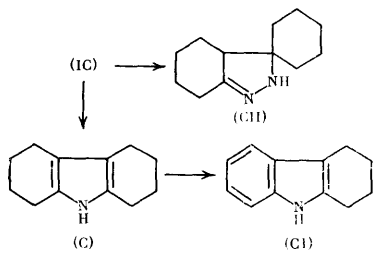
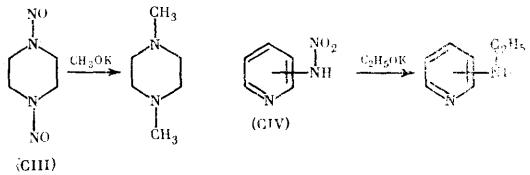
Radical reactions of benzaldehyde thiosemicarbazone (LXXXVI) led to the formation of hydrazodithioformamide (LXXXIX) and benzonitrile (XC) apparently via the benzylideneazine (XCI). On further treatment, the latter partly hydrolyses to benzoic acid (XCII) and, under the reaction conditions, trimerises partly to 2,4,6-triphenyl-1,3,5-triazine (XCIII), which recyclises to the thermally more stable 2,4,5-triphenylimidazole (XCIV):



(XCIII) (XCIV)

Benzaldehyde semicarbazone proved to be much more stable and withstood heating with alkali metal alkoxides to 300 °C without any changes.[94,97]

When the semicarbazone (XCV, R = H, X = O), the phenylsemicarbazone (XCV, R = $C_6H_5$, X = O), and the thiosemicarbazone (XCV, R = H, X = S) of cyclohexanone[98,99] are treated with both alkali metal alkoxides and catalytic amounts of Lewis acids (zinc chloride or tin dichloride), reactions of the Fischer type do not occur and only homolytic dissociation of the N–N bond takes place. It is not accompanied by *N*-alkylation but leads to the *NN'*-diacylated hydrazines (XCVIII) and the cyclohexanone azine (XCIX) as a result of the recombination of the radicals (XCVI) and (XCVII) formed:

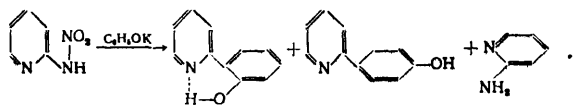


(XCV) (XCVII) (XCVI) (XCIX) (XCVIII)

(C) (CI)

[When R = Ph, the radical (XCVI) formed is stabilised as a result of its cleavage to aniline.] According to Kost and Grandberg,[100] cyclohexanone azine (XCIX) is readily converted further into octahydrocarbazole (C) and the product of its partial oxidation by atmospheric oxygen—tetrahydrocarbazole (CI) and also into 5,5-pentamethylene-3,4-tetramethylenepyrazoline (CII).

The increase in the polarity of the N–N bond as a result of conversion into the *N*-nitroso-derivative (CIII) and the *N*-nitroamino-derivative (CIV) facilitates the cleavage of the N–N bond with simultaneous *N*-alkylation on treatment with alkali metal alkoxides:[101,102]



(CIII) (CIV)

The corresponding inorganic nitrites and nitrates are evidently formed as second components of these reactions.

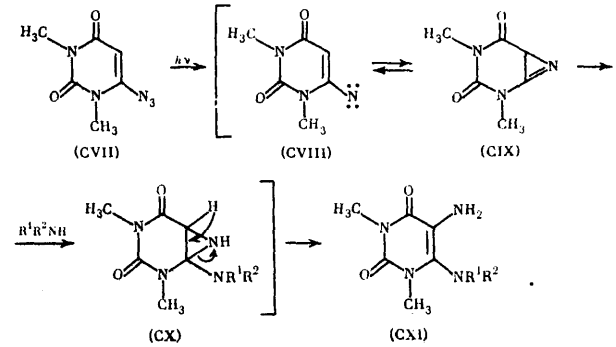
It is of interest that in the case of the isomeric 2-, 3-, and 4-aminopyridines (CIV) the ease of dissociation of the N–N bond with simultaneous *N*-alkylation increases in the sequence 4 < 3 < 2, whereas the opposite sequence of reactivities is characteristic of the analogous isomeric pyridylhydrazones: 2 < 3 < 4.[102] Thus in the preparative synthesis of 3- and 4-monoalkylaminopyridines the best results are produced by the corresponding reactions of benzaldehyde 3- and 4-pyridylhydrazones with alkali metal alkoxides, while the interaction of 2-nitroaminopyridines with alkali metal alkoxides is a more convenient preparative synthetic method for 2-monoalkylaminopyridines.[102]

In contrast to N–N bond dissociation processes with simultaneous alkylation or benzylation, when the corresponding phenoxides are used in the reaction with 2-nitroaminopyridine instead of alkali metal alkoxides benzylates,

denitroamination and arylation in the 2-position in the pyridine ring are observed:[103]

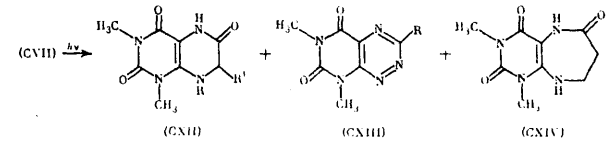
## V. ELECTROCHEMICAL AND PHOTOCHEMICAL PROCESSES

The electrochemical and photochemical processes involving the dissociation of the N–N bonds examined in the previous review[1] also developed further during the last decade. It has been shown that, in contrast to the polarographic reduction of the hydrazones (CV) in aqueous alcoholic buffer solutions, which proceeds via the addition of four electrons to the protonated form with formation of amines,[104] in an aprotic medium [dimethylformamide] (DMF) the aryl hydrazones (CV) as well as the thiosemicarbazones or acyl hydrazones of aromatic aldehydes and aliphatic aromatic ketones initially undergo an electrode reaction involving the irreversible addition of one electron to the azomethine group with subsequent cleavage of the N–N bond:[105,106]



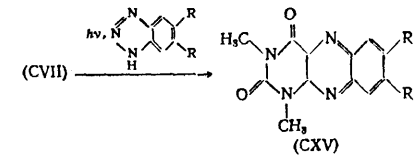
$$\underset{\text{(CV)}}{R'-NH-N=CH-R} \rightarrow \dot{N}=CHR + NH_2R' \quad .$$

The formation of the corresponding nitriles[107] or their radical-anions[109] as a result of the dissociation of the N–N bond has been demonstrated in relation to the electrochemical reduction of the disubstituted hydrazones of nitrobenzaldehyde and nitrofurfural in DMF. Aminonitrile cleavage has also been noted in the electrochemical reduction of *NN*-disubstituted hydrazones of benzaldehyde and benzoyl chloride (CVI) in an aprotic medium.[109] The following process mechanism has been proposed for the latter case:



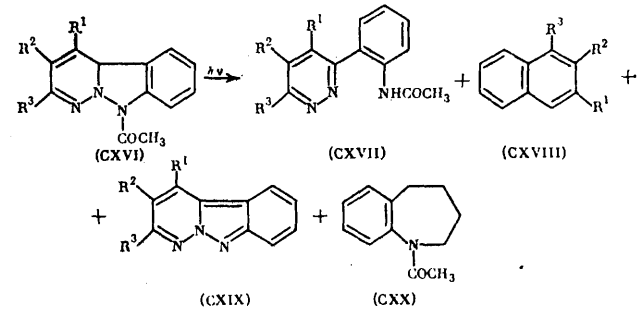
$$C_6H_5-\underset{\displaystyle Cl}{\underset{|}{C}}=N-N(C_6H_5)_2 \xrightarrow[-Cl^-]{+\bar{e}} C_6H_5\dot{C}=N-N(C_6H_5)_2 \xrightarrow{+\bar{e}} \bar{N}(C_6H_5)_2 + C_6H_5-CN \rightarrow$$
$$\xrightarrow{+\bar{e}} [C_6H_5-CN]^- \quad .$$
$$\text{(CVI)}$$

In further investigation of the mechanism of the electrochemical reduction of the aminonitrile cleavage of the hydrazone derivatives of nitrobenzaldehyde, it was established that the dissociation of the N–N bond is preceded by deprotonation, at the potentials of the second wave, of the initial depolariser by the dianion formed under these conditions. The mobility of the aldehyde hydrogen atom is then determined by many factors (the basicity, the character of the electronic polarisation of the hydrazone fragment, and the polarity of the N–N bond), discovered in a study of the $^1H$ NMR spectra and the absorption spectra of the electrochemical oxidation of the substrate at a graphite electrode and justified by quantum-chemical calculations.

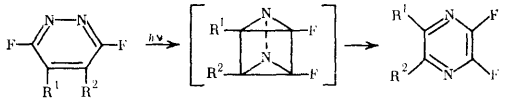


In the course of the development of the previous studies on the photolysis of various azides,[1] the photochemical reactions of 6-azido-1,3-dimethyluracil (CVII) in the presence of various primary and secondary amines have been investigated during the last decade.[111] The above reactions apparently proceed via the intermediate formation of the nitrene (CVIII) with subsequent appearance of the intermediate azirine (CIX). The nucleophilic addition of alkylamines to compound (CIX) and the electrocyclic opening of the aziridine ring (CX) formed complete the synthesis of 6-alkylamino-5-amino-1,3-dimethyluracils (CXI):

Analogous photochemical cleavage reactions of the azides (CVII) with dissociation of the N–N bond, the appearance of the energetically favourable nitrogen molecule, and the formation of a nitrene which undergoes further reactions[112] constitute the basis of the interaction of compound (CVII) with α-aminoacid esters. The final products of these photochemical reactions are lumazines—derivatives of pyrimido(4,5-*b*]-pyrazine (CXII):



Further development of this method using acylhydrazines as the amine components has led to the synthesis of 7-azalumazines (fervenulins) (CXIII),[111,113] while derivatives of pyrimido[4,6-*b*]diazepines (CXIV) have been obtained from β-aminoacid esters [111] and fervenulins (CXIII) and alloxazines (CXV) have been obtained from tetrazoles and benzotriazoles:[114]



The above reactions are accompanied by the dissociation of the N–N bonds not only in the azide group but also in the cyclic tetrazole (or corresponding benzotriazole) system.

Interesting photochemical reactions with cleavage of the N–N bond have been observed for cyclic 1,3-adducts of *N*-acetyliminopyridazinium ylides with dehydrobenzene (CXVI).[115,116] The photolysis of the corresponding 3-alkoxy-derivatives (CXVI, $R^3$ = O-alkyl) proceeds with dissociation of the N–N bond and aromatisation accompanied by the formation of 3-(2-acetamidophenyl)pyridazine (CXVII) together with the product of the elimination of molecular nitrogen (acetylnitrene) and subsequent aromatisation [alkoxynaphthalene (CXVII)] as well as the *N*-deacylated aromatic product (CXIX):[116]

The 3-methyl derivative (CXVI), $R^3 = CH_3$, is in the main converted into the *N*-deacetylated aromatic product (CXIX), while compound (CXVI, $R^3 = H$), unsubstituted in the pyridazine ring, is converted into *N*-acetylbenzazepine (CXX) with elimination of molecular nitrogen.[116]

UV irradiation of the tetrafluoropyridazine (CXXI, $R^1 = R^2 = F$) and of its perfluoroalkyl derivatives in the gas phase leads to the corresponding perfluoropyrazines (CXXIII) via the formation of the intramolecular valence isomers of the type of perfluoro-1,2-diazabicyclo[2.2.0]hexa-2,6-diene (CXXII):[117,118]

(CXXI) (CXXII) (CXXIII)

Thus the new studies on the dissociation of the N–N bond have significantly extended the theoretical ideas and preparative possibilities in organic chemistry.

# Alkyl Orthoesters and Their Applications in Organic Synthesis

L.A.Pavlova, Yu.A.Davidovich, and S.V.Rogozhin

A systematic account is given of data characterising the chemical properties of alkyl esters of orthocarboxylic acids. The suggested reaction mechanisms are discussed and the extensive possibilities of the application of the orthoesters in the solution of various problems in organic synthesis are demonstrated.
The bibliography includes 91 references.

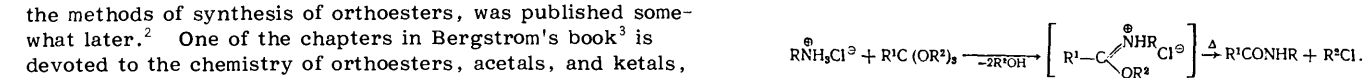
## I. INTRODUCTION

Inspection of the literature data of recent years shows that the interest in orthoesters, which are reactive chemical reagents, has not weakened and has stimulated the discovery of further new aspects of the application of these compounds. The aim of the present review is to give a systematic account of the data concerning the use of alkyl orthoesters in organic synthesis, which have been published during the period from 1971 to 1984 and which have not been included in earlier reviews.[1-6]

One of the fundamental works devoted to the synthesis and properties of orthoesters and their analogues is the book by De Wolfe[1] in which a profound analysis of all possible chemical reactions of orthoesters, thio-orthoesters, amidoacetals, ester-aminals, and orthoamides has been carried out and the proposed reaction mechanisms are discussed. A review by the same author, with an extensive coverage of the methods of synthesis of orthoesters, was published somewhat later.[2] One of the chapters in Bergstrom's book[3] is devoted to the chemistry of orthoesters, acetals, and ketals, attention being concentrated on the methods of synthesis of orthoesters and the mechanism of their hydrolysis.

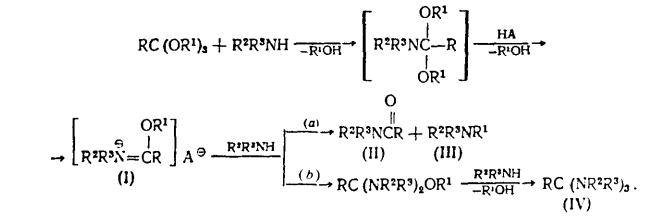


The Soviet literature on the synthesis and properties of orthoesters is represented by two reviews[4,5] and the chemistry of cyclic orthoesters is described in a collected volume.[6]

Since the modern methods of synthesis of orthoesters have been described in the above literature sources in adequate detail, the data on the hydrolysis of orthoesters have been analysed, and the data concerning the synthesis and behaviour of cyclic orthoesters have been surveyed, this review does not include the relevant sections.

## II. INTERACTION OF ORTHOESTERS WITH NITROGEN-CONTAINING COMPOUNDS

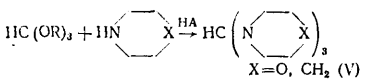
### 1. Reactions with Primary and Secondary Amines



It has been shown[7] that alkyl orthoesters can be used successfully for the acylation of primary and secondary amines and aminoacid esters. The reaction is carried out by heating briefly (70–90 °C) the amino-component in the form of the hydrochloride (or another salt) with the alkyl orthoester. An alcohol, an alkyl halide, and the corresponding *N*-acyl derivative of the amino-component, whose yield in most cases exceeds 90%, are then formed. The nature of the products obtained suggests that the reaction takes place mainly via a stage involving the formation of imidoester salts, which undergo the "Pinner" cleavage to the amide and the alkyl halide at elevated temperatures:

It is noteworthy that the mechanism of the interaction of orthoesters with amides depends in most cases on whether the amino-group is in the free state or whether the salt of the amino-component is introduced into the reaction; it also depends on whether the salt has been formed with a weak or a strong acid.

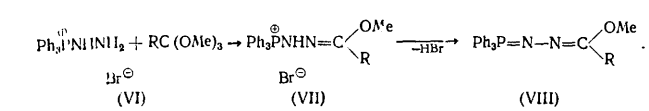
It is known[1] that the acid-catalysed reactions of secondary amines with orthoesters can lead to the formation of three types of products: amidoacetals, ester-aminals, and orthoamides. The interaction of orthoesters with secondary amines of different types has been investigated in order to



discover a convenient method for the synthesis of ortho-amides.[8] It was shown that the yield of the latter depends mainly on the reactivity and structure of the initial amine and also on the type of the acid catalyst used in the reaction. For example, when weakly basic amines, such as *N*-alkylanilines, are acted upon by orthoesters, then orthoamides are either not formed at all (both in the absence of catalysts and in the presence of toluene-*p*-sulphonic acid) or are obtained in a low yield (in catalysis by hydrochloric or acetic acid). In the presence of acids the reaction can proceed via the following mechanism:

The changes in the ratios of the products (II), (III), and (IV), obtained in the presence of different acids have been explained[8] by the influence of the anion $A^-$ on the structure of the intermediate complex (I).

The main products of the reactions of orthoformates with alkylanilines are *N*-alkylformanilides (II) and *NN*-dialkylanilines (III). *N*-Benzylmethylamine behaves analogously to *N*-alkylanilines, affording approximately equal amounts of *N*-benzyl-*N*-methylformamide and *N*-benzyl-*N*-ethylmethylamine in the reaction with triethyl orthoformate in the presence of toluene-*p*-sulphonic acid.

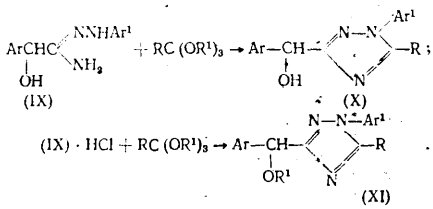


Acyclic secondary amines do not form appreciable amounts of orthoamides in their reactions with orthoesters under these conditions. Only the interaction of orthoesters with highly basic cyclic amines, such as morpholine, piperidine, and *N*-methylpiperazine led to the isolation of the corresponding orthoamides (V) in high yields regardless of the type of catalyst employed:

This method of synthesis of the orthoamides (V) is more convenient and more economical than those used previously,[9,10] although it does suffer from certain limitations: orthoamides are formed only from six-membered cyclic amines; it has not been possible to carry out similar reactions with pyrrolidine and hexamethyleneimine.

## 2. Reactions with Compounds Containing the Hydrazino-Group

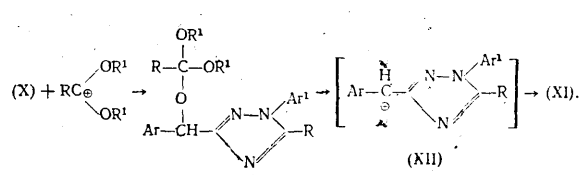
The interaction of orthoesters with hydrazinotriphenylphosphonium bromide (VI) leads to a new method of synthesis of *syn*- and *anti*-α-methoxyalkylidenetriphenylphosphazines (VIII).[11] The attack by the orthoester on the hydrazino-group of the initial compound (VI) results in the formation of α-methoxyalkylidenetriphenylphosphazinium bromides (VII), which can be readily converted into the corresponding phosphazines (VIII) via dehydrobromination:



The thermal or photochemical decomposition of compound (VIII) leads to the formation of α-alkoxycarbenes, which have been little investigated hitherto.

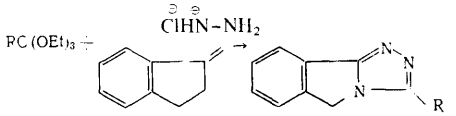
## 3. Reactions with Amino-components Accompanied by Cyclisation

Alkyl orthoesters are finding increasing applications in the synthesis of a wide variety of heterocyclic derivatives. The reaction involving the formation of triazoles from orthoesters and aryl-substituted hydrazones of carboxylic acids has been known for a long time.[12] Studies on the mechanisms of the analogous reactions and side processes are being continued.



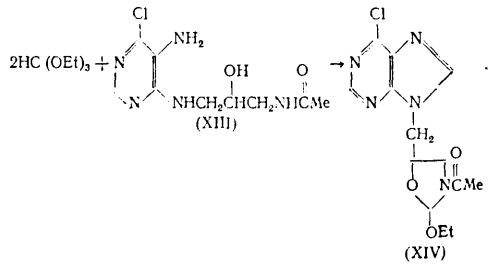
It has been shown[13] that the reactions of alkyl orthoesters with the *N*-arylamidrazones of mandelic acid (IX) (in the form of a free base) lead to the formation of 1,3,5-trisubstituted triazoles (X), the hydroxy-group in the side chain remaining unchanged. If the hydrochloride of the amidrazone (IX) is used as the initial compound, the corresponding triazole (XI) with an alkylated hydroxy-group is obtained:

The corresponding monochloro-compound (IXa, Ar = *o*-$C_6H_4Cl$) reacts with the orthoester, both in the form of a free base and in the form of a hydrochloride, to form only a triazole of type (X) with an unsubstituted hydroxy-group.



Under the influence of acid (HCl), the orthoesters are apparently converted into the corresponding dialkoxycarbonium ions, which are known to be strong alkylating agents. In the presence of acids, the hydroxy-group in the side chain of triazole is therefore alkylated, while in the absence of acid it remains unaltered. This hypothesis has been confirmed by the fact that the product (X) is converted quantitatively into compound (XI) in solutions of orthoesters after the addition of acids. The monochloro-derivative (IXa) is not alkylated, probably owing to steric factors.

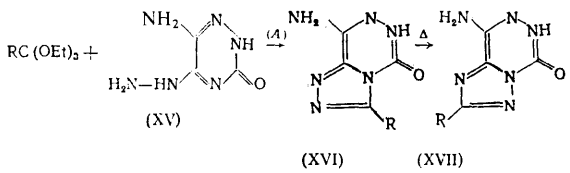
The same workers[14] traced analogous reactions of the optically active *N*-arylamidrazones of mandelic acid in the presence and absence of inorganic acids. In the absence of acids, the reaction proceeds stereospecifically: the dextrorotatory amidrazone forms a dextrorotatory triazole. The reactions with the hydrochlorides of the optically active amidrazones result in the formation of a racemic triazole alkylated at the hydroxy-group. It has been suggested that, as a result of the attack on the hydroxy-group of triazole by the dialkoxycarbonium ion, the cation (XII) is formed as an intermediate. Further reactions of this cation lead to the racemate (XI):



In certain cases the reaction between the orthoester and the amino-component is possible only in the presence of acid. For example, the reaction of ethyl orthoacetate or ethyl

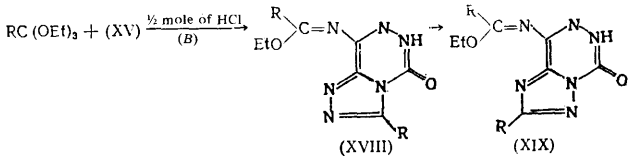
orthoformate with the hydrochloride of 1-hyrazinoisoindolenine proceeds solely as a result of the formation of dialkoxycarbonium ions.[15] Its product is a triazoloindole:

In the absence of acid, the orthoesters are passive in relation to hydrazinoisoindolenines.



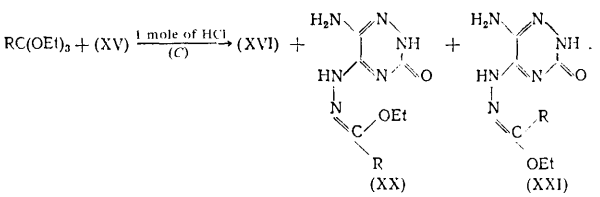
It is known that, on reaction with 5-amino-4-hydrazinopyrimidines, the orthoesters give rise to *N*-aminoimidazolopyrimidines.[16] The reaction between orthoformate and diaminopyrimidine (XIII) is of the same type:[17]

(XIII) (XIV)



However, four active groups of the initial compound (XIII) participate simultaneously in this reaction, which results in the formation of two new rings: the imidazole and oxazolidine rings. The disubstituted purine (XIV) formed is used as the intermediate in the synthesis of an acyclic analogue of puromycin.

The reaction of orthoesters with 6-amino-5-hydrazino-1,2,4-triazin-3-one (XV) does not take place unambiguously.[18] The course of this reaction is influenced by several factors: the temperature conditions, the presence of acid in the reaction mixture, and even its amount. It is noteworthy that, at room temperature in the absence of acid, the orthoesters do not interact with compound (XV). When the orthoesters are refluxed with compound (XV) without added acid [version (*A*)], cyclisation takes place initially with formation of compound (XVI), the primary amino-group not being involved. Subsequently, as a consequence of an intramolecular rearrangement, the product (XVI) is converted into the more stable compound (XVII):

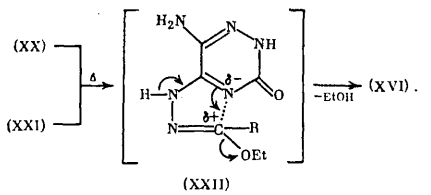


(XV) (XVI) (XVII)

At room temperature in the presence of a certain amount of hydrochloric acid [version (*B*)], a mixture of products (XVIII) and (XIX) was obtained. It was noted that compound (XVIII) gradually isomerises to compound (XIX):

(XVIII) (XIX)

When the reaction was carried out without heating in the presence of an equimolar amount of acid [version (*C*)], three products were isolated: (XX), (XXI), and (XVI). The quantitative stereoisomer ratio (XX):(XXI) in the mixture was 2:1:



(XX) (XXI)

If more than one equivalent of hydrochloric acid is introduced into the mixture of the initial reactants at room temperature [version (*D*)], then only the product (XVII) is obtained.

In contrast to other orthoesters, orthoformate reacts with the initial compound (XV) to form products of type (XVI) and (XVII) regardless of whether the acid is present in an excess or deficiency.

We shall now consider the proposed reaction mechanism.

*Version* (*A*). In the absence of acid, the reaction mixture must be heated for the reactants to react. The orthoester molecule reacts with the hydrazino-group of compound (XV) as the most reactive nucleophilic centre. This results in the initial formation of the products (XX) and (XXI), which cyclise with simultaneous elimination of an alcohol [transition state (XXII)]. Heating promotes the occurrence of this process, which ultimately leads to the formation of compound (XVI):

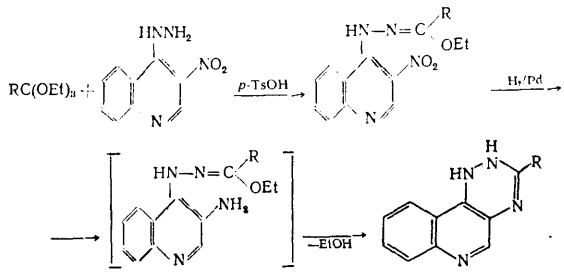
(XXII)

*Version* (*B*). When concentrated hydrochloric acid is introduced into the reaction mixture, more active electrophiles, dialkoxycarbonium ions, appear in the reaction sphere. They can apparently interact not only with the hydrazino-group but also with the less reactive, in the given instance, amino-group of the initial compound (XV). The products of this reaction are compounds (XVIII) and (XIX).

Thus, in the presence of acid, which plays the role of a catalyst and reactant, there is a possibility of the occurrence of a series of competing reactions: non-ionic interaction between the orthoester and the initial compound (XV); the reaction of the amino-component with the acid; the interaction of the orthoester with the acid; the attack by dialkoxycarbonium ions on the active groups in the initial and intermediate compounds; acid-catalysed cyclisation reactions.

Presumably the products of the substitution in the amino-group of type (XVIII) and (XIX) are not formed in versions (*C*) and (*D*) as a consequence of the protonation of the amino-group of the initial compound (XV).

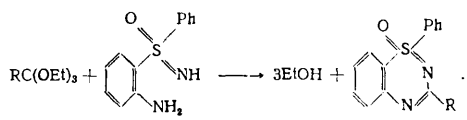
In the presence of an excess of acid in the reaction mixture, compounds (XX) and (XXI) were not detected apparently because in the presence of acid their conversion into the bicyclic product (XVI) is facilitated.



The anomalous behaviour of orthoformate can apparently be accounted for by the fact that the cations $HC^{\oplus}(OR)_2$ formed as a result of its interaction with the acid are least stable in the series of dialkoxycarbonium ions. For this reason, non-ionic processes leading to the formation of compounds

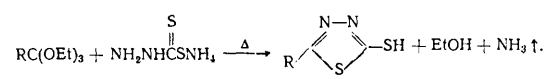
(XVI) and (XVII), which are also formed without the addition of acid, can predominate in the reactions of orthoformate. Compounds of type (XX) and (XXI), where R = H, could be formed as intermediates, but they cyclise to compound (XVI) more readily than others, which follows from the examination of the transition state (XXII).

The study of Lovelette and Geagan[18] clearly demonstrated how significant is the alteration of conditions in the reaction between orthoesters and polyfunctional amino-components.



Compounds (XXIII), possessing anti-inflammatory activity greatly exceeding that of acetylsalicylic acid, have been obtained from alkyl orthoesters and 4-hydrazino-3-nitroquinoline.[19]

The first stage represents a typical interaction of an alkyl orthoester with the hydrazino-group of the initial quinoline catalysed by toluene-p-sulphonic acid. On hydrogenation in the presence of palladium, the nitro-group is reduced to the amino-group, as a consequence of which intermolecular cyclisation becomes possible:

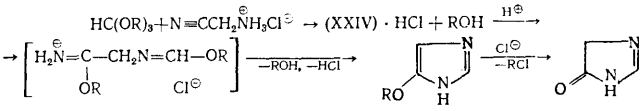


(XXIII)

New cyclic sulphoximides have been obtained by the reaction of orthoacetates (and orthoformates) with *S*-(*o*-aminophenyl)-*S*-phenylsulphoximide:[20]

Five-membered thiadiazole rings, containing the mercapto-group in the side chain, can be conveniently obtained by refluxing orthoesters with salts of *N*-aminodithiocarbamic acid:[21]

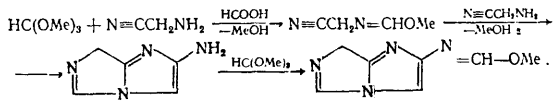
Because of the wide variety of the products obtained, the reaction between orthoesters and aminonitriles are of undoubted interest.



A fundamentally new approach to the methods of synthesis of 5-imidazolones has been described.[22] It is based on the interaction of orthoesters with aminoacetonitrile.

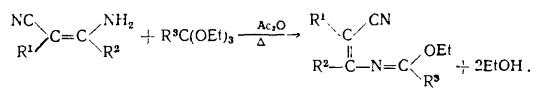
The reaction between orthoformate and aminoacetonitrile has its characteristic features. If the interaction is carried out in the presence of catalytic amounts of sulphuric acid with simultaneous removal of the alcohol, then alkyl *N*-cyanomethylacetimidate (XXIV) is obtained in a high yield:

(XXIV)



When the orthoester is made to react with the hydrochloride of aminoacetonitrile, the only product is 5-imidazolinone (XXV) (yield in excess of 90%). According to the authors' hypothesis,[22] the product (XXIV) is formed initially, its nitrile group undergoing acid-catalysed (HCl) alcoholysis. This is followed by cyclisation to 5-alkoxy-1*H*-imidazole and the latter is converted, after being attacked by the halide ion, into the 5-imidazolinone (XXV) with elimination of the corresponding alkyl halide:

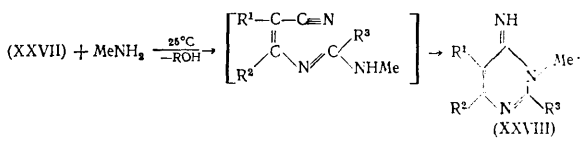
(XXV)



This method ensures a high yield of compound (XXV) and is simpler and more convenient in practice than the earlier procedures.[23,24]

Trimethyl orthoformate taken in excess reacts differently with aminoacetonitrile in the presence of catalytic amounts of formic acid. The reaction proceeds in several stages and the final product is methyl *N*-{7*H*-imidazo[1,5-*a*]-imidazol-2-yl acetimidate (XXVI), isolated in 24% yield:

(XXVI)



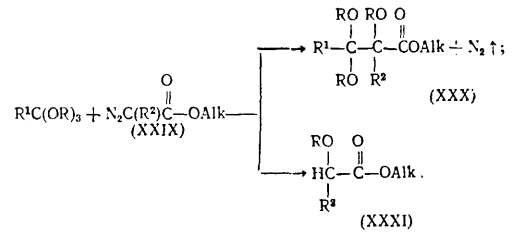
Orthoesters combined with enaminonitriles proved to be the best reagents for the synthesis of *C*-alkylated 1,6-dihydro-6-imino-1-methylpyrimidines (XXVIII).[25] The reaction of the orthoester with an enaminonitrile gives rise to the corresponding ethoxyalkylidene derivative (XXVII):

(XXVII)

The reaction proceeds, as with aminoacetonitrile, in the absence of acids[22] with the sole difference that here there is a possibility of the formation of the *cis*- and *trans*-isomers, depending on the structure of the initial enaminonitrile.

By treating compound (XXVII) with an alcoholic solution of methylamine, it is easy to achieve the substitution of ethoxy-groups. This reaction is accompanied by spontaneous cyclisation to the pyrimidine (XXVIII):

(XXVIII)

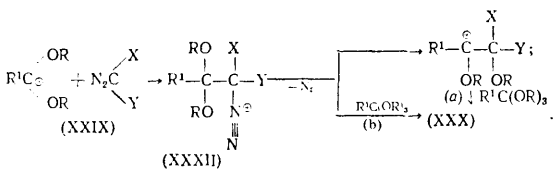


Derivatives of this type were previously difficult to obtain.[26] They are of interest as convenient objects for the study of the mechanism of the Dimroth rearrangement.[25]

A number of reactions involving orthoesters and amino-components of different types (amines, amides, and carboxylic acid amidrazones) have been examined in a book.[27]

## 4. Reactions with Diazo-compounds

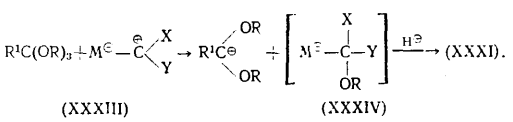
Alkyl orthoesters, particularly orthoformate, orthoacetate, and orthopropionate, readily react with diazo-compounds (XXIX).[28] The reaction is catalysed by Lewis acids:



copper(II) trifluoromethanesulphonate, rhodium tetra-acetate, and boron trifluoride etherate:

(XXIX) (XXX) (XXXI)

The reactions led to the isolation of the main product (XXX) and the side product (XXXI). Neither the reaction time nor the amount of catalyst affected the yield of the main product (XXX) and only the nature of the catalyst employed was found to be important. When copper(II) trifluoromethanesulphonate or boron trifluoride etherate are used, the amount of side product (XXXI) is small.

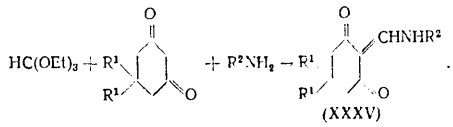


It has been suggested[28] that the catalysts enumerated, bound in a complex with the diazo-component, promote the formation of a dialkoxycarbonium ion, which is itself an active reagent. It adds to the diazo-derivative, after which nitrogen is eliminated and the product (XXX) is formed:

(XXIX) (XXXII) (XXX)

When nitrogen is split off from the intermediate (XXXII), a new electrophilic centre to which the alkoxy-group can migrate (*a*) or the usual substitution of the diazonium group takes place (*b*), is probably formed.

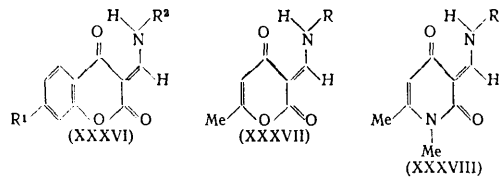
The product (XXXI) becomes the main one if transition metal compounds are used as catalysts. The transition metal and the diazo-component apparently form a dipolar carbene complex (XXXIII), to the electrophilic centre of which the alkoxy-group of the orthoester can be transferred, as a result of which one obtains the dialkoxycarbonium ion and the active complex (XXXIV). When a proton is captured by the complex (XXXIV), the product (XXXI) is formed with dissociation of the carbon–metal bond:



(XXXIII) (XXXIV) (XXXI).

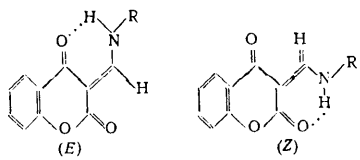
## III. THREE-COMPONENT CONDENSATIONS

One of the most promising applications involves the use of orthoesters in three-component condensation reactions. The high reactivity of orthoesters and the numerous varieties of reagents employed in these reactions create a unique possibility for the synthesis of new structures. The mechanism of the three-component condensation has been described in a general form and discussed in detail in a review.[4]



A number of studies[29–32] have been devoted to reactions in which alkyl orthoesters interact simultaneously with a carrier of an active methylene group and a carrier of an amino-group. A convenient method of synthesis of an extensive class of compounds, namely acyl- and diacyl-enamines, is based on this reaction.

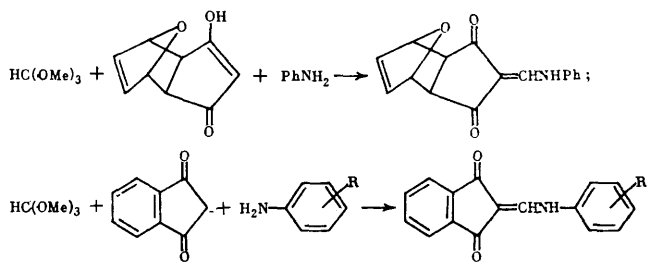
For example, orthoformates readily react with cyclohexane-1,3-diones and aromatic amines to form the corresponding enaminodiketones (XXXV), which can in their turn be converted into hexahydroquinolinediones:[29]



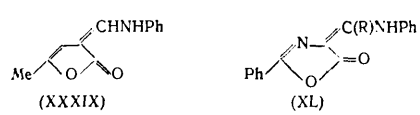
(XXXV)

Thus 3-anilinomethylenechroman-2,4-diones (XXXVI), 3-anilinomethylene-6-methyl-2,3-dihydropyran-2,4-diones (XXXVII), and 3-anilinomethylene-1,6-dimethyl-2,3-dihydropyridine-2,4-diones (XXXVIII) have been obtained from orthoformates, anilines, and cyclic six-membered 1,3-diketones of more complex structure:[30]

(XXXVI) (XXXVII) (XXXVIII)



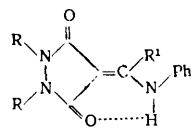
Probably by virtue of steric factors, only orthoformate can react with six-membered diketones and aromatic amines. It has been shown[30] that the reaction products consist of a mixture of stereoisomers:



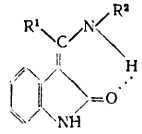
(*E*) (*Z*)

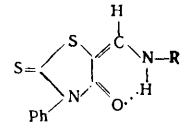
The use of five-membered cyclic 1,3-diketones in the three-component condensation also proved to be successful.[31] In this version it is possible to employ aliphatic primary amines as well as aromatic amines.

Condensed systems can also serve as the methylene components. The only important factor is that the active methylene group should belong to a five-membered ring. The following reactions proceed smoothly:[31]



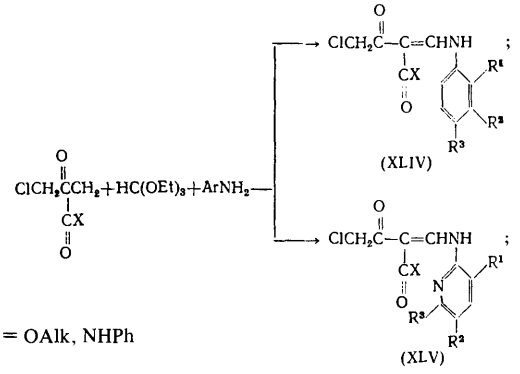
Compounds (XXXIX) and (XL), each of which can be resolved into geometrical isomers with the aid of fractional crystallisation, have also been obtained:[31]





(XXXIX) (XL)

The derivatives (XLI) and (XLII) have been synthesised with participation of orthoacetate and orthopropionate. It has

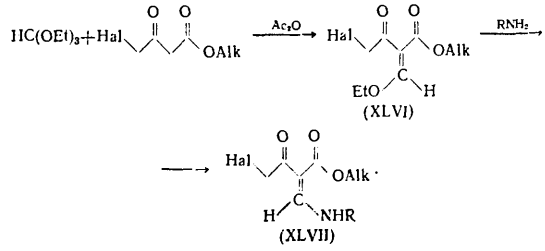


been noted that compound (XLII) has cytotoxic properties:[31]

(XLI)

(XLII)

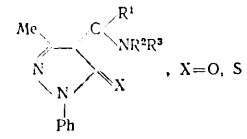
(XLIII)



Compounds (XLIII) are obtained by the interaction of orthoformates with aliphatic amines and *N*-phenylrhodanine at an elevated temperature (150 °C).[31] Alkyl γ-halogenoacetoacetates can be used successfully in three-component condensation subject to the condition that their reaction partners are orthoformate and aromatic amines.[32] The derivatives (XLIV) are then obtained from anilines and compounds (XLV) are obtained from 2-aminopyridines, both in the form of mixtures of *E*- and *Z*-isomers:

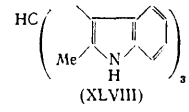
X = OAlk, NHPh

(XLIV); (XLV)



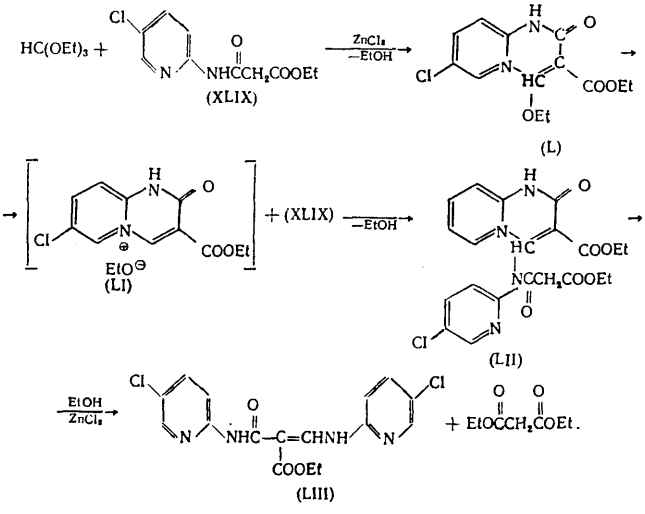
Compounds (XLIV) and (XLV) are used as intermediates in the synthesis of derivatives of 3-hydroxypyrroles, pyrido-1,2-pyrimidones, and quinolines.[32]

The three-component condensation of orthoesters, halogenoacetoacetates, and aliphatic amines is complicated by side reactions.[32] For this reason, the corresponding derivatives of *N*-alkylaminomethylene-γ-halogenoacetoacetic acid (XLVII) can be more conveniently obtained in two stages. The orthoformate is initially made to react with the methylene component in the presence of acetic anhydride, which leads to the formation of the ethoxymethylene derivatives (XLVI). The latter are treated with aliphatic amines and the required product (XLVII) is isolated:



(XLVI); (XLVII)

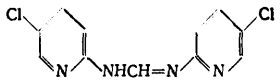
Thus it has been demonstrated clearly by means of a number of examples that the method of synthesis of ββ-diacylenamines and their analogues via a type of three-component condensation has advantages over previous procedures.[33–35] In the vast majority of cases it consists of a single stage, is carried out under mild conditions, and there is only one side product, an alcohol, which can be readily removed from the reaction mixture.



The choice of methylene components is not limited to carbonyl derivatives. Together with alkylaminomethylene-5-pyrazolinones, their thio-analogues have been obtained by the method of three-component condensation:[31]

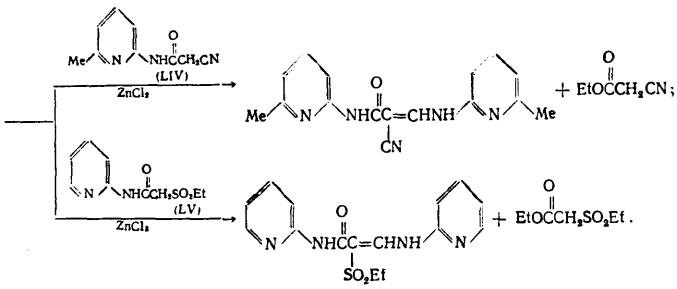
, X=O, S.

Some of the methylene components tested under the conditions of three-component condensation behaved anomalously. For example, 1-indanone and 2-methylindole reacted with orthoformate without the participation of the amino-component, to form products of type (XLVIII):[31]



(XLVIII)

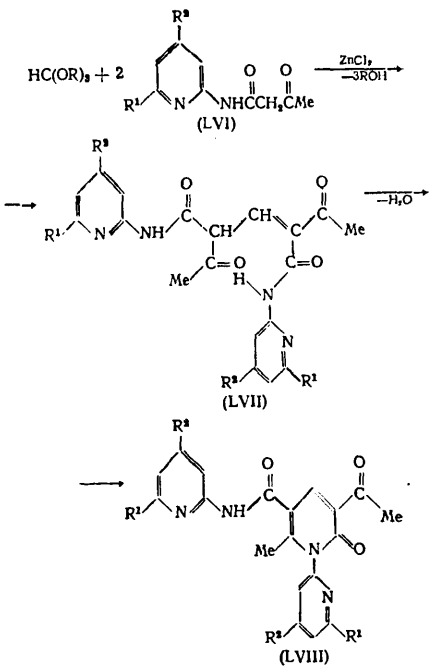
The interaction of orthoesters with polyfunctional compounds can proceed via a mechanism of the type of three-component condensation. For example, in the reaction with orthoformic ester, one molecule of 2-ethoxycarbonylacetamidopyridine (XLIX) behaves as the methylene component, while the other behaves as the amino-component.[36] The authors suggest that this reaction mechanism can be represented schematically as follows:



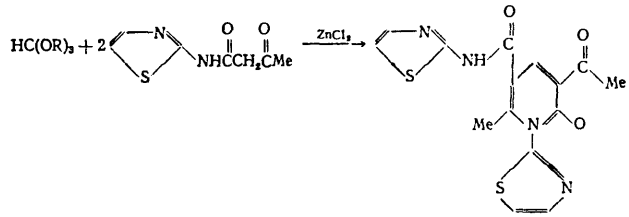
(XLIX); (L); (LI); (LII); (LIII)

The configuration of compound (L) is such that, under the influence of the electronegative nitrogen atom of the pyridine ring on the nearest ethoxy-group, the elimination of the latter in the form of the corresponding anion is facilitated. An active ionic compound (LI), which can react with the amide nitrogen atom of the initial compound (XLIX), is formed under these conditions. The product (LII) obtained undergoes alcoholysis under the influence of the alcohol, formed as a side product under the conditions of catalysis by zinc chloride, malonic ester being split off. Compound (LIII) is obtained in this way. In order to increase the yield of compound (LIII) from 24% to 41%, it was found to be sufficient to replace the acetic anhydride, normally employed as the solvent in such reactions, by ethyl alcohol.[36]

The reaction of 2-amino-5-chloropyridine with orthoformate is of the same type, the product being a formamidine:[36]

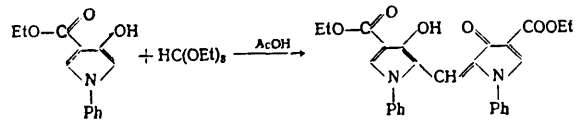


When the corresponding cyanoacetyl derivative (LIV) and the ethanesulphonylacetyl derivative (LV) were introduced into the reaction with the orthoester instead of the ethoxycarbonyl derivative, analogous products were obtained, although the yield of the main product in these cases was low (18–29%):

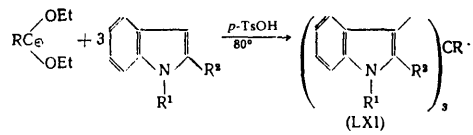


## IV. REACTIONS OF ORTHOESTERS WITH COMPOUNDS CONTAINING AN ACTIVE HYDROGEN ATOM

### 1. Interaction of Orthoesters with CH Acids



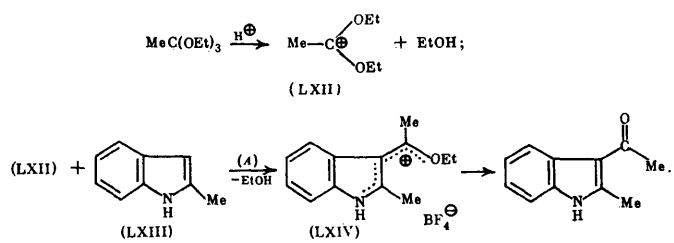
Certain reactions of this type lead to unexpected results. For example, when orthoformates interact with substituted 2-acetoacetylaminopyridines (LVI) in the presence of zinc chloride, complex tricyclic products (LVIII) are obtained.[37] Two molecules of the initial compound (LVI), which functions as the methylene component, react with a molecule of the orthoformic ester. The carbonyl and amide group approach one another so much in compound (LVII) that, under the catalytic influence of zinc chloride, intramolecular condensation takes place with elimination of a water molecule and formation of the pyridone ring (LVIII):



The interaction of orthoformate with 2-acetoacetylaminothiazole takes place analogously:[37]

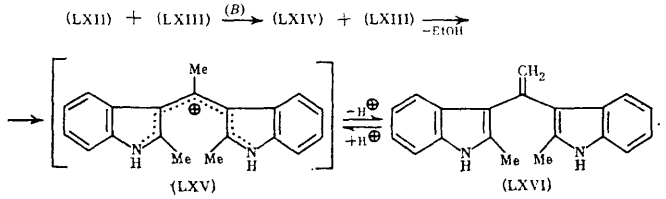
The reaction of triethyl orthoformate with 3-hydroxy-4-ethoxycarbonyl-1-phenylpyrrole [32] leads to a compound containing the hydroxypyrrole and pyrrolinone groups:

Derivatives of indole are typical representatives of CH acids. The behaviour and reactivity of orthoesters in reactions with disubstituted indoles in the presence of organic acids have been investigated[38] and it has been shown that alkyl orthoesters participate in this reaction in the form of the corresponding dialkoxycarbonium ions, which attack the 3-position, where the electron density is highest, to form tri-indolylmethanes:



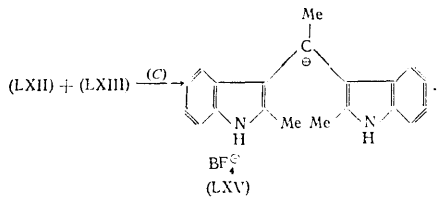
(LIX): R=H;
(LX): R=Me

Kinetic data have shown that the behaviour of the carbonium ions (LIX) and (LX) in reactions of this type is approximately the same, trimethoxycarbonium ions proving to be the least reactive.

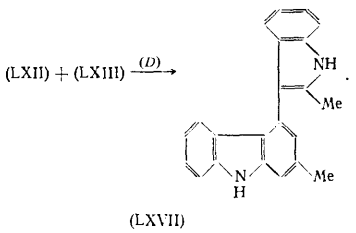


Reactions in which analogous products (XLVIII) were obtained by the interaction of 2-methylindole with orthoesters in the presence of organic bases were considered above; unfortunately the reaction mechanism was not discussed by Wolfbeis.[31]

By altering the reaction conditions, it is possible to obtain different products of the reaction of orthoesters with 2-substituted alkylindoles. A convenient method of synthesis of the pharmacologically active indolylcarbazole (LXVII) from ethyl orthoacetate and 2-methylindole has been proposed.



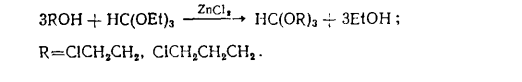
If the reaction between triethyl orthoacetate and 2-methylindole (LXIII) is carried out in methylene chloride in the presence of $HBF_4$ at 0 °C [version (*A*)], then the main product is 1-ethoxy-1-(2-methylindol-3-yl)ethyl tetrafluoroborate (LXIV). This relatively stable salt has been isolated in 46% yield. In aqueous organic media, it is gradually converted into 3-acetyl-2-methylindole.



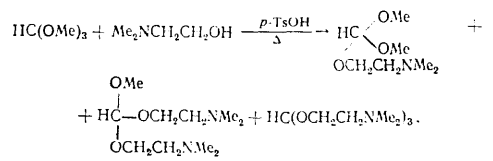
When the starting materials are refluxed in methanol in the presence of catalytic amounts of concentrated sulphuric acid [version (*B*)], the bisindolyl derivative (LXVI) is formed. The product (LXIV) formed initially apparently reacts under these conditions with yet another molecule of the initial indole (LXIII) and the intermediate bisindolylcarbonium ion (LXV) is converted on deprotonation into 1,1-bis(2-methylindol-3-yl)ethylene (LXVI) (yield 37%):

The cation (LXV) was isolated directly in the form of the tetrafluoroborate salt. For this purpose, the initial indole (LXIII) was activated with a Grignard reagent, namely ethylmagnesium bromide, and was then made to react with the orthoester in the presence of boron trifluoride [version (*C*)], the yield being 19%:

Under more severe conditions, after prolonged refluxing of the reactants in acetic acid or methanol in the presence of concentrated sulphuric acid [version (*D*)], 2-methyl-4-(2-methylindol-3-yl)-9*H*-carbazole (LXVII) is formed:



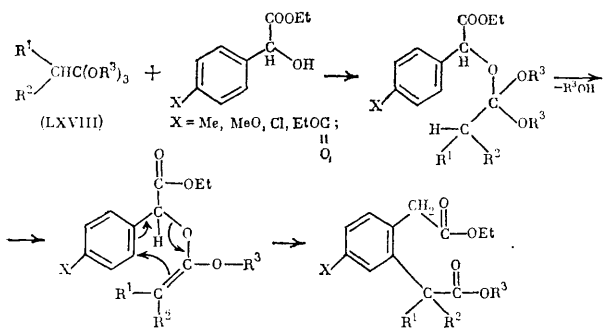
## 2. Reactions with Alcohols and Mercaptans



The reactions of alkyl orthoesters with alcohols have been investigated in fair detail.[1,2,4-6] They consist in the exchange of the alkoxy-group of the orthoesters with the corresponding alcohol residue. Using certain polyfunctional alkanols, it is possible to introduce additional active groups into the orthoester molecule. For this purpose, alkyl orthoesters are made to react with chloroalcohols, aminoalcohols, alkylaminoalcohols, and ethylenecyanohydrin.[40]

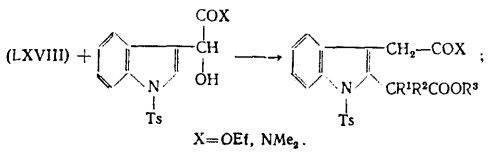
One, two, and three alkoxy-groups of the orthoester can exchange for the *O*-alkyl group of the alcohol depending on the structure of the latter and the reaction conditions (molar reactant ratio and the character of the catalyst employed). The reaction usually results in the formation of a mixture of products of similar structure, which makes it difficult to separate them.

Individual products have been obtained from ethyl orthoformate and ethylenechlorohydrin and also 3-chloropropanol in the presence of zinc chloride as the catalyst:



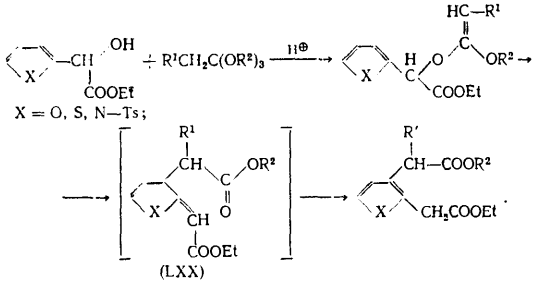
When orthoesters react with aliphatic aminoalcohols in the presence of acid catalysts (toluene-*p*-sulphonic acid, zinc chloride, or tin chloride), mixtures of mono-, di-, and trisubstituted aminoalkyl orthoesters are obtained and are separated by fractional distillation,[40-43] for example:

The mechanism of the interaction of orthoesters with unsaturated alcohols is much more complex, since reactions of this kind are usually accompanied by intramolecular rearrangements of the type of the Claisen rearrangement.[1,44-49,51,52]



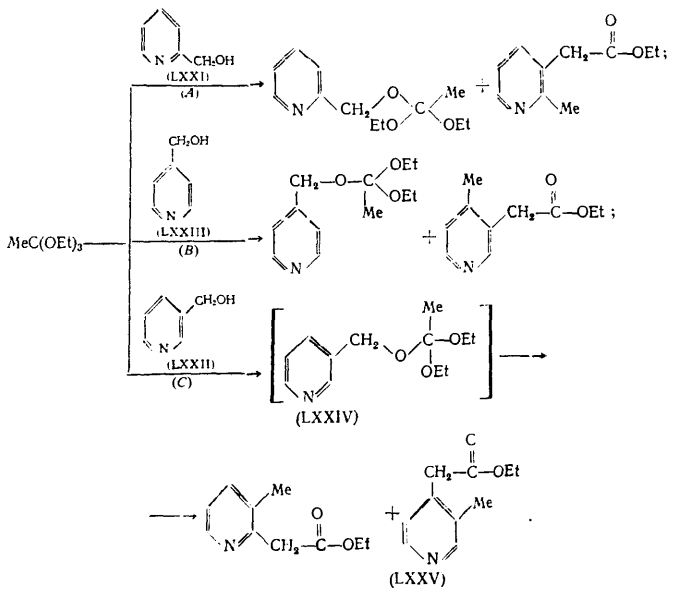
A series of studies[44-46] have been devoted to the mechanism of the interaction of orthoesters with aromatic derivatives containing a hydroxy-group in the α-position in the side chain.

A convenient method has been proposed[44] for the synthesis of substituted arenes, which is distinguished by a high regio- and stereo-specificity. It is based on the application of the reaction of orthoesters with the ethyl esters of mandelic acid and its analogues:



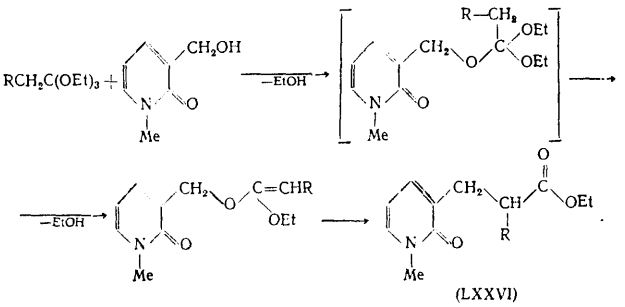
In the first stage of the synthesis, one alkoxy-group of the orthoester is substituted by the alkoxy-residue of the initial alcohol; the alcohol $R^3OH$ is split off from the product (LXIX) and this is followed by the Claisen rearrangement proper, which leads to the formation of a new carbon–carbon bond. The influence of neighbours of the hydroxy- and ethoxycarbonyl groups facilitates the intramolecular rearrangement.

The same chain of transformations is observed in the reactions of alkyl orthoesters with the esters and amides of 3-indolylglycolic acid:[44]



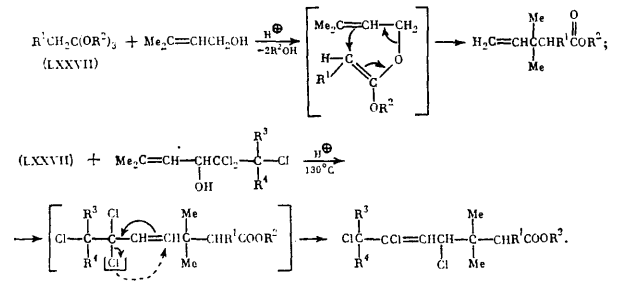
The interaction of orthoesters with other heterocyclic hydroxyesters proceeds analogously to the reaction described above,[45,46] but in this instance it is necessary to introduce an acid catalyst. 2,3-Disubstituted derivatives of furan, thiophen, and pyrrole are obtained in this way using hexanoic acid as the catalyst:[45]

The ethoxycarbonyl group stabilises the intermediate (LXX). When 3-substituted furans, thiophens, and pyrroles are used as the initial derivatives, mixtures of 2,3- and 3,4-disubstituted heterocyclic products are formed.[45]



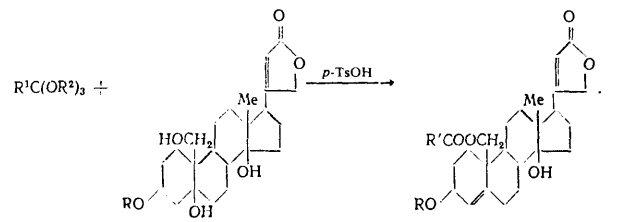
The Claisen rearrangement can also be studied for a series of hydroxymethylpyridines and hydroxymethylpyridones;[46] the authors noted that the rearrangement involving the latter proceeds in an unusual manner.

An essential condition for the smooth rearrangement in the reaction of orthoesters with the pyridine derivatives (LXXI) to (LXXIII) is an increase of temperature to 195 °C. The results of the reactions (*A*) and (*B*) of triethyl orthoacetate with 2- and 4-hydroxymethylpyridines differ from the results obtained for 3-hydroxymethylpyridine [reaction (*C*)] in which the rearranged product (LXXIV) was not isolated at all:

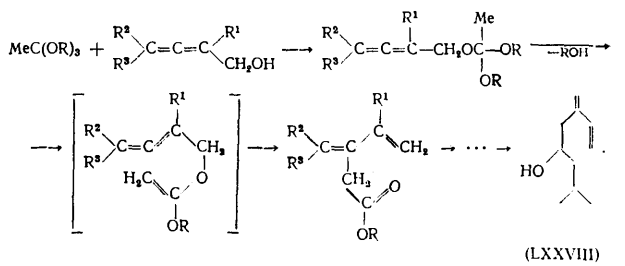


Calculation of the relative electron densities in different positions in the pyridine ring has shown that the density is a maximum in the 3-position. These data explain why the carbon–oxygen bond in compound (LXXIV) is dissociated much more readily than in the other two cases. This is why the product (LXXIV) has not been detected.

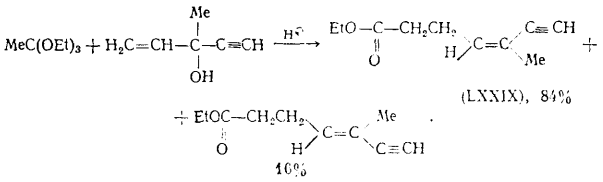
The reaction of orthoesters with 3-hydroxylmethyl-1-methyl-2-pyridine does not lead to the formation of products of type (LXXV), compounds (LXXVI) being formed instead:



The interaction with unsaturated acyclic alcohols is used for different purposes. New methods of synthesis of unsaturated carboxylic acid esters are based on the reactions of orthoesters with allyl alcohols,[47,48] including halogenoalkyl-substituted derivatives.[49] The reaction is carried out in the presence of acid catalysts with the simultaneous removal of the lower alcohol formed as a side product, while in the case of halogeno-derivatives it is performed at elevated temperatures in a stream of nitrogen:

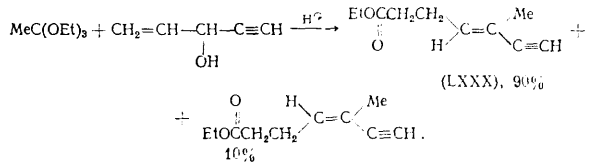


In the latter case the Claisen rearrangement is accompanied by the transfer of the chloride anion and the migration of the double bond.[49]

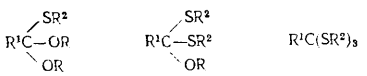


The synthesis of analogues of cardiotonic glycosides (by the conversion of cardenolides into cardadienolides) has been achieved with the aid of alkyl orthoesters:[50]

The reactions of orthoesters with alcohols of the type of allenylmethanol have been used in one of the stages of the synthesis of the terpenoids ipsenol (LXXVIII) and ipsdienol:[51]



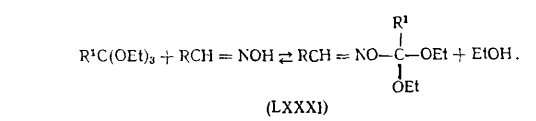
The reactions of orthoesters with vinylalkynylmethanols have been studied in detail.[52] Attention has been concentrated on the study of the structure of the product. It has been shown that the reactions of triethyl orthoacetate and tertiary allylalkynyl alcohols followed by the Claisen rearrangement yields mainly the esters (LXXIX), in which the acetylenic group occupies the *cis*-position relative to the ester side chain. The *trans*-products are formed in very small amounts, for example:



(LXXIX), 84%

The reactions of orthoesters with secondary allylalkynyl alcohols also proceed stereospecifically, although in this instance the products are mainly the *trans*-substituted compounds (LXXX):

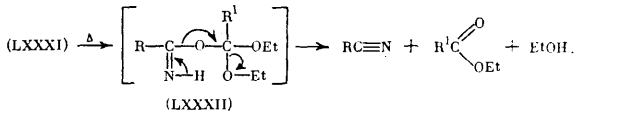
(LXXX), 90%



The reactions involving the exchange of the alkoxy-group of the orthoester for the alkylthio-group of a mercapto-compound are analogous to the reactions with alcohols[1,4-6] but proceed more vigorously. Thio-analogues of orthoesters the same three types as the products of the reactions with alcohols can be obtained:

By varying the conditions (by altering the temperature and the reactant ratio and by selecting the appropriate catalyst), it is possible to increase the yield of derivatives of all these types. For example, the use of aluminium chloride as the catalyst promotes the formation of mainly trithio-orthoesters.[53]

### 3. Reactions with Oximes

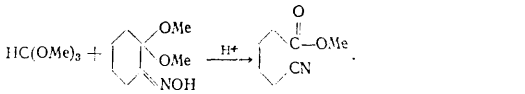


Orthoesters readily react with oximes, whereupon one alkoxy-group of the orthoester is substituted by the oxime residue formed after the abstraction of a proton:[54]

(LXXXI)

When the reactivities of the stereoisomers of oximes were compared, it was found that the *Z*-isomer reacts with the orthoester more slowly than the *E*-isomer and NMR data showed that the oxime does not isomerise under the given conditions.

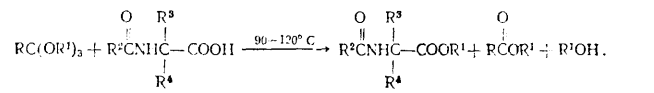
It is important to note that only in the absence of acids are the derivatives (LXXXI) relatively stable; under the conditions of acid catalysis, they undergo the "Beckmann fragmentation", which yields the corresponding nitrile, ester, and alcohol. Judging from the structure of the product (LXXXI) and the substances obtained after its fragmentation, one can postulate that the Beckmann rearrangement takes place initially and is followed by the decomposition of the product (LXXXII):



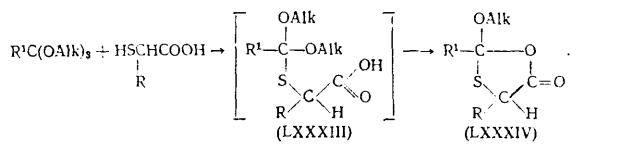
(LXXXII)

The reactions between orthoesters and oximes in liquid sulphur dioxide take place over a period of several minutes, because the solvent plays the role of the catalyst.

Thus the interaction of orthoesters with oximes constitutes an effective method of synthesis of the corresponding nitriles.[54] For example, when benzil monoxime is heated with a 10% excess of triethyl orthoformate in liquid sulphur dioxide at 75 °C, benzonitrile and ethyl benzoate can be obtained in quantitative yields:



Trimethyl orthoformate and the dimethyl ketal of 2-hydroxyiminocyclohexanone react analogously in the presence of methane sulphonic acid at −10 °C to form methyl 5-cyanopentanoate:

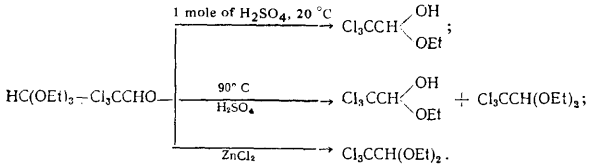


### 4. Reactions with Carboxylic Acids

The high reactivity of orthoesters makes it possible to use them for the esterification of carboxylic acids.[55] The esters of orthocarbonic and orthoacetic acids give rise to the corresponding *N*-acylaminoacid esters in quantitative yield in the absence of catalysts:[56]

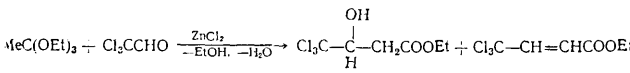
The reaction is not accompanied by side processes and racemisation and proceeds smoothly even in the case of sterically hindered aminoacids.

Orthoesters react very readily with carboxylic α-mercaptoacids.[57,58] The products are 2-alkoxy-1,3-oxathiolan-5-ones (LXXXIV). It is assumed that the orthoester initially reacts with the mercapto-group and that the heterocycle (LXXXIV) is formed from the intermediate (LXXXIII) as a result of the elimination of the corresponding alcohol AlkOH:



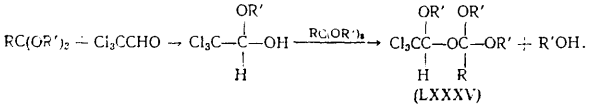
(LXXXIII) (LXXXIV)

The oxathiolanones (LXXXIV) obtained are effective reagents for the synthesis of the amides of carboxylic α-mercaptoacids.[59,60]



## V. INTERACTION OF ORTHOESTERS WITH CARBONYL COMPOUNDS

### 1. Reactions with Aldehydes and Ketones



The application of orthoesters in the synthesis of acetals and ketals has been studied in fair detail. However, there is little information in the literature about the interaction of orthoesters with perhalogeno-derivatives of aldehydes and ketones.[61,62] The reaction of orthoesters with chloral is of interest.[61] In the presence of acid catalysts chloral gives rise to hemiacetals and acetals, like all other aldehydes:

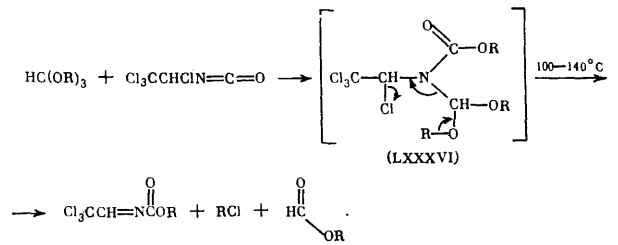
In the presence of zinc chloride, ethyl orthoformate and ethyl orthocarbonate react with chloral to form only the corresponding diethyl acetal, while ethyl orthoacetate behaves differently in this reaction. Its interaction with chloral yielded a mixture of the ethyl esters of 4,4,4-trichloro-3-hydroxybutanoic and trichlorobutanoic acids:

The reaction of orthoesters with chloral takes place in an unusual manner in the absence of catalysts:

(LXXXV)

It has been found that, when weak bases (whose p$K$ does not exceed the limits 7.4–9.2) are used as the catalyst and the reaction temperature is raised to 100 °C, the yield of the product (LXXXV) rises considerably (from 18 to 60%). The mechanism of the reaction involving bases has not unfortunately been discussed by Petrov et al.[61] A product of type (LXXXV) is formed in the reaction of orthoformate with fluoral (with a higher yield).[62]

Even in the absence of catalysts, orthoformates and orthoacetates react vigorously with the hydrates of fluoral, hexafluoroacetone, and dichlorotetrafluoroacetone, forming hemiacetals and hemiketals.[62] On raising the reaction temperature to 60 °C, ethyl orthoacetate undergoes a reaction with fluoral of the type of aldol condensation, which demonstrates the relative mobility of the α-protons in the orthoacetate molecule:

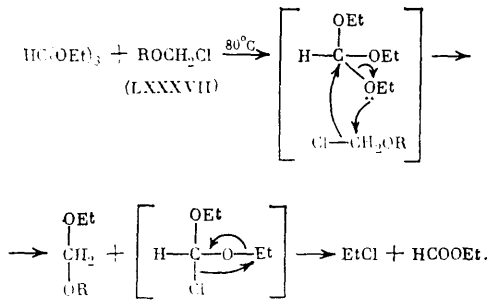


Similar products are obtained also in the reactions of alkyl orthoacetates with hexafluoroacetone and dichlorotetrafluoroacetone.

### 2. Reactions with Isocyanates

The products of the reactions of orthoesters with isocyanates vary as a function of the reactivity and structure of the isocyanate.

Being more reactive, α- and β-chloro-substituted alkyl isocyanates react with orthoesters in the absence of catalytic additives, which leads to the formation of chloro-substituted $N$-alkoxycarbonylaldimines.[63] The reaction has been followed with the aid of IR spectroscopy. The IR spectroscopic data led to the hypothesis that the intermediate (LXXXVI) is formed. The final products are an azomethine, an alkyl halide, and a formate:

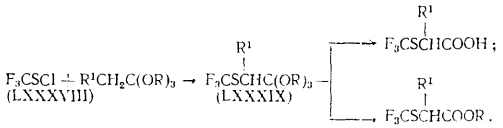


(LXXXVI)

## VI. REACTIONS OF ORTHOESTERS WITH COMPOUNDS CONTAINING AN ACTIVE HALOGEN ATOM

### 1. Reactions with Halogenoethers

One of the non-traditional methods of synthesis of mixed formals and acetals is based on the reaction of alkyl orthoesters with α-chloroethers.[64] The active halogen atom in the initial reactant (LXXXVII) is substituted by the alkoxy-group of the orthoester. The most reactive halogenoethers, for example α-chloromethyl ether, react with orthoesters at room temperature. The tentative reaction mechanism is



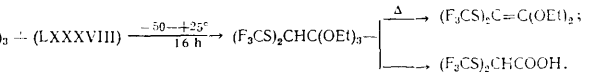
The method is simple and convenient and ensures a high yield of the required product.[64]

### 2. Reactions with Sulphenyl Chlorides

A new method for the sulphenation of orthoesters with the aid of trihalogenomethanesulphenyl chlorides has been proposed.[65] The mono- and bis-(trihalogenomethylthio)-orthoesters obtained in satisfactory yields are intermediates in the synthesis of halogenoalkylthio-derivatives of carboxylic acids.

Trifluoromethanesulphenyl chloride (LXXXVIII) is the most reactive among the proposed sulphenating agents. Its interaction with the orthoester is completed after several seconds by the formation of the monothio-derivatives (LXXXIX); the orthoester is taken in excess and the reaction is carried out

with cooling (between −10° and +10 °C):



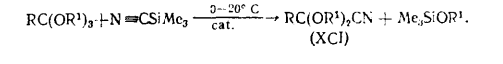
Even "inert" orthoesters such as, for example, ethyl orthoisobutyrate, react with compound (LXXXVIII), because steric factors are not decisive in this reaction:

$$(\text{LXXXVIII}) + Me_2CHC(OEt)_3 \rightarrow F_3CSCMe_2C(OEt)_3 .$$

The yield of the monosulphenated products (LXXXIX) is 75–80%. The behaviour of dichlorofluoromethanesulphenyl chloride in the reactions with orthoesters is similar to that of compound (LXXXVIII).

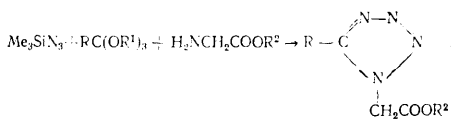
If the sulphenating agent is taken in excess and at the same time the reaction time and temperature are increased, only bis(trihalogenomethylthio)orthoesters are formed. They are less stable than the monothio-derivatives, so that they are converted into 2,2-dialkoxy-1,1-dialkylthioethylenes even during distillation with elimination of an alcohol molecule:

According to Mendelson et al.[65], trichloromethanesulphenyl chloride interacts with orthoesters via a radical mechanism. Orthoesters react with this compound only in the presence of a free radical initiator—azobisisobutyronitrile (XC):



$$MeC(OR)_3 + Cl_3CSCl \xrightarrow{(XC),\ 80^\circ C} Cl_3CSCH_2C(OR)_3 .$$

The proposed reaction mechanism is

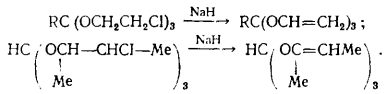


$$Cl_3CSCl \xrightarrow{(XC)} Cl_3C\dot{S} + \dot{C}l ;$$
$$\dot{C}l + CH_3C(OR)_3 \rightarrow \dot{C}H_2C(OR)_3 + HCl ;$$
$$Cl_3CSCl + \dot{C}H_2C(OR)_3 \rightarrow \dot{C}l + Cl_3CSCH_2C(OR)_3 ;$$
$$Cl_3C\dot{S} + \dot{C}H_2C(OR)_3 \rightarrow Cl_3CSCH_2C(OR)_3 .$$

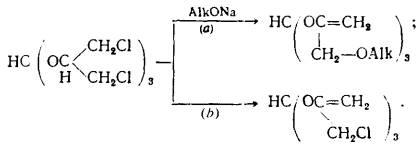
## VII. INTERACTION OF ORTHOESTERS WITH ORGANOSILICON COMPOUNDS

Alkyl orthoesters and cyanotrimethylsilane are convenient reagents for the synthesis of nitriles of type (XCI).[66,67] The reaction proceeds in the presence of Lewis acids as catalysts: tin dichloride and boron trifluoride etherate:

The reaction is not complicated by side processes and leads to the formation of dialkoxynitriles (XCI) in high yields. Previously acyl cyanides were used to introduce the cyano-group into the reaction with the orthoester; the reaction was as a rule accompanied by the formation of a number of side products.[68] It has been shown[69] that trimethylsilyl azide is an effective and at the same time a non-explosive reagent for the synthesis of 1-substituted tetrazole derivatives from orthoesters and aminoacid esters. The method ensures a high yield (90%) and a purity of the product not less than 95%:



## VIII. DEHYDROHALOGENATION OF HALOGENOALKYL ORTHOESTERS



Alkenyl orthoesters,[70] compounds which are known to be highly reactive, are obtained by the dehydrohalogenation of β-chloroalkyl orthoesters. Their application in the synthesis of di(alkenyloxy)alkyl carboxylates has been described:[70]

The dehydrohalogenation of β-chloro-derivatives of orthoesters is carried out by treatment with sodium hydride or sodium butoxide:

When halogenoalkyl orthoesters are treated with solutions of alkoxides, the exchange reaction (*a*) takes place together with the elimination reaction. This side reaction can be excluded by using potassium hydroxide in an aqueous organic medium as the dehydrohalogenating agent [reaction (*b*)]:

## IX. INTERACTION OF ALKYL ORTHOESTERS WITH SULPHUR DIOXIDE

In a number of instances liquefied sulphur dioxide is used as the solvent for reactions with orthoesters. It is noteworthy that this compound is not inert with respect to orthoesters. Depending on the conditions, the products of the interaction of alkyl orthoesters with sulphur dioxide can be various.

It has been established that,[71] at low temperatures after prolonged irradiation with UV light, orthoformates and orthocarbonates give rise to the corresponding trialkoxycarbonium ions in liquid sulphur dioxide:

$$HC(OMe)_3 \rightarrow \overset{\oplus}{C}(OMe)_3 ;$$
$$HC(OEt)_3 \rightarrow \overset{\oplus}{C}(OEt)_3 ;$$
$$C(OMe)_4 \rightarrow \overset{\oplus}{C}(OMe)_3 .$$

When the temperature is raised to −20 °C, the above carbonium ions begin to decompose and are converted into dialkyl carbonates. It has been suggested that[71] the carbonium

ions are formed with direct participation of sulphur dioxide:

$$(RO)_3C{-}H \xrightarrow[h\nu]{SO_2} (RO)_3C{-}SO_2H \rightarrow \overset{\oplus}{C}(OR)_3.$$

This reaction takes place under extensive cooling conditions (−75 °C) as a consequence of the activation of the molecules by UV irradiation.

Apart from the main product, the side product (XCII) was isolated. It is formed as a result of the addition of the nucleophile ($SO_2$) to the electropositive carbon atom of the alkoxy-group of the orthoester:

$$(MeO)_2CHOMe \xrightarrow{SO_2} \underset{(XCII)}{(MeO)_2CHOCH_2SO_2H}.$$

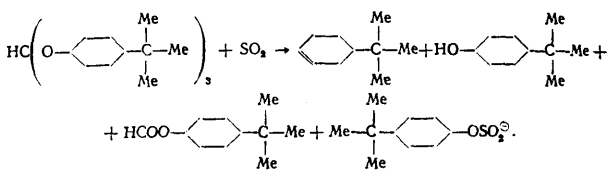
If the mixture of liquefied sulphur dioxide with the alkyl orthoester is maintained in a sealed tube at room temperature, the reaction products are dialkyl sulphites and esters:[72]

$$RC(OR^1)_3 + SO_2 \xrightarrow[24\ h]{20^\circ C} O{=}S\begin{matrix}OR^1\\OR^1\end{matrix} + RCOOR^1.$$

Orthoformate, which is relatively passive in sulphur dioxide in the absence of irradiation, is an exception. Only on heating with a large excess of $SO_2$ does it react slowly, forming diethyl carbonate in addition to ethyl formate and diethyl sulphite.

It has been shown with the aid of $^1H$ NMR [72] that the addition of even catalytic amounts of $SO_2$ to mixtures of orthoesters entails the immediate exchange of the alkoxy-groups as a consequence of the appearance of dialkoxyalkylcarbonium ions. The proposed mechanism of the reaction with $SO_2$ is as follows:

$$RC(OEt)_3 + SO_2 \underset{}{\overset{(A)}{\rightleftharpoons}} \underset{(XCIII)}{R{-}\overset{\oplus}{C}(OEt)_2{-}O{-}SO_2^{\ominus}Et};$$



$$(XCIII) \overset{(B)}{\rightleftharpoons} \overset{\oplus}{R}C(OEt)_2 + EtOSO_2^{\ominus};$$

$$R{-}\overset{\oplus}{C}(OEt)_2 + EtOSO_2^{\ominus} \xrightarrow{(C)} RCOOEt + (EtO)_2S{=}O;$$

$$(XCIII) + EtOSO_2^{\ominus} \xrightarrow{(D)} RCOOEt + EtOSO_2^{\ominus} + (EtO)_2S{=}O.$$

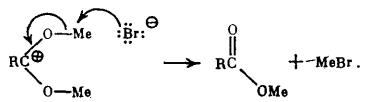
The intermediate (XCIII) is apparently formed via the coordinate bond between the sulphur atom in sulphur dioxide and the free electron pair of the oxygen atom in the alkoxy-group of the orthoester (*A*). It decomposes subsequently at the C–O bond (*B*). Both these reactions are reversible. It has been suggested that the main reaction products are obtained as a result of the attack by the alkyl sulphite anion on the dialkoxycarbonium ion (*C*) or on the intermediate (XCIII) (*D*).

The validity of the proposed mechanism has been confirmed by the behaviour of secondary trialkoxymethanes in reactions with $SO_2$ under the same conditions. The substitution by the resulting secondary alkyl sulphite anion at a secondary carbon atom of the carbonium ion (XCIV) is sterically hindered and for this reason the corresponding olefin, alkanol, secondary alkyl formate, and alkylsulphurous acid are formed. For example:[72]

Thus, in contrast to the photochemical reaction, the interaction of orthoester molecules with $SO_2$ in the absence of a supply of energy from outside leads to the formation of dialkoxycarbonium ions which are less stable than trialkoxycarbonium ions.

## X. BROMINATION OF ORTHOESTERS

The behaviour of dimethoxycarbenium bromides in liquid sulphur dioxide has been investigated.[73] The orthoesters were brominated at temperatures between −60° and −80 °C. Orthoesters react with bromine via an ionic mechanism and the reaction was followed with the aid of NMR. It is a typical nucleophilic substitution reaction. The $Br^{\oplus}$ ion abstracts the alkoxide anion from the orthoester molecule and $Br^{\ominus}$ promotes the stabilisation of the dialkoxyalkylcarbonium ion formed:



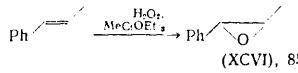
$$RC(OR^1)_3 + Br_2 \rightarrow RC\begin{matrix}OR^1\\OR^1\end{matrix}{}^{\oplus}\ Br^{\ominus} + BrOR^1.$$

It has been shown that, when the orthoesters are brominated in the presence of orthocarbonate, the more stable trialkoxycarbonium ions are formed. This takes place via the irreversible migration of the methoxy-group from the orthocarbonate to the dialkoxycarbonium ion:

$$RC\begin{matrix}OMe\\OMe\end{matrix}{}^{\oplus}\ Br^{\ominus} + Br_2 + C(OMe)_4 \xrightarrow[SO_2]{-80^\circ C} RC(OMe)_3 + MeO{-}\overset{\oplus}{C}(OMe)_2Br^{\ominus}.$$

The role of the solvent was not discussed in the above communication.

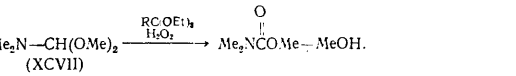
Dimethoxycarbenium bromides are stable only at temperatures below −50 °C, decomposing at higher temperatures in accordance with the following scheme:



## XI. ORTHOESTERS IN TRANSFER OXIDATION REACTIONS

It has been found[74,75] that, in the presence of orthoesters, hydrogen peroxide can be conveneintly used for the mild oxidation of olefins to the corresponding epoxy-derivative. It has been suggested that orthoesters interact with hydrogen peroxide to form the intermediate (XCV) (these are relatively stable as a result of hydrogen bonding), which serve as agents which transfer and generate atomic oxygen:

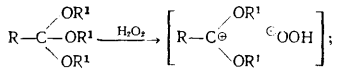
$$C(OEt)_4 + H_2O_2 \xrightarrow{-EtOH} \underset{(XCV)}{\left[\begin{matrix}EtO\cdots H\\ \diagdown\\ EtO{-}C{-}O\\ |\\ OEt\end{matrix}\right]} \xrightarrow{-EtOH} [O] + (EtO)_2CO.$$



The ethyl esters of formic, acetic, orthobenzoic, and carbonic acids have been tried together with hydrogen peroxide as transfer oxidising agents. Regardless of the structure of the olefin oxidised, the best results were obtained in the first place using ethyl orthocarbonate and then ethyl orthoacetate. This method makes it possible to obtain epoxy-derivatives which are otherwise difficult to

synthesise, for example, compound (XCVI), in a higher yield:

(XCVI), 85%



Peroxides such as 9,10-endoperoxy-9,10-diphenylanthracene, can be obtained by the same procedure. Oxidation of the amidoacetals (XCVII) by this method leads to the isolation of the corresponding carbamates:

(XCVII)

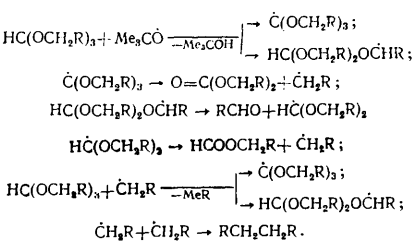
The reaction mechanism has not been specially investigated. The hypothetical structure of the intermediate (XCV) has not been confirmed by physicochemical research techniques. We believe the hypothesis that the active oxidising agent may be an ionic complex of type (XCVIII) to be acceptable.

Like other weak acids, hydrogen peroxide added to orthoesters is capable of producing dialkoxycarbonium ions, which are stabilised by combining with the anion $HOO^{\ominus}$:

(XCVIII)

R=Me (a), $OR^1$ (b), Ph (c);
$R^1$=Et.

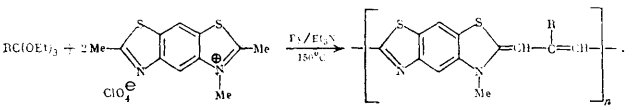
Since the complexes (XCVIIIb) are more stable than the complexes (XCVIIIa) while complexes of type (XCVIIIc) are relatively stable but sterically hindered compared with (XCVIIIa), the reason why orthocarbonate is preferable to other orthoesters becomes understandable.



## XII. FREE-RADICAL REACTIONS OF ORTHOESTERS

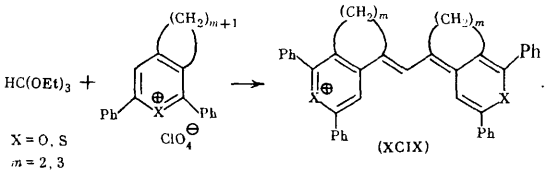
Two investigations have been made of the behaviour of trialkoxymethanes in reactions with free radicals at elevated temperatures (120–150 °C).[76,77] It has been shown by EPR that alkyl orthoformates react with free radicals to form tri- and mono-alkoxyalkyl radicals, whose fragmentation leads to the formation of the corresponding carbonates and formates. The radical reactions were initiated by t-butoxy-radicals:

Conclusions concerning the reactivity of orthoformates in reactions of the above type compared with linear and cyclic acetals were reached on the basis of kinetic data.



The mechanism of the homolytic liquid-phase reactions of alkyl orthoformates can be demonstrated in relation to triethoxymethane:

It was found that radical chain reactions involving orthoesters can be observed also at much lower temperatures (60 °C) when dicyclohexyl peroxycarbonate is used as the free radical initiator.[78] The chain of radical reactions is analogous to that described above and the main products are the same as under high-temperature conditions.



## XIII. SOME APPLICATIONS OF ORTHOESTERS

Orthoesters have been known for a long time as irreplaceable reagents in the synthesis of dyes.[4] Progress in the field of cyanine dyes has continued successfully.[79] A new method of synthesis of polymeric cyanines based on orthoesters and 2,3,6-trimethylthiazolo[4,5-*f*]benzothiazolium perchlorate in the presence of weak organic bases has been proposed:[80]

The reaction conditions make it possible to achieve a high degree of condensation, which is favourably reflected in the quality of the dyes obtained.

Pyrylocarbocyanines (XCIX),[81] which are geometrical isomers of the pyrylo-2-cyanines described previously,[82] have been obtained[81] by the reaction of diethyl orthoformate salts of the diphenyl-substituted derivatives of cyclopenta-[c]pyrylium and also its thio-analogue and 5,6,7,8-tetrahydrobenzo-3,4-pyrylium:

(XCIX)

It has been shown[81,82] that the introduction of bridging ethylene and trimethylethylene groups not only stabilises the dyes obtained but also deepens their colour.

Derivatives of isoxazolopyrimidine, which exhibit a high selective herbicidal activity before and after germination, have been obtained by a series of reactions from aliphatic alkyl orthoesters and malononitrile.[83] Propyl orthocarbonate and propyl orthobenzoate proved to be highly effective additives leading to the manifestation of synergism by certain insecticides.[84]

The possibility of using orthoesters, apart from aldehydes and epoxides, in the catalytic carbonylation reactions in the presence of carboxylic acid amides in order to obtain N-acyl-α-aminoacids has been discovered.[85]

Orthoesters have found the widest applications as components of active and stereospecific catalysts in the polymerisation of propene[86–89] and ethylene,[90] while aminoalkyl orthoesters are most widely used in the synthesis of polyurethanes[41–43] and polyisocyanates.[43]

It has been found[91] that orthoesters are essential components in the synthesis of special elastic cementing materials.

# Methods of Synthesis of Arylphosphonic and Arylphosphonothioic Acids and Their Derivatives

K.A.Petrov, V.M.Chizhov, V.P.Pokatun, and S.V.Agafonov

A systematic account is given of data on the synthesis of arylphosphonic and arylphosphonothioic acids and their derivatives by the addition of oxygen or sulphur to arylphosphonous acids, their esters, amides, and dihalides, by treating phosphoryl chloride, dialkyl phosphorochloridates, and phosphorodiamidic chlorides with aryl-substituted organometallic compounds, by the reaction of benzene and its derivatives containing various substituents in the ring with phosphorus pentoxide, phosphorus sulphide halides, phosphorus sulphides, and esters of phosphorous and phosphorothious acids, and by other less familiar methods. The methods of synthesis of aryldihalogenophosphines, which are important intermediates in the synthesis of arylphosphonic acids and their derivatives, are described.
The bibliography includes 355 references.

III. Methods of synthesis of aryl phosphonothioic acids and their derivatives 1048

## I. INTRODUCTION

By virtue of the wide variety of their properties due to the presence of two reaction centres, namely the aromatic ring and the phosphono-group, and also as a consequence of the various aspects of their possible practical applications which have been discovered, aryl phosphonic acids and their derivatives have been the subject of numerous investigations. At present there exist extensive data on this question in both Soviet and foreign literature, but there have been no surveys with the exception of two published in 1957–1958 in which the data accumulated were only partly utilised.[1,2] This review deals with data on the methods of synthesis of arylphosphonic and arylphosphonothioic acids and their derivatives which have been published up to the middle of 1984.

## II. METHODS OF SYNTHESIS OF ARYLPHOSPHONIC ACIDS AND THEIR DERIVATIVES

Arylphosphonic acids and their derivatives are obtained by various procedures which can be divided into two groups. The first group includes methods based on the oxidation of arylphosphonous acids and their derivatives and the second includes methods which lead to the formation of a phosphorus–carbon bond.

### 1. Oxidation of Arylphosphonous Acids and Their Derivatives

Apart from the oxidation of arylphosphonous acids and their salts, esters, amides, and chlorides, this Section also includes the reactions of α-chlorocarbonyl compounds with arylphosphonites. Arylphosphonous acids and their salts, esters, and amides are oxidised by oxygen,[3–5] hydrogen peroxide,[3,6] manganese dioxide,[7] calomel,[8] nitric acid,[9,10] and chlorine[11,12] to phosphonic acids and their derivatives. The reaction of the esters and ester imides of arylphosphonous acids with chloral leads to derivatives of arylphosphonic acids containing the dichlorovinyl group in the ester moiety in yields up to 79.5%:[13–15]

$$R^1C_6H_4P(OR^2)(XR^2) + OCHCCl_3 \rightarrow R^1C_6H_4(O)P(OCH{=}CCl_2)XR^2\ ;$$
$$R^1{=}H, Cl;\ R^2 = C_1\text{–}C_4\ \text{alkyl},\ (CH_2CH_2O)_2CH_3;\ X{=}O, NCH_3\ .$$

Various derivatives of chloroacetoacetic acid react similarly with arylphosphonites:[16]

$$R^1C_6H_4P(OR^2)_2 + R^2C(O)CHClCOOC_2H_5 \rightarrow$$
$$\rightarrow R^1C_6H_4(O)P(OCR^2{=}CHCOOC_2H_5)OR^2\ ;$$
$$R^1{=}H, CH_3, C_2H_5, N(CH_3)_2, N(CH_3)C_6H_5, NO_2;\ R^2 = C_1\text{–}C_4\ \text{alkyl}.$$

Aryldihalogenophosphines are oxidised by oxygen,[17–19] chlorine or bromine in t-butyl alcohol,[20] chlorine with subsequent treatment of the reaction mixture with sulphur dioxide,[21–26] acetals[27] or ketones,[28] chlorine in the presence of phosphorus pentoxide,[29–31] and sulphuryl chloride[29,32–35] with formation of arylphosphonic acid dichlorides in yields of 70–98%. Aryl dihalogenophosphines in the form of aluminium chloride complexes can be used in the oxidation reaction. In certain cases the oxidised complex is esterified with an excess of alcohol and then subjected to acid hydrolysis.[36–42]

The dichloride of phenylphosphonic acid is obtained also by the reaction of the thioanhydride of phenylphosphonothious acid with sulphuryl chloride[43] or by the successive treatment of phenylphosphonothioic dichloride (and also its mixture with phenylphosphonic acid) with chlorine and sulphur dioxide.[44,45]

### 2. Methods of Synthesis of Aryldihalogenophosphines

All the derivatives of arylphosphorous acids enumerated in the previous Section are usually obtained from aryldihalogenophosphines,[3] the main methods of synthesis of which are considered in this Section.

#### (a) Arylation of Phosphorus Halides by Aromatic Hydrocarbons

At a temperature above 550 °C benzene interacts with phosphorus pentachloride, the degree of conversion of which into dichlorophenylphosphine for a phosphorus pentachloride : benzene molar ratio of 1 : 14 reaches 8%.[19] Dichlorophenyl- and dichlorotolyl-phosphines are formed when benzene or toluene interacts with phosphorus trichloride at 500–600 °C.[46–52] The yield of dichlorophosphines reaches 70–99% when the reaction is carried out in the presence of

catalysts: oxygen,[53] alkyl halides,[54] phosgene,[55] or zeolites.[56–58] When anhydrous aluminium chloride is used as the catalyst, the phosphorylation temperature is reduced to 60–80 °C. Aryl dichlorophosphines with a small admixture of diarylchlorophosphines are obtained in the form of complexes with aluminium chloride:[36,59–61]

$$ArH + PCl_3 + AlCl_3 \rightarrow ArPCl_2 \cdot AlCl_3 + HCl \ .$$

Equimolar ratios of the aromatic hydrocarbon and aluminium chloride are usually employed with a not less than a threefold excess of phosphorus trichloride, because otherwise the amount of the diarylchlorophosphine impurity increases sharply. The reaction time varies from 1 to 8 h. After more prolonged refluxing (36 and more hours), the content of diarylchlorophosphines rises to 30% and more.[36]

Aryldichlorophosphines are isolated from the complex by treatment with phosphoryl chloride,[21,62–64] pyridine,[65,66] phosphoric acid, tri(2-chloroethyl)phosphate,[67–69] ethers and esters, ketones,[70] or the calculated amount of water.[64,71] After the decomposition of the complex, the aryldichlorophosphine is extracted with benzene,[67] petroleum ether,[9,64,72] or phosphorus trichloride[63,73] and is isolated by distillation.

The method is convenient in laboratory practice and has been tested on an experimental apparatus in the synthesis of dichlorophenyl- or dichloro-4-tolyl-phosphines.[74] It makes it possible to obtain aryldichlorophosphines containing one or several substituents in the ring. Thus, when phosphorus trichloride interacts with benzene, toluene, ethylbenzene, xylene, 1,2-diphenylethane, and diphenylmethane, dichlorophenyl-,[9,10,21,23,36,63–70,74–79] dichlorotolyl-,[21,40,73,74,80] dichloroethylphenyl-,[21,40,62,81,82] dichloroxylyl-,[77,78,80,81,83,84] dichloro(4-phenylethylphenyl)-,[80] and 4-benzylphenyldichloro-phosphines[80,85,86] are formed respectively. When biphenyl and bidenzofuran are used, the corresponding mono- and bis-dichlorophosphines are formed depending on the reactant ratio.[80,86–88]

When alkylbenzenes ($RC_6H_5$) are phosphorylated, the yield of aryldichlorophosphines ($RC_6H_4PCl_2$) diminishes with increase of the length of the alkyl group from 60–89% for $R = CH_3$ or $C_2H_5$ to 33–39% for $R = C_4H_9$.[21] The phosphorylation of monoalkylbenzenes always leads to a mixture of isomeric dichlorophosphines. For example, dichlorotolylphosphine is a mixture of the 4-, 3-, and 2-isomers in proportions of 63 : 27 : 10 and dichloroethylphenylphosphine is a mixture of the 4- and 3-isomers.[40,81] The methyl groups in the dichlorophosphine prepared from *p*-xylene are in the 2- and 5-positions,[81] while in the case of *o*-xylene the product is dichloro-3,4-dimethylphenylphosphine.[84] When trifluoromethanesulphonic acid is used instead of aluminium trichloride, the yield of dichloro-3,4-dimethylphenylphosphine is 33%.[89] The phosphorylation of pseudocumene and mesitylene leads to the formation of the corresponding dichlorophosphines in 45% yield,[90,91] while phosphorylation of the symmetrical tri-t-butylbenzene gives rise to the corresponding phosphines in 71% yield.[92] Alkylbenzenes containing a silicon atom in the side chain are phosphorylated to aryldichlorophosphines, the yield of the mixture of 4- and 2-isomers amounting to 32–52%:[93,94]

$$Cl_n(CH_3)_{3-n}Si(CH_2)_m C_6H_5 + PCl_3 \xrightarrow{AlCl_3} Cl_n(CH_3)_{3-n}Si(CH_2)_m C_6H_4PCl_2;$$
$$n, m = 1-3 \ .$$

Aryl halides are also phosphorylated: on being refluxed with phosphorus trichloride and aluminium chloride, fluorobenzene affords dichloro-4-fluorophenylphosphine in 45 to 65% yield,[24,95–97] while chlorobenzene gives rise to a mixture of the isomeric chlorophenyldichlorophosphines in yields up to 80%,[36,63,73,81,98–100] the 4-isomer predominating.[34,97,101] When bromobenzene is phosphorylated, the yield of 4-bromophenyldichlorophosphine varied from 14 to 51%, depending on the reaction conditions,[23,72,73,97] while the yield of the 2-bromoisomer is 41.5%.[32] 3-Chloro-4-tolyldichlorophosphine has been obtained from 2-chlorotoluene in 10–15% yield.[22]

After 1,2- and 1,4-dichlorobenzenes have been refluxed for a long time with phosphorus trichloride and aluminium chloride, the products are respectively 3,4- and 2,5-dichlorophenyldichlorophosphines which were identified in the form of arylphosphonic acids; the yield of products is then appreciably lower than in the case of chlorobenzene, while trichlorobenzenes do not undergo the phosphorylation reaction at all.[36]

The polyfluorobenzenes $C_6HF_4R$ with $R = NO_2$ and $CH_2SO_2$ do not undergo the phosphorylation reaction, the phosphorylation of derivatives with $R = OCH_3$ and $SCH_3$ is accompanied by the dissolution of the ester linkage, while compounds with R = H, F, or $CF_3$ produce dichlorophosphines in yields of 37–53%.[102]

The alkyl esters or thioethers of monohydric and dihydric phenols are phosphorylated by phosphorus trichloride in the presence of aluminium, iron, and zinc chlorides with formation of 4-alkoxyphenyldichlorophosphines in yields not exceeding 39%,[23,72,80,103–106] while in the presence of stannic chloride the yield is 26–91%:[107,108]

$$R^1R^2R^3C_6H_3 + PCl_3 \rightarrow R^1R^2R^3C_6H_2PCl_2$$
$$R^1 = H, C_1\text{–}C_4 \text{ alkyl}; \ R^2 = OR^1, SCH_3; \ R^3 = H, CH_3, OCH_3 \ .$$

When the dimethyl ether of resorcinal was phosphorylated in the presence of iron(III) chloride, dichloro-2,4-dimethoxyphenylphosphine was obtained in 27% yield,[109] when zinc chloride in a proportion not more than 0.06 mol per mole of the ether was used, the yield of the aryldichlorophosphine was 69%, while in the presence of an equimolar amount of zinc chloride only tris(2,4-dimethoxyphenyl)phosphine was formed in 14% yield.[35,103]

Diphenyl ether reacts with phosphorus trichloride and aluminium chloride, taken in molar proportions of 1 : 1 : 0.15, and gives rise to dichloro-4-phenoxyphenylphosphine in 13.7% yield.[110]

When 2,3-benzo-1,4-dioxan is heated with phosphorus trichloride and a catalytic amount of zinc chloride, the aromatic ring is phosphorylated in the *meta*-position, the yield of the corresponding dichlorophosphine being 50%.[111]

The phosphorylation of *NN*-dialkylanilines with phosphorus trichloride takes place in the absence of a catalyst, the yield of 4-*NN*-dialkylaminophenyldichlorophosphines amounting to 60–97%.[23,112,113] The presence of aluminium chloride reduces the yield to 36%.[8,114,115]

Aryldibromophosphines are obtained by heating aryldichlorophosphines with phosphorus tribromide or with gaseous hydrogen bromide.[97]

Dichlorophenylphosphine is obtained by heating a mixture of chlorodiphenyl- or triphenylphosphine with phosphorus trichloride to 350 °C.[116,117]

### (b) Arylation of Phosphorus Trihalides by Organometallic Compounds

Various aryldichlorophosphines have been synthesised by this method from diarylmercury;[3,8,48,80,118] for example, dichloro-2-tolylphosphine has been obtained in 78% yield:

$$Hg(C_6H_4R)_2 + 2PCl_3 \xrightarrow{130\text{–}230^\circ} 2RC_6H_4PCl_2 + HgCl_2 \ ;$$
$$R = H, Cl, CH_3, OCH_3, N(CH_3)_2 \ .$$

Dichlorophenyl-, dichloro-2-tolyl-, dichloro-4-tolyl-, and dichloro-4-ethylphenyl-phosphines have been obtained by heating phosphorus trichloride with the corresponding aryl–

zinc bromide (yields up to 32%) and 4-bromophenyldichlorophosphine has been obtained in a yield of 8%.[119,120] Dichloro-4-trifluoromethylphenylphosphine has been synthesised analogously.[25] When tetraphenyl-lead or tetraphenyl–tin is heated for a long time (180 h) with phosphorus trihalide, the yield of the dihalogenophenylphosphines reaches 93%,[121,122] while in the case where triphenyl–antimony and bismuth are used the yield is much lower.[123,124]

Aryldichlorophosphines, aminoarylchlorophosphines, and arylphosphonous acid amides have been obtained in yields of 32–85% by the reaction of arylmagnesium bromides with phosphorus trichloride.[102,125–127] On treatment with hydrogen chloride, the amides of arylphosphorous acids are readily converted into aryldichlorophosphines:[128]

$$(R^1_2N)_n PCl_{3-n} + ArMgBr \rightarrow (R^1_2N)_2 P(Ar) Cl_{2-n} \xrightarrow{HCl} ArPCl_2 ;$$

$R^1 = CH_3, C_2H_5$; $Ar = 2\text{-}BrC_6H_4CH_2C_6H_5$, 2-, 3- or 4-$FC_6H_4$, 4-$R^2C_6F_4$; $R^2 = H, F, Cl, CF_3, OCH_3$; $n = 0-2$ .

