e$ and becomes identical with the latter for $t_e \cong 1$, i.e. when the electronic conductivity predominates ($\sigma \gg \varkappa$). In this case the coupled diffusion of ions of the same sign and of electrons is formally equivalent to the diffusion of the corresponding atoms. This conclusion is entirely understandable. Indeed, when $\sigma \gg \varkappa$, electrons exist under virtually equilibrium conditions and can compensate for the charge transfer by ions having low mobilities without much difficulty. The diffusional jumps of ions therefore lead to the same migration of substance as the jumps of neutral atoms and the diffusion in electronic conductors can be described with equal success in terms of the movement of both atoms and ions in the mobile electron medium. This factor is very important for the phenomenological theory of diffusion in solids with an intermediate ionic-covalent character of the bond, for example, in semiconducting compounds of the type $A^{III}B^{V}$, where the exact atomic mechanism of diffusion is usually unknown.

### 5. Ions of Two Kinds in a Binary Compound

We shall now consider a more complex case—the crystal of a binary ionic compound $MX_r$ in which ions of both kinds are mobile. By designating the parameters of the cations and anions by the subscripts 1 and 2 respectively, we obtain $q_1 = z_1 e$ and $q_2 = -z_2 e$. For not unduly large DCS, $r = N_2/N_1 \cong z_1/z_2$ and one can therefore formulate the Gibbs–Duhem relation for the chemical potentials of the components in the form $z_2 d\mu_M + z_1 d\mu_X = 0$. Then, on substituting Eqn.(10) in Eqn.(9), we obtain the following expression:

$$\tilde{D} = \frac{\varkappa\sigma}{z_1 e^2 (\varkappa + \sigma)} \frac{d\mu_M}{dN_e} = -\frac{\varkappa\sigma}{z_2 e^2 (\varkappa + \sigma)} \frac{d\mu_X}{dN_e} \cdot \qquad (12)$$

Substitution of Eqn.(11) in Eqn.(9) leads to equivalent relations:

$$\tilde{D} = t_e N_1 (z_1 D_1 + z_2 D_2) \frac{d\ln a_M}{dN_e} = -t_e N_2 (z_1 D_1 + z_2 D_2) \frac{d\ln a_X}{dN_e} \cdot \qquad (13)$$

Eqns.(12) and (13) are analogous to the familiar Wagner formulae[7] which Wagner derived in connection with the development of the theory of the oxidation of metals.† Like Eqns.(9)–(11), they contain the absolute concentrations of the mobile components, namely the numbers of species per unit volume, as the variables.

Together with the relations quoted, an expression for $\tilde{D}$, incorporating the relative concentrations (atomic fractions) of the components, i.e. $c_1 = N_1/(N_1 + N_2)$ and $c_2 = N_2/(N_1 + N_2)$, is sometimes used in the literature. In terms of these variables, Eqns.(13) assume the simple form

$$\tilde{D} = c_2 \tilde{D}'_{1e} + c_1 \tilde{D}'_{2e} ; \qquad (14)$$

$$\tilde{D}'_{1e} = t_e D_1 \frac{d\ln a_M}{d\ln c_1} ; \quad \tilde{D}'_{2e} = t_e D_2 \frac{d\ln a_X}{d\ln c_2} \cdot \qquad (15)$$

Eqn.(14) is formally identical with Darken's equation[9] for binary metallic alloys (more precisely for atomic substitutional solid solutions—see also Chebotin,[2] p.248). However, the partial coefficients $\tilde{D}'_{1e}$ and $\tilde{D}'_{2e}$, corresponding to the coupled diffusion of cations and electrons or of anions and electrons, differ from the ICDC for neutral atoms [Eqns.(4) and (5)] and from the CCDC [Eqn.(11)] for the diffusion of ions of the same size and electrons even under conditions where $t_e \cong 1$, since in the case considered the cations and anions are distributed in different sublattices and $N_1 + N_2 = \text{const.}$, so that $d\ln c_k \neq d\ln N_k$.

All the equations quoted above were obtained by resorting to some kind of model ideas concerning the microscopic structure and the mechanisms of transport in solids. Their character is therefore phenomenological and they can be applied, in principle, to crystals with any types of disorder and with any types of chemical bonding. The diffusion coefficients of the components $D_k$ and the thermodynamic factors $F_k$ then play the role of phenomenological parameters susceptible either to experimental determination or to calculation on the basis of the microscopic theory. The subsequent exposition will concern the solution of the latter problem within the framework of the statistical-thermodynamic theory of disorder in crystalline bodies.[2]

## III. THE CHEMICAL DIFFUSION COEFFICIENT OF ELECTRONS UNDER CONDITIONS WHERE IONIC DISORDER IS DOMINANT

We shall consider below crystals with dominant ionic disorder—either with structural disorder, where the classical ions are distributed among a large number of sites, or with ionic point defects whose effective charges correspond to the state of total ionisation. In all cases we shall neglect the possibility of the capture of electrons or holes by any electron-donating or electron-accepting centres. All the excess valence electrons are then present in the conductivity band and the missing electrons (holes) are in the valence band, DCS being defined as the difference between the volume concentrations of the conductivity electrons and holes:

$$N_e = n - p \cdot \qquad (16)$$

The activities of conductivity electrons and holes, $a_n$ and $a_p$, are linked by the following equation according to the Law of Mass Action:

$$\ln a_n + \ln a_p = 2 \ln K_i , \qquad (17)$$

which corresponds to the intrinsic ionisation reaction of the crystal, $K_i$ being the reaction equilibrium constant. On differentiating Eqns.(16) and (17) with respect to $N_e$ and on substituting the derivatives $dn/dN_e$ and $dp/dN_e$ in Eqn.(8) taking into account the definition of the thermodynamic factors for conductivity electrons $F_n = d\ln a_n/d\ln n$ and the analogous expression for holes, we find

$$\tilde{D}_e = \frac{nD_n + pD_p}{n/F_n + p/F_p} \cdot \qquad (18)$$

Hence it is seen that, when one type of electron carrier predominates, the CDC for electrons ($\tilde{D}_e$) is identical with the ICDC for these carriers, i.e. with $\tilde{D}_n$ for $n/F_n \gg p/F_p$ and with $D_p$ for $p/F_p \gg n/F_n$.

The dependence of $\tilde{D}_e$ on the degree of DCS in the region of comparable concentrations of electrons and holes can be readily determined by assuming that in this region the

†In the second of Wagner's communications[7] where the concentrations were expressed in equivalents per unit volume, the coefficient $z_1$ was omitted in the denominator of Eqn.(23c).

electrons are non-degenerate as a consequence of the smallness of $n$ and $p$. Eqn.(17) then assumes the simple form

$$np = K_i^2 \tag{19}$$

corresponding to the Boltzmann statistics and the solution of Eqns.(16) and (19) with subsequent substitution in Eqn.(8) yields the following results:

$$D_e = {}^1/_2 [\tilde{D}_n + \tilde{D}_p + (\tilde{D}_n - \tilde{D}_p) N_e (N_e^2 + 4K_i^2)^{-1/2}] \cdot \tag{20}$$

The parameters, $D_n$, $D_p$, $F_n$, and $F_p$ for electrons and holes are determined from the electrophysical properties of the crystal. Thus the random diffusion coefficient of conductivity electrons is linked to their mobilities $u_n$ by the Einstein relation $eD_n = kTu_n$, while the thermodynamic factor is equal to the ratio of the Fermi–Dirac integrals whose orders are 1/2 and −1/2:[12]

$$F_n = \frac{\Phi_{1/2}(\eta)}{\Phi_{-1/2}(\eta)}; \quad \Phi_j(\eta) = \frac{1}{j!}\int_0^\infty \frac{x^j\,dx}{\exp(x-\eta)+1} \quad , \tag{21}$$

where

$$\eta = (\mu_n - E_c)/kT$$

is the reduced Fermi energy and $E_C$ the energy of the bottom of the conductivity band. Analogous relations hold also for holes.

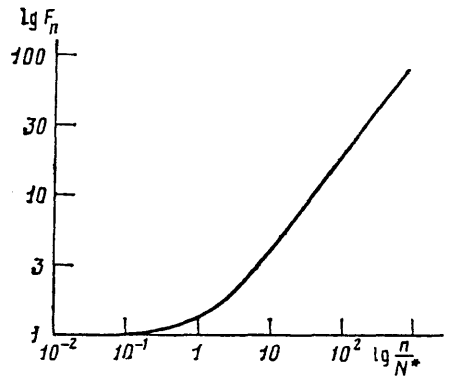

**Figure 1.** Dependence of the thermodynamic factor for conductivity electrons on their concentration.

Since $\Phi_{1/2}(\eta)$ is equal to the ratio of the concentrations of the electronic defects ($n$ or $p$) to the effective density of states in the corresponding band $N^* = 2(2\pi m^* kT)^{3/2}h^{-3}$ (where $m^*$ is the effective mass of the electron in the conductivity band and $h$ the Planck constant), Eqn.(21) makes it possible to calculate directly the thermodynamic factor $F_n$ (or $F_p$) as a function of the relative concentration of carriers $n/N^*$ or $p/N^*$. The result of this calculation, carried out with the aid of tables of Fermi–Dirac integrals,[13] is presented in Fig.1 for conductivity electrons; the result is analogous for holes. As can be seen from this plot, the electron gas can be regarded as virtually non-degenerate for $n < 0.1\,N^*$, where $F_n \cong 1$. When the degeneracy is marked, i.e. $n > 10\,N^*$, the thermodynamic factor can be defined to a satisfactory approximation by the formula

$$F_n = (\pi/6)^{1/3}(n/N^*)^{2/3}.$$

We shall establish several further useful relations between the electronic conductivity, the thermodynamic factors, and the CCD of electrons. We introduce an auxiliary quantity—the average macroscopic diffusion coefficient of electron carriers:

$$D_e = \frac{nD_n + pD_p}{n+p} = \frac{kT\sigma}{e^2(n+p)} \tag{22}$$

and define an effective thermodynamic factor for electrons with the aid of the relation $\tilde{D}_e = F_e D_e$. Comparison of the last equation with Eqn.(18) yields the expression

$$F_e = \frac{n+p}{n/F_n + p/F_p} \cdot \tag{23}$$

Hence it is seen that the quantity $F_e$ is unity in the absence of degeneracy and is equal to $F_n$ or $F_p$ when degeneracy obtains (for $n/F_n \gg p/F_p$ and $p/F_p \gg n/F_n$ respectively). Expressing $D_e$ in terms of $\tilde{D}_e$ in Eqn.(22), we obtain

$$\sigma = \frac{e^2(n+p)\tilde{D}_e}{kTF_e} \cdot \tag{24}$$

## 1. Structural Disorder

More than 300 solid-phase compounds belonging to a comparatively new class of crystal structures with properties which until recently appeared to be unique have now been synthesised. Their distinctive feature is the structural disorder of one of the components (silver, copper, or alkali metal cations and in certain alkaline earth metal or lanthanide halides at high temperatures, also the halide anions), statistically distributed among a large number of sites, several times greater than the number of ions.[1,14–18] As a result, the disordered component resembles an ionic liquid, i.e. its transport properties are similar to those of solutions or fused electrolytes. The electrical conductivity of these compounds is $10^{-2}$ – $10^{-1}$ $\Omega^{-1}$ cm$^{-1}$ even at room temperature, and, as a consequence of the high degree of disorder of the sublattice of only one of the components, the electrical conductivity of the crystal is unipolar. In the best solid electrolytes with structural disorder, also referred to as superionic conductors, the electronic component of the conductivity is negligible.[19,20] At the same time there exist a number of structurally disordered compounds which possess, together with the ionic component, also a considerable electronic component of the conductivity due to the deviations of their composition from stoichiometry.[21,22]

As a consequence of the unipolar ionic conductivity of structurally disordered phases, the effective CDC of the ions in them is identical with the ICDC of the disordered $k$ component. On the other hand, the latter is independent of the concentration of any species according to the theory of diffusion in solids[2] (p.243) and is defined by the expression

$$\tilde{D}_i = \tilde{D}_k = \frac{D_k}{[V_k]} = \nu r_0^2 \exp\left(-\frac{U_k}{kT}\right) , \tag{25}$$

where $[V_k]$ is the fraction of vacant sites in the $k$ sublattice, $\nu$ the vibration frequency of the ions, $r_0$ the length of the elementary jump, and $U_k$ the height of the potential barrier separating neighbouring sites.#

#It is easy to demonstrate that Eqn.(25) remains valid also when, as a consequence of the closeness of the allowed sites, each ion blocks $s > 1$ sites, so that the fraction of vacant sites is $1 - sN_k/N_L$, where $N_L$ is the total number of allowed sites.

Eqn.(25) reflects the following significant factor: if the $k$ sublattice contains ions of one kind only and vacancies, then the ICDC of these ions is the same as in systems with an unlimited free volume, i.e. with $[V_k] \to 1$, which are described by Einstein's diffusion theory. This result is important; it shows that an increase in the chemical diffusion coefficient owing to the increase in the thermodynamic factor occurs only for the upper limit of the quantities defined by Eqn.(25), specified by Einstein's theory.

We shall now proceed to the discussion of the CCDC of ions and electrons defined by the phenomenological Eqn.(7). Using Eqns.(3) and (25), we shall express the ionic conductivity in terms of the CDC of the ions: $kT\varkappa = q^2_k N_k \cdot [V_k]\tilde{D}_i$. Taking into account also Eqn.(24), we find from Eqn.(7) for $[V_k] \cong 1$

$$\tilde{D} = \frac{z_k^2 N_k F_e + (n+p)}{z_k^2 N_k F_e \tilde{D}_i + (n+p)\tilde{D}_e} \tilde{D}_i \tilde{D}_e \quad . \tag{26}$$

For not unduly large DCS, where $n + p \ll N_k$, the second term in the numerator in Eqn.(26) may be neglected. This is equivalent to the neglect of the second term of the phenomenological Eqn.(7), which is now formulated in a simplified form:

$$\tilde{D} = t_i \tilde{D}_e \quad . \tag{27}$$

We obtained Eqns.(26) and (27) for a crystal containing in the structurally disordered sublattice ions of only one kind $k$. It is easy to demonstrate that the above estimate of the second term in Eqn.(7) is at least qualitatively valid also for solid solutions containing ions of two or more kinds in the disordered sublattice.[23] In this case $t_i$ in Eqn.(27) should be understood as the total transport number of the ions.

The smallness of the second term in Eqn.(7) compared with the first has a definite physical basis associated with the high concentration of vacant sites $N_V$ in structurally disordered crystals. Since $N_V \cong N_k \gg |N_e|$, in most cases the relative changes in the concentrations of both ions and vacant sites actually attained remain negligibly small compared with the relative changes in the concentrations of electrons. By virtue of this relation, the intrinsic diffusional flux of ions in structurally disordered compounds is negligible and ions move virtually only under the influence of the internal electric field, which is directed in such a way that it diminishes the electron flux to a fraction $t_i$ of their intrinsic diffusional flux.

Since the mobilities and hence also the diffusion coefficients of the conductivity electrons and holes in solids are usually of the same order of magnitude, the dependence of $\tilde{D}_e$ on the degree of non-stoichiometry (Fig.1) is comparatively weak. For this reason, according to Eqn.(27), the character of the dependence of $\tilde{D}$ on $N_e$ is determined mainly by the change in the transport number of the ions. The corresponding curves have a maximum near the stoichiometric composition (for $D_n = D_p$ when the composition is exactly stoichiometric) and descend monotonically on either side of the maximum.

## 2. Fully Ionised Point Defects

We shall now consider a binary ionic crystal in which pair combinations of ionic point defects predominate for the stoichiometric composition: the Frenkel and Schottky defects or impurity atoms with effective charges corresponding to their complete ionisation. In this case the effective charges for the defects are determined by the valences of the corresponding components and amount to[1,2,24] $+z_1 e$ and $-z_2 e$ for the interstitial cations and anions, $-z_1 e$ and $+z_2 e$ for the cationic and ionic vacancies, and $\Delta q_f = q_f - q_k$ for the impurity centres formed by the substitution of the $k$ ion by an impurity ion $f$. Classical examples of crystals with impurity disorder are provided by the solid solutions AgCl + $CdCl_2$ ($\Delta q_f = +e$, compensating defects—cationic vacancies), $ZrO_2$ + CaO ($\Delta q_f = -2e$), and $ZrO_2$ + $Y_2O_3$ ($\Delta q_f = -e$, compensating defects—anionic vacancies).

In the general case the ionic conductivity of a binary compound, both pure and in the presence of impurities, can be determined by the interstitial cations and anions and also by the cationic and anionic vacancies. For this reason, the ionic conductivity of the $k$ component is expressed, according to the Nernst–Einstein relation, in terms of the diffusion coefficients of these defects:

$$kT\varkappa_k = q_k^2 (N_{ki} D_{ki} + N_{Vk} D_{Vk}) , \tag{28}$$

where the subscripts $ki$ and $Vk$ refer to the interstitial ions $k$ and the vacancies in the $k$ sublattice. According to the microscopic model of the transport of defects, their diffusion coefficients are determined by expressions of the type of Eqn.(25): $D = \nu r_0^2 \exp(-U/kT)$ and, in terms of the approximation of non-interacting defects, are independent of their concentrations and hence also of the DCS. On the other hand, within the framework of the phenomenological description of diffusion, the ionic conductivity of a binary compound is expressed in terms of the macroscopic diffusion coefficients of ions

$$D_k, \quad kT\varkappa_k = q_k^2 N_k D_k .$$

Comparison of this relation with Eqn.(28) leads to the familiar expression for $D_k$ in terms of the microscopic characteristics of the system:

$$N_k D_k = N_{ki} D_{ki} + N_{Vk} D_{Vk} , \tag{29}$$

Furthermore, if there is a local equilibrium between ionic point defects in the crystal, then their concentrations are related by the expressions for the chemical potentials of the ions (at no unduly high concentrations):

$$\mu_k = \mu_{ki}^0 + kT \ln N_{ki} = -\mu_{Vk}^0 - kT \ln N_{Vk} , \tag{30}$$

where $\mu^0_{ki}$ and $\mu^0_{Vk}$ are the standard chemical potentials of the ions and vacancies in the $k$ sublattice. By virtue of the Gibbs–Duhem relation, the following equation is then valid:

$$z_1 \mu_1 + z_1 \mu_2 = 0 . \tag{31}$$

In addition, the concentrations of the defects are linked by the electroneutrality condition for the crystal:

$$N_e = z_1 (N_{MI} - N_{VM}) + z_2 (N_{VX} - N_{XI}) + (\Delta q_f / e) N_f , \tag{32}$$

where $N_f$ is the constant volume concentration of the impurity ions.

On differentiating Eqns.(30) and (32) with respect to $N_e$ and on substituting the derivatives in Eqn.(8), taking into account Eqn.(29), we obtain the expression for the average CDC for the ions:

$$\tilde{D}_i = \frac{z_1^2 (N_{MI} D_{MI} + N_{VM} D_{VM}) + z_2^2 (N_{XI} D_{XI} + N_{VX} D_{VX})}{z_1^2 (N_{MI} + N_{VM}) + z_2^2 (N_{XI} + N_{VX})} \quad . \tag{33}$$

Here the summation has been carried out over the principal cations and anions and the contribution of the impurity ions to the transport was assumed to be negligible.

The exact dependence of $\tilde{D}_i$ on the DCS can be obtained by solving simultaneously for the concentration of the defects one of the equations of the Law of Mass Action [Eqns.(30) and (31)], which corresponds to a dominant disorder, and the simplified equation for the electroneutrality condition [Eqn.(32)]. It is readily seen that in the case of intrinsic

ionic defects (Frenkel or Schottky) the solutions are analogous to Eqn.(20) for the CDC for electrons in the absence of degeneracy and the corresponding plots of $\tilde{D}_i$ against $N_e$ are similar to those in Fig.1. In particular, for high DCS, where one kind of ionic defect predominates, the $\tilde{D}_i$ curves approach asymptotically the diffusion coefficient of the given defect: $D^i_{Mi}$ or $D_{VX}$ in the presence of an excess of the metal and $D_{Xi}$ or $D_{VX}$ in the presence of an excess of the non-metal.

In the case of the impurity disorder, the excess charge of the impurity is compensated by one specific kind of intrinsic ionic defect. For this reason, according to Eqn.(8), $\tilde{D}_i$ is identical with the ICDC of the corresponding ions $\tilde{D}_k$ and, according to Eqn.(33), has a constant value equal to the diffusion coefficient of the compensating defect ($D_{ki}$ or $D_{Vk}$) over a wide range of $N_e$.

Comparison of the results with Eqn.(29) shows that, in transport by point defects, the CDC for the ions exceed appreciably, usually by several orders of magnitude, the corresponding values of their macroscopic diffusion (self-diffusion) coefficients. The accelerating effect of thermodynamic factors, which increase $\tilde{D}$ up to the Einstein values $D_{ki}$ or $D_{Vk}$, is in this case manifested even more distinctly than in the case of structural disorder.

On comparing Eqns.(28) and (33), we also obtain a relation between the ionic conductivity of the binary crystal and the CDC for the ions:

$$kT\varkappa = e^2 [z_1^2 (N_{Mi} + N_{VM}) + z_2^2 (N_{Xi} + N_{VX})] \tilde{D}_i \quad . \qquad (34)$$

Together with Eqn.(24), this relation makes it possible to express the transport numbers of the ions and electrons in terms of the corresponding CDC and to determine the CCDC for the ions and electrons in accordance with Eqn.(7):

$$\tilde{D} = \frac{[z_1^2 (N_{Mi} + N_{VM}) + z_2^2 (N_{Xi} + N_{VX})] F_e + (n+p)}{[z_1^2 (N_{Mi} + N_{VM}) + z_2^2 (N_{Xi} + N_{VX})] F_e \tilde{D}_i + (n+p) \tilde{D}_e} \tilde{D}_i \tilde{D}_e \quad . \qquad (35)$$

The instances of not unduly high DCS, where the term $n + p$ in the numerator in Eqn.(35) can be neglected compared with the concentrations of the ionic defects, are of special interest. The solutions thus obtained will be analysed in detail in the next Section; here it is sufficient to note that the above simplification is equivalent to the formulation of the phenomenological Eqn.(7) in the abbreviated form (27). The physical significance of this simplification is the same as in the case of structural disorder: the gradients of the chemical potentials of the ions are negligible compared with those for electrons and ions move virtually only under the influence of the electric fields.

## IV. COUPLED CHEMICAL DIFFUSION COEFFICIENTS OF IONS AND ELECTRONS IN CRYSTALS WITH DIFFERENT DEFECT STRUCTURES

### 1. The Wagner Disorder. Neutral Defects

We shall refer to the Wagner disorder by the term combined ionic-electronic disorder in which the electroneutrality condition assumes one of the following simplified forms:

$$n = \zeta N^{\zeta+}_{Mi}; \; n = \zeta N^{\zeta+}_{VX}; \; p = \zeta N^{\zeta-}_{Xi}; \; p = \zeta N^{\zeta-}_{VM} \quad . \qquad (36)$$

Here the effective charge on the dominant ionic defect $\zeta$ can assume any integral value ranging from unity to one equal to the valence of the corresponding component $z_k$. The special case of the Wagner disorder, corresponding to the total ionisation of the defects ($\zeta = z_k$) satisfies the formal treatment developed in the previous Section and can be described with the aid of Eqn.(35). We shall discuss below the cases of an arbitrary degree of ionisation of defects ($\zeta \leq z_k$), including the case of dominant neutral defects.§

We shall now re-examine the binary compound $MX_r$; we shall assume that in the most general case it contains interstitial cations and anions as well as cationic and anionic vacancies with arbitrary integral effective charges $\zeta$ ranging from zero (neutral defects) to $z_k$ (fully ionised defects). Assuming that the concentration of the impurity is negligibly small, we can formulate the electroneutrality condition in the following form:

$$N_e = z_1 \sum_{\zeta=0}^{z_1} (N^{\zeta+}_{Mi} - N^{\zeta-}_{VM}) + z_2 \sum_{\zeta=0}^{z_2} (N^{\zeta+}_{VX} - N^{\zeta-}_{Xi}) \quad . \qquad (37)$$

In conformity with the last equation, the overall flux of electrons in excess of the stoichiometric composition is described by the expression

$$J_e = z_1 \sum_{\zeta=0}^{z_1} (J^{\zeta+}_{Mi} - J^{\zeta-}_{VM}) - z_2 \sum_{\zeta=0}^{z_2} (J^{\zeta-}_{Xi} - J^{\zeta+}_{VX}) \quad . \qquad (38)$$

According to the Wagner equation [Eqn.(2)], the fluxes of defects are proportional to the gradients of their electrochemical potentials, the electrochemical potentials of the defects being linked to the chemical potentials of the atoms and electrons by the obvious relations

$$\begin{aligned} \mu^{\zeta+}_{Mi} &= \mu_M - \zeta\mu_e; \; \mu^{\zeta-}_{VM} = -\mu_M + \zeta\mu_e; \\ \mu^{\zeta-}_{Xi} &= \mu_X + \zeta\mu_e; \; \mu^{\zeta+}_{VX} = -\mu_X - \zeta\mu_e \quad . \end{aligned} \qquad (39)$$

Furthermore, in the case of the Wagner disorder, the concentrations of the electron and ion carriers in the crystals are comparable according to Eqn.(36). On the other hand, since the mobility of the conductivity electrons and holes as a rule exceeds by several orders of magnitude the mobility of the interstitial ions and vacancies, such crystals always have a predominantly electronic conductivity. On this basis, we put $\sigma \gg \varkappa$. The electric field gradient $\nabla\phi$ is then determined from the condition that the electrochemical potential of the electron is constant ($\nabla\phi = \Delta\mu_e/e$) and we obtain from Eqn.(38)

$$\begin{aligned} kTJ_e = -\Bigg[ & z_1 \sum_{\zeta=0}^{z_1} (N^{\zeta+}_{Mi} D^{\zeta+}_{Mi} + N^{\zeta-}_{VM} D^{\zeta-}_{VM}) \frac{d\mu_M}{dN_e} - \\ & - z_2 \sum_{\zeta=0}^{z_2} (N^{\zeta-}_{Xi} D^{\zeta-}_{Xi} + N^{\zeta+}_{VX} D^{\zeta+}_{VX}) \frac{d\mu_X}{dN_e} \Bigg] \Delta N_e \quad . \end{aligned} \qquad (40)$$

The coefficient of $\nabla N_e$ is the CCDC for the ions and electrons $\tilde{D}$ multiplied by $kT$. Taking into account the Gibbs–Duhem relation in the form

$$d\mu_M = -\frac{z_1}{z_2} d\mu_X = -\frac{z_1 kT}{2z_2} d\ln p_{X_2} \quad , \qquad (41)$$

where $p_{X_2}$ is the partial pressure of the non-metal in the surrounding medium, we obtain the following expression for $\tilde{D}$:

$$\begin{aligned} \tilde{D} = -\Bigg[ & z_1^2 \sum_{\zeta=0}^{z_1} (N^{\zeta+}_{Mi} D^{\zeta+}_{Mi} + N^{\zeta-}_{VM} D^{\zeta-}_{VM}) + \\ & + z_2^2 \sum_{\zeta=0}^{z_2} (N^{\zeta-}_{Xi} D^{\zeta-}_{Xi} + N^{\zeta+}_{VX} D^{\zeta+}_{VX}) \Bigg] \frac{1}{2z_2} \frac{d\ln p_{X_2}}{dN_e} \quad . \end{aligned} \qquad (42)$$

§ Although the diffusion of neutral defects is not associated with the separate movement of electrons, the formal treatment employed here remains valid also for such diffusion, provided that we put $q_k = 0$ in the Wagner equation [Eqn.(2)].

Eqn.(42) is a generalisation of the formula obtained[26] for bivalent metal oxides with the Wagner disorder involving interstitial cations or cationic vacancies with arbitrary degrees of ionisation.

The reciprocal of the derivative in Eqn.(42) will be expressed in the following form taking into account Eqn.(37):

$$\frac{d N_e}{d \ln p_{X_2}} = z_1 \sum_{\zeta=0}^{z_1} \left( N_{Mi}^{\zeta+} \frac{d \ln N_{Mi}^{\zeta+}}{d \ln p_{X_2}} - N_{VM}^{\zeta-} \frac{d \ln N_{VM}^{\zeta-}}{d \ln p_{X_2}} \right) + + z_2 \sum_{\zeta=0}^{z_2} \left( N_{VX}^{\zeta+} \frac{d \ln N_{VX}^{\zeta+}}{d \ln p_{X_2}} - N_{Xi}^{\zeta-} \frac{d \ln N_{Xi}^{\zeta-}}{d \ln p_{X_2}} \right) .$$

Under the conditions of the Wagner disorder, the concentrations of all the defects are power functions of the partial pressure of the non-metallic component $X_2$: the quantities $N_{VM}$ and $N_{Xi}$ are proportional to $p_{X_2}^{1/m}$, while $N_{Mi}$ and $N_{VX}$ are proportional to $p_{X_2}^{-1/m}$. The values of the parameter $m$ can be readily calculated by the Kroger–Wink method[27] for a specified simplified form of the electroneutrality condition and those for the dominant defects can be obtained by direct experimental determination.[28] Taking into account this relation, we obtain finally

$$\tilde{D} = \frac{z_1^2 \sum_{\zeta=0}^{z_1} (N_{Mi}^{\zeta+} D_{Mi}^{\zeta+} + N_{VM}^{\zeta-} D_{VM}^{\zeta-}) + z_2^2 \sum_{\zeta=0}^{z_2} (N_{Xi}^{\zeta-} D_{Xi}^{\zeta-} + N_{VX}^{\zeta+} D_{VX}^{\zeta+})}{2 z_1 z_2 \sum_{\zeta=0}^{z_1} (N_{Mi}^{\zeta+}/m_{Mi}^{\zeta+} + N_{VM}^{\zeta-}/m_{VM}^{\zeta-}) + 2 z_2^2 \sum_{\zeta=0}^{z_2} (N_{Xi}^{\zeta-}/m_{Xi}^{\zeta-} + N_{VX}^{\zeta+}/m_{VX}^{\zeta+})} . \quad (43)$$

A special case of this formula was obtained in our earlier study in connection with the description of the coupled diffusion of oxygen ions and electrons in vanadium oxide compounds.[29]

## 2. Electronic Disorder

When electronic disorder of the intrinsic type is dominant, the concentrations of electrons and holes are equal and identical with the ionisation constant $K_i$ – $n \cong p \cong k_i$. When disorder of the impurity type predominates, the concentration of electrons is equal to the concentration of donors $N_d - n \cong N_d^+$ or the concentration of holes is equal to the concentration of acceptors $N_A - p = N_A$. The concentrations of defects in these formulae can be calculated for each specific type of disorder predominating under the conditions of the stoichiometric composition. The corresponding expressions for the CCDC, which are valid over a wide range of concentrations of defects, include only the deviation from the stoichiometric composition $N_e$ and also some of the equilibrium constants (the intrinsic ionisation constant $K_i$ and the defect formation constants $K_F$ for the Frenkel defects, $K_{AF}$ for the anti-Frenkel defects, and $K_S$ for the Schottky defects) or the impurity concentration $N_f$. As an example one may point to a study[30] in which the CCDC for ions and electrons in a uni-univalent ionic crystal with Schottky defects and dominant electronic conductivity, corresponding to a non-degenerate state, was calculated.

We shall not formulate here the exact expressions for $\tilde{D} = \tilde{D}(N_e)$ in view of their cumbersome nature and we shall confine ourselves to the analysis of simplified solutions to which the above expressions reduce in certain limiting cases of interest for practical application. All these expressions can be divided into two groups depending on the dominant type of conductivity in the crystal.

(a) *Case where the ionic conductivity is dominant* ($\varkappa \gg \sigma$, $t_i \cong 1$). This case obtains in solid electrolytes within the electrolytic region[1] where the DCS are comparatively small and the concentrations of the electronic carriers ($n + p$) can be neglected in Eqns.(26) and (35) compared with the concentrations of the ionic carriers. For both structurally disordered compounds and for crystals with point defects, intrinsic or impurity, the relation $\tilde{D} \cong \tilde{D}_e$ follows from Eqn.(27) under these conditions. From the standpoint of physics, this implies that the electrons move solely under the influence of the gradient of the chemical potential; on the other hand, ions have virtually constant chemical potentials and move solely under the influence of the electric field.

This result is analogous to that well known in the electrochemistry of solutions for the diffusion of charged species present at low concentration in the supporting electrolyte.[7,31] In the present case, such species are conductivity electrons or holes and the disordered ions form a conducting background, which fully screens off the influence of the electric field. This factor is widely used in the study of electron transport in solid electrolytes, in particular in the experimental determination of the mobilities of electrons and holes.[20,32,33]

(b) *Case where the electronic conductivity is dominant* ($\sigma \gg \varkappa$ ; $t_e \cong 1$). We shall consider initially crystals with structural disorder and with fully ionised point defects for not unduly high DCS where one can neglect the term $n + p$ in the numerators of Eqns.(26) and (35) and the first terms incorporating $\tilde{D}_i$ in their denominators by virtue of the condition $\sigma \gg \varkappa$. Further simplifications are possible in the following limiting cases.

I. Small DCS. For compositions close to the stoichiometric, where $|N_e| \ll K_i$, the concentrations of conductivity electrons and holes are approximately the same and equal to the intrinsic ionisation constant $K_i$; the electron–hole gas is non-degenerate. The concentrations of the ionic carriers in this region are also approximately constant and are determined either by the crystallography of the compound (structural disorder), or by the formation constants of the dominant ionic defects $K_F$, $K_{AF}$, and $K_S$ (intrinsic ionic disorder), or by the content of the heterovalent impurity $N_f$ (impurity ionic disorder).

In the case of structural disorder, Eqn.(26) for the CCDC is simplified to the expression

$$\tilde{D}_k = \frac{z_k^2 N_k}{2K_i} D_k . \quad (44)$$

Simplified expressions can be obtained from Eqn.(35) for various types of dominant point defects. Having used Eqn.(29) to replace the microscopic diffusion coefficients $D_{ki}$ and $D_{Vk}$ in these expressions by the macroscopic coefficients $D_k$ for all types of dominant ionic disorder, both structural and point disorder, we obtain a single formula for small DCS:

$$\tilde{D} = \frac{z_1^2 N_1 D_1 + z_2^2 N_2 D_2}{2K_i} . \quad (45)$$

II. Intermediate DCS. This includes very high degrees of DCS where $|N_e|$ is large compared with the intrinsic ionisation constant $K_i$ but small compared with the characteristic concentration of the disordered ions ($N_k$ for structural disorder and the largest of the quantities $K_F$, $K_{AF}$, $K_S$, or $N_f$ in the case of fully ionised point defects). In this region the electronic carriers consist virtually of conductivity electrons only or holes only, so that their total concentration is specified by the DCS: $n + p \cong |N_e|$. On the other hand, the concentrations of the ionic defects are the same as in the previous case. Simplified solutions for the CCDC taking into account Eqn.(29) can be represented

in a single form expressing $\tilde{D}$ in terms of the macroscopic diffusion coefficients of the ions:

$$\tilde{D} = \frac{F_e}{|\delta|}(z_1 D_1 + z_2 D_2) \ . \qquad (46)$$

The relative DCS is in this case designated by $\delta$: $\delta = N_e/z_1 N_1 = N_e/z_2 N_2$. In the absence of degeneracy of electrons, $F_e = 1$ and Eqn.(46) becomes identical with the familiar Wagner formula.[7]

Together with the two approximations considered, Eqn.(35) permits yet another approximation corresponding to the Wagner disorder under the conditions of the total ionisation of the defects. The solution for this situation constitutes a special case of the solutions examined below.

III. Large DCS. In this range of DCS the relation $|N_e| \cong n + p$ is retained and in addition the quantity $|N_e|$ exceeds the concentration of the ionic point defects characteristic of the stoichiometric composition, i.e. the largest of the constants $K_F$, $K_{AF}$, $K_S$, or $N_f$. This case corresponds to either the Wagner disorder, characterised by one of the electroneutrality conditions [Eqn.(36)], or the neutral defects $K_i^{\times}$ of $V_k^{\times}$ (an effective zero charge has come to be designated by the oblique cross $\times$). In both cases the DCS is determined by Eqn.(37). Simplified expressions for the CCDC follow directly from Eqn.(43), provided that one term, corresponding to the dominant defect, is left in its numerator and denominator.

The parameter $m$ for the dominant defects can be readily calculated, taking into account the possible degeneracy of electrons, by differentiating Eqn.(39) with respect to $\ln p_{X_2}$, having first transformed $d\mu_e$ with the aid of the relation $d \ln a_e = F_n d \ln n = -F_p d \ln p$ and taking into account Eqns.(36) and (41). Then one obtains the values of $m_1 = 2z_2(\zeta F_e + 1)/z_1$ for the dominant cationic defects $M_i^{\zeta+}$ or $V_M^{\zeta-}$ and $m_2 = 2(\zeta F_e + 1)$ for the anionic defects $X_i^{\zeta-}$ or $V_X^{\zeta+}$— both charged and neutral. In both cases Eqn.(43) reduces to simple expressions, namely under the conditions of the Schottky disorder to

$$\tilde{D}_k = (\zeta F_e + 1) D_{ki}$$

and in the case of the impurity vacancy disorder to

$$\tilde{D}_k = (\zeta F_e + 1) D_{Vk} \ .$$

When Eqn.(29) is taken into account, the above solutions reduce to the general formula

$$\tilde{D} = \frac{\zeta F_e + 1}{|\delta|} D_k \qquad (47)$$

For $F_e = 1$, this formula was obtained by Childs and Wagner.[34] The unity added to the numerator (47) compared with Eqn.(46) is due to the fact that in this case the ions move not only under the influence of the electric field but also as a result of the gradient of their chemical potential, which is related to the variable concentration of defects.

Despite the formal similarity of Eqns.(46) and (47), they determine significantly different dependences of $\tilde{D}$ on the degree of DCS $\delta$. Thus, when $F_e = 1$, the coefficient $D_k$ in region II is constant and, according to Eqn.(46), $\tilde{D}$ is inversely proportional to $|\delta|$; in region III the quantity $D_k$ is directly proportional to $|\delta|$ and, according to Eqn.(47), $\tilde{D}$ is constant.

The qualitative form of the dependence of $\lg \tilde{D}$ on $\delta$ is represented in Fig.2 for a crystal with fully ionised Schottky defects, which are converted into Wagner defects for high values of $|\delta|$ when $K_S \gg K_i$ and $D_{VM} > D_{VX}$. The maximum value of $\lg \tilde{D}$ is attained for the stoichiometric composition. The characteristic values of $\delta = \pm K_S/N_k$, for which solution II [Eqn.(46)] is converted into solution III [Eqn.(47)], are shown on the abscissa axis. For crystals with Frenkel defects, analogous relations are obtained; for the structural disorder, the difference consists in the fact that the simplified solution III is not obtained and the horizontal sections on the plots of $\lg \tilde{D}$ against $\delta$ are not attained even for the maximum value of $|\delta|$.

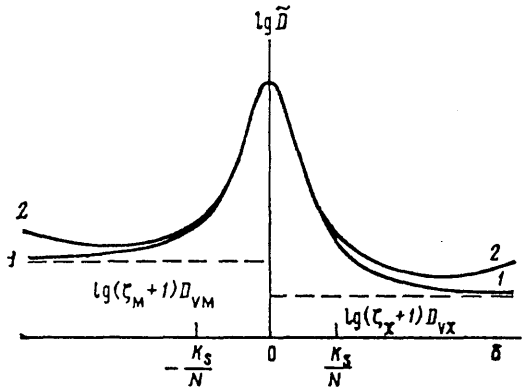

**Figure 2.** Dependence of the coupled diffusion coefficient $\tilde{D}$ on the degree of non-stoichiometry of a crystal with Schottky defects in the absence (curve *1*) and presence (curve *2*) of degeneracy of the electrons.

When electronic disorder is dominant, Eqn.(44) also simplifies markedly, but only one term corresponding to atomic defects with the maximum concentration is left in its numerator and denominator. One then obtains $\tilde{D} \cong D_{def}$— a result which is formally identical with solution II for the case where neutral defects with $\zeta = 0$ predominate. Such agreement is entirely understandable, because under conditions where the electronic disorder predominates the gradient of the chemical potential of the electrons is negligible. Under the conditions of electronic equilibrium, this also leads to a low electric field strength, since the ionic defects move only under the influence of the intrinsic chemical potential gradient.

An especially important feature of the results obtained is very high values of CCDC compared with the self-diffusion coefficients of the ions. Indeed, even for high degrees of DCS, the coefficients $\tilde{D}$ are of the same order of magnitude as the diffusion coefficient of the dominant ionic defects and, as the stoichiometric composition is approached, they increase still further in inverse proportion to $|\delta|$ in the region of moderate DCS (region II).

The large number of limiting solutions for the CCDC greatly hinders the interpretation of the experimental data even as regards fundamental characteristics such as the effective activation energy. For crystals with ionic point defects, this quantity has the simple significance of the height of the potential barrier $U$ to ion jumps only in region III. Since the values of $\tilde{D}$ in region I can vary as a function of the transport numbers of the ions from $\tilde{D}_e$ for $t_i \cong 1$ to $z_k^2 N_k D_k / 2K_i$ for $t_i \ll 1$, in this region the effective activation energy has indefinite values or totally loses its significance.

Thus, according to Weppner,[36] $\tilde{D}$ in the β-modification of silver sulphide increases with temperature in accordance with the usual exponential law only in the region of fairly high values of $\delta$; for the stoichiometric composition, this relation is reversed partly owing to the decrease of the mobility of the electron carriers with temperature.

## V. EXPERIMENTAL DETERMINATION OF CHEMICAL DIFFUSION COEFFICIENTS

### 1. Theoretical Principles

The majority of the methods for the experimental determination of chemical diffusion coefficients in solids used nowadays are based on the study of the relaxation of the concentration profile in the diffusion medium under the influence of some kind of external perturbation—an abrupt change in potential, current, or composition of the ambient atmosphere.[6,34] The problem is as a rule reduced to the solution, subject to appropriate initial and boundary conditions, of the phenomenological equation of Fick's Second Law:

$$\frac{\partial N}{\partial t} = \tilde{D}\,\mathrm{div}\,\nabla N \equiv \tilde{D}\nabla^2 N\,, \qquad (48)$$

where the effective CDC is assumed to be independent of the concentration in the experimental range. On the basis of the observed dependence of the concentration $N$ on the coordinate $x$ and the time $t$, the response of the system to the perturbation, i.e. the time variation of the measured quantity (current, potential, weight, or electrical conductivity of the specimen) is calculated. The effective CDC is found by comparing the theoretical and experimental results.

In the case of the coupled chemical diffusion considered in this review, the flux of electrons in a non-stoichiometric crystal is described by the expression

$$J_e = -\frac{t_e}{e} I - \tilde{D}\nabla N_e\,, \qquad (49)$$

where the first term corresponds to the contribution of these electrons to the electric current $I$ which has passed through the specimen. The material balance condition $\partial N_e/\partial t = -\mathrm{div}\,J_e$ converts Eqn.(49) into a differential equation, which is converted into Fick's Second Law [Eqn.(48)] for constant $t_e$ and $\tilde{D}$. Thus the principal approximation in the problem reduces to the assumption of a low degree of inhomogeneity of the diffusion medium, for which the relative change in $N_e$ or $\delta$ is small compared with unity (so that the kinetic parameters $\varkappa$, $\sigma$, $t_i$, $t_e$, and $\tilde{D}$ can be assumed constant). This requires in its turn the use in experiments of weak perturbations to stimulate the diffusion process.

Investigations during the last decade have shown that electrochemical methods using galvanic cells with solid electrolytes are most convenient and reliable.[6,37–41] We shall therefore concentrate attention on them in the present review.

In the electrochemical method the principal element of the measuring circuit is a cell of the following type:

| auxiliary electrode | solid electrolyte | test specimen | inert electrode. | (50) |
|---|---|---|---|---|

The solid electrolyte must exhibit unipolar ionic conductivity with respect to one of the ions forming part of the composition of the test compound, so that the electric current passing through the cell can serve as an exact measure of the change in the composition of the test specimen. The majority of the investigations have been carried out with $ZrO_2$, β-$Al_2O_3$, AgI, and CuBr specimens satisfying the above requirement over a fairly wide range of temperatures and compositions of the gaseous medium.[38–42] The auxiliary electrode, which is reversible with respect to the electrolyte, serves as a source of ions, which are supplied to the test specimen via the electrolyte, and also ensures the measurement of the chemical potential of the electrochemically active element at the electrolyte/specimen boundary.

### 2. Potentiostatic Method

In this method[6,38,40–46] the test specimen is first maintained under equilibrium conditions so that its composition becomes homogeneous throughout its thickness. Then, at a time $t = 0$, a potential $\Delta\phi$, different from the e.m.f. $E$ of the cell at equilibrium, is applied to this cell. The potential difference at the boundaries of the test specimen with a length $L$, given by $\phi|_{x=0} - \phi|_{x=L}$, where $\phi|_{x=0}$ is the potential at the electrolyte–specimen boundary and $\phi|_{x=L}$ the potential at the specimen–inert electrode boundary, amounts to $\Delta\phi - E$. This quantity must be sufficiently small so that it is possible to neglect the concentration dependence of the transport number $t_e$ and the diffusion coefficient $\tilde{D}$ and also the overpotential (the additional potential jump due to the slow charge transfer through the electrolyte/specimen interface and the ohmic losses in the electrolyte and the specimen). Furthermore, the cell must be constructed in such a way that there is no transport of ions through the lateral surfaces of the specimen and through its end surface opposite to the electrode. This is usually achieved by constructing the current lead at the right-hand end of cell (50) from an inert material (platinum, graphite) while the right-hand side of cell (50) is placed in an inert atmosphere. In subsequent calculations it is also assumed that the current, which during the short time interval after the application of the potential $\Delta\phi$ to the cell transports a certain amount of electricity consumed in altering the charge of the double layer at the interfaces, is likewise small.

Under these conditions at time $t = 0$, a concentration of excess electrons $N_\infty$, different from the initial concentration $N_0$ and corresponding to equilibrium in relation to the new potential, is established in the layer of specimen adjoining the electrolyte ($x = 0$). The subsequent relaxation process is effected by the coupled diffusion of ions and electrons through the specimen, as a result of which the concentration of electrons throughout the bulk of the specimen tends to the finite value $N_\infty$. Since this process involves a continuous supply of the corresponding amount of ions from the auxiliary electrode through the electrolyte, the electric current flowing through the cell is a measure of its rate. In its experimental aspect, the potentiostatic method therefore reduces to the measurement of the current as a function of time.

The current density in the cell is determined from the condition that there is no electron flux at the boundary between the specimen and the electrolyte. According to Eqn.(49), this gives rise to the boundary condition

$$t_e I = eD\nabla N_e \text{ when } x=0\,. \qquad (51)$$

At the specimen–inert electron boundary, the flux of ions is zero and the current passed through the system is wholly due to electrons ($I = -eJ_e$ and, in conformity with Eqn.(49), the second boundary condition is obtained in the form

$$t_i I = eD\nabla N_e \text{ when } x=L\,. \qquad (52a)$$

The authors of the above studies used the simpler boundary condition at $x = L$ in the form

$$\nabla N_e(L) = 0\,, \qquad (52b)$$

which is valid, as can be seen from Eqn.(52a), for small ionic transport numbers $t_1$.

In the subsequent exposition, we shall also confine ourselves to the boundary condition (52b), which is applicable to materials in which electronic conductivity predominates.

Thus, in the case of the one-dimensional diffusional problem, i.e. for plane-parallel boundaries of the specimen located at $x = 0$ and $x = L$, it is necessary to solve Fick's Second Law $\partial N/\partial t = \tilde{D}\partial^2 N/\partial x^2$ subject to the initial condition $N(x, 0) = N_0$ and the boundary conditions $N|_{x=0} = N_\infty$ and $(\partial N/\partial x)_{x=L} = 0$ (here and henceforth the subscript $e$ is omitted in the symbol $N$ denoting concentration).

The solution has the form[47,48]

$$N(x,t) = N_\infty + (N_0 - N_\infty)\,\psi(x,t)\,. \qquad (53)$$

The function

$$\psi(x,t) = \frac{4}{\pi}\sum_{n=0}^{\infty}\frac{1}{2n+1}\sin\frac{(2n+1)\pi x}{2L}\exp\left[-\frac{(2n+1)^2\pi^2\tilde{D}t}{4L^2}\right] \qquad (54)$$

assumes the following limiting values: $\psi(0, 0) = 0$, $\psi(L, 0) = 1$, and $\psi(x, \infty) = 0$. Depending on $t$, this function can be synthesised in two limiting cases.

1. Short times ($t \gg L^2/\tilde{D}$). At the beginning of the process the effective length of the diffusion zone $2(Dt)^{1/2}$ is small compared with the length of the specimen $L$ and the diffusion can be described by the solution for a semi-infinite medium: $\psi(x, t) \cong \mathrm{erf}\,[x/2(Dt)^{1/2}]$. Hence, according to Eqn.(51), we obtain the following expression for $t_e \cong 1$:

$$I \cong e(N_\infty - N_0)(\tilde{D}/\pi t)^{1/2}\,. \qquad (55)$$

Consequently the CCDC can be determined from the slope of the experimental $I$–$t^{-1/2}$ line, provided that the difference between the final and initial concentrations $N_\infty - N_0$ is known. This difference can be expressed in terms of the total amount of electricity passed through the specimen before the attainment of equilibrium: $Q = Ve(N_\infty - N_0)$, where $V$ is the volume of the specimen. However, this method is associated with the integration of the current with respect to time and can lead to a major error as a consequence of the slow decay of the current in the range of its values close to the limit of the sensitivity of the measuring apparatus.

The coulometric titration method developed by Wagner[49–51] and used widely nowadays in research practice is much more convenient for the determination of the difference between the final and initial concentrations of electrons in the specimen $N_\infty - N_0$. In this method a cell of type (50), for example

$$\mathrm{M}\,\left|\begin{matrix}\text{electrolyte}\\ \mathrm{M}^{z+}\end{matrix}\right|\,\mathrm{M}_{1+\delta}\mathrm{X}_r\,\left|\,\mathrm{Pt}\right.\,. \qquad (56)$$

is also used. A definite amount of electricity is passed through the cell, after which it is allowed to stand for a time until the attainment of a homogeneous value of $\delta$ over the entire length of the specimen; for each fixed value of $\delta$, the cell e.m.f. $E$ is measured. The $E = E(\delta)$ curve plotted in this way is a calibration curve and is used to determine the unknown value of $\delta$ from the measured e.m.f. Furthermore, the e.m.f. of cell (56) is equal to $(\mu_M^0 - \mu_M)/ze$, where $\mu_M^0$ and $\mu_M$ are the chemical potentials of the atoms M in the metallic electrode and in the compound $\mathrm{M}_{1+\delta}\mathrm{X}_r$. Graphical differentiation of the $E(\delta)$ curve therefore makes it possible to determine directly the thermodynamic factor $F_M$:

$$F_M = \frac{d\ln a_M}{d\ln N_M} = -\frac{ze}{kT}\cdot\frac{dE}{d\delta}\,, \qquad (57)$$

which can be used to calculate $\tilde{D}$ from self-diffusion data in accordance with Eqn.(4).

2. Long times ($t > L^2/4\tilde{D}$). In this case Eqn.(54) for $\psi(x, t)$ is fitted by the first member of the series and we obtain the following expression for the current (to within <1%):

$$I \cong \frac{2e(N_\infty - N_0)}{L}\exp\left(-\frac{\pi^2\tilde{D}t}{4L^2}\right)\,. \qquad (58)$$

Eqn.(58) describes the $\ln|I| - t$ straight line. $\tilde{D}$ can be determined from its slope.

Using the potentiostatic method, Rickert and Weppner,[45] determined the CCDC in non-stoichiometric wustite $\mathrm{Fe}_{1-\delta}$ = 0 in the range $0.06 \leqslant \delta \leqslant 0.13$ using all the three methods described. The discrepancy between the data obtained by different procedures does not exceed 30%, indicating their adequate reliability.

Relations similar to those described above are also obtained for the cylindrical geometry of cell (48) in which the test substance is first fused within a solid electrolyte tube.[41] In this case the overall solution of Fick's second equation is expressed in terms of Bessel functions, but for short times it is identical with Eqn.(55).

### 3. The Galvanostatic Method

This method, which is fairly simple as regards apparatus, has been widely used by many investigators.[6,11,38–46,52,53] Its theory has been developed by Yokota[11] for compounds of the type of silver sulphide exhibiting cationic and electronic conductivities. However, his equations proved valid for any binary ionic compound and we shall therefore quote the general relations.

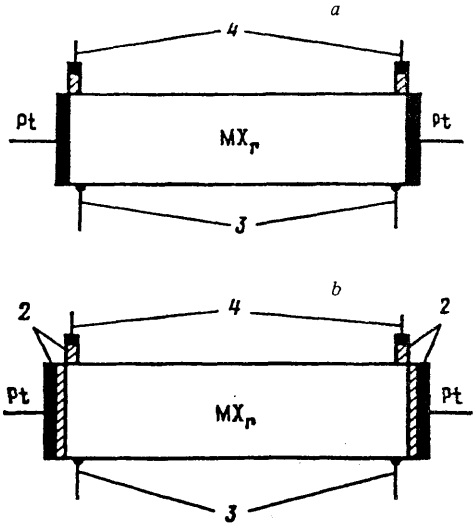

**Figure 3.** Cell with electronic (*a*) and ionic (*b*) electrodes for the determination of the CCDC by the galvanostatic method: 1) inert electrodes; 2) electrolyte; 3) electronic probes; 4) ionic probes.

We shall consider cells of two types, illustrated schematically in Fig.3. Cell *a* has electrodes made of platinum, graphite, or another inert material which is permeable to electrons only. Cell *b* is fitted with more complex electrodes, containing a layer of solid electrolyte impermeable to electrons and reversible with respect to the ions $M^{z+}$ or $X^{z-}$ forming

the given binary compound $MX_r$. Such electrodes can consist, for example, of the combinations $M|M^{z+}$ with a cation-conducting electrolyte or $X_2$, $Pt|X^{z-}$ with an anion-conducting electrolyte. ($O_2$, $S_2$, etc. can be used as the substance $X_2$ generating the anions.) Furthermore, each cell can be provided with a pair of electronic or ionic measuring probes playing the role of the corresponding electrodes.

If a direct electronic or ionic current is passed through the cell, concentration polarisation, associated with the presence of a DCS gradient, arises in it. The potential difference between like probes serves as a measure of this polarisation; the method consists of the measurement of the potential difference between the probes as a function of time when the direct current is switched on or switched off. The corresponding theoretical relations have been obtained from the solution of Fick's second equation for a specimen $2L$ long and are compiled in the Table. $\Psi(t)$ denotes the function

$$\Psi(t) = \frac{1}{L}\int_0^L \psi(x,t)\,dx = \frac{1}{L}\int_L^{2L} \psi(x,t)\,dx = \frac{8}{\pi^2}\sum_{n=0}^{\infty}\frac{1}{(2n+1)^2}\exp\left[-\frac{(2n+1)^2\pi^2\tilde{D}t}{4L^2}\right], \quad (59)$$

which varies in the range from $\Psi(0) = 1$ to $\Psi(\infty) = 0$.

Time variation of the potential difference between the probes $\phi(0) - \phi(L) = \phi(L) - \phi(2L)$ in Yokota's method when the direct current is switched on and off.

| Electrodes | Probes | $\varphi:0)-\varphi(L)=\varphi(L)-\varphi(2L)$ | |
|---|---|---|---|
| | | establishment of polarisation | decrease of polarisation |
| Electronic | ionic | $\frac{IL}{\sigma}[1-t_i\Psi(t)]$ | $\frac{IL}{\sigma}t_i\Psi(t)$ |
| Electronic | electronic | $\frac{IL}{\varkappa+\sigma}\Psi(t)$ | $-\frac{IL}{\varkappa+\sigma}\Psi(t)$ |
| Ionic | electronic | $\frac{IL}{\varkappa+\sigma}\Psi(t)$ | $-\frac{IL}{\varkappa+\sigma}\Psi(t)$ |
| Ionic | ionic | $\frac{IL}{\varkappa}[1-t_e\Psi(t)]$ | $\frac{IL}{\varkappa}t_e\Psi(t)$ |

Different workers have used cells which constituted various simplified versions of Yokota's cell and have made measurements under conditions where the current was either switched on or switched off. Experimental curves are usually analysed by comparing them with the corresponding approximate expressions for the function $\Psi(t)$.

1. For short times $t \ll L^2/\tilde{D}$, one can use the solution for a semi-infinite medium:

$$\Psi(t) \cong 1 - 2\left(\frac{\tilde{D}t}{\pi}\right)^{1/2}/L \quad . \quad (60)$$

When the partial electrical conductivity is unknown, the CCDC can be determined from the slopes of the $\phi - t^{1/2}$ linear plots in accordance with the formulae in the Table.

2. For long times, only the first term of the infinite series (59) is retained:

$$\Psi(t) \cong \frac{8}{\pi^2}\exp\left(-\frac{\pi^2\tilde{D}t}{4L^2}\right) \quad (61)$$

and the CCDC are found from linear plots in terms of the corresponding semilogarithmic coordinates in the same way as in the potentiostatic method.

A pulse method which is a version of the galvanostatic method, has been used.[6,54,55] This method involves the measurement of the potential difference between the probes when short d.c. pulses, whose duration is small compared with $L^2/2\tilde{D}$, are passed through the specimen.

## 4. The Gravimetric Method

In this method, proposed by Bruce Wagner,[34,56,57] the test specimen is maintained in an atmosphere with a fixed pressure of the non-metallic component $p_{X_2}$ until the attainment of equilibrium. At time $t = 0$, the pressure $p_X$ changes abruptly to a new value. Under these conditions, the concentration of electrons at the end-faces of the specimen for $x = 0$ and $x = 2L$ changes from $N_0$ to a new equilibrium value $N_\infty$, which is established throughout the entire specimen after a time. The change in electron concentration, which is unambiguously related to the change in the stoichiometry of the specimen, corresponds to the dissolution or removal of the non-metallic component from the test specimen and hence to a change in its mass.

Evidently the distribution of concentrations in a plate with a thickness $2L$, which is permeable to the non-metallic component on either side at $x = 0$ and $x = 2L$, is identical with the distribution defined by Eqn.(53), which is calculated under conditions where plates with a thickness $L$ are permeable on one side. Integration of Eqn.(53) with respect to the thickness of the plate permits the calculation of the change in the mass of the specimen as a function of time:

$$\frac{M - M_0}{M_\infty - M_0} = 1 - \Psi(t) \quad . \quad (62)$$

The values of $\tilde{D}$ are determined from the slopes of the experimental $M - t^{1/2}$ curves for short times ($t < 0.32L^2/\tilde{D}$) and $\lg|M_\infty - M| - t$ curves for long times ($t > 0.14L^2/\tilde{D}$) in conformity with the asymptotic formulae (67) and (68), the error of the solutions not exceeding 1%.[58] Furthermore, there exists a region $0.14 < \tilde{D}t/L^2 < 0.32$ in which the two solutions overlap. The error, associated with the representation of the specimen as an infinite plate does not exceed 1%, provided that the thickness of the plate is much smaller than its length and width.

For specimens in the form of a $2a \times 2b \times 2c$ rectangular parallel-piped, the approximate solution corresponding to long times ($|M - M_0| \geq 0.5|M_\infty - M_0|$) is described by the formula[56]

$$\frac{M_\infty - M}{M_\infty - M_0} \approx \frac{512}{\pi^6}\exp\left[-\frac{\pi^2\tilde{D}t}{4}\left(\frac{1}{a^2}+\frac{1}{b^2}+\frac{1}{c^2}\right)\right], \quad (63)$$

while for spherical specimens with a radius $R$ the solution is given by the formula[59]

$$\frac{M_\infty - M}{M_\infty - M_0} \cong \frac{6}{\pi^2}\exp\left(-\frac{\pi^2\tilde{D}t}{R^2}\right) \quad . \quad (64)$$

For specimens in the form of an infinite cylinder, the solution is expressed in terms of Bessel functions and in the general case requires numerical analysis.[60]

The solutions quoted above have been obtained on the assumption of the instantaneous attainment of the equivalent concentration of charge carriers on the surface of the specimen. When the reactions on the surface are slow, the solutions include the corresponding rate constants.[34,61,62]

An important disadvantage of the gravimetric method is its relatively low sensitivity and the associated necessity for the use of comparatively large changes in the composition of the

specimens, which leads to the breakdown of the condition that $\tilde{D}$ is independent of the degree of DCS and ultimately to a considerable uncertainty in the measured values of $\tilde{D}$.

### 5. The Conductimetric Method

This method presupposes the same experimental conditions as the gravimetric method, but differs from the latter by a higher sensitivity (for a suitable disposition of the electrodes and measuring probes).[34,56,63,64] In this method the average electrical conductivity of the specimens serves as a measure of the changes in concentration. It is assumed that the mobility of the current carriers and the effective charge of the diffusing defects remains constant. Under these conditions, the electrical conductivity varies linearly with the concentration of the excess component $N$, i.e. $\sigma = AN +$ const.,[58,60] so that the solutions are obtained from Eqns.(62)–(64) by the simple replacement of $M$ by $\sigma$ and the experimental $\sigma$–$t$ relations are analysed in the same way as in the gravimetric method. If ionic defects with different effective charges are involved in the diffusion, the proportionality between the electrical conductivity and the mass of the specimen breaks down and measurements of these quantities lead to different values of $\tilde{D}$.[26]

### 6. Other Methods

Apart from the relaxation methods described above, mention should be made of the method based on the kinetics of solid-phase reactions[4–6,34,65,66] involving the measurement of the rate of growth of the solid phases in processes involving the oxidation of metals, for example, Fe → FeO, or of lower oxides (chalcogenides) to higher oxides (chalcogenides), for example, FeO → $Fe_3O_4$ → $Fe_2O_3$. It is then assumed that the reaction product (scale) forms a compact non-porous layer in good contact with the metal or lower oxide and the oxidation reaction proceeds under diffusional conditions. According to Wagner's theory,[7] in this case the change in the thickness $L$ of the layer of scale is described by parabolic time law $L^2 = 2K_p t$ with the constant $K_p = \int \tilde{D} d\delta \cong \tilde{D} \Delta\delta$, where $\Delta\delta$ is the total change in the degree of non-stoichiometry along the thickness of the scale, which is independent of time. Wagner[66] also proposed equations for the calculation of the effective CCDC for the formation of multiphase reaction products under diffusional conditions.

Together with the direct measurements of the thickness or mass of the layer of scale as a function of time, in the study of oxidation kinetics one uses also electrochemical cells in which one of the reactants is supplied to the reaction zone by passing a current through a suitable solid electrolyte. For example, in the cell[40,41]

$$(-)\,\mathrm{Pt}\,|\,\mathrm{Ag}\,|\,\mathrm{AgI}\,|\,\underset{\mathrm{Pt}(+)}{\underline{\mathrm{Ag_2S}}}\,|\,\mathrm{NiS}\,|\,\mathrm{Ni} \qquad (65)$$

the electrolyte AgI is used to transfer silver ions from $Ag_2S$ to metallic silver; the layer of the NiS scale grows as a result of the diffusion through it of nickel ions and electrons as well as the sulphur liberated in the electrolysis of the auxiliary layer of $Ag_2S$. The cell e.m.f. then serves as a measure of the chemical potential of sulphur in $Ag_2S$ and hence of the Gibbs free energy of the sulphidisation of nickel. Since the current density is a direct measure of the rate of growth to the layer of scale $dL/dt$ in the parabolic increase of the thickness of the layer, the following time relation should be observed:

$$I = \frac{F}{v} \cdot \frac{dL}{dt} = \frac{F}{v} (K_p/t)^{1/2}, \qquad (66)$$

where $F$ is the Faraday and $v$ the equivalent volume of the scale.

The main disadvantage of the method of solid-phase reactions is the fact that the values of $\tilde{D}$ determined from the measured $K_p$ for known $\Delta\delta$ are averaged over the entire range $\Delta\delta$. In principle, the dependence of $\tilde{D}$ on $\delta$ can be found by differentiating the values of $K_p$ obtained for different cell e.m.f.'s with respect to the corresponding values of $\delta$ at the NiS|$Ag_2S$ boundary. However, since this involves considerable experimental difficulties, the method of solid-phase kinetics is used mainly for the rough estimation of the CCDC.

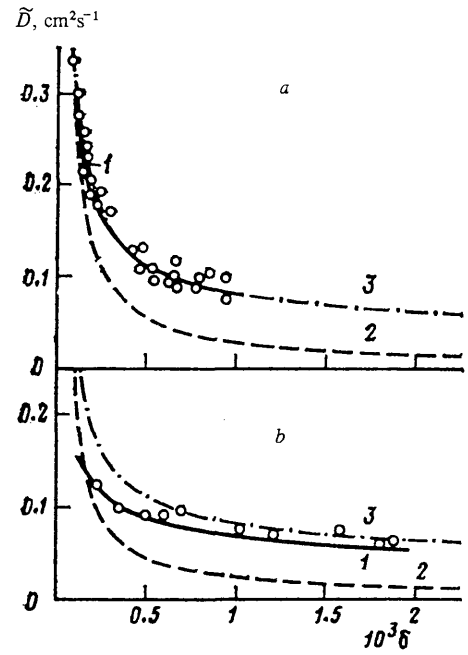

**Figure 4.** Dependence of the CCDC in the $Ag_{2(1+\delta)}S$ (*a*) and $Ag_{2(1+\delta)}Se$ (*b*) cubic phases on the excess content of silver $\delta$ at 200 °C. Circles—experimental values;[53] curves—calculation: 1) according to Eqn.(4); 2) and 3) according to Eqn.(46) for $F_e = 1$ (curve 2) and $F_e$ calculated from the data in Fig.2 (curve 3).

Finally, we may mention the method involving the study of the permeability of solids to gases.[67,68] In this method, the difference between the partial pressures of the non-metallic components $p_{X_2}$ is established on the two sides of a membrane of the test substance and the time variation of the pressure in a calibrated volume as a result of the diffusion of $X_2$ through the membrane is recorded. If the concentration of the gas within the membrane at the inlet is higher than at the outlet and the concentration at the outlet is equal to the initial value, then the pressure at the outlet begins to increase when a time $\tau = L^2/6D$ has elapsed since the establishment of the pressure difference ($L$ is the thickness of the membrane) and subsequently varies linearly with time. The determination of $\tilde{D}$ therefore reduces to the measurement of the intercept $\tau$ made by the experimental linear $p_{X_2}$–$t$ plot.

### 7. Experimental Data

(a) *Silver and copper chalcogenides.* The most reliable CCDC data as a function of the degree of non-stoichiometry have been obtained for silver[36,53] and copper[69,70] sulphides and selenides. The high-temperature cubic phases of these two compounds have a structurally disordered cationic sublattice and exhibit a mixed cationic-electronic conductivity of *n*- and *p*-types respectively. In terms of their electronic properties, they belong to the class of degenerate semi-conductors.

Fig.4 illustrates the results of the direct measurement of $\tilde{D}$ for the $Ag_{2(1+\delta)}S$ and $Ag_{2(1+\delta)}Se$ cubic phases for different excess ($\delta > 0$) contents of silver.[53] The continuous curves *1* were calculated[53] from the phenomenological formula (4) using the experimental random diffusion coefficients of silver and the thermodynamic factor found from measurements of the e.m.f.'s of a galvanic cell. We calculated curves *2* and *3* on the basis of a statistical theory, in accordance with Eqn.(46), which for the compounds considered has the simple form $\tilde{D} = F_e D_{Ag}/\delta$, derived for the first time by Fomenkov.[71] Curve *2* corresponds to the non-degenerate state of the electrons ($F_e = 1$). Curve *3* takes into account the degeneracy; the values of $F_e = F_n$ have been found from the data in Fig.2, using the ratios of the effective mass of the electron to its real mass, $m^*/m_0 = 0.21$ and 0.17, obtained by averaging the literature data[72-76] for the sulphide and selenide respectively.

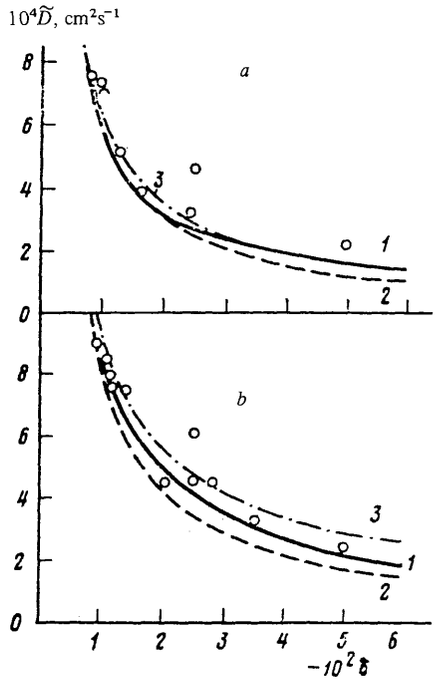

**Figure 5.** Dependence of the CCDC in the $Cu_{2(1+\delta)}S$ (*a*) and $Cu_{2(1+\delta)}Se$ (*b*) phases on the copper deficit at 400 °C. Circles—experimental values;[69,70] curves *1–3* were calculated in the same way as the corresponding curves in Fig.4.

Fig.5 presents analogous data for the $Cu_{2(1+\delta)}S$ and $Cu_{2(1+\delta)}Se$ cubic phases characterised by deficiency of copper in relation to stoichiometry ($\delta < 0$). The circles represent experimental values of $\tilde{D}$.[69,70] In the calculation of curves *1–3* for the stoichiometric sulphide and selenide, the values $D_{Cu} = 6 \times 10^{-6}$ and $8.5 \times 10^{-6}$ $cm^2\ s^{-1}$, which agree within the limits of experimental error with the corresponding $D^*_{Cu}$ for radioactive isotopes,[77,78] were adopted. The effective masses of holes $m^*/m_0 = 7.6$ and 4.6 were taken from Konev et al.[79]

Figs.4 and 5 indicate a satisfactory agreement of the experimental data with the values and relations derived from both the phenomenological and statistical theories, allowance for the degeneracy of the electronic states when $|\delta| > 10^{-3}$ and $10^{-2}$ for silver and copper chalcogenides respectively being important in the latter case. A satisfactory agreement with both theories has also been obtained for the $(Cu_{1-x}Ag_{x+\delta})_2S$ and $(Cu_{1-x}Ag_{x+\delta})_2Se$ cubic solid solutions containing both an excess and a deficiency of the metal and showing maxima on the $\tilde{D}(\delta)$ curves in the vicinity of the stoichiometric composition.[23]

The results of the study of the impedance of the $Pt|\beta\text{-}Ag_{2(1+\delta)}S$ boundary as a function of the excess content of silver in $\beta\text{-}Ag_{2(1+\delta)}S$, which is a non-degenerate *n*-type semiconductor, merit attention.[80]

A readily measurable Warburg impedance, comparable to the resistances of the traditional elements of the equivalent circuit of the cell, was observed. The temperature dependence of the logarithm of the Warburg constant, obtained from the experimental impedance hodographs for a fixed $\delta = 5 \times 10^{-5}$ and the same relation calculated subject to an assumption concerning the CDC of the ions and electrons[1] are almost parallel. The experimental and theoretical values are linked by a constant multiplier of ~0.08, which may be due to the effective area of contact of the solid phases; one can therefore speak of a satisfactory agreement between the theory and experiment in this case also.

(b) *Oxides.* The majority of the experimental data for oxides have been obtained for a large and frequently not measureable difference between the $\delta$ values. The dependences of $\tilde{D}$ on $\delta$ or $p_{O_2}$, which is of greatest theoretical interest, have been investigated for an extremely limited range of compounds.

Reliable data are available for nickel monoxide with a deficiency of the metal, which exhibits Wagner disorder.[81] These data demonstate the constancy of the values of $\tilde{D}$ at 900–1200 °C over a fairly wide range of oxygen partial pressures (from 1 to $10^{-5}$ atm). Analogous results have been obtained for a cobalt single crystal,[56,82] where $\tilde{D}$ is independent of $p_{O_2}$ at 900–1300 °C in the same pressure range.

These results are in good agreement with the expression obtained for $\tilde{D}$ in the case of the vacancy mechanism of the diffusion of cations in the absence of degeneracy of the holes:[34]

$$\tilde{D} = (\zeta_M + 1) D_{VM} . \qquad (67)$$

The validity of Eqn.(67) for $Co_{1-\delta}O$ has also been confirmed by Fryt et al.[35] At the same time Morin's results for $Co_{1-\delta}O$ at 1000 °C [83] demonstrate some (approximately by a factor of 2) increase of the chemical diffusion coefficient $\tilde{D}$ in proportion to $p_{O_2}^{1/4}$ when $p_{O_2}$ $(atm)^{1/4}$ changes from 0.2 to 1. The values of $\zeta_{Co}$, calculated by Eqn.(67), are then close to 2, while the effective charge of the dominant cationic vacancies, determined from the dependence of the electrical conductivity on $p_{O_2}$ is unity at the same oxygen pressures. According to the author,[83] this discrepancy is associated with the anomalies in the mobility of the vacancies, in particular with the dependence of their mobility on $p_{O_2}$ in the region where the $Co_{1-\delta}O$ phase exists.

The available information about the dependence of CCDC on $\delta$ or $p_{O_2}$ for other oxides is not only scarce but frequently contradictory. As an example, one may refer to the results of experiments by different investigators on wüstite $Fe_{1-\delta}O$,[34,45,57] which differ by factors amounting to hundreds for the same temperatures and values of $\delta$ and the dependences of $\tilde{D}$ on $\delta$ obtained by different methods exhibit even qualitative differences. Apparently the main cause of such discrepancy is the complexity of the defect structure of wüstite, in particular its tendency to form extended multiclusters which are not reproducible between different experiments.[2,5] The significant deviations of the defects in wüstite from ideal behaviour are indicated by the observed linearity of the dependence of the logarithm of the activity of oxygen on $\delta$ instead of the expected logarithmic relation.[45]

A considerable variety of the dependences of $\lg \tilde{D}$ on $\lg p_{O_2}$ has been observed for vanadium oxide compounds.[29] The results for the diffusion of oxygen in $VO_2$ and of sodium in $Na_{1/3}V_2O_5$, demonstrating the constancy of the coefficient $\tilde{D}$ within certain ranges of values of $p_{O_2}$, are consistent with the solutions (see Table) for the dominant electronic disorder. On the other hand, for the diffusion of oxygen in $V_2O_5$, $Na_{1/3}V_2O_5$, and $Ca_3Fe_{3.5}V_{1.5}O_{12}$, the horizontal sections on the $\lg \tilde{D}$–$\lg p_{O_2}$ plots are altogether absent and the slopes of their different sections vary from 1/6 to 1, while the theory described can explain only slopes equal to 0 and ±1. The cause of this discrepancy is probably to be sought in the formation of extended defects of the type of shear planes.[2,84] This hypothesis is supported by the observed linear dependence of the partial free energy of oxygen on $\delta$ [85] and also by the low mechanical strength of vanadium oxide compounds and by their tendency to split into separate layers.

---o0o---

Summarising the above discussion, one may conclude that the joint employment of the phenomenological theory and the statistical-thermodynamic theory based on the model of non-interacting ionic defects can yield much information about the dependence of the CCDC on the degree of CDS or the pressure of the non-metal in the gas phase. The degeneracy of the electrons exerts a significant influence on the CCDC. However, despite the major advances made with the aid of the model of non-interacting defects, its possibilities are apparently close to being exhausted.

The discrepancy between the conclusions derived from the theory and experiment for some of the systems investigated necessitates an increase in the complexity of the existing models, in the first place the allowance for the interaction of ions or point defects and also for the involvement of models of extended defects. It is quite evident that appreciable progress on these lines can be achieved by combined theoretical and experimental studies of both static and kinetic characteristics of solids at the atomic level using microscopic working models of the defect structure and of the mechanisms of the elementary transport steps.

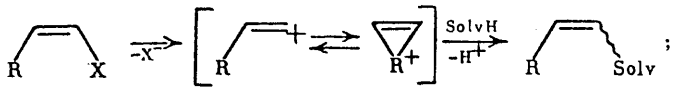
# Reactions Involving Bimolecular Nucleophilic Substitution at a Vinyl Centre

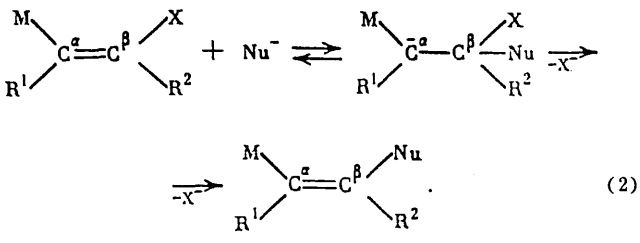
B.A.Shainyan

The present state of research into reactions involving bimolecular nucleophilic substitution at a vinyl centre is examined. Attention is concentrated on stereochemical questions and also on the influence of various details of the molecular structure of the reacting compound on the kinetics and mechanism of the reactions.
The bibliography includes 167 references.



CONTENTS

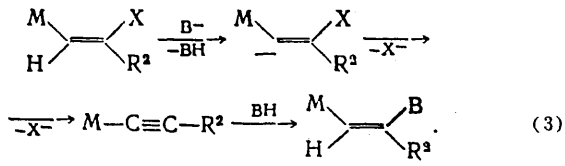
I. Introduction 511
II. Quantum-chemical study 512
III. Stereochemistry of the reactions 516
IV. Quantitative description of reactivity 520
V. Reduction and rearrangement processes in nucleophilic vinyl substitution reactions 526



## I. INTRODUCTION

The systematic study of nucleophilic vinyl substitution reactions was initiated by Italian chemists (Modena and others) approximately 25 years ago; this field of organic chemistry is much more recent than the fields which have already become classical, such as those involving the investigation of nucleophilic substitution in saturated compounds, nucleophilic aromatic substitution, or substitution at a carbonyl carbon atom. In order to characterise in broad outline the characteristics of nucleophilic vinyl substitution reactions, it is useful to compare them with the related types of reactions investigated previously, which have been enumerated above, as well as other.

Like the $S_N1$ and $S_N2$ reactions of alkyl halides, nucleophilic vinyl substitution can proceed via unimolecular (1) and bimolecular (2) mechanisms:



(1)

(2)

Reactions of the first type [reaction (1)] constitute an extensive and fairly completely investigated class of reactions and will not be considered in this review. In Scheme (2) and henceforth Nu represents the nucleophile, $C^{\alpha}$ the carbon atom linked to the activating electron-accepting group M, $C^{\beta}$ the carbon atom linked to the leaving group, and $R^1$ and $R^2$ are the substituents in the α- and β-positions respectively, which can also be the activating or leaving groups. When $R^1 = H$, the substitution can take place under the influence of strong bases via the *ElcB* elimination with subsequent addition in accordance with Scheme (3):

(3)

For brevity, reactions of types (2) and (3) will be henceforth designated as $S_N$Vin reactions.

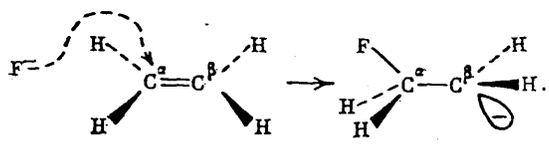
We shall compare the bimolecular nucleophilic substitution reactions with participation of substrates of different classes. The large class of nucleophilic substitution reactions of the $S_N2$ type at an $sp^3$-carbon atom has been most thoroughly investigated in all respects. However, their comparison with nucleophilic vinyl substitution reactions reveals more differences than common features. In fact, in $S_N2$ reactions the processes in which a bond with a nucleophile is formed and that with the leaving group is ruptured are to a large extent synchronised. The possibility that the bond formation process is appreciably faster than the bond dissociation is ruled out by the impossibility of the expansion of the electron shell of carbon in excess of the octet. On the other hand, in $S_N$Vin reactions of type (2) the formation of a bond with the nucleophile is as a rule rate-determining: this process predominates significantly and frequently wholly over the process in which the bond with the leaving group is broken, which leads to a stable anionic intermediate. As a result, a marked effect of the leaving group on the rate of substitution is observed in $S_N2$ reactions, whereas in $S_N$Vin reactions this effect is absent.

Another fundamental difference follows from the examination of the interaction of the nucleophile with the electrophilic substrate from the standpoint of the theory of frontier orbitals. The highest occupied molecular orbital of the nucleophile (HOMO) interacts with the lowest unoccupied molecular orbital of the substrate (LUMO); in $S_N2$ reactions the substrate LUMO is the σ* orbital of the bond between the carbon atom and the leaving group. The bond formation and dissociation reactions take place along the same axis; this is the reason for the stereochemical result—the Walden inversion. In $S_N$Vin reactions the substrate LUMO is a π* orbital localised in the plane perpendicular to that of the molecule in which the bond with the leaving group is located. The bond formation and dissociation processes are separated

both in time and as regards symmetry and the stereochemical result is determined by the relative contributions and the relative ease of the rotation and inversion processes in the intermediate carbanion—as a rule the configuration is retained.

In terms of the frontier molecular orbitals of the substrate interacting with the HOMO of the nucleophile, the $S_N$Vin reactions resemble the nucleophile substitution reactions of aromatic ($S_N$Ar) and carbonyl ($S_N$Ac) compounds. However, variations in the stereochemical result of the reaction are impossible in either $S_N$Ar or $S_N$Ac reactions and this constitutes one of the powerful instruments for the investigation of the mechanism. Nevertheless, comparison of the reactivities for the reactions of the above classes is frequently useful.

The $S_N$Vin reactions have much in common with nucleophilic addition to electron-deficient olefins (the Michael reaction); the first stage, namely the addition of a nucleophile to the double bond with formation of a carbanion, is the same in these reactions. When necessary, data for $Ad_N$ reactions are therefore resorted to in the present review. $S_N$Vin reactions are frequently complicated by elimination processes with formation of acetylenic or allenic products and sometimes they proceed simply via the $E$–$Ad_N$ mechanism (3). Questions concerning the elimination reaction will therefore be dealt with in so far as it is necessary.



The review does not include purely synthetic studies because this would unjustifiably increase its scope. Attention is concentrated on investigations in the last 10–15 years, since the entire literature on this problem published up to 1968 has been surveyed in Rappoport's review[1] (see also special reviews[2,3]).

## II. QUANTUM-CHEMICAL STUDY

The first calculations on the addition of anions to the C=C bond, modelling the first stage of $S_N$Vin reactions, were carried out by Bazilevskii and Tikhomirov[4] and by Kelsey and Bergman.[5] The addition of $CH_3^-$ to ethylene[4] has been investigated in terms of the "almost π-electron approximation" without the optimisation of the geometry but with allowance for the change in the degree of hybridisation of the reaction centre. Under the conditions of attack in the plane of the π-bond at nearly the tetrahedral angle, $CH_3^-$ undergoes exothermic addition without an activation barrier. Bazilevskii and Tikhomirov[4] concluded that their approximation is inapplicable to calculations on ionic reactions (although calculations on the addition of radicals agree satisfactorily with experiment[6]).

The problem of the elucidation of the relative ease of the nucleophilic substitution at the $sp^3$- and $sp^2$-carbon atoms has been raised.[5] Calculations were made by the extended Hückel method (EHM) with partial optimisation of the geometry for the substitution of hydrogen in ethane and ethylene by the hydride ion. The aim was to compare the heights of the activation barriers, but no barriers were found in either reaction and the authors had to resort to an extremely artificial procedure involving the analysis of a "transition" step. In addition, the attack by $H^-$ on a carbon atom, directed in the plane of the ethylene molecule at right angles to the C=C bond, was considered. Since it is clear from the form of the interacting frontier orbitals that nucleophilic attack takes place preferentially in the plane of the π-bond (in the direction of the π* orbital), this calculation cannot serve as an acceptable model of the $S_N$Vin reaction. Analysis of the mutual orientation of the reactants in the attack by the nucleophile on the π-system[7,8] has indicated that attack by the nucleophile on the π-system[7,8] takes place preferentially in the direction of the bond formed, i.e. at a Nu–C=C angle of approximately 70°. For nucleophiles containing unoccupied 3*d* orbitals, this angle is somewhat greater apparently as a result of 3*d* back bonding: $\pi_{C=C} \rightarrow 3d_{Nu}$.[8]

A non-empirical calculation for the addition of $F^-$ to ethylene[9] has shown that the formation of the *anti*-conformer of the fluoroethyl anion [the orientation of the F atom in relation to the lone electron pair (LEP) of the carbanion was considered] is more favourable than the formation of the *syn*-conformer ($\Delta E$ = 19, 22, and 21 kJ mole$^{-1}$ in terms of the STO-3 GF, 4-31 GF, and 6-31 GF basis sets respectively). This has been explained by the stabilising interaction of the LEP with the σ* orbital of the C–F bond. Calculation of the optimum path leading to the mutual approach of the reactants yielded the following addition scheme:

(4)

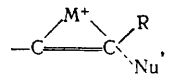
When the $C^\alpha$–F distance is changed from 4 to 2.5 Å, the C–C–F angle diminishes to 115.5°, while the further decrease of the distance from 2.5 to 1.4 Å entails a slight increase of the angle to 118.7°, which leads to the *anti*-conformer. There is no activation barrier in reaction (4), which is exothermic in terms of the STO-3 GF basis set: $\Delta E$ = −557 kJ mol$^{-1}$. However, in terms of the 4-31 GF and 6031 GF basis sets, reaction (4) is endothermic with $\Delta E$ = 60 and 67 kJ mol$^{-1}$.[9]

Calculations have been made for reaction (4) by a number of investigators in terms of various approximations. Apart from the study of Bach et al.[9], the instability of the $FCH_2 - CH_2^-$ anion in relation to decomposition has been demonstrated at the 3-21 + GF [10] and 4-31 + GF [11] levels (i.e. with additional Gaussian functions at the C and F atoms). On the other hand, calculation at the 3-21 GF level and in terms of the most refined 6-31 GF* basis set (with polarisation Gaussian functions for the *d* orbitals of heavy atoms) yields a real minimum on the potential energy surface for the β-fluoroethyl anion, the F atom and the lone electron pair being in the *anti*-conformation.[12]

A calculation has been made[13,14] for the interaction of $H^-$, $HS^-$, and $F^-$ with ethylene by the CNDO/BW method with total optimisation of the geometry. Attack by the $H^-$ or $F^-$ ion directed at right angles to the molecular plane of ethylene entails the exothermic formation of the $C_2H_5^-$ or $CH_2FCH_2^-$ anion, while attack at low angles relative to the molecular plane over a distance of approximately 2.5 Å entails the abstraction of a proton with formation of the vinyl anion $C_2H_3^-$ and the $H_2$ or HF molecule. These data agree well with the parallel course of the elimination process in $S_N$Vin reactions which is frequently observed and has been confirmed by experimental data for reactions of anions with fluoroethylenes by the method of ion–cyclotron resonance.[15]

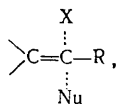
All these calculations refer to the gas phase and lead to barrier-free reactions. The attempt to take into account the influence of the medium even in the simplest version of the solvation model makes it possible to obtain reasonable activation barriers in the CNDO/BW and MINDO/3 methods.[16]

The above calculations were performed for simple ethylenes, while nucleophilic vinyl substitution and addition reactions are characteristic primarily of conjugated molecules with electron-accepting groups. An example of such a calculation is provided by the calculation in terms of the 4-31 GF basis sets of the local minima on the potential energy surface for



the $CH_2=CH-CHO+Nu^-$ system, where $Nu^- = F^-$ and $CH_3O^-$.[17] In both cases the absolute energy minima correspond to the products of the addition of the anion to the β-carbon atom of the acroleine molecule; the potentially possible competing deprotonation processes are energetically unfavourable. An experimental study of the above reactions in the gas phase by the method of ion–cyclotron resonance confirmed the results of the calculations.[17]

Analysis of the potential energy surface for the $F^- + FHC=CH-CN$ system within the framework of the CNDO/2 and MINDO/3 methods has shown that both reaction pathways, i.e. the addition of the nucleophile and the deprotonation of the substrate, are possible.[18]



A number of theoretical studies have been devoted to the analysis of the stereochemistry of the nucleophilic vinyl substitution. As a rule, these reactions proceed with retention of configuration of the molecule of the initial substrate (*Z* or *E*). A partial inversion of configuration is sometimes observed[1] and in addition cases of stereoconvergence, i.e. of the formation of the same mixture of isomers of the reaction product regardless of the configuration of the initial substrate, have been described.[19–21] In particular, stereoconvergence is observed for vinyl halides with very strong electron-accepting groups in the α-position or for weakly nucleophilic leaving groups, i.e. in the case of long-lived carbanions. Finally, there exist two types of reactions which proceed, according to the author,[22] with total inversion of configuration when the nucleophile attacks in the molecular plane. These involve the formation of onium cations having the "cyclopropenyl" structure

where M = Ar, S, Br, or I, and the opening of these rings following the attack by an external nucleophile.[22] The transition state in these reactions should have the structure

analogous to the planar structure

which was already considered in an early study by Gold[23] (see also Kelsey and Bergman[5]). In this connection Rappoport[22] concluded that nucleophilic vinyl substitution cannot be regarded as a process proceeding stereospecifically with retention of configuration. The stereochemical specificity should depend on the charge of the leaving group, the capacity for the formation of small rings, and also on the nature of the α- and β-substituents.

Stohrer concluded that configuration is retained in $S_N$Vin reactions and considered a correlation diagram including the orbitals of the reactants involved in the reaction (Fig. 1). In the $R^1R^2\bar{C}^\alpha-C^\beta XYNu$ anion, formed after the attack by the nucleophile, the *p* orbital of the $C^\alpha$ atom tends to achieve maximum stabilisation by overlapping with the antibonding orbitals $\sigma^*_{C^\beta-X}$, $\sigma^*_{C^\beta-Y}$, and $\sigma^*_{C^\beta-Nu}$.[24] As can be seen from Fig. 1, under these conditions the overlap of the $p_{C^\alpha}$ orbital with the $\sigma^*_{C^\beta-Nu}$ orbital is more favourable to the left of the point O and the overlap of the $p_{C^\alpha}$ orbital with the $\sigma^*_{C^\beta-X}$ orbital is more favourable to the right of this point.

The elimination of the leaving group X requires that the axes of the $C^\beta-X$ bond and the $p_{C^\alpha}$ orbital lie in the same plane. According to the diagram in Fig. 1, a kind of enhancement of the effect is observed—the smaller the angle between the $p_{C^\alpha}$ orbital and the $C^\alpha C^\beta X$ plane, the greater the degree of loosening of the $C^\beta-X$ bond owing to the donation of electrons from $p_{C^\alpha}$ to $\sigma^*_{C^\beta-X}$ and the greater the degree of loosening of the bond the greater the degree of further rotation, which ultimately leads to the substitution product with retention of configuration (Fig. 2).

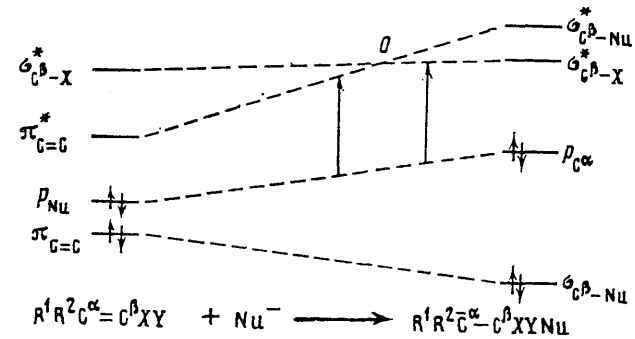


**Figure 1.** Correlation diagram for the stage involving the addition of the nucleophile $Nu^-$ to the olefin $R^1R^2C^\alpha=C^\beta XY$.

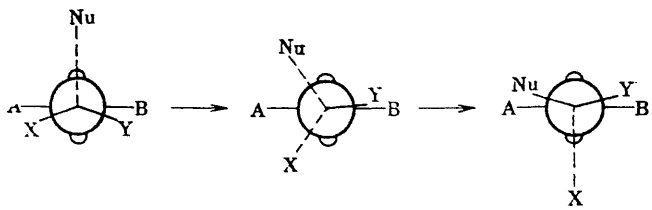

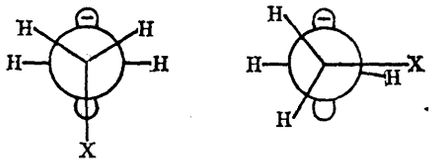

**Figure 2.** Retention of configuration in the synchronous mechanism of the substitution reaction.

An idea with a similar significance has been put forward by Texier et al.[25], who considered the elementary step in the substitution process as attack by the nucleophile at right angles to the molecular plane of ethylene "above" the leaving group within the framework of a synchronous substitution mechanism. This entails the "lateral" binding of the nucleophile to the β-carbon atom.

In the above study[24,25] the retention of configuration in $S_N$Vin reactions was readily accounted for within the framework of a single-stage synchronous substitution mechanism. However, the question of whether nucleophilic vinyl substitution is a single-stage or a multistage process was recently examined in detail by Rappoport,[26] who concluded that so far there have been no reliable examples of $S_N$Vin reactions proceeding via a single-stage synchronous substitution mechanism; on the other hand, the vast majority of the experimental data indicate a two-stage mechanism of

the $S_N$Vin reactions. For a two-stage mechanism, the main question is why the clockwise rotation by 60° in the carbanion formed initially (Fig. 3), which leads to the retention of configuration, is preferable to the anticlockwise rotation by 120°, which leads to the inversion of configuration. On a qualitative level, the preferred rotation of the first type has been demonstrated by Texier et al.[25] As regards calculations of the rotation barriers, there have been two studies devoted to non-empirical calculations for substituted ethyl anions in two conformations (A) and (B):[27,28]

(A) (B)

The calculations were performed in terms of the STO-3GF [27] and 4-31GF [28] basis sets. Overall, the conformation (A) is more favourable than (B) (except in the case where $X = BH_2$) and the energy difference $\Delta E = E^{(A)} - E^{(B)}$ increases with increasing electronegativity of X. This can be explained by the hyperconjugation interaction, which represents the sum of the stabilising interaction of the $p_{C\alpha}$ orbital with $\sigma^*_{C\beta-X}$ and the destabilising $p_{C\alpha}-\sigma_{C\beta-X}$ interaction. The greater the electronegativity of X, the greater the contribution of the stabilising interaction, which is a maximum, as regards the overlap of orbitals, for the conformation (A). It has been noted that the introduction of electron-accepting groups at the carbanionic centre diminishes $\Delta E$; thus, $\Delta E = 23$ kJ mol$^{-1}$ for $CH_2F-C(CN)_2$, while $\Delta E = 42$ kJ mol$^{-1}$ has been obtained for $CH_2F-CH_2$.[27]

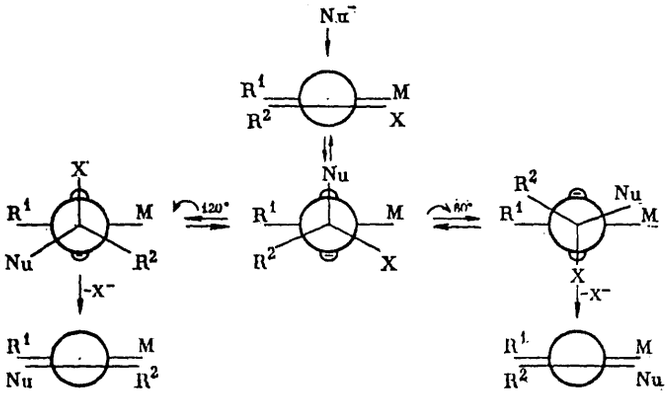

**Figure 3.** A general scheme for stereochemical transformations in the two-step carbanionic mechanism of the substitution reaction.

The application of the idea of the important role of hyperconjugation, put forward by Apeloid and Rappoport,[27] to the general scheme (Fig. 3) leads to the following conclusions: (1) if the energy of the interaction of $p_{C\alpha}$ with $\sigma^*_{C\beta-X}$ is greater than that of the interaction with $\sigma^*_{C\beta-Y}$, then the retention of configuration should be the stereochemical result; (2) when the above quantities are approximately equal, stereoconvergence should be observed; (3) if the energy of the interaction of $p_{C\alpha}$ with $\sigma^*_{C\beta-X}$ is smaller than that of the interaction with $\sigma^*_{C\beta-Y}$, then inversion should take place; (4) the stereochemical outcome is independent of the nature of the nucleophile, because the degree of hyperconjugation of $p_{C\alpha}$ with $\sigma^*_{C\beta-Nu}$ changes by the same amount on rotation by the same angle in either direction; (5) the same ratio of products with retention and inversion of the configuration should be obtained from the *Z*- and *E*-isomers of the substrate. Hence, the retention of the configuration in $S_N$Vin reactions can be explained by the fact that as a rule Y is a hydrogen atom of an alkyl or allyl group and X is a halogen or another group containing a heteroatom and the capacity of the $\sigma^*_{C\beta-X}$ orbital for hyperconjugation is greater than that of the $\sigma^*_{C\beta-Y}$ orbital. There exist examples confirming the validity of this approach.[26,27]

In the above analysis the conclusion that the stereochemistry of the reaction is independent of the nature of the nucleophile appears doubtful especially since experimental data (see Section III) indicate the opposite state of affairs. Indeed, a more detailed analysis[29] has revealed a dependence of the stereochemistry of the $S_N$Vin substitution on the nucleophile and in particular on the energy of the HOMO of the nucleophile. It has been shown that in the case of $S_N$Vin reactions it is essential to take into account the four-electron interaction of the nucleophile HOMO with the substrate HOMO in addition to the two-electron interaction of the nucleophile HOMO with the substrate LUMO usually considered. Evidently the two-electron interaction is stabilising, but the four-electron interaction is destabilising and the latter is more pronounced the lower the energy of the nucleophile HOMO, the destabilising contribution predominating for neutral nucleophiles (for example, $NH_3$). Calculations for the reactions of a large series of vinyl halides with a large set of nucleophiles in terms of the 4-31GF basis set has shown[29] that, with increase of the energy of the nucleophile HOMO, the process becomes more exothermic and there is a shift towards an earlier transition state.† This approach agrees with Hammond's postulate and makes it possible to analyse the joint influence of the nucleophile and the leaving group on the stereochemical result of the $S_N$Vin reaction.

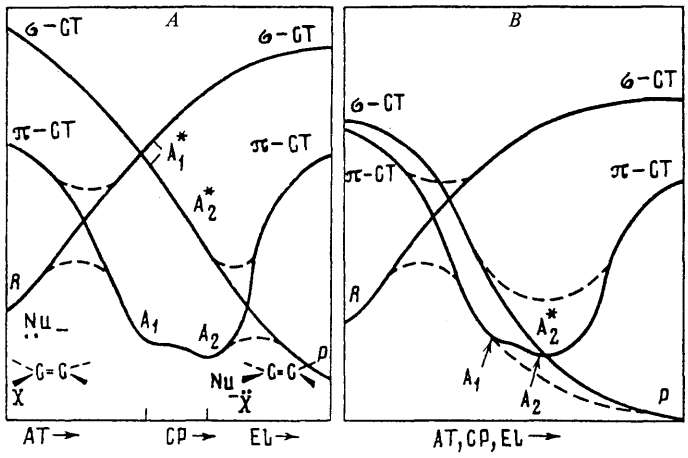
The importance of the mixing of the unoccupied substrate orbitals of the σ* and π* types, which is responsible for the presence or absence of a tetrahedral intermediate in nucleophilic reactions involving the $sp^2$-carbon atom, has been pointed out in the literature,[30] but the authors' analysis is limited to $S_N$Ac and $S_N$Ar reactions.

The most complete theoretical analysis of the stereochemistry and reactivity in $S_N$Vin reactions has been carried out by Cohen et al.[12] Bearing in mind the inconsistency

---

†It is necessary to explain what Bach and Wolber[29] referred to as the "transition state". Having chosen the Nu...C=C distance as the reaction coordinate, they observed the decrease of the height of the energy barrier to rotation about the C–C bond as the nucleophile approaches and the point at which this barrier becomes zero is called the transition state. It is assumed that at this point there is a transition from the process involving the addition of the nucleophile to one involving the expulsion of the leaving group.[29]

between many experimental data with the theory of frontier molecular orbitals and/or the Bell–Evans–Polanyi principle, the authors[12] used the method of correlation diagrams for states in order to set up a general picture describing the stereochemistry and the influence of the nucleophile and of the activating and leaving groups in $S_N$Vin reactions. The heats of reaction, the activation barriers to reactions, and the barriers to inversion in carbanions were calculated, in terms of the double-$\zeta$ basis set using the geometry obtained in terms of the 4-31GF basis set, for eight reactions. The overall correlation diagram for states, including all the reaction stages, is presented in Fig.4. The large difference between the energies of the $\pi$-CT and $\sigma$-CT levels [corresponding to charge transfer from the nucleophile to the $\pi^*$ and $\sigma^*$(C–X) orbitals respectively] predetermines a two-stage mechanism with separation of the stages involving the attack by the nucleophile and the abstraction of the leaving group. The mutual approach of the $\pi$-CT and $\sigma$-CT levels increases the probability of a synchronous process. In essence, this conclusion is analogous to an intuitive idea: the greater the nucleophilicity of the leaving group, the shorter the lifespan of the intermediate carbanion, and hence the closer is the process to being synchronous. The authors[12] were able to describe from a single standpoint the changes in the structure of the transition state, the activation barriers, and certain other reaction parameters in good agreement with experimental data.



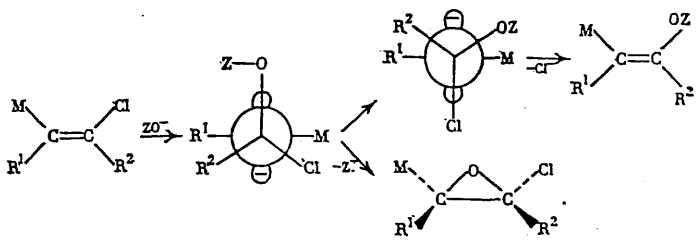


**Figure 4.** Correlation phase diagrams for $S_N$Vin reactions: *A*) two-step mechanism with separation of the steps involving attack by the nucleophile and the abstraction of the leaving group; *B*) one-step synchronous mechanism; AT—step involving attack by the nucleophile; CP—step involving the conversion of the conformer $A_1$ (with a coplanar disposition of the LEP of the carbanionic centre and the bond with the nucleophile) into the conformer $A_2$ (with a coplanar disposition of the LEP of the carbanionic centre and the bond with the leaving group); El—step involving the abstraction of the leaving group; $\pi$-CT—level corresponding to charge transfer from the nucleophile to the $\pi^*_{C=C}$ orbital; $\sigma$-CT—level corresponding to charge transfer from the nucleophile to the $\sigma^*_{C-X}$ orbital; $A_1^*$ and $A_2^*$—excited configurations of the carbanions $A_1$ and $A_2$ respectively.

The competitive course of the $S_N$Vin substitution process and the formation reaction of the epoxide when a chloroalkene is acted upon by the $ZO^-$ nucleophile, where Z is the potential leaving group, has also been discussed:[31]

The subsequent reactions of the carbanion formed in the first stage depend on the relative nucleophilicity of Cl and Z and on treatment with, for example, hypochlorite (Z = Cl), an epoxide is obtained. The rotation barriers have been calculated[31] for a large series of anions of the type $ZQCH_2$–CYY', where Y and/or Y' = H or activating groups ($NO_2$ and CN), while Q = O, $CH_2$, or S and Z = Cl, F, H, OH, $OCH_3$, OCHO, $SiH_3$, or $SH_2^+$ (the calculation was carried out in terms of the STO-3GF, 3-21GF, 4-31GF, and 6-31GF basis sets).

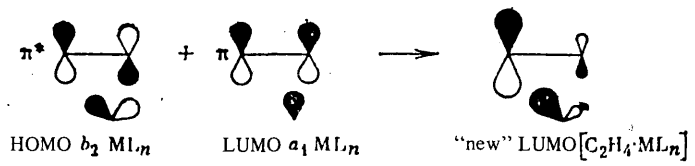

**Figure 5.** The mixing of the orbitals on passing from the symmetrical $\pi$-complex to the $\sigma$-complex.

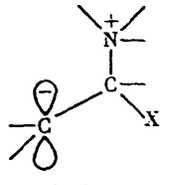
An increase of the reactivity of the double bond in relation to nucleophiles can be induced not only by the introduction of an electron-accepting group but also by complex formation with transition metals. The causes of such activation are not evident and cannot be accounted for solely by the electrostatic effect, since this phenomenon is observed for both cationic and neutral complex forming agents and for anions and neutral molecules as the nucleophile.[32] At first sight complex formation should in general deactivate ethylene, since the interaction of the LUMO of ethylene with the molecular orbitals of the complex-forming agent $ML_n$ increases the energy of the $\pi^*$ orbital and weakens its interaction with nucleophiles. If the population of the $H^-\ldots C_2H_4$ bond corresponding to the "reasonable" distance of 2 Å is chosen as the reactivity index in the calculation for the interaction of $H^-$ with ethylene activated by complex formation with $ML_n$, then in all cases the population is smaller than in the absence of the complex forming agent. However, when $ML_n$ "slides" along the C=C bond from its centre to one of the carbon atoms (Fig.5), the index increases and for a $\sigma$-complex exceeds that for free ethylene. This results in the mixing of the orbitals and the new LUMO of the complex $[C_2H_4.ML_n]$ is less reactive in relation to the nucleophile than $\pi^*_{CH_2=CH_2}$. The $\pi^*_{C=C}$ orbital naturally predominates in this new LUMO,

but the contribution of $\pi_{C=C}$ is also important, since the $(H^-...\pi^*)$ interaction component of the overall $H^-...C_2H_4$ bond population cannot exceed the analogous value for free ethylene whatever the $ML_n$ shift.



## III. STEREOCHEMISTRY OF THE REACTIONS

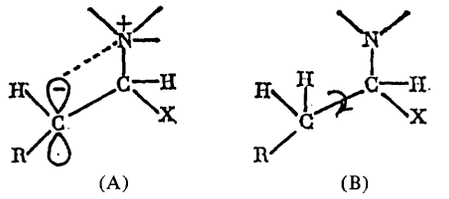
The principal electronic interactions determining the stereochemical outcome of nucleophilic vinyl substitution reactions were discussed above. We shall now consider the principal classes of compounds and specific reactions leading to the retention, stereoconvergence, or inversion of the configuration. Since the olefinic carbon atom is achiral, the above terms will be used in relation to the geometrical sequence of the groups compared with the initial compound: the retention of configuration corresponds to the disposition of the nucleophile in the same position relative to the activating group where the leaving group had been located; inversion implies the presence of the nucleophile in the opposite position; stereoconvergence implies the formation of the same mixture of products (or of one product) regardless of the structure of the initial substrate. The term "racemisation" used previously is not entirely exact because the formation of one (most stable) of the two isomers of the product,[1] which is identical with retention of the configuration of one of the isomers and the inversion of that of the other, was frequently regarded as racemisation.

We shall consider initially reactions proceeding in accordance with the direct substitution mechanism (2) via an intermediate carbon atom or zwitter-ion because the stereochemical outcome of reactions involving the elimination–addition mechanism (3) is regulated by the rules governing the addition of nucleophiles to an activated triple bond.[33]

The vast majority of the almost 80 reactions examined in a review[1] take place with retention of configuration. For reactions with amines, the formation of the thermodynamically stable *E*-isomer (with the *trans*-disposition of the activating group and the $R_2N$ residue) is as a rule observed; an exception is ethyleneimine, which reacts with retention of configuration. The causes of the preferential retention of configuration in reactions with anions as nucleophiles were examined above (Section II). There are two alternative explanations (which may also supplement one another) for the formation of the *E*-isomers of enamines in reactions with amines. The first is that a product with retention of configuration is formed initially and then isomerises rapidly to the thermodynamically more stable *E*-enamine. The ease of such postisomerisation is ensured by the strong conjugation of the LEP of the nitrogen atom with the C=C double bond. Thus, it has been shown by NMR that there is free rotation about the C=C double bond in the enamines $(CH_3)_2N-CH = C[C(O)R_2]$ ($R = CH_3$ or $OCH_3$).[34]

The other explanation is based on the zwitter-ionic character of the intermediate complex:

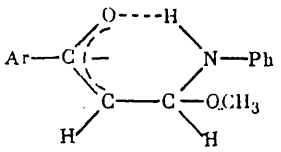
A barrier, due to electrostatic forces, preventing rotation and the attainment of the conformation with a coplanar disposition of the LEP in the carbanionic centre and the bond with the leaving group (the group X is split off in this conformation) arises in the above structure, i.e. the lifespan of the intermediate increases. The possibility of the formation of the thermodynamically most stable conformer of the intermediate, from which the enamine is formed, is thereby achieved.



If the first explanation is valid, there should be no differences in the stereochemistry of the substitution reactions with $R_2NH$ or $R_2N^-$ (in the form of sodium amide) as the nucleophile. Unfortunately, reactions with amines and with their anions have not been compared experimentally; the situation is probably complicated by the fact that the amide anions, which are very strong bases, are capable of eliminating the HX group and can thus react via a different mechanism. On the other hand, if the "zwitter-ionic" hypothesis is valid, there should be a fundamental difference between the reactivities of amines and their anions. The retention of the configuration in reactions with ethyleneimine, where effective conjugation of the LEP of the nitrogen atom with the double bond is impossible owing to the pronounced steric strain, supports the view that substitution with retention of configuration takes place also in reactions with other amines and is then followed, as a result of the postisomerisation, by the formation of the thermodynamically more stable *E*-isomer of the substitution product.

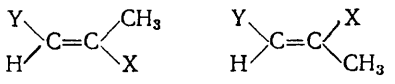
The change in the course of the reaction on moving down Group V of the Periodic System, i.e. on passing from amines to phosphines and arsines, has not been studied in detail. It has only been shown that trimethyl phosphite affords the *E*-isomer of the substitution product in reaction with 1,2-di(toluene-*p*-sulphonyl)ethylene.[35] On the other hand, the anion $Ph_2R^-$ reacts with 1,2-dichloroethylene and β-bromostyrenes with retention of configuration;[36–38] the salts of the arsine anion $Ph_2As^-$ also react with retention of configuration.[39] Mention should be made of a study[40] devoted to the stereochemistry of the substitution of the bromine atom in α-bromoacrylic acids or their esters by cuprates, i.e. by the anion $(CH_3)_2Cu^-$; here too retention of configuration was noted in all cases.

Interesting results have been obtained in studies[41,42] of the nucleophilic substitution of bromine in 2-*cis*-β-bromovinyl-5-nitrothiophen. The stereochemistry of the compound was established by $^1H$ NMR from the coupling constant $^3J_{H-H}$. It has been established for a large set of nucleophiles that the substitution proceeds with retention of configuration for tertiary amines, with partial inversion for $ArO^-$, $ArS^-$, and $N_3^-$, and with total inversion for secondary amines and sulphinate anions. Overall, the series obtained is as follows:



| Nucleophile | $R_3N$ | pyridine | $ArO^-$ | $N_3^-$ | $ArS^-$ | $ArSO_2^-$ | $R_2NH$ |
|---|---|---|---|---|---|---|---|
| Degree of inversion, % | 0 | 0 | 25 | 33 | 50 | 100 | 100 |

The sharp difference in the behaviour of tertiary and secondary amines indicates the important role of the proton, which has also been noted by Rappoport.[1] The strong electrostatic interaction between the positively charged nucleophilic residue and the carbanionic centre in the zwitter-ion probably prevents the clockwise rotation of group (A) by 120° which would lead to inversion. For secondary amines, there is a possibility of the protonation of the neighbouring carbanionic centre (B) and rotation to give the thermodynamically stable conformer is facilitated:



(A) (B) (5)

The importance of the formation of the hydrogen bond in the intermediate zwitter-ion and its influence on the stereochemical result of the reaction are indicated by the results in a study by Chu et al.[43]: the reaction of primary amines ($PhNH_2$) with *E*-3-methoxy-4'-acrylophenones proceeds with inversion of configuration, while the reaction of secondary amines ($PhNHCH_3$) takes place with retention of configuration. The hydrogen-bonded conformation

is the most favourable for the reaction with aniline with the carbanion formed on deprotonation of the zwitter-ion, and the elimination of the methoxy-group from it gives rise to the *Z*-isomer of the substitution product. In the case of *N*-methylaniline there is no hydrogen bond and the sterically less strained *E*-isomer is formed.[43]

A series of studies by French investigators[44-55] has been devoted to nucleophilic vinyl substitution in the esters and nitriles of halogenocrotonic and halogenoacrylic acids. In the reactions of the *Z*- and *E*-isomers of β-halogenocrotonic esters and nitriles (X = Cl or Br; Y = $COOC_2H_5$ or CN), i.e.

with $C_2H_5S^-$ and $PhS^-$ the configuration is retained to an extent greater than 95%.[44] However, in the presence of an excess of the nucleophile Y = CN, the *Z*-isomer of the substitution product is formed either exclusively or preferentially regardless of the configuration of the initial substrate. The author[44] explained this by the isomerisation of the product formed initially in the alkaline medium. The study of the reactions of the same compounds with various amines also revealed a number of characteristic features.[45,46] Only one thermodynamically stable *Z*-isomer of the substitution product is formed in reactions with secondary amines for both Y=CN and Y = $COOC_2H_5$. The nitriles (Y = CN) react with primary amines to form also the *Z*-isomers of the substitution product, while the esters (Y = $COOC_2H_5$) produce almost exclusively (to the extent of 91–98%) the *E*-isomers regardless of the configuration of the substrate. Ethyleneimine reacts with retention of configuration in all cases.

