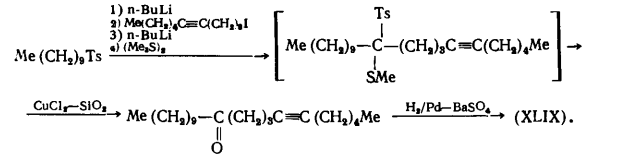
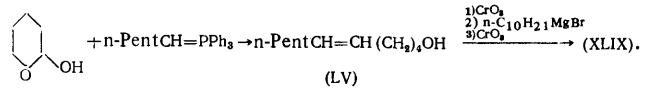
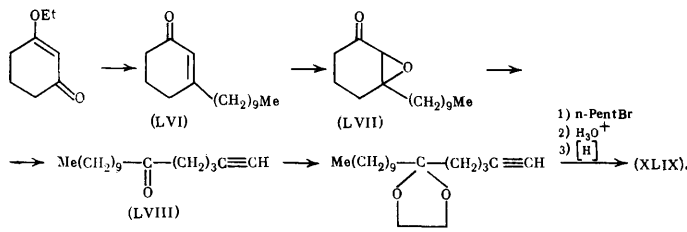
Alkylation of the lithium salt of 2-n-decyl-1,3-dithiane with subsequent hydrogenation results in the formation of the ketone (LII) whose carbonyl group is reduced by lithium tetrahydroaluminate and the triple bond is reduced to the *trans*-olefin with sodium in liquid ammonia. Catalytic hydrogenation over a nickel catalyst in the presence of EDTA affords compound (XLIX) (stereochemical purity 97%).[101]

The conversion of trialkylboranes into alkylmagnesium bromides has also been used to synthesise compound (XLIX).[102] *cis*-Deca-1,4-diene is hydroborated with 9-borabicyclononane (9-BBN), 1,5-pentamethylenedi(magnesium bromide) is added and the dec-4-enyl-9-BBN-magnesium bromide formed *in situ* is treated with copper(II) iodide and then with undecanoyl chloride, as a result of which the ketone (XLIX) is obtained in 78% yield:



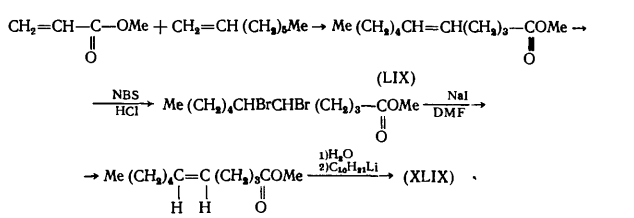
In the presence of bis(triphenylphosphine)nickel chloride, isopropylmagnesium bromide reduces the vinyl sulphide (LIII) stereospecifically to the corresponding olefin. This process has been used as the key stage in the synthesis of the unsaturated ketone (LXIX):[103]



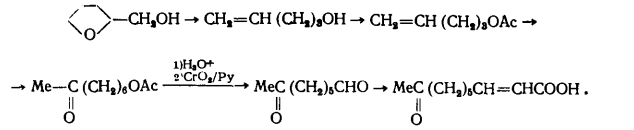


An alternative method of synthesis of the pheromone (LXIX), based on the preparation of dialkylacetylene (LIV) with subsequent Lindlar reduction,[104] is presented below:

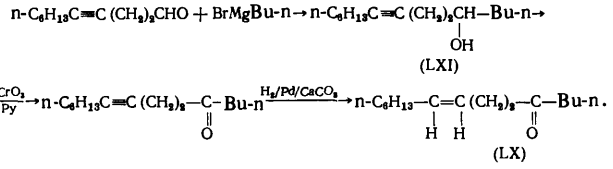
The interaction of 2-hydroxypyran with hexylidenetriphenylphosphorane leads to undec-5-enol (LV) with a very high degree of geometrical purity. Oxidation of the resulting alcohol with chromium trioxide to the corresponding aldehyde, subsequent interaction with n-decylmagnesium bromide, and repeated oxidation afford compound (XLIX):[105]



The pheromone (XLIX) has been obtained in a low yield from dihydroresorcinol in accordance with the scheme presented below:



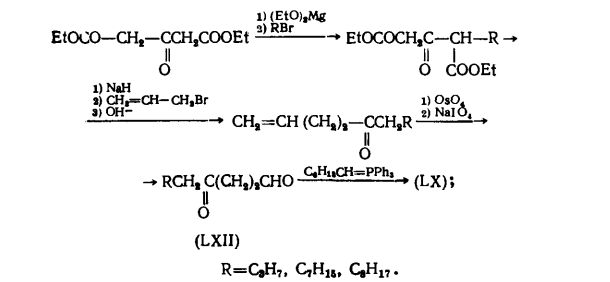
3-Ethoxy-2-cyclohexenone was converted by alkylation and hydrolysis into the αβ-unsaturated ketone (LVI), whose oxidation afforded the αβ-epoxyketone (LVII). The acetylenic ketone (LVIII) was obtained from the epoxide and then alkylated and hydrogenated over the Lindlar catalyst.[76] *cis*-Undec-5-en-2-one, an intermediate in the synthesis of pheromones, was synthesised by an analogous method.[106]



The interaction of methyl acrylate with 1-olefins in the presence of the eutectic mixture of aluminium, potassium, and sodium chlorides results in the formation of the unsaturated ester (LIX) in 40% yield, from which the pheromone (XLIX) was obtained:[107]

A simple and easy method of synthesis from tetrahydrofuryl alcohol of the intermediate for the synthesis of pheromones has been proposed:[108]

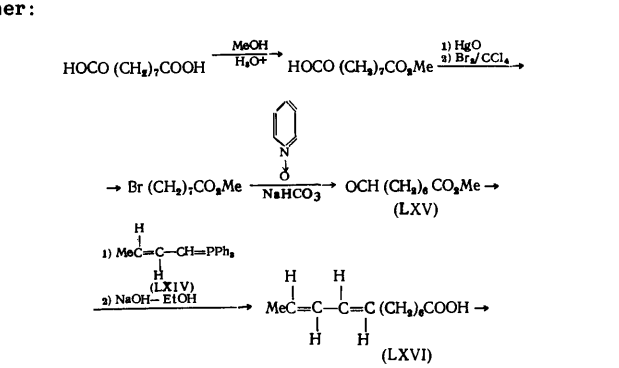
The pheromone of the peach moth *Carposina niponensis* consists of two components: the major component *cis*-eicos-7-en-11-one (LX) and the minor component *cis*- or *trans*-nonadec-7-en-11-one.[109] The key compound, 1-alkylundec-4-yn-1-ol (LXI), was obtained by treating the corresponding aldehyde[109] or nitrile[110,111] with a Grignard reagent:



(LXI)

(LX)

Regioselective two-stage alkylation of acetonedicarboxylate ester with subsequent oxidation to the γ-ketoaldehyde (LXII), which was then made to undergo the Wittig reaction, has also been used to obtain compound (LX).[112] The reaction of the ketoaldehyde (LXII) with heptylidenetriphenylphosphorane at a low temperature leads to the *cis*-olefin (LX) in 20% yield.[113] In the presence of crown-ether (12-crown-4), the same reaction proceeds with a yield of 64%[112] and the content of the *cis*-isomer in the ketone (LX) exceeds 90%:

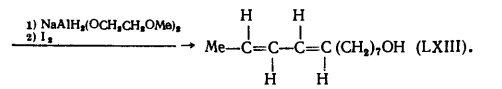


(LXII)

R=$C_5H_7$, $C_7H_{15}$, $C_9H_{17}$.

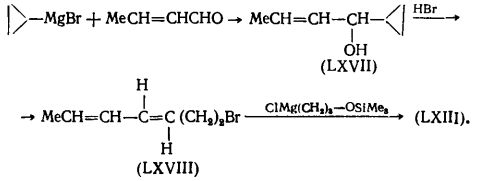
## IV. CONJUGATED DIENE ALCOHOLS, ACETATES, AND ALDEHYDES

Among the pheromones of the Lepidoptera, numerous compounds containing conjugated double bonds are known.[1,4,5] The methods of synthesis of compounds of this type discussed below illustrate the procedures used to obtain conjugated systems with the *trans*-configuration.



The pheromone of the lesser apple-worm *Laspeyresia pomonella*, *trans,trans*-dodeca-8,10-dien-1-ol (LXIII), was first obtained[114] by means of the Wittig reaction from *trans*-butenylidenetriphenylphosphorane (LXIV) and methyl 8-oxo-octanoate (LXV) in DMF in the presence of sodium methoxide. The acid (LXVI) has also been obtained as a mixture of 75% of the 8-*trans*,10-*trans*-isomer and 25% of the 8-*cis*,10-*trans*-isomer:

(LXV)

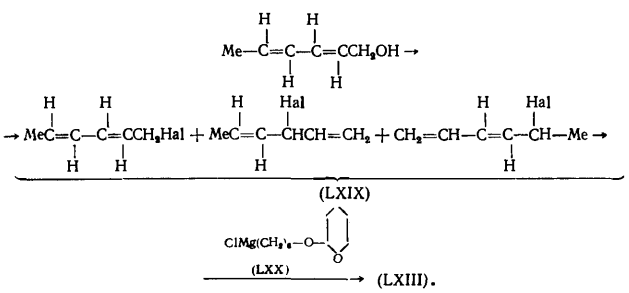


(LXIV)

(LXVI)

After reduction and isomerisation on treatment with iodine, the pure *trans*-isomer (LXIII) was obtained but in a very low yield. A high yield of the isomeric mixture consisting of 45% of the 8-*trans*,10-*trans*-isomer, 39% of the 8-*cis*,10-*trans*-isomer, and 16% of the 8-*trans*- and 8-*cis*,10-*cis*-isomers has been achieved by the reaction of the trans-ylide (LXIV) with ethyl 8-oxo-octanoate in the presence of lithium bromide.[1] The ratio of the isomers in the absence of lithium bromide is virtually the same as under the conditions of the normal Wittig reaction.[5,115,116] If tetrahydropyranyloxyheptyl bromide is converted into the triphenylphosphonium salt and the Wittig reaction with *trans*-but-2-enal is carried out, the yield is only 10% and the product (LXIII) consists of a mixture of 77% of the 8-*cis*,10-*trans*-isomer, 20% of the 8-*trans*,-10-*trans*-isomer, and 3% of a mixture of the 8-*trans*,10-*cis*- and 8-*cis*,10-*cis*-isomers.[115]

A higher stereoselectivity of the process was achieved on opening the ring of the secondary alcohol cyclopropylpropenylmethanol (LXVII) with hydrobromic acid, which leads to a mixture of 90% of 3-*trans*,5-*trans*- and 10% of 3-*cis*,5-*trans*-heptadienyl bromides (LXVIII). The Grignard reaction in the presence of $Li_2CuCl_4$ and subsequent hydrolysis lead to 79% of the alcohol (LXIII) containing 9% of the 8-*cis*,10-*trans*-isomer and 12% of the 8-*cis*(*trans*),10-*cis*-isomer:

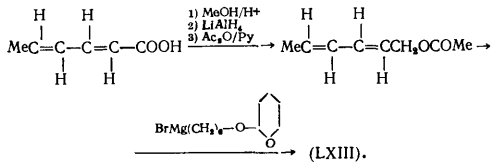


(LXVII)

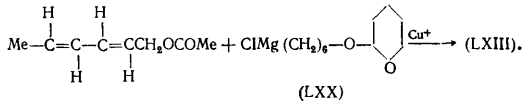
(LXVIII)

Recrystallisation of this mixture yielded the alcohol (LXIII) (with 99.5% purity).[117] In many studies *trans,trans*-dodecadodeca-8,10-dien-1-ol was obtained in a low yield and the reaction product contained also a whole series of other geometrical isomers, the stereospecificity of the reaction being unknown.[1]

The interaction of the allyl halides (LXIX) with Grignard reagents not containing double bonds, leading to a complex mixture of the geometrical isomers of the alcohol (LXIII), has been studied in detail.[118] The interaction of the isomeric mixture of the halides (LXIX) with the Grignard reagent (LXX) leads mainly to oct-2-ene and only trace amounts of a diene product:[119]



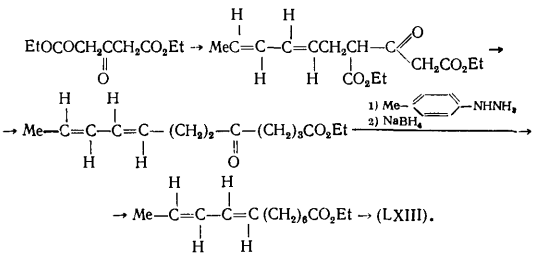
(LXIX)



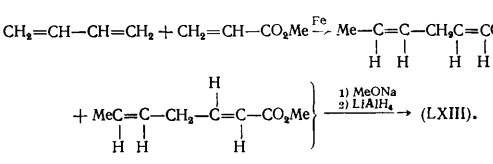
(LXX)

A number of attempts to convert sorbyl alcohol into the corresponding halide without an allylic rearrangement proved unsuccessful.[120,121] Using sorbyl bromide, obtained from sorbyl alcohol and phosphorus tribromide, various investigators were able to obtain 25–30% of the alcohol (LXIII) containing only 75% of the *trans,trans*-isomer.[122–124]

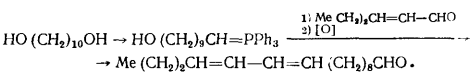
The interaction of sorbyl acetate with organomagnesium and organolithium reagents in the presence of univalent copper salts has been investigated.[125] The reaction is rigorously stereo- and regio-specific with formation of *trans,trans*-dodeca-8,10-dien-1-ol (99.7% stereochemical purity):[125,126]



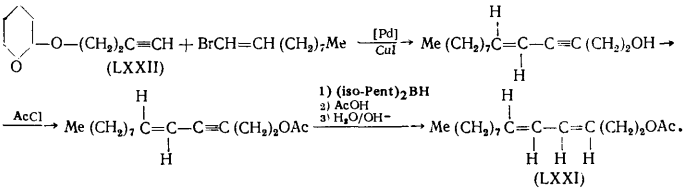
A single-stage synthesis of the dodecadienol (LXIII) from *trans,trans*-1-acetoxyhexa-2,4-diene and the Grignard reagent (LXX) has been achieved in the presence of a univalent copper salt:[127]



(LXX)

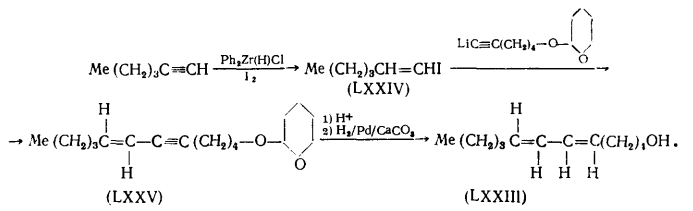


Using the selective alkylation of acetonedicarboxylate ester initially with sorbyl bromide and then with 3-bromopropionate and subsequent hydrolysis, decarboxylation, and reduction, the alcohol (LXIII) was synthesised in a fairly high yield:[128]



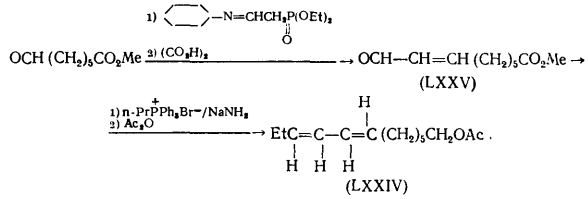
New possibilities for the synthesis of diene attractants appeared when the co-oligomerisation of 1,3-dienes with acrylates, catalysed by transition metals, was employed. The codimerisation of butadiene with methyl acrylate leads to a mixture of *cis,cis*- and *trans,cis*-hepta-2,5-dienoic acids. The isomerisation of this mixture by treatment with sodium ethoxide leads to a quantitative yield of *trans,trans*-hepta-3,5-dienoic acid, which is reduced to an alcohol:[129]

*trans,trans*-Hexadeca-10,12-dienal, the principal component of the pheromone of *Earias insulana*, has been obtained from 1,10-dihydroxydecane; the Wittig reaction, which leads to a mixture of the 10-*trans*,12-*trans*- and 10-*cis*,12-*trans*-isomers, was used as the key stage:[130]



The application of metal complex catalysis makes it possible to obtain *trans,trans*-dienes with a high stereochemical purity. Thus *cis,trans*-tetradeca-3,5-dienyl acetate (LXXI), the pheromone of *Prionoxystus rebiniae*, has been obtained by the direct stereospecific cross-coupling of the ω-substituted alkyne (LXXII) with *cis*-1-bromodecene in the presence of tetrakis(triphenylphosphine)palladium and copper(I) iodide.[131] The stereospecificity of this reaction is greater than 97%. When it is carried out under phase transfer catalysis conditions, the yield of the pheromone (LXXI) is increased to 70%:

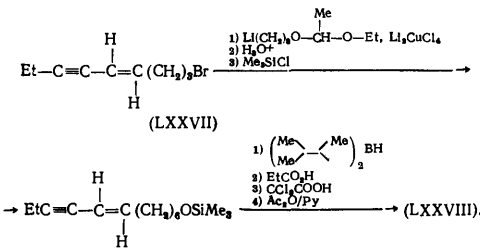
(LXXII) (LXXI)



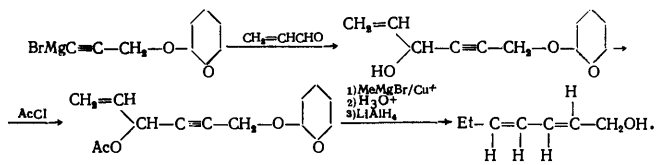
The cross-coupling of *trans*-1-iodohexene and tetrahydropyranyloxyhex-5-yne in the presence of bis(triphenylphosphine)palladium chloride was the key stage in the synthesis of *cis,trans*-dodeca-5,7-dien-1-ol (LXXII)—the pheromone of *Dendrolimus spectabilis*.[132] A regioselective synthesis of *trans*-1-iodoalk-1-enes (LXXIV) in the presence of a zirconium catalyst has been developed. The conjugated triple bond in compound (LXXV) gives rise to a mixture of 5% of the initial enyne (LXXV), 71% of the *cis,trans*-5,7-diene, and 24% of the monoene on hydrogenation over the Lindlar catalyst:

(LXXV) (LXXIII)

The stereochemically pure pheromone (LXXIII) was obtained by chromatographing the mixture on silica gel impregnated with silver nitrate. *cis,trans*-dodeca-5,7-dien-1-ol and the corresponding aldehyde are the components of the sex pheromone of *Malacosoma disstria*.[133] All four isomers of dodeca-5,7-dien-1-ol have been obtained stereoselectively by the Wittig condensation.[133]



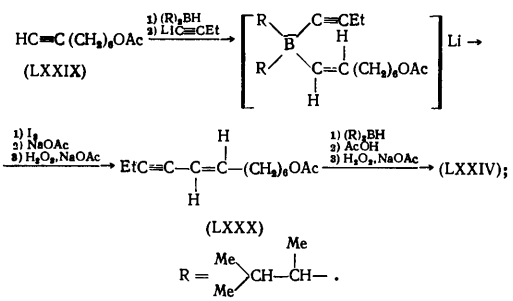
The αβ-unsaturated aldehyde (LXXV), obtained by the Horner reaction from the aldehyde (LXXVI) on treatment with didethyl 2-(cyclohexylimino)ethylphosphonate,[134] was used as the initial component for the synthesis of *trans,cis*-dodeca-7,9-dienyl acetate (LXXIV)—the pheromone of *Lobesia botrana*:[134,135,136]



(LXXV) (LXXIV)

The interaction of the aldehyde (LXXV) with propylidenetriphenylphosphorane followed by its reduction with sodium dihydrobis(2-methoxyethoxy)aluminate leads to a 30% yield of a mixture of alcohols containing 70% of the required dodeca-7,9-dienol. This method is unsuitable for the synthesis of *trans,cis*-dodeca-7,9-dienyl acetate in any kind of large amount. The synthesis using a disubstituted acetylene proved promising for this purpose.[135] The condensation of the *trans*-conjugated enyne (LXXVII) with 3-(1-ethoxy)-ethoxypropyl-lithium and subsequent reduction lead to the

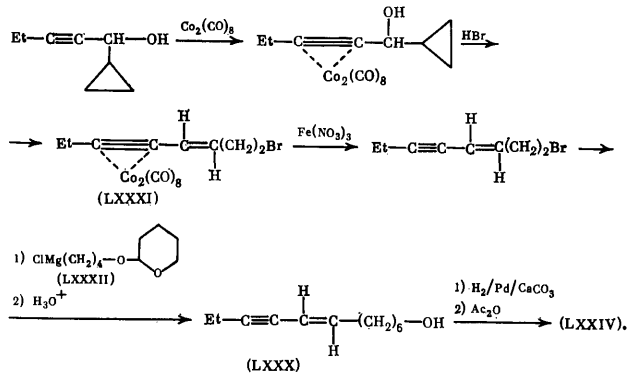
alcohol (LXXVIII) (purity 99%):[135]



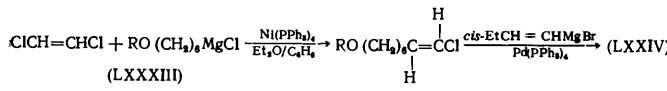
*trans,cis*-Hepta-2,4-dienol, which is a suitable intermediate for the synthesis of conjugated dienes, was obtained in accordance with the scheme:[137]

The *cis,cis*-isomer present (7%) is bound in a complex with tetracyanoethylene.