*o*-Phenylenebis(tetramethyldiaminophosphine) has been obtained in 84% yield by the reaction of (tetramethyldiamino)-2-lithiophenylphosphine with chloro(tetramethyldiamino)phosphine; on treatment with hydrogen chloride, the product is converted into *o*-phenylenebis(dichlorophosphine).[129]

Arylchlorosilanes are also used in the synthesis of dichlorophosphines. The reaction takes place only in the presence of aluminium chloride, which cleaves the silicon–carbon bond under mild conditions with formation of the corresponding organoaluminium compounds. The latter react with phosphorus trichloride and afford aryldichlorophosphines in yields of 77–85%:[130,131,132]

$$(R_nC_6H_{5-n})_mSiCl_{4-m} + mAlCl_3 + mPCl_3 \rightarrow mR_nC_6H_{5-n}PCl_2 \cdot AlCl_3 ;$$

$R = H, Cl, Br, C_1$–$C_4$ alkyl; $n = 0-5$; $m = 1-4$ .

### (c) Arylation of White Phosphorus by Aryl Halides

Aryl halides arylate white phosphorus at 250–450 °C in the presence of catalytic amounts of Lewis acids,[133–135] metal powders (Cu, Ag, and Zn),[136,137] or in the absence of a catalyst[138–140] with formation of a mixture of aryldihalogeno- and diarylhalogenophosphines, with the former predominating:

$$3R_nC_6H_{5-n}Hal + {}^1/_2P_4 \rightarrow R_nC_6H_{5-n}PHal_2 + (R_nC_6H_{5-n})_2PHal ;$$

$R = H, Cl, CH_3$; $Hal = Cl, Br$; $n = 1, 2$ .

When the reaction is carried out in phosphorus trihalide, the yield of aryldihalogenophosphines increases greatly, particularly in the presence of catalysts—sulphur, iodine, and halogeno-compounds. Thus dichlorophenylphosphine is obtained in 90% yield,[141–143] dibromo-2-tolylphosphine in 50.21% yield, and dichloro-4-fluorophenylphosphine in 73% yield.[144] Dichloro-2,4,5-trichlorophenylphosphine has been isolated in the form of a phosphonous acid in 57% yield.[145] The interaction of 1,4-dichlorobenzene with white phosphorus and $PCl_3$ leads to a mixture of 4-chlorophenyldichlorophosphine (I) and 1,4-bis(dichlorophosphino)benzene (II):

$$1,4\text{-}Cl_2C_6H_4 + {}^1/_2P_4 + 2PCl_3 \xrightarrow{I_2} \underset{(I)}{4\text{-}ClC_6H_4PCl_2} + \underset{(II)}{1,4\text{-}(Cl_2P)_2C_6H_4} .$$

The main reaction products are compound (I) at 290–300 °C and compound (II), in 38.4% yield, at 340 °C. Compound (I) is also converted into compound (II) on heating with white phosphorus and phosphorus dichloride, the yield being 24.7%.[146,147]

### (d) Other Methods

Aryldichlorophosphines are obtained when complexes synthesised from arenediazonium fluoroborates and phosphorus trichloride are reduced with magnesium or aluminium:[148–155]

$$RC_6H_4\overset{+}{N}_2BF_4^- \xrightarrow{PCl_3} RC_6H_4\overset{+}{P}Cl_3BF_4^- \xrightarrow{M} RC_6H_4PCl_2 ;$$

R=4-$CH_3$, 2-$C_6H_5CH_2$, 2-, 3- or 4-Cl, 3-Br, 2-$CH_3O$, 2-(4-$ClC_6H_4S$), 3- or 4-$COOC_2H_5$, 3- or 4-CN; M=Mg, Al .

The reaction is exothermic, but can be readily controlled.

Arylhydrazines and their hydrochlorides give rise to aryldichlorophosphines in 45–65% yield on refluxing with phosphorus pentachloride in benzene:[156]

$$4\text{-}RC_6H_4NHNH_2 + PCl_5 \rightarrow 4\text{-}RC_6H_4PCl_2 + N_2 + 3HCl ;$$

R=$CH_3$, Cl, Br .

Dihalogenophenylphosphines are formed in 8.5–11.5% yields when a mixture of iodobenzene, phosphorus trihalide, and powdered silver is irradiated with UV light.[157]

Thus aryldichlorophosphines are usually obtained by the Friedel–Crafts reaction, which has in fact been more thoroughly investigated than other methods. The reaction is simple to carry out, the initial rectants are readily available, and the dichlorophosphines are obtained in satisfactory yields. Significant disadvantages of the method are the formation of a mixture of the 2-, 3-, and 4-isomers of aryldichlorophosphines, which are difficult to separate, a large amount of industrial waste,† and a limited selection of substituents in the aromatic ring.

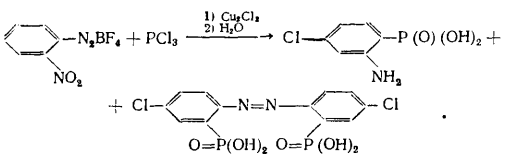
## 3. Arylation of Phosphorus Trihalides by Arenediazonium Fluoroborates

A large number of different arylphosphonic acids have been synthesised by this method, although the first attempts to employ arenediazonium salts for the synthesis of arylphosphonic acids were unsuccessful.[23,110,158,159] Later arylphosphonic acids were synthesised by the reactions of fluoroborates with phosphorus trichloride in the presence of powdered copper bronze or univalent copper halides:

$$Ar\overset{+}{N}_2BF_4^- + PCl_3 \xrightarrow{Cu \text{ or } Cu_2Cl_2} Ar\overset{+}{P}Cl_3BF_4^- \xrightarrow{H_2O} ArPO_3H_2 .$$

The reaction is carried out in an anhydrous organic solvent, mainly ethyl and isopropyl acetate or dioxan, at room temperature of 50–60 °C. The reactants are taken in equimolar proportions. Phosphorus tribromide is rarely used.[160–164] Apart from arenediazonium fluoroborates, the diazonium chlorozincate and fluorosilicate salts are used. It has been noted that diazonium fluorosilicates are more stable and more convenient to handle.[164] The required compounds are isolated from concentrated aqueous solutions in the form of monosodium (monopotassium) salts of the free acids and are purified by recrystallisation, usually from 6 *N* HCl. The yields of arylphosphonic acids normally vary in the range 10–50% and rarely exceed 70%. Diarylphosphinic acids are formed as side products in yields up to 15%.

Phenylphosphonic acid is formed from benzenediazonium fluoroborate and phosphorus trichloride in 17% yield.[161] 3- and 4-Tolylphosphonic acids have been prepared in yields of 69.8 and 60% respectively[165] and all the isomers of ethylphenylphosphonic acid have been obtained in yields of 11–18%.[166] 4-(β-Bromoethyl)phenylphosphonic and



† Between 2.2 and 2.5 kg of solid waste and resins are obtained per kilogram of aryldichlorophosphine.[74]

4-(t-butyl)phenylphosphonic acids have been synthesised in yields of 36%[167] and 55%[39] respectively, while 2- and 4-biphenylylphosphonic acids have been obtained in yields of 9 and 40%.[168] (2,5-Diphenyl)phenylphosphonic acid is formed in 17% yield.[169]

Almost all the possible isomeric monohalogenophenylphosphonic acids, other than 3-bromo- and 4-iodo-substituted derivatives, have been synthesised in yields of 20–60%. They have been identified in a free state, with the exception of the 4-fluoro-derivative, which has been isolated in the form of the 4-toluidine salt. Iodobenzenediazonium salts react with phosphorus halides with greater difficulty and the yields of iodophenylphosphonic acids do not exceed 22%.[161,163,164,170–174]

When benzene-1,3- and benzene-1,4-disdiazonium fluoroborates are treated with phosphorus trichloride, only one diazo-group is phosphorylated, while the second is substituted by chlorine and partly by fluorine.[175] Di- and trihalogenobenzenediazonium fluoroborates react with phosphorus trichloride and tribromide under the same conditions to form di- and tri-halogenophenylphosphonic acids in yields up to 32%.[163,173] The isomeric 2-chloro-5-methyl-, 3-chloro-4-methyl-, and 4-chloro-3-methyl-phosphonic acids have also been obtained by this method in yields of 36, 50, and 15% respectively.[162,176]

3(4)-Nitrophenyl- and 4(5)-nitro-2(3)-tolyl-phosphonic acids are obtained by the diazo-method in yields of 37 to 55%.[161,164,174,177] 2-Nitrophenyl- and dinitrophenyl-phosphonic acids could not be obtained by this method.[161,170] The interaction of 2-nitrobenzenediazonium fluoroborate with phosphorus trichloride is accompanied not only by the substitution of the diazo-group by the dichlorophosphonyl group but also by the reduction of the nitro-group to the amino-group and by the chlorination of the aromatic ring. 2-Amino-4-chlorophenylphosphonic acid and 4,4′-dichloro-2,2′-diphosphonoazobenzene were isolated in low yields from the reaction mixture:[178]

The catalyst is used in an equivalent amount and the $ArN_2BF_4$ : $PCl_3$ ratio is 1 : 3.5. In the presence of a smaller excess of the phosphorus halide, the yield of the arylphosphonic acid is appreciably reduced. Chloroaminophenylphosphonic acid is isolated from its complex with a copper salt on treatment with hydrochloric acid in a yield up to 15%.[179–181] The phosphorylation of monohalogeno-derivatives of 2-nitrobenzenediazonium fluoroborates proceeds without the halogenation of the aromatic ring but with reduction of the nitro-group regardless of the position of the halogen atom.[182] The use of reductants, for example, of powdered iron in hydrochloric acid, makes it possible to raise the yield of 2-amino-4-halogenophenylphosphonic acids to 33%.[182] 2-Hydroxyphenylphosphonic acid cannot be synthesised by this method; only the products of its coupling with 4-nitrobenzenediazonium chloride were isolated from the reaction mixture in a small amount.[179,183]

Alkoxyphenyl-, benzyloxyphenyl-, 3,4-di(hydroxymethyl)-phenyl-, and alkylthiophenyl-phosphonic acids have been synthesised from the corresponding diazonium salts and phosphorus trichloride in yields of 18–61%[173,174,184,185] and 2-phenoxyphenylphosphonic acid has been obtained in 63% yield.[186]

Arylphosphonic acids containing the carbonyl, sulphonamido-, and cyano-substituents, which are difficult to obtain by other methods, can be synthesised by the diazo-method in yields of 27–50%.[161,173,187]

Thus 2-carboxyphenylphosphonic acid has been obtained from the diazonium salt of anthranilic acid and phosphorus trichloride in one stage in a yield of 37%; previously its synthesis involved several stages.[173] The corresponding arylphosphonic acids have been synthesised in yields of 12–44% by this procedure from arenediazonium salts containing several different functional groups in the ring—one or two halogen (F, Cl, Br) atoms and the nitro-group,[163,173,184,188] a chlorine atom and the hydroxy-group[183] or the methoxy-group,[186] and the nitro and methoxy- or carboxy-groups.[173,177] For example, 2-methoxy-4-nitrophenylphosphonic acid has been obtained in 31% yield and used to synthesise 4-amino-2-hydroxyphenylphosphonic acid—the phosphorus analogue of 4-amino-salicyclic acid.[173]

It follows from the foregoing that the diazotisation method is simple to carry out and makes it possible to obtain arylphosphonic acids with a wide range of substituents in the aromatic ring, which are either difficult to obtain or cannot be obtained at all by other procedures. The disadvantages of the method include a comparatively low yield of the required substances, which rarely exceeds 50%, and its unsuitability for the synthesis of 2-nitro- and 2-hydroxy-phenylphosphonic acids as well as a number of other substituted arylphosphonic acids.

### 4. Arylation of Phosphorus Pentoxide and Pentasulphide

Aromatic compounds with hydroxy-, amino-, nitro-, and other groups which can undergo any kind of changes under the conditions of the synthesis are used as arylating agents in this procedure. The reaction is carried out in an autoclave at 150–225 °C using phosphorus pentasulphide and at 250–325 °C with phosphorus pentoxide, the reaction time being 5–25 h. The aromatic compound is taken in a large excess. The reaction products are hydrolysed with water to arylphosphonic acids. Thus, when anisole and phosphorus pentasulphide were used, 4-methoxyphenylphosphonic acid was obtained in 80% yield:[189–195]

$$RC_6H_5 + P_4X_{10} \xrightarrow{1)\,\Delta\ 2)\,H_2O,\,\Delta} RC_6H_4P(O)(OH)_2\ ;$$

R=H, $CH_3$, Cl, $OCH_3$, $OC_2H_5$; X=O, S .

The reaction proceeds with the preliminary dissociation of one bond in the hexagonal form of the phosphorus pentachalcogenide and the formation of a biradical or a dipolar ion, which then reacts with the aromatic compound to form the polymeric anhydrides of arylphosphonic or arylphosphonothioic acids.[189] Treatment of the anhydrides, thioanhydrides, and mixed thioanhydrides of the arylphosphonic acids with sulphuryl chloride, phosphorus pentachloride, or chlorine and then with sulphur dioxide leads to the dichlorides of arylphosphonic acids.[189,194,196–198] The latter can also be obtained by heating the aryl halides 4-$RC_6H_4Hal$ (R = H, $C_1$–$C_4$ alkyl or Cl and Hal = Cl, Br) directly with phosphorus pentoxide and phosphorus trihalide at 200–450 °C.[199]

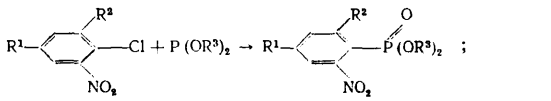
When tetra-aryloxysilanes and triphenyl borate react with phosphorus pentasulphide, compounds (III) are formed and are then hydrolysed with water to hydroxyarylphosphonic acid in yields up to 40%:[200,201]

$$(RC_6H_4O)_nZ + P_4S_{10} \xrightarrow{170^\circ} \left\{\left[-S-\overset{\overset{S}{\|}}{\underset{|}{P}}(R)\,C_6H_3O\right]_nZ\right\}_2 \xrightarrow{H_2O,\,\Delta}$$

(III)

$$\rightarrow 4\text{-}HO(R)\,C_6H_3PO_3H_2\ ;$$

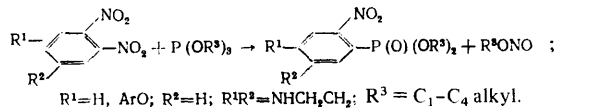
R=H, 3-$CH_3$; $n=3$, Z=B; $n=4$, Z=Si .



As a result of limitations in the choice of substituents in the benzene ring and preparative difficulties, the above procedure has not received extensive recognition.

### 5. Arylation of Phosphite Esters by Aryl Halides

This Section describes the methods of synthesis of neutral esters of arylphosphonic acids with different substituents in the ring by arylating the esters of phosphorous acids by aromatic halides or nitro-compounds.



#### (a) Arylation without Initiators

4-Substituted tetrafluorophenylphosphonates have been obtained in 25–30% yields by the prolonged (16 h) heating (to 150 °C) in an autoclave of substituted pentafluorobenzenes ($RC_6F_5$, where R = H, $CF_3$, CN, $NO_2$, or $C_6F_5$) and triethyl phosphite.[202,203] When nitro-groups are present in the benzene ring in addition to the halogen atom, the reaction takes place at low temperatures (60–120 °C) with retention of the nitro-group and yields of the phosphonate up to 95%:[204–208]

$R^1$=H, $CF_3$, Cl, CN, $NO_2$, $C_2H_5SO_2$, $CH_3COO$; $R^2$=H, Cl, $NO_2$; $R^3 = C_1$–$C_4$ alkyl.

*o*-Dinitrobenzenes without a halogen arylate trialkyl phosphites in acetonitrile with formation of *o*-nitrophenylphosphonate in yields of 50–80%:[209–214]

$R^1$=H, ArO; $R^2$=H; $R^1R^2$=$NHCH_2CH_2$; $R^3 = C_1$–$C_4$ alkyl.

The nitro-group in 5(6)-nitrobenzimidazole is readily substituted by the phosphoryl group on heating with dialkyl phosphites.[215]

#### (b) Arylation in the Presence of Catalysts

Various arylphosphonates have been obtained in yields up to 90% by heating dialkyl phosphites[216–219] or trialkyl phosphites[220–234] with aryl halides in the presence of catalysts:

$$(R^1O)_2PONa + R^2Hal \xrightarrow{CuI} R^2P(O)(OR^1)_2 ;$$

$R^1$=$C_2H_5$, $C_6H_5$; $R^2$=$C_6H_5$, 4-$CH_3C_6H_4$, 4-$NH_2C_6H_4$, 2,4,6-$(CH_3)_3C_6H_2$, $(CH_3)_5C_6$; Hal=Br, I .

The best catalysts are nickel halides, used in an amount of 0.1–20 mole %,[220–225] and palladium chloride or acetate—0.01 0.01–0.05 mole %.[228,229] Copper bronze and copper(I) chloride give poorer results even when a threeefold excess of the phosphite is employed,[230,231] while alkylation in the presence of copper(I) iodide or copper acetate proceeds at comparatively low temperatures (0–115 °C) in a solvent, the yield of the phosphonates reaching 85%.[216,217,232–234] A complex of palladium halide with triphenylphosphine is also used as the catalyst.[218,219]

On heating to 250–340 °C in the presence of catalytic amounts of iodobenzene and nickel or copper halides, triphenyl phospite isomerises to diphenyl phenylphosphonate in yields up to 90%. In the presence of iron(III) chloride, less satisfactory results were obtained.[226]

The interaction of the sodium salts of dialkyl or diaryl phosphites with aryl halides takes place in the presence of copper(I) iodide or magnesium iodide. The yields of the arylphosphonates are 54–81%:[227,235]

$$R^1_nC_6H_{5-n}Hal + R^2OP(OR^3)_2 \rightarrow R^1_nC_6H_{5-n}P(O)(OR^3)_2 + R^2Hal ;$$

$n$=1, $R^1$=H, Cl, F, $CH_3$, $C_{12}H_{25}$, OH, $OCH_3$, $OC_6H_5$, $SCH_3$, $COCH_3$, $COOCH_3$, $COOC_2H_5$, $N(CH_3)_2$, $CH_2NH_2$, $NO_2$, CN; $n$ = 3, $R^1$=H, $CH_3$, $(CH_3)_3C$, OH, $NH_2$, $HNCOCH_3$, $N(C_2H_5)_2$, N=$NC_6H_3(R^1)N(C_2H_5)_2$; $R^2$=H, $R^3$; $R^3$=$CH_3$, $C_2H_5$, *изо*-$C_3H_7$; $R^1$=H, $CH_3$, $C_2H_5$, $NO_2$; Hal=Cl, Br, I.

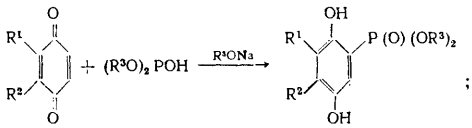
#### (c) Arylation under Ultraviolet Irradiation

When a mixture of an aryl halide with a three-fivefold excess of trimethyl or triethyl phosphite is irradiated for a long time, dialkyl arylphosphonates are formed in a satisfactory yield. The optimum reaction temperature ranges from −5° to −25 °C. Aryl iodides or bromides are best as arylating agents. The dimethyl esters of phenyl-, tolyl-, and xylyl-phosphonic acids are obtained in yields of 50 to 100%. When triethyl phosphite is arylated, a more prolonged irradiation is required than in the arylation of trimethyl phosphite; with increase of the length of the group R in the phosphites $(RO_3)P$, the yield of aryl phosphonates is sharply reduced. Thus when tri-isopropyl phosphite and iodobenzene are used, the yield of di-isopropyl phenylphosphonate is only 26%.[236–242]

The reaction of dihalogenobenzenes and trimethyl phosphite affords dimethylhalogenophenyl phosphonates, the best yields (39–92%) having been achieved using 1,3- and 1,4-isomers and a combination of halogens: I and Cl or Br; Br and F. The side products of the reaction are phenylenediphosphonates, whose yield depends on the nature and positions of the halogen atoms in the dihalogenobenzene, reaching 87% when 1,2-bromoiodobenzene is employed and 10–39% in the case of the 1,3- and 1,4-isomers.[239,240] Pentafluoro- and pentachloro-pyridines interact with the lowest phosphites to form tetrahalogenopyridylphosphonates.[241]

Various isomers of methoxy- and dimethoxy-phenylphosphonic acids,[238,242,243] hydroxyphenylphosphonic acid,[238,242] aminophenylphosphonic acid,[244] formylphenylphosphonic acid,[243] and ethoxycarbonylphenylphosphonic acid[245] have been obtained by the reaction of substituted iodobenzenes with lower trialkyl phosphites in 34–92% yields. This method proved to be unsuitable for the synthesis of nitrophenylphosphonates because of the occurrence of oxidation-reduction processes in the interaction of nitrobenzene with phosphites.[238]

The sodium or potassium salts of dialkyl phosphites and *NNN'N'*-tetra-alkylphosphorodiamidous acids interact with aryl bromides or, better, iodides in liquid ammonia on irradiation with UV light with formation of phosphonates in 87–96% yield. Without illumination, the yield of the required compound is very low (0–7%):[246–252]

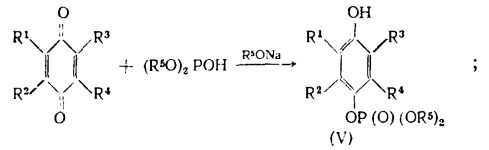


$$R^1_nC_6H_{5-n}Hal + MOPR^2_2 \rightarrow R^1_nC_6H_{5-n}P(O)R^2_2 ;$$

$n$=1, $R^1$=H, $CH_3$, $CF_3$, F, Cl, Br, I, OH, $NH_2$, $CONH_2$, $OCH_3$, $COOC_2H_5$; $n$=2, $R^1$=$CH_3$; $R^2$=$OCH_3$, $OC_2H_5$, $N(CH_3)_2$; Hal=Cl, Br; M=K, Na .

Under the same conditions, 1,3-dibromo- and 1,3-chloroiodobenzenes react with alkali metal salts of dialkyl phosphites, forming preferentially the tetra-alkyl esters of 1,3-phenylenebisphosphonic acids.[253,254] Instead of liquid ammonia, it is also possible to use other solvents (dimethyl sulphoxide, dimethyl formamide, t-butyl alcohol, and acetonitrile).[255]

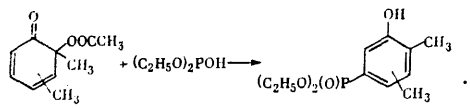
### 6. Other Methods



In the first communication[256] on the interaction of *p*-quinones with dialkyl phosphites in the presence of bases, it was suggested that the reaction product has the phosphonate structure (IV):

(IV)

$R^1=R^2=H$; $R^1R^2=(CH)_4$; $R^3 = C_1$-$C_{20}$ alkyl.



In subsequent studies[257–261] evidence was obtained showing that the product of this reaction is the phosphate (V):

(V)

$R^1=R^2=R^3=R^4=H$, Cl; $R^1=R^2=H$; $R^3R^4=(CH)_4$; $R^5=CH_3$, $C_2H_5$ .

The interaction of dimethyl phosphite with *p*-benzoquinone, which leads to the formation of a mixture of 55% of the phosphonate (IV, $R^1 = R^2 = H$, $R^3 = CH_3$), 10% of the phosphate (V, $R^1 = R^2 = R^3 = H$, $R^5 = CH_3$), and 8% of the bisphosphonate [IV, $R^1 = H$, $R^2 = P(O)(OCH_3)_2$] was later described.[262] The interaction of *p*-benzoquinone-bisbenzenesulphonyl imide with lower dialkyl phosphites also leads to a mixture of a phosphonate and a phosphoramidate whose ratio varies with the reaction conditions.[263] 3-Hydroxyarylphosphonates have been obtained in yields up to 40% by the reaction of substituted 2-acetoxy-2-methylcyclohexa-3,5-dienones with diethyl phosphite:[264]

In the study of the interaction of *p*-quinones with lower trialkyl phosphites, different workers also obtained contradictory data. Thus it has been claimed[265,266] that the products of this reaction are 2-alkoxy-5-hydroxyphenylphosphonates, in other investigations[267–269] the products were believed to be 4-alkoxyphenyl phosphates, while in yet another study[270] they were said to be 4-alkoxyphenyl phosphates with an admixture of 2,5-dihydroxyphenylphosphonate (up to 2%). The reaction of triethyl phosphite with benzoquinone and hydrogen chloride in ether at −70 °C leads to a 1:1 mixture of the phosphate and phosphonate.[271]

When aryl 4-bromophenyl sulphides or aryl 4-bromophenyl ethers are heated with equimolar amounts of phosphorus trichloride and aluminium chloride with subsequent alkaline hydrolysis, the phosphonic acids $ArXC_6H_4PO_3H_2$-4 are formed in 75–90% yields for X = O and 12.5–67% yields for X = S and Ar = $C_6H_4R^2$-4; $R^2 = CH_3$, F, Cl, or Br.[148,149]

The electrochemical oxidation of a mixture of trialkyl phosphite and an 18–25-fold excess of an aromatic hydrocarbon in acetonitrile at room temperature results in the formation of dialkyl arylphosphonates in 14–66% yields:[272–276]

$$(R^1O)_3P + R^2_nC_6H_{6-n} \rightarrow (R^1O)_2P(O)C_6H_{5-n}R^2_n ;$$

$R^1 = C_1$-$C_3$ alkyl; $R^2 = H$ or $C_1$-$C_4$ alkyl; $n = 1, 2$.

When benzene or chlorobenzene was heated with phosphorus trichloride and benzoyl peroxide, the dichlorides of phenyl- and chlorophenylphosphonic acids were obtained respectively.[277] The interaction of dialkyl phosphites with benzoyl peroxide leads to the formation of 4-carboxyphenyl phosphonates in 55% yield.[278,279] In the presence of t-butyl peroxide, dialkyl phosphites react with aromatic hydrocarbons. After the acid hydrolysis of the reaction products, aryl phosphoric acids are obtained in yields up to 65%:[280,281]

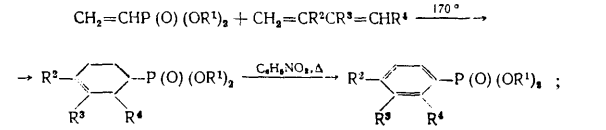
$$R^1C_6H_4R^2 + (R^3O)_2POH \xrightarrow[1,\ \Delta\ 2)\ HCl]{[(CH_3)_3CO]_2} R^1(R^2)C_6H_3P(O)(OH)_2 ;$$

$R^1$=H, $CH_3$, $CH_3O$, Br, $CH_3OOC$; $R^2$=H, $CH_3$; $R^1R^2=(CH)_4$; $R^3=CH_3$, $C_2H_5$.

In the presence of strong bases, for example, lithium di-isopropylamide, dialkyl phenyl phosphate rearranges to 2-hydroxyphenylphosphonate in yields up to 98%.[282] The diethyl esters, ester-amides, and diamides of arylphosphonic acids, containing various substituents have been synthesised by the reaction of aryl-lithium or arylmagnesium halides with dialkyl phosphorochloridates in yields of 5.7–65.4%[225,243,289–293] and with phosphorodiamidic chlorides in yields of 18–75.2%.[290,291] 2,5-Dichlorophenyl (*N*-isopropyl)phenylphosphonamidate has been obtained in 26.6% yield.[292] The reaction is carried out in absolute ether or tetrahydrofuran:

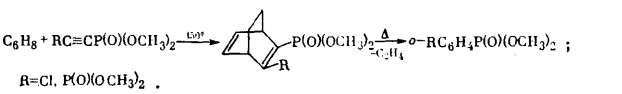
$$R^1_2P(O)Cl + R^2_nC_6H_{5-n}M \rightarrow R^1_2P(O)C_6H_{5-n}R^2_n ;$$

$R^1$=$CH_3O$, $C_2H_5O$, $NHC_6H_5$, $NC_5H_{10}$; $R^2$=H, $CH_3$, $CH_3O$, Cl, Br, $C_6H_5$, $(CH_3)_3SiCH_2$, $(CH_3)_3Si$, $C_4H_9SCH_2$; $n = 1, 2$:
M=Li, MgCl, MgBr .



Bisphosphorylated siloxanes have been obtained in this way from diphenyl phosphorochloridate in siloxanes containing two phenylmagnesium bromide groups at different silicon atoms:[293,294]

$R^1=C_6H_5$; $R^2=CH_3$; $n$=0, 4, 10, 20 .



Tetraphenyl-lead or tetraphenyl–tin arylate phosphoryl chloride on prolonged (130–180 h) heating (to 180 °C) with formation of phenylphosphonic dichloride in yields up to 58%.[121,122]

The diene synthesis reaction is sometimes used to obtain the esters of arylphosphonic acids. Thus arylphosphonates have been obtained in yields up to 68% from diethyl vinylphosphonate and substituted butadienes with subsequent dehydrogenation of the reaction products.[295]

$R^1=C_2H_5$; $R^2$, $R^3$=H, $CH_3$; $R^4=R^2$, $CH_3O$ .

2-Substituted dimethyl arylphosphonates are obtained from cyclohexadiene and dimethyl chloroethynylphosphonate or tetramethyl ethynylenediphosphonate. The reaction involves the formation of a bicyclic phosphonate which splits off ethylene at a high temperature and affords the aryl phosphonate:[296]

R=Cl, $P(O)(OCH_3)_2$ .

2,5-Diphenylphenylphosphonic acid is obtained from maleic anhydride and 3-(2,5-diphenylfuryl)phenylphosphonic acid in 10–15% yield.[170] Dialkyl 5-acyl-2-isopropyl-4-methylphenylphosphonate has been obtained by heating dialkyl 3,3-dimethyl-1-vinylallenylphosphonate and acetylacetone in the presence of sodium ethoxide.[297]

## III. METHODS OF SYNTHESIS OF ARYLPHOSPHONOTHIOIC ACIDS AND THEIR DERIVATIVES

Few methods are available for the synthesis of arylphosphonothioic acids and their derivatives and the choice of substituents in the aromatic ring (namely alkyl, alkoxy-, or halogeno-groups) is limited.

The dichlorides of arylphosphonothioic acids $R_nC_6H_{5-n}\cdot P(S)Cl_2$ ($R = C_1-C_{30}$ alkyl, F, Cl, Br, or $CF_3$ and $n = 1$ or 2) are obtained by adding sulphur to the aluminium chloride complex of an aryldichlorophosphine[95,298-300] or to free aryldihalogenophosphines in the presence of catalytic amounts of aluminium chloride[25,301] and ammonium or phosphonium salts.[302]

Successive treatment of dichlorophenyl- or chlorophenyldichlorophosphines with sulphur monochloride and sulphur dioxide or phosphorus pentoxide yields a mixture of the dichlorides of the corresponding arylphosphonic and arylphosphonothioic acids with the latter predominating.[303] On heating with thiophosphoryl chloride, 4-chlorophenyldichlorophosphine is converted into the dichloride of 4-chlorophenylphosphonothioic acid in 93.1% yield.[304] The esters, amides, and anhydrides of arylphosphonothioic acids are obtained by adding sulphur to the corresponding derivatives of arylphosphonous acids in yields up to 90%[5,34,43,104,304-306] or by oxidising the esters of arylphosphonothious acids with hydrogen peroxide.[305] The dihalides of arylphosphonothioic acids are obtained in yields of 10–79% on heating thiophosphoryl halide and an aromatic hydrocarbon with aluminium and aluminium chloride[307-311] or by heating an aromatic hydrocarbon with aluminium chloride, phosphorus trihalide, and phosphorus pentasulphide:[309,310,312-316]

$$RC_6H_5 + PSHal_3 \xrightarrow{AlCl_3,\ \Delta} RC_6H_4P(S)Hal_2 ;$$
$$R=H,\ CH_3,\ F,\ Cl;\ Hal=Cl,\ Br .$$

When aluminium chloride is used, the $PSHal_3 : AlCl_3 : ArH$ reactant molar ratios are 1:2–2.5:1–1.1. The side products are the halides of diarylphosphinothioic acids and triarylphosphine sulphides, whose amount increases with increase of the reaction time as the reactant ratio is altered. Thus, after the reactant mixture had been refluxed for 4 h, the above two impurities were isolated in yields of 30 and 70% ($Ar = C_6H_{13}C_6H_4$).[315,316]

The phosphorylation of aromatic hydrocarbons by thiophosphoryl halides[317-320] or by a mixture of phosphorus trihalide and sulphur[321] as well as the phosphorylation of aryl halides by phosphorus sulphide ($P_4S_3$) [322] or mixtures of phosphorus sulphide ($P_4S_{10}$) with phosphorus trihalides[199,323] containing red phosphorus,[324] thiophosphoryl halides,[325] or thiophosphoryl halides and red phosphorus[326] as additives leads to the formation of the dihalides of arylphosphonothioic acids $RnC_6H_{5-n}P(S)Hal_2$ ($R = H$, $C_1-C_4$ alkyl, F, or Cl; $n = 1$ or 2; Hal = Cl or Br). The same products have been obtained by phosphorylating aryl halides with a mixture of thiophosphoryl halide with white or red phosphorus[327,328] or a mixture of phosphorus trihalide with phosphorus and sulphur.[329] The yield of the products is 35–87%. All these reactions take place at 200–450 °C. The reaction temperature falls following the addition of iodine, metal iodides, and alkyl iodides in an amount equivalent to 0.01–0.1% of the weights of the reaction mass.[323,327] The phosphorylation of toluene affords a mixture containing equal amounts of the dihalides of 4-tolylphosphonothioic and benzylphosphonothioic acids.[317-319]

The tetrachlorides of 1,4-arylenebis(phosphonothioic) acids are formed in 60–66% yield when 1,4-dichlorobenzene is heated with phosphorus trichloride and pentasulphide or with thiophosphoryl chloride and white phosphorus.[323,324,327,329]

The dihalides of arylphosphonothioic acids are obtained in 30–91.2% yields when an excess of phosphorus trihalide is heated with di- and tri-aryl phosphorothioites,[330-332] triaryl phosphorotetrathioates,[333] and diaryl sulphides[334,335] and disulphides[336] at 250–600 °C in the presence of catalytic amounts of halogens, halogeno-containing heterocarbons, metal halides, or without a catalyst. The halides of diarylphosphinothioic acids are formed as side products. For example:

$$(R_nC_6H_{5-n}S)_3P + PHal_3 \xrightarrow{\Delta} R_nC_6H_{5-n}P(S)Hal_2 + (R_nC_6H_{5-n})_2P(S)Hal ;$$
$$n=1,\ R=CH_3,\ (CH_3)_3C,\ C_9H_{19};\ n=2,\ R=Hal;\ Hal=Cl,\ Br ;$$

$$(R_nC_6H_{5-n})_2S + PHal_3 \xrightarrow{\Delta} R_nC_6H_{5-n}P(S)Hal_2 + (R_nC_6H^{5-n}_2)P(S)Hal ;$$
$$R=CH_3,\ C_2H_5;\ n=1-3;\ Hal=F,\ Cl,\ Br .$$

A mixture of phosphorus trihalide with white phosphorus[337,338] or with thiophosphoryl halide and phosphorus sulphides (of the type $P_4S_n$, where $n = 3$, 5, 7, or 10) has been introduced into the reaction with diaryl sulphides and disulphides.[339] The dichlorides of arylphosphonothioic acids are also formed in 65–90% yield when phosphorus trichloride is heated with arenethiols at 250–320 °C, but this requires the preliminary refluxing of the mixture of the initial reactants at atmospheric pressure:[340]

$$R_nC_6H_{5-n}SH + PCl_3 \rightarrow R_nC_6H_{5-n}P(S)Cl_2 ;$$
$$R=H,\ Cl,\ (CH_3)_3C;\ n=1-5 .$$

The thioanhydrides of arylphosphonothioic acids are obtained in 53.2–99% yield when a tenfold excess of *o*-xylene, anisole, and phenetole is heated with phosphorus pentasulphide[191,194,201,341,342] or with a mixture of phosphorus (white or red) and sulphur:[343-345]

$$R_nC_6H_{6-n} + P_4S_{10} \xrightarrow{150-170^\circ C} (R_nC_6H_{5-n}PS_2)_2 ;$$
$$n=1,\ R=CH_3O,\ C_2H_5O;\ n=2,\ R=CH_3 .$$

The dihalides of arylphosphonothioic acids are formed in 73–90% yield when the thioanhydrides of arylphosphonothioic and arylphosphonothious acids are treated with halogens and phosphorus pentachloride.[43,194,198]

On heating with thiophosphoryl halide, phosphorus pentasulphide,[346,347] white phosphorus, and sulphur,[348] the dihalides of arylphosphonic acids are converted into the dihalides of arylphosphonothioic acids.

The ester-halides of arylphosphonodithioic acids are formed when aryldihalogenophosphines react with sulphenyl chloride and hydrogen sulphide:[349,350]

$$ArPHal_2 \xrightarrow[2)\ H_2S]{1)\ ClSCH_2CH_2OR} ArP(S)(SCH_2CH_2OR)Hal .$$

They are also formed when the above compounds are heated with sulphenyl chloride in liquid sulphur dioxide or glacial acetic acid in the absence or presence of an inert solvent (methylene chloride or chloroform) at temperatures between −40° and 35 °C:[351-354]

$$R^1C_6H_4PCl_2 + R^2SCl \xrightarrow{CH_3COOH} R^1C_6H_4P(O)(SR^2)Cl ;$$
$$R^1=F,\ Cl;\ R^2 = \text{alkyl},\ CH_2CH=CH_2,\ CH_2C_6H_5,$$
$$CH_2CH_2OCH_3,\ CH_2CH_2OAr .$$

The ester-chlorides are usually not isolated but are converted into esters and ester-amides of arylphosphonothiolic and arylphosphonodithioic acids in 70–90% yield by reactions with alcohols, mercaptans, and amines. The simultaneous addition of dichlorophosphine and sulphenyl chloride to an excess of the alcohol in the solvent leads to *OS*-dialkyl (or alkyl aryl) arylphosphonothiolates in 66–99% yield:[144]

$$R^1C_6H_4PCl_2 + R^2SCl + R^3OH \xrightarrow{-40^\circ C} R^1C_6H_4P(O)(SR^2)(OR^3) ;$$
$$R^1=F,\ Cl;\ R^2 = C_1-C_5\ \text{alkyl},\ C_6H_5;\ R^3=CH_3,\ (CH_3)_2CH .$$

The diethyl esters of 2,3,5,6-tetrafluoroarylphosphonothioic acids are formed in 37–41% yield when pentafluorobenzene derivatives are heated with sodium diethyl phosphorothioite in tetrahydrofuran.[335]

# The Reactivity of Organozinc and Organocadmium Compounds in Decomposition Reactions

L.M.Dyagileva and Yu.A.Aleksandrova

The literature data on the thermal decomposition and photodecomposition of organozinc and organocadmium compounds, on the dependence of the thermal decomposition mechanism and the kinetic stability of metal alkyls in this reaction on the decomposition conditions, and also on the relation between the reactivity of the organometallic compounds and their structure are treated systematically and discussed.
The bibliography includes 63 references.

## I. INTRODUCTION

The thermal decomposition reactions of organozinc and organocadmium compounds are of interest in connection with problems of the formation of zinc and cadmium coatings by chemical deposition from the gas phase.[1] Nevertheless the relevant literature data have not been subjected to systematic analysis.[1,2]

The lower alkyl derivatives of Group IIB metals are extremely unstable[3] and their use has until recently been limited.[4] However, during the last decade the dialkyl compounds of zinc and cadmium have found applications in the preparation of metallic and semiconductor coatings.[5-14] The use of metal alkyls in semiconductor technology has stimulated further research into the kinetic and thermodynamic stabilities of these organometallic compounds (OMC) and into the improvement of the methods of their synthesis[15,16] and analysis[17,18] in order to obtain specially pure compounds and also to develop conditions for the deposition and segregation of the condensed phase of the metal on thermal decomposition of the OMC.[19]

The existing reviews on the reactions involving the homolytic cleavage of organometallic compounds[20-24] are mainly concerned with OMC about the decomposition of which more reliable data are available (mercury, lead, tin, bismuth, antimony, gallium, arsenic, and titanium). It appears useful to discuss separately the results of experimental studies on the homolytic decomposition of organozinc and organocadmium compounds. This review presents a systematic account and a survey of data on the kinetic stability of the zinc and cadmium OMC in photodecomposition and thermal decomposition reactions.

## II. KINETICS AND MECHANISMS OF THE DECOMPOSITION OF ORGANOZINC AND ORGANOCADMIUM COMPOUNDS

### 1. Decomposition of Organozinc Compounds

Although the pyrolysis of metal alkyls with formation of the corresponding metals and radicals has been known since Paneth's classical studies, the kinetic investigations of these processes began only two decades ago and have not been systematic.[1] The kinetics of the gas-phase pyrolysis of dimethylzinc in a static system have been studied over a wide range of initial reactant pressures from 15 to 580 mmHg at temperatures in the range 280–340 °C.[25,26] It has been observed[25] that the rate of decomposition diminishes with increase of the initial pressure of dimethylzinc and that there is a simultaneous increase of the yield of the main gaseous product—methane. At a single fixed initial pressure the rate of decomposition and the yield obtained increase with increasing ratio of the reactor surface area S to the reactor volume V (the so-called heterogeneous factor $S/V$). In the high-temperature region a narrow pressure range has been found (27–55 mmHg) in which the decomposition rate constant is invariant and corresponds to a first-order kinetic law. It has been suggested that part of the methane is produced heterogeneously, although the contribution of the heterogeneous component of the reaction has not been established and the kinetic parameters of the overall reaction have not been calculated. It has been suggested that methane and ethane are formed in the stages involving the methyl radical-induced decomposition of dimethylzinc and the dimerisation of the methyl radicals respectively. Metallic zinc and polymethylene have been detected in addition to the gaseous products.

Self-inhibition of the reaction was observed in a later study.[26] The nature of the self-inhibition was not elucidated, but, by analogy with the cracking of hydrocarbons, it was postulated that it is caused by the addition of the methyl radical to the double bond in the ethylene formed with formation of a less reactive radical. The self-inhibition coefficient is independent of pressure and temperature.

The effective decomposition rate constant depends on the initial OMC concentration but a definite relation has not been observed. The effective activation energy diminishes with increase of the dimethylzinc concentration. A radical-chain mechanism of the thermal decomposition of dimethylzinc *in vacuo* under static conditions has been proposed:

$$Me_2Zn \rightarrow Me + {}^{\cdot}ZnMe, \qquad (1)$$

$$\begin{gathered}
{}^{\cdot}ZnMe \rightarrow Zn + Me, \\
Me + Me_2Zn \rightarrow CH_4 + {}^{\cdot}CH_2ZnMe, \\
{}^{\cdot}CH_2ZnMe \rightarrow :CH_2 + Zn + Me, \\
:CH_2 + Me_2Zn \rightarrow EtZnMe \rightarrow Et + {}^{\cdot}ZnMe, \\
2Me \rightarrow C_2H_6, \\
Me + {}^{\cdot}CH_2ZnMe \rightarrow CH_4 + C_2H_4 + Zn, \\
Me + Et \begin{cases} \rightarrow C_3H_8, \\ \rightarrow CH_4 + C_2H_4. \end{cases}
\end{gathered} \qquad (2)$$

The following compounds were found among the gaseous pyrolysis products (mole %): methane 88.0, ethane 4.2 to 5.5, propane 4.0–5.9, butane 1.2–1.4, ethylene 0.2–0.6, and propene 0.5–1.5.[26]

Methane is the only gaseous product of the decomposition of dimethylzinc in a sealed tube in the presence of cyclohexane (250–400 °C, pressure close to atmospheric).[27] With decrease of the fraction of cyclohexene, ethane and propane appear in the mixture of decomposition products. The following process mechanism in the presence of excess cyclohexane has been proposed:

$$Me_2Zn \rightarrow Me + ZnMe ,$$
$$Me + C_6H_{12} \rightarrow CH_4 + {}^{\cdot}C_6H_{11} ,$$
$$2{}^{\cdot}ZnMe \rightarrow ({}^{\cdot}ZnMe)_2 .$$

The activation energy for the first of these reactions has been determined as 45.5 ± 3.3 kcal mol$^{-1}$.

The use of cyclohexane in a fully deuteriated form permitted the conclusion that, under the given experimental conditions, the role of the induced decomposition reaction $Me + Me_2Zn \rightarrow CH_4 + {}^{\cdot}CH_2ZnMe$ is small even in the total absence of cyclohexane. The estimated activation energy for this reaction is ≥15 kcal mol$^{-1}$.[27]

The induced decomposition of dimethylzinc was fully eliminated when the reaction was carried out under flow conditions in the presence of an excess of toluene.[28] The following mechanism, analogous to the mechanisms of the decomposition of dimethylcadmium and dimethylmercury,[29] has been proposed for the decomposition of dimethylzinc under these conditions:

$$Me_2Zn \rightarrow Me + {}^{\cdot}ZnMe , \quad (1)$$

$${}^{\cdot}ZnMe \rightarrow Me + Zn , \quad (2)$$

$$Me + C_6H_5CH_3 \rightarrow CH_4 + C_6H_5CH_2^{\cdot} , \quad (3)$$

$$2Me \rightarrow C_2H_6 ,$$
$$2C_6H_5CH_2^{\cdot} \rightarrow (C_6H_5CH_2)_2 . \quad (4)$$

Reaction (2) does not occur at temperatures below 670 °C. It begins to play an appreciable role only above 730 °C but is complicated by the decomposition of toluene. For this reason, in the temperature range 573–700 °C it was possible to investigate the kinetics of the radical initiation reaction (1). The kinetic parameters of reaction (2) were obtained after applying a correction taking into account the yield of methane resulting from the decomposition of toluene. Both rate constants, $k_1$ and $k_2$, depend appreciably on the pressure in the system. At a fixed pressure of 16 mmHg, the following expressions were obtained for the rate constants for the elementary reactions (1)–(4):[28]

$$\lg k_1, (s^{-1}) = 11.25 - (47\,200 \pm 1000)/4.58T ;$$
$$\lg k_2, (s^{-1}) = 6.8 - 35\,000/4.58T ;$$
$$\lg (k_3/k_4^{1/2}), (mol^{-1/2})\ cm^{3/2}\ s^{-1/2} = 6.3 - 13\,000/4.58T .$$

At an overall pressure of 5 mmHg, the expression for the $k_1$ becomes[28]

$$\lg k_1, (s^{-1}) = 11.03 - 47\,300/4.58T .$$

If the reverse radical recombination reactions do not require an activation energy, the activation energies obtained for the forward reactions (1) and (2) can be regarded as equal to the dissociation energies $D_1$ and $D_2$ of the MeZn–Me and Zn–Me bonds respectively. It has been shown[28] that the thermochemical estimate $D_1 + D_2 = 82.9$ kcal mol$^{-1}$ agrees with kinetic data.

The gas-phase decomposition of diethylzinc does not have the distinctive features which characterise the pyrolysis of the methyl derivative (the dependence of the rate constant and the activation parameters on the initial reactant concentration and the self-inhibition of the reaction).

In an early study of the photolysis of diethylzinc,[30] the reactivity of the ethyl radicals formed in the primary decomposition step was investigated. At a pressure of 25 mmHg and in the temperature range 45–250 °C, ethane, ethylene, butane, and traces of hydrogen, butene and higher hydrocarbons were detected in the reaction products. The study of the influence of changes in the concentration of diethylzinc, the radiation intensity, the packing of the reaction vessel comprising an inert phase, and the pressure of an inert gas on the composition of the product led to the conclusion that butane is the product of the recombination of two ethyl radicals, while ethane and ethylene are formed as a result of the interaction of ethyl radicals with a molecule of the metal alkyl. The rate of the reaction of ethyl radicals with hydrogen becomes significant above 160 °C and its activation energy has been estimated as 9 ± 2 kcal mol$^{-1}$. The composition of the photolysis products at high temperatures is analogous to the composition of the thermal decomposition products.

Kinetic studies of the pyrolysis of diethylzinc have been carried out in a stream of toluene[31] and an inert gas,[32] in a static system,[32,33] and in a molecular beam.[33,34]

A free-radical mechanism has been proposed for the decomposition of diethylzinc in a stream of toluene, analogous to that described above for dimethylzinc, but it is more detailed as regards the reaction of all the radicals formed in the system.[31] In the mechanism of the multistage generation of radicals of diethylzinc, the second stage ${}^{\cdot}ZnEt \rightarrow Zn + Et$ is very rapid, in contrast to the reaction ${}^{\cdot}ZnMe \rightarrow Zn + Me$. The absence of induced decomposition in a stream of toluene made it possible to determine the kinetic and activation parameters for the first stage of the homogeneous initiation of radicals via the reaction $Et_2Zn \rightarrow Et + {}^{\cdot}ZnEt$ (Table 1). The presence of zinc oxide on the reactor surface greatly accelerated this reaction, which indicates a sensitivity to the nature of the surface.

The decomposition of diethylzinc under dynamic conditions in a stream of helium in tubular reactors with the surface coated by the solid products of its pyrolysis[32] obeys the first-order kinetics. For short contact times in an open system, there is insufficient time for the development of the chain process. The experimental activation energy for the decomposition of diethylzinc in a stream of helium (47.6 kcal mol$^{-1}$) is close to the dissociation energy of the EtZn–Et bond which has been estimated[31] as 47.5 kcal mol$^{-1}$. Only the unduly large pre-exponential factor ($\lg A = 16.13$) in the expression for the rate constant for the pyrolysis of diethylzinc in a stream of helium precludes a reliable assignment of the activation parameters obtained to a specific stage of the decomposition process.

In a closed system, diethylzinc also decomposes in accordance with first-order kinetics.[32] In contrast to the methyl derivative, a wide range of pressures (50–175 mmHg) has been found for this compound in which the rate constant is invariant. On passing to atmospheric pressure, the reaction continues to be first order. An inhibiting effect by the decomposition products has not been observed. The reaction involving the formation of metallic zinc from diethylzinc in the presence of added hydrogen has been noted.

A satisfactory interpretation of the results has been achieved on the assumption of a radical-chain mechanism of the decomposition:[32]

$$Et_2Zn \rightarrow Et + {}^{\cdot}ZnEt , \quad (5)$$

$${}^{\cdot}ZnEt \rightarrow Et + Zn , \quad (6)$$

$$Et + Et_2Zn \rightarrow C_2H_6 + C_2H_4 + {}^{\cdot}ZnEt . \quad (7)$$

$$Et \rightarrow C_2H_4 + H^{\cdot}, \quad (8)$$

$$H^{\cdot} + Et_2Zn \rightarrow C_2H_6 + {}^{\cdot}ZnEt, \quad (9)$$

$$2Et \rightarrow C_4H_{10} \text{ (or } C_2H_6 + C_2H_4). \quad (10)$$

The experimental effective rate constant is $k_{eff} = k_8 \cdot (k_5/k_{10})^{1/2}\ s^{-1}$. The initiation stage (5) can occur on the surface, since zinc oxide has been found to have an accelerating effect, but the process is propagated in the bulk phase (because the ratio $S/V$ has not effect and acceleration of the reaction by added hydrogen is not observed).

In order to account for the overall first order of the reaction, it is necessary to assume that the initiation reaction (5) in the gas phase is of second order, although it is known that zinc alkyls are not associated in the gas phase.[35] However, it has been observed in the liquid-phase autoxidation of dimethylzinc[36] that the initiation of the radicals does indeed take place as a result of the interaction of two dimethylzinc molecules.

In contrast to the liquid-phase pyrolysis,[32,37] in the gas-phase pyrolysis the contribution of the disproportionation reactions to the formation of ethane and ethylene is small[38] and their rate is 0.11–0.14 of the rate of recombination of ethyl radicals.

It has been observed[32] that the ethylene formed can be consumed in secondary reactions involving insertion in the C–Zn bond in diethylzinc. Thus the hydrolysis in heavy water of the condensed residue after the interaction of diethylzinc with ethylene yielded, together with monodeuteriomethane, also monodeuteriobutane. At the same time, the absence of dideuterioethane in the same experiment shows that the intramolecular and intermolecular decomposition of diethylzinc via the α-disproportionation of the ethyl groups does not occur under the given experimental conditions. It was postulated[32] that in a closed system the main gaseous product, namely ethane, is formed preferentially in the induced diethylzinc decomposition reaction (7).

The following compounds were detected in the gaseous products of the total decomposition of diethylzinc under static conditions at 270 °C [32] (in moles per mole of the substance decomposed): octane 0.0010, octene 0.0023, hexane 0.0085, hexene 0.0142, butane 0.2219, butene 0.0619, ethane 1.0443, ethylene 0.2709, and hydrogen 0.1072. Metallic zinc was found in the solid phase.

High pressures (from tens mmHg to atmospheric pressure) and low degrees of decomposition favour the abstraction of hydrogen from the diethylzinc molecule by the ethyl radical formed in the primary decomposition step.[33] Decrease of the pressure to $10^{-4}$ mmHg tends to decrease the kinetic stability of zinc dialkyls.[34] Under dynamic conditions, on passing from atmospheric pressure in a stream of helium to a high vacuum, the temperature of the total decomposition of diethylzinc decreases on the zinc coating from 310° to 130 °C and on zinc oxide from 310° to room temperature. The lines due to the molecular ions in the mass spectrum of dimethylzinc decomposing under high vacuum conditions on the solid products of its pyrolysis disappear already at 230 °C. The apparent activation energies in the temperature range 100 to 300 °C are 7.7 ± 1.5 and 6 ± 1.0 kcal $mol^{-1}$ for dimethylzinc and diethylzinc respectively. The composition of the products changes significantly in the pyrolysis of diethylzinc *in vacuo*[34] and the gas phase becomes enriched to the extent of approximately 70% in ethylene as a consequence of the vigorous dehydrogenation of ethane on pyrolytic zinc at the instant of formation.

In a high vacuum, where contact of OMC molecules with one another and also with the thermal decomposition products and the carrier gas is ruled out, the reactant decomposes heterogeneously in the adsorbed state on the catalytic centres of the reactor surface.[34] It has been suggested that, under dynamic conditions in a high vacuum, zinc alkyls decompose intramolecularly in accordance with the following mechanism:

$$Me_2Zn \xrightarrow{\text{recombination}} C_2H_6;$$
$$Me_2Zn \xrightarrow{\alpha\text{-disproportionation}} CH_4 + CH_2{:}Zn;$$
$$Et_2Zn \xrightarrow{\beta\text{-disproportionation}} C_2H_4 + C_2H_6 + Zn_{abs}.$$

*In a glass reactor.
**The reactor walls were coated by the solid pyrolysis products.

The kinetic stability and mechanism of the pyrolysis of zinc alkyls depend on the decomposition conditions. The free-radical mechanism operates at reduced and atmospheric pressures, while the molecular mechanism, characteristic of the adsorbed state, operates in a high vacuum (Table 2).

The homolytic reactions of organozinc compounds (the methyl, ethyl and phenyl derivatives) in the liquid phase and in solution in benzene in the course of their thermal decomposition and photodecomposition have been described.[39–44] The decomposition proceeds via a free-radical mechanism and is accompanied by the formation of a metallic mirror and the segregation of radical reaction products. The radical disproportionation and dimerisation reactions are characteristic of the photolysis (20–30 °C). The thermal decomposition of the OMC in the absence of a solvent entails, apart from the above reactions, the interactions of the alkyl radicals with the hydrocarbons and the initial OMC. In the solvent, the reaction takes place mainly via the mechanism involving the homolytic substitution of hydrogen in the solvent molecules by the alkyl or phenyl radicals formed.

The disproportionation and recombination reactions of the alkyl radicals are the most characteristic of the liquid-phase decomposition of the OMC, in contrast to the gas-phase decomposition, the contribution of the disproportionation to the thermal decomposition increasing with increase in the complexity of the radical on going from ethyl[45] to pentyl[46] radicals.

A method has been proposed for the preparation of zinc and cadmium coatings with a thickness up to tens of microns by the decomposition of zinc dialkyls (at 310–330 °C) and cadmium dialkyls (at 230–290 °C) by a gas-thermal method.[47] The coatings constitute a dense polycrystalline film with a grain size of approximately 1–5 μm.

## 2. Decomposition of Organocadmium Compounds

The gas-phase pyrolysis of dimethyl cadmium has been investigated under static conditions[48,49] in a stream of toluene[29] and benzene.[50] In an early study[48] measurements were made of the initial rates of formation of the principal gaseous pyrolysis products—methane and ethane. A poor reproducibility of the results was noted and considerable surface effects were observed, although the cadmium and polymethylene formed did not alter the rate of reaction. The increase of the heterogeneous factor (i.e. the increase of $S/V$) diminishes the rate of formation of ethane and methane, while the addition of hydrogen, nitrogen, helium, and nitric oxide increases them. As an alternative to the generally accepted free-radical mechanism, observed in the photolysis and thermolysis of metal alkyls, a mechanism involving the intramolecular disproportionation of the methyl groups as they approach one another, resulting from the deformation of the molecule, has been proposed:[48]

$$Me_2Cd \rightarrow CH_4 + Cd{:}CH_2 .$$

However, under the experimental conditions employed (150–200 mmHg, 212–327 °C), the role of the radical pathway should be considerable. This is indicated both by the poor reproducibility of the results, which can be accounted for by the uncontrolled change in the state of the vessel walls in the presence of impurities and by the increase of the yield of ethane with increasing temperature. The latter takes place as a consequence of the increase of the concentration of methyl radicals and the increase of the yield of their recombination product—ethane. Such findings are more likely to indicate a significant contribution of the free-radical pathways to the mechanism of the pyrolysis of

dimethylcadmium rather than the occurrence of an intramolecular rearrangement via the scheme presented by Heller and Taylor.[48]

A free-radical mechanism has been proposed[51] for the photolysis of dimethylcadmium, according to which the induced decomposition reaction

$$Me_2Cd + Me \rightarrow CH_4 + {}^{\cdot}CH_2CdMe$$

is the only source from which methane is formed.

It is believed that the mechanisms of the pyrolytic and photolytic decomposition of the majority of metal alkyls are the same. Thus a mechanism, equally probable for both pyrolysis and photolysis, has been proposed in a study[49] of the gas-phase decomposition of dimethylcadmium in a static system at a fixed initial reactant pressure of 150 mmHg and a temperature of 258 °C:

$$Me_2Cd \rightarrow Me + {}^{\cdot}CdMe \ ; \quad (11)$$

$$^{\cdot}CdMe \rightarrow Cd + Me \ ; \quad (12)$$

$$2Me \rightarrow C_2H_6 \ ; \quad (13)$$

$$Me + C_2H_6 \rightarrow CH_4 + Et \ ; \quad (14)$$

$$Me + Et \rightarrow C_3H_8 \ ; \quad (15)$$

$$Me + C_3H_8 \rightarrow CH_4 + Pr \ ; \quad (16)$$

$$Pr \rightarrow Me + C_3H_6 \text{ (polymerisation, etc.)} \quad (17)$$

It has been suggested that reaction (12) is faster than reaction (11) and that stages (13)–(16) have comparatively low activation energies and are rapid at the given temperature.

Features characteristic of the homogeneous–heterogeneous process have been observed in the pyrolysis of dimethylcadmium in a static system.[49] Extrapolation to $S/V = 0$ yielded the rate constant for the homogeneous dissociation of the first Cd–C bond: $k_{11} = 1.43 \times 10^{-5}$ s$^{-1}$ at 258 °C. The activation energy for this reaction, estimated as 43.5 ± 1.2 kcal mol$^{-1}$, has been identified with the dissociation energy of the first MeCd–Me bond. This value is close to $E_{11} = 45.8 \pm 1.0$ mol$^{-1}$, calculated[29] for the process in a stream of toluene. The dissociation energy of the second bond, calculated using thermochemical data, is $E_{12} = D_{12} = 21.4$ kcal mol$^{-1}$.[49]

When dimethylcadmium was pyrolysed in a stream of benzene,[50] a range of initial pressures was observed (80 to 163 mmHg) in which the rate constant was invariant, which corresponds to a first-order kinetic law; on the other hand, in the range of low initial pressures (10–20 mmHg), the rate constant increases with increasing pressure.[29] The mechanism of the decomposition of dimethylcadmium in toluene and benzene streams is analogous to that described above for the pyrolysis of zinc alkyls and includes, apart from the initiation stage, also reactions involving the abstraction of hydrogen from toluene and benzene by the methyl radical formed and subsequent recombination reactions of the benzyl and phenyl radicals. The kinetic and activation parameters for the individual stages of the above reaction have been published.[29,49,50] Activation energies in the range from 43.5 to 48.8 kcal mol$^{-1}$ and logarithms of the pre-exponential factor ranging from 11.9 to 13.4 have been obtained for reaction (11). The activation energy for reaction (12) has been estimated as 21.4 ± 4.0 kcal mol$^{-1}$.

The results of thermochemical studies, according to which the overall dissociation energy of the metal–carbon bonds in diethylcadmium is 52.9 ± 2 kcal mol$^{-1}$, suggest that diethylcadmium is thermally less stable than dimethyl cadmium.[1] The decomposition of gaseous diethylcadmium has been noted even at room temperature. However, detailed kinetic studies on the thermolysis of diethylcadmium and higher cadmium alkyls have not been made.

The kinetics of the deposition of metallic cadmium in the heterogeneous decomposition of gaseous diethylcadmium (temperature of the support 250–290 °C, temperature of the evaporator 19–50 °C) and di-isopentylcadmium (temperature of the support 240–250 °C, temperature of the evaporator 70–80 °C) have been investigated.[52] The amount of cadmium produced on the support depends on the temperature of the latter. The cadmium films obtained, with a thickness ranging from several microns to several tens of microns, constitute a light-coloured coating with a metallic lustre and satisfactory adhesion to the material of the support. The content of metallic cadmium in the coating is 99.5%. The microstructure and phase composition of the cadmium produced have been described.[46,47]

Solid dicylcohexylcadmium decomposes with liberation of metallic cadmium even at room temperature and for this reason the thermal decomposition has been studied in solution in benzene (100°, 30 h).[53] It was observed that the photodecomposition and thermal decomposition of dicyclohexylcadmium in benzene are accompanied by the formation of cyclohexane, cyclohexene, and bicyclohexyl.

A free-radical mechanism, in which the disproportionation of the radical formed predominates over the recombination and which is common to all metal alkyls, has been adopted for the pyrolysis of dicyclohexylcadmium [53] and di-isopentylcadmium [46] in solution and in the liquid phase in the absence of a solvent. It has also been suggested that the reaction involving the induced decomposition of the reactant via the abstraction of a hydrogen atom from the OMC molecule by the radical formed takes place. When solutions of diphenylcadmium in benzene are irradiated,[54] biphenyl and cadmium are formed preferentially, the contribution by the reaction with the solvent being small. On the other hand, the reaction involving the abstraction of hydrogen by the phenyl radical from the solvent molecule predominates in the photolysis of diphenylcadmium in dioxan.

## III. REACTIVITY AND STRUCTURE

Despite the fact that the experimental data for the kinetics of the pyrolysis of organozinc and organocadmium compounds refer solely to derivatives of lower alkyls, one can already reach certain conclusions about the reactivity of the above OMC in the decomposition reaction.

Under identical experimental conditions, the kinetic stability of the organometallic compounds formed is determined by the nature of the initial OMC, i.e. the nature of the metal atom and the radical. The kinetic stability of the lower alkyl and aryl compounds of zinc and cadmium varies in parallel with the variation of the average dissociation energy of the metal–radical bond ($\bar{D}$), although the initial step in the decomposition of the $MR_2$ molecules is their dissociation into R$^{\cdot}$ and $^{\cdot}$MR with the activation energy equal to the dissociation energy $D_1$. The second stage of the radical initiation reaction $^{\cdot}MR \rightarrow M + R^{\cdot}$ involving different compounds proceeds at different rates, as described above for zinc dialkyls. The dissociation energies of individual bonds and the average bond dissociation energies are listed in Table 3, from which it follows that, for the same metal, the energy of the abstraction of the first radical $D_1$ is greater than the energy of the abstraction of the second radical $D_2$ and the average dissociation energy of the metal–radical bond diminishes as the radical becomes more complex. The latter energy diminishes on passing from organozinc to organocadmium compounds.

With increase of the atomic number of the metal in Group IIB, the kinetic stability of the metal alkyls and metal aryls decreases, the thermal stability of the latter

being higher than that of the former.[1] The thermodynamic stability of the above OMC varies in the same sequence. It is known from thermochemical investigations that the average dissociation energy of the M–C bond for the OMC of transition elements within a single Group in Mendeleev's Periodic Table decreases with increase of the atomic number of the element.[55] For each individual element, the values of $\bar{D}$ can then be arranged in the following sequence:

$$M—Me > M—Et \cong M - n\text{-}Pr \cong M - n\text{-}Bu.$$

According to Voevodskii's rule,[60] the kinetic stability of the OMC decreases with increase of the thermodynamic stability of the radical liberated in the homolytic cleavage of the metal–radical bond. The ethyl derivatives of each metal are therefore less stable than its methyl derivatives. The thermal stability of the zinc alkyls decreases when the methyl group is replaced by the ethyl group to a lesser extent than for cadmium derivatives.

**Table 3.** The bond dissociation energies and the average metal–radical bond dissociation energies in metal alkyls (kcal mol$^{-1}$).

The kinetic stability of organometallic compounds in the decomposition process can be estimated from the reaction rate constants measured under comparable conditions for the entire OMC reaction series. Depending on the decomposition conditions, the measured rate constant can be an effective quantity representing a combination of the rate constants for the elementary reactions or (for example, when the process is carried out in a stream of toluene) it is the true rate constant for the elementary stage limiting the rate of the overall decomposition. The rate-limiting stage is usually the elementary radical initiation reaction. Only in the latter case is the experimental rate constant for the elementary reaction in the free-radical non-chain process determined by the activation energy for this stage, since isotypical elementary reactions are then compared.[60]

However, there are no experimental data for such a comparison, because there have been no kinetic studies of the decomposition of series of compounds with successively altered structures. In certain cases the role of the steric effect can be significant.

The structure of the organometallic compound determines not only the dissociation energy of the metal–carbon bond but also the steric accessibility of the metal to possible attack in bimolecular collisions. It has been noted in a series of studies[61–63] that an increase of the degree of steric shielding of the metal atom in the OMC increases the kinetic stability of the latter. A method has been proposed[62,63] for the estimation of the degree of shielding of the reaction centre M in the OMC molecule by the organic group with the aid of the solid angles formed by the substituents at the metal on cylindrical projections of the OMC molecules. The degree of steric shielding of the reaction centre determines the effectiveness of the molecular collisions and can therefore serve as a criterion for the comparison of the contributions of the entropy term to the OMC decomposition rate constant. In order to eliminate the influence of electronic effects, the degree of shielding was estimated quantitatively and compared with experimental data for compounds with the same metal atom and with different substituents.[62,63] It was shown that the degree of steric shielding of the metal atom by the substituents is the dominant factor, which determines the kinetic stability of compounds of the type $MR_n$, where M = Hg or Cd.

---o0o---

Thus it has been shown for lower zinc and cadmium alkyls and aryls that the mechanism of the thermal decomposition and photodecomposition varies with the decomposition conditions. At atmospheric and reduced pressures in a closed system and in a stream of the accompanying gas, the OMC investigated decompose via a free-radical mechanism, whilst under high vacuum conditions they decompose intramolecularly in an adsorption layer.

Although the general kinetic features of the thermal decomposition of the organozinc and organocadmium compounds as well as the kinetic and activation parameters of the radical initiation reaction in the homolytic cleavage of the first and second metal–carbon bonds have been established, systematic kinetic studies have not been made for an entire series embracing a large range of compounds with substituents of different lengths and with different degrees of branching. This limits to some extent the validity of the conclusions concerning the relation between the reactivity of the OMC considered, on the one hand, and their structure and the known thermodynamic characteristics of the dissociation of the given bond, on the other. The latter are represented in the literature only by the average metal–carbon bond dissociation energies and in certain cases the dissociation energies of specific ruptured bonds. On the other hand, there are so far no data on the average bond dissociation energies and enthalpies.

The causes of the self-inhibition of the decomposition of dimethylzinc have not so far been investigated. It is therefore important to study its decomposition under conditions which rule out self-inhibition. It is no less interesting to establish the order of the radical initiation reaction in the pyrolysis of diethylzinc in a closed system, which would help in determining the mechanism of the most difficult initial stage of the process investigated.

Complete quantitative analysis of the decomposition products for low degrees of reaction, which is essential for the determination of the detailed process mechanism and of

the role of the induced decomposition stage, has also not been carried out so far. Whereas the existence of the free-radical pathway to the decomposition of the zinc and cadmium OMC has been established unambiguously and gives rise to no doubts, additional studies are needed to solve the problem of the involvement of the intramolecular or intermolecular disproportionation reactions of the alkyl groups in the mechanism of the primary decomposition process.

# The Energy Relations and the Nature of the Bond in Anhydrous Uranyl Compounds with Acido-ligands

L.V.Kobets and D.S.Umreiko

The energy relations governing the interaction of the uranyl ion with acido-ligands in a series of anhydrous crystalline uranyl complex salts are examined. Using the ideas concerning the electronegativity of the interacting species, the amount of ionic character of the bonds between $UO_2^{2+}$ and anions has been estimated (approximately 60-70%), which makes it possible to calculate the contribution of the electrostatic interaction to the crystal lattice energies of the anhydrous salts. It is shown that the stretching vibration frequencies of the uranyl ion in its complexes with acido-ligands are in no way correlated with the basicity and the electronegativity of the ions. The vibrational characteristics of the uranyl ion depend on many parameters (the structure of the complex, the symmetry of the molecule, the nature of the acido-ligand, the outer-sphere cation, etc.). The bibliography includes 72 references.

## I. INTRODUCTION

The problem of the nature of the bonds in uranyl compounds still remains paramount in the chemistry of uranium. It is indissolubly linked with the understanding of the causes of the extremely high stability of the $UO_2^{2+}$ group in solutions and in the solid phase and also with the characteristics of its interaction with acido-ligands and neutral ligands. In view of the complexity of the problem as a whole, in the present review we shall consider only the bonding between the uranyl ion and acido-ligands in anhydrous crystalline salts.

Before proceeding to the direct estimation of the character of the bond between the uranyl ion and the acido-ligands, we shall deal briefly with the principal stages in the development of studies undertaken to understand the nature of the bonds in the uranyl group itself and the influence on the latter by equatorial ligands.

On the basis of the principle that the sum of the orders of the bonds formed by an atom in a compound is equal to the valence of the latter, Zachariasen[1] found that the multiplicity of the bonds in the uranyl group is less than two. Subsequently, in order to account for the high stability of the $UO_2^{2+}$ group, it was suggested[2,3] that the unshared electron pairs of the oxygen atoms are also involved in the reaction, which increases the multiplicity of the bonds in the OUO group. Later Vedovenko et al.,[4] who also used the valence principle, proposed a method for the estimation of bond orders somewhat different from that of Zachariasen,[1] based on the assumption that the sum of the bond orders is equal to the valence of only the central uranium atom. Here it was postulated that the bonds between uranium and the species surrounding it are covalent and that the charge on the uranium atom approaches zero ($^{+}O\equiv U\equiv O^{+}$). Equatorial ligands influence the bond strength in the OUO group in such a way that the enhancement of the electron-donating properties of the atoms entails the displacement of the unshared pairs and even of some of the valence electrons of the yl oxygen and a decrease of the uranium-oxygen bond order. Using the Pauling relation between the average bond strength $S$ and the valence of the ion, i.e. $S=V/N$, where $V$ is the valence and $N$ the coordination number, the strength of the bonds in the OUO group has been estimated[4-7] from the equation

$$R=R_1-\lg n, \qquad (1)$$

where $R$ is the length of a bond whose order is $n$ and $R_1$ the length of a bond whose order is unity and which amounts to 2.07 Å for a single bond in the $UO_3$ group. On the basis of the covalent model of the structure of uranyl compounds, a number of investigators[4-6] were able to explain a series of features of the spectroscopic properties of certain uranium(VI) coordination compounds.

The theory of the structure of uranyl compounds was developed further in the studies of Glebov,[8] who analysed in detail the possibilities of the principle in relation to uranyl compounds and showed that, for uranium(VI) coordination numbers of 6, 7, and 8, the ratio of the bond length and the bond strength is constant for almost all real uranium compounds. The following relation exists between $R_{UL}$ and $R_{UO}$:

$$R_{UL}^{N-2}=\langle R_N\rangle^N/R_0^2, \qquad (2)$$

where $\langle R_N\rangle$ is the geometrical mean of $R_{UL}$ and $R_{UO}$, which hardly changes in the series of compounds with identical coordination numbers.

At the same time the author showed[8,9] that, as a result of the endeavour to maintain the valence principle, the calculated bond orders in the uranyl group are not more than 1.5. In particular, Eqn.(1), which is satisfactorily applicable to uranates and uranium hydroxides and oxides, yields bond orders for uranyl complexes of less than 1.5. In addition, it has been noted[8] that a high multiplicity of the bonds, which entails a high degree of delocalisation of the bonding electrons of the uranyl group with a charge on the uranium atom close to zero, conflicts with structural data, according to which the equatorial ligands, including highly charged negative ligands, are disposed around the uranium atom, while in the $UO_2Cl_2$,[10] $UO_2SO_4$, $UO_2SeO_4$, $UO_2MoO_4$, $UO_2CrO_4$, and $UO_2WO_4$[12] structures the oxygen atom of the OUO group serves simultaneously as a ligand for a neighbouring layer. This presupposes a fairly high positive charge on the uranium atom and a negative charge on the oxygen atoms. The following distribution of charge in the uranyl group has been proposed: $^{-0.6}O-U^{3.2}-O^{-0.6}$,

and it has been suggested that it is in reality more ionic than would appear within the framework of the covalent model.

An anomalous dependence of the stretching vibration frequencies of the OUO group on the interatomic distances in it has also been observed.[8,9] For compounds with oxygen-containing ligands where $R_{UO}$ is in the range 1.65–1.80 Å, the stretching vibration frequencies of the bonds are smaller the shorter the bond. It has been noted that when a linear relation is maintained between the frequencies $\nu_{as}$ and $\nu_s$ of the $UO_2^{2+}$ group, the ratios between $K$ (the bond force constant, mdyn $A^{-1}$) for U–O and the distance $R_{UO}$, expressed by Badger's formula $R_{UO} = 1.08\,K^{-1/3} + 1.17$ and its various modifications ($K = 3.33 \times 10^{(2.07 - R_{UO})} - 0.73$; $R_{UO} = 1.993\,K^{-1/3} + 0.666$),[8] are inapplicable to the uranyl compounds indicated. This led the author[8] to divide all uranium(VI) compounds into two groups. Complexes with oxygen-containing ligands where the distances $R_{UO}$ in the OUO group do not exceed 1.8 Å were assigned to the first group. Compounds of the type of uranates and uranium hydroxides and oxides were assigned to the second group. It has been shown[8] that, in order to account for the observed anomalous behaviour of $\nu(UO_2^{2+})$ for uranyl coordination compounds, it is essential to take into account the contribution of the inner 6*p* and 6*s* shells to the formation of chemical bonds in the OUO group, which had been disregarded in earlier studies.

It was believed for a long time that only the 5*f*, 6*d*, and 7*s* electrons participate in the formation of the molecular orbitals of uranyl. A quasi-relativistic calculation[13] of the molecular orbitals of uranyl on the basis of the non-empirical version of LCAO-MO showed that inner 6*p* atomic orbitals interact actively with the orbitals of the oxygen atom and that their participation strengthens the bonds in the uranyl group. The inner 6*s* and 6*p* molecular orbitals ensure the presence of approximately 30% of the overall electron density in the uranyl group, which is probably equivalent to the existence of additional valence possibilities for the ions of actinide elements. It was established that a change in the distance $R_{UO}$ does not affect the populations of the outer 7*s*, 6*d*, and 5*f* orbitals of the uranium atom, altering only the electron population of the 6*p* orbitals. The latter are actively involved in the interaction with oxygen atoms for $R_{UO} \leq 1.8$ Å, whereas for longer interatomic distances ($R_{UO} \geq 1.8$ Å) the participation of the inner uranium shells in the formation of bonds is insignificant.

In the uranyl coordination compounds with $R_{UO} = 1.7$–$1.8$ Å the bonding in the OUO group is ensured by both the outer 6*d* orbitals of uranyls (the formation of $6d_\nu - 2s$ and $6d_\pi - 2p_\pi$ bonds with the oxygen atoms) and by the inner 6*p* orbitals of the uranium (the formation of bonds of the type $6p_\sigma - 2s$). The outer and inner MO of uranyl are then linked in such a way that the activation of the inner orbitals destabilises the outer MO.[8]

A complex relation is observed in the distribution of electron density. The independence of the charge density on uranium of the interatomic distance (within the limits 1.73–2.79 Å) conflicts with the traditional ideas, according to which the population of the AO diminishes with increase of the atomic distances, lowering the degree of covalence of the bonds in the OUO group and diminishing the shift of the electron density from the oxygen atoms to uranium.

In order to explain the dependence of the stretching vibration frequencies of the $UO_2$ group on $R_{UO}$, ideas concerning the shape and depth of the potential well for the OUO bonds in uranyl compounds have been used.[8,14] An increase of the depth and steepness of the potential well with decrease of the distance $R_{UO}$ corresponds to the normal relation between $\nu_{as}$ and $R_{UO}$, while the anomalous behaviour corresponds to an increase of the depth of the potential well accompanied by a decrease of its curvature.

Glebov[8,15] also attempted to take into account the influence of the ligand crystal field on the electronic structure of the uranyl group by carrying out calculations for clusters with six point charges in the equatorial plane of the uranyl group. The influence of the crystal field was characterised by a corresponding quantity, which represents the difference between the energies of the crystal field generated by the ligands on the uranium atom and on the uranyl oxygen atoms. These quantities were estimated from structural data, amounting to approximately 16–10 eV for uranates and to less than 8 eV for the coordination compounds. As a result, it was concluded that an increase of the crystal field of the equatorial ligands influences in the first place the electron populations of the outer AO of uranium, diminishing them. At the same time the populations of the inner AO of uranium change to a much lesser extent.

Thus Glebov[8,9,13–18] noted the principal contradictions arising in the interpretation of the characteristic features of the bonding in the OUO group within the framework of the covalent model and also outlined explanations of the anomalous properties of the compounds investigated. His conclusions refer predominantly to an isolated OUO group, which is virtually unperturbed by real ligands. The latter were taken into account only for oxygen-containing ligands, the class of halides as well as nitrogen-containing uranyl complexes being excluded from consideration. As before, questions associated with the constancy of the distances $R_{UO}$, which remain unaltered within the limits ~1.7–1.8 Å regardless of the coordination number of $UO_2^{2+}$ while the distances $R_{UL}$ change appreciably from one complex to another, remained unelucidated.

In discussing the bond strengths in uranyl complexes, it is necessary to take into account also the state of the substance to which they correspond. Indeed, analysis of the data for the interaction of the uranyl ion in aqueous solutions with acido-ligands such as $Br^-$, $Cl^-$, $NO_3^-$, and $SO_4^{2-}$ has shown that weak complexes are formed in this case. The logarithms of their stability constants ($\lg K_1$) are −0.3, −0.1, −0.3, and 1.9 respectively.[16–18]

## II. THE LATTICE ENERGIES OF COMPLEX URANYL SALTS

The concept of the lattice energy of the complex salts was introduced by Yatsimirskii[19] who regards it as the change in the internal energy of the substance of passing from the solid salt to the ionic gas consisting of the same ions as the crystal According to Yatsimirskii,[19] the lattice energy can be estimate from the equation

$$E_C = \Delta H_C^0 + \Delta H_A^0 - \Delta H_{CA}^0 \qquad (3)$$

where $\Delta H_C^0$, $\Delta H_A^0$, and $\Delta H_{CA}^0$ are the enthalpies of formation of the gaseous cation and anion and of the crystalline salt respec tively. Since Eqn.(3) is not related to either the nature of the ions or the nature of the forces acting between them, the lattice energies determined from it and referred to as experimental are evaluated from experimental thermodynamic data.

The heats of formation of certain anhydrous complex salts known at the present time as well as the heat of formation of the gaseous $UO_2^{2+}$ ion determined by Marcus[20] ($\Delta H_{f,298.15}^0 = 289.2 \pm 4.8$ kcal $mol^{-1}$) enabled us to calculate the crystal lattice energies for a series of anhydrous uranyl complexes. The heats of formation of the anions of certain uranyl salts are indicated in a handbook[21] and in a monograph.[19] The results of the calculation presented in Table 1 show that the lattice energies of the salts increase steadily on passing from uranyl perchlorate to the carbonate. Unfortunately, the list of complexes is limited to relatively simple uranyl salts, since there are no literature data for the heats of formation of complexes

of crystalline compounds and gaseous complexes of anions containing the uranyl group. In the absence of such data, the ionic lattice interaction energies can be calculated by means of the Kapustinskii equation,[22] which takes into account only the ionic charges and sizes:

$$E_C = 287.2 \cdot \frac{\Sigma_n Z_C Z_A}{r_C + r_A}\left(1 - \frac{0{,}345}{r_C + r_A}\right), \qquad (4)$$

where $\Sigma_n$ is the total number of cations and anions forming the molecule of the given salt, $Z_C$ and $Z_A$ are the formal ionic charges, and $r_C$ and $r_A$ are the ionic radii.

Table 1. The crystal lattice energies of uranyl compounds.

| Compound | $-\Delta H^0_{f,A(g)}$, kcal mol$^{-1}$ | $-\Delta H^0_{CA(c)}$, kcal mol$^{-1}$ | Refs. | $E^1_C$, kcal mol$^{-1}$ | $E^2_C$, kcal mol$^{-1}$ |
|---|---|---|---|---|---|
| $UO_2(ClO_4)_2$ | 91.5 | 302.5 | [21] | 408.7 | 416.3 |
| $UO_2Br_2$ | 59.9 | 271.8 | [24] | 443.2 | 460.2 |
| $UO_2Cl_2$ | 62.5 | 297.1 | [25] | 461.3 | 479.2 |
| $UO_2Cl_2$ | 62.5 | 300.0 | [26] | 464.2 | 479.2 |
| $UO_2(NO_3)_2$ | 80.0 | 330.8 | [20] | 460.0 | 468.9 |
| $UO_2(SCN)_2$ | 11.6 | 210.1 | [21] | 476.1 | 478.3 |
| $UO_2SO_4$ | 178 | 440.9 | [27] | 552.1 | 563.4 |
| $UO_2SO_4$ | 178 | 451.2 | [28] | 562.4 | 563.4 |
| $UO_2F_2$ | 66.9 | 397.9 | [29] | 553.3 | 551.4 |
| $UO_2F_2$ | 66.9 | 395.5 | [29] | 550.9 | 551.4 |
| $UO_2F_2$ | 66.9 | 394.7 | [30] | 550.1 | 551.4 |
| $UO_2(HCOO)_2$ | 107.1 | 447.1 | [31] | 521.1 | 511.4 |
| $UO_2(CH_3COO)_2$ | 122.0 | 467.9 | [29] | 513.1 | 509.9 |
| $UO_2(CH_3COO)_2$ | 122.0 | 476.1 | [32, 33] | 521.3 | 509.9 |
| $UO_2(OH)_2$ | 40.0 | 365.2 | [21] | 573.4 | 539.6 |
| $UO_2CO_3$ | 47 | 405.6 | [21] | 647.8 | 631.9 |

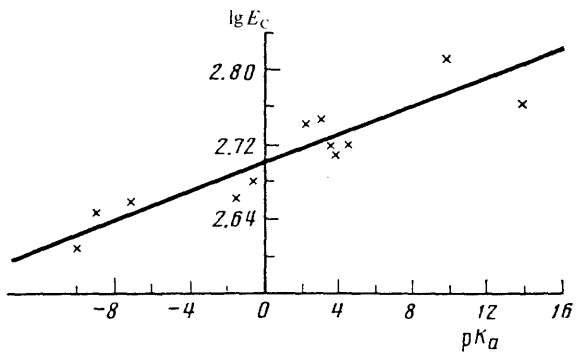
Notation: $-\Delta H^0_{f,A(g)}$ is the enthalpy of formation of gaseous anions, $-\Delta H^0_{CA(c)}$ the enthalpy of formation of the crystalline salt, and $E^1_C$ and $E^2_C$ are the lattice energies of the complex uranyl salts calculated from the Yatsimirskii and Kapustinskii equations respectively.

According to Marcus,[20] the radius of the uranyl ion is 1.40 Å. Table 1 also presents the results of the calculation of the lattice energies of the uranyl salts from Eqn.(4). Evidently the lattice energies calculated from the Kapustinskii equation, which takes into account only the electrostatic interactions between the ions, agree fairly well with the values obtained from thermal-chemical data.[3,4]

Yatsimirskii[23] believes that the interaction energy in a complex is determined in a general form by the equation

$$E_C = E_i + C + E, \qquad (5)$$

where $E_i$ is the energy of the interaction between the ions calculated from the Kapustinskii equation, $E$ the energy of extra-stabilisation by the crystal field, and $C$ the energy of formation of the covalent bond in the crystal.



The covalent component of the bond between the cation and anion, arising as a result of partial charge transfer, is as a rule determined from the difference $\Delta E_{cov} = E_C - E_i$. For the salts considered, $\Delta E_{cov}$ does not exceed +20 kcal mol$^{-1}$. This value is probably determined not only by the nature of the bonds in the compounds investigated but also by the experimental errors in the determination of the heats of formation. Overall, it follows from Table 1 that the lattice energies found for the uranyl salts agree well with the values obtained from purely electrostatic considerations. At first sight it appears that, knowing the lattice energies, it is possible to estimate fairly readily the energies of the bonds between the uranyl ion and the acido-ligands in the anhydrous salts. However, in reality this is extremely difficult because the overall compositions of the salts say nothing about the way in which the ligands are bound and about the coordination number of the uranyl group. These compounds are formally coordination-saturated and they cannot be regarded as island structures. The coordination possibilities of the $UO_2^{2+}$ group in them are utilised by the formation of polymers. This is achieved both by binding the uranyl ions via bridging ligands ($Cl^-$, $SO_4^{2-}$, $C_2O_4^{2-}$, etc.) and as a result of the involvement in the coordination of the oxygen atoms of the OUO groups in neighbouring layers.

As an illustration, one may refer to the structural data for $UO_2Cl_2$ [10] and compounds of the type $UO_2EO_4$ (where E = S, Se, Cr, Mo, or W).[11,12] The coordination polyhedron of the uranium in these complexes is a pentagonal bipyramid, whose equatorial plane is formed by four bridging chlorine or oxygen atoms of the $EO_4^{2-}$ groups and the oxygen atom which plays a dual role. In the polymer structure the uranyl oxygen atom occupying the axial position in one polyhedron belongs to the plane of the pentagonal base of another polyhedron.

Table 2. Contributions of the electrostatic components of the U–L bonds to the crystal lattice energies of uranyl complexes.

| Compound | $R_{UL}$, Å × $m$* | $i_{UL}$ | $E_e$, kcal mol$^{-1}$ | $E_C$, kcal mol$^{-1}$ | $\Delta E_{cov}$, kcal mol$^{-1}$ |
|---|---|---|---|---|---|
| $UO_2Cl_2$ | 2.73×4 | 0.66 | 321.1 | 461.3 | 139.7 |
| $UO_2SO_4$ | 2.30–2.49 | 0.74 | 409.5 | 552.1 | 142.6 |
| $UO_2F_2$ | 2.43×6 | 0.74 | 606.6 | 553.3 | –53.3 |
| $UO_2CO_3$ | 2.50×4 (2.44×2) | 0.71 | 570.3 | 631.9 | 61.6 |

* Number of bonds.

Dependence of lg $E_C$ for uranyl salts on the basicity of the acido-ligand.[34]

Returning now to the crystal lattice energies of the anhydrous uranyl complexes (Tables 1 and 2), we may note that the sequence in which the lattice energies increase for the principal inorganic anions is fairly satisfactorily correlated with the variation of the basicities of the acido-ligands. The relation between lg $E_C$ and p$K_a$ shown in Fig.1, which has been treated by the method of least squares, can be described

by the following equation:

$$\lg E_C = 0.01 pK_a + 2,70. \quad (6)$$

Analysis of the thermodynamic quantities permits a number of conclusions. Firstly, the logarithms of the crystal lattice energies of the uranyl complexes vary linearly with the basicities of the acido-ligands. Secondly the $\lg E_C - pK_a$ relation can be used for a qualitative estimation of the lattice energies of anhydrous uranyl salts whose heats of formation are unknown. Finally, the calculation of the crystal lattice energies of the uranyl complexes, taking into account the electrostatic interaction only, indicates an appreciable amount of the ionic character of the bonds between $UO_2^{2+}$ and the acido-ligands in the crystalline uranyl complexes.

## III. ESTIMATION OF THE CONTRIBUTION OF THE ELECTROSTATIC INTERACTION OF $UO_2^{2+}$ WITH ACIDO-LIGANDS

The fact that the bonds between $UO_2^{2+}$ and acido-ligands are to a large extent electrostatic agrees with the classification of the uranyl cation as a hard Lewis acid.[35-37] In this connection it therefore becomes necessary to estimate quantitatively the amounts of ionic character of the bonds and the charges of the interacting ions. In order to estimate the electrostatic contribution, we employed the concept of electronegativity (EO), in which any bond is regarded as a superposition of covalent and ionic components.[38,39] Pauling, who introduced the concept of EO,[38] characterises electronegativity as the ability of an atom in a molecule (or in general in a chemical bond) to attract valence electrons. The EO theory was developed further in other investigations.[39-41,42-44] Sanderson[39-41] demonstrated the possibility of determining not only the effective charges and the coefficients of the ionic character and covalence but also the energies of the electrostatic and covalent bonding of the atoms in the molecule. For this purpose, one finds the geometrical mean of the EO on formation of the molecule and the EO of each atom is calculated relative to it. The bonding energies calculated for hundreds of organic and simple inorganic compounds differ from the experimental values by not more than 5%.

The application to uranyl compounds of the methods for the calculation of the effective atomic charges and of the amounts of ionic character of the bonds proposed by Sanderson[39-41] did not, however, yield reasonable results for the following reasons. In these calculations no account was taken of the coordination possibilities of uranium and they are hindered by the lack of data for the change in the electronegativity of uranium following the loss of an electron. In addition, and this is most significant, in the case of uranyl complexes with oxygen-containing ligands the oxygen atoms of the OUO group and of the anions are regarded as equivalent. The latter is probably valid only for a small number of compounds such as uranates in which the lengths of the bonds between the uranium atom and all the oxygen atoms surrounding it are comparable to the lengths of the uranium–oxygen bonds in the axial positions; the very concept of the uranyl group is abolished for such compounds.

It is preferable to use formulae for the calculation of the amounts of ionic character of bonds and effective charges proposed by Batsanov[42-44] for coordination crystals. The principal difference between the latter and molecules consists in the fact that the coordination number of an atom in such crystals is greater than its valence. The average "amount of ionic character of the bond" in the crystal is given by the following formula in the case of polyvalent atoms:

$$i_{cr} = \frac{Zi_{mol} + (K - Z)i_e}{K}, \quad (7)$$

where $Z$ is the valence of the atom, $K$ the coordination number, and $i_{mol}$ the amount of ionic character of the bond determined from the difference between the EO of the anion and the metal ($\Delta X$).[42,43] The covalent component is estimated from the polarity of the bonds between $UO_2^{2+}$ and the anions. The latter is determined by the competition between two factors—the attraction of electrons by the metal atom, which is proportional to its electronegativity $X_M$, and the ability of the metal to give up electrons to the anions, which is proportional to its ionisation potential $I_A$ in the valence state. The following relation has been proposed for the determination of the polarisation component of the bond, called the "electrostatic ionic character of the bond":[42-44]

$$i_e = \frac{I_A - X_M}{I_A + X_M}. \quad (8)$$

The degree of covalence of the bond is then calculated from the difference $1 - i_e$.

The EO have been published[42-44] for acido-ligands ($NO_3^-$, $ClO_4^-$, $SO_4^{2-}$, etc.) taking into account the interactions within the corresponding group. The knowledge of $i_{cr}$ makes it possible to calculate the effective atomic charges $Z^*$, which characterise the distribution of electron density in the region of the chemical bond:

$$Z^* = Z - K(1 - i_{cr}). \quad (9)$$

The quantity in brackets corresponds to the degree of covalence of the bond, since the overall contribution of all the interactions is assumed to be unity.

The electronegativity of the uranyl ion $UO_2^{2+}$ was assumed to be 1.38.[45] Its estimation from the formulae proposed by Zhang[46] and Allred[47] leads to approximately the same value. The ionisation potentials of anions were given in a handbook[48] and in another publication.[49] In the calculation the uranyl group was regarded as a bivalent point cation in which the interaction of the uranium and oxygen atoms is disregarded. The quantity $i_{mol}$ was determined from tabulated data on the basis of the relation between the amount of ionic character of the bonds and $\Delta X$.[42,43]

The calculations showed that the amounts of ionic character of the bonds between $UO_2^{2+}$ and the anions are mainly in the range 60–70% for all the anhydrous solid complexes. The increase of the coordination number (C.N.) from four to six is not then unduly reflected in the change of the amount of ionic character of the bond, since the effective charge $Z^*_{eff}$ is very significantly reduced. Naturally the concept of the effective charge on the uranyl ion is fairly arbitrary; it reflects in only a simplified form the distribution of charges in the case where the uranyl ion is regarded as a doubly charged cation.

Like the effective charges, the amounts of ionic character of the bonds do not exhibit an explicit dependence on the nucleophilicity of the anions, although, overall, a definite tendency towards a decrease of the amounts of ionic character of the bonds between the uranyl ion and the equatorial ligands can be traced as the basicity of the ligands increases. The closeness of the amounts of ionic character of the bonds between $UO_2^{2+}$ and the acido-ligands in different uranyl compounds can serve as evidence that the mechanism of the interaction of these species is predominantly electrostatic and confirms the assignment of the uranyl[35-37] to hard Lewis acids.

Using the ideas developed by Batsanov[44] for mixed three-centre systems $A_1–M–A_2$ or $M_1–A–M_2$, it is possible to put forward certain considerations concerning the character of the bonding in the uranyl group in complexes having the general formula $UO_2X_n$. According to the Pauling principle, which requires a constant population of the metal orbitals and

the possibility of saturating the EO, an increase in the amount of ionic character of the $A_1$–M bond (or the $M_1$–A) bond should be accompanied by an increase of the degree of covalence of the M–$A_2$ (or A–$M_2$) bond. This is usually expressed by a change in the lengths of the corresponding bonds and their vibration frequencies in such a way that the greater ionic character of one of these bonds entails a greater covalent character of the other. Since the structure of uranyl compounds is such that the oxygen atoms of the OUO group are in the *trans*-positions with respect to the equatorial ligands, an increase of the amount of ionic character of the UO–L bond should probably tend to increase the degree of covalence of the U–O bonds. Indeed, analysis[50] of structural data for uranyl complexes having coordination numbers of 4, 5, and 6 shows unambiguously that the greater the $R_{UL}$, the smaller the $R_{UO}$.

In the series of isostructural anhydrous uranyl compounds $UO_2MoO_4$, $UO_2SeO_4$, $UO_2SO_4$,[11,12] and $UO_2Cl_2$,[10] in which the uranium polyhedron is a pentagonal pyramid, an increase of $R_{UL}$ (2.30–2.35, 2.30–2.49, 2.30–2.54, and 2.52–2.73 respectively) is accompanied by a shortening of the $R_{UO}$ distances (1.76 and 1.81, 1.78 and 1.79, 1.73 and 1.80, and 1.73 and 1.78 Å). This is equivalent to an increase of the degree of covalence of the uranium–oxygen bonds in the OUO with increase of the amount of ionic character of the bonds with the acido-ligands. The high degree of covalence of the bonds in the OUO group and the electrostatic character of the interaction with the acido-ligand are in good agreement with the autonomous chemical behaviour of $UO_2^{2+}$ and the constancy of the bond length $R_{UO}$ in the range 1.65–1.80 Å regardless of the nature of the ligand and the coordination number.

In contrast to *d*-block elements, the geometry of the coordination sphere of uranyl is apparently determined mainly by electrostatic and steric factors and not by the degree of overlap of the uranyl and ligand orbitals. This agrees with the absence of a correlation between $R_{UO}$ and $R_{UL}$, on the one hand, and the ligand crystal field energies, estimated by Glebov,[15] on the other. The high strengths of the bonds in the crystalline complexes of uranyl with ligands which give rise to the weakest complexes in solution ($ClO_4^-$, $Cl^-$, $NO_3^-$, and $SO_4^{2-}$) can be readily accounted for on the basis of the concept of the electrostatic character of the interaction of $UO_2^{2+}$ with acido-ligands. This is indicated by the high crystal lattice energies of uranyl sulphate, fluoride, carbonate, and nitrate (Table 1) calculated from thermodynamic data. The increase in the stability of the compounds of the above most electronegative anions in the crystalline state is probably achieved as a result of the formation of extremely strong electrostatic bonds with the acido-ligands.

On the other hand, the idea of a large amount of ionic character of the bonds between $UO_2^{2+}$ and equatorial ligands, especially the most electronegative of these, makes it possible to understand the tendency of these bonds to ionise in solution and hence their weak capacity for complex formation.

The electrostatic nature of the bonding between $UO_2^{2+}$ and the ligands agrees well with the known facts indicating the preferential interaction of the above cation with hard bases containing oxygen or halogen atoms. Under the usual conditions, the uranyl ion does not form bonds with soft bases containing nitrogen, sulphur, and phosphorus electron-donating atoms. Such reactions become possible only in a series of organic solvents exhibiting a much smaller solvating effect and polarising capacity than water.