Comparison of these results with the data obtained by the same workers for the reactions involving the addition of various amines to the acetylenic substrates $CH_3-C\equiv C-Y$ (Y = CN or $COOC_2H_5$) [47] permits reliable conclusions about the mechanism of the substitution process. It has been found that both the substitution of the halogen by an amine in crotonic acid derivatives and the addition of amines to the corresponding acetylenic esters and nitriles yield the same product or mixture of products, which led the authors to the conclusion that substitution involves the elimination–addition mechanism (3) via the acetylenic intermediate. The latter is apparently formed under the influence of the strong base $R'O^-$, whose presence in the reaction medium is due to the following equilibrium:

$$RNH_2 + R'OH \rightleftarrows \overset{+}{R}NH_3 + R'O^-.$$

The stereochemistry of the reaction along the initial section of the conversion curve (degree of reaction approximately 5%) has also been investigated.[45] It was found that the product formed under the conditions of kinetic control is thermodynamically stable only in the reaction with ethyleneimine. On the other hand, in the reactions with the remaining amines under the conditions of kinetic control products with retention of configuration were obtained and then isomerised to the thermodynamically stable isomers.[45,46] These results have been confirmed by a special study of the isomerisation of the enamines obtained.[47]

The joint effect of the nature of the leaving and activating groups and of the character of the nucleophile on the mechanism and stereochemistry of the vinyl substitution reactions has been investigated in relation to fluorene- and arene-substituted esters and nitriles of crotonic acid in reactions with $O^-$, $N^-$, and *S*-nucleophiles.[48,49] The fluoro-derivatives react with $C_2H_5O^-$ to form preferentially the *E*-isomer of the product from both the *E*- and *Z*-isomers of the substrate. The iodo-derivatives give rise to elimination products in their reactions with $C_2H_5O^-$—either acetylenes or allenes. Both iodo- and fluoro-derivatives react stereoselectively with "soft" anions ($PhS^-$, $C_2H_5S^-$), forming vinyl substitution products with retention of the configuration. The above compounds react with amines to form mixtures of isomers, the thermodynamically more stable *E*-isomers predominating; *Z*-β-iodocrotononitrile gives rise to an acetylenic derivative. The reaction with ethyleneimine proceeds as a rule with retention of configuration.

The behaviour of the same substrate in reactions with nucleophiles containing a branched hydrocarbon residue, namely $t\text{-}C_4H_9O^-$ and $t\text{-}C_4H_9S^-$, is of interest.[50] Reactions with the highly basic $t\text{-}C_4H_9O^-$ yield exclusively hydrogen halide elimination products, while in the reactions with $t\text{-}C_4H_9S^-$ the composition of the products depends markedly on the nature of the leaving group (the halogen atom) and on the structure of the substrate. On passing from F to Cl and Br and further to I, the content of the elimination and rearrangement products ($CH_2=CX-CH_2Y$) increases, the reaction of the fluoro-derivatives with $t\text{-}C_4H_9S^-$ leads exclusively to substitution products predominately with retention of the configuration, while the Z-isomers of the iodo- and bromo-derivatives afford 90–95% of the acetylenes $CH_3-C\equiv C-Y$ and only 5–10% of the substitution products. The latter (except in the case where X = F) are also formed via the elimination–addition mechanism (3), which has been confirmed by isotope exchange data.

The influence of the α-methyl group was investigated in relation to the *E*- and *Z*-isomers of the compounds $CH_3CX = C(CH_3)COOC_2H_5$ (X = Cl, Br, or I).[51-53] The allene $CH_2 = C = C(CH_3)-COOC_2H_5$ is formed in the reactions with alkoxides as in the case of β-halogeno crotonates, while a large amount of the normal substitution product $CH_3-C(Nu) = C(CH_3)-Y$ is formed in the reactions with *S*-nucleophiles, in contrast to the non-methylated substrate, which gives rise to substitution products with rearrangement, i.e. $CH_2 = C(Na)-CH_2Y$. In this case substitution also proceeds in accordance with the elimination–addition mechanism.[53] The reactions of β-halogenoacrylic esters[54] and β-halogenoacrylonitriles[55] with $C_2H_5O^-$ and $C_2H_5S^-$ also take place preferentially with either the complete retention of the configuration, although isomerisation sometimes occurs in the reaction with the more basic ethoxide anion, or with addition of a second ethanol molecule and the formation of a saturated adduct.

However, the involvement of a larger series of nucleophiles (including the carboxylate, nitrite, and thiocyanate anions) in the reaction with β-chloroacrylonitrile shows that the reaction proceeds non-stereoselectively. The more stable *E*-isomer of the substitution product is formed as a rule in reactions not only with secondary amines but also with the anions quoted above.[56] Reactions with the anions lead to identical or almost identical mixtures of products,

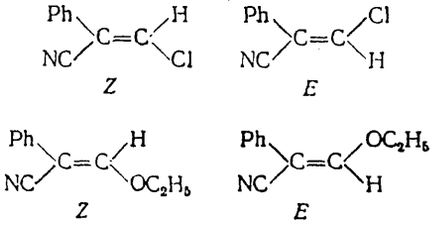
regardless of the configuration of the initial β-chloroacrylonitrile, i.e. stereoconvergence is observed. In addition, one should note that under certain conditions the *Z*- and *E*-β-chloroacrylonitriles are capable of interconversion and this is also true of the products of the substitution of the chlorine in these substances by the RO, RS, and other groups.[57] The substitution reactions under the influence of $RO^-$ and $RS^-$ proceed, as shown also by Biougne et al.[55], with preferential retention of configuration, but under more severe conditions both products and initial reactants isomerise.[57] The energy differences $\Delta G = \Delta G_Z - \Delta G_E$ have been determined for XCH=CHCN, where X = Cl, CN, $CH_3O$, n-$C_4H_9O$, iso-$C_3H_7O$, $C_4H_9S$, t-$C_4H_9S$, and $CH_3COO$. The *Z*-isomer is more stable with the exception of the cases where X = $CH_3O$ and $C_4H_9O$. The differences $\Delta E$ have also been calculated semiempirically by the CNDO/2 method, but the calculated values agree poorly with the experimental data.[57]

The substitution of the fluorine in 2-pentafluoropropenyltetrahydrofuran by alkoxide anions[58] leads to a mixture of the *Z*- and *E*-isomers with the ratio $Z/E = 2.0-5.8$, which differs from that for the initial substrate ($Z/E = 1.9$):

$$R'-CF=CF-CF_3 + RO^- \rightarrow R'-C(OR)=CF-CF_3 + F^-.$$

The author interprets these data from the standpoint of the relative stabilities of the conformers of the carbanion leading to the *Z*- and *E*-isomers of the product, but notes that the *Z*-isomer of the substrate is more reactive and the results obtained for low conversions do not therefore prove the relative stabilities of the conformers.

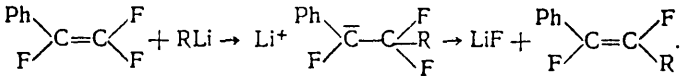
In the study of the substitution of fluorine in β-fluorovinyl sulphones it has been shown[59] that, on interaction with $CH_3O^-$ and $PhS^-$ in methanol, *E*-$PhSO_2CH=CHF$ gives rise to substitution products with retention of configuration, while the *Z*-isomer produces mixtures with the compositions $Z:E = 1:1.5$ and $3:1$ for the reactions with $CH_3O^-$ and $PhS^-$ respectively. Since the adduct $PhSO_2CH_2CHFSPh$ and the acetylenic sulphone $PhSO_2C\equiv CH$ are stable under the reaction conditions, the non-stereospecificity of the reaction of the *Z*-isomer is apparently associated with the longer lifetime of the carbanion, which permits the establishment of the conformational equilibrium before the elimination of the leaving group.



It has been shown[60] that the configuration is retained in the reactions of the *Z*- and *E*-isomers of the nitrile $(CH_3O)_2$.CHCBr=CHCN with piperidine, while the reaction with ammonia leads in all cases to the more stable *Z*-enamine. The data obtained have been compared with the stereochemical result of the reactions involving addition to the corresponding acetylenes.

The majority of the reactions described above have been investigated in proton-donating solvents, although the rule of the preferential retention of the configuration holds also in solvents of the type of dimethylformamide (DMF).[61-64]

Interesting data have been obtained in the study of the reactions of the isomeric β-bromovinyl sulphones $ArSO_2CH=CHBr$ with a series of neutral *N*-, *P*- and *S*-nucleophiles.[65-70] It has been shown that the reactions of these compounds with tertiary amines, containing at least one methyl group, involve substitution with retention of configuration. The reactions of more bulky amines (triethylamine or tri-n-butylamine) lead to the formation of the thermodynamically more stable *E*-isomer of the substitution product. On further branching (in the case of tribenzylamine), the reaction does not take place. The data obtained can be interpreted satisfactorily from the standpoint of steric interactions in the intermediate zwitter-ion.[67] The reactions of β-bromovinyl sulphones with tervalent phosphorus acid amides proceed in a more complex manner.[68,69] Both *N*- and *P*-substitution products are formed, the sulphonyl group also being substituted in a number of instances after the substitution of the bromine atom. The stereochemistry on the whole corresponds to the formation of the less sterically strained *E*-isomers, but it has been established by special investigations (EPR and $^{31}P$ CINP) that these reactions proceed via a one-electron transfer mechanism[70] and cannot therefore be interpreted unambiguously within the framework of the direct vinyl substitution mechanism (2) with participation of an intermediate zwitter-ion. It has been shown in relation to dimethyl sulphide that *S*-nucleophiles react with β-bromovinyl sulphones only under severe conditions, forming methylthiosulphonylmethylenes with retention of configuration and via the following mechanism:[65,66]

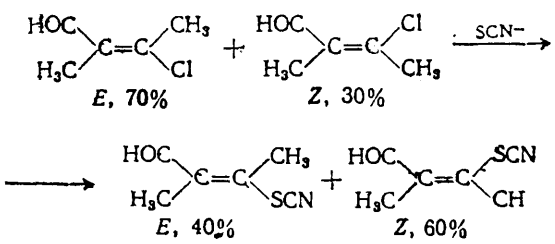


$$ArSO_2CH=CHBr \xrightarrow[100°,50h]{(CH_3)_2S} ArSO_2CH=\overset{+}{C}HS(CH_3)_2\,Br^- \xrightarrow{(CH_3)_2S} \rightarrow ArSO_2CH=CHSCH_3 + (CH_3)_3\overset{+}{S}Br^-.$$

In the presence of more than two substituents at the double bond (in the case of two protons the configuration can be readily determined from the spin–spin coupling constant $^3J_{H-H}$), the question of the unambiguous assignment of the configurations of the substrates and products when the stereochemistry of $S_NVin$ reactions is considered proves to be of fundamental importance. This is well illustrated in relation to a study[71] where the substitution of chlorine in the *Z*- and *E*-isomers of 3-chloro-2-phenylpropenonitrile under the influence of various nucleophiles ($ArS^-$, $C_2H_5O^-$, $N_3^-$, $PhO^-$, piperidine, and morpholine) was investigated:

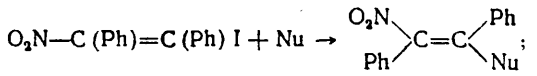
The authors[71] concluded that the substitution proceeds with retention of configuration of the nucleophile anions, while in the case of amines only one isomer is formed (regardless of the configuration of the substrate), to which the structure of the *E*-isomer was attributed. However, subsequently these data were disproved by other investigators,[72] who claimed that Rappoport and Topol[71] incorrectly assigned the structures of the products of the substitution of chlorine by the ethoxy-group, because comparison of the $^1H$ NMR spectra of the *Z*- and *E*-isomers with spectra calculated in accordance with an additive scheme leads to the opposite assignment. Subsequently it was concluded[72] that reactions with amines involve the initial formation of products with retention of configuration, one of which then rearranges to the more stable product. In contrast to the conclusions reached by Rappoport and Topol,[71] the structure of the *Z*-isomer was attributed to the latter. In the controversy which followed[73] Rappoport agreed with some of the evidence concerning the structure of the substitution product and at the same time pointed out that many discrepancies are associated with the different experimental conditions used by himself[71] and by Le Guillanton and Cariou[72] (concentration, reactant ratio, temperature, etc.) and also dealt critically with the suitability of individual methods for the determination of the structure of compounds, including the stereochemical result of the substitution reaction as one of the criteria of the structure of the initial compound.

Until recently, little was known about the $S_N$Vin reactions with participation of *C*-nucleophiles, i.e. carbanions.[1] Only in recent years have studies been published in which the nucleophilic reactivities of a large series of carbanions were investigated quantitatively in relation to the substitution of fluorine in αββ-trifluorostyrene.[74-76] The reaction takes place stereoselectively with substitution of one fluorine atom:



The *trans*-disposition of the fluorine atoms in the substitution product follows unambiguously from the values of $^3J_{F-F}$ in the $^{19}$F NMR spectra (approximately 130 Hz). The substitution of bromine in the *cis*- and *trans*-isomers of β-bromostyrene in its reactions with n-$C_4H_9$Li and n-$C_4H_9$MgBr also proceeds stereospecifically with retention of the configuration.[77]

The reactions of β-halogenovinyl ketones with the soft nucleophile ($PhS^-$) take place with retention of configuration in the initial stage, but the *E*-isomer of the reaction product isomerises at the end of the process to the *Z*-isomer.[78] The causes of this isomerisation are not altogether clear, because *E*-isomers are as a rule more stable. Thus *Z*- and *E*-β-fluoro-*p*-nitrostyrenes react with the same nucleophile ($PhS^-$) to form the *E*-isomer of the substitution product,[79] although in the initial stage under the conditions of kinetic control the *Z*-isomer reacts with retention of the configuration. These compounds react analogously also with $CH_3O^-$, forming *E*-$O_2NC_6H_4SO_2CH=CHOCH_3$.[79] The observed stereochemical differences from the β-chloro- and β-bromo-derivatives have been explained[79] by the longer lifespan of the carbanion in which the leaving group is less nucleophilic ($F^-$).

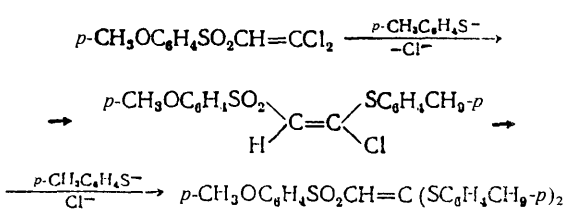


It was noted above (Section II) that, when certain conditions are maintained, stereoconvergence, i.e. the formation of the same mixture of products regardless of the structure of the substrate, can take place but not as a result of post-isomerisation (as happens frequently in reactions with amines or as happened in the study quoted above[78]) but is a consequence of the independent formation of the *Z*- and *E*-isomers from the corresponding conformers of the intermediate carbanion.[80] The number of such examples is small. For "poor" leaving groups (F, OR), this was demonstrated by the studies quoted above,[19,20] while for "satisfactory" leaving groups (Cl, I) stereoconvergence was observed in a series of other investigations.[21,81,82]

The stereoconvergence in substitution reactions with "good" leaving groups is one of the indications of the multistage nature of the $S_N$Vin substitution process[26] and it is therefore useful to examine these cases in greater detail. Korobov et al.[81] (whose study was the first where stereoconvergence was noted for a "good" leaving group despite Rappoport's claims[82]) investigated the following reaction:

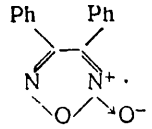
A mixture of products of the same composition is also obtained from the individual isomers and it was shown specially that the *Z*- and *E*-isomers are not interconverted under the reaction conditions.[83]

A highly reactive system with a "good" leaving group yields only one product# in reactions with a whole series of nucleophiles:[21]



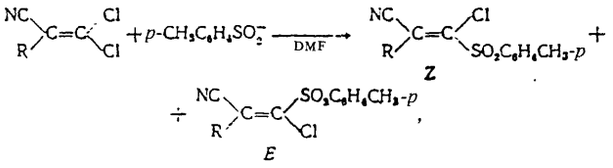
Nu = $SCN^-$, *p*-$C_6H_4S^-$, $N_3^-$, piperidine, or morpholine.

In the somewhat less reactive *Z*- and *E*-$CH_3OCOC(CN)=C(Cl)C_6H_4NO_2$ [82] and *Z*- and *E*-HOC–C(Ph)=C(Ph)Cl [84] systems, the interaction with *p*-$CH_3C_6H_4S^-$, $CH_3O^-$, *p*-$CH_3C_6H_4O^-$, and $Cl^-$ proceeds with either complete or partial stereoconvergence. The aim of the authors of the above studies[82,84] was essentially to find the frontier region between moderately activated substrates, reacting with retention of configuration, and more activated substrates giving rise to complete stereoconvergence.[21] The structure of the isomers put forward in the above communications[82,84] arouses no doubts (in contrast to those in Refs. 71–73), because X-ray diffraction analysis was carried out on individual isomers.



The use of an aprotic dipolar solvent [hexamethylphosphoramide (HMP)] makes it possible to carry out smoothly $S_N$Vin substitution reactions in usually inert unsubstituted chloroalkenes,[62,85] vinyl sulphides, and vinyl selenides.[63,64] It has been shown that, in conformity with the general rule, they react with thiolate and selenolate anions with retention of configuration. It may be that in this case the above result is a consequence of a synchronous substitution process, because this process is most likely to operate precisely in weakly activated or non-activated substrates with "good" leaving groups.[26] The study of the "effect of the element" (see Section IV) can provide an answer to this question, because the magnitude of the "effect of the element" is the most apt criterion for the choice between the synchronous and multistage processes.[20]

Systems with two geminal leaving groups substituted in succession have been investigated and it has been shown that, in the reaction



the intermediate 2-chloro-1-*p*-methoxybenzenesulphonyl-2-*p*-tolylthioethylene has the structure of the *E*-isomer.[86] Bearing in mind the general rule governing the retention of configuration in $S_N$Vin reactions, one may conclude that the chlorine atom in the *trans*-position relative to the

#In the case where $Nu = N_3^-$ the product is

α-hydrogen atom is very mobile. This conclusion agrees with the relative reactivities of the *Z*- and *E*-isomers of vinyl halides in $S_NVin$ reactions; overall, the *Z*-isomers are more reactive.[1] In the presence of substituents in the α-position the stereospecificity breaks down:[87]

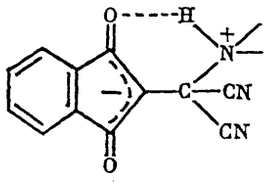
The *Z* : *E* ratios are 100 : 0, 90 : 10, and 70 : 30 for R = $C_6H_5$, $CH_3$, and t-$C_4H_9$ respectively.[87] The preferential formation of the *Z*-isomer may be associated with the increased energy of the conformer of the carbanion leading to the *E*-isomer owing to the repulsion of the like dipoles (S–O and C–N); the appreciable amount of the *E*-isomer in the case of R = t-$C_4H_9$ is evidently to be explained by the smaller steric strain in the carbanion in the interaction of the $(CH_3)_3C$ and Cl groups than in the interaction of the $(CH_3C)_3C$ and *p*-$CH_3C_4H_4SO_2$ groups.

Despite the fact that the attack by the nucleophile in the plane of the molecule is as a rule less favourable in $S_NVin$ reactions owing to both electronic and steric factors, it can apparently occur in certain special cases (see Section II). Thus the retention of both the configuration of the double bond and the chirality of the substituent in a sterically strained system containing a chiral constituent is believed[88] to be explained best within the framework of the hypothesis that the nucleophile attacks in the molecular plane, since attack in the plane of the π-bond should lead to partial or total loss of chirality.

## IV. QUANTITATIVE DESCRIPTION OF REACTIVITY

### 1. The Influence of the Nature of the Activated Group

Since the occurrence of $S_NVin$ reactions via the mechanism (2) involves the formation of an intermediate carbanion, the increase of the electron-accepting strength of the substituent in the β-position relative to the leaving group evidently accelerates the reaction. In general, this rule is observed but it has not been possible to construct a universal reactivity series for such groups. This is due in the first place to the fact that the quantitative data for the reactivity of systems with different activating groups include data for interaction with various nucleophiles. Thus, assuming that the relative activating capacities of the groups depend only slightly on the nature of the nucleophile, Rappoport[1] proposed the following series:



$$2,4\text{-}(NO_2)_2C_6H_3 > PhCO > C_2H_5CO > PhSO_2 > CN > COOC_2H_5 > > PhSO > p\text{-}NO_2C_6H_4 > PhS \gg Cl.$$

However, more detailed analysis using the data of other studies[54,55] yields another series for the reactions of $RO^-$:

$$CN > SO_2 > CO > SO > 2,4\text{-}(NO_2)_2C_6H_3 > COOR > p\text{-}NO_2C_6H_4.$$

Approximately the same kind of series holds also for the soft nucleophile $PhS^-$, although the reactions can proceed via different mechanisms [mechanism (2) for $PhS^-$ and mechanism (3) for $RO^-$]. The relative reactivity may depend on the structure of the substrate. Thus the *E*-isomer of β-bromo-2,4-dinitrostyrene reacts with $PhS^-$ faster than the *E*-isomer of β-bromovinyl sulphone while the opposite relation holds for the *Z*-isomers.[1]

The reactivity series has been derived in a review[89] from data for the direction of nucleophilic attack on the double bond activated by different groups in CHX = CHY: $NO_2$ > COR > COOR > $PO(OR)_2$. On the grounds of these considerations, the data of Rappoport and Ladkani[90] for addition to $(RCO)_2C = C(CN)_2$ yield the relation RCO > CN, which is confirmed by calculations by the extended Hückel method,[91] but it does not agree with many experimental data. Evidently the nucleophilic attack in αα-diacyl-ββ-dicyanoethylenes on the carbon atom linked to the cyano-groups, although the latter delocalise the negative charge more effectively than the carbonyl groups, can be explained by the fact that the result is not determined solely by the stability of the final carbanion, and in the given instance not even to a major extent, but is determined by the electrophilicity of the carbon atom in the initial state. Furthermore, in the systems investigated by Rappoport and Ladkani[90] the attack of the nucleophile on the carbon atom of the dicyanomethylene group promotes the formation of an intramolecular hydrogen bond and the aromatic character of the anion formed:

Mainly on the basis of the results of their own studies of reactions involving amines,[92–99] Popov et al.[99] proposed the following sequence of groups in terms of their activating strength:

The activating capacity of the nitrogen-group is estimated by comparing the activity data for α-chloro-β-nitrostyrene *E*-$PhCCl = CHNO_2$ and 1,1-dicyano-2-chloro-2-(*p*-dimethylaminophenyl)ethylene $(CH_3)_2NC_6H_4CCl = C(CN)_2$.[100] The authors estimated the ratio $k(PhCCl = CHNO_2)/k[PhCCl = C(CN)_2]$ as 0.22 in terms of the value of ρ for the substituents in the aryl group, which is 1.5, i.e. the electron-accepting properties of one nitro-group are only 4–5 times weaker than those of two cyano-groups. In the case of complete additivity (which naturally does not obtain but such an assumption is acceptable for qualitative conclusion in the given instance[101,102]), the ratio $k(NO_2)/k(CN) = 0.22k(PhCCl = CHCN)/k(PhCCl = CH_2)$ and, since the introduction of the cyano-group in the β-position accelerates the reaction by several orders of magnitude, it is evident that $k(NO_2) > k(CN)$.

Since the first stage of the $S_NVin$ reactions, namely addition to the $sp^2$-carbon atom, is analogous to the first stage in addition to the $Ad_N$ type to electrophiles, a study[103] where the reactivity series has been formulated for $Ad_N$ reactions is of special interest:

$$NO_2 > PhCO > CH_3CO > (C_4H_9)_3P^+ > RSO_2 > (CH_3)_2NSO_2 > > COOCH_3 > CN > \text{4-pyridyl} > PO(OR)_2 > CONHR.$$

In the above series the $COOCH_3$ and CN groups can change places depending on the nucleophile. The following series

follows from the authors' own data:[103]

$$PhCO > PhSO_3 > CHO > CH_3CO > PhCOO > p\text{-}CH_3C_6H_4SO_2 > > CH_3COO > CN > CONH_2 > PO(OR)_2 > p\text{-}O_2NC_6H_4$$

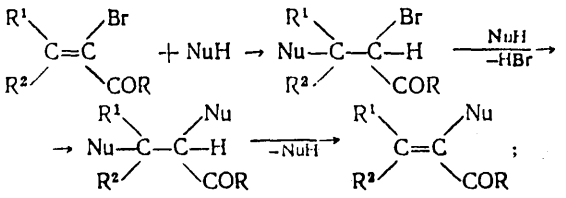
After combining all the available data, it is possible to establish the following expanded reactivity series for electron-accepting groups:

$$NO_2 > PhCO > PhSO_3 > CHO > CH_3CO > (C_4H_9)_3P^+ > PhCOO > > p\text{-}CH_3C_6H_4SO_2 > CN > (CH_3)_2NSO_2 > COOCH_3 > PhSO > > 4\text{-pyridyl} > PO(OCH_2CH_2Cl)_2 > CONH_2 > PO(OC_2H_5)_2 > > CONHR > p\text{-}O_2NC_6H_4 > PhS > Cl.$$

It is of interest that extrapolation of the temperature variations for the few available kinetic data at 200 °C yields a different sequence:

$$PhSO_3 > CH_3CO > PhCO > CHO > PhCOO > p\text{-}CH_3C_6H_4SO_2 > > CN > CH_3COO > CONH_2 > PO(OC_2H_5)_2,$$

i.e. certain members of the series have changed places.



According to Fischer and Jentzch,[104] the dimethyliminomethylene group $(CH_3)_2\overset{+}{N}=CH-$ is a powerful activating group, greatly superior to the carbonyl group, especially in reactions with mild nucleophiles.

The above analysis suggests that the available insufficiently long relative reactivity series for substrates makes it possible to describe satisfactorily the reactivity within the framework of the direct substitution mechanism (2), but their predictive power is fairly weak owing to their dependence on the nature of the nucleophile, the solvent, temperature, etc.

The influence of the second activating group in the β-position with respect to the leaving group is extremely difficult to estimate from the existing investigations, because there are no reactivity data for mono- and di-activated compounds with the same nucleophiles under identical conditions. It is known only that, whereas substrates with a single activating group CN or COOR react solely with aliphatic amines,[49,71] the analogous substrates with two such groups react smoothly with the much less basic anilines.[101] Apparently the electronic influence of two activating groups is to a first approximation additive, provided that the conjugation of each with the double bond does not break down (analogously to the non-uniform variation of the acidities of the substituted methanes with different numbers of CN and $NO_2$ groups[105]). It is noteworthy that the activating capacity of the group X does not always vary in parallel with the $pK_a$ for the corresponding acid $CH_3X$, but a correlation with the rate of ionisation of these acids is sometimes observed.[106]

If the activating group and the nucleophile in the intermediate carbanion are attached to the same carbon atom, then its influence is much weaker, since the effective stabilisation of the carbanion via the conjugation mechanism is impossible, and furthermore, additional steric hindrance arises in the transition state. These two effects can overlap the activating influence of the group. Thus the introduction of the chlorine atom in the α-position in Z-β-chlorovinyl phenyl sulphone accelerates the reaction with $CH_3O^-$ by a factor of 1.3 and with $PhS^-$ by a factor of 1.4,[1] while the introduction of a chlorine atom in the β-position retards the reaction with $CH_3O^-$ by a factor of 1.5 [107] and with $PhS^-$ by a factor of 4.4.[108]

On the other hand, if the activating group is separated from the double bond by the methylene bridge, as in $CH_2=CHal-CH_2CN$, $CH_2=CHal-CH_2COOC_2H_5$,[109] $CH_2=CCl-CH_2SO_2Ph$,[110] or $CH_2=CBr-CH_2PO(OC_2H_5)_2$,[111] then the reaction proceeds via the formation of the allyl anion and then the intermediate allene and not only with hard *O*-nucleophiles but also with soft *S*-nucleophiles.[109] If the electron-accepting group is linked directly to the double bond, as in $R^1R^2C=CBr-COR$,[112] then it polarises the C=C bond in such a way that the Michael addition of the nucleophile takes place initially and then the halogen in the saturated adduct is readily substituted via a mechanism of the $S_N2$ type as in α-halogenoketones. Finally the elimination of the conjugate acid of the nucleophile affords the substitution product:[112]

(6)

The last stage of reaction (6) can yield two different products depending on which of the nucleophile residues is split off. The above example corresponds to regiospecific substitution with retention of the configuration, but there exist examples of the formation of both possible products[113] and of the inversion of regioselectivity.[114]

Finally, the methyl groups in the α- and β-positions in the molecule reduce its reactivity, the effect in the β-position reflecting the electron-donating and steric influence of the $CH_3$ group, while the introduction of the substituent in the α-position rules out in addition the occurrence of reaction via the elimination–addition mechanism (3). In certain cases this can reduce the rate by 4–5 orders of magnitude.[115]

## 2. The Influence of the Nucleophile

It has been noted in a review[1] that the nucleophilicity sequence in $S_NVin$ reactions differs from that for $S_N2$ reactions involving an $sp^2$-carbon atom, but is close to the nucleophilicity series for $S_NAr$ reactions. The corresponding nucleophilicity series are given below:

$PhCH_2S^- > p\text{-}CH_3C_6H_4S^- >$ piperidine $> PhS^- > CH_3O^- > n\text{-}(C_4H_9)_2NH >$ cyclohexylamine $> N_3^- > I^-, Br^-, Cl^-$ (Refs.1, 116) and

$ArS^- > C_2H_5O^-$ > piperidine $> PhO^-$ > morpholine $> N_3^-$ (Ref.71)

for $S_NVin$ reactions,

$$CN^- > HS^- > I^- > SCN^- > \text{aniline} > HO^- > N_3^- > Br^- > PhO^- > Cl^- > F^- \quad \text{(Ref.117)}$$

for $S_N2$ reactions, and

$$PhS^- > CH_3O^- > PhO^- > HO^- > SCN^- > \text{piperidine} > \text{aniline} > I^- > Br^- > Cl^- \quad \text{(Refs.118-120)}$$

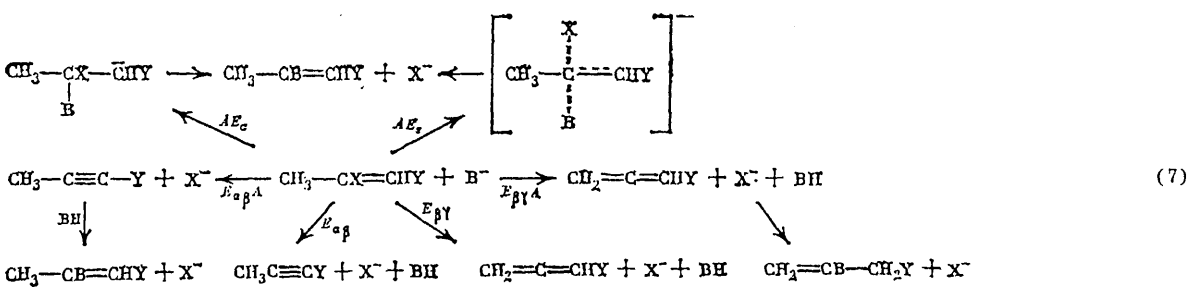
for $S_NAr$ reactions.

It is noteworthy that the above series can vary for different substrates (particularly in conformity with Pearson's "symbiosis" effect), and in addition have been obtained for proton-donating solvents. Thus the inversion of the series for $S_NAr$ reactions has been demonstrated in aprotic dipolar solvents:[121,122] $F^- \gg SCN^- > Cl^- > Br^- > I^-$. Even for a single solvent, the relative nucleophilicities can vary fairly widely for slight changes in the substrate structure. Thus piperidine reacts with 1-benzoyl-2-chloro-1-phenylethylene in DMF faster by an order of magnitude than

sodium azide, with 1-benzoyl-2-chloro-1-methylethylene the two nucleophiles react almost identically, while with 1-acetyl-2-chlorocyclopentene the azide ion reacts twelve times faster than piperidine.[123] An analogous behaviour has been observed in ethanol.

Another possibility for a sharp change in the nucleophilicity sequence is associated with the occurrence of the reaction via different mechanisms [mechanisms (2) and (3)]. This is shown particularly clearly for the $PhS^-/CH_3O^-$ pair. $PhS^-$ is usually more reactive than $CH_3O^-$ in reactions via the direct substitution mechanism, for example in reactions with the *Z*- and *E*-isomers of $PhSO_2CH=CHCl$.[1] The reaction with the *Z*-isomer of the bromo-derivative, from which HBr is very readily split off, involves the reversal of this ratio: $k(CH_3O^-) > k(PhS^-)$. For the *E*-isomer of the bromo-derivative, the $E\text{-}Ad_N$ mechanism is less probable and the ratio $k(PhS^-) > k(CH_3O^-)$ is valid. The introduction of the methyl group in the α-position relative to the sulphonyl group rules out the possibility of the elimination of HBr, so that we also have $k(PhS^-) > k(CH_3O^-)$ for $p\text{-}O_2NC_6H_4NO_2.C(CH_3)=CHBr$.[1]

However, despite the lack of a universal scale, the difference between the nucleophilicity series is too great to be attributed to the effects of the medium, non-additivity, etc. The causes of the difference may be more far-reaching and the main cause is apparently the difference in the character and energies of the frontier orbitals. The lowest unoccupied molecular orbital (LUMO) of the substrate in the $S_NVin$ reactions is a π* orbital and its energy is much lower than that of the σ* orbital (the LUMO of the substrate in $S_N2$ reactions). When the highest occupied molecular orbital (HOMO) of the nucleophile interacts with the σ* orbital of the electrophile-substrate, the nucleophilic reactivity is described quantitatively by the Swain–Scott equation.[117] On the other hand, when the LUMO of the electrophile is an orbital of the π* type, for example in carbanions, the Swain–Scott equation does not hold and Ritchie[124] proposed a new $N_+$ nucleophilicity scale in relation to the reactions of nucleophiles with the carbonium ion of the Malachite Green dye. The applicability of this scale to the reactions of nucleophiles with different π-systems, namely carbonyl-containing,[125] aromatic,[126] and electrophilic olefins,[127] was demonstrated subsequently. Consequently the nucleophilic reactivity of the anions in the $S_NVin$ reactions of activated olefins with a low-lying π* orbital should also be described by Ritchie's equation; indeed the rate of reaction of nucleophile anions with substituted 9-methylenefluorenes $R^1R^2C=CXY$ ($R^1$, $R^2$ = fluorenyl; X, Y = H, CN, or $NO_2$) increases in the sequence $CN^- < OH^- < N_3^-$, which is inconsistent with the Swain–Scott scale and is characteristic of Ritchie's scale.[106]



The influence of the nature of the nucleophile on the mechanism of the $S_NVin$ reactions is described satisfactorily in terms of the principle of hard and soft acids and bases. The two electrophilic centres in the substrate molecule, the proton in the α-position and the β-carbon atom§, tend to react respectively with hard and soft nucleophiles. The criteria used to assign the reaction to a particular mechanism are the isotope exchange when the reaction is carried out in deuteriated solvents, the kinetic isotope effect, and the sign of the activation entropy for the reaction. The occurrence of isotope exchange is an essential but not a sufficient criterion of the occurrence of the reaction via the $E\text{-}Ad_N$ mechanism; on the other hand, the positive value of $\Delta S^{\neq}$ indicates reliably the operation of the $E\text{-}Ad_N$ mechanism. The mechanisms (2) and (3) sometimes operate in parallel and the sign of $\Delta S^{\neq}$ then indicates the predominance of one or other mechanism. Only a few examples of the occurrence of the $S_NVin$ reaction with $\Delta S^{\neq} > 0$ have been noted in Rappoport's review;[1] they all take place with participation of $CH_3O^-$ or $C_2H_5O^-$ and only for the *Z*-isomers, i.e. for the *trans*-orientation of the α-hydrogen atom and of the leaving group in the β-position.

In the presence of the methyl group in the β-position, there is a possibility of βγ-elimination with formation of an allene:[44]

$$CH_3\text{—}CX{=}CH\text{—}Y\text{—}\begin{cases}\xrightarrow{RO^-,\,(Y=COOR)} CH_2{=}C{=}CH\text{—}Y \xrightarrow{ROH} CH_3\text{—}C(OR){=}CH\text{—}COOR;\\ \xrightarrow[RS^-,\,(X=Br,\,Y=CN)]{} CH_3\text{—}C{\equiv}C\text{—}CN.\end{cases}$$

As can be seen from the above scheme the elimination can also take place under the influence of the soft nucleophiles $RS^-$.[44] β-Halogenoacrylate esters $C_2H_5OCO\text{—}CH=CHX$ react with $RO^-$ to form a substitution product and the acetylenic ester $C_2H_5OCO\text{—}C\equiv CH$, the content of the acetylene increasing in the sequence X = Cl, Br, and I.[54] The corresponding β-halogenoacrylonitriles also react with $RO^-$ via the $E\text{-}Ad_N$ mechanism, which is indicated by the positive values of $\Delta S^{\neq}$ for the *Z*-isomers, the low negative values of $\Delta S^{\neq}$ for the *E*-isomers, and the high (up to $10^3$) values of the ratio $k_Z/k_E$.[55]

The study of the interaction of β-halogenocrotonates and β-halogenocrotononitriles with various *O*-, *N*-, and *S*-nucleophiles enabled Chalchat and co-workers[49,50,53] to formulate the following general reaction scheme:[50]

(7)

§ The involvement of a halogen atom in the α-position at the electrophilic centre is considered below (Section IV).

The $E_{\alpha\beta}$, $E_{\beta\gamma}$, $E_{\alpha\beta}A$, and $E_{\beta\gamma}A$ mechanisms in Scheme (7) are readily distinguishable even in terms of the structure of the products involved. As regards the mechanisms $AE_C$ (via an intermediate carbanion) and $AE_S$ [synchronous mechanism via the transition state illustrated in Scheme (7)], the authors[50] draw a distinction between them using the analysis of the stereochemistry of the substitution process. If the reaction is stereospecific with retention of configuration, a synchronous process is implied, for which the retention of configuration is the only natural result (see Sections II and III above) but, when a mixture of isomers is produced, the reaction is believed to proceed via a stable intermediate carbanion, whereupon the stereochemical outcome is determined by the relative contributions of the processes involving inversion at the carbanionic centre, rotation in the anion, and the elimination of the leaving group.

On this basis, it was concluded that β-fluorocrotononitriles and β-fluorocrotonates react with almost all *O*-, *N*-, and *S*-nucleophiles via the $AE_C$ mechanism, elimination of the $E_{\alpha\beta}$ or $E_{\beta\gamma}$ type occurring only for the highly basic and bulky t-$C_4H_9O^-$. Bromides behave analogously, although in this case the reaction does not stop at the elimination stage and proceeds via the $E_{\alpha\beta}A$ mechanism for the *Z*-isomers and via the $E_{\beta\gamma}A$ mechanism for the *E*-isomers.[50] Iodides usually react via the $E_{\alpha\beta}$ or $E_{\beta\gamma}$ mechanism ($E_{\beta\gamma}$ elimination with formation of allenes is characteristic of the *E*-isomers), but reactions with soft nucleophiles ($PhS^-$, ethyleneimine) involve substitution via the $AE_S$ mechanism. For α-methylated substrates $CH_3CX=C(CH_3)Y$, $E_{\alpha\beta}$ elimination is impossible and there is a smooth shift from the $E_{\beta\gamma}$ mechanism to the *AE* mechanism on passing from hard ($RO^-$) to soft ($RS^-$) nucleophiles.[53] It is noteworthy that the probability of the occurrence of a synchronous process has been shown[26] to be low and so far there have been no reliable examples. The $AE_S$ and $AE_C$ mechanisms presented in Scheme 7 should therefore be treated as carbanionic mechanisms with short and long lifetimes of the carbanion respectively.

### 3. The Influence of the Leaving Group (the "Element Effect")

The influence of the leaving group is one of the most interesting and informative effects in the study of the mechanisms of $S_NVin$ reactions. Most of the processes associated with this effect were examined in detail previously[1] and in the present Section we shall therefore describe briefly the main principles and will present later data which were not included in Rappoport's review.[1]

The influence of the leaving group is frequently called the "element effect", because the majority of the studies have been carried out for halogen-substituted substrates, usually for the Cl/Br pair. The causes of the fundamental importance of the "element effect" consists in the fact that the vinyl substitution process (2) is a two-stage reaction and the influence of the nature of the leaving group on these stages is markedly different. In fact, if the rate of reaction is determined by the first stage, i.e. by the addition of the nucleophile to the β-carbon atom with formation of a carbanion, then it will increase with increasing electronegativity of the halogen atom: $k(I) \leq k(Br) \leq k(Cl) \leq k(F)$. On the other hand, if the abstraction of the leaving group from the carbanion (the second stage) is rate-determining, then the opposite relation should obtain in conformity with the bond strength: $k(F) < k(Cl) < k(Br) < k(I)$. The latter sequence should hold also for a synchronous process with the simultaneous dissociation and formation of bond, as in $S_N2$ reactions at an $sp^3$-hybridised carbon atom.

Many data for the Cl/Br pair were examined in Rappoport's review[1] and only two instances were quoted for F/Cl. The results of later investigations make it possible to analyse the entire series of halogens from F to I. Thus it has been shown for the compounds $CH_3-CX=CH-Y$ (Y = COOR or CN; X = F, Cl, Br, or I) that the rate of reaction with $C_2H_5S^-$ varies in the following manner: $k(Cl) < k(F)$, $k(Br) \cong k(I)$ (Y = CN) and $k(Cl) < k(F)$, $k(Br) \leq k(I)$ (Y = COOR). The data for the *E*-isomers were used, because in this case the distortions introduced by the contribution of the elimination process are minimal.[49] For the reactions of the same compounds with t-$C_4H_9S^-$, the sequence is somewhat different: $k(F) < k(Cl) < k(Br) < k(I)$, which reflects the contribution of the elimination process.[50] Unfortunately the kinetic data for the reaction with $PhS^-$, which is uncomplicated by the contribution of the $E$-$Ad_N$ mechanism according to the results of Chalchat,[49] are lacking.

Comparison of the data for the interaction of $CH_3O^-$ and $PhS^-$ with β-fluoro-*p*-nitrostyrene with the corresponding data for the β-chloro- and β-bromo derivatives showed[79] that the ratio $k(F)/k(Cl, Br)$ depends on the nature of the nucleophile and amounts to only about 3 for the soft anion $CH_2S^-$. An analogy has been drawn[79] with $S_NAr$ reactions,[128] where this phenomenon has been attributed to Pearson's "symbiosis effect", i.e. to the tendency by substrates containing heavy polarisable leaving groups to bind in the transition state to more polarisable nucleophiles. This has been confirmed by data[129] indicating a decrease of the ratio $k(F)/k(Cl)$ in the series $RO^-$, $R_3N$, $RS^-$, i.e. with increase of the "softness" of the nucleophile, for the reactions of $Ar_2C=CHX$ (X = F or Cl) in DMF. Hence it was concluded that London dispersion forces play a significant role in determing the "effect of the element".

Another aspect of the "element effect" is examined in relation to the reaction of 1,1-dicyano-2-halogeno-2-(*p*-dimethylaminophenyl)ethylenes with anilines in acetonitrile[130] and alcohols.[131] Very low ratios $k(F)/k(Cl)$ (from 0.71 to 3.05) were observed in all the media in contrast to the normally high (approximately $10^2$) values of this parameter. This has been explained by the fact that $k_{exp} = (k_1/k_{-1})k_2$, where $k_1$ is the rate constant for the formation of the zwitter-ion, $k_{-1}$ the rate constant for its decomposition into the initial compounds, and $k_2$ the rate constant for the abstraction of the leaving group from the zwitter-ion. The "element effect" is high ($\gg 1$) for $k_1$, amounts to approximately 1 for $k_{-1}$, and is very small ($\ll 1$) only for $k_2$, because $k_2$ refers to the C–Hal bond dissociation stage (probably, by analogy with reactions of the $S_N1$ type, the "element effect" for $k_2$ amounts to $10^{-2}$–$10^{-6}$).

If the substitution proceeds via the carbanionic mechanism (2), then the "element effect" should not differ sharply for the *Z*- and *E*-isomers of the substrate. On the other hand, for reactions via the $E$-$Ad_N$ (3) mechanism, the dependence on the nature of the leaving group is qualitatively different, because the *Z*-isomers split off HHal much more readily than the *E*-isomers. Indeed, for the esters $C_2H_5OCO-CH=CHX$ (X = Cl, Br, or I), the variation of the rate of reaction with $C_2H_5O^-$ in ethanol for the *Z*-isomers is in the sequence $k(Cl) \ll k(Br) \ll k(I)$, whereas for the *E*-isomers we have $k(I) < k(Cl) \lesssim k(Br)$.[54] For the reactions of the same esters with $C_2H_5S^-$, the "element effect" is much weaker and is in the range 1–2.[54] When the methyl group is introduced in the α-position, the $E$-$Ad_N$ mechanism is ruled out and the "element effect" is close to unity [$k(Br)/k(Cl) = 1.3$].[53] β-Halogenoacrylonitriles $CN-CH=CHX$ (X = Cl or

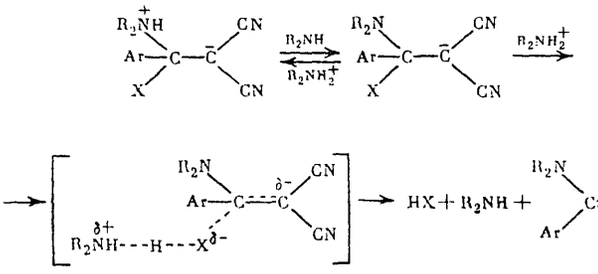
Br) behave analogously: $k(Br)/k(Cl) = 10^3$ for the *Z*-isomers and 0.82 for the *E*-isomers.[55]

Since strong bases react with activated vinyl halides as a rule via the $E\text{-}Ad_N$ mechanism while "soft" bases react via the direct substitution mechanism (2), large values of $k(Br)/k(Cl)$ are to be expected for the reactions with $RO^-$ and values close to unity for the reactions with $RS^-$. The experimental ratio $k(Br)/k(Cl)$ for ββ-dihalogenovinyl sulphones $ArSO_2CH = CX_2$ (X = Cl or Br) amounts to $10^2$–$10^3$ for the reaction with $CH_3O^-$ and to 1.7–3.3 for the reaction with $ArS^-$.[132]

Values of the "element effect" $k(Br)/k(Cl)$ close to unity (from 0.6 to 1.2), i.e. indicating that the C–Hal bond is not involved in the rate-limiting step, have been obtained for the reaction of $Ar_2C=CHX$ with $ArS^-$ in DMF,[61] but, in the reaction involving the exchange of the halogen X for $^{36}Cl$ under the influence of $Li^{36}Cl$ in DMF, the quantity $k(Br)/k(Cl)$ is much higher (5.1–7.6) and the chloride anion is much less reactive than $ArS^-$ (by 9–10 orders of magnitude).[133]

For 2-halogenovinyl ketones $ArCOCH=CHX$ (X = Cl or Br), the "element effect" has been studied for reactions with both anions[78] and with a wide range of amines.[134] In the case of $PhS^-$, the ratio $k(Br)/k(Cl)$ for the *Z*- and *E*-isomers is in the range 1.7–2.0, while in the reaction of the *Z*-isomer with $CH_3O^-$ a greater "element effect" is observed (approximately 47); for the *E*-isomer, the effect is less than unity (0.64). The high value for the *Z*-isomer is associated with the contribution by the $E\text{-}Ad_N$ mechanism, which has been confirmed by the positive activation entropy ($\Delta S^{\neq} > 0$) [78] and the ratio $k(Br)/k(Cl) < 1$ for the *E*-isomer is evidently caused by the "symbiosis effect" mentioned above. In the reaction of *E*-$PhCOCH=CHX$ with amines,[134] the "element effect" is hardly manifested [$k(Br)/k(Cl) = 0.88$–$1.23$].

The decrease of the ratio $k(Br)/k(Cl)$ with increase of solvent polarity has been demonstrated for the reaction of $p\text{-}O_2NC_6H_4SO_2CH=CHBr$ with piperidine[97] (by comparison with data for the chloro-derivative[135,136]). Hence, it was concluded that in less polar solvents, where the "element effect" is a maximum, the transition state is more "product-like", i.e. it includes a more extended C–Hal bond.



The influence of the leaving group on the substitution of species exhibiting nucleofugacity other than halogen atoms has been investigated.[101,137–139] The ratios $k(Br)/k(Cl)$ [reaction (8)], $k(OSO_2CH_3)/k(Cl)$ [reaction (9)], and $k(OSO_2C_6H_4Br\text{-}p)/k(OSO_2C_6H_4CH_3\text{-}p$ [reaction (10)] were measured:[101]

$$(CH_3OCO)_2C=CHX + ArNH_2 \rightarrow (CH_3OCO)_2C=CHNHAr + HX; \quad (8)$$
X=Cl, Br;

$$(NC)_2C=CHX + p\text{-}NCC_6H_4NH_2 \rightarrow (NC)_2C=CHNHC_6H_4CN\text{-}p + HX; \quad (9)$$
X=Cl, $OSO_2CH_3$;

$$(C_2H_5OCO)_2C=CXC_6H_4NO\text{-}p + HN\langle\rangle Z \rightarrow (C_2H_5OCO)_2C=C\langle N\langle\rangle Z \text{ (with } C_6H_4NO_2\text{-}p\text{)}; \quad (10)$$
X=$OSO_2C_6H_4CH_3\text{-}p$, $OSO_2C_6H_4Br\text{-}p$; Z=O, $CH_2$.

The observed ratios [$k(Br)/k(Cl) \cong 1$, $k(OSO_2CH_2)/k(Cl) = 1$, and $k(OSO_2C_6H_4Br\text{-}p)/k(OSO_2C_6H_4CH_3\text{-}p) = 1.63$–$1.90$] show that the rate-limiting step in the process is the formation of a bond with the nucleophile without the participation of the leaving group and the ratio $k(OSO_2C_6H_4Br\text{-}p)/k(OSO_2C_6H_4.CH_3\text{-}p) > 1$ is caused by the greater electronegativity of the β-carbon atom owing to the more electron-accepting character of the Br atom compared with the $CH_3$ group. By varying the strength of the activating group and by introducing a bulky substituent in the β-position, it is possible to alter the ratio of the rates of the individual elementary stages, so that $k_{exp}$ will include the rate of dissociation of the bond with the leaving group. Indeed, the following ratios hold for the reaction of $(C_2H_5OCO)_2C=CXC_6H_4NO_2\text{-}p$ with various nucleophiles in different solvents: $k(OSO_2CH_3)/k(Cl) = 10$–$60$, $k(OSO_2C_6H_4CH_3\text{-}p)/k(Cl) = 10$–$30$, and $k(OSO_2C_6H_4Br\text{-}p)/k(OSO_2C_6H_4CH_3\text{-}p) = 1.56$ to 2.85, while $k(Br)/k(Cl) = 0.67$–$1.32$ has been obtained for the reaction of $ArANH_2$ with $(NC)_2C=CXC_6H_4NO_2\text{-}p$ and $E\text{-}CH_3OCOC(CN)=CHX$.[137] The dependence on the nature of the leaving group has been observed in the substitution groups with weak nucleofugacity (F, CN, $C_2H_5O$).[138] The fact that the above groups do indeed show "poor" nucleofugacity has been confirmed by the base catalytic effect—the zwitter-ion formed initially reacts with a second amine molecule, abstracting a proton and forming a carbanion, which reacts in its turn with a third amine molecule:

The following sequence in terms of nucleofugacity has been observed: $C_2H_5O(1) \ll CN(10^4) \ll F(10^7)$,[138] which is close to the sequence based on the variation of the $pK_a$: $C_2H_5OH(16) > HCN(9.3) > HF(3.45)$. In the course of the continuation of these studies, the substitution of the $CF_3CH_2O$ group in 1,1-dicyano-2-(*p*-dimethylaminophenyl)-2-trifluoroethoxyethylene was investigated[139] and it was shown that the rate of substitution of the $CF_3CH_2O$ group is higher by 2–3 orders of magnitude than the rate of substitution of the $C_2H_5O$ group and the ratio $k(CF_3CH_2O)/k(C_2H_5O)$ for the amine-catalysed process is greater by an order of magnitude than for the uncatalysed process. This can be explained by taking into account data[130,131,140] for the dependence of the relative contributions of the catalytic and non-catalytic pathways on the nucleofugacity of the leaving group; evidently, the better the leaving group, the less need for the electrophilic cooperation by the solvent or the conjugate acid of the nucleophile.

One must note that the causes of the catalysis of $S_NVin$ reactions by amines may be various. It was believed for a long time[130,131,137,138] that the zwitter-ion formed in the first stage is rapidly and reversibly deprotonated to a carbanion, which then splits off the leaving group and this last stage is in fact catalysed by the amine. However, it has been shown[141,142] (the same idea has been put forward by Rappoport and Peled[139]) that, under certain conditions, in particular in the presence of strong steric hindrance, the rate-limiting stage may be the deprotonation of the zwitter-ion. Thus, in contrast to the expected diffusion-controlled values of the rate constant ($10^8$–$10^9$ $s^{-1}$), values up to $10^3$ $s^{-1}$ were obtained, i.e. smaller by a factor of approximately $10^6$.[141] In many cases this permits a critical revision of the causes of the catalysis of $S_NVin$ reactions by amines with participation of "poor" leaving groups.[142]

In the only study where the leaving group was varied for a series of substituents (in the sense that it can be described by a single set of σ constants) the substitution of the ArO group in *E*-4-aryloxybut-3-en-2-zones by various *N*- and *S*-nucleophiles was investigated.[143] The reaction proceeds via the direct substitution mechanism and the rate

is determined by the stage involving the addition of the nucleophile to the double bond. The reaction rate increases with enhancement of the electron-accepting strength of the substituent in the benzene ring, as the nucleofugacity of the leaving group increases, but the Hammett constants $\rho$ (the $\sigma$ constants were calculated from data for the ionisation of the corresponding phenols) are very low: 0.11 for the reaction with aminoethanol and 0.14 for the reaction with *N*-acetylcysteine, which also confirms the low degree of dissociation of the ArO...C bond in the transition state.

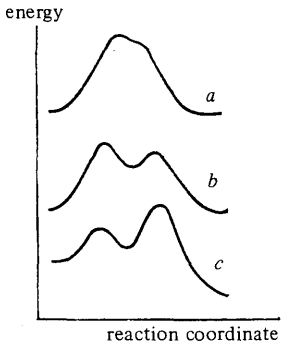


**Figure 6.** The energy profile for nucleophilic vinyl substitution reactions: *a*) one-step mechanism; *b*) two-step mechanism in which attack by the nucleophile is the rate-limiting stage; *c*) two-step mechanism in which the abstraction of the leaving group is the rate-limiting step.

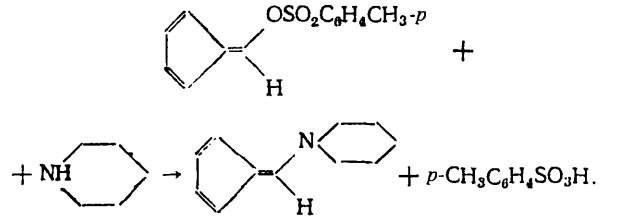
The concept of a variable transition state in $S_N$Vin reactions has been recently put forward and elaborated in detail.[26,144] It is suggested that the position of the transition state and also the presence and structure of the possible intermediates depend greatly on a series of external and internal factors, in the first place on the strength of the activating groups and on the nucleofugacity of the leaving group. We shall examine the overall variation of the "element effect" as a function of the stability of the carbanion. In the limiting case where the carbanion is extremely unstable, it can degenerate into a transition state, and the substitution can proceed as a synchronous process with a high "element effect" $k(Br)/k(Cl) > 1$ (Fig.6, curve *a*). With increase of the stability of the carbanion, so long as $k_{exp} = k_1$ the "element effect" should be approximately 1 (Fig.6, curve *b*). Finally, for very stable carbanions, where $k_{exp} = (k_1/k_{-1})k_2$, the "element effect" should again increase due to $k_2$ (Fig.6, curve c). In order to achieve the last situation, a study has been made[145] of the substitution of a halogen in the most activated system among those investigated kinetically hitherto, namely tricyanovinyl halides. However, the value of the "element effect" $k(Br)/k(Cl)$ found amounted to only 2.4, i.e. did not exceed the usual values. The authors explain the result[145] by the earlier transition state in the reaction involving the abstraction of the leaving group from the carbanion (see, for example, Thomas and Stirling[146]) and concluded that the "element effect" precludes the identification of the rate-determining state—the formation of the carbanion or the abstraction of the leaving group from the latter.



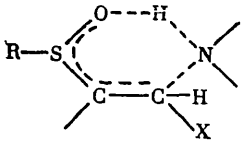
## 4. The Influence of the Solvent

The influence of the solvent on the rates and mechanism of $S_N$Vin reactions has been investigated mainly for reactions with amines. A single study,[123] permitting a comparison of the rates of the reactions of certain β-halogenovinyl ketones with piperidine and the azide ion in ethanol and DMF, is quoted in Rappoport's review.[1] Only a slight acceleration (and sometimes even a retardation) of the reaction with piperidine in DMF compared with ethanol has been observed, the acceleration of the reaction with $N_3^-$ being much greater (by a factor of 4–40). However, a dipolar aprotic solvent does not always accelerate the reaction—the rate of reaction of carbanions with αββ-trifluorostyrene in aprotic dipolar solvents increases as ethanol is added.[147] In this case the solvent influences mainly the solvation of the transition state in which a partial negative charge is transferred largely to fluorine atoms.

The influence of the solvent on $S_N$Vin reactions involving amines has been studied systematically in a series of investigations.[92,95,97,135,136,148–150] Thus the change from polar solvents (*o*-dichlorobenzene, nitrobenzene) to non-polar solvents (n-alkanes) diminishes the rate of reaction of β-halogenovinyl ketones;[92] it is of interest that this retardation is much smaller (by a factor of 4–6) for primary and secondary amines than for tertiary amines (by a factor of $10^3$). This indicates an insignificant increase of the polarity of the transition state compared with the initial state for amines containing a proton in the NH group and the sharp increase of its polarity in the absence of such a proton. The polarity of the zwitter-ion is probably reduced for primary and secondary amines owing to the formation of a hydrogen bond and ultimately the protonation of the carbanionic centre (5); hence the reason for the very sharp difference between the sensitivities to changes in solvent polarity. A monotonic increase in the rates of reaction of β-halogenovinyl sulphones[97,135] and β-bromo-*p*-nitrostyrene[148] with piperidine with increase of the dielectric constant ε has been observed for solvents whose interaction with the reactants is of the type of non-specific solvation. In addition the "element effect" diminishes steadily with increase of ε (see Section IV).

In their analysis of the interaction between substrate structure and polarity of the medium, Litvinenko et al.[136] obtained a non-additive equation reflecting the decrease of the sensitivity to solvent polarity with increasing electrophilicity of the substrate.

A varied series of solvents, including non-polar, polar, aprotic, and dipolar aprotic solvents, has been investigated for the reaction of β-halogenovinylnitrofuran with piperidine.[95,149,150] Naturally it was not possible to isolate any one parameter characterising the influence of solvents of such different nature, but, bearing in mind the possibility of the formation of solvation complexes with different structures, the influence of the acidity in the case of alcohols, the polarisability, the formation of hydrogen bonds with the amine, etc., the authors[95] explained successfully all the observed changes. The influence of solvents on the rate of reaction of piperidine with 6-(toluene-*n*-sulphonyloxy)-fulvene has been accounted for analogously:[151]



The acceleration of the reaction in the series of alcohols $CH_3OH < C_2H_5OH <$ iso-$C_3H_7OH$ is associated with the decrease of the acidity of the alcohol and hence with the increase of the activity of the amine, while the acceleration of the reaction in acetonitrile compared with chloroform is due to the increase of solvent polarity. Comparison of the data of two investigations by Rappoport and Ta-Shma[130,131] shows that the replacement of acetonitrile as the solvent[130] by alcohols[131] in the reactions of 1,1-dicyano-2-(*p*-dimethylaminophenyl)-2-halogenoethylenes with anilines leads to a change in the reaction order with respect to amines. Whereas in acetonitrile the reaction is of second order with respect to the amines where Hal = F and of "almost" first order for Hal = Cl, in alcohols the reaction order with respect to the amine decreases and is more than unity but less than two for fluorine and is unity for chlorine. Since the amine participates in the stage involving the abstraction of the leaving group, evidently an increase in the acidity of the solvent, which competes with the amine at this stage, reduces the order of the reaction with respect to the amine (an analogous decrease of the order with respect to the amine with increasing "proton-donating capacity" of the medium had been known previously for $S_NAr$ reactions[152]). On passing to "poor" leaving groups in the same substrate, the trend persists—the amine-catalysed process involving the abstraction of the leaving group predominates in acetonitrile and the non-catalysed process becomes the main reaction pathway in alcohols.[138]

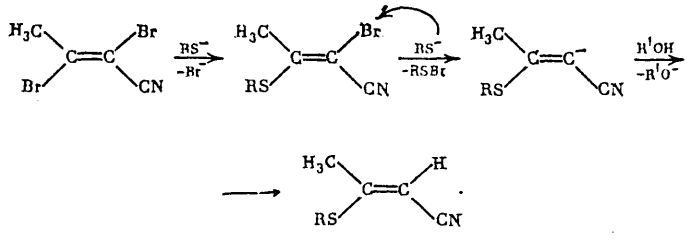
As was to be expected, an increase in the polarity of the medium (the change from the composition $CCl_4 : CH_3CN = 1:1$ to $CCl_4 : CH_3CN = 1:3$) accelerates the reaction. The rate of reaction in various alcohols is determined by the relative acidities and is a maximum for the least acid alcohol.[138] The substitution of various leaving groups by amines in $(C_2H_5OCO)_2C=CXC_6H_4NO_2$ has been investigated in acetonitrile, THF, and ethanol. In most cases the rate of substitution increases in the sequence $C_2H_5OH <$ THF < $CH_3CN$. The changes are small and for the THF/$CH_3CN$ pair can be explained by the changes in the polarity of the medium. The low rate of reaction in ethanol is due to the solvation of the ground state as a result of the formation of the hydrogen bond with amine, which is reflected also in the activation parameters of the reaction. $\Delta H^{\neq}$ increases owing to the necessity to dissociate the intermolecular hydrogen bond and $\Delta S^{\neq}$ becomes less negative, since such dissociation entails the "unfreezing" of some of the degrees of freedom.[137] The reactivity changes analogously in the series THF, $CH_3CN$, DMSO.[139] In all three media electrophilic assistance with the abstraction of the leaving group is lacking and the observed effects are associated with the change in the dielectric constant of the medium.

The accelerating effect of an aprotic dipolar solvent in the reactions of nucleophile-anions should be much stronger than for amines. Indeed, the substitution of the halogen atom in β-halogeno-*p*-nitrostyrenes by sodium methoxide in methanol is accelerated by a factor of $10^4$–$10^6$ after the addition of 85% DMSO. The increase of the DMSO content then entails an increase of the contribution of the HX elimination step.[153]

The transition state in the reactions of activated vinyl halides with amines is either an open-chain zwitter-ion or, in the case of hydrogen bond acceptor groups (CO, SO etc.), a cyclic structure of the type

The transition state of the open-chain zwitter-ionic type is more polar than the initial reactant, while the formation of a hydrogen bond can diminish the polarity of the system. Hence one may expect that in polar media, where the open-chain zwitter-ionic structure is more favourable, the rate of reaction will increase with increase of ε, while in media of low polarity it will decrease. This has not been observed for β-halogenovinyl ketones[92] but for β-halogenovinyl sulphoxides the cyclic structure is more favourable in media with low and moderate polarity, because the SO group is a better hydrogen bond acceptor than the CO group.[154] As a consequence, the rate of the reaction

$$E\text{-}p\text{-}O_2NC_6H_4SO{-}CH{=}CHBr + C_5H_{10}NH \rightarrow E\text{-}p\text{-}O_2NC_6H_4SO{-}CH{=}CH{-}NC_5H_{10} + C_5H_{10}\overset{+}{N}H_2Br^-$$



in aprotic solvents falls with increase of ε from 2 to 9 and then increases as ε increases further to 37.5.[154]

## V. REDUCTION AND REARRANGEMENT PROCESSES IN NUCLEOPHILIC VINYL SUBSTITUTION REACTIONS

All the reactions examined above are initiated by the attack of the nucleophile either on the β-carbon atom [mechanism (2)] or on the α-hydrogen atom [mechanism (3)]. However, in the molecules of vinyl halides, which are the most typical substrates in $S_NVin$ reactions, yet another centre potentially susceptible to attack by the nucleophile is present, namely the halogen atom. The ease of halogenophilic substitution increases with increasing electronegativity of the carbon atom linked to the halogen, i.e. in the sequence $C_{sp^3} < C_{sp^2} < C_{sp}$. Thus halogenophilic substitution in halogenoacetylenes is encountered fairly frequently,[155] while in the series of saturated compounds it is necessary that several electron-accepting groups should be present at the C–Hal bond.[156,157] Vinyl halides occupy an intermediate position and in the absence of an electron-accepting group in the α-position halogenophilic substitution usually does not occur. In the presence of two vicinal halogen atoms at the double bond, the halogen atom occupying the α-position which is geminal in relation to the activating group has a greater tendency to undergo halogenophilic attack. In the reaction of 3-halogeno-2-butenonitriles with thiolates the halogen atom is substituted,[44,49,53] while 2,3-dihalogeno-2-butenonitriles give rise to either disubstitution products or products of substitution with reduction depending on the nature of the halogen:[158]

$$CH_3CX{=}CXCN + RS^- \rightarrow \begin{cases} CH_3C(SR){=}C(SR)CN & (X{=}Cl); \\ CH_3C(SR){=}CHCN & (X{=}Br). \end{cases}$$

2,3-Dihalogenocrotonate esters $CH_3CX=CXCOOC_2H_5$ react analogously.[159] The reduction product is formed in the second reaction as a result of the halogenophilic attack on the bromine atom in the α-position:

When the halogen is substituted by the dimethylcuprate anion in β-halogenostyrenes[144] or in β-bromoacrylic acid derivatives,[40] reduction products are also formed, probably as a result of the halogenophilic attack by $(CH_3)_2Cu^-$. The monohalogenovinyl sulphones $PhSO_2CH=CHBr$ and $PhSO_2CH=CHI$ are formed as cyclic products in the reaction involving the substitution of bromine by iodine in the ββ-dibromovinyl sulphone $PhSO_2CH=CBr_2$ on treatment with sodium iodide.[160] The higher content of β-iodovinyl sulphone compared with β-bromovinyl sulphone is consistent with the relative ease of the halogenophilic attack on the iodine and bromine atoms.

Until recently, the available information about the rearrangements in the $S_NVin$ reactions was restricted to double bond migration reactions in the presence of the $CH_3$ group in the β-position:[49,50,53]

$$Y-CR=CX-CH_3 + NuH \xrightarrow[-HX]{} Y-CR=C(Nu)-CH_3 + Y-CHR-C(Nu)=CH_2, \quad (11)$$

or in the presence of the methylene bridge between the activating group and the double bond (the reverse reaction):[52,109]

$$Y-CH_2-CX=CH_2 + NuH \xrightarrow[-HX]{} Y-CH_2-C(Nu)=CH_2 + Y-CH=C(Nu)-CH_3. \quad (12)$$

The mechanism of both rearrangements consists of the formation of the intermediate allene $Y-CR=C=CH_2$, common to reactions (11) and (12), which can subsequently give rise to both αβ- and βγ-adducts. The product $Y-CHR-C(Nu)=CH_2$ is formed under the conditions of kinetic control owing to the greater stability of the anion $Y-\bar{C}R-C(Nu)=CH_2$ compared with $Y-CR=C(Nu)-\bar{C}H_2$, while the product $Y-CR=C(Nu)CH_3$ is formed under the conditions of thermodynamic control (as a consequence of the conjugation of its double bond with the electron-accepting group).

A new type of rearrangement in nucleophilic vinyl substitution reactions has been discovered recently:[161,162]

$$PhSO_2CH=CX_2 \xrightarrow{\text{KF.18-crown-6}} PhSO_2\diagdown\!\!\diagup C=C\diagup\!\!\diagdown H \quad (13)$$

X = Cl, Br.

In reaction (13) the rearrangement is not accompanied by substitution, but in other cases both processes take place:[132,162,163]

$$RSO_2CH=CCl_2 \xrightarrow[-Cl^-]{I^-} RSO_2CI=CHCl \begin{cases} \xrightarrow{\text{KF.18-crown-6}} RSO_2CI=CHF; \\ \xrightarrow{CH_3E^-,\ CH_3OH} RSO_2CI=CHOCH_3. \end{cases} \quad (14)$$

A rearrangement with substitution under the influence of amines takes place in compounds with similar structures:[164]

$$E\text{-}RSO_2CCl=CClSO_2R + R'NH_2 \longrightarrow (RSO_2)_2C=C(NHR')_2 + \overset{+}{R}NH_3Cl^-. \quad (15)$$

We may note that in 1977 in a review on 1,2-anisotropic rearrangements this type of rearrangement involving ethylenes was classified as "unknown but susceptible to observation" and the author expressed surprise that it had not yet been discovered.[165]

The mechanism of the rearrangement has not been fully elucidated; the first stage of reaction (13) is evidently the deprotonation of dihalogenovinyl sulphone, which is confirmed by the occurrence of the rearrangement under the influence of bases other than $F^-$.[162] The 1,2-migration of the halogen may take place in the vinyl anion formed, leading to the *Z*-isomers of the reaction products on subsequent protonation. In reactions (14) and (15) the vinyl anion can be formed as a result of the halogenophilic attack on the chlorine atom, although the authors[164] have not discussed the mechanism of the observed rearrangement. The prohibition of the 1,2-migration in anions by orbital symmetry is in this case probably proved owing to the contribution by a structure of the carbene type $RSO_2-\ddot{C}=\bar{C}X_2$, which creates an electron deficiency at a formally carbanionic centre—the α-carbon atom. We may note that the contribution of structures of the carbene type is a characteristic feature of vinyl anions and vinyl cations, in contrast to their saturated analogues; it had been considered earlier in the case of vinyl cations in order to account for their anomalous behaviour in rearrangements.[166]

The hypothesis of the 1,2-migration of the nucleophilic group in the anion was put forward[167] to explain the anomalous mode of the elimination reaction:

$$PhCH(OCH_3)-CH_2SO_2R \xrightarrow[-H^+]{} PhCH(OCH_3)-\bar{C}HSO_2R \rightleftarrows \rightleftarrows Ph\bar{C}H-CH(OCH_3)-SO_2R \xrightarrow[-RSO_2^-]{} PhCH=CHOCH_3.$$

The alternative mechanism—the elimination of HX and addition with inversion of the configuration—is unlikely in reaction (13), because the formation of 1,2-dihalogenovinyl sulphones by the addition of HX to the acetylenes $RSO_2C\equiv CX$ conflicts with the rules governing the regioselectivity in addition to activated acetylenes.[155]

--o0o--

Thus the study of the nucleophilic vinyl substitution reactions, which had not been hitherto regarded as an independent class of reactions in any of the modern textbooks of the theoretical principles of organic chemistry (apart from the fundamental monograph by C.K.Ingold, who devoted several pages to them), nowadays constitutes an entirely independent field of study characterised by interesting reactions, specific features, and significant differences from related types of reactions. In assessing the prospects for the development of the research in this field, one may expect that the most interesting results will be obtained in the study of the influence of the leaving group (previously restricted as a rule to halogen atoms), the influence of the solvent (it has been hardly studied for reactions with nucleophile-anions), the competition course halogenophilic processes, and finally, new rearrangements accompanying the nucleophilic vinyl substitution reactions.

# Polyhedral Metallaboranes, Metallacarbaboranes, and Metallaheteroboranes with the $\eta^5$-$C_5H_5Fe$ Fragment in the Polyhedron

L.I.Zakharkin, V.V.Kobak, and G.G. Zhigarëva

The literature data on the synthesis and properties of polyhedral boranes, carbaboranes, and heteroboranes with the $\eta^5$-$C_5H_5Fe$ fragment in the polyhedron are surveyed and described systematically.
The bibliography includes 74 references.

## I. INTRODUCTION

One of the most important discoveries in chemistry during the last twenty years has been the synthesis of metallacarbaboranes—a new class of compounds with a polyhedral structure. The rigorous development of this field of chemistry has led to the preparation of an enormous number of compounds differing in their geometry, the number of vertices, and various combinations of boron and carbon atoms, a heteroatom (usually the atom of a Group II–VI non-transition element), and a transition metal atom. At the present time one can speak of the establishment of a new field of chemistry—the chemistry of polyhedral metallacarbaboranes and metallaboranes. The number of new metallacarbaborane structures is large and increases consistently every year, so that the reviews published in the literature in recent times have either become obsolete, or reflect only individual studies by certain groups of investigators,[1-4] or have been devoted to narrow specialist questions in the chemistry of metallacarbaboranes.[5-9] The present review deals with the structure, methods of synthesis, and certain reactions of polyhedral boranes, carbaboranes, and heteroboranes with the CpFe group† in the polyhedron. These compounds are a link between ferrocene, on the one hand, and *commo*-ferracarbaboranes, on the other. The structural and electronic analogies between ferracarbaboranes and ferrocene derivatives together with the specific features of the compounds themselves may be extremely attractive as objects of study from both theoretical and applied points of view.

The present review deals with the literature between 1965 and 1983.

## II. THE NOMENCLATURE, STRUCTURE, AND TYPES OF BONDING IN POLYHEDRAL BORON-CONTAINING SYSTEMS WITH THE CpFe FRAGMENT IN THE POLYHEDRON

The compounds described cannot always be conveniently named in accordance with IUPAC rules.[10] For this reason, the trivial nomenclature adopted in the literature will also be used. In many cases, names will be omitted and will be replaced by graphical representations of the molecules and their overall formulae.

The structure of ferracarbaboranes, ferraboranes, and ferraheteroboranes with a CpFe fragment is described satisfactorily by the corresponding polyhedra and is determined both by the number of atoms in the polyhedral skeleton and by the type of these atoms. The types of bonding in polyhedral boron-containing systems have been discussed in a number of communications.[8,11-14] The qualitative description of the bonds in a metallacarbaborane polyhedron can be briefly formulated in terms of the following items:

1. All the electrons in the metallacarbaborane molecule are delocalised along the surface of the polyhedron.

2. Each atom in the polyhedron provides three atomic orbitals (AO) for polyhedral bonding. For the boron and carbon atoms and the atoms of other elements in the First Period, there remains one AO for bonding with another ligand (for example, a hydrogen, carbon, etc. atom). After being bound in the polyhedron, the transition metal atoms have six unoccupied AO, which are used for bonding with other ligands ($C_5H_5$, CO, $PR_3$, etc.) or are occupied by electrons not involved in bonding and localised at the metal atom.

3. The number of bonding molecular orbitals (MO) in the closed polyhedra (the *closo*-structure) with $n$ vertices ($n \geq 5$) is $n + 1$. Consequently the number of skeletal electrons is $2n + 2$. The number of occupied MO is $n + 1$.

4. If the number of skeletal electrons in the polyhedron is greater than $2n + 2$, the latter acquires an open structure. When the number of electrons is $2n + 4$ we have the *nido*-structure (one vertex is lacking for the *closo*-structure). When the number of electrons is $2n + 6$, we have the *arachno*-structure (two vertices are lacking for the *closo*-structure). When the number of electrons is $2n + 8$, the *hypho*-structure obtains (three vertices are lacking for the *closo*-structure).

5. The *closo*-, *nido*-, *arachno*-, and *hypho*-metallacarbaboranes can be regarded as electronic analogues of the corresponding carbaboranes, boranes, and also carbaborane and borane anions.

Ferracarbaboranes and ferraboranes with the CpFe fragment in the polyhedron and having the *closo*- and

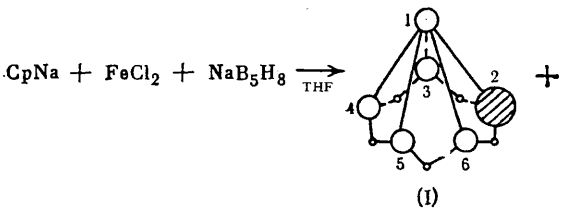
†Here and henceforth $\eta^5$-$C_5H_5Fe$ = CpFe.

*nido*-structures are widely known. The *arachno*- and *hypho*-metallacarbaboranes have been obtained comparatively recently[6] and only a few examples are known. The theory underlying the qualitative treatment of bonding in polyhedral boron- and metal-containing systems has been called the theory of the counting of skeletal electron pairs (TCSEP). It is also known in the literature as Wade's rule. In the course of further development of the chemistry of metallacarbaboranes, compounds have been obtained with a structure which could not be predicted on the basis of the TCSEP.[15-17] In addition, *closo*-ferracarbaboranes with one or several CpFe subunits and a polyhedral skeleton do not have a negative charge for the $d^5$ electronic configuration of the iron atom. Thus the total number of skeletal electrons is less than the number necessary for the *closo*-structure, the number of the missing electrons being equal to the number of the CpFe subunits in the polyhedron. The theory of bonding in the given system was developed further in the review of O'Neill and Wade.[18]

## III. GENERAL METHODS OF SYNTHESIS OF FERRACARBABORANES

Five main methods of synthesis of ferracarbaboranes, which are analogous to the general methods of synthesis of metallacarbaboranes, have been described in the literature:

1. Direct addition of the metal-containing group to the free boron-containing ligand, whereupon the ligand does not undergo structural changes.
2. Direct addition of the metal-containing group to the free boron-containing ligand in which the ligand undergoes marked structural changes.
3. Rearrangement or partial destruction of the metallacarbaborane with formation of a new complex.
4. Introduction of a boron atom into a metal complex with hydrocarbon ligands.
5. Introduction of a carbon atom into a metallaborane complex.



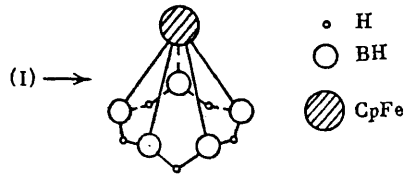
The first method of synthesis is very common. Numerous ferracarbaboranes with planar heterocyclic ligands, for example, borole, diborolin, thiadiborolin, borazine, etc. In addition, ferracarbaboranes with anionic carbaborane ligands, namely $C_2B_9H_{11}^{2-}$, $C_2B_{10}H_{12}^{2-}$, etc., have been obtained by this method. The second method of synthesis is also fairly widely known. One of the examples is the synthesis of ferracarbaboranes by the polyhedral expansion method. The third method of synthesis can be illustrated by various thermal rearrangements of the polyhedral skeleton and also by the polyhedral contraction reaction involving the ferracarbaborane nucleus. The fourth and fifth methods are so far known for only a limited number of examples, but they are undoubtedly promising and their development in the immediate future may be expected.

## IV. COMPOUNDS HAVING (6-11)-VERTEX POLYHEDRAL STRUCTURES

In the systematic description of various polyhedral complexes containing both boron and iron, the latter will be considered in terms of increasing numbers of vertices in the polyhedron.

### 1. 6-Vertex Polyhedra

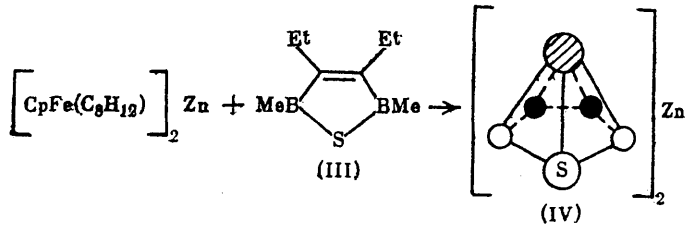
Only a limited number of examples of compounds of this type are known and all the ferracarbaboranes and ferraboranes obtained have the *nido*-structure. The ferraborane $CpFeB_5H_{10}$ (I) was obtained in a low yield together with other products on interaction of CpNa with $FeCl_2$ and $NaB_5H_8$ in THF at 25 °C:[19,20]



(I)

$$+ CpFeB_{10}H_{15} + Cp_2FeB_8H_8 .$$

H BH CpFe

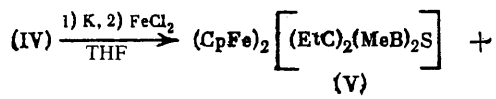


The structure of $Cp_2FeB_8H_8$ has not been established and the structure of $CpFeB_{10}H_{15}$ will be discussed below. On the basis of $^1H$ and $^{11}B$ NMR spectra, a pentagonal-pyramidal structure was assigned to complex (I). On heating in deuteriotoluene, the complex rearranges to the isomeric ferraborane (II), which is a structural analogue of ferrocene:

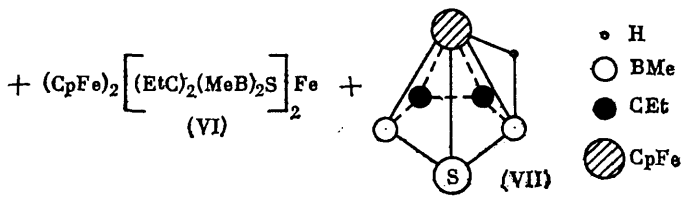
(II)

Like complex (I), the ferraborane (II) is a paramagnetic substance unstable in air.

On refluxing of the zinc salt of $\eta^5$-cyclopentadienyl-$\eta^4$-cycloocta-1,5-dienyliron in hexane with an excess of 3,4-diethyl-2,5-dimethylthiadiborolin (III), the zinc salt of the thiadiborolinyliron complex (IV) is obtained:[21]

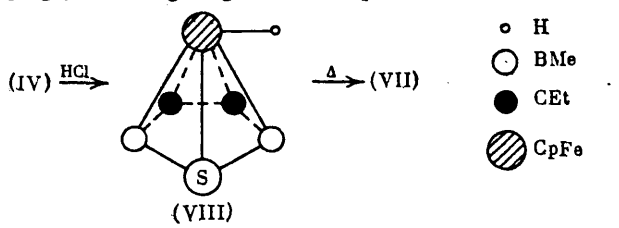


(III) (IV)



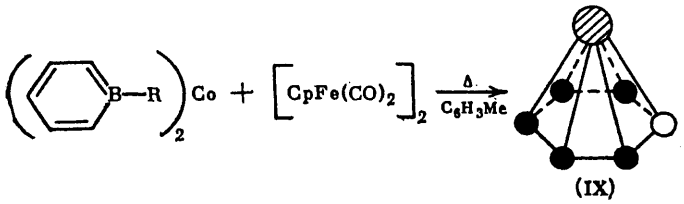
BMe CEt CpFe

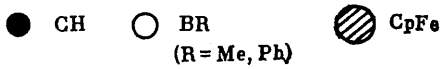
Complex (IV) has 16 skeletal electrons, which are responsible for the *nido*-structure of its pentagonal pyramid#. The interaction of complex (IV) with potassium entails the replacement of the zinc cation by the potassium cation.



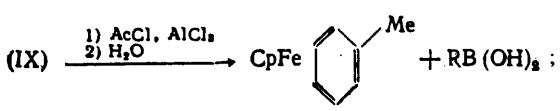
#Here and henceforth the number of skeletal electrons is calculated and its relation with the structure of the complexes considered established on the basis of the TCSEP.

The subsequent reaction with $FeCl_2$ in THF leads to the formation of a mixture of ferracarbaboranes:



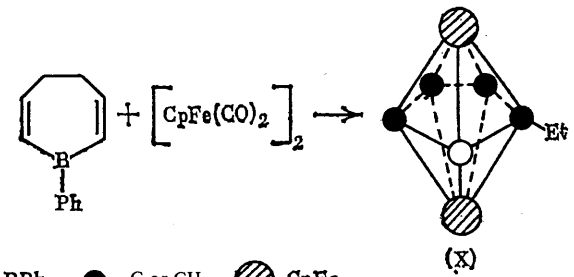


The structure of complexes (V) and (VI) will be examined below. Complex (VII), obtained in a very small amount, is isostructural with the initial complex (IV). Hydride hydrogen occupies the bridging position between the boron and iron atom, which has been demonstrated by $^{11}B$ NMR. Treatment of the zinc salt (IV) with dry HCl results in the formation of complex (VIII), containing a hydrogen atom linked to the Fe atom by a σ-bond. On heating of complex (VIII), the hydride hydrogen at the Fe atom passes to the bridging position, giving rise to complex (VII):



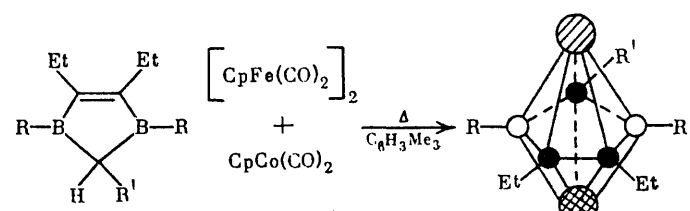
## 2. 7- and 8-Vertex Polydedra

The hexagonal-pyramidal derivatives of $\eta^6$-borarenyl-$\eta^5$-cyclopentadienyliron (IX) have been obtained by heating bis($\eta^6$-borarenyl)-cobalt with $[CpFe(CO)_2]_2$ in mesitylene:[22]



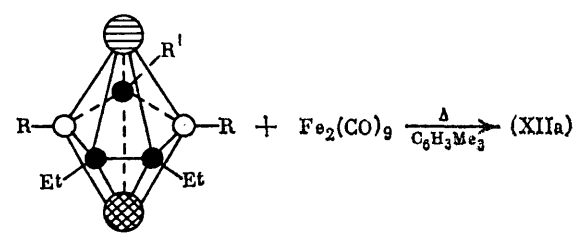
Complexes (IX) are crystalline substances stable in air. Their molecules contain 18 skeletal electrons and have the *nido*-structure. Oxidation of complex (IX) on treatment with $Ce^{4+}$ leads to the removal of the boron atom from the polyhedral skeleton and to the formation of the methyl- or phenyl-ferrocenium cation in a high yield. Acylation of complex (IX) with acetyl chloride under the conditions of the Friedel-Crafts reaction entails the replacement of the BR fragment in the borarene ligand by the CMe fragment:

R=Me; Ph.



The above group of complexes is also of interest because it contains a large number of the so-called "multidecker sandwiches". Heating of 1-phenyl-4,5-dihydroborepin with $[CpFe(CO)_2]_2$ leads to the isomerisation of the boron-containing ligand and the formation of the diamagnetic complex (X), which is a triple-decker sandwich:[4]

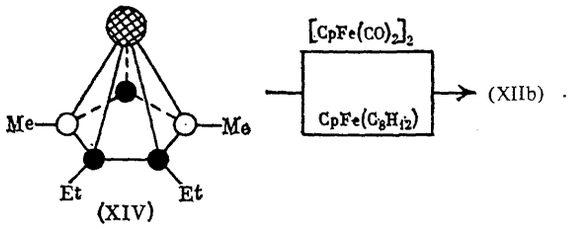
Complex (X) contains 16 electrons and has the *closo*-structure, which has been demonstrated by X-ray diffraction (the Fe–Fe distance is 3.27 Å). When the alkyldiborolin (XIa) is heated with $[CpFe(CO)_2]_2$ and $CpCo(CO)_2$ at 180–200 °C in an inert atmosphere, the mixed diamagnetic complex (XIIa), containing Fe and Co atoms in the $d^6$ configuration, is formed in a low yield:[23]



(XIa): R = Et, R' = Me
(XIb): R = Me, R' = H

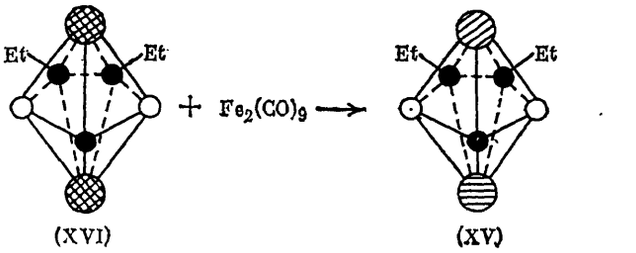
(XIIa): R = Et, R' = Me
(XIIb): R = Me, R' = H

Complex (XIIa) is stable in air and can be sublimed *in vacuo* at 120 °C. Its *closo*-structure is due to the presence of 16 skeletal electrons. The synthesis of complex (XIIa) on heating the cobaltanickelacarbaborane (XIIIa) with iron nonacarbonyl in mesitylene has been described. Complex (XIIa) is then formed in a moderate yield (~10%) together with other metallocarbaboranes:[24]



(XIIIa): R = Et, R' = Me
(XIIIb): R = Me, R' = H

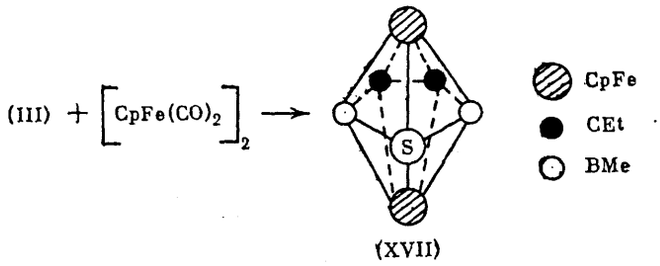
Complex (XIIb) has been obtained in a moderate yield by the reaction of the cobaltacarbaborane (XIV) with organo-

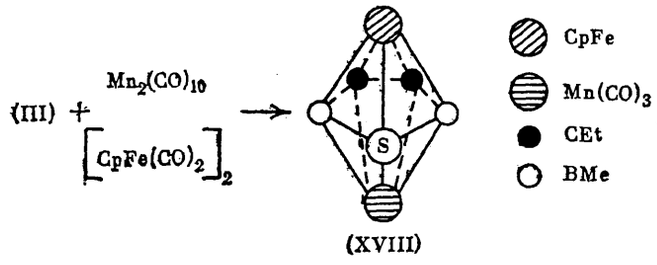


iron compounds:

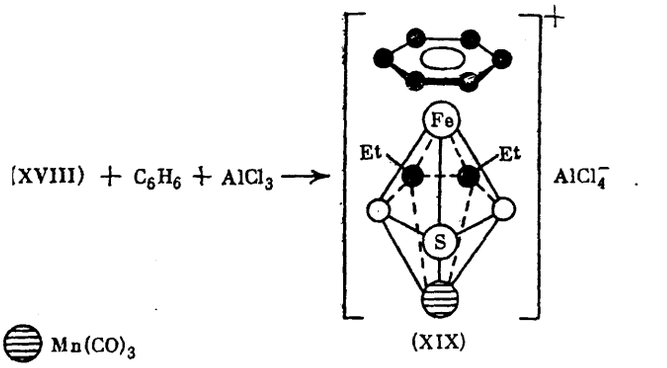
The complex is formed in a very low yield together with other metallocarbaboranes when the cobaltacarbaborane (XIV) is reduced by potassium in THF, this being followed by reaction with $CpFe(CO)_2I$. Finally, complex (XIIb) has been obtained in a high yield by the reduction of the cobaltanickelcarbaborane (XIIIb) by potassium in THF and subsequent treatment with $FeCl_2$. It is believed[24] that complexes (XII, a and b) contain 30 valence electrons (in each case 6 $\pi$ electrons of the Cp rings, 6 *d* electrons of the Fe atom, 8*d* electrons of the Co atom, and 4$\pi$ electrons of the $C_3B_2$ ligand). Complex (XIIb) has the *closo*-structure, which has been demonstrated by X-ray diffraction (the bond distances are 3.104 Å for Fe–Co, 1.624 Å for Fe–$C_3B_2$, and 1.58 Å for Co–$C_3B_2$). On treatment with potassium in THF, complex (XIIb) is converted into a paramagnetic anion (31 valence electrons), while oxidation with $AgBF_4$ in ether results in the formation of the paramagnetic cation (29 valence electrons). According to EPR data, the maximum spin density in the anion is concentrated at the cobalt atom. On the basis of Mössbauer spectra, it is believed[24] that the structure of complex (XIIb) and its cation are related in the same way as the structures of ferrocene and the ferrocenium cation. The effective magnetic moments of the cation of complex (XIIb) ($\mu_{eff}$ = 2.10 $\mu_B$), its temperature dependence, and the potentials of the anion $\rightleftharpoons$ neutral complex $\rightleftharpoons$ cation reversible transitions have been measured. The above communication[24] quotes data obtained by quantum-chemical calculations for complexes (XII, a and b) carried out using the extended Hückel method; the energies of all the 17 highest occupied MO, the types of the MO, and the contributions by the AO of the metals were determined. It follows from the calculated data that the CpFe fragment is linked to the $C_3B_2$ ring more strongly than the CpCo fragment. The EPR, Mössbauer, and electrochemical data are consistent with the main conclusions drawn from the quantum-chemical calculation.

The dinuclear ferracarbaborane (XV), containing both the CpFe and $(CO)_3Fe$ fragments in the polyhedral skeleton, has been obtained by the reaction of the dinuclear nickelacarbaborane (XVI) with $Fe_2(CO)_9$:[24]





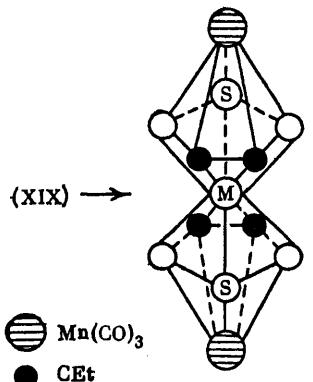
Complex (XV) is obtained in a mixture with other metallocarbaboranes, its maximum yield being obtained when the reaction is carried out in boiling mesitylene.

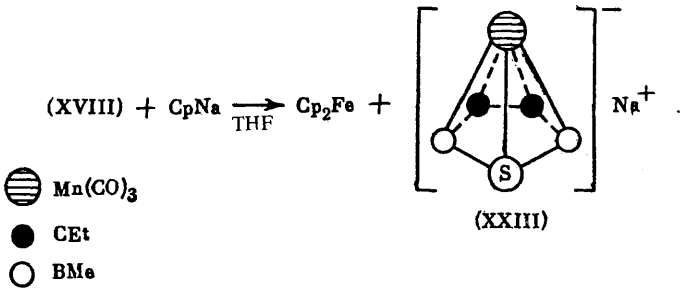


It is possible to obtain 7-vertex polyhedral ferracarbaboranes, containing an S atom in the polyhedron, by the reaction of thiadiborolin (III) with organic derivatives of transition metals (Fe, Co, Mn). The reaction with $[CpFe.(CO)_2]_2$ in boiling mesitylene affords a three-decker sandwich with two iron atoms—complex (XVII):[25]

The structure of this complex, which is a diamagnetic crystalline substance stable in air but decomposing on treatment with inorganic acids, has been demonstrated by X-ray diffraction. The $C_5H_5$ and $C_2B_2S$ rings are planar and have the transoid conformation, while the Fe–Fe distance is 3.236 Å. The interaction of the thiadiborolin (IV) with $[CpFe(CO)_2]_2$ and $Mn_2(CO)_{10}$ in boiling mesitylene leads to the formation of the diamagnetic complex (XVIII) with Fe and Mn atoms in the polyhedral skeleton:[26]

Complex (XVIII) is stable in air. Its *closo*-structure is determined by the presence of 16 skeletal electrons. Heating of complex (XVIII) in benzene in the presence of $AlCl_3$ results in the ready replacement of the Cp ligand by benzene:

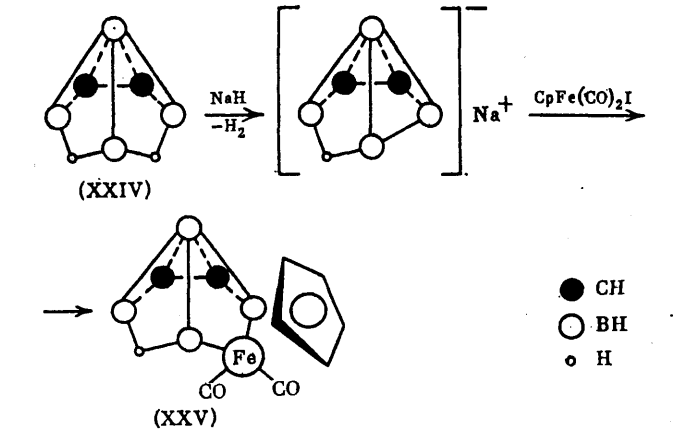




The cationic complex (XIX) formed under these conditions is extremely sensitive to hydrolysis. When it is heated *in vacuo*, a low yield of the mixed complex (XX), containing

3 metal atoms, is obtained:

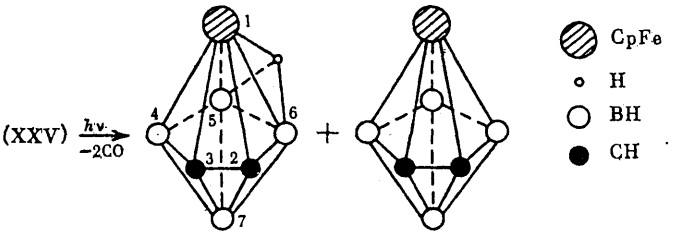
(XX): M = Fe
(XXI): M = Co
(XXII): M = Ni



Another more general method of synthesis of complex (XX) and its structural analogues consists in treating complex (XVIII) with CpNa in THF.[27] This results in the removal of the CpFe fragment and the formation of the anionic complex (XXIII):

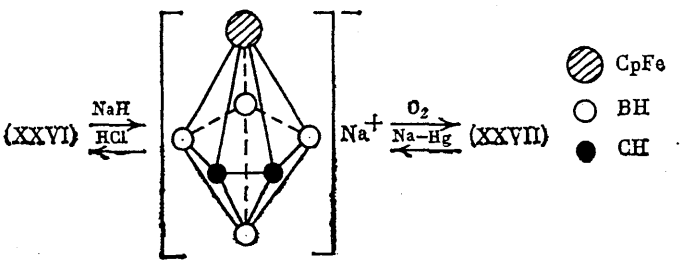
(XXIII)

Without being isolated, complex (XXIII) was made to react with transition metal chlorides of the type $MCl_2$ (M = Fe, Co or Ni) to form the trinuclear complexes (XX)–(XXII).



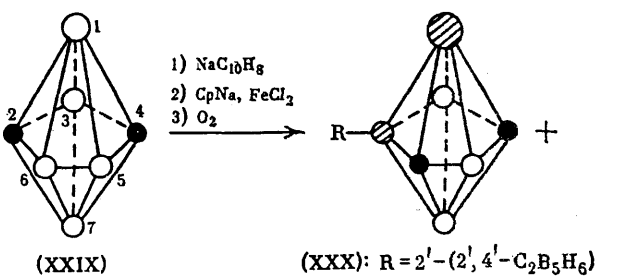
Another pathway leading to the synthesis of 7-vertex polyhedral *closo*-ferracarbaboranes involves the introduction of the CpFe fragment into the polyhedral skeleton of a *nido*-carbaborane. When the *nido*-carbaborane (XXIV) was treated with NaH in THF and then with $CpFe(CO)_2I$, the *nido*-carbaborane (XXV), which is sensitive to air and contains an Fe atom in a bridging position, was isolated in a satisfactory yield:[28,29]

(XXIV)



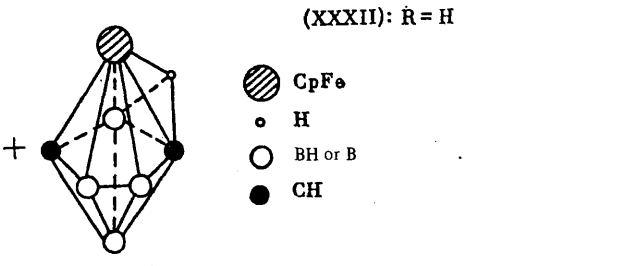
(XXV)

Irradiation of complex (XXV) with ultraviolet light leads to an almost quantitative yield of a mixture of the ferracarbaboranes (XXVI) and (XXVII):



(XXVI) (XXVII)

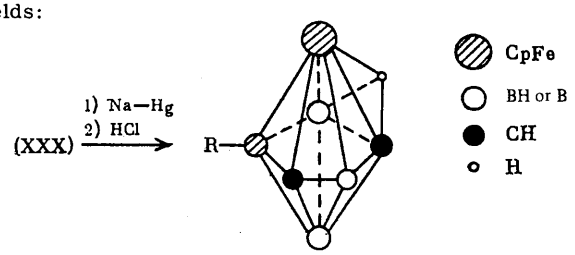
Complex (XXVI) is diamagnetic (the Fe atom has the $d^6$ configuration) and contains 16 skeletal electrons, which determine its *closo*-structure, while complex (XXVII) is paramagnetic ($\mu_{eff}$ = 2.1 $\mu_B$ $d^5$ configuration of the Fe atom) and contains 15 skeletal electrons, i.e. is electron deficient. The reversible interconversion of the ferracarbaboranes (XXVI) and (XXVII) proceeds via the anionic complex (XXVIII) in accordance with the following mechanism:



(XXVIII)

The substitution of the boron atom in the 1-position by the CpFe fragment and the formation of a mixture of the ferracarbaboranes (XXX)–(XXXIII) in a low yield via the mechanism

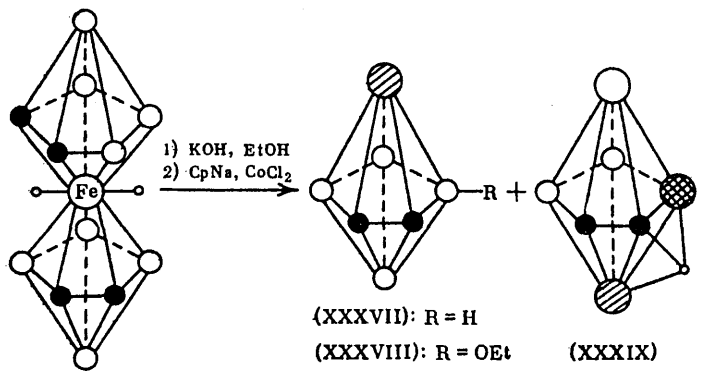
(XXIX)



(XXX): R = 2′-(2′,4′-$C_2B_5H_6$)
(XXXI): R = $C_{10}H_7$
(XXXII): R = H

(XXXIII)

have been observed in the reaction of the *closo*-carbaborane 2,4-$C_2B_5H_7$ (XXIX) with sodionaphthalene and then with CpNa and $FeCl_2$.[29] Complexes (XXX)–(XXXII) are para-

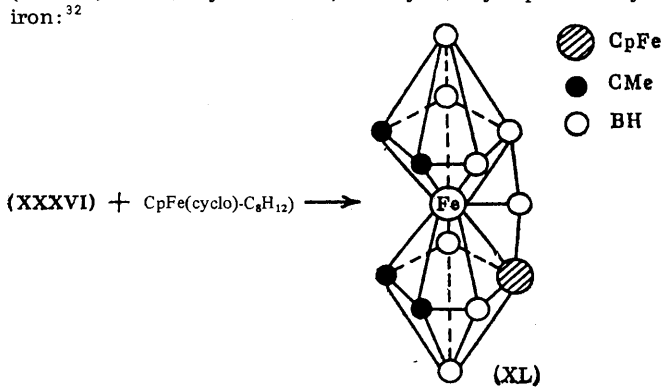


magnetic, while complex (XXXIII) is diamagnetic. Like the ferracarbaborane (XXVII), complex (XXX) is reduced by sodium amalgam to a diamagnetic derivative, whose protonation results in the formation of the diamagnetic complexes (XXXIV) and (XXXV) in overall quantitative yields:

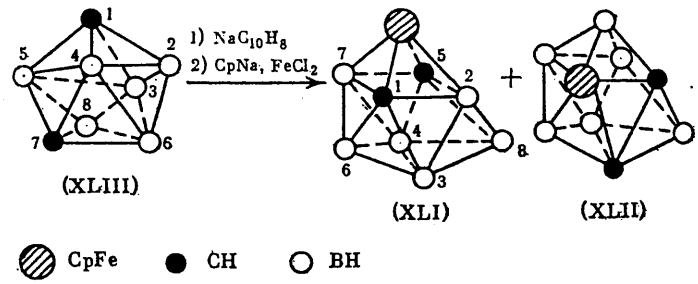
(XXXIV): R = $2^1$-($2^1$,$4^1$-$C_2B_5H_6$)

(XXXV): R = H

Yet another method of synthesis of 7-vertex *closo*-ferracarbaboranes consists in the rearrangement of the *commo*-ferracarbaborane (XXXVI) on alkaline degradation and subsequent interaction with CpNa and $CoCl_2$.[30] The formation of a complex mixture of products, the main components of which were the ferracarbaboranes (XXXVII) and (XXXVIII), was then observed:



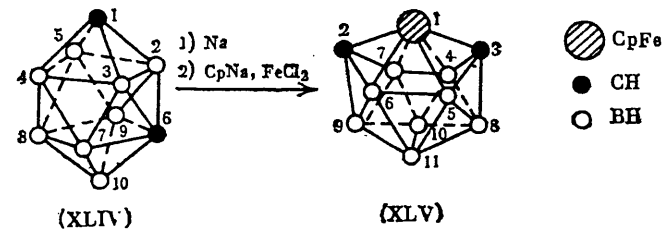
The ferracarbaboranes (XXXVII) and (XXXVIII) are paramagnetic, while the ferracobaltacarbaborane (XXXIX) is diamagnetic. Its structure was established by X-ray diffraction, from which it follows that it has the *closo*-structure. The Fe—Co distance is 2.56 Å.[31]



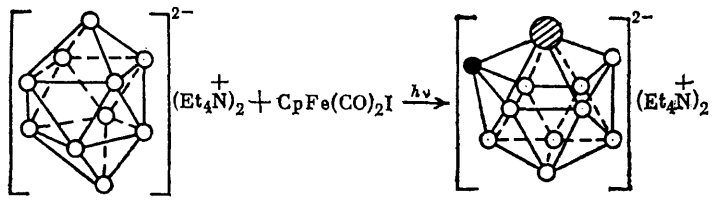
Only one example of an 8-vertex *closo*-ferracarbaborane with the CpFe fragment in the polyhedral skeleton is so far known. It was obtained from the *commo*-ferracarbaborane (XXXVI) and $\eta^4$-cyclo-octa-1,5-dienyl-$\eta^5$-cyclopentadienyl-iron:[32]

Complex (XI) consists, as it were, of two polyhedra joined together, namely the upper 7-vertex and lower 8-vertex polyhedra respectively. According to the TCSEP, the upper polyhedron lacks one skeletal electron and the lower polyhedron lacks two such electrons. Such a deficiency of skeletal electrons leads to a marked distortion of the geometry of the ferracarbaborane molecule, expressed by the "sharing" of the BH fragment by the upper and lower clusters. If two electrons could be in some way introduced into the skeleton of complex (XL), then it is believed[32] that it would acquire the normal geometry. The upper polyhedron would still remain a pentagonal bipyramid, while the lower polyhedron would be converted into a dodecahedron. It has been suggested[32] that the metallacarbaboranes whose polyhedral skeleton lacks two and more electrons be called hyperelectron-deficient.

### 3. Complexes Having the Structure of (9—11)-Vertex Polyhedra



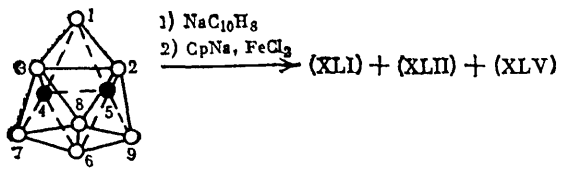
Two isomeric 9-vertex paramagnetic ferracarbaboranes (XLI) and (XLII), having the *closo*-structure and being represented by a three-cap trigonal prism, have been obtained by the polyhedral expansion of the *closo*-carbaborane 1,7-$C_2B_6H_8$ (XLIII):[33]



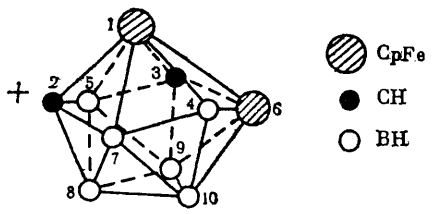
The polyhedral expansion of the *closo*-carbaborane 1,6-$C_2B_8H_{10}$ (XLIV) led to a satisfactory yield of the 11-vertex paramagnetic *closo*-ferracarbaborane (XLV):[33]

The ferracarbaboranes (XLI), (XLII), and (XLV) are readily reduced to the diamagnetic Fe(II)-forms by sodium amalgam. The dipole moments $\mu_{eff}$ have been measured[34] for the paramagnetic complexes (XLI), (XLII), and (XLV). Analysis of the EPR and $^{13}C$ and $^{11}B$ NMR spectra showed that the unpaired electron is localised not only at the Fe atom but also at the B and C atoms coordinating the metal atoms. The photochemical reaction of $(Et_4\overset{+}{N})_2B_{10}H_{10}^{2-}$ (XLVI) with $CpFe(CO)_2$ entails the polyhedral expansion of the borane skeleton with formation of the paramagnetic complex (XLVII), which is isostructural with complex

(XLV):[35]



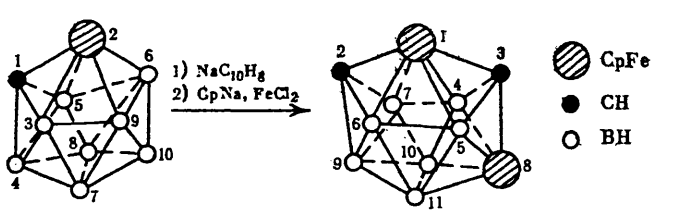
(XLVI) (XLVII)



CpFe ● CH ○ BH

Complex (XLVII) has also been obtained on refluxing a solution of $K_2^+B_{10}H_{10}^{2-}$ and $CpFe(CO)_2I$ in 1,2-dimethoxyethane.