Another key intermediate for the synthesis of the *cis,trans*-conjugated system, namely *trans,dodec*-7-en-9-ynol (LXXX), was obtained in 20% yield by the hydroboration of octynyl acetate (LXXIX) followed by treatment with butynyl-lithium:[138,139]

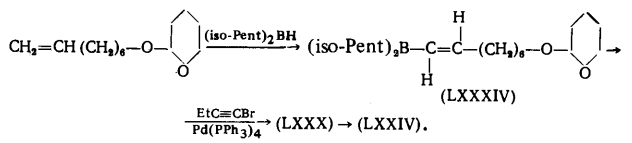


A modified method for the conversion of a *trans*-enyne into a *trans,cis*-diene, involving the selective reduction of the triple bond with zinc dust in aqueous propanol to a double bond with the *cis*-configuration, made it possible to obtain *trans,cis*-dodeca-7,9-dienyl acetate.[139,140]

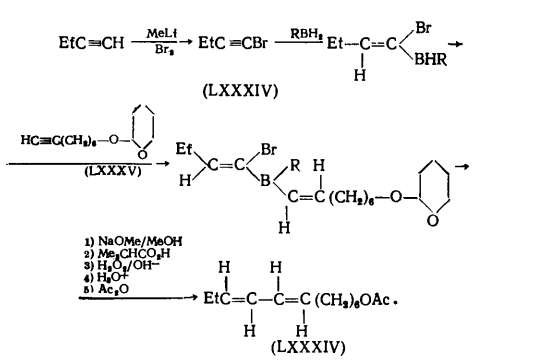


The triple bond of tetrahydropyranyloxy-*cis*-dodec-9-en-7-yne is reduced with diisopentylaluminium hydride.[141] However, owing to steric hindrance, *cis*-enynes react very slowly and after hydrolysis a mixture of the *cis*- and *trans*-isomers is obtained. Apparently the hydroalumination of the triple bond initially leads to the preferential formation of *trans*-vinylaluminium hydride, but, with increase of the duration of the reaction, the latter isomerises to the *cis*-isomer.

It was found that, when the ring of 1-cyclopropylpent-2-yn-1-ol is opened by hydrobromic acid, *cis*-1-bromooct-3-en-5-yne is formed as the main product (the *cis* : *trans* isomer ratio is 67 : 33).[142]

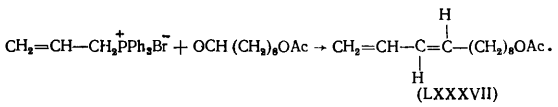


With increase of steric hindrance (as a result of the blocking of the triple bond by dicobalt octacarbonyl), the opening of the cyclopropane ring leads to the homoallyl bromide (LXXXI) with a purity of 99%.[143] When the bromide (I) reacts with the Grignard reagents (LXXXII) in the presence of copper(I), the *trans*-enyne (LXXX) is obtained in 80% yield (purity 96%). After the reduction of the triple bond over the Lindlar catalyst,[144] the yield of the dienol is 60% and the latter consists of 92% of the 7-*trans*,9-*cis*-isomer and 8% of the 7-*trans*,9-*trans*-isomer:



A new stereoselective synthesis of the pheromone (LXXIV) in 72% yield, based on the cross-coupling of *trans*-1,2-dichloroethylene with the Grignard reagent (LXXXIII) in the presence of tetrakis(triphenylphorphine)nickel, has been described recently. The reaction is accompanied by the almost complete (more than 99%) retention of the configuration at the double bond:[145]

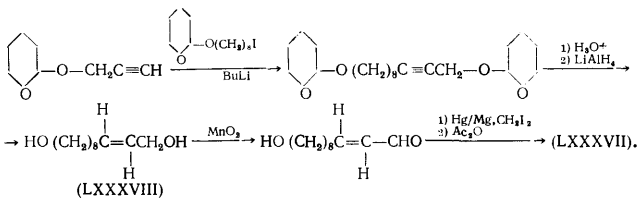
The cross-coupling reaction of diisopentyl-*trans*-8-(2-tetrahydropyranoloxy)-en-1-octylborane (LXXXIV) with 1-bromobutyne in the presence of a palladium catalyst proceeds stereoselectively. Further acylation and hydroboration of the conjugated *trans*-enyne (LXXX) made it possible to obtain the alcohol (LXXIV) in 22% yield:[146]



The stereoselective synthesis of conjugated *trans,trans*-systems was carried out by the hydroboration of the acetylenic derivatives (LXXXIV) and (LXXXV).[147] The purity of the *trans,trans*-7,9-diene (LXXXVI) is more than 99%:

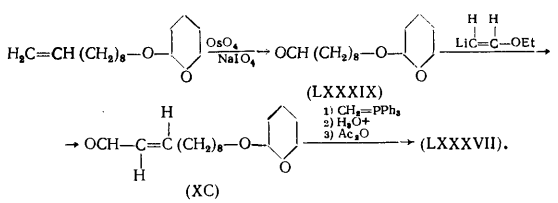
*trans*-Dodeca-9,11-dienyl acetate (LXXXVII) is the main component of the pheromone of *Disparopsis castanea*—a pest on the cottonplant. This pheromone is a multicomponent

system containing a 1 : 4 mixture of the *cis*- and *trans*-dodeca-9,11-dienyl acetates, *trans*-dodec-9-enyl acetate, dodec-11-enyl acetate, and 1-dodecyl acetate.[148] The diene is the most active, but addition of the inactive dodec-11-enyl acetate to the diene (LXXXVII) (1 : 4) caused a sharp increase in the attracting effect. Each of these compounds separately inhibits the attraction by males, while dodec-9-enyl acetate influence the orientation of females. The role of 1-dodecyl acetate has not so far been elucidated.[148]



The Wittig reaction of triphenylphosphonium 2-propenylide with 9-oxononyl acetate in the presence of lithium bromide leads to 70% of a diene containing the *cis*- and *trans*-isomers of compound (LXXXVII) in proportions of 3 : 2:[148,149]

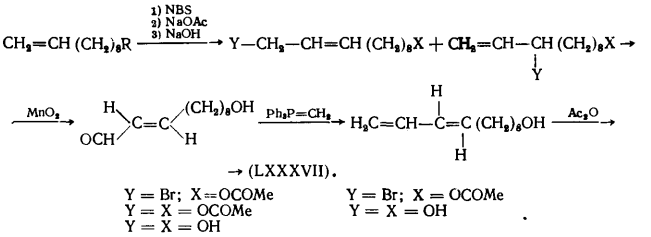
(LXXXVII)



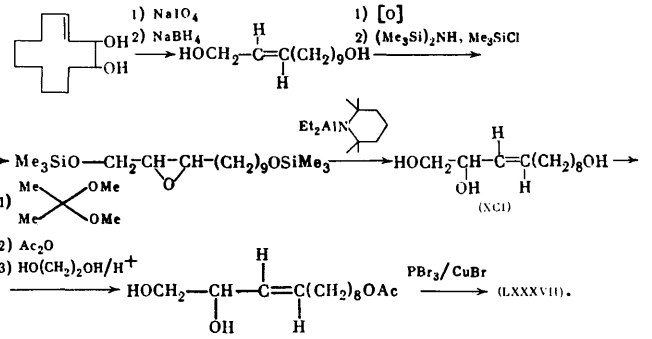
By varying the polarity of the solvent in the Wittig reaction, it is possible to achieve a 4 : 1 ratio of the *cis*- and *trans*-isomers, but a greater stereoselectivity cannot be achieved. The separation of the isomers is extremely difficult. However, by treating the products of the Wittig reaction with liquid sulphur dioxide and subsequent chromatography on Florisil, the product of the 1,4-cycloaddition of $SO_2$ was obtained. Its thermolysis takes place stereospecifically with formation of the diene (LXXXVII) whose stereochemical purity is in excess of 99%. The *cis*-isomer has been isolated in a satisfactory yield on treating the products of the Wittig reaction with tetracyanoethylene.[149,150]

Another stereospecific synthesis of the pheromone (LXXXVII) has been achieved, in which the starting compound was tetrahydropyranoloxypropyne. The key compound, the *trans*-olefin (LXXXVIII), was obtained by reducing the triple bond in a disubstituted acetylene with lithium tetrahydroaluminate:[151]

(LXXXVIII)



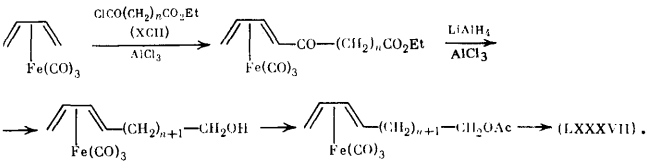
Oxidation of dec-9-enol with a mixture of osmium tetroxide and sodium metaperiodate leads to the aldehyde (LXXXIX), which is converted into the αβ-unsaturated aldehyde (XC) after condensation with β-ethoxyvinyl-lithium and subsequent rearrangement of the intermediate γ-ethoxyvinylmethanol. The aldehyde reacts with methylenetriphenylphosphorane to form the pheromone (LXXXVII)in 65% yield:[152,153]



(LXXXIX)

(XC)

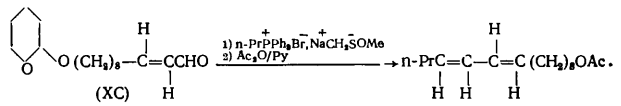
The *cis*–*trans* isomerisation of αβ-unsaturated aldehydes[154] makes it possible to obtain *trans*-11-hydroxyundec-2-enal[155] with a *cis* : *trans* ratio of 85 : 15; the acetate (LXXXVII) was synthesised from it by the Wittig reaction (purity 97%):



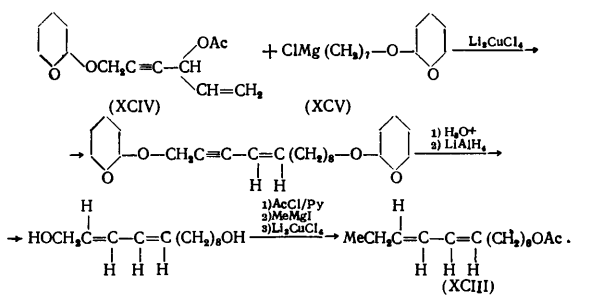
The regio- and stereo-specific opening of the oxiran ring by treatment with *N*-diethylalumino-2,2,6,6-tetramethylpiperidine has been used to convert the allyl alcohol (XCI) into the acetate (LXXXVII):[156]

The pheromone (LXXXVII) has also been synthesised by the stereospecific cross-coupling of *trans*-10-(2-tetrahydropyranyloxy)-1-decylborane and vinyl bromide in the presence of the palladium catalyst $Pd(PPh_3)_4$ in 54% yield.[146]

A novel method involving the use of the iron tricarbonyl protecting group, has been used to synthesise the pheromone (LXXXVII) with a high stereochemical purity (more than 99%). Butadieneiron tricarbonyl interacts with the acid chloride (XCII) under the conditions of the Friedel–Crafts reaction and subsequent reduction, acylation, and removal of the protecting group leads to compound (LXXXVII):[156]

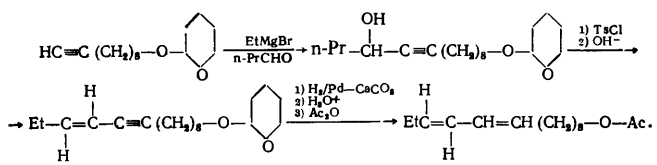


*cis*,*trans*-Tetradeca-9,11-dienyl acetate (XCIII) is the sex pheromone of the cotton pest *Spodoptera littoralis*.[148] The butterfly produces four compounds: tetradec-1-enyl acetate, *cis*,*trans*-tetradeca-9,11-dienyl acetate, *cis*-tetradec-9-enyl acetate, and *trans*-tetradec-11-enyl acetate.[10] Only the dienyl acetate has an attracting effect.[157] Tetradec-9-enyl acetate exhibits an inhibiting influence and the role of the other components has not been elucidated. Admixtures of the *cis*,*cis*- and *trans*,*cis*-isomers diminish the attracting effect.[157]



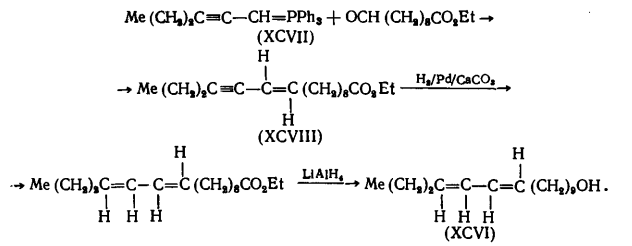
The same diene, namely *cis*,*trans*-tetradeca-9,11-dienyl acetate, forms part of the composition of the pheromone of *Spodoptera litura* in combination with *cis*,*trans*-tetradeca-9,12-dienyl acetate.[158] There are data showing that the mixture in proportions of 20 : 1 is active for *Spodoptera littoralis*.[148,157] There exist also directly opposed data

indicating that the 9-*cis*,12-*trans*-isomer inhibits the activity of the *cis*,*trans*-9,11-diene when present in proportions of 1 : 20 or 1 : 50.[159]

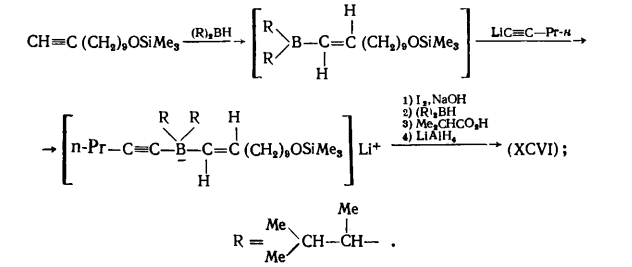


Compound (XCIII) has been synthesised from *trans*-pent-2-enyltriphenyl phosphonium bromide and 9-oxononyl acetate via the Wittig reaction, but the reaction is non-stereospecific.[148] It was later established that the ratio of the isomers in this reaction depends on solvent polarity: it is 40 : 60 in benzene, being reversed to 60 : 40 in DMSO.[160] The Wittig reaction of *trans*-pent-2-enal and 9-tetrahydropyranyloxynonylide in DMSO with subsequent acid hydrolysis and acetylation leads to a mixture of the 9-*cis*,11-*trans*- and 9-*trans*,11-*trans*-isomers in proportions of 80 : 20.[161] The interaction of *trans*-undec-2-enal with propylidenetriphenylphosphorane in THF in the presence of dimsylsodium and subsequent hydrolysis and acetylation make it possible to obtain the 9-*trans*,11-*cis*-isomer of the pheromone (XCIII) with a purity of 98%:[162]

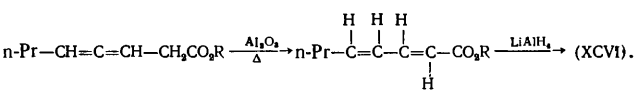
The regioselective reaction of the substituted enyne (XCIV) with the Grignard reagent (XCV) in the presence of dilithium tetrachlorcuprate and subsequent partial diacetylation make it possible to obtain compound (XCIII) in a fairly high yield:[163]



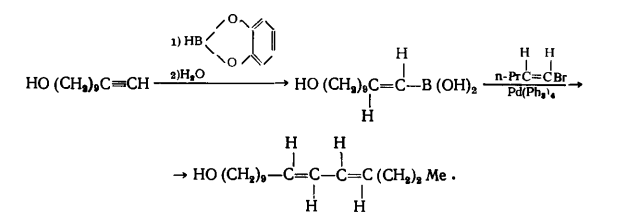
Another method, illustrated below, has also been used to synthesise compound (XCIII),[158,159] a mixture of the 9-*cis*,11-*trans*- and 9-*cis*,11-*cis*-isomers being obtained:



The attractant of the silkworm *Bombyx mori*, namely *trans*,*cis*-hexadeca-10,12-dienol (bombykol) (XCVI) was discovered by Butenand et al. in 1959.[164] It was assumed that this is the only pheromone of the butterfly, but subsequently data were obtained showing that there exist a further two components: hexadeca-10,12-dienal ("bombykal") and *trans*,*trans*-hexadeca-10,12-dienol.[165]



The pheromone (XCVI) has been obtained by the Wittig reaction involving the condensation of hex-2-ynylide (XCVII) with ethyl 10-oxodecenoate. The enyne product (XCVII) contained the *trans*- and *cis*-isomers in approximately equal amounts. The conjugated enyne (XCVIII) was hydrogenated over the Lindlar catalyst and the ester group was reduced with lithium tetrahydroaluminate to the alcoholic group:[164]