The estimated amounts of ionic character of the bonds in the uranyl compounds can be used to calculate the electrostatic contributions to the crystal lattice energies $E_{lat}$ with the aid of the equation proposed by Sanderson,[39–41] in which $E_{lat}$ is regarded as the sum of the electrostatic ($E_e$) and covalent ($E_{cov}$) contributions:

$$E_{lat} = t_e E_e + t_c E_{cov},$$

where $t_e$ and $t_c$ are respectively the coefficients of the ionic character and covalence of the bonds, whose sum is unity.

The electrostatic interaction energy is

$$E_e = t_e \times 332 e^2/R_0,$$

where $R_0$ is the bond length and 332 is a coefficient which makes it possible to express the bond energy in kcal $mol^{-1}$.

The covalent contribution is calculated as the geometrical mean of the energies of two homeopolar bonds.[39–41] We calculated[53] the electrostatic contributions $E_e$ to the crystal lattice energies for a series of uranyl salts with known structures (Table 2). In the calculation of $E_e$, the amounts of ionic character of the bonds $i_{UL}$ calculated by ourselves were adopted as the $t_e$. For $UO_2SO_4$ with different U–ligand bond lengths, their values were either averaged or the length of each bond was taken into account. Comparison of the $E_e$ with the crystal lattice energies of the uranyl salts showed that the electrostatic interactions make the main contribution to the crystal lattice energy.

The overall contribution of the covalent interaction energy and the energy of the extra-stabilisation by the crystal field can be estimated from the difference $\Delta E_{cov} = E_c - E_e$, because, according to Yatsimirskii,[23] the energy of the interaction in the complex is determined in the general form by Eqn.(5). It follows from Table 2 that $\Delta E_{cov}$ is much smaller than $E_e$; it is negative only for uranyl fluoride, which is probably associated with errors in the determination of the $UO_2F_2$ structure;[51] the structure has been discussed by Ohwada.[52] It is known[53] that this structure is atypical for uranyl halides, which have a characteristic coordination number of five.

## IV. ANALYSIS OF THE VIBRATION FREQUENCIES OF THE $UO_2^{2+}$ ION IN ITS COMPLEXES WITH ACIDO-LIGANDS

In connection with the problem of the interrelation between the structure and properties of a substance (in particular spectroscopic properties), the determination of various correlations between the above characteristics is always regarded as important. Different views on this problem are held as regards uranyl compounds. It has been noted[35] that several spectrochemical series, differing in the sequence of the ligands, have been proposed for uranyl coordination compounds. Having applied the *d*-element spectrochemical series to uranyl compounds, McGlynn et al.[54] assumed that the stretching vibration frequencies $\nu_s$ and $\nu_{as}$ of the $UO_2^{2+}$ ion decrease as a function of the nature of the ligands in the following sequence: $NO_3^- > F^- > H_2O >$ Phen ≅ Py $> NO_2^- > NCS^- > NH_3 >$ ethylenediamine $> CN^-$. The dependence of the state of the bonds in the $UO_2^{2+}$ group on the nature of the ligands in uranyl complexes has been postulated by Dyatkina and Mikhailov.[3] These ideas were developed further in a study[4] whose authors concluded that the orders of the uranyl and equatorial bonds are inter-related and that the uranyl vibration frequencies are extremely sensitive to changes in bond orders and the corresponding force constants. The bond orders have been estimated for a series of compounds, including uranates and uranium oxides, and the frequencies $\nu_s$ and $\nu_{as}$ for $UO_2^{2+}$ and the force constants have been compared. A dependence of the bond orders in the uranyl complexes on the nature of not only the ligands but also the outer-sphere cation has been noted.[56]

At the same time, there have been studies in which the absence of correlations between the vibration frequencies of uranyl and the nature of the ligands has been pointed out.

Having analysed complexes analogous to those investigated by McGlynn et al.,[54] Bullock[57] concluded that the series of frequencies estimated by McGlynn et al.[54] are erroneous. Volod'ko et al.[55] claim that the variation of the vibration frequencies of $UO_2^{2+}$ in different compounds is not correlated with the position of the ligands in the spectrochemical series.

The absence of such correlations has also been noted by Day and Venanzi,[58] who regard the variation of the uranyl vibration frequencies as a result of the superposition of vibrational and electronic interactions. The former are determined by the vibration of the bonds between the uranium atom and the equatorial ligands, the intensity of these vibrations depending on the force constants of the system (including the metal–ligand bonds) and on the mass of the ligands. The electronic interaction arises as a consequence of electron transfer to the uranyl ion and is determined by the electron-donating capacity of the ligand. It is to be expected that the $UO_2^{2+}$ vibration frequencies should decrease with increase of the electron-donating capacity. However, the superposition of the above two factors makes the changes in the vibration frequencies of the uranyl ion unpredictable. Bagnall and Wakerley,[59] who analysed 18 uranyl complexes, hold the same view.

Examination of the electronic spectra and the EO of uranyl compounds with various ligands led to the conclusion[60] that both the positions and intensities of the electronic transition bands are independent of the chemical nature of the ligands and are determined solely by the geometrical structures of the first coordination sphere of the uranium atom. The influence of the ligands can be taken into account only when the symmetries of the inner coordination sphere of uranium are identical.

A similar conclusion follows also from the theoretical analysis of the absorption spectra of uranyl complexes.[61–64] The change in the mass of the ligand from 10 to 200 a.u. in the complexes $UO_2X_n$ (where $n$ = 4, 5, 6), for an unchanged internal force field of the uranyl group and when the remaining parameters such as the mass of the atom X, the lengths of the UX bonds, and their force constants are varied within specified limits, alters the frequencies $\nu_S$ of the $UO_2^{2+}$ group by only 5 $cm^{-1}$, while the frequencies $\nu_{as}$ remain virtually constant. The frequencies $\nu_S$ and $\nu_{as}$ are also independent of the uranium–ligand bond length in the range 1.8–2.8 Å. The variation of the force field of the ligands within wide limits can alter the $UO_2^{2+}$ vibration frequencies by not more than ~10 $cm^{-1}$ in complexes with $D_{4h}$ symmetry, by ~13 $cm^{-1}$ for the $D_{5h}$ symmetry, and by ~15 $cm^{-1}$ for the $D_{6h}$ symmetry. It has also been shown for halide complexes having the general formula $M_2[UO_2X_4]$ that the frequencies $\nu_{as}$ hardly change on replacement of any number of chlorine atoms by bromine atoms regardless of the symmetry of the complex anion associated with the same cation.[63,64] The force constants of the U–O bonds in these compounds are similar and amount to 6.6 to 6.8 mdyn $A^{-1}$.

The list of investigations in which the influence of ligands on the force constants and vibration frequencies of the bonds in uranyl compounds has been discussed may be greatly expanded, since we have mentioned only some of them. We may note that in the studies quoted, with the exception of Refs.61–64, both complexes containing only acido-ligands (which consist of anions) and compounds with a mixed type of coordination sphere, containing acido-ligands and neutral ligands, were considered simultaneously. Such complexes should probably be discussed separately in order to eliminate the superposition of the two factors indicated when general relations are deduced.

In the present review we shall consider the behaviour of $\nu_{as}$ for the $UO_2^{2+}$ group in uranyl complexes containing only acido-ligands, starting with anhydrous salts (Table 3). The study of the vibrational spectra of the latter is a fairly complex task not only because of the difficulty of synthesising these compounds but also because they are extremely hygroscopic. This factor has been frequently noted by various authors; in particular, we have demonstrated this for the anhydrous compounds $UO_2Cl_2$ [65] and $UO_2(NO_3)_2$,[66] whose infrared spectra changed very markedly after an extremely brief contact of the specimen with air. Thus, apart from the three intense absorption bands at 950, 835, and 775 $cm^{-1}$, a series of additional intense bands appeared in the $UO_2Cl_2$ spectrum in the range 950–900 $cm^{-1}$. The same situation probably obtains also for $UO_2(ClO_4)_2$, $UO_2F_2$, and $UO_2Br_2$, whose spectra are not only characterised, according to the data of different workers, by different frequencies $\nu_{as}$ ($UO_2^{2+}$) but also differ as regards the number of absorption bands[64] (Table 3).

**Table 3.** The vibration frequencies $\nu_{as}$ of the $UO_2^{2+}$ group in the spectra of uranyl complexes.

| Compound | $\nu_{as}$, $cm^{-1}$ | Refs. | Compound | $\nu_{as}$, $cm^{-1}$ | Refs. |
|---|---|---|---|---|---|
| $UO_2(ClO_4)_2$ | 996,965,961 | [64] | $Cs_2[UO_2Br_4]$ | 925,920 | [64] |
| $UO_2(ClO_4)_2$ | 965 | [5] | $(PyH)_2[UO_2Br_4]$ | 935 | [64] |
| $UO_2Br_2$ | 945,905 | [64] | $Li_2[UO_2Cl_4]$ | 940 | [64] |
| $UO_2Cl_2$ | 950 | [65] | $Na_2[UO_2Cl_4]$ | 935 | [64] |
| $UO_2Cl_2$ | 990,980,965 | [66] | $K_2[UO_2Cl_4]$ | 925 | [64] |
| $UO_2Cl_2$ | 977 | [67] | $Rb_2[UO_2Cl_4]$ | 920 | [64] |
| $UO_2SO_4$ | 930 | [68] | $Cs_2[UO_2Cl_4]$ | 920 | [64] |
| $UO_2CrO_4$ | 930 | [68] | $(PyH)_2[UO_2Cl_4]$ | 924,914 | [64] |
| $UO_2MoO_4$ | 932 | [68] | $NO[UO_2(NO_3)_3]$ | 940 | [66] |
| $UO_2WO_4$ | 936 | [68] | $NH_4[UO_2(NO_3)_3]$ | 952 | [57] |
| $UO_2F_2$ | 1000 | [52] | $K[UO_2(NO_3)_3]$ | 960 | [57] |
| $UO_2F_2$ | 1040,927,923 | [64] | $Rb[UO_2(NO_3)_3]$ | 955 | [57] |

| | | | $(NH_4)_4[UO_2(CO_3)_3]$ | 888 | [55] |
| | | | $Na_4[UO_2(CO_3)_3]$ | 876 | [64] |
| | | | $K_4[UO_2(CO_3)_3]$ | 881 | [55] |
| | | | $Rb_4[UO_2(CO_3)_3]$ | 877 | [55] |
| | | | $Cs_4[UO_2(CO_3)_3]$ | 877 | [55] |
| | | | $K_2[UO_2(CO_3)_2]$ | 856 | [55] |

Analysis of the vibration frequencies in the infrared spectra of anhydrous uranyl salts has shown that they exhibit no correlations with the basicities of the ligands; this is indicated by the data in Table 3, where the compounds are arranged in order of increasing $pK_a$ of the ligands. Nor are there any correlations with the electronegativities of the anions. It is striking that the highest frequencies $\nu_{as}$ ($UO_2^{2+}$) correspond to anions with the highest EO ($F^-$, $ClO_4^-$, and $NO_3^-$). On the other hand, complexes with other anions, which also have high EO ($SO_4^{2-}$ and $CO_3^{2-}$), have frequencies $\nu_{as}$ close to the vibration frequencies of compounds with less electronegative anions ($Br^-$ and $CH_3COO^-$). Without ruling out the possibility of an inadequate reliability of the experimental vibration frequencies of certain anhydrous salts, the difficulties in determination of which were noted above, one can postulate that the above inconsistencies are determined also by the difference between the structures of the anhydrous uranyl salts. Table 3 also lists the frequencies $\nu_{as}$ ($UO_2^{2+}$) in the spectra of compounds with more complex compositions, incorporating a complex anion and outer-sphere cations. Analysis of the changes in the $\nu_{as}$($UO_2^{2+}$) listed in Table 4 following the replacement of the

ligand indicates the absence of a correlation between $\nu_{as}$ and the basicity of the acido-ligand. On the other hand, in the series of isostructural hexacoordinate uranyl complexes, containing bidentate acido-ligands, the transition from trinitrato- to triacetato- and tricarbonato-uranylates reveals a tendency towards a decrease of $\nu_{as}$ with increase of the basicities of the anions. However, the data for these three compounds are clearly insufficient to infer the existence of this type of general relation.

**Table 4.** The vibration frequencies $\nu_{as}$ of the $UO_2^{2+}$ group in the spectra of anionic uranyl complexes with $Rb^+$ as the outer-sphere cation.

| Compound | $pK_a$ | $X$ (Ref. 24) | $\nu_{as}$, $cm^{-1}$ | Refs. |
|---|---|---|---|---|
| $Rb_3[UO_2Cl_5]$ | ~7 | 3.2 | 920 | [64] |
| $Rb[UO_2(NO_3)_3]$ | ~1.4 | 3.8 | 955 | [57] |
| $Rb_2[UO_2(NO_3)_4]$ | ~1.4 | 3.8 | 945 | [55] |
| $Rb_3[UO_2F_5]$ | 3 | 4.0 | 860 | [70] |
| $Rb[UO_2(Cl_3COO)_3]$ | 4.7 | 3.0 | 924 | [55] |
| $Rb_4[UO_2(CO_3)_3]$ | 10.2 | 3.6 | 877 | [55] |

Note. The $pK_a$ and the electronegativities $X$ for the anion are quoted.

The analysis of the variation of the frequency $\nu_{as}(UO_2^{2+})$ under the influence of the outer-sphere cation is also of interest. It is known that there is competition in uranyl complexes between the uranyl ion and the outer-sphere cation: both withdraw electron density from the anion in the three-centre system U–A–M. The results of studies on chloride complexes were previously discussed by Vdovenko.[71] The data in Table 3 show that, in the series of isostructural tetrachloro- and pentafluoro-uranylates, the transition from $Li^+$ and $Cs^+$ entails a monotonic increase of the frequency $\nu_{as}(UO_2^{2+})$. From the standpoint of the theory of electronegativity, the EO of the outer-sphere cations diminishes on passing from $Li^+$ to $Cs^+$ (EO is 1.1 for $Li^+$, 0.9 for $Na^+$, 0.8 for $Rb^+$, and 0.7 for $Cs^+$).[42] Since the EO of the $UO_2^{2+}$ group is 1.38,[45] i.e. is greater in absolute magnitude than the EO of metal ions, the electron density shifts from the anion to the uranyl ion, which means that the M–A bond is more electrostatic than the U–A bond and the amount of ionic character of the M–A bonds is greater the lower the EO of the outer-sphere cation. With increase of the amount of ionic character of the M–A bonds, there is a corresponding increase of the degree of covalence of the U–A bonds. The increase of the degree of covalence of the uranium–ligand bonds should induce a decrease of the frequency $\nu_{as}$ of the uranyl ion, which has in fact been observed for the halide complexes.

In the case of complex polyatomic polyfunctional anions, this type of relation breaks down. Table 4 shows that the frequencies $\nu_{as}$ in the spectra of uranyl nitrates and carbonates are almost insensitive to the effects of the outer-sphere cation.[72] However, this not only does not conflict with the effects discussed above but actually confirms them. Indeed, the electron density shifts from the oxygen atoms of the anions in such complexes and is distributed between the uranium atom and the central atom of the acido-ligand (such as the carbon atom in $CO_3^{2-}$ or the nitrogen atom in $NO_3^-$) and not between the uranyl ion and the outer-sphere cation. As a consequence of this, the influence of the outer-sphere cation is hardly reflected in the vibration frequencies of the $UO_2^{2+}$ ion.

The above analysis of the vibration frequencies of the $UO_2^{2+}$ ion in its complexes with acido-ligands shows that, for the series of compounds indicated, the dependence of $\nu$ on the nature of the anions and in particular on their basicity is limited and cannot be regarded in isolation from the characteristics of specific structures. When the complexes contain neutral ligands, the situation probably becomes still more complex. A multiplicity of various structures of uranyl complexes having coordination numbers of 4, 5, and 6 are known; on passing from one compound to another, there is as a rule a change in not just one but immediately in a whole series of parameters characterising these structures. It is therefore almost impossible to relate the changes in the vibration frequencies of the $UO_2^{2+}$ group solely to any one of them.

---o0o---

Thus one may conclude that the energy relations governing the interaction of the uranyl group with acido-ligands in anhydrous complexes are described fairly accurately in terms of electrostatic ideas. This justifies the hypothesis that the above approach to the description of the interaction between the components of the complex is legitimate also in uranyl compounds having a more complex composition.

# Stable Radicals and the Kinetics of the Radical Polymerisation of Vinyl Monomers

E.G.Rozantsev, M.D.Gol'dfein, and A.V.Trubnikov

The literature data and the results of studies by the authors of the review on the kinetics and mechanism of the radical polymerisation of vinyl monomers in the presence of stable radicals of different classes are treated systematically and discussed. The principal kinetic features associated with the influence of the structure of the monomer and the stable radical, the type of initiation, and the nature of the initiator on the polymerisation inhibited by stable radicals are noted. Equations are presented for the calculation of the kinetic parameters of the principal elementary reactions responsible for the initiating and inhibiting effect of stable radicals.
The bibliography includes 155 references.

VI. Radical-anions 1076

The mechanism of the polymerisation of vinyl monomers has been studied in fair detail and numerous reviews and books, for example, Refs.1–4, have been devoted to this problem. The free-radical polymerisation inhibitors have aroused much interest in recent years.

## I. HYDROCARBON RADICALS

Gomberg, who synthesised hexaphenylethane,[5] believed it to be the pure triphenylmethyl radical and it was only later established, in 1909, that "Gomberg's radical" is a dimer in thermodynamic equilibrium with the triphenylmethyl radical. For example, in benzene solution at room temperature only about 2% of the dimer is dissociated into free radicals.[6] It is of interest that an extremely stable hydrocarbon with a melting point of 234 °C has been found among triphenylmethyl dimers:

The triphenylmethyl radical inhibits the thermal polymerisation of styrene.[7] As expected, the measured induction period of the polymerisation reaction proved to be much shorter than the value calculated from the consumption of the inhibitor:[3]

$$\tau = \mu \frac{[X]}{W_i} \quad ,$$

where $W_i$ is the rate of initiation, [X] the initial inhibitor concentration and $\mu$ the stoichiometric inhibition coefficient equal to the number of reaction chains broken by one inhibitor species.

Hexaphenylethane dissolved in styrene served as the source of radicals in the above investigation.[7] According to the authors' data, the rupture of one reaction chain requires 77 hexaphenylethane molecules, which corresponds to $\mu = 0.013$, in good agreement with the data of Theilacker and Ewald.[6]

In the presence of benzyl and diphenylmethyl radicals, which are more reactive than the triphenylmethyl radicals, the polymerisation of acrylonitrile and methyl methacrylate has no induction period and its rate is comparable to the rate of the initiated reaction.[8,9]

## II. HYDRAZYL RADICALS

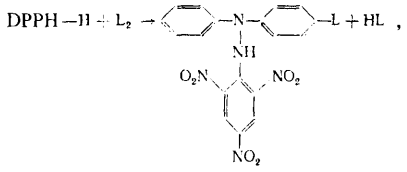
Numerous studies have been devoted to the influence of the stable 1,1-diphenyl-2-picrylhydrazyl (DPPH) radical[10] on the rate of polymerisation of vinyl monomers. The high stability and relative availability of DPPH made it possible to employ this stable radical in the study of the photolysis and radiolysis of various compounds, cage effects, and the decomposition of initiators.[11–15]

DPPH is an effective inhibitor of the polymerisation of styne and vinyl acetate.[16–19] With increase of the DPPH concentration, the induction period shortens, which is caused, according to the authors, by the additional initiation due to the stable radical. It follows from the analysis of the dependence of $\tau$ on the initiator concentration [DPPH] that approximately 10% of the initial amount of the DPPH is consumed in chain initiation. However, one should note that the amount of the hydrazyl radical consumed in the initiation of the reaction is determined by the nature of the monomer. At the end of the inhibition period the steady-state rate of polymerisation falls. The bifunctionality of DPPH (weak initiation and strong inhibition) has also been noted in the polymerisation of styrene.[20]

Despite the above experimental facts and on the basis of the high activity of DPPH in relation to the growing chain alone, Matheson, Bartlett, and co-workers believe that it is possible to use this radical for the determination of the kinetic characteristics of the polymerisation—the rate of chain initiation and the ratio of the rate constants for chain propagation and termination $k_p/k_t^{1/2}$. It is then assumed that one radical terminates only one kinetic chain.

The mechanism proposed earlier[21,22] for the interaction of DPPH with active free radicals R$^\cdot$ consisted in the addition of R$^\cdot$ in the *para*-position in one of the phenyl groups. Further investigations showed that DPPH reacts to form a complex mixture of products: biphenyl, diphenylamine, 1-(4-cyanoisopropylphenyl)-1-phenyl-2-picrylhydrazine, and small amounts of $\alpha\alpha'$-diphenyl-2-picrylhydrazine.[23,24] If the reaction is propagated in the presence of oxygen, then

the interaction of peroxy-radicals with DPPH complicates the mechanism still further.[25-27]



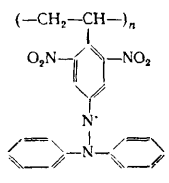
The possibility of the interaction of one DPPH species with several free radicals was first demonstrated experimentally by Hammond et al.[28] in a study of the decomposition of αα'-azobisisobutyronitrile (AIBN). It was assumed that the destruction of the cyanoisopropyl radicals with participation of DPPH is accompanied by the regeneration of the latter:

$$(CH_3)_2\dot{C}CN + DPPH \rightarrow CH_2{=}C(CH_3)CN + H{-}DPPH;$$
$$H{-}DPPH - (CH_3)_2\dot{C}CN \rightarrow (CH_3)_2CHCN + DPPH.$$

The complexity of the interaction of DPPH with free radicals was also confirmed by the result of the determination of the initiation efficiency factor $f$ for AIBN.[22] Its values proved to be appreciably lower than those obtained by other workers using independent methods.

DPPH reacts with inorganic and organic acids via an ionic mechanism:[29]

$$DPPH + L^- \rightleftarrows [DPPH{-}L]^-,$$
$$[DPPH{-}L]^- + H^+ \rightarrow DPPH{-}H + {}^1/_2L_2,$$



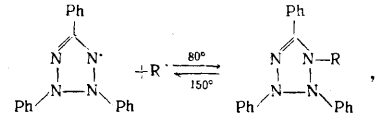
where $L^-$ is the anion. It follows from the data presented that the inhibition of polymerisation processes by DPPH cannot be regarded as proof of the radical character of the reaction.

By measuring the DPPH concentration spectrophotometrically, Bengough[30] observed that the induction period in the polymerisation of vinyl acetate is not the same as the time required for the complete disappearance of the stable radical from the reaction system. This is apparently associated with the fact that the stoichiometric inhibition coefficient is not unity.

Analogous results were obtained also in the study of the thermal polymerisation of styrene inhibited by DPPH.[31] The rate of formation of active radicals, found from the time variation of the absorption intensity ($\lambda$ = 525 nm), proved to be seven times greater than the value calculated from the equation relating the induction period to the initial concentration of the stable radical. This difference between the rates of initiation is caused not only by the stoichiometry of the inhibition but also by the characteristics of the mechanism of the thermal initiation[32,33] and the possibility of the decomposition of DPPH by UV radiation.[24]

The limits of the applicability of DPPH in the study of the kinetics of the decomposition of certain compounds and in the determination of their initiating activity have been analysed[34] and it has been shown that acceptable results are obtained only for the ratio [DPPH]/[I] ≤ 0.5.

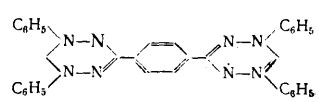
Multiradical inhibitors based on DPPH, of the type[35,36]



are of definite interest.

It follows from the literature data[16-38] that, when DPPH is used as the source of radicals, it is essential to know and take into account the chemical side reactions. Some investigators explained the decrease of the steady-state rate of polymerisation in the presence of DPPH (secondary inhibition) as the influence of the products of the primary inhibition responsible for the induction period.[37] The retardation of the reaction is usually attributed to the presence of nitro-groups. In order to test this hypothesis, 2-(2,6-dinitrophenyl)-1,1-diphenylhydrazyl was used to study the decomposition of AIBN under the conditions of heterophase polymerisation.[39] In the polymerisation of styrene[40] in the presence of this radical, there was indeed no additional initiation and the decrease of the steady-state rate was much smaller than in the case of the classical DPPH.

Braun and Peschk[41,42] prepared a series of hydrazyl radicals without nitro-groups and investigated their recombination with cyanoisopropyl and polystyryl radicals. The inhibiting activity of the hydrazyl radicals depended not only on their structure but also on the presence of oxygen in the system. The only exception was 2-(2',4',6'-trimethoxycarbonylphenyl)-1,1-diphenylhydrazyl radical, which could be used for quantitative measurements of the rate of initiation, since oxygen did not affect its inhibiting activity and the induction period was directly proportional to the radical concentration. In particular, the rate of initiation of the polymerisation of styrene (with AIBN as the initiator) determined with its aid agrees satisfactorily with the literature data.[3]



## III. VERDAZYL RADICALS

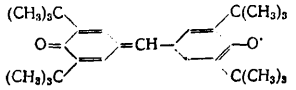
In the first study[43] devoted to this class of stable radicals, it was already shown that the 1,3,5-triphenylverdazyl radical suppresses the polymerisation of styrene. In subsequent detailed investigations[44,45] of the polymerisation of styrene, methyl methacrylate, and certain other vinyl monomers, the high efficiency of the inhibiting effect of the verdazyl radical and the possibility of using it to determine the rate of chain initiation were established. It was found that the products of the recombination of verdazyl radicals with active radicals are capable of homolytic dissociation with formation of a stable radical (the activation energy for the homolysis is approximately 140 kJ mol$^{-1}$):[46]

where R' is the initiator or polymer radical.

In the polymerisation of certain acrylic monomers (for example, oligourethane acrylate), the regeneration of the verdazyl radical was not observed and the inhibition efficiency appreciably diminished with increase of temperature.[47] In contrast to the 2,4,6-triphenyl-3,4-dehydro-s-tetrazine-1-verdazyl monoradical, the participation of the phenylenebisverdazyl radical

in the reactions entailed a sharp decrease of the rate of polymerisation.

The triphenylverdazyl radical is capable of reacting with acrylonitrile[40] via the double bond with an activation energy of about 45 kJ mol$^{-1}$, which indicates a relatively high

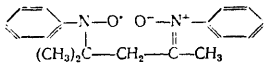


initiating activity of the verdazyl radical compared with many other stable radicals.

As in the case of DPPH, the accuracy of the determination of the rate of decomposition of the initiators with the aid of the triphenyl verdazyl radical depends on the ratio of the inhibitor and initiator concentrations. When a verdazyl radical is employed, this ratio should not exceed 2.[34]

The above characteristic features of the behaviour of verdazyl radicals limit their application to the reliable estimation of various kinetic parameters. The capacity of verdazyl radicals for relatively rapid oxidation by peroxy-compounds [48–50] at comparatively low temperatures (10–20 °C) precludes the determination of the characteristics of the initiation of polymerisation in their presence.

## IV. ARYLOXY-RADICALS

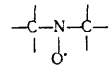


Among the radicals of this class, only the so-called galvinoxy-radical[51]

has been used in polymerisation. The decomposition of azocumene,[52] certain peroxy-compounds,[53–55] and AIBN [56] as well as the mechanism of the thermal polymerisation of deuteriated pentafluorostyrene[57] have been investigated with its aid. The galvinoxy-radical interacts with cyanoisopropyl radicals mainly by recombination. However, owing to the low photochemical and thermal stability of this radical and its ability to react with oxygen,[24] it cannot be used in accurate kinetic measurements.

## V. NITROXY-RADICALS

Until the beginning of the 1960s, only one classical nitroxy-radical, namely Banfield's radical or the nitroxynitroxide radical



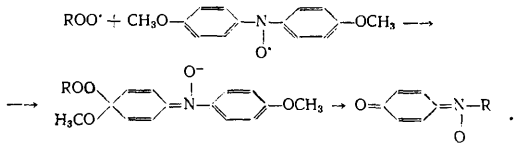
was used as the polymerisation inhibitor and free radical acceptor. Bevington and Ghenem[58] inhibited the polymerisation of styrene and methyl methacrylate with this radical. In air Banfield's radical is relatively unstable, its stability being appreciably higher in an inert atmosphere. The induction period of the polymerisation reaction in the presence of this radical is shorter than the value calculated from the formula $\tau = [X]_0/W_i$, which can be explained by its partial decomposition.

Tudos et al.[59] suggested that $\tau$ diminishes owing to the involvement of the radical in initiation reactions. Only on this hypothesis do the rates of initiation of polymerisation obtained[59,60] agree satisfactorily with literature data.

The influence of Banfield's radical, like, incidentally, that of other inhibitors, on the rate of polymerisation depends on the nature of the monomer and, in copolymerisation, also on the ratio of the concentrations of the monomers employed. Thus in solution in acrylonitrile the radical reacts with the monomer itself and the reaction is autocatalytic.[39] For this reason, Banfield's radical is unsuitable for the determination of the quantitative characteristics of the polymerisation of acrylonitrile. In the copolymerisation of acrylonitrile and styrene with participation of this radical, the stoichiometric inhibition coefficient exceeds unity,[61] which indicates the regeneration of the inhibitor in competition with the additional initiation reaction. At 50 °C and at a relatively low monomer concentration, the contribution of Banfield's radical to chain initiation in the copolymerisation of acrylonitrile with methyl methacrylate in dimethylformamide (DMF) is slight. With increase of temperature and the content of acrylonitrile, the effect becomes appreciable.[62] In the copolymerisation of styrene with maleic anhydride in solutions of acetonitrile, acetone, and tetrahydrofuran (THF) in the presence of Banfield's radical, the induction period in the process increases with decrease in the concentration of the monomers.

At the end of the induction period the rate of copolymerisation becomes lower than the rate of reaction in the absence of the inhibitor and depends appreciably on the concentration of the latter.[63] These results show that the use of Banfield's radical for accurate measurements of the rate of initiation without taking into account side reactions cannot be regarded as justified.

The successful development of the chemistry of stable radicals during the last twenty years[24,38] has led to the discovery of a new class of extremely stable non-aromatic nitroxy-radicals (iminoxy-radicals) with a localised free-radical centre:[64,65]



In the first studies[66–72] devoted to the use of nitroxy-radicals of this class as radical counters and antioxidants, interesting features of their behaviour were already observed. It was shown that, in contrast to the classical aromatic nitroxy-radicals, the non-aromatic nitroxy-radicals recombine rapidly with alkyl radicals but do not interact with peroxy-radicals.

Classical aromatic nitroxy-radicals interact with the radicals ROO'; for example, at 60 °C the rate constant for the reaction of the di-(4-methoxyphenyl)-nitroxy-radical with peroxy-radicals is $6 \times 10^5$ dm$^3$ mol$^{-1}$ s$^{-1}$.[63] It had been suggested earlier[73,74] that aromatic nitroxy-radicals interact with peroxy-radicals in accordance with the mechanism

In our view, the attack by the peroxy-radical in the *para*-position in one of the benzene rings of the diarylnitroxy-radical with formation of a quinonoid structure is more probable:[75,76]

We believe that the proposed mechanism agrees better with experimental data including the accumulation of compounds of the quinonitroxide type in the reaction products.[77] It is noteworthy that non-aromatic nitroxy-radicals can also react with peroxy-radicals if the latter have a favourable chemical structure. Thus the oxidation of primary and secondary aliphatic amines[78] results in the formation of peroxy-radicals of the iminoperoxy-type:

Such radicals interact with non-classical nitroxy-radicals to form the corresponding hydroxylamine with subsequent regeneration of the stable radical:

$$-NH-\underset{\diagdown}{\overset{\diagup}{C}}OO^{\cdot} + \rangle N-O^{\cdot} \rightarrow \rangle NOH + -N=\underset{\diagdown}{\overset{\diagup}{C}} + O_2 ;$$

$$-NH-\underset{\diagdown}{\overset{\diagup}{C}}OO^{\cdot} + \rangle NOH \rightarrow -NH-\underset{\diagdown}{\overset{\diagup}{C}}OOH + \rangle NO^{\cdot}.$$

Analogous results have been obtained in the inhibition of the oxidation of dimethylaminoethyl methacrylate.[79] In the oxidation of the alkyl methacrylates, the active intermediate chain centres are polyperoxy-radicals without reducing properties. Chain termination takes place as a result of the interaction of the nitroxy-radicals with alkyl radicals, the inhibitor not being regenerated. When a tertiary amino-group is introduced into the methacrylate, the chain termination mechanism changes—the above reactions become most important and the nitroxy-radical is regenerated.

The mechanism of the interaction of the nitroxy-radicals with alkyl radicals has been investigated.[80,81] The main product of the reaction of the 2,2,6,6-tetramethyl-4-oxopiperidin-1-yloxy-radical with the cyanoisopropyl radical was an ether derived from a heterocyclic hydroxylamine.

The view that recombination is the only pathway involved in the interaction of nitroxy-radicals with active radicals is widely held. In particular, the unique capacity of nitroxy-radicals for regeneration in reactions where they inhibit the oxidation of olefins, polyolefins, and hydrocarbons has been explained on the basis of this idea.[82-87] It follows from these investigations that the regeneration takes place as a result of the reaction

$$\rangle NOR + ROO^{\cdot} \rightarrow \rangle NO^{\cdot} + \text{products}.$$

However, the results of Shlyapnikov et al.[88] do not agree with these ideas. Experiment has shown that the 2,2,6,6-tetramethyl-4-oxopiperidin-1-yloxy-radical is regenerated approximately $10^3$ times faster than would be the case if this happened solely via the reaction presented above. According to the authors, this is associated with chain termination not only via recombination but also due to disproportionation, which leads to the formation of the hydroxylamine.

The efficiency of nitroxy-radicals as free radical acceptors has stimulated their application in the study of the mechanisms of polymerisation initiation. This application has developed in a number of investigations.[89-96] The authors established that, in the general case, when the nitroxy-radical is added to the monomer–initiator system, the polymerisation is suppressed but the radical is able to react only with some of the initiator radicals, while in the case where peroxides are used it does not interact with the primary radicals at all. For this reason, the products of the reactions of the primary radicals with the monomer are formed in this case in almost quantitative yields. They interact with the nitroxy-radicals and form stable adducts, whose structure has been reliably established. Under certain conditions, the nitroxy-radical can catalyse the decomposition of peroxides.[97]† Thus nitroxy-radicals can be used as effective analytical reagents and information about the fine details of the initiation mechanism can be obtained with their aid.

In the first studies of the influence of classical aromatic nitroxy- and iminoxy-radicals on the rate of radical polymerisation,[98,99] the rate constants for the interaction of the stable radicals with the styrene macroradicals were determined by EPR. The calculations were performed on the assumption that chain termination takes place in 1 : 1 proportions. Furthermore, a study was made of the reactions of stable biradicals with the alkyl radicals formed on decomposition of AIBN in ethylbenzene and dioxan.[100] It was observed that the probability of the recombination of the radical centre depends on the residual unpaired electron in the biradical.[101] The first reaction (with one of the localised free-radical centres) proceeds more readily than the second, which the authors explain within the framework of the adiabatic nature of the recombination reaction.

The interaction of certain mono- and di-radicals with styrene and α-methylstyrene at 100–120 °C has been investigated by EPR.[102] The authors suggest that the stable radicals are consumed in reactions involving addition to the monomer molecules (additional initiation) and in the course of recombination with the active radicals produced. The following mechanism has been proposed for the monoradicals (X):

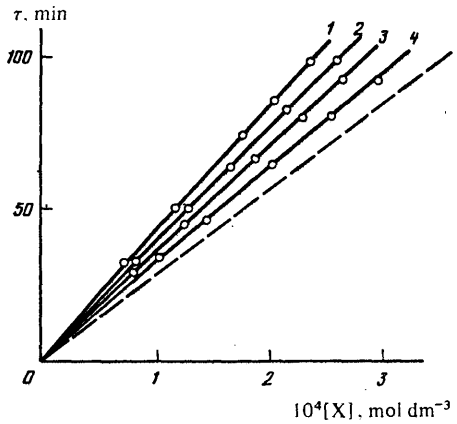
$$CH_2=\underset{C_6H_5}{\underset{|}{CH}} + X^{\cdot} \xrightarrow{k_M} X-CH_2-\underset{C_6H_5}{\underset{|}{CH}} ;$$

$$R^{\cdot} + X^{\cdot} \xrightarrow{k_X} \text{products}.$$

However, the authors did not take into account the fairly high capacity of styrene for thermal polymerisation, whose rate is high at the temperatures indicated. For this reason, some of the stable radicals should be consumed in reactions with the species initiating the thermal polymerisation. This factor has been taken into account in two investigations[103,104] of the influence of pressure on the reactions occurring in the styrene–iminoxy-radical system at 80 °C. Assuming that the thermal initiation takes place in accordance with Mayo's mechanism,[105] the authors obtained an equation for the rate of consumption of the nitroxy-radical in the monomer:

$$-d[X]/dt = 2k_{DA}[M]^2 + 2k_M[M][X] ,$$

where $k_{DA}$ is the rate constant for the reaction of the iminoxy-radical with the Diels–Alder adduct and [M] is the monomer concentration. The validity of this equation requires additional evidence in view of the uncertainty of the mechanism of the initiation of the thermal polymerisation of styrene[33] and the latest data concerning the influence of iminoxy-radicals on the rate of this reaction.[106,107]



In a study of the propagation of the chloroprene ω-polymer in the presence of iminoxy-radicals,[108] yet another piece of evidence for the free-radical nature of the ω-polymerisation of this monomer was obtained.

The advances in the chemistry of nitroxy-radicals have made it possible to synthesise polymeric free radicals in which the nitroxy-radical forms part of the composition of the polymer chain unit.[109] Such macromolecular stable radicals inhibit effectively the polymerisation of styrene and methyl methacrylate initiated by AIBN [110-112] and also the polymerisation accompanying the synthesis of unsaturated ethers.[113]

The influence of di(4-ethoxyphenyl)nitroxy-radical on the polymerisation of styrene has been investigated.[114] The decrease of the inhibiting activity of the arylnitroxy-radical in the presence of benzoyl peroxide, despite the linear dependence of τ on the concentration of the additive, was observed for the first time in the above study. In contrast to the polymerisation initiated by AIBN, a slower increase in the rate of reaction during the induction period and a decrease of the steady-state rate with increase of the arylnitroxy-radical concentration were then observed. It will be shown below that these effects are associated with the interaction of the benzoate radical with the aryl nitroxy-radical.

† This observation was subsequently used by one of the present authors for the selective inhibition of certain undesirable oxidation reactions—see, for example, Maslov et al.[154]

The 2,2,6,6-tetramethyl-4-hydroxypiperidin-1-yloxy-radical[115] was one of the first nitroxy-radicals used as the counter of active centres in the polymerisation of tetrafluoroethylene.[116] The possibility of determining the rate of chain initiation with the aid of this iminoxy-radical was justified in the above investigation by the fact that the induction period is directly proportional to the inhibitor concentration and the polymerisation is not retarded at the end of the inhibition period. A 1 : 1 stoichiometry of chain termination was adopted, as in many other studies.[117–125]

Dependence of the induction period in the polymerisation of styrene on the concentration of the iminoxy-radical: 1) 2,2,6,6-tetramethyl-4-oxopiperidine-1-yloxy-ester of α-cyano-ββ′-diphenylacrylic acid; 2) 2,2,6,6-tetramethyl-4-salicylideneaminopiperidin-1-yloxy-radical; 3) 2,2,6,6-tetramethyl-4-stearyliminopiperidin-1-yloxy-radical; 4) 2,2,6,6-tetramethyl-4-benzoylpiperidin-1-yloxy-radical; initiator—azobisisobutyronitrile ($3 \times 10^{-2}$ mol dm$^{-3}$); 45 °C; the dashed line corresponds to $\mu = 1$.

The reaction of the 2,2,6,6-tetramethyl-4-oxopiperidin-1-yloxy-radical[126] with primary and polymeric radicals in the inhibition of the polymerisation of styrene and methyl methacrylate has been studied.[127] The inhibition mechanism proposed by the authors includes a stage involving the recombination of the active and stable radicals with formation of the corresponding ethers. This conclusion is confirmed by the fact that the ether does not influence the rate of polymerisation, while the reduced radical (hydroxylamine) induces a marked decrease in the rate of the process. In fact, there is no retardation of the polymerisation at the end of the induction period.

At the same time there exist data in conflict with the idea of a simple stoichiometry of chain termination. Comparative estimation of the inhibiting activities of the iminoxy- and arylnitroxy-radicals in the initiated polymerisation of styrene showed[128] that the stoichiometries of the reactions with polystyrene radicals are the same for different classes of nitroxy-radicals. However, this fact was not explained.

The study of the inhibiting properties of the 2,2,6,6-tetramethyl-4-oxopiperidin-1-yloxy- and 2,2,6,6-tetramethyl-4-hydroxypiperidin-1-yloxy-radicals in the polymerisation of oligourethaneacrylate[47] showed that the former radical induces under identical conditions a longer induction period than the latter. This means that the 2,4-bis(2,2,6,6-tetramethyl-4-ureidopiperidin-1-yloxy)tolylene biradical inhibits the polymerisation of oligourethaneacrylate more effectively than would be the case for simple stoichiometry of the termination reaction.

In the inhibition of the copolymerisation of styrene with acrylonitrile by the 2,2,6,6-tetramethylpiperidine-1-yloxy-radical, it was found[61] that the stoichiometric inhibition coefficient depends on the nature of the initiator and is much greater than unity when AIBN is used. According to Shlyapnikov et al.,[129] the occurrence of side reactions hinders the application of the inhibitor method to the determination of the relatively low rates of the chain initiation reactions in processes involving the degradation of polymers in an inert atmosphere.

In order to refine the mechanism and find the quantitative characteristics of the inhibition by iminoxy-radicals, it is most convenient to study their influence on the polymerisation of thoroughly investigated monomers (styrene and acrylate and methacrylate esters) in the presence of initiators with known rates of decomposition (AIBN and benzoyl peroxide). In the polymerisation initiated by AIBN, the rate of consumption of stable radicals during the inhibition period is lower in all the monomers than the rate of initiation, i.e. $\mu > 1$ [130–133] (see Figure). Such increase of $\mu$ can be explained, for example, by the regeneration of the inhibitor. However, in certain cases when the period $\tau$ has come to an end, the rate of polymerisation becomes lower than the rate of the non-inhibited process. With increase of the concentration of the additive, the induction period shortens, which is apparently caused by the addition of the stable radical to the monomer at the double bond (i.e. by the additional initiation).

Thus the effective inhibition of polymerisation by iminoxy-radicals is accompanied by complex reactions. In order to elucidate certain details of the inhibition process, the influence of ethers $R_0$–X ($R_0$ is a primary radical) and hydroxylamines X–H on the polymerisation has been investigated[155] and it has been established that ethers do not affect the polymerisation kinetics, while the rate of the process diminishes somewhat in the presence of hydroxylamines. Consequently the regeneration can be explained by the fact that some of the iminoxy-radicals disproportionate in a reaction with active radicals, forming nitroso-compounds.[134] The latter suppress the polymerisation, each terminating two kinetic chains per inhibitor molecule. Apparently the involvement of iminoxy-radicals in this stage is in fact responsible for the increase of the stoichiometric coefficient, while the decrease of the steady-state rate of polymerisation is associated with chain termination by hydroxylamines.

The radical-chain mechanism of the polymerisation of vinyl monomers, initiated by AIBN, in the presence of added iminoxy-radicals can be represented in the following way on the basis of the foregoing:

$$\text{AIBN} \rightarrow 2R_0^{\cdot} + N_2\uparrow ; \qquad \text{(I)}$$

$$R_0^{\cdot} + M \xrightarrow{k_i} R^{\cdot} ; \qquad \text{(II)}$$

$$R^{\cdot} + M \xrightarrow{k_p} R^{\cdot} ; \qquad \text{(III)}$$

$$X + M \xrightarrow{k_i} R^{\cdot} ; \qquad \text{(IV)}$$

$$R^{\cdot} + X \xrightarrow{k_t} RX ; \qquad \text{(V)}$$

$$X + R^{\cdot} \xrightarrow{k_t} XH + \text{inactive products;} \qquad \text{(VI)}$$

$$X + M \xrightarrow{k_s} R^1\text{—N=O} + HM ; \qquad \text{(VII)}$$

$$R^1\text{—N=O} + R^{\cdot} \rightarrow R^1\text{—N(O}^{\cdot}\text{)—R} ; \qquad \text{(VIII)}$$

$$R^1\text{—}\underset{\underset{O^\cdot}{|}}{N}\text{—}R + R^\cdot \rightarrow R^1 - \underset{\underset{OR}{|}}{N}\text{—}R\ ; \qquad (IX)$$

$$XH + R^\cdot \rightarrow X^\cdot + RH\ ; \qquad (X)$$

$$R^\cdot + R^\cdot \rightarrow \text{polymer}. \qquad (XI)$$

The additional initiation with the aid of the stable radical proceeds slowly ($k_i \cong 10^{-6}$ dm$^3$ mol$^{-1}$ s$^{-1}$ at 60 °C), the secondary inhibition is slight, and in the course of the induction period the contribution by the quadratic termination to the overall chain termination is small. For these reasons, disregarding reactions (IV), (X), and (XI), the kinetic equation describing the consumption of the iminoxy-radicals assumes the following form:

$$-d[X]/dt = W_i(k_1 + k_2 + k_3)/(k_1 + k_2 + 2k_3). \qquad (1)$$

The inhibitor should be consumed in accordance with a linear law at a rate lower than that of initiation, which has been confirmed satisfactorily by experimental data. The stoichiometric inhibition coefficients are calculated in these cases from the formula

$$\mu = 1 + \frac{2k_3}{k_1 + k_2 + k_3}\ . \qquad (2)$$

The time variation of the rate of inhibited polymerisation obeys the Bagdasar'yan–Bamford equation:

$$-\frac{1}{\varphi} + \ln\frac{1+\varphi}{1-\varphi} = (k_X + k_3)[R]_\infty t + \text{const}\ , \qquad (3)$$

where $\phi = W_t/W_\infty$ is the ratio of the rates of polymerisation at any instant $W_t$ and the steady-state $W_\infty$, $[R]_\infty$ is the steady-state concentration of the polymeric radicals, and $k_X = k_4 + k_5$. Eqns.(1) and (2) are valid at relatively low temperatures (40–60 °C). The consumption of iminoxy-radicals increases with increasing temperature owing to the suppression of the thermal initiation and their addition to the monomer, the experimental quantity $\mu_{exp}$ therefore diminishes. The contribution of these reactions can be taken into account by calculating the rate of consumption of the inhibitor in the monomer at an elevated temperature $\omega_0 = \{-d[X]/dt\}_0$. Then, denoting the rate of consumption of iminoxy-radicals in the inhibition reaction by $\omega = d[X]/dt$, we obtain

$$W_i = \mu_{exp}(\omega_0 + \omega), \qquad (4)$$

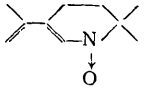
where $\mu_{exp}$ is the experimental (apparent) stoichiometric inhibition coefficient. An expression for the true value of $\mu$ can be readily obtained from Eqn.(3):

$$\mu = \frac{W_i\mu_{exp}}{W_i - \omega_0\mu_{exp}} \qquad (5)$$

The set of equations (2), (3), and (5) makes it possible to estimate the inhibition rate constant $k_X$ and the rate constant for the regeneration of the inhibitor $k_3$ as well as the activation energies $E$ for these reactions (see Table). It is essential to note that the relative errors of the tabulated rate constants and activation energies are approximately 10 and 15% respectively. The differences are most probably associated with the different structures of the stable radicals investigated. However, hitherto it has not been possible to establish a reliable correlation between the chemical structure of the iminoxy-radicals and the parameters noted above, characterising their inhibiting effect. Comparison of the quantities $k_X$, $k_3$, $E_X$, and $E_3$ suggests that the substituent exerts the main influence on the pre-exponential factor (i.e. on the steric factor) and not on the activation energy.

The tabulated $k_X$ differ from the literature data. The constants for the interaction of nitroxy-radicals with primary and polymeric radicals found by different workers vary from $10^4$ to $10^8$ dm$^3$ mol$^{-1}$ s$^{-1}$.[98,114,128,135] This scatter is not surprising, since in many cases no account was taken of the details of the inhibition mechanism associated with the complex stoichiometry of the chain termination, the inhibitor generation, the additional initiation, the influence of the type of initiation and of the nature of the initiator, the characteristic features of oxidative polymerisation, etc.

Kinetic parameters of the inhibition of the polymerisation of styrene and methyl methacrylate by iminoxy-radicals (60 °C, initiator—AIBN).* [130–133,155]



| Radical | $10^{-5}k_X$, dm$^3$mol$^{-1}$s$^{-1}$ | $10^{-5}k_3$, dm$^3$ mol$^{-1}$ s$^{-1}$ | $E_X$, kJ mol$^{-1}$ | $E_3$, kJ mol$^{-1}$ |

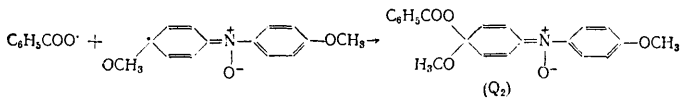
*The first and second numbers represent respectively the data for styrene and methyl methacrylate.

The kinetics and mechanism of the polymerisation inhibited by nitroxy-radicals change significantly on passing from initiation by azo-compounds to initiation by peroxy-radicals. The mechanism of the interaction of iminoxy-radicals with peroxy-radicals is determined by the chemical structure of the latter and the nature of the solvent. Thus the rates of decomposition of benzoyl peroxide (BP) in DMF and of t-butyl and dicumenyl peroxides in benzene are independent of the presence of iminoxy-radicals in the mixture.[136,137] On the other hand, the decomposition of acetylphenyl peroxide in carbon tetrachloride[138] and of dicyclohexyl peroxydicarbonate in benzene and chlorobenzene[139] is accelerated with formation of free-radicals and non-radical products.

At concentrations of the iminoxy-radicals exceeding the BP concentration by approximately a factor of two, the induced decomposition of the peroxide in the monomer takes place with formation of a heterocyclic nitroxide (nitrone)

and benzoic acid.[140]

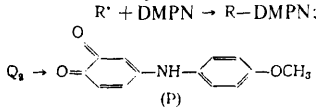
Under polymerisation conditions where [BP] ≫ [X], the formation of side products is apparently suppressed and the induced decomposition accompanied by the formation of a donor–acceptor complex $Q_1$ becomes the main process:[141]



$$BP + X \rightleftarrows Q_1 \rightleftarrows 2C_6H_5COO^\cdot + X\ .$$

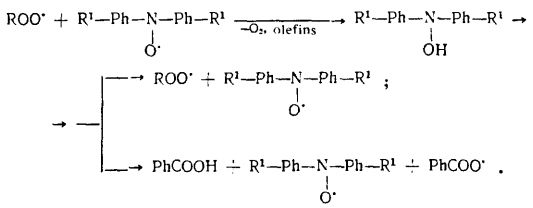
The effective rate constants for the decomposition of the BP bound in the complex are approximately $10^2$ dm$^3$ mol$^{-1}$ s$^{-1}$ in styrene and $5 \times 10^3$ dm$^3$ mol$^{-1}$ s$^{-1}$ in methyl methacrylate (60 °C). The effective activation energy for the decomposition reaction is about 80 kJ mol$^{-1}$, which is appreciably lower

than for the free initiator molecule (125 kJ $mol^{-1}$). Thus iminoxy-radicals are unsuitable for the determination of the rate of chain initiation by peroxide initiators.



The significant differences between the reactivities of iminoxy-radicals and aromatic nitroxy-radicals[24,142] lead to their different effects on the kinetics of polymerisation initiated by peroxides. Whereas the role of iminoxy-radicals reduces to the acceleration of the decomposition of BP (naturally apart from the inhibition itself), nitroxy-radicals [for example, di(4-methoxyphenyl)nitroxy-radicals (DMPN)] interact with BP to form non-radical products.[143] The reaction in the monomers proceeds via a more complex multistage mechanism:

$$BP + DMPN \rightarrow 2C_6H_5COO^{\cdot} + DMPN:$$



$$C_6H_5COO^{\cdot} + M \rightarrow R^{\cdot}$$

$$R^{\cdot} + DMPN \rightarrow R{-}DMPN:$$

The aminoquinone (P) formed is a probable polymerisation inhibitor. It follows from the above mechanism that, whereas in an inert atmosphere two stable radicals are consumed per BP molecule, in the presence of air the stoichiometry changes owing to the regeneration of the arylnitroxy-radical:[73,128,144]

The change in stoichiometry does not lead to new kinetic effects. At the end of the induction period induced by the presence of the aminoquinone, the polymerisation proceeds at a constant rate $W_\infty$, which is lower than the rate of the non-inhibited reaction $W$.

The following equation corresponds to the radical-chain polymerisation mechanism in the presence of the aminoquinone and with allowance for secondary inhibition:[130]

$$-\frac{1}{\varphi_t} - \ln(1-\varphi_t) + (1-\varphi_\infty^2)\ln\varphi_t + \varphi_\infty^2 \ln\left(\varphi_t - \frac{1}{\varphi_\infty^2}\right) = \frac{k_X}{k_p}\frac{W_\infty}{M}t + A,$$

where $\phi_t = W_t/W_\infty$, $\phi_\infty = W_\infty/W$, and $A$ is a constant. The inhibition constants $k_X$ for different monomers are in the range $10^4$–$10^5$ $dm^3$ $mol^{-1}$ $s^{-1}$ (60 °C) and the activation energy for the inhibition reaction is 23 kJ $mol^{-1}$.

## VI. RADICAL-ANIONS

In contrast to neutral stable radicals, charged radicals usually initiate ionic polymerisation.[145,146] The initiating activity of radical-anions depends on the difference between the electron affinities of the monomer and the initiator. The radical-anions formed from compounds with a very high electron affinity can therefore prove to be incapable of initiating anionic polymerisation. Having an excess charge, the radical-anions usually possess electron-donating properties and are involved in various charge-transfer reactions.

The influence of radical-anions on the polymerisation of vinyl monomers via a radical mechanism has been investigated in relation to the effect of tetracyanoquinodimethane salts, which dissociate in solution with formation of the tetracyanoquinodimethane radical-anion $TCQM^{\cdot-}$. When the polymerisation is initiated by benzoyl peroxide, the introduction into the solution of the lithium salt of tetracyanoquinodimethane (Li TCQM) leads to a sharp acceleration of the polymerisation and a decrease in the molecular weight of the polymer. An increase in the rate was observed only in those cases where the concentration of the salt did not exceed that of the peroxide by a factor greater than two and the highest rate of the process was attained for equal contents of Li TCQM and BP.[147–150]

Studies of the kinetics of the polymerisation and the interaction of BP and $TCQM^{\cdot-}$ showed that a one-electron transfer reaction takes place between the radical-anion and the peroxide molecule with subsequent reactions between the resulting neutral TCQM and the benzoate anion $R^-$ and also between the benzoate radical $R^{\cdot}$ and yet another $TCQM^{\cdot-}$ radical-anion:

$$TCQM^{\cdot-} + BP \rightarrow R^{\cdot} + R^- + TCQM:$$

$$TCQM^{\cdot-} + R^{\cdot} \rightarrow Q^-;$$

$$TCQM + R^- \rightarrow Q^-.$$

These reactions take place at a high rate even before the onset of polymerisation. The initiating radicals are formed in the oxidation-reduction interaction of the intermediates with the BP molecules which fail to react ($\overline{BP}$):

$$\overline{BP} + Q^- \xrightarrow{k_R} R^{\cdot} + R^- + R_Q^{\cdot}$$

The polymerisation is initiated by the BP–Li TCQM system by a factor of several tens faster than as a result of the thermal decomposition of BP.

If the initial Li TCQM concentration is greater than twice the peroxide concentration, then free $TCQM^{\cdot-}$ radical-anions remain in the reaction system and inhibit the polymerisation.

The study of the reactions of various organic peroxides with the $TCQM^{\cdot-}$ radical-anion has shown that, in conformity with the mechanism proposed, the radical-anion interacts only with those peroxides which possess a sufficiently high electron-accepting capacity (benzoyl and lauryl peroxide). Otherwise $TCQM^{\cdot-}$ only exhibits the polymerisation (cumenyl peroxide). In the presence of lauryl peroxide, whose electron-accepting capacity is lower than that of BP, the rate of initiation of the polymerisation diminishes.

The initiation of polymerisation by the peroxide–$TCQM^{\cdot-}$ radical-anion system is characterised by a low activation energy (~40 kJ $mol^{-1}$), which makes it possible to carry out the reaction at a high rate and a relatively low temperature.

The possibility that radical-anions can assume the role of radical polymerisation inhibitors was first demonstrated in relation to the radical-anion salt of 7,7,8,8-tetracyanoquinodimethane with dimethylviologen.[151] It was found that $TCQM^{\cdot-}$ inhibits effectively the polymerisation of styrene, acrylate and methacrylate esters, and acrylonitrile, giving rise to distinct induction periods.[152] It was established that $TCQM^{\cdot-}$ interacts not only with active radicals, inhibiting polymerisation, but also with monomer molecules, which leads to the generation of new active centres, which are immediately terminated by the radical-anion. Such additional initiation induces a relative shortening of the induction period with increase in the inhibitor concentration. The rate constant for the additional initiation $k_i$ depends significantly on the nature of the monomer and diminishes in the sequence styrene > methyl methacrylate > methyl acrylate.

The radical-anion complexes dissociate in solution in different ways depending on the nature of the cation, the concentration, the composition of the medium, and temperature. In the general case the $TCQM^{\cdot-}$ radical-anion exists in solution in the form of both free radical-anions and ion pairs, which have different reactivities. It has been shown that the additional inhibition is induced only by the $TCQM^{\cdot-}$ radical-anions present in solution in the form of ion pairs with a cation, while free-radical-anions are more active in the inhibition reaction.[153] A change in the composition of the reaction medium influences the degree of dissociation of the $TCQM^{\cdot-}$ complexes and hence the contribution of the additional initiation to the overall reaction kinetics. As a result, the duration of the inhibition of the polymerisation by the $TCQM^{\cdot-}$ radical-anions is determined not only by the ratio of the inhibitor concentration and the rate of initiation but also by factors influencing the degree of dissociation of the radical-anion salts.

The dependence of the duration of the induction period in the polymerisation of styrene on the TCQM concentration is fairly complex and is determined by the equation[152]

$$\tau = [2k_{decomp}f\alpha(1-\gamma)]^{-1}\ln\left\{1-\alpha(1-\gamma)\frac{[X]_0}{[I_0]}\right\},$$

where $\alpha = k_i[M]/k_{decomp}f$, $k_i$ is the rate constant for the additional initiation of the polymerisation by the ion pairs involving the $TCQM^{\cdot-}$ radical-anion, $k_{decomp}$ the rate constant for the initiator decomposition reaction, $f$ the efficiency of the initiation, and $[I]_0$ and $[X]_0$ are the initial concentrations of the initiator (AIBN in the study indicated) and the TCQM radical-anion salts.

As a result of the additional initiation reaction, the time variation of the rate of the inhibited polymerisation no longer obeys the Bagdasar'yan–Bamford equation[3] and is described by the more complex expression[151]

$$-2\ln(\varphi_t-\theta)-\left(\frac{1}{\theta}-1\right)\ln(1-\varphi_t)+\left(\frac{1}{\theta}+1\right)\ln(1-\varphi_t)+$$
$$+0.5\left(\frac{1}{\theta^2}-1\right)\ln\left|\frac{\varphi_t-\theta}{\varphi_t+\theta}\right|=\frac{k_X}{k_p}\frac{W_\infty}{M}\left(\frac{1}{\theta}-\theta\right)t+\text{const},$$

where $\theta = k_i[M]/k_X[R]_\infty$, $\phi_t = W_t/W_\infty$, $W_t$ is the rate of polymerisation at time $t$, and $W_\infty$ and $[R]_\infty$ are the steady-state rate and concentration of polymeric radicals.

The plot of the reduced rate of polymerisation $\phi_t$ against time is represented by S-shaped curves with a point of inflection. The parameter $\theta$ is determined from the reduced rate of polymerisation at this point ($\phi_{pi}$) from the equation

$$\theta^3-\frac{2\varphi_{pi}}{1+\varphi_{pi}^2}\theta^2-\frac{3\varphi_{pi}^4-\varphi_{pi}^2}{1+\varphi_{pi}^2}\theta-\frac{\varphi_{pi}^5-2\varphi_{pi}^3-\varphi_{pi}}{1+\varphi_{pi}^2}=0.$$

The inhibition constants $k_X/k_P$ are $10^3$–$10^4$ and vary within wide limits depending on the nature of the cation, the solvent, and the monomer, as well as temperature. Furthermore, they decrease with increase of the inhibitor concentration, while the additional initiation constants $k_i$ increase.

The interaction of the $TCQM^{\cdot-}$ radical-anions with macroradicals proceeds via different mechanisms. Together with addition, there is a possibility of electron transfer from the radical-anion to a macroradical having more pronounced electron-accepting properties. Inhibition via the electron transfer mechanism is most likely in the polymerisation of monomers whose polymeric radicals have a higher electron affinity, i.e. the rate of reaction increases in the monomer sequence styrene < methyl methacrylate < methyl acrylate. As a result of electron transfer, the radical-anion is converted into neutral TCQM, which is itself capable of terminating the reaction chains or, by reacting with the electron-donating solvent (for example, DMF), it is reconverted into the radical-anion.[152]

Thus the reactions involving the regeneration of the inhibitor are characteristic of the inhibition of the polymerisation of the methacrylic and especially acrylic monomers by the $TCQM^{\cdot-}$ radical-anion, which is manifested by an increase in the induction period and a change in the sign of the curvature of the plot of $\tau$ aginst [X].

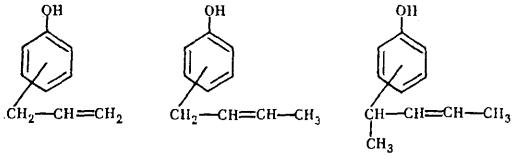
# Vinylphenols and Oligomers and Polymers Based on Them

M.R.Bairamov, S.M.Aliev, V.A.Sergeev, V.K.Shitikov, and S.G.Alieva

The review deals with the methods of synthesis of alkenylphenols and their derivatives whose ethylene bond is conjugated with the benzene ring; data are presented on the polymerisation, copolymerisation, and polycondensation of these compounds and also on the applications of polymeric materials based on them.
The bibliography includes 189 references.

CONTENTS

I. Introduction 1081
II. Synthesis of vinylphenols 1081
III. Synthesis of vinylphenol ethers 1084
IV. Oligomerisation, polymerisation, and copolymerisation of vinylphenols and their derivatives 1086
V. Polycondensation of vinylphenols with aldehydes 1089

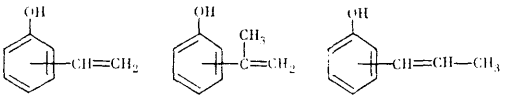


## I. INTRODUCTION

The interest in the chemistry of alkenylphenols is due to the fact that their structure contains functional groups of different nature and that reactive oligomers, polymers, and copolymers exhibiting a tendency towards further chemical reactions, particularly in the material moulding stage, can be obtained by standard oligomerisation, polymerisation, copolymerisation, and polycondensation methods; the evolution of volatile products is not observed in their processing. This approach to the preparation of polymers is extremely valuable in the manufacture of materials capable of being used under extreme operating conditions (thermostable and heat resistant plastics, polymers with three-dimensional structures, etc.).

Alkenylphenols are also of independent interest for the chemical modification of industrial polymers during their synthesis and processing.

Vinylphenol oligomers, polymers, and copolymers are used to prepare epoxyresins, in thermoplastic and thermoreactive compositions, in glues, in the manufacture of laminated plastics, press powders and varnishes, cast articles, and adhesives, in the manufacture of laminated electrically insulating materials, as anti-oxidants for rubbers, resins, and oils, etc.



From the standpoint of their reactivity in oligomerisation, polymerisation, and copolymerisation reactions, alkenylphenols can be divided into two main groups. The first group includes alkenylphenols where the ethylene bond of the alkenyl group is not conjugated with the benzene ring, for example:

Alkenylphenols of this series are synthesised by the interaction of phenol or alkylphenol with allyl or methylallyl halides or the corresponding alcohols and with conjugated and non-conjugated dienes in the presence of various catalysts.[1]

Although alkenylphenols of this type can be synthesised comparatively readily, they have not found extensive applications in the syntheses of oligomers and polymers in view of the low reactivity of the allyl group in polyaddition reactions. Alkenylphenols of this type will not therefore be considered in the present review.

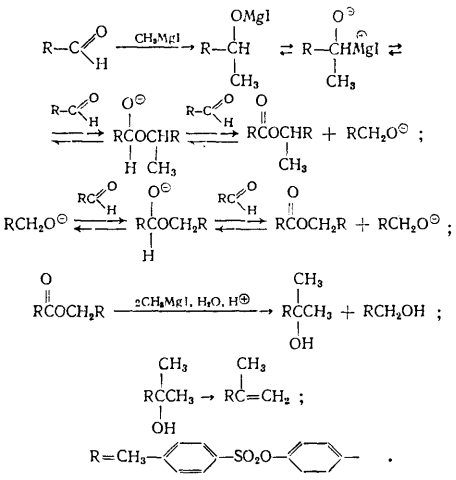
The second group include alkenylphenols in which the ethylene bond of the alkenyl group is conjugated with the benzene ring. Typical representatives of this series are vinyl-, isopropenyl-, and propenyl-phenols:

The double bond in alkenylphenols of this series is highly reactive (especially in vinylphenol), which complicates their synthesis and isolation in a pure form.

Vinyl- and isopropenyl-phenols are used to synthesise various reactive oligomers and to modify polymers manufactured industrially. There has been a considerable growth of interest in vinylphenols during the last few years, which is indicated by the numerous publications, mainly patents (especially in Japan, the Federal Republic of Germany, USA, USSR, England, etc.).

The available literature data on the methods of synthesis, properties, and practical applications of vinylphenols and the oligomers and polymers based on them are surveyed and described for the first time in the present review.

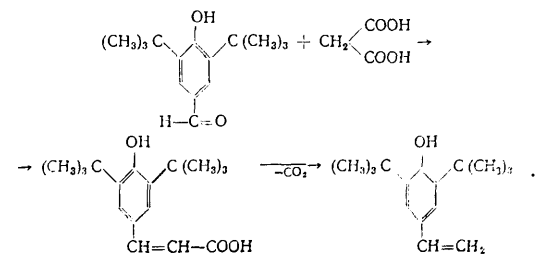
## II. SYNTHESIS OF VINYLPHENOLS



As early as 1931, it was shown that *o*-vinylphenol can be obtained by condensing phenol with epoxyethane, ethylenechlorohydrin,[2] or vinyl acetate[3] with subsequent dehydration of the resulting 2-phenoxyethyl alcohol or the rearrangement of phenyl vinyl ether. However, in practice it is difficult to obtain vinylphenol under these conditions.[4-6] An alcohol which is readily dehydrated to *p*-vinylphenol has been synthesised by the reaction of *p*-hydroxybenzaldehyde with $CH_3MgI$.[7]

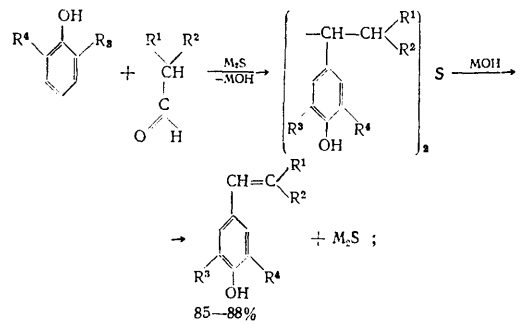
*m*-Vinylphenol can be obtained in 50% yield by dehydrating *m*-hydroxyphenylmethylmethanol at 300 °C on activated alumina, but the initial alcohol is difficult to obtain.[8]

A method of synthesis of *p*-vinylphenol by cracking 1,1-bis(4-hydroxyphenyl)ethane in the presence of aluminosilicate catalysts at 550–560 °C (yield 60%) was proposed in 1960.[9,10] *o*-Vinylphenol is obtained analogously by the pyrolysis of 2,4-dimethylbenzo-1,3-dioxan at 400–450 °C.[11] The pyrolytic methods of synthesising vinylphenol have attracted attention because of their simplicity and the wide variety of initial compounds which can be used. Thus



o-vinylphenol can be obtained by the pyrolysis of cyclo-octa-1,3,5-triene-7-one and the product of its irradiation—*cis*-bicyclo[4.2.0]octa-4,7-dien-2-one.[12] Benzene and acetone are formed together with the required product during the pyrolysis. The cracking of 1,1-bis(4-hydroxy-5-methylphenol)ethane leads to 2-methyl-4-vinylphenol.[9] Both *p*-vinylphenol and 2-methyl-4-vinylphenol synthesised in this way readily polymerised on standing in air. The above reaction was later carried out in the presence of iron, manganese, cobalt, copper, thorium, antimony, vanadium, tin, molybdenum, and tungsten oxides. $Na_2CO_3$, MgO, CaO, BaO, and $Cr_2O_3$ have been used as promoting agents. In the presence of iron–chromium catalysts promoted by $K_2CO_3$, a high degree of conversion of the starting material is attained (92–94%) and is accompanied by a high selectivity in the formation of *p*-vinylphenol (85–89%).[13]

It is of interest to note that the organomagnesium synthesis of vinylphenol does not always lead to the desired results. For example, when an attempt was made to synthesise *p*-vinylphenol by the reaction of 4-(4-$CH_3C_6H_4SO_2O$)$C_6H_4CHO$ with $CH_3MgI$, *p*-isopropenylphenol was obtained instead of the expected product,[14] probably in accordance with the following scheme:



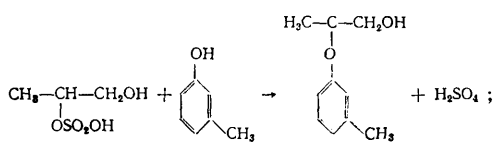
The isolation of vinylphenols in a pure form from the products of the dehydrogenation of ethylphenols and of the cracking of 1,1-bis(4-hydroxyphenyl)ethane presents considerable difficulties. In order to prevent tar formation, it is recommended that the vinylphenols be diluted with an equal volume of ethylene glycol[15] and admixtures of phenol, ethylphenols, hydrocarbons, and vinylphenol polymers are removed from vinylphenols by means of contact counter-current apparatus with aqueous alkaline solutions and organic solvents immiscible with water.[16]

Some methods of synthesis of vinylphenols (decarboxylation of the corresponding hydroxycinnamic acid, dehydration of hydroxyphenylmethylmethanols, pyrolysis of 2,4-dimethylbenzo-1,3-dioxan, etc.) have been described in a monograph.[17] However, since it is difficult to obtain the starting materials, these methods are used only for laboratory purposes. For example, the synthesis of 2,6-di-t-butyl-4-vinylphenol by the condensation of 2,6-di-t-butyl-4-hydroxybenzaldehyde with malonic acid and subsequent decarboxylation of the resulting substituted cinnamic acid has been described:[18]

2,6-Di-t-butyl-4-vinylphenol and its β-alkyl-substituted derivatives can also be obtained[19] by the condensation of 2,6-di-t-butylphenol with aldehydes in the presence of an alkali metal sulphide and the subsequent decomposition of the reaction products in accordance with the scheme

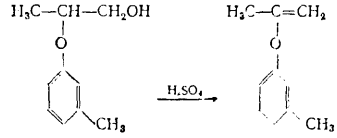
M = alkali metal; $R^1$, $R^2$ = H, Alk; $R^3$, $R^4$ = t-$C_4H_9$, etc.

The methods of synthesis of isopropenylphenols are of independent interest. Much attention has been devoted in the literature to their development. According to literature data, the catalytic decomposition of di(hydroxyphenyl)-propane, the alkylation of phenols by acetylene homologues, the dehydrogenation of alkylphenols, etc. are of greatest interest.



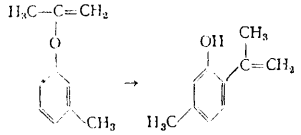
The rearrangement of isopropenyl ethers of aromatic hydroxy-compounds leads to *o*-isopropenylphenols. The reaction takes place in the presence of 10% sulphuric acid in glacial acetic acid.[20] The initial ethers can be obtained either by treating isopropenyl bromide with the corresponding potassium phenoxide or from phenol and allyl alcohol. In the latter case the isopropenyl ethers need not be isolated and a mixture of allyl alcohol and the aromatic hydroxy-compound can be used immediately for the synthesis of *o*-isopropenylphenols.

The mechanism of the synthesis of isopropenylphenols, in particular 6-isopropenyl-3-methylphenol from *m*-cresol and allyl alcohol under the influence of concentrated sulphuric acid, is represented in the following manner:[3,20]

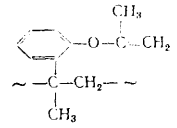


a) the addition of sulphuric acid to allyl alcohol with formation of 1-hydroxymethylethylsulphuric acid:

$$H_2C{=}CH{-}CH_2OH + H_2SO_4 \rightarrow CH_3CH(CH_2OH)OSO_2OH\ ;$$

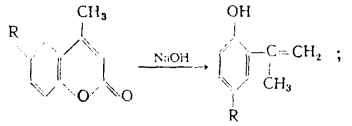


b) the interaction of 1-hydroxymethylethylsulphuric acid with *m*-cresol:



c) the dehydration of the resulting ether by concentrated sulphuric acid:

d) the rearrangement of the unsaturated ether to 6-isopropenyl-3-methylphenol:



When phenol was allowed to react with methylacetylene in the presence of potassium hydroxide,[21] isopropenyl phenyl ether was isolated as the main product in 57% yield. Isopropenyl ether of o-isopropenylphenol and its trimerisation products (with a molecular weight of ~500), corresponding to the general formula

were also obtained.

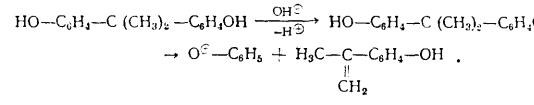
Finally o-isopropenylphenol and its ring-substituted derivatives can be obtained by the reaction of 4-methylcoumarin and its derivatives, which are intramolecular phenol esters:[22]

R=H, $CH_3$, $C_2H_5$, iso-$C_3H_7$, $OCH_3$, Cl, Br

p-Isopropenylphenols are not usually obtained from the alkenyl ethers of aromatic hydroxy-compounds; other reactions are used for this synthesis, in the first place the decomposition of di(hydroxyphenyl)propane. Isopropenylphenols are normally always formed in small amounts (up to 3%) as side products in the manufacture of di(hydroxyphenyl)propane (bisphenol-A), which is based on the condensation of phenol with acetone in the presence of acid or alkaline catalysts.[23] It has been suggested in the literature[24,25] that p-isopropenylphenol is an intermediate in the condensation of phenol with acetone under the conditions indicated. Indeed the possibility of obtaining di(hydroxyphenyl)propane from p-isopropenylphenol in the presence of acid or alkaline catalysts has been demonstrated.[26-28]

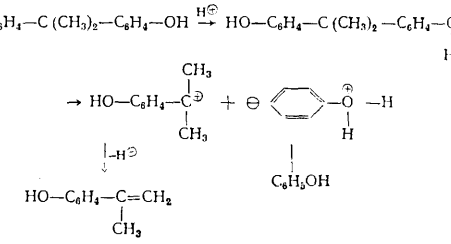
A study of the thermal decomposition of di(hydroxyphenyl)methane derivatives showed[24] that one mole of the initial reactant gives rise to one mole of phenol, ~0.5 of a mole of an alkylphenol, and tarry substances. A distillate consisting of phenol, p-isopropylphenol, and tarry products has been obtained from di(hydroxyphenyl)propane in ~80% yield by distillation at atmospheric pressure. The authors[24] believe that the decomposition of di(hydroxyphenyl)propane proceeds initially with the formation of phenol and p-isopropenylphenol and its subsequent disproportionation to p-isopropylphenol and hydrogen-depleted tarry substances. This mechanism of the disproportionation has not been proved.[25]

The decomposition of di(hydroxyphenyl)propane at 100 °C in the presence of concentrated hydrochloric acid leads to a mixture of complex composition consisting of phenol, saturated p-isopropenylphenol dimers, and tarry products. Monomeric p-isopropenylphenol was not detected under these conditions.[24]



The decomposition of di(hydroxyphenyl)propane in a flow reactor in the presence of an aluminosilicate catalyst at 550 °C and after a contact time of 0.03 s (diluent—water vapour) leads to the formation of p-isopropenylphenol and phenol.[9] However, owing to the disproportionation and isomerisation side reactions, the yield of the required products does not exceed ~46%.

Thus the use of acid catalysts in the cracking of di(hydroxyphenyl)propane promotes the conversion of the cracking products into tars, reducing thereby the yield of p-isopropenylphenol. Side reactions such as disproportionation or oligomerisation of isopropenylphenols takes place to a much lesser extent in the cracking of di(hydroxyphenyl)propane in the presence of alkalis. The use of a vacuum and the continuous removal of the cracking product from the reaction zone also promote an increase in the yield of p-isopropenylphenol under these conditions.



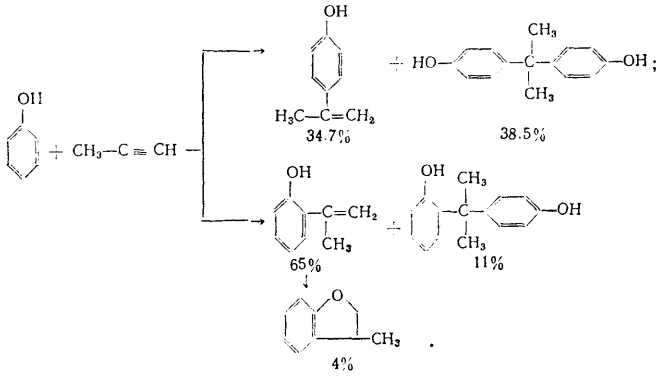
The decomposition of di(hydroxyphenyl)propane and its 2-alkyl derivatives at 170–235 °C *in vaçuo* (2–10 mmHg) in a stream of nitrogen or without it in the presence of NaOH, $Na_2CO_3$, or $CH_3COONa$ with simultaneous distillation of the decomposition products[29-31] leads mainly to phenol and p-isopropenylphenol, the yield of the latter being 90–98% of theoretical.

It is recommended that cracking of di(hydroxyphenyl)propane in the presence of sodium hydroxide be carried out at 120–180 °C and a residual pressure of 4 mmHg with two injections of alkali.[32] In this case up to 4% of p-isopropenylphenol dimer and trimer is formed together with phenol and p-isopropenylphenol.

The facilitation of the cracking of di(hydroxyphenyl)propane in the presence of alkaline and acid catalysts has been explained in different ways.[27] The hydroxy-group of one of the benzene rings gives rise to the bisphenol anion on treatment with alkali. The π electrons are then redistributed in the hydroxybenzene ring, as a result of which the bond between the central carbon atom and the second hydroxybenzene ring is broken:

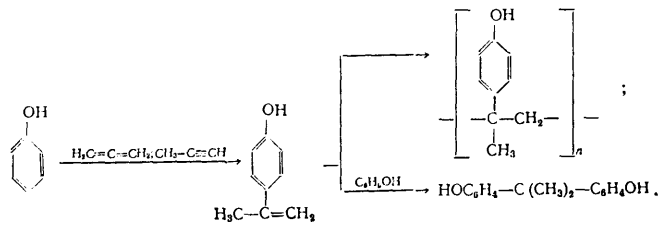
When acids are used, the bond between the central carbon atom and the hydroxybenzene ring is weakened owing to the addition of the protons to one of the OH groups, which entails cleavage. The ions formed are stabilised by being converted respectively into p-isopropenylphenol and phenol:

The side products of the manufacture of di(hydroxyphenyl)propane can also be used to synthesise p-isopropenylphenol[33] but the yield of the desired product is low after their thermolysis. The method of synthesis of isopropenylphenol[34] by the thermal decomposition of p-isopropenylphenol



oligomers when these are injected continuously into an inert organic solvent heated to 150–250 °C at a pressure of 10 to 100 mmHg is of interest. *p*-Isopropenylphenol is obtained by this procedure in 98% yield and with a purity of 94.1%. The liquid-phase cracking of bis(4-hydroxyphenyl)alkanes or bis(4-hydroxyphenyl)cycloalkanes in the presence of a basic catalyst proceeds analogously.[35]

In order to prevent the dimerisation of *p*-isopropenylphenol, it is recommended that the vapour of the di(hydroxyphenyl)propane cracking product be irrigated with a polar solvent, for example with monohydric or dihydric alcohols; *p*-isopropenylphenol is isolated by diluting the alcoholic solution with water.[36]



Overall, the cracking of di(hydroxyphenyl)propane in the presence of alkalis[26,29–31] ensures a fairly high yield (~90–98%) of the desired product—*p*-isopropenylphenol and its 2-alkyl derivatives. However, the main deficiency of this method involves the use of pure di(hydroxyphenyl)propane as the starting material which is at the present time a fairly expensive and scarce monomer, used in the manufacture of epoxy-resins. The high cost of di(hydroxyphenyl)propane is due to the complexity of the technology involved in its isolation in a pure form from condensation products and the labour involved in the utilisation of the waste produced.

All this makes the above method of synthesis of isopropenylphenol expensive, although in many instances it is nevertheless used to synthesise *p*-isopropenylphenol, a technically important product, despite being uneconomic.

The next group of methods, which makes it possible to obtain isopropenylphenols, is based on the alkenylation of aromatic hydroxy-compounds by substituted acetylenes.[37] Thus the alkylation of phenol by methylacetylene, phenylacetylene, and t-butylacetylene leads to the desired compounds. In this case of methylacetylene the reaction proceeds with formation of *p*- and *o*-isopropenylphenols, 2,2-di(4-hydroxyphenyl)propane, 2',4''-dihydroxy-2,2-diphenylpropane, and methylbenzofuran:

It is noteworthy that *p*-isopropenylphenol is also formed as an intermediate in the synthesis of di(hydroxyphenyl)propane by the reaction of phenol with allene or methylacetylene:[38]

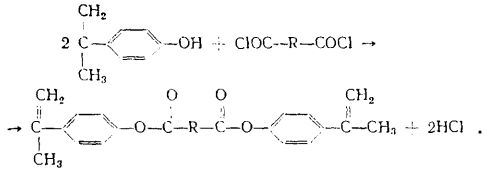
Among other methods of synthesis of vinyl- and isopropenyl-phenols which are of industrial interest, mention may be made of the alkylation of phenol by ethylene and propene with subsequent dehydrogenation of ethyl- and isopropyl-phenols. The results of a study of the alkylation of phenol by ethylene and propene over aluminosilicates have been published;[39] the resulting mixtures of isomers of ethyl- and isopropyl-phenols were dehydrogenated in the presence of the "styrene-catalyst" (79.5% ZnO, 5.5% MgO, 5% $Al_2O_3$, 5% CaO, 2.5% $K_2SO_4$, and 2.5% $K_2Cr_2O_7$). The dehydrogenation of ethylphenols was accompanied in this instance by appreciable coke and gas formation; the yield of vinylphenols was low and their isolation in a pure form was difficult because of tar formation. The dehydrogenation of the mixture of isomeric isopropylphenols proceeds analogously.

When the *m*- and *p*-isomers of ethyl- and isopropyl-phenols are dehydrogenated in the presence of Cr–Al and magnesium, iron, copper, potassium, chromium, and tin oxides in the temperature range 400–700 °C, alkenylphenols are formed in yields of ~48–56%.[6,40,41] The dehydrogenation of isopropylphenols in the presence of catalysts such as the copper–chromium No.4 catalyst, the oxide No.40 catalyst, the "styrene-catalyst", and the "R-1" catalyst without and with a diluent ($CO_2$, $H_2O$) at 495–620 °C at atmostpheric pressure[39,42–45] gives rise to satisfactory yields of isopropenylphenol.

When $Fe_2O_3$ promoted by $K_2O$ is used as the catalyst, both on a carrier (alkaline earth metal oxides) and without a carrier, at 525 °C and a space velocity of 0.3 $h^{-1}$, the degree of conversion of *p*-ethylphenol is 8% and the selectivity of the formation of *p*-vinylphenol reaches 85%.[46]

The low yield of products, the intensified cracking, the charring of the initial alkylphenols, and rapid coke formation on the catalyst proved to be serious obstacles to further development of this extremely attractive, at first sight, method of synthesis of vinyl- and isopropenyl-phenols. Furthermore, the use of a mixture of isomers of the initial alkylphenols led to the formation of an extremely complex mixture of their dehydrogenation, cracking, and oligomerisation products, which hindered the isolation of the pure isomers of vinyl- and isopropenyl-phenols from it.

Other methods of synthesis of alkenylphenols have also been described in the literature. Thus 2,6-di-t-butyl-4-isopropenylphenol has been obtained in 70% yield by the reaction α-bromoisopropyl 3,5-di-t-butyl-4-hydroxyphenyl ketone with sodium hydroxide in an alcoholic solution.[47] A method of synthesis of *m*-isopropenylphenol by the acid decomposition of di-isopropylphenyl hydroperoxide with subsequent neutralisation of the reaction mixture and distillation in the presence of alkali (pH up to 9) has been proposed.[48]



Thus one may conclude that, from the standpoint of its likely usefulness, the method involving the dehydrogenation of alkylphenols is of definite interest. However, the lack of effective catalysts precludes the wide-scale employment of this method in practice. We believe that the method based on the catalytic cracking of di(hydroxyphenyl)propane is most suitable at the present time. Here the yield of the desired product—*p*-isopropenylphenol—reaches 96% and above and the phenol formed as a side product is used to synthesise the initial di(hydroxyphenyl)propane.

## III. SYNTHESIS OF VINYLPHENOL ETHERS

The presence of the phenolic hydroxyl in vinylphenols retards their radical polymerisation compared with styrene. On converting them into their ethers, the capacity of the

ethylene bond for polymerisation increases significantly. The difference between the reactivities of the ethylene and ethyl groups makes it possible to carry out the oligomerisation or polymerisation of the vinylphenol ethers strictly via the ethylene group without involving the less reactive centres, which, forming part of the composition of the oligomers or polymers, are capable of subsequent participation in polymer-analogue transformations, imparting new practically important properties to the final polymeric product.

There is limited information in the literature, mainly in patents, about the synthesis of certain representatives of the ethers and esters of vinyl- and isopropenyl-phenols. Reactive monomers containing two isopropenyl groups in the molecule have been obtained[49] in yields up to 80% by the reaction of *p*-isopropenylphenol with the dichlorides of dibasic acids (carbonic, adipic, terephthalic, fumaric, etc.) in the presence of bases according to the scheme

The synthesis of *p*-isopropenylphenyl esters of acetic, propionic, benzoic, diethylphosphoric, and acrylic acids from their chlorides has been used as a classical method of organic chemistry, primarily to characterise chemically these individual compounds.[49-51] However, it was no less convenient to acylate the dimer or trimer of *p*-isopropenylphenol by acetic anhydride in the presence of acid catalysts with subsequent thermal or catalytic ($SiO_2$) decomposition of the di- and tri-acyl derivatives in order to obtain *p*-isopropenylphenyl acetate.[52] The initial dimers and trimers can be obtained by the cracking of di(hydroxyphenyl)propane in the presence of alkali. Among *p*-vinylphenol esters, 2,6-di-t-butyl-4-vinylphenyl acetate is known.[18,53] The silylation of *p*-vinylphenol by trialkylhalogenosilanes[54] and of 2,6-di-t-butyl-4-vinylphenol by *NN*-bis(trimethylsilyl)-acetamide has also been described.[18]

The synthesis of di[4-(*p*-isopropenylphenoxy)phenyl] sulphone by the reaction of *p*-isopropenylphenol with di(4-bromophenyl) sulphone in the presence of sodium hydroxide at 140 °C has also been described.[55] The yield of the desired product was 98.5%. The ethers of *p*-vinyl- and *p*-isopropenyl-phenols are usually obtained by the reaction of their phenoxides with the corresponding halogeno-derivatives.[56,57]

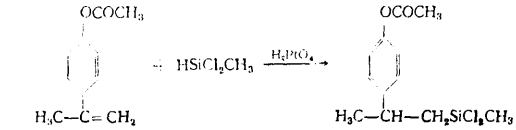
The methods of synthesis of the glycidyl ethers of vinyl- and isopropenylphenols are complicated by the dimerisation and polymerisation reactions of both the initial phenolic compounds and their glycidyl ethers. For this reason, the usual conditions for the preparation of the glycidyl ethers of phenols, alkylphenols, and allylphenols are unsuitable for the synthesis of the glycidyl ethers of vinyl- and isopropenylphenols. For example, a method of synthesis of the glycidyl ethers of allylphenol involving the gradual addition of a 40–60% aqueous solution of allylphenoxide (1 mole) to a boiling mixture of epichlorohydrin (2–2.1 moles) with benzene (1.1 mole) accompanied by the simultaneous azeotropic distillation of water has been described.[58] The yield of the glycidyl ether of allylphenol reaches under these conditions 95% relative to the allylphenol which has reacted. It has been shown that[59] under identical conditions the yield of the glycidyl ether of *p*-isopropenylphenol does not exceed 80%. This difference is explained in the first place by the characteristic features of the structures of aryl- and isopropenyl-phenols.

Whereas the ethylene bond in allylphenol is not conjugated with the benzene ring, in vinyl- and isopropenyl-phenols the conjugation of the ethylene bond with the aromatic system makes them more reactive and increases their tendency towards polymerisation. For this reason, when the glycidyl ether of *p*-vinylphenol is obtained from *p*-vinylphenol and epichlorohydrin in the presence of alkali, its yield does not exceed 11.1%.[60]

In order to suppress the polymerisation of vinyl- and isopropenyl-phenols and their glycidyl ethers, it is more useful to synthesise the latter in the presence of polymerisation inhibitors [1,4-di(2-naphthylamino)benzene and β-methyl-o-coumaric acid].[61] At the same time it has been recommended that the synthesis be performed in the presence of a large excess of epichlorohydrin and powdered alkali at 90 °C. However, even under these conditions, the yield of the desired product does not exceed 70% for the glycidyl ether of vinylphenol and 80% for the glycidyl ether of *p*-isopropenylphenol.

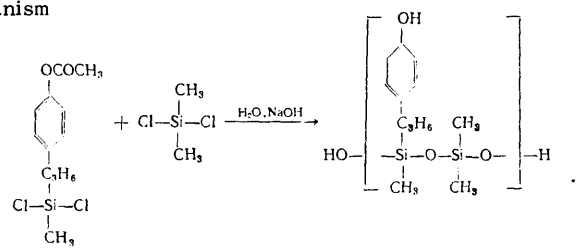
It is noteworthy that, under the conditions quoted above (elevated temperature, the presence of alkali and phenoxides in the reaction medium),[61] the epoxide ring of the resulting glycidyl ether is comparatively readily opened with an increase of the yield of side products.

The above data exhaust the available information about the synthesis of the glycidyl ethers of vinyl- and isopropenylphenols. Further studies on these lines should be directed towards finding conditions ensuring a high yield of the glycidyl ethers of vinyl- and isopropenyl-phenols and the suppression of the formation of side products. Much attention should be devoted in this connection to the simplification of the technology, a decrease of the consumption of energy and materials in the process, and the development of conditions for the isolation from the reaction products of the final ethers with a high purity and in high yields. Taking these requirements into account, the synthesis of glycidyl ethers of isopropenylphenols in a homogeneous medium at a low temperature (35–60 °C) using mono- or di-hydric $C_1$–$C_3$ alcohols as solvents has been investigated and developed recently. The yield of the desired product is 90–98%.[62]



Thus the synthesis of only some esters and glycidyl ethers of vinyl- and isopropenyl-phenols has been described in the literature. These ethers and esters can be used for the modification of known polymeric materials and the synthesis of new ones. The development of convenient, waste-free methods of synthesis of the above monomers from readily available raw materials is therefore important.

The synthesis and study of the rearrangement of esters and allyl ethers of vinyl- and isopropenyl-phenols are of no less interest from the theoretical and practical points of view. Unfortunately the application of these reactions to the ethers and esters of vinyl- and isopropenyl-phenols has until recently been disregarded by investigators despite the abundance of studies on the Claisen rearrangement of allyl ethers[63-77] and the Fries rearrangement of esters[78-96] of phenols and alkylphenols.

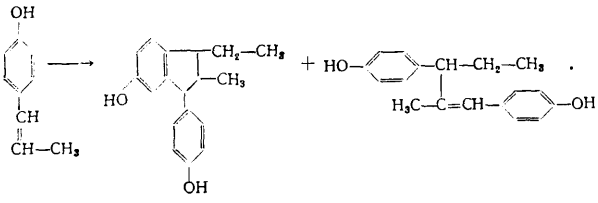


It was not until the 1980's that the first studies on the synthesis and then the photorearrangements and thermal rearrangements of allyl ethers of isopropenylphenols were published.[97,98] These investigations dealt with the reactions of *p*-isopropenylphenol and 2-alkyl-4-isopropenylphenols with allyl halides in acetone, alcohol, and water in the presence of alkali metal hydroxides and potassium carbonate. The conditions for the synthesis of new polyfunctional monomers—the allyl ethers of *p*-isopropenylphenol and 2-alkyl-4-isopropenylphenols in yields of 96.6 to 85%—have been elaborated (temperature 50 °C, *p*-isopropenylphenol : allyl halide molar ratio 1 : 4). It was shown

that the allyl ether of *p*-isopropenylphenol undergoes mainly the Claisen rearrangement both on heating (180 to 240 °C) and on exposure to UV light, with formation of a new polyfunctional monomer—2-allyl-4-isopropenylphenol in 95% yield.

The products of the hydrosilylation of *p*-isopropenylphenyl acetate at the double bond are of independent interest:[99]

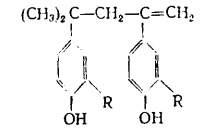
The silyl derivative [2-(4-acetoxyphenyl)propyl]dichloromethylsilane can be used as the starting material in the synthesis of hydroxyphenylsiloxanes[99] in accordance with the mechanism



The oligosiloxanes obtained are readily hardened in the presence of hardening agents by a mechanism similar to that of the hardening of phenolformaldehyde oligomers of the novolac type.[100]

## IV. OLIGOMERISATION, POLYMERISATION, AND COPOLYMERISATION OF VINYLPHENOLS AND THEIR DERIVATIVES

Studies devoted to the oligomerisation, polymerisation, and copolymerisation of vinylphenols and their derivatives are of definite practical interest.



These monomers usually readily dimerise despite the possibility of the inhibiting effect of the phenolic hydroxyl. For example, the spontaneous dimerisation of *p*-propenylphenol (anol) on storage[101] is accompanied by the formation of a product referred to conventionally as "polyanol", which is a synthetic analogue of a female sex hormone:[102]

Vinylphenols readily dimerise and trimerise on heating and also in the presence of acid catalysts.[103–105] The following catalysts have been proposed for the dimerisation of isopropenylphenols (especially the *m*-isomer):[105] $H_2SO_4$, $AlCl_3$, $PCl_3$, $C_6H_5SO_3H$, $ClCH_2COOH$, $SnCl_4$, and $BF_3 \cdot O(C_2H_5)_2$. The dimerisation takes place at 110–130 °C. The dimer obtained can be isolated by vacuum distillation. The crystalline dimer is used to synthesise epoxy-resins or novolac resins.[105]

The solid-phase oligomerisation of *p*-isopropenylphenol under UV- or γ-irradiation leads to a low yield (5–10%) of oligomers with a molecular weight of 500–700.[106]

The dimers of *p*-isopropenylphenol and its alkyl derivatives,

where R is a halogen or an alkyl group, as well as their hydrogenation products react with phosgene to form thermoplastic polycarbonates having the general formula $-[-C(O)O-X-O-]_n$, where X is a residue of the dimer or the hydrogenated dimer.[107]

The dimerisation of *p*- and *o*-isopropenylphenols leads to the formation of the following linear and cyclic dimers: 2,4-di(4-hydroxyphenyl)-4-methylpent-2-ene, 2,4-di(4-hydroxyphenyl)-4-methylpent-1-ene, 2,4-di(2-hydroxyphenyl)-4-methylpent-1-ene, 2,4-di(2-hydroxyphenyl)-4-methylpent-2-ene, 1-(4-hydroxyphenyl)-1,3,3-trimethyl-6-indanol, and 2-hydroxy-2,4,4-trimethylflavan.[23]

Linear *p*-isopropenylphenol dimers are obtained in high yields on cracking di(hydroxyphenyl)propane in the presence of alkali.[108] They can serve as starting materials for the synthesis of thermoplastic and thermoreactive compositions. In particular, *p*-isopropenylphenol dimers are used for the modification of phenolic and alkyd resins.[109]

A mixture of dimers, trimers, tetramers, and other oligomers can be obtained by the oligomerisation of *m*-isopropenylphenol in the presence of acids or without them at 135–230 °C. The mixture contains about 50% of dimers and 30% of trimers.[110] $BF_3$ and alkylbenzenesulphonic acids have also been recommended as oligomerisation catalysts. Mainly tri-, tetra-, penta-, and hexa-mers, used in the manufacture of novolac epoxy-resins with increased mechanical strength, are formed in their presence at temperatures below 20 °C.[111,112]

Linear trimers of *p*-isopropenylphenol have been obtained by the depolymerisation of its linear polymers and also of a mixture of the *p*-isopropenylphenol dimer and polymer in an organic solvent and in the presence of acid catalysts at 0–100 °C.[113,114] These trimers are used in the synthesis of thermoreactive resins and as vulcanising agents for epoxy-resins.

In order to synthesise *p*-isopropenylphenol oligomers with a molecular weight of 500–600, it is best to polymerise the phenol in the presence of iodine in benzene at 30 °C. After 40 h, the degree of conversion of *p*-isopropenylphenol reaches 79.3%.[115] The oligomers obtained can be used in adhesive compositions and in the preparation of ion-exchange resins and high-molecular-weight water-soluble compounds.

In order to obtain polymers with a relatively low molecular weight, isopropenylphenol can be introduced into a preliminary reaction with maleic anhydride[116] and other unsaturated compounds. Propenylphenol reacts analogously with maleic anhydride.[117] Thus, on condensation with maleic anhydride, *o*-propenylphenol gives rise to an adduct with m.p. 308 to 312 °C, which is soluble in alcohol. Under the same conditions, *p*-propenylphenol gives rise to a readily separable product with m.p. 113–114 °C, which has been identified as the *p*-propenylphenyl monoester of maleic acid.[117]

*p*-Isopropenylphenol and its oligomers are used to synthesise modified phenolformaldehyde resins employed in the manufacture of laminated plastics. For this purpose, *p*-isopropenylphenol and its oligomers are first condensed with unsaturated oils of plant origin and the products obtained, mixed with other phenolic compounds, are then condensed with formaldehyde.[118–128]

Compositions based on *p*-isopropenyl derivatives (consisting of *p*-isopropenylphenol and its oligomers) and compounds in the group of linear unsaturated acids, fats and oils, polydienes, and the products of their "maleic treatment" are used as corrosion- and water-resistant coatings.[115]

Questions concerning the homopolymerisation of vinylphenol are of interest. Specific attention has also been devoted to this problem in the literature. The polymerisation of *p*-vinylphenol has been investigated in the presence of radical initiators and cationic and anionic catalysts with formation of oligomers.[53] In order to synthesise polyvinylphenol, it is necessary to carry out the preliminary polymerisation of *p*-vinylphenyl acetate with subsequent hydrolysis of the resulting poly(*p*-vinylphenyl acetate) with a 10% sodium hydroxide solution containing 5–10% of alcohol. The glass point of the polyvinylphenol formed is 170–180 °C.

The polymerisation of 2-methoxy-4-vinylphenol in an atmosphere of nitrogen in the dark gave rise to di-, tri, and tetra-mers and oligomers with $n > 4$ in yields of 33, 13.4, 11, and 42.6% respectively. It has been shown[130] that, in the presence of azobisisobutyronitrile, the polymerisation reaction is of first order with respect to the initiator; it has been suggested that the oligomer is formed via a cationic mechanism as a consequence of the influence of the acidic phenolic hydroxyl.

The radical polymerisation of vinylphenol in the presence of atmospheric oxygen leads to the formation of dark-coloured polymers.[131] For the preparation of colourless polyvinylphenols, it is recommended that the process be performed in the absence of oxygen.[132] The colourless polyvinylphenols obtained are suitable for esterification [etherification?] and the formation of moulding powders and varnishes.