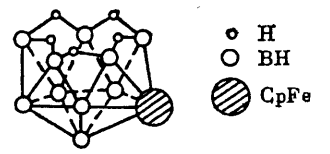
Structural distortions of the polyhedral skeleton in the electron-deficient dinuclear ferracarbaboranes is illustrated in relation to complex (XLVIII), which has been obtained, together with the ferracarbaboranes (XLI), (XLII) and (XLV), on polyhedral expansion of the *closo*-carbaborane $4,5\text{-}C_2B_7H_9$ (XLIX):[36]



(XLIX)

(XLVIII)

The ferracarbaborane (XLVIII) is a paramagnetic substance ($\mu_{eff}$ = 3.05 $\mu_B$), but it is converted in the course of a week at 20 °C into a diamagnetic isomeric form, which can be explained by the reorientation, over a period of time, of the spins of the unpaired electrons from parallel to antiparallel.[36] The structure of complex (XLVIII) was established by X-ray diffraction, from which it follows that it is a distorted two-cap Archimedes antiprism. It has one "superfluous" bond between the Fe atom at the vertex and the Fe atom in the nearest tetragonal belt. The Fe–Fe distance is 2.57 Å. The distortion of the geometry of this complex has also been discussed by Nishimura.[37]

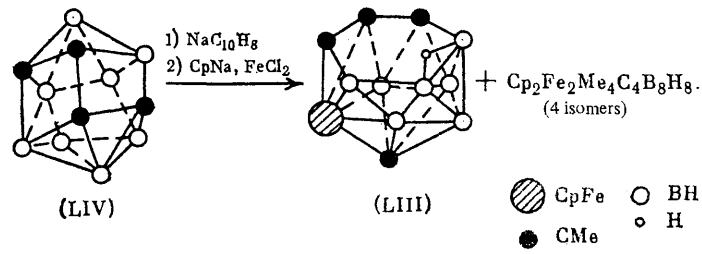


The polyhedral expansion of the *closo*-cobaltacarbaborane (L) results in the formation of the 11-vertex *closo*-ferracobaltacarbaborane (LI):[38]

(L) (LI)

Complex (LI) is a paramagnetic substance ($\mu_{eff}$ = 1.85 $\mu_B$), whose *closo*-structure has been demonstrated by X-ray diffraction.[39]

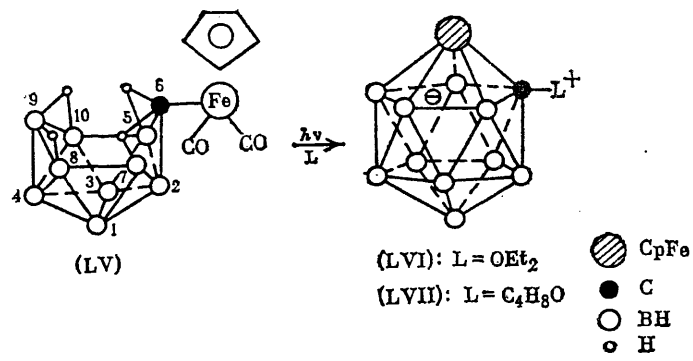
The ferraborane (LII) having the structure of the 11-vertex *nido*-polyhedron, obtained from $B_5H_8^-Na^+$, $FeCl_2$ and CpNa in a mixture with other ferraboranes, is an icosahedron from which one vertex has been removed:[20]



(LII)

Complex (LII) is diamagnetic, contains 26 skeletal electrons, and, in conformity with the TCSEP, has the *nido*-structure.

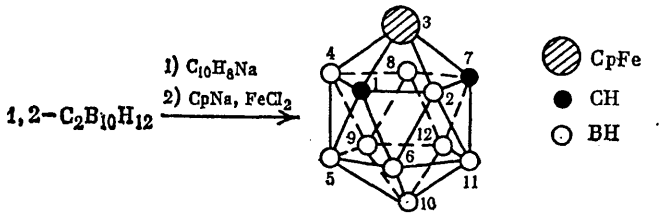
## V. COMPOUNDS HAVING 12-VERTEX POLYHEDRAL STRUCTURES



The 12-vertex *closo*-polyhedra have the icosahedral structure, while the *nido*-polyhedra have the structure of an "open" icosahedron with an open hexagonal face. The *nido*-ferracarbaborane (LIII), having 12 vertices, has been obtained, together with other products, on polyhedral expansion of the four-carbon *nido*-carbaborane $C_4Me_4B_8H_8$ (LIV):[40]

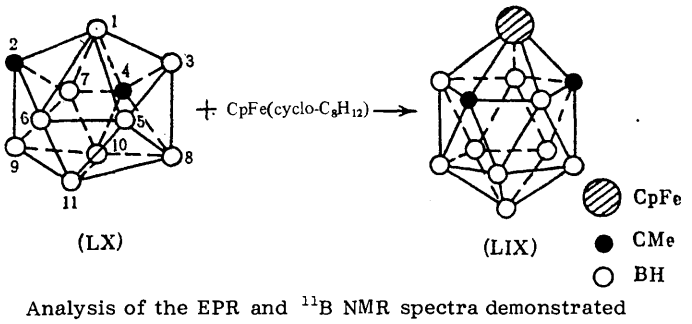
(LIV) (LIII)

The structure of complex (LIII) has been established by X-ray diffraction. The distances between the Fe atom and the C and B atoms to which it is coordinated are in the range 2.051–2.168 Å. Complex (LIII) is diamagnetic and contains 28 skeletal electrons, which give rise to its *nido*-structure in conformity with the TCSEP. The structures of the remaining products of this reaction will be discussed below.



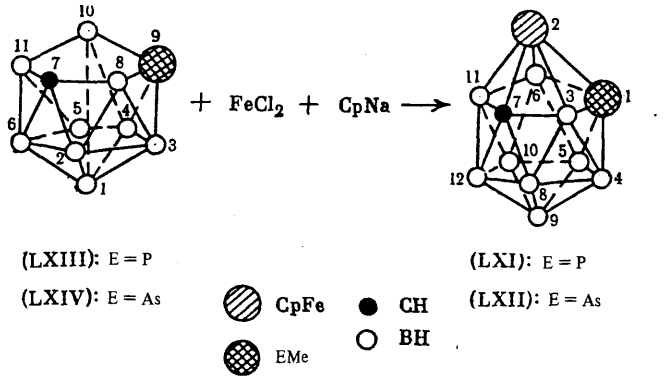
Irradiation of the σ-complex $B_{10}H_{13}$–σ-$Fe(CO)_2Cp$ (LV) with ultraviolet light in solution in ether or THF results in the "closure" of the polyhedral skeleton and the formation of a one-carbon ferracarbaborane (LVI) and (LXVII):[41]

(LV)



Complexes (LVI) and (LVII) each contain 25 skeletal electrons, i.e. one less than required by the TCSEP for the icosahedral *closo*-structure. Both complexes are isoelectronic with the ferrocenium cation. The *closo*-structure of complex (LVI) has been confirmed by X-ray diffraction.

The paramagnetic ferracarbaborane (LVIII), containing C atoms in the *meta*-positions relative to one another, has been obtained in a low yield together with other products on polyhedral expansion of *o*-carbaborane:[42]



(LVIII)

Another method of synthesis of the 1,7-dimethylferracarbaborane (LIX), an analogue of complex (LVIII), based on the polyhedral expansion of the *closo*-carbaborane 2,3-$Me_2$-2,3-$C_2B_9H_9$ (LX) in its reaction with $\eta^4$-cyclo-octa-1,5-dienyl-$\eta^5$-cyclopentadienyliron, was discovered later:[43]

(LX) (LIX)

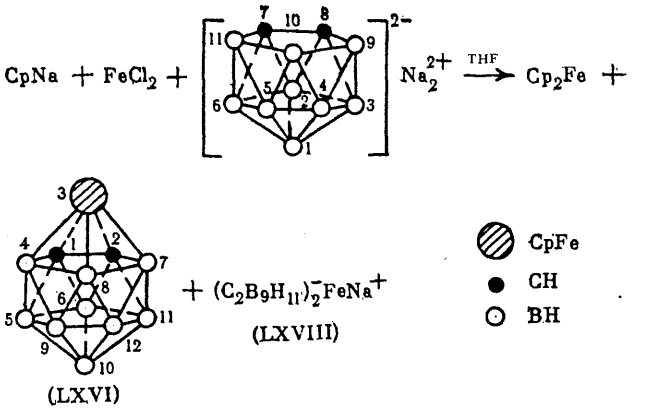
Analysis of the EPR and $^{11}B$ NMR spectra demonstrated the delocalisation of the spin density of the unpaired electron over the C(1), C(7), B(2), B(4), and B(8) atoms. The dipole moments $\mu_{eff}$ of complex (LVIII) have been measured.[44] The icosahedral ferraphosphacarbaborane (LXI)[35] and ferra-arsacarbaborane (LXII)[45] have been obtained by the reaction of the *nido*-phosphacarbaborane (LXIII) in THF and the *nido*-arsacarbaborane (LXIV) in $Et_3N$ respectively with $FeCl_3$ and CpNa:

(LXIII): E = P
(LXIV): E = As
(LXI): E = P
(LXII): E = As

Both complexes, (LXI) and (LXII), are diamagnetic and each contains 26 skeletal electrons, which give rise to their *closo*-structures.

The polyhedral expansion of the 11-vertex *closo*-ferracarbaborane (XLV) results in the formation of the 12-vertex paramagnetic complex (LXV) containing two CpFe fragments:[46]

$$(XLV) \xrightarrow[2)\ [CpFeC_8H_8]^+]{1)\ NaC_{10}H_8} Cp_2Fe_2C_2B_8H_{10}$$



(LXV)

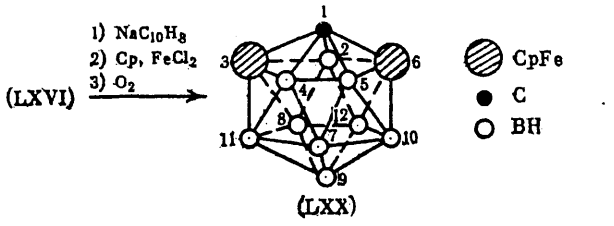
The structure of complex (LXV) has not been established. On standing for several days, it decomposes with reformation of the initial complex (XLV).

## VI. THE MOST IMPORTANT 12-VERTEX *CLOSO*-FERRACARBABORANE—$\eta^5$-CYCLOPENTADIENYL-$\eta^5$-(3)-1,2-DICARBOLLYLIRON

### 1. Synthesis and Physical Properties

The ferracarbaborane investigated in greatest detail among the icosahedral complexes is $\eta^5$-cyclopentadienyl-$\eta^5$-(3)-1,2-dicarbollyliron (LXVI), which was first obtained in a moderate yield by the interaction of CpNa, $FeCl_2$, and 7,8-$C_2B_9H_{11}Na_2$ (LXVII) in THF:[47,48]

(LXVI) (LXVIII)



Ferrocene and the *commo*-ferracarbaborane (LXIII) is then formed together with compound (LXVI). A more convenient method of synthesis of compound (LXVI), based on the reaction of *o*-carbaborane, cyclopentadiene, and $FeCl_2$ with methanolic alkali and subsequent treatment of the reaction mixture with $H_2O_2$, has been proposed.[49] Compound (LXVI) is a purple paramagnetic substance and constitutes an electronic analogue of the ferrocenium cation, i.e. its Fe atom has the $d^5$ configuration. The structure of compound (LXVI) has been established.[50] The complex is a regular icosahedron in which the Fe atom is equidistant from the C and B atoms coordinating it, its distance from these atoms amounting to ~2.07 Å. It has 25 skeletal electrons, i.e. one less than is necessary for the 12-vertex *closo*-polyhedron—the icosahedron.

When compound (LXVI) is treated with sodium amalgam in acetonitrile, the diamagnetic monoanion [3-Cp-3,1,2-$FeC_2B_9H_{11}]^-$ (LXIX), isoelectronic with ferrocene (the Fe atom has the $d^6$ configuration), is formed.[47,48] Complex (LXIX) contains 26 skeletal electrons, which fully satisfies the TCSEP requirements for icosahedral *closo*-structures. The study of the kinetics of the oxidation of the Fe(III)-form of compound (LXVI) to the Fe(II)-form (LXIX) showed that the oxidation mechanism is analogous to that of the oxidation of ferrocene to the ferrocenium cation.[51] The EPR spectra of complex (LXVI) revealed the presence of an unpaired electron.[52] Analysis of the EPR and $^{11}B$ NMR spectra demonstrated the localisation of the spin density in complex (LXVI) at the B and C

atoms coordinating the Fe atom.[34] The experimental value of $\mu_{eff}$ for complex (LXVI)[34,53] proved to be close to the calculated value.[54] The study of the Mössbauer spectra of this compound showed that its quadrupolar splitting parameters are close to the corresponding values for the biscyclopentadienyl complexes, although they are somewhat higher than the latter.[55,56] The cause of this consists in the higher density of *s* electrons at the Fe atom than in the ferrocene–ferrocenium derivatives, indicating a more effective removal of *d* electrons from the Fe atom in compound (LXVI) owing to their involvement in $\pi$ bonding with the ligands. Quantum-chemical calculation for the Fe(II)-form (LXIX) by the MO method with adjustment for self-consistency with respect to the atomic charges and atomic configurations showed that the Fe–$C_2B_9H_{11}$ interaction involves mainly the ligand $\sigma$ orbitals, while the Fe–$C_5H_5$ interaction involves the $\pi$ orbitals of the Cp ring.[57] Calculation of the total atomic charges showed that the maximum negative charge is present on the B(8) atom located symmetrically in the open $C_2B_3$ face of the dicarbollyl ligand, while the maximum positive charge is localised at the B(10) atom most remote from the Fe atom. In addition, it has been shown that the HOMO of complex (LXIX) has appreciable $d_{z^2}$ character, as in ferrocene.

## 2. The Chemical Properties of $\eta^5$-Cyclopentadienyl-$\eta^5$-(3)-1,2-Dicarbolyliron and Its Derivatives

The chemical properties and reactivity of compound (LXVI) and its derivatives have been investigated in greatest detail compared with other ferracarbaboranes. On polyhedral expansion of the Fe(III)-form (LXVI), the dinuclear complex (LXX) was obtained in a very small amount together with 13-vertex ferracarbaboranes. The regular icosahedral structure was attributed to compound (LXX) on the basis of $^{11}B$ NMR spectra:[46]

(LXX)

Although both Fe atoms in complex (LXX) have the $d^5$ configuration, the complex is diamagnetic, which can be accounted for by the antiparallel orientation of the unpaired electron spins at the metal atoms. Complex (LXX) contains 24 skeletal electrons—two less than is required by the TCSEP for icosahedral *closo*-structures, which is characteristic of ferracarbaboranes containing several Fe atoms. The formation of complex (LXX) can be explained by the presence in the reaction medium of traces of NaOH under the influence of which complex (LXVI) undergoes initially alkaline degradation with removal of the B(6) atom from the polyhedral skeleton and its subsequent replacement by the CpFe fragment.

A detailed investigation of the chemical properties of compound (LXVI) and its derivatives has been undertaken by the authors of this review[58–68] and is considered below.

*(a) Reactions of compound (LXVI) with electrophiles.* In order to study the distribution of the relative electron density, the bromination of compound (LXVI)§ and of its bromo-derivatives was investigated.[58] It was shown that complex (LXVI) is brominated stepwise at the B atoms of the dicarbollyl ligand. In the absence of a catalyst, the first bromine atom enters the 8-position, while further bromination takes place only in the presence of $AlCl_3$ in the 9- and 12-positions:

$$(\text{LXVI}) \xrightarrow{Br_2} \underset{(\text{LXXI})}{CpFeC_2H_2B_9H_8\text{-}8\text{-}Br} \xrightarrow[AlCl_3]{1)\ Br_2} \underset{(\text{LXXII})}{CpFeC_2H_2B_9H_7\text{-}8,9\text{-}Br_2}$$

$$\xrightarrow[AlCl_3]{2)\ Br_2} \underset{(\text{LXXIII})}{CpFeC_2H_2B_9H_6\text{-}8,9,12\text{-}Br_3} .$$

The structure of the bromo-derivatives (LXXI)–(LXXIII) was demonstrated by $^{11}B$ NMR and also by specific synthesis from the bromo-derivatives (LXXIV) and (LXXV), where the bromine atoms are known to be in the 9- and 9- and 12-positions:

$$\underset{(\text{LXXIV})}{CpFeC_2H_2B_9H_8\text{-}9\text{-}Br} \xrightarrow{Br_2} (\text{LXXII}) ;$$

$$\underset{(\text{LXXV})}{CpFeC_2H_2B_9H_7\text{-}9,12\text{-}Br_2} \xrightarrow[AlCl_3]{Br_2} (\text{LXXIII}) .$$

The bromination of the 4-bromo-derivative (LXXVI) leads to the 4,8-dibromo-derivative (LXXVII):

$$\underset{(\text{LXXVI})}{CpFeC_2H_2B_9H_8\text{-}4\text{-}Br} \xrightarrow{Br_2} \underset{(\text{LXXVII})}{CpFeC_2H_2B_9H_7\text{-}4,8\text{-}Br_2} .$$

The presence of bromine atoms in compound (LXVI) makes it less reactive in electrophilic substitution reactions. It follows from the bromination data that the distribution of relative electron density in the dicarbollyl ligand of compound (LXVI) is as follows: B(8) > B(9), B(12) > B(4), B(5), B(6), B(10), B(11), C(1), C(2).

When compound (LXVI) is treated with thallium(III) trifluoroacetate in trifluoroacetic acid, the B–H bond is oxidised and the 8-trifluoroacetoxy-derivative (LXVIII) is formed:[59]

$$(\text{LXVI}) \xrightarrow[CF_3COOH]{Tl(OCOCF_3)_3} \underset{(\text{LXXVIII})}{CpFeC_2H_2B_9H_8\text{-}8\text{-}OCOCF_3} .$$

The structure of complex (LXXVIII) has been established by X-ray diffraction. Its methanolysis affords the 8-hydroxy-derivative (LXXIX):

$$(\text{LXXVIII}) \xrightarrow{H^+,\ MeOH} \underset{(\text{LXXIX})}{CpFeC_2H_2B_9H_8\text{-}8\text{-}OH} .$$

The oxidation of the B–H bond when compound (LXVI) is treated with $Tl(OCOCF_3)_3$ indicates an enhanced hydride mobility of the H atom at the B(8) atom.

Mercuration of compound (LXVI) by mercury(II) trifluoroacetate in the $CF_3COOH$–$CH_2Cl_2$ mixture yielded the 9-chloromercuri-derivative (LXXX):[60]

$$(\text{LXVI}) \xrightarrow[2)\ NaCl]{1)\ Hg(OCOCF_3)_2} \underset{(\text{LXXX})}{CpFeC_2H_2B_9H_9\text{-}9\text{-}HgCl} .$$

§ $CpFeC_2H_2B_9H_9$ and $CpFeHCB_9H_9CH$ are two ways of writing the formula of compound (LXVI) ($d^5$ configuration of the Fe atom).

When it is treated with bromine, the 9-bromo-derivative (LXXIV) is produced.

*(b) Derivatives of compound (LXVI) substituted at a C atom of the dicarbollyl ligand.* The synthesis of derivatives of compound (LXVI) substituted at a C atom of the dicarbollyl ligand and their subsequent reactions have been described.[61–63] These derivatives have been synthesised from the corresponding 1-substituted o-carbaboranes, cyclopentadiene, and $FeCl_2$ in methanolic alkali:

$$o\text{-}HCB_{10}H_{10}C\text{-}R + C_5H_6 + FeCl_2 \xrightarrow[2)\ H_2O_2]{1)\ KOH,\ MeOH} CpFeHCB_9H_9C\text{-}R;$$

$$R=CH_2OH,\ CH=CH_2,\ \overset{CH_3}{\underset{|}{C}}=CH_2,\ C\equiv CH,\ CH_2OH.$$

In order to synthesise the acid (R = COOH), 7-COOH-7,8-$C_2B_9H_{11}K$ was used as the starting material. The proposed methods of synthesis of derivatives of compound (LXVI) with a functional group at a C atom of the dicarbollyl ligand make them readily available, which made it possible to investigate various reactions of 1-substituted ferracarbaboranes. Together with the usual properties of the carbaborane and cobaltacarbaboranes analogues, these reactions manifest specific features due to the presence of the ferracarbaborane nucleus. Various reactions of the hydroxymethyl derivative $CpFeHCB_9H_9CH_2OH$, namely acylation, oxidation to the aldehyde, and replacement of the OH group by OR or Cl under the conditions of acid catalysis, have been investigated.[61] The solvolysis of the chloromethyl derivative $CpFeHCB_9H_9CCH_2Cl$, which demonstrated the ability of the $CpFe^{III}HCB_9H_9C$ group to stabilise as the intermediate species the carbonium ion centre linked to it, has been investigated. The synthesis of a ketone, secondary carbinols, and the diethyl acetal of an aldehyde derived from compound (LXVI) has been described. The ability of compound (LXVI) to form hydrogen bonds with basic solvents involving the C–H bonds of both ligands has been demonstrated by infrared spectroscopy[64] and the acid character of the C–H bonds of the dicarbollyl ligand in compound (LXVI) has been confirmed,[61] since they are metallated on treatment with butyl-lithium in ether. The ionisation constants of the acids $CpFeHCB_9H_9CCOOH$ in 50% ethanol ($pK_a$ = 3.49) and $CpFeHCB_9H_9CCH_2COOH$ in 80% methylcellosolve ($pK_a$ = 5.70) have been measured. The induction constant for the $CpFe^{III}HCB_9H_9C$ group ($\sigma_i$ = 0.31) was calculated from the latter $pK_a$ by Charton's method, from which it follows that the ferra(III)carbaboranyl group exhibits an appreciable electron-accepting effect.[61] The majority of the reactions of the 1-substituted derivatives of compound (LXVI) described can be used as preparative methods for their synthesis. The conversion of the Fe(III)-form into the Fe(II)-form of the 1-substituted derivatives of compound (LXVI) has been suggested[63] and consists in reduction by $NaBH_4$ in ethanol:

$$CpFeHCB_9H_9C\text{—}R \xrightarrow[2)\ CtX]{1)\ NaBH_4} [CpFe^{II}HCB_9H_9C\text{—}R]\,Kt;$$

$$R=CH_2OH,\ CH(OH)CH_3,\ CH=CH_2,\ C(CH_3)=CH_2,\ C\equiv CH;$$

$$Ct=Cs,\ Me_4N;$$

$$X=Cl,\ Br,\ I,\ NO_3.$$

The derivatives of the Fe(II)-form of compound (LXVI) are electronic analogues of ferrocene.

*(c) Carbonium ions stabilised by the ferra(II)carbaboranyl group.* The authors of the present review investigated the carbonium ion centre linked to the $CpFe^{II}HCB_9H_9C^-$ group[63,65] and found that the group stabilises the carbonium ion linked to it much more effectively than the ferrocenyl group. Since the positive charge on the carbon atom is balanced by the negative charge on the ferra(II)carbaboranyl group, the cation-containing molecule is electrically neutral and therefore exists in the form of zwitter-ions. Such zwitter-ions have been called[63,65] carbenium zwitter-ions. The protonation of the carbinols (LXXXI), (LXXXII), and (LXXXIII) by inorganic acids gave high yields of the primary carbenium zwitter-ion (LXXXIV) and the corresponding secondary zwitter-ions (LXXXV) and (LXXXVI) respectively:

$$[CpFe^{II}HCB_9H_9C\underset{\underset{OH}{|}}{\text{—}CHR}]^- \xrightarrow{H^+} CpFe^{II}HCB_9H_9C^-\text{—}C^+\!\!<^{R}_{H}$$

(LXXXI): R=H
(LXXXII): R=Me
(LXXXIII): R=Ph

(LXXXIV): R=H
(LXXXV): R=Me
(LXXXVI): R=Ph

A convenient method of synthesis of the secondary and tertiary carbenium zwitter-ions, (LXXXV) and (LXXXVII) respectively, consists in the protonation of the corresponding olefins (LXXXVIII) and (LXXXIX):

$$[CpFe^{II}HCB_9H_9C\underset{\underset{R}{|}}{\text{—}C=CH_2}]^- \xrightarrow{H^+} CpFeHCB_9H_9\bar{C}\text{—}\overset{+}{C}\!\!<^{Me}_{R}$$

(LXXXVIII): R=H
(LXXXIX): R=Me

(LXXXV): R=H
(LXXXVII): R=Me

The carbenium zwitter-ions (LXXXIV) and (LXXXVII) have been isolated in an individual form. They are diamagnetic, stable in air, and capable of being chromatographed on silica gel in moderately polar eluents. The relative stabilities on prolonged storage in air of the carbenium zwitter-ions increase in the sequence $\overset{+}{C}H_2 \ll \overset{+}{C}HMe \ll \overset{+}{C}HPh \cong \overset{+}{C}Me_2$. Conclusions about the structure and the probable mechanism of the stabilisation of the carbonium ion centre in such systems were reached from the X-ray diffraction analysis of the phenylcarbenium zwitter-ion (LXXXVI). The carbonium ion centre is stabilised by the strong iron-carbon interaction [the Fe–$C^+$ distance is 2.23 Å and the angle between the C(carbaborane)–$C^+$ bond and the $C_2B_3$ plane is 47°].

Furthermore, the $C^+$ atom has the $sp^2$-configuration and the C(carbaborane)–$C^+$ distance is 1.38 Å, from which follows the partial double bond character of the linkage between the $C^+$ atom and the carbon atom of the polyhedron. Thus the carbonium ion centre is stabilised in two ways—both by the electron-donating effect of the ligand with formation of a fulvene-like structure and with participation of the Fe atom.

Various reactions of the carbenium zwitter-ions have been investigated.[63,65] Despite their lower reactivity compared with organic carbonium ions and ferrocenyl carbonium ions, they combine with bases via the carbonium ion centre. The reactions of the primary and secondary zwitter-ions, (LXXIV) and (LXXXV) respectively, with electrically neutral Lewis bases lead to the formation of

adducts in the form of inner salts of type (XC):

$$(LXXXIV) \text{ or } (LXXXV) \xrightarrow{L} CpFe^{II}HCB_9H_9C\text{-}\overset{R}{\overset{|}{C}}H\text{-}\overset{+}{L}\ ;$$

(XC)

R=H or Me, L=$PPh_3$, $NC_5H_5$, $SMe_2$, N≡C—Me, N≡C—CH=$CH_2$.

The acid hydrolysis of the acetonitrilium inner salt (XC, R = H, L = N≡CMe) with simultaneous oxidation by $H_2O_2$ leads to the formation of the *N*-substituted acetamide $CpFeHCB_9H_9CCH_2NHCOMe$. The reaction of the tertiary zwitter-ion (LXXXVII) with pyridine leads to the adduct (XCI) and the olefin (LXXXIX) as the deprotonation product.

$$(LXXXVII) \xrightarrow{C_5H_5N} CpFe^{II}HCB_9H_9\bar{C}—CMe_2—\overset{+}{N}C_5H_5 + (LXXXIX).$$

The primary and secondary zwitter-ions, (LXXXIV) and (LXXXV) respectively, react with organolithium compounds, combining with the organic residue via the carbonium ion centre with formation of products of type (XCII):

$$(LXXXIV) \text{ or } (LXXXV) \xrightarrow[2)\ H_2O_2]{1)\ R'Li} CpFeHCB_9H_9C—CH\begin{matrix}R\\R'\end{matrix};$$

(XCII)

R=H or Me; R'=Bu, Ph, Bu—C≡C, Ph—C≡C, 1,2-$C_2B_{10}H_9$-1.

The reaction of the primary and secondary zwitter-ions with nucleophilic anions takes place similarly, affording products of type (XCIII):

$$(LXXXIV) \text{ or } (LXXXV) \xrightarrow[2)\ H_2O_2]{1)\ Nu^-} CpFeHCB_9H_9C—CH\begin{matrix}R\\Nu\end{matrix};$$

(XCIII)

R=H or Me; Nu=CN, iso-BuO, iso-BuS, PhO, PhS, $CH_2NO_2$.

On the other hand, cyanide and thiophenoxide anions do not add to the tertiary zwitter-ion (LXXXVII) and only the deprotonation of one of the methyl groups takes place with formation of the alkene (LXXXIX), which indicates an increased acidity of the H atoms of the methyl group in the tertiary and zwitter-ion. The primary and tertiary zwitter-ions, (LXXXIV) and (LXXXVII) respectively, abstract a hydride ion from $NaBH_4$, which leads to the quantitative formation of the methyl derivative (XCIV) and the isopropenyl derivative (XCV) respectively of complex (LXVI):

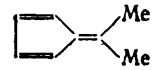
$$(LXXXIV) \text{ or } (LXXXVII) \xrightarrow[2)\ H_2O_2]{1)\ NaBH_4} CpFeHCB_9H_9C—CHR_2.$$

(XCIV): R=H
(XCV): R=Me

In contrast to this, when the primary zwitter-ion (LXXXIV) is treated with $H_2AlCl$ in ether, the diethyloxonium inner salt (XCVI), which is extremely resistant to hydrolysis, is formed:

$$(LXXXIV) \xrightarrow{H_2AlCl,\ Et_2O} CpFe^{II}HCB_9H_9\bar{C}CH_2\overset{+}{O}Et_2.$$

(XCVI)



In the absence of $H_2AlCl$, the cation (LXXXIV) does not react with ether even after prolonged heating. The more basic dimethoxyethane adds to the cationic centre of the primary zwitter-ion, giving rise to the inner salt (XCVII):

$$(LXXXIV) + MeOCH_2CH_2OMe \rightarrow CpFe^{II}HCB_9H_9\bar{C}\text{-}CH_2\overset{+}{\underset{|}{O}}\text{-}CH_2CH_2OMe.$$

Me

(XCVII)

The stabilisation of the carbonium ion centre linked to the $HCB_9H_9CHFe^{II}C_5H_4$ group has been investigated.[66] The isopropenyl derivative (XCVIII), containing a substituent in the Cp ring, has been obtained in order to synthesise this carbonium ion system from 6,6-dimethylfulvene, the 7,8-dicarbollide anion (LXVII), and $FeCl_2$ in the liquid ammonia–THF mixture:

$$+ (LXVII) + FeCl_2 \xrightarrow[2)\ H_2O_2]{1)\ NaNH_2} \rightarrow CH_2=\overset{Me}{\overset{|}{C}}—C_5H_4FeHCB_9H_9CH.$$

(XCVIII)

Complex (XCVIII) was reduced to the diamagnetic form (XCIX) with sodium tetrahydroborate:

$$(XCVIII) \xrightarrow[2)\ Me_4NBr]{1)\ NaBH_4} Me_4N[CH_2=\overset{Me}{\overset{|}{C}}—C_5H_4FeHCB_9H_9CH].$$

(XCIX)

The protonation of the alkene (XCIX) leads to the formation of a carbenium zwitter-ion (C), which was not isolated in an individual state owing to its high reactivity:

$$(XCIX) \xrightarrow{H^+} \{Me_2\overset{+}{C}C_5H_4Fe^{II}HCB_9H_9\bar{C}H\}.$$

(C)

In solution the cation (C) and the cationic component of (C) undergo a series of reactions. If the protonation is carried out in benzene, only the dimeric product (CI), which is a result of the addition of the cationic component of (C) to the double bond of the alkene (XCIX), is obtained:

$$(XCIX) \xrightarrow{H^+} \{(C)\} \xrightarrow[-H^+]{(XCIX),\ O_2} \rightarrow HCB_9H_9CHFeC_5H_4—CMe_2—CH=\overset{Me}{\overset{|}{C}}—C_5H_4FeHCB_9H_9CH.$$

(CI)

If its protonation is carried out in ether or dimethyl sulphide, then the inner salts (CII) and (CIII) are obtained together with the dimeric complex (CI):

$$(XCIX) \xrightarrow{H^+,L} L^+—CMe_2—C_5H_4Fe^{II}HCB_9H_9\bar{C}H + (CI).$$

(CII): L=$OEt_2$
(CIII): L=$SMe_2$

In the case of dimethyl sulphide, an appreciable amount of the inner salt having the dimeric structure (CIV) is formed in addition to complexes (CIII) and (CI):

$$HCB_9H_9CHFeC_5H_4—CMe_2—\overset{Me}{\overset{|}{\underset{|}{C}}}—C_5H_4Fe^{II}HCB_9H_9\bar{C}H.$$

$^+SMe_2$

(CIV)

It follows from these data that the carbonium ion centre is stabilised less effectively by the $HCB_9H_9CHFe^{II}C_5H_4$ group than by the $CpFe^{II}HCB_9H_9C$ group.

The greater stabilising capacity of the $CpFe^{II}HCB_9H_9\bar{C}$ group made it possible to obtain the stable vinyl cation (CV) and to isolate it for the first time in an individual state in the form of the zwitter-ion on protonation of the alkyne derivative (CVI):[66,68]

$$\underset{\text{(CVI)}}{[CpFe^{II}HCB_9H_9C{-}C{\equiv}CH]^-} \xrightarrow{H^+} \underset{\text{(CV)}}{CpFe^{II}HCB_9H_9\bar{C}{-}\overset{+}{C}{=}CH_2}.$$

The vinyl cation (CV) is diamagnetic and stable in air. it combines eith hydrogen halides via the vinyl cationic group to form tertiary carbenium zwitter-ions of type (CVII) in which the halogen atom is linked directly to the carbonium ion centre:

$$\text{(CV)} \xrightarrow{HX} CpFe^{II}HCB_9H_9\bar{C}{-}\overset{+}{C}\begin{matrix}\nearrow Me\\ \searrow X\end{matrix}.$$

(CVII): X=Cl, Br

When the vinyl cation (CV) is treated with nucleophiles, for example $NaBH_4$ or MeLi, only the deprotonation of the vinyl cationic group takes place with formation of the alkyne (CVI), while the products of the addition to the cationic centre, namely the alkenes (LXXXVIII) or (LXXXIX), are obtained in extremely small amounts. These data indicate the appreciable acidity of the hydrogen atoms in the vinyl cationic group.

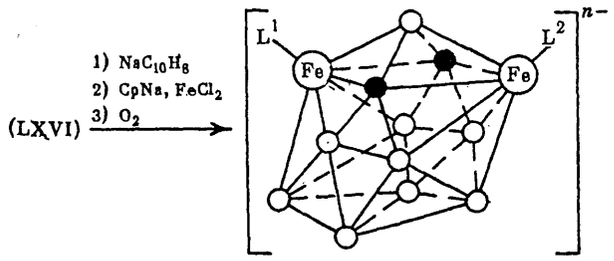
The allyl cation system, stabilised by the $CpFe^{II}HCB_9H_9\bar{C}$ group, has also been investigated.[67] When the aldehyde (CVIII) is treated with β-styrylmagnesium bromide, the phenylallyl cation (CIX) is formed in the form of the zwitter-ion:

$$\underset{\text{(CVIII)}}{CpFeHCB_9H_9CCHO} \xrightarrow{PhCH{=}CHMgBr} \longrightarrow \underset{\text{(CIX)}}{CpFe^{II}HCB_9H_9\bar{C}{-}CH{=}\overset{+}{C}H{-}CHPh}.$$

The monosubstituted allyl cation (CX) was obtained analogously for the first time from the aldehyde (CVIII) and vinylmagnesium bromide:

$$\text{(CVIII)} \xrightarrow[2)\ H^+]{1)\ CH{=}CH_2MgBr} \underset{\text{(CX)}}{CpFe^{II}HCB_9H_9\bar{C}{-}CH{=}\overset{+}{C}H{-}CH_2}.$$

Both allyl cations, (CIX) and (CX), exhibit the dual reactivity characteristic of allyl cationic systems. The addition of the hydride ion entails the formation of the corresponding allyl derivative (CXI) and the *n*-propenyl derivative (CXII) of compound (XIVI):



$$\text{(CIX) or (CX)} \xrightarrow{NaBH_4} \underset{\text{(CXII)}}{[CpFe^{II}HCB_9H_9C{-}CH_2{-}CH{=}CHR]^- + [CpFe^{II}HCB_9H_9C{-}CH{=}CH{-}CH_2R]^-}.$$

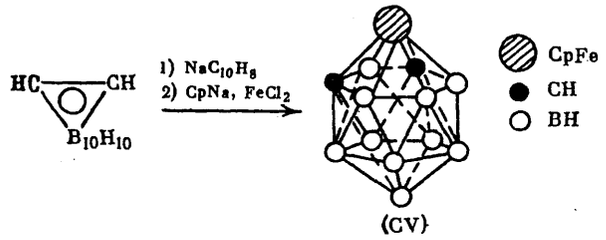
The stability of the carbonium ions stabilised by the ferra(II)carbaboranyl group have no analogy in the chemistry of both organic and organometallic carbonium ions. All the above features suggest that these are carbonium ions of a new type. Furthermore, the above reactions of the carbonium ions can be regarded as a convenient preparative method for the synthesis of various derivatives of compound (LXVI).

## VII. COMPOUNDS HAVING 13- AND 14-VERTEX POLYHEDRAL STRUCTURES

### 1. 13-Vertex Polyhedral Ferracarbaboranes

The *nido*-ferracarbaboranes containing 13 vertices are so far unknown. The *closo*-polyhedron with 13 vertices is an icosahedron containing an additional vertex. Polyhedral expansion of compound (LXVI) yielded as the main product the diamagnetic dinuclear ferracarbaborane (CXIII).[60] The diemagnetic dinuclear complex (CXIV) was obtained in a much smaller amount at the same time:

(CXIII): $L^1 = L^2 = Cp$; $n = 0$

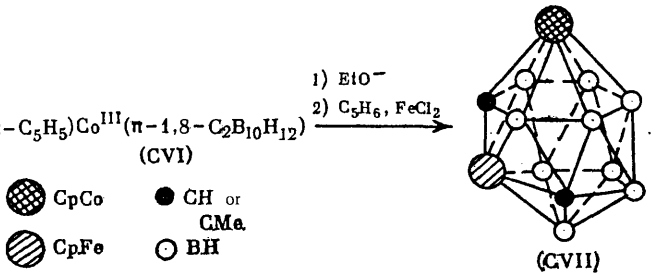


(CXIV): $L^1 = Cp$; $n = 1$

$L^2 = \eta^5$-1,2-$C_2B_9H_{11}$

● CH
○ BH

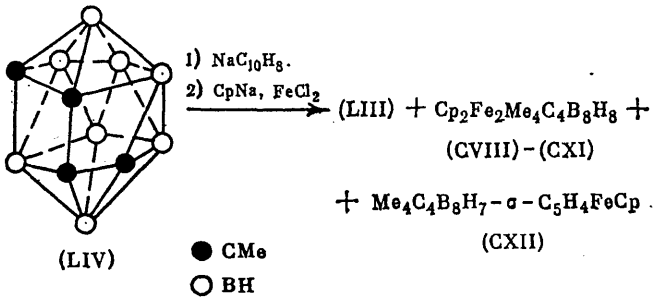
Preliminary X-ray diffraction analysis of complex (CXIII) demonstrated the absence of the Fe–Fe bond (3.2 Å). Structures have been attributed to complexes (CXIII) and (CXIV) on the basis of $^{11}B$ NMR spectra. Both Fe atoms in each complex have the $d^5$ configuration. Each complex has 26 skeletal electrons, i.e. according to the TCSEP they are electron-deficient. Their diamagnetism is due to the antiparallel orientation of the spins of the unpaired electrons, which arises in their conjugation with the π orbitals of the carbaborane ligand.



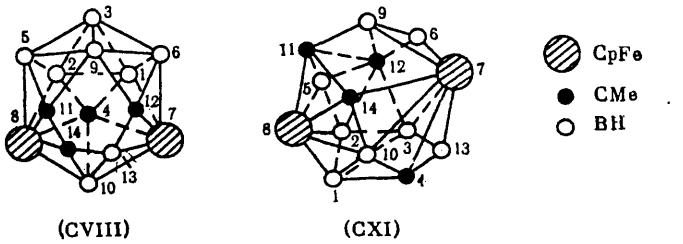
The main product of the polyhedral expansion reaction of o-carbaborane is complex (CV), which has the *closo*-structure:[42]

(CV)

The complex is paramagnetic and its reduction with $NaBH_4$ leads to a diamagnetic monoanion, which has been isolated in the form of the tetramethylammonium salt $[CpFe^{II}C_2B_{10}H_{12}]\cdot NMe_4$. The latter compound contains 28 skeletal electrons, which establish, according to the TCSEP, its *closo*-structure. The alkaline degradation of the 13-vertex *closo*-cobaltacarbaborane (CVI) entails the removal of the B(5) atom. The subsequent reaction with cyclopentadiene and $FeCl_2$ leads to the introduction of the CpFe fragment in the 5-position and the formation of the paramagnetic dinuclear *closo*-

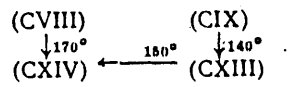


cobaltaferracarbaborane (CVII):[38,69]

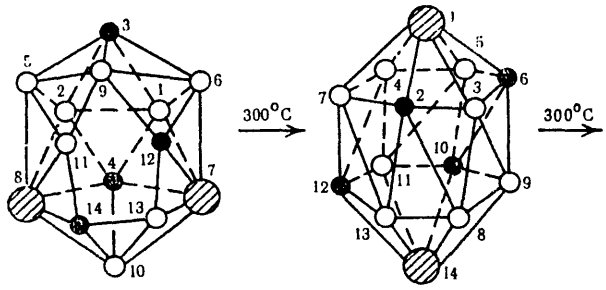


On treatment with $NaBH_4$, complex (CVII) is reduced to the diamagnetic monoanion [4-CpCo-5-CpFe$^{II}$-1,8-$C_2B_9H_{11}$]$^-$.

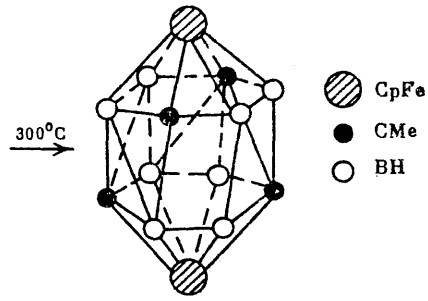
## 2. 14-Vertex Polyhedral Ferracarbaboranes



The 14-vertex *closo*-polyhedra can have structures of two types—those of a two-cap hexagonal antiprism and a six-cap cube. The 14-vertex *nido*-polyhedra can exist in several structures with a pentagonal or tetragonal open face. Polyhedral ferracarbaboranes with 14 vertices have been obtained comparatively recently and for this reason only a few examples are so far known. The polyhedral expansion of the four carbon *nido*-carbaborane (LIV) with subsequent addition of the CpFe fragment leads to the formation of a complex mixture of products containing 14-vertex dinuclear ferracarbaboranes:[40,70-73]



Compound (CXII) is a four-carbon carbaborane substituted at the B atom by the ferrocenyl group, which has been demonstrated by X-ray diffraction.[73] The dinuclear ferracarbaboranes (CVIII)–(CXI) have been obtained in the form of four diamagnetic isomers. The structures of complexes (CX) and (CXI) have not so far been established. Those of the isomers (CVIII) and (CIX) have been determined by X-ray diffraction.[70,71] Both complexes have the *nido*-structure with pentagonal B(9)–C(11)–C(14)–B(13)–B(12) [compound (CVIII)] and tetragonal Fe(7)–C(14)–C(11)–B(9) [compound (CIX)] openfaces. A mechanism has been proposed for the formation of several ferracarbaboranes of different structure from one four-carbon carbaborane, namely compound (LIV).[72]



The ferracarbaboranes (CVIII) and (CIX) each contain 30 skeletal electrons and, according to the TCSEP, should have the *closo*-structure, which is not in fact observed. This can be accounted for by the presence of an appreciable potential barrier to the transition from the 14-vertex *nido*-systems to *closo*-systems.[71] On heating in nonane, the *nido*-ferracarbaboranes (CVIII) and (CIX) rearrange:

The structure of complex (CXIII) has not been established, while the diamagnetic complex (CXIV) has been characterised by X-ray diffraction.[71] The ferracarbaborane has the *nido*-structure with an open pentagonal face. On further heating, complex (CXIV) isomerises to the *closo*-polyhedron (CXV), which is also capable of undergoing thermal rearrangement to complex (CXVI):

Complexes (CXV) and (CXVI) are diamagnetic and each contains 30 skeletal electrons, which satisfies the TCSEP requirement for 14-vertex polyhedral *closo*-structures. The structures of complexes (CXV) and (CXVI) have been proposed on the basis of the analysis of their $^{11}B$ and $^{13}C$ NMR spectra.[71] Thus the isomeric ferracarbaboranes (CVIII), (CIX), and (CXIV) are a new class of metallacarbaboranes—metallacarbaboranes which have the *nido*-structure although the *closo*-structure is preferred. They have been called pseudo-*nido*-metallacarbaboranes.[71] The greater stability of the 14-vertex dinuclear ferracarbaboranes when the CpFe fragments in the polyhedral skeleton are separated from one another to the maximum extent as a consequence of the maximum overlap of the AO between individual vertices of the polyhedron has been justified theoretically.[74] It has been suggested that the pseudo-*nido*-ferracarbaboranes be regarded as precursors of the hitherto unknown polyhedral *closo*-metallacarbaboranes with 15 vertices.[71] Thus if a CpCo fragment coordinated to the atoms of the pentagonal open face could be introduced in some way into complexes (CVIII) and (CXIV),

one could obtain 15-vertex polyhedral *closo*-cobaltferracarbaborane of the type $CoFe_2C_4B_8$, satisfying the TCSEP requirements—32 skeletal electrons for 15 vertices.

---o0o---

As can be seen from the data described above, the efforts of investigators of polyhedral ferracarbaboranes, ferraboranes, and ferraheteroboranes with the CpFe fragment in the skeleton have been largely concentrated on the development of methods for the synthesis of new polyhedral systems, while the chemistry of these interesting compounds remains, with a small exception, virtually uninvestigated. The study of the reaction of one of the ferracarbaboranes, namely $\eta^5$-cyclopentadienyl-$\eta^5$-(3)-1,2-dicarbollyliron, and of its derivatives yielded a number of interesting compounds with unusual properties. In view of the wide variety of ferracarbaborane systems, we are justified in assuming that these will be found to undergo new interesting chemical reactions.

# Reaction-sorption Methods for the Concentration of Impurities in Their Gas-chromatographic Determination in Air

Yu.S.Drugov and V.G.Berezkin

The role of the reaction-sorption (chemical-sorption) method in the analysis of contaminants in air is examined, the physicochemical principles of the method are briefly described, and examples of their practical use for the identification and quantitative determination of harmful impurities in the atmosphere and in the air of the workplace in factories are presented. The review is based on studies published in 1972-1985.
The bibliography includes 93 references.

CONTENTS

I. Introduction 546

III. The reaction-sorption method—a new version of the procedure for the concentration of impurities in analysis 547
IV. Identification of impurities in the reaction-sorption concentration method 554

## I. INTRODUCTION

The successful struggle against the contaminaton of air, water, and soil by harmful chemical compounds, mainly of anthropogenic origin, often depends on the development of effective methods for the monitoring of toxic chemicals, among which gas chromatography has quite justifiably received most attention, particularly in the analysis of volatile organic compounds.[1-5] The first studies on the gas-chromatographic determination of harmful substances in the atmosphere and in the air of the workplace in factories were published about 25 years ago and at the present time ~80% of all the determinations of organic compounds in air are made by this method.[2,3,5] The develoment of gas-chromatographic methods and the expansion of their applications have continued up to the present time[6-11] and combined or hybrid methods have been acquiring increasing importance.[3,4,6] In our view, the greatest advances in the development, improvement, unification, and wide-scale employment of chromatographic methods for the monitoring of contaminants in air can be expected on these lines.[1-4,12-14]

Together with the use of physical methods,[3,4,14] the combination of chemical and chromatographic methods has been used successfully in gas chromatography for the identification of the separated substances.[6] The chemical methods in gas chromatography are based on the use of the chromatographic separation of impurities in combination with chemical reactions of the eluate.[3,6,9] The simplicity and effectiveness of the chemical methods[6] have gained for them a well established place in the analytical chemistry of the contaminants of air, particularly in the selective gas-chromatographic determination of the most important (target) components of the contamination[3,9] and for the identification of minor components in complex mixtures of harmful substances.[3,10,11] Analytical reaction gas chromatography includes three methods: the separation method (chromatography), the method used to determine the compounds analysed (physicochemical detection), and the method for the chemical transformation of the compounds analysed.[6]

This review is devoted to the use of one of the most important versions of the gas-chromatographic analysis of impurities—the reaction-sorption method (RSM), which includes the concentration, identification, and quantitative determination of harmful substances in air.

## II. THE APPLICATION OF REACTION-CHROMATOGRAPHIC METHODS IN THE DETERMINATION OF CONTAMINANTS IN AIR

The most important problem in the analytical chemistry of the contaminants in air is that of the correct and reliable identification of volatile toxic substances after their chromatographic separation.[3] The determination of the qualitative chemical composition of a sample of complex and multicomponent mixtures of different nature is known to be extremely difficult and the validity of the analysis depends on many factors and in the first place on the method used to identify the mixture components.[4,10,14]

The traditional methods for identification from the chromatographic retention characteristics of the impurities[14] (the method of additives, the use of pure substances, the application of logarithmic relations between the retention volume or index and the properties of the compound analysed, etc.) make it possible to achieve reliable results only in the analysis of mixtures of known or partly known composition or mixtures of substances of one homologous series (class, type).[2-4] In more complex cases, in the analysis of compounds of several types, these methods are as a rule relatively ineffective and either chromatographic samples on columns with stationary liquid phases of different polarity, or analysis with the aid of selective detectors, or reaction-chromatographic determination (identification) of impurities are used in order to obtain reliable results.[2,3,5]

However, the identification of chromatographic spectra obtained on columns with different types of packing involves highly significant difficulties and, when selective detectors are used (for example, an electron capture or flame ionisation detector), the information obtained is not always unambiguous owing to the lack of information about the sensitivity of these detectors for compounds of different classes.[3]

In all cases of the analysis of complex mixturs of impurities in air the reaction-chromatographic methods for the identification of impurities, which make it possible to achieve significantly more reliable results than the standard chromatographic procedures, are more effective.[2,3,5,10,11] In the analysis of mixtures of inorganic compounds it is much easier to identify the impurities than to elucidate the complex chromatographic spectra of organic substances, which as

a rule correspond to many isotypical compounds with similar properties.[3,4] In the determination of inorganic substances, one therefore is more likely to be concerned with the improvement of the detection characteristics, the reduction of the limits of detection of impurities, and the increase in the selectivity of the determinations against the background of other compounds in the sample accompanying the determination or interfering with the latter.[3,9]

One of the most effective and simplest reaction-chromatographic procedures for the identification of impurities is the subtraction (absorption) method.[6] Its principle consists in the absorption of individual compounds or separate groups (classes) of chemical substances in a reactor placed in the chromatograph thermostat before or after the chromatographic column.[6,8] The combination of the methods for the subtraction of impurities with subsequent gas-chromatographic analysis of the eluate with the aid of selective detectors[6,10,11] or the combination of the reaction-chromatographic methods with the usual gas-chromatographic analytical procedures[3,5,6,9] is even more effective.

However, one extremely significant disadvantage is characteristic of all the methods listed above. When all the impurities present in air are concentrated simultaneously in the trap with the sorbent, the subsequent identification of the compounds is made very much more difficult and in addition there is an appreciable change in the composition of the sample (and the results of the analysis are therefore distorted) as a result of the chemical reactions of the test substances on contact with the adsorbent[3,11,14] or in the extraction of the sample from the trap by the thermal desorption method.[8]

The fractionating sampling method, which makes it possible to avoid the above difficulties and significantly increases the reliability of the idenfitication of impurities, is therefore much more promising.[2,5,8,11–13] One way of solving this problem involves the use in gas chromatography of the method of the reaction-sorption concentration of impurities.

## III. THE REACTION-SORPTION METHOD—A NEW VERSION OF THE PROCEDURE FOR THE CONCENTRATION OF IMPURITIES IN ANALYSIS

### 1. Concentration of Impurities on Solid Sorbents

Analysis of the literature in recent years,[1–13] devoted to the determination of contaminants in air, has shown that in all these publications special attention has been devoted to questions of sampling and concentration of microimpurities. This is not fortuitous. Sampling is one of the most difficult stages in the analytial procedure for the determination of impurities in air. The results of exact and careful analysis lose all significance when the sample is incorrectly taken and when the sampling procedure is invalid.[3] This is particularly relevant to the analysis of contaminants in air—a complex labile system containing a multiplicity of chemical compounds with low concentrations and subjected to the action of moisture, oxidants, radiation, etc.

Analytical chemists have nowadays concentrated attention on the problem of obtaining a representative sample of the contaminants in air, whose components differ markedly from one another in their chemical and physical properties and in their concentrations (from $10^{-4}$ to $10^{-7}$ wt.%).[3,9–11] This question is extemely important because, having entered the concentrator, the compounds of the sample pass to a completely diffierent state:[3,5,7,14] (1) the concentration of impurities increases appreciably (by a factor of 100–1000 or more); (2) substances with completely different chemical properties and concentrations (differing by factors of $10–10^8$), many of which are reactive, unstable, susceptible to oxidation, and tending to hydrolyse and to undergo other reactions, accumulate simultaneously in the trap with the sorbent; (3) the increase of the concentration of the impurities in the trap tends to increase the likelihood of chemical interactions and irreversible transformations of the sample components; (4) the active centres on the large surface area of the sorbent (and sometimes also the possible impurities in the sorbent, for example, metals) have a catalytic effect, accelerating these reactions; (5) during the enrichment of the sample on the sorbent, accompanying impurities are coadsorbed (competitively sorbed), which leads to anomalies in the saturation of the sorbent surface and the initial sample composition is distorted.

As a result of these processes, the concentrations of the impurities in the trap-concentrator with the sorbent become markedly differentiated. The adsorption of impurities takes place non-uniformly, as a result of which the quantitative composition of the concentrated impurities may differ greatly from their composition in air.[3,15,16] Furthermore, the chemical reactions of the sample in the trap alter its qualitative composition and distort the analytical results.[3,13,14]

Thus amines tend to interact specifically with free vinyl groups on the surface of Chromosorb 102 and Porapak Q.[17] The presence of traces of $O_2$ in the carrier gas (nitrogen) during the concentration of amine impurities from air and on raising the temperature of the sorbent in thermal desorption to 100 °C leads to the depolymerisation and oxidation of the sorbent.[18] As a result, false peaks ("artefacts") of aromatic ketones and other carbonyl compounds appear on the chromatograms, distorting the results of the identification of the impurity. The same sorbents interact vigorously with $NO_2$, forming NO at 25 °C, and, on raising the temperature (to 125 °C), NO and $H_2O$ are formed with simultaneous nitration of the polymeric sorbents.[19]

The sorption capacities of Tenax and Amberlite HAD-2 in relation to n-pentane, benzene, acetone, 2-propanol, and acetonitrile change significantly as a result of the nitration and sulphonation of the sorbent by the chemically active components of industrial waste (sulphur and nitrogen oxides), the maximum change in the sorbent capacity having been noted for polar sorbates.[20] All reactive gases ($Cl_2$, HCl, HBr, $ClF_3$, $F_2$, HF, $ClO_2$, $O_3$, $SO_2$, $SO_3$, $NO_2$, etc.) behave similarly, interacting with one another and with almost all known sorbents and connecting tubes of the chromatographic system.[21]

In the course of the trapping of smoke gases from air, Tenax is gradually decomposed by $NO_2$ and $SO_2$ with formation of 2,6-diphenyl-*p*-benzoquinone.[22] On sorbents such as activated charcoal, $Al_2O_3$, silica gel, Florisil, and Tenax, nitrosamines, which are initially absent from air, are formed when air is passed through them.[23] When impurities from air containing olefinic hydrocarbons and free halogens are concentrated on the surface of Tenax, Amberlites, and carbonaceous sorbents, chemical reactions take place (for example, the interaction of $Cl_2$ with but-2-ene or cyclohexene) and lead to the appearance in the mixture analysed of halogenohydrocarbons which were previously absent from it.[24]

The possibility of the appearance of false peaks during the sampling process is illustrated by the data in Table 1. By concentrating ethylbenzene, 1-hydroxyethylbenzene, acetophenone, 1-octanol, and 1-octanal from ozonised air (the $O_3$ content was 1.0–1.3 mg $m^3$) on Tenax, it was shown[25] that at room temperature these compounds are not oxidised in the column with Tenax. However, the simultaneous presence of

oxidants ($O_3$, $NO_2$, $SO_2$, $Cl_2$) and water vapour in air leads to the decomposition of Tenax and of the toluene, styrene, and cyclohexane microimpurities concentrated on it.[26] Several deuteriated oxidation, halogenation, and nitrosation products (three chlorostyrene isomers, benzaldehyde, and dimethylnitrosamine)[27] as well as acetophenone, phenol, α-hydroxyacetophenone, and epoxyethane[26] have been identified by chromato-mass-spectrometry. When analogous experiments were carried out with the preliminary passage of the air analysed through a glass filter treated with a 1% or 10% $Na_2S_2O_3$ solution, the content of the halogenation and oxidation products in the substances collected on the filter was sharply reduced.[26,27]

**Table 1.** The formation of 1,2-dichlorocyclohexane in the concentration of cyclohexenes and chlorine on Tenax.[24]

| Inorganic contaminants* | | | | Cyclohexene* | 1,2-Dichlorocyclohexane** |
|---|---|---|---|---|---|
| $O_3$ | NO | $NO_2$ | $Cl_2$ | | |
| 0 | 0 | 0 | 104 | 90 | 0 |
| 100 | 0 | 0 | 0 | 90 | 0 |
| 0 | 300 | 350 | 104 | 90 | 0 |
| 160 | 0 | 0 | 104 | 818 | 110 |
| 0 | 0 | 0 | 104 | 818 | 100 |
| 180 | 0 | 0 | 104 | 818 | 120 |
| 0 | 0 | 0 | 104 | 818 | 110 |
| 0 | 100 | 0 | 104 | 818 | 100 |
| 100 | 0 | 0 | 0 | 818 | 0 |
| 720 | 0 | 0 | 104 | 818 | 120 |

*The concentrations $10^7c$ (wt.%) are quoted.
**The amount of 1,2-dichlorocyclohexane formed (in ng) is indicated.

When styrene is concentrated by sorption in a tube with activated charcoal, there is a potential risk of a change in the initial concentration of styrene as a result of catalytic reactions.[28] During the thermal desorption of $C_4$–$C_5$ light hydrocarbons concentrated on activated charcoal, some of them isomerise at 150–250 °C, giving rise to compounds previously absent from air—*cis*-but-2-ene and *cis*-pent-2-ene.[7]

The coadsorption of impurities in the trap with the sorbent also alters the composition of the sample. The study of the quantitative characteristics of the sorption of benzene on graphitised carbon black and of their influence on the relative retention volumes of n-pentane, acetone, nitromethane, propanol, and tetrahydrofuran showed that the coadsorption of benzene can lead (depending on the degree of surface coverage of the carbon black by benzene) both to an increase (for a surface coverage of 0.3–0.5) and a decrease (for a surface coverage of less than 0.3) of the retention parameters of the impurities.[16] This is illustrated in Fig.1, which shows that the degree of sorption of acetone by Carbopack C is reduced as the free surface of the adsorbent is occupied by the benzene molecules.

Water vapour is a particularly strong competitor towards the sorption of organic impurities.[15] According to current ideas,[29] the principal cause of the strong adsorption of $H_2O$ molecules on carbonaceous sorbents is the primary adsorption centres, which are present on the surfaces of the walls of the adsorbent pores and are capable of forming hydrogen bonds. The strong sorption of $H_2O$ and $CO_2$ [15] alters the sorption of the other impurities and leads to anomalies in the process involving their concentration.[3] The polar $H_2O$ molecules can displace the previously concentrated organic impurities from the sorbent, can dissolve them, and can alter the dynamics and kinetics of the sorption of subsequent compounds in the trap. When the weight fraction of $H_2O$ in the activated charcoal is at the level of 0.02, the error of the determination is low,[15] but in the presence of an $H_2O$ weight fraction of 0.15 it amounts to 45% for ethanol and increases by 6–12% for butanol and acetone.

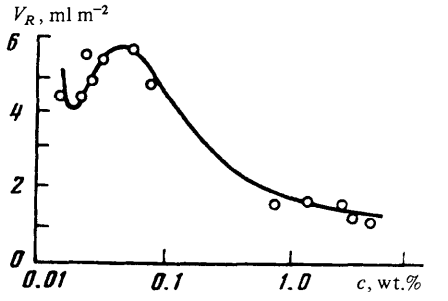

**Figure 1.** Dependence of the retention volume ($V_R$) of acetone on the benzene concentration ($c$) in the vapour phase on Carbopack C at 10 °C.[16]

Sulphates and nitrates can be formed in the preparation of the sample for analysis as a result of the reactions of some of the trapped substances with the sulphur- and nitrogen-containing gaseous oxides and acid vapours ($SO_2$, $NO_2$, $HNO_3$, etc.) present in the matrix. The above artefacts, associated with side reactions on the surfaces of sorbents, can cause an error in the determination of the impurities amounting to 8–11 mg m$^{-3}$.[8]

## 2. The Reaction-Sorption Method for the Concentration of Impurities

The reaction-sorption method (RSM) makes it possible to prevent the chemical interaction of the sample components during the concentration process and to reduce to a minimum the influence of coadsorption.[3,30,31] The essential feature of the RSM involves the preliminary removal of the intefering impurities during the sampling of air with the aid of a reactor containing sorbents or chemical reagents and placed before the concentrator. As a result of this, only the target components enter the trap with the sorbent and the method exhibits a high selectivity, which can vary within wide limits when the reactor packing is altered.[3,30] The fractionation of the compounds in the sample before their concentration not only improves the kinetics and dynamics of the sorption of the target components but also creates conditions for their more reliable identification because most of the sample components (approximately 70–80%) remain in the pre-column-reactor.

Preliminary absorption of compound interfering with analysis had already been used earlier to increase the selectivity of the determination of the toxic impurities in the air of the working zone in industrial undertakings by a linear colour [comparison?] method.[30] The analysis was carried out via a

two-step scheme: chemical separation and detection (Fig.2, Scheme *A*). The colour reactions of the impurities analysed with appropriate reagents (colorimetric and linear colour [comparison?] methods).

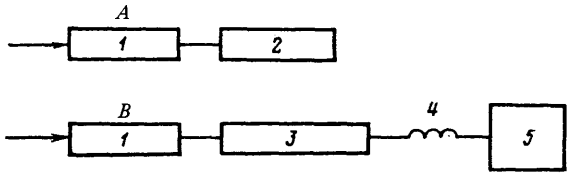

**Figure 2.** RSM schemes for the analysis of impurities: 1) column with sorbents and chemical reagents (pre-column-reactor); 2) column with indicator powder; 3) concentration column with sorbent; 4) chromatographic column; 5) chromatographic detector.

In the chemical-sorption versions of the concentration and gas-chromatographic determination of impurities,[30,31] it is useful to employ the following analytical scheme: chemical (or physical) separation—concentration—chromatographic separation—detection (Fig.2, Scheme *B*). In this version the selectivity of the separation of impurities (the overall selectivity of the separation in the pre-column and in the chromatographic column) is much higher than in the first version (Scheme *A* in Fig.2). The limit of the detection in analysis using Scheme *B* is usually lower by 3–4 orders of magnitude than in the linear colour method for the determination of impurities in air.[30]

On the other hand, the reaction-sorption method for the concentration of impurities differs significantly from the subtraction method employed in gas chromatography[31] and presupposes the selective absorption of the non-target components in combination with the subsequent concentration and chromatographic determination of the target components.[3,30] The reaction-sorption concentration method belongs to a new group of hybrid methods and is free from many of the disadvantages characteristic of the traditional procedures for the trapping of impurities from contaminated air.

We shall consider the possibilities of the RSM in its application to the solution of certain practical problems in the analysis of contaminated air.

## 3. Increase in the Reliability of the Determination (Decrease of the Probability of the Chemical Interaction of the Sample Components)

The extensive possibilities for the variation of the composition of the sorbents and chemical reagents in the packing within the fore-column-reactor make it possible to use RSM in solving a number of problems in the determination of small amounts of reactive chemical impurities in air (Table 2).

*(a) Determination of corrosive gases.* Apart from their interaction with the packing of the chromatographic column and their absorption by the connecting tubes in the chromatograph, reactive gases frequently react with one another (particularly when they are concentrated on sorbents), which hinders their gas-chromatographic determination or makes it impossible.[21] An example may be provided by the reactions in the $Cl_2$–HCl–$ClO_2$–$O_2$–$NO_2$ system, characterising the contamination of air in undertakings where inorganic syntheses are carried out.[38]

**Table 2.** Certain versions of the determination of impurities in air by the RSM method.

| Compounds analysed | Sorbent in precolumn | Impurities absorbed | Target components | Refs. |
|---|---|---|---|---|
| $SF_6$, $SF_4$, $SF_2$, HF, $S_2F_2$, $SOF_2$, $COF_2$, $SO_2F_2$ | NaF | $F_2$, HF | $SF_4$ | [32] |
| $Cl_2$, $ClO_2$, HCl, $O_2$, $NO_2$ | glass fibre, −78° C | $ClO_2$ | $Cl_2$, $NO_2$ | [21] |
| $N_2O$, NO, $NO_2$, $N_2O_4$ | 13X molecular sieve | $N_2O$, $NO_2$, $N_2O_4$ | NO | [33, 34] |
| CO, $CO_2$, $CH_4$, light hydrocarbons | 13X zeolite, Ascarite, activated charcoal, 0 °C | $CO_2$, $CH_4$, light hydrocarbons | CO | [35] |
| Olefins, $NO_2$, paraffins, $Cl_2$ | $Na_2S_2O_3$ | $NO_2$, $Cl_2$ | hydrocarbons | [36] |
| Organic and inorganic acids, aldehydes, ketones | $Na_2CO_3$ | acids | ketones, aldehydes | [36] |

When the concentration process is carried out on solid sorbents (silica gas, graphitised carbon black, porous Teflon, etc.), the components of this mixture interact even at ordinary temperatures with formation of more toxic but less reactive substances.[37,38] In many cases the principal (overall) reaction is that of chlorine and nitrogen oxides:

$$ClO_2+3NO_2 \rightarrow NO_2Cl+N_2O_5. \qquad (1)$$

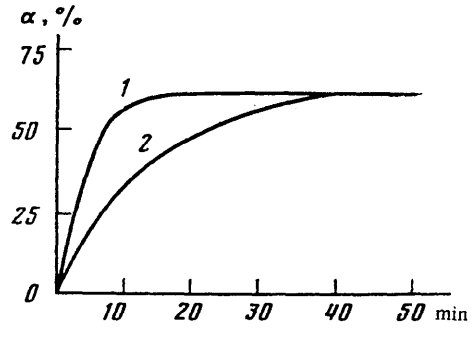

**Figure 3.** Dependence of the degree of conversion of $NO_2$ on the initial $NO_2$ : $ClO_2$ ratio; $NO_2$ : $ClO_2$ ratio: 1) 3 : 1; 2) 1 : 1.[38]

Some idea about the process kinetics can be provided by the plot of the dependence of the degree of conversion of $NO_2$ on the initial concentrations of the oxides (Fig.3). When air is passed through a tube with the sorbent (for example, graphitised carbon black) at 20–35 °C, the degree of reaction of $ClO_2$ with $NO_2$ is not less than 50% (Fig.3). If account is taken also of the numerous side reactions[38] and

of the decomposition of the concentrated sample in the thermal desorption process at 150 °C,[37,38] i.e.

$$2NO_2Cl \rightarrow 2NO_2 + Cl_2 + O_2 \qquad (2)$$

then it becomes evident that a mixture of corrosive gases having a composition different from that in the initial air enters the chromatographic column (Fig.4); as a result of the different reactions in the sample, the amount of $NO_2$ and $ClO_2$ diminishes and that of $Cl_2$ increases. A pre-column containing glass wool and cooled with dry ice traps the $ClO_2$ impurity from the mixture analysed before chromatography. After this, the gas-chromatographic determination becomes significantly more accurate—the standard deviations for $Cl_2$, $NO_2$, and $ClO_2$ decrease by a factor of 2–3.[38]

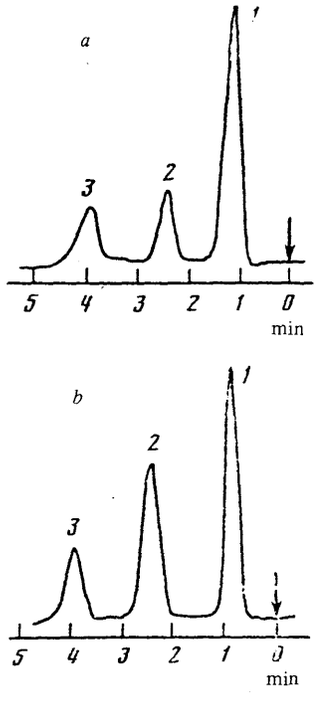

**Figure 4.** Chromatographic separation of the $Cl_2$, $ClO_2$, and $NO_2$ impurities:[38] *a*) in the usual method; *b*) in the method using a pre-column; 1) $Cl_2$; 2) $NO_2$; 3) $ClO_2$.

*(b) Nitrogen oxides.* The direct determination of NO, $NO_2$, $N_2O_4$, and $N_2O$ is difficult as a consequence of the higher reactivity of these gases.[21] The method of reaction gas chromatography (RGC), which consists in the conversion of nitrogen oxides into organic derivatives[34] requires the preliminary oxidation of NO to $NO_2$ [39] with subsequent estimation of the NO content from the difference between two determinations ($NO_2$ and the sum of NO and $NO_2$). The individual determination of NO in a mixture of nitrogen oxides† which have similar properties (and are therefore difficult to distinguish) is feasible when the mixtures are concentrated by the RSM.[33,40]

The determination of NO by the RGC method in conjunction with the RSM consists in passing the air to be analysed through a pre-column (16 cm × 5 mm) containing the 13X molecular sieve (0.5–0.25 mm fraction) subjected to a preliminary heat treatment in the course of 4 h in a stream of dry nitrogen at 350 °C. This pre-chromatographic reactor absorbs 95–97% of the admixture of $N_2O$, $NO_2$, and $N_2O_4$, but does allow NO to go through; the loss of NO (after the preliminary conditioning of the fore-column with a mixture of nitrogen oxides, in which the concentration of NO is 10 mg $m^{-3}$, for 30 min) is not more than 0.5–1.2 wt.%.

When this analytical scheme is employed, the NO content in the mixture of nitrogen oxides is determined not from the difference between the two measurements but directly (after the necessary procedure involving the oxidation of NO to $NO_2$ by $H_2O_2$) in the form of a derivative (nitrobenzene) obtained by the reaction of $NO_2$ with benzene in the presence of concentrated sulphuric acid.[39] The limit of detection of nitrogen oxides by this method is ~$10^{-6}$ wt.% with a relative standard deviation of 0.30. Fig.5 illustrates the chromatogram for the determination of NO (in the form of $NO_2$) in the exhaust gases from diesel engines, obtained using the above procedure and the RSM.[33,40]

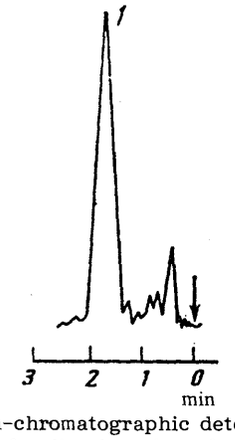

**Figure 5.** Reaction-chromatographic determination of $NO_2$ in the exhaust gases of a diesel engine after the conversion of $NO_2$ into nitrobenzene[33] (glass 1.5 m × 4 mm column with 15% of Apiezon L on Chromaton N; electron capture detector; column temperature 120 °C; detector temperature 275 °C): 1) nitrobenzene; $NO_2$ concentration in air 8 mg $m^{-3}$.

*(c) Sulphur fluorides.* Analysis of a complex mixture of corrosive sulphur fluorides ($SF_6$, $SF_4$, $S_2F_2$, $SO_2F_2$, $SOF_2$, HF, and $F_2$) is made very difficult by the active interaction of the extremely reactive HF and $F_2$ with all sorbents and constructional materials of chromatographs.[21,40] This interaction results in a low reproducibility of the determination of the target component—sulphur tetrafluoride, whose toxicity is higher than that of phosgene.[32] The content of the $SF_4$ to be determined depends on the volume of the sample injected, the presence of moisture, the ratio of the components in the mixture of fluorides, and the amount of HF and $F_2$. The relative standard deviation then varies within wide limits and can be between 0.40 and 0.8.

† The separate determination of NO and $NO_2$ is of fundamental importance for industrial labour hygiene.

Concentration of the fluoride impurities by the RSM made it possible to eliminate the influence of the reactive $F_2$ and HF. The air analysed is first passed through a pre-column (4 cm × 4 mm) with sodium fluoride (0.5–0.25 mm fraction) and the fluoride impurities are then concentrated in a trap with Porapak Q.[40] The pre-column retains almost 100% of the admixture of the corrosive $F_2$ and HF, but does not absorb $SF_4$ at low concentrations (0.1–1.0 mg $m^{-3}$). The degree of absorption of sulphur tetrafluoride by the pre-column is less than 0.4%.[32] The chromatogram of the mixture of sulphur fluorides formed in the air of a foundry during smelting in a sulphur hexafluoride atmosphere is presented in Fig.6. Concentration of the fluoride impurities by the RSM makes it possible to determine small amounts of $SF_4$ (the limit of detection is 0.05 μg) with a relative stnadard deviation of 0.22.[32,40]

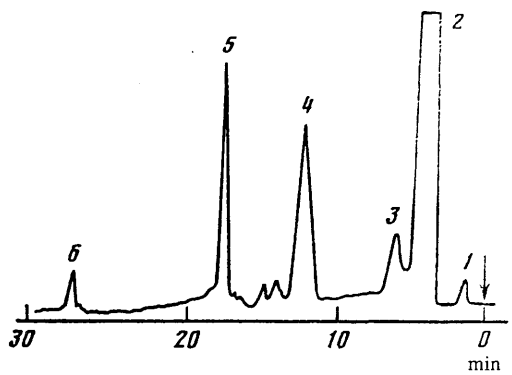

**Figure 6.** Chromatogram of sulphur hexafluoride and admixtures of lower sulphur fluorides on a 3 m × 4 mm stainless steel column with Porapak Q at 50 °C after the RSM removal of $F_2$ and HF from the mixture:[32] 1) carbon tetrafluoride; 2) sulphur hexafluoride; 3) sulphur monofluoride; 4) sulphur tetrafluoride; 5) sulphuryl fluoride; 6) thionyl fluoride.

*(d) Hydrocarbons.* It is much more difficult to discover the cause of the change in the composition of the impurities in air to be analysed in the determination of organic compounds (chemical interaction with the sorbent, coadsorption, polymerisation reactions, etc.) than in the determination of reactive inorganic gases, where chemical interaction usually predominates.[3,40] In the study of the processes involving the sorption (concentration) of organic impurities on solid sorbents with a high surface area, such changes are most clearly manifested in the thermal desorption of the sample from the sorbent, whereupon the concentrated impurities undergo thermal degradation and isomerisation reactions.[3,7,31] This factor becomes evident when the RSM concentration of the $C_5$–$C_7$ alkanes, isopentane, and hex-1-ene impurities in a trap with activated BAU charcoal is considered (Table 3).

Table 3 shows that the RSM concentration procedure makes it possible to obtain much more accurate isopentane contents than under the conditions of the traditional concentration of the hydrocarbon impurities on charcoal with subsequent thermal desorption. This finding can be accounted for by the isomerisation of the n-pentane, isopentane, and hex-1-ene impurities at the thermal desorption temperature (200 °C), which results in the formation of *cis*-but-2-ene and *cis*-pent-2-ene.[7]

**Table 3.** The reaction-sorption concentration* of isopentane in the presence of low-boiling hydrocarbons**.[36]

| $c_0$ | GC | | GC-RSM | |
|---|---|---|---|---|
| | $S$ | $c \pm \delta$ | $S$ | $c \pm \delta$ |
| 52 | 26 | 70±27 | 12 | 55±13 |
| 64 | 34 | 82±36 | 15 | 70±16 |
| 80 | 38 | 93±40 | 20 | 75±21 |
| 91 | 40 | 110±42 | 22 | 88±23 |
| 102 | 56 | 120±59 | 25 | 104±26 |

Notation: $n$ is the number of replicate determinations ($n = 6$), $c_0$ the initial isopentane concentration (mg $m^{-3}$), $c$ the arithmetical mean isopentane concentration for $n$ replicate determinations found in the presence of admixtures of other hydrocarbons (mg $m^{-3}$), $S$ the standard deviation (mg $m^{-3}$), $c \pm \delta$ the confidence interval of the concentration $c$ (mg $m^{-3}$), $\delta$ the accuracy of the direct measurement of $c$ (for a small number of measurements, $\delta = tS/n^{2/3}$, where $t$ is the Student statistic).

*The pre-column with 5A molecular sieve absorbs hydrocarbons having the normal structure.

**The values of $S$ and $c \pm \delta$ (fiducial probability $P = 95\%$), obtained by the traditional gas-chromatographic method (GC) and the method involving the RSM concentration procedure (GC–RSM) are quoted).

## 4. Reduction of the Influence of the Coadsorption of Impurities

The composition of the sample of organic impurities to be concentrated is usually distorted by the coadsorption of impurities in the trap-concentrator with the sorbent.[3,7,41] This process, which influences the validity of the analysis, takes place invariably when components of any mixtures of harmful substances are extracted from air.[3]

In order to explain the nature and mechanism of coadsorption and its influence on the parameters of the impurity sorption (concentration) process on sorbents, it is necessary to examine the behaviour of impurities in the sorption–desorption system.

*(a) Sorption dynamics.* In the concentrator containing the sorbent, the impurities to be analysed undergo frontal enrichment. Their concentration in the gas then usually diminishes sharply as air passes through the layer of sorbent. The end of the operation of the reactor (its becoming "spent") is assumed to be the instant of the appearance of the test substance (substances) beyond the layer of sorbent—to so-called "breakthrough".# Impurities are distributed in the sorbent layer in accordance with their adsorption isotherms.[42]

# In analytical practice "breakthrough" is defined as the appearance of the impurities to be analysed beyond the sorbent layer, their concentration amounting to 5 or 10% of the initial concentration of the harmful substances in air.[5,41]

The maximum operating time of the trap with the sorbent (the time before breakthrough) $\tau$ can be determined from the Shilov equation[42,43]

$$\tau = KL - \tau_0, \quad (3)$$

where $K$ is the coefficient of the protective action of the layer, $L$ the length of the sorbent layer, and $\tau_0$ the time to the end of protective action by the layer. The coefficient of protective action by the layer is defined by the expression

$$K = a_0/\omega c_0, \quad (4)$$

where $a_0$ is the equilibrium static activity, $\omega$ the flow rate, and $c_0$ the initial concentration of impurities in air.

The Shilov equation can be also presented in the following form (the Mecklenburg equation):

$$\tau = K(L - h). \quad (5)$$

It is assumed that only the adsorbent layer with the length $L-h$ is fully saturated while the layer whose length is $h$ remains unsaturated. The graphical representation of this layer is illustrated in Fig.7. The length of the unsaturated or unused layer $h$ is determined from the intercept on the abscissa axis obtained when the straight line $B$ (dashed line) is produced.[43]

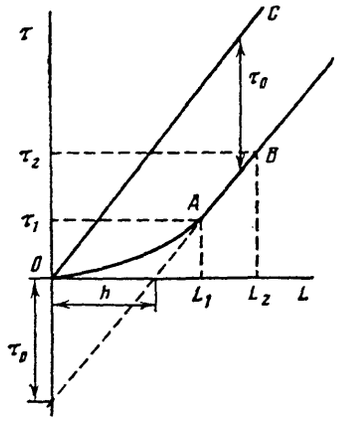

**Figure 7.** Dependence of the sorption time $\tau$ on the length of the sorbent bed $L$:[43] OC straight line—theoretical dependence of the sorption time on the length of the absorber bed for an infinitely high rate of sorption; OAB curve—actual dependence of the sorption time on the length of the absorber bed.

On comparing the Shilov and Mecklenburg equations (3) and (5), it is possible to find the relation between the loss of the time of protective action $\tau_0$ and the length of the unused sorbent layer $h$:

$$\tau_0 = Kh. \quad (6)$$

During the RSM concentration process in the pre-column, all (or most of) the accompanying impurities are removed (adsorbed), which entails a change in the sorption dynamics of the target sample components on the sorbent in the trap. It follows from Eqn.(6) that Fig.7 that a decrease of $h$ leads to a decrease of $\tau_0$. The concentrator with the sorbent located beyond the pre-column therefore works more effectively and its sorption capacity with respect to the target components increases.

*(b) Coadsorption dynamics.* The impurity adsorption processes in the trap with the sorbent and the influence of the sorption of the accompanying impurities on the adsorption of the target components can be represented by several equations analogous to the equation of the Langmuir adsorption isotherm.[3,42]

In the case of the simultaneous adsorption of the target component (whose concentration in air is designated by $c_1$) and of the accompanying impurities (concentrations $c_i$), the adsorption of the target component can be represented by the following equation:[36]

$$a_1 = b_1 c_1 N \Big/ \left[1 + \sum_{i=1}^{m} \frac{b_i c_i}{K_i}\right], \quad (7)$$

where $m$ is the number of impurities, $N$ the maximum possible number of active centres per unit area of the adsorbent, $K_i$ the specific degree of saturation of the active centre of the sorbent by the test substance, and $b_1$ the adsorption coefficient. Eqn.(7) can also be written in the following way:

$$a_1 = b_1 c_1 N \Big/ \left[1 + \frac{b_1 c_1}{K_1} + \sum_{i=2}^{m} \frac{b_i c_i}{K_i}\right]. \quad (8)$$

In this equation the term $\sum_{i=2}^{m} b_i c_i / K_i$, which determines the coadsorption of admixtures, significantly reduces the degree of adsorption of the main substance, impairing the degree of its concentration and interfering with the formation of a representative sample. This leads to systematic errors in the determination of microamounts of harmful substances in air, which it is virtually impossible to obviate in the usual version of analysis.[3,36] The employment of a pre-column enables one to increase appreciably the efficiency of the concentration of the target impurity, whose relative concentration increases in the course of the RSM concentration process to a significantly greater extent than in the usual version of the concentration procedure on sorbents. This factor creates preconditions for increasing the degree of enrichment of the sample, for reducing the detection limit for the target components (other analytical conditions being equal), and for the preparation of a representative sample of the impurities in air.[3,36,49]

*(c) Decrease of the degree of coadsorption.* The influence of coadsorption can be so great that the losses of the target component during the concentration of impurities can amount to 20–50%, which is 7–8 times greater than the losses due to the incomplete desorption of the impurities from the sorbent in the extraction of individual compounds from air.[3] The usual version of the concentration from air of small amounts of vinyl chloride in the presence of admixtures of chlorine-containing hydrocarbons which accompany it under real conditions (overall concentration 110 mg $m^{-3}$) may serve as an example. At a vinyl chloride concentration of 10 mg $m^{-3}$, a temperature of 20 °C, and for an air flow rate of 0.4 litre $min^{-1}$, breakthrough occurs after 40 min, while in the presence of impurities the time before breakthrough is reduced to 24 min. The losses of vinyl chloride in the concentration process change correspondingly from 6.2% in the concentration of vinyl chloride alone to 44% when vinyl chloride is concentrated in the presence of admixtures of chlorine-containing hydrocarbons.[49]

The coadsorption of admixtures of other organic compounds, which frequently accompany vinyl chloride in air from the workplace involved in the processing of polymers based on poly(vinyl chloride),[3,50,51] can reduce to an even greater extent the degree of adsorption of the monomer impurity by the adsorbent than halogen-containing compounds (Fig.8).

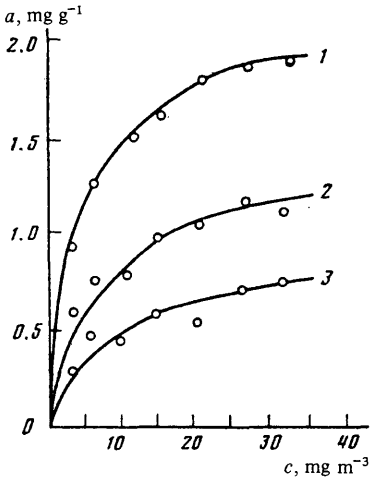

**Figure 8.** The influence of the coadsorption of accompanying admixtures (propene, methanol, acetone, acetaldehyde, and tetrachloroethylene) on the efficiency of the sorption of vinyl chloride by activated charcoal:[50] impurities: 1) vinyl chloride (adsorption isotherm); 2) vinyl chloride + admixtures (1 : 1); 3) vinyl chloride + admixtures (1 : 8); $a$ = amount of vinyl chloride adsorbed by the charcoal; $c$ = concentration of impurities.

The use of a pre-column in all the cases enumerated above gives rise to a positive result, increasing the time (volume) before the breakthrough of the target components of the sample, increasing the sorption capacity of the concentrator with the sorbent, and tending to reduce the limit of detection of the impurities. This can be illustrated by experimental data for the sorption and RSM concentration of organic impurities of different nature in a trap containing an activated charcoal (Tables 4–6).

A consequence of the increase in the volume before the breakthrough of the test substances was the corresponding increase (by a factor of 2–3) of the sorption capacity of the sorbent with respect to the target components (Table 5). The effectiveness of the sorption in the concentrator with BAU charcoal–pre-column system was compared with the analogous data calculated from the results of sorption experiments for individual compounds on the above adsorbent using literature data.[3,5,7,13,44–48] The sorption capacity was calculated from the results of the chromatography of the test mixtures, taking into account the instant of breakthrough, or was determined by a direct method involving the weighing of the tube containing the charcoal before passing the air sample through it and after breakthrough.

Tables 4 and 5 show that the removal of the accompanying admixtures by the pre-column (the sorption characteristics were calculated for each compound quoted in the Table on the assumption that all the remaining compounds are accompanying admixtures) makes it possible to avoid coadsorption and to increase the efficiency with which the target components are trapped.

**Table 4.** The change in quantity before breakthrough* using the RSM concentration of impurities on activated charcoal.[3,36]

| Compound | $c$, mg m$^{-3}$ | PDK***, mg m$^{-3}$ | $V_{br}$, litre/100 mg of charcoal | | |
|---|---|---|---|---|---|
| | | | without pre-column | with pre-column | from data in Refs. 44–48** |
| Benzene | 100 | 5 | 30 | 53 | 42 |
| Toluene | 50 | 50 | 12 | 20 | 23.1 |
| Hexane | 100 | 100 | 14 | 35 | 33 |
| Ethyl methyl ketone | 100 | 200 | 3 | 8.8 | 8.2 |
| Ethanol | 1000 | 1000 | 4.5 | 11 | 3–25 |
| Tetrachloroethylene | 100 | 10 | 8 | 24 | 33.2 |
| Triethylamine | 100 | 10 | 4 | 8 | 6.6 |
| Dipropyl sulphide | 100 | 50 | 12 | 20 | 22 |

*The volume before breakthrough $V_{br}$ was determined for individual substances in the presence of the accompanying admixtures.

**The values of $V_{br}$ used in the table were selected from the published literature data[44–48] subject to the requirement that the experimental conditions under which all the tabulated data were obtained are similar.[36]

***Transliterated Russian abbreviation which the authors do not define. Its significance is obscure (Ed.of Translation).

**Table 5.** The sorption capacity of the concentration tube containing BAU activated charcoal in the trapping of organic vapours from air.[36,49,51]

| Compound | Sorption capacity, mg/g of sorbent | | |
|---|---|---|---|
| | without pre-column | with pre-column | according to data in Refs. 7, 13, and 45–48 |
| Benzene | 30 | 53 | 60 |
| Toluene | 80 | 210 | 280 |
| Hexane | 18 | 35 | 42 |
| Ethyl methyl ketone | 36 | 75 | 90 |
| Ethanol | 15 | 35 | 42 |
| Tetrachloroethylene | 26 | 78 | 100 |
| Triethylamine | 20 | 38 | 35.5 |
| Dipropyl sulphide | 64 | 170 | 156 |

The somewhat greater sorbent capacity given in the literature can be accounted for by the fact that the values quoted in the literature were calculated for pure individual substances, while a pre-column does not remove entirely the accompanying admixtures. This influences the residual sorption (coadsorption), inducing some decrease in the degree of sorption of the target components (approximately by 15–25%).

The increase in the sensitivity of the determination is a consequence of the more effective sorption of admixtures of the target components in the RSM concentration process. Table 6 shows that the reaction-sorption concentration process makes it possible to reduce the limit of detection of principal classes of organic impurities by a factor of ~2–3.

An important result of the use of the RSM, associated with the elimination of the coadsorption of admixtures, is the improvement of virtually all the metrological characteristics of the method. This can be illustrated by the data in Table 7

which presents the results of the determination of small amounts of the vinyl chloride impurity. Comparison of the results the determination of this gas by two different methods (gas chromatography and gas chromatography + RSM) shows that the latter should be preferred (Table 7).

**Table 6.** The sensitivity of the determination ($\alpha$) of toxic impurities.[3,36,49,51]

| Compound | Sensitivity of determination*, mg m$^{-3}$ | |
|---|---|---|
| | $\alpha_1$ | $\alpha_2$ |
| Aromatic hydrocarbons | 0.10 | 0.03 |
| Paraffinic hydrocarbons | 0.10 | 0.06 |
| Halogenohydrocarbons | 0.50 | 0.25 |
| Oxygen-containing organic substances | 0.80 | 0.40 |
| Organosulphur compounds | 0.60 | 0.40 |
| Aromatic amines | 0.20 | 0.10 |

*$\alpha_1$ and $\alpha_2$ are the average detection limits in the usual version of the chromatographic analysis with the aid of a flame-ionisation detector and in the RSM analysis respectively.

**Table 7.** The validity of the analytical results in the determination of vinyl chloride*.[52]

| GC | | | GC-RSM | | |
|---|---|---|---|---|---|
| $s$ | $s_r$ | $c\pm\delta$ | $s$ | $s_r$ | $c\pm\delta$ |
| 0.28 | 0.40 | 0.70±0.20 | 0.17 | 0.18 | 0.98±0.12 |
| 0.16 | 0.36 | 0.44±0.12 | 0.56 | 0.14 | 0.56±0.10 |
| 0.05 | 0.45 | 0.11±0.04 | 0.03 | 0.30 | 0.10±0.02 |

Notation: $m$ is the sample size (μl) and $S_r$ the relative standard deviation; for the significance of the remaining symbols, see Table 3.
*The test was carried out by comparing the results obtained using the RSM with those obtained in the usual version of gas chromatography (for $n = 10$ and $P = 95\%$; $m = 10$ μl).

### 5. Improvement of the Chromatographic Separation

An important aspect of the use of the RSM in the improvement of the chromatographic separation of impurities. The absorption in the pre-column of the accompanying admixtures increases the efficiency of the separation of the target components from other compounds in the sample. Apart from the possibility of securing more reliable information about the composition of the compounds to be analysed, this procedure increases the accuracy of the determination of the target components.[3,34,36]

The direct (without the preliminary concentration of the impurities) gas-chromatographic determination of small amounts of CO, one of the principal contaminants in the air from the workplace, may serve as an example.[35] The absorption of the $C_1$–$C_3$ light hydrocarbons, $O_2$, $N_2$, $CO_2$, and water vapour, which interfere with the determination of CO, in a pre-column with Ascarite, 13X molecular sieve, and activated charcoal at 0 °C makes it possible to achieve a satisfactory separation of CO from $CH_4$ and other admixtures on an analytical column with 5A zeolite and to increase the accuracy of the determination of the concentration of CO. For CO concentrations in the range 20–50 mg m$^{-3}$, the use of the RSM permits the reduction of the error of the determination from 18–20% to 12%. A fore-column containing a layer of Chromosorb W impregnated with a 0.1 M solution of $SnCl_2$ (for the absorption of $H_2S$) and a layer of activated charcoal (210 mg) for the adsorption of oxidisable hydrocarbons is suitable for an analogous purpose.[53] In order to fractionate the mixture of reactive gases in the determination of $SO_2$ in air, the nitrogen oxides, which interfere with the determination, are absorbed in an absorber containing a 0.6% solution of sulphamic acid, while $H_2S$ is removed in a pre-column with an aqueous solution of $Pb(CH_3COO)_2$.[54]

Different versions of the RSM concentration process have been used to improve the chromatographic separation of impurities comprising hydrocarbons,[49] halogenohydrocarbons, and oxygen-containing organic compounds,[36] as well as reactive inorganic gases[34] and various inorganic compounds.[40] In order to reduce the error in the determination of low concentrations of a hydrazine and asymmetric dimethylhydrazine aerosol, the admixtures of ethyl acetate, 2-furoaldehyde, and their derivatives, which interfere with the analysis, were first removed from the mixture (in the course of the extraction of the above impurities from air) by passing the mixture through a pre-column.[55]

### 6. The Removal of Moisture

One of the important conditions for the prevention of loss in mixtures of air contaminants to be analysed, associated with coadsorption, is the removal of moisture in the course of the extraction of the impurities from air.[3,21,34] This problem has several different solutions,[34,40] the best of which involves the application of reaction-sorption systems.[30,31] The use of the RSM concentration process, which provides for the removal of $H_2O$ in pre-columns with zeolites, does not affect other compounds in the sample and does not distort the composition of the latter.[3]

In the automatic determination of ultramicroconcentrations of CO in the troposphere with the aid of an He-ionisation detector, an additional short column with the 5A zeolite, which is periodically regenerated, is placed before the analytical column in order to separate the interfering impurities ($H_2$, $O_2$, $N_2$, $CO_2$, and $H_2O$) from the bulk.[56] Another version of the RSM is based on the employment of a short column (7 cm × 4 mm) with 3A zeolite activated for several hours in a stream of dry nitrogen at 300 °C.[57] With the exception of $CH_3OH$, this pre-column vigorously retains $H_2O$, but does not sorb organic impurities. The 3A molecular sieve can therefore be regarded as the ideal drying agent for the determination of toxic microimpurities in air.[3,34,57]

## IV. IDENTIFICATION OF IMPURITIES IN THE REACTION-SORPTION CONCENTRATION METHOD

The main problem in the analytical chemistry of air contaminants is that of the reliable identification of harmful impurities in complex mixtures of air contaminants.[3,30] The traditional scheme for the gas-chromatographic analysis of contaminated air presupposes the absorption of all the chemical compounds present in air on solid sorbents, the extraction of the concentrated impurity by a solvent, and the gas-chromatographic separation and identification of the sample components.[2,3] All compounds, without exception, extracted from air are detected on the chromatogram. This

factor hinders greatly the identification of impurities, since in the general case one has to deal with mixtures of impurities belonging to different classes.[4,5-7]

The difficulty of securing reliable information about the composition of complex mixtures in harmful organic substances§ is due to the insignificant differences between the retention characteristics of the impurities (for example, the Kovac indices).[3,30] The use of a kind of "chemical filter" (such as the RSM) presupposes the successive removal from the mixture to be analysed of specific classes of organic compounds, which significantly facilitates the chromatographic identification of the contaminants and makes it more reliable.[3]

## 1. Determination of Hydrocarbons

The simplest analytical problems which can be solved with the aid of the RSM concentration procedure is the determination of toxic hydrocarbon impurities in any complex mixtures of air contaminants.[31] This is because hydrocarbons are the most inert organic compounds and the accompanying admixtures of substances with different functional groups can be removed from the air to be analysed by means of a pre-column with a powerful reducing agent such as lithium tetrahydroaluminate without affecting the hydrocarbons themselves.[3,31,58]

A pre-column containing phosphoric acid, Versamid 900, lithium tetrahydroaluminate, and lead acetate is effective for this purpose.[59] Such a reactor absorbs satisfactorily all organic impurities with the exception of hydrcarbons. This method has been used successfully for the identification and quantitative gas-chromatographic determination of hydrocarbon impurities in the atmosphere in the workplace in factories (the gas is evolved from raw and pure rubbers, polymeric materials, solvent vapours, thermal degradation products, etc.).[3,30]

A pre-column with Chromosorb P impregnated with a solution of chromium trioxide in concentrated sulphuric acid has been used for the selective absorption of reactive organic impurities from air in a study of atmospheric photochemical reactions.[60] At a temperature of 72–77 °C, the reactive unsaturated hydrocarbons, involved in the formation of the photochemical "smog" which has a fatal effect on many plant species, are extracted from the air, analysed with the aid of such a reactor, and reliably identified.[30]

For the gas-chromatographic identification of the highly toxic styrene, air has been blown[61] through a glass pre-column (6–16 cm × 4 mm), which allows only the compound sought to pass a trap containing Tenax GC. Esters were then absorbed in a fore-column with 10% NaOH on Shimalite, while carbonyl-containing compounds were absorbed in a reactor containing a 2% solution of 2,4-dinitrophenylhydrazine deposited on glass beads. Styrene passed through these pre-columns unchanged and, after being concentrated on a porous polymeric sorbent, its content was determined on a chromatograph with a flame-ionisation detector.

A novel method for the preliminary separation of a complex mixture of the products of the oxidation of various motor fuels has been proposed.[62] Nucleophilic compounds (aldehydes, ketones, alcohols, ethers, esters, etc.) can be selectively absorbed with the aid of a pre-column containing a europium complex of *p*-di(4,4,5,5,6,6,6-heptafluoro-1,3-dioxohexyl)benzene and it is thus possible to separate such substances reliably from alkanes, alkenes, aromatic hydrocarbons, and chlorohydrocarbons before the chromatographic separation of the sample components. The chromatograms of these mixtures after separation on a capillary column 30 m long and containing silicone *SE*-54 are presented in Fig.9. Involatile derivatives of the nucleophiles of the type of bis-(β-diketonates) are then formed in the pre-column by reacting with the polymeric lanthanide complex. So far the number of such examples is small but coordination compounds provide extensive possibilities of effective procedures in the analyses of air contaminants by the separation and preliminary concentration of toxic impurities having various chemical natures.[63]

A set of pre-column-reactors, some of which are listed in Table 8, makes possible reliable group and individual gas-chromatographic determinations of hydrocarbons in complex mixtures of air contaminants having purely hydrocarbon compositions as well as mixtures of hydrocarbons with organic and inorganic compounds having functional groups. After the separation from the hydrocarbon of admixtures which interfere with their identification, the use of the usual procedures in the qualitative chromatographic analysis (for example, the employment of retention indices) enables one to achieve a very high reliability of the results, comparable to that of the results of the chromato-mass-spectroscopic analysis.[3,30,31,68]

**Table 8.** Determination of hydrocarbon impurities with the aid of the RSM analysis.[30,31,64-67]

| Target components | Sorbent in pre-column | Sorbed impurities |
|---|---|---|
| Aromatic hydrocarbons | 5A molecular sieve | n-paraffins, n-olefins, and n-acetylenes |
| Paraffinic, naphthenic, and olefinic hydrocarbons | poly(vinyl chloride) | aromatic hydrocarbons |
| Paraffinic, naphthenic, olefinic, and aromatic hydrocarbons | maleic anhydride* | dienes |
| Paraffinic, naphthenic, and aromatic hydrocarbons | 1 : 1 mixture of $Hg(ClO_4)_2$ and $HClO_4$* or mixture of 20% $HgSO_4$ and 20% $H_2SO_4$* | alkenes and alkynes |
| n-Paraffins and cycloparaffins | conc. $H_2SO_4$* or mixture of 4% $AgNO_3$ and 95% $H_2SO_4$ | aromatic hydrocarbons, olefins, and acetylenes |
| Total hydrocarbons | 10X molecular sieve | aromatic hydrocarbons |

*On a diatomaceous carrier.

## 2. Determination of Oxygen-Containing Organic Compounds

A reactor with silver nitrate, phosphoric acid, Versamid 900, and lead acetate,[69] designed for the isolation of oxygen-containing organic compounds from a mixture of air contaminants, is not quite as reliable as a pre-column for the isolation of hydrocarbons. Together with oxygen compounds, n-paraffinic and naphthenic hydrocarbons pass through the reactor. In order to eliminate their interfering effect, the subsequent gas-chromatographic analysis of the substances concentrated in the trap is carried out on a superpolar stationary liquid phase (SLP) of the type of 1,2,3-tris(cyanoethoxy)propane, which makes it possible to separate the

§ In general there are greater differences between the properties of inorganic compounds and selective detectors, for example, are sufficient for their identification.[3]

paraffin–naphthene fraction from polar derivatives of hydrocarbons. On a column with 15 and 30% of such SLP, methanol emerges after n-decane and tridecane respectively.

This subtraction-isolation method, in which the oxygen-containing substances are separated from non-polar hydrocarbons in the first stage and the substances isolated are subjected to gas-chromatographic analysis in the second stage, is distinguished by a high selectivity, which is made up of the selectivities of the pre-column and the analytical column. This procedure has been used for the identification and reliable determination of toxic admixtures of methanol and other alcohols in the evaporation products of a petrol–methanol fuel,[70] in the determination of volatile compounds in air arising from various solvents,[30,31] and in the analysis of complex mixtures of organic compounds contaminating air in the processing of polymeric materials.[3,36,68]

In the determination of methanol in the exhaust gases from automobile engines,[3,36] where the air in the driving compartment contains aldehydes in addition to methanol, a reactor with $NaHSO_3$ on Chromaton N was used for the reliable identification of methanol with the aid of the RSM.[36] Whilst retaining low-molecular-weight aldehydes, such a pre-column lets methanol and hydrocarbons pass through to the trap with the sorbent; these substances were subsequently separated on a column with 0.2% PEG 1500 on graphitised carbon black and were unambiguously identified using the retention characteristics of the impurities.[3] The action of the pre-column is basedon the interaction of aldehydes with sodium bisulphite involving the formation of a substituted sodium sulphonate in accordance with the equation

$$RCHO+NaHSO_3 \rightarrow RCHOHSO_3Na.$$

In simpler cases, where the air analysed does not contain all possible contaminants but only compounds of specific classes (for example, only hydrocarbons, only halogenohydrocarbons, only alcohols and aldehydes, etc.), the identification of the impurities is greatly simplified (Table 9).

**Table 9.** The RSM concentration and identification of oxygen-containing organic impurities.[2,30,64–67]

| Target components | Sorbent in pre-column | Sorbed impurities |
|---|---|---|
| Oxygen-containing compounds | $AgNO_3$, $H_3PO_4$, Versamid 900, and $Pb(CH_3COO)_2$ | all organic substances other than paraffins and naphthenes |
| Oxygen-containing compounds | Versamid 900 and $AgNO_3$ | halogenohydrocarbons |
| Oxygen-containing compounds | poly(vinyl chloride), $AgNO_3$, Versamid 900 | halogenohydrocarbons, alkylbenzenes, olefins, and acetylenes |
| Aldehydes and ketones | $H_3BO_3$ | primary and secondary alcohols |
| Alcohols | 2,4-dinitrophenylydrazine | aldehydes and ketones |
| Ketones | *o*-dianisidine and 5A zeolite | aldehydes |
| Ethers and esters | 5A molecular sieve | carboxylic acids |
| Lower carboxylic acids | benzidine | aldehydes and ketones |
| Aldehydes, ketones, ethers, and esters | KOH | carboxylic acids |

The RSM concentration procedure has been used successfully also in the solution of certain simpler problems in the chemistry of air contaminants, for example, for the selective

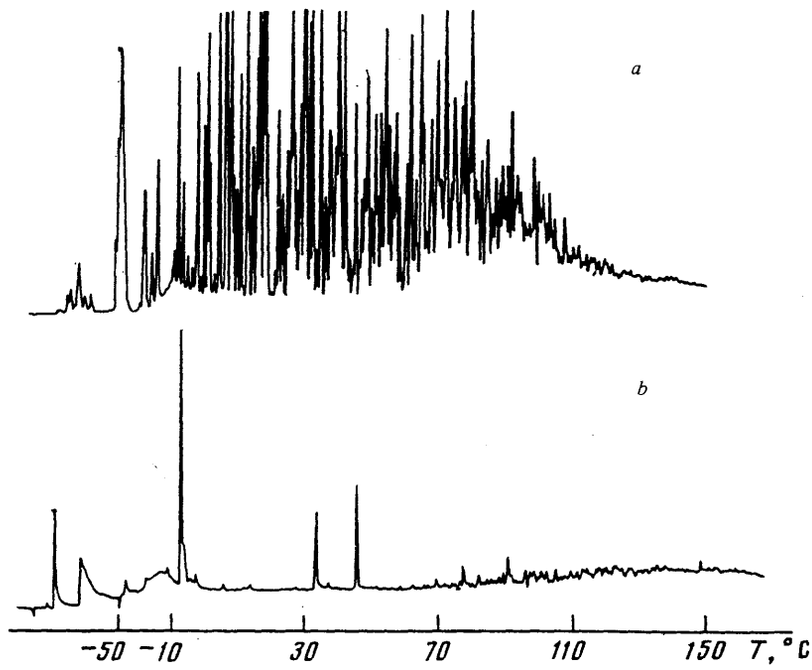

**Figure 9.** Chromatograms of compounds not retained (*a*) and retained (*b*) by the pre-column obtained in the analysis of the vapour of motor fuel subjected to thermo-oxidative cracking.[62]

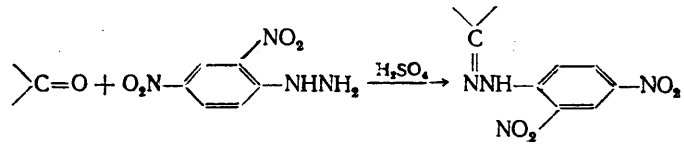

and reliable determination of admixtures of phenols or carbonyl compounds against the background of halogenohydrocarbons, hydrocarbons, or esters.[31] Organic and inorganic acids can be identified in air by a simple and effective method, for example, with the aid of a pre-column with $K_2CO_3$ [71] or with Chromosorb P impregnated with $Na_2CO_3$.[72] An analogous method of determining trace amounts of lower $C_2$–$C_5$ aliphatic acids consists in the use of a preliminary reactor with 2% NaOH on glass beads.[73] After the separation of polar acids from other compounds in the sample, they are concentrated on silica gel, desorbed with water, and then analysed on a chromatograph with a flame-ionisation detector.

A pre-column (6 cm × 5 mm) with glass beads, coated by a mixture of 0.05 g of 2,4-dinitrophenylhydrazine and 0.1 ml of $H_3PO_4$, has been used for the rapid determination of lower aliphatic carbonyl compounds in the waste gases from factories.[74] After the separation of the accompnaying impurities in this type of reactor, the carbonyl compounds were retained in a trap with 25% of 1,2,3-tris(cyanoethoxy)propane on Shimalite cooled with liquid argon to −186 °C. The concentrator was then heated to 120 °C, the sample was desorbed into a chromatographic column 1.5 m long with 5% of the same SLP on Carbopack B, and the toxic impurities were analysed at 70 °C using a flame-ionisation detector. For a reliable determination of phenolic and aliphatic acid microimpurities in air, the same authors[75] used a fore-column (7 cm × 4 mm) with 20% KOH on glass beads (0.6 to 0.25 mm). The presence of the sought compounds in the sample was inferred from the difference between the chromatograms obtained with and without a pre-column, in the latter case the sample being simply removed to a trap with Tenax GC. After the desorption of the enriched sample, the mixture was analysed on a glass column (1.75 m × 3 mm) with 0.1% SP-1000 on Carbopack C at 205–220 °C using a flame-ionisation detector.

**Table 10.** Methods for the identification of chlorohydrocarbons with the aid of the RSM.[3,64–67,79]

| Target components | Sorbent in pre-column | Sorbed impurities |
|---|---|---|
| Chlorohydrocarbons | 5A molecular sieve and conc. $H_2SO_4$ | oxygen-containing organic compounds |
| Chlorohydrocarbons | ditto | hydrocarbons and oxygen-containing organic compounds |
| Chlorohydrocarbons | metal hydrides | oxygen-, nitrogen-, and sulphur-containing compounds |
| Vinyl chloride, trichloroethylene, and tetrachloroethylene | 5A molecular sieve, $H_2SO_4$, and Versamid 900 | hydrocarbons and chlorine- and oxygen-containing compounds |

An interesting problem solved with the aid of the RSM [36] is that of the determination of ethanol impurities in respired air. The aldehydes (especially acetaldehyde) and ketones, which interfere with the determination, can be differentiated by an effective procedure which involves the use of several prechromatographic reactors ($H_3BO_3$; *o*-dianisidine; 2,4-dinitrophenylhydrazine; benzidine or hydroxylamine), which are listed in Table 11. The use of pre-columns with different combinations of the above reagents makes it possible to remove in succession ketones, aldehydes, and alcohols from the mixture analysed, in conformity with the reactions described by the equations[76]

$$RCHO + NH_2OH \cdot HCl \rightarrow RCH{=}NOH + HCl + H_2O\ ;$$

$$H_3BO_3 + C_2H_5OH \xrightarrow{H_2SO_4} (C_2H_5O)_3B + H_2O\ .$$

**Table 11.** The RSM identification of organosulphur impurities.[64–67]

| Target components | Sorbent in pre-column | Sorbed impurities |
|---|---|---|
| Mercaptans | 4A zeolite | $C_1$–$C_3$ hydrocarbons and $C_1$–$C_3$ alcohols |
| Mercaptans, sulphides, and thiophens | Versamid 900 | alkyl halides and aryl halides |
| Mercaptans | poly(vinyl chloride)* | alkylbenzenes, primary alcohols, and amines |
| Sulphur dioxide | $NaHCO_3$ | sulphides, mercaptans, and hydrogen sulphide |

*At 55–75 °C.

These methods make it possible to identify reliably the above compounds in a complex mixture of volatile substances in the respired air.

### 3. Determination of Chloro-Derivatives of Hydrocarbons

The use of the RSM analysis yields satisfactory results in the gas-chromatographic determination of organochloro-compounds, many of which exhibit a pronounced carcinogenic activity, since this procedure makes it possible to detect reliably microamounts of these toxic compounds (for example, vinyl chloride) against the background of the less dangerous accompanying impurities comprising hydrocarbons, oxygen-containing compounds, etc.[30]

A pre-column with sodium bisulphite, which forms a complex with the target compound, is used to separate vinyl chloride from the acetaldehyde, which frequently accompanies vinyl chloride and interferes with its determination.[76,77] Admixtures of light hydrocarbons and oxygen-containing compounds were effectively separated on a pre-column with 5A zeolite and concentrated sulphuric acid on glass wool.[78] Vinyl chloride was analysed at the level of the maximum permissible concentration (0.1 mg $m^{-3}$) on a column with 0.2% of Carbowax 1500 on graphitised carbon black or Polysorb-1 at 50 °C on a chromatograph with a flame-ionisation detector. One should bear in mind that all the procedures (removal of samples onto activated charcoal, desorption of the sample by chlorobenzene, storage of the sample, etc.) must be carried out at a temperature not exceeding 0 °C to avoid losses of vinyl chloride. A chromatogram of a mixture of vinyl chloride and the admixtures interfering with its determination is presented in Fig.10.

An analogous pre-column has been used also to determine other chlorine-containing hydrocarbon impurities in air (tri- and tetra-chloroethylene, chlorobenzene, etc.). After the RSM concentration, these impurities were readily identified by standard chromatographic procedures.[79]

When it is necessary to separate halogen-containing hydrocarbons from compounds of any one class (hydrocarbons, oxygen compounds, etc.), the use of the pre-columns listed in Table 10 gives satisfactory results.

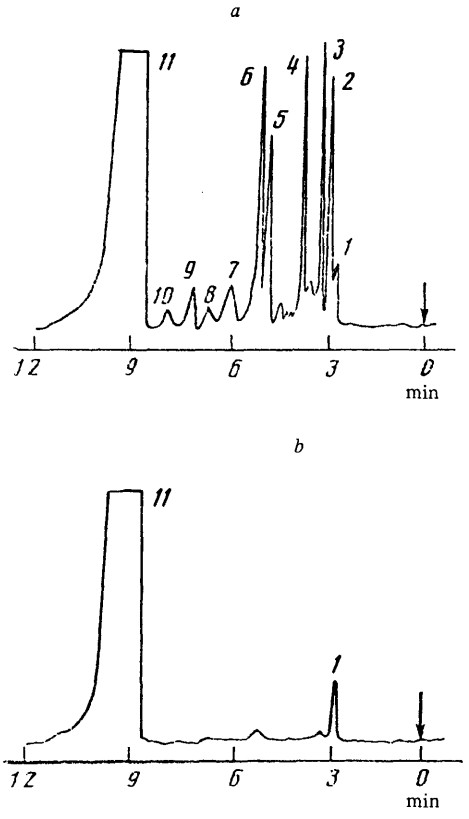

**Figure 10.** Identification of vinyl chloride in a complex mixture of volatile compounds evolved into air on heating artificial leather: *a*) without the use of a pre-column; *b*) beyond the pre-column containing 5A zeolite in sulphuric acid;[78] 1) vinyl chloride; chromatographic peaks *2–10* were not identified; 11) toluene (solvent).