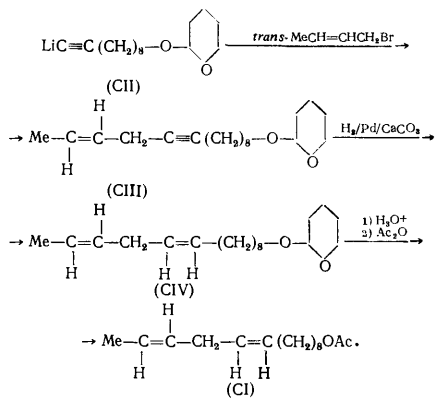
A method of synthesis in which the lithium salt of the pentyne was condensed with 1,2-epoxy-11-tetrahydropyranyloxyundecane to form an alcohol, the latter was converted into a toluene-*p*-sulphonate, and the conjugated enyne was obtained in the form of a mixture of the *trans*- and *cis*-isomers after splitting off the toluenesulphonic acid has also been used. The mixture was separated with the aid of a complex with urea and the *trans*-isomer was hydrogenated over the Lindlar catalyst. As already mentioned above, the process is relatively non-stereospecific and the yield of the desired product is low.[5] The hydroboration of the conjugated enyne system proceeds more stereospecifically. The scheme quoted below demonstrates the application of hydroboration to the synthesis of bombykol:[139]

Bombykol has also been obtained with the aid of cuprates[167] and a stereocontrolled rearrangement of a β-allene ester in the presence of alumina:[168]

The reaction of alkenylboronic acid (XCIX) and a suitable alkenyl halide, catalysed by a palladium complex in the presence of a base, leads to *trans*,*trans*-dodeca-10,12-dien-1-ol in a high yield (66–91%) and a purity of 99%:[169]

*trans*,*trans*-Hexadeca-10,12-dienal (C), the main component of the sex pheromone of *Earias insulana*, has been obtained by a four-stage synthesis, in which the key stage is the Wittig reaction, leading to a mixture of the *trans*,*trans*- and

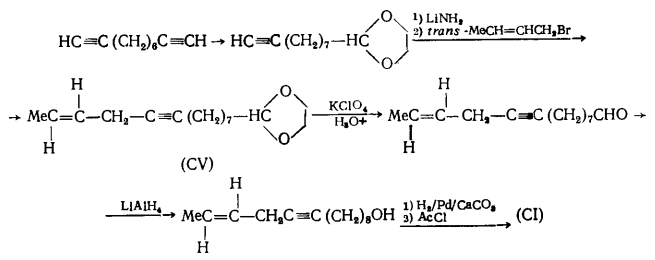
*cis,trans*-isomers of compound (C) in proportions of 1 : 4:[170]



(C)

## V. NON-CONJUGATED DIENE ALCOHOLS AND ACETATES

Non-conjugated dienes have been identified in a large number of insects of the order Lepidoptera.[5] Thus, *cis,trans*-tetradeca-9,12-dienyl acetate (CI) proved to be the pheromone of *Plodia interpunctella* and *Cadra cautella*.[171, 172] In a mixture with *cis*-tetradec-9-enyl acetate, this diene proved to be the pheromone of *Spodoptera eridania*.[173] The same compound has been identified in *Anagasta kühniella*,[174] *Ephestia elutella*,[175] *Cadra figulitella*,[176] and *Spodoptera litura*.[177] The *cis,cis*-, *trans,cis*-, and *trans,trans*-isomers of the pheromone (CI) are inhibitors. *cis,trans*-Tetradeca-9,12-dienol is an inhibitor of the pheromone of *Plodia interpunctella*.[178] Data have been published showing that *cis,trans*-tetradeca-9,12-dienyl acetate and *cis*-tetradec-9-enyl acetate are inactive in relation to *Spodoptera exigua* either individual or when combined.[179]

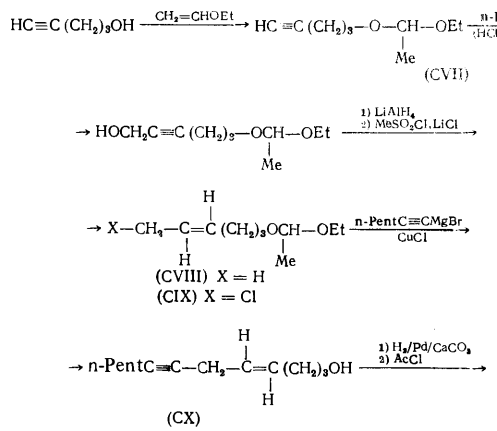


The *cis*,trans-1,4-diene system has been obtained in accordance with the scheme

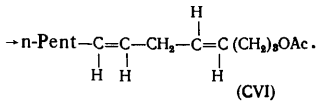
(CII) (CIII) (CIV) (CI)

The interaction of the lithium salts of the acetylene (CII) with *trans*-1-bromobut-2-ene in dioxan leads to the enyne (CIII), whose partial reduction affords an 86% yield of the diene (CIV). The acetylation of the diene gives rise to the pheromone (CI). All the other isomers of tetradeca-9,12-dienyl acetate have been obtained in accordance with the same scheme.[174,180]

An analogous method is based on the use of deca-1,9-diyne and crotyl alcohol:[181]



(CV)



The enyne alcohol (CV) has been obtained in 29% yield by the reaction of the Grignard reagent derived from *trans*-1-bromobut-2-ene with the lithium salt of an ω-substituted non-1-yne in THF in the presence of CuCl and CuCN. The formation of the 1,4-enyne (CV) by the reaction of 1-alkynyllithium and *trans*-1-bromobut-2-ene in dioxan is none other than the reaction of a strong base with an allyl halide, which always leads to a complex mixture of products. The products of the allylic rearrangement and isomerisation (a conjugated enyne) are accompanied by the products of the deprotonation of the 1,4-enyne and of further alkylation.[182,183] It has been found that the reaction of 1-alkynylsodium with allyl halide in ammonia leads to mono-, di-, and tri-alkylated compounds.[183] For example, propynylsodium reacts with one equivalent of 1-chlorobut-2-ene in liquid ammonia to give a mixture of products: 40% of the monoalkyl derivative and 55% of the dialkyl derivative. 1,4-Enynes can be obtained by the reaction of alkylmagnesium halide with allyl halide in ether[184] or THF in the presence of CuCl as the catalyst.[182,185] In the absence of a copper (I) salt, the reaction proceeds very unsatisfactorily or not at all.[186] A version of this method, which involves the interaction of allyl halide and a terminal acetylene on treatment with an amine and catalytic amounts of a copper salt (the Cadiot-Chodkiewicz method), is not very convenient for the synthesis of 1,4-enynes, because the normal alkylation product and the isomeric products of the allyl rearrangement are obtained in equal amounts. In dipolar aprotic solvents the reaction proceeds with the allyl rearrangement. Thus, the reaction of heptynylcopper with 1-bromobut-2-ene in HMP leads to a mixture of undec-9-en-6-yne and the rearrangement product (8-methyldec-9-en-6-yne) in proportions of 3 : 1 and 76% yield.[187] The enynes are formed in the same proportions in the reactions of the *cis*- and *trans*-isomers of 1-chlorobut-2-ene with copper phenylacetylide. In an attempt to reduce to a minimum the product of the allyl rearrangement, the reaction has been carried out in the presence of CuCl, whereupon 9% of the allyl product is formed in THF.[184] In THF in the presence of CuCN, *trans*-1-chlorobut-2-ene yields 15% of the allyl product, while in the presence of $LiCuCl_2$ it amounted to only 4.4%.[185]

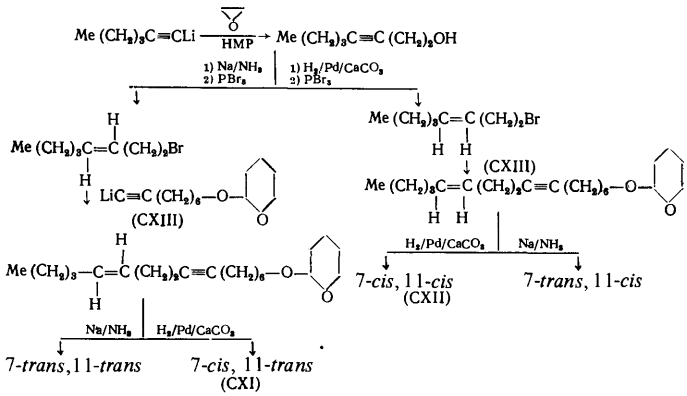
A mixture of 95% of *cis,trans*-tetradeca-9,12-dienyl acetate and 5% of the *trans,trans*-isomer has been obtained by the Wittig reaction from triphenylphosphonia-*trans*-pent-3-enylide and 9-acetoxy-1-nonanal in HMP[186] or in DMSO.[187] The 1,4-diene is oxidised in air at room temperature[185] and irradiation with ultraviolet light leads to a mixture of *cis,trans*-13-hydroperoxytetradeca-9,11-dienyl acetate and *trans,trans*-9-hydroperoxytetradeca-10,12-dienyl acetate.[188] In order to stabilise the pheromone, an antioxidant is added, namely *N*-octyl-*N'*-phenyl-1,4-phenylenediamine.[195]

*trans,cis*-Trideca-4,7-dienyl acetate (CVI) is the pheromone of *Phthorimaoea operculella*.[188] A second active component of the pheromone of this species has been identified—*trans*,-*cis,cis*-trideca-4,7,10-trienyl acetate.[189] The acetate (CVI) has been obtained in accordance with the scheme

(CVII) (CVIII) X = H (CIX) X = Cl (CX)

(CVI)

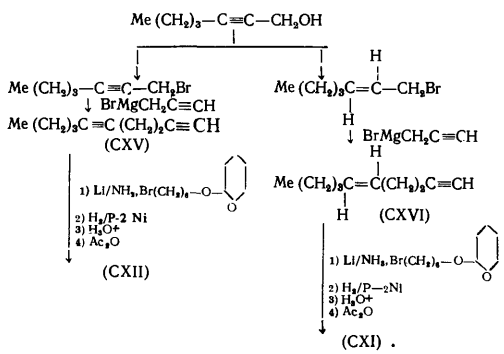
Pent-4-yn-1-ol is converted by the reaction with ethyl vinyl ether into the mixed acetal (CVII), which gives rise to the alcohol (CVIII) after treatment with n-butyl-lithium, reaction with paraformaldehyde, and reduction. The alcohol was converted into the chloride (CIX) by treatment with methanesulphonyl chloride in the presence of lithium chloride and collidine.[190] The allylic rearrangement is virtually ruled out under these conditions and the acid-sensitive acetal protecting group is unaffected. The reaction of allyl chloride (CIX) with 1-heptynylmagnesium bromide was carried out in the presence of catalytic amounts of copper monochloride. Hydrolysis with trichloroacetic acid in aqueous THF and low-temperature crystallisation of the product lead to a derivative of the enyne alcohol (CX) (purity 98.8%) in 60% yield. The corresponding *trans,cis*-4,7-diene was obtained in 98% yield on hydrogenation of the triple bond over the Lindlar catalyst in a hexane–THF mixture.[188]



The inactive 4-*trans*,7-*trans*-isomer with an admixture of a mono-olefin (9%) was obtained by reducing the 1,4-enyne (CX) with lithium in liquid ammonia in the presence of ethanol. In the synthesis of *trans,trans*-1,4-dienoic acids it was shown that the reduction with lithium in ammonia without the addition of alcohol leads only to a mixture of *trans*-monoenoic acids.[191] For example, the 6,9-dienoic acid affords under these conditions a mixture of *trans*-6- (15%), *trans*-7- (36%), *trans*-8- (33%), and *trans*-9-monoenoic acids (16%).[191] Consequently such reduction of 1,4-dienes is accompanied by the base-catalysed formation of compounds with conjugated double bonds, which are then reduced to the monoene compounds. When 1,4-enynes were treated with alkali metal amides in ammonia, a rapid rearrangement of the *trans*-isomers to the *cis*-1,3-enynes was noted.[192] Octadeca-9,12-diynoic acid has been successfully reduced to *trans,trans*-octa-9,12-dienoic acid with sodium in a mixture of ammonia and diethyl ether in an autoclave.[185]

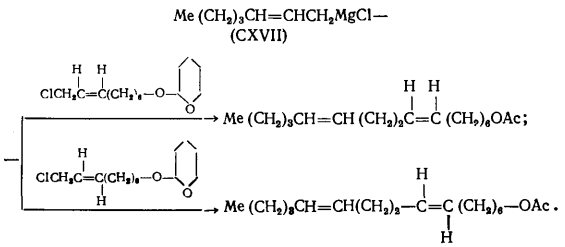
The reduction of 1,4-enynes with sodium in an ammonia–THF mixture in the presence of t-butyl alcohol is more stereospecific than in the presence of ethanol.[193] The 1,4-dienes were stabilised by adding 0.1% of 2,6-di-t-butyl-4-methylphenol.

Synthetic *trans,cis,trans*- and *trans,cis,cis*-trideca-4,7,11-trienyl acetates are not active components of the pheromone of *Phthorimaea operculella* but they do give rise to a positive response on the electroantennogram.[1]



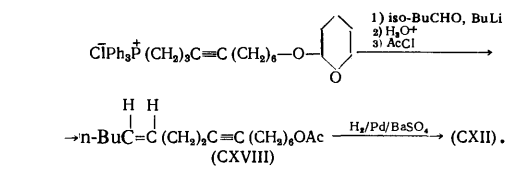
*trans*-10-n-Propyltrideca-5,9-dienyl acetate (propylure) was initially identified as the pheromone of the pink bollworm *Pectinophora gossypiella*, which is a pest on the cotton-plant.[193,194] Synthetic propylure exhibited a very weak biological activity. However, it was later found that the pheromone consists of "gossyplure"—a 1 : 1 mixture of *cis,trans*- and *cis,cis*-hexadeca-7,11-dienyl acetates.[112,193–196] The individual geometrical isomers are inactive.[195]

Synthetic *cis*-hexadec-7-enyl acetate (hexalure) proved to be an attractant of the butterfly *Pectinophora gossypiella*.[197] *cis,trans*-Hexadeca-7,11-dienyl acetate (CXI) has been identified as the pheromone of *Sitotroga cerealella*.[198] The acetate (CXI) and its 7-*cis*,11-*cis*-isomer (CXII) were obtained in a pure form via acetylenic intermediates[197–200] using an acetylenic Grignard reagent[195,201] or with the aid of the Wittig reaction.[200,202] In many studies the mixture was prepared artificially for the purpose of screening, while in others the required 1 : 1 mixture was obtained immediately by the Wittig synthesis.[115] All four possible geometrical isomers were obtained using oct-3-yn-1-ol and the lithium salt of 2-(7-octynyloxy)tetrahydropyran (CXIII):[203]



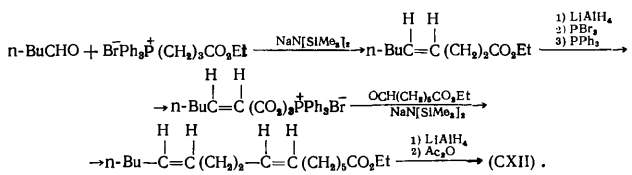
The homoallyl *cis*- and *trans*-oct-3-enyl bromides have been obtained from the corresponding alcohols by treatment with triphenylphosphine dibromide in dioxan (yield 85%) or with $PBr_3$ in a mixture of ether and pyridine (yield 56%). The condensation products were obtained by the reaction of these bromides with the lithio-derivative (CXIII) in dioxan (yield 25%)[198] or in diglyme (yield 66%).[204] The *trans*-configuration of the double bond was achieved by reduction with sodium in ammonia and the *cis*-configuration by hydrogenation over a modified Lindlar catalyst.[198]

The diyne (CXV) (79%) and the enyne (CXVI) (63%) have been obtained respectively by the interaction of propargylmagnesium bromide (CXIV) with 1-bromohept-2-yne and *trans*-1-bromohept-2-ene:[205]

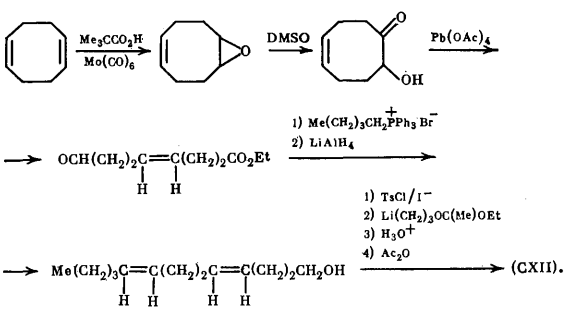


The products of the alkylation of their lithium salts by tetrahydropyranyloxyoctyl bromide were obtained in 62% yield for the diyne (CXV) and 87% for the enyne (CXVI). Acid hydrolysis and partial hydrogenation leads to the pheromone components.[206] Deca-1,5-diyne (CXV) was obtained in 40% yield by the monoalkylation of the monolithium salt of hexa-1,5-diyne with 1-bromobutane in a mixture of HMP and THF.[195] The interaction of the Grignard reagent (CXVII) with *cis*(or *trans*)-allyl chloride in THF leads to a mixture of products with straight and branched chains,[201] the straight-chain product being formed in 20% yield from *cis*-allyl chloride

in the form of a mixture of the 7-*cis*,11-*cis*, and 7-*cis*,11-*trans*-isomers in proportions of 43 : 57:



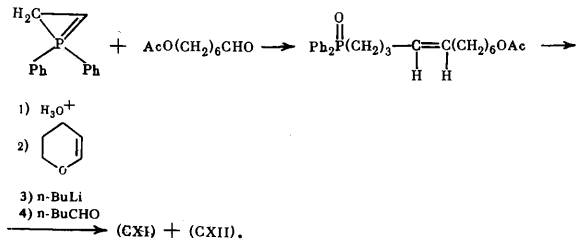
The yield of the branched-chain product diminishes to 50% when the reaction is carried out in a mixture of THF and HMP; the *cis*-11-isomer with a stereochemical purity of 94% is then obtained. Condensation of pentanal with the Wittig reagent derived from 11-tetrahydropyranyloxyundec-4-ynyl chloride leads to the enyne (CXVIII) consisting of 96% of the *cis*-isomer and 4% of the *trans*-isomer: [200]



Partial hydrogenation results in the formation of the *cis*,*cis*-isomer (CXII). *trans*,*trans*- and *trans*,*cis*-Hexadeca-7,11-dienyl acetates have been obtained by the isomerisation of bisepoxides on treatment with lithium diphenylphosphide. [207]

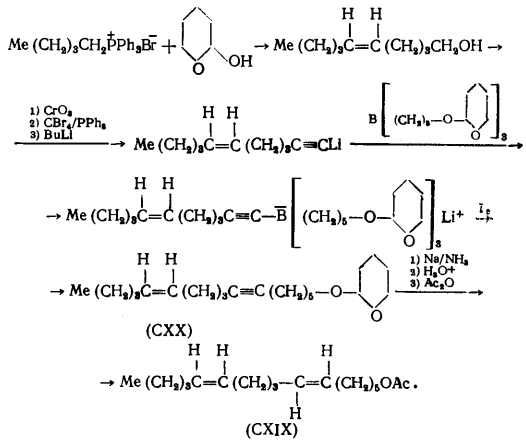
The reduction of the 1,5-enyne system with sodium in liquid ammonia, which leads to the *trans*,*trans*- and *trans*,*cis*-7,11-dienes, always affords a mixture of isomers containing 72% of the *trans*,*trans*-dienes, 18% of other dienes, and 5% of cyclic products. [200]

The Wittig reaction where sodium bis(trimethylsilyl)amide in THF is used as the base is highly *cis*-stereospecific (up to 98%): [202]



The dependence of the stereospecificity of this reaction on temperature has been observed. Thus at −78 °C the ratio of the *cis*- and *trans*-isomers in the olefinic product is 98 : 2, while at 20 °C it is 94 : 6. The components of gossyplure have been obtained also from *cis*,*cis*-cyclo-octa-1,5-diene. [115] The asymetric rupture of one of the double bonds leads to an intermediate containing not only the necessary functional groups but also a *cis*-double bond:

Next the Wittig reaction with the olefin was carried out and a study was made of the influence of various factors on the stereochemistry of this reaction. [5] It is known that an aliphatic ylide reacts with an aliphatic aldehyde to give mainly *erythro*-intermediates, which are converted into a *cis*-olefin after splitting off triphenylphosphine oxide.