Poly-*p*-vinylphenol is also readily cross-linked by formaldehyde and hexamethylenetetramine, forming thin films.[133]

The polymerisation of *p*-vinylphenol has also been investigated in the presence of $BF_3.O(C_2H_5)_2$, $BF_3$, $AlCl_3$, $SnCl_4$, $VOCl_3$, $Al(C_2H_5)_2Cl$, etc. in aliphatic or aromatic nitriles and methylene chloride. The molecular weight of the poly-*p*-vinylphenol obtained reaches 116000–530000 and the use of nitriles as solvents makes it possible to obtain polymers with the maximum molecular weight.[134,135]

A poly-*p*-vinylphenol with a comparatively low molecular weight (7000) can be obtained by polymerising *p*-vinylphenol in the presence of $P_2O_5$, HF, $H_2SO_4$, $H_3PO_4$, HCl, and boron, antimony, iron, tellurium, tin, titanium, bismuth, and indium halides.[136,137]

Comparative differential thermal analysis of polystyrene, poly-*p*-vinylphenol, poly-3-methoxy-4-vinylphenol, and their acetates has shown[138] that all the specimens investigated are stable up to 297–327 °C and that the above polymers have the same temperatures of the onset of degradation as polystyrene. The activation energy for the decomposition of poly-*p*-vinylphenyl acetate is highest (70 kcal $mol^{-1}$) and that for the decomposition of poly-*p*-vinylphenol is lowest (40 kcal $mol^{-1}$). The activation energy for the decomposition of poly-3-methoxy-4-vinylphenol is 53 kcal $mol^{-1}$. The glass point increases by 10–50 °C after the introduction of the OH and $CH_3-\overset{O}{\overset{\|}{C}}-O$ groups in the *p*-position in the benzene ring relative to the polymer chain, while the introduction of the $CH_3-\overset{O}{\overset{\|}{C}}-O$ group in the *m*-position entails a decrease of the glass point. This difference between the glass points can be accounted for by the presence of hydrogen bonds and the limitation of molecular mobility in poly-*p*-vinylphenol.[138]

A phosphorus-containing poly-*p*-vinylphenol has been synthesised by the reaction of brominated poly-*p*-vinylphenol with $P(OCH_3)_3$.[139] The resulting phosphorus-containing polymer is used to impart fire resistance to thermoplastic and thermoreactive polymer compositions.

Poly-*p*-vinylphenol is used in polymer compositions for adhesives, hermetic seals, and cross-linking agents and also in the manufacture of laminated and moulded materials.[140]

Polyvinylphenol has been manufactured in the USA under the commercial names Resin-M and Resin-MB under a Japanese licence with an annual production of 100 tonnes. These linear high-molecular-weight powders have found extensive applications as hardening agents, light-sensitive materials, combustion inhibitors, and agents imparting electrical conductivity.[141]

The copolymerisation of vinylphenol with different monomers has also been investigated. Thus copolymerisation with butadiene, isoprene, and chloroprene in emulsion, in bulk,[142] and in solution[143] in the absence of oxygen leads to the formation of light-coloured copolymers capable of being vulcanised via the residual double bonds or via a polycondensation reaction with aldehydes. Such copolymers are suitable for use in casting compositions and varnishes and as cross-linking components.

The synthesis of the copolymers of vinylphenols with cyclopentadiene in the presence of $H_2SO_4$, HCl, $SnCl_2$, $BF_3$, $POCl_3$, and $BF_3.O(C_2H_5)_2$ has been described.[144,145] The possibility of using organic peroxides as the initiators of this reaction has also been demonstrated,[122] but these proved to be less effective. The radical copolymerisation of benzyl methacrylate with the phenyl ether of *p*-vinylphenol has been studied[146] and the copolymerisation constant has been determined. In order to obtain a thermoreactive product resistant to water, alkali, and acid, it is recommended that vinylphenol be copolymerised with styrene, methylstyrene, acrylic derivatives, *N*-vinylpiperidine, and allyl derivatives with subsequent treatment of the resulting copolymers with aldehydes in an alcoholic alkaline medium.[147]

Studies[148] on the polymerisation and copolymerisation of 2,6-di-t-butyl derivatives of *p*-vinylphenol, *p*-isopropenylphenol, and *p*-isopropenylanisole with styrene showed that the last two monomers readily polymerise and copolymerise in the presence of $BF_3.O(C_2H_5)_2$, $TiCl_4$, and $Al(C_2H_5)_3$, forming polymers and copolymers with molecular weights of 3900 to 15000. Depending on the monomer ratio, soluble, partly soluble, and completely insoluble copolymers are obtained with styrene or α-methylstyrene. The yield of the polymers (copolymers) varies from 1 to 37%. The copolymerisation constants have been determined for the following pairs of monomers: 2,6-di-t-butyl-4-vinylphenol ($r_1 = 3.4$) and styrene ($r_2 = 0.046$); 2,6-di-t-butyl-4-isopropenylphenol ($r_1 = 1$) and styrene ($r_2 = 0.076$). The copolymerisation of 2,6-di-t-butyl-4-vinylphenol (10.5%) with ethylene or propene (89.5%) in the presence of $TiCl_4$ and $Al(C_2H_5)_3$ gives rise to soluble copolymers.

The copolymers of vinyl- and isopropenyl-phenols with aromatic vinyl monomers have been recommended[149,150] as hardening agents for epoxy-resins (in combination with anhydride hardening agents). The hardened compositions are characterised by an improved mechanical strength, thermal stability, dielectric properties, and resistance to the action of moisture and alkalis.

The copolymerisation of 2-methoxy-4-vinylphenol with fluorinated acrylic monomers in acetone at 60 °C in the presence of azobisisobutyronitrile makes it possible to obtain copolymers characterised by an enhanced resistance to water and oil.[151]

Vinylphenol polymers and copolymers can also be obtained using various vinylphenol ethers. An interesting method of synthesis of ion-exchange resins capable of chelate formation has been described in a British patent.[152] In this case

the vinylphenol ester (*p*-vinylphenyl acetate) copolymerises with divinyl compounds (divinylbenzene, divinyl ether, etc.). The product obtained is hydrolysed and the $NO_2$, $NH_2$, COOH, $SO_3H$, $CH_2Cl_2$ etc. functional groups are introduced into the "cross-linked" polyvinylphenols formed.

The "cross-linked" polyvinylphenols containing the AsO.$(OH)_2$ groups in the benzene ring, obtained by the reaction of the "cross-linked" polyvinylphenol with diazotised arsenilic acid or by diazotising polyvinylaminophenol and subsequent treatment with sodium arsenite, can be used to extract uranium from dilute solutions.[153]

The polymerisation of the glycidyl ether *p*-vinylphenol in bulk leads to a resin with an intrinsic viscosity of 0.81 dl $g^{-1}$ (in dioxan at 30 °C).[60] The glycidyl ether of *p*-vinylphenol and its polymer are used in the making of cast articles.

Soluble polymers have been obtained by polymerising the allyl ethers of *o*- and *p*-vinylphenols in the presence of $BF_3.O(C_2H_5)_2$ or benzoyl peroxide.[154] The polymerisation in the presence of azobisisobutyronitrile in dilute solution results in the formation of a soluble polymer, while in a concentrated solution the product is an insoluble polymer with cross links. The copolymerisation of these monomers with ethyl vinyl ether and styrene has also been carried out successfully using $BF_3.O(C_2H_5)_2$ as the catalyst. The Claisen rearrangement, cross linking induced by radical initiators, and the formation of epoxides on treatment with $C_6H_5COOOH$ are also possible for polymers obtained by the polymerisation of the allyl ether of *p*-vinylphenol.[154]

The copolymers of vinylphenols also serve as the starting materials for the synthesis of carriers for the catalysts of the oligomerisation of unsaturated hydrocarbons. Thus polymeric carriers with a high swellability in hydrocarbon solvents, a reduced hygroscopicity, and an increased stability have been obtained[155] by using tervalent phosphorus compounds to treat hydroxyl-containing copolymers of styrene with vinylphenols or their glycidyl ethers in organic solvents at 20–110 °C. The carriers obtained contain groups capable of forming complexes with a transition metal compound, in which the central atom is either coordination unsaturated or is bound to other mobile ligands which are readily displaced.

The polymerisation and copolymerisation reactions of isopropenyl- and propenylphenols have been investigated to a much lesser extent than those of vinylphenols. Thus a study has been made[156] of the copolymerisation of *p*-isopropenylphenol (PIP) with butadiene, isoprene, vinyl acetate, and methyl methacrylate, acrylonitrile, methyl acrylate, ethyl acrylate, and styrene in the presence of azobisisobutryronitrile at 60 °C. High-molecular-weight copolymers are not obtained with butadiene, isoprene and vinyl acetate. In the remaining cases the products are copolymers with molecular weights in the range 8000–50000. The reactions of *p*-isopropenylphenol with acrylonitrile and methyl acrylate give rise to alternating copolymers. In all cases an increase in the mole fraction of *p*-isopropenylphenol in the mixture of monomers entails a fall in the rate of copolymerisation. The comonomers can be arranged in the following sequence in terms of the reactivities: acrylonitrile > methyl acrylate > ethyl acrylate > methyl methacrylate. For each PIP–acrylonitrile, PIP–methyl acrylate, and PIP–ethyl acrylate pair, the copolymerisation constants $r_1$ and $r_2$ have been determined as 0.07 and 0.02, 0.28 and 0.12, and 0.65 and 0.92 respectively.

A method of synthesis of copolymers of *p*-isopropenylphenol with styrene in acrylonitrile in solution using as catalysts Lewis acids, for example $AlCl_3$, and $ZnCl_2$ or even inorganic acids ($H_2SO_4$) in an amount of 0.001–5% of the weight of the monomers has been described.[157] The copolymers have a molecular weight of 500–2000 and are readily soluble in many organic solvents and solutions of alkalis. They are suitable for the manufacture of varnishes and plastics.

The reactivity of *p*-isopropenyl phenylacetate in the free radical copolymerisation with butadiene has been estimated.[158,159] The constants for the copolymerisation of *p*-isopropenylphenyl acetate with butadiene were determined in this instance spectrophotometrically and radiometrically (at 60–80 °C). The activity factors $Q$ and $e$ have been calculated for *p*-isopropenylphenyl acetate.

A method for the synthesis of the copolymer of *o*- or *p*-isopropenylphenol 2-alkyl-4-isopropenylphenols with styrene, maleic anhydride, and acrylonitrile in the presence of t-butylperoxide (TBP) and azobisisobutyronitrile (AIBN) has been described.[160,161] For a 1:1 ratio of the isopropenylphenol and maleic anhydride and a 1:2 ratio of isopropenylphenol and acrylonitrile (at 80° and 140 °C), the yields of the copolymers were 37–49% and 92–96% respectively.

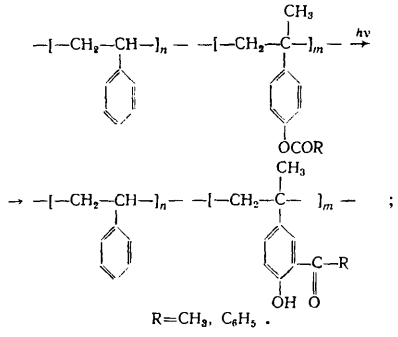
The co-oligomerisation of 1–30% of *p*-isopropenylphenol with 70–99% of styrene in the presence of 0.1–0.2% of TBP at 140 °C is completed in 30 h. The yield of the co-oligomers is 93–99%. An increase in the amount of isopropenylphenol in the initial mixture of monomers lowers the rate of copolymerisation and leads to the formation of copolymers with reduced softening temperatures and intrinsic viscosities.

One of the promising applications of the co-oligomers of isopropenylphenols with styrene, maleic anhydride, and acrylonitrile involves their use as hardening agents for industrial epoxydian resins.† The phenolic hydroxyl and the anhydride group in the co-oligomers readily react with the epoxide ring and the OH group of the epoxydian resin, such interaction resulting in a hardening product with an improved heat resistance, adhesive strength, etc.[149].

The allyl ether of *p*-isopropenylphenol copolymerises readily with styrene in bulk and in solution (in ethylbenzene) in the presence of TBP as the initiator.[162] The copolymerisation in bulk is complicated by the formation of a gel-fraction, whose yield increases with temperature and with the amounts of the allyl ether of *p*-isopropenylphenol and the initiator in the initial mixture of monomers. The copolymerisation in ethylbenzene proceeds smoothly with virtually total conversion of the monomers. In the co-oligomerisation in solution, the ethylene bond of the isopropenyl group is more reactive than that in the allyloxy-group, as a result of which the selective synthesis of co-oligomers containing reactive allyloxy-groups becomes possible.[163,164] Studies on the characteristic features of the thermal structure formation in the co-oligomers containing 10, 20, and 30% of units comprising the allyl ether of *p*-isopropenylphenol have shown that their thermal hardening at 180–240 °C proceeds with the opening of the ethylene bond in the allyl group. Coatings based on the above copolymers have improved UV- and thermo-oxidative resistances, adhesive and impact strengths, and elasticities.

The copolymerisation of the glycidyl ether of *p*-isopropenylphenol with styrene and acrylonitrile in bulk in the presence of TBP and AIBN has been studied.[165] The copolymerisation constants for the copolymer of styrene ($r_1$) and the glycidyl ether of *p*-isopropenylphenol ($r_2$) are $r_1 = 2.42 \pm 0.78$ and $r_2 \cong 0$.

The copolymers of the glycidyl ether of *p*-isopropenylphenol with styrene are readily hardened by polyethylenepolyamine, *p*-phenylenediamine, and maleic and phthalic anhydrides and also thermally and on irradiation with UV

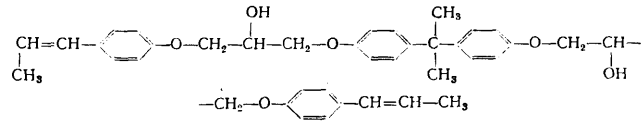


†Dian = 2,2-di(4-hydroxyphenyl)propane (Ed.of Translation).

light. The loss of weight by the "cross-linked" copolymers at 250 °C over a period of 24 h depends on the composition of the product and varies in the range 10–30% (38–40% for polystyrene).[166]

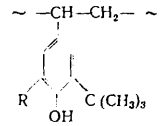
When the co-oligomers of *p*-isopropenylphenol or 4-isopropenyl-2-methylphenol with styrene and acrylonitrile were allowed to react with epichlorohydrin, a reactive oligomer containing simultaneously an epoxide ring and a phenolic hydroxyl was obtained.[167]

The heat resistance and thermal stability of the above plastics can be improved in introducing units comprising the glycidyl ethers of isopropenylphenols into the polystyrene chain with their subsequent thermal hardening. The glycidyl ether of *p*-isopropenylphenol co-oligomerises effectively with maleic anhydride and styrene in the presence of the AIBN initiator and in its absence.[168] The co-oligomerisation of the glycidyl ether of *p*-isopropenylphenol with maleic anhydride (1 : 1) and a mixture of maleic anhydride and styrene (1 : 2 : 1) both in bulk and in solution (in ketones) at 60 °C proceeds with intermediate formation of a charge-transfer complex and leads to the formation of binary and ternary co-oligomers with alternating monomer units respectively. These co-oligomers are readily hardened in the presence of moisture and also amines at 100–180 °C with the opening of the anhydride and epoxy-groups present in the co-oligomer. Coatings based on these co-oligomers are characterised, before and after hardening respectively, by impact strengths of 10 and 50 kg(force) $cm^{-2}$, elasticities of 1 and 10 mm, hardnesses of 0.72 and 0.9, and adhesive strengths of 4.0 and 89.9 kg(force) $cm^{-2}$.



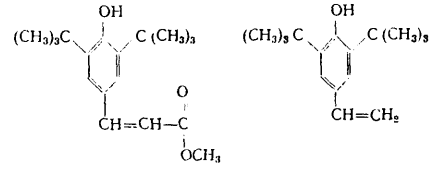
The results for the copolymerisation of p-isopropenylphenyl acetate and *p*-isopropenylphenyl benzoate with styrene in bulk in the presence of TBP have been published.[169] Under the influence of UV light, the Fries rearrangement takes place in *p*-isopropenylphenyl ester units of the polymer chain with formation of hydroxyacetophenone and hydroxybenzophenone groups, which improve the photostability of the copolymers:

R=$CH_3$, $C_6H_5$ .



A method for the modification of the p-isopropenylphenol–styrene copolymer (hydroxyl index 112–116) by the glycidyl ether of *p*-isopropenylphenol in the presence of sodium hydroxide is also known.[170] The yellow modified resin softens at 85 °C and is soluble in the majority of organic solvents. Di(isopropenylphenyl) ether has also been recommended as a modifying comonomer for the modification of properties, especially for improving the heat resistance of polystyrene.[171] It has also been suggested[172] that the linear *p*-isopropenylphenol homopolymer and epoxy-resins be used for the preparation of thermoreactive polymeric materials with high heat and chemical resistances.

A method of synthesis of "cross-linked" copolymers (Marten heat resistance 87°, Dinstat [DIN static bending test? (Ed.of Translation)] bending strength 976 kg $cm^{-2}$, specific impact strength 4.3 kg $cm^{-2}$, and hardness 1415 kg $cm^{-2}$) by the copolymerisation of ~95% of a vinyl monomer (for example, styrene) with 5% of a tetrafunctional monomer, obtained by the reaction of 2 moles of the glycidyl ether of *p*-propenylphenol with 1 mole of bisphenol, has been proposed in a patent:[173]



Shielded derivatives of vinylphenols, in particular 2,6-di-t-butyl-4-vinylphenol and 2,6-di-t-butyl-4-isopropenylphenol, are of interest for the synthesis of high-molecular-weight anti-oxidants by their copolymerisation with other monomers.[174] The dimers of 2,6-dialkyl-4-isopropenylphenols and their salts can also be used as anti-oxidants in rubbers and oils.[175]

A composition with an improved resistance to the action of oxidants has been obtained on the basis of polypropylene and poly-t-butyl-p-vinylphenol.[176]

R = H, t-butyl.

In order to improve the stability of the polymers of styrenes, vinyl acetate, vinyl chloride, ethyl acrylate, acrylonitrile, and butadiene, it has been suggested that[177] the latter be copolymerised with unsaturated sterically hindered phenols:

The reactions are carried out under a high pressure in the presence of 0.5% of AIBN in solution in toluene. The phenolic compounds are used in amounts of ~3%.

## V. POLYCONDENSATION OF VINYLPHENOLS WITH ALDEHYDES

In contrast to phenol- or alkylphenol-aldehyde resins, alkenylphenolaldehyde resins are capable of being hardened via the alkenyl groups with the evolution of little or no volatile products. Furthermore, they can be structured by vinyl monomers with formation of "cross-linked" copolymers with improved water resistance, chemical resistance, and dielectric properties. Allylphenolformaldehyde resins also have similar properties. Thus allylphenolformaldehyde resins capable of being thermally hardened at 180–250 °C have been obtained by the allylation of a novolac phenol-formaldehyde resin and the polymerisation of the allyl ether of 2,6-dihydroxymethyl-*p*-cresol with subsequent thermal rearrangement of polyallyl ethers.[178–180] The cross-linking of allylphenolformaldehyde resins has also been investigated using cross-linking monomers (styrene, α-methylstyrene, acrylonitrile, and 2-methyl-4-vinylpyridine) in the presence of cationic catalysts.[180] It was shown that the copolymerisation of the allyl ether of novolac in the presence of cationic catalysts proceeds smoothly and at a fairly high rate, while the reaction initiated by free radicals either does not occur or is characterised by a low extent of completion.

Polycondensation resins have also been synthesised using *o*-allylphenol,[126] *trans*-hydroxymethylphenylallyl ether,[181] and cardanol (a monohydric phenol with a $C_{15}$ side chain, containing double bonds, in the *meta*-position) obtained by the distillation of the oil from the seeds of *Anacardium occidentale*.[182]

Allylic resins possess a high thermal stability and moisture and chemical resistances as well as a low toxicity and are used as laminate and moulding materials and also in the form of varnish coatings.[183,184]

In contrast to allylphenolformaldehyde resins, vinyl- and isopropenyl-phenolformaldehyde resins are readily hardened via a free-radical mechanism at lower temperatures.

A method of synthesis of vinyl- and isopropenyl-phenolformaldehyde resins by the polycondensation of *m*-vinylphenol and *o*- and *p*-isopropenylphenols with formaldehyde has been described.[185-187] The unsaturated resin obtained can be readily hardened and can be used in oil-based insulating varnishes and for the preparation of moulding powders and adhesives.

A resin with improved flexibility (without impairment of its electrical properties), thermal stability, chemical resistance, and size stability has been obtained by the polycondensation of *p*-isopropenylphenol and its oligomer with formaldehyde in the presence of an acid catalyst; this resin is used as a binder in the manufacture of electrically insulating laminate materials.[188]

The condensation of *p*-isopropenylphenol or its dimer with formaldehyde can take place in the presence of bases,[189] for example, 28% of an aqueous solution of ammonia at 95 °C. The laminate plastic obtained using the resin thus synthesised is characterised by higher bulk and surface resistivities ($4.5 \times 10^{12}$) compared with the usual phenolformaldehyde resin ($10^9$–$10^{10}$).

These studies exhaust the available literature data on the polycondensation of vinyl- and isopropenyl-phenolformaldehyde resins. Thus the existing possibilities for the synthesis of alkenylphenolformaldehyde resins by the polycondensation reactions have so far been by no means fully utilised. The synthesis of *p*-alkylphenolformaldehyde and ureaformaldehyde resins modified by vinyl- and isopropenylphenols is also of theoretical and practical interest.

The literature data described above permit the conclusion that the chemistry of vinyl- and isopropenyl-phenols has developed vigorously in recent years both in the direction of the creation of effective processes for their synthesis and of the study of their oligomerisation, homopolymerisation, copolymerisation, and polycondensation. Taking into account the differences between the reactivities of the ethylene bond, the phenolic hydroxyl, and the ether and other functional groups, definite advances have been made in the synthesis of new and the modification of existing oligomers and polymers using these polyfunctional monomers. Particular mention should be made of the advances in the creation of unsaturated phenolformaldehyde oligomers, which are hardened without the evolution of volatile products, self-stabilising copolymers, and new composite materials characterised by improved physicochemical and dielectric properties.

# Intermolecular Interaction in Solutions of Graft Copolymers

S.A.Tashmukhamedov (deceased), Kh.I.Akbarov, and R.S.Tillaev

Experimental data for the intermolecular interaction in block and graft copolymers and also the relation between their molecular structure and the properties of their solutions are examined systematically and critically. Problems concerning micelle formation, the microstructure, the conformation, and especially the thermodynamic properties of solutions of graft copolymers are described and the characteristic features of the influence of individual factors on the properties of solutions of graft copolymers are discussed.
The bibliography includes 100 references.

CONTENTS

I. Introduction 1094
II. Microphase separation in multicomponent systems 1094
III. Characteristics of the behaviour of graft copolymers in solution 1095
IV. Dependence of the thermodynamic and conformational properties of the solutions on the molecular structure of graft copolymers 1096
V. The influence of various factors on the properties of solutions of graft copolymers 1101

## I. INTRODUCTION

The macromolecules of graft copolymers consisting of two or more polymeric sections of different nature, linked chemically to one another, are branched, in contrast to the statistical and block copolymers which have a linear structure. The combination of the properties of several macromolecular compounds in graft copolymers is determined by the specific features of their molecular structure. The properties of graft copolymers are determined by the number and molecular weight of the grafted branches, the molecular weight of the main chain, their molecular weight distribution, and the inhomogeneity of the composition of the macromolecules, and also the nature of the main chain and the grafted branches, the degree of their compatibility, and the conformations of the macromolecules in the solvents employed. By altering the parameters enumerated above, it is possible to regulate the molecular and supermolecular structures and to impart to them the necessary properties. Graft copolymers have found industrial applications as impact resistant thermoelastic plastics, polymeric emulsifying agents, stabilisers for multicomponent polymer systems, membranes for reverse osmosis, etc. The two-phase structure of the polymers, caused by the separation of the microphases of the incompatible components into distinct domains (in the solid state), plays a significant role in the development of such products. The degree and nature of such separation depend on many factors, which were enumerated above. Numerous studies of the characteristic features of the formation of the two-phase structure of block copolymers, the ease of formation of which is determined by the linear structure of the macromolecules, have been described in the literature.

Studies of the macromolecular interaction in ternary systems have been analysed[1-5] and a number of communications have been devoted to different aspects of the intermolecular interaction in polymer blends.[6-20] The literature data on the microphase separation in block copolymers and the influence of various factors on their properties in solution and in the solid state have been analysed;[1,21] in addition reviews and monographs have been published.[22-34] The available literature data on the macromolecular interaction in graft copolymers require a systematic treatment and need to be surveyed. On the other hand, new studies on block copolymers, which also need to be surveyed, have been published in recent years.

## II. MICROPHASE SEPARATION IN MULTICOMPONENT SYSTEMS

Numerous publications on studies of the structure of block copolymers[1,21,22,25,29] permit the conclusion that the incompatibility of the blocks in block copolymers promotes phase separation. This leads in its turn to the formation of microdomains, which are arranged regularly in space and form mesophases in the presence of a solvent. It has been noted[22,26] that the best methods for the investigation of such systems are low-angle X-ray scattering and electron microscopy, which have shown that the microdomains have the form of either lamellae, or cylinders, or spheres. The same conclusions concerning the phase separation of block copolymers have been reached by investigators who studied microphase separation by thermomechanical,[35-40] scanning calorimetric,[41,42] and sorption[43-45] methods. Investigation of the influence of the molecular structure of the block copolymer on the microphase separation have shown that, for the same molecular weight of the block copolymer, an increase in the number of blocks hinders separation into layers[35] and that the critical parameter of the interaction between blocks in "star-shaped" block copolymers is lower than for linear block copolymers.[46]

Since the microphase separation process begins to be manifested at the molecular level, the question of the dependence of the conformation of the macromolecule on the segregation factor $\chi_{AB}$, which determines both the formation and the stability of the supercrystals, becomes significant.[8] In dilute solutions of block and graft copolymers the use of selective solvents or the addition of a precipitant to a copolymer solution causes the formation of micelles at the molecular level as a consequence of the intramolecular "precipitation" of the insoluble components. Different forms of the macromolecular micelles of block and graft copolymers in dilute and concentrated solutions have been described.[1,21,22] The characteristics of the formation of

monomolecular and polymolecular micelles from block and graft copolymers have been discussed and the influence of various factors on the micelle formation process has been examined in a number of investigations.[25,26,32-34,47-54]

The literature data on the micelle formation in block and graft copolymers do not provide an answer to the question how the molecular weight of the blocks or grafted branches influences the formation of monomolecular or polymolecular micelles. However, it has been noted that, as the number of block or grafted branches increases, only monomolecular micelles can be formed in solutions of copolymers, because a large number of block or grafted branches protects the nucleus of the micelle, which hinders the formation of polymolecular micelles. The nature of the solvent also influences the formation of micelles: in solvents which are "good" for both components of the copolymer, the microphase separation is impaired, while in selective solvents the heterocontacts between unlike segments are reduced to a minimum and the possibility of the formation of monomolecular or polymolecular micelles is sharply increased. These data confirm the finding that, with increase in the difference between the parameters of the thermodynamic interaction of the components of the copolymer with the solvent $\chi_{12} - \chi_{13} = \Delta\chi$ (the "$\Delta\chi$ effect"), the compability of the components is impaired, which leads to microphase separation in the copolymers and the formation of micelles.

Micelle formation by the macromolecules of block and graft copolymers is a very important factor, since, by using different solvent–precipitant systems, it is possible to regulate the type of micelle, which enables one to obtain "hard" or "soft" forms of the polymer.[21,22] Concentrated solutions of block copolymers form ordered mesomorphic phases resembling lyotropic liquid crystals. In reality these microheterogeneous highly ordered segregated domains, made up of blocks of one type, are typical of supercrystals.[1,8,21]

## III. CHARACTERISTICS OF THE BEHAVIOUR OF GRAFT COPOLYMERS IN SOLUTION

In contrast to block copolymers, graft copolymers do not tend to form supercrystals owing to the branched structure of their macromolecules and steric hindrance. However, despite the branched macromolecular structure of copolymers, the possibility of the formation of highly organised structures of the type of dendrites as a consequence of strong specific interactions of the solvent with the grafted component via hydrogen bonding, leading to the unwinding of the grafted branches and the establishment of a definite order in the latter, has been demonstrated.[55]

It has been shown for graft poly(vinyl alcohol)–poly-2-vinylpyridine (PVA–P-2-VP), cellulose diacetate–polyacrylamide (CDA–PAA), and cellulose diacetate–poly-2-vinylpyridine (CDA–P-2-VP) graft copolymers[55-57] that an increase in the strength of donor–acceptor interactions of acetic acid molecules with PAA and P-2-VP chains causes the formation of structures of the "fern leaf" type with a distinct centre of growth, which become more ideal with increase in the content of the grafted polymer. This phenomenon is encountered fairly rarely for amorphous graft copolymers, because, under the usual conditions, the crystallisation of CDA is hindered by the breakdown of the regularity of the chain structure when some of the acetate groups are replaced by hydroxy-groups.

When solutions of the given copolymers in acetic acid are diluted, the intrinsic viscosity $[\eta]$ increases sharply, exceeding the value for the initial polymer severalfold. An even greater effect of this kind has been observed for the PVA–P-2-VP solution in formic acid, which indicates the occurrence of strong interactions of solvent molecules with the grafted chains, these being responsible for the uncoiling of the grafted chain and the sharp increase in the size of the coils. The weak temperature dependence of the viscosities of the solutions may be an indication of the stability of this conformation. In solvents without an affinity for the grafted branches (for example, in acetone), the values of $[\eta]$ for CDA–P-2-VP solutions initially decrease sharply with increasing content of the grafted P-2-VP and then remain almost unchanged. The different character of the variation of the intrinisic viscosities of solutions of graft copolymers in solvents of different nature can be readily accounted for by the characteristics of the supermolecular structure and the thermodynamic properties of the solutions. For example, the main structural element of the CDA–P-2-VP copolymers obtained from acetone solutions are globules with an indistinct aggregation, in contrast to the CDA network structures. The formation of globules is associated with the coiling up of the grafted branches of the copolymer, because P-2-VP does not dissolve in acetone. The postulated strong binding of solvent molecules by the grafted chains of the copolymer molecule is reflected in the sharp increase in the heats of solution of the CDA–P-2-VP graft copolymers in acetic acid and in the character of the variation of the Flory–Huggins interaction parameters,[55-57] calculated from sorption isotherms.

The poly(vinyl alcohol)–polyvinylpyrrolidinone (PVA–PVP) graft copolymers represent a combination of water-soluble polymers; they are known to be capable of entering into a complex formation reaction as a result of the formation of intermolecular hydrogen bonds between the hydroxy-groups of PVA and the carbonyl group of PVP (this has been confirmed by the large negative free energies of mixing of PVA and PVP [58]). A decrease of $[\eta]$ compared with the initial polymer, the absence of extrema on plots of the temperature dependence of viscosity, and also an increase of $[\eta]$ after the introduction of dimethylformamide (DMF) into the aqueous solution have been demonstrated for aqueous PVA–PVP solutions.[59] The possibility of the occurrence of specific intramolecular interactions in such systems is determined by the ability of the solvent to favour or hinder such interactions.

The differences between the behaviour of two types of macromolecules of graft copolymers based on chlorinated poly(vinyl chloride) (CPVC–PS, CPVC–PVAC†) can be traced from the variation of $[\eta]$ of their solutions in mixed solvents, one of which is selective or is a general precipitant.[56] The extremum in the variation of the viscosity with the composition of the mixed solvent, associated with the microphase separation of the branches of the graft copolymers, which is caused by the incompatibility of the main chain and the grafted chain, is observed only for CPVC–PS.[56] The observed extremum in the variation of $[\eta]$ with the composition of the mixed solvent for the CDA–PVAC, cellulose triacetate–poly(vinyl acetate) (CTA–PVAC), CDA–PVP, and CDA–PAA graft copolymers can be explained by the change in the conformational state of the macromolecules as a result of the rupture of the intramolecular hydrogen bonds.

The different types of behaviour in mixed acetone–methanol solvents of the CDA–PVAC and CDA–PVP graft copolymers are striking.[56] Whereas the variation of the viscosity for the CTA–PVAC system is determined mainly by the characteristics of the interaction of the molecules of the second

† Poly(vinyl acetate).

component of the mixture of solvents with the main copolymer chain, in the CDA–PVP system the influence of the interaction of the grafted branches with the methanol molecules is more pronounced. Furthermore, specific interactions of the type of hydrogen bonding are possible for both components of the CDA–PVP graft copolymers in the binary solvents investigated. The CDA–PAA graft copolymers, whose macromolecules contain hydroxy- and amide groups, also belong to such systems. In the acetic acid–water mixed solvent, the conformational state of the CDA and PAA macromolecule is determined by the different character of their interaction with acetic acid molecules. The behaviour of the graft copolymers in the acetic acid–water system combines a series of effects characteristic of the homopolymers and a distinct dependence of the effects on composition has been observed. Conformational changes in the macromolecules of graft copolymers in mixed solvents have also been observed by Trakhtenberg et al.[60] and Dondos.[61]

The changes in the conformation of graft copolymers can also be traced by means of the anomalous changes in the plot of the viscosities of their solutions against temperature. The extrema in the temperature variation of $[\eta]$ correspond to the conformational transition in which a "segregated" conformation is replaced by a statistical conformation. Such behaviour is common for graft copolymers regardless of the degree of compatibility and the positions of the extrema are almost independent of the composition of the corresponding graft copolymers.[56] Furthermore, such effects are manifested even under the conditions of a strong interaction (of the type of hydrogen bonding). The CDA–PAA–formic acid system, for which the temperature variation of $[\eta]$ is very complex, is therefore of interest.[57] The changes in the conformation of the macromolecule under the influence of temperature in systems of this type can apparently proceed via a series of stages.

## IV. DEPENDENCE OF THE THERMODYNAMIC AND CONFORMATIONAL PROPERTIES OF THE SOLUTIONS ON THE MOLECULAR STRUCTURE OF GRAFT COPOLYMERS

### 1. The Molecular Structure and Conformations of Graft Copolymers in Solution

Major advances have been achieved at the present time in the controllable synthesis of block and graft copolymers. However, few studies of the molecular characteristics and also of the thermodynamic, hydrodynamic, and other physicochemical properties of solutions of graft copolymers have been described in the literature. It is still not clear how the molecular weight, the number of grafted chains, and the degree of compatibility of the components of the graft copolymer, as well as the nature of the solvent influence the conformational parameters and physicochemical properties of such copolymers. By varying the above parameters, it is possible to alter particular properties of the graft copolymers, which enables one to obtain materials with previously specified properties. The influence of the length of the grafted branches on the properties of copolymers in solutions has been investigated.[62–65] It has been established for CDA–PS graft copolymers[62,63] that, firstly, the grafting of PS initially diminishes the $[\eta]$ of the graft copolymer compared with the initial CDA, when the molecular weight of the PS changes only slightly, and, secondly, it leads to an increase of $[\eta]$ of the solutions under conditions of a high content of PS chains, when their molecular weight increases sharply (to $1.08 \times 10^6$), i.e. in this region the influence of the branching and segregation is small and the overall change in $[\eta]$ is determined solely by the length of the grafted branches. Direct determinations of mean square radii of inertia $(\overline{R}_z^2)^{1/2}$ of the CDA–PS solutions in a solvent having the same refractive index as CDA, namely pyridine, have shown that the main contribution to the overall volume of the macromolecule of the graft copolymer comes from the side chain.

Measurements of light scattering by CDA–PS solutions in different solvents have shown[63] that tetrahydrofuran (THF) interacts more effectively with the components of the copolymer. For this reason, the values of $[\eta]$, $(\overline{R}_z^2)^{1/2}$, and virial coefficients $(A_2)$ for solutions of the given copolymers in THF are greater than for DMF. A very sharp increase of $(\overline{R}_z^2)^{1/2}$ is observed in dioxan, where the values of $A_2$ are much smaller than in THF and DMF, which is a consequence of the association of the copolymer macromolecules, indicated by the very high molecular weight $\overline{M}_w$. It is noteworthy that CDA and PS are thermodynamically incompatible[62] and, according to the average free energy of the blending of these polymers, the degree of their incompatibility in THF is much greater than in DMF. Consequently the incompatibility of components of these copolymers promotes a more effective interaction with the solvent.

Another picture is observed for CDA–PVP graft polymers, where the effects of branching and segregation determine the characteristic features of the hydrodynamic properties of their solutions.[64]

The thermodynamic and conformational properties of CTA–PMMA graft copolymers, synthesised by non-terminable radical polymerisation,[66] which makes it possible to regulate the molecular weight and the number of grafted branches, have been investigated. It has been established that, with increase in the number of grafted branches, the values of $(\overline{R}_z^2)^{1/2}$ for comparable molecular weights of the grafted branches and the values of $A_2$ increase. A sharp increase of the molecular weight of the grafted branches entails an increase of the values of $(\overline{R}_z^2)^{1/2}$, while $[\eta]$ changes only slightly. The $[\eta]$ for graft copolymers are very sensitive to changes in the number of grafted branches and increase sharply with increase of the latter. The isotypical character of the variation of $[\eta]$, $(\overline{R}_z^2)^{1/2}$, and $A_2$ for solutions of copolymers with increase of the molecular weight of the grafted branches is noteworthy.

Graft copolymerisation in the presence of cobalt(III) salts, which permits the regulation of the process parameters, has been carried out.[67] The molecular parameters of the graft copolymers of CTA with poly-2-methyl-5-vinylpyridine (PMVP) vary with the polymerisation conditions: $M_{cop}$ from $1.1 \times 10^5$ to $4.45 \times 10^5$, $M_{CTA}$ from $7.5 \times 10^4$ to $3.2 \times 10^5$, and $M_{PMVP}$ from $6.0 \times 10^3$ to $8.0 \times 10^4$. Despite the fact that the average number of units in the main chain between neighbouring branches varies within wide limits, from 45.0 to 712.0, the number of grafted branches increases only to 5.8, which is associated with the fact that oxidative properties, leading to a decrease of $M_{CTA}$, take place simultaneously with graft polymerisation.

The molecular characteristics and the hydrodynamic, thermodynamic, and conformational properties of CTA–PMVP copolymers have been investigated.[67,68] The intrinsic viscosities of the graft copolymers depend significantly on the molecular structure, because the latter determines the degree of branching. It is of interest to compare the dependence of $[\eta]$ on $M_{cop}$ with the analogous data for CTA. The increase of $[\eta]$ for CTA on passing from methylene chloride to formic acid is caused by the change in the conformation of the molecules owing to the specific interaction with the solvent. The intrinsic viscosity $[\eta]$ varies

analogously also for the CTA–PMVP copolymers; [η] for the copolymer is higher in this instance than for CTA with the same molecular weight. Presumably the incompatibility of CTA and PMVP in the solvents indicated leads to an unusual conformation of the copolymer macromolecules, the character of which depends on the quality of the solvent. The difference between the behaviour of the mixture of homopolymers and their graft copolymers can serve as a demonstration, on the one hand, of the grating step which is in many cases responsible for the impairment of the solubility of the graft copolymers with increase of the molecular weight of the grafted branches, and, on the other, can indicate the influence of the nature of the solvent on the thermodynamic properties. The influence of the nature of the solvent is in this case so great that even the signs of the average free energy of blending of polymers are different for the graft copolymers and their blends.[68]

The constants $K$ and $a$ of the Kuhn–Mark–Houwink equation for graft copolymers have been determined.[63,65,69,70] The low value of the power exponent $a$ is striking, indicating a weak thermodynamic interaction of the copolymer and the solvent in the absence of permeability of the copolymer macromolecules to solvent molecules. While the graft copolymers investigated by Klenin and co-workers[69,70] had a comb structure, that of the macromolecules of graft copolymers investigated by Akbarov and co-workers[63,65] must have been of the star type, because the molecular weights of the side branches were very high—much higher than the molecular weight of the main chain. For this reason, the low values of the exponent $a$ for the given copolymers with incompatible components may be a consequence not so much of the branching as of the globular form of the macromolecules, predominantly owing to the long side branches: for long grafted branches, the probability of their selective interaction with one another to form microregions of identical chemical nature increases.

A possible confirmation of the foregoing concerning the dominant influence of long grafted branches on the conformation is the decrease of the values of $A_2$ with increase of the temperature of the solution of the CDA–PS copolymer in DMF, which is confirmed in its turn by data for the phase diagrams and sorption properties quoted by Tashmukhamedov et al.[62] In other words, the CDA–PS solution in DMF has upper and lower consolute temperatures and the region of solubility is extremely limited, while the initial CDA and PS do not separate into different layers either on cooling or on heating. Consequently, even in effective solvents there is a preferential interaction of the chemically homogeneous segments, promoting the formation of microgels and hence the precipitation of the graft copolymer.

## 2. Characteristic Features of the Phase Equilibrium in Solutions of Graft Copolymers

The characteristic features of the structure of graft copolymers consisting of units of chemically heterogeneous components suggest that the critical phenomena in their solutions occur somewhat differently than in homopolymers. Here the main role may be played by segregation or intramolecular phase separation processes caused by the incompatibility of the polymeric components of the graft copolymer. For this reason, the structure and conformational state of the macromolecules of the graft copolymer in solution may have a specific influence on the phase equilibrium, as a consequence of which a difference from the properties of the corresponding initial polymers is ultimately observed.

It follows from the phase diagram obtained[62,71] for CDA–PS solutions in THF, epichlorohydrin, dioxan, and DMF that a characteristic feature of such solutions is the presence in all solvents of a lower consolute temperature of the first type (in Tager's classification) caused by the strong intermolecular bonds between the components in solution, which are broken on heating. It is also evident that, with rare exceptions, an improvement in the solubility of the CDA–PS copolymers is to be expected at room and lower temperatures owing to the influence of the branching of the copolymers.

When the lower consolute temperatures for a solution of CDA in THF and for CDA–PS are compared,[62,71] the observed differences are manifested not only in the consolute temperature and its type but also in the character of the very phase transition in the system. The phase separation in CDA–PS solutions is manifested by the formation of particles of the polymer phase in the form of unusual block formations, leading to, as it were, the "displacement" of the solvent from the solution and to a phase transition in the system. The temperature of the appearance of the first signs of particles of the polymer phase is adopted in this instance as the temperature at which separation into layers occurs. In the case of homopolymers, this is usually preceded by the appearance of a turbidity of the solution (critical opalescence), which has not been observed for graft copolymers. Analysis of the phase diagrams for the system investigated showed that the solubility of CDA–PS is a function not only of temperature but also of the composition of the copolymer,[72] which is common to all the solvents investigated. However, with increased content of PS in the copolymer, a continuous impairment of the solubility is not observed. This interesting feature is demonstrated by the fairly sharp improvement in the solubility of the CDA–PS specimen containing 77.4% PS in all the solvents investigated compared with the copolymers having a lower PS content.[72] Yet another example of such behaviour of graft copolymers in solution is provided by the CTA–PMMA copolymers investigated by Akbarov,[65] thermodynamic properties of which we shall consider in detail below.

It is known that the effect of high pressure on solutions of homopolymers tends to shift the lower consolute temperatures towards higher values and the upper consolute temperatures towards lower values, i.e. it impairs the miscibility in the polymer–solvent system. The literature data for the influence of pressure on the phase equilibrium and the thermodynamic parameters of homopolymer solutions have been analysed.[73] For the phase equilibrium as a function of pressure in block and graft copolymers, there are only a few data in the literature. As an example, one may quote studies on the solutions of CDA–PS graft copolymers in THF.[74] According to the results, the application of a pressure of the order of 20–200 bar tends to improve the solubility of CDA–PS. However, a graft copolymer with a high PS content, characterised by a poorer solubility, requires a higher pressure in order to dissolve, which is a consequence of structural characteristics of the graft copolymers investigated.

## 3. Thermodynamics of the Phase Equilibrium in Solutions of the Graft Copolymers in the Light of the Prigogine–Patterson Theory

The Prigogine–Patterson theory[75,76] is a development of the thermodynamic Prigogine–Flory theory.[77,78] The applicability of the Prigogine–Flory theory, which describes liquid–liquid systems, to polymer solutions has been demonstrated in a number of investigations[79–82] in which reduced thermodynamic functions were calculated for certain polymer

systems. The expression arising from the Prigogine–Flory theory for the interaction parameter $\chi_1$ is

$$\chi_1 = \left(-\frac{U}{RT}\right)\nu^2 + \left(\frac{C_p}{2R}\right)\tau^2 , \quad (1)$$

where $U$ is the configurational energy or the evaporation energy of the solvent, $\nu$ the parameter referring to the cohesion energy and the segmental size of the components, $C_p$ the configurational heat capacity of the solvent, which increases with temperature and tends to infinity as the critical temperature for the transition from the liquid to the vapour is approached, $R$ the gas constant, and $\tau$ a structural parameter characterising the difference between the free volumes of the polymer and the solvent, which can be calculated from the formula $\tau = 1 - T_1^*/T_2^*$, where $T_1^*$ and $T_2^*$ are the characteristic reduced temperature parameters of the solvent and the polymer respectively.

It is exceedingly difficult to use the interaction parameters $\chi_1$ in this expression in order to characterise the mixing of the polymer with the solvent including the region of the [given] phase state. A modified theory put forward by Patterson[75,76] therefore merits attention. He obtained a different expression for the critical interaction parameter having applied the van der Waals principle of the volume dependence of the configurational energy of liquid (this was pointed out previously in an early investigation by Flory[78]) and having expressed all the quantities in Eqn.(1) in terms of the reduced volume of the solvent:

$$\chi_{1,cr} = \frac{c_1\nu^2}{1-\tilde{V}_1^{-1/3}} + \frac{c_1\tau^2}{2\left[(4/3)\tilde{V}_1^{-1}-1\right]} = \frac{1}{2}\left[1+r^{-1/2}\right]^2 , \quad (2)$$

where $\tilde{V}_1$ is the reduced volume of the solvent, $c_1$ the number of degrees of freedom of the solvent molecule, $\nu^2$ and $\tau^2$ are temperature independent parameters or, in terms of Patterson's theory,[76] $c_1\nu^2$ is a factor which depends on the chemical nature of the solvent and the polymer and $c_1\tau^2$ is the structural factor, and $r$ is the number of polymer segments in the micromolecule. As in Eqn.(1), the first term of Eqn.(2) contributes to the variation of $\chi_1$ with decrease of temperature and predicts the upper consolute temperature, whilst the second contributes to the variation of $\chi_1$ with increase of temperature and predicts the lower consolute temperature. According to the theory, $\nu^2 = 0$ for systems having identical or very nearly identical chemical structures and in this case the parameter $\chi_1$ is determined solely by the structural term. Eqn.(2) then has only one root:[76]

$$\tilde{V}_1^{-1/3} = 3/4\,(1 + c_1\tau^2 Q) , \quad (3)$$

where $Q = [1 + r^{-1/2}]^{-2}$. For systems where the polymer and the solvent have different chemical structures, the theory predicts the upper and lower consolute temperatures. Thus, by calculating the molecular parameters in Eqn.(2), it is possible to characterise quantitatively the mixing of the polymer with the solvent as the temperature is varied.

In the Flory equation,[80] the quantity $r$ is determined by the ratio of the molar volumes of the polymer and the solvent, i.e. by $V_2^*/V_1^*$, and $T_1$ is calculated from the equation

$$\tilde{T}_1 = \tilde{V}_1^{-1}\left(1-\tilde{V}_1^{-1/3}\right) = T/T_1^* \quad (4)$$

where $V_1$ is the reduced volume of the solvent, which can be calculated from the formula

$$\tilde{V}_1 = \left[\frac{\alpha_1 T}{3(1+\alpha_1 T)} + 1\right] ,$$

where $T$ is the experimental critical [consolute] temperature, and $\alpha_1$ the coefficient of thermal expansion of the solvent.

The principle of the theoretical analysis of reduced temperatures involves the plotting of two graphs: the first represents the dependence of $\tilde{T}_1$ on $\tilde{V}_1^{-1/3}$ in accordance with Eqn.(4), where $\tilde{T}_1^* = T/T_1^*$ and $T_1^* = T\tilde{V}_1/(1 - \tilde{V}_1^{-1/3})$, while the second represents the dependence of $\chi_{1,cr}$, $c_1\nu^2$, and $c_1\tau^2$ on the same values of $\tilde{V}_1^{-1/3}$, the ranges of variation of the parameters $c_1\nu^2$ and $c_1\tau^2$ being taken from the literature data.[76] The main difficulty consists in the selection of critical values of the parameters $c_1\nu^2$ and $c_1\tau^2$, which must satisfy the theoretical data of Eqn.(2). The points corresponding to the intersection of the horizontal lines for the given values of $\chi_{1,cr}$ and the corresponding suitable values of $\tilde{V}_1^{-1/3}$ yield the temperature variation of $\chi_1$ which is described by Eqn.(2). $\tilde{T}_{1,theor}$ is calculated from the theoretical values of $\tilde{V}_1^{-1/3}$ already obtained in this way. In order to compare the experimental and theoretical $\tilde{T}_1$, the temperature axes are displaced in such a way that these data coincide.

The applicability of the Prigogine–Patterson theory to the description of the phase equilibrium in solutions of polar-rigid-chain polymers of the copolymer type has been demonstrated:[83] CDA in THF and CTA in methylene chloride (MC). Lower and upper consolute temperatures have been observed for the first system and an upper consolute temperature for the second. In the CDA–THF system the shift of the theoretical axis at the upper and consolute temperatures is 12° and 55 °C, while for the CTA–MC system the shift [at the upper consolute temperature] is 1.5 °C. Such a significant difference between the experimental and theoretical data in the region of the lower consolute temperature is a consequence of the fact that the new phase initiation processes, in which the polymer macromolecules are structured and aggregated and there is a transition from homophase to heterophase fluctuations, whose dimensions vary with temperature, are already prepared for in the region remote from the consolute temperature. For systems having both types of consolute temperatures, the temperature dependence of $\chi_1$ has an extremum, which can be below or above the ideal value $\chi_1 = 0.5$. The coordinates of this point are determined from the known limiting value of the parameters $c_1\nu^2$ for the case where an increase in the molecular weight of the polymer entails the mutual approach and possibly even the identity of the upper and lower consolute temperatures, giving rise to the so-called "hour glass" form.[76] This means that, when the molecular weight is greater than a certain critical value, the middle sections of the upper and lower branches of the phase diagrams merge, i.e. there appears a range of compositions where the system cannot exist as a single-phase system at any temperature. In this case the minimum in $\chi_1$ is calculated from the equation

$$\tilde{V}_1^{-1/3} = \frac{7}{8} + \frac{3}{8}(c_1\tau^2 - c_1\nu^2)\,Q , \quad (5)$$

where $Q$ assumes a value close to unity at $M \to \infty$. The limiting values of $c_1\nu^2$ calculated in this way are 0.0255 for CDA–THF and 0.01845 for CDA–MC and are correlated with the plot of $\chi_1$ against $\tilde{V}_1^{-1/3}$ and with its temperature variation.[83]

It is noteworthy that the separation of the interaction parameter $\chi_1$ in accordance with the Patterson theory into molecular parameters is important for the understanding of the temperature variation of the miscibility of the polymer solution. The temperature variation of these parameters obtained by Goloborod'ko et al.[83] from Eqn.(2) is characterised by their different role in $\chi_1$, where the term $c_1\tau^2$, leading to the separation of the system into different layers at high temperatures, makes the dominant contribution. This is apparently a distinctive feature of solutions of cellulose acetates, which are involved in complex intermolecular interaction with the solvent by virtue of the specific features of their structure.

As for homopolymers, when the molecular weight of the graft copolymer increases, the consolute temperatures approach one another, i.e. the usual picture involving an impairment of miscibility with increase of the molecular weight is observed.[74] On the assumption that the CDA–PS specimen with 77.4% PS and a very long grafted chain ($\tilde{M}_\eta$ = $1.086 \times 10^6$) can be regarded by convention and with some approximation as homo-PS, an attempt has been made[74] to apply the Prigogine–Patterson theory to this copolymer.[75,76]

The study of the phase diagrams for solutions of CDA–PS fractions in THF and DMF has shown[74] that this approach to the quantitative description of the phase equilibrium in solutions of graft copolymers is entirely acceptable. The higher theoretical reduced consolute temperatures compared with the experimental temperatures may be regarded as a consequence of the presence of lower consolute temperatures of the first type in solutions of the graft copolymers, whilst the theory provides for the presence of a lower consolute temperature of the second type in polymer systems. Nevertheless the calculated temperature dependence of the parameters of the Patterson equation represents, in the case of CDA–PS solutions, a typical picture of the variation of the phase state of polymer solutions with temperature (Fig.1). The system investigated is characterised by definite values of the structural ($c_1\tau^2$) and chemical ($c_1\nu^2$) parameters, which satisfy the theoretical data of the Patterson equation $\chi_{1,cr} = \frac{1}{2}(1 + r^{-1/2})^2$. For certain values of $\chi_{1,cr}$ and suitable $\tilde{V}_1^{-1/3}$, points representing the temperature variation of $\chi_1$ described by Eqn.(2) are obtained. The value of $\chi_1$ at any point within the temperature range describes the behaviour of the system as a function of the degree of interaction of the polymer with the solvent. According to the results of the calculation of the temperature variation of these parameters, the graft copolymer interacts with the solvents employed to different extents.[74] This conclusion is based not only on data for the consolute temperatures but also on the analysis of the character of the influence of the nature of the solvent on the miscibility with the polymer.

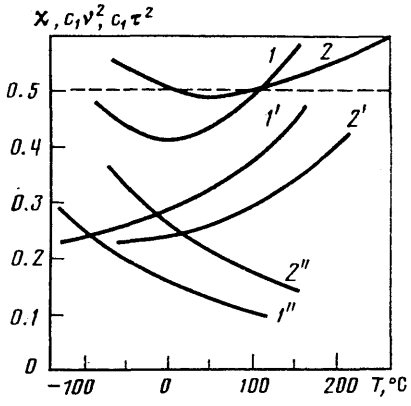

**Figure 1.** Temperature variation of the interaction parameters $\chi_1$ (curves *1* and *2*) and the molecular parameters $c_1\tau^2$ (curves *1'* and *2'*) and $c_1\nu^2$ (curves *1''* and *2''*) of Eqn.(2) for different systems:[74] *1*), *1'*), and *1''*) CDA–PS–THF; *2*), *2'*), and *2''*) CDA–PS–DMF.

## 4. Relation between the Type of Consolute Temperature and the Signs of the Thermodynamic Parameters of Mixing in Solutions of the Graft Copolymers

According to thermodynamic predictions, systems with a lower consolute temperature should be characterised by negative enthalpies and entropies of mixing. On the other hand, for systems which have both an upper and a lower consolute temperature, the enthalpies and entropies of mixing should decrease (i.e. their absolute negative values should increase). The study of the temperature variation of the sorption of dichloroethane vapour by the EPVC–PS graft copolymer[84] has shown that the system becomes unstable with increase of temperature, which is manifested by a decrease in its absolute negative free energy $\Delta g^m$ and indicates the impairment of the quality of the solvent. The data obtained[84] for the temperature variation of the free energy were used to calculate the enthalpies and entropies of mixing. They are negative over the entire temperature and concentration ranges and diminish in absolute magnitude with increase of temperature.

Comparison of the results obtained for the initial polymer and the graft copolymers show that the grafting step impairs the affinity of the solvent for the graft copolymer and limits the region of existence of the homogeneous solution, which is expressed by a decrease in the heat of solution and the free energy and by the appearance of a lower consolute temperature on the mixing diagrams. For CDA graft copolymers, whose grafted branches have different chemical nature, the change in the enthalpy component of the chemical potential makes a significant contribution to the change in the affinity of the solvent for the graft copolymer. Thus CDA–PVAC graft copolymers dissolve in acetone, which is a common solvent for the copolymer components, with a smaller heat change than the initial polymer[85] and the heat of solution falls sharply with increased content of the grafted PVAC in the copolymer.

On the basis of the finding that the interaction of grafted PVAC chains with acetone is almost athermal, one can assume that the observed decrease in the heat changes indicates not only a weakening of the interaction energy of the polar groups of the main chain of the copolymer with the solvent molecules but also a change in the structure of the graft copolymer with increased amount of the grafted polymer. This is also indicated by sorption data,[86] from which it follows that, with increase of the fraction of PVAC chains in the graft copolymer, the sorption capacity diminishes not only for acetone but also for methanol, although in the latter case an increase in the degree of sorption should have been seemingly expected, since methanol is a selective solvent for PVAC. Measurements of the specific volumes have shown[86] that the dissolution of CDA and CDA–PVAC in acetone is accompanied by a decrease in volume, i.e. the criterion of a lower consolute temperature, which obtains for the given system in the high temperature range, holds. The smaller contraction for solutions of the graft copolymer than for CDA is a consequence of the closer packing of the graft copolymer.

It is known that the contraction observed in solutions is frequently the cause of the negative contribution to the heat and entropy of mixing. According to the data obtained,[86] the $\Delta g^m$ for the CDA–acetone system become less negative with increase of temperature, as predicted by thermodynamics for systems having a lower consolute temperature. The thermodynamic functions for PVAC are positive and increase with temperature. It has been found that the behaviour of the graft copolymers is determined by the presence of the grafted component, whereupon the

positive enthalpy and entropy of mixing decrease with increasing temperature. The discrepancy between the type of consolute temperature and the signs of $\Delta H^m$ and $\Delta S^m$ for CDA–PVAC solutions is caused by the sharp difference between the thermodynamic properties of the main and grafted copolymer branches, which is the reason for their incompatibility.

In the study of CDA–PVP and CDA–PAA graft copolymers, it has also been observed[64,87] that the variation of the solubility is determined mainly by the variation of the energy component of the chemical potential. Analysis of experimental data has shown that this situation is common to CDA graft copolymers in the solution of which the energy factor plays a dominant role.

### 5. The Flory–Huggins Theory and Tager's Method in the Study of the Thermodynamic Properties of Multicomponent Systems

The extent of intermolecular interactions in solutions of graft copolymers can be estimated with the aid of the Flory–Huggins theory based on the calculation of the Flory–Huggins parameter $\chi'_{12}$ from Scott's equation.[87] The published determinations of the parameter $\chi'_{12}$ for graft copolymers have been analysed.[7] However, the influence of the length and number of the grafted branches on $\chi'_{12}$ was not investigated in the above studies. Investigations[65,89,90] in which a difference between the behaviour of mixtures of CTA and PMMA polymers and their graft copolymers with different molecular structures was demonstrated are of great interest in this connection (Fig. 2).

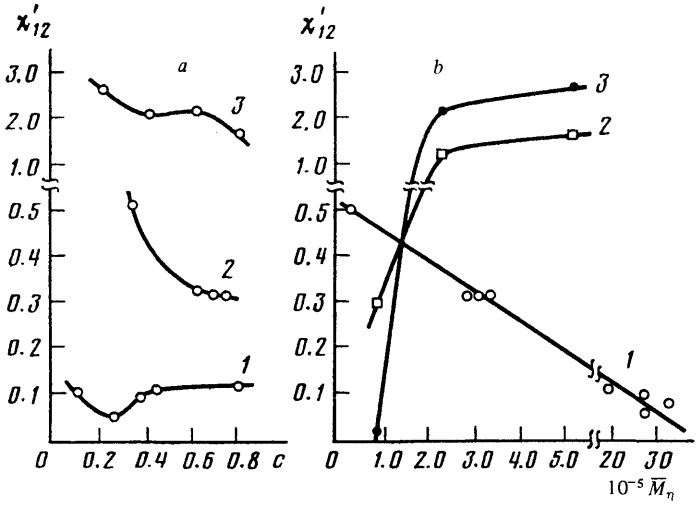

**Figure 2.** Dependence of the polymer–polymer–solvent interaction parameter $\chi'_{12}$ on the content $c$ ($a$) and the molecular weight of PMMA ($b$) in methylene chloride:[65] $a$) CTA–PMMA graft copolymers having grafted branches with high $\bar{M}_\eta$ ($1.95 \times 10^6$–$3.30 \times 10^5$) (curve *1*), CTA–PMA graft copolymers with relatively short grafted branches ($3.30 \times 10^4$ to $3.30 \times 10^5$) (curve *2*), and CTA–PMMA mixtures (curve *3*); ($b$) CTA–PMMA graft copolymers (curve *1*) and mixtures of CTA and PMMA in which the proportions of PMMA are 0.4 (curve *2*) and 0.6 (curve *3*).

The polymer–polymer–solvent interaction parameters $\chi'_{12}$ [or $\psi(a_s\phi_p)$ for graft copolymers], calculated from the Scott, Patterson, and Krause equations using the Flory–Huggins and Flory–Scott theories are directly related to the average free energies of the blending of the polymers $\Delta g_x$ determined by Tager's method.[91] Numerous determinations of the $\Delta g_x$ for polymer blends have been published—by Tager and co-workers[43–45,92,93] for block copolymers, while for the graft copolymers a series of investigations have been made by Tashmukhamedov and coworkers.[62,86,87,90,94] Tager and co-workers[43–45] demonstrated for the first time the possibility of applying Tager's method in the estimation of the thermodynamic stability of blocks in block copolymers and established that the presence of chemical bonds between the blocks of the system investigated impairs their compatibility. However, the influence of molecular weight and of the number of and ratio of the blocks on their compatibility, which would make possible a detailed analysis of the thermodynamic criteria of the compatibility of block copolymers, was not investigated in the above studies.

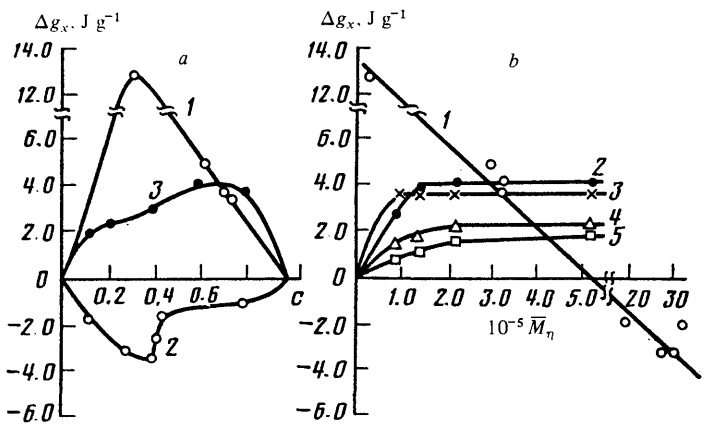

**Figure 3.** Dependence of the average free energy of mixing of the polymers $\Delta g_x$ on the content $c$ ($a$) and the molecular weight of PMMA ($b$) in methylene chloride:[65] $a$) CTA–PMMA graft copolymers having grafted branches with relatively low values of $\bar{M}_\eta$ ($3.30 \times 10^4$–$3.30 \times 10^5$) (curve *1*), CTA–PMMA graft copolymers having grafted branches with high values of $\bar{M}_\eta$ ($1.95 \times 10^6$–$3.30 \times 10^6$) (curve *2*), and CTA–PMMA mixtures (curve *3*); $b$) CTA–PMMA graft copolymers (curve *1*) and mixtures of CTA and PMMA polymers in which the proportions of PMMA are 0.6 (curve *2*), 0.8 (curve *3*), 0.2 (curve *4*), and 0.1 (curve *5*).

Graft copolymers have been studied in detail in a number of investigations[62,63,65,68,95,96] where a study was made of the relation between the molecular structure and the thermodynamic properties of solutions of graft copolymers. It was shown that $\Delta g_x > 0$ for CTA–PMMA graft copolymers with relatively low molecular weights and that the degree of incompatibility is much greater than for polymer blends (Fig. 3). For higher molecular weights of the grafted branches, the $\Delta g_x$ assume low negative values; under these conditions, curve *2*, representing the variation of $\Delta g_x$ with the content of the grafted PMMA branches, shows

a rise, which indicates microlayer formation in the system; this was later confirmed by electron microscope investigations.

The different character of the changes in $\Delta g_x$ with increase in the molecular weight of the second component in polymer blends and in graft copolymers is especially remarkable. Whereas the thermodynamic stability of polymer blends is impaired with increase of the molecular weight of PMMA, for graft copolymers $\Delta g_x$ diminishes to negative values as the molecular weight of the grafted branches rises (Fig. 3*b*, curve *1*). Such behaviour of graft copolymers can be accounted for by the "segregated" conformation of the macromolecules for low molecular weights of grafted branches and by the complete suppression of the segregation effect with increase of the molecular weight of such branches. It is noteworthy that the mean square radii of inertia and the intrinsic viscosities are higher for copolymers with a relatively low molecular weight of the grafted branches compared with those where the molecular weights of such branches are high.[95-97]

## V. THE INFLUENCE OF VARIOUS FACTORS ON THE PROPERTIES OF SOLUTIONS OF GRAFT COPOLYMERS

### 1. The Influence of the Nature of the Solvent

In the case of selective solvents the macromolecules of graft copolymers form monomolecular micelles in dilute solutions; with increase in solvent selectivity or the concentration of such a solution, polymolecular micelles are produced. Strong interactions (of the acid–base type) of the solvent with one of the components of the graft copolymer are fairly distinctly manifested in the character of the structure formation in graft copolymers in solution, in their viscosity properties {there is the sharp increase of $[\eta]$ and its weak temperature dependence} and by an increase of $A_2$ for the solutions.

### 2. The Influence of the Nature of the Polymer

On the basis of the available literature data, one cannot visualise what is the decisive factor governing the compatibility or incompatibility of the polymer pairs and the conformational, thermodynamic, and other physicochemical properties of graft copolymers which follow from this. Polymers having very similar chemical structures may split into separate layers and conversely polymers differing in chemical nature are sometimes compatible.

The nature of the grafted components influences the solubility of the copolymer as a whole, which is due to a change in the absolute chemical potential of the solvent (in some cases a change in the energy component of the chemical potential and in others in the enthalpy component). The change in the solubilities of graft copolymers based on cellulose acetates is determined mainly by the energy component of the chemical potential. The impairment of the dissolving power of the solvent in relation to the graft copolymer is a consequence mainly of the unfavourable changes in the enthalpy component of the thermodynamic potential.

The discrepancy between the type of consolute temperature and the signs of the thermodynamic functions $\Delta H^m$ and $\Delta S^m$ has been observed in certain graft copolymers, which is due to the sharp difference between the properties of the main and grafted chains of the copolymer.

### 3. The Influence of the Compatibility of the Components

In the case of incompatible components, microseparation is observed in good solvents or a preferential interaction may take place between chemically homogeneous segments, favouring the formation of microgels and the precipitation of the graft copolymer.[65]

The conformational properties and structure formation in graft copolymers depends on the compatibility of the components.[65,87] An increase in compatibility entails a decrease of $[\eta]$, $(\overline{R}_z^2)^{1/2}$, and $A_2$ for the solution. In incompatible systems structure formation depends on the nature of the solvent to a greater extent than in compatible systems.[91] The determination of the molecular parameters and the study of the inhomogeneity of the compositions of the CPVC–PS graft copolymer showed that the graft copolymers become inhomogeneous both as regards the chemical composition of the macromolecules and the molecular weight of the components constituting the copolymers.[98]

### 4. The Influence of the Number of Grafted Branches

It has been shown[22] that an increase in the number of grafted branches hinders the formation of polymolecular micelles and that in such cases monomolecular micelles are formed. An increase in the number of grafted branches promotes the formation of a segregated conformation, i.e. microseparation.[65] The intrinsic viscosity $[\eta]$ and $(\overline{R}_z^2)^{1/2}$ diminish for graft copolymers with a small number of grafted branches on microseparation, while in the case of comb copolymers an increase of $[\eta]$ and $(\overline{R}_z^2)^{1/2}$ may be observed.

### 5. The Influence of the Molecular Weight of the Grafted Branches

With increase in the length of the grafted branches, $[\eta]$ and $(\overline{R}_z^2)^{1/2}$ for solutions of the graft copolymers both increase.[62] A marked increase in the molecular weight of the grafted branches can promote the suppression of the segregation effect. It has been shown[65] that graft copolymers with relatively low molecular weights of the grafted branches and a large number of the latter proved to be incompatible and that, when their molecular weight increases considerably, the components become incompatible and the macromolecules assume a more compact form. The second virial coefficient for the solution diminishes with increase in the molecular weight of the grafted branches.[65,95-98] There are no literature data on the influence of the molecular weight of the grafted branches on micelle formation.

### 6. The Influence of Polydispersity and Inhomogeneity of Composition

The graft copolymers employed by Akbarov[65] had grafted branches with a narrow molecular weight distribution. The increments in the refractive indices of the copolymer components proved to be very similar in many solvents, which precluded the determination of the inhomogeneity of their composition and of its influence on the properties of the solutions.

Micelle formation by PVAC–PS graft copolymers in different solvents has been investigated[99] and it has been concluded that the nature of the solvent does not influence the size of the micelles and that the relatively broad distribution of the

micelles with respect to size is a consequence of the polydispersity of the initial copolymers. It has been shown for CPVC and CDA graft copolymers with certain vinyl polymers that, for the copolymers with a marked inhomogeneity of composition and polydispersity, the degree of incompatibility is greater and the values of $A_2$ for the solutions are smaller.[98] The polydispersity of the grafted component leads to a greater incompatibility of the copolymer and the homopolymer in a blend and to an impairment of the solubilisation and the homopolymer by the copolymer.[100]

Thus analysis of studies on the thermodynamic and conformational properties of solutions of graft copolymers has shown that the principal features of the behaviour of the macromolecules of graft copolymers in solution have now been quite adequately characterised on the basis of the quantitative compatibility data. Detailed investigations have been made of the thermodynamics of mixing as a function of the composition and the molecular structure of the graft copolymers. The data obtained have been interpreted in the light of modern views on the nature of polymer solutions taking into account the Flory–Prigogine–Patterson theory. Attention has been concentrated on thermodynamic properties which are most important for the understanding of the interaction of the graft copolymers with solvents of different nature.

At the same time many publications are descriptive in character, because there is so far no rigorous theory of solutions of graft copolymers.

# Scientific and Technical Progress in the Chemical Branches of the National Economy

K.M.Dyumaev

The strategy designed to accelerate the social and economic development of the country put forward at the April (1985) Plenum of the Central Committee of the CPSU has received wide support throughout the nation and has been approved by the XXVIIth Party Congress.

In the political report of the Central Committee of the CPSU to the XXVIIth Congress of the Communist Party of the Soviet Union, M.S.Gorbachev noted that acceleration is in the first place an increase of the rate of economic growth as a result of a comprehensive intensification of production on the basis of scientific and technical progress, a structural reorganisation of the economy, and effective forms of regulating the organisation and stimulation of labour.

In the principal directives for the economic and social development of the USSR in 1986–1990 and in the period up to 2000, it was stated that it was intended to solve the key political and economic problems—to accelerate comprehensively scientific and technical progress, to raise decisively the role of science and engineering in the qualitative transformation of productive forces in switching the economy onto the track leading to comprehensive intensification and in increasing the efficiency of productive forces of the community, and to direct the scientific and technical development towards the solution of social problems.

In the twelfth five-year plan as a whole for the national economy, it is already essential to achieve two-thirds of the growth in the productivity of socially useful labour by employing the advances in science and engineering and by the year 2000 the productivity of socially useful labour must be raised by a factor of 2.3–2.5. The task of the universal husbanding of resources has been set. Thus the increase in the requirements for fuel, energy, raw materials, and other materials should be satisfied to the extent of 75–80% as a result of economies. The energy consumption involved in the national product should be reduced by a factor not less than 1.4 and the consumption of metals by a factor of almost 2.

The XXVIIth congress of the CPSU placed before Soviet scientists the task of vigorously redirecting science towards the needs of the technical re-equipment of the national economy to bring it into closer contact with production and to employ for these purposes new improved forms of integration and interaction, to accelerate the incorporation of the results of research for practical purposes, and to improve the efficiency of academic and branch institutes.

A major role is assigned to chemical science and industry in the solution of the above problems.

One of the effective means of raising the level of the national income, of satisfying the growing needs of the population, and of accelerating scientific and technical progress in virtually all the spheres of activity of Soviet man is increased application of chemistry in the national economy.

After the May (1958) Plenum of the Central Committee of the CPSU, chemical industry developed at a high rate: the output of the principal forms of chemical production increased by a factor of 6–10 and that of individual products by a factor of 50 and more.

It is also noteworthy that the level of application of chemistry to the national economy of the USSR lags behind the corresponding level in the developed capitalist countries

and the majority of countries which are members of the Council for Mutual Economic Aid.

Whereas at the present time the USSR is ahead of the USA in the volume of steel smelted to the extent of 45%, in the production of cement by 60%, and in the production of saw timber by 10%, the output of the chemical industry in the USSR is of the order of 40% of that in the USA and the output of plastics is only 18% and of chemical fibres 30%. The output of the main types of chemical products, especially synthetic resins and plastics, chemical additives, and products of fine organic synthesis lags by a factor of 1.5–2 behind the needs of the national economy.

One should also bear in mind that the assortment of chemical additives, chemical plant protecting agents, paint and varnish materials, reagents and especially pure substances, special purpose rubbers, and products of organic synthesis is also inferior to that available abroad; it is necessary to improve the quality of the cinematographic and photographic materials, magnetic carriers, constructional polymers and general purpose polymers, dyes, chemical fibres, filaments, mineral fertilisers, etc.

Analysis has shown that the chemical conglomerate exceeds at the present time the average industrial indices, per unit industrial output, by a factor of 1.5–1.6 in terms of the capital invested and by a factor of 3 in terms of the energy consumed. The industrial output per worker is approximately 1.5 times higher than the industrial average.

Thus an increase of the technical level of the chemical industry and improvement of chemical technologies has a major influence on the improvement of the most important technical and economic indices as a whole and wide-scale application of chemical products influences the acceleration of scientific and technical progress in the national economy of the country.

In view of this the Central Committee of the CPSU and the Council of Ministers of the USSR approved in October 1985 a combined programme for the application of chemistry to the national economy of the USSR in the period up to the year 2000. The programme provides for the extensive application of new chemical materials and products, for the successful introduction of the Foodstuffs Programme of the USSR, the Energy programme of the USSR, the Combined Programme for the Development of the Manufacture of Consumer Goods and Services, for the improvement of the living conditions of the Soviet people, and for the strengthening of the economy of our country. Also it determines the fundamental indices and directions of scientific and technical progress in chemical industry.

The chemical branches of the economy should ensure an increase of the output of the chemical industry in 1986–1990 by 130–131% compared with 1985 and in the period 1991–2000 by a factor of 1.8–1.9 compared with 1990, should greatly reduce the specific consumption of the raw material and fuel and energy resources, and should greatly reduce the ecological contamination by chemical industry. The contribution of chemical products to the total industrial output, which was 6.3% in 1985, should increase to 8% in 2000.

The successful solution of the problems formulated requires the maximum effort and a high degree of responsibility, conscientiousness, and capacity for organisation from all scientists in branch institutes, academic establishments, and higher educational establishments and all research chemists, designers, technologists, and planners concerned with the creation of new chemical processes, technological devices, and industries.

The solution of the problems placed before the chemical branches of the economy requires a fundamentally new approach to the system used to incorporate the advances of science into industry, a profound reconstruction of the economic mechanism and the creation of an integral, effective, and flexible system of management which would make it possible to realise fully the possibilities of socialism.

The development of new technologies and the creation of a new generation engineering for the reconstruction and technical re-equipment of the existing and newly created industries are essential.

The network of scientific organisations must continuously improve and its organisation and structure must be built up in such a way that problems of the realisation of the research–planning–construction–mass production cycle are solved comprehensively and faster.

Scientific and technical progress in the leading branches of the national economy is impossible without the application of modern polymeric materials. Scientific research into the creation and application of new generation polymeric materials with a set of specific operational properties and into the development of new composite materials resulting from their modification is therefore being continuously expanded.

In the manufacture of polyethylene, it is suggested in the first place that the output of low-pressure polyethylene be developed since this will ensure the expansion of the assortment of different brands of polyethylene and in particular the production of linear high- and low-density polyethylene. This will create a basis for the creation and introduction of new technological processes designed to obtain polyethylene in suspension using new bifunctional catalysts and in solution in the presence of highly reactive catalysts on carriers and there is a prospect of employing ideal displacement reactors with catalysts having a selectivity approaching that of enzyme systems.

The production of high-pressure polyethylene is based on waste-free technological processes in plants with a potential unit output of 75 thousand tonnes per annum, which can be raised to 85 thousand tonnes per annum by increasing the degree of conversion. In many applications high-pressure polyethylene will be displaced by linear high- or low-density polyethylene. It is therefore likely that in the future the development of the production of high-pressure polyethylene will be on a smaller scale and it is suggested that the number of existing industries be redesigned for the production of pseudolinear polyethylene.

Together with polymers produced on a mass multitonne scale, constructional polymeric materials for engineering and technical purposes [polyamides, polyacetals, polycarbonate, polysulphone, poly(butylene terephthalate), etc.], having a set of effective strength and deformation properties in combination with good antifriction and electrically insulating properties and a reduced combustibility, will be developed extensively. These materials are irreplaceable in certain branches of engineering and industry. Their extensive application will make it possible to increase by a factor not less than 2 the productivity of labour, and to reduce by a factor of 10–20 the consumption of metals, and by a factor of 8–10 the consumption of energy.

The modification of existing polymeric materials is a promising and vigorously developing method of preparation of new polymeric materials with properties specified beforehand. Together with the development of traditional physical modification methods by creating compositions comprising mixtures of polymers with fillers, other polymers, reinforced fibres, and laminate materials, the methods of chemical modification in the stages involving the synthesis and processing of polymers have been used on an increasingly large scale. The fundamentally new technology of polymerisation filling is of special interest. In this technology

the active polymerisation centres are fixed in some way on the surface of the filler particles after which polymerisation is carried out directly on such particles, which makes it possible to coat the latter by polymer shells of different shape and composition, achieving thereby the specified microstructure of the composite material.

Vigorous research is being prosecuted on these lines at the present time in many scientific centres of the USSR. The results of some investigations have been applied on an experimental industrial scale and new materials are being widely introduced under real operating conditions.

Polymerisation-filled polyethylene, which has been called komponor, has been manufactured under experimental industrial conditions. This is a constructional material with a high impact strength, constructional strength, frost resistance, low combustibility, and other valuable properties. The resistance of komponor to wear is greater by a factor of 2 than that of world brands of high-molecular-weight polyethylene. Methods whereby komponor can be made into sheets, articles with a specific profile, and other articles, including those for constructional machine engineering, have been developed.

Scientific research designed to create and introduce new types of chemical fibres with a comprehensive set of properties, superior to those of traditional materials, has been extensively developed and is not likely to lose its contemporary usefulness. These include the most promising carbon fibres and the synthetic SVM† cord, high-strength, high-modulus, incombustible, and thermostable fibres, and electrically insulating, chemisorbing, hollow fibres with selective properties. The development of methods of preparation of high-strength and high-modulus fibres on the basis of fundamentally new procedures for the processing of traditional flexible chain polymers is particularly timely.

Specialists in the chemical industry together with scientists at the Lomonosov Moscow State University and the USSR Academy of Sciences have laid the scientific foundations for and deduced a new novel technological principle for the strengthening of fibres made of flexible-chain polymers, which makes it possible to increase by a factor of 1.5 the strength and by a factor of 1.5–2 the modulus of elasticity of synthetic composite film filaments and monofilaments.

Studies in this field are being continued and we can legitimately expect that the introduction of synthetic filaments manufactured by means of the new technology will yield an appreciable economic effect in the future. Thus the strength of cables made of monofilaments is higher by 10–20% than that of cables made of composite filaments having the same linear density. Tests on trawls made of monofilaments manufactured using the new technology demonstrated that their employment will increase the rate of trawling and result in a 10% fuel economy by reducing the hydrodynamic resistance of the trawl.

The new fibres will make it possible in the future to displace completely natural fibres from engineering and to direct the resources thus freed towards the manufacture of consumer goods.

Progress in modern science and the development of atomic and electronic technology and, during the last decade, information transmission technology using fibre optics and biotechnology impose increasingly severe requirements as regards the quality of specially pure substances and chemical and biochemical reagents for technological, analytical, and research purposes.

Much importance is attributed and will be attributed to the development of the manufacture of complexones—a promising class of compounds with a high sorption capacity. The use of complexone in small amounts makes it possible to solve important problems in the national economy with a large economic effect. Thus complexones prevent scale formation in rotation cycles in the water cooling of power generation equipment in electric power stations, in atomic ice-breakers, and in community heating systems. The use of complexones in the extraction of petroleum will make it possible to prevent almost completely salt deposition in the equipment used. Complexones remove interfering metals from liquid fuel, act as flame extinguishers and modifiers of the rate of combustion of solid fuel, and are used successfully in the electronic industry in the etching and thorough cleaning of surfaces. The expansion of the assortment of complexones and an increase of their industrial output are based on continuous waste-free automated technological processes, where the waste from other chemical industries is frequently used as the raw material.

Scientific research into scintillation, optical, acoustic, and semiconducting crystals for quantum electronics has supplied various branches of the national economy with materials whereby the monitoring of the operating conditions of instruments and devices can be simplified.

The latest non-silver materials have led to the prospect of creating optical discs with a higher recording density, a long storage life, and many other advantages compared with traditional magnetic carriers.

Biochemical preparations are already widely used in the food and medical industry, in agriculture, and other branches of the economy. It is noteworthy that the future development of scientific research and the utilisation of its achievements in molecular biology, genetics, biotechnology, and also bio-organic chemistry depends in many respects on the supply of these preparations.

The need to economise water has led to the expansion of the manufacture of polyelectrolytes, ion-exchange resins, organic amines, silicates, and phosphate compounds for the chemical treatment of water for the purpose of its purification and repeated utilisation.

Measures undertaken to economise on fuel and raw materials have led in recent years to an increased requirement for chemical agents such as corrosion inhibitors, biocides, chelates, antioxidants, special purpose surfactants, food additives, and fuel additives.

Scientific developments in the manufacture of mineral fertilisers have been directed primarily to the expansion of the assortment of advanced varieties. The nitrogen conversion processes in the soil are regulated and a more complete utilisation of nitrogen by plants is achieved by introducing nitrogen fertilisers with nitrification inhibitors. The organisation of the manufacture of a new type of liquid nitrogen fertilisers is proposed. They consist of a 32% solution of carbamide and ammonium nitrate and contain almost no free ammonia, which makes it possible to eliminate almost completely the loss of nitrogen.

The production of liquid fertilisers will reduce the cost of their manufacture by eliminating a number of stages in the technological process and also will result in a significant economy of labour concerned with the storage and movement of the material as a consequence of the complete mechanisation of unloading and loading. The possibility of transporting these fertilisers and their storage in the usual containers all the year round in the majority of climatic zones of the country must be included among their advantages.

---

†Possibly 'synthetic high modulus' (SHM) cord (Ed.of Translation).

The assortment of phosphorus fertilisers has been expanding due to the production of new highly concentrated fertilisers: ammonium polyphosphate (58% $P_2O_5$ and 12% $N_2$) and calcium polyphosphate (41% $P_2O_5$).

The difficulties in expanding the manufacture of phosphorus fertilisers are due to the inadequate supply of concentrated raw materials. The output of Kola apatite is being stabilised. The entire increase in the amount of phosphorus-containing raw materials will be achieved by employing the ores from the Karatau basin, which are difficult to enrich, and also by including in the economic turnover new deposits located in sparsely populated regions with severe climatic conditions. The ores from these deposits have a low phosphorus content. For this reason, new forms of fertilisers obtained from low-percentage phosphate ores are being developed and tested under industrial conditions. Superphosphate manufactured by means of a new technological scheme involving economies in the consumption of sulphuric acid has been assessed as highly effective. The output of thermophosphates and fused magnesium phosphates will be expanded.

Potassium chloride occupies a leading place in the assortment of potassium fertilisers. The task of expanding the manufacture of chlorine-free potassium fertilisers and in the first place potassium sulphate has now been formulated. The creation and introduction of continuous processes in the manufacture of chlorine-free forms of potassium fertilisers is planned.

From 1988, potassium fertilisers will be produced solely in the granulated and coarsely crystalline form. It will be suitable for use in dry fertiliser mixtures and their losses during transport and the contamination of the environment by dust fractions will be reduced.

Another problem, on which scientists are working, is closely related to the expansion of the assortment of fertilisers—namely the increase of the average content of nutrient substances in mineral fertilisers. Definite advances have already been achieved in this direction. In the XIth Five Year Plan the average content of nutrient substances in fertilisers rose by almost 4% and now amounts to 41.5%. In the immediate future it will be increased to 43–44%. In assessing the importance of this problem, one should bear in mind that an increase of the average content of nutrient substances in fertilisers under the conditions of their present output will reduce the annual amount transported by 5 million tonnes and result in the saving in agriculture of up to 5 million man hours in connection with the employment of fertilisers.

The scientific and technical progress in various branches of the economy is achieved by improving the technology and by employing plants with a high potential unit output. This is clearly seen in relation to the progress in the manufacture of ammonia. The first imported plant had an output capacity of 3000 tonnes of ammonia per year. Plants with a daily productivity of 1300 tonnes are now working in the industry. Altogether about 40 large-scale plants concerned with the manufacture of ammonia are now functioning, which constitutes more than half of such plants in the world.

The application of the technological process for the manufacture of ammonia in plants with a unit output capacity of 500000 tonnes per year makes it possible to reduce by 20 to 25% the energy consumption and by 30% the consumption of natural gas. The economic effect of production in large-scale plants is greater by 20–30% than in traditional plants.

The organisation of the manufacture of sulphuric acid under pressure in plants with a unit output capacity of 700000 tonnes per year will make it possible to reduce, compared with traditional technologies, the unit capital outlay by 20–25% and to increase the labour productivity by a factor of 1.5–2, while the amount of harmful waste discarded into the atmosphere will be reduced by a factor greater than 5. The consumption of metals by the plant will be at the same time lowered by 2200 tonnes.

In the XIIth Five Year Plan, it was proposed to develop a plasma-chemical process for the manufacture of nitric acid directly from air. The new method will make it possible to increase greatly the production of nitrogen fertilisers at a minimum cost.

It is planned to achieve scientific and technical progress in the potassium industry by introducing new devices for the excavation of potassium strata which will increase by a factor of 1.5 the labour productivity and will greatly reduce the amount of waste from potassium undertakings.

A fundamentally new process for the conversion of potassium ores is electrostatic separation whereby a 95% concentrate can be obtained with a significant economy in the energy expenditure (by 20–25%). The new technology enables one to eliminate liquid waste from the manufacturing process and to abolish sludge storage containers. The process is susceptible to automation, which will reduce the amount of labour required.

The structural alteration and expansion of the raw materials base for the manufacture of phosphorus fertilisers will be ensured by enriching poor phosphate ores with the aid of flotation, thermal, chemical, and thermochemical processes. In the relevant branch of the economy much attention is also devoted to the introduction into industry of new methods for the underground and open-cast extraction of phosphate ores, their hydroextraction, and their underground leaching.

Chemical plant protecting agents are important for agriculture. In the relevant fields plans have been laid to expand the range of prepared forms of pesticides to 90–95 items in 1990. Particular attention is devoted to the development and production of preparations used in intensive technologies for the growing of agricultural produce.

The improvement of the structure of pesticides and of their quality will be achieved on the basis of the leading manufacturing processes for preparations with a high selectivity of action, which decompose rapidly in the environment and which make it possible to reduce the norm for their consumption per hectare by a factor of 100 and more compared with those employed at the present time.

One of the difficulties in expanding the assortment of chemical plant protecting agents is the fact that the equipment used to manufacture individual preparations is frequently needed for a single item only and machine constructors are not objectively interested in its production. For this reason, one of the directions to be followed in the development of science and engineering in this field involves the creation of flexible technological systems, the so-called modular plants, which make it possible to manufacture different products using a common raw material or intermediates.

In industrial organic synthesis, new technological processes have been developed and introduced on the basis of modern apparatus systems ensuring the maximum output of the required products and the complex utilisation of the raw material and intermediates.

The plan for the period up to 2000 provides for a radical re-equipment of industry, the development and introduction of highly effective technological plants with a high unit output capacity, the intensification of the existing industries on the basis of new catalysts and catalytic systems, the application of fundamentally new less energy-consuming technologies, and the search for less expensive types of raw material.

In particular, it is intended to create plants for the pyrolysis of petroleum fractions by means of a waste-free technology using heterogeneous catalysts, to continue work on the creation of new types of biodegradable surfactants in order to expand their assortment and applications, to organise the manufacture of n-propyl alcohol and propionic acid in order to obtain chemical plant protecting agents and to employ them as preservatives for grain feed and green forage, to develop and create new industries manufacturing butyraldehydes in the presence of a rhodium catalyst, α-olefins, ethyl methyl ketone, isobutyl methyl ketone, isobutylmethylmethanol, etc., to complete the development of a less energy consuming process for the synthesis of butadiene by the single-stage oxidative dehydrogenation of butane in fluidised bed reactors, and the single-stage synthesis of isoprene from isobutene and formaldehyde with a unit output capacity of 120000 tonnes per year, which is characterised by an amount of waste water smaller by a factor of 6, energy requirements smaller by a factor of 2.6, and the consumption of formaldehyde per tonne of isoprene smaller by 25%.

The introduction of the above and other processes will permit the maximum satisfaction of the needs of the national economy for the products of organic synthesis, to reduce the consumption of raw materials and energy resources, and to achieve a saving amounting to more than 250 million roubles per year.

The problem of supplying the tyre and rubber industries with general purpose raw rubbers has now been virtually solved and the proportion of the required imported natural rubber is minimal. For this reason, in the XIIth and subsequent Five Year Plans, development of special purpose raw rubbers has been emphasised, namely the development of modified raw rubbers and both low-molecular-weight and other thermoelastoplastics, which sharply improve the quality of rubber mixtures and reduce the labour involved in their processing.

It is planned to organise the large-scale manufacture of ethylene-propene rubbers at the Nizhnekamskneftekhim PO and acrylate rubbers for the manufacture of technical rubber articles with high heat and oil resistances, to introduce thermoelastoplastics which it will be possible to process by casting under pressure and by extrusion, to eliminate the vulcanisation stage which will permit an appreciable increase in labour productivity, to improve the quality of the product, to reduce the norm for the consumption of the raw material and other materials, and to reduce the amount of imported materials. It is intended to introduce butadiene-styrene rubbers manufactured by solution polymerisation (DSSK). Their application in the tyre industry will increase the useful life of tyres by 5%, while in the light industry their use will increase the wear and frost resistance of shoe sole rubbers and in the manufacture of technical rubber articles it will lead to an increase of the heat resistance and useful life of conveyor belts by a factor of 2–2.5.

The tyre industry has at the present time an output capacity of 74 million tyres. For this reason the main task is to increase the quality of the tyres by increasing the output of radial metal-cord tyres and by employing new types of chemical additives which sharply improve the quality of rubber. The increase in the volume of production of radial tyres will be achieved by the reconstruction and expansion of the existing undertakings and by eliminating cross-ply tyres from industrial production.

At the same time it is planned to develop and introduce advanced equipment for the assembly and vulcanisation of tyres. Thus it is intended to improve the manufacture of light tyres by creating preparation-assembly aggregates of automated machines using manipulators. A technology and equipment have been devised for the vulcanisation of tyres using ultrahigh frequency currents.

The output and assortment of retreadable tyres have increased, including an increase in the output of retreaded radial tyres.

In the industry concerned with technical rubber articles provision is being made for the introduction of processes for the preparation of articles and materials from liquid hydrocarbon rubbers, which will increase the labour productivity by a factor of 2–3 and improve the quality of the articles. Work will be continued on the creation of technical rubber articles from powdered rubber mixtures. The application of this technology will reduce by 30% the consumption of the rubber mixture, by a factor of 1.5 the labour expended at the moulding and vulcanisation stage, and by a factor of 2 the amount of waste.

In the manufacture of flat wedge-shaped and ventilated belts, an improvement in quality together with an increase of useful life by a factor of 1.8–2 by improving the construction and technology of their manufacture and by using new materials are planned. Thus provision is made for the organisation of the manufacture of flat belts with polyamide cores and driving belts with a low transmission capacity from thermoelastoplastics.

The June (1985) conference at the Central Committee of the CPSU on the questions of acceleration of scientific and technical progress was devoted to a profound analysis of the existing situation as regards problems involved in the introduction of scientific developments into industry and the search for reserves which could alter radically the existing situation and increase the technical level of the industries and the quality of the products.

Problems concerning the improvement of the network of scientific organisations and an increase of their effectiveness were carefully examined at all levels of management of different branches of industry.

Comprehensive study led to the proposal for a series of organisational and technical measures and proposals have been developed for a radical improvement of the planning system and the stimulation of work on the creation of a new technology.

The most effective form of the association between science and industry under modern conditions is the Scientific-Industrial Association SIA (NPO in Russian).

In his report at the XXVIIth Congress of the CPSU "The Fundamental Directions of the Economic and Social Development of the USSR in 1986–1990 and in the Period up to 2000", N.I.Ryzhkov said: "It is necessary to work faster on the organisation of scientific-industrial associations. They have been called upon to be at the cutting edge of scientific and industrial progress. Solely by carrying out simultaneously different stages of the necessary work, by liquidating superfluous units, and by centralising management, the duration of the development cycle from research to incorporation into industry has been reduced in leading SIA on average by a factor of 1.3–1.6. The SIA have the necessary component elements for the application of their achievements in industry: scientific establishments, an experimental base, a planning section, and initiating and adjustment subsections—they act directly in the undertaking having been given by it the task of organising the future industrial plant; at the end of its construction they hand over to the undertaking the plant as a growing concern".

This form of organisation enhances the aspect of planning concerned with its programme and aim and shortens the time taken to execute the programmes.

In 1986–1987 the work on the creation of new SIA will be continued and after its completion more than 70% of the expenditure on science and on the employment of scientific workers will be concentrated in them.

In order to solve the strategic problem of accelerating the social and economic development of the country formulated by the April (1985) Plenum of the Central Committee of the CPSU and the conference of the Central Committee of the CPSU on the problems of the acceleration of scientific and technical progress, the concentration of forces and means on the priority fields of science and engineering in order to gain world leadership in such fields in the shortest possible time has acquired the greatest importance.

The decision of the Central Committee of the CPSU and the Council of Ministers of the USSR to create interbranch scientific-technical complexes and to undertake measures to ensure their proper activity has been approved. It is proposed to create in the principal fields of scientific and technical progress interbranch scientific-technical complexes designed to perform the entire cycle of work on the creation and introduction into industry of highly effective types of engineering, technology, and new generation materials and at the same time to reduce severalfold the duration of the work cycle from scientific research to practical introduction of its results into the national economy.

Scientific research establishments, constructional and technological organisations, and the associations and undertakings of the Ministries and Departments of the USSR and the Union Republics which possess the required scientific and technical potential in the relevant fields and which assist in the comprehensive solution of problems are involved in the work of the interbranch scientific-technical complexes.

The interbranch scientific-technical complexes are the leading organisations in the country concerned with the performance of tasks, given to them, in the field of science and engineering and the financial, labour, and material-technical resources, specified capital investments, and contract work, which are necessary for the realisation of plans, will be provided for in the first instance in the plans of the Ministries and Departments within the system of which these complexes are included.

Two interbranch scientific-technical complexes ISTC (MNTK in Russian) have been created for the priority fields of the chemical branches of the national economy: the "Catalyst" ISTC, the "Membranes" ISTC, and, in the field of biotechnology, the "Biogen" ISTC have been set up.

Catalytic processes, which significantly expand the possibilities and radically alter the structure of the consumption of raw materials and intermediate products, have acquired special importance in our time. Nowadays 80–85% of technological processes in the chemical industry are performed with the aid of catalysts and the total output obtained in catalytic processes has been estimated as approximately 1/5 of the entire world industrial output.

The development of catalysts is a key problem in the realisation of the fundamental pathways leading to technical progress in chemical industry, ensuring a transition from extensive to intensive forms of industrial production. The creation and utilisation of more active catalysts leads as a rule to the possibility of increasing the productivity of plants as a whole without their reconstruction. Thus, catalysts so active that they can yield up to 1.5–2 tonnes of the polymer per gram of the catalyst have been created for polymerisation processes leading to polyethylene. Such a small amount of catalyst can be left in the bulk of the polymer without impairing its quality and hence one can exclude from the technological scheme the washing stages which consume up to 40% of the entire capital expenditure on the industrial process. The application of highly active catalysts will make it possible to improve the technological parameters of many processes. For example, it will be possible to reduce the pressure from 200 to 30–50 atm in the manufacture of high-pressure polyethylene and from 300 to 100 atm in the manufacture of methanol. The period in which industrial catalysts are renewed is 7–10 years at the present time and it is planned to renew the most important catalysts each 4–5 years in the future.

Apart from the radical improvements to industrial technological processes, the development of the science of catalysis makes it possible to predict the creation in the immediate future and even more so after 10–15 years of tens of fundamentally new catalytic processes which will significantly expand the possibilities of chemistry and alter radically the structure of the consumption of raw materials and intermediate products. For example, the processes involving the formation of motor fuels and many chemical intermediate products from a mixture of carbon monoxide and hydrogen obtained by the conversion of natural gas and the gasification of coal are very close to practical realisation. This will mean a transition in the future from expensive petroleum to a new raw material in a major branch of the chemical industry, which will involve the manufacture of high-octane petrol, aromatic hydrocarbons, and polyolefins. Methanol is an important chemical raw material. Acetic acid is already being synthesised from it and a process involving the synthesis of formic acid, an important feed preservative, is undergoing experimental tests. One may expect the creation of new processes leading to the synthesis of acetaldehyde, ethylene glycol, ethanol, glycerol, carboxylic acid esters, and many other important chemical products. Processes involving the catalytic stereospecific synthesis of optically active aminoacids—feed additives and pharmaceutical preparations—and also bio-organic processes carried out with the aid of immobilised enzymes, for example, the preparation of sugars from waste in the processing of wood, etc., are close to being realised. Catalysts accelerating the conversion of coal into a synthetic liquid fuel, which constitutes an important contribution to the solution of the fuel and energy problems, are being created. For each chemical process, the trend towards a rational utilisation of energy is extremely specific. Thus, whereas the activation energies for thermal processes are 120–160 and sometimes up to 200 kJ $mol^{-1}$, in catalytic processes the energy falls to 20–30 and sometimes to 7–8 kJ $mole^{-1}$, while in processes involving bio-organic enzyme catalysts it falls even to 1 kJ $mol^{-1}$ and below. Thus the development of an active catalytic system for the synthesis of aliphatic amines made it possible to achieve a saving in the energy resources by 15%, while the intensification of the synthesis of polyethylenepolyamines in the presence of new catalytic systems resulted in a 60% saving.

The possibilities inherent in the introduction of membranes and the membrane technology into different branches of the national economy are very great. For example, the introduction of the membrane technology into thermal power engineering reduces the amount of waste water in the thermal power plant by a factor of 4 and reduces the consumption of alkali and acid by 50%.

The introduction of the resources-conserving membrane technology into the food industry may also serve as an important component for the successful realisation of the Food Programme. The membrane purification, clarification, and stabilisation methods in the production of sugar, juices, and alcohol-free drinks and also in the extraction of food dyes, plant proteins, and other useful substances from the waste generated in the processing of food products make it

possible to reduce greatly the energy expenditure in the preparation of food products, to improve their quality, to increase the storage time and food value of the products by means of cold sterilisation, to extract additional amounts of food raw materials which were hitherto irretrievably lost, and to reduce the contamination of the environment by the waste from food industries. The application of membrane processes in the combined processing of milk and secondary milk products will greatly reduce the energy consumption in the relevant industries, will increase the output of the finished products, will increase the assortment and quality of such products, and will greatly reduce the cost of transport in the delivery of the milk raw material. The introduction of methods for the storage of fruit, vegetables, and grain in a modified gaseous medium using membranes increases the storage time and makes it possible to supply consumers with fresh produce all the year round with a significant reduction of losses during the storage process.

The role of membranes and membrane technology in the protection of the environment from contamination is incontrovertible. Membrane devices and apparatus are used for the analytical monitoring of the environment (sewage and gaseous waste). Furthermore, the use of membrane technology leads to the possibility of creating effective desalination processes for salt and brackish waters and also the creation of closed water cycles in industrial manufacturing processes.

One of the most important ways of increasing the technical level of the chemical sub-branches in industry and of carrying out the tasks involving their intensive development consists in the comprehensive expansion of the cooperation with the Academy of Sciences of the USSR, the Academicians of the Academy of Sciences of the Union Republics, and higher educational establishments in the USSR.

It is generally known that, whatever the advances in the relevant fields of science, it is impossible to raise the technical and economic level in industry to leading positions without an adequate and profound fundamental effort and without cooperation with academic organisations and higher educational establishments. For this reason, starting from the Tenth Five Year Plan, nine regional centres, covering the entire Soviet Union and coordinating joint research and developments, have been active in chemical industry. This is consistent with the task formulated in the report by M.S.Gorbachev at the June conference in the Central Committee of the CPSU, who noted that: "... we should look upon scientific tasks through the prism of the requirements of the present time—requirements for the decisive redirection of science towards the needs of the consumer industry and of the industry towards science. All the units of the chain connecting science, engineering, and industry must be analysed and strengthened from these standpoints".

During the Eleventh Five Year Plan 80 higher education establishments and 95 academic institutes participated in the joint developments concerned with the coordination of plans with branch institutes. The effectiveness of such cooperation is evident. Thus the theoretical principles and technology of the industrial manufacture of film filaments for hay binding twine were developed and the production was organised jointly with the Lomonosov Moscow State University. This made it possible to satisfy fully the needs of agriculture and to achieve a saving amounting to 73 million roubles. A theoretical and practical approach to the welding of polymeric materials, especially polymer tubes, was developed for the first time in world practice jointly with the Paton Institute of Electric Welding of the Ukrainian Academy of Sciences. This problem has now been solved. The economy now receives plants for the welding of polyethylene tubes having diameters ranging from 11 to 1200 mm.