The employment of molecular sieves can lead to the adsorption (up to 8–12%) on the outer faces of the zeolite crystals of the impurities being concentrated, i.e. can lead to additional sorption which is not taken into account.[31] This factor must be allowed for in the interpretation of the results of the identification of impurities using the 5A, 10X, and 13X zeolites as pre-column packing.[3,31,64]

## 4. Determination of Sulphur-Containing Organic Compounds

Sulphur-containing organic compounds, many of which are powerful odorants, are encountered in many petrochemical industries and contaminate the air in the workplace in petroleum refineries.[3]

It has been found that concentration by the RSM is a no-less effective procedure for the identification of organosulphur compounds than the use of flame-photometric and photo-ionisation detectors selective with respect to sulphur.[3,36] The former does not give rise to a significant signal with hydrocarbons but responds to many compounds with functional groups.[80] Although the latter makes it possible to determine picogram amounts of sulphur compounds,[3,40] it gives a signal with alkylbenzenes and certain other hydrocarbons of almost the same magnitude.[81]

In certain instances of practical gas-chromatographic analysis, especially when it is necessary to differentiate mercaptans and sulphides from hydrocarbons, the use of the pre-columns listed in Table 11 yields satisfactory results.

The RSM procedures for the concentration of impurities have proved effective in the identification of sulphur-containinng impurities in air contaminated by the vapour of BR-2 motor fuel[82] and white spirit,[30] in the volatile components of pure rubbers based on natural butyl-rubber,[83] and in the analysis of air from the workplace in petrochemical undertakings.[36,49] A pre-column with $NaHCO_3$ makes it possible to separate microamounts of sulphur dixoide from hydrogen sulphide, mercaptans, sulphides, and disulphides.[84]

## 5. Determination of Nitrogen-Containing Organic Compounds

In this case the RSM analysis is most difficult, because nitrogen compounds are very reactive. It is therefore very difficult to select chemical reagents and sorbents which would absorb the accompanying admixtures (including inert hydrocarbons) and would not react with nitrogen compounds (amines, amides, nitriles, nitro-compounds, lactams, etc.).[3,30,31] Thus a reactor with the 5A molecular sieve and Versamid 900 retains only hydrocarbons, certain oxygen-containing hydrocarbon derivatives, and a reactive halogen compound. Nevertheless, even when only 40–50% of all the admixtures interfering with the analysis are removed with the aid of this pre-column, we may hope for an appreciable increase in the reliability of the subsequent gas-chromatographic identification of the nitrogen compounds.[30,36]

**Table 12.** The RSM identification of nitrogen-containing organic compounds.[3,30,65]

| Target components | Sorbent in pre-column | Sorbed impurities |
|---|---|---|
| Amines | $H_3BO_3$ | alcohols and phenols |
| Amines | 2,4-dinitrophenylhydrazine | aldehydes and ketones |
| Amines | zinc oxide | carboxylic acids, alcohols, and phenols |
| Amines | KOH | carboxylic acids, phenols, cresols, ethers, and esters |
| Nitrogen-containing compounds | Versamid 900 and silver nitrate | halogen-containing hydrocarbons |

In certain cases, for example, those listed in Table 12, concentration by the RSM yields entirely satisfactory results. These procedures have been used in analytical practice for the analysis of air contaminants, for the identification and determination of amines in the gases evolved from rubber articles,[36,49] and in the elucidation of the composition of the volatile substances released into the air of the workplace in the manufacture of polymers and their processing.[3,30,36]

A pre-column with glass wool or a glass filter impegnated with [(4-nitrophenyl)methyl]propylamine has been used for the identification and quantitative determination in air of trace concentrations of aminocarbonyl derivatives of toluene.[85]

A method involving the preliminary removal of nitrites by ion exchange and denitrosation with the aid of sodium iodide or sulphanilamide is used for the determination in the air of the workplace in industrial undertakings of admixtures of *N*-nitroso-compounds (formed from anticorrosion additives to lubricating-cooling liquid compositions).[86] For the correct identification in air of microamounts of *N*-nitroso-compounds, which eliminates the interfering influence of amines (precursors of *N*-nitroso-compounds), one uses in sampling a two-section cartridge with sulphamic acid for the absorption of amines in the first section and a mixture of sulphamic acid with magnesium silicate for the trapping of *N*-nitroso-compounds in the second section. After sampling, the contents of the second section are desorbed with acetone and analysed by gas chromatography.[87]

### 6. Determination of Inorganic Compounds

The reaction-sorption concentration method has been used successfully also in the determination in air of trace amounts of toxic inorganic substances.[3,21,30,34,40] In order to determine nitrous oxide, air is initially freed from the $H_2O$ and $CO_2$ impurities, which interfere with the analysis, by passing the sample through a pre-column containing anhydrous $CaSO_4$, $Mg(ClO_4)_2$, and Ascarite.[88] The column with 13X zeolite retains irreversibly the $NO_2$ and $N_2O$ impurities, but it is possible to separate on it $O_2$, $N_2$, and NO;[33,89] this enables one to achieve the preliminary separation of the reactive nitrogen oxides, whose separate determination has always constituted a difficult problem.[21,34,40]

In order to eliminate the mutual influence of inorganic gaseous impurities, a thin-fibre polystyrene filter, containing iron chelate compounds, is employed. The concentration of the $NO_2$, $NH_3$, $H_2S$, and $SO_2$ impurities in air after it has been passed through such a filter at a rate of 0.1 litre $min^{-1}$ diminishes by a factor of ~50 compared with the initial concentration.[90] In order to separate the highly reactive sulphur trioxide, which tends to polymerise, from one of the most important contaminants in air, namely sulphur dioxide, the air to be analysed is passed through an absorber containing 97%[91] or 100%[92] sulphuric acid, which effectively absorbs $SO_3$. The influence of $SO_2$, which interferes with the gas-chromatographic determination of $H_2S$ microimpurities, can be eliminated by a preliminary step in which the air to be analysed is passed through a tube filled with glass beads treated with $Na_2SO_3$. In the subsequent chromatography of the sample on a column with Porapak Q at 100–200 °C, it was possible to determine selectively an admixture of $10^{-7}$% of hydrogen sulphide in air over various regions of the Atlantic Ocean.[93]

---o0o---

The hybrid reaction-sorption method, based on the simultaneous employment of chemical subtraction and sorption concentration methods, makes it possible to increase significantly the reliability and reproducibility of the identification of impurities in complex mixtures of air contaminants. The application of the RSM has greatly expanded the field in which gas chromatography can be used to determine organic and inorganic impurities in air (and in various gaseous media). The employment of the RSM concentration of impurities in their determination in various liquids (solvents, natural and waste water, brines, technological water, etc.) is undoubtedly also promising.

The reaction-sorption method is universal and can be used in combination with any analytical procedure (chromatographic, spectroscopic, electrochemical, etc.). The application of the RSM improves almost all the metrological characteristics of the methods for the determination of impurities (selectivity, detection limits, reliability, reproducibility, etc.) and expands the range of the active methods and procedures available in analytical chemistry.

# The Forms of Trace Elements in the Abiotic Phases of Natural Aqueous Media

A.K.Prokof'ev

The literature data on the phase, physicochemical, and chemical properties of trace elements (microelements) in the abiotic phases of natural aqueous media—the atmosphere, the surface microlayer of water, natural waters, suspended and colloidal particles, bottom deposits, and pore waters, as well as the mechanisms of the interconversions of these forms are surveyed and critically examined. The ways in which trace elements are absorbed and removed via the interfaces of these phases and on mixing in the estuary as well as the causes of such sorption and removal are considered. It is shown that the form of the trace elements in the phases of all types of natural waters (in oceans, seas, rivers, estuaries, lakes, and bogs) plays a decisive role in their transport, biological availability, and biogeochemical cycles.
The bibliography includes 368 references.

## I. INTRODUCTION

In many industrially developed countries the present degree of pollution of individual internal water basins and regions of coastal sea waters by chemicals of anthropogenic origin exceeds the ecologically safe level. Together with organochlorine compounds and petroleum, the toxic elements Hg, Pb, Cd, As, Cu, Se, as well as others whose concentration in natural waters (NW) is less than 1 mg $kg^{-1}$ (1 p.p.m.) constitute a special danger. They are referred to as trace elements (TE) and they do not include biogenic and radioactive elements or dissolved gases.

The determination of such extremely low TE concentrations in natural aqueous media constitutes an extremely difficult analytical problem. The situation is greatly complicated by the fact that at any stage of the analysis, especially in the removal and preliminary treatment of samples, it is very easy to contaminate the latter from the sampler, air, reagents, the vessels used, and other sources. This is particularly important for ocean waters, in which the concentration of many TE is lower by several orders of magnitude than in surface waters and can amount to 1 ng $kg^{-1}$ (p.p.t.). As the above causes of the contamination of samples in analysis have been eliminated and the sensitivity and selectivity of the analytical methods for the determination of TE have improved, their measured content in NW, including ocean waters, has steadily decreased during the last decade, by orders of magnitude despite the constantly increasing anthropogenic injection of TE into NW. However, this trend has been sharply retarded in recent years and the concentrations of many TE established at present, even in ocean waters,[1,2] may be regarded as sufficiently reliable. They will be quoted below in the appropriate sections. However, the main bulk of the data concerning the content of the TE in sea waters, published up to 1975,[1] and in river waters, probably up to 1973, must be rejected.

However, the overall content of TE in aqueous media still does not reflect the true degree of pollution of the latter. Studies in various countries of the causes of numerous instances of the poisoning of hydrobionts by TE made it possible many years ago to reach the important conclusion that the biological accessibility and toxicity of TE depends very greatly on the form in which they exist. The data accumulated at the present time also permit the assertion that the forms in which TE exist plays a decisive role in their transport in the biogeochemical cycle. The knowledge of the form in which TE exist in aqueous media has therefore assumed first class importance.

Two main approaches are used to study the forms in which TE exist in NW. The first is theoretical and involves the calculation of the equilibrium concentrations of all the dissolved forms with the aid of mathematical models based on the employment of the experimental concentrations of TE and ligands as well as the published stability constants of the TE–ligand bonds. Chemical modelling embraces at the present time all possible competing equilibria; computer programs are employed for thermodynamic calculations. The accuracy of the computer modelling is however greatly reduced as a consequence of the uncertainty of the published stability constant and activity coefficient data. Furthermore, many parameters influencing the forms in which TE exist are not as a rule included in the calculation in view of the lack for the majority of them of qualitative and quantitative data concerning the pH, the redox potential, the nature of the vast majority of organic ligands, colloidal particles and the adsorption on them, the interfacial precipitation reactions, dissolution and sorption, biological and physical processes, etc. These factors as well as the lack of information about the non-equilibrium conditions which exist in many NW yield calculated results which are extremely doubtful. The advances in the field of chemical modelling have been described elsewhere.[3-6]

Another approach to the study of the forms of TE is analytical. All the experimental forms of TE in the abiotic phases of natural aqueous media can be usefully divided into three large groups—the phase, physicochemical, and chemical forms. The particular phase form to which the TE belongs is determined by the principal phases of aqueous media in which the TE is present—the natural atmospheric layer, the surface microlayer (SML) of water, NW, suspended and colloidal particles, deposits in aqueous media, and pore waters. A classification based on the physicochemical forms depends on the presence of the TE in specific fractions of aqueous media (for example in the dissolved organic fraction, the suspended inorganic fraction, and the sorbed fraction), which are subdivided either in terms of their size (established, for example, by ultrafiltration and gel filtration) or in terms of the lability of the fraction in relation to the analytical technique employed (for example, ion exchange or inversion voltamperometry are used for this purpose). The chemical forms can exist in aqueous media as compounds of TE in various oxidation states [for example inorganic arsenic(III) and arsenic(V)], as organoelemental compounds (for example, MeHgCl and $Bu_2SnMe_2$), or as complexes (for example, vitamin $B_{12}$). In this classification the chemical forms of TE are frequently their physicochemical forms; the overall amount of TE in these forms yields the overall content of TE in each phase of natural aqueous media.

The distribution of TE and their forms in the phases of aqueous media enumerated above takes place via very complex pathways as a result of various chemical, physicochemical, physical, and biological processes, the mechanisms of which are still little understood. The available chemical data and phenomenological models do not permit the prediction of the distribution of TE, let alone their forms, between different phases of aqueous media, which constitute extremely complex systems usually possessing variable qualitative and quantitative compositions.

The analytical determination of the forms of TE in NW cannot be regarded as a problem which has been solved, firstly, owing to their extremely low concentrations and, secondly, owing to their sensitivity to the salt composition, pH, the content of dissolved organic and high-molecular-weight compounds, colloidal and suspended particles, and other conditions which depend both on the type of the NW and on the time of year. It is important to note that the equilibrium concentrations of different forms of TE in NW inevitably change when samples are taken, as a consequence of their contact with atmospheric oxygen and the walls of the sampler and changes in temperature and pressure, and also in the course of their separation (isolation) and analysis. These changes are indefinite, but it is essential to minimize them in all cases. A number of reviews have been published on the methods for the determination of the physicochemical[3,7–14] and chemical[7] forms of TE in NW.

The aim of the present review is to examine the phase, physicochemical, and chemical forms of TE in the abiotic phases of natural aqueous media—the atmosphere, the SML, NW, suspended and colloidal particles, deposits in aqueous media, and pore waters, and also the mechanism of their interconversions. Individual aspects of this question were discussed earlier in relation to TE,[15] Hg, Cd, and Zn,[16] Cd in sea water,[17] organoelemental compounds,[18,19] and TE in ocean waters.[20] The types and causes of the absorption removal of different forms of TE through the interfaces of the above phases and in estuarine mixing are also examined.

In view of the existence of the above problems in the analytical determination of TE and their forms in aqueous media, we shall consider here, with rare exceptions, only data published during the last 5–7 years. Owing to the limited size of the article, they will be only briefly described and many publications concerned with the topic under discussion will not be mentioned. Preference is given to the latest, fundamental information and also review articles.

## II. THE ATMOSPHERE

The substances present in the atmosphere in the liquid (water), solid (aerosols), and gaseous states exist in variable concentrations. Among them impurities of natural origin include particles of sea salts, dust from active volcanoes and continental erosion, etc. while anthropogenic impurities comprise different types of smoke and gases ejected by industrial undertakings, automobile transport, etc. The chemical composition of aerosols and atmospheric deposits has assumed great importance both for the investigation of the pollution of the environment on a global scale and for the determination of their role in the establishment of the chemical composition of NW.

It has been shown that Hg, Pb, Cd, Se, Sb, and other TE are transported in the atmosphere over long distances above the oceans.[21] The content of these TE exceeds by 2–3 orders of magnitude their average concentration in the Earth's core. This applies, for example, to the aeolian suspension over the pelagic regions of the Atlantic Ocean,[22] but the latter has, however, a different origin.[23]

In the marine aerosols, whose content varies in the range 0.003–30 μg $m^{-3}$,[24] many TE have been determined.[21–24] For example, the concentrations of Cr and Se over the Atlantic Ocean are 0.54 and 0.033 mg $m^{-3}$ [24] and those of Pb are 0.98 and 0.15 mg $m^{-3}$ in the southern and northern hemispheres,[25] whereas over the Pacific Ocean the concentrations of these TE are respectively 0.73, 0.028,[24] and 0.2 mg $m^{-3}$.[26] It is noteworthy that the TE in natural marine aerosols exist preferentially in the water-soluble, exchangeable, and weakly bound forms.[24]

The content of the TE and their forms in rain water and in the gas phase has been studied to a lesser extent than in aerosols. The following amounts of TE have been observed in rain water (ng $litre^{-1}$): Hg 2 (open ocean),[27] Cd 320 (Lake Michigan),[28] Se(IV) 52.4 and Se(VI) < 5 (California),[29] As(III) < 2, As(V) 13.7, $MeAsO(OH)_2$ < 2 and $Me_2AsO(OH)$ 12 (California),[30] As(III) 214 and As(V) 4850 (Belgium),[31] Ge(IV) 0.5–0.7, $Me_2Ge$(IV) 1.0–5.9, and $Me_3Ge$(IV) 0.2–1.0 (Florida),[32] Sn(IV) 11, MeSn(IV) 5.9, $Me_2Sn$(IV) 7.4, and $Me_3Sn$(IV) 0.22 (Florida),[33] $Me_nEt_mPb$(IV), ($n$, $m$ = 0–3) < 2–68 (Belgium),[34] Hg (inorganic) and Hg (organic) 12.2 and 0.8 respectively (Japan),[35] and Pb (inorganic) 133 × $10^3$ and 280 × $10^3$ [Antwerp, Belgium, suburbs and city centre respectively (Translator)].[34]

The fraction of mercury in the gaseous form corresponds to more than 99% of its entire content in the atmospheric forms in the natural atmosphere over the sea.[27] In the northern and southern hemispheres its concentrations in the pure atmosphere over the sea are respectively ~1.5 and ~1.0 ng $m^{-3}$,[27,36] ~10% being present in the form of $Me_2Hg$.[36] About 50% of the mercury in the coastal sea atmosphere may be present in the organic form.[27] Data concerning the formation and fate of volatile molecular forms of TE have been surveyed.[37]

There is a constant reciprocal transfer of TE through the ocean–atmosphere interface, which are thus involved in the establishment of the chemical composition of both phases. The direction and rate of transfer are determined by the forms of the TE. The estimates of the fluxes for different TE and different regions of the world ocean can

differ markedly. Rains, which carry TE in a water soluble form, apparently play the greatest role in the atmospheric transport of TE to the ocean. It has been suggested[38] that, up to a depth of 100 m in the North Atlantic waters, 100% of Pb, 50% of Zn, Cu, and Mn, and up to 25% of Cd, Cr, and Al and other TE are of atmospheric origin. This has been demonstrated for Mn[39] and has been postulated for Se and Bi.[40] The atmospheric input of Pb has been studied in particularly great detail.[25,26,41,42] For example, it has been calculated that 24% of the lead entering the atmosphere annually is deposited on the ocean surface of the North Atlantic region.[25]

However, the exact sources of the TE brought through the atmosphere remain obscure. In certain regions of the world ocean Pb, Ni, Cu, and Zn are probably to a large extent of anthropogenic origin. They are formed, for example, by combustion of mineral fuels.[38,43] However, according to Jaworowski et al.,[44] the natural input of Pb, Hg, and Cd, for example, with atmospheric dust and products of volcanic eruptions, is of decisive importance.

The transfer of TE from the surface of the ocean to the atmosphere takes place as a result of wind action; TE are contained in the air bubbles bursting on the surface of the ocean and in the vapour. It has been observed that Cu, As, Hg, Pb, and other elements are mainly concentrated in the submicron fraction of sea aerosols,[23] in the establishment of the chemical composition of which the SML plays a major role, the latter being usually greatly enriched in TE compared with the bulk of the sea water (see Section III).

It has been suggested that considerable amounts of certain TE, particularly those forming gaseous methyl derivatives in the marine medium (Hg, As, Pb, etc.), pass from the surface of sea water to the atmosphere, since otherwise it would be impossible to balance their global cycles.[23,24] This can be regarded as proved for mercury.[27]

## III. THE SURFACE MICROLAYER ON WATER

Studies in recent years have demonstrated that extremely important chemical and biological processes occur on the surfaces or at the interfaces of different NW phases. The latter include the interface between the ocean and the atmosphere—the SML, which is the site where many substances of natural and anthropogenic origin are concentrated (TE, petroleum and chlorinated hydrocarbons, detergents, etc.) as well as the habitat of a varied and abundant flora and fauna (neuston) with a much higher biological activity than in the lower water layers. The marine SML with its enormous size plays an especially important role. A series of reviews on chemistry and biology have been devoted to it.[45,46]

The physical stability of the SML is ensured by surface tension forces and by the presence of organic films. At the same time it is a climatically unstable medium subjected to much greater oscillations in temperature and salinity ($S$) than the subsurface water layer. In order to explain the available facts, a model has been proposed,[45] according to which the upper layer of the marine SML consists of a unimolecular lipid film 10–20 Å thick, below which there is a polysaccharide protein layer 100–300 Å thick and a layer, closely linked to it, of abiotic suspended matter of bacterioneuston, yeast, and mould (to a depth of ~1 μm). In marshes (saline bogs near the sea) two types of SML have been observed.[47] The commonest of these is opaque and is enriched in organic matter, while the second type encountered much more rarely, has a bluish colour and is enriched in iron.

Various SML serve simultaneously as sources and traps for substances in the atmosphere and in bulk water. The methods whereby TE and their forms are transferred in the ocean–atmosphere system have been described in Section II. They pass from the bulk of the water to the SML as a result of upwelling, convection, diffusion, and bubble flotation.

In the SML of all types of NW the concentrations of TE (Pb, Cu, Cd, etc.) and their forms are usually much higher than in the subsurface water layers. This has been demonstrated for lake,[48] river,[49] marsh,[50] and sea[43,51] waters. The above difference is especially large for the bound dissolved[49] and suspended[48] forms of TE. Their concentrations can differ by an order of magnitude and more [differences in concentrations reaching 4 orders of magnitude have been observed for $Bu_3Sn(IV)$, $Bu_2Sn(IV)$, and the total Sn in various NW of Canada[52]], which reflects a much higher content of suspended materials and of dissolved organic material in the SML compared with the bulk water. Although the forms of TE in the SML and their exchange with the bulk water and with the atmosphere are controlled by a series of processes which are not yet fully understood, it appears likely that the most important of these are surface adsorption on the suspension and complex formation involving the dissolved organic substance. The influence of a surface-active dissolved or colloidal organic substance on the chemical form and transport of Pb, Cu, and Hg through the marine SML has been discussed.[53] A decrease of the Fe and Mn contents in the SML as a consequence of the precipitation of the mineral particles carrying them[43] as well as the lack of enrichment by basic ions (K, Mg, Ca, Cl, and Br) have been observed.[51]

It is essential to note that many fundamental questions associated with the SML, including the entry, redistribution, and fate of TE and their forms have been clearly inadequately investigated. For example, the relative contribution of aerosols and bubble flotation to the enrichment of the marine SML by suspended TE remains obscure. According to some data,[43] they are approximately the same, while according to others, flotation predominates.[54] Furthermore, the lack of generally adopted samplers and methods for taking SML samples whose depths may differ by several orders of magnitude in the work of different investigators[45] makes it very difficult and sometimes even impossible to compare the experimental results.

## IV. NATURAL WATERS

### 1. The Overall Content and Distribution of TE

As already noted above, the major advances in analytical chemistry during the last ten years and the elimination of contamination at all the stages of the analysis[2,55,56] made it possible to demonstrate that the concentration of the majority of TE in unpolluted ocean waters are in fact lower by 1–3 orders of magnitude than had been believed previously.[1,2]

The present data about the concentrations of all the elements in the Periodic System in open ocean waters have been compiled in two publications.[1,57] The first indicates for each element the proportions of inorganic forms in oxidised sea water calculated as described by Stumm and Morgan[4] and Turner et al.,[5] the range and average values of the concentrations, and the type of distribution and the the second gives the concentrations in the surface and deep (~1000 m) waters and predicts the average concentrations, the type of distribution, and the relation to the chlorine content. Table 1 lists the concentrations and types of pollution of the most important TE.[1]

It has been suggested that the vertical TE profiles be subdivided into 7 main types depending on the characteristics of the processes controlling them:[1] (1) the conservative type, which corresponds to the case where the concentration of the TE is independent of the salinity as a consequence of their low reactivity in sea water (this has been observed, for example, for Pb, Cs, and $MoO_4^{2-}$); (2) the biogenic type, in which the surface layers are depleted and the deep layers are enriched in trace elements as a result of their involvement in the biogeochemical cycle: the TE are removed from the surface layers of water by the plankton and the biological suspended particles formed, which descend to deeper regions, where the TE are regenerated via their oxidation or transition to a soluble state (for example, Cd, Zn, Se, and Ni); (3) surface enrichment and depletion in deeper regions when TE enter the upper layers of water (for example, from the atmosphere and rivers) and are then rapidly and constantly removed from the water (for example, Pb and Mn); (4) the minimum TE concentrations occur at an intermediate depth when TE fall on the surface of the ocean and are regenerated near its bottom, or are scavenged (adsorption on submerging particles) during passage through the bulk of the water (for example, Al and Cu); (5) the maximum TE concentration occurs at an intermediate depth due to hydrothermal activity (for example, Mn); (6) the minimum or maximum TE concentration occurs at an intermediate depth within incompletely oxidised layers associated with the occurrence of reductive processes in the bulk of the water or deposits on the adjoining continental slope [for example, Mn(II), Fe(II), and Cr(III)]; (7) the maximum or minimum TE concentration occurs in oxygen-free waters, established as a result of the interconversion of the $SO_4^{2-}$–$H_2S$ air [for example, Mn(II), Fe(II), and Cr(III)].

Table 1. The concentrations and type of distribution of TE in ocean water.[1]

| Element | Concentration, nmol $kg^{-1}$, for $S$ = 35%* | | Type of distribution |
|---|---|---|---|
| | range | mean | |
| Ag** | (0.5—35) | (25) | biogenic |
| Cd | 0.001—1.1 | 0.7 | » |
| Cr | 2—5 | 4 | » |
| Ni | 2—12 | 8 | » |
| Zn | 0.05—9 | 6 | » |
| Ge** | ≤7—115 | 70 | » |
| As | 15—25 | 23 | » |
| Se | 0.5—2.3 | 1.7 | » |
| Be** | 4- 30 | 20 | biogenic and scavenging |
| Cu | 0,5—6 | 4 | ditto |
| Al | (5—40) | (20) | minimum at intermediate depth |
| V | 20—35 | 30 | weak surface depletion |
| Mn | 0.2—3 | 0.5 | depletion in deep regions |
| Fe | 0.1—2,5 | 1 | depletion on the surface and in deep regions |
| Co | (0.01—0.1) | (0.02) | ditto |
| Pb** | 5—175 | 10 | high content in surface waters, depletion in deep regions |
| Sn** | (1—12) | (~4) | high content in surface waters |
| Sb | (1.2) | — | not established |

| Au** | (25) | — | » |
| Hg** | (2—10) | (5) | » |

*The round brackets show that the data are unreliable.
**The concentrations are given in pmol $kg^{-1}$.

In addition to the data quoted by Bruland,[1] vertical profiles have also been described for Ni, Cu, and Cd,[58,59] Zn,[58] Co,[60] Ag,[61] Fe,[62] Pb,[42] Hg,[63] Cr,[64,65] Mn,[66] V,[67] and the lanthanides.[68]

It is essential to note that concentrations of TE differ markedly in different oceans[2,55,69-71] as a consequence of the differences between the hydrographic parameters, biological productivity, and atmospheric input. The data for the same ocean obtained by different investigators[2] also show discrepancies due to the lack of a single methodological approach to the determination of TE. This has been confirmed by the comparison of different samplers[2,72] and analytical methods[73] and also by intercalibrations.[74]

The concentrations of TE in epicontinental seas and coastal waters are usually higher than in the open regions of the oceans (Table 2). We may also note data for the content of Hg (ng $litre^{-1}$) in the Sea of Japan (4.8[80] and 16.7[81]), the Sea of Japan [near the middle part of the mainland of Japan] (6.3 and 12.4),[81] the Bering Sea (5.8), the East and South China Seas (5.2),[80] and in the coastal waters of the USA (0.2–1.0[82] and 12.7[83]) and Japan (2.9—12.5),[84] and the content of Cr in the Sea of Japan (~0.45 μg $litre^{-1}$)[85] and of Co in the San Francisco Bay (0.05–1.2 μg $litre^{-1}$).[60] A comparative study of the distribution of TE in oceans and coastal waters has been carried out.[71]

Table 2. The concentrations of TE in epicontinental seas and coastal waters (μg $litre^{-1}$).

| Region | Cd | Cu | Mn | Ni | Pb | Zn | Refs. |
|---|---|---|---|---|---|---|---|
| Baltic Sea | 0.027 | 0.661 | 0.341 | 0.810 | 0.016* | 0.922 | [75] |
| North Sea | 0.033 | 0.925 | — | — | 0.148 | — | [71] |

Table 3. Concentrations of dissolved TE in rivers (μg $litre^{-1}$).

| River | Fe | Mn | Cr | Zn | Ni | Cu | Cd | Refs. |
|---|---|---|---|---|---|---|---|---|
| St. Laurence | 55 | 6.3 | — | 8.6 | 1.5 | 2.5 | 0.11 | [86] |
| Mississippi | 10 | 10 | 0.3 | — | 1 | 2 | 0.1 | [87] |
| Amazon | 2.0 | 19 | 2.0 | — | 0.27 | 1.8 | — | [88] |
| Yukon | 50 | 20 | 2.3 | — | 0.43 | 2.0 | — | [88] |
| Hudson | 32 | 1.5 | — | 4.6 | 1.9 | 3.2 | 0.20 | [89] |

The contents of dissolved TE in certain rivers are listed in Table 3. It is important to note that the majority of the TE are bound to a suspension (see Section V). In tropical rivers during the monsoon period, the concentrations of TE can decrease by a factor of several tens.[90] The average content of Hg is ~20 ng $litre^{-1}$ in ten rivers of the USA,[83] 4.3–21.1 ng $litre^{-1}$ in the surface waters of Japan,[35,91] 9.8 ng $litre^{-1}$ in the River Thames,[92] and 6.6 ng $litre^{-1}$ in the Ottawa River and 26.2 ng $litre^{-1}$ in the Suimon River.[93]

## 2. The Physicochemical Forms of TE

Dissolved TE can be present in NW as part of the composition of the various physicochemical forms differing in their dimensions (Table 4). Several general schemes for the determination of these forms of TE have been proposed,[7,10] differing in the analytical methods employed and also in the procedures used for separation and decomposition.

Table 4. The possible physicochemical forms of TE in NW and their dimensions.[10]

| From | Example | Approximate size, μm |
|---|---|---|
| Suspended | — | >0.45* |
| Simple hydrated ions of elements | Cd (II) $(H_2O)_6$ | 0.0008 |
| Simple inorganic complexes | Pb $(H_2O)_4Cl_2$ | 0.001 |
| Simple organic complexes | Cu glycinate | 0.001—0.002 |
| Stable inorganic compounds | PbS, $ZnCO_3$ | 0.001—0.002 |
| Stable organic complexes | Cu fulvate | 0.002—0.004 |
| TE adsorbed on inorganic colloids | Cu (II) — $Fe_2O_3$; Pb (II) — $MnO_2$ | 0.01—0.50 |
| TE adsorbed on organic colloids | Cu(II)-humic acid | 0.01—0.50 |
| TE adsorbed on mixed organic and inorganic colloids | Cu(II)-humic acid/$Fe_2O_3$ | 0.01—0.50 |

*It is retained on a filter with a pore size of 0.45 μm.

It must be emphasised that the dissolved organic matter, the main bulk of which (up to 80%) consists of highly oxidised biologically stable high-molecular-weight compounds, resembling the humic substances (HS) isolated from soil, play the main role in the distribution of the dissolved physicochemical forms. The rest of the organic matter consists of a mixture of polypeptides, polysaccharides, aminoacids, aliphatic acids, hydrocarbons, vitamins, and other compounds whose extremely low concentrations (usually less than $10^{-6}$ M) create serious analytical difficulties in their identification. The role of organic matter in river[94] and sea[95,96] waters has been examined in detail.

The exact structure of aqueous HS is unknown. They are high-molecular-weight polyelectrolytes of variable composition.[97,98] On the basis of chemical and spectroscopic data, it is believed that[98] marine fulvoacids and humic acids (HA) are structurally very similar, differing mainly by the absence of aromatic character in the former, and consist of cross-linked auto-oxidised polyunsaturated aliphatic acids.

The mechanism of the chemical binding of TE ions by HS is unknown, but it is believed that this interaction takes place via the formation of complex bonds of different types as a result of ion exchange, surface adsorption, and chelation.[99–101] The role of the HS is significant in the formation of complexes by TE, especially Hg, in surface waters,[102,103] but is much smaller in ocean waters (for example, for Cd, Pb, and Zn[104]), which can be accounted for by the different concentrations of the HS in these waters.

The specific organic forms of the TE in NW, with the exception of the vitamin $B_{12}$, chlorophylls, and a series of chemical forms, cannot currently be determined due to their extremely low concentrations. For this reason one either finds the overall content of the organic forms of TE or one analyses fractions with a specific molecular weight (MW). It is noteworthy that the great variety of methods for the determination of these forms of TE (with or without their isolation from the sample) greatly hinders the comparison of the results obtained by different investigators. Organic forms of different TE in sea water[53,105–109] and surface waters[110] have been observed.

These forms have been investigated in greatest detail for Cu, Hg, and Cr. It has been shown that, among the dissolved forms, the organic Cu fraction can amount to between 3 and 98% in marine waters[53,105–109,111–115] and 50% in surface waters.[116] On the basis of the analysis of EPR spectra, it has been suggested[117] that Cu is bound in these complexes to various reaction centres of the ligand via oxygen atoms. Mercury in the bound state amounts to 4–50% in sea water[53,63,83,84] and 27–100% in surface waters.[35,83,118] The vertical distribution of various forms of mercury in ocean waters is illustrated in Fig.1.[63] The following elements can exist in the organic form in sea water: Cr—45–60%,[85] Fe—12%, Mn—11%,[106] and Ni—up to 8%;[107] Se is present in the organic form to the extent of 40–60% in NW[119] and Pb is present in the organic form to the extent of 20–80% in river and estuary waters.[120] It is noteworthy that usually the highest concentrations of many TE are present in the organic fraction with MW = $10^3$–$10^4$ (see, for example, Refs.63, 121, and 122). The role of organic matter in the binding of TE in NW[99,100] and the methods for the determination of the complexes formed,[3,7,10,123,124] as well as problems concerning the measurement of the complex-forming capacity and of the conventional stability constants for the ligands in NW[125] have been considered.

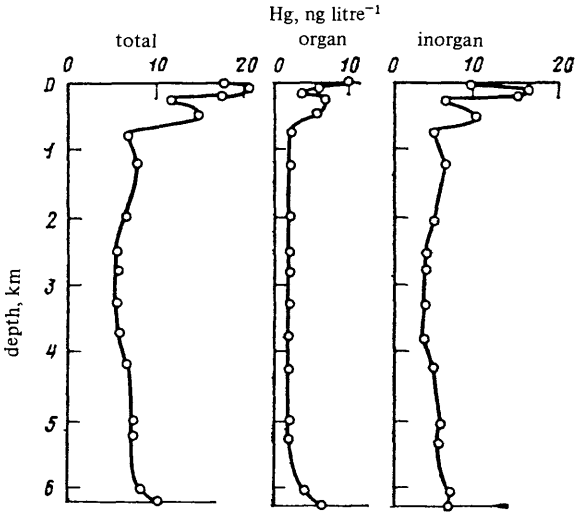

Figure 1. Vertical distribution of the different forms of mercury in the north western part of the Pacific Ocean.[63]

Among other dissolved physicochemical forms of TE, mention should be made of a labile form to which the free ion of the elements and labile complexes are usually assigned.[7,10] The concentrations of the labile mercury are 0.1–0.5 ng litre$^{-1}$ in the Pacific Ocean[82] and 6–60 ng litre$^{-1}$ in the North Sea.[126] The proportion of this form may correspond to the main bulk of the Mn in the <0.015 μm fraction in surface

waters.[127] The labile form is subdivided in its turn into the very labile, moderately labile, weakly labile, and inert forms.[128,129] This specification, which has a kinetic base, can be useful in the study of the biological accessibility of TE. It has been shown that Cd and Zn exist in river waters in more labile forms than Cu and Pb.[128] Overall, only a small proportion of the overall content of TE in NW corresponds to the labile fractions.

The forms of TE and their concentrations can vary greatly in oxygen-free deep waters, which exist, for example, in the Black and Baltic Seas and the fjords of Canada and Norway. The study of the vertical profiles of the dissolved TE in the Baltic Sea has shown that, on passing through the $O_2$–$H_2S$ interface (the anoxic wedge), the Fe, Mn, and Co concentrations increase by a factor not less than 100 and there is a simultaneous increase of the Cu concentration by a factor not less than 100 and Zn, Cd, and Ni concentrations by a factor of 3–5 compared with oxidised waters.[130] The solubility of many TE is then controlled by the formation of disulphide and polysulphide complexes and the elements themselves exist in reduced forms, for example, Cu(I), Fe(II), and Mn(II). The Mn,[131,132] Fe, and Cr[131] redox cycles were investigated previously and it was shown, in particular, that the dissolved Mn(II) accumulates in deep anaerobic waters as a result of the reduction of the suspended $MnO_2$ when it is submerged via the anoxic wedge.

### 3. Chemical Forms of TE

The chemical forms of TE in SW have come to be determined only recently and a limited range of TE in different oxidation states (Cr, As, Sb, Se, and V) have now been investigated. It is noteworthy that the forms in the highest and lowest oxidation states predominate for each of the above TE in the oxidised and reduced SW respectively.

In sea and surface waters the concentration of inorganic Cr(VI) have been found to be 0.1–1.0 μg litre$^{-1}$ [65,133–135] and 0.05–3.75 μg litre$^{-1}$,[133,136] while those of inorganic Cr(III) are 0.002–1.0 μg litre$^{-1}$ [65,85,133,135] and 0.20–2.36 μg litre$^{-1}$.[136] Vertical profiles have been obtained for these forms in ocean waters[64,85] and it has been shown that dissolved oxygen oxidises Cr(III) to the thermodynamically more stable Cr(VI), $MnO_2$ being a powerful catalyst of this process.[137] However, the ratio of the oxidised and reduced forms is not very well understood; it is believed that it is probably controlled kinetically.[138]

The following forms of As[30,31,139–143] and Sb[143–146] have been found in various types of SW (the two elements are designated by the general symbol E): E(III), E(V), MeE(V), and $Me_2E(V)$. Among the inorganic forms, E(V) predominates in the oxidised waters, while in the reduced waters the main form is E(III) and a sharp change in the ratio E(III)/E(V) is observed on passing the anoxic wedge,[143,147] owing to the reduction of E(V) and the possible formation of thiocomplexes.[143,146] In oxidised estuary waters, pronounced seasonal variations in the concentrations of the As forms have been noted;[142] in particular As(III) and the methyl forms of As are absent during the cold months at water temperatures below 9–12 °C probably owing to the sharp decrease of natural biomethylation.

The MeE(V) and $Me_2E(V)$ forms are encountered throughout the photic zone in the oceans but their proportion is only ~10% of the total content of the corresponding dissolved TE.[141,145] The vertical profiles of the chemical forms of As, Sb, and Ge in the Baltic Sea (where the anoxic wedge is at a depth of 170 m) (Table 5)[143] are controlled by biogeochemical cycles.

The concentrations of inorganic Se(IV) and Se(VI), which increase with the depth in the oceans, are in the range 4–64 and 40–120 ng litre$^{-1}$ respectively.[148,149] In the oxygen-free sea water Se(-II) has been detected mainly in the form of Se-aminoacids and (or) peptides with the Se–C bond.[150] It has been shown that Se(IV) and Se(VI) are present in greater amounts in sea water than in surface water;[29,151] the opposite assertion is valid for Se(-II,0).[151] Among the different forms of vanadium, V(IV) and V(V) have been determined in river waters.[152]

Table 5. The vertical profiles of the chemical forms of As, Sb, and Ge (nmol litre$^{-1}$) in the Baltic Sea (the Gotland Depression).[143]

| Depth, m | MeAs | $Me_2As$ | As (III) | As (V) | MeSb |
|---|---|---|---|---|---|
| 10 | 0.43 | 2.79 | 1.44 | 3.12 | 0.032 |
| 40 | 0.23 | 0.20 | 0.18 | 8.46 | 0.030 |
| 100 | 0.04 | 0.07 | 0.11 | 11.6 | 0.022 |
| 150 | <0.04 | 0.07 | 0.18 | 13.2 | 0.019 |
| 175 | 0.06 | 0.15 | 12.3 | 2.63 | 0.013 |
| 200 | 0.08 | 0.21 | 11.2 | 3.55 | 0.034 |
| 215 | 0.04 | 0.24 | 10.7 | 3.30 | 0.032 |

| Depth, m | $Me_2Sb$ | Sb (III) | Sb (V) | MeGe * | $Me_2Ge$ * |
|---|---|---|---|---|---|
| 10 | <0.006 | 0.008 | 0.56 | 78.4 | 54.5 |
| 40 | <0.006 | 0.002 | 0.50 | 79.6 | 39.6 |
| 100 | <0.006 | 0.003 | 0.31 | 94.3 | 54.6 |
| 150 | <0.006 | 0.004 | 0.20 | 114 | 67.8 |
| 175 | <0.006 | 0.008 | 0.25 | 88.2 | 54.3 |
| 200 | <0.006 | 0.150 | 0.18 | 83.3 | 53.4 |
| 215 | <0.006 | 0.137 | 0.18 | 108 | 75.3 |

*In pmol litre$^{-1}$.

The dominant dissolved forms of other important TE in certain oxidation states cannot be determined in NW with the aid of the analytical methods employed. They include Pb(II), Mn(II), Co(II), Ni(II), Fe(III), and Sn(IV).

Organoelemental compounds have now been found in NW only for Group IV and V and also mercury owing to the hydrolytic and oxidative instability of the element-carbon bonds for other TE. With rare exceptions, only the methyl derivatives of TE have been detected in NW, although thousands of tonnes of ethyl, butyl, and phenyl compounds of the most toxic TE (Hg, Pb, As, and Sn), some of which ultimately enter the NW, are produced annually by the chemical industry. However, these compounds are unstable and decompose in NW as a consequence of microbiological and chemical processes accompanied by the subsequent natural methylation with formation of methyl derivatives of TE (see Section VII).

The methyl compounds of As and Sn were examined above. Among the methylmercury derivatives, MeHg(II) has been found in the coastal sea waters of Japan at a concentration of 0.1 ng litre$^{-1}$ [81] and in the river waters of Japan and Canada at concentrations in the range 2–8 ng litre$^{-1}$,[93] which amounts to 1 and 30% respectively of the total content of mercury in these waters. In addition $Me_2Hg$ at concentrations of 0–4 ng litre$^{-1}$ has been detected in the surface waters of Japan.[153]

More detailed data have been compiled for Group IV elements. The methyl compounds of germanium have been found in the Sargasso and Bering Seas and also in the

river and estuary waters of the USA and Portugal at concentrations in the following ranges (ng litre$^{-1}$): Ge(IV)—0.4–12.3 and 0.6–7.4, MeGe(IV)—18.2–24.5 and 0–19.6, $Me_2Ge$(IV)—8–11.5 and 0–12, and $Me_3Ge$(IV)—0 and traces.[32] The vertical profiles for MeGe(IV) and $Me_2Ge$(IV) in the Baltic Sea are presented in Table 5.

The concentrations of methyltin derivatives in the rivers of the USA and Europe are indicated in Table 6. Only 5% of the total tin exists in the methyl form[154] but its content in the form of these compounds increases sharply in the polluted rivers of Florida (up to 54%)[33] and in the Rhine (up to 94%).[154] The following amounts of different tin derivatives have been found in the coastal waters and surface waters mainly in the USA and Canada (ng litre$^{-1}$): MeSn(IV)—0–42[33,155,156] and 0–1220,[33,52,56] $Me_2Sn$(IV)—0–200[33,155–157] and 0–400,[33,52,156] $Me_3Sn$(IV)—0–400[33,157] and 0–50,[33,52] and $Me_4Sn$—480 and 930.[157]

Table 6. The content of the chemical forms of tin (pmol litre$^{-1}$) in certain rivers of the USA and Europe.[154]

| River | MeSn (IV) | $Me_2Sn$(IV) | $Me_3Sn$(IV) | Sn(inorg.) | Sn (total) |
|---|---|---|---|---|---|
| Colorado | traces | 1.7 | 1.7 | 21.1 | 24.5 |
| Mississippi | 11.8 | 26.1 | 0.8 | 1036 | 1075 |
| Ochlockonee | 1.7 | 0.8 | 0.8 | 35.4 | 38.7 |
| Rhine | 592.3 | 1769 | 13.5 | 155 | 2530 |
| Main | — | 3.4 | 2.5 | 101.1 | 107 |

Large concentrations of butyl derivatives of tin have been detected in Lake Michigan and in the surface waters of Canada (ng litre$^{-1}$): BuSn(IV)—56–8480; $Bu_2Sn$(IV)—10–7300,[52,156] and $Bu_3Sn$(IV)—10–2910. The content of the last form in the rivers and lakes of Switzerland is only 1–15 ng litre$^{-1}$.[158] It is believed that these butyl compounds are of anthropogenic origin and enter NW as a result of, for example, leaching from the paint on boats and ships or as a result of transport through the atmosphere.[52] A difference has been discovered in the interaction of various forms of tin with inorganic and organic substances in NW.[159] The stability and degree of decomposition of organotin and organolead compounds under natural conditions in aqueous systems depend greatly on the number of organic groups linked to the metal.[160,161] Silicones at concentrations ranging from 2.0 to 54.2 μg litre$^{-1}$ have been detected in the rivers of Japan.[162]

## V. COLLOIDAL AND SUSPENDED PARTICLES

### 1. Composition, Properties, and Distribution of Particles

It has come to be assumed that filtration of samples of NW through membrane filters with a pore size of ~0.45 μm makes it possible to separate the suspended forms of any chemical ingredients from the dissolved forms. However, it has been frequently found that the dissolved forms usually contain fairly numerous submicron particles and organic macromolecules (see, for example, Refs.10, 163, 164), which are colloidal particles in terms of their size and whose origin, composition, and nature have so far been little investigated. It has been shown that the composition and content of 0.0012–0.4 μm colloidal particles isolated from river and estuary waters depend on the time of year and the salinity.[165] During the winter, fresh water colloids, which consist mainly of the products of continental erosion (argillaceous minerals and iron oxide), become enriched in carbon with increase of the salinity of water and their content falls sharply from 28.6 to 0.6 mg litre$^{-1}$. During the summer, these colloids are enriched mainly in carbon of biogenic origin and their concentration changes insignificantly, from 1.9 to 0.7 mg litre$^{-1}$, with increase of the salinity of water. According to data obtained by the pyrolysis of the organic fraction of these colloids, it is suggested that it consists mainly of the secretions and decomposition products of the phytoplankton and micro-organisms.[166] It has been shown[167] that the average content of colloidal carbon in coastal sea waters is 0.15 mg litre$^{-1}$ regardless of the season, which corresponds to 11% of the total non-suspended carbon. It has been found that Fe(III) in river waters is present in the form of colloids stabilised by organic matter,[163,164,168,169] detergents, silicates, and phosphates, but not chlorides, nitrates, hydrogen carbonates, and sulphates.[169] The main bulk of colloidal Al is also coated by organic matter; the degree of adsorption of TE by these colloids depends on the stability of the complexes formed by the TE with organic ligands.[170]

The colloids in fresh water consist of electrically charged particles, whose charge is due to the presence of unsaturated and ruptured bonds on the surface of the crystal and the substitution of structural cations in the mineral lattice by cations in another valence state. The charge on the surfaces of inorganic colloids can be both positive (Al hydroxides at a high pH) and negative (quartz or argillaceous minerals), while in organic colloids (HS) it can only be negative. The negative charge of the colloids is balanced by binding the TE as a result of ion exchange, surface adsorption, and chelation.[99,171]

The content of the suspension in river waters varies from a fraction of a milligram to tens of grams per litre. Its average concentration in world rivers is ~0.5 g litre$^{-1}$ and the maximum and minimum concentrations in the rivers of Asia and South America are 1.28 and 0.095 g litre$^{-1}$ respectively.[172] In the waters of the open ocean its content is lower by several orders of magnitude: depending on the season, it changes by up to several hundreds of micrograms per litre in surface waters and is on average 10 μg litre$^{-1}$ at depths in excess of 200 m.[173] The main bulk of the suspended particles have dimensions less than 10 μm in both river[94] and sea[173] waters, but the size of the biological particles formed in the ocean can reach 1 mm.[173]

The river suspension contains an amount of organic matter ranging from several tenths to 20%[172,174] while in ocean water it is 30–70%.[173] Quartz and argillaceous minerals (illite, chlorite, montmorillonite, and kaolinite) predominate in the terrigenous (mineral) river suspension,[172] while aluminosilicate particles, incorporating clay and non-aqueous minerals and also non-aluminosilicate minerals (quartz, pyrite, dolomite, barite, titanite, and iron and titanium oxides) predominate in coastal sea water.[175]

The main bulk of the suspension in surface ocean waters is of biological origin, consisting of carbonates, opal, and cellular and amorphous organic matter.[173,176] Its fraction is 60–90% of the total amount of the suspension entering deep waters down to 5000 m[177–180] (for example, the suspension collected in deep water traps contained 0–25% of clay, 60–70% of $CaCO_3$, 0–15% of opal, and 8–12% of organic carbon[180,181]), despite the fact that most of the suspension is mineralised and is consumed by hydrobionts following submersion.

The terrigenous component of the entire oceanic suspension is only 0.5–10%,[176] but, in contrast to the biogenic suspension, it does not dissolve and does not change in the bulk of the water and in sediments in water. A suspension of anthropogenic origin has been found in deep waters.[182]

It follows from data for the basic chemical composition of the suspensions in many world rivers[94,172] and also from the average compositions[172,183] that river suspensions occupy, in terms of their composition, an intermediate position between sedimentary rocks and soils. This indicates the source from which they originate. The basic chemical composition of a marine suspension has also been investigated.[184,185]

## 2. The Overall Content and Distribution of TE

Table 7 presents the content of certain TE in suspensions in the major world rivers. Among individual countries, this question has been most fully investigated in Japan, where 21 suspended TE have been determined in each of 166 rivers.[187] The highest concentrations in the suspension are usually those of Fe and Mn and in the Mississippi, for example, their contents reach 46.1 and 1.3 mg $g^{-1}$ respectively.[87]

Table 7. The contents of TE in suspension in certain world rivers (μg $g^{-1}$).

| River | Co | Cr | Cu | Ni | Pb | V | Zn | Refs. |
|---|---|---|---|---|---|---|---|---|
| Amazon | 41 | 193 | 266 | 105 | 105 | 232 | 426 | [183] |
| Congo | 25 | 175 | — | 74 | 455 | 163 | 400 | [183] |
| Ganges | 14 | 71 | 30 | 80 | — | — | 163 | [183] |
| Garonne | 39 | 255 | 51 | 33 | 381 | 150 | 874 | [183] |
| Mekong | 20 | 102 | 107 | 99 | 113 | 175 | 300 | [183] |
| Mississippi | 21 | 72 | 42 | 55 | 45 | — | 184 | [183] |
| Niger | 40 | 150 | 60 | — | — | 180 | — | [183] |
| Yangtze Kiang | 25 | 83 | 70 | 78 | 65 | — | 108 | [186] |
| Yellow River | 12 | 72 | 33 | 38 | 35 | — | 75 | [186] |
| Danube | 16 | 140 | 189 | 89 | — | — | 322 | [172] |
| Dnieper | 5 | 86 | 90 | 93 | — | 90 | 260 | [172] |
| Don | 12 | 143 | 200 | — | — | — | 870 | [172] |
| Volga | 11 | 183 | 86 | 76 | - | 102 | 260 | [172] |

The contents of the suspended forms of TE in surface waters depend on the concentration of the suspension, its mineralogical and granulometric compositions, the climatic zone, and the time of year. Thus the concentrations of the suspended TE in various sections of the river proved to be inversely proportional to the content of the suspension in those sections,[188] while in Lake Ontario they were found to depend on the distance from the shore and amount on average to 50–80, 10–40, 20–60, and >60% of the overall concentrations of Cu, Ni, Cd, and Pb respectively.[189]

The contents of the suspended Hg and MeHg(II), which predominate during spring flooding, fall sharply during the summer period.[190]

It is impossible to say *a priori* which of the principal various forms of the TE, suspended or dissolved, is the main one in river waters. Al, whose suspended form always predominates, is an exception.[86,172,183] It has been shown that Fe and Mn,[86] Fe,[191,192] Fe, Mn, Ni, Co, Cr, and Pb,[183] and Cd, Pb, and Cu[193] predominate in the river suspensions; there is more than 90% of the Fe, Mn, Cd, Cr, Cu, Ni, Pb, and Zn in the suspension from the Mississippi[87] and more than 98% of the Hg from the Thames.[92] The relative importance of the suspended forms diminishes in the sequence Al > Fe > Mn > Co > Zn > Ni > Cu > Cd.[86] On the other hand, the dissolved form predominates for Ni, Cu, Zn, and Cd[86] and for Mn;[193,194] ~70% of Mn, Cu, and Zn and 100% of Cd[191] and more than 75% of Fe, Cd, Cu, and Zn[195] exist in this form. In order to arrive at correct conclusions from geochemical studies, it is desirable to carry out monthly measurements of the concentrations of these forms of TE in rivers over a period of many years.[86] Nevertheless one should note that the vast majority of TE are transported in rivers mainly in the suspended form.[88,172,183]

As a consequence of the low concentrations of the suspension in sea water and particularly ocean waters, they contain much smaller amounts of suspended TE than river waters. For example, the concentrations in the waters of the Central Atlantic are as follows (ng $litre^{-1}$): Al—78, Mn—3.5, Fe—222, Cr—3.1, Ni—1.8, Cu—3.6, Pb—4.5, and Zn—16;[22] the concentrations found in the Southern Indian Ocean are (in ng $litre^{-1}$ and μg $g^{-1}$ respectively) Pb—35 and 260, Cd—3.5 and 26, Cu—100 and 730, and Zn—230 and 1700.[196] The suspended TE have also been determined in the waters of the Baltic Sea,[184] the Alaska Bay,[185,197] and in the plankton of the Pacific Ocean.[198] Turning now to individual TE, we may note that the concentrations of suspended mercury are (ng $litre^{-1}$) 0.2–0.3 in the coastal waters of Japan[94] and 0.5–0.9 in the Pacific Ocean and the Sea of Okhotsk[63] and those of suspended Cr are 80 in the Sea of Japan and 70 in the Pacific Ocean.[85] Pressure can exert a considerable influence on the interaction of the dissolved Al with the inorganic detritus in the bulk water, the bottom deposits, and at the water–deposit interface.[199] The importance of adsorption on the submerging organic suspension for the rapid decrease of the concentration of Hg in coastal sea waters has been emphasised.[122]

The proportions of the suspended forms of TE relative to their total content may be as follows: 3–10 for Hg,[63] 10–30 for Ag (Pacific Ocean),[61] and 1.7, 3.3, and 9.8% respectively for Zn, Cd, and Cu (Baltic Sea).[200]

The majority of the dissolved TE are finally removed into the deposit in the seas and oceans by becoming adsorbed on suspended particles. Biogenic particles formed initially in the surface layer from the phytoplankton and ultimately submerged into deep regions in the oceans in the form of detritus (the main bulk of which consists of fecal pellets whose rate of submersion ranges from several to thousands of metres per day) play an especially important role in controlling the distribution of TE in oceans.[1] A different fraction of each TE in the suspension is remineralised and passes to the bulk water, while another fraction of TE is found in pelagic clays and iron–manganese concretions and is then returned to surface waters by upwelling.

The rates of scavenging, which is an important factor limiting the concentrations of certain TE in oceans, and of the removal of TE from deep waters into deposits have been found.[181,201–203] For example, the rates are 20–50 μmol $cm^{-2}$ $g^{-1}$ for Mn and Fe and 0.1–0.4 μmol $cm^{-2}$ $g^{-1}$ for Cu, Co, Ni, Zn, V, and Sr.[203] The fluxes of suspended TE directed towards deep waters can undergo seasonal variations connected with the cyclic nature of the primary production,[202]

biogenic particles binding TE more strongly than mineral particles.[204]

### 3. Physicochemical Forms of TE

In a suspension TE can exist in stationary forms (the crystal lattice of undecomposed fragmented and argillaceous minerals) and mobile forms (surface sorption on organic matter and Fe and Mn hydroxides), only the latter being biologically accessible. It is noteworthy that there are at present no methods for the independent determination of the individual physicochemical forms of TE in a suspension, which seriously hinders comparison of the results obtained by different workers.[172, 205, 206]

The crystalline form and Fe and Mn hydroxides are usually most important in river suspensions.[172] For example, in the Amazon and Yukon rivers these forms comprise together 65–92% of Fe, Mn, Co, Cr, and Cu.[88] The predominance of both mobile[172,207] and organic and Mn hydroxides[207] forms has been noted for a series of TE. Differences between the ratios of different forms of TE in different granulometric fractions of the suspension have also been discovered.[207, 208]

In conformity with the significant difference between the compositions of river and marine suspensions noted above, it has been shown[209] that up to 70% of Al, Mn, Zn, Cu, Pb, and Li in the suspensions in the Indian Ocean exist in the adsorbed form and the form bound to Fe and Mn hydroxides and only 15% of these TE exist in the organic form, while in the inner seas the latter form reaches 30–70%, which is apparently associated with the vigorous absorption of the TE by the phytoplankton.

### 4. The Mechanisms of the Binding of TE

The suspended particles and deposits in aqueous media concentrate TE via three main mechanisms:[206] via their physicochemical adsorption from the bulk of the water, via their biological absorption, and via the sedimentation of the TE-enriched suspension. The degree of physicochemical adsorption, subdivided into physical and chemical, and also ion exchange[210] are influenced by the nature of the surface of the suspension or of the deposit in the aqueous medium.

The physicochemical adsorption of TE in different types of NW on the surfaces of clay, solid organic substances, and metal oxides is of greatest importance. Although previously very much more attention was devoted to the sorption of TE by clays, it is believed nowadays[206] that, in the adsorption of TE from NW, clays probably play the role of supports covered by organic matter or metal oxides. The surface of the clay will therefore not be considered here.

There exist three types of organic surfaces:[206] (1) the surfaces of living organisms such as bacteria and algae and, which is particularly important, the surface of marine plankton in which the main bulk of the TE are bound to non-skeletal organic phases and not to calcium carbonate and opal;[198] (2) the surface arising on decomposition of plant and animal matter and also on condensation of low-molecular-weight organic substances to form high-molecular-weight organic substances; it possesses many of the properties of polyelectrolytes and colloidal particles; (3) the surface formed by low-molecular-weight organic substances sorbed on clay or metal oxide supports.[211, 212]

Although the differences between these three types of organic surfaces have not been ultimately elucidated from the standpoint of the method of concentration of the TE by the latter, it has come to be assumed that salicylic acid is involved in the binding. The participation of carboxylic and phenolic functional groups[212,213] and also peptides[214] in the mechanism of the binding of TE has also been suggested.

We may note that the models of the reactions taking place on the surface in the absence of organic matter cannot be applied to natural systems, because in this case organic matter is adsorbed on the surface of the suspension,[213, 215] which is at least partly responsible for the negative electrostatic charge on almost all suspended particles.[211, 216] The amount of adsorbed organic matter then depends on the chemical composition of the surface of the suspension.[215]

Hydroxy-groups are present in water on the surfaces of metal oxides, the most important of which are $Al_2O_3$, FeOOH, and $MnO_2$.[4] The specific adsorption of cations and anions is therefore regarded as a result of their interaction with these groups at the water–oxide interface. The degree of binding of TE ions on the surface depends on the concentration of the reacting groups and the competing ions and also on the pH and the ionic strength of the medium.[206] Several mechanisms have been proposed to explain the sorption of TE,[217] including ion exchange, surface ionisation, and complex formation—in particular the formation of Zn and Pb phosphates.[218]

The picture becomes still more complex where one considers heterogeneous oxide surfaces, where the strengths of the bonds between TE and various centres can differ by an order of magnitude.[219] Hydrated oxide surfaces can adsorb organic matter also via ligand exchange. The degree of adsorption then depends on the pH and the MW.[206]

It must be emphasised that natural organic matter binding TE can be present in NW both in the dissolved state and in the form of a thin film coating the suspended particles. Natural organic matter can be regarded as the most important factor in the TE cycle in NW.[201, 205] This has been demonstrated for the waters of the open ocean where the distribution of the majority of TE is controlled by their biological absorption on the surface and their regeneration in deep waters from submerged biogenic residues.[1]

## VI. ESTUARINE MIXING

Estuaries, which may be any water area where sea water mixes with the fresh water from the continental slope, namely river mouths, coastal bays, marshes, and basins behind a coastal bar constitute at the same time zones where there is a transition from the continent to the ocean and the continuity of the properties of the environment breaks down. A wide variety of hydrodynamic, physicochemical, and biological processes take place in estuaries at the geochemical river–sea barrier.

As a result of the sharp decrease of the flow rate of the river, estuarine mixing entails the deposition of more than 90% of the river suspension together with the TE bound to it.[172,220–223] Small particles whose size is less than 2–5 μm can be removed from the bulk of the water also as a result of the increase in their size as a consequence of coagulation, which arises on neutralisation or charge transfer involving clay particles, caused by the mixing of river waters with sea water, which is a strong electrolyte.

The concentrations of the inorganic and organic substances present in the suspended, colloidal, and dissolved states change sometimes very considerably, not only as a result of the mutual dilution of the fresh and sea waters but also as a consequence of various physicochemical transformations occurring under the non-steady conditions of the estuarine environment owing to the sharp changes over small distances

in salinity, pH, the content of the suspension, and other factors. Such transformations include precipitation, sorption, flocculation, complex formation, and other processes. The 2% isohaline is regarded as the hydrochemical boundary between the river and sea waters,[172] although the relative contents of the principal ions are almost constant only after 10% has been reached.

The causes of the observed variations in the content of both suspended and dissolved principal and trace elements in estuarine waters are not, however, altogether clear owing to the lack of complete hydrochemical and hydrodynamic information.[220,224] Sorption processes are frequently invoked to account for these causes. It has been shown that, among the principal cations, the Ca in the suspension exchanges for Na and to a lesser extent for K, while Mg is little involved in exchange reactions.[225] Among the TE, Fe,[226] Mn,[224,227] Cu,[224,228] Cd,[227,229] Pb,[120] and Ba, Co, Cs, and Zn[229] are desorbed into water. The increase in the concentrations of the dissolved TE, for example, Cu, is frequently attributed to their mobilisation from the resuspended deposits in aqueous media at high salinities[228] (for further details, see Section VII).

Overall, a clear idea about the role of sorption in estuarine processes is lacking. On the other hand, there is important evidence for the predominance of the influence of physical[224,230,231] (for example sedimentation and hydrological[230]) processes, and not physicochemical processes, on the chemical composition of the suspension in estuaries.

In the estuarine mixing of waters, the suspended or dissolved components behave conservatively when they participate only in a physical (mechanical) mixing process or non-conservatively when they are involved in various physicochemical reactions or in biological turnover. In the former case their concentrations depend linearly on the salinity and the input or removal of the components can therefore be estimated from the observed deviations from the straight line.[220]

An extremely important process for dissolved inorganic and organic substances in the estuary zone is their flocculation, i.e. their transformation into suspended amorphous particles, which takes place with increase of the salinity and pH of the water. The most important precondition for flocculation is the presence in river waters of dissolved Fe, which is believed, on the basis of a series of indirect data, to exist mainly in the form of Fe(III) hydroxides stabilised in the colloidal state by chemical binding to HA[99,163,168] (although recently objections have been raised against the latter hypothesis[232]). In the estuarine mixing of waters, the colloidal Fe and HA flocculate as a consequence of their destabilisation by cations from sea water.[163,168] However, it is not altogether clear whether this destabilisation of river colloids is associated with complete[163] or only partial[233] neutralisation of the negative charge. In contrast to Fe and HA, dissolved organic matter behaves conservatively.[164,168,233–235] The rate of flocculation increases with increasing salinity up to 15–18% and, for certain salinities, the bulk of the floccules are formed in the first 0.5 h after the start of mixing.[236,237]

Flocculation is the principal mechanism of the removal of dissolved TE from river water via coprecipitation and adsorption on the Fe hydroxide and HA floccules formed.[236,237] For example, TE can be removed from river water to the following extent:[236] 95% for Fe, 20% for Al, 40% for Cu and Ni, 25–45% for Mn, and 10% for Co. As[142] and Hg, Bi, and Sn[229] also flocculate. We may note that 65% of their HA is then lost, which, however, corresponds to only 3% of the dissolved organic matter.[168] The content of organic matter in river waters can be a regulating factor in the removal of TE;[238] the lanthanide elements are removed to the extent of 60–95% at a high concentration of organic matter and remain in the water at a low concentration. The removal of TE in the estuarine zone has been the subject of field observations.[115,163,172,224,239,240] The degree of removal can depend significantly on the form of the TE. For example, the inorganic colloidal form of Fe is removed quantitatively, while the organic form is removed only to the extent of 50%.[119] Estuaries behave as traps for TE in the course of their transfer from river to sea water, which may serve as one of the explanations of the relatively low concentrations of TE in the marine environment compared with the river environment.[241]. At the same time the conservative behaviour of Mn,[164,172,235] Cu,[115,242,243] Ni,[242,243] Cd and Zn,[242] and Cr[244] has been demonstrated. The form of the TE can strongly influence its behaviour: for example, compounds having the composition $R_nPb$ (where R is an organic group) behave conservatively, while inorganic Pb behaves in the opposite manner.[245]

Overall, the geochemistry of the TE in estuaries, which depends also on their type and the physicogeographical conditions in the environment, is very complex and so far has been little investigated. The ideas concerning the behaviour and estimation of the losses of dissolved and suspended TE in various river estuaries are frequently contradictory and vary markedly. The atmospheric input of TE also has an effect.[246] Nevertheless it can be regarded as demonstrated that estuaries serve as traps for the majority of the dissolved and suspended substances on their way to the ocean.

## VII. BOTTOM DEPOSITS AND PORE WATERS

### 1. Total Content and Distribution of TE

Marine, coastal, and estuarine deposits usually consist of two layers—the upper oxidised reddish-brown layer and the lower reduced olive-green layer. Variations in the thickness of the oxidised layer up to 1 mm depend on the input of organic matter on the bottom and on the rates of its decomposition (destruction). Oxygen diffuses downwards through the oxidised layer and the free $H_2S$, formed in the reduced layer by sulphate-reducing bacteria, diffuses upwards (sometimes without being evolved[247]). The reduced layer contains benthic organisms. It has been shown recently[248] that the colour transition from brown to green in marine deposits is accompanied by the reduction of Fe(III) to Fe(II) in pore waters.

In water areas with limited circulation, for example in the Black Sea and in fjords, oxygen does not reach deep waters and for this reason $H_2S$ is present even near the bottom layer. In this case the deposits are coloured black and contain no benthic organisms.

The pore waters impregnating the bottom deposits always differ in their chemical composition from the water covering them (bottom water) by the fact that their concentrations of dissolved $O_2$ and $SO_4^{2-}$ are reduced and those of bicarbonate are increased. Not only $SO_4^{2-}$ may be reduced to $H_2S$ but also $CO_2$ and $NO_3^-$ may be reduced to $CH_4$ and $NH_3$ respectively in the pore waters of the reduced deposits.

As a consequence of the occurrence of diagenetic processes in ageing deposits, mainly in the pore waters, the chemical composition of the latter is important for the elucidation of the mechanism of the diagenesis. However, despite the fact that pore waters are usually enriched in the TE by a factor of 10 and more compared with the main bulk of the water, the contribution to the overall TE content in the wet deposit is insignificant (for the bibliography, see Warren[249]).

The bottom deposits are enriched in TE mainly as a result of three processes: (1) the sinking to the bottom of suspended particles; (2) the transfer of suspended particles along the bottom (in rivers); (3) the sorption of dissolved TE from water when the latter comes into contact with a deposit. The most important process is the sedimentation of the suspension in which one can isolate the detritus, biogenic, and deposited fractions. The particles of detritus contain TE within crystal lattices, in the adsorbed state on the surface, in the exchange centres of argillaceous minerals, and in surface layers formed by metal hydroxides or organic matter. Biogenic particles can contain TE within skeletal inorganic substances, in the adsorbed state on the surfaces, in exchange centres, in organic matter, in a bound form, and in the envelopes coating metal hydroxides. In the deposited fraction, which includes calcium carbonates and metal hydroxides and sulphides, the adsorbed TE are present on the surface.[249]

The content of TE in deposits from different water areas varies markedly, sometimes by 2–3 orders of magnitude, mainly in connection with the different degrees of their contamination. The concentration of TE in coastal,[250] lake and sea[249] deposits have been considered in a number of reviews. The contents of cadmium in deposits of different types have been analysed.[251] There exist data on the concentration of TE in river,[252,253] lake,[189,254] coastal,[197,255–264] and ocean[265] deposits.

The estuarine deposits, which behave as traps for the many suspended and dissolved TE carried out by the rivers, belong to the class of the most polluted. Their contents of some TE are listed in Table 8. The Rhine estuary and New Jersey river estuaries, whose deposits contain considerable concentrations of Pb and Cu, have attracted attention. The concentrations of As in the deposits in 27 estuaries in Great Britain differ by 3 orders of magnitude. In particular, its content in the Thames estuary is 4–6 μg $g^{-1}$,[274] while its maximum concentration reaches 2500 μg $g^{-1}$.

Table 8. The average TE concentrations in estuarine deposits (μg/g of dry mass)

| Estuary | Mn | Cu | Cd | Ni | Pb | Hg | Zn | Refs. |
|---|---|---|---|---|---|---|---|---|
| Ems | — | 24 | 0.7 | 27 | 47 | — | 150 | [266] |
| Rhine | — | 99 | 5.0 | 31 | 213 | — | 870 | [266] |
| Weser | — | 42 | 2.4 | 58 | 154 | — | 393 | [267] |
| St. Laurence | — | 24 | 0.22 | 33 | 30 | 0.45 | 115 | [268] |
| Miramichi | 417 | 27 | — | 45 | 83 | 0.34 | 219 | [269] |
| Ko-Jima | 703 | 37 | 0.61 | — | 27 | — | 177 | [270] |
| New Jersey rivers | — | 66 | 2.24 | 36 | 128 | 0.66 | 218 | [271] |
| Mersey | 564 | 41 | 5.3 | — | 57 | — | 236 | [272] |
| St. John | 296 | 16 | 0.16 | 16 | 24 | 0.04 | 53 | [273] |

The distribution of mercury has been studied in particular detail in European countries. Thus its content in the deposits in more than 30 estuaries in Great Britain is 0.018–29 μg $g^{-1}$,[275–279] while the deposits of 220 Swedish lakes contain 0.05–0.5 μg $g^{-1}$ of mercury[280] although sewage had never been previously discharged into the lakes investigated. The mercury content in oceanic deposits is correlated with the underwater volcanic activity.[281]

The TE which have entered various water areas in a wide variety of ways—from the atmosphere, from rivers, from sewage discharges, etc.—inevitably accumulate in the bottom deposits. The bore cores of bottom deposits removed without disturbing the stratification can therefore reflect the entry of TE into the water basins over any period of time, up to 100 years. The geochronology of bottom deposits is usually determined by analysing the distribution of the $^{210}Pb$ isotope with respect to depth, but, in order to achieve a more accurate dating, combinations of different isotopes are employed, their number being fairly considerable (for example, $^{137}Cs$, $^{238}Pu$, $^{239,240}Pu$, $^{241}Am$, and $^{244}Cm$).[282]

The TE concentrations in the surface layers of lake, estuary, and coastal sea deposits in the vicinity of mining, industrial, and city regions can be a factor of 5–10 higher than 50–100 years ago, which indicates their anthropogenic origin. Apart from the information contained in a study mentioned previously,[16] there exist data on the geochronology of TE in the bottom deposits in fords,[283] lakes,[282,284–288] rivers,[282,289] estuaries,[290,291] fjords,[292–294] and coastal sea regions.[295–298] The historical record in the vertical Zn, Pb, Cr, Cu, As, Ni, Cd, and Hg profiles in the Rhine deposits over a period greater than 50 years is illustrated in Fig. 2.[289]

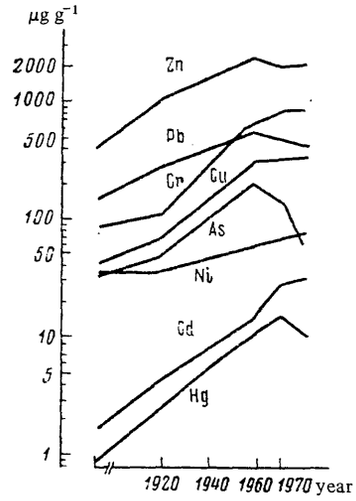

Figure 2. Time variation of the concentration of TE in the bottom deposits of the River Rhine.[289]

However, TE are distributed non-uniformly in deposits and their concentrations usually increase with decreased particle size.[249] The difference between the concentrations reaches in some cases an order of magnitude and more. The observed scatter can be appreciably reduced by employing different correction procedures.[15,299] A fraction whose size is less than 63 μm is usually analysed,[300] although it has been shown[299] that the content of many TE in a fraction up to 20 μm in size from estuarine deposits varies several times less from sample to sample than for a fraction whose size is up to 63 μm. Systematic investigation of different types of bottom deposits is therefore essential for a final selection of the fraction size most suitable for the monitoring of TE.

## 2. The Physicochemical and Chemical Forms of TE

The TE within bottom deposits are distributed between various physicochemical forms (geochemical fractions), which depend on Eh and pH[301] and differ in their mobility, leachability, and biological accessibility. In order to make it easier to understand the geochemical distribution of TE, the deposits are usually fractionated geochemically by methods involving single- or multi-stage consecutive extraction, which make it possible to leach selectively, with the aid of suitable chemical reagents, each of the identified fractions. The TE linked to the crystal lattice of silicate rocks are referred to as lithogenic and the corresponding fractions are called residual. The TE present in all the remaining geochemical fractions are referred to as non-lithogenic and the degree of pollution of the given deposit (water area) can be inferred from the level of their concentrations.

The single-stage extractions (they have been assessed and compared in a number of studies[302–304]) make it possible to determine either some one of the non-lithogenic TE fractions or their various combinations depending on the pH[305] and the reagent employed. In order to investigate more fully the physicochemical forms of TE, extractions comprising two,[289] three,[306] four,[272] five,[267, 303, 307] six,[308] and seven[15] steps are used. The advantages and disadvantages of the extraction methods have been discussed.[15, 302, 309, 310] It must be emphasised that the multistage consecutive extraction methods are not fully selective, the reactions being always influenced by factors such as, for example, the extraction time, temperature, the ratio of the volumes of the deposit and the extractant,[15, 309] and the readsorption of the TE.[311] Despite this, they are used widely.

Depending on the origin, composition, and degree of pollution of the deposit, the main bulk of the TE may be located in different geochemical fractions. The non-lithogenic TE are frequently bound to organic matter,[205, 269, 272, 308, 312, 313] which is particularly characteristic of mercury,[259, 275, 277, 278, 314] and also to the oxides of Fe (the main bulk of As[315–317]) and Mn,[205, 259, 308, 317–320] sulphides,[259, 313, 320] carbonates,[320–322] and phosphates.[319] Oceanic deposits have also been investigated.[317, 323]

Table 9. The physicochemical forms of TE (%) in the bottom deposits of the Rhine (A) and the Ems estuary (B).[15]

| Forms | Zn | | Ni | | Cu | | Pb | | Cd |
|---|---|---|---|---|---|---|---|---|---|

Examples of the application of the seven-stage extraction to deposits from the Rhine and from the Ems estuary are presented in Table 9,[15] whose data indicate an appreciable decrease of the proportion of the residual fraction for Zn, Cu, and Pb, despite the increase of their overall concentration, as a consequence of the pollution of the deposit. Appreciable amounts of Zn, Cu, Cd, and Pb are present in the carbonate fraction, while the proportion of the exchangeable form is appreciable only for cadmium.

With the exception of mercury, the chemical forms of TE have been little investigated in deposits. It has been shown that the MeHg(II) content in various estuarine and coastal deposits is usually less than 1% of the total Hg.[275, 278, 324] The MeHg(II) concentration is largely controlled by the content of sulphides and not of the total Hg and organic matter. At a specific concentration of sulphides, the level of MeHg(II) falls sharply, apparently as a consequence of a disproportionation reaction:

$$2\mathrm{MeHg(II)} + S^{2-} \rightarrow (Me_2Hg)_2S \rightarrow HgS + Me_2Hg.$$

The dimethylmercury formed vaporises and is transferred through the bulk water to the atmosphere.[279]

The predominance of a particular form of tin depends on the type of deposit.[155] In partly reduced and polluted marine deposits MeSn(IV) predominates, in oxidised and polluted deposits the main component is $Me_2Sn(IV)$, while in oxidised and unpolluted deposits $Me_3Sn(IV)$ is the main component. It has been shown[155] that the deposits from the Baltic and Mediterranean Seas contain 0.5 and 0 ng g$^{-1}$ of the first form respectively, 0.3 and 2.6 ng g$^{-1}$ of the second form respectively, and 0 and 8.6 ng g$^{-1}$ of the third form respectively. The following butyltin derivatives have been detected in deposits from Canadian lakes (μg g$^{-1}$):[325] $BuSn(IV)$—0.013–0.58, $Bu_2Sn(IV)$—0.05–0.35, and $Bu_3Sn(IV)$—0.11–0.40. Mixed compounds, formed apparently as a result of methylation, have also been found: $Bu_2SnMe_3$—0.011–0.012 μg g$^{-1}$ and $Bu_3SnMe$—0.011–0.023 μg g$^{-1}$. The deposits from Swiss lakes contain 0.002–0.016 μg g$^{-1}$ of $Bu_3Sn(IV)$.[158] The river and coastal deposits were found to contain respectively 0.3–5.8 μg g$^{-1}$ [162, 326] and 0.61 μg g$^{-1}$ [326] of silicones.

## 3. Pore Waters

The concentration and distribution of TE and of their different forms in pore waters depend on Eh, pH, and the content and forms of organic matter and Fe and Mn compounds (amphoteric oxides, sulphides, carbonates, etc.). Pore waters constitute a medium in which TE are transported within surface deposits. The upper layer of these deposits 10–20 cm thick is most important for the exchange between deposits and the water near the bottom.[327] In marine deposits in the oxidised zone the concentrations of Mn and Ni are the same as in the water near the bottom, while in the Mn-reduced zone they are higher approximately by factors of 10 000 and 40 respectively.[328] The Cu content in oxidised pore waters is higher by a factor of 10 and more than in the water near the bottom.[328–330] This is due to the binding of copper by organic matter,[328, 330] which is also the cause of the increase in the Mo, V, and Cr concentrations in the reduced deposits with increase of depth.[331]

The pore waters in polluted deposits contain a particularly large amount of TE. For example, it was found that the pore waters in a lake contain approximately 0.15 mg litre$^{-1}$ each of As(III) and As(V),[332] river pore waters were found to contain 5.85–6.88 g litre$^{-1}$ of total As [including 6–10% of inorganic As and ~90% of $MeAsO(OH)_2$],[333] and the estuarine pore waters were found to contain 3.8 μg litre$^{-1}$ of Hg.[334] In the last case an increase of the Cr, Cu, Zn, Pb, Ag, Ni, and Fe concentrations by a factor of 7.3–15 and of the Mn and Co concentrations by factors of 620 and

37 respectively compared with the water near the bottom was noted.[335] Large seasonal variations have been observed in the Fe, Mn, Cu and Mo contents.[336] The Fe, Cr, and Cu concentration profiles in the bottom water and in the pore waters of coastal marine deposits are presented in Fig.3.[322]

## 4. The Remobilisation of TE

Under the influence of chemical changes in NW and microbiological processes in aqueous media, the TE present in bottom deposits can be remobilised and returned to the water. The remobilisation is induced by four types of chemical changes in water:[15] (1) by an increase of the concentrations of salts whose alkaline earth metal cations can compete with TE ions for sorption on particles; (2) by a change in the oxidation–reduction conditions, usually in connection with the decrease of the oxygen content as a consequence of increased eutrophication, whereupon Fe and Mn hydroxides dissolve, either partly or completely, owing to the reduction to Fe(II) and Mn(II) and some of the TE bound are then liberated (remobilisation of Mn, Cu, and Cd from partly reduced deposits with subsequent vertical transfer to the surface waters has been used to explain the increase in their concentrations in the shelf waters of Great Britain[337]); (3) by a decrease in pH, which leads to the dissolution of hydroxides and carbonates and also to an increase in the desorption of TE as a consequence of competition with $H^+$; it takes place either on oxidation of sulphides in uncontaminated surfactants or on precipitation of acid rain, which is characteristic of many lakes in Northern Europe and North America; in the latter case it has been shown[320] that Zn, Co, and Ni are remobilised mainly from the fraction of readily reducible deposits—Cd is remobilised from the organic phase, while Cu and Pb pass to water to only a slight extent; (4) by the increased employment of natural and synthetic complex forming agents, capable of forming soluble and stable complexes with TE, which would have otherwise been adsorbed on solid particles.

The biological remobilisation of TE can be achieved indirectly as a result of the activity of benthic organisms, which increase the ventilation of the deposits by the oxidised bottom waters[338, 339] and prevent thereby the formation of virtually insoluble sulphides of class B TE in pore waters.[340, 341]

The microbiological proesses in deposits where TE are bound to organic matter having a higher MW and a smaller number of functional groups as a result of diagenesis are more important. The remobilisation of TE takes place mainly in three principal ways:[15] (1) by the decomposition of the organic matter to compounds having a smaller MW but binding TE more effectively (see, for example, Graybeal and Heath[342]); (2) by the change in the physical properties of the medium, for example Eh and pH, as a consequence of metabolic activities; (3) by the conversion of inorganic TE compounds into organoelemental compounds.

## 5. Natural Methylation

Biomethylation is of greatest importance among the microbiological processes, since hitherto there has been no convincing proof of the biosynthesis of organoelemental compounds containing other alkyl or aromatic groups.[343] Apart from the experimental evidence for the biomethylation of TE in deposits described in reviews,[16,18,343,344] the biomethylation of As by fresh water green algae,[345] the methylation of Sn in estuary deposits,[157,346] and the methylation of Hg in the bulk of river,[347] lake,[348] and sea[349] waters have been observed recently. The seasonal variations in these processes[190,348] and the influence of sea salts on the formation and stability of MeHg(II) under aerobic and anaerobic conditions[350] and of the pH on the formation of methyl compounds of Hg and As[351] have been investigated.

The contents of the methyl derivatives of Hg, Sn, Pb, As, Sb, and Se in NW, in suspensions, and in deposits were indicated above in the appropriate Sections. In biological systems, in particular in micro-organisms, the methylating agents are Me–$CoB_{12}$, *S*-adenosylmethionine, and $N^5$-methyltetrahydrofolates. The mechanism of methylation by the $MeCOB_{12}$ reagent depends on the oxidation state of the TE and the reduction potential and can be electrophilic or radical.[18,343,352]

The biomethylation of TE is always accompanied by the reverse biodemethylation of their methyl derivatives,[16,344] which explains, in particular, the low concentrations of MeHg(II) in NW and deposits. The amount of mercury in this form is less than 1% of its total content.

However, one should note that by no means all biotransformations of TE have been elucidated. Thus, despite previous experimental data, the absence of the biomethylation of Pb[353] and $Me_3SnCl$[354] has been demonstrated recently. The compounds $Me_4E$ (E = Sn or Pb), formed as a result of chemical disproportionation, for example, in the presence of sulphur compounds, have been detected:[354,355]

$$2Me_3E(IV) \xrightarrow{S^{2-}} (Me_3E)_2S \rightarrow Me_4E.$$

In river deposits HA and fulvoacids can also methylate Hg(II) to MeHg,[103,356] and, among the methylating agents forming part of their composition, the most powerful is

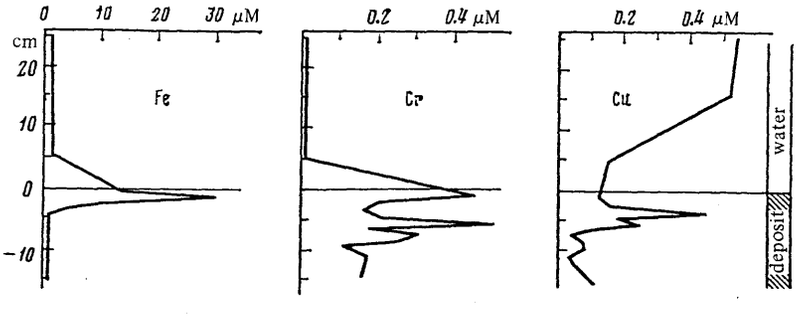

Figure 3. Vertical distribution of Fe, Cr, and Cu in the bottom water and the pore water of the coastal sediments in the Mediterranean.[322]

2,6-di-t-butyl-4-methylphenol and the weakest are mesitylene and *p*-xylene.[357]

In aqueous solutions MeHg(II) has been obtained from Hg(II) also in the presence of methanol, acetic and propionic acids, and aliphatic α-aminoacids (on photolysis), as well as a result of transmethylation:[18,343]

$$Me_3E(IV) + Hg(II) \rightarrow MeHg(II) + Me_2E(IV);\ E = Si, Sn, Pb.$$

The role of such reactions in the geochemical TE cycles is not altogether clear.

### 6. Iron–Manganese Concretions

In connection with the exploitation of the resources of the Pacific Ocean, the autogenic components of its bottom deposits, namely the iron–manganese concretions whose chemistry had been examined previously,[358] have become important. The results of the latest research into the role of TE and their forms in the concretions of the Pacific Ocean are described below.

The density of the concretions can reach 300 units per $m^2$ or 30 kg $m^{-2}$. Their dimensions are on average about 4 cm, but concretions up to 20 cm are encountered. They increase at an average rate from 30 to 300 mm in one million years.[359] Their Mn/Fe ratio varies from 5.6 to 70 and more than 99% of the Mn is in the form of Mn(IV),[360] although the main diagenetic source is probably Mn(II) formed from Mn(IV) in the vicinity of the deposit–water interface.[361] This process is part of the well investigated remobilisation of Mn from deposits,[328,330,362] which exerts a decisive influence on its distribution in bottom waters.

The concretions respond to this remobilisation by a faster increment in their volume on the side in contact with the deposit.[363] This side grows faster, compared with the upper part almost by a factor of 4.[359] A typical concretion consists of two separate non-detritus components having different compositions:[359] the bottom part is enriched in Mn, Mg, Ca, U, and Sb and the upper part in Fe, Ni, Cu, Zn, Co, Th, and the lanthanides. These differences in the chemical compositions of individual parts of the concretions are explained by the variable contributions of the following processes:[364] (1) the hydrogenic process which leads to the direct precipitation or accumulation of colloidal TE oxides from sea water; (2) oxidative diagenesis which takes place in oxidised deposits and tends to increase the content of TE in the concretion; (3) reductive diagenesis, which ensures the reduction of Mn(IV) to Mn(II) by the organic matter with its subsequent reoxidation to Mn(IV). Concretions have also been found in regions with very slow sedimentation of the suspension. In this case the increment in the mass of the concretions takes place at the expense of bottom waters with an increased content of suspended and dissolved TE brought there by bottom streams.[365]

The TE in concretions and also in a series of autogenic minerals (apatite, barite, opal, and carbonate) are mainly concentrated in the aluminosilicate and Mn and Fe oxide phases, owing to the characteristic features of the chemical forms of the TE in sea water and the physicochemical properties of these phases.[366] It has been shown that the TE in a concretion have different oxidation states—for example, Co(III), Pb(II), Pb(IV), and Ti(IV)[367] and Cu(II) and Ni(II).[368]

---o 0 o---

Significant advances have been made in recent years in the study of the forms of TE in natural aqueous media. The discovery of the relation between the forms of TE in the abiotic phases of natural aqueous media and their effect on hydrobionts is especially important. However, the experimental data to date are insufficient to reach definite conclusions about the influence of various forms of TE of anthropogenic origin on the health of specific water basins, which is one of the principal tasks of biogeochemistry.

# The Concept of Vibronic Interactions in Present-day Chemistry

I.B.Bersuker

The present review deals with the chemical aspects of a new concept in the structure and properties of molecules and crystals, namely the concept of vibronic interactions, where the movements of the electrons and the nuclei are not described separately, and account is taken of the mixing of electronic states by the displacements of the nuclei. The applications of this concept to the description of vibronic structure by means of orbital vibronic constants, vibronic reactivity, and chemical activation on coordination, and to electron-conformational interactions, have been examined. The concept of vibronic interactions provides a basis for a deeper understanding of the origins of the structure and transformations of molecular systems.
The bibliography contains 48 references.

## I. INTRODUCTION

The structure and properties of a molecular system are determined by the motion of its electrons and nuclei, and the interaction between them. The principal laws governing this motion were established in the thirties, immediately after the discovery of quantum mechanics. Because of the mathematical difficulties, restricting but physically justified approximations are introduced in the quantum-mechanical description of the properties of molecules. The most general of these is the Born–Oppenheimer adiabatic approximation (see, for example, Refs.1 and 2), according to which, in view of the very large difference between the masses of the electrons and the nuclei, and hence the appreciable difference in their rates of movement, it is possible to establish the steady motion of the electrons for each instantaneous position of the nuclei. In other words, the electrons follow the motion of the nuclei in inertialess fashion (adiabatically), and the nuclei move in the averaged field created by the electrons.

Thus in this approximation the electrons are assigned only the general ("classical") role of the sources of the average electrostatic field, and the details of the electronic structure do not appear in the description of the motion of the nuclei.

Also in the thirties, some of the most obvious departures from the adiabatic approximation were understood. In 1934, Landau, in a conversation with Teller, first put forward the idea that when there is electronic degeneracy (two or more electronic states with the same energy), the nuclear configuration may be unstable, and undergo spontaneous deformation. This idea, subsequently verified by Jahn and Teller for all types of (non-linear) molecules, formed the basis of the Jahn–Teller theorem, whose consequences are now widely used to analyse the structure and properties of polyatomic systems.[1–5] When the so-called Jahn–Teller effect operates, the electrons do not follow the nuclei adiabatically, and the state of the latter is determined not by the average field of the electrons but by its details, which depend, in particular, on the nature of the degeneracy. The consequent complex relationship between the electronic and nuclear movements is the first and an extremely significant departure from the adiabatic approximation. Cases of degeneracy in the ground state of a molecule are themselves fairly frequent, and their number increases greatly when account is taken of excited states (without which a sufficiently complete study of the structure and properties of molecules is impossible).

In 1957, Opik and Pryce[6] were the first to point out that phenomena analogous to the Jahn–Teller effect may be encountered when there is quasi-degeneracy (pseudo-degeneracy), when for some nuclear configuration of the core of the electronic energy levels are fairly close, but do not coincide as in the case of degeneracy (Jahn–Teller pseudo-effect). The criterion for this pseudo-degeneracy contains the relationship between three parameters of the system, so that the concept of similarity in electron energies becomes relative (see below for more details). Thus the Jahn–Teller pseudo-effect in principle covers all molecular systems, without exception, and the only problem is that in some systems the effect is small and can be neglected.

The theory of the Jahn–Teller effect and pseudo-effect and its applications began to be developed intensively in the early sixties, and has grown into a new field in the physics and chemistry of molecules and crystals, encountered fairly frequently in the literature under the general name of the Jahn–Teller effect (although the term "vibronic effects" is more appropriate). The fields of application of these effects cover the whole of spectroscopy, from Mössbauer via the ultraviolet, visible, and infrared ranges to the entire range of radiofrequency spectroscopy (EPR, NMR, NQR), polarisability and magnetic susceptibility, crystal chemistry, and crystal physics, including such important branches as the nature of the formation of crystal structures, structural phase transformations in ferroelectricity, and reactivity (orbital symmetry rules).

In recent years a new field has begun to develop, in which vibronic interactions are taken into account to explain the origin of the effects of the mutual influence of molecular groups in their chemical binding (coordination), both in the case of chemical reactions and more particularly in the case of the influence of a catalyst.[3,7–10] This trend introduces fundamentally new elements into the allowance for the effects of vibronic interaction, extending them to the case of molecular transformations. With the inclusion of this trend, the approach overall becomes a concept which from a definite viewpoint analyses all the properties of molecules, including their transformations. The mathematical basis of this concept involves abandoning the adiabatic approximation, or taking systematic account of vibronic interactions (see below). To obtain a deeper general understanding of the phenomens, the new concept takes a more systematic account of the role of the electrons and the details of the electronic structure, in the production of the nuclear configuration and its dynamics, and the influence of the latter on the spectral and stereochemical properties and reactivity of molecules.

In a vertain sense, the systematic "introduction" of this concept into chemistry develops a new and more fruitful way of thinking for research workers. In fact, all courses on the structure of molecules present the adiabatic approximation, according to which the electrons follow the nuclei adiabatically, and the nuclei move in the average field of the electrons, and with very few exceptions it is not pointed out that in most cases this picture is incorrect. This creates in research workers a restricting stereotype, according to which the electrons, as already noted, are assigned the classical role of the sources of the electrostatic field, and the extremely important details of the electronic structure of the valence shell related to quantum effects are ignored completely. In the process, the understanding of how changes in the structure of the valence shell of a molecule lead to a change in the nuclear configuration, and a correct understanding of the nature of chemical transformations, are lost. The new concept based on the non-adiabaticity of the interactions of electrons and nuclei (taken into account by the vibronic mixing of different electronic states) directs the thinking of research workers to a more adequate reflection of the structure and properties of polyatomic systems and their chemical transformations.

The present review characterises briefly the essential features of the concept of vibronic interactions and various aspects of its applications in present-day chemistry. The analysis of the latter, for lack of space, has been restricted to examples from chemical reactivity and activation in catalysis, and electron-conformational effects. The review does not deal with the many applications of this concept in spectroscopy, which have developed particularly extensively in the form of new branches of electronic spectroscopy and EPR, or with problems of crystal chemistry, structural Jahn–Teller phase transformations, and ferroelectricity (cooperative effects). These and other interesting aspects of this topic can be found in the literature (see Refs.1–4 and the detailed bibliography in Ref.5).

## II. VIBRONIC INTERACTIONS

The examination of some general equations will help to introduce the terminology and notation. The stationary Schrodinger equation for a molecular system $H\Psi = E\Psi$ can be considered, and the Hamiltonian $H$ represented as the sum of three terms:

$$H = H_Q + H_r + V(r, Q) \qquad (1)$$

where $H_r$ is the part of the Hamiltonian that depends only on the coordinates of the electrons, $H_Q$ the operator of the kinetic energy of the nuclei, and $V(r,Q)$ the operator of the electron–nucleus and nucleus–nucleus interactions ($r$ and $Q$ denote the sets of coordinates of the electrons and nuclei respectively).

It is assumed that a solution of the Schrodinger equation has been found for fixed positions of the nuclei ($H_Q = 0$):

$$[H_r + V(r, Q)]\varphi_k(r, Q) = \varepsilon_k(Q)\varphi_k(r, Q)\,. \qquad (2)$$

In this case the energy levels $\varepsilon_k(Q)$ and wavefunctions $\phi_k(r,Q)$ depend on the coordinates of the nuclei as parameters. The complex wavefunction $\Psi(r,Q)$ can be sought as the expansion with respect to the series of functions $\phi_k(r,Q)$:

$$\Psi(r, Q) = \sum_k \chi_k(Q)\cdot\varphi_k(r, Q) \qquad (3)$$

Substituting $\Psi(r,Q)$ in the equation $H\Psi = E\Psi$ and taking account of Eqn.(2) gives an infinite system of equations for

the functions $\chi(Q)$:

$$[H_Q + \varepsilon_m(Q) - E]\chi_m(Q) - \sum_k A_{mk}\chi_k(Q) = 0$$
$$m = 1, 2, \ldots \quad (4)$$

Here, $A_{mk}$ are the matrix elements of the so-called non-adiabaticity operator. These quantities depend on the derivatives of the functions $\phi_j(r,Q)$ with respect to the coordinates of the nuclei $Q$.[2] This is an effect of non-adiabaticity with the mixing of different electronic states.

If the electronic functions depend little on the coordinates of the nuclei $Q$, the terms $A_{mk}$ in Eqn.(4) are small and can be neglected. The system of equations (4) then takes the form

$$[H_Q + \varepsilon_m(Q) - E]\chi_m(Q) = 0, \; m = 1, 2, \ldots \quad (5)$$

For each electronic wavefunction it is possible to construct $\Psi_m(r,Q)$ as the product

$$\Psi_m(r, Q) = \varphi_m(r, Q)\chi_m(Q) .$$

The function $\chi_m(Q)$ has the significance of the wavefunction describing the motion of the nuclei. This is the adiabatic approximation.

The nature of the adiabatic approximation can be discussed from another viewpoint. The operator $V(r,Q)$ can be expanded in a series with respect to small displacements $Q$ in the region of the point $Q = 0$:

$$V(r, Q) = V(r, 0) + \sum_\alpha \left(\frac{\partial V}{\partial Q_\alpha}\right)_0 Q_\alpha + \frac{1}{2}\sum_{\alpha,\beta}\left(\frac{\partial^2 V}{\partial Q_\alpha \partial Q_\beta}\right)_0 Q_\alpha Z_\beta + \ldots \quad (6)$$

The non-zero terms in this equation (linear, quadratic, etc.) are called the operators of the electronic–vibrational or vibronic interaction. The solution of the electronic Schrodinger equation taking account of only the zeroth term of the expansion (6), $V(r,0)$, gives wavefunctions $\phi(r,0)$ and energy levels $\varepsilon(0)$ which are independent of $Q$ (simple adiabatic approximation). For small displacements of the nuclei $Q$, the dependence of the electronic wavefunction on $Q$ is determined according to perturbation theory by the matrix elements of the linear terms of the vibronic interaction

$$F_\alpha^{(ij)} = \left\langle \varphi_i(r, 0) \left| \left(\frac{\partial V}{\partial Q_\alpha}\right)_0 \right| \varphi_j(r, 0) \right\rangle \quad (7)$$

which are called the linear vibronic constants. Thus the simple adiabatic approximation is equivalent to neglecting the vibronic interaction. On the other hand, systematic allowance for vibronic interaction automatically takes account of non-adiabaticity. It can be shown[2] that the physical significance of this conclusion is preserved in the complete adiabatic approximation.

Thus in the general case, when account is taken of vibronic interaction, the complete wavefunction is represented in the form of Eqn.(3), including excited states. In other words, vibronic interactions "mix" the ground and excited electronic states of the molecule, obtained in the simple adiabatic approximation for fixed positions of the nuclei.

A criterion of the applicability of the adiabatic approximation is provided by the strong inequality

$$\varepsilon_2 - \varepsilon_1 \gg \hbar\omega \quad (8)$$

where $\hbar\omega$ is the quantum of the vibrations in the ground electronic state, and $\varepsilon_2 - \varepsilon_1$ the lowest energy of electronic excitation.

If criterion (8) is fulfilled, then allowance for the vibronic terms in the expansion (6) leads only to small corrections to the quantities found in the adiabatic approximation. If however this criterion is not fulfilled, then allowance for vibronic interactions leads to qualitatively new effects. To classify and analyse these effects it is convenient to use the adiabatic potential surface (or curves), that is the energies of the electronic terms as functions of the nuclear displacements. Fig.1 gives three types of adiabatic potential in the range of the intersection or approach of two electronic terms (for convenience, the one-dimensional case is considered). The greatest breakdown of the adiabaticity criterion takes place when $\varepsilon_2 = \varepsilon_1$ (the case of degeneracy of the electronic state), when the inequality (8) is not fulfilled for any values of $\hbar\omega$. For this case, Jahn and Teller, on the basis of Landau's idea, proved that (in present-day terms) at the point of electronic degeneracy (that is in a nuclear configuration for which the energies of two or several electronic states coincide), the adiabatic potentials do not have a minimum (Fig.1*a*), so that the nuclear configuration is unstable.

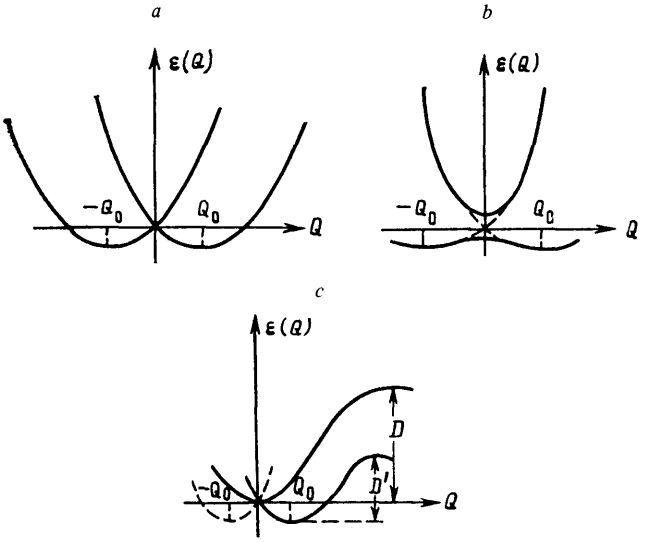

Figure 1. Schematic representation of the three principal cases of vibronic effects: *a*) case of degeneracy (Jahn–Teller effect), *b*) case of pseudo-degeneracy (Jahn–Teller pseudo-effect), *c*) case of electronic rearrangement or vibronic effects at large distances.

Fig.1 also shows that the minima of the adiabatic potential correspond to distorted configurations. This does not mean, however, that it is possible to detect a distorted configuration of the nuclei instead of a highly symmetrical configuration by direct measurements. In fact, there are always two or more of these minima (sometimes an infinite number—a continuum of minima), with equivalent energies, which complement one another in such a way that overall, the original symmetry is preserved. Thus the so-called Jahn–Teller effect reduces not simply to distortion of the geometry of the molecule but to extremely complex nuclear core dynamics which give rise to a whole range of new effects and regularities.[1-5] Because this feature was neglected, until about 1960 all attempts to detect directly the distortions of a system related to the Jahn–Teller effect, generally speaking, were unsuccessful. At about this time, the present author[1-3] observed one of the clearest manifestations of the complex dynamics of molecular systems with allowance

for vibronic effects—the existence of pulsating motions in which molecules spontaneously (and at a definite frequency) change between configurations corresponding to different equivalent minima of the adiabatic potential (similar to those given in Fig. 1*a*). This new phenomenon, together with the observed effects and regularities (and applications) based on it, was registered (in 1978) in the USSR as scientific discovery No. 202.[11]

A situation similar to that arising when $\varepsilon_1 = \varepsilon_2$ is found at a point of the nuclear configuration where the energy levels $\varepsilon_1$ and $\varepsilon_2$ are fairly close to one another (Jahn–Teller pseudo-effect, Fig. 1*b*). Here, together with effects which are consequences of the Jahn–Teller theorem, various new regularities appear.[1-5]

The similarity in energy observed for nuclear displacements in a certain direction $Q$ is fairly characteristic. It was recently shown[12-14] that mixing of the electronic states is the only source of dynamic instability in molecular systems (and that it may be considerable even for large differences $\varepsilon_2 - \varepsilon_1 \cong 10$ eV). This result is important for interpreting the stereochemical properties of molecular systems[3,15] and transition states in chemical reactions,[3,12] and for explaining the nature of structural (including ferroelectric) phase transformations in crystals,[16,17] the "plasticity" of the coordination sphere of certain transition metals, and distortion isomers.[18,19]

Finally, in the last case, illustrated in Fig. 1*c*, there may be effects which appear at large distances from the point of degeneracy (or pseudo-degeneracy). Different situations relating to this case are discussed in more detail below.

## III. DESCRIPTION OF MOLECULAR STRUCTURE BY MEANS OF ORBITAL VIBRONIC CONSTANTS

From the above discussion, it follows that the effects of the vibronic mixing of different electronic states are determined by the vibronic constants (7). These can be written in a more convenient form by making use of the symmetry properties of the molecules. If the coordinates of the displacements of the nuclei used in the expansion (6) are the generalised symmetry coordinates (or normal coordinates) $Q_{\Gamma\gamma}$, which transform as the row $\gamma$ of the irreducible representation $\Gamma$ of the symmetry point group of the molecule, then the linear vibronic constant can be written as

$$F_{\tilde{\Gamma}\tilde{\gamma}}^{(\Gamma\gamma,\Gamma'\gamma')} = \left\langle \Gamma\gamma \left| \left( \frac{\partial V}{\partial Q_{\tilde{\Gamma}\tilde{\gamma}}} \right)_0 \right| \Gamma'\gamma' \right\rangle \qquad (9)$$

where $|\Gamma\gamma\rangle$ and $|\Gamma'\gamma'\rangle$ denote the electronic wavefunctions for fixed positions of the nuclei, transforming as the corresponding rows of the irreducible representation. If the mixed states are not degenerate, then the representations $\Gamma$ and $\Gamma'$ each contain only one row $\gamma$ and $\gamma'$. In this case $\tilde{\Gamma}$ is also non-degenerate, and the symbols for the row $\gamma$ are omitted in $F_{\tilde{\Gamma}}^{(\Gamma,\Gamma')}$. If however one or both of these states is degenerate, then there exist several vibronic constants, corresponding to the number of possible combinations of the rows of the representations. These constants, however, differ from one another only in a numerical factor (the Clebsch–Gordan coefficients), obtainable from Tables.[2,3] Thus the vibronic mixing of two (any) states is described essentially by one vibronic constant.

Some of the vibronic constants have a clear physical significance. In particular, the diagonal linear vibronic constant $F_{\tilde{\Gamma}}^{(\Gamma\Gamma)} \equiv F_{\tilde{\Gamma}}^{\Gamma}$ is equal to the force with which the electronic cloud in the state $\Gamma$ deforms the core in the direction of the symmetrised (normal) displacement $\tilde{\Gamma}$. The molecule is obviously in an equilibrium (but not necessarily stable) state when $F_{\tilde{\Gamma}}^{\Gamma} = 0$ for all $\tilde{\Gamma}$.

In addition to linear vibronic constants, it is possible to introduce quadratic, cubic, etc. vibronic constants. It is possible, for example, to define the quadratic vibronic constants. The general expression for a matrix element of the coefficient of the quadratic terms in the expansion (6) can be written as:

$$K_{0\tilde{\Gamma}\tilde{\gamma}}^{(\Gamma\Gamma')}(\Gamma_1 \times \Gamma_2) = \frac{1}{2} \left\langle \Gamma \left| \left\{ \left( \frac{\partial^2 V}{\partial Q_{\Gamma_1} \partial Q_{\Gamma_2}} \right)_0 \right\}_{\tilde{\Gamma}\tilde{\gamma}} \right| \Gamma' \right\rangle . \qquad (10)$$

Here, the shaped brackets denote tensor convolution, that is a combination of the second derivatives with respect to the coordinates $Q_{\Gamma_1\gamma_1}$ and $Q_{\Gamma_2\gamma_2}$, which transforms as the row $\tilde{\gamma}$ of the representation $\tilde{\Gamma}$ contained in the product of the representations $\Gamma_1 \times \Gamma_2$. The totally symmetric part of the diagonal element (10) denoted $K_{0\tilde{\Gamma}}^{\Gamma}$) has a completely clear physical significance; it defines the curvature of the adiabatic potential (force constant) of the system $K_{\tilde{\Gamma}}^{\Gamma}$, corresponding to the coordinates $Q_{\tilde{\Gamma}}$:[2,3]

$$K_{\tilde{\Gamma}}^{\Gamma} = K_{0\tilde{\Gamma}}^{\Gamma} - 2 \sum_{\Gamma'}{}' |F_{\tilde{\Gamma}}^{(\Gamma\Gamma')}|^2 / \Delta_{\Gamma'\Gamma} \qquad (11)$$

where $\Delta_{\Gamma'\Gamma}$ is equal to half the difference between the energies of the states $\Gamma$ and $\Gamma'$; $\Delta_{\Gamma'\Gamma} = (1/2)(\varepsilon_{\Gamma'} - \varepsilon_{\Gamma})$. Thus keeping for $K_{0\tilde{\Gamma}}^{\Gamma}$ the earlier description as the curvature of the surface or the force constant (the curvature of the surface at the equilibrium point, where $F_{\tilde{\Gamma}}^{\Gamma} = 0$, coincides with the force constant), all the remaining matrix elements (10) (namely the non-totally-symmetric parts $\tilde{\Gamma} \neq A_1$ of the diagonal elements $\Gamma = \Gamma'$ and all the off-diagonal elements) can be called quadratic vibronic constants and denoted $G_{\tilde{\Gamma}}^{(\Gamma\Gamma')}$. $(\Gamma_1 \times \Gamma_2)$.

Similarly, it is possible to derive cubic vibronic constants, some of which (or their combinations) make a direct contribution to the anharmonicity of the system.

An important step towards chemical applications of the theory of vibronic interactions can be taken by introducing orbital vibronic constants. In the molecular orbital (MO) method it is possible to introduce linear, quadratic, etc. vibronic constants for each orbital state. For this purpose the MO energy levels and MO wavefunctions can be denoted $\varepsilon_i$ and $\psi_i(\mathbf{r})$ respectively, and use can be made of the additive operator of the electron–nucleus interaction ($N$ is the number of nuclei):

$$V = \sum_i V_i(\mathbf{r}_i);\ V_i(\mathbf{r}_i) = -\sum_\alpha \frac{e^2 Z_\alpha}{|\mathbf{r}_i - \mathbf{R}_\alpha|} + \frac{1}{N} \sum_{\alpha,\beta} \frac{e^2 Z_\alpha Z_\beta}{|\mathbf{R}_\alpha - \mathbf{R}_\beta|} . \qquad (12)$$

By analogy with the integral constant (8), the linear orbital vibronic constant (OVC) is then determined from the equation:

$$f_{\tilde{\Gamma}}^{(i)} = \left\langle \psi_i(\mathbf{r}_i) \left| \left( \frac{\partial V_i}{\partial Q_{\tilde{\Gamma}}} \right)_0 \right| \psi_j(\mathbf{r}_i) \right\rangle . \qquad (13)$$

In exactly the same way, by analogy with Eqn. (9), the orbital matrix elements of the quadratic terms of the vibronic interaction are written as:

$$k_{0\tilde{\Gamma}\tilde{\gamma}}^{(ij)}(\Gamma_1 \times \Gamma_2) = \frac{1}{2} \left\langle \psi_i(\mathbf{r}_i) \left| \left\{ \left( \frac{\partial^2 V_i}{\partial Q_{\Gamma_1} \partial Q_{\Gamma_2}} \right)_0 \right\}_{\tilde{\Gamma}\tilde{\gamma}} \right| \psi_j(\mathbf{r}_i) \right\rangle . \qquad (14)$$

Here also, the totally symmetric part of the diagonal element $i = j$ with $\tilde{\Gamma} = A_1$ and $\Gamma_1 = \Gamma_2 = \tilde{\Gamma}$, $k_{0\tilde{\Gamma}}^{(ii)} \equiv k_{0\tilde{\Gamma}}^{i}$ makes a direct contribution to the orbital force constant, and the

non-totally symmetric (for degenerate MO) and off-diagonal elements are the orbital quadratic vibronic constants $g_{\bar{\Gamma}}^{(ij)}(\Gamma_1 \times \Gamma_2)$.

The physical significance of the orbital constants can be considered. First of all it can be seen that the diagonal linear OVC $f_{\bar{\Gamma}}^{(ii)} \equiv f_{\bar{\Gamma}}^{i}$ has the significance of the force with which an electron situated in the $i$th MO deforms the original nuclear configuration in the direction of the symmetrised coordinate $Q_{\bar{\Gamma}}$ (or $Q_{\bar{\Gamma}\bar{\gamma}}$ for degenerate coordinates) minus the corresponding part of the repulsion in this direction (see Eqn.(12)). It is difficult to determine the orbital components directly from experimental data. It is therefore of interest to find the relationship between these orbital contributions and the corresponding integral quantities for the molecule as a whole. This can be done using the combination theorem,[7,9] according to which

$$F_{\bar{\Gamma}\bar{\gamma}}^{\Gamma} = \sum_i q_i^{\Gamma} f_{\bar{\Gamma}\bar{\gamma}}^{i} \qquad (15)$$

where $q_i^{\Gamma}$ represents the occupation numbers of the MO (0, 1, or 2) in the state $\Gamma$ of the molecule. In other words, the total force with which the electron cloud acts on the nuclear core (in a certain direction $Q_{\bar{\Gamma}\bar{\gamma}}$) is equal to the sum of the contributions from each MO. An analogous relationship applies for the diagonal quadratic OVC.