Olefinic phosphine oxides obtained from cyclic phosphonium ylides are of great interest for the synthesis of the components of gossyplure—hexadeca-7,11-dienyl acetates: [209]

When the Wittig reaction was carried out in dipolar aprotic solvents (DMF, DMSO, HMP) both in the presence and absence of a lithium salt, identical results were obtained. In non-polar solvents the stereochemistry of the olefinic products depends on the nature of the inorganic salts. [1,5,209] *trans*,*cis*- and *cis*,*cis*-Octadeca-3,13-dienyl acetates are the pheromones of *Synanthedon pictipes* and *Synanthedon exitiosa*. [210–212] All four isomers of octadeca-3,13-dienyl acetate were obtained via acetylenic intermediates. [213]

*trans*,*cis*-Hexadeca-6,11-dienyl acetate (CXIX) is the pheromone of the oak silkworm *Anthreraea polyphemus* in a 9 : 1 mixture with the corresponding aldehyde. The acetate (CXIX) has been obtained in accordance with an analogous scheme via acetylenic intermediates. [214,215]

Both components of the pheromone of *Antheraea polyphemus* were also synthesised from the enzyme compound (CXX) using the Wittig reaction to generate the *cis*-11-double bond; the *trans*-6-olefin was synthesised by reduction with sodium in liquid ammonia:

The isomeric purity of the resulting *trans*,*cis*-hexadeca-6,11-dienyl acetate and the corresponding aldehyde is in excess of 97%. [216,217]

# The Role of Molecular Complexes in the Preparation of Highly Pure Materials

G.G.Devyatykh, P.G.Sennikov, and S.V.Yan'kov

Various aspects of the influence of molecular complexes on the efficiency of two-phase methods for purifying substances have been examined (for the case of the volatile inorganic hydrides of the elements of groups IIIa–VIIa). Data published in the last 10 years on the experimental and theoretical study of intermolecular interactions in these systems have been discussed. Chemical methods for purifying hydrides, including the formation of stable molecular complexes, have been examined briefly. The bibliography contains 172 references.

## I. INTRODUCTION

Highly pure substances contain individual impurities at the level of $10^{-4}$–$10^{-8}$% and below, and a total concentration of impurities of $10^{-3}$–$10^{-4}$%.[1]

Methods for preparing highly pure materials are based on differences between the properties of the impurity and the substance being purified, which in turn are generally revealed as differences in the interactions between the particles (atoms, molecules, ions) of the impurities and the main material.[2] The forces of interparticle interaction can be classified as long-range (van der Waals) and short-range (chemical or specific).[3] Methods of purification, in turn, can be classified as physicochemical or chemical, according to the type of interactions responsible for the separation effect. Both types of purification method are being intensively developed, and have been the subject of a number of books and reviews (see Refs.2 and 4 and references therein, and also Refs.5–7).

An important case of interactions occupying an intermediate position between van der Waals and chemical interactions is the formation of molecular complexes.[8] This term covers electron donor–acceptor (EDA) complexes or charge-transfer complexes (CTC), and also complexes with hydrogen bonding (H-complexes).

The formation of molecular complexes, taking place against a background of non-specific van der Waals interactions, influences the efficiency of purification processes; previously, however, there was practically no discussion of this question in the literature. The aim of the present review is to examine various aspects of extensive purification processes, associated with the formation of molecular complexes. The examination will be restricted to only a few classes of substance and purification methods. The discussion will deal chiefly with the two-phase methods of fractional distillation and, to a lesser extent, crystallisation, the theory of which in systems with non-specific interactions is most fully developed at the present time.[5,7] Molecular complexes of different stability play an important role in methods of purification by extraction. Since however these methods are relatively unsuitable for preparing highly pure materials, and since there are no rigorous theories to describe two-phase equilibria in extraction systems,[9,10] this group of methods is not examined in the present review.

The materials chosen to examine the influence of the formation of molecular complexes on the efficiency of extensive purification are the volatile inorganic hydrides of the elements of groups IIIa–VIIa. This choice was made for the following reasons. Volatile inorganic hydrides are fairly widely used to obtain highly pure elements and structures based on them.[11,12] In spite of the considerable progress made in their purification,[1,12] however, the removal of some impurities (for example water) still represents a difficult problem. There are indications that in a number of such cases, hydride–impurity molecular complexes may be formed, leading to a decrease in the efficiency of purification. Finally, the weak specific and more particularly non-specific intermolecular interactions (IMI) in systems based on the hydrides examined, although insufficiently studied, have nevertheless been more fully studied at the present time than other classes of substance obtainable in a highly pure state. The review covers data on non-specific and weak specific interactions in volatile inorganic hydrides, obtained by various experimental methods and also by quantum-chemical calculations and semi-empirical estimates.

In spite of these restrictions, the procedure used to analyse the role of molecular complexes is general in character, and can be used to examine other purification methods and other systems.

## II. BASIC IDEAS FROM THE THEORY OF MOLECULAR COMPLEXES

A large number of papers have been devoted to various aspects of the theory and practical utilisation of molecular complexes of both types (EDA and H-complexes). It is sufficient to mention the most important monographs and reviews published chiefly in the last 10 years in the Soviet Union and other countries.[13–20]

The theory of molecular complexes (usually referred to in the literature as the theory of donor–acceptor interaction) was developed by Mulliken in the early fifties and applied to systems consisting of molecules, one of which has a low ionisation potential (the electron donor D) while the other has a high electron affinity (the electron acceptor A). The nature of the interacting orbitals of the donor and acceptor molecules formed the basis for the generally accepted classification of molecular complexes.[20]

Donor–acceptor interactions in the sense of Mulliken's classical theory are closely related to the problem of the hydrogen bond. In H-complexes, the hydrogen atom acts as a bridge joining atoms X and Y, which generally have a high electronegativity: X–H...Y. In the case of organic molecules, the fragment Y may be a π-electron system.

Intermolecular interactions in molecular complexes of both types can be classified as weak ($\Delta E$ = 0.1–1 kcal mole$^{-1}$, $R_{DA(HY)}$ = 0.30–0.35 nm) medium ($\Delta E$ = 5–15 kcal mole$^{-1}$, $R_{DA(HY)}$ = 0.27–0.30 nm), and strong ($\Delta E$ = 20–60 kcal mole$^{-1}$, $R_{DA(HY)}$ = 0.22–0.25 nm).[3,21] Thus the energies of formation of molecular complexes at one extreme are close to those of van der Waals systems ($\Delta E = 10^{-2}$–$10^{-1}$ kcal mole$^{-1}$,

**Table 1.** The impurity composition of volatile inorganic hydrides (mass %).[12]

| Hydride | Impurity | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|
| | $B_2H_6$ | $SiH_4$ | $GeH_4$ | $NH_3$ | $PH_3$ | $AsH_3$ | $SbH_3$ | $H_2S$ | $H_2Se$ | HCl |

*The concentration of water in unpurified HF reaches 8.4 mass %.

$R$ = 0.30–0.40 nm), and at the other extreme are close to those of chemically combined molecules ($\Delta E$ = 80–100 kcal mole$^{-1}$, $R$ = 0.10 nm).

Table 1 gives a number of typical impurities in unpurified volatile inorganic hydrides of elements of groups IIIa–VIIa.[12] In spite of the fact that the impurity composition of the hydrides depends to a large extent on the method of synthesis, it is possible to distinguish two groups of impurity in these compounds: inorganic impurities, including the hydrides of analogue elements, higher hydrides, and various gases (CO, $N_2$), and organic impurities, including saturated, unsaturated, and aromatic hydrocarbons, and also hydrocarbons containing heteroatoms with a lone pair of electrons. All this is responsible for the complex character of the IMI in the hydrides being considered. For highly pure hydrides containing most impurities at the level of $10^{-5}$–$10^{-7}$ mass %, it is mainly the weak specific interactions of the hydride–hydride and hydride–impurity type that are important. In starting materials containing from 0.5–1.0 mass % to $10^{-5}$ mass % impurities (Table 1), impurity–impurity molecular complexes are probably also formed.

As noted above (section I), the weak specific interactions leading to the formation of molecular complexes are present against a background of non-specific van der Waals interactions. It is therefore appropriate to discuss in more detail the contributions made to the energy of the interaction of a pair of molecules of a volatile inorganic hydride by specific and non-specific interactions.

The van der Waals interactions in volatile inorganic hydrides are usually characterised quantitatively using the familiar Lennard-Jones potential. Since the model is approximate, the numerical values of the parameters of the potential $\varepsilon$ and $\sigma$ depend on the set of properties from which they are determined.[3] Since the purification processes examined below are based on phase equilibria, it is appropriate to use the values of $\varepsilon$ and $\sigma$ calculated from the vapour pressure and the density of the liquid on the liquid–vapour equilibrium line.[5] The relationships required for this were obtained in Ref.22; Table 2 gives the values of $\varepsilon$ and $\sigma$ obtained in the work cited for volatile inorganic hydrides. The values of $\varepsilon$ for different substances lie mainly in the range 400–800 kcal mole$^{-1}$, and the values of $\sigma$ in the range 0.30–0.45 nm. The values given are the effective values, including the contribution from weak specific interactions when these are present. Specific interactions have comparatively little influence on the magnitude of $\sigma$, but have a considerable influence on the value of the parameter $\varepsilon$, characterising the depth of the potential well.

**Table 2.** The parameters of the Lennard-Jones potential for the volatile inorganic hydrides of the elements of groups IIIa–VIIa.[22]

| Substance | $\epsilon$, cal mole$^{-1}$/$\sigma$, nm | Substance | $\epsilon$, cal mole$^{-1}$/$\sigma$, nm |
|---|---|---|---|
| $CH_4$ | 296/0.374 | $NH_3$ | 723/0.330 |
| $SiH_4$ | 443/0.398 | $PH_3$ | 517/0.399 |
| $GeH_4$ | 503/0.426 | $AsH_3$ | 584/0.407 |
| $SnH_4$ | 604/0.444 | $SbH_3$ | 719/0.427 |
| $H_2O$ | 882/0.305 | HF | 918/0.312 |
| $H_2S$ | 614/0.372 | HCl | 471/0.352 |
| $H_2Se$ | 666/0.388 | HBr | 588/0.375 |
| $H_2Te$ | 767/0.426 | HI | 674/0.401 |

General information on the structure and the nature of the chemical bonding in the molecules of the hydrides of the elements of groups IIIa–VIIa [11] can be used in a preliminary discussion of their tendency to form molecular complexes. The chief characteristic of the hydrides is the presence of a hydrogen atom forming a covalent bond with the central atom of the element. In the examination of these compounds, therefore, it is necessary first of all to take account of the tendency for an intermolecular hydrogen bond to be formed. In addition, the hydrides of boron and aluminium may act as strong $\nu$-type electron acceptors in EDA complexes, using the unoccupied $p$ orbitals of the B and Al atoms.

The polarity of the bonds in the hydrides increases on going from left to right along the periods. The ability of these compounds to form intermolecular H-bonds should increase in the same order. On the other hand, the polarity of the bond decreases on going down the groups, and this should lead to a decrease in the proton-donor power of the hydrides of periods 3–7. The elements of groups Va and VIa have lone pairs of electrons, so that the corresponding hydrides, having low ionisation potentials,[23] can not only form intermolecular H-bonds but also act as $n$-type electron donors towards inorganic and organic electron acceptors.

This is illustrated by the values of $\varepsilon$ given in Table 2. The systematic decrease down the groups in the values of $\varepsilon$ for the hydrides of the elements of groups Va–VIIa, due to the decrease in the contribution of van der Waals interactions, breaks down for ammonia, water, and hydrogen fluoride, because of the large contribution made to the value of $\varepsilon$ by the energy of the hydrogen bond, which is much greater than the corresponding values for phosphine, hydrogen sulphide, and hydrogen chloride. No significant change in the contribution of H-bonds is observed on going from left to right along periods 3–5.

Experimental and theoretical data on the ability of the volatile inorganic hydrides of the elements of groups IIIa to VIIa to form molecular complexes are examined in more detail below. Particular attention will be paid to the systems in Table 1, or related systems.

## III. TWO-PHASE METHODS OF EXTENSIVE PURIFICATION AND THE FORMATION OF MOLECULAR COMPLEXES

Among the physicochemical methods of extensive purification used at present, two-phase distillation and crystallisation methods have found extensive application. The difference between the compositions of the equilibrium phases is characterised by the distribution coefficient of the impurity:

$$K^{vl} = x_2^v/x_2^l;\ K^{sl} = x_2^s/x_2^l \qquad (1)$$

where $x_2$ is the concentration of the impurity in the vapour (v), liquid (l), or solid (s) phases (in mole fractions). The phase equilibrium condition gives the relationship between the distribution coefficients and the chemical potentials of the impurities in the equilibrium phases. Thus the study of the influence of specific interactions on the efficiency of two-phase purification methods is directly related to the study of their influence on the thermodynamic properties of dilute solutions. The methods used for this purpose have been reviewed,[24] and their details will not be discussed further. Interesting data have been published[25] on the purification of the chlorides of various elements tending to form complexes.

Before analysing the influence of specific interactions, the nature of two-phase equilibria in dilute solutions with non-specific interactions can be discussed briefly. A statistical-thermodynamic description of phase equilibria in dilute solutions with non-specific interaction between the molecules, and methods for calculating the distribution coefficient based on it, have been described.[5–7,24] From these methods, that based on the theory of conformal solutions can be selected,

since it is simple and at the same time sufficiently exact.[26,27] By applying this method to a solution for which the interaction between the molecules is described by the Lennard-Jones potential, an expression for the liquid–vapour distribution coefficient has been found in the approximation of an ideal vapour phase.[27,28] Here, only the quantities on which the distribution coefficient depends will be given:

$$K^{vl} = f\left(\frac{kT}{\varepsilon_{11}}, \frac{\varepsilon_{21}}{\varepsilon_{11}}, \frac{\sigma_{21}}{\sigma_{11}}\right) \quad (2)$$

where $T$ is the temperature.

The parameters of the interaction potential of the particles of the impurity and the base are given by the equations:

$$\sigma_{21} = (\sigma_{11}+\sigma_{22})/2;\ \varepsilon_{21} = \xi(\varepsilon_{11}\varepsilon_{22})^{1/2} \quad (3)$$

where $\varepsilon_{ii}$ and $\sigma_{ii}$ are the parameters characterising the interaction of the particles of the base ($i = 1$) and the impurity ($i = 2$) components. The parameter $\xi$ in the Lorentz–Berthelot combination rules (3) for solutions with non-specific interactions is usually taken as 1.

Table 3 compares experimental data with the results of calculations of the distribution coefficients from Eqn.(2) for a number of systems in which specific interactions are weak or non-existent. The calculation of the distribution coefficient using the Lennard-Jones potential for $\xi = 1$ in most cases gives correctly the nature of the deviations from Raoult's law, so that this potential can be regarded as a satisfactory effective potential for this case. The deviations from 1 in the values of $\xi$ found from the values of $K^{vl}_{expt}$ are relatively small, confirming that there are no appreciable donor–acceptor interactions between the components of the solutions studied. The values of $\xi \leqslant 0.97$ are apparently due to the inaccuracy of the values of the experimental distribution coefficient used.

**Table 3.** Results of the calculation of the distribution coefficient in systems based on volatile inorganic hydrides at their normal boiling points.[6]

| System | $K^{vl}_{id} = p_{02}/p_{01}$ | $K^{vl}$ | $K^{vl}_{expt}$ | $\xi$ |
|---|---|---|---|---|
| $SiH_4$—$GeH_4$ | 0.23 | 0.26 | 0.26 | 1.00 |
| $SiH_4$—$PH_3$ | 0.22 | 0.26 | 0.23 | **1.01** |
| $SiH_4$—$AsH_3$ | 0.05 | 0.075 | 0.078 | **1.00** |
| $SiH_4$—$H_2S$ | 0.02 | 0.076 | 0.093 | 0.99 |
| $SiH_4$—$B_2H_6$ | 0.28 | 0.26 | 0.73 | 0.95 |
| $SiH_4$—HCl | 0.17 | 0.35 | 0.35 | 1.00 |
| $SiH_4$—$C_2H_4$ | 0.60 | 0.63 | 0.76 | 0.99 |
| $SiH_4$—$C_2H_6$ | 0.23 | 0.46 | 0.26 | 1.03 |
| $SiH_4$—$C_3H_8$ | 0.009 | 0.013 | 0.03 | 0.97 |
| $GeH_4$—$SiH_4$ | 2.92 | 3.11 | 2.52 | 1.01 |
| $GeH_4$—$AsH_3$ | 0.27 | 0.33 | 0.38 | 0.99 |
| $GeH_4$—$H_2S$ | 0.18 | 0.32 | 0.31 | 1.00 |
| $GeH_4$—$C_2H_4$ | 2.26 | 2.09 | 2.23 | 1.00 |
| $GeH_4$—$C_2H_6$ | 1.01 | 1.62 | 1.21 | 1.02 |
| $GeH_4$—$C_3H_8$ | 0.071 | 0.082 | 0.081 | 1.00 |
| $PH_3$—$AsH_3$ | 0.29 | 0.30 | 0.68 | 0.96 |
| $AsH_3$—$PH_3$ | 2.57 | 2.83 | 3.03 | 1.00 |

Notes. $p_{01}$ and $p_{02}$ are the saturated vapour pressures of the pure base and the impurity; the values of the parameter $\xi$ in Eqn.(3) were found from Eqn.(2) using the experimental values of the distribution coefficient $K^{vl}_{expt}$.

Donor–acceptor interactions make the phase equilibria more complex. In solutions whose components form molecular complexes, azeotropes are fairly frequently produced. In this case, the estimation of the distribution coefficient from Raoult's law may lead to a qualitatively incorrect result, namely to an incorrect indication of the phase in which the impurity is concentrated.