Many such examples can be quoted.

At the same time the existing level of cooperation does not satisfy all the increasing modern needs by academic institutes and higher education establishments. The absence of an adequate experimental base retards the application of the results of completed research in industry. Also the problem of the economic stimulation of the participation of scientists at academic institutes and higher education establishments in the incorporation of scientific developments in industry has not been solved.

In laying the plans for the XIIth Five Year Plan, a fundamentally important resolution was adopted, namely the resolution to achieve a transition to improved forms of planning of joint developments—a programme for the interdepartmental scientific and technical cooperation of the Ministry of Chemical Industry, the Academy of Sciences of the USSR, the Academies of Sciences of the Union Republics and the higher education establishments controlled by ministries.

The principal methods of cooperation for 1986–1990 and for the period up to the year 2000 have been approved. The most important of these is the creation of a new generation of technological processes based on the fundamental work already completed. A comprehensive Programme for scientific and technical progress in the member countries of the Council for Mutual Economic Aid CMEA (Russian abbreviation SEV) up to the year 2000 was adopted at the 41st session of the CMEA. The meeting of the General Secretary of the Central Committee of the CPSU Comrade M.S.Gorbachev with the heads of delegations of the socialist countries and the Secretaries of the Central Committees of the fraternal parties, participating in the session of the CMEA, was especially important. The fundamental approach to the radical questions of the acceleration of scientific and technical progress and internal economic and international politics described at the meeting received full support and understanding.

The consistent realisation of the Comprehensive Programme will accelerate the social and economic development of our country and fraternal states on the basis of the latest scientific and technical advances, will ensure a radical improvement in labour productivity, and will strengthen technical and economic independence. A more complete utilisation of the possibilities of the economic interaction with fraternal socialist countries in ways including the application of progressive forms—wide-scale scientific and technical and industrial cooperation, direct links, and the creation of joint associations and undertakings—is linked to the Programme's realisation.

Major tasks within the framework of the Comprehensive Programme are also to be performed by chemists. Thus in the field of "Biotechnology" the USSR, Czechoslovakia, Hungary, and the German Democratic Republic will create a joint assortment of hundreds of named reagents which will improve the scientific level and shorten the time taken for research in the field of genetic engineering, biology, and biochemistry. New generations of medicinal and enzyme preparations will be introduced into the health service.

New biological plant-protecting agents and veterinary preparations will be introduced for the needs of plant cultivation and animal husbandry.

An important role is attributed to an increase of output in the manufacture of protein feeds.

In the field "Electronisation of the National Economy", technologies have been developed for the manufacture of tens of designated new specially pure substances for microelectronics, including the equipment for their industrial manufacture, analytical monitoring methods, and special

packing. This will improve the speed and reliability of the operation of electronic circuits in electronic computers and will increase the sensitivity of various instruments.

Technological plants based on the block-modular principle will be developed and created jointly with Czechoslovakia, which will permit the manufacture of a large assortment of low-tonnage chemical products with the aid of rapidly readjustable schemes.

Tasks directed to the creation of new polymeric materials for radioelectronics, electrical engineering, machine construction and other leading fields are planned within the framework of the priority field "New Materials and the Technology of Their Manufacture and Treatment". The application of these materials in place of traditional ones will ensure technical progress in the branches of economy consuming them and will increase the reliability and useful life of the products in the course of their employment and will reduce their cost.

Provision is also made for the development and introduction of new and improved technological processes for the manufacture of polymeric materials and articles made from them with a wide-scale employment of computer and micro-processor technology and highly selective catalytic systems stimulating energetic effects.

The task of accelerating scientific and technical progress imposes new, more stringent, requirements on cadres and the style and method of their work. There is a need to achieve throughout a freedom from conservatism, paper work, and a formal attitude to work. The complex and large-scale tasks formulated by the Party require a creative initiative and diligent labour by each worker in chemical industry. The successful performance of the planned tasks and the making of scientific and technical progress in the major fields of development of the given branch of the national economy are the tasks faced nowadays by workers in Soviet industry.

# Problems in Modern Chemistry

V.A.Legasov and A.L.Buchachenko

This review deals with the fundamental problems and the main directions of modern chemistry whose current developments offer both immediate and prospective practical advantages while stimulating continuing progress in chemistry and in related areas of science and technology.

## I. INTRODUCTION

In sciences (as in any other creative activity) the creative process is less important than its outcome, and seeking is less important than finding. However, finding without seeking is an exceedingly rare occurrence, and therefore most of the effort, expenditure, and resources in science are devoted to seeking. Modern science is an expensive undertaking, and society cannot allow its scientists to engage in aimless searches. Of course, one can stumble on something interesting and valuable even on the path of aimless research, but no serious research worker will wish his success to be determined by the laws of chance. Every investigation, every scientific endeavour should have a declared aim, and should be able to predict the practical results and potential applications of the work and to evaluate its contribution to related fields of science.

Modern chemistry is a many-sided undertaking, involving extensive enquiries in many different directions. Many of its branches have developed into sciences in their own right (inorganic chemistry, colloid chemistry, radiochemistry, organic chemistry, analytical chemistry, physical chemistry, crystal chemistry, chemical physics, electrochemistry, geochemistry, biochemistry, polymer chemistry, etc.). Each of these sciences has its own objectives and well defined boundaries, its own problems, its experts, and its acknowledged leaders. However, in modern chemistry we find many fundamental problems which are common to a variety of areas of enquiry: these attract the combined attention of all branches of chemistry and stimulate contributions from all chemical sciences, whatever their specific objectives and problems. It is important to recognise these "cosmopolitan" problems so as to formulate clearly the most important directions in which further advances can be expected and to achieve greater coherence, relevance, and therefore also effectiveness of the work.

The aim of this review is to define the most important problems in modern chemistry, to present a predictive analysis of their recent developments, and to identify the most timely and relevant achievements.

## II. CHEMICAL STRUCTURE AND FUNCTION

The number of known chemical compounds (approximately eight million at present) is still growing rapidly. The atomic-molecular architecture and electronic structure of these compounds (whether extracted from naturally occurring materials or synthesised) vary between wide limits. Their physical and chemical properties, and therefore also their functions, show similarly extensive variations. In order to identify a substance having prescribed properties and applications (i.e. a prescribed function) we usually need to examine between 3 and 10 thousand compounds: the ambitious task of converting a prepared compound into a substance aimed specifically at serving mankind and at advancing civilisation has a disappointingly low effectiveness. Clearly, establishing a relation between the electronic structure of a compound or material and its functional behaviour is a problem of fundamental importance, which must be solved if we wish to predict the function and usefulness of a substance. In practice the inverse problem is even more important: how should a substance be constructed, what should be its molecular architecture and electronic structure, in order to achieve a prescribed set of properties and a required function?

Modern chemistry has had some undeniable (though modest) successes, based on a rich and varied stock of experimental results, in the solution of both the direct and the inverse problem. We can now confidently predict the dependence of the polymerisation behaviour of monomers on their structure, the main types of chemical reaction and the reactivity of various functional groups, the changes in the electrophysical properties of semiconductors caused by changes in their structure, etc.

A clear example of a successful search for the relationship between structure and function is provided by the synthesis of organic and metal-organic electrical conductors: molecular metals (see Chapter V). Thus the compound $Hg_{3-\delta}AsF_6$, synthesised in 1971, has a high, typically metallic conductivity, and becomes a superconductor at low temperatures. Chemical analysis gives this compound the composition $Hg_3AsF_6$, but

the geometric dissimilarity between the position of the constituent atoms in the crystal lattice produces vacancies of $AsF_6$ groups, so that the composition of the unit cell becomes $Hg_{3-\delta}AsF_6$, where $\delta = 0.18$. The unit cell of a crystal of this compound (Fig.1) shows an unusual molecular structure, consisting of two components: a framework of $AsF_6^-$ anionic octahedra and cationic chains of mercury atoms, accommodated within the channels of the anionic framework along the principal axes (*a* and *b*) of the crystal.

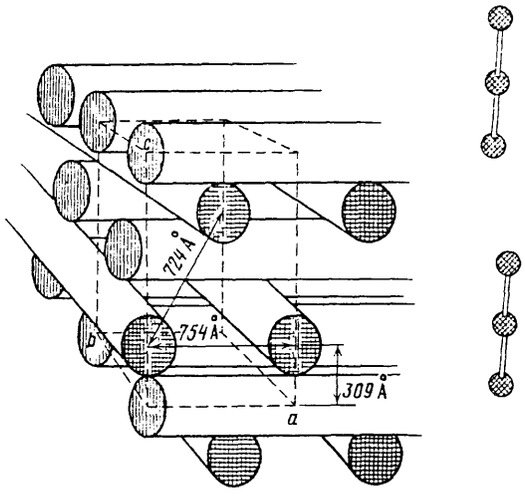

Figure 1. Molecular-structural organisation of $Hg_{3-\delta}AsF_6$; the cationic chains of atoms are shown as cylinders, between which are located the anionic $AsF_6$ octahedra.

This structure imparts special electrical conduction features to the material. The chains of mercury atoms behave as a one-dimensional ordered metal with a high conductivity. This feature results in an electrical conductivity in the crystal along the chains (i.e. in the *a* and *b* directions), coupled with a low conductivity in the perpendicular direction (i.e. along the *c* axis). Lowering the temperature activates the interaction between the conducting chains (first the parallel, and then the perpendicular), leading to superconductivity at temperatures below 4.1 K.

The most important feature of this crystal structure are the linear chains of atoms with delocalised (generalised) electrons, which are responsible for the new function of the material: its metallic conduction and superconductivity. The concept of this structural feature is exploited in all attempts to synthesise molecular metals: organic substances in which $\pi$-electron molecules are packed in the crystal as one-dimensional chains with overlapping delocalised $\pi$ electrons. The motion of the electrons along the chains is responsible for electrical conduction in these compounds, and occasionally for superconductivity at low temperatures (see Chapter V). The structure of one typical organic superconductor, [*bis*(ethylenedithiolo) tetrathiofulvalene]$_2^+I_3^-$, is shown in Fig.2.

Establishing the correlations in the structure–property–function chain is the scientific aim of chemical materials science, and is directly relevant to the development of any new material (polymers, phosphors, materials for semiconductor and laser technology, chemical reagents and catalysts etc.) It is especially important in biochemistry and medicine, where the functional properties of medicinal preparations, hormones, and other physiologically active compounds determine their functional effects in living organisms. This is a very large field, which includes major topics such as the chemistry of memory and the chemistry of thought (a relatively obscure subject, with fundamental practical and intellectual connotations).

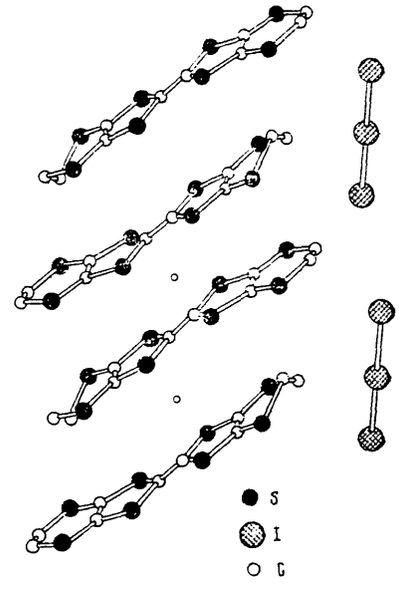

**Figure 2.** Projection of the crystal structure of the organic superconductor [*bis*(ethylenedithiolo)tetrathiofulvalene]$_2^+I_3^-$.

We can solve the direct problem, i.e. establish the structure–function relationship, at two distinct levels: the empirical level, confined to a simple formulation of the relationship between structure and function, and the non-empirical level, involving the study and the identification of the atomic-molecular mechanism by which a given structure can fulfil its function. However, modern chemistry can often formulate and solve the inverse problem: to create a structure having a prescribed function. For example, substances having oxidising properties stronger than those of normal oxidisers ($F_2$, $PtF_6$, $RhF_6$, $IF_5$, etc.) are needed in chemical synthesis. Compounds of the "inert" elements (xenon and krypton) were obtained by using the new oxidisers. The strongest oxidisers ($ICl_5$, $AuF_6$) should activate other elements of Group VIII, and induce previously unreported chemical reactions. This hope is not unrealistic: not many years ago the preparation of chemical compounds of xenon would have seemed out of the question, and yet these compounds are now a conventional part of the chemist's working arsenal. Stable organic paramagnetic materials are now equally familiar: the nitroxyl radicals, which offer a range of functions and are therefore

widely used in physics, chemistry, molecular biology, medicine, and technology.

A similar problem can be formulated in respect of high-energy substances, involving the search for chemical structures with a high energy content. One path to this goal is the synthesis of compounds with atoms in unusual valency states or with an unusual hybridisation of chemical bonds (for example, organic compounds containing a non-tetrahedral saturated carbon atom). This type of problem can (and should) be formulated in all branches of chemistry.

Quantum theory has a large part to play in solving these problems, and its status and role in modern chemistry are beginning to change very markedly. Whereas the task of quantum chemistry was previously to seek (often, successfully) an explanation of the physical origin of various chemical phenomena and structural-chemical effects, its principal aim is now the theoretical prediction of chemical structures, of their existence regions and stability conditions, and of whether their synthesis can be realistically attempted. In this sense quantum chemistry has now moved into the front rank of chemical science, where it directs the experimenters towards molecules and substances with realistic thermodynamic and energy parameters. This new style of quantum chemistry is already apparent from the effort now devoted by quantum chemists to calculations of "exotic" molecules (for example, molecules with a non-tetrahedral carbon atom, hypermetallic molecules, hypothetical "spherical" molecules containing 120 or 60 carbon atoms in $sp^2$ hybridisation, with a high electron density inside the sphere. The molecule with 60 atoms has been called footballene because of its outward similarity to the ball used in that game).

Both the chemical structures and the functions of substances are extremely varied, and the relationships between them are even more varied; the development of adequate systematics is therefore an urgent problem at present. Existing classifications distinguish types of substances by structure-chemical criteria (aldehydes, sulphides, ketones, fluorides, olefins, chalcogenides, etc.) rather than by functions. Modern chemistry requires, in addition, a systematisation based on the structure–property–function principle. Computer-accessible chemical data-bases should play an important part in its development (banks of structural-chemical and functional data, computer systems for identifying and distinguishing chemical compounds according to their functions, etc.). The development of these new methods of classification and the establishment of relationships in structure–property–function series should offer an effective and clear strategy of scientific enquiry in the field of chemistry.

## III. CONTROL OF CHEMICAL PROCESSES

The complexity of chemical processes can be both troublesome and advantageous to the chemist: it allows the adoption of a flexible hierarchy of methods of process control at various levels, from the atomic–molecular level to the level of supermolecular organisation and organisation in terms of mass and energy transfer, aimed at establishing a state of concentration and energy "comfort" for the chemical process.

A chemical reaction is a physical process resulting in the regrouping of atoms and the rearrangement of electronic shells, leading to the conversion of the initial species (reagents) into the final products. The process is controlled by two fundamental characteristics: energy and angular momentum (the moment of the quantity of motion). The importance of the former has long been recognised in chemical science, whereas the role of angular momentum in chemical reactions was recognised only recently.

The great majority of chemical reactions require additional energy to be supplied to the reacting species in order to overcome an energy barrier. The height of this barrier (or, in other words, the amount of energy to be supplied to a particle to allow it to react) is a problem for which a general solution has not yet been found. Theoretical calculations of barriers and of potential energy surfaces for chemical reactions by the most recent techniques of quantum chemistry (non-empirical or semi-empirical) have failed to solve the problem so far: they are cumbersome, their scope is limited, and they are often unreliable. Many empirical relationships for calculating energy barriers and reaction rates (Polanyi's rule, Hammett's equation, Tafel's law, the Woodward–Hoffman rules, the Brønsted–Winstein relation, etc.) are also of limited application as well as being only rough approximations. On the whole, the problem of chemical reactivity—i.e. of the relationship between the electronic and nuclear structure of chemical species and the rate (or barrier height) of their reactions is a classical on-going problem, still far from being solved. This is mainly because the range of chemical species (atoms, molecules, ions, radicals) is enormous, offering a wide range of Coulombic or exchange interaction potentials and of chemical reaction paths. The multitude of types of electron shell and of paths available for their transformation prevents the development of a single, general quantitative theory of chemical reactivity, though in terms of theoretical physics the most elementary chemical interactions are relatively simple and consist exclusively of electromagnetic interactions (nucleus–nucleus, electron–electron, and electron–nucleus).

Controlling a chemical reaction, i.e. changing its rate or its direction, implies firstly changing the height of the energy barrier and secondly adding energy to the internal degrees of freedom in a form usable by the chemical species in overcoming the barrier.

The first control principle is chemical: it relies on modifying the electron shells of the reacting particles by solvation or complex formation. The study of solvation with the aim of discovering effective means of controlling the reactivity and the direction of chemical reactions is one of the main topics of modern chemistry. The main contribution to solvation effects usually comes from complex formation. Modern physical methods have led to important advances in our understanding of complex formation: direct evidence of the delocalisation of the electron shells of the partners in the complex has been obtained, the electronic orbitals involved in the "joint" between the partners have been identified (in some cases), the main types of complex have been recognised and the diagnostics and criteria of complex formation have been formulated, the structural, physical, and dynamic properties of many complexes have been determined, and it has been established that even in the gas phase, chemical reaction is often preceded by complex formation.

Complex formation should affect the reactivity of any chemical species, since it influences the distribution of electric charges, the energy of the molecular orbitals, and the geometric screening (and therefore also the energy barrier) which the reaction must overcome. A much more difficult problem is to establish the extent and the direction of the resulting change in chemical reactivity: is the chemical activity of the reacting particles enhanced or suppressed by the complex formation? The question is not easily answered, and the answer cannot be general or unique. It depends on two factors of fundamental importance: 1) is the complex located on the correct reaction coordinate, and 2) how often do the reacting particles pass over the energy barrier in the direction of the reaction coordinate, and is the transition adiabatic or non-adiabatic. Many examples of activation and of passivation of chemical species by complex formation have been

reported; in some cases partial rules (applicable only to some types of reaction) have been established, but there are as yet no general principles allowing the reliable prediction of complex formation and reactivity effects.

These comments are equally applicable to solvation effects. The solvation concept is a more general one, and includes electrostatic effects as well as complex formation effects. The contribution from electrostatic interactions to chemical reactivity is not yet fully understood. There is evidence that the contribution has often been overstated, since chemical reactions between particles (even charged) are mainly short-range effects, involving exchange interactions rather than long-range Coulombic forces.

Being chemical methods of controlling the chemical reactivity of particles, complex formation and solvation often affect the mechanism of chemical reactions by varying the composition of the reacting species (free ions or ion pairs, radicals and their complexes, molecules and molecular associations, isolated atoms and clusters, etc.). The term reaction mechanism denotes the succession of elementary chemical processes which convert the initial substances into the final products. The mechanism is usually identified from the composition of the final and of the intermediate products, from the kinetics of disappearance of the reacting particles and of the formation of intermediates and products, from the composition of the intermediate active species (detected by physical methods), etc. We now have fairly reliable methods, indications, and criteria for establishing reaction mechanisms, but in general the formulation of a reaction mechanism in full detail remains a difficult problem which is only rarely (and not always unambiguously) solved.

Finding the mechanism is not an end in itself: it is a necessary stage in the determination of the rate-limiting step and in identifying the principal and the secondary reaction paths. The final aim is to find an effective method of controlling the chemical process and of increasing its yield and selectivity. Thus the identification of the mechanism is an important step forward towards the creation of highly selective, fast, and low-energy chemical technologies.

The discussion so far has been limited to chemical methods of controlling reactions; physical methods of stimulating and controlling chemical reactions involve the transfer of energy into the internal degrees of freedom of the reactants in an amount sufficient to overcome the energy barrier. Exposure to light, radiolysis, and plasmas are all physical methods of stimulating reactions by injecting energy into the electron shell. In most cases the electronically excited species thus formed have a high reactivity and react almost with a zero activation energy. However, this method of stimulating reactions has the following disadvantages: firstly, electronically excited states can react differently from the ground state, and therefore physical stimulation is often accompanied by a change of mechanism and a change in the composition of the final products; secondly, in the vast majority of cases the energy transfer process has a low efficiency, and only a small fraction of the energy supplied to the system is used in the chemical transformation.

Infrared lasers can pump energy into vibrational degrees of freedom, and they are often used to stimulate chemical reactions. This work has attracted a great deal of interest in recent years, and it has been shown that vibrational excitation is effective in overcoming the endothermic part of an energy barrier while having almost no effect on barrier crossing in thermally neutral or exothermic reactions. Thus the laser dissociation of molecules and the associated methods of isotope separation are now well established. These are endothermic processes, involving the energy pumping of vibrational levels. In neutral or exothermic reactions the utilisation coefficient of the vibrational energy to give chemical reaction is not more than 1–2%.

Mechanical activation can be an important source of stimulation in chemical reactions (for example, process in shock waves, at high pressures, under conditions of shear deformation, etc., see section VI). We know that mechanical deformation produces unusual chemical reactions, accompanied by luminescence, electron emission, and electric discharges. Similar effects are observed in phase transitions and structural rearrangements in crystalline solids. An unusual phenomenon was discovered recently: low-temperature "explosions", in which the elastic energy stored in glasses at low temperatures induces fast chemical reactions at temperatures below the boiling point of liquid helium. The paths and the physical principles by which the mechanical energy is converted into chemical energy are not yet understood, and their identification is an important problem whose solution may stimulate the development of new technologies and of a new type of chemical energetics (section VII).

As well as being energy-forbidden, chemical reactions can be forbidden in respect of the angular momenta of the reacting particles. This quantity must be conserved, and reactions involving a change in angular momentum are forbidden: only reactions not accompanied by a change in angular momentum are allowed.

Many chemical reactions require a change in orbital angular momentum; however, the orbital momentum rule is not rigid, since this momentum is strongly coupled to the motion of the molecule as a whole, and is transferred to external degrees of freedom. The rule with respect to spin angular momentum is much more strict: this appears in reactions involving free radicals, in the reactions of triplet molecules and ions, and in many other reactions involving paramagnetic species. The recently discovered magnetic effects in chemical reactions are the physical result of the spin angular momentum rule. They include spin polarisation of electrons and nuclei, the effect of external magnetic fields on the reaction, the magnetic isotope effect, and radio-frequency emission in chemical reactions. These newly discovered properties of chemical reactions involving radicals open new approaches to the control of reactions by using d.c. magnetic fields, or radio-frequency and ultra-high frequency electromagnetic fields, to influence electronic and nuclear spins and to remove the spin angular momentum rule. This new branch of chemistry (we could call it "spin" chemistry) is developing rapidly, and recent progress in this area has resulted in new methods of studying chemical reaction mechanisms and in the formulation of chemical radiophysics and of new principles for separating nuclear isotopes and isomers.

## IV. MOLECULAR AND SUPERMOLECULAR ORGANISATION OF CHEMICAL PROCESSES (MOLECULAR DESIGN)

The vast majority of chemical reactions used in industry and in science belong to the "non-organised" type, i.e. the participating species react through collisions which are random in time, in location, and in the mutual orientation of the particles. In other words, there is no molecular or supermolecular organisation of the chemical interaction in space and time.

On the other hand in molecular biology an entirely different situation exists: molecular and supermolecular organisation is a characteristic property of biochemical processes (for example, the synthesis of proteins, the transport of ions and other substances through membranes, electron transport along a chain of cytochromes and the associated phosphorylation, photosynthesis, enzyme catalysis, etc.). Enzymes can bind and orient the reagents, and thus organise the elementary

chemical acts and produce a high level of stereospecificity, reagent selectivity, and selectivity of reaction type, of localisation of the reaction, of temperature and pH, etc. In biochemical processes not only the elementary acts but also whole cascades of reactions are organised: for example, in photoreception processes each light quantum absorbed by the retina in the eye triggers a large cascade of chemical reactions which produce (in quantum yields up to $10^4$) cyclic guanosine monophosphate, producing an electric potential in the membrane which later appears in the brain as the result of the light perception. Because of their high level of organisation biochemical reactions achieve a selectivity, functionality, and operating speed which cannot be matched by ordinary chemical reactions.

Examples of supermolecular organisation of processes in cheimstry are still few. An unusual example is the interaction of methyl radicals with palmitic acid ($C_{16}$). In ordinary, "non-organised" chemical processes the most reactive site in the molecule is the $\alpha$ position, adjacent to the carboxylic acid group. On the other hand if the molecules of the acid are organised as a two-dimensional layer on a water surface the attachment of methyl radicals (formed by an electrical discharge or by irradiation of methane in the gas phase) takes place at the "tail" of the molecule and is accompanied by an increase in the length of the molecular chain (forming the $C_{17}$, $C_{18}$, etc. acids). This is a striking example of the molecular organisation of an ensemble on the reactivity (and even the direction) of a chemical reaction. This reaction is believed to have played an important role in the chemical evolution of life on Earth, since it can account for the synthesis of the initial substances used in the construction of biological membranes.

The simplest method of supermolecular organisation in chemical reactions relies on the use of molecular beams to deposit the reacting layers according to a given programme (layer thickness, periodicity, etc.) in order to prepare chemical compounds and compositions. In particular, this principle can be used to produce semiconductor structures and solid-state superstructures—crystals grown by depositing semiconductor layers a few atoms thick with a strictly periodic alternation of *n*- and *p*-type doping. These new materials offer a unique set of electrophysical properties and now have an important place in semiconductor technology and solid-state physics. Their preparation by the ordinary methods of "non-organised" chemistry would be impossible.

The structural elements which determine the molecular and supermolecular organisation of chemical processes could be micelles, vesicles, adsorbed monolayers, molecular membranes, clathrates, liquid crystals, clusters, interfacial boundaries, etc. There are known examples of the use of these structures in chemistry (interfacial catalysis, catalyst immobilisation, etc.). In these systems space–time organisation and periodic oscillations in properties are possible. For example, in the water–oil system in the presence of surface-active substances we observe oscillations in pH and in the electrochemical potential similar to those which occur in nerve cells, muscular tissues, and in mitochondria. Other examples of space–time organisation in chemical processes is the periodic precipitation of a solid product during the mixing of two substances (Liesegang rings), the Belousov–Zhabotinskii periodic reaction and its many analogues, the self-oscillations in the rate of many heterogeneous catalytic reactions, etc.

Many important processes cannot be carried out in the framework of conventional ("non-organised") chemistry. Thus, the photosensitised dissociation of water into hydrogen and oxygen (abiogenic photosynthesis, see section VII) requires three elementary stages: photo-generated charge separation, i.e. the formation of spatially isolated electrons and holes, the interaction of the electron with a water molecule (and reduction of the water to hydrogen), and the interaction of the hole with a water molecule (and oxidation of the water to molecular oxygen). The process must be organised so as to prevent the recombination (annihilation) of the electron and the hole, and therefore the reduction and the oxidation of the water must take place on different catalysts.

An example (perhaps not the best) of the molecular organisation of this process is shown in Fig.3. The catalysts are deposited on opposite sides of colloidal particles of the semiconductor $TiO_2$ (metallic platinum and ruthenium oxide). The photo-excitation of a sensitiser S results in its ionisation, and an electron is transferred to the $TiO_2$ either directly or through the intermediate carrier R. The electron then migrates into the conduction band of the $TiO_2$, it reaches the Pt, and it reduces a water molecule on the platinum. The hole migrates to the $RuO_2$ and oxidises the water to oxygen on this catalyst.

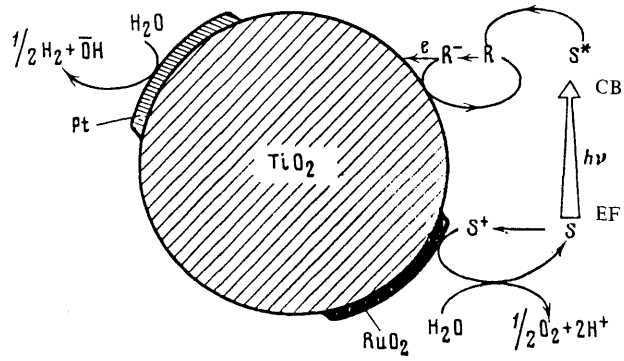

**Figure 3.** Organisation of abiogenic photosynthesis: EF is the Fermi level, CB is the conduction band.

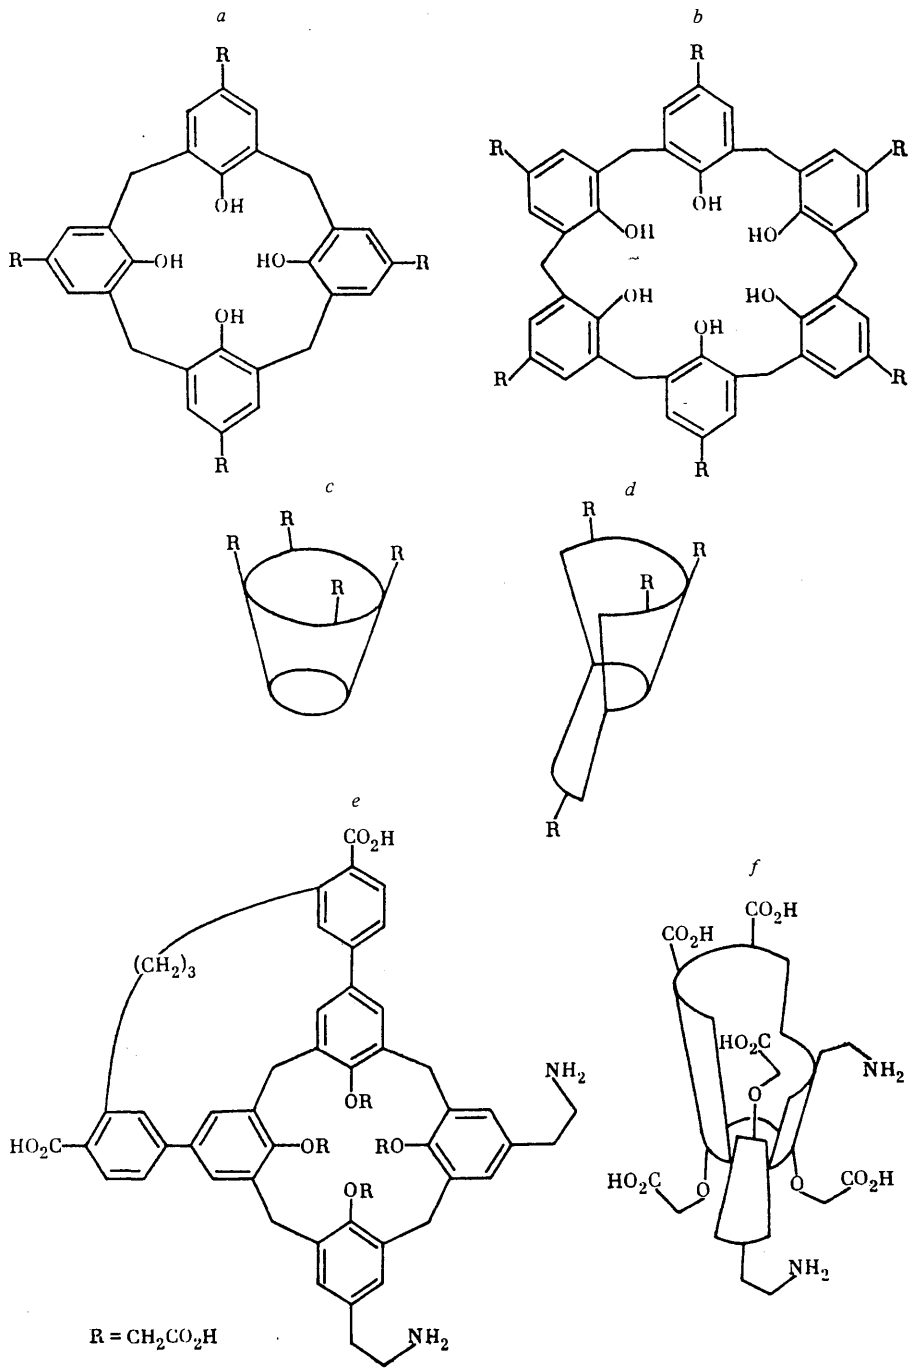
This very simple version of an organised chemical system actually works, but its efficiency is low because of the many possible side-reactions. Clearly, a more perfect organisation is needed: the basic approach to the solution of the abiogenic photosynthesis problem is to seek a suitable organisation.

The development of organisational principles and the creation of organised chemical systems simulating biochemical systems (biomimetic systems) are among the most general and promising lines of attack used in modern chemistry, and the first tentative steps have already been taken (with some success) in this direction. A good example of a biomimetic system is provided by the calyxarenes (cyclic products of the alkaline condensation of phenols with formaldehyde, Fig.4). These molecules have a very unusual structure: the benzene rings with their substituents are arranged to form an enclosed space, so that the whole molecule is reminiscent of a vase (and is named from the Greek *calyx*, a vase). This "molecular vase" can have closed walls [in the form of a truncated cone, with a base consisting of the hydroxy groups (Fig.4*c*)], or the walls may be partly open if some of the benzene rings are folded outwards, forming windows in the wall of the vase (Fig.4*d*).

Because of their special structural organisation the calyxarenes can transfer metal ions through hydrophobic membranes, and they are superior even to crown ethers as carriers. Adding various functional groups to the calyxarene molecules produces catalytic properties simulating those of enzymes.

For example, the calyxarene whose structure is shown in Fig. 4*e* is a model of the enzyme aldolase and has the characteristic functions of this enzyme. We know that similar biomimetic properties are found also in some other molecules (for example, the cyclodextrins, which form inclusion compounds in which the chemical transformations of the substrate take place).

The most obvious supermolecular organisation effects are found in chemical reactions taking place in crystals. In the case of molecules organised as a crystal the intrinsic reactivity



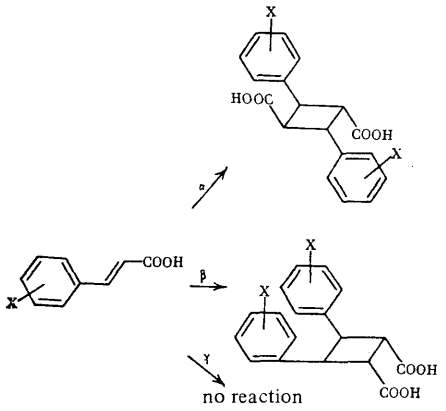


Figure 4. Structural formulae of some calyxarenes and diagrams of their three-dimensional organisation: calyxarene with four (*a*) and six (*b*) benzene rings; the wall of the cavity in calyxarene *a* can be closed (*c*) or partly opened (*d*) through the rotation of one of the four benzene rings; simulation of the function of the enzyme aldolase (*e*) and diagrams of its three-dimensional organisation (*f*).

(determined by the structure of the electron shells) is less important to the course of the reaction than the method by which the molecules are packed and stacked in the crystal. The direction of the reaction is determined by the intermolecular distances in the crystal, by the mutual orientation of the molecules, and by the three-dimensional symmetry of this crystal.

The features of solid-state reactions are clearly seen in the photodimerisation of *o*-ethoxy-*trans*-cinnamic acid:

The α form of the acid crystallises from acetone; it has a centre of symmetry, and neighbouring molecules are packed in a head-to-tail configuration. The product of the photodimerisation is a centrosymmetric molecules which retains the elements of symmetry of the initial pair of monomer molecules. The β form crystallises from benzene; the crystal has a plane of symmetry and the molecules are packed in a head-to-head configuration. The photo-dimerisation product retains the symmetry elements of the initial pair. The distances between double bonds are 3.6–4.1 Å in the α form and 3.9–4.1 Å in the β form. The stacking of the molecules is shown in Fig. 5 for one of the crystal projections; here R denotes the $C_2H_5OPh$ group, and the black rectangle the $CO_2H$ group. The γ form crystallises from aqueous ethanol solution; in this form the stacking of the molecule is unfavourable to the reaction (see Fig. 5), the distance between double bonds is 4.2–5.1 Å, and no reaction takes place.

The polymerisation of substituted diacetylenes (Fig. 6) to give conjugated polymers (organic semiconductors and organic metals, see section V) is determined by the same topological relationships between the structure of the crystals of the monomeric molecule and that of the crystals of the product. The monomeric molecules are organised in the crystal in such a way that only a slight rearrangement of the crystal structure is needed for the polymerisation. The dimer $(NS)_2$ is polymerised in the crystal in a similar way, giving the superconducting polymer $(SN)_x$ (see section V).

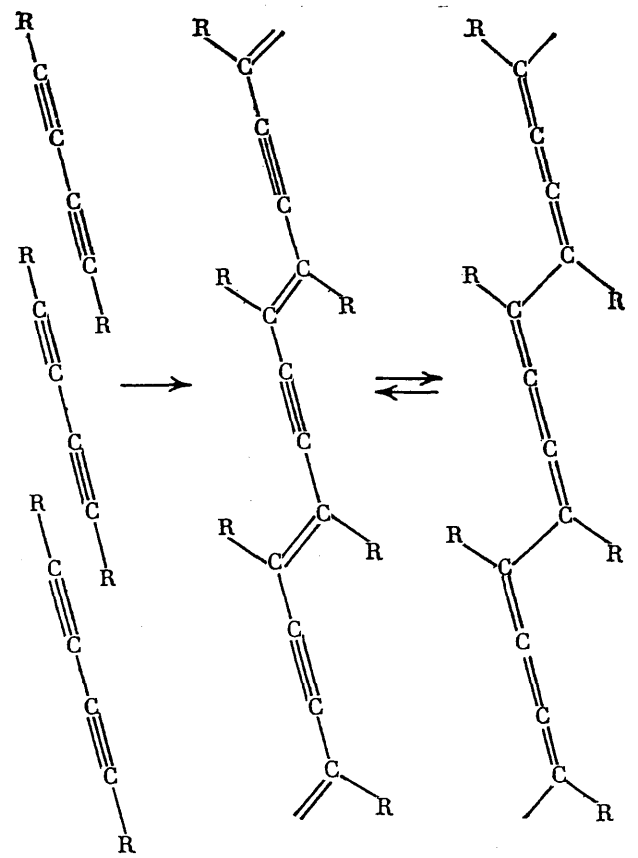

**Figure 6.** Arrangement of the molecules of diacetylene in the crystal and conversion into a conjugated macromolecule.

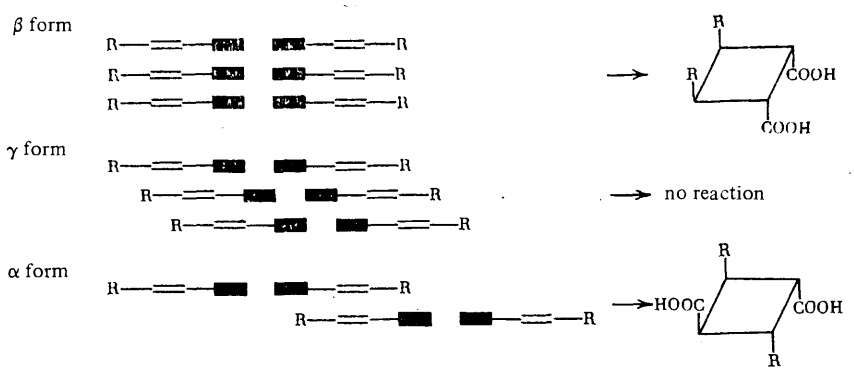

**Figure 5.** Arrangement of the molecules of *o*-ethoxycinnamic acid in the crystal and corresponding types of chemical reaction.

Pure optically active polymeric structures can also be obtained by the same method through the polymerisation of enantiomeric monomers in their crystalline form.

Crystal structure also allows topochemical control of the photo-induced transfer of a hydrogen atom to the keto group and to the C=C double bond. In the first case only the transfer of hydrogen atoms at a distance of 2.26–2.58 Å from the oxygen atom is allowed, i.e. at a distance smaller than the sum of the van der Waals radii of the H and O atoms (2.72 Å). In the second case atoms at a distance of 2.6–2.89 Å from the carbon atom of the double bond are transferred (again, at a distance smaller than the sum of the van der Waals radii of the H and C atoms, 2.90 Å).

Photo-dimerisation, oxidation ozonolysis, halogenation, and dehydrochlorination reactions also take place with a high stereoselectivity in crystals and on their surfaces. Many examples of extreme selectivity and topological control have been observed for reactions in crystals but not for the same reactions in solutions or in melts.

The organisation of molecules in crystals offers new possibilities of controlling the reactivity of a system and new pathways in synthetic chemistry. Many crystals display a high degree of polymorphism. Thus, methanol can crystallise in two forms (α and β) differing in the symmetry of their unit cell: cinnamic acid (discussed above) has three forms; more than 30 crystal forms are known for crystalline sulphur; many organic substances have several (up to 10 or 12) crystal-chemical modifications. We are eftectively discussing a new branch of chemistry: crystal-chemical engineering, whose objective is the construction of crystals matched to specified chemical programmes.

The molecular and supermolecular organisation of ensembles of reacting molecules (or, in other words, the supermolecular design of chemical reaction) is an important new principle for the control of chemical processes and a valuable asset of chemical engineering. So far this principle has not been fully explored, and few applications have been reported, but we can expect "organised" chemistry to play a leading role in chemical science and technology in the near future.

## V. CHEMICAL MATERIALS SCIENCE

Chemistry is the main source of materials for all areas of science and technology, from electronics and metallurgy to agriculture and medicine: in this sense chemistry genuinely stands at the centre of science. The development and evaluation of new substances, preparations, and materials, and the improvement of known or currently used materials, are the principal aims of modern chemistry. Its constituent elements are the synthesis of new substances and materials, the study of their properties, and the analysis of their behaviour under the conditions and regimes to which the materials will be exposed in practical applications. These topics can be combined under the general title of chemical materials science.

A traditional and ever-present problem is the development of highly stable inorganic materials: glasses and vitreous-crystalline materials (glass ceramics and ceramics). Important advances have been made in these topics, including the production of high-quality optical, heat resistant, and semi-conducting glasses with a high mechanical strength, thin-film and lamellar glasses with a high elasticity and thermal and dielectric strength, etc. Porous glasses with pores and channels of a given size (down to 10 Å or less) have been developed for use as filtering media (in particular, in the filtration of biomolecules, viruses, etc., and in the preparation of pure microbiological cultures).

New types of ceramic with a high mechanical, chemical, and dielectric strength have been obtained. These have a low thermal expansion coefficient, and they are widely used in technology, electronics, and radio. Metallic glasses have also been prepared: amorphous, vitreous metals with a high chemical stability and corrosion resistance.

Inorganic composite materials consisting of fibres in a metallic or ceramic matrix offer very attractive prospects. They can satisfy two apparently incompatible requirements: high strength and high crack resistance. For example, the boron-aluminium composite developed at the Solid-state Physics Institute of the USSR Academy of Sciences has a strength of 100–150 kgf $mm^{-2}$ (in the armouring direction), an elastic modulus of ~25000 kgf $mm^{-2}$, and a density of 2.7 g $cm^{-3}$, i.e. it combines the mechanical properties of a good quality steel with the density of aluminium. Ceramic fibre composites have a work of fracture an order of magnitude greater than that of the best homogeneous ceramic, and they can be used to produce light-weight components able to withstand hostile mechanical and thermal conditions.

Problems currently studied still include the development of corrosion-resistant alloys and materials, of inorganic semiconductors, photoresists, light detectors and photoelectric energy converters with a high quantum yield and a high selectivity and sensitivity towards chosen regions of the optical spectrum, and the development of piezoelectric, ferroelectric, and other materials for acousto-electronics.

Improvements are being sought in mineral fertilisers of high food value, assimilability, and optimum composition, in new rubbers based on polyurethanes and polysiloxanes, fluororubbers, etc., offering a high thermal and chemical resistance, frost resistance, and good elastic and relaxation properties, in new plastics, resins, and ion-exchanger materials and adsorbents, in long-life lubricants and viscosity additives, in lacquers with a high adhesion and high-grade electrical insulation and anticorrosion properties, in glues, sealants, and surface-active substances and coatings, in porous and filtration media for separating and purifying substances in the food industry, in technology, and in medicine, and in strong fibres (both synthetic and modified natural fibres), etc.

The development improved or new pigments, phosphors, scintillators, and laser generation materials is a continuing problem. Light-fast dyes are needed for optical lasers, laser shutters, and modulators. New substances are being developed for chemical light sources (substances which resemble luminol in converting chemical energy into light energy with a high efficiency).

Polymer materials and their most recent modifications (polymer composites) occupy an important place in modern materials science. Current developments include various composites reinforced with organic or inorganic fibres (glass, boron, asbestos, graphite, and carbon fibres, and fibres based on boron nitride, $TiO_2$, $Al_2O_3$, etc.). This wide variety of composites offers a wide range of useful properties: electrical strength, chemical stability, elasticity, mechanical strength in shear and compression, resistance to plastic flow, etc. Further substantial improvements in the mechanical and thermal strength of these composites can be expected when the fundamental problem of lowering the concentration of localised stresses at the fibre–polymer matrix interface has been solved. Various approaches to this problem are being studied: for example, by inserting a boundary layer with an elastic modulus intermediate between those of the fibre and of the matrix, or by applying artificial elastic deformations to the boundary to suppress (or compensate) the main stresses generated between the fibre and the matrix. The same problem arises in the development of high-strength inorganic composites.

Dispersion-strengthened or filled (usually with an inorganic filler) polymer materials are similar to polymer composites. With all these materials the material production stage can be by-passed, and the article can be formed directly, but this requires a very precise and reliable control over the properties of the chosen composite.

Other important materials include incombustible or fire-resistant coatings and cloths, and anti-static materials for use in situations where electrification or static electricity can present sanitary, explosion, or fire hazards (floor coverings in computer rooms or in medical X-ray rooms, materials for protective clothing in tanker fleets, in the petrochemical and gas industries, etc.). Light and cheap (preferably organic) materials are also needed for protecting electronic and radio equipment from stray electromagnetic fields, and for absorbing electromagnetic radiation.

Methods of preparing entirely new materials (organic semiconductors and metals) have been discovered in recent years. Their precursors were the polymers with a conjugated $\pi$-electron system (polyacetylene, polyphenylene, etc.), prepared by polymerising the appropriate monomer in solution; these were amorphous substances with a high concentration of defects, a low electrical conductivity, and a poor chemical stability towards oxygen and other reagents. An important step forward was made by the production of perfect (almost defect-free) conjugated polymers by polymerising the monomers in crystals (see section IV). Another success was the discovery of ways of modifying the conduction properties of organic semiconductors by treatment with bromine, iodine, $AsF_5$, or inorganic salts: this operation (doping, or alloying) creates local impurity centres in the semiconductor structure and results in a large increase (by 10–11 orders of magnitude) in the concentration and mobility of the charge carriers and therfore also in the conductivity of the material. This type of doping converts polyacetylene (for example) into a substance with an almost metallic conductivity. Furthermore, thin films of these conjugated polymers prepared by polymerising the monomer in a crystal offer unique and reversibly controllable thermal and optical properties.

Organic batteries and accumulators with potentials up to 4.5 V and capacities up to 300 W $kg^{-1}$ have been produced from doped conjugated polymers. According to estimates made in the USA the scale of production of organic semiconductors (for electronic applications only) was 10000 tonnes in 1981, and had doubled by 1984. They are used in electrical noise suppression systems, in cable sheaths, in accumulators and current sources, in photovoltaic apparatus and converters, and in micro-electronic circuits. Further improvements can be expected, and the new materials with improved electrophysical properties have a promising future.

A good example of a successful development in chemical materials science is the discovery of an entirely new type of substance: organic metals. These are organic compounds with a crystalline molecular organisation which results in a high electronic conductivity (up to $10^5\ \Omega^{-1}\ cm^{-1}$), approaching that of the best metallic conductors (for example, mercury). Typical materials of this type are the ion-radical salts, in which the cation is a radical such as tetrathiafulvalene (TTF), tetraselenafulvalene (TSF), tetramethyltetraselenafulvalene (TMTSF), etc., and the anion is a radical such as tetracyanoquinodimethane (TCNQ) or its dimethyl derivative (DMTCNQ), or an inorganic anion ($PF_6^-$, $AsF_6^-$, etc.). In crystals of these compounds the cation radicals are stacked with their planes in a parallel orientation, forming small stacks (one-dimensional chains in which strong interactions between the electrons of the $\pi$ system develop, producing a high electrical conductivity). The anions are also arranged in one-dimensional chains, parallel to the cation chains (the molecular organisation of these crystals is discussed in detail in section II).

Organic metals have a high electrical conductivity (up to $10^3\ \Omega^{-1}\ cm^{-1}$) even at room temperature; at lower temperatures their conductivity is still higher. For example, it is $10^5\ \Omega^{-1}\ cm^{-1}$ for $(TMTSF)^+(DMTCNQ)^-$ near 40 K, and $10^4\ \Omega^{-1}\ cm^{-1}$ for $(TMTSF)^+(ClO_4)^-$ at 50 K. The one-dimensional packing of the conducting cation chains results in a highly anisotropic conduction: the ratio of the conductivities along and across the chains is 500–1000.

The behaviour of the organic metals includes two surprising features. The first stems from the instability of the one-dimensional chains, predicted by Peierls in 1954, and consists in a change from a uniform distribution to an alternation of intermolecular distances at low temperatures, producing waves of charge density (or spin waves in the case of chains of paramagnetic particles). Because of the alternation of intermolecular distances in the one-dimensional chain the energy band containing the levels of the valency $\pi$ electrons splits into two systems of levels: a lower system, filled with electrons, and an upper, empty system. In order to cause conduction we must transfer an electron from the filled into the empty system, i.e. we must surmount the energy barrier separating the full and the empty band. It follows that at low temperatures (below the Peierls transition temperature) the organic conductor becomes a semiconductor (or even an insulator if the energy gap between the two bands is wide enough). Among the organic metals we find many compounds which become superdielectrics at low temperatures (12–180 K), with a dielectric constant $\varepsilon \cong 3000$ and a strong anisotropy ($\varepsilon_\parallel/\varepsilon_\perp \cong 500$).

Another surprising property of the one-dimensional organic metals is their transition to the superconducting state, first discovered in 1979 for the compound $(TMTSF)_2^+(PF_6)^-$: at 0.9 K and 12 kbar pressure this organic metal is converted into a superconductor. It was later shown that other salts of composition $(TMTSF)_2^+X^-$, where $X = AsF_6$, $TaF_6$, $SbF_6$, and $ReO_4$, become superconductors at low temperatures and high pressures; the salt $(TMTSF)_2^+(ClO_4)^-$ is a superconductor at 1.2 K even under normal pressure.

The superconductivity mechanism in organic superconductors is still not clear. The formation of Cooper electron pairs and their organised motion in the superconducting state may be controlled by coordinated vibrations of the lattice, and in particular by vibrations of the anion chains (as in classical metallic superconductors). However, a different mechanism (proposed by Little in 1964) is also possible: the motion of the Cooper pairs is controlled by waves of electron polarisation travelling along the side chains. The classical mechanism of superconductivity seems the more likely to apply to the organic metals so far synthesised.

Many inorganic and mixed salts have also been shown to have a near-metallic electrical conductivity. They include the platinum salts $K_2Pt(CN)_4Cl_{0.3}\cdot 3H_2O$ and $K_2Pt(CN)_4Br_{0.3}\cdot 3H_2O$, the mercury salts $Hg_{3-\delta}AsF_6$ and $Hg_{3-\delta}SbF_6$ (where $\delta = 0.14$), and also sulphonitride $(SN)_x$, a polymer with metallic conduction. The last three compounds also show superconductivity. The molecular organisation of their crystals is discussed in section II.

Synthetic organic metals, superdielectrics, and superconductors have only recently come to the fore in science: their discovery has created an entirely new field in materials science, with attractive prospects. This field includes some unusual magnetic materials: organic ferromagnetics, whose synthesis is being intensively studied at present.

Chemistry plays an important role in agriculture and medicine. The chemical problems in these areas are fundamental: creating new and effective medicinal preparations (in particular, anticarcinogens), immobilising drugs and immunological

substances on the macromolecules of synthetic or natural polymers in order to increase their effectiveness and to extend their useful life, and developing pesticides, agricultural chemicals, pheromones, and other biologically active compounds. This group of topics includes the development of gel polymers and of synthetic polymeric materials for artificial organs used in surgery, and the modification of their surface to produce antithrombogenic properties. Another important problem is the development of artificial blood substitutes (for example, the perfluorohydrocarbons, which are chemically passive, have no metabolic activity in the organism, and offer a high oxygen capacity, recently shown to be due to complex formation between the oxygen and the fluorine atoms of the fluorinated molecules.

Even this list of materials is not exhaustive, and it is being continually extended. Because of the rapid developments in technology and in the adjacent scientific areas it is difficult to predict which materials will be most widely applied in the near future: it is important for all chemists to remember that the creation of new substances and materials is the fundamental aim of chemistry, and that all their efforts should continue to be devoted to the achievement of this aim.

## VI. CHEMICAL TECHNOLOGY

The previous section dealt with existing and likely future developments in chemistry: we shall now consider the methods by which these developments can be realised, i.e. we shall discuss new methods and new principles in chemical technology. Improving existing technologies and developing new technologies is one of the main responsibilities of chemical science. Simplicity, dependence on few stages (preferably, one stage), reliability, moderate energy requirements, high operating speed and yield, continuous operation, absence of residues, acceptance of untreated raw materials, these are the main criteria to be aimed at in new technological developments.

Undoubtedly the central place among the new technologies belongs to catalysis. At present 85% of all industrial processes, responsible for 70% of all chemical production, are based on catalysis. Processes offering a high selectivity and operating speed, economically attractive, and with low energy requirements can be discovered and developed only by using catalysis. This state of affairs has traditionally been found in both heterogeneous and homogeneous catalysis. Significant advances have been made, and many highly effective processes have been adopted by industry, but even greater prospects are seen in advances whose application is still awaited. These include metal-complex catalysis, which allows many reagents to be converted directly into the wanted products without intermediate synthetic stages. For example, the carbonylation of methanol to give acetic acid can take place on rhodium complexes with a methanol selectivity of 99%, and the oxidation of ethylene to acetaldehyde on palladium catalysts has a selectivity of ~95%. Highly effective processes of hydroformylation, the direct synthesis of aromatic isocyanates from nitroaromatic compounds, the synthesis of vinyl acetate from ethylene and acetic acid, and other valuable processes have been developed. The high selectivity of metal complex catalysis is found also in electrochemical processes (for example, the electrochemical oxidation of olefins in the presence of osmium salts gives an almost 100% yield of glycols).

The phenomenon of catalytic metathesis is being studied as a path to the industrial production of new organic compounds and new materials, especially macrocycles, and unusual substances like catenanes (cyclic molecules whose rings are "threaded" through each other like the links of a chain). The synthesis of a catenane from a cyclic diene can be represented schematically as follows:

The first stage is the formation of an inner loop which then becomes fixed by a metathesis reaction; the final result is a catenane.

In another interesting development catalytic processes are conjugated so that the energy evolved by one reaction is used to stimulate another. This possibility exists both in heterogeneous and in homogeneous metal complex catalysis. A good example of conjugated catalytic reactions in cells is the synthesis of ATP by the oxidative phosphorylation of ADP followed by the use of the energy evolved in this reaction to stimulate energy-deficient reactions (including "difficult" reactions such as the biological reduction of molecular nitrogen).

The metal-complex catalysts in the present state of development have a number of shortcomings which can partially (or, on occasions, wholly) offset their advantages. The most serious of these is the need to generate a molecular organisation for the catalyst which ensures long-lived operation of each active centre without decomposition, coupled with ready access of the reacting species to this centre and easy removal of the reaction products. The following principles are being studied as a means of achieving this organisation: the immobilisation of the active centres on the surface of a solid, the "clusterisation" of a group of active centres on solid surfaces (an approach which almost totally eliminates the distinction between homogeneous and heterogeneous catalysis), and the introduction of active centres into the molecular structure of organic crystals (for example, between the planes of carbon atoms in graphite).

A promising approach is the immobilisation of homogeneous complex catalysts in gel polymers, i.e. the chemical or quasi-chemical bonding of the catalyst to a macro-molecule. The immobilisation principle is very close to the operating principle of natural enzymes, which consist of metal-organic catalysts incorporated in the structure of protein macromolecules and whose economy and efficiency are unrivalled. This principle of catalyst organisation offers one fundamental advantage: it can be applied to processes which require the participation of several active catalytic centres (as in the enzyme nitrogenase, in which two active centres contribute to the reduction of nitrogen). The immobilisation of active centres on macromolecules followed by control of the molecular conformation can be used (if necessary) to produce "many-centre" catalysis.

The immobilisation principle is often treated as an enzyme modelling principle: this is a very important and forward looking new attitude in chemical research. A closely related and actively investigated topic is catalysis on immobilised enzymes, which offers attractive prospects in artificial food technology (the synthesis of proteins, aminoacids, and glucose), in medicine, in the chemical analysis of biologically active compounds, in immunology, in micro-energetics (especially in fuel cells, see section VII), and in organic synthesis. Though this work is still on a modest scale because of the high cost of enzymes, current developments in biotechnology and genetic engineering should make enzymes more accessible and increase their "practicality", thus leading to the adoption of immobilised enzymes as an important element of the chemical technology of the future.

Catalysis should play an important role in the new technologies of natural gas and petroleum treatment to give valuable chemical products: the key element in these processes will probably be the catalytic activation of saturated hydrocarbons (especially methane). In view of the world shortage of

energy, great interest is shown in the development of low-energy and high-yield technologies for the treatment of solid fuels (coal, shales, peat, wood cellulose, etc.), aimed at producing hydrogen, carbon monoxide, and artificial petroleum and petrochemicals.

An equally pressing problem is the treatment of inorganic raw materials (ores and minerals). We require improved flotation techniques, more selective flotation reagents, and extractants offering a more quantitative separation of non-ferrous and rare metals and of fluorine and other elements. Chemical methods of metal extraction have long been used in metallurgy (for example, the cyanide method of gold extraction), but their importance is now increasing because of the exhaustion of the richer ores. New technologies can be developed on the basis of organic compounds such as complexones and extractants which react selectively with the ions of the given metals and transfer them from the complex ore into the solution. We could witness the development of a new branch of metallurgy: solvato-metallurgy, differing from traditional metallurgy in not requiring energy-wasteful melting processes.

"Microbiological" metallurgy offers even more attractive prospects. It is based on the ability of some micro-organisms to "treat" ores and selectively extract certain metals from them. These chemolithotrophic (literally, "rock-eating") micro-organisms live in water and they obtain their life-supporting energy from the enzymatic oxidation of inorganic substances, thus "freeing" the metal from its ore and transferring it to the aqueous solution. The large-scale microbiological production of copper is already carried out in several large mining concerns; in the USA more than 10% of the copper production uses this method, and uranium production by the same method is planned. In principle, cultures of micro-organisms which selectively "produce" any wanted metal could be "grown" by genetic engineering: this approach is part of an important new scientific area, biotechnology, which seems likely to expand the possibilities of chemical technology on a vast scale.

Another important success of modern chemistry was the discovery of the reduction (fixation) of molecular nitrogen by homogeneous catalysts. We now await the corresponding development of an industrial nitrogen fixation technology offering a high operating speed and selectivity and a low energy consumption. A similar problem exists in respect of carbon dioxide: an inorganic raw material available in almost limitless quantities. Catalysis can be expected to play a key role in solving this problem. The catalytic utilisation of $CO_2$ for the synthesis of substances currently listed as "petrochemical" and expected to be in short supply in the very near future should be treated as a pressing chemical problem. Some initial work in that direction has already been reported: we know that the interaction of $CO_2$ with hydrogen on Ni, Co, and Ru catalysts gives methane, whereas methanol is obtained on oxide catalysts. There are also non-catalytic methods of fixation of $CO_2$, but they are much less cost-effective. For example, the electrolysis of an aqueous solution of $CO_2$ and sodium sulphate was shown to produce methanol (in these experiments the current source was a gallium arsenide solar cell).

Combustion processes play an important role in chemistry. They are mainly used in chemical energetics, to produce thermal and mechanical energy. The problem includes the combustion of gases in engines, and the gasification and combustion of liquid and of solid fuels. The main partner of the fuel in combustion processes is oxygen (free, or bound), and the main products are water and carbon dioxide. Combustion technology is continuously advancing, and wider applications are being found. These include mixing-chamber ignition in internal combustion engines, the organisation of combustion within the seam to improve the yield of petroleum deposits, underground gasification in coal mines, etc. All these problems are important, and no effort should be spared in seeking their solution.

Interesting new possibilities were recently identified in the use of combustion processes in industrial inorganic synthesis. A new type of heterogeneous combustion process, not involving oxygen, was discovered: the combustible material is a high-melting metal (Ti, Zr, Hf, Nb, Ta, etc.), and the oxidiser is a non-metal (B, C, Si, molecular nitrogen, hydrogen, etc.). Using combustion processes in these systems a new technology was developed: the self-propagating high-temperature synthesis of high-melting inorganic compounds and materials. The advantages of the technique include low energy consumption, high operating speed, the production of substances and materials having a prescribed composition, physicochemical properties, particle size, and porosity, high-purity products, simple technological design, and ecological purity.

The new technology is being rapidly assimilated in inorganic synthesis: it has already been used to produce more than 200 compounds, including carbides (TiC, ZrC, HfC, NbC, SiC, SC, $Cr_3C_2$, $B_4C$, etc.), mixed carbides (TiC–WC, TiC–WC–$Mo_2C$, TiC–ScC, etc.), nitrides (TiN, ZrN, NbN, TaN (cubic, and hexagonal), BN (cubic), AlN, $Si_3N_4$), single-phase solid solutions of nitrogen in Ti and Zr, borides ($TiB_2$, TaB, CrB, NbB, MoB, $MoB_2$, MnB, NiB, $LaB_6$, etc.), silicides ($MoSi_2$, $TiSi_2$, $Ti_5Si_3$, $SrSi_2$, $TaSi_2$, etc.), compounds of S and Se with Nb, Ta, W, Mo, V, Nd, and the mixed chalcogenides $WNbS_2$ and $MoNbS_2$, hydrides ($TiH_2$, $ZrH_2$, $NbH_2$, $ScH_2$, etc.), intermetallics (NiAl, FeAl, NbGe, NiTi, etc.), solid solutions of carbide nitrides of variable composition (TiN–TiC, TaC–TaN, NbC–NbN, etc.), and solid inorganic alloys and composites (TiC–$TiB_2$, WC–Co, $B_4C$–$Al_2O_3$, Vn–Fe, etc.). All these materials are refractory, super-hard, and wear resistant, and they are used in various areas of technology as hard alloys, abrasives, wear resistant and thermally stable coatings, high-temperature heating elements, alloy steels, fire-resistant materials, etc.

The physicochemical mechanism of this process (the motion of a high-temperature combustion region, leaving a trail of synthesis products, (see Fig.7) offers a number of additional technological possibilities, including the direct preparation of refractory articles of any shape without going through the material production stage; this facility avoids the difficult technological process of forming the refractory material into the desired shape. The new technology is being developed very rapidly because it has firm scientific foundations as well as offering attractive prospects.

Interesting effects have been observed in materials under the combined effects of high pressure and shear deformation: these conditions lead to a number of unusual reactions such as the formation of salts by the interaction of solid metals and solid organic acids, the polymerisation of benzene and other monomers which do not polymerise under normal conditions, the penetration of metal atoms into graphite through the reaction of graphite with solid metals, the formation of solid solutions from a mixture of metal powders, etc. These are apparently the conditions met in shock waves, though in the latter the non-isothermal compression and the shear deformation take place in times of $10^{-12}$–$10^{-6}$ s (as opposed to static conditions). Many unusual chemical effects take place in shock waves: the conversion of graphite into diamond, the synthesis of metal nitrides and of boron carbide and nitride, the polymerisation of benzene, etc. The further development and improvement of these technological possibilities is of great interest.

The creation of photochemical technologies such as photolithography is of definite (though specialised) interest. However, there are two problems of more general interest in which

photochemical processes play a major role: silverless photography and the fixation of solar energy (the latter will be examined in more detail in section VII, devoted to chemical energetics).

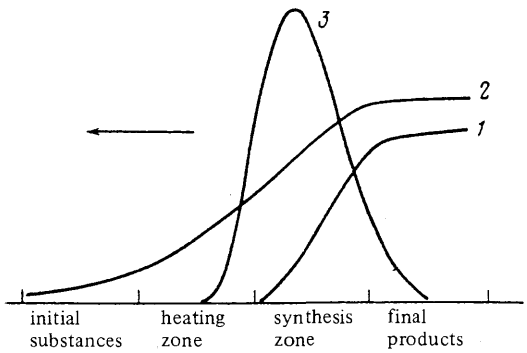

Figure 7. Motion of the combustion zone during self-propagating high-temperature synthesis: *1*) conversion, *2*) temperature, *3*) rate of evolution of heat; the arrow denotes the direction of the combustion wave.

The search for silverless light-sensitive materials and the development of new photographic techniques based on these materials have been stimulated not only by the world shortage of silver (though this is often quoted as the main incentive) but also by the special requirements of modern technology. Significant advances have been made in the synthesis of silverless photosensitive materials of various types (diazotype, vesicular, photochromic materials, etc.), which offer unique properties including high resolution, colour capability, absence of the development stage, reversibility of information recording, and the possibility of repeated use of the same photographic material. The most important problem still outstanding is to improve the light sensitivity of these materials (to the level of $10^7$ cm$^2$ J$^{-1}$ or better). Various suggestions have been made for increasing the quantum yield of the formation of the product responsible for the development of an image. These include the use of radical chain reactions (for example, photo-induced polymerisation), photostimulated phase transitions (for example, the crystallisation of an amorphous substance in the *cis* form stimulated by the presence of the *trans* isomer formed from the *cis* isomer under the influence of light), and catalytic reactions (for example, redox reactions of metal ions "set free" from inactive complexes by exposure to light). The latter include enzyme catalysis reactions: under the influence of light the enzyme is converted from an inactive into an active state, and the image-forming materials are produced as a result of the photo-activation. The term photoenzography has been applied to this new type of photography.

Silverless photography is being developed along several different paths at present, and the best approach has not yet been identified. Sensitisation, which offers higher sensitivity and wider spectral limits (as it does with silver-based photographic materials), is also being studied in conjunction with the new materials.

Plasma-chemical and laser-chemical technologies are also of interest, and have been applied in a number of processes. For example, some evidence of isotope separation by laser chemistry has been observed, but the yield of the method appears to be low. Radiation-chemical technologies are of far greater practical significance because of the large-scale construction of powerful nuclear reactors and of the on-going integration of chemical technology with nuclear energetics. Radiation chemistry has now penetrated the technology of rubber and resin cross-linking and modification, and is widely used in the production of plastics, polymers, and composites as well as in the sterilisation of medical products. Radiation-chemical techniques also offer attractive prospects in chemical energetics (see section VII).

Photochemical, plasma-chemical, and laser-chemical technologies occupy an important place in an important area of modern industry: microelectronics, and their potential applications in this area are still far from being exhausted. The technologies are aimed at the deposition of metallic, oxide, or semiconducting thin films and epitaxial layers by the thermal, photochemical, or plasma-chemical decomposition of metal-organic compounds in the gas phase or by the laser-chemical decomposition of the same compounds adsorbed on the surface. The advantages of this technology include a high purity of the product, relatively low operating temperatures, the possibility of depositing coatings of any type on any surface in any sequence, and generally good adhesion of the layers. Further advantages are the possibility of doping the semiconductors by decomposing metal-organic compounds with laser or electron beams, and the possibility of preparing photographic stencils and protective or diffusion masks without resorting to photolithography or to chemical etching. Similar technologies can be used to prepare super-pure metallic or semiconducting coatings, and magnetic materials (ferrites, magnetic tapes, etc.) with particles of micron or sub-micron size. Almost all the elements of microelectronics (conductors, resistors, semiconductors, dielectrics, microcircuit elements, or even the entire microcircuits) can now be prepared by these techniques.

Many of these processes have already been adopted by industry, but even greater technological possibilities remain to be exploited. The development and improvement of technological methods of using metal-organic compounds in microelectronics is a problem of the first importance. Together with organic semiconductors and metals, and their use in electronics (see section II), the use of metal-organic compounds in microelectronics is a new area of work which could be called organic microelectronics. This is yet another striking example of the integration of different sciences, leading to the birth of new technologies.

This integration has also produced a new and promising technology: the nuclear chemical synthesis of elements, which could be described as a modern "alchemy". We know that semiconductor devices require silicon of the highest purity, doped with phosphorus. The distribution of the doping element (i.e. of the phosphorus in the silicon) must be extremely uniform, and an adequate uniformity is difficult to achieve by chemical methods of doping. A brilliant solution of this problem relies on the fact that as a result of neutron irradiation a silicon atom absorbs a neutron and is rapidly converted into a stable phosphorus isotope by beta-decomposition. This process results in very uniform doping and has already been adopted on a production scale.

This is just one example of the "alchemical" introduction of a required chemical additive. The inverse problem (purification of a material) is also soluble in principle: this approach

replaces the multistage, complex, and expensive chemical purification by neutron irradiation, resulting in transmutation ("alchemical" conversion) of harmful impurities into harmless atomic species.

Nuclear-chemical technology has been used to synthesise a large group of chemical elements (for example, plutonium, technetium, and the entire transuranic group). Furthermore, in the case of some elements which are usually extracted from the atmosphere or from the earth by conventional techniques (for example, xenon, palladium, platinum) the nuclear-chemical technology could have economic advantages. The large-scale practical application of these technologies could have far-reaching economic consequences. Obviously, nuclear-chemical synthesis and its adoption in industry and in materials science will require a well coordinated effort from scientists in nuclear and neutron physics and in nuclear chemistry and radiochemistry. Chemists must be prepared to contribute to the development of this promising branch of modern (and future) chemistry.

## VII. CHEMICAL ENERGETICS

The development of effective methods of converting chemical energy into other forms of energy and the creation of chemical means of storing energy in high-energy substances are two areas being actively developed in present-day chemistry, which can be combined under the title of chemical energetics. Its place in modern energetics is still relatively modest, but some predictions of future energy requirements and of the energy structure of world economics (which we shall not attempt to analyse here) foresee an important role for chemical energetics in the future.

The development of methods of converting chemical energy into other forms of energy is one of the oldest problems known to mankind. For many thousands of years it had only one solution: the combustion of high-energy substances (fuels, such as coal, petroleum, gas, wood, peat, and shale). In spite of the very great technological progress in the organisation of combustion processes in order to maximise their efficiency this method remains economically the least attractive. The direct conversion of chemical into electrical energy (i.e. the combustion of the fuel in an electrochemical fuel cell) is a far more effective method of conversion. The development of electrocatalytic methods of combustion and of methods of raising the energy conversion efficiency in fuel cells is one of the fundamental problems in modern chemistry. Important advances have been made towards these goals, and electrochemical energetics are now applied in practice but on an industrial scale still too small to justify classifying the electrochemical approach as "large-scale energetics".

A special variant of the chemical fuel cell is the biochemical cell, whose operation depends on the use of immobilised enzymes to carry out oxidation–reduction reactions. For example, hydrogenase immobilised on a graphite electrode can oxidise molecular hydrogen, producing a hydrogen potential on the electrode. On a second electrode oxygen can be reduced to water by using an oxidase enzyme immobilised on graphite (for example, polyphenol oxidase). The combination of these two half-cells offers an ecologically clean biochemical fuel cell with a high efficiency. Of course, these cells also have some serious shortcomings (short life, the need to purify the fuel to avoid poisoning the enzyme, etc.), but their further development and improvement could be useful.

Among the other methods of converting chemical energy we should mention chemiluminescence, i.e. the generation of light in chemical reactions, and the generation of coherent radiation in chemical lasers.

Another important branch of chemical energetics is the development of cost-effective methods of producing high-energy substances such as hydrogen, methane, etc., which are convenient to use, easily transportable, and capable of storing energy for indefinitely long periods. The most important energy carrier of this type is hydrogen, whose purest (and practically inexhaustible) source is water. The production of hydrogen from water is a problem of strategic importance. Another equally important problem is the development of effective methods of utilising solar energy. These two problems are closely interrelated. We know that solar energy is an important source of energy, and that the only practical method of exploiting it in large-scale energetics is the development of photo-hydrogen energetics.

Various methods of obtaining photo-hydrogen from water have been described; the simplest is the electrolysis of water using electrical energy generated by semiconductor energy converters (Si, GaAs, CdSe, etc.). For a light conversion coefficient of 14% (the normal efficiency of modern silicon photocells) and a 70% utilisation factor of the electrical energy in the electrolytic cell we obtain an overall efficiency of ~10% in the conversion of solar energy into photo-hydrogen. This approach is still expensive and unattractive for large-scale application (the "bottle-neck" being the high cost of the semiconductor photo-converter), but it seems reasonable to devote further effort to it, and to examine (in particular) the possibility of using organic semiconductors.

An alternative approach is photoelectrocatalysis, i.e. the electrolysis of water on a semiconductor surface (for example, $TiO_2$) coated with a deposited catalyst (for example, metallic platinum). A hole-electron pair is generated in the semiconductor by photolysis, and the electron migrates towards the Pt where it reduces the water to molecular hydrogen, whereas the hole migrates towards the $TiO_2$ surface and oxidised the water to molecular oxygen. This approach is also relatively ineffective at present, but it has a promising future (through the selection of more suitable semiconductors, the modification of their surface, etc.).

The most attractive path to photo-hydrogen production at present is the third: the identification of molecular photocatalytic and photosensitised systems. It is the nearest approach to natural photosynthesis, which can be interpreted most simply as the photogeneration of an electron and a hole through a series of intermediate steps: the ultimate result is the reduction of $CO_2$ to carbohydrates (by the electron) and the oxidation of the water to oxygen (by the hole). The only difference between molecular photocatalysis and photosynthesis is that in the former the electron reduces the water rather than $CO_2$, and therefore the process is also called artificial (or abiogenic) photosynthesis.

These studies have met some serious problems, many of which have already been fully formulated and are being actively solved. The two most important problems in this area are: 1) to ensure the separation of the charges created in the primary photolysis act, so as to prevent their recombination by the inverse reaction, and thus to increase the efficiency of the photolysis; 2) to separate the secondary charge carriers and to prevent their premature recombinations (i.e. their annihilation) so as to ensure their participation in useful oxidation–reduction reactions with the water. Various methods of overcoming these problems have been suggested, all based on the specific attributes of the supermolecular organisation of the photoprocess (see section IV). In model systems both the half-reactions have been realised separately: the reduction of water to hydrogen and its oxidation to oxygen. There are also reports of the combination of these half-reactions into a single process, but we are still a long way from the creation of an effective and economically viable process.

Abiogenic photosynthesis is of interest also because of the possibility of exploiting visible light, whereas photoelectrolysis and photoelectrocatalysis on semiconductors offer a high sensitivity only with ultraviolet radiation, which is present only in small amounts in the solar spectrum.

The radiation-chemical method of producing hydrogen from water offers good prospects, especially in conjunction with high-temperature thermolysis. It relies on the joint application of radiation and heat from nuclear reactors. In the direct, low-temperature radiolysis of water the yield of hydrogen is low because of the reverse recombination of the hydrogen atom with a hydroxyl group. However, at high temperatures the yield of hydrogen increases as a result of the reaction

$$H+H_2O\rightarrow H_2+OH$$

To maximise the hydrogen yield we must remove the hydroxyl from the reaction system. This can be done by using an acceptor with a high effectiveness and selectivity towards hydroxyl: carbon monoxide, which reacts with hydroxyl as follows:

$$OH+CO\rightarrow CO_2+H$$

Thus in the presence of CO the process becomes a chain reaction, which often increases its effectiveness and the hydrogen yield. The overall balance equation for the chemical products is

$$H_2O+CO\rightarrow H_2+CO_2$$

In practice these conditions lead to the chain reduction of water to hydrogen coupled with the oxidation of CO to $CO_2$; chain initiation is radiation-chemical. The same process can be used for the direct conversion of carbon and water into hydrogen and carbon dioxide:

$$C+2H_2O\rightarrow CO_2+2H_2$$

Other thermodynamic cycles leading to the reduction of water to hydrogen are being studied at present: they all rely on the use of waste heat from nuclear reactors, and all can be classified as variants of hydrogen energetics.

Lastly, chemical energetics and the synthesis of high-energy substances should not be confined to the production of photo-hydrogen. We need to develop the principles by which chemical reactions can be coupled so that the energy evolved by one reaction can be utilised in a high-energy synthesis by another reaction (as in the well known synthesis of ATP and high-energy substances in coupled biochemical reactions). The realisation of these principles and of chemical systems based on them, resembling molecular heat engines, would be an important milestone in both chemical technology and chemical energetics.

Equally attractive is the prospect of the direct conversion of mechanical into chemical energy (for example, the direct mechano-synthesis of calcium carbide from the carbonate, or of hydrogen from water). The mechano-synthesis of high-energy substances is possible, in principle, through chemical reactions under pressure and in the presence of shear deformation (see section VI). Of course, the replacement of hydroelectric stations by hydro-hydrogen stations seems a flight of fantasy at the moment, but the prospect is entirely realistic and worthy of scientific effort.

## VIII. ECOLOGICAL CHEMISTRY

The problems of chemical ecology were created by man himself as a result of the continuous (and, during the past century, almost explosive) growth in the industrial activity of mankind. Hence, these problems are artificial to a great extent. However, it would be naive to assume that they can be solved merely by eliminating all sources of ecological pollution, by creating effluent-free (closed) technologies, etc. Some man-made effects in the environment are now too widespread to be reversible, others are slowly reversible, and their elimination would require a great effort and a long time, and a third group of effects are the unavoidable consequences of various technologies (for example, waste products from the nuclear energy industry, contamination from the working of petroleum-bearing underwater shelves, etc.). Hence we need to develop and formulate scientific principles for the elimination, normalisation, and control of harmful or dangerous anthropological effects in the environment, and ecological chemistry should play a major role in this work.

Man-made effects are most marked in the atmosphere, stratosphere, and hydrosphere. Sources of chemical pollution of the atmosphere include the emission of the oxides of nitrogen, sulphur, and carbon, of aromatic hydrocarbons, olefins, and saturated hydrocarbons. The main problem in atmospheric chemicstry is the analysis of chemical reactions in this multi-component system, the quantitative formulation of their kinetics, and the analysis of oxidation processes by molecular oxygen assisted by photolysis due to sunlight. From such a "catalogue" of atmospheric chemical reactions and their kinetics and energetics we must formulate generalised kinetic models of the chemistry of the atmosphere, including processes such as heat and mass transfer (by diffusion and convection of air masses), the development of temperature gradients, humidity, intensity of the solar radiation, etc. The aim of these models is to identify the most harmful components of atmospheric pollution and to predict their long-term and global consequences. The real (and even pressing) need to solve this problem was underlined by recently discovered effects such as "acid rain", which has caused serious economic and ecological losses in the eastern United States, in Scandinavia, in Europe, and in other regions.

Similar problems are found in the chemistry of the stratosphere. However, they include an additional problem of global importance: the fate of the ozone layer, whose role in determining the life support capability of our planet is well recognised. Concern for the fate of the ozone layer in the stratosphere was first expressed in 1970 in connection with the flight of supersonic aircraft emitting oxides of nitrogen. The latter initiate the decomposition of ozone by the reactions

$$NO+O_3\rightarrow NO_2+O_2$$
$$NO_2+O\rightarrow NO+O_2$$

whose sum produces the overall reaction

$$O_3+O\rightarrow 2O_2$$

with long kinetic chains. Chain generation is by the reaction

$$N_2O+O\rightarrow 2NO$$

and the photolysis of oxygen and ozone provides the source of oxygen atoms.

In addition to supersonic aircraft, the natural life processes of nitrogen fixing bacteria (which are a part of the overall nitrogen fixation cycle) contribute to the emission of $N_2O$. Furthermore, $N_2O$ is a product of the metabolism of nitrogen-containing fertilisers.

It is now clear, however, that the combined threat from all these sources to the ozone layer has been overstated, and that the main threat is from the Freons (especially $CFCl_3$ and $CF_2Cl_2$), now used on a large scale as refrigerants, aerosol

propellants, etc. The photolysis of these compounds produces chlorine atoms which decompose the ozone:

$$Cl + O_3 \rightarrow ClO + O_2$$
$$ClO + O \rightarrow Cl + O_2$$

The chlorine atoms catalyse the overall chain process, in which the chain length can reach $10^5$. Chain breaking is produced by the reaction of the chlorine atom with methane, but the concentration of methane in the stratosphere is very low (of the order of 1.5 parts per million).

It has been calculated that if the use of Freons continues at the present level the amount of ozone in the stratosphere could be decreased by 17% by the end of the century (a dangerously high figure). Therefore one of the main problems in ecological chemistry is to produce reliable models of stratospheric chemistry, based on the quantitative kinetics and on the quantum yields of all the elementary thermal and photochemical reactions, allowing for data on the spectroscopy and optics of the atmosphere and of the stratosphere and for recent information on the complex formation of molecular oxygen with fluorine atoms in fluorinated molecules. The latter effect is important because the formation of complexes between Freons and oxygen and their photochemical decomposition could be an effective method of breaking down the Freons in the atmosphere.

The protection of the hydrosphere is an important part of ecological chemistry. The problem includes effluent waters from industrial and agricultural activities and natural effluents containing toxic chemicals, fertilisers, and pesticides leached from the soil. The analysis and control of chemical contaminants and the development of reliable and simple methods of purification have long been recognised as the traditional problems of the ecological chemistry of the hydrosphere.

The contamination of the oceans by petroleum products is another important problem. Petroleum and petroleum chemicals distributed as a thin film on the water surface are oxidised by molecular oxygen (partly by enzyme reactions and partly photochemically) by the well known radical chain mechanism. The resulting products (especially the organic acids) are surface-active substances which cover vast water surfaces and affect the evaporation of the oceans, with serious effects on the biology of the ocean through the dissolution of the oxidation products (many of which are poisonous) and through the alteration of the oxygen balance of the ocean.

The ecological effects of the contamination of the ocean and their long-term consequences have not yet been evaluated: studies of the chemistry of the process, and of their kinetics and thermodynamics, are required in order to establish predictive models.

Chemical and ecological effects in the atmosphere, stratosphere, and hydrosphere can lead to perturbations of the thermal balance and to serious meteorological and climatological consequences. Therefore an overall "chemical" monitoring of the environment is required. It should be organised as a control of the chemical state of the atmosphere, stratosphere, and hydrosphere, aimed at detecting sources of pollution and analysing the evolution of these contaminants under natural conditions. The problem includes the development of methods of chemical analysis with high-level quantitative characteristics (which are also needed in technology and in materials science, see section IX).

Lately, an important topic in ecological chemistry is the evaluation of the chemical effects of socially hazardous undertakings such as the production and testing of substances for chemical warfare and nuclear tests. Their danger and social unacceptability should be obvious not only from social considerations but also from the standpoint of ecological chemistry.

## IX. DIAGNOSTIC AND ANALYTICAL CHEMISTRY

Progress in chemical materials science and in chemical industry would be impossible without a corresponding progress in diagnostic and analytical chemistry. The improvement of existing principles and methods of chemical analysis, and the development of new ones, are important problems in modern chemistry.

It is often said that chemists have received many valuable gifts from physicists: optical and vibrational spectroscopy, X-ray diffraction, neutron and electron diffraction, electronic and nuclear magnetic resonance, etc. This point of view is understandable, but not entirely correct, since the opposite view could be put forward. Undoubtedly, in addition to normal analytical methods (traditional chemical analysis, neutron activation and electrochemical analysis, chromatography, emission spectroscopy, etc.) physical methods are widely used in chemistry for the analysis and characterisation of substances, materials, and processes (X-ray and photoelectron spectroscopy, mass spectrometry, low-energy electron diffraction, Mössbauer spectroscopy, dynamic light and neutron scattering, microwave spectroscopy, etc.). Chemists have made a major contribution to the development of these methods and to the expansion of their metrological and analytical capabilities. Effective advances in analytical and diagnostic chemistry can be expected from the application of general advances in chemistry, physics, and instrument design.

Modern technology requires improved analytical and metrological systems for controlling technological processes, the state of the reactor and of its surroundings, and for detecting the need for corrective action at a usefully early stage thus ensuring stable and reliable process control. This type of system should convert the information on the state of the materials, of the processes, and of the surroundings into signals which can be processed in the normal way, and it should be small, sensitive, and fast acting, so as to respond to rapidly changing conditions.

The sensor detectors are systems of this type: they are cheap and small, fast-responding devices designed to measure the parameters of the surrounding medium and of the technological process (pressure, temperature, chemical composition, etc.), and they have been intensively developed in recent years. They include electrochemical sensors (using solid or traditional electrolytes), piezo-sensors (used for the microweighing of adsorbed gases), sensors based on ion-selective membranes, and others. However, the most sensitive devices are those which use semiconductors as the sensing element. They differ from sensors of other types in being smaller, more reliable, and in responding more rapidly to changes in concentration.

The use of metal-oxide and other semiconductors for determining concentrations in gases relies on the change in impurity conduction of these materials upon the adsorption of certain gases. Adsorption sensors are usually prepared from the semiconducting oxides of various metals (Sn, Zn, Ti, Ni, V, and some others). The initial conductivity of these semiconductors is low, and therefore even the adsorption of a small amount of gas causes a large change in resistance of the detector. The threshold sensitivity of these primary converters is $10^6$–$10^8$ $cm^{-3}$.

The sensors can measure the concentration of different gases: $H_2$, $O_2$, $H_2O$, NO, CO, $CO_2$, $H_2S$, $SO_2$, hydrocarbons, etc. However, their selectivity is low, due to the specific properties of adsorption and diffusion through selective membranes. The extent to which selectivity is a requirement in semiconductor sensors depends on the application envisaged. In many cases a modest selectivity is acceptable (when it is known that only a particular combination of gases can be met

under the experimental conditions). For example, sensors for methane used in coal-mine gas detectors do not need a high selectivity, and their ability to respond to many reducing gases in addition to methane is unimportant.

However, in other situations we need to determine gas concentrations in an atmosphere of unknown composition. In this case the sensor should respond to changes in the concentration of only one component of the atmosphere. A proposed solution of this problem relies on the use of a set of different low-selectivity sensors.

Sensors containing different semiconductors and operating at different temperatures give different responses to the adsorption of different gases. The temperature dependence of the conductivity of a pellet of $SnO_2$ baked at 500 °C and treated in $SO_2$ at 350–500 °C for 15 min during the adsorption of different gases is shown in Fig.8. We conclude from these plots that by an appropriate choice of sensor and of working temperature we can produce a set of detectors which can jointly identify uniquely any composition of the gas mixture to which they are exposed. The signals from the sensors can be converted into a system of equations which are solved by a micro-processor so as to determine the concentration of all the components in any gas mixture. This method of solving the problem of producing a selective detector is more promising and rational than attempting to construct an intrinsically selective sensor, which usually results in a serious loss of sensitivity.

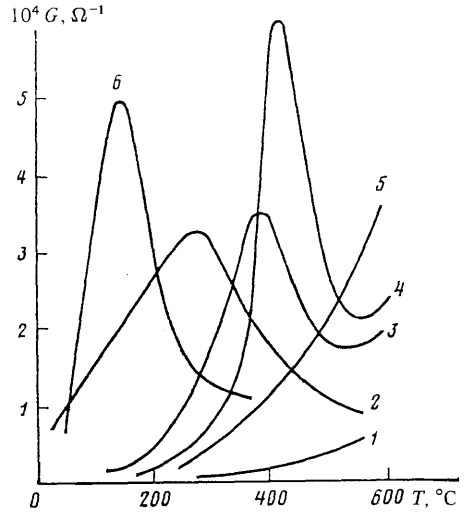

**Figure 8.** Temperature dependence of the sensitivity of a sensor based on $SnO_2$ baked at 500 °C and activated with $SO_2$ (1000 ppm) at 350–500 °C: *1*) air, *2*) $SO_2$, *3*) n-pentane (1000 ppm), *4*) ethylene and butane (0.7%), *5*) methane and ethane (1000 ppm), *6*) hydrogen sulphide (40 ppm).

These sensors have a relatively high sensitivity. A typical threshold sensitivity is 1 ppm (part per million) or less, but for some gases it can be a few ppb (parts per billion). In the detection of active gas particles (atoms, radicals, excited molecules) the sensitivity of semiconductor sensors is even higher (up to $10^{-6}$ mg $cm^{-3}$). It can even exceed the physiological sensitivity of the human nose.

One of the most important characteristics of the sensor is its response time, i.e. its speed of action. Clearly, the shorter the response time, the sooner can an operator monitoring the displayed signal take the required corrective action in response to changes in composition within the reactor or in the surroundings. The response times of the sensors can be long, reaching several minutes in the piezo-detector and in detectors relying on solid electrolytes, but in semiconductor sensors the response time can be ~10 ms.

The main advantage of semiconductors over other types of sensor is their small size and weight. The size of any semiconductor device is determined primarily by the size of the dielectric substrate on which the semiconductor is carried: this is not usually more than a few square millimetres, with a thickness of the order of 1 mm. A whole set of semiconductor detectors can be deposited on a single dielectric substrate to give a multiple assembly weighing only a few grammes.

An important problem in the development of sensor devices is their technological feasibility on a large scale. In recent years micro-electronic and computer technology have reached such a high level that information processing and display systems working in real time can be produced routinely in industry. Semiconductors can therefore be produced in large batches by existing microelectronic technologies.

The development and formulation of new analytical and metrological principles, systems, and devices is another problem in modern chemistry. The range of applications is almost limitless: from the analysis of the chemical composition of substances from the composition of their vapour, even at very low pressures, to the detection of trace impurities and of toxic substances in the atmosphere and to the control of the state of materials, articles, and assemblies. For example, the ageing of concrete produces various gases, varying in amount and composition as the ageing proceeds. A diagnosis of the age of concrete and a prediction of the likely collapse of concrete structures can be based on this effect. This new principle in technological non-destructive testing can be applied to the diagnosis of the state and likely future behaviour of the most diverse materials and structures. Obvious application are in geophysics, vulcanology, gas and petroleum prospecting, and other branches of science and technology.

The principles of analysis with semiconductor detectors can also be applied successfully in medical diagnostics. For example, the composition of gaseous metabolic products in a living organism (evolved in breathing) and the presence of some trace components can be used to diagnose functional anomalies in certain organs and to detect illnesses at an earlier stage than by using conventional methods of diagnosis.

## X. CONCLUSIONS

Chemistry, like any other science, solves or tries to solve a very large number of problems covering a wide range of level and scale, economic importance, and general value, and it is important not to lose sight of the main outlines of chemical science and of their changes with time in the ever-increasing flow of publications.

The aim of the present review was to define the most important and most up-to-date directions in modern chemistry. We tried to assess these directions objectively, and to avoid any bias from our personal scientific interests and commitments. We could be accused of presenting an incomplete or cursory

analysis of the problems, but as any thoughtful reader will understand a fully comprehensive discussion is out of the question in a review of this type.

Every scientific endeavour, every scientific search (including chemical ones) should answer three main questions: what, why, and how. The first question concerns what to seek, what to do, what is the value of the search; the second asks why should the work be done, are the expected results useful, or necessary, where can it be applied, how can it affect various areas of science, technology, and production; the third question asks what is the most rational method of carrying out the work, and how to choose the best, quickest, and most reliable and economical path towards an unambiguous solution of the problem as defined. This logical organisation of scientific research corresponds to that used in the present review: part of the review deals with the questions "what" and "why" (sections V–X), and part with the question "how" (sections II–IV).

We hope to take up the theme of this paper again in a few years, and to assess the extent to which the problems outlined here have been solved and the correctness of the present predictions.

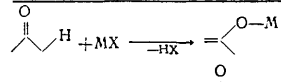
I. Introduction 1130
II. General characteristics of oxallyl complexes and methods of their synthesis 1130
III. Reactions with participation of oxallyl complexes 1131

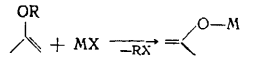
## I. INTRODUCTION

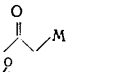
The allyl compounds of metals constitute one of the most thoroughly investigated classes of organometallic compounds. Numerous reviews and monographs have been devoted to the use of the allyl complexes in synthesis. The metal oxallyl complexes, in which one of the carbon atoms of the allyl system has been replaced by oxygen and which have a similar structure, have been investigated to a much lesser extent. At the same time the continuous growth of interest during the last 5–10 years in the use of oxallyl complexes in organic synthesis and metal complex catalysis makes it essential to survey the scattered literature data available in this field. The present review is the first survey of the employment of oxallyl complexes of transition metals in organic synthesis.

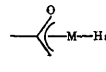
## II. GENERAL CHARACTERISTICS OF OXALLYL COMPLEXES AND METHODS OF THEIR SYNTHESIS

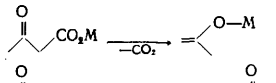
Oxallyl complexes can exist in three forms: (a) as enolates having an oxygen–metal σ-bond (I); (b) as 2-oxoalkyl derivatives of metals having a carbon–metal σ-bond (II); (c) as π-oxallyl complexes (III):

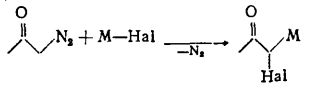


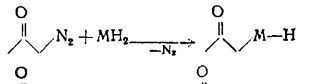


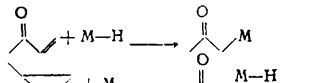


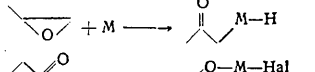


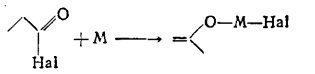


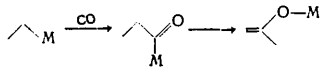












(I) (II) (III)

The existence of oxallyl complexes in a particular form depends on the nature of the metal itself and on the ligands linked to it. In solution there may be equilibrium between the above forms analogous to the equilibrium between the σ- and π-allyl structures of allyl complexes.[1] For example, the transition of the σ-oxallyl complex (II) of iron to the π-oxallyl form (III) under mild conditions has been described.[2] Since many oxallyl complexes are active intermediates in chemical reactions, they cannot be always isolated or identified in solution by spectroscopic methods. In this case their intermediate formation can be inferred from the structure of the reaction products or on the basis of kinetic data.

Metal oxallyl complexes can be obtained (usually *in situ*) by various methods which are summarised in Table 1.

Enol ethers and α-halogeno-, α-diazo, and β-carboxy-substituted and αβ-unsaturated carbonyl compounds are most often used to obtain oxallyl complexes. In addition, they can be obtained from epoxides, acid chlorides, and acyl or

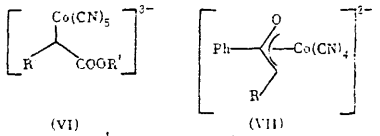
## III. REACTIONS WITH PARTICIPATION OF OXALLYL COMPLEXES

### 1. Reactions Without the Formation of New C–C Bonds

#### (a) Hydrogenation

The hydride and other complexes of molybdenum,[28] iron,[49] cobalt,[32,50,51] ruthenium,[52] rhodium,[53] osmium,[25] and iridium[54] have been used as reagents or catalysts for the reduction of the double bond in αβ-unsaturated carbonyl compounds. As a rule, the reduction takes place under mild conditions (20–65°) at normal hydrogen pressure with a high yield of the saturated carbonyl compound.

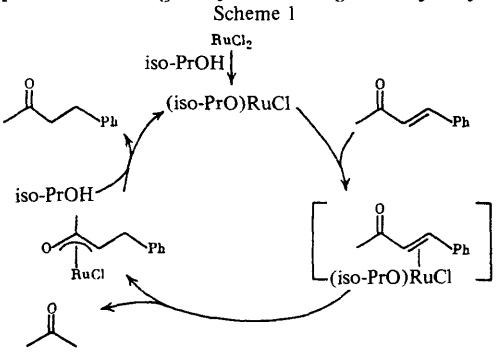


Metal oxallyl complexes are formed as intermediates in the hydrogenation reaction, which has been demonstrated, for example, in the reaction of $Cp_2MOH_2$ with esters of maleic, fumaric, and acrylic acids[28] and also in the reaction of the hydride derivative of cobaloxime (IV) with methyl acrylate:[51]

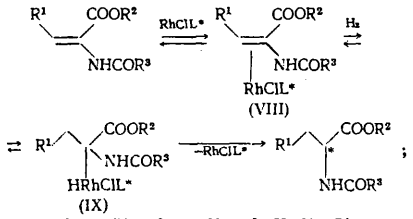
(IV) (V)

The cobalt complex (V) has been isolated and its thermal stability and chemical properties have been investigated.[51] Metal oxallyl complexes of this type are models of the active intermediates in enzyme reactions with participation of coenzyme $B_{12}$.[35]

In the presence of hydrogen the hydrogenation of αβ-unsaturated carbonyl compounds proceeds as a catalytic reaction. Cobalt carbonyls[55] or $Na_2Co(CN)_5$[31,51,56,57] are more often used as catalysts. The intermediate complexes (VI)[31] and (VII)[51] have been detected spectroscopically in these reactions:



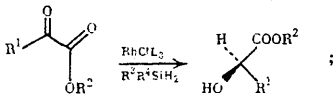
(VI) (VII)
R = H, Me; R' = H, Et R = Me, Et



Ruthenium catalysts, for example $RuCl_2(PPh_3)_3$ at 180 °C in a primary or secondary alcohol, have also been used for the catalytic reduction of αβ-unsaturated carbonyl compounds (Scheme 1, the phosphine ligands are not shown). The catalytic yield of the hydrogenation products was $10^4$–$10^5$%.[52]

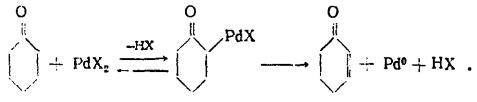
The reduction of αβ-unsaturated ketones in the presence of the complexes $IrXL_n$ (X = Cl, I, $ClO_4$; L = o-phenanthroline, bipyridyl, or substituted bipyridyls) and KOH in ethanol proceeds analogously with a high catalytic yield.[54]

Scheme 1



The reduction of prochiral olefins catalysed by rhodium complexes with chiral phosphine ligands takes place stereoselectively and leads to the formation of (*R*)- or (*S*)-substituted α-aminoacid esters with an optical purity of 85–89%.[53,58,59] The intermediate complexes (VIII) and (IX) have been isolated and characterised:[59,59]

R¹=H, Ph; R²=H, Me; R³=H, Me, Ph.

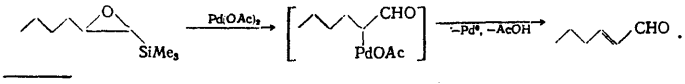


The reduction of α-ketoacids esters by silanes, catalysed by rhodium complexes with chiral ligands, for example, (*R*)-(+)-benzylmethylphenylphosphine, makes it possible to obtain (*R*)-lactates with an optical purity of 30–85%.[60] The mechanism of this reaction is probably similar to that quoted above:

R¹ = Me, Ph; R² = Et, n-Bu, iso-Bu, Ph;
R³ = R⁴ = Me, Et, Ph.

#### (b) Dehydrogenation

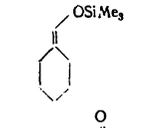
With the aid of the metal complexes, it is possible to achieve the αβ-dehydrogenation of carbonyl compounds. Palladium(II) compounds are as a rule used for this purpose: $PdCl_2$,[3,4,12] $PdCl_2(MeCN)_2$,[61] $PdCl_2(PhCN)_2$,[4,5,12] $PdCl_2$·$(PhCN)_2$–AgOTf,[62] $PdCl_2(PPh_3)_2$,[23] $Pd(OAC)_2$,[12,63,64] and $Pd(OAc)_2$–dppe.[65,67]† The dehydrogenation proceeds via a stage involving the formation of oxallyl complexes of palladium(II), which have been in many instances isolated and characterised:[12]

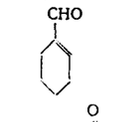


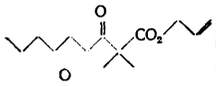
The reactivity of aliphatic and alicyclic ketones in the dehydrogenation reaction catalysed by $PdCl_2(PhCN)_2$ decreases in the sequence cyclohexanone > cyclopentanone > cyclo-octanone > 2-heptanone ≅ 4-heptanone, i.e. cyclic ketones are more reactive than aliphatic ones.[4] Dicyclic ketones are dehydrogenated less effectively than monocyclic ones.