The derivation of the analogous relationships for the off-diagonal OVC is more complicated, since the latter depend on the excited states. In the approximation of "frozen orbitals" (in this approximation, in an excitation $\Gamma \to \Gamma'$ associated with a change in the state of one electron $i \to j$, the states of the other electrons do not change), it has been shown[3] that

$$F_{\bar{\Gamma}\bar{\gamma}}^{(\Gamma\Gamma')} = f_{\bar{\Gamma}\bar{\gamma}}^{(ij)}, \qquad (16)$$

$$K_{\bar{\Gamma}}^{\Gamma} = \sum_i q_i^{\Gamma} k_{\bar{\Gamma}}^{i}, \qquad (17)$$

$$k_{\bar{\Gamma}}^{i} = k_{0\bar{\Gamma}}^{i} - 2\sum_j{}' |f_{\bar{\Gamma}}^{(ij)}|^2/\Delta_{ji} \qquad (18)$$

where $\Delta_{ji} = (1/2)(\varepsilon_j - \varepsilon_i)$.

It can be seen that in the approximation of frozen orbitals, the off-diagonal OVC coincide with the total vibronic constants, and the force constants of the molecule can also be represented additively in terms of the orbital contributions, although the latter also involve other orbitals. Analogous equations can be derived for the cubic and other contributions of higher orders.

The orbital vibronic constants supplement the data on the electronic structure of molecules in the one-electron MO approximation (the set of one-electron energy levels and wavefunctions is a stationary or static picture) with important information on the action of the electrons on the nuclear core (the dynamic picture). The description of the electronic structure of molecules in MO terms is at present the most adequate and the most easily applied in practice. It can be used to analyse chemical processes in convenient and clear terms, facilitating a deeper understanding of their nature. In this approximation, however, no account is taken of the influence of the electron cloud on the positions of the nuclei, so that it is not clear whether the configuration of the nuclei will be the equilibrium configuration for the given electron distribution. Moreover, this static picture does not indicate how the configuration of the nuclei changes with change in the electronic structure.

Allowance for the vibronic constants makes it possible to eliminate most of this unsatisfactory feature of the description of the electronic structure: the integral vibronic constants characterise the deforming forces and force constants corresponding to the given electronic structure. The orbital vibronic and force constants characterising the contributions of the individual MO to these dynamic characteristics are particularly useful. Knowing the orbital vibronic and force constants, it is possible to predict the behaviour of the nuclear core with change in the electronic structure: the change in its equilibrium configuration, force constants, anharmonicity constants, etc. These data can be used to predict the nature of the change in reactivity. Thus the orbital and vibronic and force constants supplement considerably the static description of the electronic structure in the MO approximation.

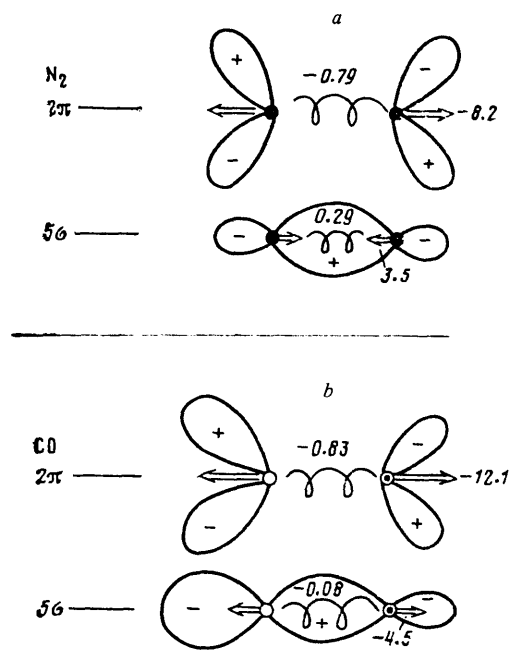

Figure 2. Illustration of the vibronic structure of molecules: *a*) 5σ HOMO (bonding) and 2π LUMO (antibonding) of the $N_2$ molecule; *b*) HOMO and LUMO of the CO molecule; HOMO—weakly antibonding, LUMO—strongly antibonding. The contribution of the orbital electrons to the deforming force is shown by arrows, figures in $10^{-4}$ dyn; the contribution to the force constant is shown by the spring, figures in $10^6$ dyn cm$^{-1}$.

In Fig.2, the concept of the structure of polyatomic systems described above is illustrated for the highest occupied MO (HOMO) 5σ and the lowest unoccupied MO (LUMO) 2π of the simplest diatomic molecules $N_2$ and CO (the numerical characteristics of these MO are discussed in section IV). Fig.2 shows that in the $N_2$ molecule, the electron in the 5σ MO "attracts" the nuclei with a force $f_R^{5\sigma}(N_2) = 3.51 \times 10^{-4}$ dyn

($R$ is the distance between the nuclei), whereas in the CO molecule the electron in the analogous orbital "repels" the nuclei with a force $f_R^{5\sigma}(CO) = -4.5 \times 10^{-4}$ dyn. The electrons in the $2\pi$ orbitals "repel" the nuclei with a force $f_R^{2\pi}(N_2) = -8.18 \times 10^{-4}$ dyn and $f_R^{2\pi}(CO) = -12.1 \times 10^{-4}$ dyn.

The contributions to the force constant (shown as springs in Fig.2) have the following values (dyn cm$^{-1}$):

| | $5\sigma$ | $2\pi$ |
|---|---|---|
| $N_2$ | $0.23 \cdot 10^{-6}$ | $-0.73 \cdot 10^{-6}$ |
| CO | $0.08 \cdot 10^{-6}$ | $-0.83 \cdot 10^{-6}$ |

These data show first of all that the $5\sigma$ orbital in the $N_2$ molecule is bonding, and that in CO is antibonding, whereas the $2\pi$ MO are antibonding in both molecules. Moreover, the above data contain quantitative information on the degree of bonding or antibonding character of each MO and its contribution to the deforming force and the force constant of the bond. As already noted, this information is particularly valuable in the analysis of the influence of the rearrangement of the electron cloud on the behaviour of the nuclear core (see section IV).

In the case of polyatomic molecules, the orbital and force vibronic constants carry much richer information than the simple representation of the bonding or antibonding character of the MO. Thus in accordance with the rules of group theory, the orbital linear vibronic constant $f_{\bar{\Gamma}}^{(ij)} = \langle i | (\partial V / \partial Q_{\bar{\Gamma}})_0 | j \rangle$ is non-zero if the product of the representations $\Gamma_i$ and $\Gamma_j$ according to which the $i$th and $j$th MO transform, contains the representation $\bar{\Gamma}$ corresponding to the symmetrised direction $Q_{\bar{\Gamma}}$. For different $\Gamma_i$ and $\Gamma_j$, the representation $\Gamma$ can be any one. For $i = j$ the representation $\Gamma$ is contained in the symmetrised square $[\Gamma_i \times \Gamma_i]$, so that if the $i$th MO is non-degenerate, the representation $\bar{\Gamma}$ is totally symmetric. In other words, the electrons in the non-degenerate MO deform the molecule without changing its symmetry. The MO are also bonding or antibonding, depending on the sign of $f_{\bar{\Gamma}}^{ii}$. For degenerate MO the product $\Gamma_i \times \Gamma_j$ contains not only the totally symmetric but also non-totally symmetric representations, so that the electrons in the degenerate MO can deform the molecule with a change in its symmetry (in complete correspondence with the Jahn–Teller theorem[2]). Moreover, in accordance with Eqn.(18), which contains $f_{\bar{\Gamma}}^{(ij)}$, the "softening" of the molecule brought about by the orbital electron can take place in any direction (depending on the mixed states $i$ and $j$ with small $\Delta_{ji}$).

## IV. VIBRONIC REACTIVITY AND CHEMICAL ACTIVATION ON COORDINATION IN CATALYSIS

Vibronic effects may have a significant influence on the reactivity of a molecular system. Thus as can be seen, for example, from Eqn.(11), as a result of vibronic mixing the curvature of the adiabatic potential of the ground state decreases by an amount $F^2/\Delta$. This decrease in the curvature of the adiabatic potential surface evidently leads to a decrease in stability (in the limit ($F^2/\Delta > K_0$) the system becomes unstable) and to an increase in reactivity.

This last statement requires explanation. First of all it is necessary to give a quantitative definition of the reactivity of molecules, and even this is an extremely difficult task. Reactivity should obviously characterise the rate of the elementary act of a chemical reaction, so that it is natural to try to relate it to the activation energy of the reaction. The latter, however, may depend not only on the given molecule but also on the molecule with which it reacts.

In the study of the change in the reactivity of a given molecule under the influence of vibronic effects or a change in its electronic structure, a measure of its reactivity in a given chemical reaction is provided by the quantity $D$, the activation energy of the given reaction, associated with the activation of the molecule being considered (see the discussion in Refs.3 and 10). To determine $D$ it is necessary to know the ascending section of the potential energy curve along the reaction coordinate from its minimum to the maximum of the barrier. Comparison of these sections, constructed with and without allowance for vibronic effects, other conditions being equal, shows that the vibronic effects decrease considerably the activation energy of the reaction taking place along the coordinate $Q$ active in the Jahn–Teller effect or pseudo-effect, that is along the displacements of the nuclei for which the vibronic mixing of the electronic states is a maximum.

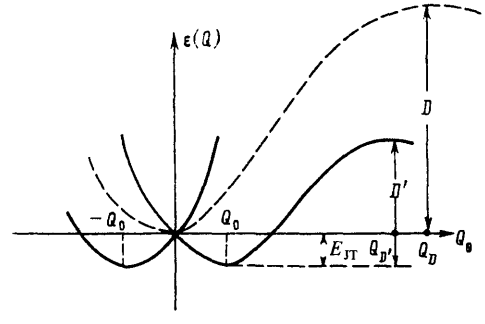

Figure 3. Adiabatic potential in the direction of the coordinate $Q_\theta$ active in the Jahn–Teller effect, at large distances, illustrating the lowering of the activation energy $\Delta D = D' - D$ for the reaction taking place in this direction, compared with the same reaction in the absence of the Jahn–Teller effect (broken curve).

This conclusion is illustrated in Fig.3 for the case where there is a Jahn–Teller effect in the original highly symmetrical nuclear configuration $Q = 0$, and the system at this point does not have an energy minimum with respect to the nuclear displacements described by the generalised coordinate $Q$; the displacements at the point $Q = \pm Q_0$ at which the initial nuclear configuration is distorted have minimum values. It can readily be seen that the change in the activation energy in this case may be considerable, since the points $Q_0$ and $Q_D$ are not very far from one another (the distortions due to the Jahn–Teller effect are of the order of tenths of an Ångstrom unit, and the distances to the activation barrier are usually greater, but not by much; in any case, they are quantities of the same order of magnitude).

An example is provided by substitution or unimolecular decomposition in an octahedral complex of a transition metal having a doubly degenerate $E$ term, for example for copper(II), for which a strong Jahn–Teller effect is observed. As a result of the Jahn–Teller effect, the adiabatic potential of the system has three minima,[1-4] at which the octahedron is elongated along a tetragonal axis so that the two ligands on the four-fold axis are at a greater distance than the other four. In the tetragonal coordinates $Q_\theta$ and $Q_\varepsilon$,[1,2]

the distortion (elongation of the octahedron) takes place along the coordinate $Q_\theta$, which is thus the coordinate along which the activation energy of the reaction decreases (relative to the other directions, other conditions being equal).

Thus these reactions should take place in the direction of the displacements $Q_\theta$ for which the two axial ligands move apart (and the four equatorial ligands approach one another). For a unimolecular reaction, this means the dissociation of two ligands in the *trans*-position, and for substitution it means the replacement of these two ligands, giving *trans*-substituted complexes. In other words, when elongated octahedra are formed (during the pulsations), the two ligands in the *trans*-position are less strongly held and are more susceptible to attack by substituting reagents.[20]

This result agrees completely with available experimental data obtained in the study of the behaviour of octahedral complexes of copper(II) in solution or in the gas phase. Thus these complexes first lose two ligands in the *trans*-position to give a square-planar structure, and substitution reactions give only *trans*-substituted complexes (an exception is provided by bidentate ligands, which can only form bonds in two *cis*-positions). On the other hand, it can readily be seen that in this system, if other conditions are equal the Jahn–Teller effect is suppressed, the rate of replacement is lowered considerably; this has also been confirmed experimentally.[21] According to the theory, similar effects should be expected for octahedral complexes of $Cr^{II}$, $Mn^{II}$, $Ag^{II}$, and other systems with an $E$ term.

Other terms (or other nuclear configurations with an $E$ term) will correspond to other mechanisms of this reaction. They can be examined qualitatively from the distortions expected as a result of the Jahn–Teller effect and pseudo-effect. In particular, for a tetrahedral system with a $T$ term (of the type $CH_4^+$), which as a result of the Jahn–Teller effect should be expected to give four minima of the adiabatic potential with one elongated bond and three shortened bonds, dissociation and replacement with a lowered activation energy can be expected at this elongated bond.

In some cases it is possible to obtain quantitative estimates of the change in the reactivity of molecules (the decrease in the activation energy of the chemical reaction) as a result of vibronic interactions.[7–10] The above example of an octahedral system with an $E$ term can be considered. To analyse the ascending part of the adiabatic potential along the reaction coordinate, it can be approximated by a polynomial of the third degree:[3,7–10]

$$\varepsilon(Q) = aQ + bQ^2 + cQ^3 \ . \qquad (19)$$

Without allowance for vibronic effects, the curve has a minimum at the origin of coordinates, and $\varepsilon(Q)$ is described by the expression

$$\varepsilon(Q) = \frac{1}{2}KQ^2 - \gamma Q^3 \qquad (20)$$

where $K$ is the force constant, and $\gamma$ takes account of the deviations from harmonicity. With allowance for vibronic effects, the curve has the form

$$\varepsilon'(Q) = FQ + \frac{1}{2}K'Q^2 - \gamma' Q^3 \qquad (21)$$

where $F$ is the linear vibronic constant corresponding to the Jahn–Teller effect, which for the case of an $E$ term is related to the stabilisation energy $E_{JT}$ (Fig. 3) by the relationship: $E_{JT} = F^2/2K$.

In the case being considered, the greatest contribution to the change in the form of the adiabatic potential along the coordinate $Q_\theta$ is made by the linear terms of the vibronic interaction.[2] To estimate the effect, therefore, the changes in the force constant and the anharmonicity constant in this direction are neglected. In this case $K' = K$ and $\gamma' = \gamma$, and the change in the activation energy $\Delta D = D' - D$ is given by the following expression (more detailed calculations are given below):

$$\frac{\Delta D}{D} = -3p\left(1 - p + \frac{p^2}{3}\right) \qquad (22)$$

where $p = (4E_{JT}/3D)^{1/2}$.

It can be seen that the change in the activation energy as a result of the Jahn–Teller effect is considerable. For example, for $E_{JT}/D = 0.1$, $(\Delta D/D) \cong 0.7$, that is the activation energy is lowered by 70%. It should be emphasised that this decrease in the activation energy takes place only in a definite direction, namely in the direction of the coordinates active in the Jahn–Teller effect or pseudo-effect (in the case being considered in the direction of the coordinate $Q_\theta$ for which two ligands in the *trans*-position are moved apart). Thus when there are strong vibronic effects in one or both reacting systems, the reaction mechanism is dictated by these effects.

The following general question arises from the vibronic reactivity examined above. If it is known how the vibronic effects, by decreasing the stability, increase the reactivity, that is lower the activation energy of chemical reactions in definite directions, is it not possible to change the reactivity of a molecule in a required direction by external influences (perturbations)? In other words, knowing the vibronic structure, it might be possible, using the concept of vibronic interactions, to develop methods for the vibronic activation of molecular systems. It is possible to given an affirmative answer to this question, and one method of studying the chemical activation of molecules, based on vibronic theory, is examined below.

The orbital vibronic constants introduced in section III, and the picture of the vibronic structure of molecules developed from it, provide a good base for a new approach to the problem of chemical transformations, and in particular to a deeper understanding of the nature and to a semi-quantitative description of the action of one molecular system on the reactivity of another during the reaction between them.[7–10,22–24] This last feature is particularly important in catalysis, where the coordination of a reagent molecule to the active centre of a catalyst (homogeneous or heterogeneous) leads to a marked change in its activity (reactivity) with respect to the chemical reaction with another atom or molecule (or unimolecular decomposition). In view of the importance of this catalytic aspect of the problem and to introduce a more specific content, the discussion here will deal chiefly with the problem of the activation of molecular systems in their reaction with a catalyst, although, as shown below, the proposed approach can also be applied to other aspects of the problem of molecular transformations.

As noted above, the diagonal linear orbital vibronic constant $f^i_{\bar{\Gamma}\bar{\gamma}}$ characterises the force with which an electron in the $i$th MO deforms the core in the direction of the symmetrised displacements $Q_{\bar{\Gamma}\bar{\gamma}}$, minus the fraction of the nuclear repulsion force in this direction corresponding to one electron. The total force deforming the molecule in this direction (the integral diagonal vibronic constant $F^\Gamma_{\bar{\Gamma}\bar{\gamma}}$) in the state $\Gamma$ is determined by the combination rule (15), from which it can be seen that if the system in the given configuration of the nuclei in the direction of the symmetrised coordinate $Q_{\bar{\Gamma}\bar{\gamma}}$ is stable, the following equality applies

$$F^\Gamma_{\bar{\Gamma}\bar{\gamma}} = \sum_i q^\Gamma_i f^i_{\bar{\Gamma}\bar{\gamma}} = 0 \qquad (23)$$

that is the generalised forces produced as a result of the action of the electrons on the nuclear configuration in the direction $\bar{\Gamma}\bar{\gamma}$ are compensated at the equilibrium point, although for each MO this force, generally speaking, is non-zero, and the forces $f^i$ are different for different orbitals (the force of nuclear repulsion in a given direction for a given nuclear configuration is constant, and is independent of the orbital, whereas the electron distribution changes significantly from one orbital to another).

It can be seen from Eqns.(17) and (18) that formally, there is also a combination rule for the orbital force constants: the curvature of the adiabatic potential surface in a given direction $K_{\bar{\Gamma}}^{\Gamma}$ is equal to the sum of the orbital contributions $k_{\bar{\Gamma}}^{i}$. Unlike the linear vibronic constants, however, the force constant $k_{\bar{\Gamma}}^{i}$ is determined not only by the given orbital but also by the contributions of vibronic mixing with other orbitals. Of the latter, it is necessary to take into account only the unoccupied or partly occupied orbitals, since the contributions of the vibronic mixing of completely filled orbitals appear twice with opposite signs in the expression for $K_{\bar{\Gamma}}^{\Gamma}$, and compensate one another.

Any effect of a given molecular system on another (van der Waals interaction, hydrogen bonding, static polarisation, chemical bonding with sharing of electrons, oxidation, reduction, excitation, ionisation, coordination) begins with a change in the less inert (more mobile) electron distribution in it, which then leads to changes in the more inert nuclear configuration. If the change in the electronic structure is sufficiently small, it can be described in a first approximation by the change in the electron populations of the MO, $\Delta q_i$. So long as the values of $\Delta q_i$ are not too large (of the order of one electron), it is possible, in Koopmans' approximation (the approximation of frozen orbitals), to use this description (in fact, as a result of the change in the interelectronic repulsion, change in $q_i$ also leads to a change in the wavefunctions of the MO, but this effect is of second order with respect to $\Delta q_i$; it can be included at the cost of a marked increase in the complexity of the equations).

The new values of the orbital populations $q_i^{\Gamma} + \Delta q_i$ naturally lead to a change in the electron distribution and to decompensation of the orbital deforming forces and force constants. Thus if initially the system was in equilibrium with $F_{\bar{\Gamma}} = 0$ and $K_{\bar{\Gamma}} > 0$ (here and subsequently, for convenience, the index of the state $\Gamma$ is omitted), then replacing $q_i$ by $q_i + \Delta q_i$ in Eqns.(15) and (17) gives (here and subsequently, $q$ is in units of e)

$$F_{\bar{\Gamma}} = \sum_i \Delta q_i f_{\bar{\Gamma}}^{i} , \qquad (24)$$

$$\Delta K_{\bar{\Gamma}} = K'_{\bar{\Gamma}} - K_{\bar{\Gamma}} = \sum_i \Delta q_i k_{\bar{\Gamma}}^{i} + \sum_{i,j}{}' q_i \Delta q_j |f_{\bar{\Gamma}}^{(ij)}|^2/\Delta_{ji} . \qquad (25)$$

Thus a rearrangement of the electron cloud in which there is a change in the populations of some orbitals produces a non-zero deforming force $F_{\bar{\Gamma}}$ in the symmetrised direction $Q_{\bar{\Gamma}}$; in this direction the corresponding $f_{\bar{\Gamma}}^{i}$ (for which $\Delta q_i \neq 0$) are non-zero (deforming effect), and the force constant changes by $\Delta K_{\bar{\Gamma}}$ (softening effect). It can immediately be stated how the direction of the deforming force depends on the symmetry of the $i^{\text{th}}$ orbital, which transforms according to the representation $\Gamma_i$: as already noted $f_{\bar{\Gamma}}^{i}$ is non-zero if $[\Gamma_i \times \Gamma_i]$ contains $\bar{\Gamma}$. If $\Gamma_i$ is not degenerate, then $\bar{\Gamma}$ can only be totally symmetric, that is non-degenerate MOs deform the molecule only along the totally symmetric displacements, without changing their symmetry. For non-degenerate $\Gamma_i$ the representation $\bar{\Gamma}$ may also be non-totally-symmetric, but only in the same way as in the Jahn–Teller effect.[2] $\bar{\Gamma}$ for $\Delta K_{\bar{\Gamma}}$ may be either, particularly as a result of the second term of the sum (25), in which $f_{\bar{\Gamma}}^{(ij)}$ is non-zero if $\bar{\Gamma} \quad \Gamma_i \times \Gamma_j$. Analogous equations can be written for the change produced by electron rearrangement in the anharmonicity constants, etc.

The deforming forces and the changes in the force constants and anharmonicity constants produced under the influence of electron rearrangement explain naturally the change in the reactivity of the molecule and its activation, and, when the changes are sufficiently large, its chemical transformation. It will be shown below how it is possible to determine approximately the quantitative dependence of these changes on the degree of electron rearrangement. However, from Eqns.(20) and (21), it is already possible to reach various general conclusions about the conditions corresponding to the greatest influence of electron rearrangement in coordination. Thus it follows from these equations that the deforming and softening effect of the coordination centre on a given molecule is linearly dependent on the orbital charge transfer $\Delta q_i$. The total transfer $\Delta q = \sum_i \Delta q_i$ cannot be large, from thermodynamic considerations. Thus the values of $\Delta q_i$ can in principle be large if bond formation between the coordination centre and the given molecule involves more than one orbital and if $\Delta q_i$ have different signs for different orbitals.

In the case, frequently encountered, where the orbitals most active in chemical bond formation are two in number, namely the bonding HOMO (for which $f^{(1)} > 0$) and the antibonding LUMO ($f^{(2)} < 0$), the orbital charge transfers have different signs: $\Delta q_1 < 0$ and $\Delta q_2 > 0$. Overall, for example, the deforming force from Eqn.(24) is equal to:

$$F = \Delta q_1 f^{(1)} + \Delta q_2 f^{(2)} = -(|\Delta q_1 \| f^{(1)}| + |\Delta q_2 \| f^{(2)}|) , \qquad (26)$$

In other words, in this case the sum of the absolute magnitudes of the contributions of the two orbitals is taken (the situation for the contributions to the change in the force constant $\Delta K$ is analogous). Thus the greater the absolute magnitude of the orbital charge transfers of different sign, the greater the effect of one molecule on the other in the case being considered. When more than two orbitals are active in bond formation, the number of favourable combinations increases with increase in the vibronic influence, but the total transfer $\Delta q$ remains small. This leads to a conclusion about the role of many-orbital bonds in the vibronic effect of one system on another (in particular in catalysis). From this viewpoint, the unique role of transition metals (and lanthanides) in catalysis is attributed to the possible formation of many-orbital bonds by these elements and their compounds with other molecular formations.

If the resulting deforming force $F$ and the change in the force constant $\Delta K = K' - K$ and the anharmonicity constant $\gamma' - \gamma$ are known, Eqns.(20) and (21) can be used to obtain the following relationships ($Q_0$ is the displacement of the minimum of the potential energy curve as a result of the action of the deforming force $F$, and $Q_D$ and $Q_D$, the positions of

the maxima of the barrier before and after coordination; see Fig. 3): [7-10]

$$D = K^3/54\gamma^2;\ Q_D = K/3\gamma = (6D/K)^{1/4};\ Q_{D'} = K'/3\gamma' - Q_0 \qquad (27)$$
$$Q_0 = (K'/6\gamma')\{1 - [1 + (12\gamma' F/(K')^2]^{1/4}\},$$

$$D' = (K' - 6\gamma' Q_0)^3/54(\gamma')^2 = (K')^3/54(\gamma')^2 - K'Q_0/3\gamma' + 2K'Q_0^2 - 4\gamma' Q_0^3$$
$$\Delta D = D' - D = -D[1 - (K'/K)^3(\gamma/\gamma')^2] - (K')^2 Q_0/3\gamma' + 2K'Q_0^2 - 4\gamma' Q_0^3. \qquad (28)$$

The last equation can be simplified. The coefficients of the cubic terms $\gamma$ can be expressed in terms of the spectroscopic corrections for anharmonicity $\omega x$, [25] which in many cases are known from experimental data. Thus $\gamma/\gamma' = \beta^{1/2}(K/K')^{3/2}(\hbar\omega'/\hbar\omega) = \beta^{1/2}(K/K')$, where $\beta = \omega x/\omega' x'$ (when the electron rearrangements are not too great, $\beta$ is close to 1). Finally:

$$\Delta D = -D[1 - \beta(K'/K)] - K'Q_0(6\beta KD)^{1/2}/K + 2K'Q_0^2[1 - 2KQ_0(54\beta KD)^{-1/2}] \qquad (29)$$

This equation makes it possible to calculate the change in the activation energy $\Delta D$ for the reaction being considered with a given $D$, if the values are known for the vibronic constants and the changes in the electron populations in the electron rearrangement, in terms of which $K'$, $Q_0$, and $\beta$ are defined. Eqn. (29) can also be regarded as an empirical equation relating $\Delta D$ to the experimentally observable parameters of the molecule $K$, $K'$, $Q_0$, and $\beta$.

For a complex molecule with many degrees of freedom, these discussions and conclusions relate to each normal coordinate, and in partiular to that along which the reaction being considered takes place (which may be a linear combination of normal coordinates). In these multidimensional cases, the equations given above can also be used to determine the change in the geometry of the molecule with change in the electronic structure.

Eqn. (29) is approximate, and has meaning only when the changes in the electronic structure relative to the original structure are not too large and have not yet led to the formation of an essentially new molecular system. These electron rearrangements take place in the above-mentioned processes of oxidation, reduction, exitation, ionisation, and coordination of a given molecule to another (in a chemical reaction, as a ligand in coordination systems, on a solid surface during adsorption in heterogeneous catalysis), etc.

The last cases, which can be combined under the general term of activation on coordination, are particularly important. Here, the values of the changes in the MO populations due to charge transfer to and from the coordination centre are fractional. Cases of the transfer of integral charges (in oxidation, reduction, ionisation, excitation, etc.) can in principle be studied by other methods (for example by calculating the total electronic structure of the initial and final systems), but the analysis of the change in the properties of a system with fractional charges can apparently be carried out only by the method examined, with the introduction of orbital vibronic constants.

The assumption that the change in the electronic structure on coordination is slight is justified in most cases; this is confirmed by spectroscopic studies, which indicate that the molecule for the most part retains its individual characteristics, which are not too greatly changed under the influence of coordination. This does not apply to such cases, as for example, the coordination of the $H_2$ molecule when it dissociates completely, although in these cases, the above method can also be used to determine qualitatively the direction in which the initial stage of the process takes place (for example to explain why and predict when $H_2$ will dissociate on coordination).

The practical application of the equations obtained requi suitable methods for determining the parameters appearing them. It follows from Eqn. (29) that the change in the activation energy of a chemical reaction with another molecule with change in the electronic structure of a given molecule, including its coordination to any coordination centre, depends on the parameters of the molecular orbital structure of the activated molecule, including the vibronic constants and the change in the MO populations $\Delta q_i$. In the general case, $\Delta q_i$ are determined not only by the electronic structure of the given molecule but also by the state of the coordination centre and the coordination geometry. The latter determines which orbitals of the molecule, overlapping the orbitals of the centre, undergo the greatest change in population $\Delta q_i$.

From general considerations, confirmed by specific calculations, it follows that, apart from certain special cases, the greatest changes when simple molecules are coordinated are undergone by only two orbitals, the HOMO and the LUMO. If the change in the populations of the inner orbitals is neglected, Eqns. (24) and (25) are simplified considerably, and they can be written in the following form (the superscripts 1 and 2 refer to the HOMO and LUMO respectively):

$$F = f^{(1)}\Delta q_1 + f^{(2)}\Delta q_2, \qquad (30)$$

$$\Delta K = k^{(1)}\Delta q_1 + k^{(2)}\Delta q_2, \qquad (31)$$

$$\beta - 1 = C^{(1)}\Delta q_1 + C^{(2)}\Delta q_2. \qquad (32)$$

The force constants $k^{(1)}$ and $k^{(2)}$ introduced are combinations of the corresponding vibronic constants, and they show how the force constant will change when one electron is added to the corresponding orbital. The last equation, like the first two, describes the linear dependence of the ratio of the anharmonicity constants on the charge transfer $\Delta q_i$; the coefficients $C^{(1)}$ and $C^{(2)}$ are complex combinations of the cubic orbital vibronic constants (and orbital vibronic constants of lower degrees).

All six coefficients ($f^{(1)}$, $f^{(2)}$, $k^{(1)}$, $k^{(2)}$, $C^{(1)}$, and $C^{(2)}$) can readily be calculated if the values of $F$, $\Delta K$, and $\beta$ are known for any two independent electron rearrangement processes (for two pairs of values of $\Delta q_1$ and $\Delta q_2$, except the trivial case $\Delta q_1 = \Delta q_2 = 0$). These processes may be, for example, ionisation ($\Delta q_1 = -1$, $\Delta q_2 = 0$), reduction ($\Delta q_1 = 0$, $\Delta q_2 = 1$), or excitation ($\Delta q_1 = -1$, $\Delta q_2 = 1$), so long as the corresponding empirical parameters are known. For the deforming force $F$, Eqn. (36) gives

$$F = -K'Q_0[1 - KQ_0(6\beta KD_0)^{-1/4}] \qquad (33)$$

where $K$ and $D_0$ are the constants for the non-perturbed molecule ($D_0$ is the dissociation energy of the molecule in the direction being considered), and $K'$, $Q_0$, and $\beta$ relate to the molecule which has undergone electron rearrangement.

The force constants $K$ and $K'$ are readily found from the corresponding vibration frequencies. It is more difficult to determine the deformation of the molecule $Q_0$ in the direction $Q$; direct X-ray diffraction data are not always available. For simple electron rearrangements such as ionisation or excitation, $Q_0$ can be determined from spectroscopic data. In a number of cases, particularly for simple molecules, $Q_0$ can be determined from the known value of $K'$, using empirical relationships between them (see for example Ref. 26). In this case the theory becomes one-parameter; [23,24] all the quantities are determined by one parameter, namely the change in the corresponding vibration frequency in the coordinated state. This version is best in the parametrisation of the theory being considered, since in the experimental

determination of $Q_0$, for example by X-ray diffraction, the formation of the lattice may influence its numerical value, with a significant effect on the results (the value of $Q_0$ must be known with a relatively high accuracy).

Knowing the coefficients in Eqns.(30)–(32), it is possible to use the charge transfer to determine the deforming force and the changes in the force constant and the anharmonicity constant in the direction of the chemical reaction, and then to use Eqn.(29) to estimate the change $\Delta D$ as a function of $D$. On the other hand, if $F$ and $\Delta K$ are known for the perturbed molecule, it is possible to determine $\Delta q_1$ and $\Delta q_2$ for the HOMO and LUMO.

As already noted, Eqn.(29) can also be used as an empirical relationship between $\Delta D$ and $D$:

$$\Delta D = aD + bD^{1/4} + c + dD^{-1/4} \qquad (34)$$

where the coefficients $a$, $b$, $c$, and $d$ are determined from the known empirical parameters $K$, $K'$, and $Q_0$, and $\beta$. Frequently, the value of $D$, that is the activation energy of the reaction being considered in the absence of a catalyst, is unknown. In these cases it is possible, by constructing the $\Delta D = f(D)$ curves for each coordination centre (or any other source of electron rearrangement), to compare them with one another and to determine the relative efficiency of different centres (or sources) for each value of $D$.

Specific examples can be considered. The electronic structure and spectroscopic parameters of the CO molecule have been well studied, so that it is comparatively easy to determine its fundamental vibronic constants and force constants. Its HOMO is the $5\sigma$ orbital, and the LUMO the $2\pi$ orbital. Knowing from experimental data the values of $K$ for the original CO molecule and the values of $K'$, $\beta$, and $Q_0$ for the ionised molecule $CO^+$ [25,27] ($\Delta q_1 = -1$, $\Delta q_2 = 0$) and for the excited state of CO ($5\sigma^2 2\pi^0 \rightarrow 5\sigma^1 2\pi^1$ transition; $\Delta q_1 = -1$, $\Delta q_2 = 1$), [26,28] it is possible to obtain from Eqns. (30)–(32) the following values (for the configurations $5\sigma^1 2\pi^1$, the average values for the two terms $A\,^1\Pi$ and $a\,^3\Pi$ were used):

$$\begin{array}{ll} f^{(1)} = -4.54\cdot10^{-4}\ \text{dyn} & f^{(2)} = -12.1\cdot10^{-4}\ \text{dyn} \\ k^{(1)} = -0.080\cdot10^{6}\ \text{dyn cm}^{-1} & k^{(2)} = -0.83\cdot10^{6}\ \text{dyn cm}^{-1} \\ C^{(1)} = 0.134 & C^{(2)} = 0.0104 \end{array} \qquad (35)$$

The values of both the vibronic constants and the force constants show that both orbitals ($5\sigma$ and $2\pi$) are antibonding, the latter being much more antibonding than the former. Unlike the qualitative picture of the nature of the corresponding orbital (antibonding or bonding), which can often (but not always) be obtained without using the vibronic approach, the latter, as can be seen from the figures obtained, makes it possible to determine quantitatively the degree of participation of the corresponding orbital in the deforming force and the force constant.

Knowing the constants (35), it is possible to analyse the behaviour of the carbon monoxide molecule in any other situation, in particular when coordinated. If the charge transfer $\Delta q_1$ and $\Delta q_2$ resulting from coordination is known, it is possible to determine the values of $F$, $\beta$, and $\Delta K$, and hence $\Delta D$ (for a given $D$), and conversely. The values of these constants show that the negative (antibonding, and hence decreasing the activation energy) force $F$ and the negative $\Delta K$ (acting in the same direction) will be greater, the greater the positive values of $\Delta q_1$ and $\Delta q_2$, that is the greater the increase in the populations of the HOMO and LUMO. Since the HOMO is completely occupied by electrons, however, $\Delta q_1$ may be either zero or negative. Thus the activation of CO will be greater, the greater $\Delta q_2$ and the smaller the absolute magnitude of the negative $\Delta q_1$, so that, for example, for linear coordination the catalyst of the corresponding reactions will be more effective, the stronger its $\pi$-donor properties and the weaker its $\sigma$-acceptor properties.

The linear coordination of CO to a nickel atom on an NiO surface can be considered. Experimental data for this system give the value $K' = 1.710 \times 10^6$ dyn cm$^{-1}$, [27] and the relationship between $K'$ and $Q_0$, [25] namely $K' = (1.7957 - 8.2926\,Q_0\,[\text{Å}]) \times 10^6$ dyn cm$^{-1}$, can be used to obtain $Q_0 = 0.0126$ Å, $F = -2.119 \times 10^{-4}$ dyn, and $\Delta K = K' - K = -0.192 \times 10^6$ dyn cm$^{-1}$; Eqns.(30)–(32) then give $\Delta q_1 \cong -0.32$, $\Delta q_2 \cong +0.26$, and $\beta = 0.93$. This gives the details of the mechanism of the activation of CO on nickel oxide: coordination is accompanied by the transfer of an electron charge of ~0.3 e to the metal from the weakly antibonding $5\sigma$ orbital of CO, and by approximately the same transfer of charge from nickel to the strongly antibonding $2\pi$ orbital of CO.

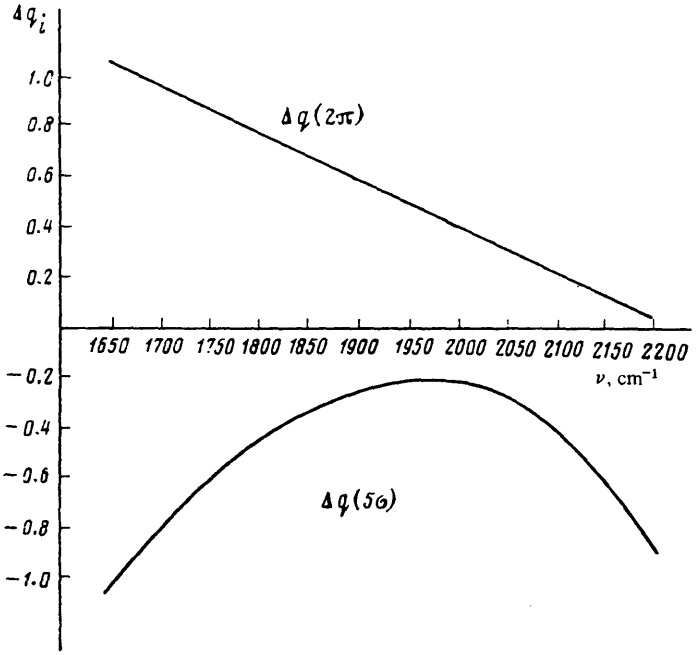

Figure 4. Dependence of the charge transfer $\Delta q(5\sigma)$ and $\Delta q(2\pi)$ to the CO molecule on its vibrational frequency in the coordinated state in the one-parameter two-level theory of vibronic activation on coordination. [23,24]

The relationship between $K'$ and $Q_0$ given above can be used to obtain a correlation diagram relating the vibration frequency of CO and the transfer of charge from the $5\sigma$ HOMO to the active centre ($-\Delta q_1$) and from the latter to the $2\pi$ LUMO ($\Delta q_2$) on coordination, [23,24] shown in Fig.4. It may be noted, however, that the empirical relationship $K' = f(Q_0)$ was obtained for the range where the charge transfer and the change in the CO vibration frequency are not too small. With allowance for the correlation between $K'$ and $Q_0$, the vibronic theory of activation becomes one-parameter, that is all the results depend on one parameter, namely the value of the vibration frequency of CO in the coordinated state (or $K'$).

In this approximation, the change in the reactivity of CO on the NiO surface, obtained from Eqn.(29), gives the following relationship (values of $D$ and $\Delta D$ in kcal mole$^{-1}$):

$$\Delta D = -0.17D - 1.40D^{1/4} + 0.78 - 0.15D^{-1/4} \cdot \qquad (36)$$

The $\Delta D = f(D)$ curve for this case, together with other analogous curves obtained for a number of coordination centres which activate CO, is given in Fig.5.[22]

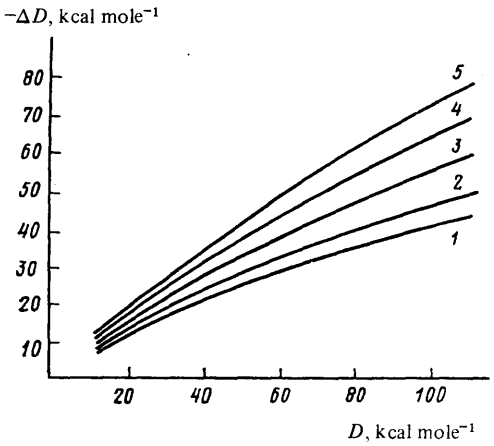

Figure 5. $\Delta D = f(D)$ relationships for the activation of the CO molecule on coordination to various systems, constructed from vibronic theory for the systems: *1*) Pd–Co, *2*) Ni–Co, *3*) $Fe(CO)_5$, *4*) $V(CO)_5$, *5*) $Mn(CO)_5$.

To estimate the efficiency of Eqn.(36) it is necessary to obtain the numerical values of $\Delta D$ for a known $D$ and to compare them with the experimental values. If it is assumed that the activation energy of the reaction $CO + O_2 \rightarrow CO_2 + O$ in a flame ($D$ = 48 kcal mole$^{-1}$)[29] corresponds to the activation of CO, then for linear coordination on a nickel oxide surface, according to Eqn.(36), the activation energy decreases by $\Delta D \cong -17$ kcal mole$^{-1}$ and becomes equal to $D' = D + \Delta D \cong 31$ kcal mole$^{-1}$, in good qualitative agreement with the experimental data for this reaction on a nickel catalyst, for which (in an excess of CO) $D_{expt}$ = 25.4 kcal mole$^{-1}$.[30]

Interesting results have been obtained in a study of the vibronic activation of CO on transition metal clusters.[23] It has been found, in particular, that CO molecules coordinated simultaneously to two (in $Co_2(CO)_8$) and more particularly to three (in $Rh_6(CO)_{16}$) metal atoms are activated to a much greater extent than when coordinated to one atom. On the other hand, in $Mn_2(CO)_{10}$ the axial CO groups are activated to a much greater extent than the equatorial groups.

The $N_2$ molecule, which is isoelectronic with CO, also has a $5\sigma$ HOMO and a $2\pi$ LUMO. The experimental data for $N_2^+$ and the excited states $a^1\Pi g$ and $B^3\Pi_g$[31] (the latter correspond to the excitation $5\sigma^2 \rightarrow 5\sigma^1 2\pi^1$ with $\Delta q_1 = -1$ and $\Delta q_2 = 1$) give from Eqns.(30)–(32) the following values for the vibronic parameters:[7–10]

$$\begin{aligned} f^{(1)} &= 3.51 \cdot 10^{-4} \text{ dyn} \\ k^{(1)} &= 0.286 \cdot 10^{6} \text{ dyn cm}^{-1} \\ C^{(1)} &= 0.112 \\ f^{(2)} &= -8{,}18 \cdot 10^{-11} \text{ dyn} \\ k^{(2)} &= -0{,}785 \cdot 10^{6} \text{ dyn cm}^{-1} \\ C^{(2)} &= 0.127 \end{aligned} \qquad (37)$$

It can be seen that the highest occupied $5\sigma$ orbital of the $N_2$ molecule, unlike that of CO, is bonding, but the $2\pi$ LUMO, as in CO, is antibonding. Thus in contrast to CO, for the activation of $N_2$ the coordination centre for longitudinal linear coordination should be a good $\pi$-acceptor and $\pi$-donor. In principle, an analogous effect brings about charge transfer to the coordination centre through the $\pi$-bond, which in the case of linear coordination may take place from the deeper-lying $\pi_u$ orbital. For transverse coordination this transfer can take place only from the antibonding $\sigma_u$ orbital. This explains the differences in the activation of $N_2$ with respect to the coordination geometry (see Refs.7–9 for more details). Estimates of the orbital vibronic constants are also given in Ref.32.

The Table gives examples of calculations of the changes in activation energy and charge transfer for a number of specific cases of the coordination of an $N_2$ molecule to transition metal complexes.[3,10] The vibrational frequencies of coordinated $N_2$ were taken from Ref.33, and the values of $Q_0$ were estimated from the empirical equation ($\nu'$ in cm$^{-1}$):

$$Q_0, \text{ Å} = 0.9482 - 0.7105(\nu' \cdot 10^{-3}) + 0.1302(\nu' \cdot 10^{-3})^2 \qquad (38)$$

The Table shows particularly, that as expected in the general case, the greatest contribution to $\Delta D$ on coordination is due to the linear vibronic effect, that is to the production of the deforming force (terms with coefficients $b$ and $c$ in Eqn.(34)), that the softening influence (the quadratic term with coefficient $a$) makes a smaller contribution, and that the anharmonicity terms (with coefficient $d$) make a very small contribution.

Semi-empirical estimates of the charge transfer to the HOMO $\Delta q_1$ and LUMO $\Delta q_2$ and the lowering of the activation energy $\Delta D = aD + bD^{1/2} + c + dD^{-1/2}$ of the $N_2$ molecule on coordination (one-parameter approximation).

| Coordination system | $\nu'$, cm$^{-1}$ | $10^{-6}K'$, dyn cm$^{-1}$ | $10^{-6}\Delta K$, dyn cm$^{-1}$ | $C_0$, Å | $10^4 F$, dyn | $\Delta q_1$ | $\Delta q_2$ | $a$ | $b$ | $c$ | $d$ |
|---|---|---|---|---|---|---|---|---|---|---|---|
| $[RuH_2(N_2)(PPh)_3]$ | 2147 | 1.900 | −0.394 | 0.0229 | −4.19 | −0.16 | 0.44 | −0.14 | −2.72 | 2.87 | −0.01 |
| $[\{Ru(NH_3)_5\}_2N_2]^{4+}$ | 2100 | 1.821 | −0.479 | 0.0303 | −5.25 | −0.57 | 0.41 | −0.21 | −3.37 | 4.81 | −2.28 |

Note: tol = toluene, dmpl = $Me_2PCH_2CH_2PMe_2$, $\Delta K = K' - K$.

Analogous estimates of the activation on coordination have been carried out for a number of other small molecules, including NO, $O_2$, $C_2H_4$, $C_3H_8$, etc.[3,10]

## V. ELECTRON-CONFORMATIONAL INTERACTIONS. APPLICATIONS TO METALLOPORPHYRINS AND HAEM-CONTAINING PROTEINS

In the previous section it was shown how a change in the electronic structure of a molecular system leads via vibronic coupling to the production of a force which deforms the core of the molecule in a definite direction, to a change in the force constant, which "softens" this system (or makes it "harder"), to a change in the anharmonicity constants, etc. These changes alter the form of the adiabatic potential, including its behaviour at large distances, that is the reactivity of the system. The change in reactivity has an influence, however, in the interaction of the given system with another system, with which it undergoes a chemical reaction. Under different conditions (in the absence of this interaction), other effects, resulting from the above changes in the parameters of the system, are more significant.

In particular, a direct result of the production of a non-zero deforming force

$$F_{\bar{\Gamma}} = \sum_i \Delta q_i f^i_{\bar{\Gamma}}$$

(Eqn.(24)) is a change in the spatial configuration (geometry) of the system in the direction $Q_{\bar{\Gamma}}$. The latter is determined by the symmetry of the molecular orbitals $i$, for which the orbital vibronic constant $f^i_{\bar{\Gamma}}$ and the changes in the populations $\Delta q_i$ are non-zero. The representations $\bar{\Gamma}$ for which $f^i_{\bar{\Gamma}}$ is non-zero, as already noted, are found directly. If the $i$th MO is non-degenerate, then $\bar{\Gamma} = \bar{\Gamma}_i \times \bar{\Gamma}_i = A_1$, that is the direction $Q_{\bar{\Gamma}}$ can only be totally symmetric. In other words, a change in the population of the non-degenerate molecular orbitals changes only the interatomic distances, without changing the symmetry of the system (without distorting it). If however the orbital state $\Gamma_i$ is degenerate, then $\bar{\Gamma} = [\Gamma_i \times \Gamma_i]$ contains both totally symmetric and non-totally-symmetric representations, so that the presence of electrons in these orbitals leads to distortion of the system; the direction of the distortion coincides with the direction of the distortion in the Jahn–Teller effect.[2]

If the change in the electronic structure changes the populations $\Delta q_i$ of not one but several MO, and the directions of the deformation of the core, determined by the coordinate $Q_{\bar{\Gamma}}$, are different for these orbitals, then the total distortion will be equal to their vector sum. To determine the latter it is also necessary to know the magnitude of the distortion $Q_{0\bar{\Gamma}}$ in each of the directions $Q_{\bar{\Gamma}}$. In the approximation linear with respect to the vibronic interaction, it is determined directly from the relationship

$$Q_{0\bar{\Gamma}} = F_{\bar{\Gamma}}/K_{\bar{\Gamma}} \qquad (39)$$

where $K_{\bar{\Gamma}}$ is the force constant in the direction $Q_{\bar{\Gamma}}$. With allowance for the change in the latter and the anharmonicity constant as a result of the change in the electronic structure, the expression for $Q_{0\bar{\Gamma}}$ becomes more complex, and takes the form given in Eqns.(27). Substituting the expression for $F_{\bar{\Gamma}}$ in Eqn.(39) gives

$$Q_{0\bar{\Gamma}} = \sum_i \Delta q_i f^i_{\bar{\Gamma}}/K_{\bar{\Gamma}} \ . \qquad (40)$$

From this it can be seen that in the directions $Q_{\bar{\Gamma}}$ for which $f^i_{\bar{\Gamma}}$ is small and the hardness of the molecule is high ($K_{\bar{\Gamma}}$ large), $Q_{0\Gamma}$ is small. In other words, a contribution to the distortion of the molecule in the given direction is made only by those orbitals for which the vibronic constant is sufficiently high, which is the case when the orbital being considered is sufficiently effectively involved in the bonding (antibonding) system in the given direction. On the other hand, appreciable distortions may take place in those directions in which the system is sufficiently "soft" (that is $K_{\bar{\Gamma}}$ is small). Similarly, Eqn.(25) makes it possible to estimate the softening or hardening (in the sense of the change in the force constant and the vibrational frequency) of the system in the direction $Q_{\bar{\Gamma}}$.

In simple cases these effects are qualitatively completely understandable from general considerations, but the above equations give quantitative estimates for these effects in the general case, and make it possible to predict them.

The change in the configuration of a molecule and its hardness with change in its electronic structure is directly related to the so-called electron-conformational interactions. The latter essentially coincide with the vibronic interactions, and the apparatus developed above can be used directly to analyse electron-conformational effects. Most frequently, electron-conformational transitions in which the appearance or disappearance of one electron leads to a change in the conformation of the system are considered. In this formulation, the problem is solved approximately using the above scheme, in which the additional population of the $i$th orbital ($\Delta q_i = 1$) with $f^i_{\bar{\Gamma}} \neq 0$ leads to fairly strong distortion of the system in the direction $Q_{\bar{\Gamma}}$, particularly if the value of $K_{\bar{\Gamma}}$ in this direction is small. For large systems, the appearance of an electron in a given position, usually in the active centre, leads to a local distortion $Q_{0\bar{\Gamma}}$ which initiates a conformational transformation of the system as a whole (the so-called trigger mechanism).

The electron-conformational transitions in biological systems are of particular interest. For example, in haemoglobin the displacement of the iron atom from the haem plane in the deoxy-form and its return on oxygenation, according to Perutz,[34,35] initiates a conformational $T \rightarrow R$ transition. This transition is determined by the cooperative properties of the four active iron centres in haemoglobin, and leads to the unusual $S$-shaped kinetic curve for the oxygenation (the "trigger" mechanism of the oxygenation of haemoglobin). The analogous haem-centres in various proteins have a wide range of functions, from electron transfer to the oxidation of saturated hydrocarbons, and all of these functions are related in some form or other to electron-conformational interactions. As noted above, the distortions of the molecular system due to electron rearrangement (Eqn.(40)), like the Jahn–Teller effect and pseudo-effect, are greater, the softer the system (that is the smaller $K_{\bar{\Gamma}}$) in the direction $Q_{\bar{\Gamma}}$ being considered.

A distinguishing feature of biological systems is that, because of the large number of atoms present, there are soft modes which give the vibronic effects a high efficiency. On the other hand, because of the large dimensions, the initial ("trigger") electron rearrangement generally takes place locally in an active centre, initiating the conformational transition of the system as a whole.

The electron-conformational and other vibronic effects in metalloporphyrins and haem-containing proteins[36–43] can be considered as examples illustrating these ideas. In addition to their independent interest for biology, these examples are of general importance, since the behaviour of the active

centre in them reflects the general situation arising in many coordination and organometallic compounds similar to metalloporphyrins. A distinguishing feature of these systems is the presence of close energy levels of the *d* electrons of the metal and the π-system of the porphyrin ring (or other similar ligands). If for example (as in metalloporphyrins) these states mix as a result of nuclear displacements of type $A_{2u}$, which move the metal atom from the plane of the porphyrin ring (Fig.6), then when it is sufficiently strong, this vibronic mixing softens the system or even makes it unstable with respect to this displacement of the metal from the plane (Jahn–Teller pseudo-effect). The explanation for the displacement of the metal atom from the plane of the porphyrin ring is that this displacement leads to the formation of additional metal–ligand π-bonds (for the metal atom situated in the plane of the porphyrin ring, the overlap of the corresponding orbitals is equal to zero), whose contribution to the bond energy is greater than the decrease in the strength of the corresponding σ-bonds.

As a result of the Jahn–Teller pseudo-effect, the force constant $K$ for displacements in the direction $Q$, as noted above, decreases by $F^2/\Delta$, where $F = \langle 1|(\partial V/\partial Q)_0|2\rangle$ is the corresponding vibronic constant; if $(F^2/\Delta) > K$, the system becomes unstable with respect to $Q$-displacements. For the metalloporphyrins with $D_{4h}$ symmetry being considered, the $Q$-displacement of the metal atom from the plane of the porphyrin ring relates to the $A_{2u}$ representation (Fig.6). This means that in order to have $F \neq 0$, the product of the representations of the mixing states 1 and 2 must contain the representation $A_{2u}$.

Fig.7 gives the highest occupied and lowest unoccupied energy levels of the molecular orbitals of a number of metalloporphyrins of Mn, Fe, Co, Ni, Cu and Zn, and (for comparison) manganese phthalocyanine (MnPc), obtained from a calculation for the planar configuration.[44,45] Figs.5 and 6 show that, for example, for FeP the ground state is $^3E_g$, so that the excited state, which is displaced with it for $A_{2u}$ displacements, should have $^3E_u$ symmetry ($E_g \times A_{2u} = E_u$); for MnP, MnPc, and CoP, the corresponding excited states are $^4A_{2g}$, $^4E_g$, and $^2A_{2u}$. They can all be obtained by one-electron excitation from the $a_{2u}(\pi)$-level of (mainly) the porphyrin ring into the unoccupied $a_{1g}(d_{z^2})$-level of (mainly) the metal; here, $2\Delta \cong \varepsilon(a_{1g}) - \varepsilon(a_{2u})$ is comparatively small. For other metalloporphyrins, NiP, CuP, and ZnP, this $a_{1g}$ orbital is occupied by electrons (Fig.7), and the next MO with the same symmetry are very high above it (not shown in Fig.7). Thus the last three metalloporphyrins show practically no Jahn–Teller pseudo-effect with respect to displacement of the metal atom from the plane, whereas the effect can appear in other systems.

To estimate this possibility, it may be noted that the calculated values of $2\Delta$ in the series MnP, FeP, CoP, and MnPC are 0.15, 0.2, 0.6, and 1.0 eV respectively.[44,45] The vibronic constant estimated[38] for FeP is $F \cong 10^{-4}$ dyn (for other metalloporphyrins, calculations for the same states give values of $F$ of the same order of magnitude), and the force constant of the $A_{2u}$ displacement is $K \cong 10^4$ dyn cm$^{-1}$ Thus $(F^2/K) \cong 0.1$ eV, that is $F^2/K$ and $\Delta$ are of the same order of magnitude, so that the ground state is softened considerably as a result of the Jahn–Teller pseudo-effect. The porphyrins MnP and FeP ($\Delta \cong 0.08$ eV and 0.1 eV) may be unstable, since for them $\Delta < F^2/K$, whereas for CoP and MnPc ($\Delta \cong 0.3$ and 0.5), the position of the metal is softened, although it is stable. These results are in complete qualitative agreement with experimental data.[46,47]

Thus the observed displacement of the iron atom from the plane in the deoxy-form of haemoglobin (and in other analogous systems) is satisfactorily explained in terms of the Jahn–Teller pseudo-effect (the existence of a bond with the imidazole residue (Fig.6) does not lead to qualitative changes, since the energy levels $a_{1g}$ and $a_{2u}$ do not move apart to a significant extent;[48] see Refs.41–43 for more details). It is of interest to explain from the same viewpoint the return of the iron atom to the haem plane on oxygenation, initiating the above-mentioned conformational $T \rightarrow R$ transition. Fig.8 gives the MO energy levels for planar FeP, the deoxy-form of haemoglobin (Hb), and the changes in these levels when $O_2$ and CO are coordinated.[44,48] It can be seen that the comparatively small difference $2\Delta = \varepsilon(a_{1g}) - \varepsilon(a_{2u})$, which ensures softening and instability in the first two systems, including the deoxy-form of haemoglobin, increases sharply when $O_2$ or CO are added ($2\Delta \cong 3$ eV for $HbO_2$ and $2\Delta \cong 4$ eV

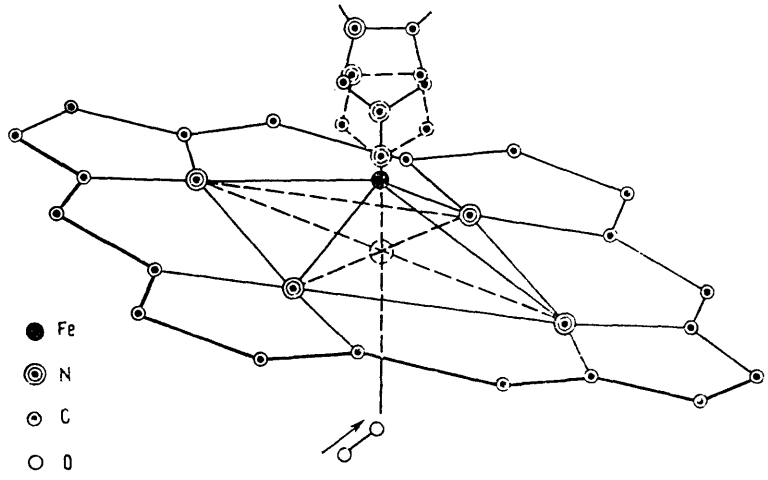

**Figure 6.** The structure of metalloporphyrins and the corresponding fragments of haem-containing proteins. The two positions of the iron atom together with the imidazole group of histidine correspond to the deoxy-form (continuous lines) and the oxygenated configuration (broken lines).

for HbCO). The increase in $\Delta$ removes completely the Jahn–Teller pseudo-effect, and the position of the iron atom becomes stable in the haem plane; this leads to the above-mentioned $T \rightarrow R$ conformational transition in the system (the trigger mechanism of the oxygenation of haemoglobin). At the same time, the increase in $\Delta$ may (and does, see Fig. 8) lead to a change in the spin state from $S = 2$ to $S = 0$, which is extremely typical of the compounds of iron and various other transition metals, and is known as "cross-over" (the conversion of the high-spin to the low-spin state takes place when $\Delta > \Pi$, where $\Pi$ is the binding energy of the electrons in the corresponding orbitals.[1] This question is examined in more detail in Refs. 41–43.

It may be noted that since the geometry and multiplicity of metalloporphyrins depends on the interaction of the $a_{2u}(\pi)$-orbital, which is sensitive to the introduction of substituents at the periphery of the ring, with the $a_{1g}(d_{z^2})$ orbital, which is affected by the axial ligands of the metalloporphyrin, the properties of these systems may depend markedly on the protein environment in haem proteins, as in fact observed.

It has been found that not only the displacement of the metal from the plane and its return with change in the electronic structure, but also the geometry of the coordination of small ligands (NO, $O_2$, CO, etc.) and the unusual quantum yield of photolysis, which depends markedly on this geometry, are explained by vibronic effects, critically dependent on the electronic structure.[39–43] Overall, the approach is of course general in character and can be applied to any molecular formations in chemistry and biology.[3]

The chemical aspects of the concept of vibronic interactions examined above make it possible to reach a number of conclusions of general importance for present-day chemistry. The concept of vibronic interactions involves taking more detailed account (compared with the adiabatic approximation) of the effect of the electrons on the nuclear configuration and its dynamics, resulting from the vibronic mixing of the electronic states by the nuclear displacements. The orbital vibronic constants introduced provide a new and more complete (extended into the dynamic range) description of the electronic structure of molecules in the molecular orbital approximation. The new description makes it possible to predict changes in the nuclear configuration and its dynamics with change (perturbation) in the electronic structure.

It follows from vibronic theory that the only source of dynamic instability in molecular systems is the vibronic mixing of the ground state with one (or possibly several) excited states. This conclusion opens up extensive possibilities for explaining and predicting the stereochemistry and crystal chemistry of chemical compounds, and also for analysing the origin and studying the intermediate states of chemical reactions.

It has been shown that vibronic effects lead to a lowering of the barriers to reaction with other molecules in definite directions, that is to an increase in reactivity for certain reaction mechanisms. The knowledge of the mechanism for the production of instability and reactivity has been used to develop a theory of the process by which reactivity is induced under the influence of another molecular system, that is the theory of chemical activation on coordination. The

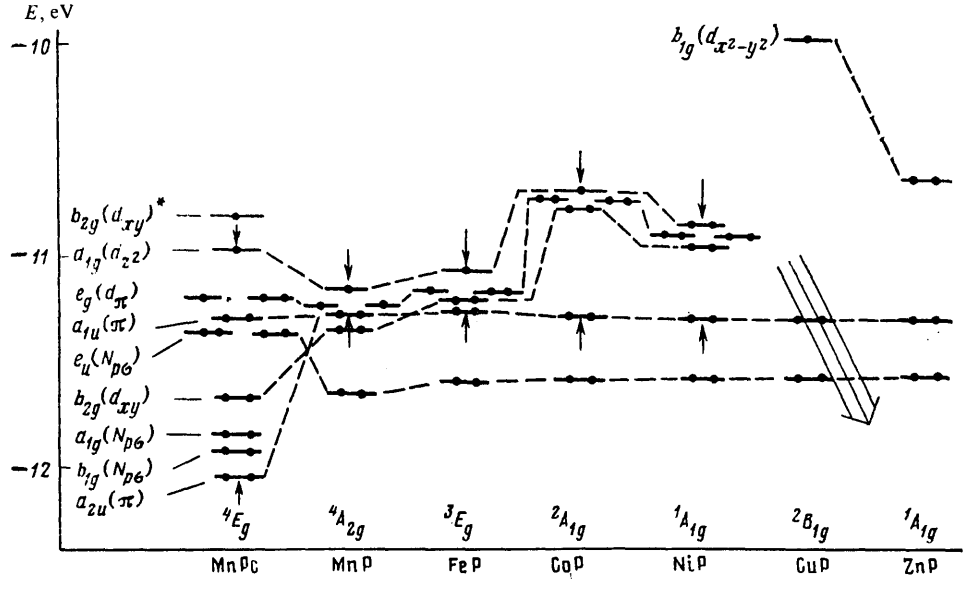

Figure 7. Energy levels of some HOMO and LUMO for metalloporphyrins and manganese phthalocyanine (MnPc); the ground terms of the systems in the configuration with the metal in the plane of the porphyrin (phthalocyanine) ring are indicated. The arrows indicate the energy gaps $2\Delta$ between the ground and lowest excited states, which are mixed in the $A_{2u}$ displacements of the metal.

orbital vibronic constants have been used to develop a semi-empirical two-level version of the theory, which makes possible an approximate prediction of chemical activation (lowering the activation energy of the reaction) on coordination to a given catalyst active centre.

In addition, vibronic effects form the basis of electron-conformational transformations in chemistry and biology, as has been demonstrated for specific examples, namely metalloporphyrins and haem-containing proteins.

Each of these conclusions (except the first) requires further development in detail, and the applied aspects, with some development, may each become a starting point for a new direction in this field of study. This confirms the conceptual character of the new approach to the structure–property problem briefly presented in the present review.

In general, as already noted, the concept of the mixing of electronic states as a result of nuclear displacements (produced by abandoning the separate description of the movements of the electrons and the nuclei in the simple adiabatic approximation) introduces new elements into the chemist's way of thinking, making it possible to avoid restricting stereotypes. In the new understanding, in particular, the ground and excited states of a molecule for a given configuration of the nuclei, strictly speaking, no

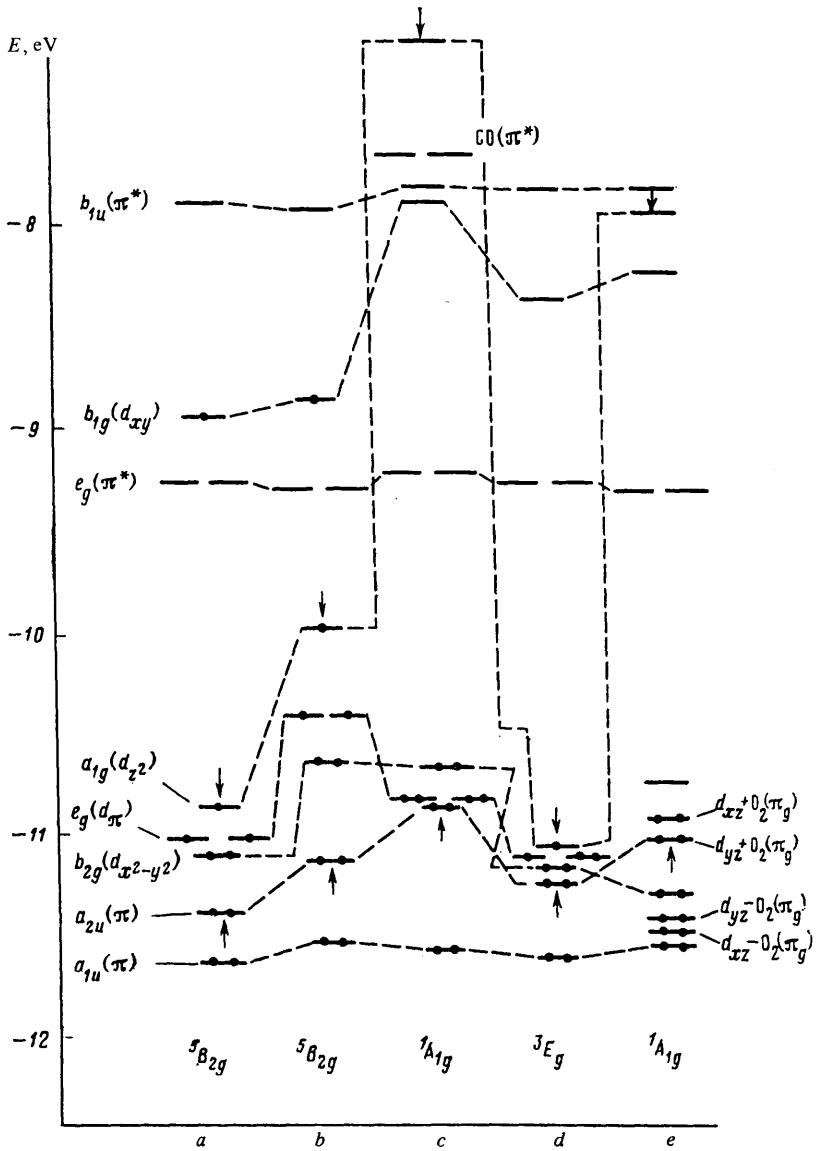

**Figure 8.** Energy levels of some HOMO and LUMO: *a*) FeP in the configuration with the Fe atom displaced from the porphyrin plane by $\Delta R = 0.49$ Å; *b*) the deoxy-form of haemoglobin with $\Delta R = 0.62$ Å; *c*) Hb–CO system; *d*) planar FeP, that is $\Delta R = 0$; *e*) Hb–$O_2$ system. The ground term and (arrows) the gap $2\Delta$ between the states mixed in the displacement of the iron atom from the plane of the porphyrin ring are indicated.

longer exist as independent concepts; they may be mixed considerably when allowance is made for the displacements of the nuclei. In other words, the excited electronic states of the molecular configuration being considered may determine its properties in the ground state to the same extent as the ground electronic state in this configuration.

# The Preparation and Properties of Indium Phosphide

V.P.Talyzin and A.Ya.Nashel'skii

The present review examines recent work on the synthesis of polycrystalline specimens of indium phosphide and the growth of single crystals of this compound for the modern electronics industry. The synthesis of polycrystalline indium phosphide by different methods is examined. Particular attention has been paid to work on the preparation of highly pure material and the growth of single crystals with a low concentration of dislocations and single crystals oriented along ⟨100⟩.
The bibliography contains 45 references.

CONTENTS

I. Introduction 597
II. The preparation of highly pure indium phosphide crystals 597
III. The growth of single crystals of indium phosphide by liquid hermetic sealing of the melt 600

## I. INTRODUCTION

In recent years, in the development of work in optoelectronics (the use of optical and electronic effects in semiconductors to create instruments and information systems of fundamentally new types) and SHF (super-high-frequency) technology, there has been a marked increase in interest in single crystals of indium phosphide. Indium phosphide now occupies third place in the world after silicon and gallium arsenide in importance for application in special instruments. Non-doped single crystals of indium phosphide are used as supports in the manufacture of instruments in SHF technology. The main requirement in this material is a low concentration of impurities, which affect the parameters of the instruments, and a low density of dislocations. Field transistors are produced on supports of single crystals of semi-insulating indium phosphide with a high specific resistance ($\rho > 10^7$ Ω.cm). The main application of single crystals of indium phosphide, however, is in optoelectronics, for producing radiation sources and receivers operating in the wavelength range 1.0–1.6 μm.

## II. THE PREPARATION OF HIGHLY PURE INDIUM PHOSPHIDE CRYSTALS

Non-doped polycrystalline indium phosphide is obtained chiefly by the following methods: horizontal directed crystallisation, horizontal zone fusion, crystallisation of melts with non-stoichiometric composition in a temperature gradient (so-called "synthesis with diffusion through a melt"), and synthesis in quasi-hermetic reactors. Polycrystalline indium phosphide is used in liquid-phase epitaxy and as starting material for growing single crystals.

### 1. Horizontal Directed Crystallisation (HDC)

The synthesis of indium phosphide by HDC has been carried out in an autoclave.[1,2] Boats of pyrolytic boron nitride (PBN) or quartz containing indium and red phosphorus were placed in a sealed quartz ampoule (reactor). The synthesis was carried out at the melting point of the indium–indium phosphide melt (1070 °C) at the equilibrium vapour pressure of phosphorus, 27.5 atm (the temperature of the section of the ampoule containing phosphorus was ~600 °C). The boat containing indium was heated at a rate of 20–35 K $h^{-1}$, and that containing phosphorus at a rate of 10 K $h^{-1}$. The pressure of inert gas in the autoclave was raised simultaneously. The low heating rates prevented rupture of the ampoule with increase in the phosphorus vapour pressure. When the reaction was complete, the temperature of the hot zone (the zone containing the indium–indium phosphide melt) was lowered at a rate ensuring crystallisation (0.2–0.5 cm $h^{-1}$). Indium phosphide ingots with a mass of 110 g were obtained after 170 h.[2] The concentration of principal current carriers in these ingots was $n = (2–5) \times 10^{15}$ $cm^{-3}$ (300 K).

HDC has been used[3] to obtain polycrystalline indium phosphide ingots with a mass of 1100 g. The synthesis was carried out in an autoclave, in a quartz ampoule with diameter 34–38 mm and length 300 mm. This gave a product with $n = (5–50) \times 10^{15}$ $cm^{-3}$ and a mobility of principal charge carriers $u = (1.5–2.5) \times 10^4$ $cm^2$ $V^{-1}$ $s^{-1}$ (77 K). The concentration of silicon did not exceed $(2–3) \times 10^{-5}$ at.% or $(4–6) \times 10^{15}$ atom $cm^{-3}$. The authors cited consider that the main source of silicon in the indium phosphide is impurities in the original indium.

In Ref.4, the purity of indium phosphide was increased by heating the indium at 700 °C successively (100 h) in a stream of moist hydrogen and in a vacuum at $10^{-7}$ mmHg, and heating the phosphorus in a vacuum at 300–335 °C for 24 h. The quartz parts of the reaction vessel, after etching, were heated in a vacuum at 1000 °C before assembling the reaction vessel. The PBN boats were also specially treated. Under these conditions, ingots of polycrystalline indium phosphide with $n = 10^{15}$ $cm^{-3}$ and $u = (3–4) \times 10^4$ $cm^2$ $V^{-1}$ $s^{-1}$ (77 K) were obtained.

A significant increase in the purity of polycrystalline indium phosphide is achieved by recrystallising its non-stoichiometric melts. In Ref.5, indium phosphide synthesised at the equilibrium vapour pressure of phosphorus had $n = 3.50 \times 10^{15}$ $cm^{-3}$ and $u = 2.52 \times 10^4$ $cm^2$ $V^{-1}$ $s^{-1}$ (77 K), whereas the material obtained at a lower phosphorus vapour pressure above the melt (lower than 10 atm) had $n = 3.16 \times 10^{15}$ $cm^{-3}$ and $u = 3.89 \times 10^4$ $cm^2$ $V^{-1}$ $s^{-1}$. The crystallisation of melts with non-stoichiometric composition, however, requires a decrease in the crystallisation rate (12 mm $d^{-1}$).

To increase the purity of indium phosphide synthesised by HDC, indium(III) oxide was added to the reaction vessel to an atomic fraction of $10^{-4}$–$10^{-5}$. The doping with oxygen was carried out for two sets of growth conditions, with one high-temperature zone (1080 °C) in an ampoule with length 100 mm, and with two zones (1080 °C and 630 °C) in an ampoule of length 300 mm.[6]

Measurement of the electrical parameters by the Hall effect method showed a decrease in the concentration of charge carriers and an increase in their mobility compared with specimens not doped with oxygen only when the doped indium phosphide was grown in a single temperature zone: the values were $(1.5–7) \times 10^{15}$ cm$^{-3}$ and $(2–3.3) \times 10^{4}$ cm$^2$ V$^{-1}$ s$^{-1}$ (77 K) respectively. The influence of oxygen under these conditions is due to the decrease in the concentration of the silicon fine donor impurity in the indium phosphide crystal.

To increase the productivity of the synthesis of indium phosphide by HDC and to prevent possible rupture of the sealed quartz reactors, they are fitted with a quartz bellows, which connects the quartz rod to the pressure measuring device in the autoclave.[7] The signal from the measuring device is passed to a system which equalises the pressure in the reactor and the autoclave (Fig.1). In an autoclave fitted with this system it is possible to synthesise in 1 h 2 kg of indium phosphide with parameters $n = 1.5 \times 10^{16}$ cm$^{-3}$ and $u = 1.5 \times 10^{4}$ cm$^2$ V$^{-1}$ s$^{-1}$ (77 K).

In work at one of the leading firms producing semiconducting compounds, Metal Chemical Products (England),[8] the pressure in the ampoule and in the autoclave is controlled using a quartz reaction vessel, in the end face of which there is sealed a corrugated quartz diaphragm, connecting the rod to the pressure measuring device. The signal from the measuring device operates solenoid valves to supply gas to the autoclave or to release the pressure when the phosphorus vapour pressure in the reactor increases. This system gives a differential pressure difference of 0.25–0.5 atm, depending on the sensitivity of the diaphragm.

The conditions for obtaining ingots of indium phosphide with improved parameters were investigated in the same study: the main requirement was additional treatment of the starting materials. Indium was heated in a vacuum at 900 °C (12 h). The time taken to synthesise a melt with a mass of 2 kg in quartz boats at a phosphorus vapour pressure of 24.5–30 atm was 20 h, and the crystallisation rate was 10–20 mm h$^{-1}$. The polycrystalline indium phosphide ingots obtained under these conditions had $n = 5 \times 10^{5}$ cm$^{-3}$ and $u = (2–4) \times 10^{4}$ cm$^2$ V$^{-1}$ s$^{-1}$ (77 K); the silicon concentration was $2 \times 10^{-5}$ mass % or $2 \times 10^{15}$ atom cm$^{-3}$.

## 2. Horizontal Zone Fusion (HZF)

The HZF directed crystallisation method is widely used by Western European firms to obtain polycrystalline highly pure indium phosphide. The product has been synthesised in an autoclave, in a sealed quartz ampoule.[9,10] The temperature of the molten zone was 1100 °C, and the phosphorus vapour pressure 27.5 atm. The ampoule was moved relative to the inductor at a rate of 6 cm h$^{-1}$, and after 6 h, 1.3 kg of polycrystalline indium phosphide was obtained:[10] $n = (5–10) \times 10^{15}$ cm$^{-3}$, $u = 3700–4700$ cm$^2$ V$^{-1}$ s$^{-1}$ (300 K). The concentration of silicon in the indium phosphide ingots obtained did not exceed $10^{16}$ atm cm$^{-3}$. The main source of silicon in the product was the impurities in the original indium.

With increase in the temperature of the molten zone from 1050 °C to 1180 °C, the concentration of principal charge carriers increased approximately 100-fold, due to an increase in the silicon concentration.[11] The authors cited point out that decrease in the phosphorus vapour pressure in the ampoule to 2 atm makes possible an approximately five-fold decrease in the concentration of principal charge carriers. To increase the purity of the polycrystalline specimens obtained, the original indium was heated beforehand in a vacuum (3 h) at 450–950 °C. The temperature conditions of the preliminary vacuum treatment of the original indium had the greatest influence on the purity of the synthesised indium phosphide. In the opinion of the authors cited, the concentration of silicon in polycrystalline indium phosphide is lower if the original metallic indium contains oxides, which decompose in a vacuum at >800 °C. Increase in the indium heating temperature from 700 °C to 800 °C led to a sharp increase in the concentration of both the principal charge

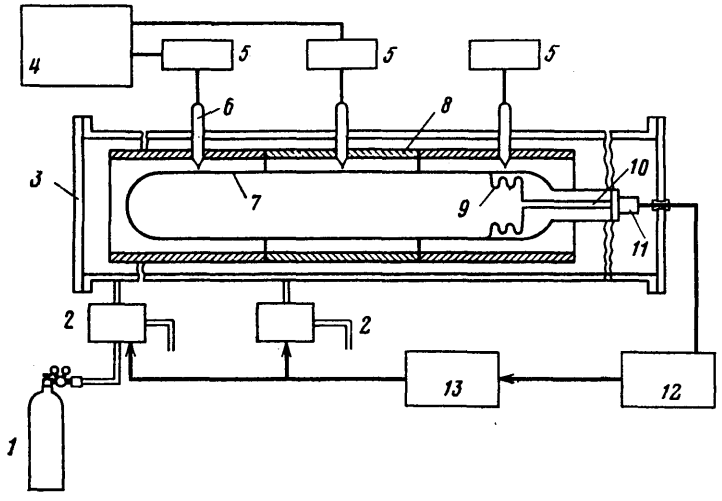

**Figure 1.** Block diagram of the high-pressure apparatus for synthesising polycrystalline indium phosphide ingots, fitted with a system balancing the pressure in the reactor and the autoclave: *1*) cyclinder of inert gas, *2*) high-pressure valve, with electric drive, *3*) autoclave, *4*) potentiometer, *5*) blocks of high-precision temperature regulators (HTR), *6*) thermocouple, *7*) reactor containing boat with indium and red phosphorus (not shown in the diagram), *8*) heater, *9*) quartz bellows, *10*) rod, *11*) high-pressure measuring device, *12*) amplifier, *13*) automatic regulator controlling the operation of the high-pressure valve.[7]

carriers and silicon in the polycrystalline indium phosphide obtained. The authors cited consider that the reaction of indium oxides with phosphorus vapour gives phosphorus(V) oxide, whose partial pressure in the ampoule increases, and the equilibrium[12]

$$10SiO_2(solid) + P_4(gas) \rightleftarrows 10SiO(gas) + P_4O_{10}(gas)$$

is displaced to the left, leading to contamination of indium phosphide by silicon from the quartz boat. Highly pure polycrystalline indium phosphide with $n = 3.2 \times 10^{15}$ cm$^{-3}$ and $u = 3.7 \times 10^4$ cm$^2$ V$^{-1}$ s$^{-1}$ (77 K) has been obtained.[11]

### 3. Crystallisation of a Melt with Non-stoichiometric Composition in a Temperature Gradient

This method of synthesising indium phosphide, called "synthesis with diffusion through a melt", is used mainly by Japanese firms. Recently, however, it has attracted interest from Western European research workers. The chief advantages are the simplicity of the equipment, which does not require the use of autoclave assemblies, and the high purity, compared with HDC and HZF, of the material obtained, resulting from the use of low synthesis temperatures (750–910 °C).

In Ref.13, indium phosphide was synthesised in a sealed quartz ampoule, placed in a two-zone furnace. The starting materials were red phosphorus (5 g) and indium (37.5 g), heated beforehand in a stream of hydrogen at 850 °C for 72 h. A quartz crucible containing red phosphorus was placed in the upper part of the ampoule, and indium in the lower part. The synthesis was carried out at 850 °C and a phosphorus vapour pressure of 0.8 atm (temperature of the upper part of the ampoule 400 °C). The temperature gradient required to crystallise indium phosphide from the saturated solution was created along the height of the melt. Under these conditions the synthesis was continued for 10 d to give a single-crystal ingot of indium phosphide with length and diameter 15 mm, mass 5.5 g, density of dislocations $N_d = 10^2$ cm$^{-2}$. When the process was complete, the indium was found to contain thin plates of indium phosphide with dimensions of several millimetres. The growth rate was 0.15 cm d$^{-1}$. The indium phosphide obtained under these conditions had $n = 2.3 \times 10^{14}$ cm$^{-3}$ and $u = 5.02 \times 10^4$ cm$^2$ V$^{-1}$ s$^{-1}$ (77 K).

To increase the purity of the product, indium was heated beforehand at 900 °C for 6 h; the red phosphorus was also heated beforehand (120 °C for 6 h). At a melt temperature of 910 °C and a temperature gradient in the melt of 20 K cm$^{-1}$, the indium phosphide obtained had $n = 6.4 \times 10^{14}$ cm$^{-3}$ (300 K) and $u = 7.91 \times 10^4$ cm$^2$ V$^{-1}$ s$^{-1}$ (77 K).[14] Later, the same authors reported the preparation of indium phosphide with $n = 5.9 \times 10^{14}$ cm$^{-3}$ (300 K) and $u = 9.67 \times 10^4$ cm$^2$ V$^{-1}$ s$^{-1}$.[15] The principal donor impurities in the indium phosphide are silicon and sulphur.

### 4. Synthesis of Indium Phosphide in Quasi-hermetic Reactors

The most productive method of obtaining polycrystalline indium phosphide is by synthesis in quasi-hermetic reactors, in an autoclave assembly. Fig.2 gives a diagram of the apparatus for synthesising polycrystalline indium phosphide ingots.[16] A hydraulic seal was used to connect the separate parts of the reactor, that is the quartz part containing red phosphorus and the graphite part containing the quartz crucible with indium.

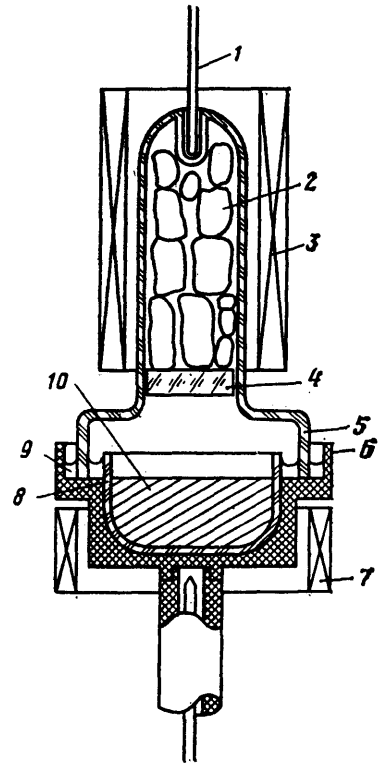

**Figure 2.** Diagram of the quasi-hermetic apparatus for synthesising indium phosphide by the reaction of phosphorus vapour with molten indium: *1*) thermocouple, *2*) phosphorus, *3*) electrical resistance heater, *4*) quartz plate, *5*) quartz reactor, *6*) graphite support, *7*) crucible heater, *8*) quartz crucible, *9*) channel of hydraulic seal, filled with indium, *10*) molten indium.[16]

A weighed specimen of indium (from one to several kilograms) was placed in the crucible. The corresponding stoichiometric quantity of red phosphorus, together with the calculated excess to fill the free volume of the reactor and to compensate the loss through the hydraulic seal (several percent of the total quantity) was placed in the quartz part of the reactor. The high-pressure chamber was evacuated, and then filled with an inert gas at a pressure such that after the heater was switched on, the working pressure in it was 60 to 70 atm. The red phosphorus was then heated to a temperature ensuring that the phosphorus vapour pressure created in the reactor was greater than the equilibrium vapour pressure over the molten compound with the stoichiometric composition (25 atm), and the crucible with the molten indium was heated to 1060 °C, and kept until the synthesis was complete. The temperature of the melt in the crucible was then lowered slowly to give a polycrystalline ingot of the compound. The material had electron conductivity and $n = (1–2) \times 10^{16}$ cm$^{-3}$ and $u = 3500–4500$ cm$^2$ V$^{-1}$ s$^{-1}$ (300 K).[16]

The time required to carry out the synthesis in a quasi-hermetic reactor by the HZF and HDC methods was calculated from the Nernst equation:[17]

$$\tau = \frac{-2.303 \cdot V \cdot \lg[(C_e - C_\tau)/(C_e - C_0)]}{F \cdot \alpha}$$

where $\alpha$ is the reaction coefficient (the rate constant of the first-order reaction taking place on the melt surface), cm $s^{-1}$; $F$ the surface area of the melt, $cm^2$; $C_e$ and $C_0$ the equilibrium (for the given temperature of the melt and vapour pressure of the volatile component) and initial concentrations of the volatile element in the melt, g $cm^{-3}$ or atom $cm^{-3}$; $V$ the volume of the molten non-volatile element, $cm^3$; and $C_\tau$ the concentration of the volatile element in the melt at moment of time $\tau$, g $cm^{-3}$ or atom $cm^{-3}$.

Fairly full thermochemical parameters of the synthesis of indium phosphide are given in Ref.18.

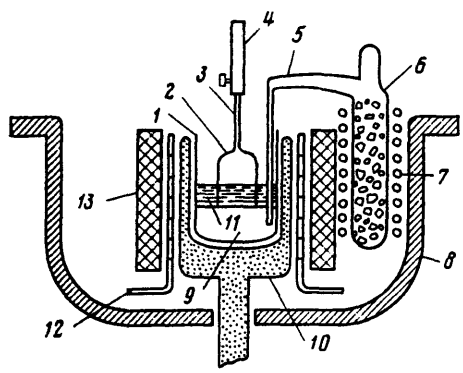

**Figure 3.** Diagram of the thermal unit of the high-pressure apparatus for obtaining indium phosphide crystals by the combined method (synthesis followed by crystal growth): *1*) crucible, *2*) crystal, *3*) seed, *4*) seed holder, *5*) tube for supplying phosphorus vapour from the reservoir, *6*,*7*) electrical resistance heater, *8*) autoclave body, *9*) melt, *10*) graphite support, *11*) layer of flux ($B_2O_3$), *12*) graphite electrical heater, *13*) heat reflecting screen.[19]

### 5. Combined Process

To increase the purity of polycrystalline and single-crystal indium phosphide, a combined process has been used: the synthesis was carried out directly in the apparatus used to grow single crystals; phosphorus vapour (30.6 atm) was supplied to molten indium under a layer of molten boric oxide (Fig.3).[19] The synthesis was carried out at the temperature of the indium–indium phosphide melt (1100 °C) for 1.5 h. This gave indium phosphide crystals with $n = (1.85–2.57) \times 10^{15}$ $cm^{-3}$ and $u = (3.03–3.18) \times 10^4$ $cm^2$ $V^{-1}$ $s^{-1}$ (77 K). The parameters of indium phosphide crystals obtained in quartz and PBN crucibles, and the silicon concentrations [$(0.3–0.5) \times 10^{-4}$ mass % or $(6–10) \times 10^{15}$ atom $cm^{-3}$], differed little. Approximately the same quantity of silicon is present in polycrystalline indium phosphide synthesised by other methods.

Examination of the methods for synthesising polycrystalline indium phosphide leads to the following conclusions.

1. To obtain weakly-doped single crystals with a concentration of charge carriers lower than $10^{17}$ $cm^{-3}$, the most suitable method is horizontal zone fusion. When systems controlling the pressure in the hermetic reactor and the gas pressure in the autoclave are developed, this method will satisfy all the requirements of ecological purity and safe operation.
2. Material to be used to grow highly-doped indium phosphide single crystals is best synthesised in a quasi-hermetic reactor. This method has a high productivity, and the cost of the final product is low.
3. The liquid-phase epitaxy of layers of indium phosphide and solid solutions based on it requires a relatively small quantity of highly pure polycrystalline indium phosphide. This material can be obtained by different versions of the directed crystallisation of indium–phosphorus melts with non-stoichiometric composition. Crystallisation at temperatures not exceeding 900 °C ensures minimum contamination of the final product by the reaction of the melt with the material of the container.

## III. THE GROWTH OF SINGLE CRYSTALS OF INDIUM PHOSPHIDE BY LIQUID HERMETIC SEALING OF THE MELT

### 1. Apparatus and Conditions for Growing Single Crystals of Indium Phosphide without Twins

One of the most widely encountered versions of the Czochralski method[18] is the so-called method of liquid hermetic sealing of the melt with a flux (LHM), widely used to grow single crystals of semiconducting compounds which may decompose. Single crystals of indium phosphide are grown by LHM in autoclave assemblies using resistance or high-frequency heating. The process is carried out in an inert gas (nitrogen or argon) atmosphere at a pressure of 30–60 atm. Boric oxide is used as flux.

Workers at the Nippon Telegraph and Telephone Public Corporation (Japan) have grown single crystals of indium phosphide in MSR6R high-pressure assemblies (Metals Research, England) using resistance heating. The temperature of the melt in the quartz crucible was kept constant to within ±0.1 K using a thermocouple placed at the bottom of the crucible. The starting material, synthesised by HZF, with $n = (8–40) \times 10^{15}$ $cm^{-3}$ (300 K), was placed in crucibles with diameter 50 mm or 100 mm (95 g and 300 g respectively). The thickness of the layer of flux varied from 6 mm to 24 mm.[20–22] Single crystals of indium phosphide were grown in the crystallographic direction <111>; the seed was raised at a rate of 10–12 mm $h^{-1}$. The crucible and the seed were rotated in the same direction at rates of 5 r.p.m. and 3 r.p.m. respectively. A nitrogen pressure of 35 atm was maintained in the chamber. This gave non-doped single crystals of indium phosphide with diameter 25 mm, with $n = 4.8 \times 10^{15}$ $cm^{-3}$ and $u = 2.68 \times 10^4$ $cm^2$ $V^{-1}$ $s^{-1}$ (77 K).[22]

Specialists at Bell (USA) used an autoclave assembly with induction heating (450 kHz) to grow single crystals of indium phosphide. The original polycrystalline material with $n = (2–5) \times 10^{15}$ $cm^{-3}$ (77 K) was synthesised by HDC. The single crystals were grown in the crystallographic direction <111> under the following conditions: nitrogen pressure in the compartment 38 atm; seed raised at a rate of 13–17 mm $h^{-1}$; rate of rotation 20–30 r.p.m.; thickness of layer of flux 5 mm (15 g boric oxide). The crucibles, with diameter

38 mm, were made of quartz or PBN. The non-doped single crystals of indium phosphide with diameter 30 mm and 80 mm had $N_d = 7 \times 10^3 - 5 \times 10^5$ cm$^{-2}$.[1,2,23]

Single crystals of indium phosphide with large diameter (greater than 40 mm) have been grown in MSR6R and Melbourn (England) assemblies. In the first assembly, crystals were grown in the crystallographic directions <111> and <100> in quartz or PBN crucibles with height and diameter 100 mm, containing the original polycrystalline indium phosphide (1 kg). Crystallisation at a rate of 9 mm h$^{-1}$ gave non-doped single crystals of indium phosphide with diameter 45–60 mm, mass 800 g, and $N_d = (1-10) \times 10^4$ cm$^{-2}$.[10]

Single crystals of indium phosphide with diameter 80 mm and mass 3 kg were grown in the Melbourn apparatus from crucibles with height and diameter 150 mm containing the original polycrystalline indium phosphide (3.5 kg). The density of dislocations in these crystals was $(3-8) \times 10^4$ cm$^{-2}$.[10]

The main technical difficulty in the growth of single crystals of indium phosphide by LHM is twinning of the crystals in the initial stage of growth. When the process is carried out in the crystallographic direction <111>, to prevent twinning, the crystal is grown from a seed to a constant diameter at an angle ≤19° 68′ relative to the growth axis.[1,2,20–28] These growth conditions prevent twinning along the (111) planes (Fig. 4), which lie at an angle of 70° 32′ to the direction of growth.

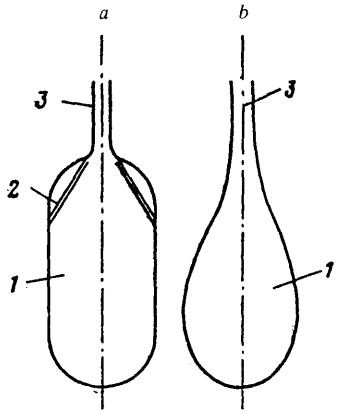

**Figure 4.** Profile of single crystals of indium phosphide grown from the seed to the nominal diameter in the <111> direction at an angle greater than (a) and less than (b) 19° 68′: *1*) single crystal, *2*) twinning planes, *3*) seed.[2]

When single crystals of indium phosphide are grown in the crystallographic direction <100>, the probability of twinning is reduced considerably if the crystal is grown from the seed to a constant diameter without vertical movement of the seed (angle of growth relative to the growth axis ~90°).[10]

During growth, twins may be produced in the crystal as a result of the introduction into the crystallisation front of foreign inclusions (oxides, gas bubbles, etc.) present on the surface of the molten indium phosphide. Special preparation of the flux to obtain a pure melt (without bubbles) has been carried out in a platinum crucible at 1000 °C in a vacuum for 24 h.[1,29] Before use, the boric oxide was kept in a quartz ampoule in a vacuum at $5 \times 10^{-6}$ mmHg. The residual bubbles were removed from the flux by rotating the seed at an increased rate (greater than 20 r.p.m.).

The thermal decomposition of the indium phosphide single crystal after its removal from under the layer of flux may lead to the flow of the free indium liberated along the crystal to the crystallisation front.[21] Thus to prevent decomposition of the surface of the single crystal of indium phosphide it is necessary, after removing it from under the layer of flux, to cover it with a thin layer of flux. To achieve this, the temperature of the flux must be kept at ~550 °C.

The probability of twinning in single crystals of indium phosphide is reduced by decreasing the thermoelastic stresses produced during growth, and also by doping the indium phosphide with strengthening impurities such as zinc and sulphur (not more than $10^{18}$ atom cm$^{-3}$ [29] or antimony $(1.7-7.2) \times 10^{-3}$ mass %.[30]

## 2. Preparation of Highly Pure Non-Doped Single Crystals of Indium Phosphide

During the growth of single crystals of indium phosphide by LHM, the product is contaminated by impurities entrained by the faces of the granules of the original polycrystalline material and impurities present in the flux (boric oxide).[29] Another source of contamination is the volatilisation of impurities from the graphite screens.[15] Thus when screens previously heated in a vacuum at 1300 °C were used, the concentration of principal charge carriers in indium phosphide was lowered by a factor of approximately two. Silicon is the chief background impurity, and it produces marked changes in the characteristics of instruments based on indium phosphide:[15,21,22,29] the concentration of silicon is $(6-16) \times 10^{15}$ atom cm$^{-3}$.[22,31]

During the growth of single crystals in a quartz crucible, silicon is transferred to the melt as a result of a reaction between indium phosphide and silicon(IV) oxide.[15] To decrease the concentration of silicon in the melt and the crystal, PBN crucibles are used. Another source of silicon is low-melting borosilicate glass, a thin layer of which is formed on the walls of the quartz crucible.[32] Since the chemical bond between silicon and oxygen is weaker in this layer, the transfer of silicon to the indium phosphide melt is facilitated. An increase in the concentration of silicon in the flux (boric oxide) has been detected after indium phosphide crystals have been grown in a quartz crucible. In the flux situated at the centre of the crucible, the silicon concentration was 62 times that in the original boric oxide, and at the wall of the quartz crucible the corresponding factor was 2200. When PBN crucibles were used, the concentration of silicon in the flux after the growth of indium phosphide crystals remained unchanged. This confirms that PBN crucibles must be used to grow highly pure indium phosphide crystals by LHM.

A change in the nature of the distribution of silicon in a crystal grown in a PBN crucible has been detected:[32] the effective distribution coefficient increased to $k > 1$. This change is apparently due to the extraction of silicon from the indium phosphide melt by the boron(III) oxide flux.

It should however be noted that the use of PBN crucibles leads to appreciable contamination of indium phosphide by boron, and in some cases to the appearance of traces of a second phase during growth, as a result of the reaction of boric oxide with PBN.[9]

To increase the purity of indium phosphide, melts with non-stoichiometric composition have been crystallised;[33] the original polycrystalline material, synthesised by HZF in a high-pressure assembly, was crystallised (at a rate of 6 mm $h^{-1}$) by LHM with the addition of 10 mass % and 20 mass % indium. The addition of 20 mass % indium gives best results. In the first case (10 mass % indium), original material with $n = 4 \times 10^{15}$ $cm^{-3}$ and $u = 1.815 \times 10^{4}$ $cm^2$ $V^{-1}$ $s^{-1}$ (77 K) gave an indium phosphide crystal with $n = 3.24 \times 10^{15}$ $cm^{-3}$ and $u = 3.015 \times 10^{4}$ $cm^2$ $V^{-1}$ $s^{-1}$ (77 K). In the second case (20 mass % indium), a material with $n = 9.02 \times 10^{15}$ $cm^{-3}$ and $u = 7.5 \times 10^{3}$ $cm^2$ $V^{-1}$ $s^{-1}$ gave a crystal with $n = 9.36 \times 10^{15}$ $cm^{-3}$ and $u = 1.517 \times 10^{4}$ $cm^2$ $V^{-1}$ $s^{-1}$ (77 K). The concentration of silicon in the best indium phosphide specimens obtained by LHM was (1.0–1.5) $\times 10^{-6}$ at.% or (2–3) $\times 10^{14}$ atom $cm^{-3}$.

### 3. Production of Doped Single Crystals of Indium Phosphide

To obtain single crystals with electron and hole conductivity and a high concentration of principal charge carriers, used to produce optoelectronic instruments, indium phosphide is doped with the donor impurities tin and sulphur and the acceptor impurity zinc (see Table).

Parameters of single crystals of indium phosphide with diameter 40–55 mm, produced by Sumimoto (Japan) in 1982.[34]

| Dopant | Electrophysical parameters at 300 K | | | Dislocation density, $cm^{-2}$ (not more than) |
|---|---|---|---|---|
| | concentration of principal charge carriers, $cm^{-3}$ | mobility of principal charge carriers, $cm^2V^{-1}s^{-1}$ | specific resistance, Ω.cm | |
| Tin | $5\times10^{17}$–$6\times10^{18}$ | 1200–2500 | $5\times10^{-4}$–$6\times10^{-3}$ | $5\times10^{4}$ |
| Sulphur | not less than $2 \times 10^{18}$ | 800–1800 | not more than $1.8 \times 10^{-3}$ | $5\times10^{3}$ |
| Zinc | not less than $2 \times 10^{18}$ | 35–60 | not more than $5 \times 10^{-2}$ | $5\times10^{3}$ |
| Zinc | $1\times10^{18}$–$5\times10^{18}$ | 80–150 | 1.5–80 | $5\times10^{4}$ |

In the USSR, single crystals of indium phosphide doped with tellurium are also used (diameter 20–40 mm; length not less than 25 mm), with $n = (5–500) \times 10^{16}$ $cm^{-3}$, $u = (1$ to $2.5) \times 10^{3}$ $cm^2$ $V^{-1}$ $s^{-1}$ (300 K), and $N_d < 5 \times 10^{4}$ $cm^{-2}$.

Doping indium phosphide with iron and chromium impurities gives single crystals with a high specific resistance. The specific resistance (ρ) of single crystals of indium phosphide doped with chromium does not exceed $5 \times 10^{3}$ Ω.cm,[35] whereas doping with iron gives a material with $\rho > 10^{7}$ Ω.cm.[2,15,19,35–38] Thus iron is usually employed to obtain semi-insulating indium phosphide.

Single crystals of semi-insulating indium phosphide have been grown by LHM in the crystallographic directions <111> and <100>. The starting material was indium phopshide with maximum purity ($n = 5 \times 10^{15}$ $cm^{-3}$ and $u = (2.5–3.5) \times 10^{4}$ $cm^2$ $V^{-1}$ $s^{-1}$),[15,34] giving crystals with $\rho > 10^{7}$ Ω.cm with a low concentration of iron in the melt (0.002–0.04 mass %).

Fig.5 gives the dependence of the specific resistance of indium phosphide on the proportion of crystallised melt for different concentrations of iron in it. To obtain crystals with $\rho > 10^{7}$ Ω.cm along the entire length it is evidently necessary to add 0.02–0.04 mass % iron to the melt. With increase in the concentration of iron in the melt to 0.1 mass %, the production of single crystals is made difficult by twinning as a result of non-metal inclusions on the surface of the melt.[15] To ensure thermal stability of the material during annealing after iron implantation, it is necessary to lower the iron concentration to 0.022 mass %. If the iron concentration in the crystal exceeds $8.8 \times 10^{15}$ atom $cm^{-3}$, then the specific resistance after annealing the indium phosphide specimens at 750 °C is lowered.[36]

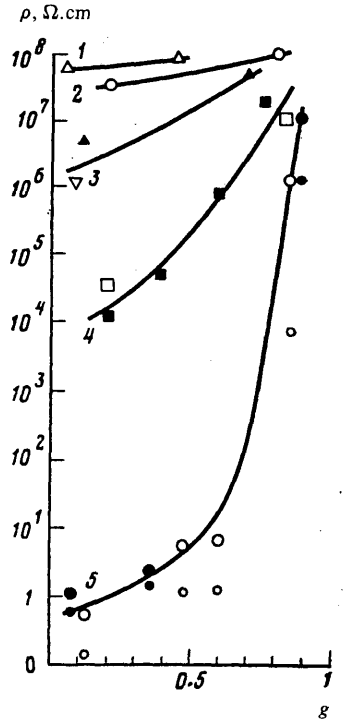

**Figure 5.** Distribution of the specific resistance along the length of a single crystal (*g*) of semi-insulating indium phosphide doped with iron (mass % in the melt): *1*) 0.15; *2*) 0.04; *3*) 0.02; *4*) 0.01; *5*) 0.005.[15]

Single crystals of semi-insulating indium phosphide with diameter 45–55 mm have been grown in the crystallographic direction <100> in autoclave assemblies under a nitrogen pressure of 50 atm (seed raised at a rate of 7–10 mm $h^{-1}$, rate of rotation of the seed and the crucible 7–15 r.p.m.) from under a layer of flux with thickness 18–20 mm. The temperature gradient in the region of the flux–melt boundary was about 100 K $cm^{-1}$. The dislocation density was (2–4) $\times 10^{4}$ $cm^{-2}$ in the initial section of the ingots, and (6–15) $\times 10^{4}$ $cm^{-2}$ in the final section.[36]

Polycrystalline indium phosphide with $n = (2–4) \times 10^{15}$ $cm^{-3}$ and $u = (2.5–3.0) \times 10^{4}$ $cm^2$ $V^{-1}$ $s^{-1}$ (77 K) has been used[26] to obtain cobalt-doped ($2 \times 10^{-3}$ mass %) semi-insulating indium phosphide with $\rho > 10^{7}$ Ω.cm. The effective distribution coefficient of cobalt in the indium phosphide was $4 \times 10^{-5}$, and the concentration of cobalt in the initial section of the crystal was $4 \times 10^{15}$ atom $cm^{-3}$. At this concentration of cobalt in the crystals, however, there was considerable separation of secondary phases—cobalt(III) phosphide and

phases of indefinite structure containing 70 mass % phosphorus and 30 mass % cobalt.[26,39] The separation of secondary phases began approximately half way along the length of the ingot.

### 4. Preparation of Low-Dislocation and Dislocation-Free Single Crystals of Indium Phosphide

To obtain low-dislocation and dislocation-free semiconductor single crystals, the thermoelastic stresses $\tau_{te}$ produced in the crystal during growth and cooling should not exceed the critical stresses of dislocation formation $\tau_{cr}$. The values of $\tau_{te}$ can be lowered, and the minimum density of dislocations in single crystals of indium phosphide obtained, by growing under temperature conditions ensuring the minimum axial and radial temperature gradients.

Dislocation-free non-doped single crystals of indium phosphide with diameter not greater than 15 mm have been obtained by growing a thin "neck" on the seed.[20-22] This method made it possible to obtain dislocation-free single crystals on seeds with a dislocation density of $10^5$ cm$^{-2}$. After the annihilation of the dislocations in the "neck", new dislocations were produced in the crystal when the diameter exceeded the critical value, which depends on the axial and radial gradients. Small temperature gradients $\partial T/\partial x$ were achieved by increasing the thickness of the layer of boric oxide ($\delta$). Thus for $\delta$ = 6 mm, $\partial T/\partial x$ = 175 K cm$^{-1}$, which ensured the production of non-doped dislocation-free single crystals of indium phosphide with diameter 8 mm. At $\delta$ = 13 mm and $\partial T/\partial x$ = 55 K cm$^{-1}$, the diameter of the dislocation-free crystals increased to 15 mm.[21]

A theoretical calculation[21] has shown that to obtain non-doped dislocation-free single crystals of indium phosphide with diameter 25 mm it is necessary to decrease the temperature gradient to 20 K cm$^{-1}$, or to 5 K cm$^{-1}$ for a diameter of 50 mm. It is practically impossible, however, to achieve these gradients, either by increasing the thickness of the layer of flux or by other methods. Thus the maximum diameter of non-doped dislocation-free single crystals of indium phosphide is not greater than 15 mm. With increase in the diameter of the crystal, dislocations are generated at the periphery of the ingot and multiply into the depth of the crystal.

The dislocation density in indium phosphide crystals with a large diameter (>40 mm) during growth has been reduced using a system for automatically controlling the diameter by weighing the crucible.[15,24-27,36] The stresses in the crystal after growth were removed by annealing at a high inert-gas pressure (~38 atm).[2,23] This decreased the dislocation density by a factor of approximately ten.[2]

A more promising method for decreasing the dislocation density in indium phosphide is by increasing $\tau_{cr}$ by doping with strengthening impurities. Impurity atoms with dimensions smaller than those of the atoms of the components of the semiconducting compound being replaced lower considerably the dislocation density in single crystals of these compounds. The same applies to a lesser extent to large atoms (Fig.6).[40] Zinc, sulphur, and germanium are used as impurities of this kind.[24,41,42]

Calculation shows that the maximum thermoelastic stresses produced during the growth of single crystals of indium phosphide correspond to 800 °C. The difference in the values of $\tau_{cr}$ for non-doped single crystals and single crystals doped with zinc ($2 \times 10^{18}$ atom cm$^{-3}$) is extremely large (Fig.7). This calculation confirms the temperature range of dislocation formation obtained by analysing the characteristic features of the dislocation structure.[42]

Increase in the concentration of zinc to $10^{19}$ atom cm$^{-3}$ and of sulphur to $10^{19}$ atom cm$^{-3}$ has been used to obtain dislocation-free single crystals of indium phosphide with a diameter of not more than 30 mm.[41] Combined doping with zinc and sulphur to a total concentration of $2 \times 10^{19}$ atom cm$^{-3}$ made it possible to lower the dislocation density in single crystals of indium phosphide with diameter 30 mm to $10^2$–$10^3$ cm$^{-2}$.[43]

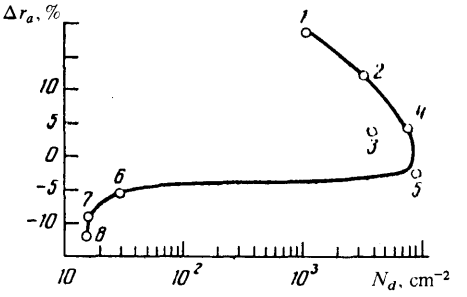

**Figure 6.** Influence of the difference between the tetrahedral radii of the impurity and the atom of the compound being replaced ($\Delta r_a$) on the dislocation density ($N_d$) in single crystals of indium phosphide and gallium arsenide doped with various elements: *1*) InP(Te); *2*) GaAs(Te); *3*) InP(Se); *4*) GaAs(Zn); *5*) InP(Sn); *6*) InP(S); *7*) InP(Zn); *8*) GaAs(S).[40]

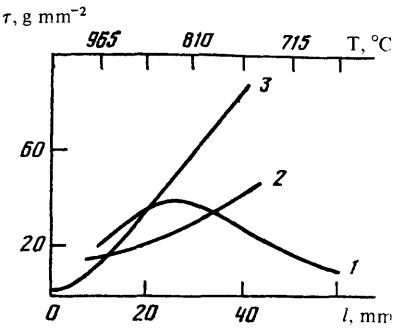

**Figure 7.** Comparison of the thermoelectric stresses ($\tau_{te}$) along the axis of indium phosphide crystals and the critical stresses of dislocation formation ($\tau_{cr}$) at corresponding temperatures at a distance $l$ from the crystallisation front: *1*) $\tau_{te}$; *2*) $\tau_{cr}$ for non-doped indium phosphide; *3*) $\tau_{cr}$ for indium phosphide doped with zinc ($p = 2 \times 10^{18}$ cm$^{-3}$).[42]

Single crystals of indium phosphide with diameter 26 mm, doped with germanium ($1.5 \times 10^{17}$–$1.6 \times 10^{19}$ atom cm$^{-3}$), have been grown in the crystallographic direction <111>.[24] Dislocation-free crystals were obtained with $n = 1.1 \times 10^{19}$ cm$^{-3}$ and $n = 1.6 \times 10^{19}$ cm$^{-3}$; in other cases the dislocation density was $(2.2–5) \times 10^4$ cm$^{-2}$. Decrease in the dislocation

density began at a germanium concentration greater than $7 \times 10^{18}$ atom $cm^{-3}$. A disadvantage of doping with germanium is that large defects (>50 nm) of unusual shape (oval), lying on dislocation lines, appear in the indium phosphide structure.[25,27,37,42,44] Thus in practice, doping with zinc and sulphur is used to decrease the dislocation density in indium phosphide. In Japan, low-dislocation single crystals of indium phosphide with $N_d < 10^2$ $cm^{-2}$ and diameter 20–30 mm have been obtained on the industrial scale.

Attempts to dope indium phosphide with isovalent impurities, which have been used successfully to dope gallium arsenide (antimony, arsenic, etc.), have not yet given satisfactory results.[45]

### 5. Some Characteristic Features of the Dislocation Structure of Single Crystals of Indium Phosphide

Selective chemical etching of indium phosphide specimens has revealed several types of etch pit, corresponding to linear dislocations, dislocation loops, and dislocation clusters. In addition, in some specimens, *s*-shaped etch pits of non-dislocation character (fine-point background) have been detected. This background has been observed in single crystals of indium phosphide doped with tin ($2 \times 10^{18}$ atom $cm^{-3}$; density of *s*-shaped etch pits $6 \times 10^4$ $cm^{-2}$) and sulphur ($10^{19}$ atom $cm^{-3}$; density of *s*-shaped etch pits $2 \times 10^3$ $cm^{-2}$).[41]

Structural defects of the dislocation cluster type have been detected by selective chemical etching and X-ray topography both in non-doped indium phosphide single crystals and in specimens doped with germanium, tin, iron, and selenium.[21,25,27,37,41,44] The size of the clusters varied from 5 nm to 200 nm. They consist of a central region, surrounded by prismatic dislocation loops, ordered along twelve <110> axes. The central region consists of a compact accumulation of dislocations, and contains complexes of two types: triangular, with dimensions 0.5–8 nm, and spherical, with dimensions 5–8 nm.[25,40] The chemical nature of the clusters is not clear, but studies have shown that there is an excess of indium at the points where they are situated. A model has been proposed[37] for the production of the clusters, based on the interaction of antistructural defects with moving dislocations.