The influence of specific interactions on the distribution coefficients can be analysed in two ways. In the first, the interaction potential, which in some form takes account of the specific components, is directly related to the distribution coefficient. In the second, explicit account is taken of the presence of various complexes and associates formed as a result of specific interactions, and the expression for the distribution coefficient includes the equilibrium constant of the complex formation process.

In the first approach, the main consequences of the existence of specific interactions follow directly from Eqns. (2) and (3) when the depth of the potential well $\varepsilon_{ij}$ is separated into non-specific $\varepsilon^0_{ij}$ and specific $\delta\varepsilon_{ij}$ components:

$$\varepsilon_{ij} = \varepsilon^0_{ij} + \delta\varepsilon_{ij};\quad \varepsilon^0_{ij} = (\varepsilon^0_{ii}\varepsilon^0_{jj})^{1/2} \quad (4)$$

(for the separation of these components, see also section VI). It follows from Eqns.(4) and (5) that

$$\xi = \frac{\varepsilon^0_{21} + \delta\varepsilon_{21}}{[\varepsilon^0_{11}\varepsilon^0_{22} + (\varepsilon^0_{11}\delta\varepsilon_{22} + \varepsilon^0_{22}\delta\varepsilon_{11} + \delta\varepsilon_{11}\delta\varepsilon_{22})]^{1/2}}. \quad (5)$$

For $\delta\varepsilon_{ij} = 0$, $\xi = 1$. A relatively small contribution of specific interactions to $\varepsilon_{21}$ gives values of $\xi < 1$, and increase in the contribution $\delta\varepsilon_{21}$ (or decrease in $\delta\varepsilon_{ii}$) gives $\xi > 1$. It follows from Eqn.(3) that decrease in $\xi$ leads to an increase in the value of $K^{vl}$, and a positive azeotrope may be produced, whereas increase in $\xi$ decreases $K^{vl}$ and leads to the production of a negative azeotrope.

Special mention may be made of cases when specific interactions lead to qualitative (from the viewpoint of the sign of $\ln K^{vl}$) deviations from Raoult's law. If the boiling point of the impurity component is higher than that of the main component, these qualitative deviations ($K^{vl}_{id} < 1$, $K^{vl}_{expt} > 1$) are produced when $\xi < 1$ (for example if $\delta\varepsilon_{11} = \delta\varepsilon_{21} = 0$ and $\delta\varepsilon_{22} \neq 0$). If the boiling point of the impurity component is lower than that of the main component, qualitative deviations ($K^{vl}_{id} > 1$, $K^{vl}_{expt} < 1$) are observed when $\xi > 1$ (for example if $\delta\varepsilon_{11} = \delta\varepsilon_{22} = 0$ and $\delta\varepsilon_{21} \neq 0$).

The quantitative estimation of the distribution coefficients of impurities in solutions in which the interactions have a specific component $\delta\varepsilon_{11}$ can be carried out using the methods[5–7] for solutions with non-specific interactions only when the specific component makes a small contribution: $\delta\varepsilon_{11} \lesssim 0.1\varepsilon_{11}$. In other cases, quantitative estimates require more rigorous models of the impurity–base and base–base interaction potentials (see section VI).

The properties of dilute solutions with specific interactions can be examined further by taking explicit account, via the equilibrium constants, of the processes of molecular complex formation. When the energy of formation of impurity–impurity and impurity–base complexes is sufficiently high, when their lifetime becomes greater than the characteristic time of the thermal motions in the liquid, $\tau \cong 10^{-12}$ s, it is reasonable to regard the complexes as different molecular forms of the impurity.

The formation of a molecular complex can be represented by the equation

$$iA + jB \rightleftharpoons A_iB_j \quad (6)$$

where A is the main component, and B the impurity. The equilibrium constants of the complex formation reactions in the vapour $K_V$ and liquid $K_l$ phases

$$K_{v,l} = \frac{[A_iB_j]_{v,l}}{[A]^i_{v,l}[B]^j_{v,l}} \quad (7)$$

and the distribution coefficients of the impurity in the monomeric and associated forms

$$K_m^{vl} = [B]_v/[B]_l;\ K_{ass}^{vl} = [A_iB_j]_v/[A_iB_j]_l \qquad (8)$$

can be introduced. The generalised distribution coefficient of the impurity[29,30] [compare Eqn.(2)]:

$$K^{vl} = \frac{[B]_v + j[A_iB_j]_v}{[B]_l + j[A_iB_j]_l} \qquad (9)$$

characterises the equilibrium distribution of the impurity B, irrespective of its specific molecular form.

Eqn.(9) can be examined for two particular cases: the formation of impurity–base and impurity–impurity dimers. In the first case, Eqn.(9) gives two equivalent relationships:

$$K^{vl} = \frac{1 + K_v}{1 + K_l} K_m^{vl};\ K^{vl} = \frac{(1 + K_v)K_l}{(1 + K_l)K_v} K_{ass}^{vl} \qquad (10)$$

It follows from Eqns.(10) that $K^{vl}$ takes values intermediate between $K_m^{vl}$ and $K_{ass}^{vl}$. When $K_v$ and $K_l \ll 1$, $K^{vl} \cong K_m^{vl}$, and when $K_v$ and $K_l \gg 1$, $K^{vl} = K_{ass}^{vl}$. Similarly, the cases where $K_V \gg K_l$ and $K_V \ll K_l$ reduce only to a renormalisation of the quantity $K^{vl}$.

Eqn.(9) has more interesting consequences when impurity–impurity dimers are formed:

$$K^{vl} = K_m^{vl} \frac{1 + 2K_vK_m^{vl}[B]_l}{1 + 2K_l[B]_l} \qquad (11)$$

In this case, $K^{vl}$ depends on the concentration. In the absence of specific interactions, the distribution coefficient becomes independent of concentration at $[B]_l \leqslant 10^{-2}$.[24] It follows from Eqn.(11) that at high values of the equilibrium constants of the complex formation process, a concentration dependence may also be observed at lower concentrations. It also follows from Eqn.(11) that $K^{vl} = K_m^{vl}$ as $[B]_l \to 0$ as the equilibrium for the dimerisation is displaced towards the formation of the monomers with decrease in the concentration of the impurity. Since usually $K_v \leqslant 1$ and $K_m^{vl} \cong 1$, Eqn.(11) shows that for a concentration dependence in the range $[B]_l \cong 10^{-3}$, it is necessary that $K_l \cong 5 \times 10^2$.

Quantitative estimates of the proportions of impurities in different molecular forms require methods for calculating the equilibrium constants in the liquid phase. These calculations can be based on published rigorous statistical-thermodynamic expressions[31] for the quantities $K_l$ (see also the published review[32]).

The possibility of considerable deviations from the laws of ideal solutions and the production of different molecular forms of the impurities have a significant influence on the behaviour of impurities during purification, so that their study is important for the practical preparation of highly pure materials. It also follows that the chief question which must be investigated is whether molecular complexes are formed in the given system, and if so, whether they are stable or unstable.

Since at present there is no single theory which might be used to predict reliably the formation of donor–acceptor complexes (including H-complexes) the question raised can be answered by undertaking: 1) an experimental study of complex formation under the actual conditions of the given method of purification, or, if this is difficult, under model conditions with subsequent extrapolation of the results obtained to the real conditions; and 2) a theoretical (quantum-chemical) calculation, in a given approximation, of the energy of formation of the complex (the energies of the interaction of the complex-forming molecules) and other thermodynamic parameters.

## IV. EXPERIMENTAL METHODS FOR STUDYING MOLECULAR COMPLEXES

Practically all present-day physicochemical methods are used in the study of molecular complexes. Exhaustive reviews of these topics have been published.[13–16,18,20] The information on weak EDA and H-complexes is of greatest interest. At the present time, therefore, most experimental studies of molecular complexes are aimed at increasing the sensitivity of existing methods both by introducing new techniques and by improving existing methods. Molecular complexes are studied in all states of aggregation. Since their formation is exothermic, and since the reactions take place with a decrease in the number of moles, the most significant results should be obtained by using low temperatures and/or high pressure.

All methods of studying molecular complexes can be provisionally divided into two large groups: spectroscopic (in practically all ranges of the electromagnetic spectrum) and non-spectroscopic (calorimetry, chromatography, measurement of dipole moments, second virial coefficients, etc.).

The first group of methods can be examined in slightly more detail. The traditional method of studying EDA complexes of different stability is electronic spectroscopy in the ultraviolet or visible ranges, used to record the charge-transfer (CT) band. The spectroscopic characteristics of the CT bands are used to determine the thermodynamic characteristics of EDA complexes, usually in the liquid or gas phases (extensive reviews of these data have been published,[14,15,23,68] chiefly for organic compounds). This method has been used to study various complexes of hydrogen sulphide.[34] It can obviously also be used for other systems based on hydrides having a lone pair of electrons ($n$-donors).

The use of vibrational spectroscopy to study EDA complexes is most effective when strong donor–acceptor bonds are formed, since it is only then that the corresponding intermolecular vibrations are completely characteristic. Far infrared spectroscopy is particularly promising in this connection.[35] On the other hand, infrared spectroscopy is still the chief source of information on the hydrogen bond in H-complexes of different stability, as indicated by recent reviews.[18,20,36] Measurement of the spectroscopic characteristics of the $\nu_{XH}$ stretching band (its displacement to shorter wavenumbers and the increase in its strength when a complex is formed) gives valuable information on the nature of the hydrogen bond and the thermodynamic characteristics of H-complexes in the liquid or gas phase.

Comparatively few experimental papers have been published on the study of H-complexes formed by the volatile inorganic hydrides of the elements of groups IIIa–VIIa in solution or in the gas phase (see Table 5). Exceptions are water (although in this case most attention has been paid to associates $(H_2O)_n$ [37–39]) and, to some extent ammonia and hydrogen halides.[40,41] The spectroscopic study of intermolecular interactions in these systems encounters considerable difficulty. Thus most complexes based on the hydrides being considered are very weak (see section V). At the same time, in systems such as $H_2O$–HCl, $NH_3$–HCl, and $NH_3$–$H_2O$ at high concentrations of the components in solution in a polar substance or even in the gas phase, protonated species (ion pairs) may be formed.[42] The nature of the IMI in these systems should be different, however, in dilute solutions based on one of these components.

Extensive possibilities for studying H-complexes of both types (with and without proton transfer) are provided by infrared spectroscopy in low-temperature matrices of nitrogen and noble gases. This method is now being used in many laboratories (see the published reviews[43,44]). Unfortunately, the H-complexes of volatile inorganic hydrides have been insufficiently studied by this method. Data on the $\nu_{HHal}$ stretching wavenumbers and the relative wavenumber displacements $\Delta\nu/\nu$ in the spectra of H-complexes of hydrogen halides with the molecules of a number of substances which are potential impurities in these compounds have been reviewed[45] (see Table 1). Attempts have been made to establish correlations between the properties of H-complexes and the molecular characteristics reflecting the nature of the electronic structure of the partner molecules.[41,45,46] Most frequently, use is made of the proton-acceptor (electron-donor) power of the base PA, determined by various methods. Although the absolute magnitude of the relative wavenumber displacement of the $\nu_{HHal}$ band of the complex generally increases with increase in the PA, there is no simple relationship between these quantities. The H-bonds formed by hydrogen halides with molecules containing atoms with lone pairs of electrons (water, dimethyl ether, etc.) are fairly strong.

The study of IMI in systems based on water by infrared spectroscopy in low-temperature matrices is important, since, as can be seen from the data in Table 1, water is a universal impurity, most difficult to remove, in all volatile inorganic hydrides, and also in many other volatile compounds (for example the chlorides of the elements of groups IIIa–Va [47]). The study of these complexes by ordinary infrared spectroscopic methods is fairly complicated. On the other hand, comparatively few papers on matrix-isolation studies have been published. Most have been devoted to the dimers $(H_2O)_2$ and the polymers $(H_2O)_n$ (see the published review[48] and other papers[49,53]).

Table 4 gives the wavenumbers of the stretches ($\nu_1$ and $\nu_3$) and deformations ($\nu_2$) of the O–H bond in a molecule of free water and water combined with proton acceptors (argon matrix). Like the H–Hal stretching wavenumbers, $\nu_1$ and $\nu_3$ decreases relative to monomeric water on complex formation, and the magnitude of the wavenumber shift $\Delta\nu$ characterises in a definite sense the stability of the H-complexes formed. According to this characteristic, the strength of the H-bonds in matrix-isolated water systems changes in the order:

$$NH_3 < (CH_3)_2O > H_2O > HCl \approx H_2S \approx Cl_2 > CO_2$$

**Table 4.** Wavenumbers of the principal vibrations of the $H_2O$ molecule ($cm^{-1}$) in the free state and combined in a complex[50–52,54–56] (the type of matrix is given in brackets).

| Type of vibration | $H_2O$ (monomer) | | | | Complex $H_2O$–X | | | | |
|---|---|---|---|---|---|---|---|---|---|
| | (Ar) | ($N_2$) | X=$(CH_3)_2O$ (Ar) | X=HCl (Ar) | X=$H_2S$ ($N_2$) | X=$H_2O$ (Ar) | X=$CO_2$ ($N_2$) | X=$Cl_2$ ($N_2$) | X=$NH_3$ ($N_2$) |
| $\nu_1$ | 3638 | 3634 | 3506 | 3631 | 3628 | 3575 | 3632 | 3631 | 3414–3374 |
| $\Delta\nu_1$ | — | — | 132 | 7 | 6 | 63 | 2 | 7 | 240 (ср.) |
| $\nu_2$ | 1589 | 1597 | 1615 | 1590 | 1597 | 1611 | 1598 | 1597 | — |
| $\nu_3$ | 3734 | 3728 | 3706 | — | 3719 | 3710 | 3725 | 3726 | 3697 |
| $\Delta\nu_3$ | — | — | 28 | — | 9 | 24 | 2 | 8 | 31 |

Among the systems of interest for the present review, mention may be made of published data on the complexes formed by hydrogen sulphide and ammonia, obtained by matrix-isolation methods.[53,54,56–60]

The chief disadvantage of the matrix-isolation method is that in the rigid matrix the systems being studied are in a non-equilibrium state, so that the experimental determination of the thermodynamic functions of the complex is impossible. An alternative method of study is provided by infrared cryospectroscopy, where liquid noble gases, which are highly transparent, are used as solvents.[61–64] In the study of the state of impurities in inorganic hydrides and similar compounds which have a simple molecular structure and which are liquefied at low temperatures, it is probably possible to use the compounds themselves as solvents, at temperatures close to the boiling point (if they are transparent in the given spectral range).

Important information on the structural, electric, and in some cases energy characteristics of the weak molecular complexes of simple molecules in the gas phase at low pressure can be obtained by various forms of rotational spectroscopy developed in the last ten years: microwave spectroscopy with Stark modulation; electron-resonance spectroscopy in molecular beams; and pulse microwave Fourier spectroscopy in a supersonic gas beam with adiabatic expansion from a vessel at high pressure.[65–67] These methods have been used to study a number of systems containing the hydrides of the elements of groups Va–VIIa and the molecules of potential impurities (see for example Refs.65 and 68).

In non-spectroscopic methods for studying molecular complexes, in contrast to spectroscopic methods, the thermodynamic parameters of the complexes are determined by measuring properties of the solution which depend only on the number of particles in it, and not on the physical parameters of the particles of different type. An important representative of this group of methods is gas–liquid chromatography.[69,70] The advantages of this method are the direct determination of the equilibrium constants from the retention volumes without the more complicated measurement of the concentrations of the substances in two phases, and also the possibility of working with low concentrations at which the laws of dilute solutions are applicable. This last feature is particularly important in the study of the state of impurities in highly pure volatile substances, and gas chromatography has for long been used successfully for the quantitative analysis of these materials.[71]

The above brief review of various physical methods for studying molecular complexes shows that it is still necessary and important to identify and determine the thermodynamic properties of both EDA and H-complexes and complexes formed in a large excess of one of the components (in dilute solution) or at equivalent ratios of the components at low temperatures ($NH_3$–HCl, $NH_3$–$H_2O$, etc.).

At the same time, primary information on the energy and structure of these complexes can also be obtained from quantum-chemical calculations. The number of published papers in this field, including those devoted to the complexes formed by the volatile hydrides of the elements of groups IIIa–VIIa, is increasing continuously. Some of these will be examined in the next section.

## V. QUANTUM-CHEMICAL METHODS FOR STUDYING MOLECULAR COMPLEXES

The use of modern methods of quantum chemistry to solve the problems being discussed in the present review, related to the theory and practice of the preparation of highly pure materials, is necessary for the following reasons. Firstly, after establishing the impurity composition of the substance being purified, it is necessary to estimate quantitatively the

possibility of specific interaction beween the impurity molecules and the molecules of the main material, and of impurity–impurity interactions when the concentration of individual impurities is appreciable. Calculation methods now available often make it possible to obtain information on at least the relative stability of possible associates more easily than by experiment. It must be remembered, however, that the result obtained will relate to an isolated molecule of the complex, without allowance for the solvation energy.

Secondly, one of the principal problems in the theory of the preparation of highly pure materials is the development of reliable methods of calculating the distribution coefficient of an impurity for two-phase purification methods. In most cases, increase in the accuracy of calculations of the distribution coefficient requires primarily refinement of the interaction potentials. Quantum chemistry can now be used to calculate these potentials. Quantum-chemical interaction potentials can be used for the *a priori* estimation of other quantities characterising the preparation of a highly pure substance: solubility, diffusion coefficient, rate of the introduction of impurities from the material of the apparatus into the substance being purified.

The most reliable data on the energy and geometry of molecular complexes (EDA and H-bonded) are obtained from non-empirical (*ab initio*) calculations by the method of molecular orbitals (MO) in the self-consistent field (SCF) approximation. The present state of different versions of these calculations has been reviewed.[15,20,72–74] The present section deals briefly with the principal concepts of the method and discusses published data on the stability of some of the two-component systems with weak specific interactions discussed in Table 1. Since they are particularly important for the problems being discussed in the present review, topics related to the construction of quantum-chemical IMI potentials are discussed separately in the next section.

In the MO SCF approximation, a molecular complex is regarded as a supermolecule whose energy of formation (the IMI energy) is equal to the difference between the total energy of the complex $E_{DA}$ and the energies of the components $E_D$ and $E_A$:

$$\Delta E = E_{DA} - E_D - E_A$$

The accuracy of non-empirical calculations of $\Delta E$ depends chiefly on the number of basis atomic orbitals (AO) used to construct the MO. The generally accepted notation used below for different basis sets is explained, for example, in Ref.74. In the SCF approximation, no account is taken of the correlation of the motion of the electrons at each moment of time, as a result of which the electrons in individual orbitals are situated as far as possible from one another. The correlation energy $\Delta E^{corr}$ corresponding to this process constitutes only a small fraction of the total energy $\Delta E$, but allowance for it is important in rigorous calculations of the stability of complexes. For example, for the dimer $(H_2O)_2$, $\Delta E = -4.5$ kcal mole$^{-1}$, and the contribution of the correlation energy is $-1.1$ kcal mole$^{-1}$.[75] In practice, allowance for $\Delta E^{corr}$ reduces to the calculation of the dispersion energy using either perturbation theory[76] or multipole expansion, in which the coefficients are determined from experimental data on the polarisability of the molecules.[77] An alternative method of taking account of the correlation energy is the configuration interaction (CI) method.[75,78] Even when a minimum basis set is used without allowance for correlation energy, non-empirical calculations are usually carried out for molecules containing a comparatively small number of atoms (10–15) belonging to the second and third periods.