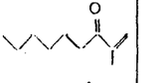
The oxidative decarboxylation of salts of carboxylic β-keto-acids when these interact with $PdCl_2(PPh_3)_2$ also leads to αβ-unsaturated ketones.[23]

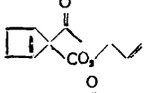
αβ-Unsaturated β-aminoketones have been synthesised by dehydrogenating β-aminoketones with the aid of $PdCl_2L_2$ (L = MeCN) in the presence of triethylamine in 50–95% yield.[61]

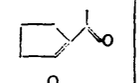


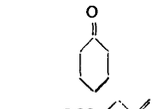


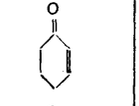


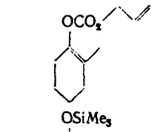


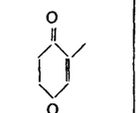


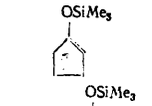


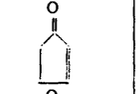


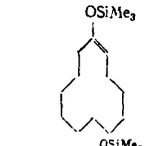


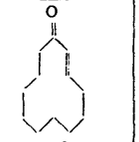


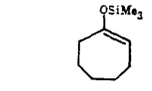


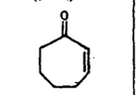


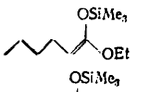


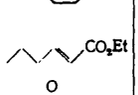


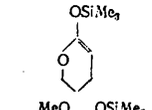


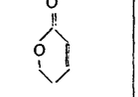


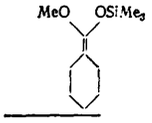


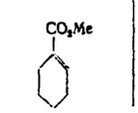












A somewhat unusual method of synthesis of αβ-unsaturated aldehydes and ketones from αβ-epoxysilanes has been proposed:[63]

†Tf = $CF_3SO_2$ and dppe = diphenylphosphinoethane.

Apart from the dehydrogenation of carbonyl compounds and their derivatives by a stoichiometric amount of palladium(II), catalytic versions of this reaction have been developed in recent years (Table 2). The simplest of these is the catalytic dehydrogenation of ketones with the aid of $Pd(OCOCF_3)_2/Cu(OCOCF_3)_2/O_2$ system.[6] The reaction can be carried out catalytically also in the presence of methylallyl carbonate, which behaves as an oxidant in relation to zerovalent palladium (Scheme 2).[67,68] Methylallyl carbonate is consumed in the course of this reaction with formation of $CO_2$ and propene. The silyl ethers of enols are usually employed in this catalytic system.[67]

**Table 2.** Catalytic dehydrogenation of carbonyl compounds and their derivatives in the presence of palladium complexes.*

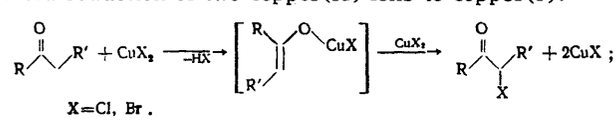
*[substrate]/[Pd] = 10—100.
**AMC = allyl methyl carbonate.

Note. Numbers in square brackets denote references (Ed. of Translation).

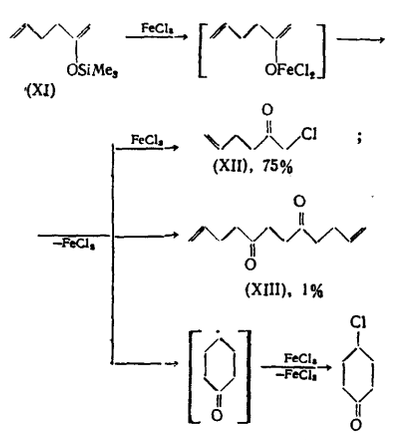
The αβ-unsaturated ketones are formed via an analogous mechanism from enol acetates in the presence of methylallyl carbonate[69] and also from allylenol carbonates[67] and the allyl esters of carboxylic β-ketoacids.[66] In all these catalytic reactions the common key intermediates are mixed allyloxallyl complexes of palladium (X) (see Scheme 2).



Scheme 2

(X)

(c) Halogenation

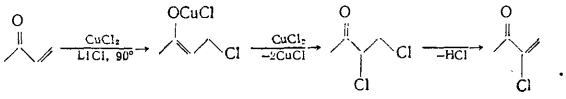


Copper(II) and iron(III) salts are used as a rule for the halogenation of carbonyl compounds (aldehydes, ketones, and esters). The α-halogenocarbonyl compound is formed on halogenation by copper salts probably as a result of the concerted reduction of two copper(II) ions to copper(I):[70]

X=Cl, Br.

The relative reactivity of aliphatic ketones in the reaction with $CuCl_2$ varies in the sequence 2,2-dimethyl-3-pentanone (0.05) < 3-methyl-2-butanone (0.25) < 2-butanone (0.5) ≅ 2-hexanone (0.5) < acetone (1.0). The following sequence has been obtained for cycloalkanones: cyclobutanone (0.01) ≪ cyclopentanone (0.38) < 2-methylcyclohexanone (0.53) < 4-t-butylcyclohexanone (0.94) < cyclohexanone (1.0).[71]

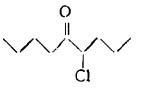
α-Halogenoketones have also been obtained by the interaction of the silyl ethers of enols with $CuCl_2$ or $FeCl_3$ at 20 °C in dimethylformamide (DMF) or MeCN respectively (Table 3). In the presence of $FeCl_3$, the diketone (XIII) and chlorocyclohexanone (XIV) are also formed from the ether (XI) in addition to the main product (XII), which may indicate a cryptoradical mechanism of the chlorination reaction:[14]

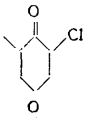


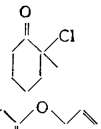
(XI)

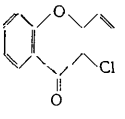
(XII), 75%

(XIII), 1%







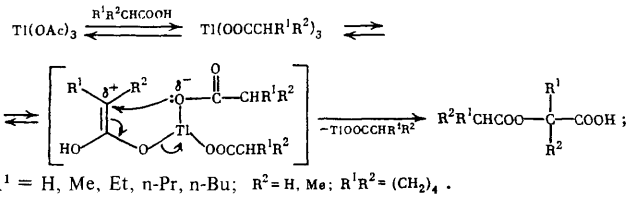


(XIV), 24%

The halogenation of αβ-unsaturated carbonyl compounds also proceeds with retention of the double bond in accordance with the following postulated scheme:[70]

The halogenation of acetylenecarboxylic acid esters with copper chloride or bromide leads to esters of αβ-dihalogeno-substituted αβ-unsaturated acids.[72]

Table 3. The synthesis of α-chloroketones from the corresponding silyl ethers.[14]*

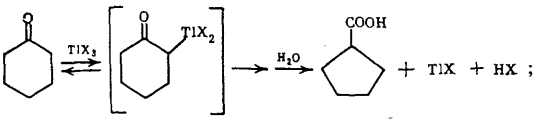


| Metal chloride | α-Chloroketone | Yield, % |
|---|---|---|
| $CuCl_2$ |  | 65 |
| $CuCl_2$ |  | 70 |
| $CuCl_2$ |  | 58 |
| $CuCl_2$ |  | 58 |
| $FeCl_3$ |  | 76 |
| $CuCl_2$ |  | 61 |

*Solvent—DMF ($CuCl_2$) or MeCN ($FeCl_3$); molar ratio ether/salt = 1:(2–3) for $CuCl_2$ and 1:(4–5) for $FeCl_3$; reaction temperature 20 °C.

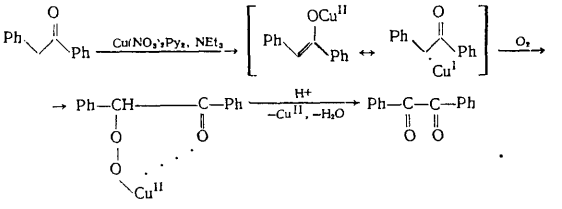
(d) Oxidation

The oxidation of carbonyl compounds by metal salts can also proceed via two pathways: with formation of compounds having a functional group in the α-position or oxidative cleavage products.



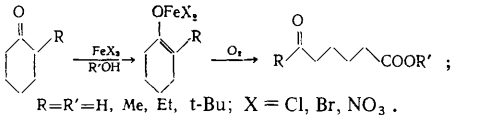
When thallium(III) carboxylates are heated in an excess of carboxylic acid (120–160 °C), α-acetoxyacids are formed[73] in 65–96% yield, thallium(III) being reduced under these conditions to thallium(I). A reaction mechanism involving the formation of an enolate complex has been proposed:

$R^1$ = H, Me, Et, n-Pr, n-Bu; $R^2$ = H, Me; $R^1R^2 = (CH_2)_4$.



Branched carboxylic acids are oxidised by thallium(III) acetate less effectively than acids having the straight-chain structure. The reactions involving the use of mercury[74] and lead[74] carboxylates proceed analogously.

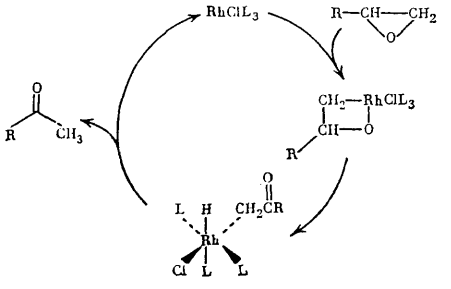
The oxidation of cyclohexanone by thallium(III) ions leads to the formation of cyclopentanecarboxylic acid:[75]



X = OAc.

When certain ketones and esters are oxidised by oxygen in the presence of catalysts (pyridinecopper complexes), α-diketones or α-ketoacid esters are formed in 40–70% yield:[76–78]

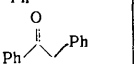
The alkyl esters of carboxylic 6-ketoacids have been obtained in 65–95% yield by oxidising 2-alkylcyclohexanones or the acetates of the corresponding enols with oxygen in an alcohol–benzene medium at 60 °C, the reaction being catalysed by iron(III) salts [ketone/Fe(III) = 20–50]. The reaction also probably takes place via the intermediate formation of the oxallyliron(III) complex:[79]

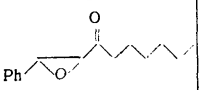


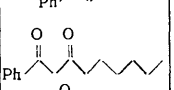
R=R′=H, Me, Et, t-Bu; X = Cl, Br, $NO_3$.

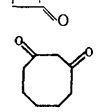
(e) Isomerisation of Epoxides and Other Compounds

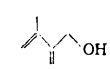
1,2-Epoxides are isomerised to carbonyl compounds in the presence of palladium, rhodium, or ruthenium catalysts (Table 4). The mechanism of the isomerisation reaction (Scheme 3) has been investigated in relation to catalysis by rhodium complexes.[80,81] The oxallyl complex (XV; R = Me or Ph; L = $PMe_3$), formed as an intermediate as a result of the oxidative addition of the epoxide to $ClRhL_3$ and subsequent transfer of the β-hydrogen atom, has been isolated and characterised.[80] The rate of isomerisation of *trans*-stilbene oxide to benzyl phenyl ketone, catalysed by the complexes $(p\text{-}XC_6H_4P)_3RhCl$, increases in the following sequence of substituents X: Cl < H < Me < OMe.

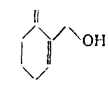












Scheme 3

The phosphine complexes of ruthenium[82] are less effective isomerisation catalysts than the rhodium complexes.

The isomerisation of α-ketoepoxides catalysed by $Pd(PPh_3)_4$ leads to 1,3-diketones,[83] while the isomerisation of the monoepoxides of 1,2-dienes using the same catalysts affords either substituted allyl alcohols or βγ-unsaturated carbonyl compound, depending on the structure of the epoxide.[84]

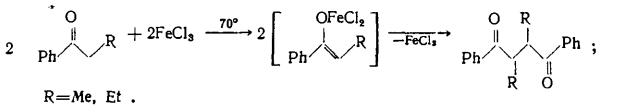
*In the examples quoted, the degree of conversion of the epoxide was ~85–95% and the yield of product with respect to the epoxide which has reacted was ~100%.

Note. Numbers in square brackets denote references (Ed. of Translation).

The isomerisation of phenyl-substituted epoxides in the presence of $Fe(CO)_5$ is a stoichiometric reaction and takes place only under the influence of UV irradiation.[85]

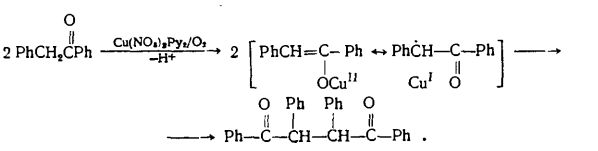
The isomerisation of trimethylsilyl-substituted allyl alcohols (XVI), catalysed by $HRh(CO)(PPh_3)_3$ in the presence of a small amount of α-trimethylsilylketone (1 mole per mole of the complex) at 105 °C in benzene, leads to trimethylsilyl enol ethers:[86]



(XVI)

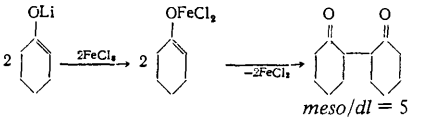
R = n-$C_5H_{11}$, n-$C_{10}H_{21}$, Ph, $C_6H_{11}$.

## 2. Reactions with Formation of New C=C Bonds



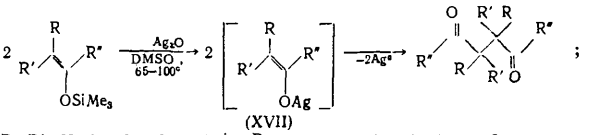
### (a) Dimerisation of Carbonyl Compounds and Their Derivatives

One-electron oxidants, namely iron(III) and copper(II) salts, $TiCl_4$, or $Ag_2O$, are used for the dehydrodimerisation of carbonyl compounds. Thus the dehydrodimerisation of alkyl aryl ketones in the presence of $FeCl_3$ leads to substituted 1,4-diketones in 50–85% yield relative to the oxidant:[87]



R=Me, Et .

1,4-Diketones are formed analogously from 2-butanone and 2-methyl-4-pentanone, but in a smaller yield (25–35%), when acted upon by the pyridine complex of copper(II) in the presence of $PPh_3$ in methanol at 40 °C.[77] The dehydrodimerisation of deoxybenzoin in the presence of pyridine-copper complex and oxygen proceeds as a catalytic reaction:[76]

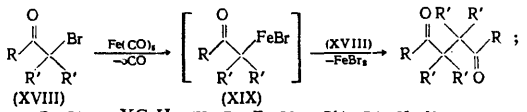


Lithium enolates[88,90] and silyl ethers of enols[91] have also been used as the starting compounds for the synthesis of 1,4-diketones. For example, the oxidative dimerisation of the lithium enolate derived from cyclohexanone, catalysed by $FeCl_3$, leads to a mixture of diastereoisomeric diketones with the *meso*-isomer predominating:[88]

*meso*/*dl* = 5

The yield of the 1,4-diketone obtained from the lithium t-butyl methyl ketone enolate is also influenced by the nature of the anion in the copper salt:[89] $CuCl_2$ (92) > $CuBr_2$ (64) > $Cu(acac)_2$ (60) > $Cu(OAc)_2$ (24).

It is believed that the reaction of silyl ethers of enols with $Ag_2O$ proceeds with the intermediate formation of the silver enolate (XVII):[15]



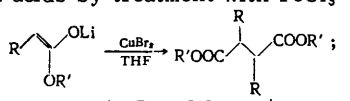
(XVII)

R=R′=H, Me; R″=Me, Et, iso-Pr, Ph; R, R′=$(-CH_2-)_n$; n=3, 10 .

The yield of the 1,4-diketone (mixture of *meso*- and *dl*-diastereoisomers) is 40–80% and diminishes with increase of the number and bulk of the substituents at the double bond of the silyl enol ether.

The mechanism of the reaction of the enolate (XVII) has not been considered, but it has been shown[92] that $n\text{-}C_4H_9Ag(PPh_3)$ decomposes with formation of n-octane probably via a homolytic mechanism in the coordination sphere of silver ions (via an intermediate dinuclear complex).

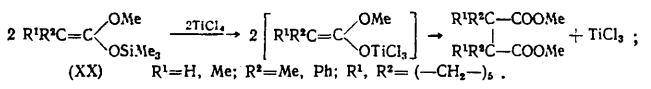
1,4-Diketones can be obtained by the reductive dimerisation of α-halogenoketones. When α-bromoketones (XVIII) were allowed to interact with $Fe(CO)_5$ in dimethoxyethane at 95–100 °C, 1,4-diketones were synthesised in 30–65% yield, depending on the structure of the substituents:[2]



(XVIII) (XIX)

R=Ph, $p$-$XC_6H_4$ (X=Br, F, OMe, Ph); R′=H, Me.

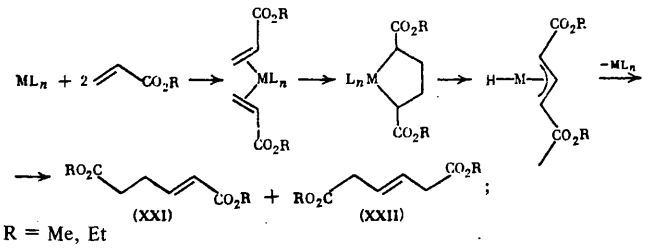
The intermediate oxallyl iron complex (XIX, $R = p$-$PhC_6H_4$, $R' = H$) has been isolated and characterised.



The esters of substituted succinic acids have been obtained in 50–85% yield from the lithium enolates derived from carboxylic acids by treatment with $FeCl_3$ [88] and $CuBr_2$: [93]

R=H, Me, Ph, iso-Pr, n-$C_5H_{11}$; R′ = Et, t-Bu.

The mechanism of this reaction is apparently analogous to that of the dimerisation of ketones and their derivatives.

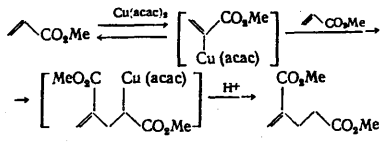


Carboxylic acid derivatives, namely the silyl esters (XX), are also converted into dimeric products—substituted succinic esters (mixture of *meso*- and *dl*-diastereoisomers)—on interaction with $TiCl_4$. The yield is 75–80%.[16] These esters are obtained in a low yield in reactions with copper(II) and iron(III) halides:[16]

(XX) R¹=H, Me; R²=Me, Ph; R¹, R²=(—$CH_2$—)$_5$.

The "tail to tail" dimerisation of αβ-unsaturated carbonyl compounds is catalysed by palladium and rhodium complexes.[94,95] The main product of the dimerisation of methyl acrylate in the presence of $[(C_2H_4)_2RhCl]_2$ or $PdCl_2(PhCN)_2$ catalysts and Lewis acids ($FeCl_3$, $AgBF_4$, and $AgPF_6$) is the unsaturated ester (XXI) containing 90% of the *trans*-isomer [(XXI)/(XXII) = 9] (Scheme 5).

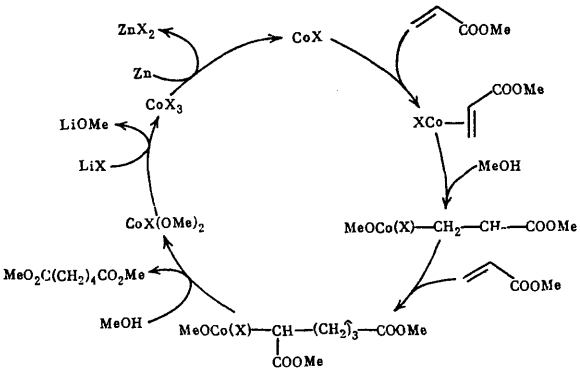
Scheme 5



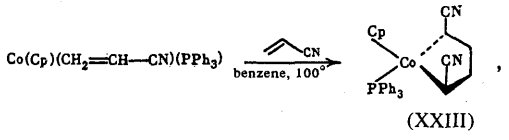
R = Me, Et

The number of catalytic cycles in the presence of the rhodium catalyst at 75 °C reaches 280.

Copper(II) acetylacetonate and CuO catalyse the "head to tail" dimerisation of methyl acrylate in the presence of t-butyl isocyanide in t-butyl alcohol (olefin/Cu = 50). The catalytic yield of the dimerisation product is 50–550% (Scheme 6).[96]



Scheme 6

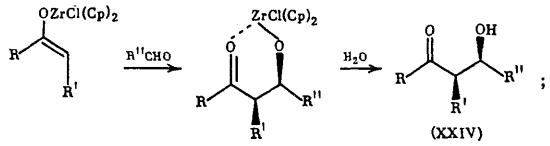


Saturated "tail to tail" dimers have been obtained (2–11 moles per mole of the catalyst) by the hydrodimerisation of methyl vinyl ketone and acrylate esters in methanol on treatment with metallic zinc in the presence of $[Co(bipy)_3]ClO_4$ or $CoBr(PPh_3)_3$.[97,98] The hydrodimerisation of methyl acrylate catalysed by cobalt complexes leads to the dimethyl ester of adipic acid in 25–90% yield relative to the initial acrylate and 50–700% yield relative to the catalyst,[99] the yield of the ester depending on the nature of the anion in the complex $CoX(PPh_3)_3$ and increasing in the following sequence of substituents X: Cl < Br < I.

The proposed reaction mechanism is presented in Scheme 7.[99]

Scheme 7

In the given instance one probably cannot rule out also a mechanism similar to that discussed above for the dimerisation of acrylates in the presence of palladium and rhodium catalysts (see Scheme 5).[95] This is indicated, in particular, by the fact that the intermediate complex (XXIII) (in the form of two geometrical isomers) was isolated in the presence of cobalt catalysts:[100]



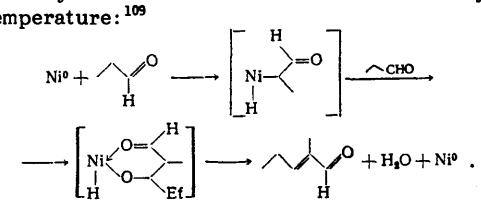
(XXIII)

(b) The Aldol and Crotonic Condensations and Similar Reactions

The use of transition metal complexes makes it possible to achieve the stereo-selective synthesis of aldols from carbonyl compounds and their derivatives.

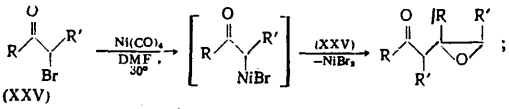
The zirconium enolates derived from ketones and acid esters and amides, obtained from $ZrCl_2(Cp)_2$ and the corresponding lithium enolates, react with aliphatic and aromatic aldehydes at −78 °C in tetrahydrofuran (THF)[101,102] with formation of more than 90% of the *erythro*-aldol (XXIV):

(XXIV)



R = OMe, O-t-Bu, S-t-Bu, $N(CH_2)_4$, N(iso-Pr)$_2$, Et,
R′ = Me; R, R′ = (-$CH_2$-)$_3$, (-$CH_2$-)$_4$; R″ = n-Pr, n-Bu, Ph.

The greatest stereoselectivity (95–99%) has been observed for the reaction of zirconium enolates obtained from acid amides with aldehydes having nitrogen-containing heterocyclic substituents.[103] The hydrolysis of the amides yielded the corresponding carboxylic *erythro*-β-hydroxy acids.



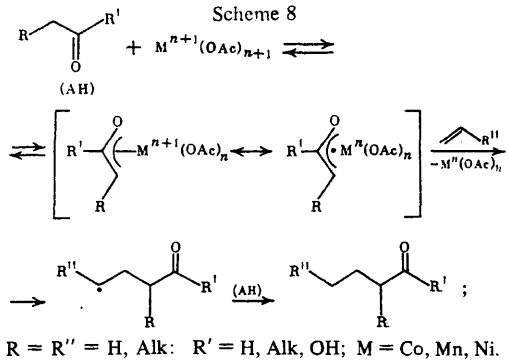
Titanium(IV),[42,104] mercury,[105] and tin[106] enolates react analogously in the presence of $BF_3.OEt_2$ with aliphatic and aromatic aldehydes, forming 70–90% of the *erythro*-aldol. The reaction can also be carried out catalytically using the silyl ethers of enols, for example, when the latter interact with α-alkoxyaldehydes in the presence of $TiCl_4$.[107] The

reaction of silyl ethers of enols with optically active α-keto-acid esters in the presence of $TiCl_4$ leads to the formation of aldols with two optically active centres.[108] The extent of the asymmetric induction (35–70%) is in this case much higher than in the case where organomagnesium compounds are employed.

Complexes of zerovalent nickel, for example (bipy)Ni.$(PPh_3)_2$, catalyse the crotonic condensation of aldehydes at room temperature:[109]

The aldol condensation of α-bromoketones in the presence of $Ni(CO)_4$ leads to substituted βγ-epoxyketones in 50–85% yield:[110]

(XXV)



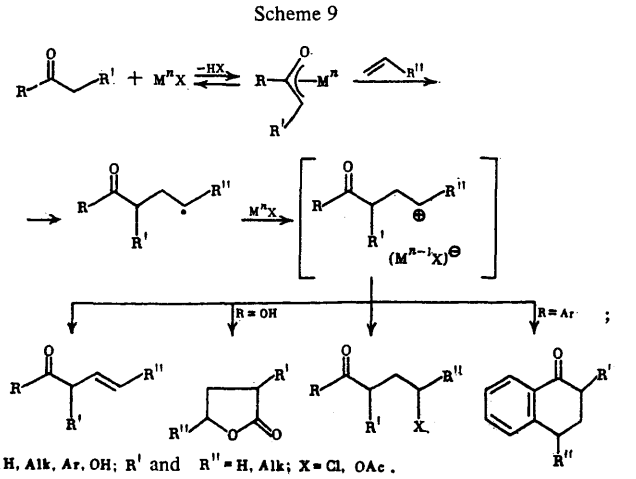
R = Me, Et, t-Bu; R′ = H, Me.

This is the simplest and most effective of the existing methods of synthesis of βγ-epoxyketones.

(c) Alkylation of Carbonyl Compounds

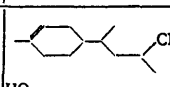
The α-alkylation of aldehydes, ketones, and carboxylic acids by olefins has been achieved on treatment with $Mn(OAc)_3$[111,112] or the redox systems $Mn(OAc)_2/O_2$[113] and $Co(OAc)_2/O_2$[113] (Table 5). The study of the characteristics and kinetics of the alkylation of aldehydes led to a catalytic mechanism of the reaction involving the intermediate formation of oxallyl complexes in which the oxallyl ligand has a radical character (scheme 8):[114]

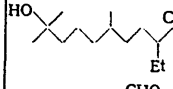
Scheme 8

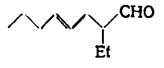


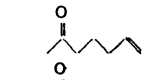
R = R″ = H, Alk: R′ = H, Alk, OH; M = Co, Mn, Ni.

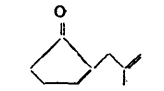
In terms of their selectivity in the α-alkylation reaction, the catalysts can be arranged in the following sequence:[113] Co(II) > Mn(II) ≅ Ni(II) > Ce(III) > Cr(III).

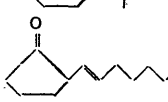


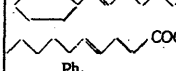


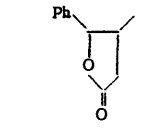










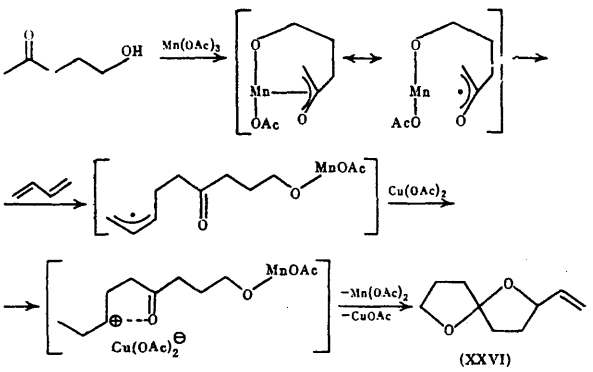


The reaction involving the homolytic *oxidative addition* of aldehydes, ketones, and carboxylic acids to multiple bonds is important for synthetic purposes. Its difference from the alkylation reaction considered above consists in the oxidation of the intermediate adduct-radical to a carbonium ion intermediate. Depending on its structure and the reaction conditions, the latter is capable of reacting via different pathways, for example, β-elimination with formation of an ethylenic bond, of cyclising to a substituted lactone,[118–121] tetralone, and similar compounds,[122] or of interacting with external nucleophiles to form products substituted by functional groups in the γ-position[111,115,119,123] (Scheme 9):

Scheme 9

R = H, Alk, Ar, OH; R′ and R″ = H, Alk; X = Cl, OAc.

Table 5. The synthesis of α-alkyl-substituted carbonyl compounds.



| Carbonyl compound | Unsaturated compound | Initiating system* | t, °C | α-Alkylation product | Yield % | Refs. |
|---|---|---|---|---|---|---|

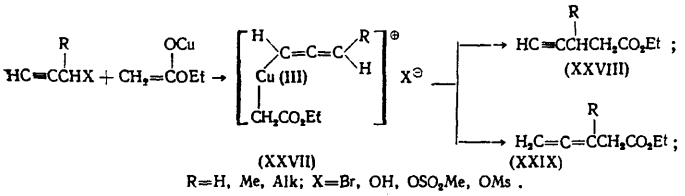
| » | *trans*-β-methyl-styrene | Mn(III) | 135 |  | 79 | [117] |

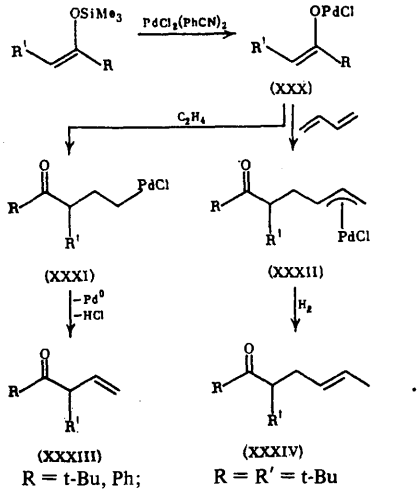


*Metal acetates were used.

Note. Numbers in square brackets denote references (Ed. of Translation).

Other pathways are also possible in this reaction. Thus the vinyl-substituted spiroketal (XXVI)—the direct precursor of chalcogran, which is a pheromone of the conifer bark beetle,[124] has been obtained by the reaction of acetylpropyl alcohol with butadiene catalysed by the $Mn(OAc)_3/Cu.(OAc)_2$ system (Scheme 10). Vinyl-substituted 2,8-dioxa-*cis*-bicyclo[3.3.0]octane is formed together with the spiroketal (XXVI) in this reaction.[124] The reaction of acetone with butadiene proceeds analogously:[124]

Scheme 10



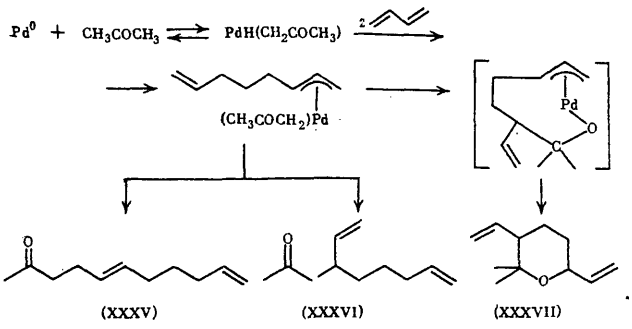
(XXVII) (XXIX)

R=H, Me, Alk; X=Br, OH, $OSO_2Me$, OMs .

The reactions of the oxallyl complexes of copper(I), obtained from the corresponding lithium enolates, with propargyl alcohol and its derivatives result in the formation of the substituted allenes (XXIX) in 45–70% yield. The acetylenic compound (XXVIII) is formed as a side product in this reaction with the ratio (XXIX)/(XXVIII) = 10–20 : 1. The use of lithium enolate in the above reaction leads to only the acetylenic compound (XXVIII). The authors explain the difference by the fact that, in the case where copper enolates are used, the unstable complex (XXVII) is formed as an intermediate.[125]

Palladium(II) complexes have been used in another group of reactions of carbonyl compounds with olefins and dienes. In the presence of $PdCl_2(PhCN)_2$, the silyl ethers of enols react with ethylene and butadiene.[13] The reaction proceeds via the intermediate formation of the palladium enolate (XXX). The complexes (XXX) are isolated in a dimeric form. The reaction of the complex (XXX) with ethylene at 50 °C and a pressure of 50 atm leads to the βγ-unsaturated ketone (XXIII) in 60–75% yield, while the reaction with butadiene leads to the allyl complex (XXXII), whose reduction with hydrogen afforded the γδ-unsaturated ketone (XXXIV) in 65-90% yield (Scheme 11):

Scheme 11



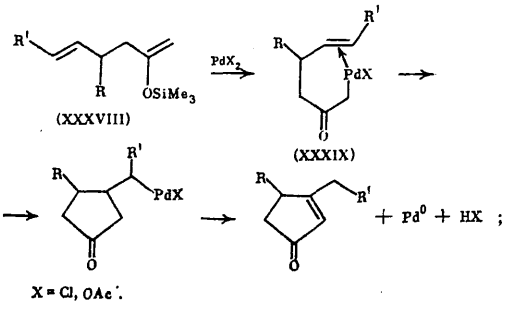
(XXXIII) (XXXIV)

R = t-Bu, Ph; R′ = t-Bu

R = R′ = t-Bu

Palladium complexes, for example $Pd(PEt_3)_4$, also catalyse the addition of two butadiene molecules to acetone[126] (Scheme 12).

Scheme 12



(XXXV) (XXXVI) (XXXVII)

The reaction results in the formation of the isomeric unsaturated ketones (XXXV) (*trans* : *cis* = 10) and (XXXVI) in proportions of 10 : 1 in 11% yield and also 2,2-dimethyl-3,6-divinyltetrahydropyran (XXXVII) (*cis* : *trans* = 3) in 20% yield. The comparatively low yields of the products (XXXV)–(XXXVII) are associated with the side reaction involving the catalytic dimerisation of butadiene to octa-1,3,7-triene. When the trimethylphosphine ligand is replaced by the triphenylphosphine ligand in the initial palladium complex, only the dimerisation of butadiene takes place.

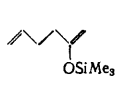
The reaction of cycloalkanones with butadiene in the presence of a palladium catalyst[127] leads to 2-alkadienylcycloalkanones, whose structure is analogous to that of the ketones (XXXV) and (XXXVI) (the ketone with the unbranched substituent predominates). In terms of their reactivity, the cycloalkanones can be arranged in the following sequence: $C_5 > C_8 \cong C_6 > C_7$. The yield of the addition products is 5–30% relative to the initial compound and (3–25) × $10^3$% relative to the catalyst.

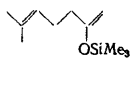
The αβ-unsaturated cycloalkanones have been obtained by cyclising the unsaturated silyl enol ethers (XXXVIII) in the presence of palladium(II) compounds[128,129] (Scheme 12a).

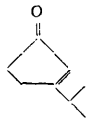
Scheme 12a

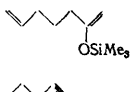
X = Cl, OAc .

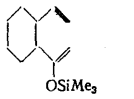
The intermediate oxallyl complexes (XXXIX, R = Ph, R′ = H; RR′ = $(-CH_2-)_{3-5}$] have a dimeric structure. They have been isolated and characterised by physicochemical methods.[129]

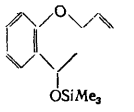












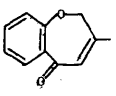


Table 6 presents the known examples of the cyclisation of unsaturated silyl enol ethers catalysed by $Pd(OAc)_2$ in acetonitrile.

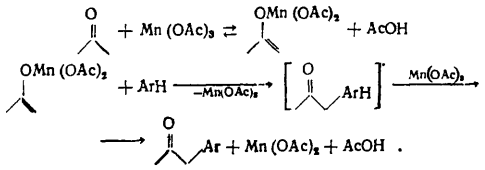
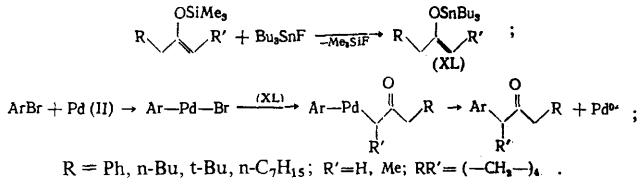
(d) Arylation of Carbonyl Compounds

The reactions of acetone with aromatic and heteroaromatic compounds catalysed by $Mn(OAc)_3$ make it possible to introduce the acetonyl group into the aromatic ring under comparatively mild conditions (50–80 °C).[130,131] The reactions



with naphthalene, furan, and thiophen proceed exclusively at the α-carbon atom of the aromatic ring. The yield of 3-aryl-2-propanones is 40–95% with respect to the oxidant.

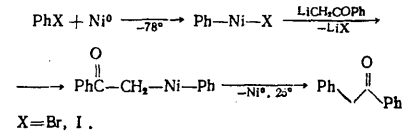
Table 6. The synthesis of αβ-unsaturated cyclic ketones.[129]*



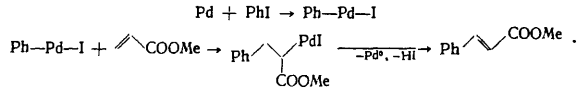
| Silyl enol ether | Ketone | Yield, % |
|---|---|---|
|  |  | 87 |
|  |  | 40** |
|  |  | 36 |
|  |  | 99 |
|  |  | 25 |

*$Pd(OAc)_2$/(silyl enol ether) = 1:1, MeCN, 20 °C.
**Oxidant—$PdCl_2(PhCN)_2$.

In monosubstituted benzenes substitution takes place predominantly in the *ortho*-position in the benzene ring, electron-donating substituents in the ring facilitating the reaction.[131] The reactivities of aromatic compounds in the reactions with acetone decrease in the following sequence: sylvan [α-methyfuran] > furan ≅ naphthalene > thiophen > anisole > benzene ≅ chlorobenzene > benzonitrile.[132] The following reaction mechanism has been proposed:



The α-arylation of aliphatic and cyclic ketones is achieved by the interaction of trimethylsilyl ethers of enols or enol acetates with ArBr (Ar = Ph or substituted phenyl) in the presence of $Bu_3SnF$ [133] or $Bu_3SnOMe$ [134] and $PdCl_2[P(o\text{-}MeC_6H_4)_3]_2$ (ArBr/Pd = 30–100) as the catalyst at 80–100 °C in benzene or toluene. The yield of α-aryl-substituted ketones is 30–100%:



R = Ph, n-Bu, t-Bu, $n\text{-}C_7H_{15}$; R′=H, Me; RR′ = $(-CH_2-)_4$.

α-Aryl-substituted carbonyl compounds have also been obtained by the reaction of phenyl halides with $LiCH_2COPh$ in the presence of $Ni(PPh_3)_4$ [PhX/Ni(0) = 4].[135] The mechanism of this reaction is similar to that quoted above:

X=Br, I.

β-Aryl substituted carbonyl compounds can be obtained by the reaction of aryl halides with αβ-unsaturated carbonyl compounds. Thus the reaction of iodobenzene with methyl acrylate (PhI/Pd = 30), catalysed by metallic palladium (palladium black), at 125 °C in acetic acid in the presence of sodium acetate leads to the formation of methyl cinnamate in accordance with the following suggested mechanism:[136]

When $Pd(PPh_3)_4$ is used as the catalyst, bromobenzene and substituted aryl bromide also enter into this reaction.[137]

The reactions of benzene with α-substituted chalcones in the presence of $Pd(OAc)_2$ (chalcone/Pd = 1–15) in acetic acid lead to saturated or unsaturated ββ-diphenyl-substituted ketones, depending on the structure of the chalcones[138] (Table 7):

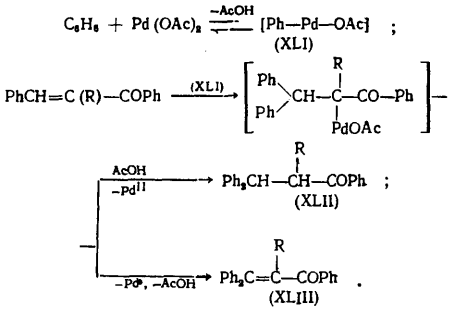


Table 7. The yields (%) of the products of the reactions of benzene with chalcones in the presence of $Pd(OAc)_2$*[138]

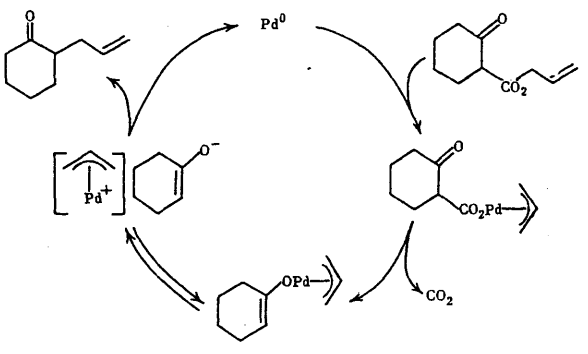
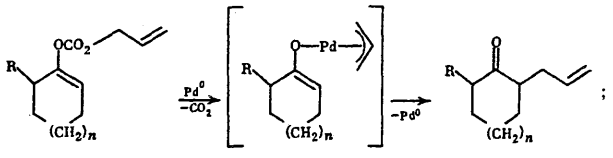


| Product | R | | | | | |
|---|---|---|---|---|---|---|
| | H | Ph | COPh | $NO_2$ | $CO_2Et$ | $CH_2Ph$ |
| (XLII) | 25 | — | 52 | 20 | 12 | — |
| (XLIII) | 75 | 46 | 8 | — | 56 | 66 |

*[chalcone]/[Pd] = 1:1.

(e) α-Allylation of Carbonyl Compounds

A convenient method for the introduction of alkenyl groups into the α-position in carbonyl compounds is based on the use of mixed allyloxallyl complexes of palladium(II) (XLIV) which are formed, for example, from allyl β-ketocarboxylates (Scheme 13).[23]

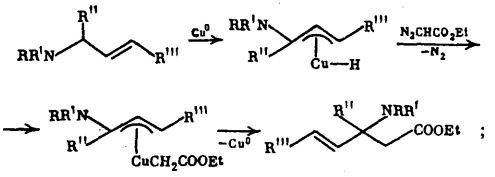


Scheme 13

(XLIV)

In the presence of $Pd(PPh_3)_4$ (ester/Pd = 20), α-allyl-substituted alkanones and cycloalkanones were obtained at room temperature in 60–95% yield.

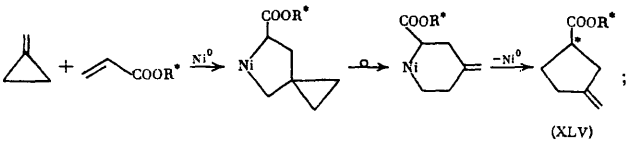
α-Allyl-substituted carbonyl compounds are also synthesised from allyl carbonates at 0 °C in dimethoxyethane:[139]



R = H, Me; $n = 0, 1$.

The complexes $Ni[P(OEt)_3]_4$, $RhH(PPh_3)_4$, and $Mo(CO)_6$ can be used as catalysts of this reaction in addition to $Pd(PPh_3)_4$.[140] However, more severe conditions are required (60–110 °C).

Apart from the two reactions examined above, the syntheses of α-allylalkanones and α-allylcycloalkanones by the reaction of silyl enol ethers[64,141] or enol acetates[142] with allyl methyl carbonate in the presence of $Pd(dppe)_2$ and also by the reaction of allyl acetates with tributyltin enolate in the presence of $Pd(PPh_3)_4$ [143] at 20–80 °C in dioxan or THF have been described.

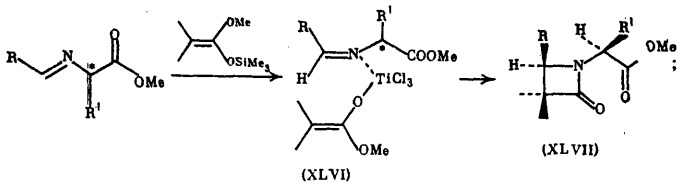


The reactions of ethyl diazoacetate with allylamines (allylamine/metal = 40), catalysed by the $Cu(acac)_2/AlEt_3$ and $Rh_2(OAc)_4/AlEt_3$ systems in the presence of $PEt_3$, $PBu_3$, or pyridine in benzene at 20 °C, lead to esters of β-amino-β-vinyl-substituted carboxylic acids in 20–60% yield.[144] The reaction probably proceeds via the following mechanism:

$RR' = (-CH_2-)_5$, $(-CH_2-)_2-O-(-CH_2-)_2$;
R'' = H, Me; R''' = H, Me, $C_5H_9$.

(f) Cycloaddition to αβ-Unsaturated Carbonyl Compounds

Zerovalent nickel complexes catalyse the cycloaddition of strained molecules, for example, methylenecyclopropane and its derivatives [initial compound/Ni(0) = 30] to αβ-unsaturated ketones and acrylates with formation of substituted methylene-cyclopentanes in 60–90% yield.[145] The reaction is stereoselective. Thus esters of 3-methylenecyclopentanecarboxylic acid (XLV) having two chiral centres have been obtained from methylenecyclopropane and optically active acrylate esters in the presence of Ni(cyclo-octadiene)$_2$ (ester/Ni = 100) at −20–+40 °C. The degree of the asymmetric induction for the second chiral centre is 25–65%.[146]

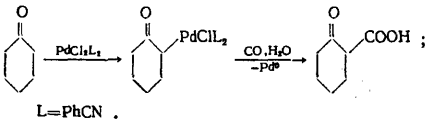


(XLV)

R* = (−)-bornyl, (−)-menthyl, (−)-8-phenylmenthyl.

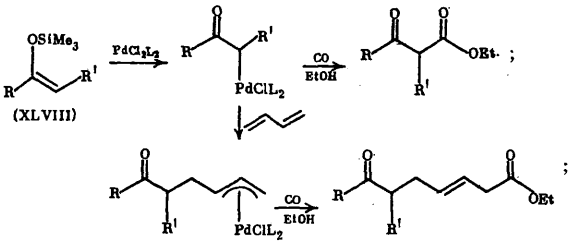
The cycloaddition of bicyclo[2.1.0]pentane in methyl acrylate, dimethyl maleate, and dimethyl fumarate, catalysed by $Ni(CH_2{=}CHCN)_2$, probably proceeds via a similar mechanism.[147,148]

The reaction of the *O*-trimethylsilyl derivatives obtained from methyl isobutyrate with the Schiff bases obtained from aldehydes and chiral α-aminoethers in the presence of $TiCl_4$ leads to the formation of β-lactams with high regio- and stereo-selectivities.[149,150] Its mechanism involves the formation of the titanium(IV) enolate (XLVI) (detected by spectroscopic methods), which undergoes intramolecular cyclisation with formation of the β-lactam (XLVII), having the (*S*,*R*)-configuration to the extent of 60–99%:



(XLVI) (XLVII)

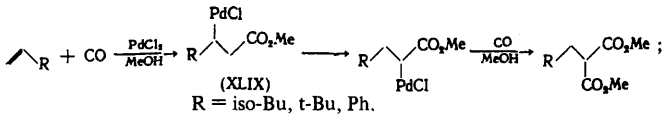
R = Et, iso-Pr, iso-Bu; R′ = Me, iso-Pr, $CH_2Ph$, $CH_2COOMe$.



(g) Reactions with Participation of Carbon Monoxide

When the oxallyl complexes of palladium are acted upon by carbon monoxide, carboxylic β-ketoacids are formed in 40–75% yield:[4]

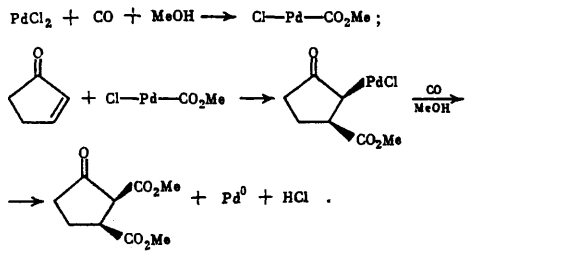
L=PhCN.



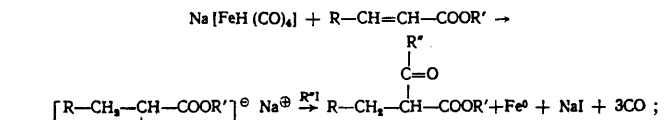
The esters of carboxylic β-ketoacids have been synthesised in 85–100% yield by carbonylating in an alcoholic medium the palladium complexes obtained from silyl enol ethers (XLVIII) (50 °C, 50 atm CO pressure); in the presence of butadiene, the above reaction leads to esters of unsaturated ketoacids:[13]

(XLVIII)

L = PhCN; R = t-Bu, Ph; R′ = t-Bu.



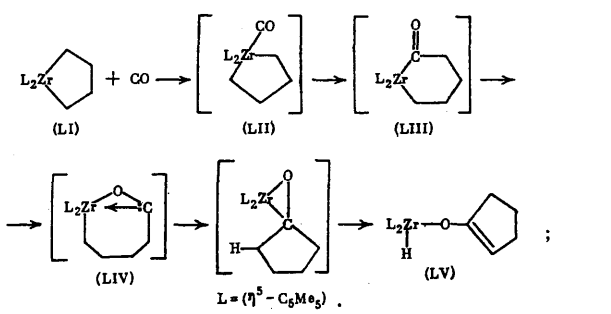
The esters of alkylmalonic acids can be obtained by the carbonylation of alkenes, catalysed by $PdCl_2$, in the presence of an excess of $CuCl_2$,[151] probably via a medium involving the rearrangement of the organopalladium intermediate (XLIX):



(XLIX)

R = iso-Bu, t-Bu, Ph.

The carbonylation of αβ-unsaturated ketones, catalysed by the $PdCl_2/CuCl_2$ system (ketone/Pd = 10–50, 20 °C, 3 atm CO pressure), leads to esters of substituted succinic acids.[152] The reaction with cyclopentenone results in the 99% yield of the ester of *cis*-3-oxocyclopentane-1,2-dicarboxylic acid:

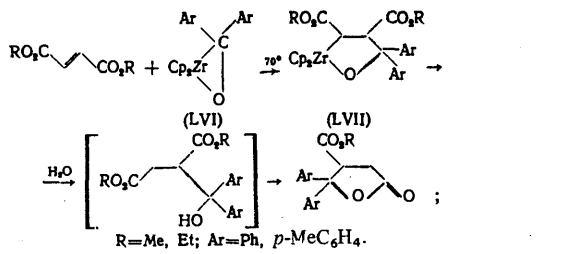


The hydroacylation of esters of αβ-unsaturated carboxylic acids takes place in THF at 20–50 °C with participation of $Na[FeH(CO)_4]$ (stoichiometric amount) and allyl iodide; the yield of β-ketoacid esters is 50–80%.[153] The intermediate oxallyl complex (L, R = H, R′ = Me) was isolated and characterised:

(L)

R=H, Me; R′=R″=Me, Et .

The carbonylation of alkylzirconium complexes leads to the formation of derivatives of carbonyl compounds in high yields (80–95%).[43,154,155] Thus the zirconium complex (LI) readily combines with CO at 25 °C to form the white crystalline enolate (LV), which is quantitatively converted into cyclopentanone on treatment with HCl.[43] The reaction probably proceeds via the successive formation of the carbonyl intermediates (LII), the acyl intermediate (LIII), and the carbenoid intermediates (LIV):

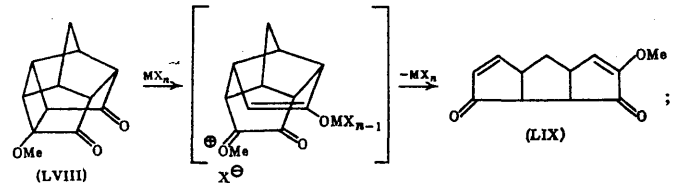


(LI) (LII) (LIII) (LIV) (LV)

L = ($\eta^5$-$C_5Me_5$) .

(h) Other Reactions

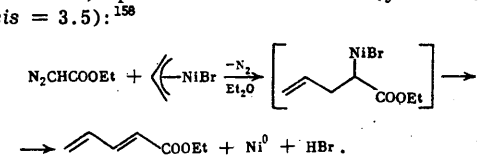
γγ-Diarylbutyrolactones have been synthesised in 80–85% yield by the reaction of maleate and fumarate esters with organozirconium compounds (LVI):



(LVI) (LVII)

R=Me, Et; Ar=Ph, *p*-$MeC_6H_4$.

The intermediate oxallyl complexes (LVII) have been detected by $^1H$ NMR.



The unsaturated diketone (LIX) has been obtained in 65–70% yield as a result of the catalytic decyclisation of the polycyclic ketone (LVIII) at 40 °C in benzene or $CHCl_3$ (ketone/$MX_n$ = 10):[157]

(LVIII) (LIX)

$MX_n = TiCl_4, PdCl_2$ .

The reaction of ethyl diazoacetate with (π-allyl)NiBr at 0 °C leads to 2,4-pentadienoic acid ester (yield 90%, *trans*/*cis* = 3.5):[158]

Thus examination of the data presented shows that the oxallyl complexes of transition metals plays an important role in the reactions of carbonyl compounds and their derivatives such as hydrogenation, oxidation, halogenation, dimerisation, alkylation, etc. Many of these reactions are catalytic and involve the formation and further reaction of oxallyl intermediates. The use of oxallylmetal complexes in stoichiometric and catalytic reactions makes it possible to synthesise various carbonyl compounds under mild conditions with a high regioselectivity and, in a number of instances, also high stereoselectivity.

The chemistry of oxallyl complexes of transition metals constitutes a branch of metal complex catalysis which has been rapidly developing since the middle 1970's. There is every reason to suppose that further studies on these lines will lead to the creation of new highly selective catalytic methods for the synthesis of carbonyl and other oxygen-containing compounds.

---o0o---

During the preparation of the review for the press, additional data were published in the literature. In particular, the oxallyl complexes of molybdenum, tungsten, and rhenium were synthesised from α-chloroketones.[159] Titanium(IV) enolates have been obtained by treating aliphatic ketones, aldehydes, and carboxylic acid esters or amides with $Cp_2Ti{=}CH_2$.[160] The isomerisation of an acyl complex of iron in a primary aliphatic alcohol in the presence of $HOSO_2CF_3$ resulted in the synthesis of the corresponding oxallyl complex.[161] The oxallyl complexes of rhodium(III) have been

obtained by the reaction of aliphatic alkanones with octaethylporphyrin complexes of rhodium.[162,163] The oxallyl complexes of ruthenium(II) (mixture of two stereoisomers) have been synthesised by the reaction of $HRuCl(CO)(PPh_3)_3$ with dimethyl fumarate.[164]

A review has been devoted[165] to the isomerisation of 1,2-epoxides in the presence of phosphine complexes of rhodium(I) and iridium(I).

Cerium enolates, obtained from the corresponding lithium enolates derived from ketones, react with alicyclic ketones or aromatic aldehydes at −78 °C, forming a *threo*-aldol in more than 90% yield[166] (when zirconium enolates are used, mainly the *erythro*-aldol is obtained[101,102]). The aldol condensation of vinyl ketones with aldehydes at 40–110 °C in the presence of $HRh(PPh_3)_4$ affords β-hydroxy-α-methyleneketones in 30–460% yield relative to the catalyst.[167]

The interaction of lithium or rhodium enolates derived from ketones or carboxylic acids with esters of αβ-unsaturated acids or with vinylketones in the presence of iron carbonyls leads to carboxylic acid esters substituted by a functional group in the β-position.[168–170]

A convenient method of synthesis of heterocyclic compounds involves the intramolecular alkylation of unsaturated esters or amides of α-halogeno-substituted carboxylic acids, catalysed by zerovalent palladium or nickel complexes.[171–173] The palladium complexes are more effective in this reaction than the nickel complexes.

Another example of the intramolecular alkylation is provided by the synthesis of bicyclic ketones from the trimethylsilyl ethers of the enols of α-allylcyclohexanones catalysed by $Pd(OAc)_2$.[174]

The reaction of $PPh_3$ with CO and acetone, catalysed by $[RhCl(CO)_2]_2$ led to the synthesis of α-benzylacetone in a yield of 2.2–11 moles per mole of the catalyst.[175]

Depending on the conditions, the stoichiometric reaction of 1,1-dibromocyclopropanes with $Ni(CO)_4$ leads to cyclopropanecarboxylic acid esters or amides or the corresponding γδ-unsaturated derivative.[176–178]

αβ-Unsaturated bicyclic ketones have been obtained by the intramolecular cyclisation of alkeneacetylenic [vinyl ethynyl?] ethers with participation of $Co_2(CO)_8$ and CO.[179]

The reaction of vinyl triflates with acrylic monomers, which results in the formation of β-cyclohexenyl-substituted αβ-unsaturated carboxylic acid aldehydes, esters, or amides, proceeds via a stage involving the formation of intermediate oxallyl complexes.[180]

# Intramolecular [4 + 2] Cycloaddition

M.S.Salakhov and S.A.Ismailov

The results of studies in intramolecular [4 + 2] cycloaddition carried out in recent years are surveyed. The synthetic possibilities of this reaction for the preparation of natural products and its high stereoselectivity and regioselectivity are demonstrated. The differences and similarities between intramolecular and intermolecular [4 + 2] cycloaddition reactions are elucidated.
The bibliography includes 207 references.

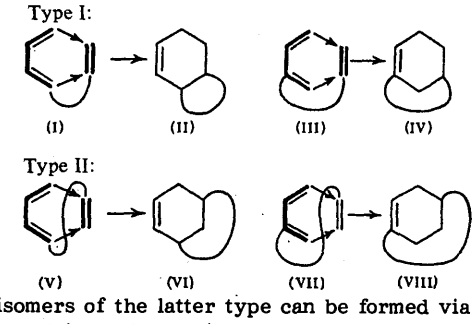
## I. INTRODUCTION



The study of the intramolecular [4 + 2] cycloaddition {IAMC[4 + 2]} reaction has attracted much attention by investigators[1-3] owing to the specific possibilities of the synthesis of polycyclic natural products, in particular sesquiterpenes, antibiotics, alkaloids, vitamins, etc., with its aid[4] and also because of its high stereoselectivity and regioselectivity which makes it possible to synthesise many skeletal structures which are difficult to obtain by other methods.[5-11] Although it is believed[1-3] that the first IAMC[4 + 2] reaction was described in 1953 by Alder,[12] who discovered the diene synthesis in 1928,[13] one should note that it was known as early as 1948 in relation to the Diels–Alder intramolecular reaction of cyclooctatetraene.[14] The existing reviews in the literature[1-3] devoted to the IAMC[4 + 2] reaction cover the period between 1953 and 1978. After the appearance of these reviews, the number of publications on this field increased greatly. In these communications attention was concentrated on the treatment of the mechanism of this type of cycloaddition characterised by the concerted but non-synchronous formation of bonds, by supra- and also antara-facial interactions of the orbitals, the reactivity and selectivity of the interacting components, the influence of the side chain linking the diene and the dienophile on the structure of the transition state (TS), the influence of catalysts on the stereoselectivity and regioselectivity of the reaction, etc.

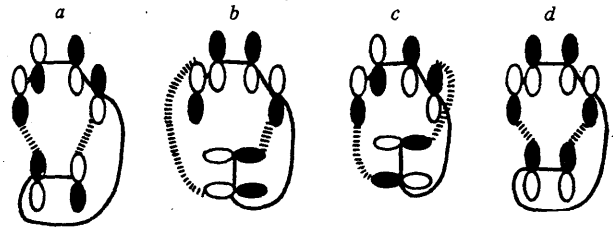
These and other problems are important for the elucidation of the mechanism of the Diels–Alder reaction in general and the IAMC[4 + 2] reaction in particular. In the present review we attempted to examine these problems concentrating attention on the publications covering the period 1979–1983.

## II. CHARACTERISTIC FEATURES OF INTRAMOLECULAR-[4 + 2]CYCLOADDITION

### 1. Stereoselectivity and Regioselectivity

Depending on the site where the dienophile fragment is linked to the diene fragment, the IAMC[4 + 2] reaction can lead to the formation of different isomers.[15] The different orientations of the reacting fragments in the TS [(I) or (V), (III) or (VII)] create additional possibilities for the formation of different regioisomers [(II) and (VI), (IV) and (VIII)]:

Regioisomers of the latter type can be formed via four pathways: (a) by the *s*,*s*-interaction of the HOMO of the diene and the LUMO of the dienophile; (b) by the *a*,*a*-interaction of the LUMO of the diene and the HOMO of the dienophile; (c) by the *a*,*a*-interaction of the HOMO of the diene and the LUMO of the dienophile; (d) by the *s*,*s*-interaction of the LUMO of the diene and the HOMO of the dienophile (Fig.1). However, the *s*,*s*-interactions (a) and (d) are geometrically unfavourable compared with the *s*,*s*-interactions for the TS (I) and (III).



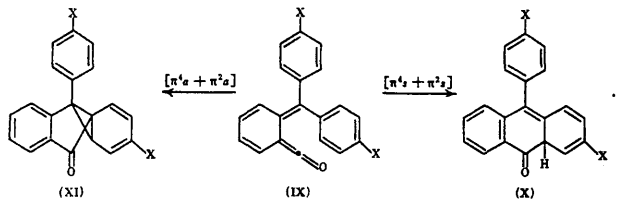


Figure 1. The possible pathways in the interaction of the diene and dienophile orbitals on formation of the regioisomers (VI) and (VIII).

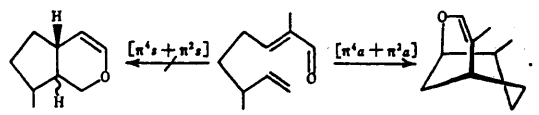
It is noteworthy that, by virtue of the presence of bridging chains of atoms between the diene and dienophile fragments, the TS for the IAMC[4 + 2] is electronically asymmetric and

the coefficients of the atomic orbitals of the diene and dienophile fragments should be different. This determines the *s,s*- or *a,a*-interaction between the diene and dienophile orbitals[16] and also the regioselectivity of the cycloaddition. The higher coefficients for C(4) and C(2′) and also for C(1) and C(1′) favour the *a,a*-interaction of the orbitals, while the higher coefficients for C(1) and C(2′) or C(1′) and C(4) favour the *s,s*-interaction, which is a feature distinguishing the regioselectivity of the IAMC[4 + 2] from the intermolecular [4 + 2]cycloaddition {IRMC[4 + 2]} (Fig. 2).

Thus knowing the structure of the final adduct, the HOMO and LUMO energies of the diene and the dienophile, and the coefficients of the atomic orbitals, it is possible to infer readily the pathway followed in the interaction of the orbitals. As an example, one may quote the IAMC[4 + 2] of the triene (IX), where norcaradiene (XI) was discovered instead of the expected product (X):[17,18]



(XI) (IX) (X)

The introduction of the electron-donating dimethylamino-substituent X increases the coefficient of the HOMO in the *p*-position in the benzene ring. On the other hand, the central carbon atom of the keten group, located in the plane of the π* orbitals, is electrophilic, so that the cycloaddition entails the formation of a bond between this atom and the *p*-carbon atom of the *NN*-dimethylaminophenyl group (Fig. 3).

Calculation of the total energy and of the coefficients of the frontier orbitals of the atoms in terms of the CNDO/2 approximation demonstrated that the HOMO of *NN*-dimethylaniline and the LUMO of the unsaturated keten differ little as regards energy and that the interaction between the corresponding fragments therefore gives rise to additional stabilisation in the TS in the cyclisation of the triene (IX).

The IAMC[4 + 2] of 2,6-dimethylocta-2,7-dienal (XII) using $BF_3$ as the catalyst affords a 47% yield of *exo*-4,8-dimethyl-2-oxabicyclo[3.3.1]non-3-ene (XIII), which is an intermediate in the synthesis of iridiomyrmycene—the insecticidal iridoid isolated from *Iridomyrmex himilus*:[19]

(XIV) (XII) (XIII)

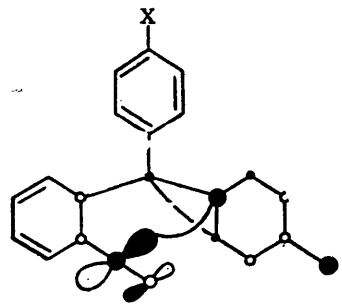


**Figure 3.** The antarafacial interaction of the orbitals in compound (IX).

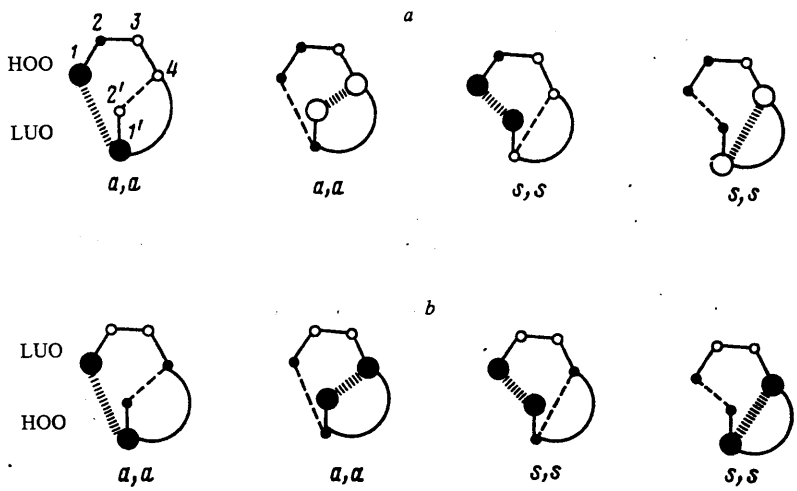
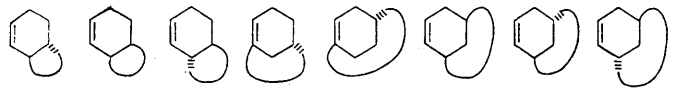
The catalyst apparently reduces the LUMO of the dienal in this reaction as a consequence of the formation of the complex[20] and thus favours the *a,a*-interaction of diene and dienophenyl orbitals, which results in the formation of the product (XIII) and not (XIV).





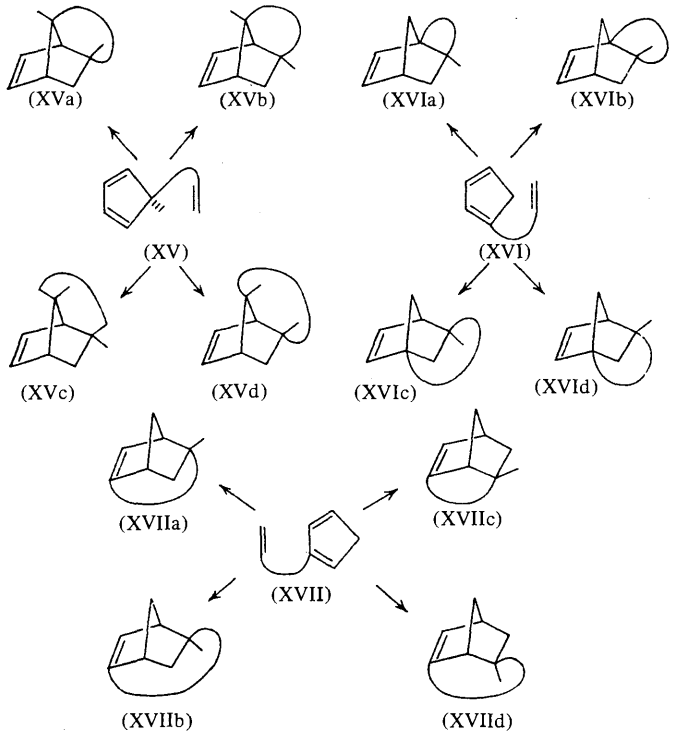


**Figure 2.** The regiospecificity in IAMC[4 + 2]; schematic representation of the atomic coefficients of the diene (*a*) and dienophile (*b*) orbitals.

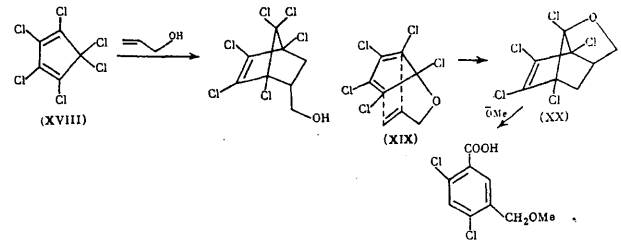
The structure of the TS in the cycloaddition reaction and the establishment of a particular configuration in the junction of the rings (*cis*- or *trans*-, *endo*- or *exo*-) undoubtedly depend on the *E*- or *Z*-configuration of the initial trienes. The trienes containing the buta-1,3-diene fragments can give rise to eight stereoisomers when account is taken of the *trans*- and *cis*-junctions in the adducts:

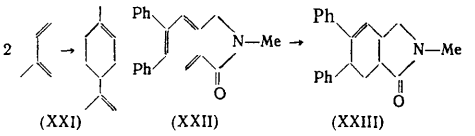
For the triene consisting of cyclopentadiene and ethylene fragments, one may expect formally the formation of twelve structures:



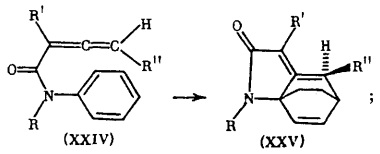
In contrast to the other structures, the formation of the isomers (XVa), (XVd), (XVIc), (XVIIb), and (XVIId) requires the twisting of the linking bridge chain.

## 2. Structure and Reactivity

It is self-evident that the structure of the substrate not only influences the stereochemistry of the reaction but also determines the substrate reactivity in the reactions investigated and the reactivities of the given reactant in different reaction series are therefore different. This leads to the question of the difference between the reactivities of the same diene in the IAMC[4 + 2] and IRMC[4 + 2] processes.



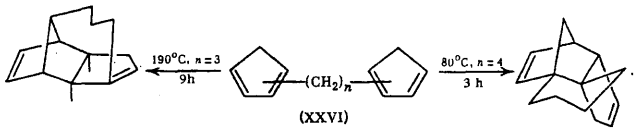
It is known[21] that the IRMC[4 + 2] of hexachlorocyclopentadiene (XVIII) to allyl alcohol proceeds under fairly severe conditions (125 °C, two days, sealed tube), while 5-allyloxy-1,2,3,4,5-pentachlorocyclopentadiene (XIX), obtained by nucleophilic substitution in the diene (XVIII) on treatment with allyl alcohol, is converted spontaneously into the final product (XX) at room temperature:[22]



A new rearrangement was observed on treatment of compound (XX) with sodium methoxide.[23]

The presence of substituents in the dienophile component of the triene does not prevent the occurrence of the IAMC[4 + 2] reaction. In this case steric factors probably predominate.

It is known[25] that the entropies of activation for pericyclic reactions, including IRMC[4 + 2], play a major role and that an increase of their negative values indicates a greater order in the system. It was expected that the TS in the IAMC[4 + 2] reaction would be more ordered than for the IRMC[4 + 2] reaction. However, there are virtually no suitable examples of such a comparison in the literature. Comparison of the $\Delta S^{\neq}$ for the dimerisation of isoprene and the IAMC[4 + 2] reaction of compound (XXII) to give the product (XXIII) showed that the value of $\Delta S^{\neq}$ obtained for the dimerisation of isoprene is more negative than for the reaction (XXII) → (XXIII) (−41 and −14.4 e.u. respectively), which is unexpected[2] and is apparently due to the non-synchronous formation of bonds in the IAMC[4 + 2].[26–29]



The IAMC[4 + 2] of the allene fragment to the benzene ring in compound (XXIV) proceeds readily with formation of the product (XXV), although such a thermal reaction is forbidden for IRMC[4 + 2]:[30]

R = Me, H, Ph;
R' = Me, H, $SiMe_3$;
R'' = H, $SiMe_2Ph$.

It is essential to take into account the fact that IAMC[4 + 2] does not always proceed at a higher rate than IRMC[4 + 2]. For example, the dimerisation of cyclopentadiene takes place readily at room temperature,[31] but the IAMC [4 + 2] of the polymethylenecyclopentadienes (XXVI, $n = 0 - 12$),[32] requires more severe conditions:

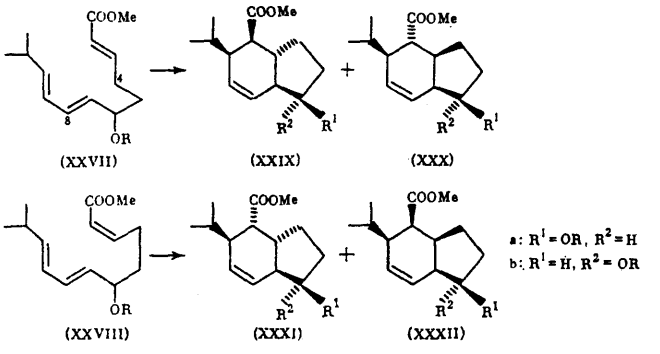
It follows from the data in Table 1 and the information contained in the earlier reviews[1–3] that the reactivity of the trienes is significantly determined by the length and conformational characteristics of the bridge chain linking the diene and dienophile fragments in the triene.

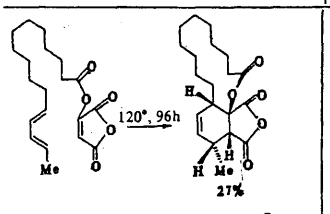
## III. THE FORMATION OF ANNELATED SYSTEMS

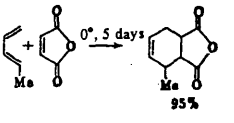
### 1. The 6/5-Annelated System

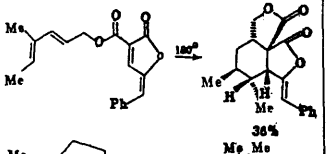
Vigorous study of the formation of the 6/5-annelated cyclic system (condensed rings consisting of six- and five-membered fragments) is being prosecuted mainly by three groups of investigators.[39–44,49–53]

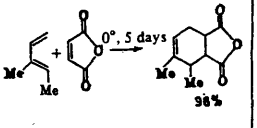
In order to study the possibility of the total synthesis of (±)-dendrobine, the stereochemistry of the IAMC[4 + 2] of methyl (*E*,*E*,*E*)- and (*Z*,*E*,*E*)-6-alkoxy-11-methyldodeca-2,7,9-trienoates (XXVII) and (XXVIII) was examined:[39]

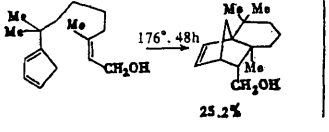


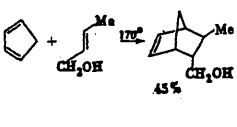












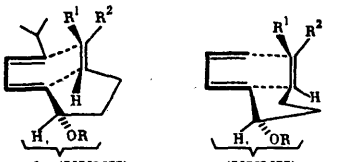


Table 1. The influence of the side chain connecting the diene and the dienophile on the parameters of IAMC[4 + 2] compared with IRMC[4 + 2].

| IAMC[4 + 2] | Refs. | IRMC[4 + 2] | Refs. |
|---|---|---|---|
|  | [33] |  | [36] |
|  | [34] |  | [37] |
|  | [35] |  | [38] |

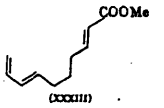
It was established that in all cases *trans*-hexahydroindene rings [compounds (XXIX) and (XXXI)] are formed to a greater extent than the *cis*-isomers (XXX) and (XXXII). A decrease of the reaction temperature favours the formation of the *trans*-isomers (XXIX) and (XXXI). The TS in the boat form, which leads to the formation of the isomers (XXXIIa, b) is unfavourable owing to the steric interaction between the H atoms of the C(8) atom and the OR group, which accounts for the ratio (XXX)/(XXXII) found in the reaction products. Analysis of the molecular model showed that such geometry is more readily achieved in the TS leading to the *trans*-joined products [*endo*-(XXVII) and *exo*-(XXVIIIa)] than in the TS leading to the *cis*-joined products [*exo*-(XXVII) and *endo*-(XXVIIIa)].

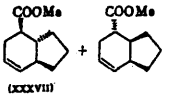
*endo*-(XXVII) *exo*-(XXVII)
*exo*-(XXVIIIa) *endo*-(XXVIIIa)

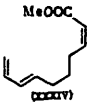
This effect is believed to be sufficiently large to compete with Alder's *endo*-rule in determining the stereochemical consequences of the cyclisation of the triene (XXVIIIa).

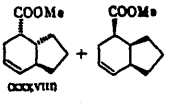
The predominance of the *trans*-isomers (XXXVII), (XXXVIII), (XXXIX), and (XL) is also observed in the IAMC[4 + 2] of methyl deca-2,7,9-trienoates (XXXIII), (XXXIV), (XXXV), and (XXXVI) (Table 2).[40,41]

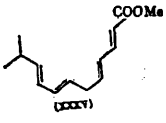
Table 2. IAMC[4 + 2] of methyl deca-2,7,9-trienoates.[40,41]

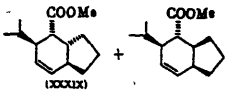


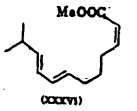


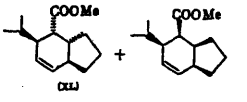


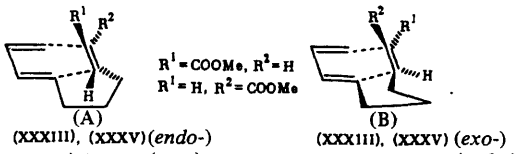












| Trienes | Conditions | Products | Yield, % | *trans*/*cis* |
|---|---|---|---|---|
|  (XXXIII) | 150°, 24h |  (XXXVII) | 65 | 60:40 |
|  (XXXIV) | 180°, 5h |  (XXXVIII) | 75 | 65:35 |
|  (XXXV) | 150°, 40h |  (XXXIX) | 72 | 72:28 |
|  (XXXVI) | 180°, 5h |  (XL) | 75 | 67:33 |

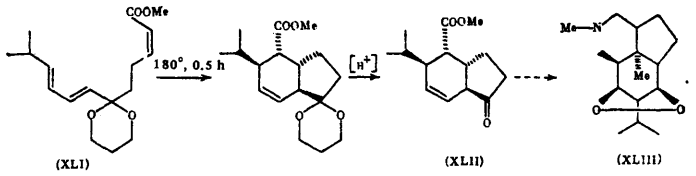


Table 2 shows that the selectivity for the *trans*-joined adducts does not in essence depend on the stereochemistry of the dienophile and the *endo*-rule is undoubtedly a consequence of the cyclisation of the trienes (XXXIV) and (XXXVI). The secondary orbital interaction does not influence the consequences of the cyclisation of the *trans*-trienes (XXXIII) and (XXXV), since it stabilises the *endo*-TS. The breakdown of the *endo*-rule may be a consequence of the strain in the TS (B) compared with (A), which hinders the formation of the boat conformation of the cyclohexene ring in the TS (B).

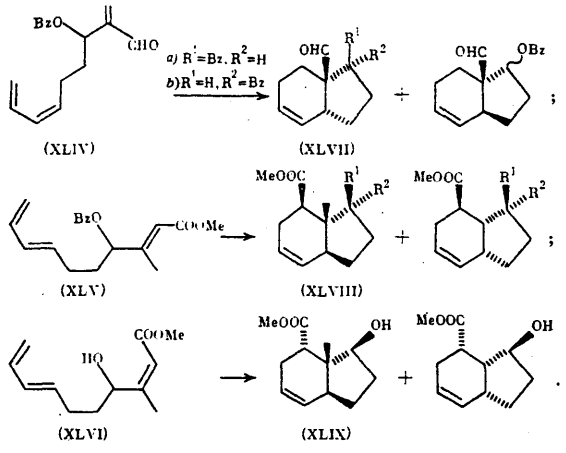
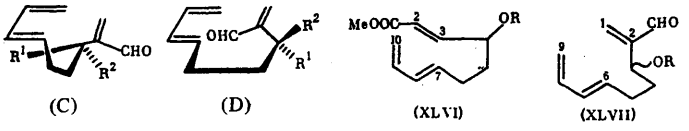
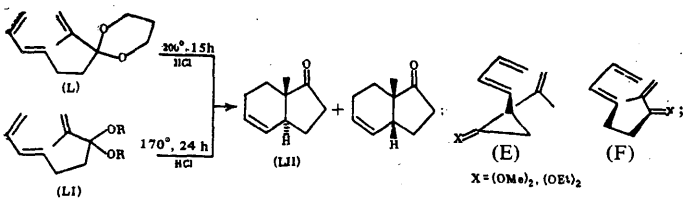
Furthermore, steric interactions between the hydrogen atoms of the methylene group in the 4-position and of the methylidyne group in the 8-position are observed only for



the TS (B), where these atoms are in the eclipsed positions.

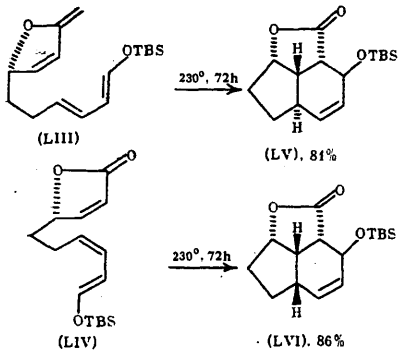


The unusual *trans*-stereoselectivity of the IAMC[4 + 2] for the triene (XLI) ensured the success of the key stage in the improved synthesis of hexahydroindenone (XLII), which is a precursor of dendrobine (XLIII): [42,43]

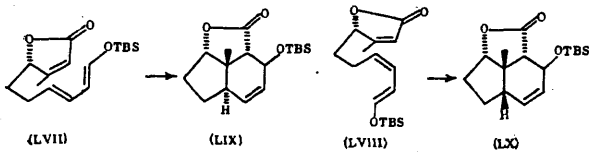


The IAMC[4 + 2] of the angularly methyl-substituted trienes (XLV) and (XLVI) also gives rise predominantly to the *trans*-isomers (XLVIII) and (XLIX); [44] the adducts obtained are important structural elements in the synthesis of derivatives of vitamin D:

It is of interest that the cyclisation of compound (XLIV) exhibits the opposite behaviour—preferential *cis*-selectivity. The main product derived from the triene (XLIV) is obtained from the TS (C) in which the aldehyde group occupies an *exo*-position relative to the diene. However, the *cis*-joined TS (C) is energetically less favourable than the *trans*-(D). It has been established that the LUMO coefficients for C(1) and C(9) are higher than for C(2) and C(6). This fact is crucial in the formation of the *cis*-isomer (XLVII) and the concerted rather than the synchronous interaction of the orbitals of the diene in the dienophile is therefore preferable.

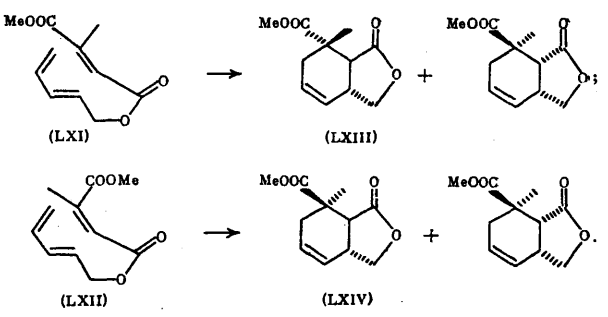


The preferable formation of the angularly substituted *trans*-hydroindenone (LII), containing an oestrogen fragment, is observed in the thermolysis of the trienes (L) and (LI): [45,46]

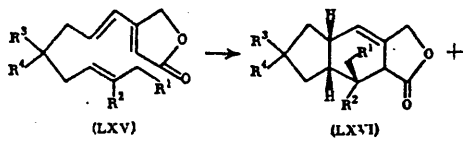


The *endo*-TS (E) is characterised by an appreciable steric hindrance owing to the interaction between one of the alkoxy-groups and the butadiene system, where the corresponding *exo*-TS (F) is more stable.

The *trans*-hydroindene system, which is a synthon for 11-deoxyprostaglandin and 11-ketosteroid, has been synthesised from the triene (LIII) and (LIV): [47]

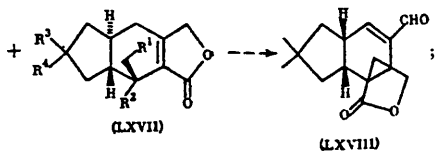


It is of interest that the *E*,*E*-triene (LIII) affords only the *trans*-product (LV), while the cyclisation of the *E*,*Z*-triene (LIV) leads exclusively to the *cis*-isomer (LVI). The results of investigations have demonstrated the preferential *exo*-orientation of the butenolide fragment in the TS for the cyclisation reaction. The angularly methyl-substituted analogues of these trienes also react entirely stereoselectively, i.e. *E*,*E*-(LVII) → (LIX) and *E*,*Z*-(LVIII) → (LX):



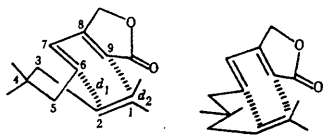
It has been suggested that the rigid structure of the butenolide promotes the necessary orientation of the dienophile in the TS in view of the stereoselectivity of the IAMC[4 + 2] reaction.

The IAMC[4 + 2] of the esters of mesoconic acid (LXI) and sorbyl citraconate (LXII) gives rise preferentially to the *trans*-isomers (LXIII) and (LXIV): [48]



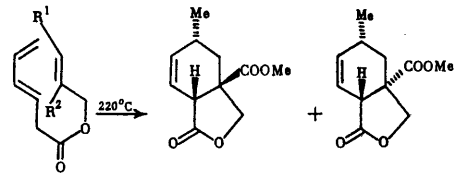
The *trans*:*cis*-ratio is 4.3:1.

The *trans*-stereoselectivity of the cyclisation is also observed in the IAMC[4 + 2] of the triene (LXV), which leads to the synthesis of marasmic acid (LXVIII)—a sesquiterpene antibiotic: [49–51]



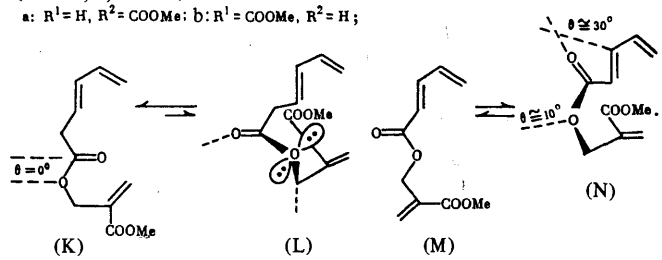
(LXV) (LXVI)

$R^3 = R^4 = Me$
$R^1 = COOMe, CN, COOBu$
$R^2 = H, COOMe, CN$



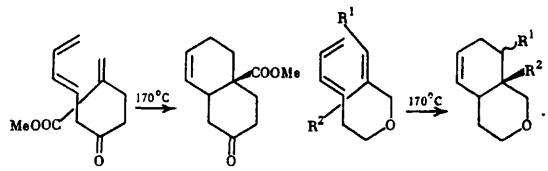
(LXVII) (LXVIII)

The main requirement for the formation of *trans*-hydroindenes is the non-bonding interaction of the diene and dienophile fragments, which leads to an asymmetric TS. The secondary orbital interaction is energetically incapable of overcoming the unfavourable non-bonding interactions in the TS, which leads to the *cis*-isomer:



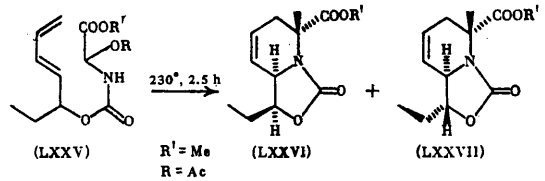
The absence of a steric effect of the substituents on the stereochemistry of the cyclisation can be accounted for by the asymmetric TS in which the distance $d_1$ between the C(6) and C(2) atoms is smaller than the distance $d_2$ between the C(9) and C(1) atoms. This is due to the greater coefficients of the MO at C(2) than at C(1) as a consequence of the strong polarisation of the dienophile fragment of the molecule by the substituents at C(1). Kinetic data have shown that the rate of cyclisation is strongly influenced by the nature of the substituents in the triene. The higher rate of cyclisation when the substituent COOR is used at C(1) compared with CN is consistent with literature data[52] concerning the influence of the substituents (COOR > CN) on the rate of IRMC[4 + 2]. The relatively smaller increase of the rate of reaction by the second substituent COOR at C(1) compared with CN can be explained by the steric inhibition of the resonance as a consequence of the impossibility of a coplanar disposition of the two COOR groups and the C=C bond. It is assumed that the lower rate of cyclisation of the triene (LXV, $R^3 = R^4 = Me$) to the *trans*-hydroindene (LVII) compared with the corresponding *cis*-isomer is due to the fact that the introduction of the methyl groups into the connecting chain increases the fraction of the cisoid conformers with a disposition of the diene and dienophile favourable for cyclisation, which decreases $\Delta S^{\neq}$ by approximately 3 e.u.

The influence of the structure of the connecting chain on the formation of products has also been demonstrated in relation to the reactions of the trienes (LXIXa, b).[53] In both cases the IAMC[4 + 2] led to γ-lactones instead of the expected δ-lactones and the nature of the rearrangement is obscure:



(LXIXa, b) (LXXa)

a: $R^1 = H$, $R^2 = COOMe$; b: $R^1 = COOMe$, $R^2 = H$;

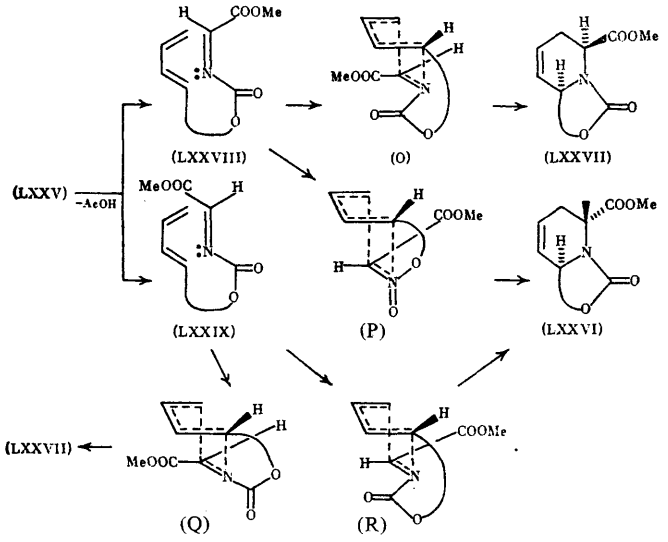


(K) (L) (M) (N)

It is believed that the rearrangement of the double bonds in the trienes (LXIXa, b) is the rate-limiting stage of the reaction. In the case of the TS (L) the dihedral angle between the π-system of the CO group and the unshared electron pair of oxygen should be 90°, which prevents the overlap of diene and dienophile orbitals. On the other hand, in the case of the TS (N) there are no such limitations and the IAMC[4 + 2] takes place readily. In order to confirm this, the IAMC[4 + 2] of the model compounds (LXXI) and (LXXIII), in which there is no ester group and hence there is no orbital interaction between the π-system of CO and the unshared electron pair at the oxygen atom, has been carried out. As was to be expected, this results in the formation of the cyclisation products (LXXII) and (LXXIV), which indicates the decisive role of the above interactions in the stereocontrol of the IAMC[4 + 2]:

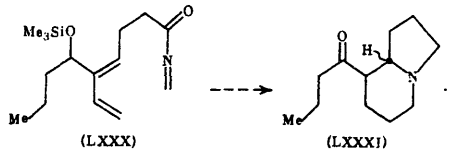
(LXXI) (LXXII) (LXXIII) (LXXIV)

In order to synthesise the spermidine alkaloids such as palustrine and anhydrocannabisativine, the IAMC[4 + 2] reactions of the triene (LXXV) have been investigated and it has been shown that its thermolysis proceeds entirely stereoselectively with formation of a mixture of the *trans*-products (LXXVI) and (LXXVII): [54–56]



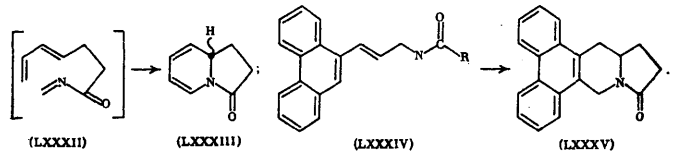
(LXXV) (LXXVI) (LXXVII)

$R' = Me$, $R = Ac$

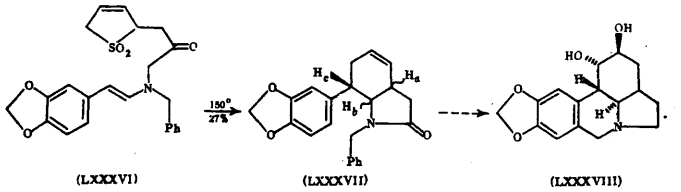


The yield is 59% and the isomer ratio is 55–45. It is assumed that the precursors of the products (LXXVI) and (LXXVII) may be the Z-imine (azamaleate) (LXXVIII) or the E-imine (azafurmarate) (LXXIX) obtained by the elimination of AcOH in the thermolysis of the diene (LXXV); the imines

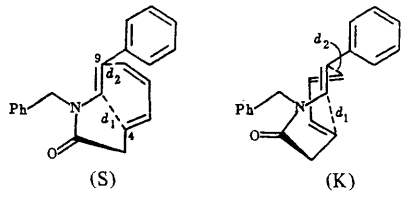
give rise to the corresponding cycloaddition products:



In contrast to Roush's hypotheses, the authors of the above studies[54–56] assume that the length of the bridging chain does not influence the stereochemistry of the final products and the *exo*-azamaleate TS (P) is energetically preferable to the TS (O). The TS (O) does not lead to the expected product; for this reason, the formation of the azamaleate in this process is rejected; the authors[54–56] suggest that the secondary orbital interaction between the CO group at the nitrogen atom and the diene component of the molecule is responsible for the stereocontrol of the cyclisation and that the latter proceeds via the azafumarate (LXXIX), which leads to the TS (I).

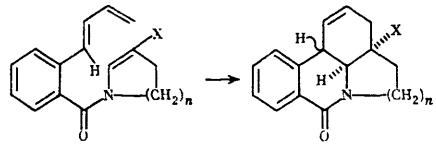


The IAMC[4 + 2] of the suggested intermediate dieneacylimine (LXXX) is the key stage in the synthesis of the alkaloid eleokanine A (LXXXI):[57]

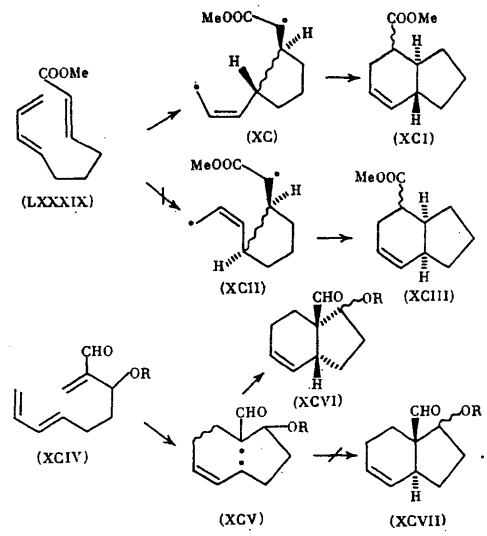


Two indolizidine alkaloids—α-coniceine (LXXXIII) and tylophorine (LXXXV)—have also been synthesised by the IAMC[4 + 2] of the trienes (LXXXII) and (LXXXIV):[58]

The *trans*-stereoselectivity of the cyclisation has been also observed in the synthesis of the antibiotic lycorine (LXXXVIII) from the triene (LXXXVI), as described by Martin et al:[59]

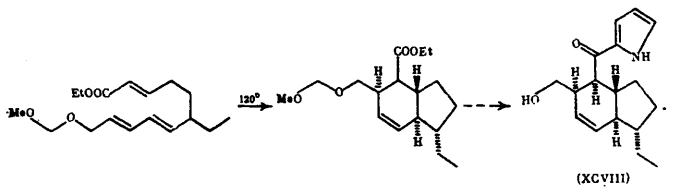


In order to interpret the stereochemical consequences, models of the concerted cycloaddition with an asymmetric biradical or zwitter-ionic TS have been considered.



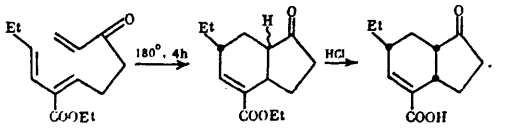
The relative rate of cycloaddition depends on the stabilisation of the radical centre by neighbouring groups. If the aryl substituent at C(9) stabilises the free radical to a greater extent than the nitrogen atom at C(8), the formation of the C(4)–C(8) bond will be preceded by the formation of the C(1)–C(9) bond, i.e. $d_2 < d_1$ for the TS (K). Thus one can predict the stereochemistry of the cyclisation; in the case considered the *trans*-stereoselectivity of the reaction is observed and the TS (S) should lead to a *cis*-joined product.

The galanthan system, which constitutes the nucleus in many *Amaryllidacaea* alkaloids, has been synthesised with the aid of IAMC[4 + 2] in accordance with the scheme[60]



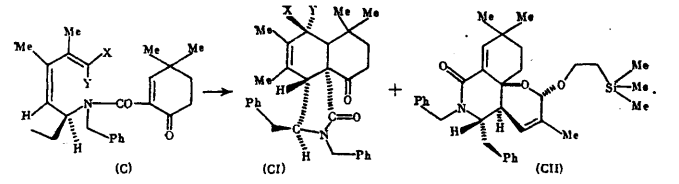
$n = 1, 2$; X = COOMe.

The biradical character of the TS in the IAMC[4 + 2] reaction has also been investigated in relation to the trienes (LXXXIX) and (XCIV):[61]



The preferential formation of the *trans*-isomer (XCI) from the triene (LXXXIX) and the *cis*-isomer (XCVI) from the triene (XCIV) can be accounted for by a concerted rather than synchronous TS in the cyclisation reaction; in particular, the "zigzag" TS (XCII) is energetically more favourable than the TS (XC). If the bonds are formed non-synchronously in the cyclisation of the triene (XCIV), then the TS should assume the configuration of a nine-membered ring. This is a state in which the steric strain in the formation of *cis*-hydroindene is reduced to a minimum.

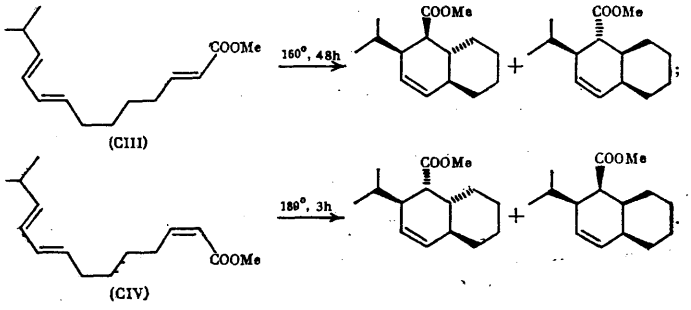
The "right-hand" half of the new ionophore antibiotic X-14547A (XCVIII) is obtained in a high yield [62] from the *trans*-hydroindene:



(XCVIII)

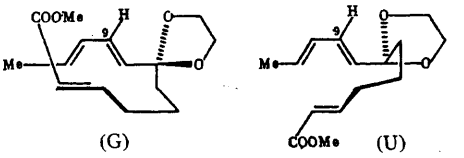
(±)-Coronafacic acid (XCIX), isolated from the culture medium of *Pseudomonas coronafacience*, is a structural fragment of the phytotoxin coronatine and is obtained from the hydroindene system in an overall yield of 7%: [63,64]

(XCIX)



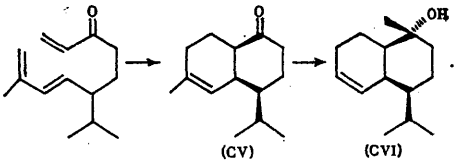
IAMC[4 + 2] constitutes a novel method of synthesis of chiral compounds; in particular the cyclisation of the chiral trienes (C a, b) (a: X = Y = H; b: X = $OCH_2CH_2SiMe_3$; Y = H or $OCH_2CH_2SiMe_3$) proceeds stereo- and enantioselectively,[65-67] as a result of which the product (CIa, X = Y = H) is obtained from the triene (Ca), while the triene (Cb) gives rise to a mixture of the products (CIa, X = $CH_2$ – $CH_2SiMe_3$, Y = H) and (CII), which are precursors of cytochalasin *C*:

(C) (CI) (CII)



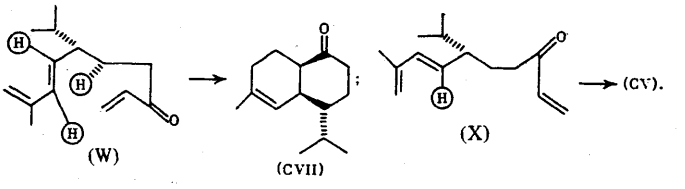
## 2. The 6/6-Annelated System

The formation of the 6/6-annelated system is to some extent stereochemically different from the formation of the 6/5-system. In the total synthesis of chlorothricin, it was observed that the IAMC[4 + 2] of the 2,8,10-trienoates (CIII) and (CIV) leads preferentially to *cis*-joined products: [68]



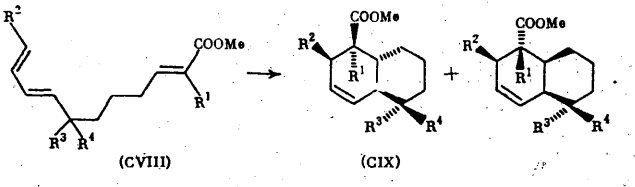
(CIII) (CIV)

Examination of Dreiding molecular models of the *cis*- and *trans*-TS (G) and (U) showed that the eclipsed 1,3-interaction between the H atom at C(9) and the OR group at C(7) develops in the *trans*-TS (G), while it is absent in the *cis*-TS (U). This interaction explains fairly satisfactorily the increasing selectivity also for other undecatrienes having substituents at C(7).