Dislocation clusters with a density of $10^2$–$10^3$ $cm^{-3}$ have been detected[27] in non-doped single crystals of indium phosphide and in specimens doped with germanium. No relationship was detected between the germanium concentration and the appearance of the clusters. The distribution of the clusters along the length of the ingot was regular, although some specimens showed a decrease in their density towards the end of the ingot. The density of the clusters increased with increase in the quantity of macroscopic defects (such as twins). After annealing the specimens at 800 °C for 1, 4, and 8 h, the density of the clusters increased from $1.8 \times 10^2$ $cm^{-2}$ to $4.3 \times 10^2$ $cm^{-2}$. If the specimen did not contain clusters, they were not formed during annealing. An important characteristic of the annealing was the increase in the size of the clusters as a result of the enlargement of the dislocation loops, and not an increase in the number of dislocations.

In the opinion of the authors cited,[25,27] the main reason for the appearance of clusters is the presence of water in the flux. The reaction of water with indium phosphide gives phosphorus vapour, whose inclusion leads to the production of stresses and to the formation of clusters. Dehydrating the flux by heating made it possible to obtain crystals without dislocation clusters.

# The Oxidative Cleavage of the Silicon-Silicon Bond

G.A.Razuvaev, T.N.Brevnova, and V.V.Semenov

Data on the oxidative cleavage of single and double silicon-silicon bonds in inorganic and organic polysilanes with linear and cyclic structures have been summarised. Particular attention has been paid to studies in which the mechanisms of the oxidation are discussed. The nature of the silicon-silicon bond in organopolysilanes and disilenes has been briefly reviewed. The bibliography contains 248 references.

## I. INTRODUCTION

Compounds with silicon–silicon bonds have not yet found such wide application as, for example, organopolysiloxanes, but the chemistry of compounds of this class[1-23] is now being intensively developed. Important recent achievements include the synthesis of stable disilenes, that is compounds with a silicon–silicon double bond.[24,25] The possible use of polysilanes to obtain silicon carbide materials,[26-30] as components of catalytic systems for the polymerisation of ethylene hydrocarbons,[31,32] and as stabilisers of polyvinyl chloride,[33] silylating and reducing reagents,[34] and also semiconductors,[35-36] is being studied.

The aim of the present review is to show how the reactivity of the Si–Si bond with respect to oxidation reactions of different types depends on the type of polysilane, the substituents on the silicon atom and in the organic group, the size of the ring, the length of the $-(-\mathrm{Si}-)_n-$ chain, and various other factors. Of greatest interest in this connection are studies in which the mechanisms of the oxidation reactions are discussed, and also studies from which it is possible to reach definite conclusions about the influence of the structure of the polysilane on its reactivity. Material on the application of reactions of this type in synthesis have not been considered, since this topic has been dealt with in detail in a number of reviews.[1,2,7-9,17,18] The photochemical and thermal reactions of polysilanes, taking place via radical, silylene, and sila-alkene intermediates, are discussed very briefly. The review does not deal with reactions taking place under the influence of catalysts.

Extensive material on the study of the properties of the Si–Si bond by spectroscopic methods has now accumulated. The use of spectroscopic data is extremely fruitful in the examination of the reactivity of polysilanes. For this reason, a separate section deals briefly with the properties of the silicon–silicon bond, based chiefly on ultraviolet spectroscopic data.

## II. THE NATURE OF THE SILICON–SILICON BOND

In 1962, the ultraviolet spectrum of hexaphenyldisilane was found to contain a band at 240 nm,[37] not observed for tetraphenylsilane. At first, the authors cited attributed the appearance of this band to strong interactions between the phenyl groups via the 3*d* atomic orbitals (AO) of the two silicon atoms of the disilane bridge. It was subsequently shown,[38-40] however, that the absorption in the region of 240 nm is characteristic of the $-(-\mathrm{SiR_2}-)_n-$ and $\mathrm{Ph}-(-\mathrm{SiR_2}-)_n-$ systems, that is that the chain of silicon atoms itself shows chromophoric properties and also undergoes conjugation with the π-electrons of the aromatic ring. Increase in the length of the polysilicon chain and the pres- of phenyl or vinyl substituents at its ends displace the absorption band maximum to longer wavelengths. The ultraviolet spectra of linear and cyclic organopolysilanes with different substituents on the silicon atoms,[41-57] and compounds containing chains of other group IVb elements (Ge, Sn, Pb),[58,59] have been studied. The photoelectron spectra (PES) and electronic absorption spectra of charge-transfer complexes (CTC) show that the electrons of the silicon–silicon bond have a relatively low first ionisation potential (8.69 eV for hexamethyldisilane), which decrease with increase in the polysilane chain length. These data indicate that the energy levels of the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO) of polysilanes approach one another with increase in the number of silicon atoms. A similar phenomenon is observed more clearly in conjugated polyenes. In alkanes also, there is a slight displacement of the absorption maximum towards longer wavelengths. It was therefore concluded[55,60] that as in saturated hydrocarbons, in polysilanes there is delocalisation of electrons through the $\sigma_{C-C}$ or $\sigma_{Si-Si}$ bonds, the delocalisation being very slight in alkanes, but considerable in polysilanes. Thus the $-(-\mathrm{MR_2}-)_n-$ (M = Si, Ge, Sn) systems as it were occupy an intermediate position between saturated hydrocarbons and polyenes, that is they show signs of "double-bond character".

The unoccupied 3*d* AO of silicon have been used to explain the delocalisation of electrons along the $-(-\mathrm{SiR_2}-)_n-$ chains. For example, the absorption in the region of 240 nm has been attributed[39,41] to transitions of the π or $\sigma_{Si-Si}$ electrons of the $\mathrm{Ph}-(-\mathrm{SiR_2}-)_n-$ fragment into non-bonding molecular orbitals formed by the combination of unoccupied 3*d* AO of the silicon atoms; the possible partial transfer of the electron density of the $\sigma_{Si-Si}$ bond into the 3*d* AO and delocalisation through the system of *d* orbitals of silicon in the ground state: Si–Si ↔ Si⋯⋯Si have been assumed.[4,5] It has been suggested[61-64] that the π electrons of multiple bonds or

the lone pairs of electrons of the oxygen atoms in alkoxypolysilanes may be partly transferred not only to the first silicon atom ($p_\pi$, $d_\pi$ conjugation) but also to subsequent atoms ($p_\pi$, $d_\pi$, $d_\pi$ conjugation). It has been shown,[65] however, that to explain the photoelectron spectra of permethylsilanes it is not necessary to introduce the unoccupied 3*d* AO of silicon. Electron delocalisation can take place through the system of $\sigma_{Si-Si}$ bonds ($\sigma$, $\sigma$ conjugation).[20-22] For example, in octamethyltrisilane the original level of the $\sigma_{Si-Si}$ electrons ($\alpha_{Si-Si}$ = 8.69 eV) is split into two $\sigma$-orbital levels $\alpha_{Si-Si} + \beta$ and $\alpha_{Si-Si} - \beta$. A quantitative expression of the interaction of two $\sigma_{Si-Si}$ bonds is provided by the magnitude of the resonance integral $\beta_{Si-Si}$, which has been estimated as −0.5 eV.[65]

It has been shown[14,15,56,66-73] that a system of $\sigma_{Si-Si}$ bonds can interact with different $\pi$- and *n*-electron systems (phenyl, naphthyl, vinyl, −O−, −S−). Analysis of data obtained from the photoelectron spectra and electronic absorption spectra of CTC shows that significant interaction of a $\sigma_{Si-Si}$ bond with $\pi$- and *n*-electron systems takes place at differences in the levels of the HOMO ($\Delta E$) of the interacting fragments up to 0.5–0.6 eV. At these $\Delta E$ values, the $\sigma_{Si-Si}$–$\pi$ or $\sigma_{Si-Si}$–*n* interaction is 0.25–0.72 eV. At $\Delta E$ = 1 eV or more, the $\sigma_{Si-Si}$–$\pi$ interaction is slight, and amounts to less than 0.1 eV. In the ultraviolet spectrum of a substituted disilane, the long-wave absorption maximum may undergo an appreciable bathochromic shift, as for example in vinylpentamethyldisilane and 1,2-divinyltetramethyldisilane.[73] The displacement of the absorption maximum to longer wavelengths without a significant change in the first ionisation potential of substituted polysilane is attributed to the interaction of the $\sigma^*_{Si-Si}$ and $\pi^*$ molecular orbitals.[73]

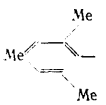
The high polarisability of the silicon–silicon bond is revealed by the ability of organopolysilanes to form charge-transfer complexes with various electron acceptors, for example tetracyancethylene,[74,75] and by their higher reactivity, compared with aliphatic hydrocarbons. Some similarity in chemical behaviour between Si–Si and C=C bonds can be demonstrated for reactions with such electrophilic reagents as peroxybenzoic acid and bromine. The reaction takes place with cleavage of the Si–Si or C=C bonds via the formation of donor–acceptor complexes, in which electron density is transferred from the $\sigma_{Si-Si}$ or $\pi_{C-C}$ bonds to the molecular orbitals of the electrophile.

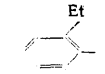
$$R_3SiSiR_3 + PhCO_3H \rightarrow R_3SiOSiR_3 + PhCOOH$$

$$R_3SiSiR_3 + Br_2 \rightarrow 2R_3SiBr$$

$$RCH{=}CH_2 + PhCO_3H \rightarrow RCH(O){-}CH_2$$

$$RCH{=}CH_2 + Br_2 \rightarrow RCH(Br){-}CH_2(Br)$$





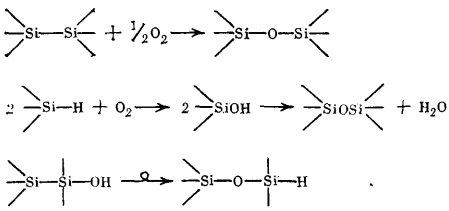
At the same time, organopolysilanes also take part in transformations characteristic of saturated hydrocarbons, for example isomerisation.[11]

$$Me_3SiSiMe_2SiMe_2SiMe_3 \xrightarrow{AlCl_3} (Me_3Si)_3SiMe$$

$$MeCH_2CH_2Me \xrightarrow{AlCl_3} Me_3CH$$

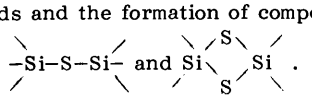
In 1981, West and co-workers reported the synthesis of tetramesityldisilene, the first stable compound with a silicon–silicon double bond.[24,25] This was followed by the preparation of several more representatives of this class of compound, including some with alkyl substituents. The chief factor leading to stabilisation of the Si=Si bond is the presence of bulky substituents on silicon. Some physicochemical characteristics of a number of disilenes are given in the Table.[76-89] The Si=Si bond length is approximately 0.18–0.20 Å shorter than the typical silicon–silicon single bond length.[78,84] The decrease in length due to $\pi$-bonding is 8–9% for disilenes, and about 12% for alkenes.[78] The four Si–C bonds in tetramesityldisilene are approximately coplanar.[76,79] From data on the measurement of the anisotropy of the $^{29}$Si chemical shift it was concluded that the electronic structures of the Si=Si and C=C bonds are completely analogous.[79] The contribution of the $\pi$–component is considerable.

Physicochemical characteristics of disilenes $R_2Si{=}SiR_2$.



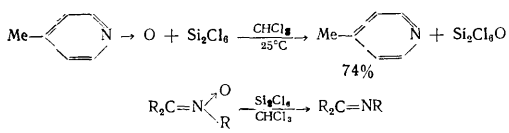
| R | $r_{Si=Si}$, Å | $\lambda_{max}$, nm | M.p., °C | Refs. |
|---|---|---|---|---|
|  | 2.16 | 420 | 178 | [24,25, 76–79] |
|  | — | 422 | 216–217 | [80,82] |
|  | 2.14 | 426 | 201–204 | [84] |
| $Me_3CCH_2$— | — | 400 | — | [85] |
| $Me_3C$— | — | 433 | — | [83,87] |
| $Me_2CH$— | — | 400 | — | [86] |
| $Et_2CH$ | — | 390 | — | [81] |

All prepared disilenes, in solution or the solid state, are bright yellow. The ultraviolet absorption maximum lies at 400–430 nm, and for aryl derivatives it is displaced to longer wavelengths as a result of the perturbation produced by the $\pi$-system of the aryl groups (an exception is tetra-t-butyldisilene, for which an unusually high value of $\lambda_{max}$ = 433 nm is observed[83]). The absorption band in the range 400–430 nm is evidently due to a $\pi$–$\pi^*$ transition, whose energy is much lower in disilenes than in alkenes. The first ionisation potential ($I_1^D$) of tetrakis(2,6-dimethylphenyl)-disilene (8.40 eV)[83] is close to the known values for phenyl-substituted disilanes: $Me_5Si_2Ph$ (8.39 eV), $PhMe_2SiSiMe_2Ph$ (8.23 eV).[90]

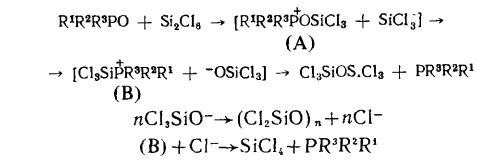


## III. THE OXIDATION OF INORGANIC COMPOUNDS CONTAINING A SILICON–SILICON BOND

Among inorganic silicon derivatives, the highest reactivity towards oxidising agents is shown by the hydrides, with linear, branched $Si_nH_{2n+2}$ ($n$ = 1–6),[3-5,7] and cyclic $(SiH_2)_n$ ($n$ = 5,6) structures.[18,91-93] They are rapidly decomposed by alkalis, and the reaction with oxygen and chlorine takes place with the production of flames or an explosion. The spontaneous flammability of silanes increases in the order $SiH_4 < Si_2H_6 < Si_3H_8$.[3-5] Disilane derivatives such as disilanyl ether $(Si_2H_5)_2O$, bis(disilanyl) sulphide $(Si_2H_5)_2S$, tris(disilanyl)amine $(Si_2H_5)_3N$, and



iododisilane $Si_2H_5I$ are also very sensitive to oxygen.[3] The polymeric silicon hydrides $(SiH_m)_n$ ($m = 1-2$), obtained by different methods,[4,5] are also oxidised in air. The rate of oxidation may vary over a wide range, depending on the method of preparation and the Si/H ratio. In the reaction of amorphous polysilane $(SiH)_n$ with oxygen, three types of transformation are assumed:[4,5,94]



Oxidative cleavage of the Si–Si bond as a result of rearrangement is also possible for polysilanes with alkoxy or thiol groups.[6,16,17,95] In some cases of this kind the reactions are explosive.[16,17] A necessary condition for these rearrangements to take place is the fullest possible replacement of all the remaining valences in the $-(-Si-)_n-$ chain by OH, OR, or SR groups.

Halogenopolysilanes[6,18,19,23,96-99] are much more stable to oxygen than the corresponding silicon hydrides. The perfluorinated compounds are most easily oxidised. Decafluorotetrasilane and the subsequent members of the series, and also the higher fluorides of silicon $(SiF_2)_n$ and $(SiF)_n$ inflame spontaneously in air.[6,100] Perchloropolysilanes react with oxygen much more slowly. For example, the subchloride $(SiCl_2)_n$ inflames in a dry air atmosphere only when heated to 150 °C.[6] The reaction of the subhalides $(SiCl_2)_n$ and $(SiBr_2)_n$ with sulphur[6] takes place at an increased temperature (~170 °C) with cleavage of the Si–Si bonds and the formation of compounds containing the fragments  .

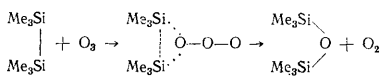
Hexachlorodisilane has been proposed as a reducing agent for the synthesis of organic derivatives of nitrogen, sulphur, and phosphorus.[101-104] The possibilities provided by the method are demonstrated by some examples given below.

The products are obtained in high yields. The reduction takes place rapidly and under mild conditions. This last feature is particularly important for preparing optically active phosphines and their oxides, since racemisation takes place at increased temperatures. The reduction of acyclic phosphine oxides takes place with inversion of the configuration and with a high stereospecificity. The proposed[102] mechanism of reduction includes several successive stages. The reaction begins with nucleophilic attack by the oxygen atom of the oxide on the silicon atom. The trichlorosilyl anion formed reacts with the intermediate (A) to give the trichlorosilylphosphonium cation (B) and a trichlorosiloxy-anion (inversion of the configuration at the phosphorus atom takes place at this stage). The $Cl_3SiO^-$ anion is 70% decomposed to perchloropolysiloxane $(Cl_2SiO)_n$ and $Cl^-$. The remaining 30% $Cl_3SiO^-$, and also $Cl^-$, react with the trichlorosilylphosphonium cation to give hexachlorodisiloxane, silicon tetrachloride, and the optically pure phosphine.

Phosphetane oxides and phosphine sulphides are reduced by hexachlorodisilane with complete preservation of the configuration at the phosphorus atom.[102] Reducing properties are also shown by perchloropolysilanes $Si_nCl_{2n+2}$ ($n > 2$) and by the vat residues from the direct synthesis of methylchlorosilanes.[105] The reactions of oxidative cleavage of the Si–Si bond in chloropolysilanes present in residues from direct synthesis have been reviewed.[106]

## IV. THE OXIDATIVE CLEAVAGE OF THE SILICON–SILICON BOND IN ORGANOPOLYSILANES

### 1. Oxidation of Organopolysilanes with a Linear Structure



#### a) Reactions with oxygen and ozone

Peralkylated organopolysilanes with linear and branched structures are stable to atmospheric oxygen even at increased temperatures. Polysilanes containing the substituents OR, $CH{=}CH_2$, H, Cl, Br, and I in addition to alkyl and aryl groups on the silicon atoms also are not oxidised in air at room temperature. Fluoro-derivatives with the general formula $Si_2F_nMe_{6-n}$, containing two or more fluorine atoms, react with oxygen at 20 °C.[107] The reaction of 1,2-difluorotetramethyldisilane gives a mixture of products:

$$FMe_2SiSiMe_2F \xrightarrow{O_2} (FMe_2Si)_2O + (CH_2O)_n + H_2O + \text{polysiloxanes}$$

The isomeric 1,1-difluorotetramethyldisilane is oxidised much more slowly, and the main product is the corresponding disiloxane. 1,1,2-Trifluorotrimethyldisilane and 1,1,2,2-tetrafluorodimethyldisilane react with oxygen by a free-radical mechanism, analogous to that proposed for the oxidation of distannanes.[108]

Hexamethyldisilane reacts exothermally with ozone to give hexamethyldisiloxane in 95% yield. Bis(trimethylsilyl) peroxide was not found in the reaction products. The cleavage of the silicon–silicon bond by ozone takes place more readily than that of the Si–$C_{alkyl}$ bond. The marked difference in the oxidation rates ensures a high yield of hexamethyldisiloxane. It is assumed that the reaction takes place via a three-membered intermediate complex, and that ozone acts as an electrophilic reagent.[109]

The products and kinetics of the reactions of ozone with a number of organic derivatives of group IVb elements $R_4E$, $R_3EX$, $R_3EER_3$ (X = H, Cl, Br, OR; E = Si, Ge, Sn, Pb) in different solvents have been studied.[110-115] The reactions take place by a bimolecular heterolytic mechanism. The reactivity of the hetero-organic compound and ozone is increased by non-specific solvation. The sensitivity of the reaction to non-specific solvation is greater, the greater the reactivity of the hetero-organic compound (HOC) towards ozone. This result agrees with the suggestion that the polarity of the activated "HOC–ozone" complex is greater than that of the original reagents, and confirms that the

ozonolysis of the HOC takes place by a heterolytic mechanism. It has been shown that ozone takes part in the formation of the activated complex in an amphi-ionic form, in which the nucleophilic centre is localised chiefly on one oxygen atom. The values of the rate constants of reactions of $E_2Et_6$ (E = Si, Ge, Sn, Pb) with $O_3$ correlate satisfactorily with the values of the effective electronegativity of the heteroatom in these compounds, which increase in the order Pb < Sn < Ge < Si. The reactivity of the compounds decreases on going from Pb to Si.

b) Reactions with metal salts and oxides

Organopolysilanes reduce salts of mercury, nickel, platinum, and copper to the corresponding metals.[116–118]

$$Me_3SiSiPh_3 + Hg(OCOMe)_2 \xrightarrow{200^\circ C} Hg + Me_3SiOCOMe + Ph_3SiOCOMe$$
$$(MeO)_2MeSiSi(OMe)_2Me + CuCl_2 \rightarrow Cu + 2MeSi(OMe)_2Cl$$

Silver nitrate and vanadium(V) oxide oxidise disilanes to disiloxanes at increased temperatures.[116,117] Hexaphenyldisilane is very inert towards various oxidising agents. It begins to react with silver or sodium nitrate only when heated to 198 °C or 360 °C respectively.[119]

The oxidative cleavage of the Si–Si bond in polysilanes under the influence of tungsten and molybdenum chlorides has been studied.[120] The linear polysilanes $Si_nMe_{2n+2}$ ($n$ = 2, 3, 4, 6) and the branched polysilane $Si(SiMe_3)_4$ react exothermally with tungsten hexachloride or molybdenum pentachloride in benzene, chlorobenzene, or $CCl_4$ to give chlorosilanes and $WCl_4$ or $(MoCl_3)_x$. In decamethyltetrasilane, the terminal trimethylsilyl groups are removed first.

$$n\text{-}Si_4Me_{10} \xrightarrow{WCl_6} Me_3SiCl + ClMe_2SiSiMe_2SiMe_3$$

The product of the cleavage of octamethyltrisilane–pentamethylchlorodisilane–reacts with $WCl_6$ ten times more slowly than the original trisilane. A linear correlation was established between the first ionisation potentials of the polysilanes and the logarithms of the relative rate constants of the cleavage of the Si–Si bonds. Decrease in $I_1^D$ is accompanied by an increase in the rate of the reaction of the polysilanes with $WCl_6$, indicating that the rate-determining stage of the reaction is the transfer of the electrons of the $\sigma_{Si-Si}$ bond to $WCl_6$.

c) Reactions with halogens

Organopolysilanes are split by halogens to give halogenosilanes.[121–129]

$$R_3SiSiR_3 + X_2 \rightarrow 2R_3SiX$$
$$X = Cl, Br, I$$

When solutions of $Si_2R_6$ (R = Me, Et) and halogens ($Br_2$, $I_2$) are mixed, the ultraviolet spectrum shows a new strong charge-transfer band due to the donor–acceptor complex (DAC) $Si_2R_6.X_2$, not observed in the spectra of the starting materials and final reaction products.[126] In an excess of hexa-alkyldisilane, the rates of consumption of the DAC and the halogen are equal, indicating that the following equilibrium is rapidly established:

$$Si_2R_6 + X_2 \rightleftarrows Si_2R_6 \cdot X_2 .$$

The reaction is of first order with respect to each reagent, and takes place by a molecular mechanism, probably via the DAC detected, in which transfer of electron density takes place from the $\sigma_{Si-Si}$ bond to the molecular orbitals of the halogen.[126,129] The energy and entropy of activation for the reaction of 1,2-diphenyltetramethyldisilane with bromine in $CCl_4$ are 10.5 kcal mole$^{-1}$ and −25.4 e.u. respectively.[128]

The reactivity of the Si–Si bond in polysilanes towards halogens depends markedly on the nature of the substituents on silicon. Hexa-alkyldisilanes react very readily,[123,124] hexa-aryldisilanes react slowly,[123,130] and hexahalogenodisilanes react only at high temperatures.[6,123] The relative reactivity of the halogens decreases in the order $Cl_2 > Br_2 \gg I_2$.[8] In hydrogen-containing disilanes, the Si–H bond reacts first.[123]

$$R_3SiSiR_2H + X_2 \rightarrow R_3SiSiR_2X + HX$$
$$X = Br, I$$

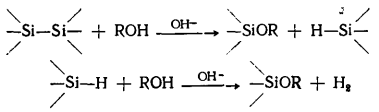
Kinetic studies[122] have shown that the replacement of one methyl group in hexamethyldisilane by a chlorine atom decreases the rate of cleavage by iodine by a factor of approximately ten. The introduction of a second chlorine atom leads to a further decrease in the reaction rate. The silicon–silicon bond in $Cl_2MeSiSiMe_2Cl$ and $Cl_2MeSiSiMeCl_2$ is stable towards halogens.[6,9] On irradiation with light, the methyl groups are chlorinated. The rates of the reactions with halogens are increased by Friedel–Crafts catalysts.[123] In α,ω-dichloropermethylpolysilanes $Cl(Me_2Si)_nCl$ ($n$ = 4–6), the terminal Si–Si bond is less reactive towards chlorine than the inner Si–Si bonds, which are also split by the action of halogen. The relative reactivity of these compounds in chlorination[125] decreases with decrease in $n$: $6 \geq 5 \geq 4 > 3 \gg 2$. In $n$-decamethyltetrasilane, contrary to the result expected from the statistical factor, the inner Si–Si bond is split by bromine more rapidly.[123]

$$n\text{-}Si_4Me_{10} + Br_2 \rightarrow \begin{cases} 2Me_3SiSiMe_2Br\ 57\% \\ Me_3SiBr + BrMe_2SiSiMe_2SiMe_3\ 43\% \end{cases}$$

These data are consistent with electrophilic attack by the halogen on the polysilane molecule. There is a qualitative analogy with the electrophilic addition of halogens to a C=C bond.[131] In the reactions of polysilanes, the nucleophilic centre is the $\sigma_{Si-Si}$ bond. In spite of this, the opposite mechanism has been proposed[127] for the cleavage of aryl-substituted disilanes by bromine, where the silicon atoms of the Si–Si bond act as electrophile centres.

d) Reactions with acids and alkalis

In the reaction of hexamethyldisilane with concentrated sulphuric acid, one or two methyl groups are removed. Subsequent treatment of the reaction mixture with ammonium chloride gives pentamethylchlorodisilane and 1,2-dichlorotetramethyldisilane.[132] In the linear permethylpolysilanes $Me(Me_2Si)_nMe$ ($n$ = 2–4), partial rupture of Si–Si bonds takes place.[8] Gaseous HCl splits the Si–Si bond in permethylpolysilanes[8,9] only at high temperatures.



$$Me_3SiSiMe_3 + HCl \xrightarrow{450^\circ C} Me_3SiCl + Me_3SiH$$

Concentrated nitric acid reacts with hexamethyldisilane according to the equation:[8]

$$Me_3SiSiMe_3 + 2HNO_3 \rightarrow Me_3SiOSiMe_3 + 2NO_2 + H_2O$$

The reactivity of organopolysilanes towards aqueous and alcoholic solutions of alkalis[2,9,133] depends on the substituents on the silicon atoms. Electronegative substituents facilitate cleavage of the Si–Si bond. Peralkylated disilanes do not react with aqueous or alcoholic or alkali solutions, and the ethoxy-substituted $Si_2Me_n(OEt)_{6-n}$ react more rapidly, the smaller $n$; for example, hexa-acetoxydisilane[134] reacts

with aqueous NaOH solution with vigorous liberation of hydrogen. The reaction with alcoholic alkali solutions takes place according to the scheme:

The reaction is used for the quantitative determination of Si–Si bonds in various polysilanes. The reactions of alkalis with disilanes containing halogen atoms in the organic group are more complex.[135]

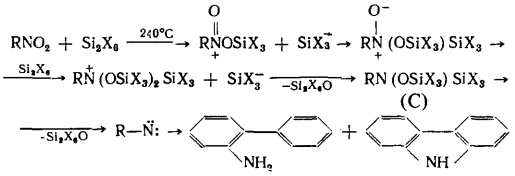
e) Reactions with oxides of nitrogen

Oxides of nitrogen split not only the Si–Si bonds but also Si–C bonds in alkylsilanes.[136]

$$Me_3SiSiMe_3 \xrightarrow{NO_2,\ 20^\circ C} Me_3SiOSiMe_3\ 95\%$$
$$Et_3Si{-}Et \xrightarrow{NO_2} Et_3SiOSiEt_3 + MeCOOH\ 90\%$$

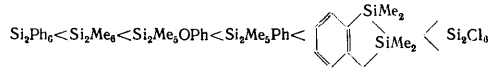
The activity of the oxides in these reactions decreases in the order: $NO_2 > NO_3 > NO > N_2O$. Hexaphenyldisilane does not react with oxides of nitrogen in diethyl ether.[130]

f) Reactions with amine N-oxides



Trimethylamine oxide and pyridine N-oxide behave as nucleophilic reagents towards disilanes. A study of the oxidation of various *meta*- and *para*-substituted phenoxypentamethyldisilanes $Me_5Si_2OC_6H_4X$ by pyridine N-oxide[137] show that the reaction rate increases when electronegative substituents are introduced into the phenyl ring ($\rho = +1.18$). Vinylpentamethyldisilane is oxidised by trimethylamine oxide to vinylpentamethyldisiloxane; the vinyl group is unaffected.[137]

$$H_2C{=}CH{-}SiMe_2SiMe_3 \xrightarrow{Me_3NO} H_2C{=}CH{-}SiMe_2OSiMe_3$$



Organodisilanes can be used as reducing agents in the synthesis of various organic compounds.[138,139] Their reducing power is weaker than that of perchloropolysilanes. For example, hexamethyldisilane does not react with phosphine oxides[102] or amine N-oxides[137] at 70 °C. Aryl-substituted disilanes do not react with dimethyl sulphoxide on prolonged heating up to 100 °C.[140] On the other hand, hexachlorodisilane readily reduces these compounds even at room temperature.[102]

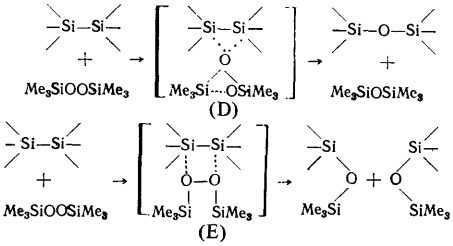
g) Reactions with aromatic nitro-compounds

The reducing properties of substituted disilanes with respect to aromatic nitro-compounds have been studied.[139] When a solution of the reagents in *o*-dichlorobenzene is heated to 240 °C, reaction takes place with the intermediate formation of a nitrene. The reaction mechanism proposed by the authors cited is fairly complex, and involves the nucleophilic attack by $RNO_2$ on silicon with subsequent heterolysis of the Si–Si bond. The nitrene is formed as a result of the removal of the disiloxane from the bis(silyl)hydroxylamine intermediate (C). [With 2-nitrobipherryl the products are as shown in the scheme. Ed.]

The reducing power of the disilanes is determined by their structure, and increases in the order:

Hexaphenyldisilane does not show reducing properties, probably because of the steric hindrance created by the phenyl groups. In contrast to this, the introduction of a substituent into the molecule of the compound being reduced in the *ortho*-position to the nitro-group has practically no influence on the rate of the reaction with hexamethyldisilane.

h) Reactions with hydrogen peroxide



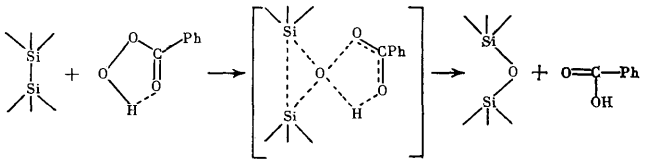
The silicon–silicon bond in permethylpolysilanes is not oxidised by hydrogen and sodium peroxides.[8,9] Hexaphenyldisilane is very inert towards various oxidising agents, and does not react with organic hydroperoxides and 30% $H_2O_2$ on boiling for 43 h in mixed THF–$CCl_4$ solvent.[119] Splitting takes place when an oxidising mixture consisting of $H_2O_2$ and NaOH in THF is used. The chief reaction products are triphenylsilanol and hexaphenyldisiloxane.

i) Reactions with bis(trimethylsilyl) peroxide (BTMSP)

Hexamethyldisilane reacts with BTMSP at 80 °C.[107]

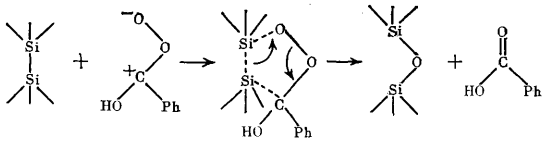
$$Me_3SiSiMe_3 + Me_3SiOOSiMe_3 \rightarrow 2Me_3SiOSiMe_3$$

After 42 h in an excess of the peroxide, the extent of the transformation of hexamethyldisilane was 40%. Methylfluorodisilanes $Si_2F_nMe_{6-n}$ ($n = 1-4$) are oxidised by BTMSP even at temperatures from −10 °C ($n = 4$) to +20 °C ($n = 1, 2$).[107] The compounds with $n = 1, 2$ give the corresponding disiloxanes as chief products, whereas the oxidation of tri- and tetrafluorodisilanes ($n = 3, 4$) give in addition $Me_3SiF$, $Me_3SiOSiMe_2F$, and $Me_3SiOSiMeF_2$. The rate of the oxidation of 1,2-difluorotetramethyldisilane does not decrease when the inhibitor 2,4,6-tri(t-butyl)phenol is added. It is suggested that the reactions take place via the intermediate states (D) and (E). The oxygen atoms of BTMSP act as nucleophilic centres.



For the tri- and tetrafluorodisilanes, the free-radical direction may make a contribution. Pentamethyldisilane is oxidised by BTMSP more rapidly than hexamethyldisilane, to give a

mixture of products.



$$Me_5Si_2H + Me_3SiOOSiMe_3 \rightarrow (Me_3SiO)_2SiMe_2 + Me_5Si_2OSiMe_3 + (Me_5Si_2)_2O + (Me_3SiOSiMe_2)_2O + (Me_3Si)_2O + H_2O$$

j) Reactions with peroxyacids

Hexamethyldisilane, 1,2-diphenyltetramethyldisilane, and the disilanes $XC_6H_4Si_2Me_5$ (X = H, Me, MeO, Cl) are oxidised by peroxybenzoic acid in dichloromethane or benzene to the corresponding siloxanes.[141] The reactions obey a kinetic equation of second order, first order with respect to each reagent. The satisfactory correlation between lg $k$ and $\sigma^+$ gives for the reaction constant the value $\rho = -0.29$, which characterises the disilane and the peroxyacid as nucleophilic and electrophilic reagents respectively. The author cited proposed a mechanism analogous to that of the epoxidation of alkenes, including electrophilic attack and the insertion of an oxygen atom of the peroxyacid at the Si–Si bond.

A bipolar 1,3-addition mechanism, analogous to that of the epoxidation of alkenes in strongly polar solvents, has also been proposed.[9]

It might have been expected that disilanes having electronegative substituents (Cl, Br, OR, OCOR) on the silicon atoms would be oxidised by peroxybenzoic acid more slowly than the peralkylated compounds. It was found, however, that these compounds react more rapidly than hexamethyldisilane.[142–144] The reactions are of first order with respect to each reagent, and give as the only products the corresponding disiloxanes and benzoic acid.

$$XMe_2SiSiMe_2Y + PhCO_3H \xrightarrow[\text{hexane}]{20^\circ C} XMe_2SiOSiMe_2Y + PhCOOH$$

| X | Y | $k$, litre mole$^{-1}$min$^{-1}$ | X | Y | $k$, litre mole$^{-1}$min$^{-1}$ |
|---|---|---|---|---|---|
| Me | Me | 0.008 | $Me_3Si$ | Cl | 0.42 |
| Me | n-Bu | 0.006 | $Me_3Si$ | $OSiMe_2Cl$ | 0.06 |
| Me | Cl | 0.28 | Cl | Cl | 0.15 |
| n-Bu | Cl | 0.15 | Me | OCOPh | 0.20 |
| Ph | Cl | 0.09 | Me | OEt | 0.06 |

The increased reactivity is evidently due to the existence of $n,\sigma$-conjugation in disilanes having $n$-donor substituents on the silicon atoms. Effects of this kind raise the HOMO of the polysilene,[71] and this should be revealed by an increase in its nucleophilic activity towards soft electrophiles, and in particular towards peroxybenzoic acid. As a result of the combined influence of the $Me_3Si$ group and the $n$-donor substituent in 1-chloroheptamethyltrisilane, only the Si–Si bond adjacent to the chlorine atom reacts initially. Cleavage of the second bond takes place much more slowly ($k_1/k_2 = 7$).[142]

$$Me_3SiSiMe_2SiMe_2Cl + PhCO_3H \xrightarrow{k_1} Me_3SiSiMe_2OSiMe_2Cl + PhCOOH$$
$$Me_3SiSiMe_2OSiMe_2Cl + PhCO_3H \xrightarrow{k_2} Me_3SiOSiMe_2OSiMe_2Cl + PhCOOH$$

The influence of the dielectric constant and basic strength of the solvent on the rate of the oxidation of pentamethylchlorodisilane by peroxybenzoic acid is extremely slight.[143] This agrees with the low absolute values of the Hammett ($\rho = -0.29$)[141] and Taft ($\rho = -0.56$) reaction constants,[143] which indicate that the intermediate state of the system in the oxidation is weakly polar.

Vinylpentamethyldisilane (I) can be converted quantitatively into the epoxydisiloxane (II) by treating with peroxyacids.[141]

$$Me_5Si_2\text{–}CH{=}CH_2 + 2PhCO_3H \xrightarrow[24\,CH]{CH_2Cl_2,20^\circ C} Me_3SiOSiMe_2\text{–}CH(O)CH_2 + 2PhCOOH$$
(I) (II)

At an equimolar reagent ratio, the chief product (79%) is the disilanyl epoxide (III).[145]

$$(I) + RCO_3H \rightarrow Me_5Si_2\text{–}CH(O)CH_2 + (II) + Me_3SiOSiMe_2\text{–}CH{=}CH_2 + RCOOH$$
(III)

The reaction takes place in stages, and in the first stage the vinyl group is oxidised preferentially. The relative rates of oxidation of the C=C bond in $Me_3SiOSiMe_2Vin$, $Me_3SiVin$, and $Me_5Si_2Vin$ are 1.0, 2.1, and 5.6 respectively. Thus the $Me_5Si_2$ group shows stronger donor properties than the $Me_3Si$ and $Me_3SiOSiMe_2$ fragments. *m*-Chloroperoxybenzoic acid (MCPBA) reacts with allylpentamethyldisilane[145] according to the equation:

$$Me_5Si_2\text{–}CH_2CH{=}CH_2 \xrightarrow{MCPBA} Me_3SiOSiMe_2\text{–}CH_2CH{=}CH_2 +$$
$$+ Me_3SiSiMe_2\text{–}CH(O)CH_2 \xrightarrow{H^+} Me_3SiSiMe_2CH_2CH_2C(=O)H$$

k) Reactions with benzoyl peroxide and di-t-butyl peroxide

The reactions of hexamethyldisilane,[146,147] hexaethyldisilane,[148] and pentamethylchlorodisilane[149] with di-t-butyl and benzoyl peroxides take place only at the temperatures of the decomposition of the peroxides to free radicals. In the reactions of hexamethyl- and hexaethyldisilanes, the Si–Si bond is not split by the peroxide compounds or the radicals formed by their thermal decomposition. The reaction of pentamethylchlorodisilane with di-t-butyl peroxide is accompanied by the formation of siloxane products, but the latter are obtained as a result of secondary reactions of $Me_5Si_2Cl$ with t-butyl alcohol and not with the peroxide or its radicals. The reaction of pentamethylchlorodisilane with benzoyl peroxide gives a complex mixture of products as a result of radical and exchange reactions.[149]

$$Me_5Si_2Cl \xrightarrow[80-90^\circ C]{(PhCOO)_2} Me_3SiCl + Me_2SiCl_2 + Me_2SiOCOPh + Me_5Si_2OCOPh + PhCOOH + \text{polymer}$$

The free-radical reactions of organopolysilanes with peroxides have been reviewed,[150] and are used for preparative purposes.[9,17]

l) Reactions with t-butyl hydroperoxide and its derivatives

In Ref. 151, an attempt was made to obtain two peroxides with a silicon–silicon bond in the molecule by the reaction of pentamethylchlorodisilane (IV) and 1,2-dichlorotetramethyldisilane (VII) with t-butyl hydroperoxide (TBHP) in the presence of pyridine. Instead of the compounds

expected, the authors cited obtained t-butoxypentamethyldisiloxane (VI) and the siloxane peroxide (X), whose formation was attributed to successive substitution and rearrangement:

$$\underset{(IV)}{Me_3Si_2Cl} + Me_3COOH \xrightarrow[-C_5H_5N\cdot HCl]{C_5H_5N} \underset{(V)}{Me_3SiSiMe_2OOCMe_3} \xrightarrow{O} \underset{(VI)}{Me_3SiOSiMe_2OCMe_3}$$

$$\underset{(VII)}{ClMe_2SiSiMe_2Cl} + Me_3COOH \xrightarrow[-C_5H_5N\cdot HCl]{C_5H_5N} \underset{(VIII)}{ClMe_2SiSiMe_2OOCMe_3} \xrightarrow{O}$$

$$\xrightarrow{O} \underset{(IX)}{ClMe_2SiOSiMe_2OCMe_3} \xrightarrow[-C_5H_5N\cdot HCl]{Me_3COOH/C_5H_5N} \underset{(X)}{Me_3COOMe_2SiOSiMe_2OCMe_3} .$$

It was subsequently established,[152] however, that the reaction of equimolar quantities of compound (IV) and TBHP, in addition to compound (VI), gives t-butylperoxypentamethyldisiloxane (XII) in up to 20% yield, which increases to 65% when a two-fold excess of TBHP is used. When the reaction is carried out not with TBHP but with its lithium salt, the yield of compound (XII) increases to 80%. The reaction begins not with the replacement of the chlorine atom but with the oxidation of the Si–Si bond in compound (IV):

$$\begin{gathered} \underset{(IV)}{Me_3Si_2Cl} + Me_3COOLi \rightarrow \underset{(XI)}{Me_3SiOSiMe_2Cl} + Me_3COLi \\ (XI) + Me_3COOLi \rightarrow \underset{(XII)}{Me_3SiOSiMe_2OOCMe_3} + LiCl \\ (XI) + Me_3COLi \rightarrow \underset{(VI)}{Me_3SiOSiMe_2OCMe_3} + LiCl \quad . \end{gathered}$$

Analogous reactions with $Me_3COOLi$ are undergone by the disilanes $RMe_2SiSiMeR'Cl$, where R and R' = Me, Ph, Bu, $Me_3SiO$.[153,154] Pentamethylchlorodisilane is not reactive towards nucleophilic reagents, so that the peroxide (V) is not formed.[143,152]

Compound (VII), 1,2-dichlorotetramethyldisilane, has a greater tendency to undergo nucleophilic substitution, compared with pentamethylchlorodisilane,[143,153] so that the reaction of compound (VII) with TBHP and its lithium salt begins with the replacement of one of the chlorine atoms by an $Me_3COO$ group, with subsequent rearrangement of the peroxide (VIII) to 1-chloro-3-t-butoxytetramethyldisiloxane (IX) (see above). The reaction is complicated by the parallel oxidation of the Si–Si bond in compound (VII) and the subsequent transformation of the siloxanes (XIII) and (XIV) formed:

$$\underset{(VII)}{ClMe_2SiSiMe_2Cl} \xrightarrow[-Me_3COLi]{Me_3COOLi} \underset{(XIII)}{ClMe_2SiOSiMe_2Cl} \rightarrow$$

$$\xrightarrow[-LiCl]{Me_3COOLi} \underset{(XIV)}{Me_3COOMe_2SiOSiMe_2Cl} \xrightarrow[-LiCl]{Me_3COOLi} Me_3COOMe_2SiOSiMe_2OOCMe_3 .$$

The driving force of the rearrangement of the disilanyl peroxide (VIII) is evidently the transformation of the unstable structure Si–Si–O–O into the thermodynamically more stable state with three strong Si–O bonds. A calculation based on the bond energies[155] shows that the gain in energy in the rearrangement is 99 kcal $mole^{-1}$.

The reactions of 1- and 2-chloroheptamethyltrisilanes with $Me_3COOLi$ are multistage successive and parallel processes, beginning with the oxidation of one Si–Si bond.[154] In 1-chloroheptamethyltrisilane (XV), the disilanyl fragment joined to the chlorine atom is oxidised first.

$$\begin{gathered} \underset{(XV)}{Me_3SiSiMe_2SiMe_2Cl} + Me_3COOLi \rightarrow Me_3SiSiMe_2OSiMe_2Cl + Me_3COLi \\ \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad (XVI) \\ (XVI) + Me_3COOLi \rightarrow \underset{(XVII)}{Me_3SiSiMe_2OSiMe_2OOCMe_3} + LiCl \\ (XVI) + Me_3COLi \rightarrow \underset{(XVIII)}{Me_3SiSiMe_2OSiMe_2OCMe_3} + LiCl \\ (XVII) + Me_3COOLi \rightarrow Me_3SiOSiMe_2OSiMe_2OOCMe_3 + Me_3COLi \\ (XVIII) + Me_3COOLi \rightarrow Me_3SiOSiMe_2OSiMe_2OCMe_3 + Me_3COLi \end{gathered}$$

The yield of the peroxide (XVII), containing an Si–Si bond in the molecule, reaches 75% when the reaction is carried out with a three-fold excess of $Me_3COOLi$.

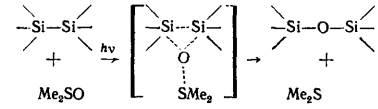
The reaction of the organochloropolysilanes $RMe_2SiSiMe_2Cl$ (R = Me, n-Bu, $Me_3Si$) with lithium t-butyl peroxycarbonate[144] takes place in two directions. The first involves the formation of the unstable peroxycarbonate (XIX), which liberates $CO_2$ to give the disilanyl peroxide (XX); the latter undergoes rearrangement to the t-butoxysiloxane (XXI):

$$RMe_2SiSiMe_2Cl + Me_3COOC(O)OLi \rightarrow \underset{(XIX)}{RMe_2SiSiMe_2OC(O)OOCMe_3} + LiCl$$

$$(XIX) \xrightarrow{-CO_2} \underset{(XX)}{RMe_2SiSiMe_2OOCMe_3} \xrightarrow{O} \underset{(XXI)}{RMe_2SiOSiMe_2OCMe_3} .$$

The second direction involves the oxidation of the Si–Si bond by the peroxycarbonate and the subsequent transformations of the chlorodisiloxane (XXII) formed.

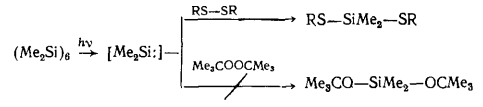
$$RMe_2SiSiMe_2Cl \xrightarrow[-Me_3COC(O)OLi]{Me_3COOC(O)OLi} \underset{(XXII)}{RMe_2SiOSiMe_2Cl} \rightarrow$$



$$\xrightarrow[-LiCl]{Me_3COOC(O)OLi} RMe_2SiOSiMe_2OC(O)OOCMe_3 \xrightarrow{-CO_2} RMe_2SiOSiMe_2OOCMe_3$$

m) Photolytic reactions of organopolysilanes in the presence of oxygen-containing reagents

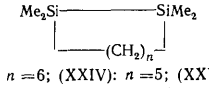
The photolysis of organopolysilanes in the presence of alcohols, ketones, and other organic compounds containing one or several oxygen atoms in the molecule gives products containing the fragments Si–O–Si and Si–O–C.[12,13,140,156–166] Reactions of this type involve several stages, and take place with the initial formation of silylenes, which undergo subsequent transformations to give the final siloxane products. For example, the irradiation of a mixture of dodecamethylcyclohexasilane and dimethyl sulphoxide (DMSO) gives dimethylsilylene, which is then oxidised by DMSO to dimethylsilanone. The latter, in the absence of reagents which act as traps, undergoes oligomerisation.[162]



$$(Me_2Si)_6 \xrightarrow{h\nu} [Me_2Si:] \xrightarrow{Me_2SO} [Me_2Si{=}O] \rightarrow (Me_2SiO)_n$$

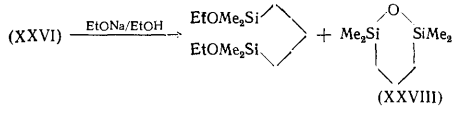
In the photolysis of pentamethylphenyldisilane, 2-phenylheptamethyltrisilane, and other aryl-substituted polysilanes in the presence of DMSO, one of the directions of the reaction involves the oxidation of the photo-excited Si–Si bond by dimethyl sulphoxide to give the corresponding siloxanes.[140,161,163,164]

Dimethylsilylene is introduced at the S–S bond of the



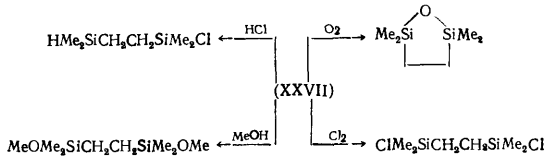
disulphides. The corresponding reaction with di-t-butyl peroxide does not take place.[165]

## 2. Oxidation of Cyclic Organopolysilanes



### a) The influence of ring size on reactivity

The organopolysilane ring size is one of the important factors determining the reactivity of these compounds in oxidative cleavage. The reactivity of the Si–Si bond is also influenced strongly by the size of the substituents on the silicon atoms and the nature of the heteroatoms in the ring. The increase in reactivity with decrease in ring size can be followed in the series of tetramethyl-1,2-disilacycloalkanes (XXIII)–(XXVII).[167]



(XXIII): $n=6$; (XXIV): $n=5$; (XXV): $n=4$; (XXVI): $n=3$, (XXVII): $n=2$

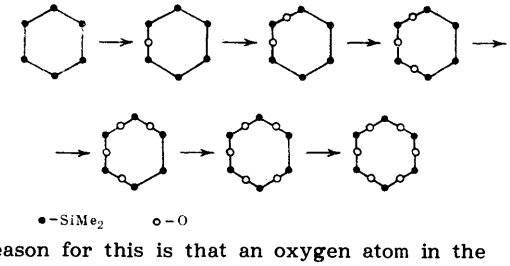
In these compounds, the influence of internal angular strain on the reactivity of the Si–Si bond begins to appear in the six-membered ring of compound (XXV). The action of sulphuric acid on disilacyclo-octane (XXIII) and disilacycloheptane (XXIV), as in the case of hexamethyldisilane, does not split the Si–Si bond, and the methyl group is replaced, whereas the reactions of compounds (XXV) and (XXVI) with concentrated sulphuric acid lead to cleavage of the Si–Si bond. The greater angular strain in compound (XXVI), compared with compound (XXV), is revealed in the reactions with oxygen, bis(trimethylsilyl) peroxide,[107] and sodium ethoxide.[157] 1,2-Disilacyclohexane (XXV) does not react with oxygen, whereas 1,2-disilacyclopentane (XXVI) absorbs oxygen exothermally, and is converted into the corresponding siloxane derivative (XXVIII). The reaction of compound (XXV) with BTMSP takes place only on heating to 50 °C, whereas compound (XXVI) reacts readily even at 20 °C. The silicon–silicon bond in compound (XXV) is not split by a solution of sodium ethoxide in ethanol at 90 °C, whereas in compound (XXVI), quantitative cleavage of the Si–Si bond takes place:

(XXVIII)

With further decrease in the ring size there is a sharp increase in the reactivity of the disilacycloalkane. 1,1,2,2-Tetramethyl-1,2-disilacyclobutane (XXVII) is extremely reactive.[168] It can be kept for a long time only at liquid nitrogen temperature. At 20 °C, the polymer $-(-CH_2CH_2.SiMe_2SiMe_2-)_n-$ is formed. The reactions of compound (XXVII) with oxygen, chlorine, hydrogen chloride, and methanol take place very vigorously.

A decrease in the reactivity of the Si–Si bond with increase in ring size was also observed[169] in the reactions of the 1,2-disilacycloalkanes (XXIV)–(XXVI) with *m*-chloroperoxybenzoic acid. The relationship between the kinetic parameters of the oxidation and the energies of charge transfer ($E_{ct}$) in the disilane–tetracyanoethylene complexes was studied. On going from the linear hexamethyldisilane to 1,2-disilacyclopentane (XXVI), the reaction rate constant increases by a factor of 2000. The entropy of activation remains practically constant, and the enthalpy of activation decreases. With decrease in the ring size, $E_{ct}$ decreases regularly, indicating that the HOMO level of the disilacycloalkane is raised, probably as a result of strain in the ring. The observed linear relationship between the enthalpy of activation and the energy of charge transfer indicated that in the transition state of the reaction, an important role is played by electronic donor–acceptor interaction between the disilane (donor) and the peroxyacid (acceptor).

The data on the oxidative splitting of organocyclopolysilanes, given below, also show that the reactivity of these compounds increases with decrease in the ring size.

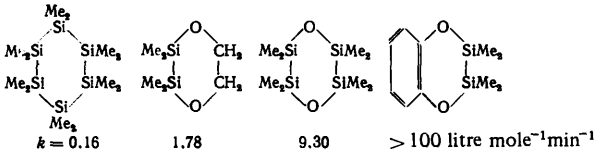


### b) The oxidation of six-membered cyclic compounds containing silicon–silicon bonds

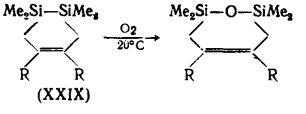
A fairly large number of varied six-membered cyclic compounds containing from one to six Si–Si bonds in the molecule are now known. In addition to disilanyl fragments, the ring may contain

$-(CR_2-)_n-$, $-CR=CR-$, $\diagdown C=PR_3$, $-NH-$, $-NR-$ $\diagdown N-NH_2$, $\diagup$

$-O-SO_2-O-$, etc. groups, and also elements such as oxygen and sulphur.[1,2,7,9,17,18,21,22] Most of these compounds are inert towards atmospheric oxygen at room temperature. The instability of some of them[52,170,171] in air may be due to the presence in the ring of a phosphorus-containing ligand such as $\diagdown P-Ph$.
$\diagup$



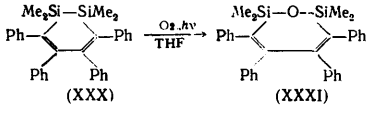
The six-membered ring $(Me_2Si)_6$ is the most stable thermodynamically. The equilibrium in a mixture of the compounds $(Me_2Si)_n$ ($n$ = 5, 6, 7) in the presence of Na/K alloy is displaced towards the formation of dodecamethylcyclohexasilane.[172] The latter undergoes practically no oxidation by atmospheric oxygen and 30% hydrogen peroxide solution at 80 °C. Chromium oxide, potassium dichromate, and potassium permanganate oxidise dodecamethylcyclohexasilane to a complex mixture of siloxane products.[173] MCPBA splits all six Si–Si bonds in $(Me_2Si)_6$, and each successive oxygen is introduced into the bond adjacent to that already oxidised.[174]



•–$SiMe_2$ o–O

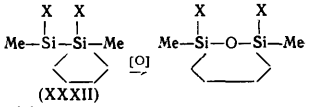
The reason for this is that an oxygen atom in the $-(-\overset{|}{\underset{|}{Si}}-)_n-$ chain activates the neighbouring Si–Si bond towards oxidation by peroxyacids. The first stage is the slowest, so that the intermediate oxygen-containing rings formed do not accumulate to significant concentration in the

reaction mixture. Comparison of the rate constants for the reactions of various six-membered rings with peroxybenzoic acid (benzene, 35 °C)[144] shows the magnitude of the activating influence of oxygen (particularly when combined with the π-system of the benzene ring[159]) on the Si–Si bond being oxidised.



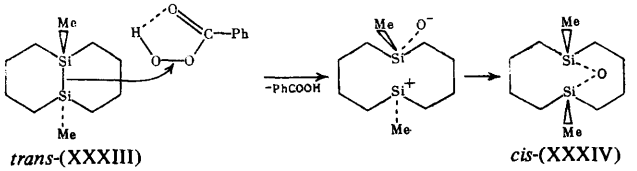
The presence of one multiple bond in the six-membered silicon–carbon ring of compound (XXIX) increases its ability to be oxidised by oxygen, compared with 1,2-disilacyclohexane (XXV).[157–177]

(XXIX)



The cyclodisilane (XXX), which contains a diene group, is not oxidised by oxygen in acetone under the influence of light and in the presence of a sensitiser, but the reaction takes place readily in tetrahydrofuran (THF). MCPBA converts compound (XXX) quantitatively into the cyclodisiloxane (XXXI) at 20 °C.

(XXX) (XXXI)

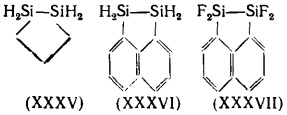


The reactions with di-t-butyl peroxide and t-butyl hydroperoxide take place only at 60–100 °C.[178]

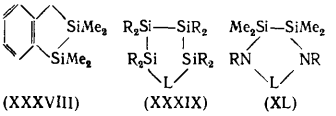
The reactions of the stereoisomeric 1,2-disilacycloalkanes (XXXIIa,b) with peroxybenzoic acid or bis(trimethylsilyl) peroxide take place with preservation of the configuration, indicating that the oxidation takes place by a molecular mechanism.[179,180]

(XXXII)
(a) X=F;
(b) X=Ph.

In the reactions of *trans*-9,10-dimethyl-9,10-disiladecaline (XXXIII) with $PhCO_3H$ and $Me_3SiOOSiMe_3$, inversion of the configuration is observed, due to the fact that the *trans*-isomeric siloxane oxidation product has considerable strain, whereas the *cis*-isomer (XXXIV) is unstrained. In the opinion of the authors cited, the inversion takes place at the moment of electrophilic attack by the peroxide on the Si–Si bond.[181,182]



*trans*-(XXXIII) *cis*-(XXXIV)

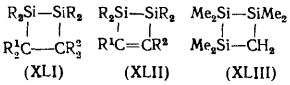


c) The oxidation of five-membered cyclic compounds containing Si–Si bonds

Five-membered silicon or silicon–carbon rings containing Si–Si bonds are more strained than six-membered rings. This is revealed by the slightly higher reactivity of these compounds towards oxygen and other oxidising agents. Dodecamethylcyclohexasilane does not react with atmospheric oxygen, whereas decamethylcyclopentasilane is slowly oxidised in air.[183,184] Compounds with more bulky substituents on the silicon, such as decaphenyl- and decaethylcyclopentasilanes, however, do not react with atmospheric oxygen.[1,185] The cleavage of decamethylcyclopentasilane by chlorine is much more rapid than that of dodecamethylcyclohexasilane.[125] Sulphur or selenium are inserted into the polysilicon ring $(Me_2Si)_5$ at 190 °C.[186] Dodecamethylcyclohexasilane does not react with sulphur and selenium under analogous conditions.

1,2-Disilacyclopentane (XXXV) was found to be extremely reactive towards $O_2$, probably due to not only the deformation of the Si–Si bond but also the presence in the molecule of easily oxidised Si–H bonds. In contrast to this, the Si–Si and Si–H bonds in 1,2-disila-acenaphthene (XXXVI) are stable to atmospheric oxygen.[187] It was previously noted that fluorodisilanes with a linear or cyclic structure, containing two or more fluorine atoms on silicon, are rapidly oxidised in air.

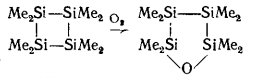
(XXXV) (XXXVI) (XXXVII)



The disila-acenaphthene (XXXVII), however, whose molecule contains four fluorine atoms, was found to be stable to oxygen.[187] 1,1,2,2-Tetramethyl-1,2-disila-4,5-benzocyclopentene (XXXVIII) reacts under mild conditions with MCPBA and oxygen to give the corresponding siloxane. The higher rate of oxidation of this compound compared with pentamethylphenyldisilane has been noted.[188]

(XXXVIII) (XXXIX) (XL)

The introduction of the heteroelement into the ring alters the sensitivity of the product to oxygen. For example, compounds with the general formula (XXXIX) with R = Me, Ph and L = O, NH, NR are stable in air. The boron- and phosphorus-containing heterocycles with L = $BNMe_2$, PPh[52,170,189] were found to be very sensitive to oxygen and moisture. In all known five-membered heterocycles with the general formula (XL),[190,191] the Si–Si bond remains inert to $O_2$. In the phosphorus-containing heterocycles, the heteroelement is oxidised.[190]



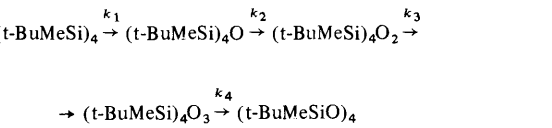
d) The oxidation of four-membered cyclic compounds

The even greater angular strains of the Si–Si, Si–C and C–C bonds in di- and trisilacyclobutanes (XLI), (XLIII), disilacyclobutenes (XLII), and cyclotetrasilanes $(R_2Si)_4$ lead to a further increase in the reactivity of these compounds. The tetrafluorodisilacyclobutenes (XLII) (R = F, $R^1$ and $R^2$ = H, Me, Et, $Me_3C$)[192] and 1,1,2,2,3,3-hexamethyl-1,2,3-trisilacyclobutane (XLIII)[193] are thermally unstable, and rapidly oxidised in air.

(XLI) (XLII) (XLIII)

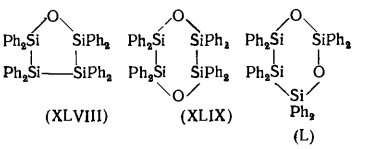
The disilacyclobutanes (XLI) and disilacyclobutenes (XLII) with methyl substituents on the silicon atoms[194,198] are fairly stable to heat, but are very sensitive to oxygen, and are oxidised in solution to the corresponding siloxanes. The aryl-substituted compounds (XLI) (R = phenyl, *m*- or *p*-tolyl) are stable to atmospheric oxygen, but are transformed into siloxanes by the action of MCPBA.[199,200]

Octamethylcyclotetrasilane (XLIV) is very reactive towards oxygen. The formation of small quantities of this compound in the reaction of dimethyldichlorosilane with sodium–potassium alloy in THF has been assumed.[201] In spite of the precautions taken, the authors cited could not isolate this compound from the reaction mixture, because of its rapid oxidation by even traces of oxygen. Kumada and co-workers[202,203] obtained compound (XLIV) by the photolysis of a cyclohexane solution of dodecamethylcyclohexasilane in a nitrogen atmosphere. It was impossible to avoid partial oxidation of compound (XLIV) to the monoxide (XLV) during the reaction and the isolation of the product.



(XLIV) (XLV)

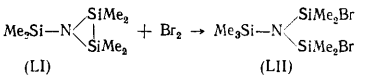
1,2,3,4-Tetraethyltetramethylcyclotetrasilane is also unstable in air.[204] Sulphur or selenium are inserted at the Si–Si bonds of octamethylcyclotetrasilane to give five-membered and symmetrical six-membered rings.[205,206]



1,2,3,4-Tetra-t-butyltetramethylcyclotetrasilane (XLVI), prepared by West and co-workers,[207] showed a number of unexpected properties, namely the lowest first ionisation potential of all known polysilanes (7.42 eV, PES) and the maximum long-wave ultraviolet absorption (300 nm),[51,208,209] indicating that the energies of the ground and the first excited states differ little. The silicon–silicon bond length (2.377 Å) is greater than the known values for permethylated cyclopolysilanes (2.338 Å for dodecamethylcyclohexasilane). It should be expected that in the strained four-membered ring of compound (XLVI), the strongly deformed silicon–silicon bond with a low value for the first ionisation potential would readily be split by oxidising reagents. It was found, however, that this compound is stable to oxygen and warm concentrated sulphuric acid. The unusual chemical inertness of compound (XLVI) is attributed to the steric effects of the bulky t-butyl groups.[210] All four isomers of $(t\text{-BuMeSi})_4$ are oxidised by MCBPA, but at different rates.[211]

The oxygen atom in the ring is activated towards oxygen by the neighbouring Si–Si bonds, but the ring strain still predominates, so that $k_1 > k_2 > k_3$. The Si–Si bond between the *cis*-substituents is most easily oxidised. The triply-oxidised product $(t\text{-BuMeSi})_4O_3$ does not accumulate in the reaction mixture, but is rapidly oxidised to the tetrasiloxane ($k_4 \gg k_3$).

Perphenylated cyclotetrasilane $(Ph_2Si)_4$ (XLVII), which is thermally stable, is slowly oxidised by atmospheric oxygen to give octaphenoxytetrasilacyclopentane (XLVIII) and a siloxane polymer.[1,2]

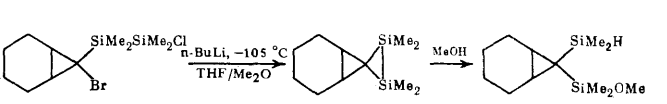


(XLVIII) (XLIX) (L)

Octaphenylcyclotetrasilane is oxidised by atmospheric oxygen in toluene at 100 °C and by ozone in $CCl_4$ or carbon disulphide. Compounds (XLVIII) and (XLIX) were isolated from the products of these reactions.[1,2] Nitrobenzene reacts with compound (XLVII) to give as main product the 1,3-dioxide (L). Benzaldehyde oxidises compound (XLVII) rapidly, whereas benzyl alcohol, acetophenone, paraldehyde, and pentyl nitrite react slowly. The products of these reactions are the monoxide (XLVIII), the 1,4-dioxide (XLIX), and a polymer.[1,2] The silicon–silicon bond in octaphenylcyclotetrasilane is readily split by halogens, hydrogen halides, mercury halides and acetate, tin(IV) chloride, phosphorus(V) chloride, and various organic halogeno-compounds. Decaphenylcyclopentasilane is more stable to these reagents, and cleavage requires more severe conditions.[1,2,17,212,213]

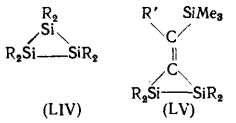
Thus four-membered cyclic compounds containing from one to four Si–Si bonds in the ring have different thermal stabilities, but practically all are fairly sensitive to oxidising agents, and cleavage of the Si–Si bonds, and not the Si–C, C–C, or C=C bonds, always takes place. Bulky substituents have an appreciable stabilising influence on the cyclosilane molecule.[214,215]

e) The oxidation of three-membered rings



The first three-membered ring with an Si–Si bond in the molecule, namely N-trimethylsilyltetramethylcyclodisilazane (LI), was obtained in 1963;[216] it is thermally stable, and is not oxidised in air. Prolonged boiling of compound (LI) in a solution of alkali in hexanol leads to only partial cleavage of the Si–Si bond. On the other hand, the reaction with bromine in $CCl_4$ takes place readily to give the dibromo-derivative (LII).

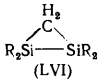
(LI) (LII)



Compound (LI) is slowly hydrolysed by water to give ammonia and siloxanes. Its low reactivity may indicate that there is very little or no deformation of the Si–Si bond.

Disilacyclopropane (LIII), synthesised in 1976, exists only at temperatures below −100 °C. As expected, the most reactive bond in this compound is not the Si–C but the Si–Si bond, which is split by methanol at −105 °C.[217]

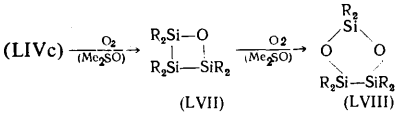
(LIII)



The subsequent search for methods of synthesising silicon-containing rings[80–86,218–221] gave a number of di- and trisilacyclopropane systems (LIV)–(LVI), which were found to be completely stable to heat and fairly inert towards oxygen or moisture.

(LIV) (LV)

R = 2,6-dimethylphenyl (a) (Ref.80), neopentyl (b) (Ref.85), t-butyl (c) (Ref.219), 1-ethylpropyl (d) (Ref.81), isopropyl (e) (Refs.81, 86)

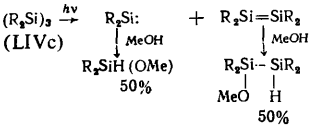


R = mesityl, R′ = trimethylsilyl (a) or phenyl (b) (Ref.218)

(LVI)

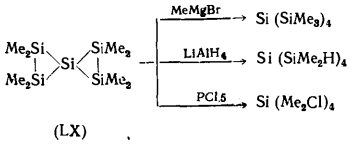
R = 2,6-dimethylphenyl (Ref.82)

An exception is hexaisopropylcyclotrisilane (LIVe), which decomposes slowly when kept, and reacts rapidly with atmospheric oxygen.[81,86] Hexa(2,6-dimethylphenyl)-cyclotrisilane (LIVa) is readily split by chlorine.[80] Hexa-t-butylcyclotrisilane (LIVc) in toluene is oxidised very slowly by atmospheric oxygen to the mono- and dioxa-derivatives (LVII) and (LVIII). The reaction with dimethyl sulphoxide in boiling toluene is similar.



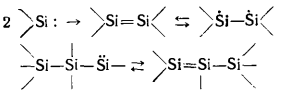
(LVII) (LVIII)

MCPBA successively splits all three silicon–silicon bonds in compound (LIVc) at room temperature, the final product being hexa-t-butylcyclotrisiloxane (LIX).

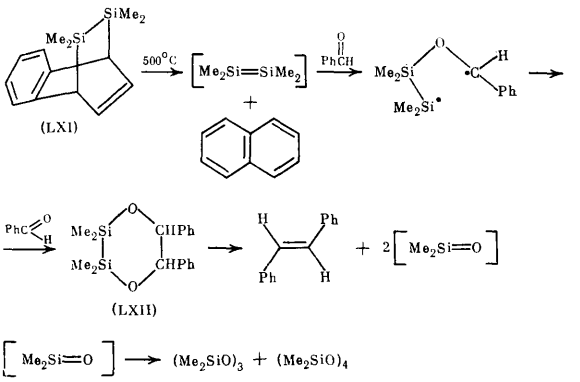


(LIX)

Sulphur and selenium are inserted at the Si–Si bond of hexa-t-butylcyclotrisilane in boiling toluene to give the four-membered rings $(R_2Si)_3Z$ (Z = S, Se).[220] The reaction of compound (LIVc) with methanol with irradiation by ultraviolet light takes place with the intermediate formation of di-t-butylsilylene and tetra-t-butyldisilene.[219]



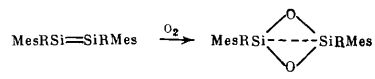
The disilacyclopropanes (LVa, b) do not react with alcohols at room temperature.[218] Compounds (LIVd) and (LVI) are oxidised to the corresponding mono-oxa-derivatives by atmospheric oxygen[81] or MCPBA.[82] The high thermal stability and low chemical activity of the silacyclopropanes (LIVa–d), (LV), and (LVI) is attributed to the steric shielding of the silicon atoms by the bulky substituents. According to Ref.221, unexpected thermal stability is shown by octamethylspiropentasilane (LX), which has practically no stabilising bulky substituents on the silicon atoms. Its chemical activity is fairly high, however.



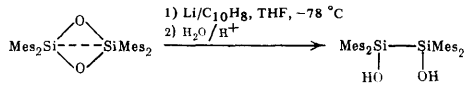
(LX)

## V. THE OXIDATIVE CLEAVAGE OF THE SILICON–SILICON DOUBLE BOND

The formation of disilene as a short-lived intermediate compound in the thermal decomposition of benzo-7,8-disilabicyclo[2,2,2]-octa-2,5-dienes, for example compound (LXI), was first postulated in 1972.[222] It was subsequently shown that disilene intermediates[223] may be obtained by the dimerisation[224,225] and rearrangement[226,227] of silylenes.

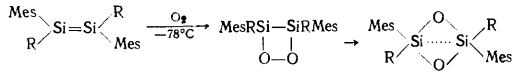


These highly active species behave as disilenes[228] or as biradicals,[229–231] depending on the substituents on silicon and on the reaction conditions. Disilenes undergo cycloaddition with dienes,[232,233] and dimerise to cyclotetrasilanes;[234,235] the reactions with oxygen-containing compounds[233,236] give products with Si–O bonds. For example, tetramethyldisilene, obtained by decomposing compound (LXI), reacts with benzaldehyde to give hexamethylcyclotrisiloxane, octamethylcyclotetrasiloxane, and trans-stilbene.[236] The proposed scheme includes the formation of radical and silanone intermediates.



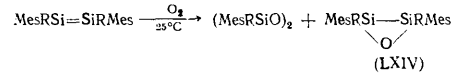
(LXI) (LXII)

Evidence in support of this scheme is provided by the fact that 1,2-disila-3,5-dioxacyclohexane (LXII), obtained by direct synthesis, decomposes at 500 °C to give the same products.



The latest achievements in the synthesis of stable disilenes[24,25,76–88,237–248] have made it possible to investigate their reactivity towards various oxidising reagents under ordinary conditions, that is in solution and at room temperature. The disilenes known at present differ in their thermal stability and reactivity, which are determined by the steric effects of the substituents on the silicon atoms. The mesityl[25,77] 2,6-dimethylphenyl,[80] and 2,6-diethylphenyl[84] groups give fairly stable compounds, which withstand heating for a short time up to the melting points (see Table). Alkyl-substituted disilenes are less stable. Thus the half-decomposition time of tetra-t-butyldisilene at room temperature is 4–10 h;[83,87] tetraisopropyldisilene is even less stable.[86] The disilenes with the highest thermal stability are slightly less active in reactions with oxidising reagents. Overall, the chemical properties of disilenes are similar to those of alkenes, but their activity is appreciably greater. The yellow colour characteristic of disilenes disappears rapidly on contact with air. Oxygen reacts with the powdered disilenes MesRSi=SiRMes [R = Mes (mesityl), $Me_3C$, $(Me_3Si)_2N$] at 25 °C to give the corresponding cyclodisiloxanes.[237]

X-Ray diffraction[238] has shown that in the cyclodisiloxanes, the silicon atoms are situated at a distance shorter than the length of an ordinary silicon–silicon bond. Thus in tetramesitylcyclodisiloxane the Si–Si distance is 2.31 Å, whereas the length of the silicon–silicon bond in 1,1,2,2-tetramesityldisilane is 2.35 Å. Thus bonding is possible between the silicon atoms in cyclodisiloxanes.[238–243] This is confirmed by the reaction of tetramesitylcyclodisiloxane with naphthalene–lithium, which takes place with preservation of the Si–Si bond and gives 1,1,2,2-tetramesityldisilandiol after hydrolysis.[238]



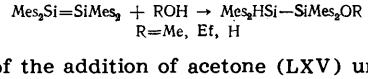
The oxidation of *trans*-dimesityldi-t-butyldisilene by oxygen in solution in pentane or THF at −78 °C gives the disiloxetane (LXIII), which undergoes quantitative rearrangement into *trans*-dimesityl-di-t-butylcyclodisiloxane when the solution is heated to room temperature.[237]

(LXIII)

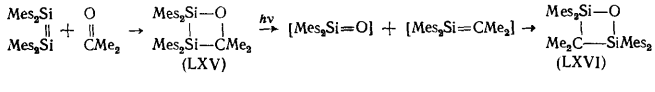
When the reaction is carried out in pentane at 25 °C, the products are *trans*-dimesityldi-t-butylcyclodisiloxane and the disilanyl epoxide (LXIV).

(LXIV)

The disilanyl epoxide (LXIV) is stable to oxygen, but it can be converted into the cyclodisiloxane by the action of MCPBA.[237]

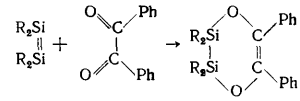


Hydrogen chloride splits the silicon–silicon double bond in tetramesityldisilene to give 1-chloro-2-H-tetramesityldisilane.[25,77]



The reaction with chlorine in benzene gives 1,2-dichlorotetramesityldisilane.[77]

If however the reaction is carried out in alkanes, the product is 1-chloro-2-H-tetramesityldisilane, and this was attributed to the radical mechanism.[77] Tetramesityldisilene reacts with alcohols and water at 50 °C,[25,77] and also with carbonyl compounds.[77]



The product of the addition of acetone (LXV) undergoes rearrangement on irradiation to give the 1,3-isomer (LXVI).

(LXV) (LXVI)

The reactions of tetramesityldisilene[76] and tetra-t-butyldisilene[87] with benzil takes place as [2 + 4]-cyclo-addition.

Carbene is inserted at the silicon–silicon bond to give disilacyclopropane.[82]

The reaction with sulphur gives the episulphide.[237,243]

The reaction of tetra-t-butyldisilene with dienes takes place as [2 + 2]- or [2 + 4]-cyclo-addition.[83,87] Tetramesityldisilene does not react with traditional disilene traps such as anthracene, 2,3-dimethylbutadiene, 1,4-diphenylbutadiene, and phenyl(trimethylsilyl)acetylene, but it undergoes cycloaddition with phenylacetylene.[77]

---o0o---

The oxidative cleavage of the silicon–silicon bond may take place by free-radical, molecular, or heterocyclic mechanisms, depending on the type of polysilane and oxidising agent. The cleavage may be due to rearrangement of the polysilane, in which the $R_3Si$ group migrates from the silicon atom to a more electronegative element. The silicon–silicon bond acts as the nucleophilic centre in reactions with electrophilic reagents such as peroxyacids and halogens. Cleavage by nucleophilic reagents takes place more readily if the silicon atoms are surrounded by electron-acceptor substituents. The influence of ring size and the size of the substituents on the reactivity of the Si–Si bond can be clearly seen. The reactivity of the silicon–silicon double bond is appreciably greater than that of $\sigma_{Si-Si}$ and $\pi_{C-C}$ bonds.

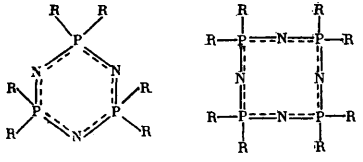
# The Nuclear Magnetic Resonance Spectroscopy of $^{15}N$-Labelled Cyclophosphazenes

B.Thomas and G.Grossmann



The $^{31}P$ NMR spectra of $^{15}N$-labelled cyclophosphazenes contain additional information compared with the unlabelled compounds, namely, apart from the spin-spin coupling constant $J_{PN}$, it is also possible to obtain information, in the case of homosubstituted compounds, about the spin-spin coupling constants $J_{PP}$ and $J_{NN}$. The $^{15}N$ NMR spectra of these compounds yield the same information and in addition the chemical shift of the $^{15}N$ signal. All these NMR parameters are sensitive to changes in the electronic structure of the cyclic P-N systems, which depend on the type and number of substituents and also on the ring size. Studies on labelled halides, amino-derivatives, ethers, thioethers, and alkyl-substituted derivatives of cyclic phosphazenes containing between three and six P-N structural units are examined. The NMR data are interpreted on the basis of empirical relations and also with the aid of semiempirical quantum-chemical methods.
The bibliography includes 109 references.

## I. INTRODUCTION

Cyclophosphazenes are inorganic cyclic compounds with alternating phosphorus and nitrogen atoms. Their simplest representatives are cyclotriphosphazenes with three $NPR_2$ fragments and cyclotetraphosphazenes with four $NPR_2$ fragments.

The P–N bond length is intermediate between the lengths of single and double bonds. For identical substituents, all the bonds in the ring are likewise identical, i.e. there is no alternation of double and single bonds between the P and N atoms. According to the model of Craig and Paddock,[1] a more or less pronounced cyclic delocalisation of molecular $\pi$ orbitals is postulated, while Dewar et al.[2] suggest that the conjugation terminates at each phosphorus atom (the island model). In addition some workers[3,4,5] have postulated the presence of transannular P–P bonds, which are particularly evident in hexafluorocyclotriphosphazene.

There exist numerous derivatives of cyclophosphazenes differing from one another by ring size and also by the type, number and positions of the substituents R; NMR has proved to be a convenient method for the identification and investigation of these compounds.

The first measurement of the chemical shift of the $^{31}P$ signal in the NMR spectra of cyclophosphazenes was made by Van Wazer et al.[6] in 1956. Among 200 phosphorus compounds investigated, there were also hexachlorocyclotriphosphazene and, in addition, according to the authors, a linear phosphazene. In 1959 Becke-Goehring and Koch[7] used $^{31}P$ NMR to identify cyclophosphazene oligomers and polymers. In the same year $^{31}P$ NMR was also employed to investigate aminocyclotriphosphazenes with different numbers of substituents.[8] The possibility of investigating the NMR spectra of suitable magnetic nuclei forming part of the composition of the substituent R in order to determine the molecular structure of cyclophosphazene as well as their isomers was first reported in 1961. Ray and Shaw studied the $^{1}H$ NMR spectra of dimethylaminocyclotriphosphazenes[9] and Chapman et al.[10] as well as Heffernan and White[11] investigated the $^{19}F$ NMR spectra of trimeric chlorofluoro-derivatives.

In recent years one of the principal methods for the determination of the structures of aminocyclophosphazenes as well as their ethers and thioethers and other phosphazenes with proton-containing substituents has been $^{1}H$ NMR. In order to simplify the spectra, homonuclear decoupling has been used in some cases.[12] This method made it possible to identify unambiguously in many instances the substitution products (the geminal and *cis*- or *trans*-non-geminal positions of the substituents).

The wide-scale use of $^{31}P$ NMR for the determination of the structures of cyclophosphazenes did not begin until the middle 1970s. As an example, one may quote a study[13] on aminophosphazenes. As Fourier transform spectroscopy and the associated possibility of measuring the $^{13}C$ NMR spectra of compounds with the natural abundance of carbon isotopes developed, it became possible to employ this method to investigate cyclophosphazenes with organic substituents.[14-18] Mason et al. published in 1977 a report[19] in which they describe studies of cyclophosphazenes by broad-line $^{14}N$ NMR. Other nuclei forming part of the composition of the P–N rings were first investigated in this way and the nitrogen chemical shifts were measured for certain triphosphazenes and cyclotetraphosphazenes with the same substituents.

In the majority of investigations of cyclic phosphazenes, NMR is used to identify the reaction products or to investigate the structure of the compound synthesised but not in systematic research permitting an interpretation of the NMR parameters. The aim of our studies was to determine, by investigating the NMR spectra of $^{15}N$-labelled cyclophosphazenes, additional parameters which yield much information about these cyclic P–N systems.

Phosphazenes with identical substituents, fully labelled by $^{15}N$, are spin systems of the type AA'A"XX'X" in the case of the trimeric compounds and of the type AA'A"A"'XX'X"X"' in the case of tetrameric compounds, provided that spin–spin coupling with the substituents is absent or is suppressed. The higher-order NMR spectra obtained permit the determination of the following parameters: (1) the chemical shifts $\delta_P$ and $\delta_N$, (2) the coupling constants $^1J_{PN}$ and $^2J_{PP}$, and (3) the coupling constants $^2J_{NN}$ and $^3J_{PN}$. The latter quantities are very small for cyclophosphazenes and are not resolved in the experimental spectra. This is indicated by the results of studies on cyclophosphazenes with mixed substituents.[20–23] The neglect of these coupling constants greatly simplifies the analysis of the spectra. This also applies to the coupling constants $^4J_{PP}$[20,24–26] and $^4J_{NN}$ for the spectra of tetrameric phosphazenes.

The $^{31}P$ and $^{15}N$ NMR spectra of cyclic phosphazenes with identical substituents are symmetrical and the positions of the centres yield information about the chemical shifts (Fig. 1). The coupling constants $^1J_{NN}$ can be obtained from both spectra; the distance between the outer intense lines given by

$$2^1J_{PN}+{}^3J_{PN}$$

is used to determine it. Since $^3J_{PN}$ is negligible, half this distance represents the value of $^1J_{PN}$. In order to obtain the coupling constants $^2J_{PP}$ for cyclotriphosphazenes[27] and cyclotetraphosphazenes[28] we developed graphical methods based on the continuous variation of the distances between the additional spectral lines as a function of the ratio $^2J_{PP}/{}^1J_{PN}$. In this way it is possible to do without the computer modelling for the simulation of the spectra. We may note that analysis of the spectra in such cases does not yield information about the relative signs of the coupling constants.

$^{15}N$-Labelled cyclophosphazenes with mixed substituents also give rise to $^{31}P$ and $^{15}N$ NMR spectra containing high-order lines. In most cases preliminary data can be extracted from these spectra by means of first-order analysis. Modelling of the spectra enables one to refine these estimates.[20,21,23] In some cases it is then possible to determine the relative signs of the coupling constants.

The empirical interpretation of the NMR parameters permits the conclusion that the atoms of the substituents linked directly to phosphorus, i.e. the oxygen atoms in ethers, the nitrogen atoms in amino-derivatives, etc., exert a direct influence on such spectra. Relations are then observed between the NMR parameters and the positions of the corresponding elements in the Periodic System.[29] This simplified treatment is useful also in the interpretation of NMR data with the aid of semiempirical quantum-mechanical calculations for model compounds.[30,31]

It is therefore of interest to investigate how the NMR parameters vary (a) with the substituents R (in the first place one considers substituents of the same type), (b) with ring size (under the same conditions), and (c) with the degree of substitution (when cyclophosphazenes with mixed substituents are considered). Attention will be concentrated in this review on the possibility of obtaining from NMR data information about the characteristics of the P–N bond system in cyclophosphazenes.

## II. THE $^{31}P$ CHEMICAL SHIFTS

The $^{31}P$ NMR chemical shifts have been determined for almost all the hexa-substituted cyclotriphosphazenes synthesised, for example, for R = F,[32–35] Cl[6–8,35–41] etc., Br,[32,35,42,43] NCS,[41,44,45] $N_3$,[46] OMe,[30,39,47] OEt,[30,39,44,47] OPh,[30,39,48,49] SMe,[50] SEt,[37,51] SPh,[20] $NH_2$,[21,32,41] NHMe,[8,13,30] NHEt,[13,30] NHPr-iso,[13] NHPh,[30] $NMe_2$,[8,13,30] $NEt_2$,[13,30] $NC_5H_{10}$,[13] Me,[30,52] and Ph.[41,53,54] This also applies to the octa-substituted cyclotetraphosphazenes with R = F,[32,35] Cl,[7,32,35–37] Br,[32,35,42] NCS,[32,44] OMe,[28,47] OEt,[44] OPh,[28] SEt,[51] NHMe,[13] NHEt,[13,28] NHBu-t,[13] $NMe_2$,[13,28] Me,[28,52] and Ph,[13] to certain decasubstituted cyclopentaphosphazenes with R = F,[55] Cl,[35,36] OMe,[47,55] $NMe_2$,[55] and Me,[52] and to dodecasubstituted cyclohexaphosphazenes with R = Cl,[35,36] OMe,[47,55] and $NMe_2$.[55] Finally we may mention $(NPCl_2)_7$[35,36] and $(NPCl_2)_8$.[36]

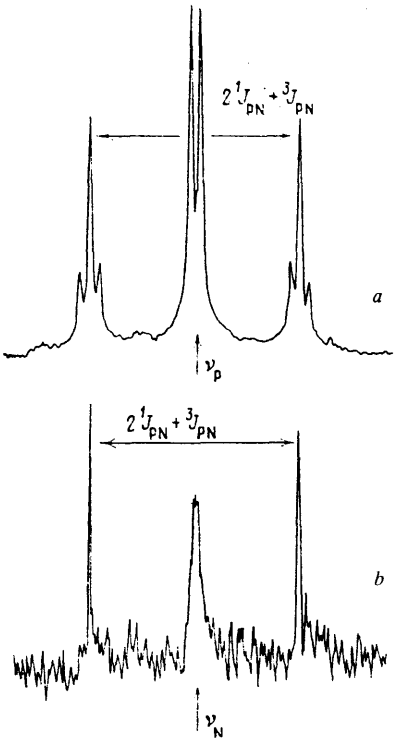

**Figure 1.** Experimental spectra of the compound $(^{15}NPBr_2)_3$: a) $^{31}P$ NMR spectrum; b) $^{15}N$ NMR spectrum.

Table 1 presents the $^{31}P$ chemical shifts for certain identically substituted cyclophosphazenes. The results presented were obtained in our laboratory,[28,30,55] since the available literature data for the chemical shifts had been obtained under different conditions which made it difficult to compare them. For example, it is completely impossible to compare the data[41,45] for the compound $[NP(NCS)_2]_3$ and in other cases the difference between the chemical shifts obtained in different studies for the same compounds reach several p.p.m., for example, for $(NPMe_2)_{3,4}$ (Grushkin et al.[54] and Thomas et al.[28,30]), $[NP(NH_2)_2]_3$ (Moeller[32] and Latscha[41]), $(NPPh_2)_3$ (Reddy and Weis[53] and Grushkin et al.[54]), $[NP(OEt)_2]_3$ (Nielsen et al.[44] and Dhathathreyan et al.[47]), $(NPF_2)_3$ (Allen et al.[33] and Moeller[32]), and $(NPBr_2)_3$ (John and Moeller[42] and Engelhardt et al.[43]). These differences can be understood if one takes into account the fact that the measurements were performed on spectrometers of different degrees

of accuracy and, in addition, for different states of the test substance, for example, without a solvent in the fused state, or after dissolution in various solvents such as water, ether, benzene, $CS_2$, $CH_2Cl_2$, etc. and that the concentration of the test substance also varied within wide limits. Our measurements were performed at 302 K after dissolving the substance in $CDCl_3$; in most cases the concentration of the substance was kept constant (at ~0.5 M) with the sole exception of the $[NP(NH_2)_2]_3$ solution.

In the first major investigation by Van Wazer et al.[6] devoted to phosphorus compounds, which was already mentioned above, the influence of substituents on the $^{31}P$ chemical shift was discussed. The following series of substituents was found for tetracoordinate phosphorus:

$$Se > S > C_{aliph} > C_{arom} \cong P > N \cong Cl > O > F.$$

A similar series was established also for cyclophosphazenes with the exception of $[NP(NHPh)_2]_n$ or $[NP(OPh)_2]_n$, where the phenyl substituent at the nitrogen or oxygen atom influences also the chemical shift of phosphorus.

A qualitative correlation between the electronegativity of the group linked to the phosphorus atom and the $^{31}P$ chemical shift has been established.[40] The electrophilic character of the group R linked to the phosphorus atom is responsible for the partial delocalisation of the free electron pair of the nitrogen atoms in the ring and the formation of additional P–N π-bonds which decreases the chemical shift of phosphorus.

It is seen from the data in Table 1 that the $^{31}P$ chemical shift for cyclophosphazenes with a given ring size diminishes when the substituents are altered in a way corresponding to moving from left to right along the same Period in Mendeleev's Table (from alkylphosphazenes to the fluoro-derivatives and from the thioethers to the chloro-derivatives) and, when substituents belonging to a single Group are varied, $\delta P$ increases on passing from an element in the Second Period to one in the Third Period (from ethers to thioethers and from fluoro-derivatives to chloro-derivatives). Like phosphoryl halides, the bromo-derivatives have very low chemical shifts which has not been explained satisfactorily.

On passing from trimeric to tetrameric phosphazenes with retention of the number and nature of the substituents, $\delta P$ appreciably diminishes, but, on further increase of ring size, the shift decreases more slowly, gradually reaching a limiting value. A decrease of the P–N bond length with increase of ring size corresponds to these changes.[56] This can be explained by the effect which was responsible for the influence of the substituents, i.e. by the more or less effective involvement of the free electron pair of the nitrogen atom in the π-bond system. Thus a correspondence is observed with the results of a quantum-mechanical calculation,[57] according to which there exists a satisfactory correlation between the chemical shifts in the $^{31}P$ NMR spectra of the compounds $(NPCl_2)_n$ (where $n$ = 3, 4, or 5) and the overall overlap of the π-bonds $\Sigma_\pi(PN)$.

The appreciable difference between the $^{31}P$ chemical shifts, and, as will be shown below, between other NMR parameters for cyclotriphosphazenes and cyclotetraphosphazenes is in our view caused by the difference between the molecular geometries. Whereas cyclotriphosphazenes have a virtually planar ring structure, higher oligomers consist of non-planar rings. This unusual structure of cyclotriphosphazenes is reflected in other properties of these compounds, for example, in their dipole moments,[58] which is manifested in its turn by the corresponding behaviour in the chromatographic separation of the test substance.[29,59]

For a more detailed interpretation of the relation between the $\delta P$, $\delta N$, $^1J_{PN}$, and $^2J_{PP}$ parameters of the cyclophosphazenes investigated and the properties of the substituents influencing the geometry and the P–N bond system of the ring, semiempirical quantum-chemical calculations have been carried out for model compounds by the CNDO/2 method and the paramagnetic contributions of the shielding constants as well as the interaction constants were calculated.[29–31,35] The calculations were performed in terms of the parametrisation of Pople[60] and Santry;[61] account was taken of the *d* orbitals for phosphorus, whereas only the *s* and *p* orbitals were used for substituents comprising the elements in the Third Period (chlorine and sulphur).

The shielding constant $\sigma_A$ for a nucleus A in the molecule can be represented, according to Ramsay,[62] by the sum of two contributions, which depend on the choice of the origin of coordinates:

$$\sigma_A = \sigma_{dia,A} + \sigma_{para,A} . \qquad (1)$$

The paramagnetic contribution in this equation can be estimated in accordance with the approximation proposed by Pople.[63] The changes in the diamagnetic contributions on passing from one compound to another are small and can therefore be disregarded. According to Pople's approximation mentioned above, the paramagnetic contribution by the given nucleus A can be calculated as follows:

$$\sigma_{para,A} = -\frac{e^2\hbar^2}{2m^2c^2} \cdot \frac{1}{\Delta E} \cdot \langle r_p^{-3} \rangle \cdot \sum_B Q_{AB} , \qquad (2)$$

where

$$Q_{AB} = \frac{4}{3}\delta_{AB}(p_{x_Ax_B} + p_{y_Ay_B} + p_{z_Az_B}) - \frac{2}{3}(p_{y_Ay_B}p_{z_Az_B} + p_{z_Az_B}p_{x_Ax_B} + p_{x_Ax_B}p_{y_Ay_B}) + \frac{2}{3}(p_{y_Az_B}p_{z_Ay_B} + p_{z_Ax_B}p_{z_Bx_A} + p_{x_Ay_B}p_{y_Ax_B}) . \qquad (3)$$

Here B is any atom in the molecule, $\delta_{AB}$ is the Kronecker delta, $p_{ij}$ are the elements of the density matrix, and $\langle r_P^{-3} \rangle$ is the expected value of the reciprocal of the cube of the radius of the 3*p* orbital of phosphorus or the 2*p* orbital of nitrogen. The latter values were calculated from the Hartree–Fock atomic functions[64,65] using a linear interpolation for the non-integral charges.

The 3*d* orbitals of the phosphorus atom are probably also important for the description of the chemical bonds in cyclophosphazene but their influence on the chemical shift is small, because the expected value of the reciprocal of the cube of the radius of the 3*d* orbitals of phosphorus is smaller by several orders of magnitude than the corresponding value for the 3*p* orbitals; the contribution of the 3*d* orbitals is not therefore taken into account in Eqn.(2).

In the calculations of the $^{31}P$ chemical shift in the NMR spectra of cyclophosphazenes, the quantity $\Delta E$ may be regarded as constant and one can thus compare the experimental chemical shifts with the products $\langle r_P^{-3} \rangle \sum_B Q_{AB}$.

It is then found that allowance for the distribution of the charge on the phosphorus atom $\langle r_P^{-3} \rangle Q_{PP}$ alone leads to results which are not in sufficiently good agreement with experimental data. Evidently the bond between phosphorus and the neighbouring nitrogen atoms, taken into account by the quantity $2Q_{PN}$, makes a large contribution to the $^{31}P$ chemical shift, so that comparison of the experimental chemical shifts with the product $\langle r_P^{-3} \rangle (Q_{PP} + 2Q_{PN})$ leads to satisfactory results.[35] Additional allowance for the influence of the atoms of the substituents, expressed in terms of $2Q_{PX}$, does not entail an appreciable improvement of the agreement between the calculation and experiment.

Quantum-chemical calculations have been performed for the following compounds: $(NPF_2)_3$, $(NPF_2)_4$, $(NPCl_2)_3$, $(NPCl_2)_4$, and $[NP(CH_3)_2]_3$. $[NP(OH)_2]_3$, $[NP(OH_2]_4$, $[NP(SH)_2]_3$, $[NP(NH_2)_2]_3$, and $[NP(NH_2)_2]_4$ were chosen as model compounds for the ethers, thioethers, and amino-derivatives.[30,31] The planar molecular structure was adopted for cyclotriphosphazenes and the tetrameric fluoro-derivative, while the structures of other cyclotetraphosphazenes were assumed to be in the form of a saddle with approximately $D_{2d}$ symmetry.[29] The bond lengths and bond angles were taken from the literature (for example, Allcock[56]) or were estimated for model compounds.

Fig.2 illustrates the correlation between the chemical shift $\delta$P and the quantity

$$\langle r_p^{-3}\rangle \sum_B Q_{AB}$$

for cyclotriphosphazene. With an increase of the positive charge on the phosphorus atom, the paramagnetic component as a rule diminishes, which is evident from the comparison of data for substituents in the series C, N, O, F and also Cl, F and S, O. However, when the substituents C and Cl are compared, an increase of the paramagnetic contribution is observed. The coefficient of the correlation between the chemical shift and the calculated paramagnetic contribution, amounting to 0.74, is not satisfactory. The points for the chloro-derivative and the thioether in Fig.2 deviate markedly from the regression line. If account is taken only of compounds in which the substituent atoms are those of elements in the Second Period in Mendeleev's table, a better correlation coefficient is obtained (0.88). This is also observed for the correlations with other NMR parameters (see below). The deviations observed for substituent atoms which are those of elements in the Third Period, arise owing to the lack of validity of the method of approximation employed. Fig.2 does not include compounds containing a phenyl group (the anilino-, phenoxy-, and phenylthio-derivatives), since the phenyl group has a strong influence on the $^{31}$P chemical shift.

An analogous correlation has been observed for cyclotetraphosphazenes between the $^{31}$P chemical shift and the quantity

$$\langle r_p^{-3}\rangle \sum_B Q_{AB}.$$

The change in $\delta$P in the upfield direction with increase of ring size and specially the marked change in $\delta$P on passing from cyclotriphosphazene to cyclotetraphosphazene cannot be explained by the distribution of electrons at the phosphorus atom alone, because it is virtually the same for the trimers and tetramers; in these cases too it is essential to take into account the contributions of the bonds with the neighbouring nitrogen atoms. The cause of the change in the chemical shift should be sought primarily in the change of the contribution of the bonding $3p-2p$ orbitals on passing from the planar trimeric compounds to the nonplanar tetrameric compounds.[35] In the case of the fluoroderivative the large change in $\delta$P on passing from cyclotriphosphazenes to cyclotetraphosphazenes must have other causes, because the planar structure is retained in this instance.[29] Indeed it is found that the change in $\delta$P is not adequately described by the values of

$$\langle r_p^{-3}\rangle \sum_B Q_{AB},$$

if it is assumed that

$$\sum_B Q_{AB} = Q_{PP} + 2Q_{PN}.$$

This change in $\delta$P can be described more adequately if account is taken of transannular bonds with other phosphorus atoms ($2Q_{P\ldots P}$). These transannular bonds are particularly marked in hexafluorocyclotriphosphazene.[35]

Numerous studies have been devoted to cyclophosphazenes with mixed substituents. Data on the $^{31}$P chemical shifts are presented in monographs[56,67-70] and numerous later publications. Cyclotriphosphazenes with mixed substituents, giving rise to spectra of the $A_2X$, $A_2B$, AMX, ABX, or ABC

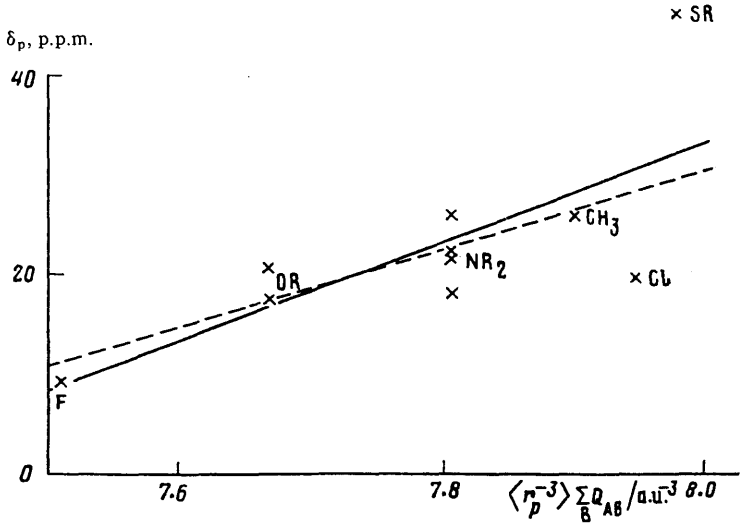

Figure 2. Correlation between the $^{31}$P chemical shift in the NMR spectra of compounds of the type $(^{15}NPR_2)_3$ and the quantity $\langle r_p^{-3}\rangle \sum_B Q_{AB}$; the correlation coefficients are $r = 0.74$ (continuous line) and $r = 0.88$ (dashed line); the crosses represent experimental points.

types, as well as a series of cyclotetraphosphazenes with mixed substituents for which there is a possibility of spectra of types $A_2X_2$, $A_2B_2$, AA'XX', $A_2MX$, $A_2BX$, $A_2BC$, ABMX, ABXY, ABCX, ABCD, and AA'BB', were investigated in the first place. Since higher-order spectra are observed in many cases, the exact chemical shifts and interaction constants can be obtained only by modelling the spectra.

The available $^{31}P$ chemical shifts provide answers to the questions how the chemical shift changes when two different substituents are attached to the same phosphorus atom and what is the influence of the substituents at the other phosphorus atoms. Answers to these questions have been provided in relation to the series $N_3P_3Cl_{6-n}(SEt)_n$ ($n = 0-6$) and $N_4P_4Cl_{8-n}(SEt)_n$ ($n = 0-8$), in which geminally substituted compounds are formed exclusively.[51] In the selected examples the chemical shifts for the phosphorus atoms with two identical substituents, i.e. for $PX_2$ and $PY_2$, differ markedly and the chemical shifts for phosphorus atoms with mixed substituents (PXY) are always intermediate between these values (but are not their averages). In the case of aminochlorophosphazenes, where the shifts change only slightly on passing from $PX_2$ to $PY_2$ (Table 1), the $\delta$P for PXY are sometimes not intermediate between these values.[13,22] Thus the fact, known for other phosphorus compounds, that the dependence of the chemical shift of phosphorus on the contributions of the substituents is not additive, has been confirmed also for cyclophosphazenes. For this reason attempts are no longer made to create a system of increments for the empirical calculation of the chemical shifts similar to the systems which exist for $^{1}H$ and $^{13}C$. The finding[72] that the chemical shift for phosphorus atoms with mixed substituents is usually displaced downfield compared with the average value holds also for cyclophosphazenes (Tables 2 and 3).

**Table 1.** $^{31}P$ Chemical shifts (in p.p.m.*) for cyclophosphazenes of the type $(NPR_2)_n$.

| Compound | $n=3$ | $n=4$ | $n=5$ | $n=6$ |
|---|---|---|---|---|

***Saturated solution in $CDCl_3$.

****The value of $\delta$p depends strongly on the solvent.

The effect of substituents at other phosphorus atoms on the $\delta$p is also evident from the data presented in Tables 2 and 3. The change in $\delta$p is by several p.p.m. for the identical immediate environment of the phosphorus atom and a distinct regularity is not observed. It is known that the bond lengths and angles in cyclophosphazenes vary quite markedly when substituents are introduced. The change in the geometry of the environment of the phosphorus atom can be to some extent responsible for the change in $\delta$p.

An attempt has been made recently[74] to calculate the $^{31}P$ chemical shifts for a series of geminally disubstituted tetrachlorocyclotriphosphazenes from the increments in the shifts caused by substituents. Very satisfactory results have been obtained for the dialkyl derivatives probably because the changes in the chemical shifts in this group of compounds are small. In the case of compounds with mixed alkyl and halogeno-substituents, appreciable deviations are observed unless special corrections are applied. For *para*-substituted monoarylphosphazenes, Harris[74] observed a satisfactory correlation with the Hammet $\sigma$ parameters.

## III. $^{15}N$ CHEMICAL SHIFTS

Chemical shift data for endocyclic nitrogen atoms were published by ourselves for $^{15}N$-labelled cyclophosphazenes.[20-23,28,30,35,55] Apart from these data, the results of Mason and co-workers,[19] who used the broad line $^{14}N$ NMR, are available in the literature. These results are not accurate, since they were obtained under different conditions (without a solvent, in the melt, and in various solvents) and, furthermore, the line width is in the range 165–700 Hz. A detailed analysis of the experimental chemical shifts of nitrogen is possible only when $^{15}N$ NMR is used.

Table 4 presents the nitrogen chemical shifts for cyclophosphazenes with identical substituents, which we obtained in the study of endocyclic $^{15}N$-labelled compounds. The

measurements were performed for solutions of the compound in $CDCl_3$; the exceptions will be indicated separately.

Mason et al.[19] obtained the following series based on the influence of the substituents at the phosphorus atom on the nitrogen chemical shift:

$$NMe_2 > OMe > F > NCS > Cl > Br .$$

This sequence does not coincide either with that observed for the $^{31}P$ shift or with the reverse of the latter. The authors[19] attempted to give a semiempirical explanation of the phosphorus and nitrogen chemical shifts; they were able to establish a correlation by comparing the paramagnetic contributions of the atom–ligand system for phosphorus and nitrogen, i.e. the contributions which include the diamagnetic component of the ligand.[75]

**Table 4.** $^{15}N$ Chemical shifts (in p.p.m. relative to nitromethane) for cyclophosphazenes with substituents of one kind and different ring sizes.

*Solution in water; in the remaining cases—solution in $CDCl_3$.

The virtual absence of a difference in the $\delta_N$ for different substituent atoms of elements in the Second Period attached to the phosphorus atom is striking in the study of the nitrogen chemical shift. For example, on passing from alkylphosphazene to the fluoro-derivative in the series of cyclotriphosphazenes, the chemical shift $\delta_N$ changes by only 5 p.p.m. This finding is particularly surprising in view of the fact that the basicities of the above phosphazenes differ markedly[76] and the basicity centres are in fact located at the ring nitrogen atoms. Evidently there is no direct relation between the basicity and the nitrogen chemical shift.

The $^{15}N$ chemical shift varies markedly for phosphazenes with substituents involving elements belonging to the same Group. For example, on passing from fluoro- to bromocyclotriphosphazene, the chemical shift increases by 74.4 p.p.m., while in the case of the corresponding cyclotetraphosphazenes the increase is by 83.6 p.p.m. In order to account for these changes, one cannot assume that $\Delta E$ is constant in the series of similar compounds, because the nodal planes of the $\pi$ orbitals or the non-bonding $p$ orbitals pass through the $^{15}N$ nucleus or in its vicinity.[35] Such orbitals exert a major influence on the shielding of the nucleus.[77] As in the interpretation of the $^{17}O$ chemical shifts by one of the present authors and his co-workers,[78] the difference between the energies of the lowest unoccupied and the highest occupied orbitals, where the $\pi$ electrons of nitrogen are mainly localised, was adopted as a measure of $\Delta E$:

$$\Delta E = \epsilon_{LUMO} - \epsilon_{HOMO} .$$

The relation between $\delta_N$ and $\Delta E$ is illustrated in Fig. 3. The slight change in $\delta_N$ in the presence of substituents comprising elements of the Second Period corresponds to a slight change in $\Delta E$ and a marked change in $\delta_N$ within the Groups and also corresponds to a marked change in $\Delta E$.

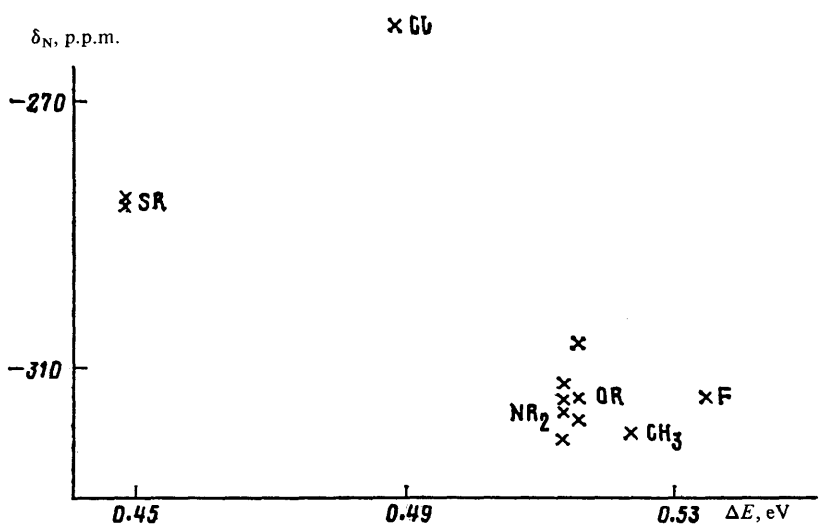

**Figure 3.** Dependence of the $^{15}N$ chemical shift on the calculated value of $\Delta E$ for cyclophosphazenes of the type $(^{15}NPR_2)_3$.

However, the $\Delta E$ for the thioethers is smaller than would be expected from the upfield displacement of $\delta_N$ relative to the chloro-derivative. This deviation can be caused by the fairly considerable contribution of the sulphur orbitals to the HOMO.

The $^{15}N$ chemical shift in the NMR spectra of cyclotetraphosphazenes has undergone a downfield displacement compared with the spectrum of cyclotriphosphazenes. This is probably caused by the change in molecular structure to a non-planar form, indicated by the identical chemical shifts for the compounds $(^{15}NPF_2)_3$ and $(^{15}NPF_2)_4$. The $^{15}N$ chemical shift for the pentameric cyclophosphazenes has undergone an upfield displacement compared with the spectrum of the tetrameric cyclophosphazenes, which can be accounted for by the fact that, on passing from $(NPR_2)_4$ to $(NPR_2)_5$, the quantity $\Delta E$ should change only slightly, while $Q_{PN}$ should diminish, which agrees with the change in the $^{31}P$ chemical shift. In the calculation of the paramagnetic contribution in the case of $^{15}N$ account is also taken of the values of $Q_{PN}$, as for $^{31}P$, and the above analogy in the instances quoted is understandable. On further increase of ring size, $\delta_N$ undergoes a slight upfield shift and probably approaches a limiting value.[55]

Cyclophosphazenes with mixed substituents but with identical substituents at the phosphorus atoms adjoining the nitrogen atom are characterised by a $^{15}N$ chemical shift which is almost independent of the substituents at the phosphorus atom remote from the ring nitrogen atom. In this case a simpler picture is observed than for the $^{31}P$ NMR spectra. The shifts $\delta_N$ for the phenylamino-derivatives of cyclotriphosphazene and cyclotetraphosphazene are presented as an example in Tables 5 and 6.

**Table 5.** $^{15}N$ Chemical shifts (in p.p.m.) for chloro(phenylamino)cyclotriphosphazenes.

*Solution in $(CD_3)_2CO$.

The values of $\delta_N$ for the same ring size depends mainly on the nature of the substituents at the neighbouring phosphorus atoms. A fairly linear relation between $\delta_N$ and the degree of substitution is observed regardless of whether the substitution is geminal or non-geminal. It is easily seen that the shifts quoted in the middle columns of Tables 5 and 6 are approximately equal to the arithmetical means of the values in the extreme columns. The same type of behaviour has been observed also for linear phosphazenes; for example, in the series of compounds $(EtO)_nCl_{3-n}P = N-P(O)(OEt)_mCl_{2-m}$, where $n = 0-3$ and $m = 0$ or $n = 3$ and $m = 1$ or 2, the gradual substitution of chlorine by ether groups entails a uniform upfield displacement of $\delta_N$.[79] The additivity of the influence of substituents on the chemical shift of nitrogen holds also for all other cyclophosphazenes which we investigated: $^{15}N_3P_3Cl_4F_2$,[21] $^{15}N_3P_3Cl_4(SEt)_2$,[20,21] $^{15}N_3P_3Cl_4(SPh)_2$ and $^{15}N_3P_3Cl_2(SPh)_4$,[20] and $^{15}N_4P_4Cl_4(SEt)_4$[20] and $^{15}N_3P_3Cl_4.(NH_2)_2$.[21]

The effect of substituents at phosphorus atoms which do not adjoin the given nitrogen atom on $\delta_N$ is insignificant in all the cases investigated. The electronic structure of cyclophosphazenes differs clearly from the delocalised aromatic bond system in cyclic organic compounds (Table 7). An appreciable influence of substituents on the $^{13}C$ NMR chemical shift has been observed in many instances in the case of monosubstituted benzenes for atoms in both *ortho*- and *para*-positions (transmission of the influence of substituents via the delocalised system of ring $\pi$ electrons), while for the geminally disubstituted cyclotriphosphazenes a marked influence only the neighbouring nitrogen atom is observed. The absence of an appreciable long-range influence is evidence against the ring delocalisation of $\pi$ electrons in cyclophosphazenes (see also, Thomas et al[22]).