For more complex molecules and complex compounds, extensive use is made of semi-empirical methods, usually based on the neglect of differential orbital overlap and using SCF equations (CNDO, INDO, etc. methods).[79] These methods are much less laborious and therefore more accessible. For molecular complexes, however, these methods give absolute values of the energy of IMI which are systematically several times too high. Data on the use of these methods to calculate the energy and geometry of EDA and H-complexes have been reviewed.[74,80] Recently, interesting parametrisation schemes for familiar versions of the CNDO and INDO methods have been proposed, making it possible to obtain various geometric and energy characteristics of complexes containing hydrogen bonds of the type O–H...O, O–H...N, and N–H...O.[81,82] Semi-empirical methods are useful for estimating the relative characteristics of IMI in a series of structurally related molecular complexes. Thus it is possible to obtain information fairly rapidly on the relative stability of practically all the hydride–impurity and impurity–impurity dimers given in Table 1.

The results of non-empirical calculations of the complex-forming power of the molecules of the hydrides of the elements of the second and third periods, given in Table 1, both with respect to one another (dimers) and with respect to various inorganic and organic molecules (heterodimers) can be discussed in more detail. Detailed calculations have been carried out for complexes involving $BH_3$, $AlH_3$, $NH_3$, $PH_3$, $H_2O$, $H_2S$, HF, and HCl. There are no published data on the quantum-chemical description of the IMI in silane, although a number of papers (for example Refs.83 and 84) give detailed calculations of the structure and properties of the $SiH_4$ molecule by non-empirical methods.

**Table 5.** Energies of the hydrogen bonds (kcal mole$^{-1}$) for the hydrides of the elements of the second and third periods, from the results of non-empirical quantum-chemical calculations*.[85–87]

| Electron donor | Proton donor | | | | | |
|---|---|---|---|---|---|---|
| | $NH_3$ | $PH_3$ | $H_2O$ | $H_2S$ | HF | HCl |
| $NH_3$ | 4.3 (4.5±0.4) [88] | 1.2 | 8.9 | 4.4 | 16.3 | 10.8 (15.2±±0.3) [89] |
| $PH_3$ | 2.2 | 0.8 | 4.0 | 2.1 | 6.9 | 4.3 |
| $H_2O$ | 4.1 | 1.1 | 8.1 (5,1) [91]; (6±3) [90] | 3.8 | 13.4 | 8.2 |
| $H_2S$ | 2.1 | 0.6 | 3.9 | 1.8 (1.7±0.3) [92] | 5.8 | 3.5 |
| HF | 3.6 | 1.0 | 5.4 | 2.5 | 5.8 (5–7) [93] | 4.6 |
| HCl | 1.6 | 0.4 | 2.5 | 1.1 | 3.4 | 2.0 |
| $H_2CO$ | 1.4 | 0.2 | 3.4 | 0.6 | 6.2 | 5.3 |

*The experimental values of the energies of the complexes (from infrared spectroscopy) are given in brackets.
Note. Numbers in square brackets denote references (Ed. of Translation).

As already noted, the chief aim of this section of the present review is a comparative analysis of the stability of weak complexes of various hydrides, that is a comparison of the energies of IMI found under identical conditions. The data obtained for ~40 dimers and heterodimers in a 4-31G restricted basis set[85–87] are of particular interest in this connection (Table 5). The results of these calculations agree satisfactorily with experimental data (gas-phase infrared spectra). According to published estimates,[86] the data given in Table 5 are all slightly high (5–50%), relative to

the experimental data and the best non-empirical results, and the more stable the complex, the greater the error. Nevertheless, these data lead to the following conclusions.

1. All the hydrides considered tend to undergo self-association by H-bonds of low or medium energy.

2. The tendency to form dimers decreases in the order $H_2O > HF > NH_3 > HCl > H_2S > PH_3$. The energy of the hydrogen bond varies from $-16.3$ kcal mole$^{-1}$ for $HF-NH_3$ to $-0.4$ kcal mole$^{-1}$ for $PH_3-HCl$. The strongest bonds are formed with hydrogen fluoride or hydrogen chloride as proton donor.

3. The proton-acceptor power decreases sharply on going from the hydrides of the second period to those of the third period.

4. In the heterodimers of the hydrides of the elements of the second period, ammonia shows electron-donor properties with respect to water and hydrogen fluoride; water acts as electron donor only towards HF. In the heterodimers of the hydrides of the third period, the hydride of an element of a group with a smaller number acts as an electron donor with respect to that of an element of a subsequent group. For the heterodimers of the hydrides of the elements of the second and third periods, the following apply: HCl is a proton donor towards $NH_3$, $H_2O$, and HF; $H_2S$ is a proton donor towards $NH_3$, but an electron donor in the complex with HF. In its reaction with $H_2O$, hydrogen sulphide shows both electron-donor and proton-donor properties, to equal extents. Finally, $PH_3$ forms weak complexes with ammonia, water, and hydrogen fluoride, in which it is an electron donor.

5. The most stable complexes with other hydrides are formed by HF, $H_2O$, and HCl.

6. Judging from the calculated values of the H-bond energy, in practically all these hydrides at least part of the impurity water must be present in the combined state, and the probability of water–hydride molecular complex formation decreases in the order: $HF > NH_3 > HCl > H_2S \cong PH_3$.

In connection with the relative role of specific interactions, it is of interest to compare the energies of the dimers (Table 5) with the effective energies $\varepsilon$ of the paired interactions (Table 2). The difference between these quantities for a given substance are related to two factors: firstly, the quantity $\varepsilon$ includes a contribution from hydrogen bonds, averaged over all nearest neighbours, and not only over those forming bonds; and secondly, the absolute magnitude of the average energy of a hydrogen bond in the condensed phase is lower than that of the energy of the bond in the gas phase. Thus the values of $\varepsilon$ in Table 2 are lower than the values of the energy given in Table 5 for systems with a high hydrogen bond energy, and are close to those for systems with a low bond energy. This comparison for systems for which data are given in both Tables shows that the role of the hydrogen bond is a minimum for phosphine and a maximum for water.

Calculations of the energies of the molecular complexes formed by various hydrides with carbon dioxide, carbon monoxide, nitrogen, fluorine, and sulphur dioxide have been published.[94–100]

To estimate the efficiency of the extensive purification of such strongly polar hydrides as water and ammonia, it is important to have information on the IMI in the complexes with the ions of the elements of groups Ia and IIa, and also with the molecules of the halides of these elements. Data on these complexes have been published;[101–105] their stabilisation energy is several tens kcal mole$^{-1}$.

In Refs.106–109 it was shown for the first time by a non-empirical method in an expanded basis set that many of the hydrides examined in the present review form EDA complexes with the neutral atoms of the metals of the groups Ia–IIIa, and that the latter act as electron acceptors. The formation of associates of this kind must apparently be taken into account in the examination of: a) the contaminating effect of the apparatus (hydride–surface interaction); b) the state of suspended particles in hydrides; and c) the preparation of highly pure elements by the thermal or photochemical decomposition of the volatile hydrides.

The above results of non-empirical quantum-chemical calculations for dimers and heterodimers based on various volatile hydrides make it possible to estimate their stability in the sense of the IMI energy in the ideal-gas state. For the theory of the preparation of highly pure materials, however, it is no less important to have information on the ability of these complexes to dissociate at the temperature of the separation process, characterised by the Gibbs free energy. The processes of complex formation described by Eqn.(6) are generally accompanied by a decrease in entropy. Thus for weak IMI at comparatively high temperatures, the entropy factor may play an important role in the formation of molecular complexes, and conclusions about their stability based only on the values of $\Delta E$ (the enthalpy of formation) may generally speaking be incorrect. The thermodynamic stabilities of weak molecular complexes, based on theoretically determined $\Delta E$ values, have been analysed in a series of papers,[110–113] where the values of $\Delta G_T^0$ were calculated for the formation of the H-complexes $H_2O-HF$, $H_2O-H_2O$, HF–HF, HF–HCl, HCl–HCl, $CO_2-HF$, $Si(OH)_4-H_2O$, and $(H_3Si)_2O-H_2O$ at temperatures of 100, 298.2, and 500 K.

Thus present-day methods of quantum chemistry make it possible to obtain comparatively reliable data on the stability of weak molecular complexes of different types, including those formed by the volatile hydrides of the elements of the second and third periods in the gas phase or in a non-polar solvent. In the study of the same processes of complex formation in polar media, and processes involving molecules formed by the elements of lower periods, experiment provides the only source of reliable information at present.

## VI. THE INTERACTION POTENTIALS OF SYSTEMS WITH MOLECULAR COMPLEXES AND THE RESULTS OF THEIR STUDY BY NUMERICAL EXPERIMENT METHODS

The problem of selecting optimum potential functions, whose components would have a rigorous physical significance, to describe interactions with a specific contribution has not yet been solved. Various versions of paired potentials are used: atom–atom potentials and their extentions, namely site–site potentials, and combinations of spherically symmetrical and non-central compounds. The most systematic models, however, are apparently those in which the contributions of specific and van der Waals interactions are separated:[114]

$$U_N = \sum_{i<j} \{\Phi_{ij} + B(ij)\,u(ij)\} \qquad (12)$$

Here, $\Phi_{ij}$ is the potential energy of the paired-additive interaction of the molecule, characterising the non-specific interactions (for example the Lennard-Jones potential); $u(ij)$ the energy of the donor–acceptor interactions; and $B(ij)$ the characteristic function of bond formation between the given molecules $i$, $j$, equal to unit if a saturated (specific) interaction is localised between the molecules, and otherwise equal to zero.

Various interaction potential parametrisation methods are used. The first, traditional method uses an empirical paired potential, whose parameters are determined from the

condition for the minimum mean-square deviation of the calculated from the experimental values of some characteristic. For a system with hydrogen bonds, this empirical potential is a combination of Lennard-Jones and Coulomb terms and a Morse function, which is assumed (see for example Ref.115) to describe effectively the contribution made by charge transfer to the total energy of the H-bond. A large number of other empirical potentials, of simpler form, for calculating the IMI energy in liquids with weak hydrogen bonds are known.[116] In this traditional approach for dilute solutions, the separation of the contribution of donor–acceptor interactions has been used[117,118] to calculate the distribution coefficient in solutions of various volatile hydrides (see section III). In this method, the components describing the non-specific and weak specific interactions are separated in the parameter $\varepsilon$ of the Lennard-Jones potential (1). For hydrogen sulphide it was found[117] that the contribution of hydrogen bonds to the depth of the potential well (see Table 2) is 60–70 cal mole$^{-1}$. The estimated non-specific component for water, 360–480 cal mole$^{-1}$,[118] also agrees with published data.[119]

Care must be taken, however, when using these parametrisation methods. For example, a calculation of the structure of liquid ammonia using a model potential whose parameters were obtained from data on the second virial coefficient[120] showed the complete absence of any association in the liquid, contrary to experimental data.

A second method of IMI potential parametrisation is based on the results of non-empirical quantum-chemical calculations. In recent years it has become possible to determine comparatively rapidly the energy of dimers at different points of configuration space, that is to obtain fairly complete information on the potential energy surface of the interacting molecules. The parameters of the analytical expressions for the paired potential functions (usually in the form of the sum of the electrostatic and atom–atom contributions) are selected to reproduce most effectively the calculated potential surface.

The IMI potential constructed using the approximate first method or the more accurate second method is then used for a statistical-thermodynamic calculation of the structure and characteristics of pure liquids and solutions with donor–acceptor interactions.

Promising possibilities for practical application to the calculation of the structure and properties of systems with both van der Waals and donor–acceptor interactions are provided by the methods of computational physics: the method of molecular dynamics (MD) [121] and the Monte Carlo (MC) method[122] (see also the published monographs[123,124] and reviews[125,126]). These methods are well known, and will not be described here. It may be noted, however, that algorithms for calculating[127,128] thermodynamic quantities, including the entropy component, for systems with specific interactions have apparently not yet been developed. For these systems, quantities such as the pressure (density), energy, heat capacity, and structural characteristics are calculated.

The principal results of the study of the structural and thermodynamic properties of various liquid hydrides of the elements of the second and third periods with weak specific interactions by numerical experiment methods using rigorous quantum-chemical IMI potentials can be examined.

*Water.* The familiar exceptional chemical and biological importance of water is responsible for the vast amount of published information on various properties of this most widely encountered associated liquid (see for example the published reviews[38,130–132]). The preparation of highly pure water[133] and, on the other hand, as noted repeatedly above, the removal of traces of water from various inorganic and organic materials, are extremely urgent problems. It is in the case of aqueous systems, whose properties are determined to a large extent by comparatively strong intermolecular H-bonds, that the methods usually employed to calculate the distribution coefficient[5–7] and the solubility[134] do not give the desired results.

In pioneering work by Clementi and co-workers,[135] 216 different geometries of the $(H_2O)_2$ dimer, corresponding to four types of configuration, were calculated in an almost Hartree-Fock basis set. The results were approximated by a fairly cumbersome expression consisting of the sum of 16 paired contributions, nine of which describe the electrostatic interaction between the hydrogen atoms and the lone pairs of electrons of the oxygen atoms, while the others describe the attraction and repulsion between the oxygen and hydrogen

**Table 6.** Thermodynamic functions of liquid hydrides from the results of computer experiments using non-empirical potentials.

| Hydride | Calculation method, ensemble | Basis set | $N$ | $T$, K | $E$ | $C$ | $\Delta E_{vol}$ | Experiment | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|
| | | | | | | | | $E_v$ | $C_v$ | $C_p$ | $E_{vol}$ |
| $H_2O$ | MC, (NVT) (Ref.75) | SCF CI | 343 | 298 | −6.8±0.2 | 13.5±2 | — | −8.1 | 17.9 | 18.1 | — |
| | MC, (NPT) (Ref.129) | SCF CI | 100 | 298 | −7.1±0.3 | 20.6±7 | | | | | |
| | MC, (NVT) (Ref.143) | STO-3G | 125 | 298 | −6.6 | 12.7 | | | | | |
| HF | MC, (NVT) (Refs.144, 145) | STO-3G | 108 | 273 | −4.33 | 17.1 | 5.46 | — | ≤17 | — | 6.7 |
| | | 6-31G | 108 | 273 | −5.62 | 11.8 | 6.85 | | | | |
| | MD, (NPT) (Refs.146–147) | SCF | 216 | 278 | −3.97 | 14.3 | 5.2 | | | | |
| HCl | MD, (NVT) (Ref.150) | 4-31G | 216 | 296 | −2.28 | — | | −2.48 | | | |
| | MD, (NVT) (Ref.154) | SCF CI | 216 | 304 | −2.33 | 8.4 | | | 7.3 | | |
| $NH_3$ | MC, (NVT) (Ref.156) | STO-3G | 128 | 239.7 | −3.05 | 13.3 | 4.88 | −3.75 | 12.7 | — | 5.58 |
| | MD, (NVT) (Ref.157) | SCF | 108 | 269.6 | −5.2 | — | | | | | |

Notation: $E$ is the internal energy, kcal mole$^{-1}$ ($E_v$ in an NVT ensemble, and $E_p$ in an NPT ensemble); $C$ the heat capacity, kcal mole$^{-1}$ K$^{-1}$ ($C_v$ in an NVT ensemble, and $C_p$ in an NPT ensemble); $N$ is the number of particles.

atoms, due to non-electrostatic forces. The potential found in this way was used to calculate the structure of liquid water in an isochoric–isothermal ensemble (NVT ensemble).

The thermodynamic functions of liquid water (Table 6) show good agreement with experiment. A calculation[129] of the thermodynamics of liquid water in an isobaric–isothermal ensemble (NPT ensemble, see Table 6) using the Clementi potential gave good agreement with published data.[135]

The Clementi potential,[75,135,136,141] obtained on the basis of rigorous non-empirical calculations with allowance for CI, is still the best for the theoretical determination of the structure and properties of liquid water, although a number of other potentials, which give sufficient accuracy when used in calculations, were later proposed.[137–140]

On the other hand, a number of authors have studied the possibility of using minimum and restricted basis sets to construct the IMI potentials of associated liquids. The most fruitful results using this approach have been obtained by Jorgensen.[141–145] The potential surface of the water dimer was calculated[142] in an STO-3G minimum basis set (291 configurations) and approximated by a 12-6-3 potential:

$$U = \sum_{i<j}^{N} \frac{q_i q_j}{r_{ij}} + \sum_{\mu,\nu} \left( \frac{b_{mn}}{r_{\mu\nu}^3} + \frac{c_{mn}}{r_{\mu\nu}^6} + \frac{d_{mn}}{r_{\mu\nu}^{12}} \right) \qquad (13)$$

The first term takes account of the long-range electrostatic interaction between four point charges, and the summation is carried out over all pairs of charges belonging to N monomeric molecules. The second sum is taken for all pairs of atoms $\mu$, $\nu$ of type $m$ (O atom) and $n$ (H atom). Liquid water has been modelled by the MC method using potential (13).[143] The data in Table 6 show that the thermodynamic functions of water obtained by Jorgensen by much less laborious calculations also show good agreement with experiment and with Clementi's data.

*Hydrogen fluoride.* A potential of type (13) has also been used to model liquid HF by the MC method.[144,145] The potential surface of the dimer $(HF)_2$ was found in a 6-31G basis set for 250 configurations[144] and in an STO-3G minimum basis set for 285 configurations. An analysis of the calculated atom–atom distribution functions showed that liquid hydrogen fluoride consists of long highly bent chains of molecules (in the solid and gas phases, on the other hand, the chains are linear).

The structure and properties of liquid HF have been studied by the MD method.[146,147] The potential was constructed using the results of calculations of the potential surface of the dimer $(HF)_2$ in an almost Hartree–Fock basis set.[148] The radial distribution functions $g_{FF}$, $g_{HH}$, and $g_{FH}$ and various equilibrium and non-equilibrium properties of liquid HF were calculated (see Table 6).

The main conclusion about the structure of liquid hydrogen fluoride, reached in the works cited, agree with Jorgensen's conclusions,[145] but the first peak of the function $g_{FF}$ in Ref.147 was found to be split into two, and the second and third peaks of all the radial functions were broadened considerably, which does not agree with the fairly high structural order of liquid HF beyond the first coordination sphere. These anomalies are possibly related to the neglect of many-particle interaction, whose contribution reaches 10% of the total energy. The potential of the HF–HF intermolecular interaction has also been obtained.[149]

*Hydrogen chloride.* It follows from what was said above that the ability of HCl molecule to form intermolecular H-bonds is weaker than that of water and hydrogen fluoride. Computer modelling of liquid hydrogen fluoride has been carried out using quantum-chemical potentials.[150–154] In Refs.150 and 151, liquid HCl was studied by the MD method using several potentials which approximated the potential surface of the $(HCl)_2$ dimer, calculated in a 4-31G basis set. The best agreement with experiment (Table 6) was obtained using the potential from Refs.146 and 147. According to these data, hydrogen chloride is a weakly associated liquid, in which chains are formed to a smaller extent than in HF.