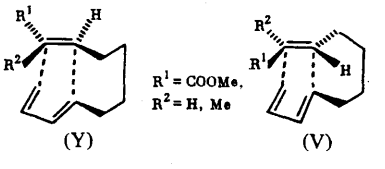
(G) (U)

The synthesis of a crystalline sesquiterpene alcohol (±)-torreyol (CVI) also proceeds via the formation of the *cis*-joined product (CV): [69]



(CV) (CVI)

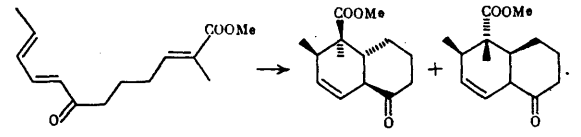
The formation of the *cis*-isomer (CV) and not the *trans*-isomer (CVII) can be accounted for by the steric hindrance in the TS (W) ("chair"), because the isopropyl group is in the *syn*-position relative to the angular H atom; on the other hand, in the TS (X) ("boat") such hindrance is absent:



(W) (CVII) (X) (CV).

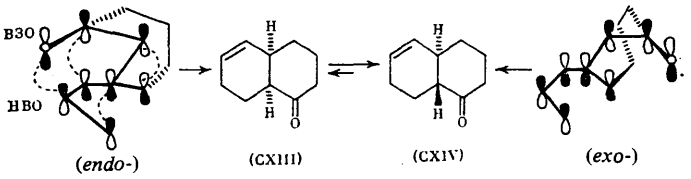
The characteristics of the stereochemistry of the IAMC[4 + 2] of various trienes (CVIII, $R^1$ = Me, $R^2$ = H, Me, $R^3$ = $R^4$ = OAlk, $R^3$ + $R^4$ = $OCH_2CH_2O$) make it possible to synthesise the chlorothricolide (CIX)—a fragment of the molecule of chlorothricin produced by a culture of *Streptomyces antibioticus*: [70]

(CVIII) (CIX)



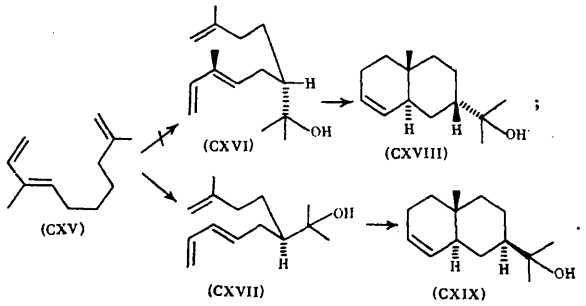
The following features were demonstrated: (a) the somewhat unexpected preferential formation of *cis*-joined products; (b) the absence of a dependence of the reaction selectivity on the stereochemistry of the dienophiles; (c) the independence of the stereochemical reaction pathway of the secondary orbital interaction. In most cases the main products are formed via a TS of type (Y). Consequently the *endo*-group breaks down in the reactions of *E,E,E*-trienes:

(Y) (V)



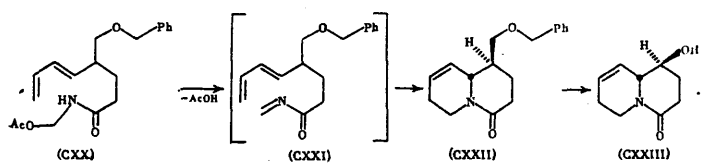
It has been established that the cyclisation is kinetically controlled. One should therefore assume that the *cis*-joined TS (Y) has a somewhat lower energy than the *trans*-joined TS (V) (by 1.0–1.2 kcal $mol^{-1}$). In all cases the selectivity depends strongly on fine steric conformational effects. Another well known factor influencing the stereochemical

consequences of the IAMC[4 + 2] is the nature of the hybridisation of the atoms or atomic groups in the chain connecting the diene and the dienophile.[71] The $sp^2$-hybridised atoms in the allyl position in the diene increase the coplanarity of the latter in the reaction TS; thus the orbitals overlap along the reaction coordinate. The $sp^2$-hybridisation in the allyl position in the diene leads to a result opposite to that of the $sp^3$-hybridisation, which has been confirmed[71] in relation to the cyclisation of the diene (CX):



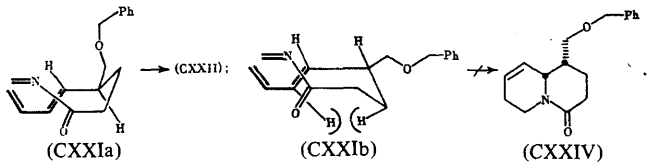
(CX) (CXI) (CXII)

The (CXI):(CXII) ratio is 65:35. Inspection of Dreiding models suggested that the C=O group becomes coplanar with the butadiene fragment; thus the above configuration can be readily obtained only for the transoid disposition, which leads to the preferential formation of the *trans*-joined product (CXI). In order to explain this, the secondary orbital interaction favouring the *endo*-TS has been invoked to account for this phenomenon in a number of other similar examples.[72] The transition from compound (CXIII) to the product (CXIV), which constitutes a kinetically controlled reaction, ensures the preferential *endo*-stereoselectivity of the cyclisation with respect to the C=O group:



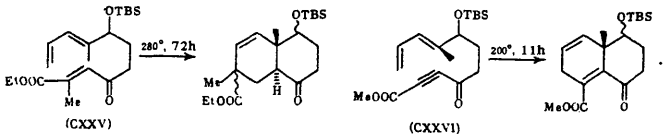
(*endo*-) (CXIII) (CXIV) (*exo*-)

The preferential formation of *trans*-joined rings has been observed in the synthesis of the crystalline sesquiterpene alcohol α-eudesmol (CXIX) from the triene (CXV) with the aid of IAMC[4 + 2].[73] By virtue of the axial position of the hydroxyisopropyl fragment in the TS (CXVI), a steric interaction of this fragment with the remainder of the molecule is observed, which does not occur at all in the case of (CXVII):



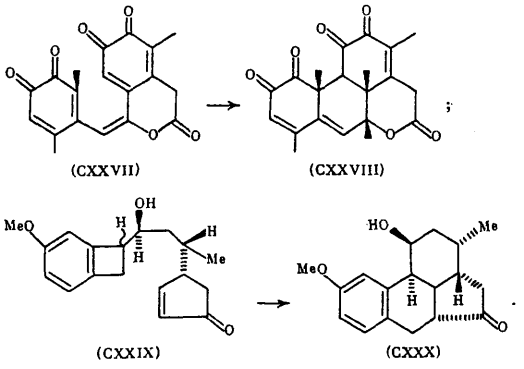
(CXV) (CXVI) (CXVIII) (CXVII) (CXIX)

In the effective synthesis of epilupinine (CXXIII), which belongs to the class of quinolizidine alkaloids, it was discovered[74] that the IAMC[4 + 2] of the triene (CXX) proceeds strictly stereoselectively via the imino-reaction pathway proposed previously:[54-56]



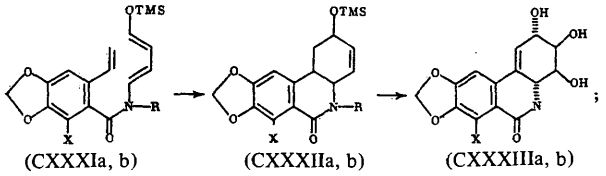
(CXX) (CXXI) (CXXII) (CXXIII)

It has been suggested that the imine (CXXI) cyclises via the TS (CXXIa). Both in the TS (CXXIa) and the TS (CXXIb), the *endo*-disposition of the C=O group is observed, so that the bulky $OCH_2Ph$ group occupies a quasi-equatorial position in the lactone ring. In the TS (CXXIa) the connecting chain assumes a quasi-boat form and such TS leads precisely to the product (CXXII). On the other hand, the lactam ring in the TS (CXXIb) assumes a quasi-chair conformation and the corresponding product (CXXIV) is not detected. Examination of the model shows that in the quasi-chair TS (CXXIb) an unfavourable non-bonding interaction takes place between the hydrogen atom in the vinyl component of the diene and the quasi-axial hydrogen atom in the connecting chain:



(CXXIa) (CXXIb) (CXXIV)

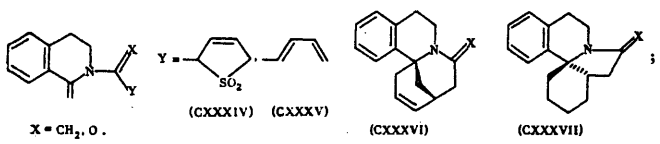
The *trans*-joined decalin system containing an angular methyl group, which is a structural component of terpenoids and steroid natural products, can be readily obtained[75] from the triene (CXXV) and the tetraene (CXXVI):



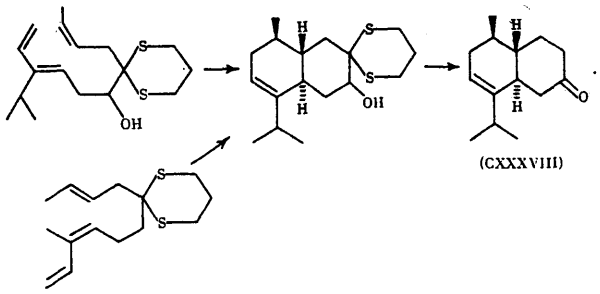
(CXXV) (CXXVI)

The diterpenoid compound quassin (CXXVIII), which contains seven asymmetric centres, can be synthesised stereoselectively from the *o*-quinone (CXXVII) by means of IAMC[4 + 2].[76] Compounds of this type are dehydrated terpenes with a high oxygen content and are present in the plants *Simaroubaceae*. Another possible pathway leading to the synthesis of compound (CXXVIII) involves[77] IAMC[4 + 2] of the benzocyclobutene derivative (CXXIX), whose product (CXXX) is converted into quassin via several stages: (CXXVII)

(CXXVII) (CXXVIII) (CXXIX) (CXXX)

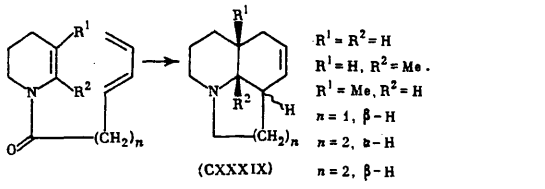


Licoricidin (CXXIIIa) and narciclasine (CXXIIIb) are of considerable interest because of their biological activity; in particular, they inhibit protein synthesis and exhibit a powerful antitumour activity. They can be readily synthesised[78] from the trienes (CXXXIa, b) by IAMC[4 + 2]:

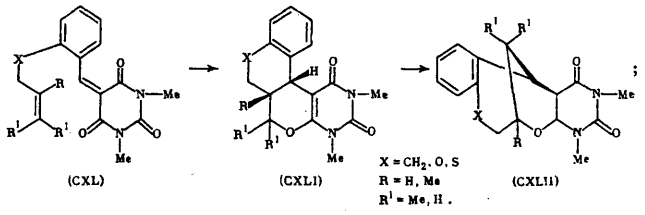


(CXXXIa, b) (CXXXIIa, b) (CXXXIIIa, b)

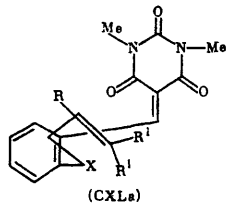
a: X = H; b: X = OH.



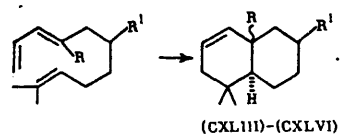
The IAMC[4 + 2] reactions of the enamines and enamides (CXXXIV) and (CXXXV) have been investigated[79,80] in order to develop a new method of synthesis of alkaloids with a tetracyclic spiran skeleton, which is characteristic of erythrin alkaloids; however, instead of the expected compound (CXXXVII), the reaction resulted in the formation of the bridged adducts (CXXXVI):



*trans*-Stereoselectivity of cyclisation has been observed in the synthesis of the cadalane sesquiterpene epizonarene (CXXXVIII) with the aid of IAMC[4 + 2]:[81]



However, the *cis*-joined products (CXXXIX) are formed in the synthesis of *Aspidosperma* alkaloids:[82]

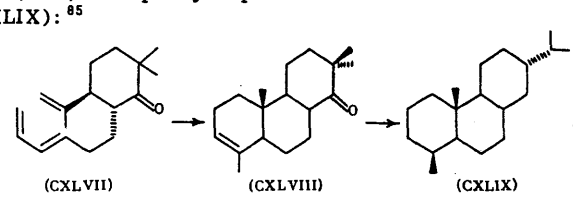


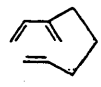
The thermolysis of the trienes (CXL) yields 20 : 1 mixtures of the products (CXLI) and (CXLII):[83]

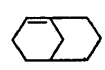
The formation of the bridged product (CXLII) shows that the TS (CXL) has the conformation (CXLa):

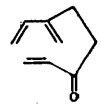
A short synthesis of (±)-ambrinol (one of the components of ambergris) with the aid of IAMC[4 + 2] leads to four possible stereoisomers, namely (CXLIII, R = α-H, $R^1$ = H), (CXLIV, R = β-H, $R^1$ = Me), (CXLV, R = α-Me, $R^1$ = H), and (CXLVI, R = α-Me, $R^1$ = Me), among which compounds (CXLIII) and (CXLIV) possess the strong scent of ambergris:[84]

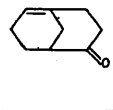
The IAMC[4 + 2] of the triene (CXLVII) proceeds stereoselectively with the preferential formation of compound (CXLVIII), which is converted into the angularly substituted *trans*,*anti*,*trans*-perhydrophenanthrene—(±)-fichtelite (CXLIX):[85]

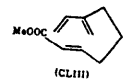


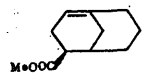


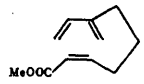


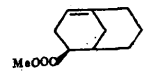


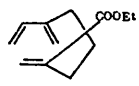












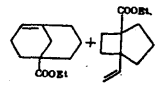


Table 3. Data for the IAMC[4 + 2] of certain trienes leading to the formation of strained bicyclo[*n*.3.1]alkenes.[15]

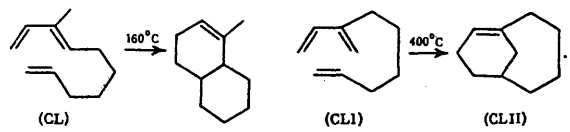
| Initial triene | Conditions | Products | Yield, % |
|---|---|---|---|
|  | 420°, 23 s |  | 32 |
|  | 395°, 18 s |  | 72 |
|  (CLIII) | 318°, 18 s |  | 76 |
|  (CLIV) | 365°, 12 s |  | — |
|  | 390°, 12 s |  | 50 |

The formation of bridged bicyclo[*n*.3.1]alkenes with the double bond at the bridgehead conflicts with the Bredt prohibition,[86] but, when IAMC[4 + 2] is used, this prohibition sometimes loses its force.[15] However, it has been shown that the reactivity of the triene (CL) in cyclisation is greater than that of the triene (CLI), which has been attributed to the excess strain in compound (CLII). Cycloaddition takes place with formation of the *trans*-cyclooctene ring:



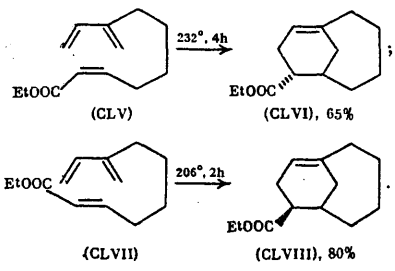


Table 3 shows that the two isomeric trienes *E*-(CLIII) and *Z*-(CLIV) give rise to the same bridged olefin. Kinetic studies have demonstrated that electron-accepting groups accelerate the reaction and that the latter proceeds *exo*-stereoselectively. The cyclisation of compounds *Z*-(CLV) and *E*-(CLVII), leading to the isomeric olefins (CLVI) and (CLVIII), is particularly interesting:

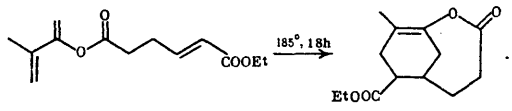
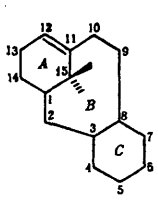


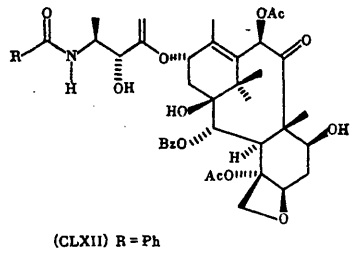
(CLV) (CLVI), 65%

(CLVII) (CLVIII), 80%

These isomers can be readily distinguished on the basis of physicochemical and spectroscopic data. The ratio $k_{(CLV)}/k_{(CLVII)} = 13$ (201 °C) shows that the secondary orbital interaction cannot determine the stereoselectivity of this type of IAMC[4 + 2].



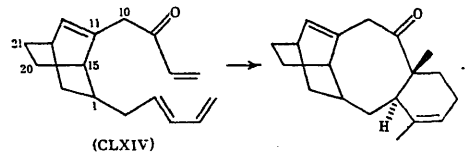
The IAMC[4 + 2] reaction of ethyl 1-methylene-2-methyl-(propenyl)hex-2-enedioate (CLIX), leading to the formation of the bridged enol lactone (CLX) in a high yield, has also been investigated: [87]



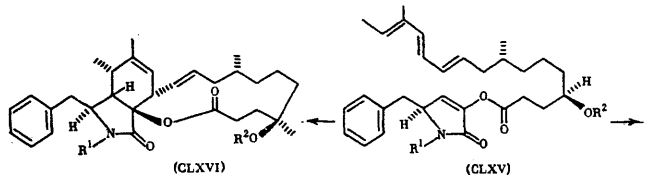
(CLIX) (CLX), 78%

### 3. The 6/<6-Annelated System

It is noteworthy that this system is rarely encountered; despite this, it has attracted the attention of organic chemists, since representatives of compounds of this class exhibit unique properties. For example, taxane diterpenes, isolated from certain *Taxus* species, contain the unusual tricyclic carbon skeleton (CLXI), in which the eight-membered *B* ring is sterically strained. [88] Taxol (CLXII) and cephalomannine (CLXIII) exhibit extremely high antileukaemic and antitumour activities.

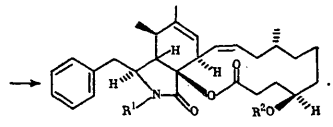


(CLXI)



(CLXII) R = Ph
(CLXIII) R = —CMe=CHMe

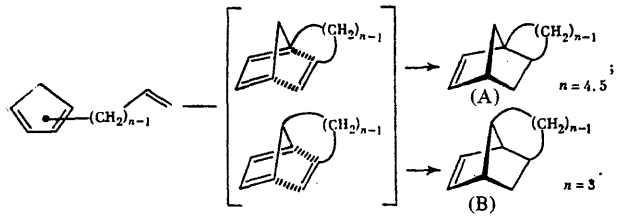
Although the difficulty of effecting the closure of the *B* ring makes it difficult to obtain compounds of this kind, the IAMC[4 + 2] of the triene (CLXIV) takes place readily. The closure of the B ring is facilitated by the rigid disposition of the five carbon atoms C(2), C(1), C(15), C(11), and C(10), which is due to the fixed boat conformation of the *A* ring: [89]



(CLXIV)

The formation of the macrocyclic lactam ring is one of the complex tasks in the synthesis of cytochalasin *B* and related compounds. [90] The above product has been successfully synthesised in the two stereoisomeric forms (CLXVI) and (CLXVII) by the application of a novel and simple procedure involving the IAMC[4 + 2] of the triene (CLXV): [91]

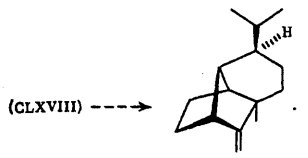
(CLXVI) (CLXV)



(CLXVII)

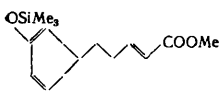
## IV. THE FORMATION OF BRIDGED CYCLIC SYSTEMS FROM ENDOCYCLIC DIENES

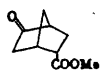
### 1. Cyclopenta-1,3-diene and Furan

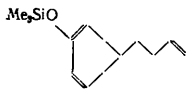


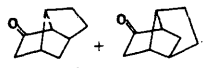
Experiments have shown that, depending on the length of the chain connecting the diene and the dienophile, the IAMC[4 + 2] of alkenylcyclopentadienes yields only two types of tricyclic adducts, (A) and (B), out of the possible twelve isomeric forms: [92,93]

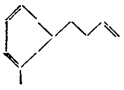
It is remarkable that, when $n = 4$ or 5, then IAMC[4 + 2] leads specifically to a structure of type (A) [via the 1-(*n*-alkenyl)-isomer], while $n = 3$ affords exclusively tricyclo[4.3.0.0$^{3,7}$]non-4-ene [type (B)] via the 5-(*n*-alkenyl)-isomer.

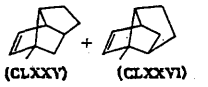


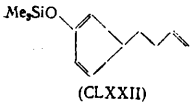


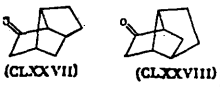












The IAMC[4 + 2] of certain alkenylcyclopentadienes has been carried out [94] (Table 4). The formation of only one regioisomer (CLXVIII) from the triene (CLXIX) is fully consistent with the prediction based on the frontier molecular orbital theory. [95] The cycloaddition of the trienes (CLXX), (CLXXI), and (CLXXII) is extremely important, since the unusual instance, where the formation of the products (CLXXIII), (CLXXV) and (CLXXVII) rules out the biradical cyclisation mechanism, is demonstrated here. [96] It is noteworthy that the precursors of compounds (CLXXIII),

(CLXXIV), (CLXXVI) and (CLXXVIII) are unstable and are converted into a stable form at the instant of their synthesis. The sesquiterpene tricyclic hydrocarbon (±)-sativene (CLXXIX) is readily and stereoselectively synthesised from compound (CLXVIII) in 32% yield: [97]

(CLXXIX)

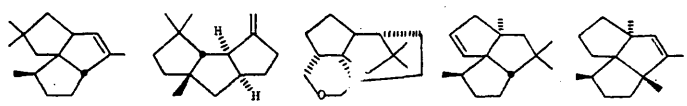


Table 4. Data for the IAMC[4 + 2] of the alkenylcyclopentadienes (CLXX), (CLXXI), (CLXXII), and (CLXIX). [94]

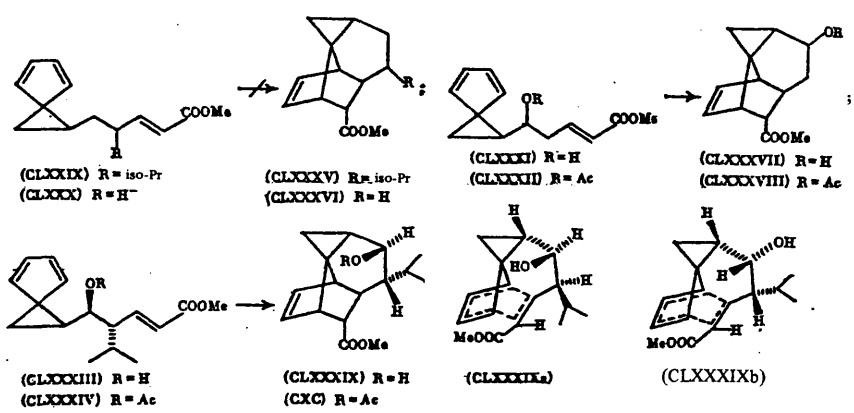
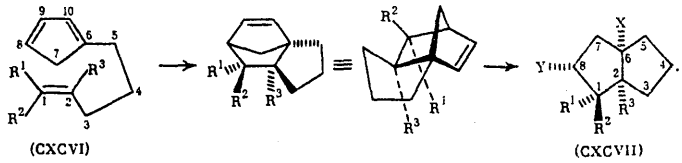
| Trienes | Conditions | Products | Yield, % |
|---|---|---|---|
|  (CLXIX) | 110°, 3 days |  (CLXVIII) 100 : 0 | 95 |
|  (CLXX) | 250°, 24 h |  (CLXXIII) (CLXXIV) 54 : 46 | 72 |
|  (CLXXI) | 250°, 24 h |  (CLXXV) (CLXXVI) 73 : 27 | 30 |
|  (CLXXII) | 250°, 24 h |  (CLXXVII) (CLXXVIII) 78 : 22 | 77 |



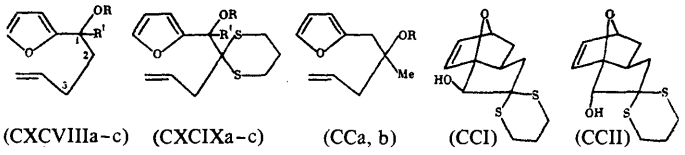
The influence of oxygen-containing substituents in the side chain on the reactivity in the IAMC[4 + 2] of the 5-(spiro-2,4-hepta-4,6-dien-1-yl)pent-2-enoates (CLXXIX)–(CLXXXIV) has been discussed in detail. [98]

The compounds obtained are intermediates in the synthesis of sesquiterpenes—sinularene, longifolene, sativene, etc. It was observed that the trienes (CLXXIX) and (CLXXX) do not cyclise in the course of 65 h at 195 °C, while the trienes (CLXXXI) and (CLXXXII) are converted into compounds (CLXXXVII) and (CLXXXVIII) in 60% yield after 6 h at 180 °C. It is of interest that the simultaneous employment of both substituents (OR and iso-Pr) in the side chain does not suppress the cyclisation under these conditions. It has been established that, in the presence of oxygen-containing substituents, the dienophile component of the triene is oriented relative to the plane of the cyclopentadiene ring in a way ensuring a position favouring cyclisation. This has been confirmed by the analysis of the $^1$H NMR spectra of the initial trienes: it was found that the signals of the β-hydrogen atoms in the dienophile component resonate about 5.0 p.p.m. instead of the usual range 6.5–7.5 p.p.m., which indicates the shielding of these atoms by the cyclopentadiene ring. This type of phenomenon has not been observed for the trienes (CLXXIX) and (CLXXX). In the cyclisation of the trienes (CLXXXIII) and (CLXXXIV), only one TS (CLXXXIXb) is actually produced of the two possible TS (CLXXXIXa) and (CLXXXIXb). The formation of one isomer can be accounted for by the unfavourable interactions between the isopropyl group and the *exo*-hydrogen atom in the TS (CLXXXIXa). However, the cause of the appearance of conformations suitable for IAMC[4 + 2] when oxygen-containing substituents in the C(5) position are used remains unknown.



In order to synthesise polyquinane natural products, in particular pentalenene (CXCI), capnellene (CXCII), quadrone (CXCIII), silphinene (CXCIV), and isocomene (CXCV), a study has been made of the IAMC[4 + 2] reactions of several alkenylcyclopentadienes ($n$ = 4). [99]

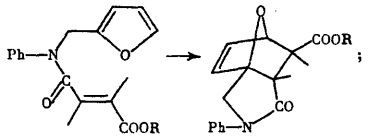
The basic skeleton of these compounds, namely the bicyclo[3.3.0]octane ring (CXCVII), is readily produced by the cleavage of the double bond in the adducts obtained by the



IAMC[4 + 2] of the trienes (CXCVI):

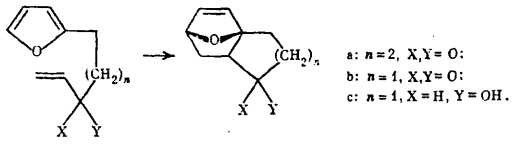
(CXCVI) (CXCVII)

It has been established that, under the conditions of the *trans*-disubstitution in the dienophile component, the reaction proceeds fairly readily and with a high yield of products. In each case two epimeric compounds are produced. Geminal substitution in the C(4) position in the side chain greatly accelerates the IAMC[4 + 2], which indicates the appearance of the TS conformation favourable for the interaction of the diene and dienophile components of the trienes. The stereochemistry of the adducts has been investigated using the nuclear Overhauser effect.



In contrast to alkenylcyclopentadienes, in the case of alkenylfurans the stereochemistry of the junction between the rings formed between the diene and ene fragments is more definite owing to the absence of 1,5-migration in the furane ring.[100] The influence of substituents and solvents on the IAMC[4 + 2] reaction where the α-substituted furan ring is used as the diene component has been investigated.[101] For this purpose, a study has been made of the cyclisation of compounds [CXCVIII, R = R′ = H (a); R = $PhCH_2$, R′ = H (b); R = H, R = Me (c)], [CXCIX, R = R′ = H (a); R = Bz, R′ = H (b); R = H, R′ = Me (c)], and [CC, R = $PhCH_2$ (a); R′ = H (b)]:

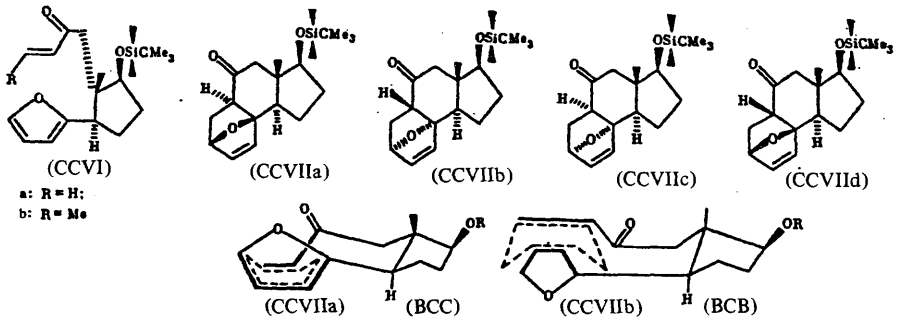
(CXCVIIIa-c) (CXCIXa-c) (CCa, b) (CCI) (CCII)



It has been shown that the trienes (CXCVIIIa-c), which have no substituents at the C(1) atom in the side chain, do not undergo the IAMC[4 + 2] reaction. Thermolysis of the trienes takes place *exo*-stereoselectively. The mixture of the (CCa) epimers used gives rise to only traces of the four isomeric reaction products. The triene (CCb) proved to be unreactive under these conditions. The presence of the dithian ring at the C(2) atom in the side chain of compound (CXCIXa) promotes the successful occurrence of the reaction, as a result of which one obtains a mixture of the epimers (CCI) and (CCII) in 63% yield. Geminal substituents at the C(1) atom greatly influence the yield and rate of reaction; thus the presence of the Me and OH geminal groups in the triene (CXCIXc) appreciably accelerates the rate of reaction, while the replacement of the OH group by the ester group in compound (CXCIXb) retards the cyclisation compared with the triene (CXCIXa). The low yield of products in the cyclisation in water compared with the reaction in other solvents can be accounted for by micelle formation. Thus the rate of reaction and the yield of products obtained from α-alkenylfurans greatly depend on the nature of the substituents in the bridging carbon chain; a correct choice of substituents makes it possible to obtain a five-membered carbon ring with a high yield.

The kinetics of the cyclisation of the triene (CCIII) has been investigated spectroscopically;[29] the activation parameters found ($E_A^{\neq}$ = 72.5 kJ $mol^{-1}$, $\Delta H^{\neq}$ = 69.8 kJ $mol^{-1}$, $\Delta S^{\neq}$ = −62 J $mol^{-1}$ $K^{-1}$, and $\Delta V^{\neq}$ = −25 $cm^3$ $mol^{-1}$) show that the bulk of the TS in the IAMC[4 + 2] diminishes with increase of pressure to a lesser extent than in the case of IRMC[4 + 2].

(CCIII)
R = H, Et.

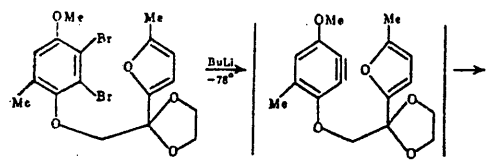


The IAMC[4 + 2] reaction of the trienes (CCIVa–c) has been used to develop a new method of synthesis of corticosteroids and certain characteristic features of this cyclisation have been discovered:[102,103]

a: n = 2, X,Y = O;
b: n = 1, X,Y = O;
c: n = 1, X = H, Y = OH.

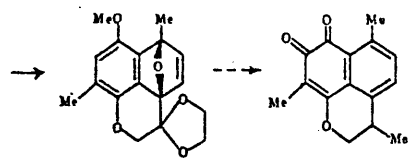
(CCIVa-c) (CCVa-c)

A series of model experiments established that, in order to construct the simple oxatricyclo[$6.2.1.0^{1,6}$]undecene system (CCVa, n = 2), it is essential to activate the dienophile in the triene (CCIVa). Indeed the ketone (CCIVa) is readily converted into the corresponding *exo*-adduct (CCVa), while the replacement of the C=O group by OH in the initial triene prevents the IAMC[4 + 2]:



(CCVI)
a: R = H;
b: R = Me

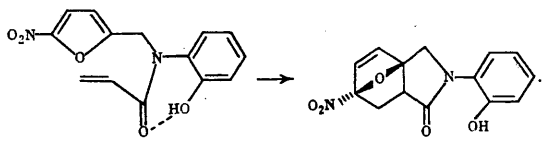
(CCVIIa) (CCVIIb) (CCVIIc) (CCVIId)



(CCVIIa) (BCC) (CCVIIb) (BCB)

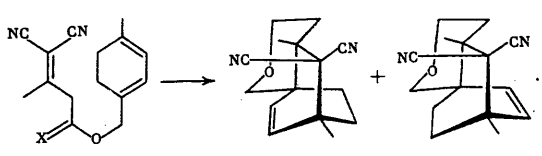
Only the products (CCVIIa) and (CCVIIb) are formed in proportions of 1:8 and in an overall yield of 61% in the thermolysis of compound (CCVIa) out of the four possible isomers (CCVIIa–d). Under these conditions, the methyl-substituted triene (CCVIb) does not react. The formation of only the *exo*-adducts (CCVIIa) and (CCVIIb) in this reaction is not surprising, since the structures of the adducts (CCVIIc) and (CCVIId) are more distorted.[104] It is of interest that at low temperatures the adduct (CCVIIb) is formed preferentially. Investigation revealed that the TS from which the product (CCVIIa) is obtained has the boat-chair-chair (BCC) conformation. Calculation of the force field showed that the boat-chair-boat (BCB) conformation is preferable in cyclododecane, which suggests that the TS for the reaction has the preferred BCB conformation.

Mansonone-E (CCX) isolated from the wood of *Mansonia altissima*, which is an *o*-naphthoquinone widely distributed in nature, can be smoothly synthesised from compound (CCVIII);[105] the key stage in the synthesis is the IAMC[4 + 2] of the intermediate triene (CCIX) containing the furan and benzene fragments:



(CCVIII) (CCIX)

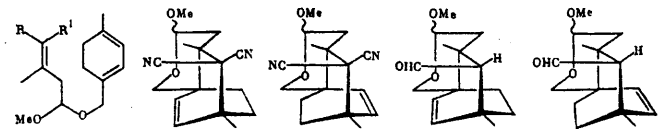
(CCX)



The IAMC[4 + 2] of the triene (CCXI) affords the product (CCXII) in a satisfactory yield,[106] the stereospecificity of the reaction being determined by the intramolecular hydrogen bond between the amide C=O group and the phenolic hydroxyl:

(CCXI) (CCXII)

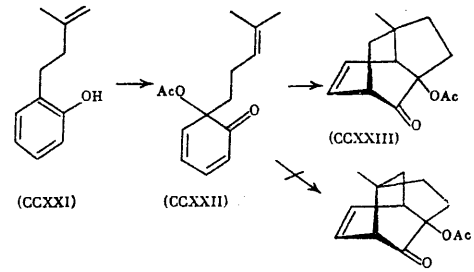
## 2. Cyclohexa-1,3-diene



Alkenylcyclohexa-1,3-dienes also enter smoothly into the IAMC[4 + 2] reaction. It has been established that the triene (CCXIII, X = $H_2$) readily gives rise to the cyclisation products (CCXIV) and (CCXV) in proportions of 2.2:1:[107]

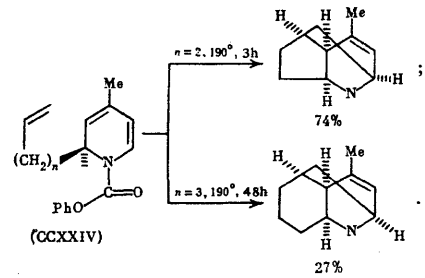
(CCXIII) (CCIV) (CCV)

However, its nearest homologue (CCXIII, X = O) does not cyclise under these conditions but polymerises.



The thermolysis of the triene (CCXVIa) at 210 °C in the course of 22 h produces smoothly a mixture of the cyclic products (CCXVII) and (CCXVIII) in proportions of 1.8:1 in 80% yield. It is of interest that in both cases the axial disposition of the OMe group is preferred (*a*:*e* = 2.75:1). Cyclisation is possible also in the presence of only one electron-accepting group. For example, the IAMC[4 + 2] of the *E*-aldehydoacetal (CCXVIb) affords the products (CCXIX) and (CCXX) in proportions of 12.8:1 (*a*:*e* = 1:1 in both cases). The desired product is not formed in the IAMC[4 + 2] of the corresponding *E*-ester (CCXVIc); instead methanol is eliminated from the acetal and an inactive tetraene is therefore generated:

(CCXVI) (CCXVII) (CCXVIII) (CCXIX) (CCXX)

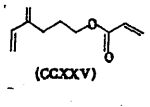


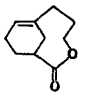
a: R = $R^1$ = CN;
b: R = CHO, $R^1$ = H;
c: R = COOEt, $R^1$ = H

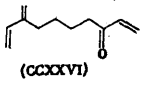
Vessely oxidation of *o*-isopentenylphenol (CCXXI) by $Pb(OAc)_4$ in acetic acid gives rise to the substituted cyclohexa-2,4-dienone (CCXXII), which is converted into isotwist-8-en-2-one (CCXXIII), without isolation, on heating in boiling xylene:[108]

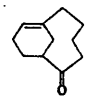
(CCXXI) (CCXXII) (CCXXIII)

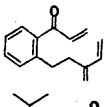
The IAMC[4 + 2] reaction of the dihydropyridines (CCXXIV) has been used to synthesise the various *cis*-decahydroquinoline alkaloids such as gephyrotoxin:[109]

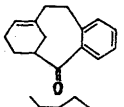


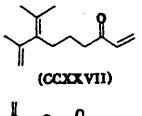


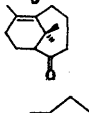


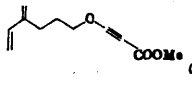


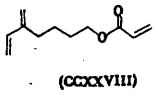


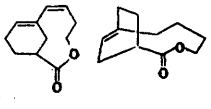






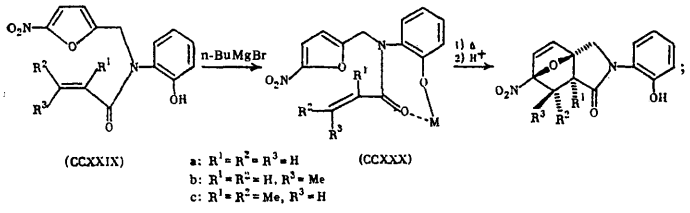






(CCXXIV)

## V. CATALYTIC INTRAMOLECULAR [4 + 2]CYCLOADDITION



Lewis acids have been used as catalysts in order to increase the rate of pericyclic reactions.[110,111] The catalytic effect of Lewis acids is effectively manifested also in intramolecular Diels–Alder reactions, where fairly severe conditions are required in many instances to achieve regio- and stereo-specificity.[112] For example, the IAMC[4 + 2] of compounds in which the dienophile component is attached to the diene component in the 2-position, leading to the formation of strained bridged cycloalkenes, requires a high temperature.[15] Various Lewis acids have been used in the IAMC[4 + 2] reaction of 4-methylenehex-5-enyl acrylate

(CCXXV). This triene undergoes thermal cyclisation at 139 °C ($\tau_{1/2}$ = 1.8 h). The complex formed between the triene and the Lewis acid is $10^4$ times more reactive than the triene itself; this is comparable with the increase of the rate of the IRMC[4 + 2] catalysed by Lewis acids ($10^5$ at 21 °C).[113] The rate of the catalytic reaction of the triene (CCXXV) is slightly influenced by the polarity of solvents; on passing from pentanes to methylene chlorides, the rate changes only slightly ($k_{CH_2Cl_2}/k_{C_5H_{12}}$ = 2.8). Table 5 presents data on the catalytic IAMC[4 + 2] of certain trienes. It is of interest that the methylated trienone (CCXXVII) is much more reactive than the non-methylated homologue (CCXXVI) under catalytic conditions. This finding conflicts with the result of thermal cyclisation, where the trienone (CCXXVI) is more reactive than compound (CCXXVII). A high reactivity is manifested by dienes when electron-accepting dienophiles are employed in catalytic processes.[114] However, Lewis acids influence only insignificantly the regioselectivity of the IAMC[4 + 2] reaction.[115] The thermal cyclisation of the triene (CCXXVIII) (180 °C, 12 h) affords a mixture of the 1,3- and 1,4-adducts in proportions of 10:1. In the presence of $Et_2AlCl$ (1 equivalent), the cyclisation is completed after 1 h at 21 °C with formation of the same products in proportions of 81:19. The slight change of regioselectivity in favour of the 1,4-isomer agrees with the predictions of the frontier molecular orbital theory.[116] It has also been discovered that the regioselectivity of the IAMC[4 + 2] reaction depends little on temperature.

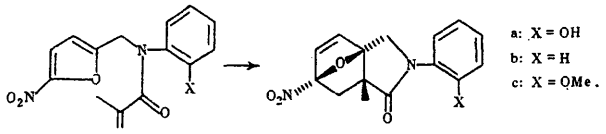


Table 5. Data for the catalytic IAMC[4 + 2] of certain trienes.[112]

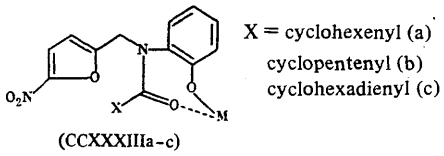
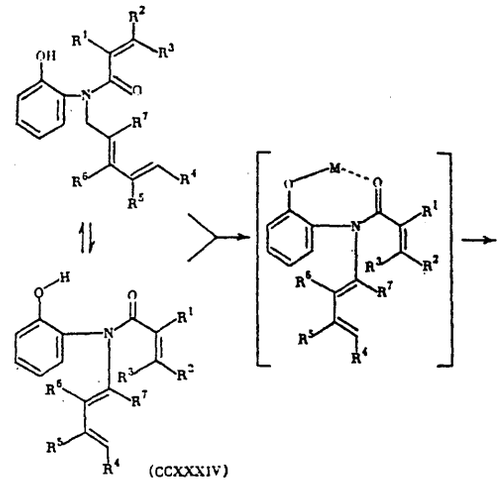
| Trienes | Products | Conditions | Yield, % |
|---|---|---|---|
|  (CCXXV) |  | 21°, 4 h | 85 |
|  (CCXXVI) |  | 21°, 2 h | 75 |
|  |  | 21°, 1 h | 71 |
|  (CCXXVII) |  | 21°, 5 min | 70 |
|  |  | 21°, 12 h | 85 |
|  (CCXXVIII) |  | 21°, 1 h | 90 |

As a result of its aromaticity, furan is a relatively unreactive diene and the IRMC[4 + 2] reaction of nitrofuran with electron-accepting dienophiles should be even more difficult.[114] Despite such an unfavourable combination of the diene and dienophile, the IAMC[4 + 2] of the trienes (CCXXIX) can be achieved readily after treatment with butylmagnesium bromide:[117]

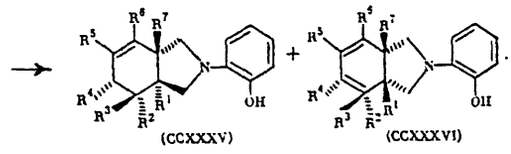


The formation of the complex (CCXXX) as a result of the intramolecular coordination between the phenoxide and amide groups leads to the mutual approach of the diene and dienophile fragments, favouring cyclisation. Subsequently this reaction was investigated in the absence of Grignard reagents, the substituent in the benzene ring being varied:

(CCXXXIa-c) (CCXXXIIa-c)



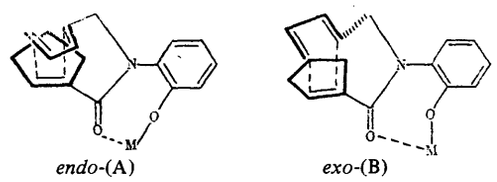
After 7 h in benzene, the product (CCXXIIa) is obtained in 75% yield, while the yields of the products (CCXXXIIb) and (CCXXXIIc) are only 30 and 11% respectively. The shift of the absorption by the C=O group in the IR spectrum confirmed the presence of an intramolecular hydrogen bond between the hydroxyl proton and the C=O group in the initial compound (CCXXXIa), which leads to the coplanarity of the dienophile part of the molecule and hence to an increase of the reaction rate. The solvation effects have only a slight influence on the yield and rate of the cyclisation reaction. One of the main factors determining the course of the cycloaddition is the steric hindrance in the dienophile component of the triene.



(CCXXXIIIa-c)

Examination of molecular models shows that the axial proton in the cyclohexene ring of cyclohexene-1-carboxamide (CCXXXIIIa) hinders the approach of the cyclohexene ring to the furan ring, which has not been observed for the trienes (CCXXXIIIb) and (CCXXXIIIc). It has been shown that molybdenum and tungsten complexes of the type $[MCl(CO)_2(\eta^3\text{-allyl})(NCMe)_2]$ appreciably accelerate this reaction.[118] The steric structures of the products have been established by NMR using the nuclear Overhauser effect; the *exo*-configuration with the *anti*-position of the Me group relative to its bridging oxygen atom has been attributed to them.

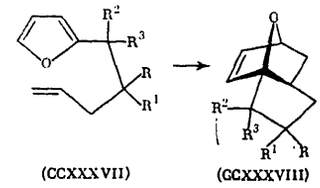
The IAMC[4 + 2] reaction between acyclic diene and αβ-unsaturated amide fragments has been thoroughly investigated[118,120] using intramolecular coordination with participation of metal salts:



(CCXXXIV)

(CCXXXV) (CCXXXVI)

When magnesium salts are used, the IAMC[4 + 2] of *N*-(*trans*,*trans*-alka-2,4-dienyl)-*N*-(2-hydroxyphenyl)acrylamide derivatives (CCXXXIV) is greatly accelerated and the corresponding products (CCXXXV) and (CCXXXVI) are obtained in high yields; the *exo* : *endo* isomer ratio is approximately 3 : 2. The analogous reaction with *N*-(*trans*,*trans*-alka-2,4-dienyl)-*N*-(2-hydroxyphenyl)cyclopentene-1-carboxamide results in the preferential formation (from 60 : 40 to 85 : 15) of *trans*-joined *exo*-products in a satisfactory yield. The addition of 4-t-butylcatechol in catalytic amounts to the reaction mixture inhibits the polymerisation process. The preferential formation of the *exo*-products is not surprising because, on coordination of phenol to the magnesium salts, the coordination of magnesium to the oxygen of the C=O group makes the molecular conformation more rigid and the TS (A) in the *endo*-cyclisation becomes more strained than the *exo*-TS (B):



*endo*-(A) *exo*-(B)

When strong Lewis acids such as aluminium or tin salts are used, a balance between the steric control and control by secondary orbital interaction is observed, so that two products are obtained in almost identical amounts, as in the non-catalytic reaction.

It has been shown[40,41] that the thermal cyclisation of methyl deca-2,7(*E*),9-trienoates (XXXIII)–(XXXV) produces the preferentially *trans*-joined hexahydroindenes (XXXVIIa)–(XL) (Table 2). The catalytic cyclisation of the *trans*-decatrienoates (XXXIII) and (XXXV) using Lewis acids such as $AlCl_3$, $EtAlCl_2$, $Et_2AlCl$, $BF_3.Et_2O$, etc. proceeds fully stereospecifically with formation of *trans*-joined products.[115] However, this procedure is not feasible for *cis*-decatrienoates, i.e. the stereoselectivity of the catalytic cyclisation of these compounds hardly differs from that of the thermal cyclisation. The lack of a change in the stereoselectivity of the cyclisation of the trienes (XXXIV) and (XXXVI) can be explained by the fact that the enhancement of the secondary orbital interaction between the ester carbonyl group and the Lewis acid is insufficient to overcome the hindrance to the formation of the *trans*-TS.

The thermal cyclisation of the methyl esters of the (*E*,*E*,*E*)- and (*Z*,*E*,*E*)-12-methyltrideca-2,8,10-trienoic acids (CIII) and (CIV) proceeds non-stereospecifically with formation of 50 : 50 mixtures of *cis*- and *trans*-joined products. In the presence of Lewis acids ($Et_2AlCl$), the stereoselectivity and the yield of products changed to a significant extent.[68] The acid-catalysed cyclisation proceeds mainly with formation of *endo*-products, since the stereocontrol of the reaction is due to the secondary orbital interaction. β-Cyclodextrin has been used successfully as the catalyst in the IAMC[4 + 2] of 1-(2-furyl)-1-hydroxy-2-R,2-R′-pent-4-ene (CCXXXVII) which resulted in the formation of a mixture of the products (CCXXXVIIIa) and (CCXXXIIIb) in an overall yield of 91%:[121]

(CCXXXVII) (GCXXXVIII)

a: $RR^1 = S(CH_2)_3$, $R^2 = H$, $R^3 = OH$
b: $RR^1 = S(CH_2)_3$, $R^2 = OH$, $R^3 = H$.

Thus the data published in recent years permit the conclusion that IAMC[4 + 2] is of enormous interest and we hope that further development of this unique field of chemistry will lead to extensive possibilities for the specific synthesis of the most important natural products and their analogues.

---o0o---

During the preparation of the manuscript for the press, a fairly large number of publications devoted to IAMC[4 + 2] appeared.[122–207] One of these is a review[122] which deals with the latest advances in the intramolecular Diels–Alder reaction and its application to the synthesis of complex natural products. In particular the synthesis of the bicyclo[4.3.0]nonene, bicyclo[4.4.0]decene, and bicyclo-[5.4.0]undecene systems and bridged bicyclo[*n*.3.1]alkenes is discussed. In contrast to the above review,[122] in the present review attention has been concentrated on the discussion of the synthesis of products from the corresponding trienes and on catalytic IAMC[4 + 2].

The main trend in other investigations[123–207] involved the study of the stereo- and regio-selectivities of IAMC[4 + 2] for the construction of the basic skeletons of natural products using various synthetic procedures, in particular catalysts of various type, an activated double bond, bulky substituents at chiral centres, etc.

The vigorous growth of the number of publications on the IAMC[4 + 2] reaction during such a brief period (1984–1985) again indicates the timely and promising nature of this branch of organic chemistry.

# The Mechanism of the Reaction of C-Nitroso-compounds with Alkenes

L.M.Kogan

Published data on the study of the chemical aspects of the reaction of C-nitroso-compounds with alkenes have been examined and critically reviewed. The multi-stage nature of the process has been emphasised. The dependence of the mechanisms of the primary stage and subsequent stages of the reaction on the structure of the reagents and the reaction conditions has been discussed. An attempt has been made to explain the contradictory data on the structure of the final reaction products in terms of the variety of possible directions for the transformation of the intermediates. The characteristics of the chemical reaction of C-nitroso-compounds with diene polymers have been examined.
The bibliography contains 117 references.

## I. INTRODUCTION

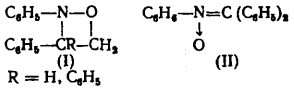
The considerable practical importance acquired in recent years by C-nitroso-compounds, which have found application as rubber modifiers and stabilisers both at the polymer formation stage[1-5] and in its conversion to finished rubber articles,[6-12] has led to increased interest in the study of the chemical aspects of the reaction of an unsaturated hydrocarbon chain with C-nitroso-compounds.

However, in spite of the fact that a fairly large number of published papers have been devoted to the mechanism of the reaction of C-nitroso-compounds with alkenes, this extensive but extremely contradictory experimental material has not been reviewed (apart from a brief review[13] dealing only with the reactions of C-nitroso-arenes and covering the literature up to 1970). In the present work an attempt is made to fill this gap.

Most workers who have studied the reaction of C-nitroso-compounds with monoalkenes point out that it is a multistage process, but there is lack of agreement on its basic parameters: the stoichiometry, the reaction centre in the alkene molecule, the nature of the primary attack on the alkene by the nitroso-compound and the intermediate stages, and the structures of the final products. Thus depending on the structure of the reagents and the conditions of the process, the following nitrogen-containing final reaction products have been isolated and identified: alkenylaryl- or alkenylalkyl-hydroxylamines, nitrones, azoxybenzenes, secondary and primary amines, azomethines, oxazetidines, oxadiazoles, isoxazolines, and oxime ethers.

The following main mechanisms have been proposed for the first stage of the reaction of nitroso-compounds with alkenes: 1) "Diels–Alder pseudo-condensation" ene synthesis with the formation of a tertiary hydroxylamine and prototropic displacement of the double bond; some authors assume intermediate 1,2 cyclo-addition with the formation of an oxazetidine; 2) direct radical allyl condensation with the transfer of an allyl proton to the NO group and the formation of a hydroxylamine derivative; 3) the formation of a 2:1 molecular adduct of the nitroso-compound and the alkene as a substituted oxadiazole; 4) a homolytic process involving direct electron transfer from the C=C bond to the NO bond with the formation of nitroxide radicals; 5) the formation of a charge-transfer complex from the alkene and the nitroso-compound and its decomposition via a radical–ion stage.

The products obtained in the first stage undergo further heterolytic and homolytic transformations to give the final products indicated above.



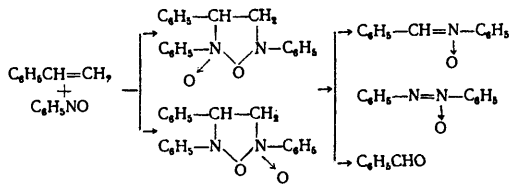
To introduce greater order into the often confused and contradictory published data, the present review is restricted to the study of the reactions of C-nitroso-compounds with alkenes with and without an allyllic hydrogen atom.

The present review examines the reactions of both aromatic and stable aliphatic nitroso-compounds, such as nitrosotrihalogenomethanes and nitroso-t-butane, which although differing in many of their characteristics (spectral,[14] polarographic,[15] etc.), are similar in their chemical properties, in particular in their reactions with alkenes.

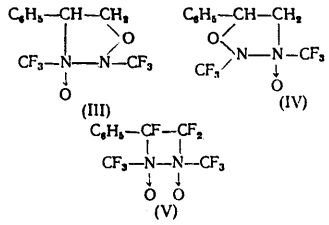
## II. REACTIONS OF C-NITROSO-COMPOUNDS WITH ALKENES NOT CONTAINING γ-PROTONS

This group of alkenes includes styrene, stilbene, 1,1-diphenylethylene, and their fluorinated analogues, but particular attention has been paid to the reactions of styrene. This interest in styrene is understandable, since aromatic nitroso-compounds are excellent inhibitors of free-radical reactions, and in the study of the processes of radical polymerisation and copolymerisation of styrene, which have found industrial application, it is important to investigate not only the stage involving the termination of the growing polymer chain but also the direct reaction of the inhibitor with the monomer.

In an early paper,[16] the adducts of styrene and 1,1-diphenylethylene with nitrosobenzene were assigned the oxazetidine structure (I).

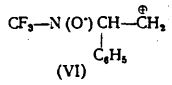


(I) R = H, $C_6H_5$ (II)



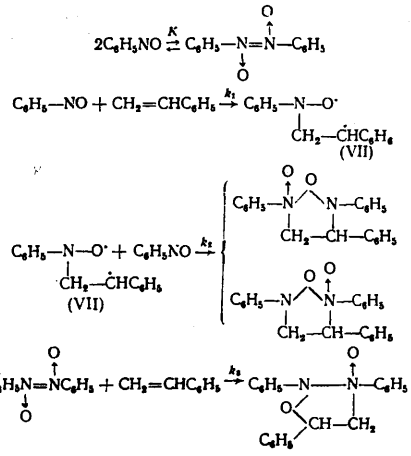
This view was criticised even at the time, however. According to Ref.17, the product of the reaction of nitrosobenzene with 1,1-diphenylethylene has the nitrone structure (II).

Hepfinger[18] considers that the products of the reaction of nitrosobenzene with styrene are unstable isomeric oxadiazole N-oxides, which decompose to give the α,N-diphenylnitrone,



azoxybenzene, and benzaldehyde:

At the same time, one of a cycle of studies of the reaction of trifluoronitrosomethane with alkenes[19] showed that, depending on the reaction temperature, the products may be adducts of this nitroso-compound with styrene and trifluorostyrene in the ratio 2:1 (<−70 °C) and 1:1 (>−70 °C); the 1:1 adduct was assigned the oxazetidine structure (I), and the 2:1 adducts the structures (III) and (IV) for styrene, and (V) for trifluorostyrene:



According to Ref.20, the first stage of the process gives a donor–acceptor complex, whose transformations are determined by the structure of the alkene. Paramagnetic intermediate species were detected, and in the case of the reaction of trifluoronitrosomethane with styrene they were assigned the radical–cation structure (VI):

Nitroxide radicals are also formed in the reaction with trifluorostyrene.[21]

The authors cited, however, do not suggest a mechanism which could explain the formation of the cyclic products (III)–(V).

Developing the ideas of Refs.18 and 19, a group of Japanese workers,[22] who studied the reactivity and kinetics of the reaction of nitrosobenzene with styrene, and also the reaction of the corresponding substituted derivatives, proposed the following scheme for the process:

They consider that the data they obtained on the kinetics of the reaction (order of the reaction with respect to nitrosobenzene between 1 and 2; its dependence on the initial concentration of the reagents—an increase with increase in concentration while preserving first order with respect to styrene) confirm the proposed mechanism, since in dilute solutions, the nitroso-compounds, which tend to dimerise,[23] are present chiefly in the monomeric form.

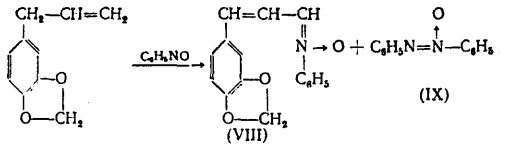
A study of the reactivity of substituted nitrosobenzenes showed that the presence of electron-donor substituents in the *p*-position decreases the reaction rate, whereas the presence of electron-acceptor substituents increases the reaction rate; a linear relationship was obtained between the reaction rate constants for the substituted nitrosobenzenes and the Hammett constants of the substituents for electrophilic reactions $\sigma^{\oplus}$, in good agreement with the view that the double bond in the styrene molecule is nucleophilic.

Among substituted styrenes, α-methylstyrene is much more reactive than β-methylstyrene; this is attributed not only to the more nucleophilic character of the double bond in the α-isomer and the stabilisation of the intermediate biradical (VII) but also to steric hindrance in the β-methylstyrene molecule.

The possible reaction of styrene with various derivatives of nitrosobenzene in the dimeric form has been noted.[24] The reaction is of second order with respect to the nitroso-compound, and paramagnetic species are formed in the reaction.

Thus although different workers have different views on the nature of the reaction of nitroso-derivatives with unsaturated hydrocarbons not containing γ-protons, most believe that cyclic products of the addition of the nitroso-compounds to the double bond are formed. Paramagnetic species are produced in the reaction. Benzylidene-N-phenylnitrone, azoxybenzene, and benzaldehyde have been separated from the decomposition products of the cyclic adducts of nitrosobenzene with styrene.

Some authors[25] have studied a series of alkenes without distinguishing between those which contain an allyl hydrogen atom and those which do not, and have examined their reactions with nitroso-compounds from the same viewpoint. The data given below, however, show that the presence or absence of γ-protons in the alkene has a significant influence on the mechanism of the process.

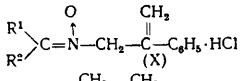


## III. THE REACTION OF C-NITROSO-COMPOUNDS WITH ALKENES CONTAINING AN ALLYL HYDROGEN ATOM

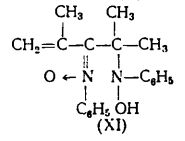
Before reviewing studies devoted directly to the mechanism of the reactions of nitroso-compounds with alkenes containing primary, secondary, or tertiary hydrogen atoms in the allyl position, the structure of the final products of this reaction can be considered.

### 1. Structure of the Final Products

A critical review of published data on the products of the reactions of C-nitroso-compounds with alkenes containing an allyl hydrogen atom is difficult, since on the one hand, workers studying these processes encounter objective difficulties in identifying the final products, because of their tendency to undergo interconversion, and, on the other hand, some authors try to transfer experimental data relating to alkenes and nitroso-compounds with particular structures to other compounds of these classes. In the examination of the experimental material on the structure of the final products, therefore, specific reference will be made to the reagents for which the various regularities have been established.



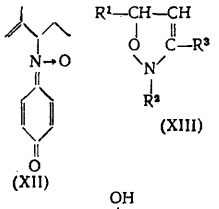
The reaction of C-nitroso-compounds with alkenes (safrole and various others) was first reported in Ref.26; the authors considered that the chief products of the reaction of nitrosobenzene with safrole are the nitrone (VIII) and azoxybenzene (IX).



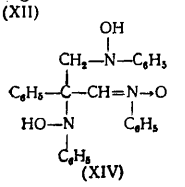
(VIII) (IX)

It was later shown[27] that azoxy-derivatives are formed in the reactions of *p*-nitro- and *p*-bromo-substituted nitrosobenzenes with cyclopentene, cyclohexene, propene, isobutylene, but-1-ene, *cis*- and *trans*-but-2-enes, and stilbene, the reaction taking from several seconds to several days, depending on the structure of the starting materials. The complete conversion of the nitrosobenzene into the azoxybenzene requires at least an equimolar quantity of the alkene. An appreciable quantity of azoxybenzene was isolated in the reaction of nitrosobenzene with 2-methylpent-2-ene.[28] The formation of nitrones in the processes studied was not reported.[27,28]

On the other hand, nitrones were identified as products of the reaction of α-methylstyrene and other alkenes containing an allyl hydrogen atom with chloronitrosoadamantane and other α-chloronitroso-compounds, where the nitrones were isolated as the hydrochlorides (X),[29] and also as products of the reaction of nitrosobenzene with tetramethylallene (in this case the bifunctional product (XI) with nitrone and hydroxylamine groups is formed).[30] In the last case, azoxybenzene was also isolated, but only as the product of the high-temperature treatment of compound (XI).



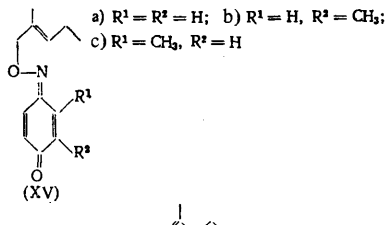
(X)



(XI)

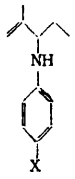
When examining the possible separation of α-alkenylnitrones in the reactions of nitroso-compounds with alkenes, it must be borne in mind[31] that they are stable only when they have a structure capable of undergoing tautomerisation to give more stable forms (for example, the alkenylquinonimine oxide (XII), isomeric with the expected nitrone, is obtained from nitrosophenol and 2-methylpent-2-ene)[31,32] or have a high degree of resonance stability (the nitrone (VIII), isolated in the reaction of nitrosobenzene with safrole).

(XII) (XIII)



(XIV)

Unstable α-alkenyl-N-arylnitrones may undergo intramolecular cyclisation or react further with the alkene and the unreacted nitroso-compound.[33-38] These reactions naturally also take place with comparatively stable nitrones, but under more severe conditions; for example, the isoxazoline ring (XIII) is formed by intramolecular cyclisation.

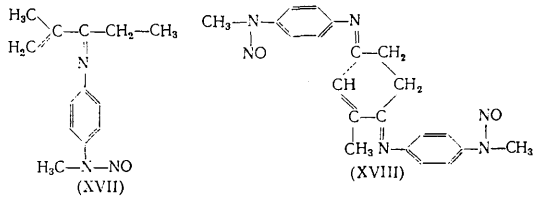


The instability of the products of the reactions of nitroso-compounds with alkenes is confirmed by the data of Ref.39. The author cited considers that at low temperatures (-10 °C), nitrosobenzene reacts with α-methylstyrene to form the 3:1 adduct α-[1-phenyl-1,2-di(N-phenylhydroxylamino)ethyl]-N-phenylnitrone (XIV), which subsequently at room temperature loses one N-phenylhydroxylamine fragment to form the cyclic 2:1 adduct, a substituted isoxazoline. Another example is the thermal rearrangement of alkenylquinonimine N-oxides (XII), formed as indicated above by the reactions of nitrosophenols with 2-methylpent-2-ene, to give O-alkenyl quinonimine oxime ethers (XV).[32] This rearrangement, which is analogous to the familiar thermal rearrangement of allylamine oxides into O-alkenylhydroxylamines[40-42] and of nitrones into O-alkenyl oxime ethers,[43,44] takes place only at comparatively high temperatures (100–120 °C) so that oxime ethers were found in appreciable quantities only in the products of the reaction of nitrosocresols with 2-methylpent-2-ene, which requires high temperatures.

The main products isolated[13,31,45] in the reaction of 2-methylpent-2-ene with *p*-nitrosophenol and N,N-dimethyl-*p*-nitrosoaniline are the corresponding *p*-substituted alkenylanilines (XVI).

a) $R^1 = R^2 = H$; b) $R^1 = H$, $R^2 = CH_3$; c) $R^1 = CH_3$, $R^2 = H$

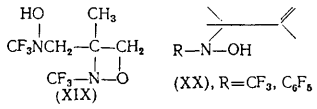
(XV)



(XVI): X = OH, $N(CH_3)_2$

A characteristic feature of the reaction conditions in Ref.31 is a 12-fold excess of the alkene. In this case, in addition to the *p*-substituted N-alkenylanilines, the authors cited isolated a large number of resinous products, which they believed to be condensed nitrone structures. A small quantity of azoxybenzenes, azobenzenes, and primary *p*-substituted anilines, products of side reactions, was also obtained.

The comparative simplicity of the single-stage synthesis of N-alkenyl-*p*-phenylenediamines—a new class of effective antioxidants—by the reaction of N-substituted *p*-nitrosoanilines with alkenes[46] makes this process fully competitive with the industrial method for the production of familiar antioxidants with a similar structure, namely N-alkyl-*p*-phenylenediamines, which are usually obtained by hydrogenating nitroso-compounds followed by reductive alkylation of the anilines with ketones.[47]



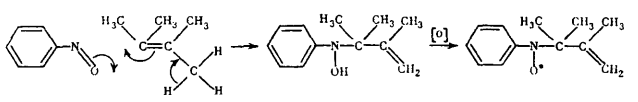
Another possible final structure is indicated in Ref.48, where the products of the reaction of N-methyl-N,4-dinitrosoaniline with alkenes are assigned the anil structure; the reaction with 2-methylpent-2-ene gives the 1:1 adduct (XVII), and the reaction with methylcyclohexane gives the 2:1 adduct (XVIII). The authors of Ref.13 consider, however, that the data given in Ref.48, on the basis of which the functional group in the final products (XVII) and (XVIII) was identified

as the azomethine group, can equally be related to an azomethine oxide (nitrone).

(XVII) (XVIII)

The cyclic products of the reaction of nitroso-compounds with alkenes not containing γ-protons, which are apparently the main final products or intermediate products in the case of allyl alkenes, have been reported to contain not only cyclised nitrones but also oxazetidines[49-51] or compounds containing hydroxylamine and oxazetidine groups.[51] Thus in the opinion of the authors of Ref.51, the 2:1 adduct of trifluoronitrosomethane and isobutylene has the structure (XIX).

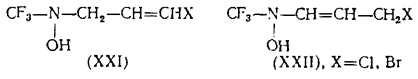
(XIX) (XX), R=$CF_3$, $C_6F_5$



Some authors[25,51,52] consider that the final products of the reactions of alkenes with fluorinated nitroso-compounds are alkenylaryl- or alkenylalkylhydroxylamines (XX). Most workers, however, believe that substituted hydroxylamines are only intermediate compounds, and undergo further transformations, discussed below.

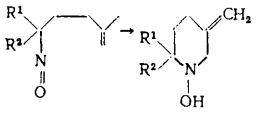
Analysis of published data on the structure of the final products of the reactions of nitroso-compounds with alkenes containing allyl hydrogen leads to the following conclusions: 1) in a large excess of the alkene, the reaction apparently takes place mainly to give the secondary amine and the nitrone or its transformation products; 2) in the absence of an excess of the alkene, appreciable quantities of azoxy-derivatives are found in the reaction products; 3) for perfluorinated nitroso-compounds, the formation of compounds with hydroxylamine or oxazetidine groups as final products is possible.

## 2. Mechanism of the Primary Stage of the Reaction



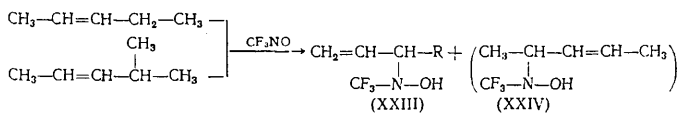
Most workers who have studied the reactions of C-nitroso-compounds with alkenes containing γ-protons consider that the initial stage is the ene addition of the nitroso-compound to give an unsaturated hydroxylamine. However, since these hydroxylamines are unstable and can be isolated and identified only in rare cases, there are other ideas regarding the primary stage.

The possibility of an ene reaction between a nitroso-compound and an alkene containing hydrogen on the α-methylene carbon atom was first reported in 1965.[53] Data were soon published[28] on the formation of a stable alkenyl aryl nitroxide radical, obtained by oxidising an extremely reactive alkenylarylhydroxylamine—an adduct of nitrosobenzene or some of its *o*-, *m*-, and *p*-derivatives with tetramethylethylene, chosen as an alkene whose symmetry makes it possible to obtain a resolved triplet in the EPR spectrum of the reaction product. The intermediate unstable alkenylarylhydroxylamine could not be isolated, and its formation was proved indirectly.



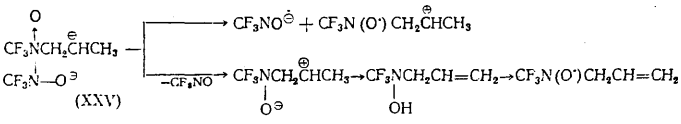
The possibility of ene synthesis with subsequent oxidation of the alkenylhydroxylamine to a nitroxide radical was confirmed in Ref.25, where the ene adduct of pentafluoronitrobenzene and tetramethylethylene was isolated in quantitative yield. Trifluoronitrosobenzene reacts similarly with an alkene. Many other authors also regard ene synthesis as the initial stage of the reactions of nitroso-compounds with alkenes.[20,46,52,54,55] The study of the reactivity of alkenes with different structures in the ene reaction is of considerable interest. The reactivity of butenes towards trifluoronitrosomethane decreases in the following order:[55] *cis*-$CH_3$–CH=CH–$CH_3$ > *trans*-$CH_3$–CH=CH–$CH_3$ > $(CH_3)_2C=CH_2$ > $CH_3$–$CH_2$–CH=$CH_2$, which is apparently determined by the nucleophilic character of the double bond in the alkene molecule and by steric factors. The presence of electron-acceptor substituents on the allyl carbon atom decreases the reaction rate considerably. A similar conclusion was reached[56] in a study of the kinetics of the reactions of alkenes with different structures with N,N-dimethyl-*p*-nitrosoaniline, which established that the highest rate in this reaction is shown by alkenes with the isostructure, containing an internal double bond on the tertiary carbon atom. A study of the kinetics of the reaction showed that it is formally of first order with respect to both reagents in a large excess of one of them.

To prove that a reaction is an ene reaction, it is important to establish the exact position of the hydroxylamine group in the chain or, if this is impossible because of the ease of oxidation of the hydroxylamine, to establish the position of the resulting nitroxide radical from the hyperfine structure of the EPR spectrum. Thus the presence or absence of hydrogen on the α-carbon atom (relative to the nitroxide group) has a significant influence on the EPR spectrum. Contradictory data are also obtained with this approach, however. Thus the product of the reaction of allyl halides with trifluoronitrosomethane according to some authors[55] is the one adduct (XXI) and according to others[20] the isomeric product (XXII).



(XXI) (XXII), X=Cl, Br

Nevertheless, many authors give irrefutable data which indicate that the ene adduct is formed, that is that the nitrogen of the nitroso-group is added to the carbon of the double bond with the simultaneous transfer of the allyl hydrogen to the oxygen of the nitroso-group and prototropic displacement of the double bond. One interesting proof is the formation of a cyclic hydroxylamine by an intramolecular ene reaction in nitrosoalkenes:[57]

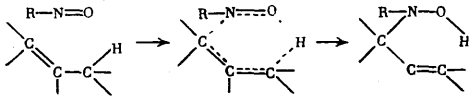


The nitroso-group adds on to the α- or β-unsaturated carbon atom, depending on the nature of the allyl hydrogen atom. The primary and secondary γ-protons are approximately equally readily transferred to the oxygen atom of the nitroso-group,[55] and the proton of the methine group is much more difficult to remove. Thus pent-2-ene reacts with trifluoronitrosomethane to give a mixture of isomers (XXIII) and (XXIV) as a result of the transfer of a hydrogen atom from the $CH_3$ and $CH_2$ groups respectively, whereas with 4-methylpent-2-ene, where there is a choice between CH and $CH_3$ groups, only compound

(XXIII), with R = iso-$C_3H_7$, is formed.

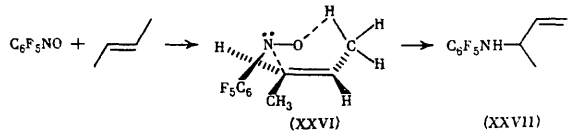
For alkenes with the iso-structure, the position at which the nitroso-group is added depends not only on the nature of the allyl hydrogen but also on the electronegativity of the carbon of the double bond. Thus an analysis of the EPR and NMR spectra[58] established that nitrosobenzene reacts with 2-methylpent-2-ene to give an ene adduct at the =CH— fragment of the alkene molecule.

Different views of the mechanism of formation of the ene adducts of nitroso-compounds with alkenes, in particular of the structure of the intermediates, have been put forward. In Ref.20 it is stated that the reaction of a nitroso-compound with an alkene gives initially a 2:1 donor–acceptor complex,[25] in which the alkene is generally the donor, and the nitroso-compound the acceptor. An exception is provided by acrylates or vinyl compounds with strong electron-acceptor substituents, where at increased temperatures the unsaturated compound may act as the electron acceptor, and the nitroso-compound as the electron donor. The decomposition of this complex to give 1:1 adducts, for example for the reaction of trifluoronitrosomethane with propene, takes place according to the scheme:



The author cited bases his idea of a single redox mechanism for this process on the reactivity of alkenes with different structures, which is consistent with the values of the ionisation potentials, characterising the donor properties of the alkene,[59] and also with the tendency of the alkenes to form charge-transfer complexes with other acceptors,[60] and the reactivity of alkenes in reactions with electrophilic reagents.[61]

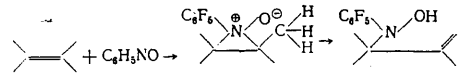
According to another opinion,[50] the reaction involves the formation of a four-membered oxazetidine ring, which subsequently breaks down to give the hydroxylamine derivative.



These ideas have been criticised,[55] however, and as proof of the absence of the zwitterion intermediate (the bipolar ion (XXV) in Ref.20), the reaction with β-pinene, which is not accompanied by rearrangement, is considered.

The heterolytic, and not homolytic, character of the first stage of the reaction of a nitroso-compound with an alkene is confirmed by the addition to the alkene carbon, and not to the carbon which was initially the allyl carbon.

In Ref.25 it is considered that the intermediate state of the ene reaction is a six-membered internal associate, and this reaction is regarded as a familiar "synchronous transfer" reaction.



According to these ideas, the formation of the secondary amine (XXVII) as the product of the reaction of pentafluoronitrosobenzene and *trans*-but-2-ene is explained by the role of the steric factors in the intermediate state (XXVI) of the ene reaction.[25]

The recent increased interest in ene reactions with different enophiles such as oxygen,[62–64] triazolinediones,[65,66] and compounds with S=N bonds,[67] however, has led to a re-examination of the idea of a six-membered intermediate state.

Thus a study of the isotope effects produced by the deuteriation of tetramethylethylene led to the conclusion that its reaction with pentafluoronitrosobenzene takes place in two stages,[52] and that the first stage of the process, which is the limiting stage, gives a three-membered cyclic compound, an aziridine oxide, which subsequently undergoes rapid splitting of the C–H and C–N bonds to give the ene product:

The transformations of the ene product, including the formation of nitroxide radicals, will be examined below. It has been suggested, however, that nitroxide radicals in the reactions of nitroso-compounds with alkenes are not necessarily formed by the oxidation of an intermediate alkenylhydroxylamine, particularly since paramagnetic species have also been obtained in the reactions of nitroso-compounds with unsaturated compounds not containing allyl hydrogen, that is in cases where the formation of an ene adduct is impossible. These species have been observed in reactions with styrene,[22] trifluorostyrene,[21] vinyl acetate, and derivatives of acrylic acid (these paramagnetic species were assigned the corresponding radical–cation and radical–anion structures[20]).

Thus a study[68] of radical processes in a nitroso-compound–alkene system (for the reactions of nitrosobenzene and *p*-chloronitrosobenzene with oct-1-ene, cyclohexene, butadiene, and cycloheptatriene) leaves open the question of the mechanism of the first stage of the process. The following reaction scheme is given:

$$ArNO + CH_2{=}CHR \rightarrow ArN(O^{\cdot})CH_2{-}\dot{C}HR \quad (1)$$

$$2ArN(O^{\cdot})CH_2{-}\dot{C}HR \rightarrow [ArN(O^{\cdot})CH_2{-}CH(R){-}]_2 \quad (2)$$

$$ArNO + ArN(O^{\cdot})CH_2{-}CH{-}\dot{C}HR_2' \rightarrow ArN(O^{\cdot})CH_2CH{=}CR_2' + ArNHO^{\cdot} \quad (3)$$

$$ArNO + ArN(O^{\cdot})CH_2{-}\dot{C}HR \rightarrow ArN(O^{\cdot})CH{=}CHR + ArNHO^{\cdot} \quad (4)$$

$$ArNO + ArN(O^{\cdot})CH_2{-}\dot{C}HR \rightarrow ArN(O^{\cdot})CH_2CH(R){-}N(O^{\cdot})Ar \quad (5)$$

The biradical formed according to Eqn.(1) reacts rapidly according to Eqns.(2)–(5) to give other radicals which are then transformed more slowly by disproportionation, recombination, or reaction with the starting materials to give nitrones, hydroxylamines, azoxybenzenes, etc.

The approach in Ref.68 to the determination of the mechanism of the primary stage of the reactions of nitroso-compounds with alkenes appears too cautious; the nitroxide radicals are most probably formed by the oxidation of the intermediate alkenylhydroxylamine by the nitroso-compound. Data confirming this view are given below.

### 3. The Mechanism of the Subsequent Stages of the Reactions of C-Nitroso-compounds with Alkenes

The examination of the mechanism of the subsequent stages of the reactions of nitroso-compounds with alkenes should essentially be concerned with the reactions of disubstituted

hydroxylamines with nitroxide radicals, that is the intermediates whose formation (at least one of them) is postulated by most authors.

*a) Reactions of disubstituted hydroxylamines*

The chemistry of alkylarylhydroxylamines and alkenylarylhydroxylamines has been little studied; most data relate to their decomposition and oxidation.

The chief products of the thermal decomposition of these compounds are a nitrone and a secondary amine,[69,70] formed by the disproportionation of two moles of the disubstituted hydroxylamine. It has been confirmed[13] that the decomposition is of second order with respect to the hydroxylamine, and that the decomposition rate depends on the nature of the substituent; electron-donor substituents increase the reaction rate. A study of the thermal decomposition of *p*-substituted N-phenylhydroxylamines showed that the reaction products are nitrones and azoxy-arenes.[13] Another possible direction of transformation of substituted hydroxylamines when heated is dehydration to give an azomethine.[48]

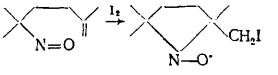
However, the most important reaction of alkenylarylhydroxylamines as intermediate products of the reaction of nitroso-compounds with alkenes is undoubtedly their oxidation by oxygen in the reaction mixture or, if it is not present, by the unreacted nitroso-compound.

The mechanism of this reaction can be considered. Thermodynamic studies have shown[71,72] that stable radicals X$^{\cdot}$ may be produced by the removal of only mobile hydrogen by the reaction:

$$RN{=}O + XH \rightarrow RNHO^{\cdot} + X^{\cdot} \qquad (6)$$

The low dissociation energy of the OH bond in alkenylaryl- and alkenylalkylhydroxylamines[73] facilitates this reaction. Reaction (6), which involves molecular homolysis by the rupture of a simple bond under the influence of the reagent, in the opinion of the authors of Ref.72 corresponds more closely to the experimental data than two other reactions which may give radicals, namely the reaction of two π-systems to give biradicals, and donor–acceptor electron exchange to give two radicals or a radical–ion.[74] Under certain conditions, the last type of homolysis is probably involved in the reactions of nitroso-compounds with unsaturated compounds not containing γ-protons.

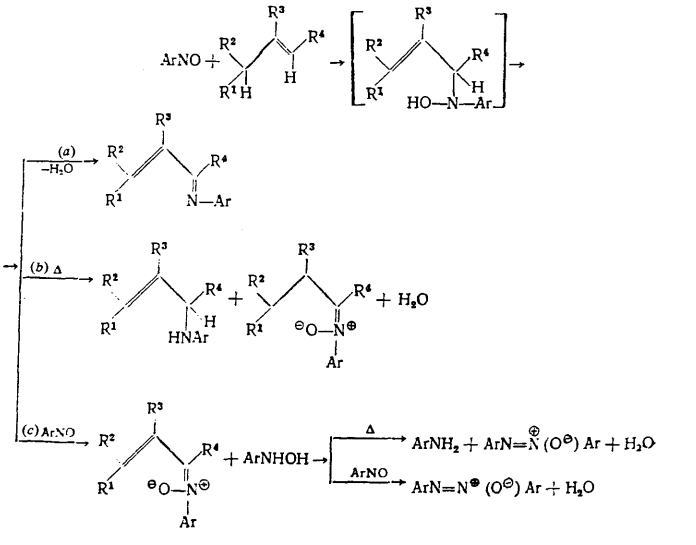
Direct proof of the formation of nitroxide radicals in the reactions of nitroso-compounds with hydroxylamines has been given.[75]



Evidence of a reaction of type (6) between a nitroso-compound and an N-substituted hydroxylamine is also provided by recent data on the formation of nitroxide radicals in the reactions of nitroso-compounds with other compounds containing active hydrogen: carbonyl compounds capable of enolisation, thiols, and phenols,[54] thiophenols,[76], imines in the enamine tautomeric form,[77] diketones,[78] etc.

At the same time, the importance of the photolysis of nitroso-compounds in the production of nitroxide radicals in a reacting system has been emphasised:[72] the light source may be natural light or ordinary artificial laboratory illumination.

$$RN{=}O \xrightarrow{h\nu} R^{\cdot} + NO^{\cdot}$$
$$R^{\cdot} + RNO \rightarrow R_2NO^{\cdot}$$



Nevertheless, most authors attribute the formation of nitroxide radicals in the reactions of C-nitroso-compounds with alkenes to the oxidation of an intermediate hydroxylamine,[20,25,28,55,57,58] the oxidant usually being the nitroso-compound itself (when the reaction is carried out in an inert medium), although if the aim is to obtain the nitroxide it is possible to introduce oxidising agents specially, for example silver oxide[79] or iodine.[80]

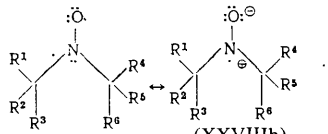
The last paper is of particular interest, since it proposes a general method for synthesising cyclic nitroxides by the action of iodine on δ, ε-unsaturated nitroso-compounds.

There are very few published data on the final oxidation products of disubstituted hydroxylamines. The final products of the oxidation of N-benzyl-N-phenylhydroxylamine by different *p*-substituted nitrosobenzenes are the α,N-diphenylnitrone and *p*-substituted azoxybenzenes.[13] When the aromatic nitroso-compound contains strong electron-donor substituents, an appreciable quantity of derivatives of primary amines is found in the reaction mixture, in addition to azoxybenzenes.

From their experimental data and an analysis of published data, the following scheme was proposed for the reactions of nitroso-compounds with alkenes containing an allyl hydrogen atom:[13]

According to this scheme, the first stage of the reaction is an ene reaction, leading to the formation of an alkenylarylhydroxylamine, which subsequently undergoes transformations characteristic of disubstituted hydroxylamines: oxidation (*c*), thermal decomposition (*b*), and dehydration (*a*) to give the nitrone, azoxybenzene, amines, and an azomethine.

An undoubted advantage of the proposed scheme is that the authors tried to use known reactions to explain the transformation of N-substituted hydroxylamines into products which in the opinion of many workers are the final products of the reactions of nitroso-compounds with alkenes containing an allylic hydrogen atom.



At the same time, the scheme has a serious shortcoming, in that it ignores the fact that nitroxide radicals are formed in the reactions of nitroso-compounds with alkenes, and the relationship between the structures of the radicals and the final products.

Since there are no published data on this relationship, those reactions of nitroxide radicals which can apparently take place during the formation of the products of the reactions of nitroso-compounds with alkenes will be considered.

*b) Reactions of nitroxide radicals*

The chemistry of nitroxide radicals is a widely studied field, to which a large contribution has been made by Soviet scientists.[81–83] The thermodynamic stability of nitroxide radicals

is determined by the degree of delocalisation of the unpaired electron between oxygen and nitrogen (XXVIIIa, b); for dialkyl nitroxides the delocalisation energy is ~30 kcal mole$^{-1}$.

(XXVIIIa) (XXVIIIb)

In general, the stability of the free radicals correlates well with the dissociation energy of the bonds broken on radical formation.

Thus reactions such as the oxidation of hydroxylamines having a low energy of removal of the hydrogen of the hydroxyl group[73] or the "spin capture" of carbon-centred radicals by spin traps such as nitroso-compounds and nitrones[84] lead to the rapid formation of nitroxide radicals.

An important condition for the stability of disubstituted nitroxide radicals is the absence of hydrogen atoms on the α-carbon atom.[85] At the same time, monosubstituted nitroxides and dialkyl or alkyl aryl nitroxides containing methyl, methylene, or methine groups in the α-position, that is the radicals most frequently formed in the reactions of nitroso-compounds with alkenes, are generally insufficiently stable, and undergo recombination and disproportionation, and also react with reagents or intermediates in the reaction system.

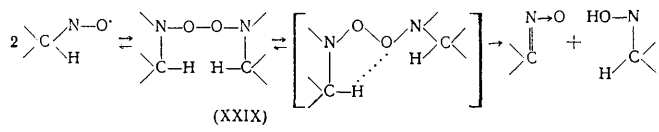
The chemical properties, in particular the ability to undergo recombination and disproportionation, of mono- and disubstituted nitroxides can be considered separately.

*Monoaryl and monoalkyl nitroxides.* The oxidation of N-phenyl-hydroxylamine by nitrosobenzene to give the phenyl nitroxide radical was first reported in Ref.86; the study of this reaction in different media shows that it gives azoxybenzene; the intermediate is a radical–anion in the presence of a strong base, and a nitroxide radical in the absence of a strong base.

A study of the kinetics of the decomposition of methyl, isopropyl, t-butyl, and phenyl nitroxides in solution[71] established that both reversible disporportionation to hydroxylamino- and nitroso-derivatives, and slower recombination to give an azoxy-compound, take place. For the phenyl derivative, the equilibrium constants and rates of the following reactions were calculated:

$$2C_6H_5NHO^{\cdot} \overset{K}{\rightleftharpoons} C_6H_5NHOH + C_6H_5NO \qquad (7)$$

$$2C_6H_5NHO^{\cdot} \xrightarrow{k_{azo}} C_6H_5N{=}NC_6H_5 + H_2O \qquad (8)$$

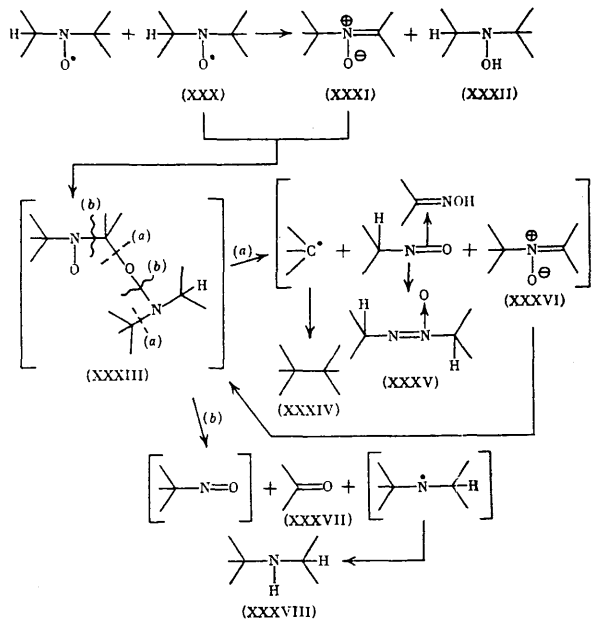


$$\downarrow O$$

The authors assume, however, that direct condensation of nitrosobenzene and N-phenylhydroxylamine to give azoxybenzene may take place.

At the same time, a study of the catalysis of this reaction using $Fe^{2+}$ and $Fe^{3+}$ salts[87] showed that the formation of azoxybenzene undoubtedly involves the dimerisation (recombination) of the nitroxide radical, that is according to Eqn.(8).

Important results were obtained in a study of the dependence of the stability of nitroxide radicals on the concentration in the solution. The rate of the decomposition of these radicals increases with decrease in their concentration.[71,86]

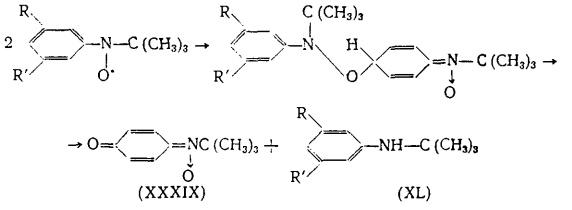


*Disubstituted nitroxide radicals.* The most stable radicals are di-t-alkyl nitroxides. In contrast to this, nitroxides having at least one hydrogen atom on the α-carbon atom usually disproportionate to hydroxylamines and nitrones. According to Refs.88 and 89, the mechanism of this reaction involves the dimerisation of the nitroxide and the subsequent slow decomposition of the diamagnetic dimer:

(XXIX)

The participation of the α-hydrogen atom in the limiting stage of the process was proved by replacing it with deuterium. The reaction shows a strong isotopic effect ($k_H/k_D \cong 9$).[93] At the same time, the structure of the dimer (XXIX) is not considered to have been proved,[90,91] since a thermochemical examination of the process[88,91] indicates that the formation of the O–O bond is endothermic, with an energy expenditure of 28 kcal mole$^{-1}$. The formation of at least three types of dimer with O–N, O–C, and N–N bonds has been reported.[92]

In a study of the decomposition of t-butyl isopropyl nitroxide radicals, doubt was cast[93] on the mechanism involving dimerisation, and the following scheme was given for the process:

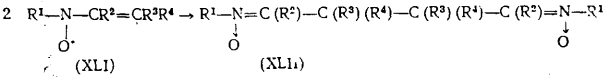


(XXX) (XXXI) (XXXII) (XXXIII) (XXXIV) (XXXV) (XXXVI) (XXXVII) (XXXVIII)

According to this scheme, the disproportionation of the nitroxide radicals (XXX) gives a hydroxylamine (XXXII) and a nitrone (XXXI), which being an excellent spin trap reacts with the original nitroxide radical to give an unstable secondary radical (XXXIII); decomposition of the latter gives products such as the alkane (XXXIV), the dimer of the nitroso-compound (XXXV), the oxime (XXXVI), the ketone (XXXVII), and the secondary amine (XXXVIII). Under certain conditions, the nitrone may be formed not by the disproportionation of the nitroxide but by its oxidation by an oxidant present in the system; this takes place in the formation of dibenzyl nitroxide from dibenzylhydroxylamine.[94]

Aryl t-alkyl nitroxides are much less stable than di-t-alkyl nitroxides. At first sight this fact is difficult to explain, since in the aryl derivatives the phenyl ring provides an additional region for delocalisation of the unpaired electron, and this should have led to an increase in the stability of the radical. The reason for this phenomenon is the dimerisation of the aryl t-alkyl nitroxides by the formation of a bond between the oxygen atom of the nitroxide and the *para*- or

*ortho*-positions of the benzene ring with subsequent decomposition of the dimer to the *p*-benzoquinone-N-t-alkylimine (XXXIX) and N-t-alkylaniline (XL).[95-100]



(XXXIX) (XL)

The formation of the dimer is inhibited by the presence of substituents in the *ortho*-position, which prevents the delocalisation of the electron density of the nitroxide group and hence decreases the spin density in the aromatic ring.[98] Bulky substituents in the *para*- or *meta*-positions also stabilise the radical as a result of the production of steric hindrance for radical attack.[95,98,100]

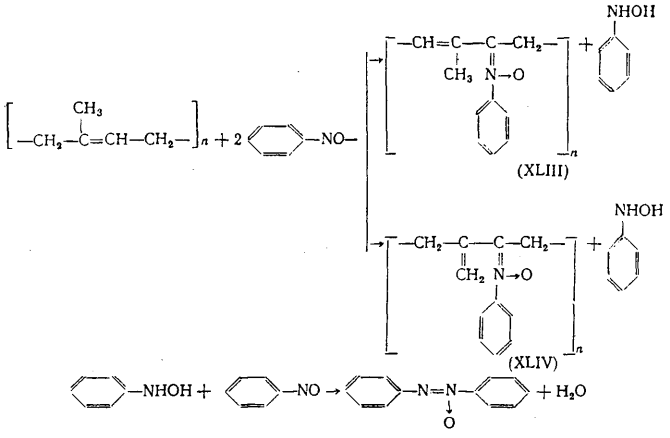
The influence of the structure of substituents on the stability of nitroxide radicals is effectively illustrated not only by their decomposition but also by their ability to recombine with hydrocarbon radicals. Thus aromatic nitroxides react with triphenylmethyl,[101] whereas nitroxides with aliphatic substituents do not react with it.[102]

Vinyl nitroxide radicals represent another important type of paramagnetic species for the chemistry of homolytic processes taking place in the reactions of nitroso-compounds with alkenes. These radicals may be formed either according to the scheme proposed in Ref.68 or by the oxidation of nitrones containing a hydrogen atom in the β-position, which in the opinion of many authors are among the main products of the reactions of nitroso-compounds with alkenes. As might have been expected, vinyl nitroxides are further stabilised by the delocalisation of the unpaired electron by conjugation with the vinyl group. At the same time they are fairly reactive.[103]

The recombination of vinyl nitoxide radicals (XLI) to give nitrones (XLII) takes place by the formation of a C–C bond in the β-position.

(XLI) (XLII)

Nitroso-compounds, nitrones, dienes, etc. also add on to the β-position of the vinyl group. The length of the chain is increased, with the formation of substituted nitroxide radicals.[103] These data illustrated a familiar fact in the chemistry of nitroxide radicals: the dependence of their stability and reactivity on their structure is determined by a combination of thermodynamic and kinetic factors, that is the degree of delocalisation of the unpaired electron and the steric hindrance at the atoms with a high spin density.



Thus analysis of published data on the reactions of nitroxide radicals shows that the compounds detected in the products of their recombination, disproportionation, oxidation, etc. include many of those compounds (azoxybenzenes, hydroxylamines, nitrones, secondary amines) which are regarded as the main products of the reactions of nitroso-compounds with alkenes. This confirms that these products may be formed in the reactions of C-nitroso-compounds with alkenes via nitroxide radicals as intermediates.

At the same time, the indefinite nature of conclusions about the structure of the reaction products is apparently due to the wide range of possible directions for the reactions of nitroxide radicals, characteristic of all homolytic processes, the results of which depend on the structure of the starting materials and on the reaction conditions. These reactions generally have a low selectivity and often give mixtures of products.

## IV. CHARACTERISTIC FEATURES OF THE REACTION OF NITROSO-COMPOUNDS WITH DIENE POLYMERS

The study of the reaction of nitroso-compounds with diene polymers to determine the reaction mechanism is difficult, because of the difficulty of isolating and identifying the functional fragments; on the other hand, however, this study extends the possibility of estimating the changes in the dimensions of the molecules taking place in the course of the reaction.

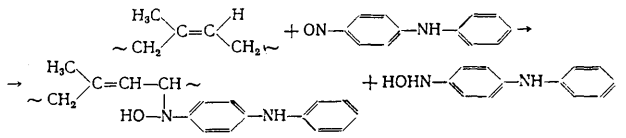
The reaction of nitroso-compounds with natural *cis*-1,4-polyisoprene was first studied in Ref.26, and in more detail in Ref.104, where a reaction scheme was proposed, based on the reaction of three moles of the nitroso-compound with one monomer unit, leading to the formation of two isomeric conjugated nitrones and azoxybenzene.

(XLIII)

(XLIV)

The authors cited, however, could not decide between the adduct structures (XLIII) and (XLIV).

In a development of these ideas, it was concluded[105] that the nitrone of "iso-rubber"† (the terminology of the authors cited) can be obtained in pure form only by carrying out the reaction without heating, in a nitrogen atmosphere.



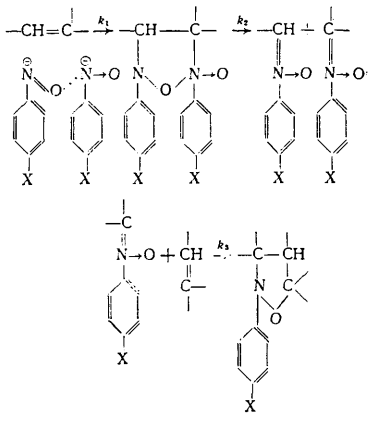
This scheme was adopted by various workers as a possible mechanism of structure formation in saturated rubbers with C-nitroso derivatives[106] and of the modification of polyisoprene by N-substituted *p*-nitrosoanilines.[107]

Alternative structures suggested for the functional fragment formed in the reaction of polyisoprene with N-methyl-N,4-dinitrosoaniline are the anil structure,[48] and in the reaction with *p*-nitrosodiphenylamine the secondary amine[6,108] and hydroxylamine[109] structures; in the last case the reaction product is not the ene adduct but the product of the addition of the nitroso-group to the allyl carbon (XLV).

The authors of Ref.48 describe the mechanism of the process as ene synthesis with subsequent dehydration of the intermediate alkenylarylhydroxylamine and the formation of a Schiff base, whereas in Ref.109 the mechanism of the process is described as molecular homolysis with the removal of allyl hydrogen and the subsequent recombination of the radicals

†The term iso-rubber refers to *cis*-1,4-polyisoprene with isomeric location of the double bonds in the 1,5- and 1,4-positions.

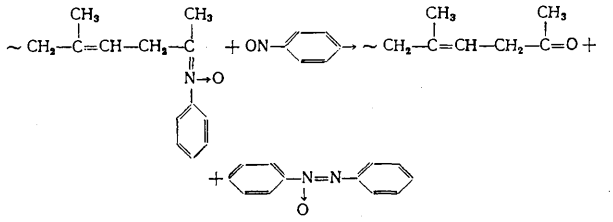
to give diphenylaminohydroxylamine in the free state or combined with the polymer chain.



The main characteristic of the reaction of a nitroso-compound with a polydiene is the degradation of the polymer chain. In the case of the reaction with low-molecular-weight alkenes, only the authors of Refs.18 and 26, who describe the reaction of styrene with nitrosobenzene, note the possibility of rupture of the hydrocarbon chain, whereas for the diene polymer the effect of degradation is marked.

However, although in Ref.109 it is suggested that the nitroso-compound initiates the thermo-oxidative degradation of the polymer at a high temperature (143 °C), it has been shown[100–112] that rupture of the polymer chain takes place as a result of the chemical reaction of the polydiene with the nitroso-compound, and that there is a good correlation between the nitroso-compound : polyene molar ratio and the molecular mass of the degradation product.[110–113] Conditions have been found for the synthesis of oligoisoprenes over a wide range of molecular masses.[114,115]

Comparison of the number-average molecular masses of the original and reacted polyisoprene with the number of functional groups combined with the rubber shows that an average of about two molecules of the nitroso-compound is added on for every rupture of the macromolecule.[113] A more detailed analysis of the molecular structure of the oligoisoprenes formed[116] showed that the maximum of the distribution of the oligomer with respect to functionality corresponds to 2, and the molar concentration of bifunctional molecules reaches 40. At the same time, an appreciable quantity of mono-, tri-, tetra-, and pentafunctional molecules, and a small quantity of molecules of higher functionality, were detected in the oligomer.



These experimental data, together with the results of a study of the kinetics of the reaction (first order with respect to the nitroso-compound in an excess of the polymer)[113] and an analysis of the structure of the final products[117] led to the proposal of the following scheme for the degradation and subsequent branching of the polymer molecules:

X = N($C_2H_5$)$_2$, $NHC_6H_5$

According to this scheme, the final reaction products are nitrones or the products of their transformation.[113,117]

At the same time, Japanese workers isolated,[110] in addition to degradation products which were also identified as polymeric nitrones, side products: an aldehyde (or ketone) and azoxybenzene.