## IV. $^{31}P-^{15}N$ SPIN–SPIN COUPLING CONSTANTS

The spin–spin coupling constants $^1J_{PN}$ have been determined in recent years for individual compounds and also for a series of different classes of compounds (mainly for organophosphorus compounds), using both $^{15}N$-enriched materials and compounds with the natural abundance of isotopes.[81-90] We determined the $^1J_{PN}$ coupling constants for $^{15}N$-labelled cyclophosphazenes.[20-23,27,28,30,35,55] The interaction constants for different cyclophosphazenes with substituents of one kind are compared in Table 8.

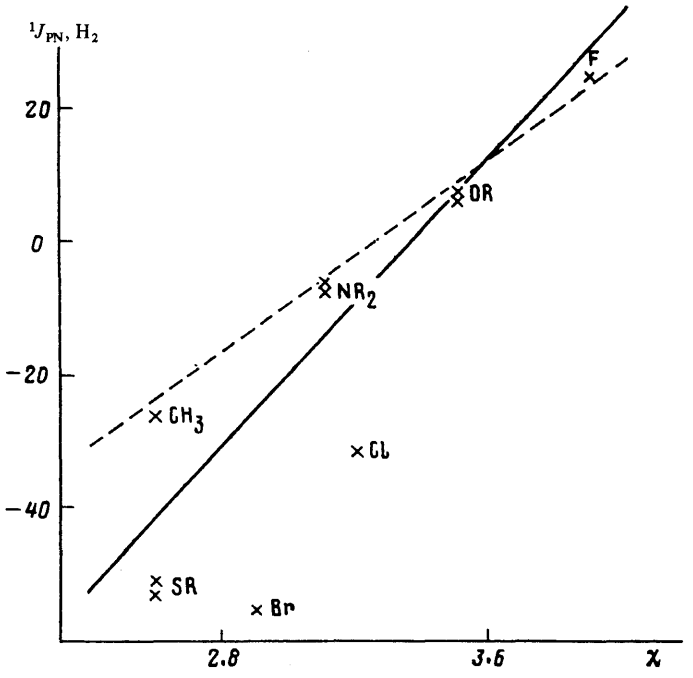

**Figure 4.** Correlation between the coupling constant $^1J_{PN}$ for compounds of the type $(^{15}NPR_2)_3$ and the electronegativity of the substituent atoms χ; the correlation coefficients are $r = 0.83$ (continuous line) and $r = 0.99$ (dashed line).

**Table 8.** Coupling constants $^1J_{PN}$ (in Hz) for cyclophosphazenes with substituents of one kind and different ring sizes.*

*The signs of the constants were not determined experimentally.

**For such a low value of the constant, it is impossible to predict the sign of the latter.

It was found that the absolute values of the coupling constant $^1J_{PN}$ are not correlated either with the parameters of the P–N bond or with those of the substituent. In order to account for the observed changes in $^1J_{PN}$ as a

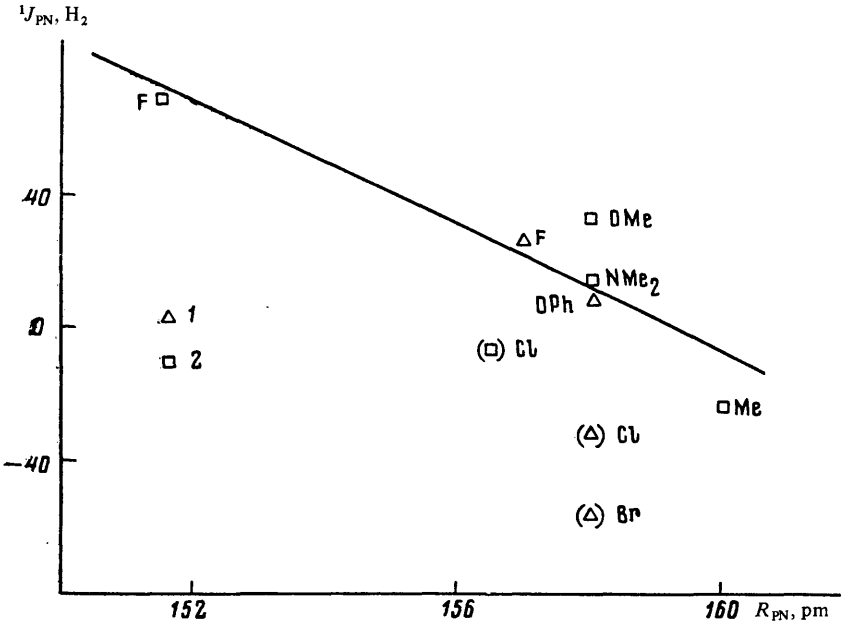

**Figure 5.** Correlation between $^1J_{PN}$ and the PN bond length ($R_{PN}$) for cyclotriphosphazenes (1) and cyclotetraphosphazenes (2). The continuous line corresponds to the correlation coefficient $r = 0.91$.

function of the position in the Mendeleev table of substituents linked directly to the phosphorus atom considered, it was necessary to assume that the increase of the atomic number of the substituent element within a Period and within a Group entails the reversal of the sign of $^1J_{PN}$. It is known from the literature[90-92] that $^1J_{PN}$ can be both positive and negative. The sign changes probably within the framework of one class of compounds. Since in most cases it was impossible to determine experimentally the sign of the coupling constants for cyclophosphazenes, the signs were selected in such a way that the changes in $^1J_{PN}$ were reasonable (Table 8). The legitimacy of this approach is confirmed by the results obtained for geminally disubstituted cyclotriphosphazenes[21] and for endocyclically $^{15}N$-labelled chloro(phenylamino)cyclotetraphosphazenes[23] (see below).

The coupling constants thus obtained are satisfactorily correlated with the electronegativity of the substituents atoms linked directly to the phosphorus atom, which can be seen in relation to cyclotriphosphazenes (Fig.4). The correlation coefficient is 0.83; an improved correlation ($r$ = 0.991) can be achieved by considering only the elements of the Second Period as the substituents. The same relations are observed in the series of cyclotetraphosphazenes.[28] The correlation established between the coupling constants $^1J_{PN}$ and the electronegativity of the substituent atoms is as expected, since the structure of the P–N bond systems in cyclophosphazenes depends to a large extent on the nature of the substituents.

In addition, Table 8 shows that $^1J_{PN}$ increases with increasing ring size when cyclophosphazenes with substituents of only one kind are considered and in most cases the greatest change is observed on passing from trimeric to tetrameric phosphazenes.

The examples presented below show that there is a linear correlation between the P–N coupling constant and other experimental data for the molecules. When the $^1J_{PN}$ and the P–N bond lengths for cyclotriphosphazenes and cyclotetraphosphazenes are compared (Fig.5), it is again striking that a satisfactory correlation is observed when account is taken only of the substituents whose atoms, linked to the phosphorus atom, are those of elements in the Second Period. The scatter of the points around the regression line can be accounted for to some extent as, on the one hand, the bond lengths are specified only to within 0.5 pm or even 1 pm (in the main the literature data were taken from the 1960s) and, on the other hand, the bond lengths can change somewhat on passing from a solid to a solution.

The constants $^1J_{PN}$ for cyclophosphazenes are in the given instance extremely sensitive to changes in the P–N bond lengths: when $d_{PN}$ changes from 151 pm in $N_4P_4F_8$ to 160 pm in $N_4P_4Me_8$, the P–N coupling constant changes from +68.8 Hz to -23.8 Hz. Compared with this, the change in the coupling constant $^1J_{CC}$ resulting from the marked alteration of the C–C bond length on passing from ethane (153 pm) to ethylene (134 pm) and acetylene (121 pm) is relatively small—from 34.6 Hz[94] to 67.6 Hz[95] and 171.5 Hz.[95]

Comparison of the P–N interaction constants with the frequencies of the antisymmetric stretching vibrations obtained from the infrared spectra reveals a very satisfactory correlation for substituents in which an element of the Second Period is linked to phosphorus (Fig.6). For other substituents, an appreciable deviation from this relation is observed; however, Fig.6 shows that some regularities can be observed for these elements too (this is indicated by dashed lines connecting points for substituent elements of the Third Period and the halogens).

It has been observed for pyridine and the pyridinium ion[93] that the free electron pair localised at the nitrogen atom influences the interaction constant $^1J_{NC}$. Since the free electron pair localised at the nitrogen atom in cyclophosphazenes is responsible for their basic properties, there should have been a direct relation between $^1J_{PN}$ and the basicities of the corresponding compounds. In fact such a relation is observed only within the limits of a single Period. An increase in the basicity of cyclophosphazenes[76] corresponds to a decrease of the P–N interaction constant.

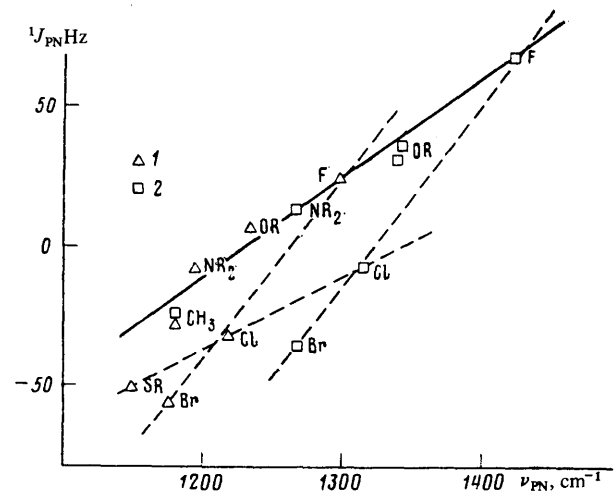

Figure 6. Correlation between $^1J_{PN}$ and the antisymmetric stretching vibration frequency for cyclotriphosphazenes (1) and cyclotetraphosphazenes (2); the correlation coefficient $r$ = 0.87 in all cases.

For a qualitative interpretation of the coupling constants, quantum-chemical model calculations were performed by the CNDO/2 method. The indirect spin–spin coupling constant is determined by three contributions: the Fermi contact contribution (*FC*), the orbital contributions (*OD*), and the spin–dipole contribution (*SD*). For coupling via one bond, the last two contributions are much smaller than that of the Fermi contact interaction and it is therefore possible to consider only the latter. Our calculations did indeed show that the *FC* contribution is greater by two orders of magnitude than the others, which is also confirmed by the data of a number of other investigators. For example, a linear correlation has been observed[83,84] between the experimental coupling constants and the *FC* contributions, also calculated by the CNDO/2 method using the theory of finite perturbations. On the other hand, Duangthai and Webb,[96] who used the INDO method, found, that, although the *SD* contribution remains small, nevertheless the orbital *OD* contribution plays an appreciable role, particularly when it is necessary to obtain the absolute values of the coupling constant.

According to Pople, the expression for the *FC* contribution in terms of the $\Delta E$ approximation is

$$J_{AB}^{FC} = \frac{32}{9}\pi\hbar\gamma_A\gamma_B\beta^2\,(^3\Delta E)^{-1}\langle s_A|\delta(r_A)|s_A\rangle\langle s_B|\delta(r_B)|s_B\rangle\, p^2_{s_As_B}\,, \quad (4)$$

where $\gamma_A$ and $\gamma_B$ are the gyromagnetic ratios of the interacting nuclei, $\beta$ is the Bohr magneton, $^3\Delta E$ the "average triplet excitation energy", $\langle s|\delta(r)|s\rangle$ the expected value

of the 2s or 3s function at the location of the nucleus, and $p_{s_A s_B}$ the order of the s-bond. Assuming that

$$K_{AB} = \frac{2\pi}{\hbar\gamma_A\gamma_B} J_{AB} , \quad (5)$$

it is possible to obtain the conventional coupling constant $K_{AB}$:

$$K_{AB}^{FC} = \frac{64}{9}\pi^2\beta^2 (^3\Delta E)^{-1} \langle s_A|\delta(r_A)|s_A\rangle\langle s_B|\delta(r_B)|s_B\rangle p^2_{s_A s_B} . \quad (6)$$

If it is assumed that $\Delta E$ and the expected values of the s-function do not vary, then the interpretation of the experimental coupling constants reduces to their comparison with the square of the s-bond order.

Examination of the experimental coupling constant $^1J_{PN}$ as a function of the calculated *FC* contribution jointly for cyclotriphosphazenes and cyclotetraphosphazenes yields the relation in the form of a regression line (Fig.7). For compounds with substituent elements of the Second Period, a very satisfactory correlation coefficient, amounting to 0.990, has been obtained. The inclusion in the consideration of compounds with substituent elements of the Third Period results in an appreciable worsening of the correlation.

Our method of calculation does not allow the observation of a change in the sign of the coupling constant. The quantum-chemical methods of calculation used in other studies[83,96] lead to different signs of $^1J_{PN}$. However, the changes in the signs of the coupling constants observed in these investigations[83,96] are due to the appreciable differences between the structures of the compounds considered. It has been found[90] that $^1J_{PN}$ depends greatly on the coordination number and hence on the bond system of the phosphorus atom involved in the coupling. These observations were subsequently confirmed. In a later study[96] devoted to the interpretation of the coupling constants $^1J_{PN}$ known at the time, certain refinements were introduced: the constant for coupling with tricoordinate phosphorus was found to be positive, electronegative substituents at the interacting P or N atoms increasing the s-electron density at the nuclei and hence increasing the coupling constant. For tetracoordinate phosphorus, negative coupling constants are frequently observed. Here the decisive factor, determining the sign of the constants, becomes the s character of the free electron pair at the nitrogen atom.

In cyclophosphazenes with identical ring sizes, a marked variation of the geometry is not observed when the nature of the substituent is altered; an exception is the fluorotetramer, having, in contrast to other cyclotetraphosphazenes, a planar ring structure. The marked change in the coupling constant on passing from $(^{15}NPF_2)_3$, for which $J_{PN}$ = +24.9 Hz, to $(^{15}NPBr_2)_3$ with $J_{PN}$ = −55.8 Hz must be caused by the different electron negativities of the substituents at the phosphorus atoms (Fig.4).

Table 9. Coupling constants $^1J_{PN}$ (in Hz)* for compounds of the type $^{15}N_3P_3Cl_{6-n}(SPh)_n$ (where $n$ = 0, 2, 4, or 6).

*The sign of the constants were not determined experimentally.

**The P–N bond types I, II, III, and IV correspond to isolated P–N bonds in the fragments $Cl_3P{-}N{-}PCl_2$, $Cl_2P{-}NP(SPh)_2$, $Cl_2PN{-}P(SPh)_2$, and $(PhS)_2P{-}N{-}P(SPh)_2$ respectively.

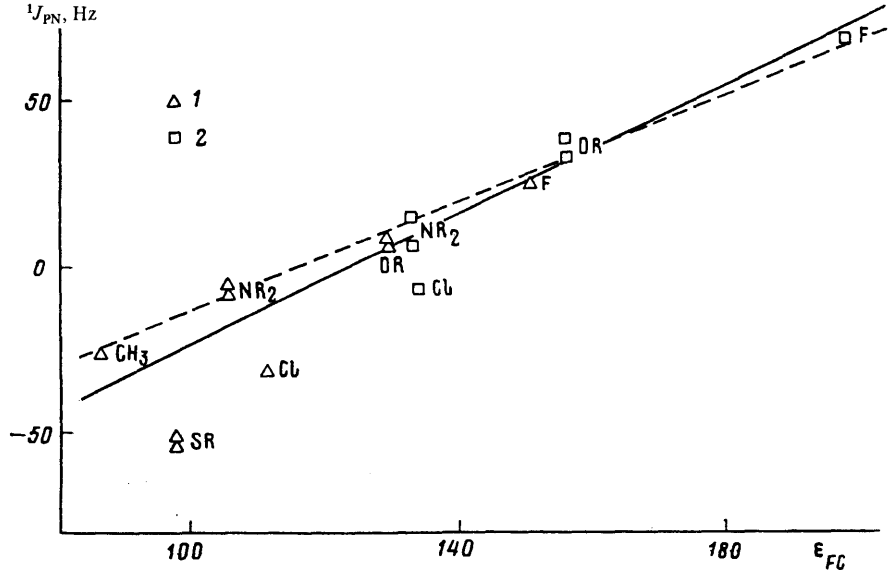

**Figure 7.** Correlation between $^1J_{PN}$ and the contribution of the Fermi contact interaction $\varepsilon_{FC}$ for cyclotriphosphazenes (1) and cyclotetraphosphazenes (2); the correlation coefficients are $r$ = 0.90 (continuous line) and $r$ = 0.990 (dashed line).

Tables 9 and 10 illustrate the influence of the nature of the substituents on the coupling constants $^1J_{PN}$ in relation to chloro(phenylthio)cyclotriphosphazenes[20] and chloro(phenylamino)cyclotetraphosphazenes.[16] The values of $^1J_{PN}$ depend in the first place on the nature of the substituents at the phosphorus atom involved in the P–N coupling considered and only then on the substituents at the other phosphorus atom linked to the given nitrogen atom. It is seen from Tables 9 and 10 that the differences between the coupling constants for bonds of types II and III are much greater than between the constants for bonds of types I and II or III and IV, the differences between the constants for bonds of one type being insignificant.

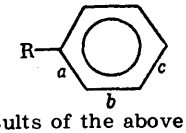

**Table 10.** Coupling constants $^1J_{PN}$ (in Hz) for chloro(phenylamino)cyclotetraphosphazenes $^{15}$N-labelled endocyclically.

| Compound | Type of P–N bond* | | | |
|---|---|---|---|---|
| | I | II | III | IV |
| $N_4P_4Cl_8$ | −6.9 | — | — | — |
| $N_4P_4Cl_7NHPh$ | −6.2; −7.0 | −2.9 | 5.7 | — |
| 6,8-$N_4P_4Cl_6(NHPh)_2$ | −8.6 | −3.0 | 8.0 | 6.7 |
| 4,8-$N_4P_4Cl_6(NHPh)_2$ | — | −3.5 | 6.6 | — |
| Mean value | −7.2 | −3.1 | 6.8 | 6.7 |

*The P–N bond types I, II, III, and IV correspond to isolated P–N bonds in the fragments $Cl_2P–N–PCl_2$, $Cl_2P–NPCl(NHPh)$, $Cl_2PN–PCl(NHPh)$, and (PhNH).ClP–N–PCl(NHPh) respectively.

The observed effect of the nature of substituents on $^1J_{PN}$ enabled us to confirm the change in the sign of $^1J_{PN}$ in relation to the geminal difluoro-derivative $^{15}N_3P_3Cl_4F_2$.[21] For chloro(phenylamino)cyclotetraphosphazenes, it was actually possible to determine directly, by modelling higher-order spectra, the relative sign of $^1J_{PN}$ on the assumption that $^2J_{PP}$ is positive. Thus the signs which we proposed in Table 8 are indeed justified.

It is of interest to compare the influence of substituents on the coupling constants $^1J_{PN}$ for cyclophosphazenes with their influence on the interaction constants $^1J_{CC}$ for monosubstituted benzene derivatives. The constants $^1J_{CC}$ had been determined[97] for C–C bonds occupying different positions in the molecules (see the scheme below) of more than 30 different benzene derivatives.

According to the results of the above study, the maximum changes in the C–C coupling constants for the *a* bond reached 21.3 Hz on passing from R = F to R = $SiH_3$, up to 4.7 Hz for the *b* bond on passing from R = NHMe to R = I, and 1.9 Hz for the *c* bond on passing from R = NCS to R = CHNOH. The coupling constant $^1J_{CC}$ depends on the electro-negativity of the substituent atom linked to the carbon atom.[96] Thus a profound analogy is observed between the changes in the $^1J_{PN}$ for geminally disubstituted cyclotriphosphazenes[21] and the $^1J_{CC}$ for monosubstituted benzene derivatives. The effect of remote substituents on the coupling constants for compounds with ring-delocalised π-systems is weak, in contrast to the influence on the chemical shift of the $^{13}$C signal.

We may note that the endocyclic coupling constants $^3J_{PN}$ are negligible; the exocyclic constants $^3J_{PN}$ for amino-cyclophosphazenes[22,23] will not be considered.

## V. $^{31}$P–$^{31}$P SPIN–SPIN COUPLING CONSTANTS

The coupling constants $^2J_{PP}$ were first determined for chlorofluorocyclotriphosphazenes.[10,11] In many cases the determination of $^2J_{PP}$ was complicated by the additional interactions of the $^{31}$P nuclei with other magnetic nuclei, in the first place protons. The development of the method involving the proton decoupling of the $^{31}$P nuclei was an important step both for the determination of the coupling constants and for the exact determination of the chemical shift $\delta_P$. Numerous constants of this kind are quoted in the literature for cyclotriphosphazenes. The number of such data for cyclotetraphosphazenes is much smaller, since the determination of $^2J_{PP}$ frequently requires model calculations of the spectra. These constants have been determined for certain tetrameric thioethers,[16,37,51,98] ethers,[99] and amino-derivatives.[13,23,100,101]

Analysis of the experimental P–P coupling constants for cyclotriphosphazenes led Finer[102] to the conclusion that $^2J_{PP}$ depends virtually only on the nature of the substituents located about the phosphorus atoms involved in the coupling but is independent of the substituent at the third phosphorus atom. Finer proposed a formula from which it is possible to calculate approximately the P–P coupling constant (in Hz) for any cyclotriphosphazenes:

$$^2J_{PP} = (\lambda_A+\lambda_B)(\lambda_C+\lambda_D). \qquad (7)$$

**Table 11.** Coupling constants $|^2J_{PP}|$ (in Hz) for chloro(ethylthio)cyclotriphosphazenes.

*Values obtained from spectra of $^{15}$N-labelled compounds.

Here $\lambda_A-\lambda_D$ represents specially selected parameters for the substituents attached to the interacting phosphorus atoms. The values of λ are satisfactorily linearly correlated with the electronegativities of the substituent atoms linked directly to phosphorus. The coupling constants $^2J_{PP}$ can be predicted with a satisfactory accuracy in many cases by means of the Finer formula or the set of values of λ for other substituents can be supplemented.[103–105] Our detailed investigation of the constants $^2J_{PP}$ for hetero-substituted chloro(ethylthio)cyclotriphosphazenes showed that the Finer formula does not lead to correct predictions in all cases (Table 11). Sometimes the values of $^2J_{PP}$ for the same combination of interacting nuclei differ markedly. Judging from the average values quoted in Table 11, $^2J_{PP}$ passes through a minimum as the number of SEt groups

substituting chlorine increases. It is difficult to find a satisfactory explanation of this phenomenon. We therefore suggest that in the above series the sign of $^2J_{PP}$ is reversed after the attainment of the minimum. The Finer formula cannot reflect the above feature.

In the case of substituted 2,2,6,6-tetraethylthiocyclotetraphosphazenes,[16] the sign of $^2J_{PP}$ should also change (Table 12). Indeed, different signs of the P–P coupling constants have been obtained for chloro-2,2-diethylthiocyclotetraphosphazene by model calculations of the $^{31}P$ NMR spectra.[51] The variation of the average constant $^2J_{PP}$ with the degree of substitution for compounds of the type $N_4P_4Cl_{8-n}(SEt)_n$ and $N_3P_3Cl_{6-n}(SEt)_n$ is illustrated in Fig.8. The $^2J_{PP}$ curves for compounds of the trimeric and tetrameric series are parallel if it is assumed that the sign of the constant $^2J_{PP}$ changes on passing from the $PCl_2$–N–$PCl_2$ fragment to the $P(SEt)_2$–N–$P(SEt)_2$ fragment. The above constants for cyclotriphosphazenes are somewhat greater than for cyclotetraphosphazenes. The same tendency has been observed for aminochlorocyclophosphazenes[99] and for chlorophenoxycyclophosphazenes[101] (see also, Sulkowski et al.[106] and Samir et al.[107]).

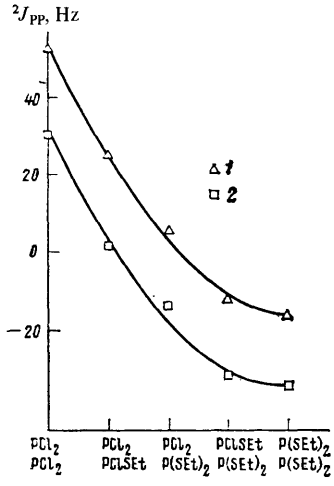

**Figure 8.** Coupling constants $^2J_{PP}$ for cyclotriphosphazenes (1) and cyclotetraphosphazenes (2) with different numbers of Cl and SEt substituents in fragments of the type $R_2PNPR_2$.

**Table 12.** Coupling constants $^2J_{PP}$ for substituted 2,2,6,6-tetraethylthiocyclotetraphosphazenes.

| Interacting nuclei in fragments | $\lvert {}^2J_{PP} \rvert$, Hz | Compound |
|---|---|---|
| $P(SEt)_2$, $P(SEt)_2$ | 31.6* | $N_4P_4(SEt)_8$ |

| » | 10.1 | $N_4P_4(SEt)_4Cl(OEt)_3$ |
| $P(SEt)_2$, $P(OEt)_2$ | 18.5 | $N_4P_4(SEt)_4Cl(OEt)_3$ |
| Ditto | 18.5 | $N_4P_4(SEt)_4(OEt)_4$ |
| $P(SEt)_2$, $P(OMe)_2$ | 20.0 | $N_4P_4(SEt)_4(OMe)_4$ |

*Value obtained from the spectrum of a $^{15}N$-labelled compound.

Almost all the P–P coupling constants mentioned hitherto have been obtained for cyclophosphazenes with mixed substituents. The determination of the constant $^2J_{PP}$ for the homosubstituted cyclotriphosphazenes $(NPR_2)_3$ and cyclotetraphosphazenes $(NPR_2)_4$ is possible only when the above compounds contain, apart from phosphorus, other magnetic nuclei with $I = 1/2$, so that higher-order spectra are obtained in which the required constants are reflected. However, Finer et al.[108] were unable to obtain the constants $^2J_{PP}$ from the proton spectra of such compounds by model calculations of the spectra, since the resulting spectra were not sufficiently well resolved.

The possibility of obtaining the P–P coupling constants for $^{15}N$-labelled homosubstituted cyclophosphazenes was already mentioned in the introduction. The graphical method for the determination of these compounds has been discussed in detail.[27,28] The constants are presented in Table 13 but only approximate values of some of them could be obtained, since in the case where the ratio $^2J_{PP}/^1J_{PN}$ is large the spectra do not reflect adequately the required constant.[27,28] The spectra of highly symmetrical compounds contain no information about the relative sign of $^2J_{PP}$ compared with $^1J_{PN}$. The signs listed in Table 13 were selected according to the considerations described above.

**Table 13.** Coupling constants $^2J_{PP}$ (in Hz)* for hexasubstituted cyclotriphosphazenes and octasubstituted cyclotetraphosphazenes.

| Compound | n = 3 | n = 4 |
|---|---|---|
| $(^{15}NPMe_2)_n$ | 4.4 | 10.7 |
| $[^{15}NP(NHMe)_2]_n$ | — | — |
| $[^{15}NP(NHEt_2)]_n$ | — | — |
| $[^{15}NP(NHPh)_2]_n$ | 30–70 | 35–45 |
| $[^{15}NP(NMe_2)_2]_n$ | — | — |
| $[^{15}NP(NEt_2)_2]_n$ | — | — |

| $[^{15}NP(OEt)_2]_n$ | 90–120 | — |
| $[^{15}NP(OPh)_2]_n$ | — | 80.6 |
| $[^{15}NP(SEt)_2]_n$ | −14.7 | −31.6 |
| $[^{15}NP(SPh)_2]_n$ | −23.5 | — |
| $(^{15}NPF_2)_n$ | 160–180 | 155.0 |
| $(^{15}NPCl_2)_n$ | 45–55 | — |
| $(^{15}NPBr_2)_n$ | (−)4.8 | −27.2 |

*The signs of the constants were not determined experimentally.

Fig. 9 illustrates the dependence of $^2J_{PP}$ for cyclotriphosphazenes and cyclotetraphosphazenes on the electronegativity of the substituent atoms; evidently there is a fairly satisfactory correlation between the values, the straight line for the trimeric compound lying above that for the tetrameric compounds.

Quantum-chemical calculation of these coupling constants in accordance with the $\Delta E$ approximation does not lead to satisfactory results. The Fermi contact contributions to the P–P coupling calculated by Eqn.(6) proved to be smaller approximately by two orders of magnitude than the contributions to the P–N interaction, while the experimental $^2J_{PP}$ and $^1J_{PN}$ coupling constants are mainly of the same order of magnitude. The additional allowance for other contributions (*OD* and *SD*) did not improve appreciably

the agreement between the experimental and calculated data. The approximate method of calculation of the coupling constants is evidently unsuitable for the spin–spin interactions of atoms separated by two bonds.

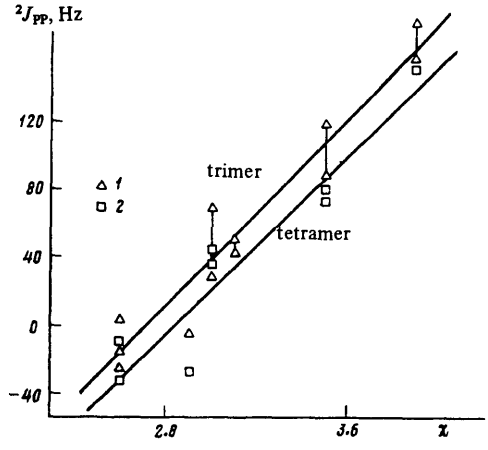

**Figure 9.** Coupling constants $^2J_{PP}$ for hexasubstituted cyclotriphosphazenes (1) and octasubstituted cyclotetraphosphazenes (2) as a function of the electronegativity of the substituent atom.

The coupling constants $^4J_{PP}$ for cyclotetraphosphazenes are small, as might have been expected. Only in certain cases has it been possible to determine them;[99,101,109] the values obtained for the aminochloro-derivatives, chloroethers, and aminoethers are in the range from −0.7 to −2.2 Hz.

## VI. CONCLUSION

The nature of the substituents R at the phosphorus atoms in cyclophosphazenes influences the electronic structure of the $(P-N)_n$ ring as well as the $^{31}P$ and $^{15}N$ chemical shifts and the $^1J_{PN}$ and $^2J_{PP}$ coupling constants. A change in ring size also alters the NMR parameters. A correlation is observed between the electronegativity of the substituent atoms and $\delta_P$ as well as the $^1J_{PN}$ and $^2J_{PP}$ coupling constants, whereas no such correlation exists for $\delta_N$. This has also been confirmed by calculations by the CNDO/2 method, according to which there is a linear correlation between the $\delta_P$ and the part of the paramagnetic contribution which depends on the distribution of electrons, while this type of correlation cannot be traced for $\delta_N$.

In considering the values of the individual parameters, one may reach a number of conclusions. The chemical shift of phosphorus $\delta_P$ depends directly on the nature of the substituents attached to the given phosphorus atom. The substituents at the other phosphorus atoms exert only an insignificant influence on $\delta_P$. Despite this, it is impossible to calculate $\delta_P$ with an adequate accuracy using a system of increments. With increase of ring size, $\delta_P$ undergoes an upfield shift.

The nitrogen chemical shift $\delta_N$ depends on the nature of the substituents at both neighbouring phosphorus atoms, but is independent of the substituents at the more remote phosphorus atoms. In this sense, cyclophosphazenes differ markedly from aromatic compounds with a delocalised π-system. The chemical shift $\delta_N$ varies linearly with the degree of substitution. On passing from trimeric to tetrameric phosphazenes, $\delta_N$ undergoes a downfield shift, while, on further increase of ring size, there is an upfield shift.

The coupling constants $^1J_{PN}$ can be both positive and negative. They depend primarily on the nature of the substituents at the phosphorus atoms involved in the coupling. To a lesser extent, their values are determined by the effect of the substituents at the other phosphorus atom linked to the nitrogen atom considered. The effect of the substituents at the more remote phosphorus atoms has not been observed. With increase of ring size, the constant $^1J_{PN}$ increases. There is an unambiguous relation between $^1J_{PN}$ and the P–N bond length and also the P–N stretching vibration frequency. Semiempirical quantum-chemical calculations have shown that there is a satisfactory correlation between the experimental coupling constants and the Fermi contact contributions. Thus $^1J_{PN}$ is the NMR parameter containing most information from the standpoint of the description of the electronic system of the skeleton of the $(P-N)_n$ rings.

The coupling constants $^2J_{PP}$ can be both positive and negative. They depend mainly on the nature of the substituents at both phosphorus atoms involved in the given coupling and to a lesser extent on the substituents at the other phosphorus atoms. With increase of ring size, $^2J_{PP}$ diminishes.

All the NMR parameters tend to limiting values with increase in ring size.

# The Physical Chemistry of the Intramolecular Cyclodehydration Reactions of Prepolymers

I.B.Rabinovich, N.V.Karyakin, A.L.Rusanov, and V.V.Korshak

The experimental data on the thermodynamics of the intramolecular cyclodehydration reactions of prepolymers in the solid phase are examined and treated systematically. The changes in the thermodynamic functions of the above processes have been analysed in detail over a wide temperature range. The temperature ranges corresponding to the formation of polyheteroarylenes which are "defect-free" to the maximum extent have been estimated.
The bibliography includes 65 references.

## I. INTRODUCTION

Among the numerous thermostable polymers, the heterocyclochain polymers containing different heterocyclic fragments in the main macromolecular chain are of special importance.

The principal methods of synthesising such polymers involve the polycondensation reactions of di- or tetracarboxylic acids and their derivatives with polyfunctional amines. Polymer macromolecules can then be formed both in one and in several stages.
The diphenyl or dimethyl esters of the corresponding acids and polyamides or their derivatives are usually employed as the initial compounds in polycondensation in the melt; as a result, a heterocyclochain polymer (a polyheteroarylene) is formed in one stage. When the synthesis is carried out in solution, polyamines and free carboxylic acids are as a rule used to obtain polyheteroarylenes in one stage and the solvent is normally polyphosphoric acid.

In the two-stage method of synthesis of polyheteroarylenes, intermediate products, the so-called prepolymers, are obtained in the first stage by the polycondensation of amines or their derivatives with the di-anhydrides (halides) of tetra- or di-carboxylic acids in an amide solvent. The prepolymers are converted in the second stage (thermal cyclisation at 400–650 K at a reduced pressure) into the final product—the heterocyclochain polymers. This polycondensation method is superior to the first two mentioned above. The majority of polyheteroarylenes are insoluble and infusible polymers, because they have a fairly rigid structure; however, in two-stage polycondensation articles can be made from the prepolymer and their heat treatment can impart to them the properties of the final polymer.

This is the explanation of the increasing interest in the thermal cyclodehydration reactions of prepolymers, demonstrated by the large number of publications both in the Soviet Union and abroad. This applies primarily to the study of the kinetics of the solid-phase cyclisation reactions of polyamidoacids.[1-11] The relevant data have been published[12-16] for reactions involving the synthesis of polybenzoxazoles via the intramolecular cyclodehydration of poly(*o*-hydroxyamides). The cyclisation reactions of polyhydrazides in the solid phase have been investigated.[17-22] The quantitative kinetic results and the mechanism of the formation of polybenzimidazoles and polybenzoylenebenzimidazoles have been described by Dawans and Marvel, Izyneer, and Korshak and co-workers[23-29] and by Colson et al, Teleshov et al., Laius et al., and Korshak et al.,[30-33] respectively. In the list quoted above we did not include studies whose results have been discussed in the monographs by Adrova et al.,[34] and Korshak and Vinogradova[35] and also studies devoted to general questions of the synthesis of polyheteroarylenes which have been described in detail in other reviews.[36-39]

In the study of the kinetics of the cyclisation of prepolymers, the vast majority of investigators have used infrared (IR) spectroscopy which makes it possible to follow the process from the change in the intensities of the characteristic absorption bands. Different versions of the same method have been used also to determine the degrees of cyclisation of the final polymers. Information about the IR spectra of various cyclic and heterocyclic molecules can be found in Bellamy's monograph.[40] In the case of polyimides one may employ the book of Adrova et al.,[34] while the paper of Rusanov et al.[41] deals with poly-1,3,4-oxadiazoles; the IR spectra of polybenzoxales have been described by Korshak et al.[42] The IR spectra of other polyheteroarylenes have been described in the original papers dealing with their synthesis.[34,36-39]

Systematic treatment of the available experimental literature data permits the conclusion that the cyclodehydration reactions of prepolymers are intramolecular and in the general case are described by a first-order kinetic equation. They have a number of general kinetic characteristics: (1) the effective rate constants for the cyclisation reactions of prepolymers diminish when the latter are converted into the final polyheteroarylenes and the degree of cyclisation–time isotherms show clearly the instant when the process comes to a stop;[43] (2) with increase of the degree of cyclisation, the activation energies for the above processes increase significantly;[44] (3) with increase of temperature, the limiting degree of cyclisation of the polyheteroarylene also increases.

A number of factors, from which it is possible to interpret the above features of the intramolecular cyclodehydration reactions of prepolymers in the solid phase, have been described in the literature. We shall only note that the majority of investigators attribute the increase of the

activation energy and the decrease of the rate constants for the cyclodehydration process to the increasing rigidity of the polymer chains in this process or, in other words, to the decrease of the number of groups in the polymer unit which are capable of hindered rotation. Here the idea has been put forward that, for kinetic reasons, the reaction involving the synthesis of polyheteroarylenes proceeds at an appreciable rate only in the region of the highly elastic state of the polymer.[25-29]

At the same time, one should note the complete absence of literature data for the thermodynamics of the cyclisation reactions of prepolymers in the solid phase. The authors of this review applied for the first time the classical calorimetric methods to the analysis of these reactions. All this made it possible to determine the enthalpies, entropies, Gibbs free energies, and equilibrium constants for the thermal cyclisation reactions of prepolymers. From our point of view, the results obtained are of undoubted theoretical and applied interest, because they make it possible to predict the average degree of polycondensation and the number-average molecular weight of the polyheteroarylene formed. We therefore believe it essential to survey and treat systematically the experimental data obtained previously for the thermodynamics of the intramolecular cyclodehydration reactions of a number of prepolymers.

## II. THERMODYNAMICS OF THE INTRAMOLECULAR CYCLODEHYDRATION REACTIONS OF PREPOLYMERS

This Section deals with the results obtained in the study of the thermodynamics of the synthesis of a series of polyheteroarylenes via the intramolecular cyclodehydration of the corresponding prepolymers.

The general approach to the solution of the problem was as follows. A study was made of the heat capacity $C_p^0$ of the prepolymers and the corresponding polyheteroarylenes in the temperature range 60–650 K. For this purpose, use was made of the adiabatic calorimeters described in detail by Lebedev and Lityagov.[45] The accuracy of the heat capacities of the polymers obtained was to within 0.2–0.3% in the temperature range 60–300 K, to within 0.7–1.0% in the range 300–500 K, and 1.5% at higher temperatures. Extrapolation of the experimental curves for the heat capacities of the prepolymers from 60 to 0 K was carried out in terms of the two-parameter Tarasov equation:[46,47]

$$C_p^0(1,3) = K\left\{D_1\left(\frac{\Theta_1}{T}\right) - \left(\frac{\Theta_3}{\Theta_1}\right)\left[D_1\left(\frac{\Theta_3}{T}\right) - D_3\left(\frac{\Theta_3}{T}\right)\right]\right\}, \quad (1)$$

where $\Theta_1$ and $\Theta_3$ are the characteristic temperatures, $D_1$ and $D_3$ the Debye functions of the heat capacities of the one-dimensional and three-dimensional continua, and $K$ is a constant coefficient for the given polymer.

The Kelley–Parks–Huffman extrapolation method was employed for the polyheteroarylenes:[48]

$$C_p^0 = (a + bT) \cdot C_p^0\,(\mathrm{PP}),$$

where $C_p^0$ is the heat capacity of the given polyheteroarylene, $C_p^0$ (PP) the heat capacity of the corresponding prepolymer at the same temperatures, and $a$ and $b$ are empirically selected constants.

The coefficients and characteristic temperatures were chosen such that the heat capacities calculated from the corresponding equation do not differ from the experimental values of $C_p^0$ in the range 60–80 K by more than 0.3%. The thermodynamic functions of the polymers were calculated from the equations

$$H^0(T) - H^0(0) = \int_0^T C_p^0\,\mathrm{d}T;\ S^0(T) - S^0(0) = \int_0^T C_p^0\,\mathrm{d}\ln T;$$
$$G^0(T) - H^0(0) = [H^0(T) - H^0(0)] - T\,[S^0(T) - S^0(0)]\ . \quad (2)$$

The integrals were calculated by Simpson's method[49] or with the aid of a computer. As mentioned above, the reactions leading to the synthesis of polyheteroarylenes by intramolecular cyclodehydration of the prepolymer are carried out in the solid phase and are accompanied by a considerable increase of the rigidity of the macromolecular chain. They hardly ever go to completion and the polyheteroarylene formed is a heterounit polymer containing the structural fragments of the prepolymer in its composition. This factor leads to the necessity for the determination of the degree of cyclisation of the prepolymer (the extent to which the polyheteroarylenes have a heterounit structure). The method employed for this purpose[50,51] is based on the additivity of the enthalpies of combustion of the statistical copolymers relative to the corresponding homopolymers:[52]

$$M_2'\Delta h_c^0(298,\ \mathrm{PHA}) = N_2\Delta H_c^0(298,\ \mathrm{PHA}) + (1 - N_2)\,\Delta H_c^0(298,\ \mathrm{PP}), \quad (3)$$

where $M_2' = N_2M_2 + (1 - N_2)M_1$ is the average molecular weight of the repeat unit of the real polyheteroarylene specimen, $N_2$ the mole fraction of the heterocycles in the polyheteroarylene specimen investigated, and $M_1$ and $M_2$ are the molecular weights of the prepolymer units and the polyheteroarylene respectively; $\Delta H_C^0$ (298, PP) and $\Delta H_C^0$ (298, PHA) are the standard enthalpies of combustion of the prepolymer and the ideal 100% polyheteroarylene at 298.15 K respectively and $\Delta h_C^0$ (298, PHA) is the standard specific enthalpy of combustion of the real polyheteroarylene specimen at 298.15 K. Eqn.(3) can be written in the following form

$$[N_2M_2 + (1 - N_2)\,M_1]\,\Delta h_c^0(298,\ \mathrm{PHA}) = N_2\Delta H_c^0(298,\ \mathrm{PHA}) + (1 - N_2)\,\Delta H_c^0(298,\ \mathrm{PP}).$$

Bearing in mind that $\Delta H_C^0$ (298, PP) − $\Delta H_C^0$ (298, PHA) = $\Delta H_r^0$ (298) is the enthalpy of cyclisation of the prepolymer at 298.15 K, we obtain

$$N_2 = [\Delta H_c^0(298,\ \mathrm{PP}) - M_1\Delta h_c^0(298,\mathrm{PHA})]/[\Delta h_c^0(298,\ \mathrm{PHA})(M_2 - M_1) + \Delta H_r^0(298)]\ . \quad (4)$$

The quantity $\Delta h_C^0$ (298, PHA) was determined experimentally in an isothermal bomb calorimeter at 298.15 K under standardised combustion conditions. A V-08 calorimeter[53] was used for this purpose; twice the standard deviation of the quantities obtained did not exceed 0.1%.

The $\Delta H_C^0$ (298, PP) were calculated from the experimental enthalpy of formation of the prepolymer in solution taking into account the enthalpies of solution of the starting materials and the polymer as well as the standard enthalpies of combustion of the monomers. Compared with the method based on the direct combustion of the prepolymer, this procedure for the determination of $\Delta H_C^0$ (298, PP) can eliminate the influence of the possible presence of the solvent in the polymer on the enthalpy of combustion of the prepolymer being determined.

The equilibrium water vapour pressure over the prepolymer in the course of its cyclisation reaction was used to determine the enthalpy of cyclodehydration. The tensimetric version of the static method was selected.[54] The absolute values of the measured water vapour pressure in duplicate experiments differed by not more than (1–2) × $10^{-1}$ kPa, which led to an error in the determination of the enthalpies of cyclodehydration of the prepolymers not exceeding ±2.0 kJ mol$^{-1}$.

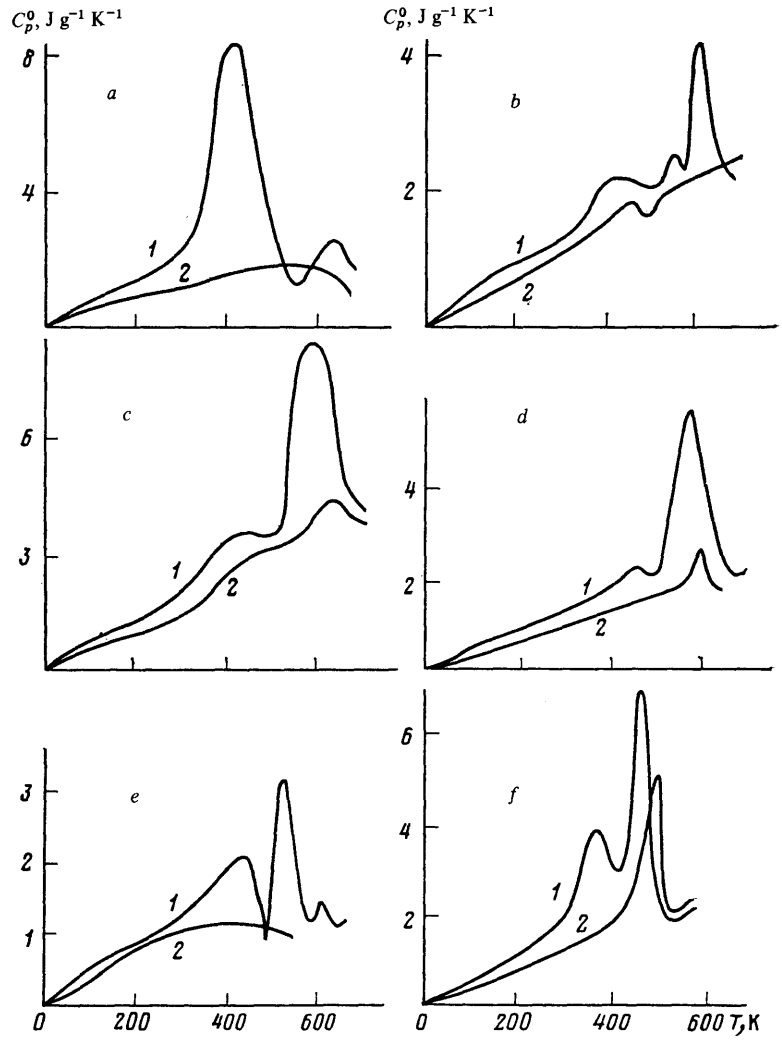

**Figure 1.** Temperature variation of the specific heats: *a*) of the polyamidoacid (PAA, curve *1*) and poly(*pp'*-diphenyl oxide)pyromellitimide (PI, curve *2*);[55] *b*) of poly(*o*-amido)-1,2,4-triazole (PATA, curve *1*) and polytriazoloquinazoline (PTAQ, curve *2*);[56] *c*) of poly(*o*-aminophenyl)benzimidazole (PBA, curve *1*) and polybenzimidazoloquinazoline (PBIQ, curve *2*);[62] *d*) of poly(*pp'*-diphenylphthalide)hydrazide (PH-P, curve *1*) and poly(*pp'*-diphenylphthalide)-1,3,4-oxadiazole (POD-P, curve *2*);[57] *e*) of poly(*pp'*-diphenyl oxide)hydrazide (PH-O, curve *1*) and poly(*pp'*diphenyl oxide)-1,3,4-oxadiazole (POD-O, curve *2*);[58] f) of poly(4,4'-dihydroxy-3,3'-isophthalamidodiphenylmethane) (POA, curve *1*) and poly[2,2'-(*m*-phenylene)-5,5'-dibenzoxazolymethane (PBO, curve *2*).[59]

→αβωε [6~]

In most cases the vapour phase was analysed chromatographically to determine the possible content of the corresponding solvent. For the given heterogeneous reaction, the equilibrium constant is determined by the expression $K_p = P^n(H_2O)$, where $n$ is the number of moles of water evolved in the cyclisation of the prepolymer per repeat unit. The equation of the reaction isobar can therefore be expressed as $d \ln P^n/dT = \Delta H_p/RT^2$; when the integration is carried out in terms of the approximation that $\Delta H_P$ is independent of $T$ over a narrow temperature range, this expression yields $n \ln P = -\Delta Hp/RT + C$, i.e. a linear relation between $\ln P$ and $1/T$. In view of this, the enthalpy of cyclodehydration $\Delta H_r^0(T)$ at a certain average temperature $T$ in the experimental temperature range was determined from the plot of the linear relation $\ln P = f(T^{-1})$. The same quantity at $T = 298.15$ K was calculated from the Kirchhoff formula taking into account the heat capacities of the polymer and water. (It has been established[55] that the heat capacities of polyheteroarylene specimens with a high degree of cyclisation differ little from the heat capacity of the corresponding 100% polyheteroarylene).

The heat capacities and thermodynamic functions of 100% polyheteroarylenes were calculated from the thermodynamic properties of real polyheteroarylene specimens and the known degree of their heterounit structure assuming additivity. For example, the entropy of 100% polyheteroarylene at the given temperature is defined by the relations

$$M_2'S^0(\text{PHA}) = N_2S_M^0(\text{PHA}) + (1 - N_2)S^0(\text{PP}); \quad (5)$$
$$S_M^0(\text{PHA}) = \{[N_2M_2 + (1 - N_2)M_1]S^0(\text{PHA}) - (1 - N_2)'S^0(\text{PP})\}N_2^{-1},$$

where $S^0$(PHA) is the specific entropy of the polyheteroarylene investigated at the given temperature, $S^0_m$(PHA) the molar entropy of the 100% polyheteroarylene, and $S^0$(PP) the molar entropy of the prepolymer at this temperature.

The entropies of cyclodehydration at each temperature were calculated from the entropies of the reactants. The zero-point entropy of the polymer, which is not taken into account in the given instance, introduce a small error into the determination of the entropy of reaction, because the difference between the zero-point entropies of polyheteroarylene and the corresponding prepolymer is comparatively small.

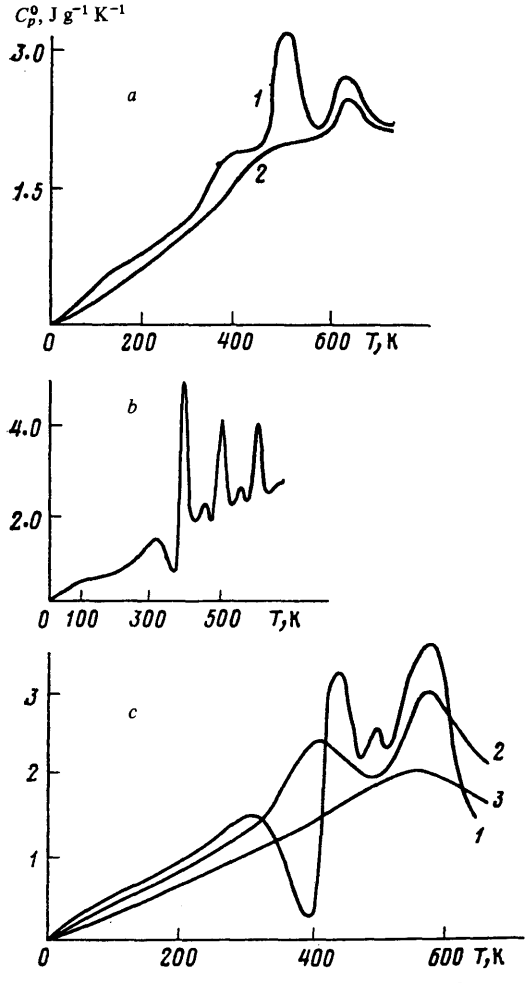

**Figure 2.** Temperature variation of the specific heats: *a*) of poly[*N*-terephthaloylbis(*N'*-phenyl-*o*-diphenylamine)] (PPDA, curve *1*) and poly[2,2'-(*p*-phenylene)-1,1'-diphenyl-5,5'-dibenzimidazole] (PPDBA, curve *2*);[60] *b*) of polyaminoamidoacid (PAAA);[50] *c*) of poly(*o*-carboxy) benzoylamidrazone (PCBA, curve *1*), polyamidinoimide (PADI, curve *2*), and polybenzoylene-*s*-triazole (PBTA, curve *3*).[63]

The Gibbs free energy of cyclodehydration at each temperature was calculated by the Gibbs–Helmholtz equation from the enthalpies $\Delta H^0_r(T)$ and entropies $\Delta S^0_r(T)$ obtained. The equilibrium constant was calculated from the equation of the reaction isotherm: $\Delta G^0_r(T) = -RT \ln Kp$.

## III. THE HEAT CAPACITIES OF PREPOLYMERS AND POLYHETEROARYLENES

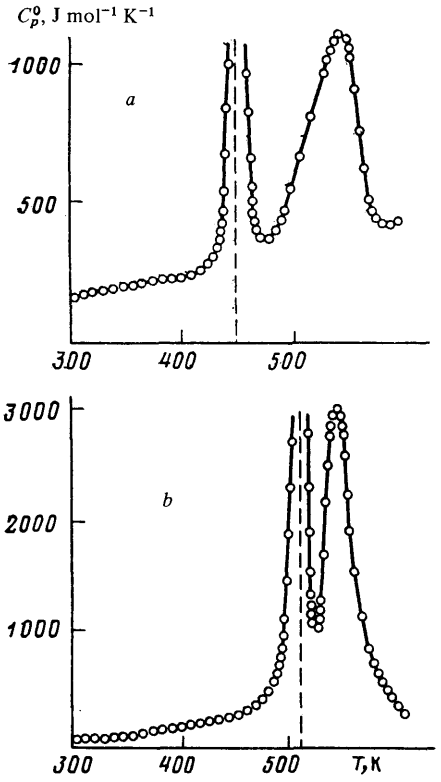
In the range 60–300 K the heat capacities of prepolymers and polyheteroarylenes increase monotonically with increase of temperature. As a consequence of the greater rigidity of the macromolecular chain of polyheteroarylenes, their heat capacities are always smaller than the corresponding $C^0_p$ for the prepolymers at the same temperatures. At higher temperatures the curves representing the temperature variation of the heat capacities of the prepolymers investigated exhibit distinct anomalies in the form of endothermic peaks. These anomalies are associated with the intramolecular cyclodehydration reactions of the prepolymers.

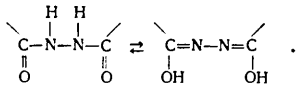
In most cases a single peak is observed:[55–63] in the temperature ranges 350–550 K (PAA, Fig.1*a*), 550–650 K (PATA, Fig.1*b*), 550–650 K (PBA, Fig.1*c*), 520–600 K (PH-P, Fig.1*d*), 500–560 K (PH-O, Fig.1*e*), and 450–520 K (POA, Fig.1*f*). The curves for the temperature dependence of the heat capacities of the other prepolymers investigated have two (PPDA, Fig.2*a*) and even three endothermic peaks (PAAA, Fig.2*b*, and PCBA, Fig.2*c*). In many instances, the appearance of the endothermic peak is preceded by a jump in heat capacity due to the devitrification of the initial prepolymer in the temperature ranges 352–420 K (PATA, Fig.1*b*), 380–450 K (PBA, Fig.1*c*), ~510 K (PH-P, Fig.1*d*), 400–450 K (PH-O, Fig.1*e*), 280–350 K (PAAA, Fig.2*b*), and 350–400 K (PPDA, Fig.2*a*).

In view of this, one can assume that the intramolecular cyclodehydration reactions in general actually occur at temperatures above the glass point of the corresponding prepolymer, where there is a sharp increase of the mobility of the polymer segments. Precisely under these conditions, the kinetic energy of the polymer units can exceed the energy of the activation barrier to the reaction and there is a possibility that a transition state may be formed. The occurrence of cyclodehydration in several stages can be accounted for in the same way, i.e. by kinetic causes. For example, in the reaction involving PAAA (Fig.3*b*), two water molecules are split off from the repeat unit of the polymer in the first stage at ~410 K with formation of polyamidoimide (PAI).

It is easy to suppose that the activation energy for the reaction PAA → PAI + $2H_2O$ is appreciably lower than the activation energy for the simultaneous elimination from the polyamidoacid unit of four water molecules with formation of polybenzoylenebenzimidazole (PAAA → PBBA + $4H_2O$). It was more difficult to explain why the elimination of two water molecules from the polyamidoimide unit with its conversion into a polybenzoylenebenzimidazole unit (PAI → PBBA + $2H_2O$) and also the elimination of two water molecules from the polyamidinoamide unit with its conversion into polybenzoylene-*s*-triazole (PADI → PBTA + $2H_2O$) or of two water molecules from the poly[*N*-terephthaloylbis(*N'*-phenyl-*o*-diphenylamine)] via the reaction PPDA → PPDBA + $2H_2O$ proceeds in two stages. We suggest that these are not two different processes or two stages of an overall process but one and the same process occurring partly in one temperature range and partly in another. The point is that, when the cyclodehydration reaction of the prepolymer cannot occur, for kinetic reasons, at a realistic rate at a temperature corresponding to the vitreous state of the polymer, it begins only after the system has been heated above the devitrification temperature. However, having

begun, the process itself leads to an increase of the rigidity of the polymer chain and hence to an increase of the glass point. For this reason, whereas at the beginning of the process, when the system is heated, the devitrification of the polymer due to the increase of temperature predominates over the vitrification process due to the increased fraction of cyclic fragments in the polymer as a consequence of the cyclodehydration reaction, after the attainment of a certain degree of conversion of the prepolymer into the final heterocycle, the relative contributions of the above processes are reversed, which leads to the arrest of cyclisation. However, on further increase of temperature, whereupon the polymer again passes to the highly elastic state, the cyclodehydration process continues. From this standpoint, the difference between the thermodynamic and kinetic parameters of the individual stages of the reaction can be accounted for by the different rigidities of the polymer chains and by the different interchain interaction energies in these stages and also directly by the difference between the temperatures of both ranges where the given processes take place.





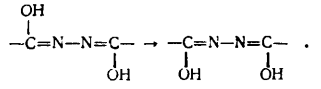


**Figure 3.** Temperature variation of the heat capacities of the *NN'*-dibenzoylhydrazide of diphenylphthalide-4,4'-dicarboxylic acid (*a*) and the *NN'*-dibenzoylhydrazide of (diphenyl oxide)-4,4'-dicarboxylic acid (*b*).[63]

If the rigidity of the polymer chain plays an important role in prepolymer cyclodehydration processes, their occurrence should depend significantly on the initial structure of the polymer. The authors of this review therefore carried out a comparative study of the cyclodehydration reactions of polyhydrazides and their low-molecular-weight analogues of different structure. It has been suggested[64] that the occurrence of the cyclodehydration of polyhydrazides is associated with the formation of a transition state in the system whose conformation is close to that of the *cis*-form of the hydrazide fragment:

At the same time, analysis of three-dimensional models and conformational calculations for chains of analogous structure[64] have shown that, from the standpoint of the interchain interaction and packing effects in the solid polymer, the *trans*-form of the hydrazide fragment is the most favourable. In view of this, the formation of the transition state is preceded by the rotational isomerisation of the hydrazide group:

Consequently the composition and structure of the initial polyhydrazide should have a significant influence on the tendency of the hydrazide groups towards intramolecular cyclodehydration, because the chemical nature of the fragments determines the initial flexibility of the polyhydrazide chain.

For comparative analysis, Karyakin[63] investigated poly-2,5-(*pp'*-diphenyl oxide hydrazide) (PH-O), poly-2,5-(*pp'*-diphenylphthalyl hydrazide) (PH-P), and their low-molecular-weight analogues: *NN'*-dibenzoylhydrazide of diphenylphthalide 4,4'-dicarboxylic acie (M-P) and *NN'*dibenzoylhydrazide of (diphenyl oxide)-4,4'-dicarboxylic acid (M-O).

It follows from Fig. 3 that the heat capacity of M-P increases monotonically with increase of temperature from 300 to 420 K. At 450 K M-P crystals begin to melt. In the range 460–560 K (the maximum heat capacity is observed at 530 K) a second endothermic peak, associated with the cyclodehydration of M-P and its conversion into the corresponding cyclic compound, appears. An analogous picture is observed also for M-O (Fig. 3*b*). The endothermic peak in the range 520 to 580 K (the temperature of the maximum is 530 K), due to the cyclodehydration of M-O, is preceded by the fusion of the polymer at 510 K. Thus one may conclude that the thermal cyclodehydration of the model compounds M-O and M-P with formation of the corresponding 1,3,4-oxadiazoles takes place at an appreciable rate only in the melt of the initial hydrazide. With increase of the rigidity of the molecules of the model compound M-P compared with that of M-O, both the temperature range of the cyclodehydration reaction and the range between the melting point and the temperature of the maximum rate of cyclisation is observed.

Accordingly, the introduction of the bulky phthalide group into the polymer chain, which increases the rigidity of the chain and diminishes thereby the number of groups in the polyhydrazide unit capable of internal rotation, leads, firstly, to an incrase of the glass point of PH-P compared with PH-O (510 and 440 K respectively) and, secondly, increases the cyclodehydration temperature (which is higher by ~50 K for PH-P than for PH-O). An analogous effect is observed also on comparing the temperature variations of the heat capacities of the heterounit PH-P, the degree of cyclisation of which is 0.5, and the uncyclised PH-P. The increase of the rigidity of the system in the former case entails an increase of the glass point and of the temperature of the onset of cyclodehydration.[63]

## IV. THE WATER VAPOUR PRESSURES OVER THE PREPOLYMERS IN THE COURSE OF THEIR CYCLODEHYDRATION

In order to calculate the enthalpies of the intramolecular cyclodehydration of the prepolymers, a study was made of the equilibrium vapour pressure of water over the corresponding polymers during their cyclisation.[55-63] The data obtained are fully consistent with the above conclusions concerning the character of the solid-phase cyclisation reactions. As an illustration, Fig. 4 presents such data for a polyaminoamidoacid and poly[*N*-terephthaloylbis(*N'*-phenyl-*o*-diphenylamine)]. The cyclodehydration of the polyaminoamidoacid (Fig. 4*a*) takes place in three stages: the elimination of two water molecules with conversion into PAI (curve *1*) and the subsequent elimination of two water molecules with conversion of the PAI units into PBBA [poly(benzoylene)benzimidazole - Ed. of translation] units. The cyclodehydration of PPDA (Fig. 4*f*) takes place in two stages, in each of which two water molecules are split off from the repeat unit of the initial polymer with formation of PPDBA.

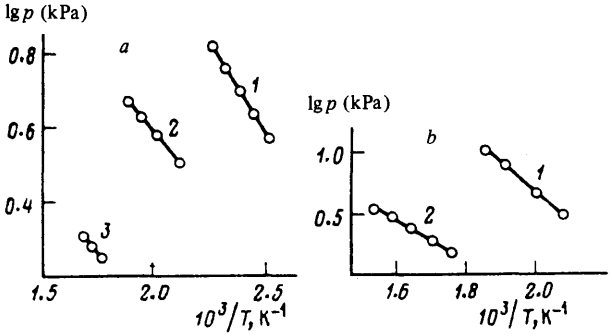

**Figure 4.** Temperature variation of the water vapour pressures over PAAA[50] (*a*) and PPDA[60] (*b*) in the course of their cyclisation: 1)–3) successive water elimination stages in the reactions.

Table 1 lists the coefficients of the corresponding equations $\lg p = f(T^{-1})$, which describe the experimental water vapour pressures over a series of prepolymers. Table 2 presents the results of the determination of the degrees of cyclisation of various polyheteroarylenes by Eqn. (4). Evidently, the polyheteroarylenes investigated are indeed heterounit polymers whose composition includes also the uncyclised units of the initial prepolymer.

## V. ANALYSIS OF THE THERMODYNAMIC CHARACTERISTICS

The data on the thermodynamic properties of the prepolymers and the corresponding polyheteroarylenes described above have been used to calculate the standard enthalpies, entropies, and Gibbs free energies (Table 3). Analysis of the results permits a conventional subdivision of all the prepolymers investigated into two groups (Table 4). $\Delta H_r^0(T) < 0$ is observed at temperatures in the range 100–300 K for the group I prepolymers (PAAA, PCBA, PAA, PAI, PADI, and POA), while $\Delta H_r^0(T) > 0$ occurs at the same temperature for the group II prepolymers (PH-P, PBA, PATA, and PPDA). Above 373 K, the enthalpies of cyclodehydration are positive for polymers of both groups which is caused mainly by the elimination of water in the vapour state. Under these conditions, $\Delta H_r^0(400)$ for the group I prepolymers is lower than for those in group II (Table 4).

**Table 1.** The coefficients of the equations $\lg p = A - B/T$ (the pressures $p$ are expressed in kPa).

| PBA | PBIQ | 16387±10 | 31.03±0.03 | 31.0±3.0 | 0.93 | [62] |

Notation: $\Delta H_c^0$(298, PP) is the enthalpy of combustion of the prepolymer, $\Delta h_c^0$(298, FP) the specific enthalpy of combustion of the final polyheteroarylene, and $\Delta H_r^0$(298) the enthalpy of cyclisation of the prepolymer.

In terms of the sign and the absolute order of magnitude, the entropies of cyclodehydration are the same for both groups of prepolymers, because the entropies of the final and intermediate polymers do not differ greatly and the quantity $\Delta S_r^0(T)$ is mainly determined by the entropy of two moles of water.

**Table 3.** Thermodynamic characteristics of the intramolecular solid-phase cyclodehydration of a series of prepolymers at atmospheric pressure.

The free energy $\Delta G_r^0(T)$ for the group I prepolymer is negative at all temperatures, because at low temperatures (100–300 K) the cyclodehydration processes are exothermic and their entropies are either small and negative or (usually) positive. At higher temperatures ($T \geq 400$ K) the enthalpies of these reactions are in all cases positive, but they are characterised by large positive entropies (Table 5), so that the role of the entropy factor becomes decisive: $T\Delta S_r^0(T) > \Delta H_r^0(T)$.

*Twice the average standard error of the calculated Gibbs free energies for the cyclodehydration reaction.

$\Delta G_r^0(T) > 0$ is observed for the group II prepolymers at temperatures from 100 to 400 K, because the corresponding processes are endothermic and their positive entropies do not compensate for the enthalpy of the process: $\Delta H_r^0(T) > T\Delta S_r^0(T)$. At temperatures above 400 K, $\Delta G_r^0 < 0$ for the cyclodehydration reactions of group II prepolymers.

For the majority of the cyclodehydration reactions investigated, the standard Gibbs free energies vary linearly with temperature (Table 5), which make it possible to estimate $\Delta G_r^0(T)$ and the equilibrium constants of these processes at the temperatures used in practice for the heat treatment of the prepolymers. Such data are listed in Table 6 together with the degrees of polycondensation of polyheteroarylenes ($P_n$) calculated from the Carothers formula[65] and the degrees of conversion $X$ of the initial prepolymer into the final heterocyclochain polymer. Comparison of the data obtained with the results quoted in Table 2 shows that the cyclisation of the corresponding prepolymers in the case of PBIQ, PPDBA, POD-P, and PI at experimental temperatures went to completion, because the values of $N_2$ and $X$ are equal within the limits of the error of the calculations. The cyclisation reaction of the prepolymers associated with PTAQ, PBO, and, especially, PAI and PADI do not go to completion, because $N_2 < X$ at the experimental temperatures (Tables 2 and 6).

**Table 6.** The standard Gibbs free energies ($\Delta G_T^0$), the equilibrium constants ($Kp$), and the degrees ($X$) of the cyclodehydration reactions of the prepolymers and the degrees of polycondensation ($\bar{P}_n$) of the polyheteroarylenes formed.

The character of the temperature variation of $X$ is significantly different for the cyclodehydration reactions of prepolymers of different groups. For the group II prepolymers (PH-P, PATA, PPDA, and PBA, Fig.5), the values of $X$ are low (0.001–0.354) in the temperature range 300 to 400 K; the degree of reaction then increases sharply with increase in temperature, reaching values virtually equal to unity (100% polyheteroarylene) at 600 K for PH-P, 650 K for PATA, 750 K for PPDA, and 850 K for PP. At these precise temperatures the equilibrium constants of the cyclodehydration reactions become equal to $5 \times 10^3$–$1 \times 10^4$.

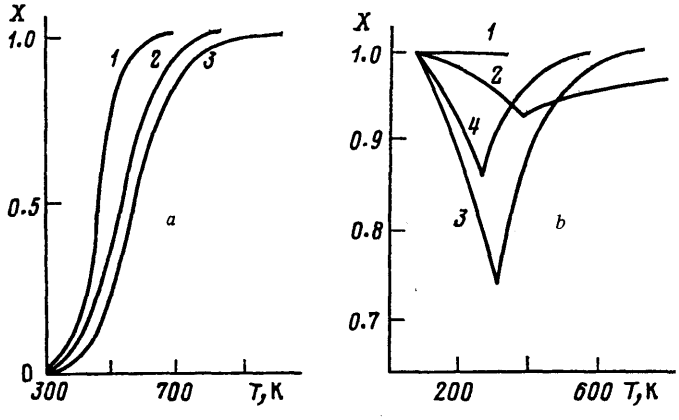

**Figure 5.** Temperature variation of the degrees of conversion $X$ in the cyclodehydration reactions: *a*) PATA (curve *1*), PPDA (curve *2*), and PBA (curve *3*); *b*) PAAA (curve *1*), PADI (curve *2*), POA (curve *3*), and PAI (curve *4*).[63]

From the thermodynamic standpoint, the preparation of fully cyclised (homounit) polyheteroarylenes from the prepolymers of the first group is possible both at low (100 to 150 K) and relatively high temperatures (500–600 K). The fact that the $N_2$ for PBO, PAI, PADI, PBBA, and PBTA do not reach limiting values determined by the equilibrium constants of the corresponding cyclodehydration reactions can be accounted for only by kinetic causes. In such cases the rigidity of the heterounit polymer formed is apparently so great that this leads to a virtual inhibition of the cyclisation process at the experimental temperature even for relatively low degrees of cyclisation ($N_2$ = 0.82 to 0.88).

## VI. CONCLUSION

It follows from the data described above that the physical state of the prepolymer is a decisive factor in the practical realisation of solid-phase cyclodehydration reactions. Namely the chemical nature of the substituents and of the atomic groups constituting the polymer chain determines the initial flexibility of the polymer macromolecules and hence the glass point of the polymer on which depends the temperature range of the cyclisation reaction. Together with this, the rigidity of the polymer increases with increasing degree of cyclisation and hence the glass point also rises. As a result, the intramolecular cyclodehydration processes hardly ever go to completion and the polyheteroarylenes formed are always heterounit polymers, i.e. contain a definite number of fragments of the corresponding initial prepolymer. In order to obtain a polyheteroarylene with a high content of cyclic fragments, the cyclisation process is therefore carried out under non-isothermal conditions.

The experimental data also show that the determination of the thermodynamic characteristics of the corresponding polymers and of their reactions constitutes an extremely effective method for the investigation of the solid phase cyclisation reactions. The study of the temperature variation of the heat capacities of the prepolymers and the final polymers and of the water vapour pressure over the prepolymers in the course of their cyclodehydration makes it possible to determine the temperature ranges in which the above reactions take place. Calorimetric study of the enthalpies of combustion of the prepolymers and the final products and of the enthalpies of cyclisation led to the development of a universal method for the determination of the degree of cyclisation of the prepolymers in intramolecular cyclodehydration processes (the method based on the calculation of the extent of the heterounit structure of polyheteroarylenes).

Analysis of the thermodynamic characteristics of the intramolecular cyclodehydration reactions makes it possible to subdivide the prepolymers into two groups differing in the character of the variation of their thermodynamic functions in the solid-phase cyclisation processes. The enthalpies of cyclisation of the group I prepolymers are negative (i.e. the reactions are exothermic) up to 373 K and positive above this temperature, the entropies of cyclisation are positive at $T$ > 100 K, and the standard Gibbs free energies are positive over the entire temperature range. The enthalpies of the cyclisation reactions of group II prepolymers are positive (the reactions are endothermic), the entropies are positive at $T$ > 100 K, and the Gibbs free energies become negative only above 400 K.

The determination of the equilibrium constants of the cyclodehydration reactions makes it possible to calculate the average degrees of polycondensation of the polyheteroarylenes at a specified temperature. These results enable

one in their turn to estimate the temperature ranges in which "defect-free" or homounit polyheteroarylenes can be obtained, which is extremely important for the development of a scientific basis for the synthesis of such polymers and for the preparation of thermostable materials from them.

# The Applications of Chromadistillation in the Injection of Large Samples in the Gas-chromatographic Determination of Impurities

S.M. Yanovskii

The characteristic features of the injection of large samples into the chromatographic column with allowance for chromadistillation are considered. The theory of the chromadistillation processes occurring in the initial section of the column, which permits a rational choice of the injection parameters, is discussed and the methods and devices for the direct injection of the sample into the column are surveyed.
The bibliography includes 131 references.

## I. INTRODUCTION

The application of chromatography for the preparative isolation of pure substances, high-temperature analysis, concentration of impurities, and various physicochemical measurements has required a continuous development of methods for the injection of large amounts of the substance to be analysed into the column. It became possible to meet these requirements with effective solution of these problems using a new version of chromatographic separation—chromadistillation (CD), developed in the USSR in recent years.[1-6] In the course of CD in a column on an inert solid filler and in a stream of carrier gas, numerous processes involving the condensation and evaporation of the components in the mixture analysed take place. Complete mixture separation is achieved either as a result of the application of a temperature field with a negative temperature gradient (thermal CD)[1,7] or as a result of preliminary injection into the column of a specified dose of a substance more volatile than any of the mixture components (limiting CD).[2,8,9] Isothermal elution (IE) of a mixture without the introduction of a limiting agent can also be included among CD processes.[10-14] The so-called "chromatography of nearly saturated vapours" (CNSV), which the present author has proposed,[15,16] occupies an intermediate position between traditional gas chromatography and CD. As in the usual chromatography, the CNSV process takes place on an adsorbent or a stationary phase (SP). However, owing to the large amount of liquid on the sorbent, the concentrations of the substances analysed in the gas phase approach the values corresponding to saturation. The limiting[9] and thermal[17] versions of CNSV have also been realised.

The development of the theory of CD methods[18,19] and the explanation of the mechanisms of the processes occurring[20-22] demonstrated their possible application for the analysis of mixtures,[23,24] continuous preparative synthesis of pure substances,[25-27] fractional distillation of mixtures of petroleum products in terms of their boiling points,[28-37] and the determination of the physicochemical characteristics of pure substances and solutions.[6,20,21,29,38-40] The characteristics of the CD process can be used to simplify the detection system[20-22,36,37,39] and also to concentrate and determine the "light" and "heavy" impurities in liquids;[33,45-50] a method has been described for the use of a CD pre-column with injection of large samples into a capillary column (CC) in the determination of impurities.[51]

A large series of studies by Grob and co-workers, who introduced the so-called "solvent effect" (SE)[52] manifested in the direct (without splitting of the stream) [splitless] injection of the sample into the column,[53-55] can be regarded as a separate special application of CD to the determination of impurities on CC. From the standpoint of classical chromatographic ideas,[56,57] a 2 μl sample exceeds the maximum permissible size for packed columns by a factor of at least 10[54] and according to estimates[56,58] the dose introduced into a CC should not be greater than $2 \times 10^{-4}$ μl. However, the sample size in studies on the SE reaches 10 μl for CC and in studies on CD using filled columns even several millilitres can be employed without impairing the efficiency of the separation. The sharp increase in the dose leads to new qualitative results. The presence of liquid components on the column (including the solvent as the main mixture component) creates conditions for the formation of narrow fronts at the boundary between the zones of the components being separated and hence for the concentration of the impurity components at these boundaries. The solvent must be regarded as the most important factor determining the efficiency of the analysis; its presence is essential for injection and it is therefore unnecessary to take steps for its removal from the system, which is usually done in the traditional injection methods.[59,60,79]

The direct injection of a large sample into the chromatographic column and also the employment of the entire initial sample (without any being discarded) in a single analytical cycle creates a new direction in the field of injection, since it makes it possible to improve the quantitative characteristics of the analysis. The amount of the component to be determined injected into the column with the sample, is then increased and the errors associated with the diversion of the stream and the fractionation of the components on evaporation are eliminated, and the probability of the thermal decomposition in the analysis of unstable compounds is reduced, since the injection is carried out at lower temperatures. With increase of the dose, the sensitivity of the

determination of the impurity component increases. In view of the great possibilities of the direct methods for the injection of the sample into CC, there has been a sharp increase in recent years of the number of publications on this field (in 1982 there were more than 100)[61] and special symposia and schools designed to learn the new injection technique have been organised.[62,63] In connection with the development of the injection methods, studies have been carried out by major investigators such as Zhukhovitskii, Grob, Schomburg and others.

The choice of the the injection system (with or without stream-splitting) depends on the specific analytical problem.[62] The direct injection methods using the SE constituted a significant step forward in the field of injection. However, the rational development of these methods was appreciably held back by the fact that the SE theory was erroneous (see below), because the processes occurring at the initial section of the column were regarded as purely chromatographic. In fact they are to a large extent of the distillation type and are covered by the new version of chromatography—chromadistillation. From our point of view, the studies on the SE can be regarded as an important application of CD for the determination of impurities in solvents. In these methods the high efficiency of the CC is combined with the possibility of greatly increasing measurement sensitivity. The fact that the development of the CD and SE processes has occurred independently in different chromatographic schools can be accounted for by the vast flood of available information which created conditions such that investigations could occur independently even in closely related fields.

The aim of the present review is to examine the entire range of problems arising in the injection of large samples into the chromatographic column. It became possible to explain all the results obtained by the SE method from the standpoint of the CD theory. Such a treatment permits a deeper understanding of the mechanisms of the processes occurring during the direct injection and indicates further ways of improving the injection technique.

## II. PRINCIPAL CONCEPTS AND TERMS

For subsequent exposition it is essential to establish a definite correspondence between the terms used in CD[5,6] and in the SE methods.[64] The processes occurring in the injection of large samples can be most rationally classified in accordance with the character of the sorption isotherms of the substances being separated. In the injection of large amounts on the SP, concave sorption isotherms are always observed (Fig. 1) and are described by the equation[65]

$$a = \frac{mp/p^0}{1 - p/p^0}, \qquad (1)$$

where $a$ is the degree of sorption, $m$ the amount of the SP, $p$ the partial pressure of the component, and $p^0$ the vapour pressure. At low relative pressures $p/p^0$ Eqn. (1) becomes identical with the linear equation for the classical gas–liquid chromatography (GLC). With increase of $p/p^0$, the non-linearity of the sorption isotherms is manifested to an increasing extent and, when $p/p^0 \to 1$, $a$ tends to infinity. Sorption isotherms of an analogous character are observed also in adsorption in capillary condensation.[66] The concave section of the sorption isotherms corresponds to the conditions in the chromatography of vapours near saturation.[15] In the absence of the SP ($m = 0$) and when pure substances are injected onto an inert layer, the sorption isotherms have the form of vertical straight lines passing through the $p = p_i^0$ points (Fig. 1). The principal version of CD corresponds to this case.[1,6,7]

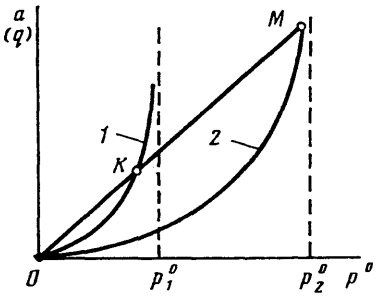

Figure 1. The sorption isotherms for components *1* and *2* at high concentrations;[9] continuous line—CNSV; dashed lines—CD; the straight line *OM* corresponds to the material balance of the components at the boundaries between the zones; $q$ is the amount of liquid per unit volume of the bed in CD.

CD processes occur in CC in two versions of the sample injection without splitting the stream (splitless injection[67]): injection with preliminary evaporation of the sample (via an evaporating injector) and with its subsequent condensation on a cooled column[53,54] or direct injection (without preliminary vaporisation) into the cooled column (direct cold on-column injection).[67] CD processes are sometimes observed even in the injection of large samples with small stream splitting coefficients (split injection).[68] The process occurring on the surface of a clean CC wetted by the liquid (flooded inlet)[69] corresponds to ideal CD.[6,7] Analysis on a SP saturated by the solvent (phase soaked)[70,71] should be included in CNSV according to the present author's ideas.[15] The isothermal process in the distribution of the sample in the form of a film (sample film)[64] corresponds to isothermal CD elution.[10–14,20,21] The preliminary deposition of the pure solvent on the layer (solvent film)[64,72,73] corresponds to the limiting versions of chromatography and CD.[8,9]

Depending on the character of the solutions of the impurity components formed with the main mixture component (solvent), different elution sequences of the impurities are observed on the chromadistogram (CDG). If the solution is ideal, the components emerge in accordance with the increase of their boiling points ($t_b$): less volatile impurities (heavy) emerge at the closing solvent front and more volatile impurities (light) emerge at the leading front.[49] In solutions with marked positive deviations from Raoult's law (with azeotropy or layer formation in the system) the elution sequence may not correspond to the $t_b$ of the components.[74] The components with $t_b$ greater than that of the solvent, which emerge at the leading front of the main component, should then be classified as light impurities. In the isothermal elution of the mixture there is a possibility of either the emergence of a less volatile impurity component after the solvent (solute lagging)[21,75] or the loss of light components simultaneously with the disappearance of the solvent zone (solute escape).[6,76] Retaining the term "solvent effect" as being more general, Grob and co-workers[77,78] introduced the concept of "solvent trapping" for all processes in which

a large sample can influence the results of sample injection, by analogy with low-temperature extraction (cold trapping). It is therefore suggested that impurities be divided into those fully retained by the solvent (trapped) and those which are only partly retained or not retained at all, which corresponds to our classification of impurities into heavy and light.[49]

Several approaches to the investigation of the impurity zone formation processes on injection of a large sample onto the column have now arisen. In studies on CD [6] the theory of processes occurring on a column with an inert filler for concentrated solutions of the components of the initial mixture has been mainly considered (on the basis of balance equations). In experiments designed to test the theory, the inlet to the column was connected directly to the detector (Fig. 2*a*), which made it possible to record the changes in the concentrations of the components in the zones formed. Additional information about the mechanism of the distribution of the liquid was provided by visual studies on the wetted section of the column. The determination of the impurities can be considered, within the framework of CD, as the limiting case where the concentrations of the components to be determined are small compared with that of the principal component. For the separate determination of the impurity components, a portion of their sample was directed to the chromatographic column after the preliminary enrichment on the CD column (Fig. 2*b*); the main bulk of the solvent was then discarded to the atmosphere.

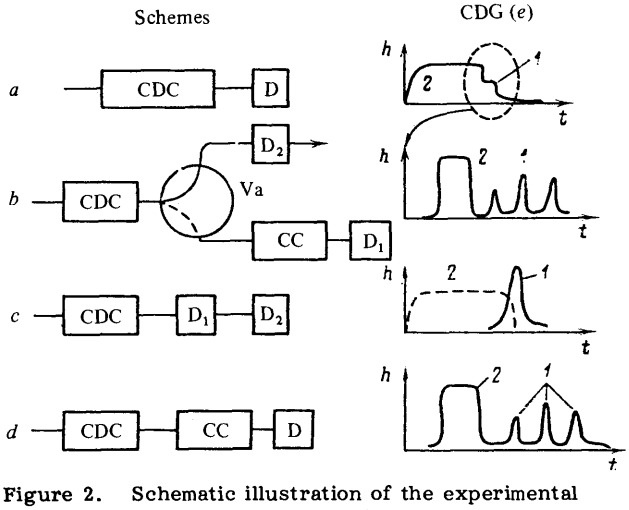

Figure 2. Schematic illustration of the experimental apparatus for the investigation of CD processes (*a*–*d*) and the corresponding elution curves (*e*); *h* = height of the signal on the recorder strip; *t* = time; CDC = chromadistillation column; CC = capillary column; Va = valve; D = detector; 1) impurity; 2) solvent.

The isolation of an impurity from the solvent has been studied both theoretically and experimentally.[72] In order to determine the location of the impurity on the elution curve, the author used an additional selective detector (Fig. 2*c*).

The approach which arose in the development of the SE is strictly experimental and involves the determination of impurities solely on CC. The samples were deposited directly in the CC and the processes occurring along its initial section could be inferred solely from the results of the separation of the components in the main section of the column containing the SP.[79] In later investigations[52,70] special attention was paid to the section for the sample distributed (in Fig. 2*d* we have specified it as the CD column) and the processes occurring along this section were studied by both visual and chromatographic (sampling) methods. The principal data were obtained as a result of detailed and laboratory experiments and the treatment was confined to the framework of development chromatography.

In the subsequent exposition we shall consider initially the theory of the process and then its experimental test and possible applications.

## III. ISOTHERMAL ELUTION OF THE MIXTURE

In isothermal elution the mixture analysed is deposited in the liquid form on an inert carrier (without SP) and is eluted from the column by a stream of carrier gas at a constant temperature. Isothermal elution (IE) is the initial stage in any of the versions of the CD separation and it is therfore essential to consider its mechanism in detail.

### 1. Theory of Isothermal Elution

Our studies in the field of CD were preceded by Kiva's investigations[10–14] on the azeotropy of solutions in which the IE of the mixture from the surface of an inert carrier was first carried out (Fig. 3*a*). The elution curve has in this instance a stepped form (Fig. 3*b*). Under IE conditions, only partial separation of the mixture takes place. The less volatile component does not emerge in a pure form until the final zone is reached. However, the result of such separation is by no means trivial. According to the theory of customary distillation,[80] when a solution evaporates from a flask, the composition of the effluent mixture must vary continuously, becoming gradually enriched in the less volatile component *1*, which is evolved in a pure form only with the last drop of the solution.

The observed picture of separation under IE conditions is determined by the occurrence of distillation processes under chromatographic conditions where a multiplicity of mixture condensation and evaporation steps are attained as the component bands move along the bed. Despite the fact that in the given case there is no sorbent familiar to workers in the field of chromatography, the processes occurring can be considered by approaching them from the standpoint of frontal-desorption chromatography,[56] i.e. in the given instance the mixture analysed is, as it were, resolved "spontaneously" as it moved along the bed. If it is supposed that the mixture components *1* and *2* have markedly different vapour pressures and that component *1* is almost involatile, then the rear edge of the zone of component *2* will migrate forwards along the column in accordance with chromatographic laws (Fig. 3*c*). On the other hand, if the less volatile component *1* has an appreciable vapour pressure, then its rear boundary will also move along the column (Fig. 3*d*). The rate of migration of the zone boundaries $u_i$ as well as the composition of the solutions formed in the zones are in general determined by the material balance equations at the zone boundaries.[6,21] This approach

is equivalent to considering the theory of the equilibrium process on the assumption that the height equivalent to the theoretical plate (HETP) is zero. In the IE of a binary mixture, the material balance equations with respect to both components at the boundary where component *2* ends yield

$$u_2 = \frac{\alpha c_2^0}{q^{II}} = \frac{\alpha c_1^0 (1 - N_1)}{q^I - q^{II} N_1}, \qquad (2)$$

where $\alpha$ is the linear flow rate, $c_i^0$ the concentrations of the saturated vapour of components *1* and *2*, $q^I$ and $q^{II}$ the amounts of liquid per unit volume of the column for bands I and II, and $N_1$ the mole fraction of component *1* in the initial mixture, Here and henceforth we shall neglect the amount of substance in the gas phase compared with the amount in the liquid phase. Having expressed $q^I$ in terms of $q^{II}$ with the aid of Eqn.(2), we obtain

$$q^I = q^{II}[\beta_{1,2} + (1 - \beta_{1,2}) N_1]. \qquad (3)$$

The equation for the rate of migration of the rear boundary of the zone of component *1* then assumes the following form:

$$u_1 = \frac{\alpha c_1^0}{q^I} = \frac{\alpha c_1^0}{q^{II}[\beta_{1,2} + (1 - \beta_{1,2}) N_1]} \qquad (4)$$

where $\beta_{1,2} = c_1^0/c_2^0$. All the principal characteristics of the IE process follow from Eqns.(2)–(4). The existence of a unique solution to the system of material balance equations shows that the zone corresponding to the mixture should be followed in the bed by the appearance of the zone of the pure less volatile component *1*. Within the limits of this zone, component *1* is present on the carrier in the liquid state and its concentration in the gas phase corresponds to the saturated vapour ($c_1^0$). According to Eqn.(3), the amount of liquid per unit volume of the column in the zone of component *1* is less than in the initial zone ($q^I < q^{II}$), since the multiplier in square brackets in Eqn.(3) is less than unity. It must be emphasised that, under the conditions of the rapid attainment of equilibrium between the vapour and the liquid, for which the equations presented are significant, the zone of component *1* is formed immediately after the introduction of the mixture. Indeed, comparison of Eqns.(2) and (4) shows that $u_1 < u_2$. For this reason, however short the time interval $\Delta t$ from the start of the experiment (provided that there is no spreading and on the assumption that the HETP is zero), a certain distance $\Delta x$ arises between the boundaries and increases as the process proceeds. This explains Fig.3*e*, which presents parts of the migration of the boundaries of the zones of components *1* and *2*.

The formation of the zone of the pure component *1* with a definite amount of liquid within the limits of the zone $q^I$ [see Eqn.(3)] and at the concentration in the gas phase corresponding to the saturated vapour ($c_1^0$) occurs as a result of repeated mixture condensation and evaporation steps. One cannot assume that the more volatile component *2* is eluted from the section where it was initially located, as usually happens in chromatography. The less volatile component *1* evaporates simultaneously. Its concentration in the vapour phase of the zone formed is higher than that in the initial zone. Component *1* condenses (dissolves) at the boundary between the zones and forms a corresponding zone I (Fig.3*d*) with a definite thickness of the liquid film. The components are separated by distillation at the boundary between the zones in such a way that the entry of one of the components into a neighbouring zone (as a result of diffusional spreading) leads to its removal as a result of the difference between the vapour pressures of the substances being separated. The opposed effects of these processes give rise to a stationary distribution of the substance between the zones whose boundary migrates in accordance with the laws governing CD equilibria.[18] By virtue of the distribution of liquid in the form of a thin layer on the packing, conditions are created which ensure the effective saturation of the gas stream by the vapours of the substances analysed. As a result, the spreading of the stationary fronts is insignificant.[19] According to the material balance equation (4), the zone of the pure component *1* should arise at the rear edge of the band. For this, it is sufficient that the two fronts of components *1* and *2* (Fig.3*d*) should traverse a distance equal to the width $\mu_2$ of the diffuse boundary (between the zones of components *1* and *2*). In the absence of equilibrium, under conditions where the HETP is not zero, the relaxation time required for the appearance of the zone of component *1* is

$$t_{rel} = \frac{\mu_2}{u_2 - u_1}. \qquad (5)$$

In non-equilibrium fractionation,[80] the attainment of a stationary distribution with formation of the zone of the pure component *1* requires that the mass-exchange and countercurrent hydrodynamic processes should go to completion throughout the volume of the sample. As in chromatography, numerous separation steps are achieved more readily in CD than in distillation.

The theory of the IE of the impurity component follows directly from the general theory of equilibrium isothermal CD[18] as a special case where the fraction of one of the components in solution tends to zero. In this case the usual CDG (Fig.3*b*) is converted into the CDG of the solvent (Fig.3*f*), at the closing front of which only a small hump due to the impurity component is observed. If the main component *2* is not registered by the detector, the observed zone of the impurity *1* should have an extended low, stepped section terminating in a narrow peak (Fig.3*g*).

We shall consider special cases of the application of Eqn.(3).

(1) When $N_1 \to 0$, the impurity is the less volatile component. The amount of liquid in the neighbouring zones is then linked by the equality $q^I = \beta_{1,2} q^{II}$. As mentioned above, in the general case $q^I < q^{II}$, since $\beta_{1,2} < 1$. This result confirms the conclusion that the zone of component *1* arises immediately (under equilibrium conditions) after the start of the IE process and that the amount of liquid within the limits of this zone should be rigorously defined and constant as a function of time (for a uniform initial distribution of the liquid).

(2) When $N_1 \to 1$, component *1* is the main one in the mixture and the impurity is more volatile than the solvent. The amount of liquid in the zones then remains virtually unchanged, i.e. $q^I = q^{II}$.

(3) When $\beta_{1,2} \cong 1$, the vapour pressures of the components are similar and the equality $q^I = q^{II}$ holds regardless of mixture composition.

(4) When $\beta_{1,2} \to 0$, the less volatile component has an extremely low vapour pressure compared with the solvent. The amount of liquid in the zone of component *1* formed then depends on its mole fraction $N_1$ in the initial mixture.

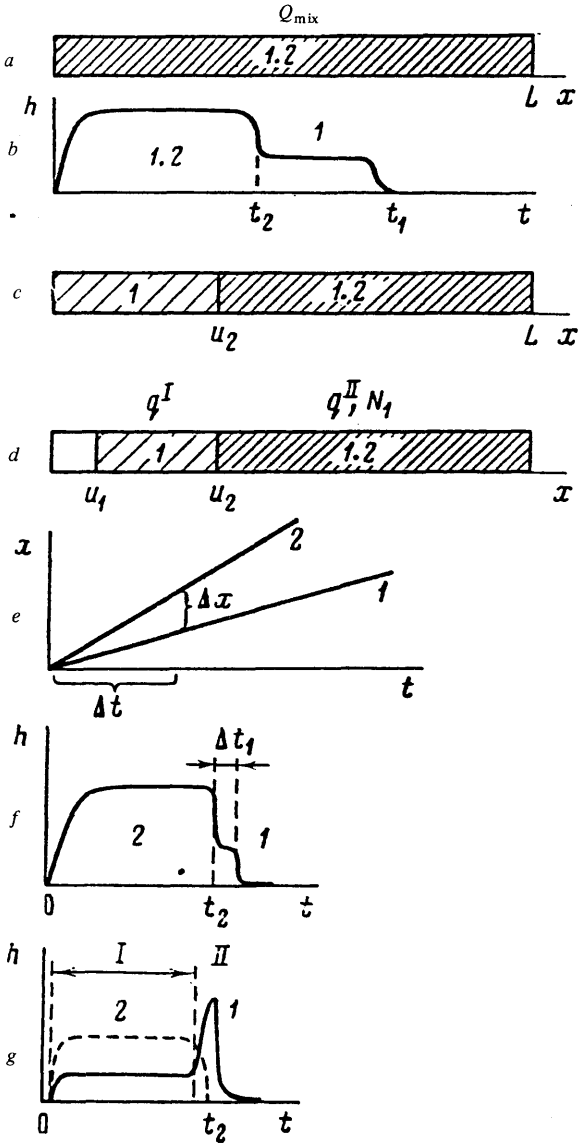

**Figure 3.** Schematic illustration of isothermal elution;[6,21] $x$ = distance along the bed; L = length of wetted section of the bed.

We shall now consider the factors which influence the impurity zone width. The width of the rear zone on the CDG (Fig.3*b*) corresponds to the less volatile component *1*. Its length ($\Delta t_1 = t_1 - t_2$) depends on the total amount of the deposited mixture ($Q_{mix}$), which wets a section of the column having a length $L$. Each boundary of the zone of component *1* crosses this section at its own rate determined by Eqns.(2) and (4). As a result, the equation for the component *1* band width on the CDG is

$$\Delta t_1 = \frac{L}{u_1} - \frac{L}{u_2} = t_2(\beta_{2,1} - 1)N_1, \qquad (6)$$

where $t_2 = Q_{mix}/v_0 c_2^0$, $\beta_{2,1} = c_2^0/c_1^0$, $Q_{mix} = q^{II}SL$, $v_0 = \alpha S$ is the volume flow rate, and $S$ the cross-sectional area of the column. It follows from Eqn.(6) that, with decrease of the fraction of component *1* in solution ($N_1 \to 0$) and as the vapour pressure of the impurity component approaches that of the solvent ($\beta_{2,1} \cong 1$), the width of the impurity zone $\Delta t_1$ diminishes. However, it must be emphasised that, under equilibrium elution conditions, component *1* is present in the liquid form within the limits of its zone, however small the latter may be, and its concentration in the gas phase corresponds to the saturated vapour ($c_1^0$). The conditions governing the formation of the pure component *1* band are defined by the relations

$$\beta_{1,2} \neq 1 \quad \text{or} \quad c_1^0 < c_2^0. \qquad (7)$$

Indeed, when $\beta_{1,2} = 1$, it follows from Eqns.(2)–(6) that $q^I = q^{II}$, $u_1 = u_2$, and $\Delta t_1 = 0$. This means that the rates of migration of the boundaries are the same and that the bands of components *1* and of the mixture of components *1* and *2* are indistinguishable in terms of the amount of liquid. When $\beta_{1,2} < 1$ and $N_1 \to 0$, the step corresponding to component *1* becomes narrow and, on spreading, it is converted into a peak on the rear solvent edge (Fig.3*g*).

Losses of the less volatile component *1* are possible in IE simultaneously with the emergence of the *1,2* solvent band (Fig.3*g*, Section 1). Knowing the rate of migration of the rear boundary of the solvent zone along the bed [Eqn.(2) for $u_2$], it is possible to obtain an expression for the retention volume at this boundary:

$$V_2 = t_2 v_0 = \frac{L}{u_2} v_0 = \frac{Lq^{II}}{\alpha c_2^0} v_0 = \frac{Q_{mix}}{c_2^0}. \qquad (8)$$

Eqn.(8) shows that the retention volume $V_2$ is independent of the way the liquid is distributed along the bed ($q^{II}$ does not enter into the final expression) and is determined by the total amount of the mixture $Q_{mix}$ introduced into the column and by the vapour pressure of the most volatile component *2*. Furthermore, regardless of the composition of the initial mixture, $V_2$ remains constant and equal to the retention volume of the pure solvent sample with a dose equal to $Q_{mix}$. This finding is associated with the fact that, when the solution is diluted, the amount and vapour pressure of the solvent in the mixture diminish to an equal extent, in proportion to its mole fraction $N_2$ in the solution.

In order to calculate the losses of the impurity component *1*, it is necessary to take into account the concentration at which it is evolved from the column during the elution period of the volume $V_2$:

$$Q_{loss,1} = V_2 c_1^0 N_1 = Q_{mix} N_1 \beta_{1,2} = Q_{init,1}\beta_{1,2}, \qquad (9)$$

where $Q_{init,1}$ is the initial content of component *1* in the initial mixture. It follows from Eqn.(9) that the fraction of component *1* lost ($Q_{loss,1}/Q_{init,1}$) is independent of mixture composition and is determined by the ratio of the concentrations of the saturated vapours of the components and the solvent ($\beta_{1,2} = c_1^0/c_2^0$). An analogous formula has been obtained in other studies.[72,76]

We shall consider an example illustrating the employment of the formulae derived. Suppose that 2 μl of hexane containing 20 p.p.m. of dodecane ($N_1 = 2 \times 10^{-5}$) has been injected into the column under normal conditions. We shall now estimate the width of the impurity zone and the losses. The amount of solvent corresponding to the dose indicated

is $2 \times 10^{-5}$ mole. For the hexane vapour pressure $p_6^0 \cong 120$ mmHg, the concentration of the saturated hexane vapour in the gas phase is $0.7 \times 10^{-2}$ mol litre$^{-1}$. If the flow rate is $v_0 = 2$ ml min$^{-1}$, then the evaporation time of the main component $t_2$ is ~$10^2$ s. With increase of the number of carbon atoms in the series of alkanes by unity, the relative volatility changes by a factor of ~3 and we therefore have for hexane and dodecane $\beta_{2,1} \cong 3^6 \cong 10^3$. Having substituted the numerical data in Eqns.(6) and (9), we find that $\Delta t_1 = 2$ s (i.e. the impurity zone is quite long) and the losses are ~0.1%.

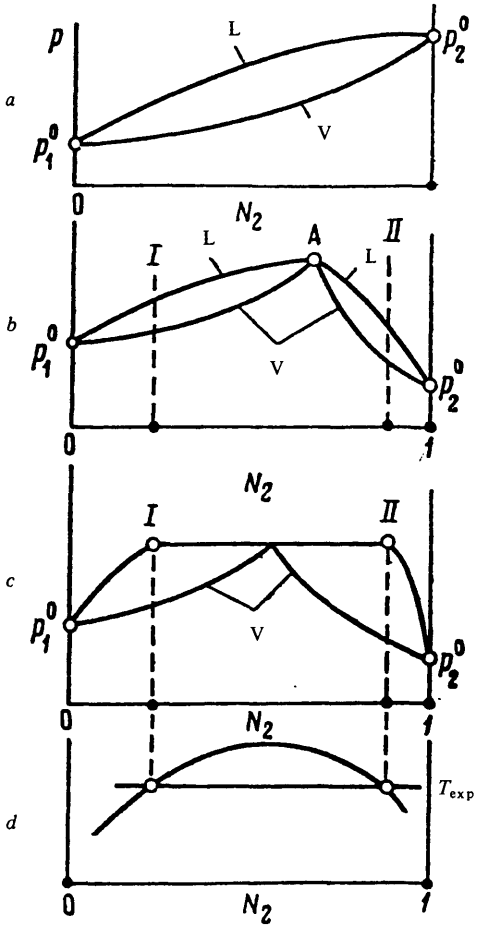

**Figure 4.** Schematic representation of the equilibrium diagrams for various systems:[80] L = liquid line; V = vapour line; *A* = point corresponding to the azeotrope: *a*) ideal solution; *b*) azeotropic mixture; *c*) heterogeneous liquid mixture (two layers); *d*) solubility curve.

We shall consider the case where the main system component (component *1*) is less volatile than the impurity (component *2*). The form of the elution curve of the impurity component and its location relative to the main mixture component will depend on the type of vapour–liquid equilibrium diagram (Fig.4). If the solution is ideal (Fig.4*a*), then, as shown in a number of studies,[10–14,74] the more volatile component *2* is evolved first and is then followed by the less volatile solvent *1* in a pure form ($p_2^0 > p_1^0$), in conformity with distillation laws. The occurrence of azeotropy or layer formation in the system (Figs.4*b*–4*d*) can alter the elution sequence of the zones on the CDG. In this case the azeotropic mixture or the solution separating into layers behaves (as in the usual distillation) as a single most volatile component. Depending on the mixture composition (I or II in Fig.4*b*) in relation to the azeotrope (points *A* in Fig.4*b*), IE can lead to the formation of the zone of one of the mixture components at the rear edge.[14,74] Thus, even if the impurity has a lower vapour pressure than the solvent ($p_2^0 < p_1^0$), there is a possibility of the evolution of the impurity component at the leading solvent edge for azeotropic and heterogeneous liquid systems.

In conformity with the above features of the IE under equilibrium conditions, the band of the volatile impurity should have a rectangular shape on the CDG. It remains to discover the amplitude and duration of this signal on the elution curve. In contrast to the heavy impurity, the concentration of the light impurity in the IE of the mixture is not higher than the concentration of the initial mixture. The concentration of component *2* in the gas phase over the solution is defined in accordance with the law governing the equilibria in real solutions:

$$c_2 = c_2^0 \gamma_2 N_2, \qquad (10)$$

where $\gamma_2$ is the activity coefficient of component *2*.

It must be emphasised that the CD analytical methods based on IE bear some similarity to the widely used vapour phase analysis,[81,82] since in both methods the components are not enriched in the gas phase. In contrast to the vapour phase analysis, in the CD methods for the direct determination of impurities[45,49] the sample injection is carried out more rationally: all the impurity is extracted from the sample and there is no need to know exactly the equilibrium parameters and hence to maintain rigorously the experimental parameters.

According to Eqns.(8) and (10), for an ideal solution the duration of the rectangular pulse of the impurity component remains constant with decrease of the concentration $N_2$ ($V_2 = \text{const.}$), while the amplitude diminishes. The activity coefficient of the impurity in a real solution can influence significantly the retention volume in the impurity band:[38,49]

$$V_2 = \frac{Q_{cm}}{c_2^0 \gamma_2}. \qquad (11)$$

As a rule, dilution of solutions with pronounced positive deviations from Raoult's law (Figs.4*b* and 4*c*) entails a sharp increase of the activity coefficient $\gamma_2$ ($\gamma_2$ may amount to tens and hundreds of units[83,84]), which may lead to an appreciable decrease of the width of the impurity component zone.

We shall quote an example of the determination of the butanol impurity in water. Suppose that the sample size is 0.1 ml ($5 \times 10^{-3}$ mole). At room temperature (25 °C), the vapour pressure of butanol is 7 mmHg, which corresponds to the gas-phase concentrations $c_2^0 = 4 \times 10^{-3}$ mol litre$^{-1}$. According to Eqn.(11), the component forming an ideal solution ($\gamma_2 = 1$) would be evolved under these conditions in a volume $V_2 = 10^3$ ml or after 50 min for a volume flow rate $v_0 = 20$ ml min$^{-1}$. Since $\gamma_2 \cong 45$ for butanol,[84] the time required to evolve the impurity is ~1 min.

We shall consider the studies on the SE mechanism in the light of the IE theory described above. In a series of communications by Pretorius and co-workers,[64,75,76,86] an attempt was made to derive an equation for the rates of migration of the solvent and sorbate boundaries and also

to determine the conditions governing the appearance of various SE regimes. A general disadvantage of the approach employed by Pretorius and co-workers,[64,75,79,85] which led to a series of incorrect conclusions, is their attempt to regard the processes in which the sorbate moves in the solvent as purely chromatographic. For example, it is impossible to set up the material balance equation at the closing solvent front immediately with respect to both components [see Eqn.(1) in Ref.85]. According to the IE theory which we described above, two cases are possible. If the impurity is lighter than the solvent, it moves ahead along the column and should not be taken into account in the material balance. For impurities heavier than the solvent, it is essential to formulate the material balance equations for both boundaries formed (Fig.3*d*). For this reason, Eqn.(6) quoted by Pretorius et al.[85] for the rate of migration at the closing edge of the solvent film can be valid only if one neglects the sorbate concentration in the gas phase.

The stages involving the formation of the sorbate film (initial and final) have been arbitrarily differentiated.[75] As mentioned above, a film of the less volatile impurity component is formed immediately (under equilibrium conditions) simultaneously with the onset of elution. Eqn.(12) obtained by Pretorius et al.[75] for the ratio of the thickness of the films in the solvent and impurity zones has narrow limits of applicability. The authors[75] assumed that the solvent, moving out of a wetted section, leaves on the surface an amount of impurity corresponding to its fraction in the initial solution. As shown above, this is possible only for $\beta_{1,2} \cong 0$ [see the special case 4 of Eqn.(3) described above]. As a result an inequality [inequality (14)[75]] was obtained, which imposes unduly rigorous requirements on the conditions for the appearance of the impurity zone:

$$\frac{p_1^0}{p_2^0} < \frac{n_1}{n_2}, \qquad (12)$$

where $p_1^0$ and $p_2^0$ are the vapour pressures of the impurity and the solvent and $n_1$ and $n_2$ are the molar concentrations of the impurity and the solvent in the initial mixture. It follows from condition (12) that the probability of the appearance of an impurity film is extremely low and it can be formed only for hydrocarbons with a molecular weight in excess of 500.[75] The CD theory presented above and the numerical example show that the impurity zone can be formed only when condition (7) is fulfilled and its formation is entirely realistic for a dodecane solution in hexane at a concentration of $2 \times 10^{-2}$ g litre$^{-1}$.

In order to compress the peaks, it has been suggested[86] that a section of CC be established in which the so-called "retention gap" is present. For this purpose, the SP is partly or fully washed out of the initial section I of the column (Fig.5). The possible mechanism of the operation of such a section has been examined: the sorbate band *1* is hardly retained and rapidly traverses section I after the solvent *2* and then, when the substance passes from the SP to the CC (Section II, Fig.5b), it is compressed. If programmed temperatures are employed, then the heavy impurity mixture components begin to be eluted from the initial section I of the column only after the attainment of the appropriate temperature.

In another communication[87] schemes designed to explain the authors' idea about the mechanism of the "retention gap" are described. In their view, the sorbent is concentrated because in section I one edge of the sorbate band (the rear edge) moves at a higher rate ($u_1'$, Fig.5c), while in the next section II, containing the SP, the other edge of the sorbate band (the leading edge) migrates at a lower rate ($u_1''$). However, this explanation of the concentration process is clearly unsatisfactory. It follows from the analysis of the operation of compound columns[56,88] that the degree of narrowing of the band is predetermined by the ratio of the rates of migration of the sorbate in the zones indicated. It must be emphasised that the concentration of the test substances in the gas phase does not change under these conditions. The sorbate band may be compressed without a change in the sorbate concentration in the gas phase on passing through the boundary at which the sorption capacity (the Henry coefficient $\Gamma_i$, Fig.5*d*) changes. Suppose that the initial width of the sorbate band is $\mu_1$ for a uniform distribution of the substance with the concentration $c_0$ in the gas phase. The rate of migration of the band along section I is $u_1' = \alpha/\Gamma_1$. The entire band passes through the boundary during the period $\tau = \mu_1/u_1' = \mu_1\Gamma_1/\alpha$. During the same period, the leading edge of the band for the same concentration in the gas phase $c_0$ traverses a distance $\mu_2 = \tau\alpha/\Gamma_2 = \mu_1\Gamma_1/\Gamma_2$ in section II at a rate $u_1'' = \alpha\Gamma_2$. If the degree of sorption in the second section is greater ($\Gamma_2 > \Gamma_1$) the band is compressed by a factor $\Gamma_2/\Gamma_1$, although the concentration of the test substance in both parts of the column remains unchanged ($c_0$).

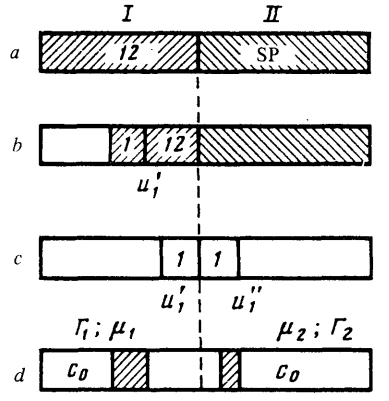

**Figure 5.** Schematic explanation of the "retention gap" mechanism;[56,86] $u$ = rate of migration of boundary; $\mu$ = width of the sorbate band; $\Gamma$ = Henry coefficient; $c_0$ = concentration of sorbate in the gas phase.

From the standpoint of the CD theory, the results described by Grob[86,87] can be readily accounted for in the following manner. The removal of the SP brings the experimental conditions closer to those of the isothermal CD on an inert carrier[6,21] (Fig.3). In the IE of the mixture on section I (Fig.3*b*), the solvent (*1*, *2*) is followed by the impurity component *1* in the liquid form. As a result of this, its concentration in the gas phase becomes a maximum and corresponds to the vapour pressure at the given temperature. Consequently, long before the rear solvent edge approaches section II with the SP (Fig.5), an increased sorbate concentration will have already appeared on section I. This increase of the concentration is in fact responsible for the narrowing of the band on the chromatogram. Furthermore, when the results of these experiments are considered, it is also essential to take into account the transition to zone

II of part of the impurity component during the elution of the mixture on section I. The final formation of the narrow peak corresponding to the entire amount of the impurity component in the sample takes place as a result of the subsequent CNSV processes (Section VI).

The explanation of the mechanism of the compression of impurities reduces, according to Grob,[52,79] to the consideration of the elution of the sorbate on a phase containing the solvent with a variable amount of liquid along the bed (Fig.6). When the sample is injected via an evaporating injector, the solvent forms, when condensed, a mixture on the SP with a constantly increasing (in the direction of motion) film thickness (zone I, Fig.6). In the first stage of the separation process, the solvent *2* moves forward relative to the sorbate 1. Next the leading edge of the migrating sorbate band in section I encounters a greater amount of the liquid phase than the closing edge. As a result of the movement at different rates of the sorbate band boundaries, the band is compressed and peaks which are narrower than in the case of split injection are formed.

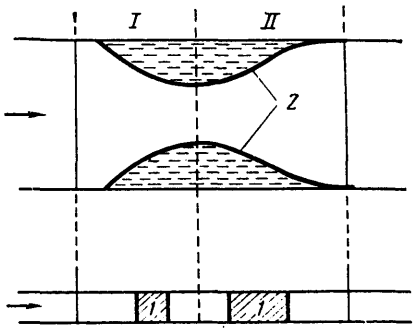

**Figure 6.** Schematic explanation of the SE mechanism in the gradient distribution of the solvent in the column:[52] 1) sorbate; 2) solvent; I) and II) direct and reverse SE zones.