In Ref.154, liquid HCl was modelled by the MD method using a paired potential obtained by calculating the IMI in the dimer in an expanded basis set. The second virial coefficient of gaseous HCl and the atom–atom radial functions of liquid hydrogen chloride and some of its thermodynamic functions were calculated (Table 6). The experimental and calculated heat capacities of liquid HCl showed good agreement. In a preliminary report[155] a potential was proposed for the description of hydrogen chloride, including Lennard-Jones, dipole, and quadrupole components, and also polarisation terms. This gave a good description of the structure of the dimers in the gas phase and the structure of the liquid and the solid.

*Ammonia.* The dimerisation energies of various hydrides, given in Table 1, indicate that the tendency of ammonia to form H-bonded dimers is intermediate between those of water and hydrogen chloride. The potential surface of the $(NH_3)_2$ dimer has been calculated[156] in an STO-3G basis set (250 configurations). The results were described by a 12-6-3-1 potential (13), which was subsequently used to model the liquid by the MC method. The structural and thermodynamic data obtained in this way, however, showed insufficiently good agreement with experimental data (see Table 6). The agreement was much better when the modified potential (13) was used.

Various properties of liquid $NH_3$ have been determined by the MD method.[157] The potential surface of the dimer was calculated in an almost Hartree–Fock basis set with allowance for correlation energy (61 configurations). Although the thermodynamic functions found for liquid $NH_3$ showed satisfactory agreement with published data (Table 6), none of the three potentials used[157] made it possible to obtain simultaneously with sufficient accuracy both the thermodynamic functions in Table 6 and the second virial coefficient. The data on the structure of liquid ammonia obtained in Refs.156–158 agree well with one another and indicate only weak (compared with HF and $H_2O$) association in the liquid phase.

The use of quantum-chemical potentials in model pure associated inorganic liquids is at present practically limited to the above systems.

*Dilute solutions.* For a wide range of applied problems, including the calculation of the distribution coefficient, it is necessary to have structural and thermodynamic information on solutions of associated liquids, including their dilute solutions. For this it is necessary to carry out a non-empirical calculation of the potential surface of the base–impurity heterodimer. The number of published papers dealing with this topic is fairly small.

Some of these papers deal with aqueous solutions of simple organic molecules, because of the considerable interest in the hydrophobic effect.[159] The water–methane system[129] provides an example. The potential surface of this heterodimer was calculated in a 4-31G basis set for 28 configurations. The IMI paired potential took account of the interaction between the nuclei and the interaction between the lone pair of electrons of the oxygen atom and the hydrogen atoms in the methane molecule. The Clementi potential was used for the potential of the water–water dimer. The MC

method for an NPT ensemble (number of particles 64, $T = 298$ K, 4-31G basis set) was used to determine the partial molar internal energy, equal to $-11 \pm 15$ kcal mole$^{-1}$. The large uncertainty in its calculation is due to the fact that it represents the difference between the two large values of the energy of the solution and the individual components.

The $H_2O-CH_4$ system was also studied[160,161] in an NVT ensemble, where the potential surface was calculated in a 6-31G basis set for 225 configurations. Data have also been published on the quantum-chemical potentials of the water–ethane,[162] water–benzene,[163] and various other systems.

The results examined in this section demonstrate the fruitfulness of the approach to the study of the structure and properties of liquids, which are characterised by more or less strong specific interactions between the molecules, based on computer modelling with the use of non-empirical quantum-mechanical potentials. Two fundamental difficulties are encountered in this approach. The first is that all the calculations assume the paired additivity of the IMI. This is obviously not completely correct, particularly for systems with fairly strong donor–acceptor bonds. This is indicated in Refs.141 and 164–166, where it is pointed out, in particular, that the magnitude of the correction for the three-particle interaction of water molecules may be comparable with that of the correlation energy. On the other hand, other authors[167,168] assume that the non-additivity observed in the H-bonded systems $H_2S-(H_2O)_2$, $(CH_4)_3$, $(NH_3)_3$ does not play a significant role in the calculation of the structure of associated liquids. To some extent, a way out of this position involves the use of data on the properties of condensed systems in the parametrisation of the potential. This makes it possible to take effective account of the role of non-additive interactions.[169]

The other difficulty in obtaining analytical expressions for the potentials from non-empirical calculations is that the results of the latter depend on the basis set chosen. As already noted, the results with the most reliable accuracy are obtained in calculations in almost Hartree–Fock basis sets taking full account of electron correlation. These methods are laborious and expensive, however, so that they can as yet be used only to solve problems of fundamental importance. If however account is taken of the fact that the rate of increase in the efficiency of computers shows no sign of decreasing,[170,171] then in spite of the above difficulties, it can be expected that further progress in the calculation of various parameters characterising the efficiency of the preparation of highly pure associated liquids will in one way or another be related to the approaches examined in this section, based on the methods of quantum chemistry and numerical experiments.

## VII. CHEMICAL METHODS OF PURIFICATION AND THE FORMATION OF MOLECULAR COMPLEXES

The data examined in sections II–VI relate to the formation of weak molecular complexes by the volatile inorganic hydrides of the elements of groups IVa–VIIa. It has been shown that even in this case, appreciable deviations may be expected from the regular relationships familiar from the theory of extensive purification, based on allowance for only non-specific IMI.

At the same time, complex-forming substances giving stable molecular complexes with energies of several tens of kcal mole$^{-1}$, either with impurities or with the main material, have for long been used to separate and purify various compounds. These methods, based on the marked difference in the complex-forming power of the components, represent a form of chemical method for purifying substances.[2,4]

In chemical methods of purification based on the formation of molecular complexes, the separation factor is proportional to the ratio of the equilibrium constants of the processes of complex formation involving the main material and involving the impurity, and is higher, the greater the difference in the complex-forming power of the impurity and the main material with respect to the complex-forming reagent.[2]

Examples of the use of the ability of various hydrides of the elements of groups IIIa, Va, and VIa to form stable EDA complexes with various Lewis acids and bases in the preparation of highly pure materials can be found, for example, in Refs.9–11.

New interest in chemical methods of purification are also being stimulated by work on the preparation of materials for fibre light carriers, where it is necessary to remove one particular impurity which leads to the absorption of electromagnetic radiation in the range of the spectrum where the fundamental mechanisms of absorption make the minimum contribution. To use these methods successfully in practice, it is necessary to carry out a detailed preliminary study (theoretical and experimental) of the processes of molecular complex formation in each specific case. Studies of this kind are also necessary for the development of new methods of reaction gas chromatography, used successfully to analyse highly pure substances.[172]

## VIII. SUMMARY

The material discussed in the present review makes it possible to point out various important problems in the preparation of highly pure substances, whose solution is related to some extent to the problem of molecular complexes. Firstly, the determination of the state of impurities in substances being subjected to extensive purification. Secondly, the theoretical and experimental determination of the parameters characterising the efficiency of extensive purification. Thirdly, the development of methods of extensive purification and analysis using effective complex-forming reagents.

Complete information on the state and behaviour of impurities in a substance being purified would make possible a directed and justified selection of the method of purification. This requires an experimental and theoretical study of the possible formation of molecular complexes both under model conditions (at comparable concentrations of the components or with a slight excess of one of them) and under real conditions (dilute solutions).

High demands are made of experimental methods for studying molecular complexes, particularly at micro-concentrations of one of the components. It is desirable to use methods which simultaneously give information on the quantitative concentration of impurities and on their molecular state (for example infrared spectroscopy). In some cases, useful information on the state of impurities can be obtained by both semi-empirical and non-empirical quantum-chemical calculations. It is difficult to overestimate their role in the study of the structure and properties of molecular liquids with weak specific interactions. The numerical data obtained by these methods are necessary for predicting at a quantitative level the efficiency of two-phase methods of purification in systems of this kind. The fairly fully developed and universal character of many present-day methods in quantum chemistry makes the approaches described in sections V and VI accessible for the solution of practical problems, including those in the field of extensive purification.

The investigation of the chemical form of impurities in a solution of a substance being purified is also important in connection with the use of complex-forming substances as additives to systems in which the distribution coefficient of

an impurity is close to 1. Selective complex formation should probably also be more widely used in the gas-chromatographic analysis of highly pure substances.

The role of molecular complexes in the preparation of highly pure substances has been examined in the present review for the case of the volatile inorganic hydrides of the elements of groups IIIa–VIIa of the second and third periods, which are important compounds in the preparation of highly pure elements and structures based on them. It can be seen from published data, however, that the intermolecular interactions of different strength in hydrides (particularly in the liquid phase), with a few exceptions (boron hydrides, water, ammonia, hydrogen halides) have as yet been insufficiently studied. There are even fewer published data on the hydrides of the elements of the same groups from the fourth, fifth, and sixth periods. With increase in the requirements to be satisfied by the purity of volatile inorganic hydrides, allowance for the influence of the formation of molecular complexes on the efficiency of extensive purification will become even more necessary. This applies particularly to the extensive purification of inorganic chlorides and organometallic compounds, that is substances whose molecules have a much greater tendency to form molecular complexes than most of the hydrides examined in the present review. Thus both theoretical and experimental work on the detailed study of IMI in systems of this kind is extremely urgent. The data obtained will also undoubtedly increase knowledge of the nature of intermolecular interactions as a whole.

# The Present State and Problems of the Theory of the Kinetics of Electrode Reactions Accompanied by the Adsorption of Inactive Substances and Reagents

V.S.Krylov (deceased), B.B.Damaskin, and V.A.Kir'yanov

Problems in the theoretical description of the influence of the adsorption of dissolved species on the rates of electrode processes have been discussed. Present-day theories of the mechanism of the interaction between adsorbed species and ionic reagents have been used to develop a general statistical-mechanical approach to the quantitative examination of the macrokinetics of heterogeneous transformations complicated by the adsorption of ionic or dipolar components of the solution, including the adsorption of the reagents themselves.
The bibliography contains 84 references.

## I. INTRODUCTION

The adsorption of both electrochemically inactive substances and reagents has a significant influence on the kinetics of electrode processes. Extensive experimental material has now been accumulated on the influence of the adsorption of electrochemically inactive substances on the kinetics of electrode reactions. A number of papers also discuss the problem of the existence of a stage involving the adsorption of the reacting species themselves (the ions or dipolar molecules of an organic depolariser) in the resulting electrode process.

An extensive literature has been devoted to various theoretical approaches to the description of the influence of surface-active substances (SAS) on the rates of electrochemical reactions. As yet, however, there is no unique method of interpreting experimental data in terms of current theories of the nature of the elementary stage in electrochemical processes and the mechanism of reactions between reagents and adsorbed species. At the same time, the problem of the mechanism of the influence of SAS and the kinetics of the adsorption of reagents on the rates of electrochemical reactions is of fundamental importance. The problem of the influence of SAS is closely related to the development of a scientific basis for improving many processes in electrochemical technology. The mechanism of this influence must be known in order to investigate the factors determining the anti-corrosion, flotation, extraction, and other properties of SAS of practical importance. These factors characterise the efficiency of the application of surface-active substances in chemical engineering, technology, and other fields. Most existing approaches to the above theoretical problems are based on the so-called transition state method, in which the original problem is formulated in a general phenomenological basis. A specific method for examining the kinetics of reactions in an adsorption layer has also been developed, based on the thermodynamic theory of "partial charge transfer".

The importance of allowance for the electrical double layer in the description of the kinetics of electrode processes was first pointed out in 1933 by Frumkin. He introduced into the equation for retarded discharge (the Tafel equation) two, now familiar, corrections corresponding to the physical "renormalisation" of two quantities: the electrode potential $\phi_0$ in the exponent in the Tafel equation and the bulk concentration of the reagent $c_{0X}$. The quantity $\phi_0$ was renormalised to $\phi_0 - \psi_1$, and $c_{0X}$ to $c_{0X} \exp[-z_{0X}F\psi_1/RT]$, where $\psi_1$ is the potential in the plane in which the reacting species is situated, $z_{0X}$ its charge, $F$ the Faraday number, $R$ the gas constant, and $T$ the absolute temperature.

The equation for retarded discharge with Frumkin corrections provides a qualitative explanation of the observed regular features of the kinetics of charge transfer, and in some cases it makes possible a quantitative interpretation of the experimental data (the $\psi_1$-potential is usually identified with the potential of the outer Helmholtz plane). When there is adsorption of ions or surface-active organic substances (SAOS), however, it is difficult to explain the experimental data on the basis of the classical theory of retarded discharge. The influence of the specific adsorption of inorganic ions (chloride, bromide, and iodide) on electrochemical kinetics was first observed by Iofa and co-workers.[1] They detected an appreciable decrease in the overpotential of hydrogen liberation on mercury in the presence of these ions. The simple theory of retarded discharge could not explain these facts.

In 1952, Frumkin[2] proposed the following equation for the magnitude of the current in the presence of SAS

$$i = \text{const} \cdot f(\theta) \cdot \exp\left\{-\frac{\alpha n F(\varphi_0 - \psi_1) + z_{0x}F\psi_1}{RT}\right\} \qquad (1)$$

where $f(\theta)$ is a function of the degree of coverage $\theta$ of the electrode surface by the inhibitor, $n$ the number of electrons transferred in an individual step, and $\alpha$ the electron transfer coefficient. If an equation of the type $k = k_0(1 - \theta) + k_1\theta$ [3,4] is taken for the standard reaction rate constant, then when

the condition $k_0 \gg k_1$ is fulfilled, the dependence of the function $f$ on $\theta$ will have the form $f(\theta) = 1 - \theta$.[5] The existence of this relationship means that, other conditions being equal, the probability of the penetration of the reacting species into an adsorption layer containing SAOS is equal to the fraction $1 - \theta$ of the probability of their penetration into the same layer not containing the organic substance. In the electrochemical literature, this factor corresponding to the inhibition of electrode processes by added SAOS has been called, not very systematically, the "blocking effect" (it is assumed that the adsorbed molecules of the SAOS are segregated on the electrode and that they block a fraction of the surface $\theta$, and that the electrochemical reaction takes place only on the free area of the surface, corresponding to the fraction $1 - \theta$).

The expression $f = (1 - \theta)^b$ has been proposed for the function $f(\theta)$,[6] but the parameter $b$ was not given a clearly defined physical significance. In Ref.7 the function $f(\theta)$ was approximated by an expression of the form $f = \exp(-\Delta U/RT)$, where the quantity $\Delta U$ is related to the additional activation energy in the presence of the SAS (the potential barrier due to the hindered penetration of the reagent species into the compact layer).

Since surface-active halide ions have an extremely marked influence on the liberation of hydrogen, it was suggested[8] that the influence of adsorbed anions is not due to a change in the $\psi_1$-potential (in other words, to the $\psi_1$-effect), but is due to a decrease in the activity coefficient of the activated complex.

It was subsequently shown,[9,10] however, that if this suggestion is correct, hydrogen ions will be adsorbed and accumulate on the electrode surface. This is not observed experimentally, however. To eliminate this contradiction, it was suggested[9] that the coefficient $l (l \ll 1)$ be introduced into the equation for retarded discharge:

$$i = \text{const} \cdot \frac{f_{\text{Ox}} c_{\text{Ox}}}{f_{\neq}} l \cdot \exp\left\{-\frac{(\alpha n - z_0) F\psi_1 + \alpha n F\varphi_0}{RT}\right\}. \qquad (2)$$

This coefficient characterises the degree of inhibition of the transfer of an ion from the bulk of the solution into a surface layer with a much lower dielectric constant. In Eqn.(2), the quantities $f_{0X}$ and $f_{\neq}$ represent the activity coefficients of the discharging species in the initial state in the bulk of the solution and in the intermediate complex, and $c_{0X}$ is the bulk concentration of the reagent.

The introduction of the coefficient $l \ll 1$ means that only a small proportion of hydrogen ions penetrates into the compact layer from which discharge takes place, and that the potential of the outer Helmholtz layer changes little, so that no appreciable adsorption of these ions takes place. The coefficient $l$ has been interpreted quantatively.[11,12] Thus according to Ref.12, it is possible to write for the coefficient $l$ the expression $l = l_0 \cdot \exp(-k_D\theta - 2a\tilde{\gamma}\theta)$, where $k_D$ is a coefficient characterising the decrease in the dielectric constant in the compact layer when a SAS is introduced into the solution, and $\tilde{\gamma}$ a coefficient which corrects for the mutual attraction of the reagent species in the compact layer. The problem of the influence of ions undergoing specific adsorption on the kinetics of electron transfer has been discussed repeatedly in the literature. In a study[13] of the influence of electrochemically inactive anions undergoing specific adsorption on the kinetics of electrode processes, it was assumed that it is possible to use Frumkin's equation, in which the $\psi_1$-potential can be identified with the potential in the plane within the compact part of the double layer in which the activated complex is situated. The charge of the specifically adsorbed ions was assumed[13] to be continuously distributed throughout the inner Helmholtz plane. In Ref.14, account was taken of the discrete nature of the specifically adsorbed charge, and the $\psi_1$-potential was identified with the micro-potential at the point where the centre of the activated complex was localised.

The effects of the discrete character of the charge in the kinetics of electrode processes were dealt with in a paper[15] which derived the dependence of $\lg(k_{q_1}/k_0)$ on $q_1$ (here, $k_{q_1}$ is the charge transfer rate constant for a density of specifically adsorbed ions $q_1$, and $k_0$ the rate constant for $q_1 = 0$). The derivation is analogous to that of the equation for retarded discharge with a correction for the double layer. It was assumed[15] that the plane in which the centres of the reagent ions are situated coincides with the inner Helmholtz plane, and the effect of the discrete character of the charge is taken into account both in the calculation of the activity coefficient of the reagent ion and in the calculation of the free energy of activation. In all the works cited, the dependence of $\lg(k_{q_1}/k_0)$ on $q_1$ is linear, whereas the experimental data, at least for the discharge of the hydrogen ion in the presence of iodide ions, give relationships which deviate considerably from linearity, particularly at high values of $q_1$.