In contrast to the reaction in solution, the reaction of *cis*-1,4-polyisoprene with *p*-nitrosodiphenylamine in the mass at high temperatures is often accompanied by the formation of a cross-linked rubber. According to Ref.109, structure formation takes place by the recombination of the hydrocarbon polymeric radicals produced in this reaction. A specific feature of the chemical modification of diene polymers by so-called small additives is that the process is carried out in a large excess of one of the reagents (the polymer), so that some of the reactions which are observed in the reaction of equimolar quantities of the nitroso-compound and the alkene or in an excess of the nitroso-compound cannot be observed in this case.

Even with allowance for this characteristic feature, however, and also for the specific features of the transformations in the polymer chains, it must be said that the schemes given for the reactions of nitroso-compounds with diene polymers are oversimplified, and do not take critical account of the extensive experimental material accumulated in the study of the mechanism of the reaction of a nitroso-compound with low-molecular-weight alkenes, so that they require, at the least, serious refinement.

---o0o---

Progress in fundamental and applied studies of the use of C-nitroso-compounds as paramagnetic inhibitors, spin traps, stabilisers and modifiers of rubber and plastics, and promoters of the reaction of rubber with technical carbon has stimulated interest in the investigation of the mechanism of the reactions of nitroso-compounds with alkenes. For this reaction, as for other processes involving the formation of extremely reactive intermediates, the possible directions of the reaction and the structures of the final products depend on the nature of the substituents in the reagents and on the reaction conditions. In this respect, each new study carried out on individual representatives of both classes of compound extends the picture of the reaction as a whole.

Many general features of the reactions with alkenes with and without an allyl hydrogen atom have now been established, however. These general characteristics apparently include the heterolytic character of the first stage of the addition, attack by the nitroso-compound on the carbon atom of the double bond, the formation of paramagnetic species in one of the subsequent stages, etc.

The achievements in the application of C-nitroso-compounds have increased interest in their reactivity and the mechanism of their reactions with alkenes; the data obtained have in turn led to new ideas for the practical utilisation of this reaction.

Thus the experimentally observed rupture of the hydrocarbon chain in the reaction of a polymeric alkene with a nitroso-compound has made it possible to synthesise for the

first time an oligoisoprene with the *cis*-structure with functional polar groups, that is a material which has not yet been prepared by polymerisation methods. The paramagnetic species in the reaction system under certain conditions can be used to initiate the radical grafting of unsaturated polar compounds to an unsaturated hydrocarbon substrate.

There is no doubt that this extremely important reaction in organic chemistry will continue to attract the attention of research workers for a long time.

# Structural Vacancies in Compounds of Variable Composition

A.I.Gusev, S.I.Alyamovskii, Yu.G.Zainulin, and G.P.Shveikin

The results of studies of compounds of variable composition based on the high-melting metals of the IVa and Va subgroups (oxides, nitrides, carbides, oxide carbides, oxide nitrides, carbide nitrides) have been systematically examined. Problems of atomic ordering in these compounds are discussed, including the development of an inhomogeneous structure and the control of the vacancy concentration while retaining the original chemical composition and type of crystal structure at high pressures and temperatures. The thermodynamics of the formation of structural vacancies in compounds of variable composition are discussed.
The bibliography includes 123 references.

## I. INTRODUCTION

Several new compounds of both fixed and variable composition, including compounds with an ordered structure, have been discovered in the last 15–20 years in many well known binary systems of the M–C, M–N, and M–O type (where M is a transition metal from subgroup IVa or Va). Many were obtained by controlling the concentration of vacancies in the crystal lattice, and their distribution. This is true, in particular, of the compounds of the interstitial phase type based on high-melting metals.

The most characteristic feature of compounds of variable composition of this type is the presence of a close-packed sublattice of the pure metal, which acts as a matrix for different atoms accommodated in its interstitial cavities and forming a non-metal sublattice. In this sense the pure metal can be formally treated as a special state of the compound of variable composition in which all the interstitial sites are vacant. In this case the vacant interstitials should be treated as a species equivalent to an interstitial atom rather than as a simple hole in the crystal lattice. When the non-metal sublattice is partially filled the vacant interstitial sites (or structural vacancies) can diffuse through the lattice and behave in some respects like real interstitial atoms.

Structural vacancies, like interstitial atoms, can affect practically all the properties of compounds of variable composition of the interstitial phase type.[1-8] Therefore the defects in the crystal structure should be treated as one of the most important properties of the carbides, nitrides, and oxides of the transition metals, and also of the solid solutions based on them.[1,4-15] These substances, which have a wide homogeneity region, can be described as chemical formations whose composition includes, in addition to metal atoms and non-metal atoms, structural vacancies[5,8] in the non-metal or in the metal sublattice, or in both sublattices simultaneously. It was pointed out[4] in 1969 that vacancies (like metal atoms and non-metal atoms) are independent components of the system and they can affect its properties even more markedly than the atoms.

In addition to "compounds of variable composition", the term "non-stoichiometric compounds" is now generally used in scientific publications, but not always with the same meaning. It has been suggested[4] that the new term is incorrect, since a non-stoichiometric compound has a fixed composition though it is represented by a formula with fractional indices. If we adopt this point of view we must classify the compound $Cu_{31}Sn_8$ (of constant composition) as stoichiometric or as non-stoichiometric according to the method of writing the formula (since simplification produces fractional indices: for example ($Cu_{15.5}Sn_4$ or $Cu_{3.875}Sn$). The same applies to the many organic compounds with a molecular structure, often with a complex chemical composition, which can be expressed by formulae with integral or with fractional indices. Nevertheless their compositions obey the law of multiple proportions, and the compounds are not non-stoichiometric.

In a realistic and soundly based definition[5] of a "non-stoichiometric compound" the concept is associated with the perturbation of the ideal crystal structure. Any compound having a geometrically regular crystal lattice is classified[5] as stoichiometric.

We consider that any compound of fixed composition and having a lattice shown (by diffraction methods) to be ideal should be classified as stoichiometric. The integral indices in the chemical formula of a stoichiometric compound can have any value (not necessarily small), determined from chemical analysis and structural studies. The term non-stoichiometric should be applied to compounds having a homogeneity region, whose width can be determined by analytical methods (mainly, compounds with structural vacancies in their unit cell). The distribution of atoms of different kinds (or of atoms and structural vacancies) in each of the sublattices of a non-stoichiometric compound can be random or ordered.

Clearly, the terms "compound of variable composition" and "non-stoichiometric compound" used in scientific publications have equivalent meanings. The carbides, nitrides, and oxides of the transition metals have wide homogeneity regions and are most correctly referred to as non-stoichiometric compounds of variable composition of the interstitial phase type. This description most fully reflects the special features of the crystalline structure of these substances (the position of the added atoms in the interstitial sites of the metal sublattice, and the presence of a homogeneity region), but the term is too long, and in this review we shall use the shorter term "compounds of variable composition".

## II. ATOMIC ORDERING IN COMPOUNDS OF VARIABLE COMPOSITION

It was initially assumed that structural vacancies in the crystal lattice of compounds of variable composition in their homogeneity region are randomly distributed. This belief applied, in particular, to the monocarbides and the mononitrides of the transition metals of subgroups IVa and Va over the whole of their temperature region of existence, as shown in the standard monographs.[1,9,11,12,16] However, ample evidence was subsequently found of the existence of both short-range and long-range order in the crystal lattice of these compounds and of their solid solutions.

Using mainly crystallographic arguments Parthe and Yoon[17] defined eight possible types of ordered structures in carbides: $M_2C$, $M_3C_3$, $M_8C_5$, $M_3C_2$, $M_4C_3$, $M_5C_4$, $M_6C_5$, and $M_8C_7$ (where M = Ti, Zr, Hf, V, Nb, Ta). Most of these have already been prepared. In multi-component compounds and in solid solutions the number of possible variants of the structure is, of course, even greater. In the systems M–C, M–N, M–C–O, M–N–O, and M–C–N more than 70 ordered phases have already been discovered: they are formed from the basic structures with face-centred cubic (FCC), body-centred cubic (BCC), and close-packed hexagonal (CPH) crystal lattices. The many superstructures listed in Table 1 were identified by using high-sensitivity diffraction methods (especially neutron diffraction) and lengthy heat treatments (hundreds of hours) at relatively low temperatures (1300 K or less).

The kinetics of the order–disorder transition are largely determined by the previous history of the sample. Thus, the ordering of non-stoichiometric compounds was found[69] to be assisted by the addition of hydrogen. A similar effect was observed[70] after the simultaneous introduction of small amounts of oxygen and nitrogen into the crystal lattice of the hexagonal carbides $Nb_2C$ and $V_2C$. Reports that ordering is assisted by additions of oxygen, nitrogen, and hydrogen appear also in Refs.71 and 72. In the non-stoichiometric compounds of the V–C system the order–disorder transition was found[73] to depend also on the micro-structure of the sample. Furthermore, two different cubic forms of titanium monoxide $TiO_{1.00}$ have been reported[27] (one of the NaCl type, with a random distribution of vacancies, and another with a partially ordered distribution of vacancies and a 3 times greater lattice constant), stable at 1500–2100 K and 1250–1500 K respectively. A third, monoclinic modification of $TiO_{1.00}$ with a fully ordered distribution of vacancies is stable at temperatures below 1250 K. However, other workers prepared compounds of the $TiO_y$ type at 1270 K [74] and 1070 K,[75] but failed to observe the ordering reported[26,27] for the compound $TiO_{1.00}$ (and also for other $TiO_y$ compositions). Only one cubic structure (NaCl type) was found in the entire homogeneity region by using "preparations in X-ray diffraction equilibrium".

The data in Table 1 suggest that ordering in the non-stoichiometric monocarbides of the group V transition metals produces mainly phases of composition $M_6C_5$ having monoclinic and trigonal structures. A structural feature common to all ordered phases of the non-stoichiometric monocarbides of the group IV and V transition metals is an alternation of completely filled and partially filled carbon planes in the $[111]_{NaCl}$ or equivalent directions.

In the ordered lower carbides $M_2C$ the characteristic feature is an alternation (in the direction perpendicular to the *c* axis) of carbon planes filled to different extents with carbon atoms.

We also note from Table 1 that the ordered phases of non-stoichiometric cubic titanium, vanadium, and niobium mononitrides have tetragonal structures and differ substantially from the corresponding ordered carbides. In the unit cell of the ordered titanium and niobium nitrides the vacancies are accommodated in the sites of a body-centred tetragonal lattice. In the cubic monoxides different ordered phases can be formed according to the oxygen content and the heat treatment conditions: they have cubic, tetragonal, rhombic, or monoclinic lattices.

The overall conclusion from the data in Table 1 is that ordering phenomena are relatively common in non-stoichiometric compounds of the interstitial phase type, and they are associated with a redistribution of the non-metal atoms over the octahedral interstitials of the metal sublattice.

## III. INHOMOGENEOUS STRUCTURE IN COMPOUNDS OF VARIABLE COMPOSITION

The previous history of the sample, which affects the rate of the order–disorder transition, includes the impurities initially present in the materials or introduced during the synthesis, the type and duration of the heat treatment adopted (homogenising, recrystallising, stress relieving), and the chosen cooling regime.

These effects are clearly illustrated by a full and detailed study of short-range and long-range order in the non-stoichiometric niobium carbide $NbC_y$ by NMR,[57,76,78] structural neutron diffraction, X-ray diffraction,[57,58] and magnetic susceptibility.[57,77] It was found that even $NbC_y$ samples quenched from 1800–2300 K contain some short-range order, but the degree of ordering is small. This increases as the temperature is lowered to the transition point, but no long-range order is observed. The structural phase transition, associated with ordering of the carbon atoms and of the structural vacancies in the non-metal sublattice of $NbC_y$, begins near 1300 K. The NMR spectra for the $^{93}Nb$ nuclei in $NbC_y$ and the magnetic susceptibility of the niobium carbide samples containing the ordered $Nb_6C_5$ phase are markedly different from those for the disordered state of niobium carbide.[76–78]

On the other hand the NMR spectra and the magnetic susceptibility are almost unaffected by the amount of ordered phase in the sample, i.e. they are insensitive to the long-range order parameter. It follows[57,77] that in niobium carbide samples containing an ordered phase and prepared with different heat treatment regimes the short-range order parameter $\alpha$ for $NbC_y$ of any composition is almost the same and close to the maximum possible value. This conclusion is confirmed by calculations of $\alpha$ from magnetic susceptibility data.[57,77] Hence the equilibrium state of niobium carbide in the two-phase region near the transition temperature has a high proportion of short-range order, approximately the same in the two phases. On further decrease in the temperature the proportion of disordered phase decreases and finally disappears.

An analysis of the ratio of short-range to long-range order in $NbC_y$ showed[57] that the presence of the maximum possible amount of short-range order for the given composition is a necessary but not a sufficient condition for the appearance of long-range order. It follows that short-range and long-range order can be formed by different mechanisms in niobium carbide: only the long-range interactions (probably, the phonon subsystem) can account for the formation of long-range order, whereas short-range order may be caused

by interactions with a radius of action comparable with the interatomic distance (electronic subsystem).

NMR studies of non-stoichiometric vanadium compounds[79] also detected an effect of the interstitial C, N, and O atoms on the degree of short-range order and on the distribution of vacancies. In $VC_y$ and $VN_y$ the type of short-range order is determined by the mutual repulsion of the vacancies. The insertion of oxygen atoms into the crystal lattice of vanadium monocarbide produces a random distribution of vacancies in a mutually ordered arrangement of carbon and oxygen atoms in the resulting oxide carbide $VC_{0.5}O_{0.5}$. The insertion of hydrogen atoms into $VC_y$ and $VN_y$ does not affect the type of short-range order. Thus we may conclude from that work[79] that the interactions between vanadium atoms and their nearest neighbours are responsible for the formation of short-range order.

The above results (especially those of Ref. 57) show that compounds of variable composition prepared under different conditions can be structurally inhomogeneous. In other words, depending on the synthesis and heat treatment conditions the samples may contain regions in which the ordering differs in extent and in type, and the individual regions may

Table 1. Characteristics of the ordered phases formed in non-stoichiometric carbides, nitrides, and oxides and in their solid solution.

be combined in different ways. The relative amount and size of the regions can also differ between samples. So far these effects in interstitial phases have tended to be ignored, in spite of the extensive data available on this problem in the case of metal alloys (see, for example, Ref.80). The type of structural inhomogeneity in the sample can have a marked influence on the physicochemical properties of the substance: these effects are often incorrectly attributed to electronic factors. In this sense establishing a state close to equilibrium becomes especially relevant to the solution of the fundamental problem in physicochemical analysis: the study of the composition–structure–property dependence.

Most of the alloys and solid solutions used in modern technology are in a hetero-phase state which gives them special physical properties: a high mechanical strength, hardness, and heat resistance, a low electrical conductivity, etc. Many structural and physical studies have shown that the properties of interstitial and of substitutional solid solutions are determined by the morphology, substructure, and nature of the conjugated phases. The required types of substructure are generated by using appropriate methods of heat treatment: quenching, annealing, etc.

Neutron diffraction, X-ray diffraction, and electron microscopic work has shown that hetero-phase structures are very diverse and differ in the shape of the inclusions and in their orientation relative to the crystallographic axes of the host crystal, as well as in their mutual disposition. In metal alloys we often find a periodicity (or a modulation) in the distribution of the inclusions: under these conditions the phase which is precipitated by the decomposition of the cubic (uniform) solid solution can have a similar or a lower symmetry. The periodicity of the distribution of inclusions can be so marked as to generate an additional diffraction pattern.

In terms of conventional thermodynamic considerations the shape of a crystal of the new phase can be related to its surface tension; this point of view suggests that the deposited crystals should be in the form of regular polyhedra. However, in studies of hard alloys based on interstitial phases (carbides, nitrides, carbide nitrides) it was found that the crystals of the new phase often consist of platelets or needles, whereas regular grids are formed by the precipitated phases in metallic alloys. On the other hand from the standpoint of classical thermodynamics as applied to phase transitions the free energy of a two-phase system depends on the total volume of each phase, but not on the relative position of the inclusions or on the area of their faces: it follows that the distribution of the inclusions should be random.

The special features of phase transitions in solids cannot be explained without allowing for the elastic stresses created during the transitions. The orientational relationships, the shape, and the mutual arrangement of the mother phase and of the precipitate are inexplicable otherwise. However, this approach has not so far been adequately explored in respect of non-stoichiometric compounds of the interstitial phase type. One of the few studies of the effect of the elastic deformation energy on the formation of solid solutions of carbides and nitrides[81] established a correlation between the elastic deformation energy, the decomposition temperature of the solid solution, and the possibility of developing short-range and long-range order. In particular it was shown that short-range order is observed in solid solutions of compounds of variable composition when the maximum energy of the elastic deformation is approximately 3–5 kJ mole$^{-1}$. Thus from a knowledge of the elastic deformation energy we can assess the extent of disturbance of the crystal lattice and the likely type of short-range order, and we can identify hidden regions for the decomposition of the solid solution, which strongly affect the physicochemical properties of these solutions.

## IV. FILLING OF STRUCTURAL VACANCIES IN COMPOUNDS OF VARIABLE COMPOSITION

Problems associated with the filling of structural vacancies in the crystal lattice of compounds of variable composition at high temperatures and pressures are of direct interest. The possibility was first suggested as a result of a study[82] of the monoxide $FeO_y$ at high temperature and pressure. It was later shown[83] that defect-free $FeO_y$ can be obtained by the simultaneous application of high pressure (7.74 GPa) and temperature (1920 K) to the material (which contained ~14% of vacancies in each sublattice in its initial state). Large increases in the density and in the lattice constant of the sample were observed. The partial or complete filling of the vacancies as a result of thermo-baric treatment has been observed also in other materials:[84–92] for example, in titanium and vanadium monoxides, in the oxide carbides of titanium, vanadium, and niobium, and in the oxide nitrides of titanium and vanadium (Table 2).

From the data listed in Table 2 we conclude that the vacancies can be filled only by the combined application of high temperature and pressure. Vacancies can be filled in either sublattice up to a predetermined threshold value, when all the sites in the sublattice are occupied by atoms of the appropriate kind and all the vacancies have disappeared. We should stress that vacancy filling is possible only under static loading conditions. Dynamic (shock) compression does not result in the disappearance of structural vacancies. The data in Table 2, like other published results,[84–92] suggest a definite sequence (in space and time) of processes stimulated by the thermo-baric treatment: in other words, they suggest a diffusion mechanism for the filling of vacancies.

The thermo-baric treatment produces not only vacancy filling but also a change in the state of charge of the atoms. This is shown by the fact that the X-ray emission spectra of the samples of composition $TiO_{0.88}$ and $TiO_{1.27}$ have a different shape[6,92] after the thermo-baric treatment (Table 2). The decrease in the concentration of structural vacancies and the change in the charge state of the atoms caused by the application of high temperature and pressure should produce marked changes in the properties of compounds of variable composition. It has long been assumed that the states established at high temperatures and pressures can be studied only under those conditions, because the state is not retained when the pressure is lowered to normal values.

We have shown[88] that the state induced by high temperature and pressure can be preserved indefinitely even under normal conditions: in this way the characteristics of a substance subjected to thermo-baric treatment can be investigated by conventional methods.

The changes in properties are clearly seen in the case of the monoxide $VO_{0.91}$.[93,94] After thermo-baric treatment the magnetic susceptibility (which initially obeyed the Curie–Weiss law) becomes temperature-independent; it also changes by a large amount.[94] A study of the effect of thermo-baric treatment on the electronic structure of $VO_{0.91}$ (by comparing calculations by the SCF MO LCAO method in the MWH approximation with X-ray emission spectra) showed that the change in the parameters of the electronic structure (electronic configuration of the atoms, effective charges, bond occupancies in nearest-neighbour atoms) varies monotonically with pressure. An increase in pressure changes the occupancy of the valency orbitals of vanadium towards the value for the neutral atom. This is confirmed by X-ray emission

data, which indicate, in particular, a decrease in the degree of $p-d$ hybridisation of the wave functions of the vanadium atoms.[93]

The use of high pressures and temperatures, especially in the case of compounds with structural vacancies in both sublattices, has helped to solve another important problem: the preparation of the so-called imaginary compounds whose existence had been predicted by Mendeleev.[95] A detailed discussion of this problem will be found in Refs. 88, 92, and 96–100: we shall only state that the imaginary chemical compound concept is one of the chemical methods of predicting not only the region of existence of compounds of variable composition but also the possibility of preparing new compounds.

Table 3. Conditions for the formation of the cubic carbides $V_2C$, $VC_{1.0}$, and $Nb_2C$.

| $T$, K | $V_2C$ (Ref. 108) | | $VC_{1.0}$ (Ref. 108) | | $Nb_2C$ (Ref. 102) | |
|---|---|---|---|---|---|---|
| | $\Delta G$, kcal mole$^{-1}$ | $p$, GPa | $\Delta G$, kcal mole$^{-1}$ | $p$, GPa | $\Delta G$, kcal mole$^{-1}$ | $p$, GPa |
| 700 | 0.97 | 43.6 | 4.5 | 92.3 | — | — |
| 1000 | 1.77 | 79.6 | 10 | 205.0 | 5.0 | 205.0 |
| 1300 | 2.04 | 92.7 | 19 | 389.5 | — | — |
| 2000 | — | — | — | — | 7.0 | 285.0 |
| 3000 | — | — | — | — | 11.0 | 450.0 |

The crystal-chemical conditions for the production of imaginary chemical compounds in interstitial phases have been formulated:[88,92,98–102] they state that thermo-baric treatment can be used to change the concentration of structural vacancies (up to the complete elimination of vacancies) in one or in two sublattices simultaneously with formation of a stoichiometric compound. Hence, it is pointed out[88,92,98–100] that the stability regions of the cubic carbides and nitrides of subgroup IVa–Va metals can be shifted as far as the compositions $M_2C$, $M_2N$ (lower limit) and $MC_{1.0}$, $MN_{1.0}$ (upper limit), which are not accessible under normal conditions. The most detailed thermodynamic treatment of this phenomenon will be found in Refs. 101 and 103–106. It has been used in calculations of the thermo-baric conditions of formation of stoichiometric, defect-free titanium monoxide,[103] and zirconium[101,104,106] and vanadium carbides.[105,106]

The writers,[102] using Leipunskii's method[107] in the quasi-one-component approximation, have calculated the formation conditions at high $p$ and $T$ (Table 3) of the cubic modification of the lower niobium carbide $Nb_2C$, which usually crystallises in the hexagonal system. The free energy difference $\Delta G$ between the hypothetical cubic carbide $Nb_2C$ and the hexagonal carbide obtained in practice was identified with the quantity $p\Delta V$, where $\Delta V$ is the change in volume of the crystal accompanying the transition between the two modifications (ignoring the baric compression and the thermal expansion of the crystal[102]). The same approach was later used[108] to calculate the conditions for the thermo-baric synthesis of the cubic (NaCl type) $V_2C$ and $VC_{1.0}$ carbides. As Table 3 shows, extreme values of $p$ and $T$ are needed to yield these compounds. The estimated pressures needed to give the cubic modifications of the carbides $Nb_2C$, $V_2C$, and $VC_{1.0}$ are probably too high because of the neglect[102,108] of baric and thermal effects. According to our calculations[105,106] the thermo-baric synthesis of the defect-free cubic vanadium carbide $VC_{1.0}$ at 700, 1000, and 1300 K requires pressures of 20, 27, and 37 GPa respectively, i.e. much lower than those given in Ref. 108. Nevertheless all theoretical estimates[101–106,108] of the effect of thermo-baric treatment on compounds

Table 2. Chemical composition, lattice constants ($a$), density ($\rho$), and number of formula units in the unit cell ($n$) of the monoxides, oxide carbides, and oxide nitrides of titanium and vanadium before (I) and after treatment at pressure $p$ and temperature $T$ for time $\tau$ (II).

of variable composition lead to the same conclusion: the concentration of vacancies can be lowered, and new modifications of the compounds can be produced, by using this treatment.

On the whole, both the experimental and the theoretical studies of compounds of variable composition under thermobaric conditions so far reported indicate the possibility (previously unknown) of controlling the properties of a substance only by changing the concentration of vacancies in the unit cell while retaining the initial composition and structure type.

## V. THERMODYNAMICS OF THE FORMATION OF STRUCTURAL VACANCIES

It is clear from the above discussion that structural vacancies should be distinguished from the point defects of the vacancy type usually discussed in the literature, which are formed either at high temperatures (thermal vacancies) or by irradiation (Frenkel defects).

In the description of point defects[109] the energy of formation of the vacancies ($E$) is assumed to be constant: under these conditions the change in the free energy of the crystal due to the formation of $n$ vacancies is

$$\Delta G = nE - T\Delta S \qquad (1)$$

where $\Delta S$ is the entropy change resulting from the addition of $n$ vacancies to the crystal. In the case of point defects the contribution of the vibrational component of the entropy to $\Delta S$ is assumed to be negligibly small (on the evidence of experimental data on thermal vacancies). Therefore the quantity $\Delta S$ is practically equal to the configurational component of the entropy, i.e.

$$\Delta S = k \ln \frac{N!}{n!\,(N-n)!} \qquad (2)$$

where $N$ is the number of sites in the crystal and $k$ is Boltzmann's constant.

By minimising the free energy and simplifying we can obtain from Eqns.(1) and (2) the following expression for the concentration of point defects of the thermal vacancy type:

$$c = \frac{n}{N} = \exp\left(-\frac{E}{kT}\right) \qquad (3)$$

The energy of formation of thermal vacancies in metal and metal-like compounds is $E \cong 1$ eV (for example, $E$ is 1.27, 1.10, and 0.95 eV in copper, silver, and gold respectively[110]). At room temperature this value of $E$ corresponds to a very low relative number of thermal vacancies ($c \cong 10^{-17}$), i.e. the average distance between thermal vacancies is of the order of a millimetre. At 2000 K the equilibrium relative number of vacancies becomes $c = 2 \times 10^{-3}$. Hence, as reported,[109] the equilibrium concentration of thermal vacancies in metals is negligibly small even near the melting point.

In compounds of the interstitial phase type such as transition metal carbides, nitrides, and oxides a high concentration of structural vacancies is a characteristic property, and the concept of point defects in these materials is almost meaningless.[111] Furthermore, in compounds of the interstitial phase type (for example, oxides) vacancies can exist in two sublattices at the same time (the non-metal and the metal sublattice); vacancies in the two sublattices have different effects on the properties of the compound.[112] Obivously, the vacancies in compounds of variable composition have a non-thermal origin, and their formation is closely related to the structural properties of the interstitial phase: these vacancies are therefore now called structural.

The presence of a large number of structural vacancies in compounds of variable composition has a marked effect on the vibrational entropy, which cannot be neglected in this case. The thermodynamic description of non-stoichiometric compounds allowing for the formation of structural vacancies[2,3,9,13,14,113–116] is based on the following considerations.

Consider a compound (in equilibrium at some temperature $T$) consisting of $i$ non-equivalent sublattices each containing $n_i$ vacancies and $N_i$ filled sites. The free energy $\Delta G(n)$ of such a crystal at constant pressure can be written[3]

$$\Delta G(n) = \Delta G + \sum \int_0^{n_i} \Delta H_i \, \mathrm{d}n_i - T\left(\Delta S_\kappa + \int_0^{n_i} \Delta S_i \, \mathrm{d}n_i\right) \qquad (4)$$

where $\Delta G = \Delta H - T\Delta S$ is the free energy of the defect-free crystal, $\Delta H$ is the heat of formation of the defect-free crystal, $\Delta S$ is the change in entropy accompanying the formation of the defect-free crystal, $\Delta H_i$ is the energy of formation of the structural vacancies in the $i$-th sublattice of the crystal, $\Delta S_i$ is the change in vibrational entropy due to the formation of vacancies in the $i$-th sublattice, and

$$\Delta S_\kappa = k \sum \ln[(N_i + n_i)!/N_i! n_i!]$$

is the change in the configurational component of the entropy on formation of the vacancies.

It follows from (4) that the heat of formation of a crystal containing structural vacancies is

$$\Delta H(n) = \Delta H + \sum \int_0^{n_i} \Delta H_i \, \mathrm{d}n_i \qquad (5)$$

and the entropy change is

$$\Delta S(n) = \Delta S + \Delta S_\kappa + \sum \int_0^{n_i} \Delta S_i \, \mathrm{d}n_i \qquad (6)$$

Eqn.(4) can therefore be written in terms of the free energy of formation of the structural vacancies:

$$\Delta G_i = \Delta H_i - T\Delta S_i \qquad (7)$$

In general Eqn.(4) assumes a dependence of $\Delta H_i$ and $\Delta S_i$ on the concentration of structural vacancies, i.e. it assumes interactions between the vacancies. Assuming that $\Delta S_i$ is negligibly small and that no interaction takes place between the vacancies (i.e. adopting the weak defect interaction approximation) gives a change in the energy of formation of vacancies proportional to their number, so that Eqn.(4) reduces to Eqn.(2). Thus formula (2) is a special case of Eqn.(4) which can be used to describe the behaviour of both structural vacancies and point defects; the parameters of this description are the quantities $\Delta H_i$ and $\Delta S_i$.

On reaching the equilibrium vacancy concentration for the given temperature $c_i = n_i/N_i$ the free energy $\Delta G(n)$ goes through a minimum, i.e. $\partial \Delta G(n)/\partial n_i = 0$. Using this condition in conjunction with the Stirling formula for the series expansion of $\Delta S_i$ we obtain from (4), after simplification, an expression relating the equilibrium concentration of structural vacancies in the $i$-th sublattice to their energy of formation and to the vibrational component of the entropy:

$$kT \ln c_i = -\Delta H_i + T \cdot \Delta S_i \qquad (8)$$

It follows from (8) that at any temperature above the absolute zero the vacancies are thermodynamically stable and their concentration can be decreased indefinitely but not brought to zero. Furthermore, if $\Delta H_i$ and $\Delta S_i$ are constant and independent of the number of structural vacancies we can expect a linear relationship between $\ln c_i$ and $T^{-1}$.

Data on the congruent evaporation of titanium and zirconium nitrides have been used[117,118] to determine the energies of formation of structural vacancies in the nitrogen sublattice

of these compounds on the assumption that vacancy interactions are negligible: the result (expressed for one molecule) was 0.94 ± 0.32 and 1.13 ± 0.06 eV respectively. The change in the vibrational component of the entropy caused by the formation of vacancies in zirconium nitride was found[118] to be $(0.31 \pm 0.04) \times 10^{-3}$ eV $K^{-1}$. However, the calculation[118] of the heat of formation $\Delta H^{\circ}_{298}$ and of the free energy of formation $\Delta G^{\circ}_{298}$ of zirconium nitride in its homogeneity region from the observed energies of formation and vibrational entropy changes of the structural vacancies gave a discrepancy between experiment and calculation increasing with the number of nitrogen vacancies and reaching 25% at the lower boundary of the homogeneity region. The discrepancy was attributed[118] to the neglect of the concentration dependence of the energy of formation of the vacancies. A comparison of experimental and calculated values of the activity of carbon in the homogeneity region of zirconium carbide similarly led to the conclusion[119] that satisfactory agreement between experiment and calculation is obtained only by allowing for the dependence of the energy of formation of the vacancies on the composition of the compound.

A detailed analysis[13,14,115] of existing experimental data on the congruent evaporation of a series of carbides and nitrides with a structure of the NaCl type has shown that the dependence of ln c on $T^{-1}$ is non-linear, and therefore that a change in defect density in these materials affects either the energy of formation of the vacancies, or the vibrational component of the entropy, or both, i.e. that vacancy interactions are present.

In compounds of variable composition with an NaCl type structure each metal atom is octahedrally surrounded by six sites of the non-metal sublattice which form the first coordination sphere; the second coordination sphere consists of twelve metal atoms. Let us consider a compound containing structural vacancies in only one of the sublattices (for example, the non-metal sublattice). We shall assume that the interaction between the non-metal atoms is limited to the first coordination sphere. When all the sites in the non-metal sublattice are filled the energy of formation of the vacancies will be denoted by $\Delta H_1$, and the vibrational component of the entropy by $\Delta S_1$. If all the sites of the non-metal sublattice adjacent to a given non-metal atom are vacant we shall use the symbols $\Delta H_2$ and $\Delta S_2$. In general, when some of the sites are occupied by non-metal atoms but some ($n$) are vacant, the energy of formation of the vacancies can be expressed as the sum

$$\Delta H_n = (1-n)\Delta H_1 + n\Delta H_2 \qquad (9)$$

Similarly, we can write for the vibrational component of the entropy

$$\Delta S_n = (1-n)\Delta S_1 + n\Delta S_2 \qquad (10)$$

If only the vibrational component of the entropy increases with the defect density, by inserting (10) into (4) and solving the resulting equation we obtain an expression for the equilibrium concentration of vacancies which allows for the dependence of $\Delta S_B$ on the number of vacancies in the homogeneity region of the compound:

$$kT \ln c_i = (1-n)T\Delta S_1 + nT\Delta S_2 - \Delta H \qquad (11)$$

If only the energy of formation of the vacancies $\Delta H_B$ varies with the number of defects the corresponding expression is

$$kT \ln c_i = T\Delta S - (1-n)\Delta H_1 - n\Delta H_2 \qquad (12)$$

Lastly, if both $\Delta H$ and $\Delta S$ are dependent on the defect density we have

$$kT \ln c_i = (1-n)T\Delta S_1 + nT\Delta S_2 - (1-n)\Delta H_1 - n\Delta H_2 \qquad (13)$$

Eqns.(11)–(13) assume the existence of a self-consistent solution for the equilibrium concentration of vacancies $c_i$ at a given temperature $T$ for known values of the parameters $\Delta H_{1,2}$ and $\Delta S_{1,2}$.

Thus even allowing for interactions only in the non-metal sublattice and assuming a simple linear dependence implies considering three types of solution and determining which of these solutions best describes the experimental data.

The quantities $\Delta H_1$, $\Delta H_2$, and $\Delta S_1$, $\Delta S_2$, have been determined,[13,14,115] and their statistical significance in describing the equilibrium concentration of structural vacancies in titanium, zirconium, and niobium carbides and nitrides by Eqns.(11)–(13) has been assessed by using the Fisher criterion, $F$.[120] By comparing the dispersion obtained for each of these equations with the $F$ criterion we obtain a statistical proof of the dependence of the energy of formation of vacancies and of the vibrational component of the entropy on the defect density of the compound; this suggests the presence of interactions between the vacancies, in keeping with earlier data.[57,76,68,79] An analysis of these results[13,14,115] also showed that the allowance for the dependence of the vibrational component of the entropy on the number of structural vacancies is more important than the corresponding correction for the energy of formation of the vacancies. As the defect density increases, the energy of formation of vacancies $\Delta H_B$ in the carbides and nitrides of titanium, zirconium, and niobium decreases (Table 4), denoting the presence of mutual repulsion between the vacancies.

Table 4. Energies of formation of structural vacancies $\Delta H_B$ and changes in the vibrational component of the entropy $\Delta S_B$ in the formation of structural vacancies in non-stoichiometric compounds.

| Compound | $\Delta H_B$, eV | $10^3 \Delta S_B$, eV $K^{-1}$ | Refs. |
|---|---|---|---|
| $ZrC_{1-n}$ | 0.524—0.520$n$ | 0,009—0.318$n$ | [13, 115] |
| $VC_{1-n}$ | 0.150 | 0,010 | [3] |
| $NbC_{1-n}$ | 0.532—0.411$n$ | —0,002—0,089$n$ | [115] |
| $TiN_{1-n}$ | 1.347—0.401$n$ | 0,415—0.241$n$ | [14] |
| $ZrN_{1-n}$ | 1.867—0.614$n$ | 0,726—0.462$n$ | [13,14] |

The quantities $\Delta H_B$ and $\Delta S_B$ for vanadium carbide were determined[3] in the approximation of non-interacting atoms, because the precision of the experimental data on the heat of formation of vanadium carbide was insufficient to determine the dependence of the energy of formation of the vacancies and of the vibrational entropy on the number of vacancies. The temperature dependence of the free energy of formation of the vacancies in the carbon sublattice for the vanadium carbide $VC_y$ (for one formula unit of the compound) was found to be[3]

$$\Delta G, \text{ eV} = 0.415 + 1.574 \cdot 10^{-3} T + 7.553 \cdot 10^{-8} T^2 - 0.17 \lg T - 0.458 \cdot 10^{-3} T \lg T + 4.522\, T^{-1}$$

In compounds with defects in both sublattices, such as the cubic modifications of titanium and vanadium monoxides, for which congruent evaporation data are not available, the energy of formation of the structural vacancies can be calculated by using Eqn.(5). An attempt to calculate the energy of formation of vacancies in titanium monoxide has been reported.[121] However, no attempt was made to evaluate

the precision of the experimental data on the heat of formation of $TiO_y$ in the homogeneity region, and as a result the form of the dependence of the energy of formation of the vacancies on the defect density of the metal and of the oxygen sublattice was incorrectly chosen; the results[121] cannot therefore be treated as reliable. In Refs.2 and 116 the energies of formation of the metal and the oxygen vacancies in $TiO_y$ and $VO_y$ are calculated by using the methods of mathematical statistics to allow for the precision of the experimental data, giving more meaningful results.

It follows from Eqn.(5) that the heat of formation of the crystal containing defects ($\Delta H(n)$) can be expressed in terms of the heat of formation of the defect-free crystal ($\Delta H$) and the energy of formation of vacancies in each of the sublattices. For the monoxides of vanadium and titanium (compounds with a double set of defects) we have

$$\Delta H(n) = \Delta H + \int \Delta H_M \, d n_M + \int \Delta H_O \, d n_O \qquad (14)$$

where $\Delta H_M$ and $\Delta H_O$ are the energies of formation of vacancies in the metal and the oxygen sublattice respectively.

The form of the dependence of $\Delta H_M$ and $\Delta H_O$ on the composition of the compound is not known, but these quantities can be determined by using existing experimental data on the composition dependence of the heats of formation in the homogeneity regions of titanium and vanadium monoxides[111,122] in conjunction with structural data[23,123] for these compounds. In the zeroth approximation we assume that the energy of formation of the vacancies is independent of the composition of the compound: this gives

$$\Delta H(n) = \Delta H + \Delta H_M n_M + \Delta H_O n_O \qquad (15)$$

According to (15) the heats of formation of the monoxides should be directly proportional to the numbers of defects in the metal and in the oxygen sublattice. However, it has been shown experimentally that the dependences deviate from linearity and have a point of inflection near the equiatomic composition.[111,112] The deviations may be due to experimental error, or to the dependence of the interatomic bond energy on the composition of the monoxides, resulting in a change in the energy of formation of the vacancies in the homogeneity region of the compound.

To allow for possible interatomic interactions we shall assume that $\Delta H_M$ depends on the interaction between metal atoms and $\Delta H_O$ on the interaction between oxygen atoms in the first coordination spheres of the metal and oxygen atoms respectively. Let $\Delta H_{M_1}$ and $\Delta H_{O_1}$ be the energies of formation of vacancies in the metal and in the oxygen sublattice in the perfect (defect-free) lattice of the monoxide, and let $\Delta H_{M_2}$ and $\Delta H_{O_2}$ be the energies of formation of vacancies in the metal and the oxygen sublattice when all the sites in the metal or the oxygen sublattice adjacent to the given metal or oxygen atom are vacant. In general, when only some of the lattice sites are occupied by metal or oxygen atoms, the energy of formation of metal and oxygen vacancies can be expressed as (as was done for the carbides and the nitrides) as a sum of the products of $\Delta H_{M_1}$ and $\Delta H_{M_2}$ (or $\Delta H_{O_1}$ and $\Delta H_{O_2}$) by the fractional number of filled and of empty sites in the metal (or in the oxygen) sublattice:

$$\Delta H_M = (1-n_M)\Delta H_{M_1} + n_M \Delta H_{M_2};$$
$$\Delta H_O = (1-n_O)\Delta H_{O_1} + n_O \Delta H_{O_2}$$

Allowing for the nature of the dependence of $\Delta H_M$ and $\Delta H_O$ on the concentration of vacancies, four variants of the description of the heat of formation of a crystal containing defects in terms of the energy of formation of the vacancies in each of the sublattices are possible. According to (14) these variants correspond to the following cases: 1) the energies of formation of vacancies $\Delta H_M$ and $\Delta H_O$ are constant and independent of the vacancy concentration; 2) only $\Delta H_M$ varies with the concentration of vacancies, whereas $\Delta H_O$ stays constant; 3) $\Delta H_O$ varies, and $\Delta H_M$ stays constant; 4) $\Delta H_M$ and $\Delta H_O$ vary simultaneously. The Fisher criterion $F$ has been used[2,116] to identify which of these four assumptions has the highest probability, i.e. gives the best description of existing experimental data allowing for their precision. By comparing the dispersion with the value of the $F$ criterion it was shown that in the case of titanium monoxide the energies of formation of the vacancies in both sublattices are dependent on the concentration of the appropriate defects. Clearly, a similar dependence can be expected in vanadium monoxide, but the precision of the experimental data[112] on the heat of formation of $VO_y$ in the homogeneity region is too low to establish this fact unambiguously. The energies of formation of structural vacancies in the metal and the oxygen sublattice of titanium monoxide $TiO_y$ are $\Delta H_M$, eV $= -15.104 - 1.225\, n_M$ and $\Delta H_O$, eV $= -2.068 + 12.678\, n_O$ respectively.[116] For the vanadium monoxide $VO_y$ the energy of formation of vacancies in the metal and in the oxygen sublattice is $\Delta H_M = 5.32$ eV and $\Delta H_O = 8.172$ eV respectively.[2]

Thus by treating structural vacancies as analogues of interstitial atoms we can describe non-stoichiometric compounds in terms of a simple thermodynamic model. The change in the energy of formation of vacancies in the homogeneity regions of these compounds allows us to identify the nature of the interatomic interactions. Knowing the energy of formation of structural vacancies in the carbides, nitrides, and oxides of the transition metals we can calculate the synthesis conditions of the defect-free compounds.[101,104-106]

---o0o---

The above discussion shows that structural vacancies in compounds of variable composition can be treated as analogues of interstitial atoms: for example, the deviation from stoichiometry can be wholly described as the formation in the nonmetal sublattice of a substitutional solution whose components are interstitial atoms and structural vacancies. Evidently, the defect state of the crystalline structure, i.e. the presence of a high concentration of structural vacancies, is the most important property of compounds of variable composition of the interstitial phase type.

The presence of a large number of structural vacancies offers some additional flexibility in the controlled synthesis of compounds of variable composition having prescribed properties. One possibility is to use a thermo-baric treatment to vary the vacancy concentration while preserving the initial composition and structure of the compound. Another means of fine control of all the properties of a compound of variable composition relies on the redistribution of the interstitial atoms and vacancies over the sites of the nonmetal sublattice. The study of vacancy distributions is of direct scientific interest because it offers a key to an understanding of the nature of interatomic interactions in compounds of variable composition. This is because the rearrangement of atoms and vacancies in a crystal lattice is a manifestation of interactions at the atomic level. So far the effect of the nature of the vacancy distribution on the properties of non-stoichiometric compounds has not been adequately studied, but we consider this approach to be very promising from a practical as well as a scientific aspect.

# The Physicochemical Properties of Ionomer-containing Interpenetrating Polymer Networks

Yu.S.Lipatov and L.M.Sergeeva

The physicochemical properties of interpenetrating polymer networks of a new type, containing an ionomer as one of the components, have been examined. The results of the study of the morphology, viscoelastic properties, mechanical strength characteristics, and adhesive properties have been described. Data on the thermodynamic compatibility of the components in the systems studied have been given.
The bibliography contains 78 references.

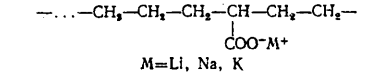
## I. INTRODUCTION

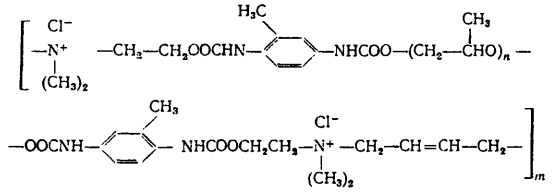
In recent years, an increasing number of papers have been published on the synthesis and study of the properties of interpenetrating polymer networks (IPN) and materials based on them.[1-4] This is due to the fact that, in addition to traditional binders for composite polymer materials, increasing use is now being made of complex binders consisting of components of different chemical character, which are second-generation binders, or hybrid binders.[5] A characteristic feature of hybrid binders is that after setting, they themselves are composite polymer materials, since as a consequence of the thermodynamic incompatibility of the components, setting is accompanied by the separation of microphase particles of one of the components, which can be regarded as the filler, distributed in a matrix of the other component.

Interpenetrating polymer networks are typical representatives of hybrid binders, whose use makes it possible to achieve much more complex combinations of different polymer structural states in composite materials, providing extensive possibilities for controlling the properties by the action of the filler.



A number of papers[6-15] describe the study of a new type of interpenetrating polymer network, namely systems in which one of the components is an ionomer. Ionomers have been studied particularly intensively in the last 10–15 years. The term ionomer was previously used to describe only copolymers of α-alkenes with unsaturated mono- and dicarboxylic acids, in which some of the acidic groups were neutralised by metal ions.[16] The term ionomer now covers a wider range of polymers. Thus according to one definition,[5] ionomers are polymers whose chains contain a small quantity of ionogenic groups, usually not more than 10 mole %, so that the hydrocarbon chain is the main component, in contrast to poly-electrolytes, which have a high density of ionogenic groups in the chain. Other definitions of the term ionomer have been given; for example, ionomers have been defined[10] as ion-containing polymers in which the concentration of ionogenic groups is insufficient to ensure their solubility in water.

Ionomers based on polymers of different classes have been obtained. For example, fluorinated ionomers with the following structure have been prepared:[17]



M=Li, Na, K, Rb, Cs

The structural formula of an ionomer based on ethylene and acrylic acid[18] is:

M=Li, Na, K

Ionomers with quaternary nitrogen atoms in the main chain are often called ionenes.[19] For example, a polyurethane ionene based a glycol oligoether, tolylene di-isocyanate (TDI), 2-dimethylaminoethanol, and 1,4-dichlorobut-2-ene has the following structural formula:[19]

The good operational characteristics of ionomers and the possibility of using them in various branches of technology have led to a considerable increase in studies of their synthesis and properties.

Theoretical ideas on the structure of ionomers are being developed by Eisenberg.[12,13,20,21] According to his ideas, the thermodynamic incompatibility of the salt groups and the polymer matrix, and the electrostatic interaction of the ionogenic groups, lead to the formation of multiplets and clusters. Multiplets consist exclusively of ionogenic groups, and contain a maximum of 8–10 ion pairs; clusters consist of multiplets separated by polymer chains, that is clusters contain both ionogenic groups and polymer chains. According to Eisenberg, cluster formation is observed in ionomers when a certain critical concentration of ionogenic groups in the chains has been reached. This is consistent with ideas on microphase separation in block copolymers and other multicomponent systems where the blocks are thermodynamically incompatible. Experimental studies of various ionomers based on ethylene, styrene, ethyl acrylate, etc.

by electron microscopy, neutron scattering, X-ray diffraction, and infrared spectroscopy[6,20,23] confirm Eisenberg's view that aggregates of two types, multiplets and clusters, exist. This explains the sharp change in a range of physicomechanical and thermophysical properties, such as the viscosity of the melt, the glass-transition temperature $T_g$, the modulus of elasticity, and the dynamic mechanical characteristics, when ionogenic groups are introduced into polymer chains.

A number of comparatively recent papers[10,11,15,24-30] describe the study of the properties of polyurethane ionomers. Polyurethanes show microphase separation at the level of the flexible and rigid blocks, leading to the formation of systems with a high level of heterogeneity.[22] Moreover, in addition to a chemical bond network, these polymers contain a network of physical bonds, which determines to a large extent the properties of materials based on polyurethanes.[31] The introduction of ionogenic groups into polyurethanes creates an additional, "ionic", network, which has a considerable influence on a range of properties of these systems.

The data obtained to date in the study of the properties of polyurethane ionomers are not unambiguous. On the one hand, in a series of papers[25-28] on the study of segmented polyurethanes in the ionic form by infrared spectroscopy, it was concluded that in these materials the network of hydrogen bonds is broken down, and that hydrogen bonds of a new type are formed, leading to a rearrangement of the segments of the polymer chain and to disordering of the rigid domains; it was also concluded that there is a deterioration in the conditions for self-association of the urethane groups, contrary to the previously proposed[32] scheme based on an increase in the self-association of the urethane groups and the segregation in polyurethane ionomers. On the other hand, other data indicate an increase in the segregation of the blocks of different chemical character when ionic centres are introduced into polyurethanes.[29] An increase in micro-phase separation is assumed to be responsible for the decrease in $T_g$ for the flexible blocks in polyester–polyurethane ionomers, compared with non-ionogenic polyurethanes.[30] The ambiguity in the conclusions about the influence of ionogenic groups on the structure of polyurethane ionomers indicates a need for systematic studies in this field.

The combination of ionomers with polymers with a three-dimensional structure, leading to the formation of ionomer-containing IPN, is a promising method of obtaining new types of composite polymer materials. At the same time, the production of these complex systems unavoidably complicates the structure of the materials by changing the nature of the microphase separation, and hence influences the final properties of the materials. Studies published up to the present on ionomer-containing IPN are examined in the present review.

## II. MORPHOLOGY AND STRUCTURE

The determination of the influence of ionogenic groups on the morphology and structure of ionomer-containing IPN is of decisive importance.

A large proportion of the structural studies of IPN containing ionogenic groups, as for IPN of other types, has been carried out by electron microscopy. An electron-microscope study of IPN based on sulphonated cross-linked polystyrene (PS) and polyvinylpyridine (PVP) (see Fig.1) showed that the specimens of all the compositions studied had a cellular structure, indicating phase separation in the IPN.[33,34] When its concentration is high, the sulphonated PS forms a continuous phase with quaternised PVP distributed in it as inclusions with dimensions of 60–80 nm (Fig.1*a*). The size of the PVP domains decreases from 60–80 nm to 30–40 nm on going from specimens with a higher PS concentration to IPN specimens with a component ratio of 1:1 (Figs.1*b* and 1*c*). At medium compositions (Fig.1*c*), both phases are continuous, and with further decrease in the PS concentration, PVP becomes the continuous phase (Fig.1*d*). In this case the size of the PS domains is 10–20 nm. Inversion of the phases takes place with change in the PS/PVP ratio from 1:1 to 1:4.

Thus the ionomeric IPN examined above, like non-ionomeric IPN, have a cellular structure, but in some cases this structure is not clearly defined, possibly due[33] to some mixing of the two components of the IPN at the molecular level. The chief difference between the morphology of the ionomer-containing IPN being considered and ordinary IPN, however, is that analysis of the photomicrographs of IPN specimens with different compositions has shown that in addition to phase separation of the individual components in the IPN, in the ionomeric components themselves there is additional separation with the production of regions with a higher concentration of ionogenic groups.[33] Thus systems of this type will be provisionally four-phase systems, and not two-phase systems like ordinary IPN.

For IPN based on sulphonated PS and quaternised PVP, the size of the domains obtained experimentally was compared with that calculated using Donatelli's equation:[35,36]

$$D_2 = \frac{2\gamma W_2}{RT\nu_1[1/(1-W_2)-1/2]}$$

where $D_2$ is the size of the domains of component 2, forming inclusions in component 1, $W_2$ the weight fraction of component 2, $\gamma$ the interphase tension between the components of the IPN, $\nu_1$ the density of cross-linking of component 1, $R$ the universal gas constant, and $T$ the temperature. Comparison of the experimental and calculated values of $D_2$ in relation to the component ratio showed good agreement between theory and experiment only at a PVP concentration of 50% and above. At low PVP concentrations, the theoretical and experimental values differ considerably.

The introduction of ionogenic groups into one of the components of an IPN makes it possible to change the morphology and hence the mechanical properties of materials on thermal treatment. This was shown in a study of the influence of annealing on the morphology of IPN based on a triple copolymer of butadiene, styrene, and methacrylic acid (polymer 1) and a copolymer of styrene with divinylbenzene (polymer 2).[37] Polymer 1 was obtained in both the acidic form and the salt form. In the last case, films of polymer in the acidic form were treated with a 10% solution of sodium or caesium hydroxide; after this treatment, the polymer no longer dissolved in organic solvents, but only swelled, indicating the formation of an elastomer "cross-linked" by physical bonds. Only IPN specimens with medium compositions, with a component ratio of 1:1, were studied. The materials were treated by the method described above, except that to obtain contrast the specimens were treated with osmium tetroxide. Analysis of the electron-microscope photographs showed that in the original IPN the ionomeric component in the acidic form gives a continuous phase, with domains of the copolymer of styrene and divinylbenzene with dimensions of 10–13 nm distributed in it; a small quantity of domains with dimensions up to 70 nm is also present. On annealing (in this case thermal treatment at 110 °C for 24 h), both components of the IPN form continuous phases. When the ionomeric component is in the salt form, annealing gives the same effect, but to a lesser

degree. The observed phenomena are related to the fact that the ionic "cross-linkages", which are thermally labile, become weaker and undergo rearrangement on prolonged thermal treatment, leading to a change in the structure of the IPN and hence to a change in the physicomechanical properties.[37]

This possibility of rearranging ionic "cross-linkages" by thermal treatment has led to the production of thermoplastic IPN in which both components (one of which is an ionomer) are "cross-linked" by physical bonds.[38] One IPN of this type consists of a system based on a triple copolymer of styrene, ethylene, and butene (polymer 1) and an ionomer obtained by the copolymerisation of styrene, methacrylic acid, and isoprene (volume ratio of the components 90 : 10 : 1), followed by neutralisation of the COOH groups with an aqueous solution of NaOH or CsOH (polymer 2).[39,40,41,42] The triple copolymer, in the molecules of which the terminal styrene blocks are physical "cross-linkages", is a thermoplastic elastomer. In the ionomer, the ionogenic groups form domains which are also nodes of the physical network, so that at room temperature the ionomer behaves as a cross-linked polymer, and at high temperatures, as a result of the breakdown of the domains, flow of the material takes place, that is the ionomer behaves as a linear polymer.

Two methods can be used to obtain thermoplastic IPN. In the first method, polymers 1 and 2 are synthesised separately, after which they are blended in the molten state. These are mechanically blended thermoplastic IPN (MBT IPN). In the second method, the IPN are obtained by polymerising polymer 2 in a common solution in the presence of the previously prepared polymer 1. These are chemically blended thermoplastic IPN (CBT IPN). Thus thermoplastic IPN are materials intermediate between IPN and blends of thermodynamically incompatible polymers. The study of the morphology of these materials has revealed certain characteristic features.

Analysis of electron-microscope photographs of IPN specimens with a component ratio of 1 : 1 has shown[40] that when the acidic form of polymer 2 is used in CBT IPN, polymer 2 is the continuous phase. At 100% neutralisation of the methacrylic acid fragments, inversion of the phases is observed; polymer 1 becomes the continuous phase, and polymer 2 (the ionomer) is distributed in it as globules with dimensions of 100–200 nm. At a lower degree of neutralisation (15% and 20%), partial inversion is observed; there are regions in which both phases (polymers 1 and 2) are continuous. The structure of the mechanically blended thermoplastic IPN (MBT IPN) differs slightly from that examined above for the CBT IPN.[41] Thus in the case of the acidic form of polymer 2, although it is the continuous phase with domains of polymer 1 distributed in it (size of the domains 50–150 nm), the degree of blending is less than for the CBT IPN. Here also, inversion of the phases takes place on complete neutralisation, but the dimensions of the domains of polymer 2 show extensive scatter, from 500 nm to 2000 nm with a small quantity of even smaller domains (400–100 nm).

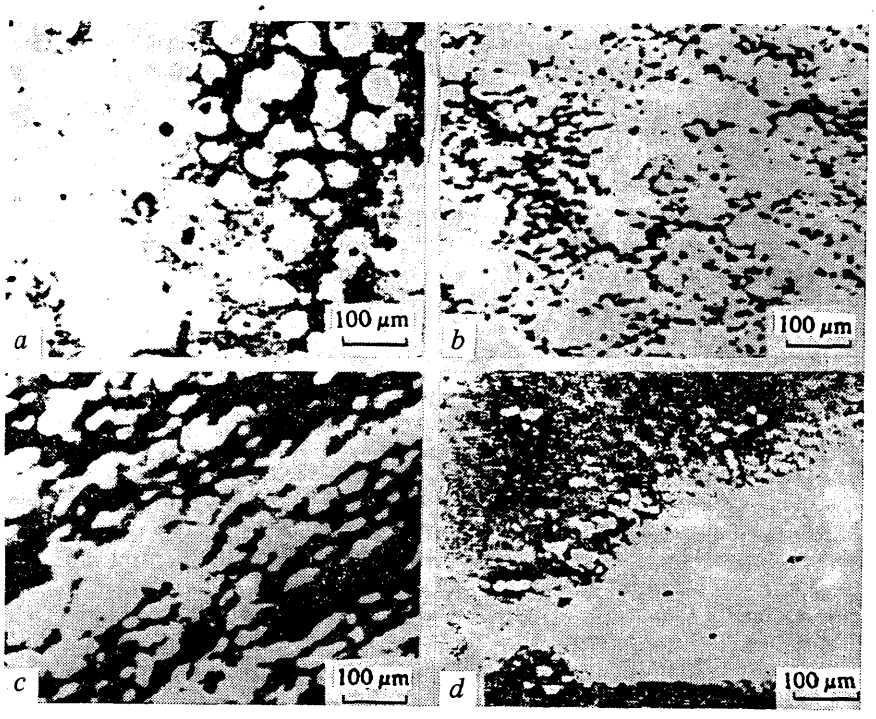


**Figure 1.** Photomicrographs of ionomer-containing IPN based on cross-linked polystyrene and polyvinylpyridine; PS/PVP ratio: *a*) 76/24, *b*) 58/48, *c*) 50/50, *d*) 20/80.[33]

Individual "islets" of polymer 2 consist of cells with domains of polymer 1 disseminated in them.

The change in the degree of phase continuity with increase in the degree of neutralisation of the polymethacrylic acid fragments in polymer 2 is an important characteristic of thermoplastic IPN. These changes in structure on going from the acidic to the salt form have been attributed[39-41] to a change in the viscosity of melts of these forms of polymer 2, which has been demonstrated experimentally.[39] The polymer with the lower viscosity, for example polymer 2 in the acidic form, generally tended to become the continuous phase. Increase in the degree of neutralisation led to an increase in the viscosity of the melt of polymer 2, and it became the dispersed phase. The component ratio naturally also has a significant influence on the phase continuity in IPN.

The morphological data for the CBT IPN studied were used to construct a generalised "phase continuity" diagram,[39] characterising the change in the degree of continuity with change in the component ratio in the IPN and degree of neutralisation of the groups of polymer 2.

For many CBT IPN compositions, inversion of the phases, although observed, ofter remains incomplete, that is there is to some extent continuity of both phases, attributed to the fact that the viscosities of the melts of the two polymers in the IPN are approximately equal.[39]

Thus study of the morphology of thermoplastic ionomer-containing IPN has shown that, like ordinary IPN, they have a high degree of heterogeneity, but (particularly CBT IPN) they have a finer structure than ordinary IPN, with smaller domain dimensions than in ordinary IPN and polymer blends. Moreover, the structure of these IPN can be varied over a wide range by varying the concentration of salt groups in the ionomer.

Small-angle X-ray scattering gives more complete information on the polymer structure than electron microscopy; in particular, it makes it possible to determine the size of the heterogeneous inclusions in the range 1–100 nm and other characteristics of the heterogeneity in amorphous systems. This estimation has been carried out for IPN based on the non-ionic form of network polyurethane and a polyurethane ionomer.[43] The ionomer was obtained from polyoxypropylene glycol, 2,4-tolylene di-isocyanate (TDI), 2-dimethylamino-ethanol, and 1,5-dibromopentane.

Analysis of the large-angle diffraction patterns of the individual polymers making up the IPN showed that they are typical amorphous polymers with a more or less developed heterogeneity, resulting from the segregation of the rigid and flexible blocks in the polyurethanes.[22] The degree of segregation can be estimated quantitatively by comparing the theoretical value of the mean-square fluctuation of the electron density $\Delta\bar{\rho}_c^2$ and the mean square fluctuation of the electron density of the real system studied $\Delta\bar{\rho}^2$; the parameter $\alpha = \Delta\bar{\rho}^{2\prime}/\Delta\bar{\rho}_c^2$ is introduced.[22] The quantity $\Delta\bar{\rho}_c^2$ characterises a so-called "ideal" two-phase system in which the micro-regions have the densities of the pure components, and the thickness of the interphase layer tends to zero. The value of $\Delta\bar{\rho}^{2\prime}$ depends both on the electron density of the components and on their degree of segregation in the system. The results of calculations of $\alpha$, $\Delta\bar{\rho}^{2\prime}$, and $\Delta\bar{\rho}_c^2$ for the individual networks (the non-ionic form of polyurethane and the polyurethane ionomer) showed that the $\Delta\bar{\rho}_c^2$ values differ little; at the same time, $\Delta\bar{\rho}^{2\prime}$ for polyurethane is 100 times that for the ionomer. Correspondingly, the degree of segregation $\alpha$ for polyurethane is 8 times that for the ionomer. Thus the results indicate that the original networks deviate considerably from the ideal two-phase structure.

The large-angle diffraction patterns showed that the interpenetrating polymer networks based on polyurethane and a polyurethane ionomer are also amorphous polymers. The results of the small-angle X-ray study of the IPN specimens show that there is modification of the heterogeneous structure of the network components as a result of the formation of the system. Firstly, qualitative differences are observed between the diffraction patterns of the original components and the IPN for most compositions studied. The diffraction curves for the IPN are more diffuse, and many curves show two intensity maxima, more or less clearly defined. A particularly marked difference is observed between the diffraction curves for the IPN containing small quantities of the ionomer and the scattering curve for the non-ionic form of polyurethane. It was suggested[43] that the introduction of small quantities of the ionomer into the polyurethane leads, during the production of the IPN, to the formation of micro-regions for which the periodicity of the distribution is determined by the microphase distribution of the polyurethane and the ionomer, leading to the production of the first maximum on the small-angle scattering curves. The second maximum is due to the effect of periodicity at the level of the blocks of different chemical character in the polyurethane. The maxima on the small-angle scattering curves for IPN with medium compositions are very poorly defined. This indicates that the periodicity at the level of the distribution of polyurethane and the ionomer and at the level of the flexible and rigid blocks is broken down to a considerable extent.

To obtain further information on the nature of the heterogeneity revealed in the IPN studied, the experimental values of $\Delta\bar{\rho}^{2\prime}$ were compared with the theoretically calculated $\Delta\bar{\rho}_c^2$ for different models of the heterogeneous structure.[43] Three models were used to calculate $\Delta\bar{\rho}_c^2$. The first model assumes a microphase distribution with the formation of polyurethane and the ionomer, within which there is complete blending of the flexible and rigid blocks. In contrast to the first model, the second model assumes complete distribution of the blocks of different character in the micro-regions of polyurethane and the ionomer. The third model, like the first two, assumes complete distribution of polyurethane and the ionomer, but unlike the first and second models it assumes that the micro-regions of polyurethane and the ionomer retain the degree of segregation characteristic of the individual networks. The calculations showed that the third model gives the best approximation for the description of the heterogeneous structure of the IPN.

When the third model is adopted, the $\Delta\bar{\rho}_c^2$ values are greater than $\Delta\bar{\rho}^{2\prime}$, particularly at high concentrations of the ionomer. This indicates that the micro-regions of the phase separation in real IPN are more "diffuse" than assumed by the third model. In other words, the IPN studied show a high degree of blending of polyurethane and the ionomer; this is generally characteristic of those cases where the separation of the phases during the production of the complex polymeric system stops at some intermediate stage. As in individual network polymers, the incomplete separation of the phases may be due to retardation of the movement of the molecular chains during the production of the three-dimensional structure.[22,44] The introduction of ionogenic groups into one of the components, leading to the formation of "ionic" cross-linkages, produces even greater retardation of the phase separation. These suggestions are confirmed by the results of morphological studies of ionomer-containing IPN given in the preceding section.

Thus morphological and X-ray diffraction studies of ionomer-containing IPN indicate that systems of this type have a complex structure with different levels of hetero-

heterogeneity at the level of the components and heterogeneity within each component at the level of the blocks of different chemical character and regions with different concentrations of ionogenic groups. As noted in Ref. 43, the formation of "diffuse" micro-regions of phase separation with a wide range of values of the degree of segregation of the components is possible, depending on the nature of the intermolecular interactions in systems of the given type and on the previous history of these systems.

## II. THERMODYNAMIC PROPERTIES

The introduction of ionogenic groups into one of the components of IPN, even when they are of similar chemical character, leads to thermodynamic incompatibility of the components in the IPN.[45] This has been demonstrated for IPN containing polyurethane and a polyurethane monomer; the composition dependence of the thermodynamic compatibility of the components was studied, the coefficients of self-diffusion of the solvent calculated, the fraction of the free volume and the change in it with change in the component ratio in the IPN determined, and the influence of the filler on the thermodynamic interaction at the interface examined.[45,46,47] The polyurethanes were based on the adduct of trimethylolpropane and tolylene di-isocyanate (TMP + 2,4-TDI) and a copolymer of propylene oxide and tetrahydrofuran[33] or polyoxytetramethylene.[45] The ionomers used were a polyurethane ionomer with a three-dimensional structure based on polyoxypropylene glycol (MM 3000), 2,4-TDI, 2-dimethylaminoethanol, and 1,5-dibromopentane[45] (ionomer A) or a linear ionomer based on polyoxytetramethylene, 2,4-TDI, and potassium dihydroxybenzoate[45] (ionomer B).

An analysis of the isotherms for the sorption of organic vapours by specimens of these IPN and the individual components made it possible to calculate the thermodynamic parameters. Thus the concentration dependence of the mean free energy of mixing of the solvent with the individual networks and the IPN, and the method proposed by Tager,[48] were used to calculate the change in the free energy of mixing of the polyurethanes and the polyurethane ionomers in the IPN. The results of the calculation are given in Fig. 2. $\Delta G_m$ is positive throughout practically the entire range of compositions, that is the components of the system are thermodynamically incompatible. The greatest separation into phases is observed for medium compositions (in the case of ionomer A) and at low concentrations of ionomer B in the polyurethane. An exception is the range corresponding to small quantities of added ionomer A, where $\Delta G_m$ is negative, that is the components are compatible. Compatibility in restricted ranges of this kind is observed for many heterogeneous systems.[49,50] The components of the polyurethane–linear ionomer (ionomer B) system, that is in the semi-IPN, are incompatible throughout the composition range (curve 2 in Fig. 2); the degree of incompatibility increases with increase in the proportion of ionomer. Thus even when the components of the IPN are very similar in chemical character, the introduction of ionogenic groups into one of the components leads to thermodynamic incompability of the components, producing the heterogeneity of the systems as a result of phase separation during the formation of the IPN.

As already noted, the interpretation of most experimental data on the properties of ionomers is based on the idea that multiplets and clusters are formed.[21] The ability of the ionomer to undergo association will probably have a significant influence on the phase separation processes in ionomer-containing IPN. The introduction of even small quantities of polyurethane into an ionomer with a linear structure[46] will apparently lead to a sharp increase in the degree of association of the latter. Polyurethane, added in small quantities, probably cannot form a continuous network, for the reasons examined in Ref. 51, and it will be distributed by diffusion as individual fragments in the bulk of the ionomer, facilitating self-association of the ionomer in the IPN system. Self-association of the ionomer B is also facilitated by its linear structure, which gives greater mobility of the segments (compared with the three-dimensional ionomer A) and leads to the formation of associates of ionic groups.

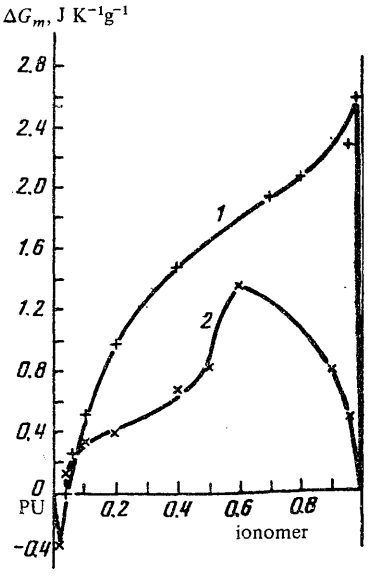

**Figure 2.** Composition dependence of $\Delta G_m$ for IPN based on polyurethane (PU) and ionomers A (1) and B (2).[45]

The self-association of the ionomer apparently intensifies the microphase separation in the IPN. As a result, the concentration dependence of the free energy of mixing of the components shows a maximum for small quantities of added polyurethane (see Fig. 2). At a higher concentration of polyurethane in the semi-IPN (medium compositions and the range of low concentrations of the ionomer in polyurethane), self-association is probably observed to a smaller extent, since the formation of the three-dimensional structure of the polyurethane, which is the matrix in these composition ranges, retards the process of phase separation in the IPN. The conditions of phase separation in these composition ranges are apparently close to those in IPN not containing ionomers.[52,53]

Microphase separation in the IPN leads to a redistribution of the free volume.[45–47] Quantitative treatment of data on the sorption of the vapours of substances with low molecular weight by IPN specimens using Fujita's theory[54,55] enabled the authors cited[45–47] to calculate the fraction of free volume in the ionomer-containing IPN.

The results are given in Fig. 3. For IPN containing the cation-active ionomer with a three-dimensional structure (ionomer A), at low concentrations of the components, the value of $f(T)$ is lower than the additive value, but for

intermediate compositions the IPN specimens show an increased proportion of free volume; for the IPN containing the anion-active ionomer (ionomer B), $f(T)$ deviates from the additive value towards higher values throughout the composition range, that is the IPN have a higher proportion of free volume.

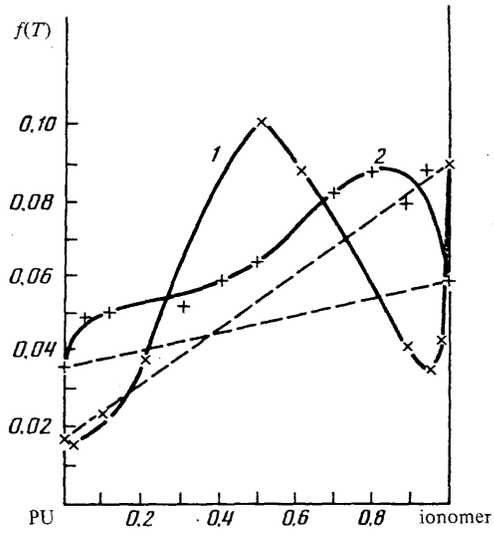

**Figure 3.** Dependence of the fraction of the free volume $f(T)$ on the component ratio for IPN containing ionomer A (curve *1*) and ionomer B (curve *2*); the broken lines give the additive relationships.[46]

Comparison of the concentration dependence of $f(T)$ and $\Delta G_m$ shows two common extremal points (curves *1* in Figs. 2 and 3), a minimum at low fractions of the ionomer A in the IPN, and a maximum at medium compositions, that is the compatibility range has a lower proportion of free volume than the individual components, and the range of greatest separation of the phases in the system corresponds to an excess of free volume. The self-association of the cation-active ionomer in the IPN system, leading to an increase in the segregation of the components in these systems, is apparently less marked than in the case of the anion-active ionomer (at least in the range of low concentrations of one of the components), since for the individual ionomers the formation of associates is more characteristic of the anion-active ionomers, as noted earlier. This is possibly due not only to the nature of the salt centres but also to the fact that ionomer A has a network structure, and ionomer B a linear structure. In this connection, phase separation accompanied by the formation of loose intermediate regions is more characteristic of the IPN with the linear ionomer (ionomer B),[3] leading to the production of an excess free volume throughout the composition range (curve *2* in Fig. 3).

The addition of a filler to the composition in the production of the IPN introduces its own characteristic features into the thermodynamic properties of these systems. Thus the introduction of small quantities (2–10%) of carbon fibres into IPN based on polyurethane and ionomer A leads to a decrease in their sorptive power;[47] the sorption decreases irregularly with increase in the concentration of the filler. This may be due to the competing action of two simultaneous processes: the formation of a more compact boundary layer and polymer–filler bonds, leading to a decrease in sorption, and the production of defects in the network (a decrease in the number of chemical nodes, "free" ends in the network) formed in the presence of the filler, leading to an increase in sorption.[51] Another noteworthy feature is that in the formation of two polymer networks in the presence of a filler for which the networks have different affinities, selective adsorption of one of the polymers will take place; this will lead to a change in the composition of the boundary layers in the final IPN structure produced, at the same time changing the extent of the sorption of the vapours of low-molecular-weight substances by the filled IPN.

For the case of a decrease in sorption in filled polymers compared with non-filled polymers, a thermodynamic cycle has been proposed[56] for estimating the extent of the reaction of the polymer with the filler.

$\Delta G^*_{p-f}$, that is the free energy of formation of the polymer–filler bond, which is a measure of the interaction of the polymer with the filler, is determined experimentally from the isotherms for the sorption of the vapours of organic solvents by the free polymer, the filler, and the filled polymer.[56] $\Delta G^*_{p-f}$ is calculated using the equation:

$$\Delta G^*_{p\text{-}f} = \Delta G_1 + n\Delta G_2 - \Delta G_3$$

where $\Delta G_1$ and $\Delta G_3$ are the free energies of the reactions of the polymer and the filled polymer with a large quantity of solvent, and $\Delta G_2$ the free energy of the reaction of the filler with a large quantity of the solvent.

Calculation showed[47] that for the polyurethane–carbon fibre system, the free energy of the polymer–filler interaction $\Delta G^*_{p-f}$ is negative in the range of filler concentrations studied. This indicates that the system is thermodynamically stable. For the polyurethane ionomer, only the composition with a low concentration (2%) of carbon fibres was found to be thermodynamically stable. Further increase in the filler concentration leads to destabilisation of the system, and the free energy becomes positive. Polymer–polymer contacts become energetically more favourable than polymer–filler contacts. Thus the ionomer macromolecules are less effectively adsorbed on the carbon fibres than the polyurethane macromolecules.

For filled IPN, the sign of $\Delta G^*_{p-f}$ depends on the component ratio at which the filler is introduced into the composition; at low concentrations of the ionomer (up to 10%) in the filled IPN, $\Delta G^*_{p-f}$ is negative, that is the system is thermodynamically stable; at an ionomer concentration of 30% or more, $\Delta G^*_{p-f}$ is positive, that is the system is destabilised. Here it is evidently necessary to take account of the influence of the filler on the microphase separation taking place during the formation of the IPN. According to the ideas developed in Ref. 5, in the formation of composite materials based on hybrid binders, the rate of the microphase separation and the degree of segregation in the hybrid binder depend on the reaction of the components with the filler. Thus if the filler reacts preferentially with one of the components, the rate of the microphase separation increases, and the degree of segregation should be greater. This probably takes place when carbon fibre is introduced into a polyurethane–polyurethane IPN containing 30% or more of the ionomer, where $\Delta G^*_{p-f}$ is positive. At low concentrations of the ionomer, in spite of a possible increase in the rate of the microphase separation under the influence of the filler, $\Delta G^*_{p-f}$ remains negative.

## IV. THE SWELLING OF IONOMER-CONTAINING INTERPENETRATING POLYMER NETWORKS

The swelling of ionomer-containing IPN obtained by sequential setting have been studied;[33,34,57] the ionogenic groups were introduced into one of the components of the IPN [57] or into both components.[33,34] The swelling of the IPN based on cross-linked polystyrene (network 1) and the copolymer of ammonium acrylate with ethyl acrylate (network 2) was carried out using toluene (a "good solvent" for network 1) and water (a "good solvent" for network 2). The experimental values of the swelling were compared with the values calculated using the additivity rule and assuming that the networks do not influence one another. All the IPN specimens studied undergo appreciable swelling in water and toluene, but to a much smaller extent (smaller by a factor of 3-6) than that calculated from the additivity rule. In the opinion of the authors cited, this behaviour indicates indirectly that both networks in the IPN system are continuous.[57]

Detailed studies have been made[33,34] of the swelling of cross-linked polystyrene, polyvinylpyridine, and IPN based on them, with and without ionogenic groups of different types; the anion-containing component of the IPN was obtained by sulphonation of the phenyl ring of polystyrene, and the cation-containing component by quaternisation of the pyridine ring by treating polyvinylpyridine with methyl fluorosulphonate solution.[33,34] The data on the swelling of the IPN and its components, not containing ionogenic groups, were analysed using the Flory–Rehner[58] and Thiele–Cohen[59] equations. The last equation was derived from the Flory–Rehner equation for application to homo-IPN, that is IPN based on two or more polymers of the same chemical character, so-called "Millar IPN".[60] The final form of the equation is

$$\ln(1-v_1-v_2)+v_1+v_2+\psi_s(v_1+v_2)^2=V_s(\nu_1)'(1/v_1^0)^{2/3}\times \times(v_1^{1/3}-v_1/2)-v_s(\nu_2)'(v_2^{0\,2/3}v_2^{1/3}-v_2/2) \quad (1)$$

where $\nu_1$ and $\nu_2$ are the volume fractions of polymers 1 and 2 in the swollen state, $\nu_1^0$ and $\nu_2^0$ the same in the non-swollen state, $\psi_S$ the molar volume of the solvent, $\nu_1'$ and $\nu_2'$ the density of cross-linking of polymers 1 and 2 in mole $cm^{-3}$, found from the Flory–Rehner equation, and $(1/\nu_2^0)^{2/3}$ a correction coefficient (front factor) for the change in the internal energy on swelling.

In the analysis of the data on the swelling of IPN not containing ionogenic groups, the experimentally determined values of the volume fraction of the polymer in the swollen IPN specimens, $\nu$, were compared with the values calculated from Eqn.(1), in which $\nu = \nu_1 + \nu_2$. It was concluded that in the IPN studied, in the swollen state at least, there is no additional chemical and physical cross-linking, which might have been expected on formation of the IPN. The addition of ionogenic groups to IPN based on polystyrene and polyvinylpyridine introduces its own characteristic features into the behaviour of the specimens on swelling. Thus for swelling in water at different pH values, the magnitude of $\nu$ (the maximum swelling) is greatest in weakly acidic or neutral media for all IPN compositions.[33] The value of $\nu$ increases with increase in the concentration of quaternised polyvinylpyridine, that is sulphonated polystyrene undergoes swelling to a greater extent than quaternised PVP. The addition of NaCl to water leads to different behaviour of the IPN, depending on their composition: specimens enriched in sulphonated PS, as before, give the minimum values of $\nu$ in neutral and weakly acidic media; specimens enriched in quaternised PVP give a maximum value of $\nu$ (that is minimum swelling) in these media. The observed differences in the swelling of ionogenic IPN, depending on the composition of the "solvent", are attributed to the shielding effect produced on the addition of, in this case, $Na^+$ and $Cl^-$ ions, which influence the electrostatic repulsion of the ions in the actual network.[33,60] Thus the introduction of ionogenic groups into the IPN makes it possible to vary the degree of interaction of these systems with the solvents over a wide range by changing the composition; this is important when IPN are used as ion-exchange resins and membranes.

From an analysis of the results of the study of the swelling of IPN specimens consisting of a copolymer of styrene with divinylbenzene (ST + DVB) and a copolymer of methacrylic acid with divinylbenzene (MA + DVB), an attempt was made[61] to obtain a criterion of the degree of interpenetration in IPN. The IPN indicated were obtained by sequential setting; specimens of the ST + DVB copolymer were first obtained, after which they were swollen in an MA + DVB monomer mixture, followed by polymerisation of the system. The IPN were obtained in the $H^+$- and $Na^+$-forms, and the swelling of the individual components and the IPN in a series of solvents was studied. Determination of the density of cross-linking from the swelling data showed that the experimental values of $\nu_e$ (the effective density of nodes in the network) of the IPN specimens are much greater than the values calculated from the additivity rule. From the assumption that the IPN is a heterogeneous system provisionally consisting of three phases (the phases of the individual components and the intermediate range), and an analysis of the swelling data, the following criteria for the degree of interpenetration in IPN were proposed:[61] 1) the difference between the sum of the specific volumes of the gels of networks 1 and 2 and the specific volume of the IPN gel

$$\Delta V = V_1\cdot v_1(1-P_1)+V_2\cdot v_2-V_i(1-P_i) \quad (2)$$

and 2) the difference between the volume fraction of the copolymer in the IPN gel and the sum of the volume fractions of the copolymers in the gels of networks 1 and 2:

$$\Delta v_g = v_{g_i}-(v_{g_i}\cdot v_1+v_{g_i}\cdot v_2) \quad (3)$$

where $V_1$, $V_2$, and $V_i$ are the specific volumes of networks 1 and 2 and the IPN, $\nu_1$ and $\nu_2$ the volume fractions of networks 1 and 2 of the IPN, $P_1$ and $P_i$ the porosities of network 1 and the IPN, and $\nu_{g_1}$, $\nu_{g_2}$, and $\nu_{g_i}$ the volume fractions of the copolymer in the gels of networks 1 and 2 and the IPN.

The proposed criteria, like Frisch's interpenetration criterion,[62] are applicable only when the number of nodes in the networks of the individual components is identical to that for the components in the IPN system; this is not observed in practice, since IPN are micro-filled systems,[3] to which all the ideas developed for filled polymers are applicable.[51] Thus the proposed interpenetration criteria can be criticised. The most appropriate criterion of the degree of interpenetration is apparently the degree of segregation, as noted above (see section II).

The fact that the experimental values of $\nu_e$ and the other parameters deviate considerably from the values calculated from the additivity rule for ionomer-containing IPN [61] indicates not only and not so much an increase in the degree of interpenetration in IPN, but also and more particularly the characteristic features of systems of this type determined by the increased self-association of the ionomeric component in the IPN system. This question will be discussed later.

## V. MECHANICAL AND RELAXATION PROPERTIES. TRANSITION TEMPERATURES

The study of the composition dependence of the mechanical properties of ionomeric IPN revealed the same regularity as for IPN of other types and mixtures of linear polymers, that is the extremal character of the change in properties with change in the component ratio. Thus an IPN consisting of polyurethane and a polyurethane ionomer[46] showed an extremal increase in the tensile strength at low concentrations (5%) of the polyurethane ionomer.[43] The breaking strain also showed an unexpected increase. An extremal change in properties with change in composition is a general regular feature of binary systems: mixtures of linear polymers, IPN, semi-IPN, and filled polymers. The reasons for this phenomenon are undoubtedly related to the characteristic features of the structural changes in the composites with change in their composition, but in spite of a number of attempts to explain the observed extremal values for different systems, no general explanation of these phenomena has yet been given.

The method of preparation of ionomer-containing IPN has a significant influence on their mechanical and relaxation properties. This has been demonstrated for thermoplastic IPN: chemically and mechanically blended IPN based on copolymers of styrene, ethylene, and butene (copolymer 1) and styrene, methacrylic acid, and isoprene (copolymer 2) (CBT IPN and MBT IPN respectively) differ in various mechanical properties. Both CBT IPN and MBT IPN with the ionomeric component in the acid form have lower strength values than IPN with the ionomeric component in the salt form.[40] When copolymer 2 is neutralised, the resulting more rigid component (the ionomer) acts as a characteristic filler for copolymer 1, leading to an increase in the mechanical strength of the IPN. CBT IPN have a higher tensile strength and a greater elongation at rupture, but a lower modulus of elasticity, compared with MBT IPN. This change in mechanical properties was related[18] to the morphology of these IPN; thus the lower modulus of elasticity of the CBT IPN was attributed to the greater degree of dispersion of copolymer 2 (the ionomer) in the matrix of copolymer 1.

The relaxation properties of the above systems have also been studied.[40,41] Data on the temperature dependence of the imaginary part $E''$ of the complex modulus $E^*$ established that the individual copolymer 1 has two glass-transition temperatures; the first, at −60 °C, is due to the presence of blocks of ethylene and butene, and the second, at 102 °C, is due to glass formation by the styrene blocks. The ionomer shows one glass-transition temperature at 140 °C. These three glass-transition temperatures also appear on the curves giving the temperature dependence of $E''$ for CBT IPN, without any deviations; this indicates that there is little blending at the molecular level of the components in the systems considered, in contrast to polyurethane–polyurethane ionomer systems,[43] discussed above.

The mechanical properties of these IPN have been described using the theoretical models of Takayanagi, Budyanskii, Davis, and Kerner.[40] The experimental data are most accurately described by Davis' equation, which assumes that both phases in the two-phase system are continuous. For MBT IPN, continuity of both phases is probably more characteristic, since Davis' equation provides a better description of the mechanical properties for MBT IPN than for CBT IPN. This correlation is illustrated directly by the electron microscope data given in the previous section, which show "double" continuity of the phases.

Systems related to ionomer-containing IPN are those in which one of the components is a polyelectrolyte such as acrylic acid and its derivatives. These systems[63] and their relaxation properties have been studied. They are IPN and semi-IPN based on polyoxyethylene (POE) and polyacrylic acid (PAA), obtained by sequential setting. Polyoxyethylene with a molecular mass of 7800–9000 was dissolved in a mixture of the monomer, a cross-linking agent (DVB), and an initiator (benzoyl peroxide), after which the polymerisation was carried out. This gave semi-IPN. The complete IPN were obtained by swelling the previously cross-linked POE in a mixture of the monomer and the cross-linking agent, followed by polymerisation. Study of the dynamical mechanical properties of the semi-IPN and total IPN obtained showed that the curves giving the temperature dependence of $E''$ and $\tan\delta$ for specimens with medium compositions or compositions close to them have a single maximum, indicating that there is one temperature transition in systems of this kind. Thus the specimens studied consist of single phases. For specimens in which PAA predominates, and in particular for the semi-IPN with 75 mass % PAA, two maxima are observed; one corresponds to that for the IPN with the equimolar component composition, and the other corresponds to the glass-transition temperature of PAA. For the complete IPN with approximately the same composition, a sharp second maximum is not observed; the curve shows only a slight shoulder. For semi-IPN and IPN enriched in POE, one broad transition is observed, with a maximum at a temperature slightly below the melting point of POE.

These results are interpreted in terms of the formation of complexes between POE and PAA molecules as a result of the production of hydrogen bonds between the COOH groups of the acid and the oxygen atoms of POE.[63]

The question of the association of PAA and POE during the polymerisation of acrylic acid in the presence of POE was examined earlier[64–66] by one of the authors of Ref.63. It is suggested that dynamic mechanical analysis shows that the formation of a single-phase system in IPN and semi-IPN with medium compositions and compositions close to them is due to complex formation. IPN with a low concentration of PAA, according to Ref.63, show microphase separation of POE domains and domains of POE + PAA complexes; IPN with a high PAA concentration show microphase separation of domains of PAA and the complexes. The degree of microphase separation or segregation is greater for the semi-IPN than for the complete IPN, and this is attributed to preliminary cross-linking of the POE during the preparation of the complete IPN. The interpenetration of the components and the formation of interpolymer complexes probably also explains the decrease in the crystallinity of POE in the system of semi-IPN and complete IPN.[63]

Analysis of the strength properties of IPN based on POE and PAA [63] or on polymethacrylic acid[67,68] revealed a characteristic feature of systems of this kind, of practical importance: for low mechanical strain, considerable elongation of the IPN specimens is observed, due to the possible dissociation of the POE + acid complexes and their rearrangement under the influence of the strain.

The characteristics of the reaction between the components and the molecular mobility in IPN based on polymers of related character (polyurethanes) have been studied.[69] NMR spectroscopy was used to study the temperature dependence of the second moment of the absorption line $\Delta H_2^2$ for IPN based on polyurethane (PU) and a polyurethane ionomer (PUI). The latter was obtained by the reaction of oligotetramethylene glycol, TDI, and sodium dihydroxybenzoate.

The curve giving the temperature dependence of $\Delta H_2^2$ for PU showed three main transitions: transition I in the low-temperature range (−130 °C) due to the defreezing of the molecular mobility of the methyl groups:[70] transition II, which begins at −90 °C and is due to the retarded rotation of the methylene groups; and transition III at −10 °C,

apparently due to the start of the segmental movement of large parts of the molecules,[71] possibly sections of the polyurethane chains between the transverse cross-linkages. Unlike PU, the PUI does not show sharply defined temperature transitions: $\Delta H_2^2$ decreases gradually with increase in temperature. For the IPN specimens, transitions I and II are preserved, but transition II is displaced to lower temperatures with change in the ionomer concentration. Transition II, observed at low concentrations of the ionomer, becomes "blurred" with increase in the quantity of the latter.

The preservation of the IPN of the transitions characteristic of the individual components indicates that two phases are present, in spite of the similarity in the chemical character of the components. In the two-phase system there may be intermolecular interactions of different kinds between the components. The nature of the interaction between PU and the PUI in the IPN was therefore estimated from the magnitude of $(\Delta H_2^2)_{int}$, determined as follows:

$$(\Delta H_2^2)_{int} = (\Delta H_2^2)_{expt} - (\Delta H_2^2)_{theor}$$

where $(\Delta H_2^2)_{theor}$ is the second moment of the absorption line of the two-component system, calculated from the additivity rule. The quantity $(\Delta H_2^2)_{int}$ may take positive or negative values if there is an intermolecular interaction between the components of the system, in spite of the absence of chemical transformations. In the absence of interactions, $(\Delta H_2^2)_{expt} = 0$. Calculations showed that the values of $(\Delta H_2^2)_{int}$ for all IPN specimens at the lowest temperature used (−130 °C) are negative, indicating that the molecular mobility of the IPN is greater than that of the individual components. The study of the thermodynamic compatibility of the components in IPN of this type (see section II) showed that the components are incompatible (the free energy is positive). Thus the system studied, like non-ionogenic IPN, shows separation of the phases during its formation, leading to the production of an intermediate range, which, as in non-ionogenic IPN, has a loose structure, as indicated by the negative values of $(\Delta H_2^2)_{int}$.

Calculation of the activation energy of the transitions in the IPN and its components showed that the value of the activation energy $E$ changes non-additively and irregularly with change in composition. For non-ionogenic IPN, the value of $E$ for the transitions also changed irregularly with change in composition; for all IPN specimens, however, the value of $E$ was always less than the additive value and less than the values for the individual components;[72] this was attributed to the formation of a loose intermediate range, facilitating molecular movement in it. In ionogenic IPN, the value of $E$ is lower than the additive value only for IPN specimens containing up to 20–30% of the ionomer. At high concentrations of the ionomer, $E$ is greater than the additive value.

These results were interpreted[69] using the theory of multiplet and cluster formation in ionomers, developed in a number of studies.[6,21,73,74] The ability of the ionomer in the IPN to undergo self-association possibly intensifies the microphase separation. At the same time, the formation of a loose intermediate region, having an excess free volume, facilitates the self-association of the ionomeric component in the IPN system, compared with the individual ionomer. The association of the ionogenic groups is probably the decisive factor in the change in molecular mobility in the IPN when it contains ionomer concentrations of 20–30%, so that $E$ is greater than the additive value. At lower concentrations of the ionomer, when the matrix is PU, the self-association of the ionomeric component is not so marked, and the molecular movement in the system is determined chiefly by the existence of the intermediate range. In this case $E$ is lower than the additive value.

A study of the temperature transitions in an epoxide resin–polyurethane ionomer system (based on polyoxypropylene glycol, TDI, dimethylaminoethanol, and dibromopentane) [75] showed that for IPN of all compositions, two transitions are observed, lying in the region of the glass-transition temperatures of the component networks. In the IPN, however, the glass-transition temperatures are displaced along the temperature scale, as indicated in Fig. 4. The temperature of the transition, which is due to the glass transition of the epoxide resin (curve *1* in Fig. 4), in the IPN changes with change in composition along a curve which has two minima at concentrations of each component of about 10%. The second transition, which lies in the negative temperature range and is due to the glass transition of the polyurethane ionomer (curve *2* in Fig. 4), is displaced to higher temperatures with increase in the proportion of resin in the IPN.

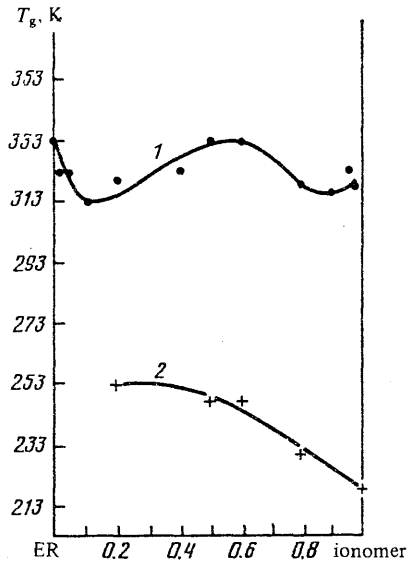

**Figure 4.** Change in the glass-transition temperature with change in composition for IPN based on polyurethane and epoxide resin (ER): *1*) glass-transition temperature of the epoxide resin, *2*) glass-transition temperature of the polyurethane ionomer.[75]

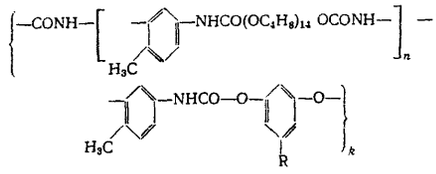
The results were interpreted[75] in terms of the degree of completeness of the processes of microphase separation and the degree of segregation. At a low degree of segregation, leading to the formation of an appreciable proportion of interphase regions, as in the case of blending at the molecular level, the temperature transitions characteristic of the individual components may not be observed.[76] The presence of two glass-transition temperatures in the IPN indicates, however, that there is a fairly high degree of segregation of the components even at low concentrations of each of them. In the range of medium concentrations, however, where the glass-transition temperature of the epoxide resin in the IPN is approximately equal to that for the pure epoxide resin, the degree of segregation is probably very high, and the phase separation is extensive.

Thus the formation of ionic "cross-linkages" in IPN as a result of the introduction of ionogenic groups into one of the components has a significant influence on the mechanical and relaxation properties. This is apparently related to the increase in the degree of segregation of the components of the system due to the increase in the association of the ionogenic groups in the IPN compared with the pure ionomer. The association of the ionogenic groups is also possibly responsible for the marked difference between the experimental and theoretical values of $\nu_e$ (see section III), as follows from Ref. 61; the associates of ionogenic groups are characteristic nodes of the network, leading to an increase in $\nu_e$.

The question of the formation of multiplets and associates in individual ionomers of different character is still being discussed in the literature. Analysis of the results of studies in this field indicates that the nature of the ionogenic groups has a decisive influence on the association: associates are detected for polymers of different classes with anion-containing ionomers; associates are less frequently detected in cation-containing ionomers. This field is now being intensively studied.[6,20]

## VI. ADHESIVE PROPERTIES

Adhesives and coatings based on IPN show good adhesion to supports of different kinds;[3,4] no systematic studies of the adhesive properties of these coatings, or of coatings based on ionomer-containing IPN, have been described, however. The use of an ionomer as one of the components of the IPN to obtain adhesives and coatings will apparently make it possible to obtain materials with good adhesive power and low hydrophilic character (compared with the individual ionomers).



Influence of the nature of the counter-ion and the concentration of salt groups on the adhesive strength (N $m^{-1}$) of coatings on substrates of different character*.

| Type of salt | Steel | | | Glass | | |
|---|---|---|---|---|---|---|
| | $n$=1 | $n$=2 | $n$=3 | $n$=1 | $n$=2 | $n$=3 |
| Lithium salt | 340 | 220 | 180 | 280 | 210 | 140 |
| Sodium salt | 280 | 200 | 170 | 230 | 160 | 130 |
| Potassium salt | 220 | 200 | 100÷95 | 210 | 180 | 130 |

| Type of salt | Dural | | | Brass | | |
|---|---|---|---|---|---|---|
| | $n$=1 | $n$=2 | $n$=3 | $n$=1 | $n$=2 | $n$=3 |
| Lithium salt | 220 | 170 | 95 | 320 | 240 | 220 |
| Sodium salt | 160 | 140 | 100 | 310 | 180÷200 | 200÷220 |
| Potassium salt | 90 | 120 | 75 | 212÷200 | 180 | 110 |

*Temperature of formation of the coatings 80 °C.

The adhesion to various supports (steel, brass, glass, Dural) has been studied[77] for coatings based on IPN consisting of network polyurethane and polyurethane ionomers with the general structure

where $n$ = 1, 2, 3; $R$ = COOLi, COONa, COOK; and $k$ is the degree of poly-addition. The study of the influence of the concentration of salt groups in the chain of the ionomers studied on the strength of the adhesion (at separation) showed that increase in the concentration of salt groups in the structure of the polymer chain (that is decrease in $n$) increases the adhesive strength of the ionomeric coatings for all supports studied (see Table). The fact that a significant increase in the adhesive strength of the ionomers is observed only at a high concentration of salt groups in the composition makes these polymers unsuitable as protective coatings, because of their highly hydrophilic nature; their use as one of the components of the coating gave good results, however.[71]

Fig. 5 gives typical curves showing the change in the equilibrium work of adhesion for coatings based on ionomer-containing IPN with change in composition. At low concentrations of each component, an extremal increase in adhesion is observed; this is particularly clearly defined at low concentrations of the ionomer. At the same time, the coatings are only slightly hydrophilic, and this is important from the practical viewpoint. The extremal point on the graph giving the dependence of the hydrophilic character on the concentration composition of the IPN probably corresponds to the range of concentrations at which the ionomeric component becomes the continuous phase.

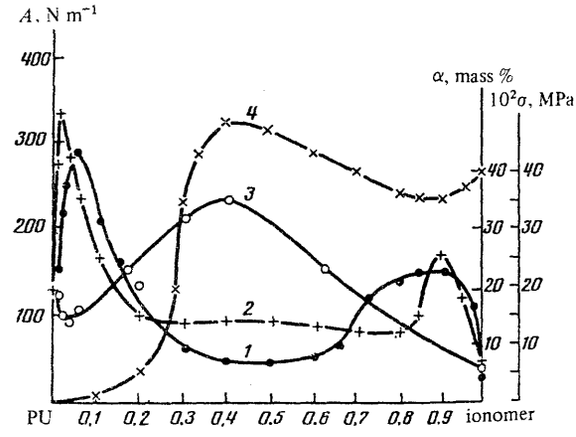


**Figure 5.** Dependence of the quasi-equilibrium work of adhesion $A$ (*1*, *2*), hydrophilic character $\alpha$ (*3*), and internal stresses $\sigma$ (*4*) on the component ratio.[77]

In the production of coatings, the influence of the solid surface of the support is superimposed on the process of IPN formation, that is selective adsorption of a particular component on the surface is possible, leading to an irregular distribution of the components in the boundary layer of the coating. Thus analysis of the surface tension values, and also data on the temperature dependence of the adhesive strength of the above coatings, indicated[77] that the polar groups of the ionomeric component are oriented on the surface of the substrate, leading to an increase in the adhesion of the coating. The principal feature of the dependence of the strength of adhesion on the composition of the IPN, however, is the presence of extremal points.

Up to a certain composition, the microregions of one of the components, distributed in the matrix of the other component, apparently act as a reinforcing filler, leading to an

improvement in various characteristics of the materials based on IPN, in particular the adhesion of coatings. In the range of medium and similar compositions, however, inversion of the phases is observed, that is the component acting as the micro-filler gradually becomes the matrix; in this range there is generally a deterioration in both the mechanical and the adhesive properties (see curves *1* and *2* in Fig.5). The gradual transformation of the filler component into the matrix component produces strained structures, as indicated, for example, by the marked increase in internal strain in the coatings (curve *3* in Fig.5). This in turn leads to a decrease in the strength of adhesion.

Thus the use of an ionomer as one of the components in the production of coatings based on IPN makes it possible to obtain coatings whose adhesive strength is considerably greater than that of the individual components. A more detailed explanation of the reasons for this phenomenon requires further studies on a wider range of systems.

---o0o---

The above analysis of published data indicates that the introduction of ionogenic groups into IPN systems leads to a significant change in the mechanical, structural, and relaxational properties of materials based on these IPN. In contrast to non-ionogenic IPN, where a change in properties is achieved only by varying the component ratio in the system, in the case of ionomer-containing IPN it is possible to vary the properties of the materials obtained more widely by changing the quantity and nature of the salt groups in the ionomeric component of the IPN. Information on the preparation and study of ionomeric IPN began to be published only in the last 5–7 years. Reports indicate,[78] however, that studies in this field are being extended; the synthesis of new IPN with ionogenic groups in both components, with opposite charges, is being suggested. Methods are being developed for obtaining IPN in which interpolymer complexes are formed.[67,68]

The use of polymers of more complex chemical character with active groups in the chains as components of IPN naturally complicates the production of the system, and alters its final properties considerably. A comparative study of IPN consisting of polymers of the same chemical character with and without ionogenic groups has not yet been carried out, however. Nevertheless, judging from the above results of structural studies of ionomer-containing IPN, the conditions of the chemical reactions, and also the conditions of microphase separation, in these systems will differ from those in non-ionogenic IPN. The task of the immediate future is to carry out studies in these directions.

Thus ionomer-containing IPN represent a new type of hybrid binder, whose use will make it possible to develop more complex combinations of different polymer structural states and to create new possibilities for controlling the physicomechanical properties of polymeric materials based on them.