The previously proposed picture of the concentration process (for section I in Fig.6) was subjected to a quantitative treatment[60,89] on the basis of the concepts adopted in GLC. It was shown that the retaining capacity of the liquid phase increases in parallel with the variation of its distribution profile. On this basis, it is concluded that the band of the impurity component on the elution curve is compressed (and the component is therefore concentrated), The correct explanation of the increase in the concentration of the impurity can be achieved on the basis of the CD theory.

The question of the concentration of the sorbate band for a longitudinal gradient of parameters (sorbability, capacity, and rate) has been frequently considered in the literature in connection with the development of versions of chromatography such as chromathermography,[56] where a moving temperature field with a negative gradient is used, and chromarheography,[90] in which a flow rate gradient is employed. It was shown in these studies that, in the absence of the flow rate gradient under the conditions of a stationary gradient of the Henry coefficient (achieved by altering the temperature or the amount of the phase), the concentration of the component cannot increase. The compression of the sorbate band does not lead to an increase in concentration, because the degree of adsorption of the component increases by a factor which is exactly the same as the factor by which the band has been compressed. Only the change in sorption capacity with time leads to an increase of concentration, as happens in chromatography with a programmed temperature[91] and in stationary chromathermography.[56] In both these versions thermal enrichment takes place, its extent being determined by the ratio of the Henry coefficients at the temperatures at which the sorbate is injected into the column and at the outlet from the latter. Furthermore, in chromathermography the "width enrichment", induced by the difference between the rates of migration at either boundary of the sorbate band, is manifested in the course of the migration of the temperature field. Grob[52,60] took no account of the capacity gradient migration factor. Only processes associated with the migration of the solvent front, the removal of the solvent by distillation, and the subsequent programming of the column temperature lead to the concentration of the impurity in the gas phase. We shall consider below the experimental data which confirmed the validity of the theoretical ideas presented above concerning the CD processes occurring in the course of IE as well as certain examples of the determination of impurities in solvents.

## 2. Distribution of the Liquid in the Column

Visual methods are important for the understanding of the mechanisms of the processes occurring in the injection of large samples. In a glass column filled with an inert carrier, which may consist of glass (etched) or metallic beads as well as diatomaceous carriers for chromatography, the section soaked with the liquid is readily seen.[21,22] A technique has been developed for the visual observation of the condensation process along the initial section of a CC.[52] The CC was first filled with a 1 *N* NaOH solution and was kept in boiling water for 4 h. As a result of leaching, the walls of the CC became appreciably clouded. It was established empirically that a thin film of the SP on the column (with a thickness $d_f = 0.12$ μm) is invisible—the column has a milky colour and is opaque. Large amounts of liquid ($d_f > 0.25$ μm) fill the pits in the column making it transparent and can be readily observed from the width of the transparent section of the column. The experiments were performed with the column thermostat at room temperature and the length and position of the ends of the soaked zone were measured after each 12 s.[52] Immediately after the injection of several microlitres of hexane through an evaporating injector, a relatively short soaked zone spread rapidly along the CC. After several seconds, the movement of the leading edge slowed down and the edge began to migrate in jerks. Within the limits of the soaked zone, waves arise and are carried forward in the form of a liquid plug which breaks up along the leading edge. After a time, the film at the closing edge became thinner and vanished. As both edges of the soaked zone move along the bed and the solvent evaporates, the leading edge slows down, whilst the rear edge accelerates until it overtakes the leading edge and the soaked zone vanishes completely.[69] The above picture of the distribution of liquid along the bed fully confirms our observations in experiments on columns filled with an inert carrier.[21] The distribution of the liquid on the surface of the filler could be assessed quantitatively from the rate of migration of the rear boundary of the soaked layer with the aid of

Eqns.(2)–(4) obtained previously. The amount of liquid $q$ retained under isothermal conditions on the carrier surface in the presence of a gas stream was calculated. This quantity amounted to 0.05 ml of liquid in 1 ml of the column for various solvents and was almost independent of the flow rate and the grain size of the carrier. An appreciable increase of $q$ at the bend in the U-shaped column is observed when the latter is positioned vertically. The constancy of $q$ enabled us[21] to develop on the basis of the theoretical equations (2) and (4) a simplified method for the analysis of a binary mixture and for the calculation of the physicochemical parameters of liquids (the vapour pressures of the components and the activity coefficients). By comparing the velocity of the soaked front and that of hexane along the SP, it was possible to estimate approximately the thickness of the solvent film in the CC, which amounted to 40 μm according to Grob's data.[52] This quantity is close to that calculated on the basis of geometrical considerations and corresponds to a fraction of liquid in the column of 0.25.

The dependence of the length of the soaked section $L$ and of its evaporation time $t_2$ on the experimental parameters has been studied.[21,69] It was found that $L$ depends only slightly on the volatility of the solvent, the carrier gas flow rate, the inlet pressure, the flow rate and method of injection of the sample, and the grain size of the carrier in the column. According to Eqn.(8), the quantity $t_2$ is proportional to the dose and decreases in inverse proportion to the volatility of the solvent.

### 3. Distribution of the Sorbate along the Bed and Determination of Heavy Impurities

When the sample is injected directly into the column, the liquid and sorbate are distributed uniformly. This can be inferred from the stepped CDG obtained when the detector is connected to the outlet from the CD column (Figs.2*a* and 2*c*). The constancy of the signal during the period of the elution of the different zones indicates the constancy of the concentrations within the limits of the zone of the distributed liquid. The application of a selective detector with respect to the impurity[72] made it possible to demonstrate this yet again. In the above study the author actually repeated Kiva's principal results[14] in the determination of impurities and, on the other hand, to some extent foresaw certain CD and SE postulates. Experiments were performed on an inert carrier (Teflon) using two detectors—a flame-ionisation detector with a high sensitivity with respect to organic substances and virtually unresponsive towards water as well as a thermal conductivity detector for water. The impurity component (Carbitol) was readily soluble in water and was less volatile. The column was maintained at a temperature below the boiling point of water. The volume of the aqueous samples was 40 μl. When the mixture was injected, the following remarkable fact, which is valid for dilute solutions, was observed. Whereas pure Carbitol in the absence of water is hardly retained in the column, when its aqueous solution is injected part of the Carbitol (*1*) is eluted together with water (zone I in Fig.3*g*), while the main bulk of the Carbitol is evolved in the form of a narrow peak (zone II) at the rear edge of water (*2*). The size of the peak formed on the "tail" of the main component is proportional to the concentration of the impurity and sample size. Deans[72] (see also his later investigation[92]) recommends that the injection of large samples into one of the columns be combined with the ejection of the main component into the atmosphere and subsequent transfer of the impurity (by means of special switching devices) to another separating column, which facilitates the operation of the latter. An example of the determination of 0.04 p.p.m. of 1,2-dimethylcyclohexane in isooctane from a 0.4 ml sample was quoted.

In our determinations of heavy impurities in organic solvents by the CD method[44,93] the sample was injected several times in succession under isothermal conditions into the column. A step associated with the impurity component (octane), whose height corresponded to its vapour pressure, was observed on the CDG after the solvent (hexane) zone. The width of the step increased in proportion to the dose, whose maximum size was about 10 ml. These experiments showed that CD makes it possible to obtain high enrichments—the concentration of the impurity increases from the initial value in solution ($N_1$) to the maximum value corresponding to the pure liquid ($N_1 = 1$) and the enrichment coefficient is $10^3$–$10^4$. In the development of an indirect CD method[45] for the determination of impurities in water (with preliminary extraction of the sample by a volatile solvent and its subsequent CD analysis) the losses of the impurity component arising in isothermal analysis [see Eqn.(8)] were taken into account in constructing a linear calibration.[93]

Whereas on filled columns the solvent and the sorbate are as a rule distributed uniformly, on CC, in particular when the sample is injected through an evaporating injector, certain characteristic features are observed. The use of a solvent during the concentration of the sorbate induces in many instances a distortion of the peaks—they are greatly broadened and even split into two components on the chromatogram. The distribution of the sorbate within the limits of the soaked section of the CC has been investigated using the method described by Grob.[69] The distribution of perylene on the surface of the CC after the introduction of concentrated perylene solutions was investigated in ultraviolet light (in a separate chamber). Subsequent experiments with dilute perylene solutions were performed under the same injection conditions with recording of the chromatogram and were compared with visual observations. When the sample is injected directly into the CC at 25 °C, the impurity is not always distributed on the column in the form of a uniform film. Depending on the conditions, most of the impurity component is concentrated at the ends of the liquid zone with a length amounting to several centimetres. In this case split peaks are observed on the chromatogram, the first of which is usually higher than the second. When perylene is injected through an evaporating injector, it is concentrated mainly in the hot zone at the inlet to the CC. The peaks then have the form of a "stool" with the flat portion turned towards the start of the experiment. The distorted peaks of all the components were clearly seen in experiments on a mixture of $C_{12}$–$C_{36}$ n-alkanes diluted with acetone ($1 : 2 \times 10^5$) in which the temperature was programmed in the range from 30° to 300 °C.

The conditions governing the formation of a narrow band of impurities when the sample was injected into the CC through an evaporating injector have been investigated.[79] The evaporator and column temperatures during the injection period are kept constant (25 °C). Ten solvents of different classes with $t_b$ up to 69 °C were investigated. In order to improve separation, the author recommends that the column temperature be reduced, that a less volatile solvent be chosen for the analysis of heavier alkanes, that a fairly large amount of liquid be deposited, etc.

The main principles governing the broadening of the bands on the bed in CC and the distortion of the peaks on the elution curve have been formulated.[86] It has been shown in relation to the analysis of the $C_{22}$, $C_{26}$, and $C_{30}$ n-alkanes that repeated decrease of the thickness of the SP film (by washing it off) in the range from 2 to 0.03 μm leads to a proportional decrease of the peaks. In fact the author proceeded to the examination of CD on an inert carrier in this instance.

Experience gained in the application of the SE showed that the injection of large doses in CC washes the SP out of the initial section of the column, leads to its accumulation at some distance from the point of injection, and finally results in the impairment of the efficiency of the column and even in its blocking. In order to eliminate these undesirable phenomena, a method has been developed in which the SP is washed out of the first two metres of the CC in a preliminary step.[94] For this purpose, approximately 150 μl of methylene chloride, containing 0.1% of Carbowax 1000, was introduced from a microsyringe via an elastic connection, and then, after several seconds, the liquid was blown out in the opposite direction. The operation was repeated three times. Along the section of the CC 2 m long, it is possible to deposit 5–8 μl samples. Various procedures for the preparation of CC without SP along the initial section, in which the SP is extracted or burnt off, have been described in detail.[87] Empty pre-columns connected to the CC either by a flexible Teflon tube or via screw thread or glued junctions have also been used. The MEGA Company supplies prepared CC with an empty end section (3 m long).

A series of new factors leading to the broadening and distortion of the peaks have been treated systematically[77,78,95] and the mechanism of the formation of the sorbate band as a function of the experimental conditions has been considered. The only injection method ensuring sharp initial sorbate bands involves split injection. The remaining methods require a concentration process over a period up to at least 0.1 s (or over several mm along the bed). The broadening of the bands in the injection of large samples can arise for two reasons. Firstly, when samples are injected through an evaporating splitless injector, the process in which the sample is transferred from the evaporator to the CC bed entails an appreciable increase in the injection time (on average up to 30–60 s), which induces the spreading of the peaks on the chromatogram—the so-called "band broadening in time". The peaks of the components on the chromatogram have the same width. The broadening of the peaks is eliminated by improving the condensation conditions, by employing an additional solvent (limiter) (see Section IV), and by programming the CC temperature (the broadening of the peaks is not observed for substances which are eluted at a column temperature 60–80 °C higher than the initial temperature). The second cause of the broadening of the band is associated with the distribution of the liquid and together with it also of the sorbate over a definite fairly long section of the CC—the so-called "band broadening in space". On average, the soaked section can occupy between 10 and 60 cm of the length at the inlet to the CC. In this case the magnitude of the effect depends on the ratio of the lengths of the wetted and SP-coated sections of the column. Thus approximately 2% of the length of a 15 m column is wetted, which decreases the number of theoretical plates (NTP) by a factor of ~5. The "band broadening in space" is manifested for peaks of heavy components (with a relative capacity $k' > 30–50$) and is independent of the programming of the temperature. It has been noted[77,78] that all the types of spreading indicated above depend on the ratio of the vapour pressures of the substance analysed and the solvent. The processes on the solvent are regarded as the first stage of the chromatographic separation. In order to investigate the process involving the isolation of the impurity from the solvent, a method has been developed for sampling at different stages of the distillation of the solvent.[78] A capillary section 1 m long, deactivated with Carbowax, was placed between the injector and the CC. This pre-column, containing the entire sample, was maintained for a definite period at the inlet of the CC and then the residue from the sample was blown out into the atmosphere and the experiment was terminated. When a non-polar solvent (hexane) was used, the higher-boiling alkanes always emerged in the form of narrow peaks and were eluted from the pre-column attached to the CC together with the last portion of the solvent. If the experiment was performed under conditions where there was no condensation (using pentane as the solvent injected via an evaporator), then all the peaks were broadened to the same extent, corresponding to the time taken to transfer the sorbate onto the CC. The formation of narrow alkane peaks can be accounted for by the occurrence of two types of CD processes. In the first place, less volatile impurities, having a much lower vapour pressure than the solvent, are concentrated near the rear solvent edge along a short section between the evaporator on the CC. Furthermore, as a result of limiting CNSV processes (see below), the possibility of the appearance of steps before the peaks is eliminated. The influence of these two CD processes on the formation of narrow peaks was not considered by Grob.[77,78]

### 4. Distribution of the Sorbate along the Bed and Determination of Light Impurities

In the development of a direct method for the analysis of organic impurities in water, it was established that all hydrocarbons sparingly soluble in water emerge from an isothermal CD column almost at once in a single peak.[45,46] The possibility of evolving the impurity in the form of a narrow zone, enabled the authors to develop a series of CD methods for the determination of petroleum products in water.[49] The possibility of determining the solubility of $C_6$–$C_9$ alkanes in water at concentrations of 1–10 mg litre$^{-1}$ and also of determining the content of petrol fraction hydrocarbons in water has been demonstrated.

In the determination of light impurities on CC, their evolution with the first portions of the solvent was also observed.[78] Thus approximately 90% of 2-propanol was transferred from hexane to the CC over a period of 20 s. As a rule, such conditions arose when there was a marked difference between the polarities of the solvent and the sorbate (for example, for ethanol as the impurity, hexane as the solvent).

Together with the normal SE, the "reverse solvent effect", manifested by the broadening and distortion of the peaks due to substances emerging before the main component, has also been discussed.[96] Both light impurities ($C_7$–$C_{10}$ n-alkanes and certain aromatic compounds) and heavy impurities (durene and dodecane) have been determined in solution in undecane. The experiments were performed with slight stream splitting (1:100) for a dose of 0.015–8.0 μl. The efficiency, expressed in terms of the number of theoretical plates, fell with increase of the dose by a factor of 2–4 for the light components. The explanation is that the sorbate band falls within a field with a negative liquid phase distribution gradient (section II, Fig.6). As a result of the arrest of the rear edge of the band and the acceleration of the leading edge, a reverse SE, leading to the distortion

of the peaks, is manifested. For the heavy component (durene), an increase of the NTP by a factor of 9 was observed.[96] This effect has also been discussed by Yang et al.[97] and Brötell et al.,[98] who obtained anomalously high efficiencies with respect to $C_8$ and $C_{10}$ n-alkanes (4390 and 14400 plates $m^{-1}$ respectively). The formal application of the familiar expression for the NTP (Fig.7).

$$n = \frac{5.54}{L}\left(\frac{t_R}{\mu}\right)^2$$

leads to unduly high values of this quantity. In the determination of the true retention times of the components for the correct calculation of the thermodynamic characteristics of the substances and their identification, it is essential also to take into account the shift of the retention times. The use of a heavier solvent results in an increase of the elution time of the impurity components. This effect is attained on a lighter solvent (pentane, hexane) with increase of the dose.

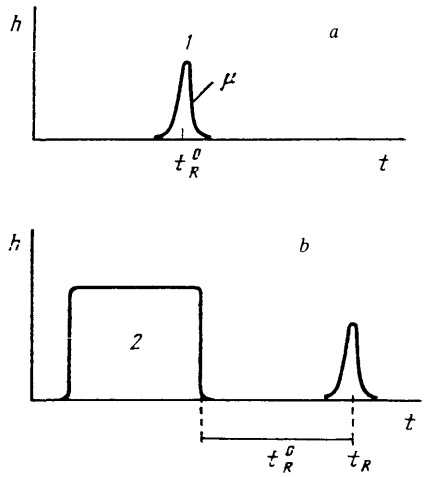

Figure 7. Schematic explanation of the calculation of the NTP ($n$) in the injection of a sample without solvent ($a$) and with solvent ($b$): 1) impurity; 2) solvent; $t_R$ = retention time; $\mu$ = peak width.[96]

Factors leading to the distortion of the peaks have been examined in relation to the determination of chloroform impurities in solvents.[99] The authors claim that the distortion of the peak owing to the partial trapping of the impurity cannot be eliminated with the aid of the subsequent process on the solvent-saturated SP. Chloroform peaks with ideal shape were obtained only when water, acetone, and diethyl ether were used as solvents combined with a polar SP. In the first two cases the successful result can be accounted for by the formation of azeotropes in the systems indicated, which lead (as mentioned above) to the rapid separation of the impurity from the main component.

Studies have been made[100,101] on the additional spreading of the peaks due to substances emerging before the solvent. In experiments with model mixtures of $C_5$–$C_{12}$ n-alkanes in octane and ethanol, it has been shown that "effectively" trapped components emerge in narrow peaks and "poorly" trapped components emerge in the form of broad steps. It is noteworthy that the boundary between the "poorly" and "effectively" trapped impurities is indefinite and is associated, according to the authors,[100] with distillation processes. In conformity with the classification of impurities into light and heavy presented above,[49] one must distinguish impurities capable of forming solutions having a vapour pressure greater or smaller than that of the solvent. Thus when ethanol is used as the main component, all the alkanes up to n-heptane form azeotropic mixtures[83] and are evolved at the leading edge of the solvent. Higher-boiling n-alkanes, which do not form azeotropes, should emerge after the more volatile solvent. The recommended increase of the initial column temperature in order to reduce the solvent injection time can lead only to a partial narrowing of the peaks.[100] A more radical means of compressing the peaks of light impurities involves the creation of a negative temperature gradient (see Section V).

The questions examined in this Section show that isothermal elution constitutes the initial stage of the CD separation and in many instances can be used directly to concentrate and determine impurities.

## IV. LIMITING CHROMADISTILLATION

In the previous Section it was shown that the IE of a mixture entails extensive spreading of the peaks of both light and heavy impurity components. The broadening of the sorbate bands as well as the losses of substances associated with the evolution of the impurity component together with the solvent zone can be eliminated with the aid of limiting CD.[2,8,9]

Limiting CD consists in a procedure where a dose of the pure substance, whose vapour pressure is greater than or equal to the vapour pressures of the mixture components is deposited beforehand, before the injection of the mixture to be separated in a column filled with an inert carrier. The main mixture component (the solvent) can be used as a compound of this kind, referred to as the limiter, when the determination of the lighter components is not required.

The mechanism of the action of the limiter on a column without a SP is explained in Fig.8. In the initial instant the limiter *3* is deposited on section II of the column and the mixture (*1*, *2*) is deposited on section I (Fig.8*a*). In the first elution stage (Fig.8*b*), the following processes take place. The frontal IE of the mixture, described previously (Fig.3) and leading to the evolution of the pure less volatile component *1*, takes place at the rear edge. At the leading edge of the *1*, *2* zone the saturated vapour is transferred by the stream of carrier gas to section II and is condensed at the rear edge of the limiter. In conformity with distillation laws,[80] the formation of the zone comprising the mixture having the initial composition should be accompanied by the simultaneous liberation of the pure more volatile component *2*, which forms its own zone intermediate between the zones of the mixture and the solvent. It follows from the theory of limiting CD[21] that the rate of migration of the rear edge of the mixture zone ($u'_2$) (Fig.8*c*) is greater than the rate of migration of the leading edge ($u''_2$):

$$u'_2 = \frac{\alpha c_2^0}{q_{1,2}} > u''_2 = \frac{\alpha c_1^0}{q_{1,2}}, \qquad (13)$$

where $q_{1,2} = q^{II}/(N_2 + \beta_{2,1}N_1)$ is the amount of the liquid mixture *1*, *2* per unit volume of the column on section II, as a result of which the zone of the *1*, *2* mixture on the bed disappears and ultimately the mixture components are fully

separated (Fig. 8*d*). A typical CDG for this case is illustrated in Fig. 8*e*. Thus the separation in limiting CD is a result of numerous frontal separation processes at the rear and leading edges of the liquid. A relation has been derived[6,8] between the amount of limiter $Q_{lim}$ and the dose $Q_{mix}$ (of a mixture of known composition) which ensures complete mixture separation:

$$\frac{Q_{lim}}{Q_{mix}} > \frac{N_2 + \beta_{2,1} N_1}{\beta_{2,3}(\beta_{2,1} - 1)}, \qquad (14)$$

where $\beta_{2,1} = c_2^0/c_1^0$ and $\beta_{2,3} = c_2^0/c_3^0$. It follows from this relation that a definite length of the bed is required along which the rear boundary of the *1*, *2* zone formed (Fig. 3c) should be able to catch up with the leading boundary before it emerges from the column. In essence the main mixture separation process takes place and is completed on section II of the limiter. Special cases for two problems in the determination of impurities follow from Eqn. (14).

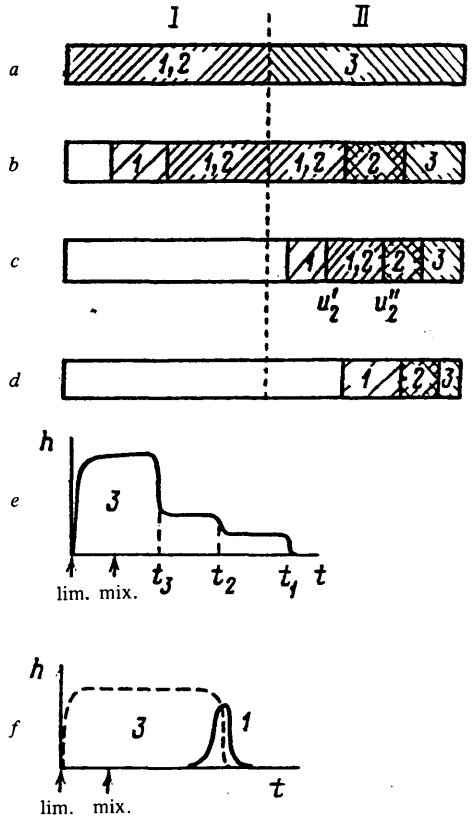

**Figure 8.** Schematic illustration of limiting CD.[21]

$N_1 \to 0$—determination of a heavy impurity. For this purpose it is useful to employ the pure solvent as the limiter. Then $\beta_{2,3} = 1$ and we obtain the relation

$$Q_{lim} \geqslant Q_{mix}(\beta_{2,1} - 1). \qquad (15)$$

In contrast to the CDG of the impurity component obtained in IE (Fig. 3*g*), in this case a narrow peak of the impurity (without a low-slope stepped section) is observed on the elution curve and is located at the rear edge of the solvent (Fig. 8*f*).

$N_1 \to 1$—determination of a light impurity. Under these conditions, Eqn. (14) assumes the form

$$Q_{lim} \geqslant Q_{mix}\beta_{3,1}/(\beta_{2,1} - 1). \qquad (16)$$

The impurity will be concentrated at the boundary between the limiter and the main mixture component.

It follows from Eqn. (14) and its corollaries that in most practical cases ($\beta_{2,1} < 2$) the complete separation of the mixture and the removal of the impurity require that the volume of the limiter should as a rule exceed the dose of the mixture to be separated. Large amounts of the limiter are required both in the separation of the mixture components with similar vapour pressures and in the isolation of the more volatile mixture component and when a more volatile limiter is employed.

Questions concerning the theory of the impurity isolation process, which in fact constitutes limiting CD, have also been examined by Pretorius et al.[76] A relation was obtained for the solvent and sample doses which ensure the complete isolation of the heavy impurity component in the form of a single peak on the chromatogram. It is identical with our Eqn. (15). The derivation was based on the consideration of the elution of the impurity component zone in terms of the more volatile solvent. The authors determined the rate of migration of the leading edge $u_2''$ in accordance with the partition coefficient, which is in the general case incorrect because, it follows from Eqn. (13), that at high sorbate concentrations the rate $u_2''$ depends on the mixture composition.

We carried out an experimental test of the principal relations of limiting CD on a packed column[6,8] and showed that the use of the limiter leads to the concentration of the substances. Thus, if the concentration of the test substance in the gas phase is less than the vapour pressure and the substance enters the column filled with the more volatile solvent together with the stream, then the given component will accumulate at the rear edge of the solvent and, as a result of the CD separation, can form a zone of the pure liquid at the concentration of the saturated vapour in the gas phase. This accumulation principle has been realised[43,44] in the determination of heavy impurities in a solvent and it has been shown that, after a single injection of the limiter dose, it is possible to inject repeatedly the mixture doses and obtain a proportional accumulation of the impurities.

Analysis of light impurities in solvents, even when the impurity components are sparingly soluble, is frequently hindered by the slowness of their evolution. Thus, in the direct analysis of alcohols in water, the impurity zone emerges from the preliminary CD column in the course of several minutes in the form of a peak with an extended "tail". The introduction of the limiter (ethanol) makes it possible to collect the entire test substance in the form of a narrow step at the closing front of the limiter. In studies [48,51] on the analysis of impurities as fermentation products (wine-making materials, brandies, etc.), it was noted that the accumulation of impurities at the boundary between two solvent zones (ethanol–water) leads to additional compression of the impurity peaks. A method was developed for the determination of impurities in wine-making materials, which are evolved at the leading front of ethanol, at the boundary between ethanol and water and at the rear edge of water.[48]

In studies by non-Soviet workers, the principle of limiting CD has been used to determine impurities using direct injection.[72,73]

The preliminary injection of the solvent to ensure the complete isolation of the impurity was first used by Deans.[72] Thus, in order to determine Carbitol to an aqueous 20 μl sample, 20 μl of pure water was introduced into the column beforehand. The author points out in this connection the necessity to select the appropriate solvent dose in order to attain the complete isolation of the impurity component.

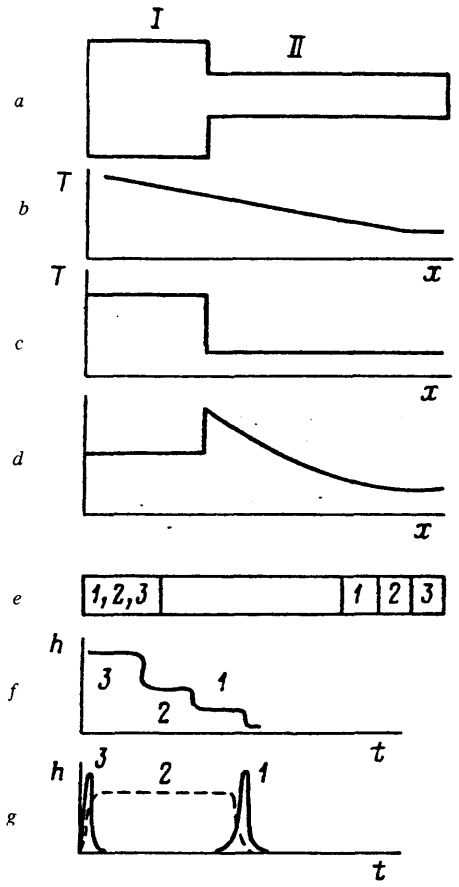

**Figure 9.** Schematic illustration of thermal CD:[7] *a*) junction between the injector (I) and the column (II); *b*) temperature field in thermal CD; *c*) ditto with evaporating injector; *d*) ditto along CD column; *e*) distribution of components I, II, and III along the bed; *f*) CDG of the mixture; *g*) CDG of impurities *1* and *3* in the solvent *2*.

A method for the injection of large gaseous samples (in vapour phase analysis), which is a development of the direct injection method with SE, has been considered.[73] Samples of mixtures of octane and air were injected by means of the usual injector, permitting the splitting of the stream. These experiments must be regarded as the version of limiting CD in which the condensation of large gaseous samples in the CC is achieved with the aid of the preliminary introduction of the solvent into the column. The unduly low heights of the octane peaks observed in experiments following an increase of the interval between the injection of the liquid and gaseous samples are due to the fact that the main bulk of octane failed to "catch up" with the rear edge of the limiter (Fig. 8c). The conditions under which the SE is manifested were investigated quantitatively in the above study. The simultaneous injection of the solvent and the gaseous sample naturally led to a negative result—the bulk of the octane passed through the CC without being retained on hexane. After the replacement of the solvent by pentane and the increase of the dose from 2.5 to 3.5 μl, the limiting effect was not observed at a CC temperature of 35 °C (apparently pentane did not condense). At room temperature a moderate impurity retention effect was noted.

The limiting CD process examined in this Section constitutes an effective means for isothermal concentration and isolation of impurities from solvents.

## V. THERMAL CHROMADISTILLATION

As already mentioned above, the IE of a mixture involves only partial separation into individual components (Fig. 3). In order to achieve complete separation of the mixture, it is necessary to ensure conditions for the condensation of the saturated vapours formed at the leading edge of the band. The simplest method whereby condensation conditions can be created involves the use of a temperature field with a negative gradient (the temperature should decrease monotonically from the inlet to the outlet from the column—Fig. 9*a* and 9*b*). Under the conditions of thermal CD,[7] the repetition of the condensation and evaporation processes is achieved as a result of the movement of the entire mixture along the bed, which leads to its separation into the pure substances at the outlet from the column (Fig. 9*e*). The elution curve (the CDG) has a stepped form (Fig. 9*f*), where the height of the step corresponds to the vapour pressure and its length to the amount of each component. In CD the impurities are concentrated at the leading or rear edge of the main component (depending on the type of solution formed).[49] As a rule, the concentration of the impurity substance in the sample is insufficient to form a separate zone and for this reason the impurities are isolated in the form of narrow bands (Fig. 9*g*).

The temperature gradient is the most effective means of separation in CD. In contrast to chromatography, a stationary temperature field in CD results in the concentration of the substances, since repeated mixture condensation steps take place continuously along the bed, each leading to the liberation, in conformity with distillation laws,[80] of the lighter component and to the separation of the mixture as a whole. It is noteworthy that a longitudinal temperature gradient also arises in fractionation, but its character is wholly determined by the composition of the mixtures formed in each section of the column. In the continuous separation of a mixture under adiabatic conditions, a stationary distribution of concentrations arises along the packing. The heat supplied to the lower part of the column leads to the boiling of the liquid in all the sections; the temperature can then vary only in the range of the $t_b$ of the components to be separated. In contrast to fractionation, the temperature gradient in CD is specified from outside. The process is based neither on boiling nor on evaporation. The discrete nature of the injection, the absence of a countercurrent flow, and movement along the bed, as in chromatography, lead to a simpler way of achieving multiple separation steps, which

makes it possible to increase the efficiency of the separation. In contrast to chromatography, under conditions where components are separated by thermal CD (Fig. 9e) stationary fronts are observed[19] and there is no progressive spreading of the bands. In thermal CD the separation proceeds not only via frontal stages at the rear and leading liquid edges (as in limiting CD) but also along the entire layer of the mixture, since condensation takes place in all the sections of the column. Visual studies of thermal CD have shown that each component of a mixture boiling over a wide range occupies a definite section of the column within the limits of which a uniform distribution of the liquid on the bed is maintained ($q$ = 0.2 ml of the liquid in 1 $cm^3$ of the column). Both boundaries of a strongly wetted section (leading and rear) migrate along the bed in such a way that the zone width remains unchanged. This made it possible to develop a simple visual method for the analysis of high-boiling substances.[22]

In contrast to IE (section III) and vapour phase analysis,[81,82] thermal CD leads to the concentration of light impurities. Thus it has been shown[50] that, in the analysis of a butanol–water mixture on an isothermal column, butanol emerges in the form of a peak with a highly extended base despite the presence of positive deviations from Raoult's law ($\gamma_2$ = 45). The creation of a longitudinal temperature gradient compresses the alcohol band and enriches it by a factor of 250. As mentioned above, in effective thermal CD, the impurities are evolved at both edges of the principal component. There is therefore a possibility of different versions of the group separation of impurities. In relation to the isolation of butanol and acetic acid from water, it has been shown[15] that, by varying the dose, it is possible to regulate the distance between the components indicated.

All the principal results in the analysis of impurities have been obtained under the conditions of thermal CD. The methods described were developed mainly for the determination of impurities in aqueous systems.[49] Two versions of analysis are proposed: the direct version where the aqueous mixture to be analysed is injected directly into the CD column and the indirect version where the substances to be determined are first extracted with a solvent. The degree of the additional enrichment as a result of extraction was (depending on the ratio of the volumes of the aqueous sample and the solvent) between 40 and 200. On the basis of the first version of analysis, the following procedures have been developed:[45,51] determination of hydrocarbons dissolved in water, isolation of the petrol fraction and its separation by group distillation, the determination of light alcohols ($C_1$–$C_5$) which are readily soluble in water, and the separate determination of the sparingly soluble fractions of high-boiling alcohols ($C_7$–$C_{13}$). A method for the determination of impurities, which are evolved before ethanol, at the ethanol–water boundary, and after water, has been developed for the analysis of fermentation products containing two main components (water and ethanol). The relative standard deviation in the determination of alcohols at the level of 10–100 mg $litre^{-1}$ was 0.2–0.5 for a fiducial probability of 0.95. When measurements were made at the level of the limiting permissible concentrations (LPC) of alcohols in drinking water (0.1 mg $litre^{-1}$), a 20–30% change in the composition of the solutions was observed after several hours. The use of a solvent in the indirect methods (hexane or carbon tetrachloride) as well as an additional solvent in the direct methods (ethanol) permits the determination of components which are sparingly soluble in water and which form emulsions with the latter. The sensitivity of the indirect analytical methods for the petroleum products with $t_b$ corresponding to the $C_7$–$C_{20}$ n-alkanes was 0.014 mg $litre^{-1}$ and was limited by the purity of the solvents employed.[45,93]

The characteristics of CD, which arise when a moving temperature field with a negative gradient is employed—the so-called chromathermodistillation (an analogue of chromathermography), have been considered.[15,105,106] This method ensures the concentration of impurities less volatile than the solvent as a result of their evolution at higher temperatures and also makes it possible to shorten the duration of the analysis.

We shall now consider studies in which the SE was ensured by a negative temperature gradient along the column. In the initial version of the direct injection method,[53,55] the usual injectors were employed for the CC in which the outlet for discarding the carrier gas was closed during the injection period (30 s). A sharp temperature gradient was then employed (Fig. 9c)—the sample was evaporated at a high temperature (210 °C) and was condensed on the CC at room temperature. In the first studies the compression of the impurity band was observed. In order to investigate the compression effect, the sample was injected over different periods ($\tau_{inj}$) and the width of the sorbate band on the elution curve ($\tau_{el}$) was measured. The ratio of these quantities characterised the degree of enrichment, which gradually increased in the series of cycloalkanes from $C_4$ to $C_8$ and amounted to ~10. A method was also developed for analysis in which the solvent is discarded. A section of a capillary 1.6 m long was connected to the injector, the working flow rate was established, the sample was injected into the evaporator (at 210 °C), and it was condensed on the capillary at 25 °C over a period of 30 s. The gas flow was then stopped, the outlet end of the capillary was connected by means of a Teflon tube to the main CC, and the experiment with programmed temperature was begun. It was then shown that the losses of light components ($C_4$–$C_5$), emerging after the solvent, are 60–80% and those of the heavy $C_6$ component are 10%. The experiments in which the inlet capillary was cut into three sections (40, 40, and 80 cm) and the contents of the latter were subsequently analysed on the CC confirmed that volatile impurity components accumulate at the closing solvent front in CD. The use of an unduly short (albeit with a high gradient) temperature field (Fig. 9c) for a small difference between the vapour pressures of the solvent and the substances analysed leads to a decrease of the efficiency of the CD separation. The incomplete extraction from the solvent of even heavy impurities shows that a single condensation step in the thermal version of CD is insufficient.

It has been noted[79] that the difference between the temperatures of the evaporator and the CC can be used both in the vapour phase analysis in the absence of a solvent and in the analysis of a sample with a solvent. When the column is moved in the thermostat, a large gradient is established which improves the shape of the peaks.[86]

It was not clear from previous studies of the SE to what extent this effect determines the impurity concentration process, because one could also postulate that it is associated with the low-temperature extraction. The conditions making it possible to differentiate these processes have been investigated[94] using an injector, for the direct injection of the sample into the CC.[67]

Certain theoretical questions associated with the distortion of the sorbate band in direct injection into a cooled column have been examined.[102] The authors assumed that direct injection leads mainly to a distribution of the liquid with decreasing amount of the latter along the carrier gas stream. For this reason, one should have observed a distortion due to the reverse SE (Fig. 6, section II).[96] When the initial

section of the CC is unduly cooled, a temperature gradient, increasing along the CC, arises, which also enhances the "reverse SE". It follows from the examination of the retention characteristics adopted in GLC[89] that this entails the broadening of the band in the temperature field. The authors[102] suggest that the peaks be compressed by establishing a negative temperature gradient, i.e. in essence by intoducing the elements of thermal CD into the experimental technique. For this purpose, in the devices described by Galli and co-workers[103,104] it is necessary to supply cooling air in the direction opposite to the flow of the carrier gas from the side of the warmer column thermostat.

In order to assess the possibilities of the proposed method and also for comparison of the expected results with the data actually obtained we shall carry out the following calculation. We shall assume that the concentration of the impurity substance is measured by a flame-ionisation detector whose sensitivity is the same in all the methods compared and amounts to $c_{fid} \cong 10^{-4}$ (vol.%). With the aid of a linear detector, such a concentration can be recorded on the $10^{-11}$–$10^{-12}$ A electrometer scales. The minimum concentration which can be determined in the initial mixture (injected into the chromatograph) is related to the experimental parameters by the following formula:

$$c_{min} = \frac{c_{fid} v_0 t_\mu M}{2.24 V_{ds}} \text{ (mg litre}^{-1}\text{)},$$

where $v_0$ is the carrier gas flow rate (ml min$^{-1}$), $t_\mu$ the peak width on the chromatogram (min), $M$ the molecular weight of the substance analysed, assumed to be 100, and $V_{ds}$ the volume of the sample injected (ml). We shall examine the numerical data for two principal cases.

1. Analysis on a filled chromatographic column with injection of the sample into the CD pre-column. We shall assume that $v_0 = 20$ ml min$^{-1}$, $t_\mu = 0.5$ min, and $V_{ds} = 1$ ml. In this case $c_{min} = 5 \times 10^{-2}$ mg litre$^{-1}$, while the concentration actually determined[45] was $5 \times 10^{-3}$ mg litre$^{-1}$.

2. Analysis on a CC using the direct sample injection methods. If $v_0 = 2$ ml min$^{-1}$, $t_\mu = 2$ s, and $V_{ds} = 10$ µl, then $c_{min} = 3 \times 10^{-2}$ mg litre$^{-1}$. The results of the analysis of solutions containing 1–20 p.p.m. of the test substance have been quoted in studies on the SE. In both cases presented here, $c_{min}$ is of the same order of magnitude despite the difference in the dose by a factor of 100. This can be explained by the higher efficiency of the CC, working at a lower flow rate, which leads to the isolation of the impurity in a small volume and hence to a greater sensitivity of the measurements on the CC. It follows from the data presented that the use of the CD pre-column in combination with a CC can increase the sensitivity by a further two orders of magnitude, whilst retaining the efficiency of the CC, which makes it possible to attain a level of measurable concentrations of about 0.1 p.p.m.

Studies on thermal CD have shown that the temperature gradient influences the mixture separation to the greatest extent. In order to enhance the concentrating effect, one can combine the limiting and thermal CD processes.[74]

## VI. CHROMATOGRAPHY OF NEARLY SATURATED VAPOURS

This Section deals with studies in which the stationary phase is greatly overloaded by the solvent during the sample injection period. The isolation of the impurity components along the initial section of the column is accompanied by the interactions of the sorbates not only with the SP and the solvent but in many cases also with one another. These phenomena are described by the chromatography of nearly saturated vapours[9,15,17] in which one considers processes at high concentrations corresponding to the concave sections of the sorption isotherms (Fig.10*a*).

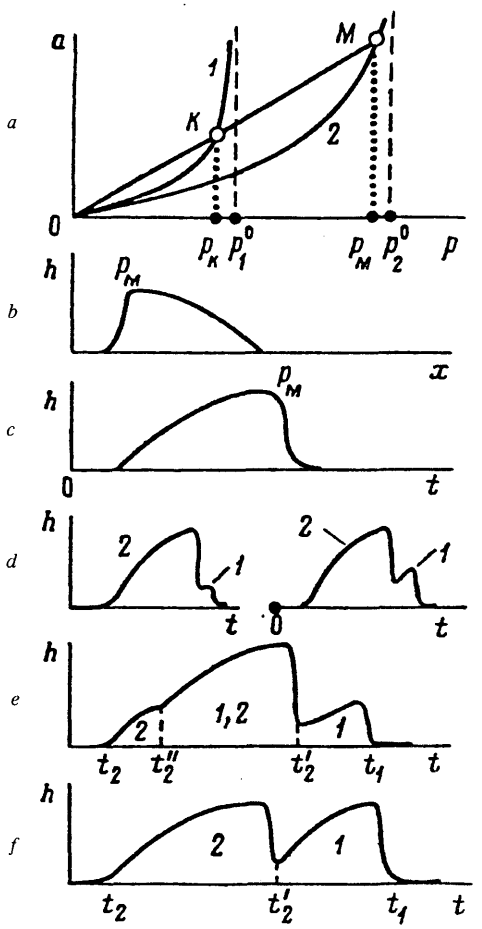

Figure 10. Schematic illustration of the CNSV process:[15] *a*) sorption isotherms for components *1* and *2* to be separated; *b*) distribution of the component along the bed; *c*) CDG for a single component; *d*) the possible CDG in the enrichment of the impurity; *e*) CDG for partial separation of the mixture; *f*) CDG for complete separation of the mixture.

It is known from the general theory of chromatography[56,88] that, under the conditions of concave sorption isotherms, the band of the substance analysed should have a greatly diffuse leading front and a cut-off rear edge (Fig.10*b*). A diffuse "tongue" and an abruptly terminated "tail" are recorded on the elution curve (Fig.10*c*). Chromatograms of this kind are observed in gas–liquid and gas–adsorption chromatography at concentrations close to saturation. The injection of large samples into the chromatographic column leads to concave sorption isotherms both for the solvent *2* and for the impurity *1*. The rate of migration of the points in the leading diffuse front along the bed is described by the derivative of Eqn.(1), while the rate of migration of

the curtailed rear edge along the bed is determined, in conformity with the material balance, by the slope of the straight line *OM* (Fig.10*a*) drawn from the origin of coordinates *O* through the point *M* corresponding to the maximum concentration at the front. The straight line *OM*, drawn for the rear edge of the more volatile component *2*, intersects the isotherm of component *1* at the characteristic point *K*. All the points in the leading front of component *1*, for which the derivative is less than the slope of the straight line *OM*, move along the bed faster than the rear edge of component *2* and can therefore catch up with it. This leads to the "limiting effect"—component *1*, dissolving at the rear edge of the limiter *2*, is retarded and concentrated. According to the material balance at the zone boundary, the following equation should hold:

$$a_2/c_{2M}=a_1/c_{1K}, \qquad (17)$$

where $c_{1K}$ and $c_{2M}$ are the concentrations in the gas phase corresponding to the points *K* and *M* and $a_1$ and $a_2$ are the degrees of adsorption at these concentrations. It must be emphasised that the final result of the enrichment is determined by the isotherms of the individual components and is independent of the character of the solutions formed in the intermediate zone between the components. The chromatogram of the less volatile impurity component *1* can have either the stepped form, when the initial concentration was smaller than at the point *K*, or can have a growing leading front in the opposite case (Fig.10*d*). However, in both cases Eqn.(17) should hold for the concentrations at the rear solvent boundary.

The advantages of the injection of large samples into a column with a SP for the separation of mixtures have been demonstrated.[5,15,17] It is known[56,57] that an increase of the dose in traditional chromatography leads to the overloading of the column and to the impairment of the separation owing to the overlap of the peaks. However, further increase of the dose makes it possible to attain operating conditions where CD effects exert an influence. The influence of the interaction of sorbate molecules not only with the SP but also with one another is then manifested. In contrast to CD, in the CNSV there is a possibility of using the sorbent selectivity for the improvement of the separation. The temperature gradient and the limiter promote the occurrence of distillation processes. The action of all the remaining auxiliary separation factors has been illustrated by means of examples.[5,15] Thus, after the injection of 0.1 ml of a liquid heptane–cyclohexane mixture into an isothermal column (at 10 °C) with tricresyl phosphate, a chromatogram similar to that illustrated in Fig.10*e* is obtained. The frontal processes at the leading and rear edges of the band lead to the partial isolation of the components, while the intermediate zone contains the unseparated components *1* and *2*. The use of a negative temperature gradient (from 75° to 10 °C) makes it possible to attain complete mixture separation (Fig.10*f*). From the standpoint of traditional chromatography, this result is paradoxical, since an increase of column temperature should impair the selectivity of the separation. The results obtained are associated with the CD processes on the SP. An analogous effect is attained by employing a limiter. In contrast to CD, in the CNSV there is a possibility of the separation of azeotropes or systems which are otherwise difficult to separate. This has been demonstrated[5,15] in the separation of the heptane–isooctane and benzene–cyclohexane mixtures on α-iodonaphthalene as the SP. Whereas the components are not separated under isothermal conditions (0 °C) for a dose of 0.04 ml, the application of a gradient (85–0 °C) leads to complete mixture separation.

CNSV processes are manifested and are used in the concentration and determination of impurities. A short (20 cm) chromatographic column with a thermal pulse has been used[44] at the concluding stage after repeated CD accumulation of $C_9$–$C_{11}$ alkane impurities in heptane. The lowest concentration which could be determined with the aid of a katharometer was $10^{-3}$ vol.%.

In order to transfer the impurity from the preliminary CD column to the next, separating CC, it is necessary to create favourable conditions for the occurrence of the CNSV. In the analysis of the butanol impurity in water[51] without a limiter (ethanol) or under conditions which rule out the condensation of the alcohol (CC heated above the $t_b$ of ethanol), highly diffuse butanol peaks appear on the chromatogram. In this case the butanol band passes from the CD column to the CC in a large volume of gas (20 ml). If a temperature difference is maintained between the columns (from 70° to 20 °C), ensuring the condensation of ethanol in the initial section of the CC, then the width of the butanol peak on the chromatogram diminishes by a factor of 7. The possibility of combining a CD pre-column with the CC in order to increase the size of the injected sample at least by an order of magnitude was demonstrated in the same study.

The role of the SP in the concentration of impurities from a large sample has been discussed briefly.[72] Harris[107] considered the influence of large samples injected into a column with a SP on the retention of the component under the conditions of marked deviations from Raoult's law. Taking into account the dependence of the activity coefficients on the mole fraction of the component in solution, the author determined qualitatively the character of the change in the retention volume of the impurity with change in the size of the dose. In fact Harris[107] stated the necessity to take into account the intermolecular interaction in the complex system comprising the components of the mixture to be analysed and the SP and the influence of this interaction on the results of the separation. It has been shown[77] that the presence or absence of the SP on the initial section of the CC does not affect the shape of the peaks when the latter spread. This is associated with the presence of a large amount of the solvent, which predominates along the section and forms an unusually large film. However, for comparable amounts of the SP and the solvent, their mutual influence on the isolation of the impurities is manifested.

A suitable solvent was selected[79] for the injection of the sample using the SE and it was established that there must be a definite correspondence between the polarities of the SP, the solvent, and the sorbate.

Jenkins[108] made a special study of the influence of solvent polarity on the shape of the peaks for the direct injection of the sample into the CC. A new method was developed involving the preliminary injection of an additional solvent:[73] several solvent samples were introduced by a single syringe using an air gap to separate different solvents. It was established[108] that the use of non-polar sorbates (alkanes) for injection in a polar solvent (methanol) leads to symmetrical peaks on silicone phases (of the type of SE 30 and 52). The use of a weakly polar secondary solvent (cyclohexane), which is injected before and after the main sample and forms an azeotrope with the first solvent, makes it possible to isolate alkanes in the form of narrow peaks. The solvent evaporation processes occurring are similar to azeotropic distillation.

A number of methods for "correcting" the shape of the peaks, corresponding to our ideas about the CNSV process, have been proposed.[102,108] It has been noted that polar compounds in a polar solvent have normal peaks, but the

shape of some of them is distorted. This is associated with the fact that the condensed solvent prevents the penetration of non-polar substances to the SP on the surface of the CC. In order to improve the process, it is recommended that one should use a mixture of solvents forming an azeotrope, which is equally permeable to both polar and non-polar substances. The prospects for the employment of two solvents simultaneously in order to elucidate whether the split peak corresponds to one substance or several substances have been discussed.[102]

In the course of several years, starting in 1976, a number of studies on the effects occurring in gas-liquid preparative chromatography when samples with a large content of the main component are injected have been published.[109-112] A number of characteristic features of the CNSV considered above and observed in the isolation of impurities from *m*-xylene (dose volume up to 10 μl) on a 640 × 1.4 cm column filled with Spherochrome with the PEGA 25% phase have been noted: for concave *m*-xylene sorption isotherms, an extended leading front of the main component is observed, while the rear edge is sharply cut off, which promotes a clear-cut isolation of the impurity; an increase in sample size shifts the retention times of the impurity components; the observed decrease of the width of the impurity peak following the main component, compared with the injection of an equal amount of an individual impurity component, has been observed.

The last two factors leads to a sharp increase of the formal HETP (by a factor of 10–20), which was also noted by Berezkin[113] and was discussed in Section III of the present review. This treatment of the mechanism of the phenomena occurring is close to that put forward by Jennings[60,89] and Grob[52,79] and is based on the consideration of the elution of the impurity band against the background of a binary solution with a concentration gradient of the main component in the SP.[114] It has been noted[109] that the transfer of the impurity in the field of a variable sorption capacity is analogous to the processes occurring in non-stationary chromathermography. Considering the processes from the standpoint of GLC, Mar'yakhin and Vigdergauz[109] clearly formulated the idea that the main component can play the role of the "sorbate-concentrator" (in other words the limiter). The sooner the impurity is eluted after the main component, the greater the increase in concentration under these conditions. It has also been noted that the main component can be introduced after injecting the mixture containing the components to be concentrated. It is convenient to use a main component which is not recorded by the detector. These features of the CD methods for the concentration of impurities (in the absence of a SP on an enrichment column) were used in our later investigations.[43-45]

The mechanism of the formation of a narrow zone of the impurity component under CNSV conditions, determined by the occurrence of frontal-sorption processes on the SP, has been confirmed in a series of studies published in 1983.[70,71,99-101] The authors investigated experimentally the band forming processes on two sections of the initial part of the CC. On section I (Fig.5), the SP is saturated by the solvent vapour. As noted above and demonstrated in a number of studies,[10,21,49,72] after the elution of the sample from the section I, not all the impurity substance is contained on the rear edge of the solvent. The complete isolation of the impurity component in the form of a single peak is attained by employing a limiter. However, in a number of experiments also without the limiter a complete isolation of the impurity in the form of a sharp peak has been observed on the chromatogram—this occurs in the subsequent separation of the injected sample on the SP in the CC. In order to investigate the process mechanism, a detailed experiment has been performed in which the distribution of the substance along the bed was determined.[70] A 20 m column consisted of a short etched capillary (1 m) and 15 sections on which a SP (OV-1) was deposited and which were connected by Teflon tubes. Some time after the injection, the column was taken apart and the sorbate contained in the part of the CC located between the injector and the disassembly point was blown out into the atmosphere. The CC was then reassembled and the chromatographic process was completed. The large number of disassembly points in the first half of the CC and experiments carried out with a shift of 2–15 s made it possible to obtain a detailed picture of the change in the distribution of the sorbate along the bed as a function of time. The results obtained can be represented by means of the series of diagrams in Fig.11. On the elution curve for the impurity extracted from the first section, a low "base" (110 s long) is observed, while at the end of the zone there is a narrow "tower" (5 s long), whose area corresponds to 70% of the injected octane. This result is fully consistent with the above description of the elution curves obtained on an inert carrier.[10,72] The theory of this process was examined by ourselves in a study of the isothermal CD elution of a mixture[21] (see above).

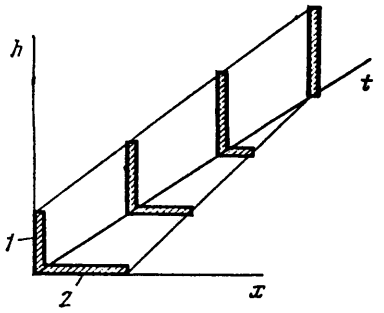

Figure 11. Distribution of the sorbate along the section of the column with SP at different times;[70] $h$ = height of band on the bed; $x$ = width of band: 1) "tower component"; 2) "base".

The experiments[70] in which the movement of the sorbate along the SP in a CC was investigated have shown, over the first 0.8 m, that the band consisting of a planar "base" and a narrow "tower" migrates almost without change. Then, over a section of the CC between 2 and 5 m from the origin, the "base" is rapidly shortened as a consequence of the increase of the area of the "tower" part of the peak and towards 6 m the entire substance is concentrated in a single narrow peak. This result has been confirmed by data obtained by comparing the rates of migration of the leading edge of the "base" of the octane band and of its rear "tower" component. Over the first 5 m, the "base" migrates at a rate of 2.4 cm $s^{-1}$, which is associated with its presence within the limits of a zone with a high content of the solvent. At a distance of 5–6 m from the start of the CC with a SP, the rate of migration of the leading octane front increases to 8.5 cm $s^{-1}$, corresponding to a linear rate of migration of octane along the SP in the complete absence

of the solvent. The "tower" component of the band passes slowly only over the first 2 m and then, at a distance of 2–3 m from the start of the CC, it acquires the maximum rate of 9 cm $s^{-1}$, which enables both fronts to be united after 3.3 min in the vicinity of the 6 m marker. The passage of the sorbate band through a narrow rear edge of the solvent leads, according to the authors,[70] to a concentrating effect. Initially the solvent band migrates more slowly than the sorbate band, which adjoins, via its "tower" component, the rear edge of the solvent over a long period. This can be seen from plots of the migration (Fig.12). Over the section from 2 to 5 min, the rear edge of the solvent begins to overtake by 2–3 s the rear edge of the impurity. During this period, both rear boundaries (of the solvent and impurity) are accelerated and in the vicinity of 5 m they combine with the leading boundary of the impurity, which migrates slowly within the limits of the solvent-saturated SP. Next, the rear solvent edge overtakes both boundaries of the impurity band and continues to migrate along the column. In short columns (5–10 m) an impurity peak 0.6–1.1 s wide was obtained directly behind the solvent zone after 3–5 min.

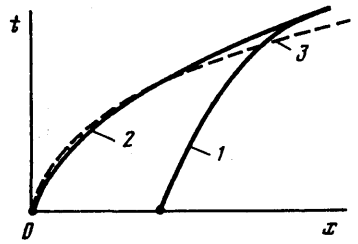

**Figure 12.** Graphical representation of the movement of the sorbate and solvent edges:[70] 1) and 2) leading and rear sorbate edges; 3) rear solvent edge.

It has been emphasised[71] that the concentrating effect on a solvent-saturated SP is associated with the difference between the rates of migration of the solvent and sorbate edges. The reduced rate of migration of the rear solvent edge accompanied by a high rate of migration of the sorbate along the solvent-free SP in fact leads to the compression of the band from 120 s to 1 s. The authors calculated the retention coefficient $K_{ret}$ defined as the ratio of the rates of migration of the sorbate along the SP in the presence and absence of the solvent. In experiments with repeated successive injection of the sample and additional "supply" by the carrier gas saturated by the solvent vapour, a study was made of the dependence of $K_{ret}$ on the nature of the SP, the solvent, and the sorbate. When solutions of decane in pentane ($1:10^3$) were injected at 3 min intervals, individual decane peaks, moving in succession at intervals of ~60 s ($K_{ret} \cong 3.5$) were observed. Analogous results were obtained in differential CD[16] with solutions of volatile components which were used instead of SP. It is noteworthy that the injection of a dose of the pure solvent makes it possible to select experimental conditions such that the impurity can be collected in the form of a single peak from several successive injections of the sample.[44]

We reached previously[2,9,15] the conclusion that the zone boundaries should adjoin on the basis of the study of the concave sorption isotherms of the components. The mechanism of the concentrating effect can be accounted for by the occurrence of a limiting process in CNSV. As the solvent band moves, it spreads and the concentration at the maximum on the curve falls. The increase of the rate of the sharp rear edge of the band is associated with the decrease of the slope of the *OM* secant on the plot of the sorption isotherm (Fig.10*a*). The solvent *2* therefore initially functions as a limiter until the secant drawn from the point *M* on the solvent sorption isotherm (corresponding to the maximum concentration) intersects the sorbate (impurity) sorption isotherm *1*. This period is in fact responsible for the effect involving a sharp increase of the concentration. It follows from this explanation that the impurity concentrations in the gas and liquid phases should increase. As the solvent migrates along the layer of SP, its concentration at the maximum falls and it moves ahead as the lighter component, while the concentrated impurities migrate in narrow bands further along the column in accordance with their partition coefficients in the SP.

The study of the mechanism of the concentrating process on the basis of the sorption isotherm makes it possible to predict the final result of the enrichment of the impurity at the rear solvent edge. This does not rule out the approach associated with allowance for chromatography on the SP with a gradient distribution of the latter. However, in this case it is essential to consider the movement of the SP along the bed. Certain quantitative relations describing the migration of the sorbate fronts at high concentrations have been published.[15]

## VII. DEVICES FOR THE INJECTION OF LARGE SAMPLES AND THE RESULTS OF THEIR APPLICATION

The direct injection methods examined above require the creation of new designs of injectors. In the present Section we shall consider only the injectors in which the sample injection is accompanied by the formation of a large amount of liquid in the initial section of the column where the CD processes are manifested. The injection system and the method of injecting substances in many respects determine the quality of the separation. When a highly effective injection system is used, the following requirements must be met:[97] the absence of the overlap of the solvent peak with the peaks of the components to be separated; the elimination of the fractionation of the sample components; the reproducibility of the injection times with a relative standard deviation less than 0.1%; the reproduction of the normalised peak areas with a relative standard deviation less than 1%; the reduction to a minimum of the thermal decomposition and sorption processes as well as reactions; the constancy of the column efficiency; quantitative and representative extraction of both impurity and main sample components; independence of the injection processes of the operating conditions of the column.

In the studies on the CD determination of impurities[43–51] the sample was injected into the column through the usual injectors used in commercial chromatographs (Tsvet-100, LKhM-8MD, etc.). The initial section of the column (about 10 cm) was located in the evaporator of the injector and the sample was injected by means of a syringe directly onto the bed. Glass and metallic U-shaped and spiral CD columns, up to 3 m long and 2–4 mm in diameter, filled with metallic or etched glass beads (0.25–0.5 mm fraction) were employed.[44,45,49,50] In experiments designed to

isolate impurities under the conditions of thermal CD, a temperature field with a negative gradient was created along a section up to 1 m long. The gradient was established by employing a furnace with a variable-pitch nichrome spiral winding. The temperature along the field was varied from $t_b$ for the solvent to room temperature. The temperature in the evaporator was kept somewhat below $t_b$ of the solvent (Fig. 9d) in order to prevent the entry of the sample into the inlet connectors, since the injection of large amounts of liquid into a strongly heated column entails an increase of pressure. The use of a preliminary CD column made it possible (with the aid of a switching tap) to inject samples with volumes up to several millilitres.

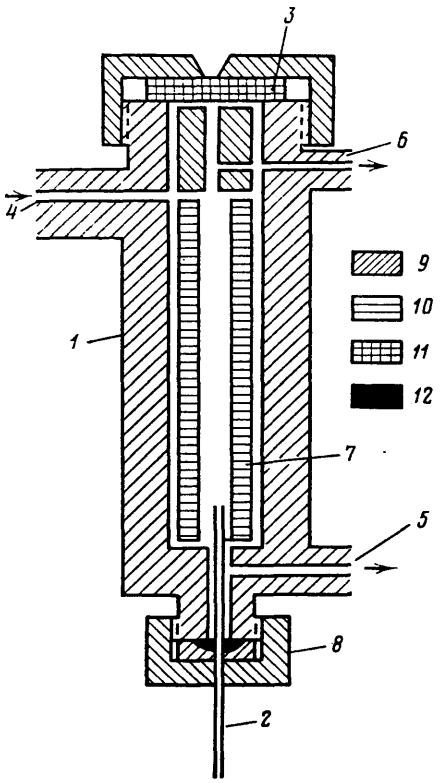

Figure 13. Schematic illustration of the evaporating injector for the splitless introduction of the sample:[52] 1) evaporator; 2) CC; 3) septum; 4) and 5) entry and exit of carrier gas; 6) flushing of the septum; 7) insert; 8) attachment of the CC; 9) metal; 10) glass; 11) rubber; 12) graphite.

Special injectors have been developed for the direct splitless injection of samples into a CC. The sample was initially[52] injected from the usual injectors (Fig. 13) in which the carrier gas disposal line 5 was initially closed during the transfer of the sample from the evaporator to the CC. In order to eliminate the influence of the septum 3 of the injector, a special device with a controlled leakage of the gas has been used.[5] The Carlo Erba Company later designed an injector[52,55] where the septum was in contact with a separate stream 6. The advantages of splitless injection have been demonstrated in analyses of an admixture of benzene and pentane (0.01 p.p.m.), steroids, and the components of tobacco scent and tobacco smoke. Injection without stream splitting has been used successfully for the analysis of natural scents and specimens of the ambient medium.[79] The Hewlett Packard Company has published manuals for the use of commercial injectors in routine analyses.[89]

Having analysed the system for injection into CC existing at the time, Yang et al.[97] concluded that the best injection system is one without stream splitting.

Data for the reproducibility of the injection method without stream splitting have been obtained[97] using the automatic injector of the Varian-3700 apparatus in relation to the analysis of a mixture of $C_{13}$–$C_{32}$ n-alkanes with the temperature programmed in the range from 120° to 280 °C. The solvent was n-decane. The relative standard deviation of the retention time based on the results of 11 measurements was on average 0.05% and that for peak areas was 1%. The optimum parameters were chosen[97] using a simplex experimental design method. It has been suggested that one should be guided by the following rules for the selection of the parameters: sample size from 0.1 to 10 μl; rate of sample injection about 1 μl $s^{-1}$; sample injection time more than 20 s; time during which the blower is switched on after injection more than 40 s; effective dynamic range of sample dilution $10^5$: 1; evaporator temperature not more than 230 °C (for solvents with $t_b$ < 100 °C); the solvent should have $t_b$ smaller by 25 °C than the $t_b$ of the lightest component to be determined, since otherwise it is lost together with the eluted solvent; the initial constant temperature should be lower by 15–30 °C than the $t_b$ of the solvent; the components evolved before the solvent can be determined quantitatively only when their relative capacity is sufficiently different from that of the solvent.

The splitless conditions ensuring the entry of 95% of the sample into the CC have been investigated.[115] The injector produced by the Carlo Erba Company for models 2900 and 4160 was used.

The injection of large samples (up to 50 μl) of solutions of $C_{11}$–$C_{16}$ n-alkanes containing pesticides into large-diameter (0.77 mm) CC using an electron capture detector has been described.[98] The injection system, described by Grob and Grob,[52] in which the values for the ejection of the stream and for the flushing of the septum were closed throughout in order to eliminate the possible losses and to ensure the constancy of the flow rate through the column, was used in the above study on the basis of the Varian-1400 apparatus. Since the injection of large samples distorts the peak retention times, the results of the analyses were characterised by the separation factor $K_1$ for the DDT pesticide vapour. The relative standard deviation in the determination of $K_1$ varies from 1.5 to 5.5% depending on the solvent selected. The maximum value of $K_1$ was obtained when a 2–4 μl sample was injected. On further increase of sample volume, no significant decrease of $K_1$ up to 100 μl was observed.

In a number of instances where a SP is used, it is possible to achieve injection with stream splitting.[68] This permits a decrease of the stream splitting coefficient and hence an increase of the amount of sample injected. By virtue of the decrease of the volume of the vapour on condensation, the additional amount of substance is as it were "sucked"

onto the column. Under such conditions, the stream splitting coefficient is more stable and does not change during the injection period.

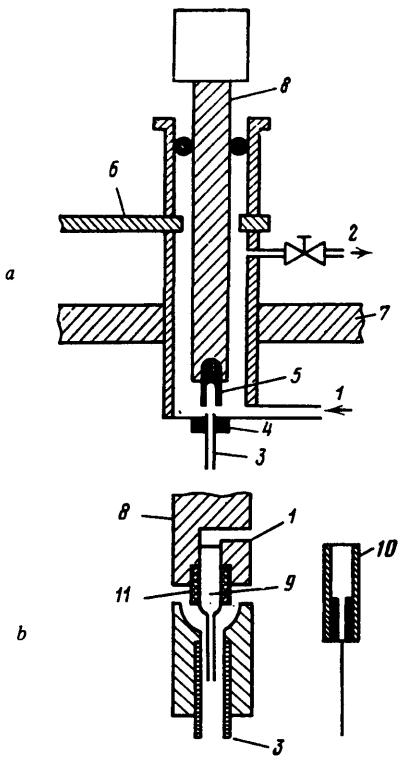

**Figure 14.** Schematic illustration of the injector for the direct introduction of the sample into the CC:[117] *a*) "macro"-version; 1) and 2) entry and exit of carrier gas; 3) CC; 4) seal; 5) crucible; 6) valve; 7) insulation of the thermostat; 8) valve shaft; *b*) "micro"-version: 9) and 10) micropipette; 11) silicone rubber.

Schomburg et al.[116-118] were the first to point out that the splitless method employing an evaporator is irrational. This is because ultimately one has to inject the initial liquid sample directly into the CC; for this reason the intermediate operations involving evaporation and condensation are superfluous in splitless injection. The disadvantages characteristic of the usual injection systems with stream splitting can then have an effect. Schomburg was the first to employ the direct injection of liquid into CC of normal size (0.3 mm) and described two designs for injectors:[117,118] the "macro"- and "micro"-versions. In the first case (Fig.14*a*) a 5–10 μl sample is placed in a small glass crucible *5* attached with the open end downwards to the shaft *8* of a sliding valve *6*. The shaft is exposed to the carrier gas which flows along line *1* in the CC *3*. In order to inject the sample, the liquid in the crucible *5* is brought into contact with the end of the CC. Under the influence of capillary forces, the liquid to be injected enters the CC. In the "micro"-version of the direct method (Fig.14*b*), the extended end of a micropipette (with a volume of several nanolitres) is inserted into the CC with the aid of the same valve *6*. The carrier gas blows the liquid into the CC. Special care must be taken to ensure that the CC and the pipetter are coaxial. The characteristics of the three injection methods (with and without stream splitting and also the direct method described) have been compared. The relative standard deviation (reproducibility error) in the determination of the composition of a mixture of $C_{18}$–$C_{34}$ n-alkanes was not worse than 1% for all the methods. Two completely identical chromatograms for the analysis of the products of the Fischer-Tropsch reaction with a dose of 1 μl have been published. In the direct injection, the sample was diluted by a factor of 100 with octane and in injection with stream splitting the splitting coefficient was 1:100. Direct injection has the following advantages:[118] the separate evaporator unit with all its disadvantages (superfluous volume and surface, selection of flushing conditions, and the creation of a uniform gas mixture) is eliminated, there is no rubber septum, there is no need for a syringe, and there is no stream splitting. The disadvantages of the direct injection include the contamination of the inlet section of the CC by involatile sample components, the washing off of the SP, and the difficulty of replacing the injected volume.

The methods for sample injection with stream splitting have been criticised[67] and conclusions similar to those of Schomburg and co-workers[116-118] have been reached. In a general assessment of the methods of injection with stream splitting, it has been concluded[63] that the reproducibility is excellent but the results are poor.

Another version of the direct injection of the sample into the CC (Fig.15), differing from Schomburg's method by the fact that the injection is via the usual microsyringe through a special valve[119] without a septum, has been achieved.[63] Initially the needle of the syringe, whose outer diameter is smaller by 0.05 mm than the inner diameter of the CC (0.3 mm), is inserted in the channel *5* of the injector up to the shaft of the valve *4* sealing hermetically the channel. The shaft is then moved back and a small controlled ejection into the atmosphere is established in the gaps between the walls. The syringe is lowered and the needle is inserted into the CC via the guiding channels *3*. Samples with a volume of 0.1–0.2 μl are injected rapidly and those with larger volumes are injected at a controlled rate. The injector is placed in an insulating beaker with air cooling. The volume of the sample injected can be measured with the aid of such a device and the rate of supply of the sample, the cleanness of the surface, etc. can be monitored. The continuous operation of the injector described in the course of a year confirmed its advantages and led to an insignificant modification:[94] the lock nut was replaced by a two-position Teflon tap (open-shut) and cooling was achieved by means of a radiator exposed to air from the thermostat ventilator.

The results of the analysis of dilute solutions of polynuclear aromatic compounds in methylene chloride showed[67] that the relative standard deviation in the determination of the content of substances with the aid of the injector developed is 3–5%, which is smaller by a factor of 4–5 than the value obtained with the aid of an evaporating injector. The results of the use of the above system for the analysis of thermally unstable compounds—mustard oil and wide-boiling fractions of the methyl esters of $C_8$–$C_{22}$ aliphatic acids—are quoted in the above study. The

relative standard deviation was 1.2–1.7% and was respectively smaller by factors of 3 and 5 than in injection with and without stream splitting.

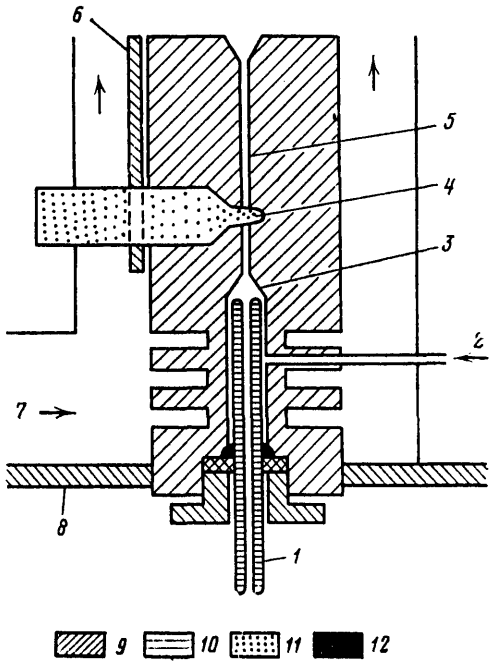

**Figure 15.** Schematic illustration of the injector for the direct introduction of the sample into the CC:[94] 1) CC; 2) entry of carrier gas; 3) centreing cone; 4) closing valve; 5) membrane replacement channel; 6) valve spring; 7) entry of cooling air; 8) thermostat insulation; 9) metal; 10) glass; 11) Teflon; 12) graphite.

The direct injection method[120] has been used as a reference procedure for the estimation of the accuracy of injection by other methods employing stream splitting after the evaporation of the sample. The technique of sample injection from a syringe was varied (cold and hot needle, air or solvent plug). In most cases concordant results were obtained for $C_9$–$C_{20}$ alkanes, while for high-molecular-weight hydrocarbons close to $C_{44}$ the usual method leads to losses of the test substance amounting to 25–75%. The authors believe that the components of a mixture with a wide boiling range are fractionated on the hot needle of the syringe. When the needle is heated to a temperature exceeding the $t_b$ of the solvent, the high-boiling components are concentrated on the liquid meniscus at the piston and do not reach the CC. This required a change in the technique of direct injection onto the column[67] (also using a syringe) in the part concerned with the improvement of the cooling system.[103] In the "Fractovap" model 4160 injector,[121] provision is made for additional channels to allow the passage of cooling air and a heat exchanging insert is placed in the connecting ring, which makes it possible to cool the CC from the inlet to a distance 10 mm below the level of the column thermostat.

The accuracy and reproducibility of the injection by three methods (direct injection onto a cooled column and injection with and without stream splitting) were compared in the analysis of samples containing extremely high-boiling compounds—triglycerides.[122] The samples were prepared in hexane with added pentadecane as the standard. Direct injection onto the cooled column (modified version of the injector[103]) ensured the best results—the relative standard deviation in the determination of the peak area did not exceed 1–3%. However, the losses calculated taking into account the sensitivity of the flame-ionisation detector ranged from 3 to 10%. When the injection technique without stream splitting, described by Grob and Grob,[123] was used with evaporation of the sample at 400 °C, the losses of the test substance were even greater (14–20%) and the reproducibility of the analyses was to within 9–13%. The usual injection method with stream splitting yielded unsatisfactory results. The losses of the test substance increased to 25–50% and the error in the reproducibility rose to 15–30%. The causes of the errors in the method involving direct injection onto a cooled column have been examined.[104,124] Attention has been concentrated on the stage involving the transfer of the liquid from the syringe needle onto the inner surface of the CC wall. It is emphasised that this must be a purely mechanical process without evaporation. The partial loss of the components is ruled out when the syringe plunger is moved rapidly (several metres per second). Injection of 1 μl samples (from a 10 μl syringe) showed that appreciable losses of $C_{20}$ and $C_{28}$ n-alkanes (in hexane and pentane) are observed for an injection time reaching 1 s. Use of 0.5 μl syringes proved unsuccessful. Direct injection onto a cooled column permits an extensive variation of the sample volumes. The upper limit is determined by the risk of washing off the stationary phase and the lower by the possibility of the incomplete transfer of the sample from the syringe. An increase of column temperature diminishes the extent of the washing off of the stationary phase but, as the $t_b$ of the solvent is approached, it induces the reverse flow of the test substance from the CC. In order to avoid contamination of the column by the stationary phase, the phase is first removed from a large section of the column. A reasonable maximum dose for CC is 10 μl. When pentane and an initial temperature of 30 °C were used, a relative standard deviation of 0.3–1.5% was obtained without an appreciable loss of the component. The minimum permissible dose was 0.2 μl and satisfactory results were obtained with large 5 and 10 μl syringes. When the column temperature (140 °C) exceeds the $t_b$ of the sovent (hexane), the sample is appreciably condensed on the outer walls of the needle even under the conditions of rapid injection (the losses reached 20%); if the time during which the needle remains in the injector is 5 s, then the losses are doubled. The possible operating conditions involve a temperature of the CC slightly exceeding $t_b$—by 7 °C for pentane and hexane.

The test of the operation of the usual injectors with heated septums showed that, when syringes (with any injection technique) and systems in which the sample is evaporated are used, it is impossible to avoid a partial loss of the components ($C_{20}$ and higher alkanes).[125] The only reasonable alternative involves direct injection onto a cooled column.

Galli and Trestianu[104] paid particular attention to the selection of operating conditions preventing the "ejection" of part of the sample from the CC in the direction opposite to that of the flow. Knauss et al.[126] considered the

mechanism of the distribution of liquid along the initial section of the CC under the conditions of a temperature gradient. Badings et al.[127] and Chaudhan and Darbre[128] described designs for glass direct injection devices. A comparative study has been made[129] of various types of injections: direct injection with a crucible—the "macro"-version (Fig.14); direct injection using a syringe and an injector (Fig.15) with additional cooling; injection with stream splitting and injection without stream splitting using a standard injector (Fig.13). Both direct injection methods yield satisfactory results. The version with the crucible is technically simpler, but leads to a greater error—the relative standard deviations in the determination of the area are respectively 2.5 and 0.7. When these methods were used to determine the sensitivity coefficient of methyl octanoate (in relation to n-dodecane) the relative standard deviations were 0.25 and 0.14% respectively. Schomburg et al.[130] estimated the level of losses of $C_{10}$–$C_{40}$ alkanes when a stream splitter was used. The application of a dodecane instead of an octane sample as the solvent and reduction of the evaporator temperature from 310° to 210 °C made it possible to increase the $C_{40}/C_{13}$ peak area ratio from 0.13 to 1.02.

Comparison of the direct injection methods with and without stream splitting demonstrated a statistically significant difference between the reproducibilities and accuracies of the analysis of 10 aliphatic acids (from $C_{16}$ to $C_{22}$) in rape seed oil.[131] The relative error was on average 2.3% for the direct method and 6.4 and 6.0 respectively for injection without and with stream splitting.

---o0o---

A review of studies on injection methods for the determination of impurities shows that the mechanism of the processes occurring is in fact related to the new separation method introduced by the present author,[1-9,15-51] namely chromadistillation (CD), which takes place along the initial section of the column. All the existing methodological versions of CD have found an application: isothermal elution, limiting chromatography, CD, the chromatography of nearly saturated vapours, and thermal CD.

Analysis of a fairly large number of publications on the "solvent effect" has shown that their authors actually arrived at the conclusion that the CD principles must be employed. Studies on the SE constitute an important step forward in the field of injection. It has become possible to introduce samples up to 10 μl into capillary columns, whereby the accuracy of the results has been improved. A further significant (by two orders of magnitude) increase of the sample injected (and hence of the sensitivity of the measurements) is possible as a result of the employment of special CD pre-columns or injectors. The CD theory helps in the formulation of the principal requirements ensuring the optimum operating conditions of the injection system: the sample must be introduced directly (without preliminary evaporation) into the column under the same conditions as the mixture to be analysed and the injecting syringe, and the site of injection must have a sufficiently large volume (0.2–1 ml) to permit the distribution of the sample; along the sample distribution section, it is essential to create conditions for the repeated condensation of the mixture components—a temperature gradient must be set up (with a decrease of temperature from the closest possible value to the $t_b$ of the solvent) or an additional solvent must be introduced. The above description makes it possible to improve the design of the injector for capillary and packed columns.

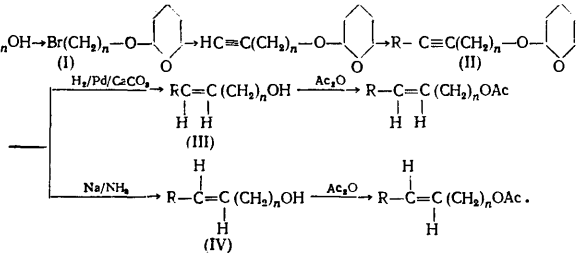
# The Synthesis of Lepidoptera Pheromones

E.D.Matveeva, A.L.Kurts, and Yu.G.Bundel'

The review surveys the data in numerous publications of the synthesis of the pheromones of scale-winged insects (Lepidoptera). Attention is concentrated on problems of the sterospecific synthesis of pheromones.
The bibliography includes 217 references.

CONTENTS

I. Mono-olefinic alcohols and acetates 672
II. Disparlure 675
III. Unsaturated ketones 676
IV. Conjugated diene alcohols, acetates, and aldehydes 678
V. Non-conjugated diene alcohols and acetates 683



During recent years, several new promising trends have arisen in the fight against harmful insect species, involving high selectivity and also virtually complete safety for man and warm blooded animals. In the first place one should include among these, methods based on the employment of biologically active substances—pheromones. Pheromones are chemical substances secreted by insects and inducing specific behavioural and physiological responses in other insects exposed to them. Among the pheromones known at the present time (sex pheromones, tracking pheromones, aggregation pheromones, food pheromones, and fear pheromones), the sex pheromones appear to be the most promising. Their exceptional biological activity and species selectivity give rise to the hope that they may be used in the active suppression of the multiplication of pest populations without contaminating the biosphere and without disturbing the biological equilibrium in nature, and also as a means for the operative allowance for the number of pests present. Extensive experimental data devoted to the identification, synthesis, and applications of insect pheromones have accumulated during the last ten years. These data have been surveyed in a number of reviews[1-4] and a monograph,[5] but most studies have been published during the last four years.

This review is devoted to the synthesis of insect sex pheromones and embraces mainly the studies during 1970 to 1983. All the reviews considered deal with scale-winged insects (Lepidoptera). These compounds are unsaturated aliphatic alcohols, acetates, and aldehydes,[1,2,5] but recently ketones have also been isolated and identified.[6] The difference between their structures is one of the principal factors in the reproductive isolation of insects. It has been found recently that Lepidoptera pheromones are multicomponent mixtures of compounds:[7] certain insect species secrete mixtures of *cis*- and *trans*-isomers as pheromones,[8] while others secrete a mixture of aldehydes,[9] an acetate–aldehyde mixture,[10] or other mixtures.[11] An attractant for one insect species can be an inhibitor for another; thus the attractant of *Paralobesia viteana*—*cis*-dodec-9-enyl acetate—inhibits the attracting activity of *Phyacionia buoliana*.[12] The quantitative ratio of the components in such mixtures is an important factor which enables sympatric insect species (species living in the same area) to avoid cross breeding.[13]

For the majority of representatives of Lepidoptera, the ratio of the *cis*- and *trans*-isomers in the mixture is important. For example, *cis*-dodec-8-enyl acetate is an attractant for the oriental fruit moth *Grapholitha molesta*, but the greatest attracting effect has been observed in the presence of 7% of the *trans*-isomer;[14,15] for the males of the European pine shoot moth *Rhyacionia buoliana*, the greatest activity has been shown by the mixture of *trans*-dodec-9-enyl acetate and 1.15% of its *cis*-isomer.[16] The high species specificity of pheromones is achieved precisely by the exact proportions of geometrical isomers, which requires appropriate methods of synthesis and a high degree of chemical, geometrical, and stereochemical purity.

## I. MONO-OLEFINIC ALCOHOLS AND ACETATES

One of the commonest methods of synthesis of pheromones involves the use of mono- or di-substituted acetylenes as key compounds. Thus about 100 unsubstituted unbranched $C_{10}$–$C_{16}$ compounds containing a terminal triple bond and the acetate group have been synthesised by Japanese investigators.[17] Screening led to the discovery of substances attracting specifically 93 species of insects belonging to 15 Lepidoptera families of Japan (the *Torticidae*, *Noctuidae*, etc. families). All the specimens were synthesised in accordance with the following scheme:

The complex of lithium acetylide and ethylenediamine was condensed in THF, HMP, and HMP/THF with the corresponding tetrahydropyranyloxyalkyl bromide (I) in order to obtain an almost quantitative yield of the key compound—a disubstituted acetylene (II), which was subsequently hydrogenated over the Lindlar catalyst to obtain a product containing more than 95% of the *cis*-isomer (III). The corresponding *trans*-isomers (IV) were obtained by reduction with lithium in liquid ammonia.

A classical method for the synthesis of mono-substituted acetylenes involves the splitting off of hydrogen halides from the corresponding halogenoethylenic compounds.[18] The hydrogen halide is usually split off by means of a potassium hydroxide solution in absolute ethanol, ethylene glycol, and

cellosolve, a potassium hydroxide melt,[19] or sodium in liquid ammonia or in the form of a suspension in a mineral oil.[20–22] Here one must bear in mind that the classical version of the dehydrohalogenation reaction leads to the migration of the triple bond into the interior of the molecule,[23] while the use of sodium amide in a mineral oil has the opposite effect of shifting the triple bond to the end of the chain.[23] A modified method, based on the use of a suspension of fine ground KOH in dimethyl sulphoxide (DMSO), is more effective. The terminal acetylene is thus obtained in 50–100% yield.[24]

A method for dehydrohalogenation in the two-phase catalytic system aqueous NaOH–heptane or methylene chloride using tetrabutylammonium hydrogen sulphate as the phase transfer catalyst has been developed in recent years. The reaction proceeds with an almost quantitative yield for the lowest members of the series, but, for compounds containing long aliphatic chains, the yields are sharply reduced owing to the poor solubility of the compounds.[25]

In view of the low solubility of higher alkyl halides and alkali metal salts of acetylene in liquid ammonia, the lithio-derivatives of terminal alkynes are alkylated in dipolar aprotic solvents: DMSO,[26] HMP,[27] and dimethylformamide (DMF)[28] and also in mixtures of these solvents in THF.[29,30] The yields of alkyl acetylenes increase when a complex of lithium acetylide and ethylenediamine (EDA) is used:[17,31]

$$EDA\cdot LiC{\equiv}CH + RX \rightarrow RC{\equiv}CH + LiX + EDA.$$

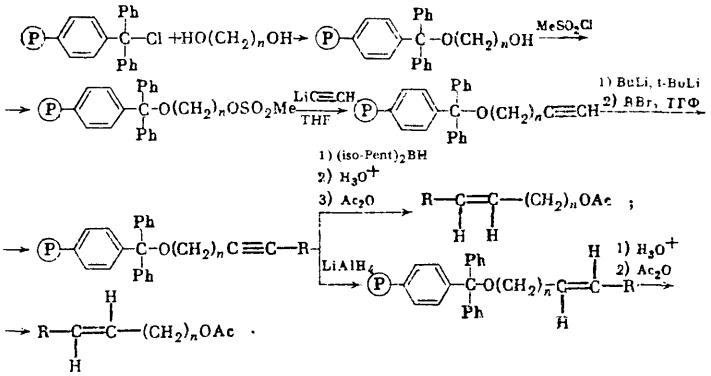
However, even in this case the yield of reaction products depends very greatly on the concentrations of the reactants and the order in which the reactants are mixed.[31]

In order to obtain higher acetylenic alcohols from alkylacetylenes, hydroxyalkyl halides with a protected alcohol group are used as alkylating agents.[32] HMP is the most suitable solvent for such reactions, because the yields of disubstituted acetylenes reach 60–80%.[33] The replacement of chlorine by bromine in tetrahydropyranyl (THP) ethers increases the yield by 10–15%. Unsubstituted ω-bromo-1-alkanols (V) or terminal acetylenic alcohols (VI) can also be used successfully for the syntheis of hydroxyalkylacetylenes:[34–36]

$$\left.\begin{array}{l} R{-}C{\equiv}CH + Br(CH_2)_nOH \\ \quad\quad (V) \\ H{-}C{\equiv}C(CH_2)_nOH \\ \quad\quad (VI) \end{array}\right| \xrightarrow[2)\ RHal]{1)\ LiNH_2/NH_3} R{-}C{\equiv}C(CH_2)_nOH.$$

In the latter case a mixture of a disubstituted acetylene and an ether—the *C*- and *O*-alkylation products respectively—is formed.[37] The fraction of the *C*-alkylation product can be increased sharply by carrying out the reaction in dipolar aprotic solvents,[38] in which there is a sharp increase of the nucleophilic reactivity of the carbanions. The yields of disubstituted acetylenes fall sharply to 28–33% when liquid ammonia, THF, and DMF are used as solvents owing to the poor solubility of the initial reactants.[1,39–41] Best results can be achieved by using DMSO[26,42] and the complex with EDA:[43]

$$HC{\equiv}CLi\cdot EDA + Br(CH_2)_8OH \xrightarrow{DMSO} HC{\equiv}C(CH_2)_8OH.$$



The tosylates [toluene-*p*-sulphonates] or brosylates [*p*-bromobenzenesulphonates] of the corresponding acetals can be used as alkylating agents, which makes it easier to carry out the reaction in liquid ammonia, because arenesulphonate esters are readily soluble in this solvent and are fairly resistant to ammonolysis:[44]

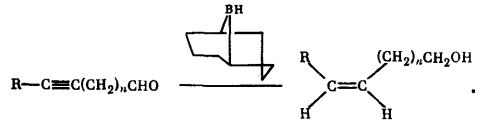
$$R{-}C{\equiv}C{-}Na + Ts(CH_2)_5CH(OMe_3)_2 \rightarrow \underset{(VII)}{R{-}C{\equiv}C(CH_2)_5CH(OMe_3)_2}.$$

However, the yields of the acetals (VII) fall sharply to 2–10% on passing to higher acetylenes or when higher alkyl bromides are used in this reaction.[45]

Acetylenic alcohols are converted into olefinic alcohols with the *cis*-configuration of the double bond by partial hydrogenation over the Lindlar catalyst. The reaction proceeds with a high overall yield. It is best to employ petroleum ether as the solvent.[46] On hydrogenation at 20 °C, the admixture of the *trans*-isomer is 1.5–3%, while on raising the temperature its content increases.[47] At low temperatures (between −10° and −30 °C) the degree of selectivity is higher and the admixture of the *trans*-isomer does not exceed 0.5%.[1] Other catalysts have also been used, namely $Pd/BaSO_4$,[35,48] nickel catalysts,[43] and others,[49] but they are less stereoselective. The degree of stereoselectivity is 98% in the hydrogenation by diisopentylborane with subsequent treatment by a carboxylic acid.[50] This method requires the use of a freshly prepared diisopentylborane, since otherwise the yields of the *cis*-isomer fall to 5%.[1]

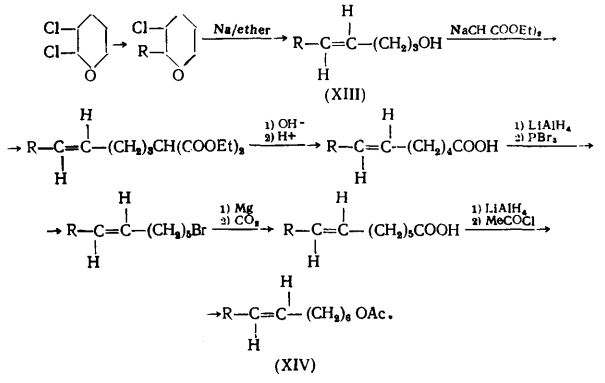
The corresponding *trans*-isomer is obtained by reducing the alkyne with metallic sodium or lithium in liquid ammonia,[51] but the initial alkyne then remains in the reaction mixture, which is due to the limited solubility of higher acetylenic compounds in ammonia. The reaction proceeds with rigorous stereospecificity and an admixture of the *cis*-isomer is not detected.[52] The triple bond is reduced by lithium tetrahydroaluminate to a double bond with the *trans*-configuration in a high yield.[53] The reduction of alkynes by lithium tetrahydroaluminate in the presence of titanium tetrachloride leads to a mixture of isomers whose proportions depend on the temperature, the fraction of the *trans*-isomer diminishing as the temperature is reduced.[54] A method of synthesis of the *trans*-isomers of attractants on a polymeric support, which blocks one of the alcoholic groups of the initial diol or the alcohol group of the halogenoalcohol, has been developed. The polymer can be employed repeatedly, avoiding thereby laborious isolation processes. It has been established that the triple bond is not reduced by sodium in liquid ammonia on a polymeric support. In order to obtain the *cis*-isomer, diisopentylborane has been used as the reducing agent:[55–57]

*cis*-Dodec-8-enyl acetate, the pheromone of the oriental and common fruit moths (*Grapholitha molesta and Cydia molesta*), has been synthesised by a modification of the scheme described above:



$$CH_3(CH_2)_2C{\equiv}CH + I(CH_2)_6Cl \rightarrow \underset{(VIII)}{CH_3(CH_2)_2C{\equiv}C(CH_2)_6Cl} \xrightarrow{NaCN} \underset{(IX)}{CH_3(CH_2)_2C{\equiv}C(CH_2)_6CN} \rightarrow \underset{(X)}{CH_3(CH_2)_2C{\equiv}C(CH_2)_6COOH} \rightarrow$$

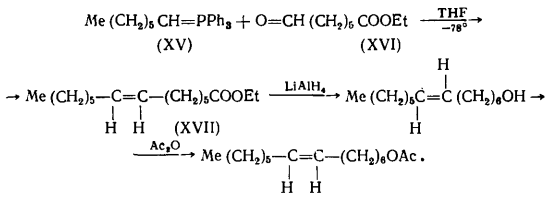
$$\rightarrow CH_3(CH_2)_2C{\equiv}C(CH_2)_6CH_2OH \xrightarrow[2)Ac_2O]{1)H_2/Pd/CaCO_3} \underset{(XI)}{CH_3(CH_2)_2C(H){=}C(H)(CH_2)_7OAc}.$$



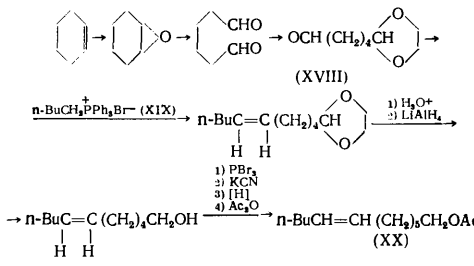
The lithium salt of pent-1-yne is alkylated by 1-chloro-6-iodohexane and the resulting chloroacetylene (VIII) is converted via the nitrile (IX) into the acid (X). Hydrogenation over the Lindlar catalyst with subsequent reduction of the carbonyl group and acetylation affords 46% of *cis*-dodec-8-enyl acetate (XI).[50,58] Sodium acetylides have been alkylated by chloro- and bromo-alkanes in DMSO [59] or by esters of carboxylic ω-chloroacids under the same conditions,[60] which led to the corresponding acid (XII) in 70% yield:

$$Cl(CH_2)_nCOOR + NaC{\equiv}CR' \xrightarrow{DMSO} R'{-}C{\equiv}C(CH_2)_nCOOR.$$

1-Alkenols, the active components of sex pheromones, are obtained by reducing acetylenic aldehydes by complex alkali metal hydrides with subsequent partial hydrogenation of the triple bond over the Lindlar catalyst.[60,61] Together with the *cis*-isomer, one then obtains up to 10% of the *trans*-isomer. A method has been developed for the synthesis of *cis*-alkenols in a high yield with the aid of 9-borabicyclo-[3.3.1]nonane—an effective reductant for carbonyl compounds, capable of simultaneous stereoselective reduction of the triple bond to the double bond having the *cis*-configuration:[62]



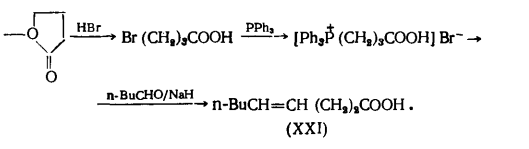
The stereoselective method of synthesis of *trans*-acetates involves the opening of the ring of 2-butyl-2-chlorotetrahydropyran with sodium in ether to form *trans*-4-non-4-en-1-ol (XIII); the chain is subsequently lengthened with the aid of diethyl malonate. The content of the *cis*-isomer is 1.3%.[63] The method has been used to synthesise *trans*-dodec-7-en-1-yl acetate (XIV):



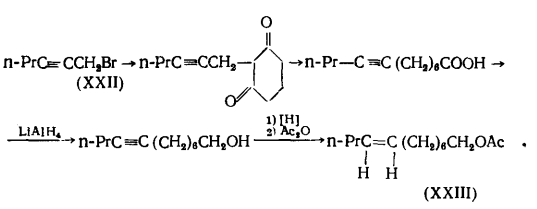
(XIV)

However, the yield of the acetate (XIV) was only 10% and the attractant obtained showed only a low activity in biological tests, evidently owing to the presence of impurities.

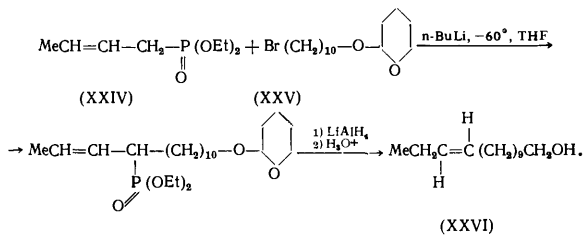
Numerous *cis*-mono-olefinic alcohols and their acetates have been synthesised by the Wittig reaction. The usual version of this process, involving the interaction of alkylidenetriphenylphosphoranes with carbonyl compounds, makes it possible to obtain olefins as mixtures of the *cis*- and *trans*-isomers. The high stereospecificity of this reaction, carried out in order to obtain the *cis*-isomer, is achieved using aliphatic phosphoranes and aliphatic aldehydes in non-polar solvents in the absence of lithium salts[64] and in dipolar aprotic solvents.[65–68] The formation of phosphorus ylides from the corresponding phosphonium salts by treatment with an alkali metal bis(trimethylsilyl)amide followed by subsequent interaction with aldehydes leads to *cis*-alkenes with 98% stereochemical purity.[69] This method has been used to synthesise attractants containing one unsaturated bond—*cis*-dodec-7- and *cis*-dodec-9-enyl acetates, *cis*-tetradec-7-enyl acetates, and others.[69–72] For example, the condensation of the ylide (XV) with the aldehyde (XVI) in THF at −78 °C leads to the unsaturated ester (XVII) with the ratio *cis* : *trans* = 98 : 2:[72]



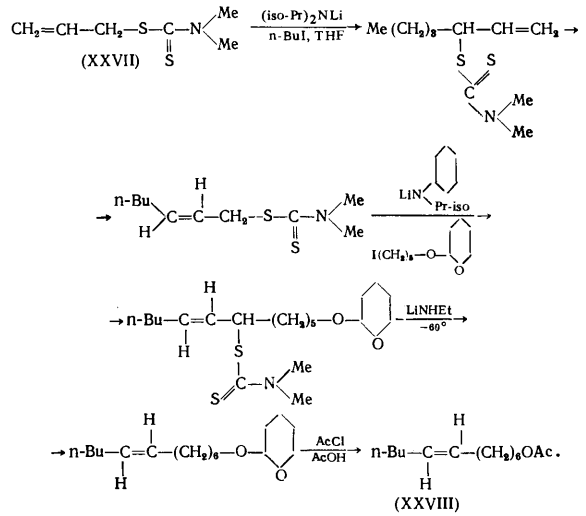
The geometrical isomers of dodec-7-en-1-yl acetate (XX) are the pheromones of the cabbage moth *Trichoplusia ni* and the leafroller *Argyroploce leucotreta*. These isomers were synthesised in cyclohexene in 27% yield. 6-Ethylenedioxy-1-hexanal (XVIII) was condensed with the phosphorane obtained from compound (XXIX):



The mixture of the *cis*- and *trans*-isomers was separated chromatographically on silica gel impregnated with silver nitrate.[73]

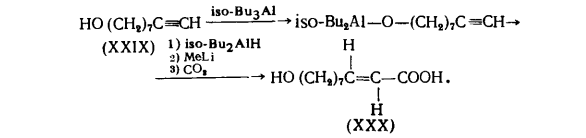


The yields and ratios of the isomers in the Wittig reaction differed depending on the nature of the solvent; thus the yield of non-4-enoic acid (XXI) was 46% in DMSO (with a ratio of the *cis*- and *trans*-isomers of 86 : 14), while in HMP the yield was 21% (91 : 9):[74]

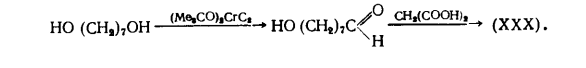


The highest stereospecificity has been observed in DMSO, DMSO/THF, DMF, or acetonitrile, where the fraction of the *cis*-isomer exceeds 90%.[75] *cis*-Dodec-8-enyl acetate (XXIII) has been obtained from cyclohexane-1,3-dione and the bromide (XXII):[76]

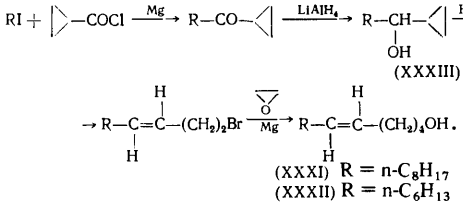
Alkylation of the lithio-derivatives of the γ-allylphosphonates (XXIV) in the α-position by various ω-substituted alkyl halides, for example, compound (XXV), with subsequent reduction by $LiAlH_4$ leads exclusively to the *trans*-isomer (XXVI):[77]



The stereoselective synthesis of *trans*-dodec-7-enyl acetate (XXVIII) has been achieved with the aid of the 3,3-sigmatropic rearrangement of the product of the alkylation of S-allyldithiocarbamate (XXVII):[78]

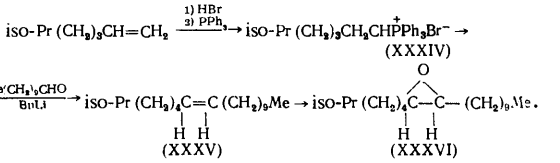


Mixed Kolbe electrolysis of carboxylic acid salts has also been used to obtain the acetate (XXVIII), but large amounts of dimerisation, transesterification, and disproportionation side products are formed.[74]

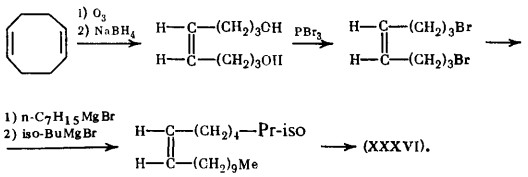


*trans*-10-Hydroxydec-2-enoic acid (XXX) is a component of royal jelly and a bee pheromone. It is synthesised from non-8-ynol (XXIX):[79]

The hydroxy-group in the nonynol (XXIX) is protected by introducing the diisobutylaluminium residue, after which the reaction mixture is treated with diisobutylaluminium hydride. The vinylalane formed is treated with methyllithium and subsequent carboxylation leads to the acid (XXX). The yield of 80% and the method is vigorously stereospecific. A simpler method of synthesis of the acid (XXX) with a smaller number of stages from readily available starting materials, involving the condensation of malonic acid with 8-hydroxyoctanal has been proposed:[80]



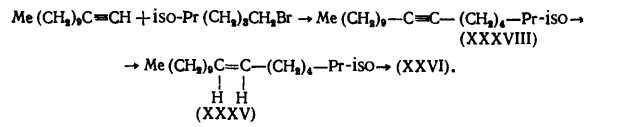
An interesting stereoselective synthesis of unsaturated $C_{12}$–$C_{15}$ alcohols and their acetates and epoxides has been achieved. Among them *trans*-tetradec-5-enol (XXXI) is a "pheromone simulator" (it stimulates the action of the natural pheromone) of the emarginate-winged moth *Pyncho pocha*, while *trans*-dodec-5-enol (XXXII) is the pheromone of the cereal fly *Tricimba cinctra*.[81] A characteristic feature of this method consists in the fact that the ethylenic bond in the final compound is formed on opening of the cyclopropane ring present in the initial carbinol (XXX):



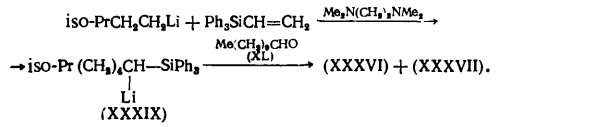
## II. DISPARLURE

An epoxide acting as a pheromone has been discovered hitherto only in the gypsy moth *Porthetria dispar* and has the structure of *cis*-7,8-epoxy-2-methyloctadecane—disparlure (XXXVI).[82] Biological tests of the enantiomers of compound (XXXVI) showed that the natural pheromone is a *cis*-(+)-isomer while the *trans*-isomer (XXXVII) and the *cis*-(−)-isomer are inactive.[83] These data indicate the chiral character of the receptor system of the gypsy moth.[84,85]

The racemic *cis*-disparlure has been synthesised in different ways. Condensation of the phosphonium salt (XXXIV) with 1-undecanal in DMSO in the presence of butyl-lithium in accordance with the Wittig reaction afforded the olefin (XXXV) with a ratio of the *cis*- and *trans*-isomers of 88 : 12.[82] The same reaction in HMP led to an isomer ratio of 96 : 6.[86] By reducing the reaction temperature to −78, it was possible to obtain the olefin (XXXV) and from the latter the epoxide (XXXVI) in 75% yield, the content of the *trans*-isomer not exceeding 2%:[87]

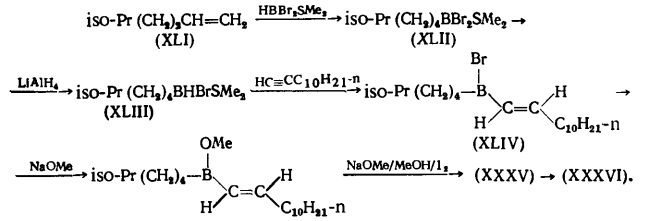


Racemic disparlure has been synthesised from cyclo-octadiene. The necessary *cis*-geometry of the double bond is determined by the stereochemistry of the initial cyclo-octadiene. Selective ozonolysis with subsequent treatment of the ozonide with sodium tetrahydroborate, the Grignard reaction, and epoxidation lead to disparlue in 25% yield:[88]

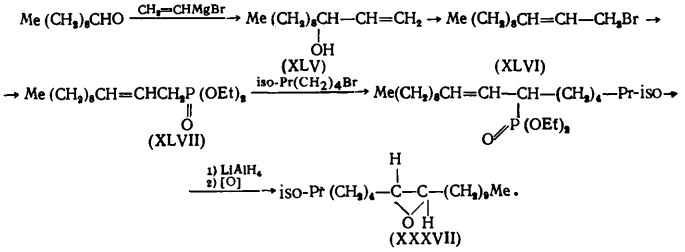


Disparlure has also been obtained from linear butadiene and isoprene oligomers by reaction with methyl acrylate. The synthesis is based on the Wittig reaction, which gives rise to an 85–95% yield and a ratio of the *cis*- and *trans*-isomers of the product of 3 : 1.[89]

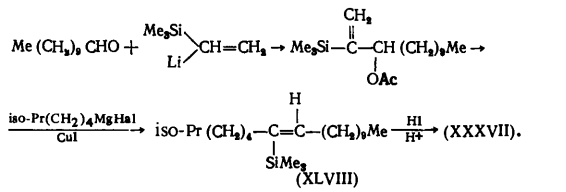
The key stage in another method of synthesis of the racemic epoxide (XXXVI) involves the formation of the cisoid double bond, which is achieved by the controlled hydrogenation of 2-methyloctadec-7-yne (XXXVIII):[90–93]



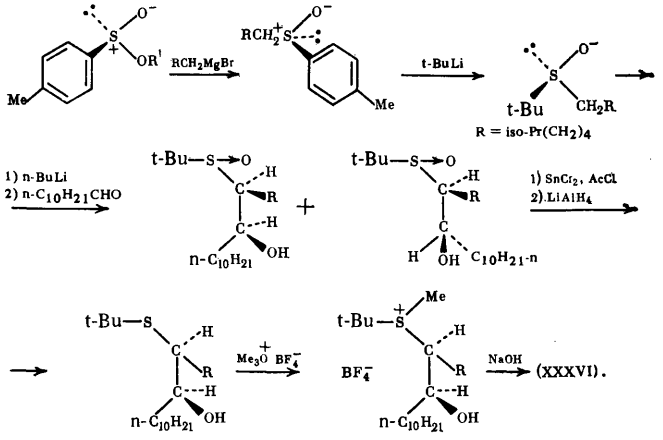
A method for the alkylation of the salts of aceylenes in HMP with a 35–45% yield of dialkylacetylenes has been developed for a large series of compounds.[93] Hydrogenation of the alkyne (XXXVIII) over the Lindlar catalyst leads to the *cis*-olefin, while reduction with sodium in liquid ammonia affords the *trans*-isomer. The purity of the *cis*-olefins obtained was 99%.



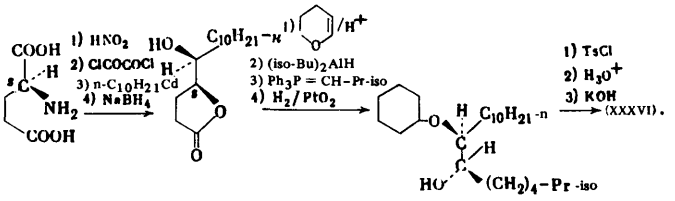
Condensation of 6-methyl-1-triphenylsilylheptyl-lithium (XXXIX) and 1-undecanal (XL) followed by epoxidation yielded a 1 : 1 mixture of the *cis*- and *trans*-isomers of disparlure:[94]



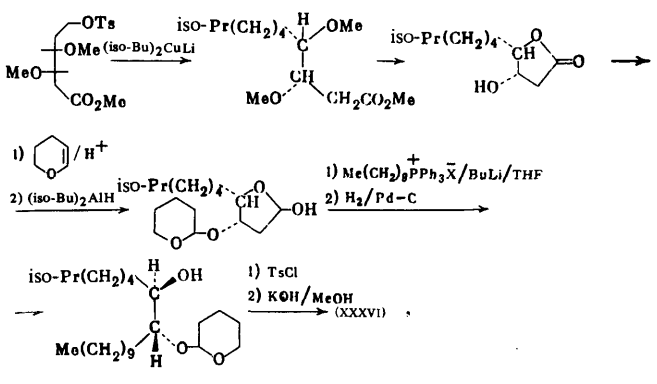
A convenient stereospecific synthesis of racemic disparlure using organoboranes has been proposed.[25] 5-Methylhex-1-ene (XLI) was converted into dibromo-5-methylborane-dimethyl sulphide (XLII), which was treated with lithium tetrahydroaluminate and the resulting bromoborane (XLIII) was added to dodec-1-yne:



Treatment of the organoborane compound (XLIV) with sodium methoxide followed by iodination in the presence of sodium methoxide in methanol leads to the *cis*-isomer of the olefin (XXXV) in 55% yield (the isomeric purity is more than 99%). Disparlure was obtained by oxidation with *m*-chloroperbenzoic acid. In order to test the pheromone-inhibitor, the racemic *trans*-isomer of disparlure (XXXVII) was synthesised.[96] Nonylvinylmethanol (XLV), obtained by the reaction of 1-decanal with vinylmagnesium bromide, was treated with concentrated HBr. The resulting bromide (XLVI) was heated with triethyl phosphite and the corresponding phosphonate (XLVII) was alkylated with 5-methylhexyl bromide. The subsequent reduction with lithium tetrahydroaluminate and oxidation with *m*-chloroperbenzoic acid lead to the *trans*-isomer (XXXVII) in 81% yield:

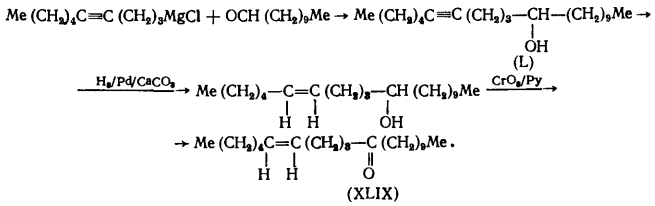


The *trans*-isomer (XXXVII) has been obtained in 65% yield by the protodesilylation of the corresponding vinylsilane (XLVIII):[97]

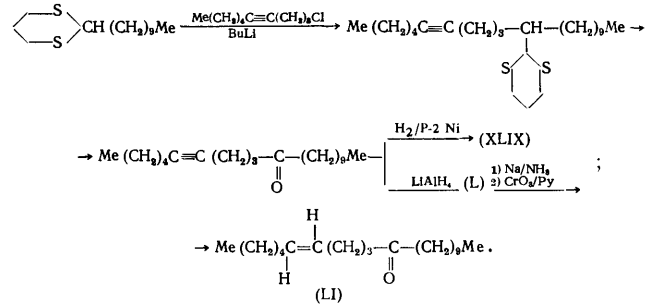


A six-stage synthesis of the optically active *cis*-(+)-disparlure in 15% yield has been proposed:[98]

An elegant synthesis of *cis*-(+)-disparlure has been achieved via (*S*)-(+)-glutamic acid:[99]



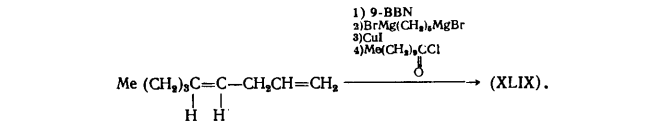
The same compound has been obtained with a high optical purity (98%) from (L)-(+)-tartaric acid:[100]



## III. UNSATURATED KETONES

Ketones are extremely rare among the known Lepidoptera pheromones. *cis*-Heneicos-6-en-11-one (XLIX) has been identified in *Orgyia pseudotsugata*.[101] It was

synthesised by the Grignard reaction from 1-undecanal and 1-chlorododec-4-yne; hydrogenation of the triple bond in the resulting alcohol (L) and oxidation of the alcoholic group lead to the pheromone (XLIX) with an admixture of 4% of the *trans*-isomer:[1]



The *trans*-isomer (LI) was obtained in accordance with the scheme presented below:[101]