For a more detailed explanation of the experimentally observed effect of a marked decrease in the hydrogen overvoltage in the presence of specifically adsorbed halide ions in terms of statistical thermodynamics, a theory was developed[16-18] on the assumption that associates or ion pairs are formed, including the reagent ions and adsorbed inactive species. The effect of an increase in the rate of electrode processes as a result of the association of the reagents with inert ions, predicted in the works cited, shows qualitative agreement with available experimental data.[19-23]

The study of the effects related to the change in the rate of an electrochemical reaction when an organic substance capable of being adsorbed on an electrode surface is introduced into the solution is of considerable practical and theoretical interest. Many studies, mainly experimental, have been carried out in this field, and the results have been discussed in many monographs and reviews.[24-32] Theoretical aspects of the influence of SAOS on electrochemical kinetics have been dealt with.[33-36] An equation has been obtained[37] for the current density $i$

$$i = \text{const} \cdot \bar{\Phi}(\Gamma) \cdot \exp\left\{-\frac{\alpha n F\varphi_0}{RT} + \bar{\gamma}(\varphi_0 - \varphi_m)^2\right\} \qquad (3)$$

which takes account of the stage involving the adsorption of the organic depolariser. The quantities $\bar{\gamma}$ and $\theta_m$ in Eqn.(3) are empirical constants, and $\bar{\Phi}(\Gamma)$ the familiar Gibbs adsorption ($\Gamma$) function of the surface-active substance. The influence of the nature and degree of coverage of an electrochemically inactive organic adsorbate on the kinetics of an electrode process has been studied.[38]

The state of the theory in 1977 and the mechanisms proposed in the literature at that time for the influence of SAOS on the kinetics of electrode processes have been fairly fully reviewed.[35] Here, therefore, only the most widely encountered recent theories will be briefly discussed.

To construct a theory of the influence of SAOS on the kinetics of electrode processes, it has been assumed[32,38] that as a result of the different reaction conditions on regions of the electrode surface occupied by an adsorbate and on unoccupied regions, the surface becomes non-uniform with respect to the electrochemical process. Assuming that the rate of the electrode process on the surface occupied by the adsorbate is independent of $\theta$, the expression

for the rate constant is written in the form $k = k_0(1 - \hat{c}) + k_1\theta$, where $k_0$ and $k_1$ are the rate constants of the process on the regions formally unoccupied and occupied by the adsorbate respectively. On the basis of the theory of absolute reaction rates, the authors cited[32,38] essentially postulated that the quantities $k_0$ and $k_1$ depend on $\theta$ in different ways. In particular, in the range $\theta < 0.9$ with the condition that the composition of the solution, the positions of the centres of the activated complexes, and the mechanism of retarded discharge remain unchanged, the following expression was proposed for $k$:

$$k = k_0(1-\theta)\cdot\exp(-s_1\theta - s_2\theta^\sigma) \quad (4)$$

where the parameters $s_1$ and $s_2$ characterise the electrostatic, orientational, and dispersion interactions in the adsorption layer, and the parameter $\sigma$ takes account of the dependence of the energy of interaction on the distance between the adsorbed species.

A slightly different approach to the problem of the influence of SAOS on the kinetics of electrochemical processes was proposed in Refs.5 and 35. The authors cited also started from the theory of absolute reaction rates, but made a number of additional assumptions. In particular, in accordance with Refs.9 and 10, they introduced into the expression for the rate constant a coefficient $l \ll 1$, which takes account of the inhibition of the stage of ion transfer from the bulk of the solution into the structured surface layer consisting of molecules of the solvent and the SAOS. They also introduced an additional parameter $r$, equal to the number of solvent molecules displaced from the electrode surface by the activated complex. Assuming that the $\psi_1$-potential and the free energy associated with the change in the dielectric constant in the surface layer are linearly dependent on $\theta$, they obtained the following equation:

$$k = k_0(1-\theta)^r\exp(-s\theta) \quad (5)$$

The coefficient $s$ characterises the properties of the surface layer, and takes account of the possibility of specific interaction between the activated complex and the molecules of the adsorbate, and can take both positive and negative values. A similar equation was obtained in Ref.39. The problem of the influence of SAOS on the kinetics of electrode processes has also been examined in terms of the thermodynamics of surface phases;[40] equations of type (5) were again obtained, and various particular cases analysed.

A common unsatisfactory feature of most published work on the problem being discussed is that no sufficiently convincing theoretical basis has been given for the original relationships used to calculate the rates of electrode reactions in the presence of SAS. The semi-empirical or purely phenomenological equations used for specific calculations are often questionable, and in a number of aspects simply unsatisfactory.

In the present review, particular attention has been paid to the analysis of theoretical studies in which attempts have been made to develop a more correct approach to the quantitative examination of electrochemical processes complicated by adsorption phenomena at the metal–electrolyte solution interface. The estimation of the significance of these studies and the extent to which they correspond to real electrochemical systems starts from the fundamental fact that any adequate theory must be based on a correct statistical analysis of the process of going from the elementary act of charge transfer through the metal–solution interface to the resulting rate of the electrochemical process. Thus from the physical viewpoint, a feature of fundamental importance is that, in accordance with the Franck–Condon principle, electron transfer takes place at fixed values of the coordinates of the "heavy" species (ions, molecules) in the system. In the absence of specific adsorption, this transfer takes place at fixed positions of the ions or dipoles in the electrical double layer and in the solution. When specifically adsorbed ions or dipoles are present, however, this transfer takes place at fixed positions of all other heavy species. At the same time it is obvious that the rate of the overall heterogeneous process is averaged over the different configurations of all the heavy species in the system, that is the local probability of electron transfer must be averaged in accordance with the corresponding distribution function of all the "heavy" species in the system.

Another problem, directly related to the previous one, is associated with taking account of the effects of the discrete character of the ion or dipole charges in the system, including species undergoing specific adsorption at the metal–solution interface. Thus the local electric field acting on the discrete particles (ions, dipoles) close to the interphase boundary, as a result of the polarisation of the boundary by these particles, differs from the average field described by the Maxwell equations for a continuous distribution of dipole moments or free charges. The characteristic relaxation times of the forces of the "intrinsic electrostatic image", that is the redistribution times of the bound charges of the solvent on the interfacial surface (as a result of the polarisation of this surface by species present in the solution) are about $10^{-14}$–$10^{-15}$ s. The characteristic times of many types of electrochemical reaction, however, have orders of magnitude comparable with those of the fluctuational reorientation times of dipolar solvent molecules in the solvation layers of reactant ions ($\sim 10^{-11}$ s), that is they are greater by several powers of ten than the relaxation times of the forces of the "intrinsic electrostatic image". Thus the discrete character of the charged species and dipolar molecules adsorbed at the interface should influence the probability of the elementary act of electrochemical processes. Moreover, since the magnitude of the electric field created by the forces of the "intrinsic electrostatic image" depends to a significant extent on the state of the polarisation of the solvent close to the electrode, it follows that in a quantitative examination of the influence of the electric double layer and the effects of the discrete nature of the charge on the rate of electrode processes, an important role should also be played by a physically adequate description of the spatial non-uniformity and dispersion of the dielectric characteristics of the solvent in the layer next to the electrode.

## II. PHENOMENOLOGICAL APPROACH TO THE DESCRIPTION OF THE INFLUENCE OF ORGANIC SURFACE-ACTANTS ON THE RATE OF THE DISCHARGE STAGE

### 1. The Physical Premises of the Theory

As noted above, the adsorption of organic substances has a significant influence on the rate of charge transfer. This influence is due to a number of factors which in the presence of organic substances lead to changes in the concentration of the reactant species in the layer next to the surface and in the activation energy of the electrode process. Thus for example if the adsorbed molecules of an organic substance are uniformly distributed over the electrode surface and the degree of coverage of the surface by these molecules is $\theta$, then the probability of the introduction of the reactant species into the adsorption layer without allowance for all

other factors will be a fraction 1 − θ of the probability of their introduction into the adsorption layer in the solution in the absence of the added organic substance. Under these conditions, the factor 1 − θ can be related to the change in the configurational entropy of activation $\Delta\Delta S^{\neq}$:

$$1-\theta=\exp(\Delta\Delta S^{\neq}/R)$$

The interactions of the reacting species with the molecules of the SAOS and the solvent are generally different. The difference between the energies of these interactions is an additional (energetic) reason for the change in the surface concentration of reactant species in the presence of SAOS. The replacement of some solvent molecules by SAOS molecules close to the reactant species also leads to a change in the energy of reorganisation of the medium, and this in turn brings about a change in the activation energy of the elementary act of discharge. Finally, the adsorption of an organic substance on an electrode leads to a change in the distribution of the electric field of the double layer. In other words, in the presence of SAOS there is a change in the $\psi_1$-potential at the point where the activated complex is localised. It follows from the theory of retarded discharge that a change in the $\psi_1$-potential influences the rate of an electrode process both as a result of a change in the surface concentration of the reactant species (if they are charged) and as a result of a change in the activation energy (in all cases).

In many published studies, the theoretical examination of the problems of the inhibition of electrode reactions by added SAOS has taken account of the individual factors indicated, or some combination of them, with the introduction of appropriate corrections into the final equation of the theory of retarded discharge.

Thus the following equations have been obtained, reflecting the dependence on θ of the ratio $i_\theta/i_{\theta=0}$ where $i_\theta$ and $i_{\theta=0}$ are the current densities of the discharge stage at degrees of coverage of the surface by the SAOS of θ and θ = 0 respectively:

$$i_\theta/i_{\theta=0}=1-\theta \qquad [3—4]$$

$$i_\theta/i_{\theta=0}=(1-\theta)\exp(-s\theta) \qquad [5]$$

$$i_\theta/i_{\theta=0}=(1-\theta)\exp(-s_1\theta-s_2\theta^\sigma) \qquad [38]$$

$$i_\theta/i_{\theta=0}=(1-\theta)^r \qquad [6]$$

$$i_\theta/i_{\theta=0}=(1-\theta)^r\exp(-s\theta) \qquad [35]$$

The inhibition parameters $s$, $s_1$, $s_2$, $\sigma$, and $r$ appearing in these equations in papers by different authors often have a different physical significance, depending on the model used and the assumptions made in the derivation of the equation. To avoid this ambiguity, a different more correct method is used in the present work to derive the fundamental inhibition equation, which does not require the introduction of corrections into the final equation of the theory of retarded discharge and which takes account of the combined adsorption of the reactant substances and the SAOS molecules.

## 2. Derivation of the Fundamental Inhibition Equation

It is assumed that the electrode reaction is the reduction of Ox to Red

$$Ox+ne\rightarrow Red \qquad (6)$$

the rate of which is limited by the discharge stage. Since the current density $i$ is determined by the rate $v$ of reaction (6), it follows from Faraday's law that

$$i=nvF \qquad (7)$$

From the theory of absolute reaction rates, the quantity $v$ can be represented as:

$$v=(kT/h)\varkappa c_{\neq} \qquad (8)$$

Here, $k$ is the Boltzmann constant, $h$ Planck's constant, $\varkappa$ the transmission coefficient, and $c_{\neq}$ the concentration of the activated complex. To use Eqn.(8) for a real electrochemical system in which reaction (6) is taking place, the numerator and denominator are multiplied by the activity coefficient of the activated complex, $\gamma_{\neq}$, and by the activity of the substance Ox in the adsorbed state, $a_{Ox}^{(ads)}$. Substituting the result in Eqn.(7) and taking account of the fact that $c_{\neq}\gamma_{\neq}=a_{\neq}$ gives

$$i=nF\varkappa\frac{kT}{h}\cdot\frac{a_{Ox}^{(ads)}}{\gamma_{\neq}}\cdot\frac{a_{\neq}}{a_{Ox}^{(ads)}} \qquad (9)$$

The theory of absolute reaction rates assumes that equilibrium is established between the original state of the system (the substance Ox in the adsorbed state and $n$ electrons in the metal) and the activated complex. The condition for this equilibrium is given by the expression

$$\bar{\mu}_0^{(ads)}+n\bar{\mu}_e^{(m)}=\bar{\mu}_{\neq}^{(ads)} \qquad (10)$$

relating the electrochemical potentials of the participants. Since the activity of the electrons in the given metal is constant, that is

$$\bar{\mu}_e^{(m)}=\bar{\mu}_e^{0(m)}$$

$$\bar{\mu}_{Ox}^{(ads)}=\bar{\mu}_{Ox}^{0(ads)}+RT\ln a_{Ox}^{(ads)}$$

$$\bar{\mu}_{\neq}^{(ads)}=\bar{\mu}_{\neq}^{0(ads)}+RT\ln a_{\neq}$$

the condition for equilibrium (10) can be rewritten as:

$$-\Delta\bar{G}_{\neq}^0=\bar{\mu}_{Ox}^{0(ads)}+\bar{\mu}_e^{0(m)}-\bar{\mu}_{\neq}^{0(ads)}=RT\ln[a_{\neq}/a_{Ox}^{(ads)}] \qquad (11)$$

where $\bar{\mu}_j^0$ represents the standard electrochemical potentials different components $j$, and $\Delta\bar{G}_{\neq}^0$ the standard electrochemical free energy of activation of process (6). Substituting the ratio $a_{\neq}/a_{Ox}^{(ads)}$ from Eqn.(11) in Eqn.(9) gives

$$i=nF\varkappa\frac{kT}{h}\frac{a_{Ox}^{(ads)}}{\gamma_{\neq}}\exp\left(-\frac{\Delta\bar{G}_{\neq}^0}{RT}\right) \qquad (12)$$

Eqn.(12) is usually the starting point for the derivation of the basic relationships of the theory of retarded discharge. There is lack of agreement among different authors, however, on whether the activation energy $\Delta\bar{G}_{\neq}^0$ contains an electrical component or is determined only by the chemical activation energy. As shown above, the quantity $\Delta\bar{G}_{\neq}^0$ contains both chemical and electrical components.

To use Eqn.(12) it is necessary to obtain explicit expressions for the quantities $\Delta\bar{G}_{\neq}^0$, $a_{Ox}^{(ads)}$, and $\gamma_{\neq}$. The quantity $\Delta\bar{G}_{\neq}^0$ can be calculated using a schematic diagram representing the change in the standard electrochemical free energy of the system along the reaction path (Fig.1). This path, which corresponds to movement along the abscissa, represents provisionally the sequence of states through which the reaction system passes in the course of the reaction described by Eqn.(12).

The initial state *I* corresponds to the component Ox in the volume of the solution and $n$ electrons in the metal; state *II* to the component Ox in the adsorption layer and $n$ electrons in the metal; the state ≠ represents the activated complex (in the adsorption layer); state *III* corresponds to the component Red adsorbed on the electrode; and the final

state *IV* to the same component in the bulk of the solution. It is assumed that the transfer of all $n$ electrons takes place in one elementary act.

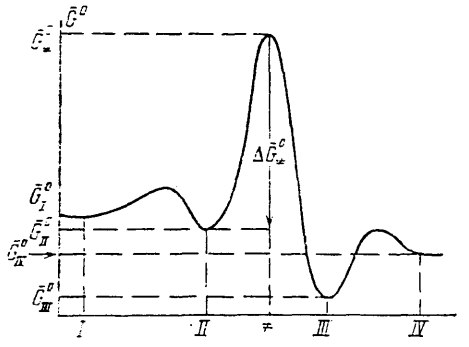

**Figure 1.** Diagram representing the change in the standard electrochemical free energy of a system $\bar{G}^0$ along the reaction path.

Fig.1 shows that $\Delta\bar{G}^0_{\neq} = \bar{G}^0_{\neq} - \bar{G}^0_{II}$. On the other hand, in accordance with Bronsted's principle, several different interpretations of which are possible at present, the standard electrochemical free energy of activation is given by

$$\Delta\bar{G}^0_{\neq} = \Delta\bar{G}^0_{0\neq} + \alpha(\bar{G}^0_{III} - \bar{G}^0_{II}) \qquad (13)$$

where $\alpha$ is the transfer coefficient ($0 \leq \alpha \leq 1$), and the constant $\Delta\bar{G}^0_{0\neq}$ corresponds to the standard free energy of activation with the condition $\bar{G}^0_{II} = \bar{G}^0_{III}$ (see Fig.1).

Analysis of the quantities appearing on the right-hand side of Eqn.(13) shows that the final expression for $\Delta\bar{G}^0_{\neq}$ can be recast in the form

$$\Delta\bar{G}^0_{\neq} = \Delta\bar{G}^0_{0\neq} + \alpha[g_{Ox} - g_{Red} - nF\psi_1 + nF(\varphi_0 - \varphi^0_0)] \qquad (14)$$

where $g_{Ox}$ and $g_{Red}$ are the standard energies of specific adsorption of the species Ox and Red (for positive adsorption, $g_{Ox} > 0$ and $g_{Red} > 0$), and $\phi^0_0$ the standard electrode potential corresponding to reaction (6). Since the standard values of $\Delta\bar{G}^0_{0\neq}$, $g_{Ox}$, $g_{Red}$, and $\phi^0_0$ are independent of the presence of SAOS in the system, it follows that at a given electrode potential ($\phi_0$ = const), the dependence of $\Delta\bar{G}^0_{\neq}$ on $\theta$ is due entirely to the change in the distribution of the electric field in the double layer and is revealed by the corresponding change in the $\psi_1$-potential.

To find the quantities $a_0^{(ads)}$ and $\gamma_{\neq}$ appearing in Eqn.(12), it is assumed that the adsorption of each component of the solution $j$ (except the solvent molecules) is described by isotherms of the form

$$B_j a_j = \frac{\theta_j}{r_j\left(1 - \sum_k \theta_k\right)^{r_j}} \exp\left\{-r_j \sum_k A_{jk}\theta_k + \frac{z_j F\psi_1}{RT}\right\} \qquad (15)$$

Here, $B_j$ is the adsorption equilibrium constant, which depends on the potential; $r_j$ the coefficient of the displacement of the solvent (water) by the component $j$; $A_{jk}$ the constant of the intermolecular interaction between the components $j$ and $k$; and $z_j$ the charge number of the component $j$ (with allowance for the sign).

Eqn.(15) represents a generalised isotherm describing the combined adsorption of both charged and neutral species within one common adsorption layer.

As shown recently,[76] it follows from Eqn.(15) that

$$a_{Ox}^{(ads)} = a_{Ox}\exp\left(\frac{g_{Ox} - z_{Ox}F\psi_1}{RT}\right) \qquad (16)$$

and under conditions in which Ox represents a weakly adsorbed inorganic ion and the solution contains no other surface-active components apart from the SAOS,

$$\gamma_{\neq} = [(1-\theta)^r \exp(rA\theta)]^{-1} \qquad (17)$$

Here, $a_{Ox}$ is the bulk activity of the substance Ox; $r = r_{\neq}$ the coefficient of the displacement of the solvent by the activated complex; $\theta$ the degree of coverage of the surface by the SAOS; and $A$ the constant of the intermolecular interaction between the activated complex and the SAOS molecules.

Substituting Eqns.(14), (16), and (17) in Eqn.(12) gives an expression for the discharge current of reaction (6) in the presence of SAOS:

$$i_\theta = nFk^0_s \cdot \exp\left\{\frac{(1-\alpha)g_{Ox} + \alpha g_{Red} + (\alpha n - z_{Ox})F\psi_{1(\theta)}}{RT}\right\} \times$$
$$\times a_{Ox} \cdot \exp\left[-\frac{\alpha nF(\varphi_0 - \varphi^0_0)}{RT}\right] \cdot (1-\theta)^r \exp(rA\theta) \qquad (18)$$

where $k^0_S = (\kappa kT/h).\exp(-\Delta\bar{G}^0_{0\neq}/RT)$ is the absolute heterogeneous rate constant of the electrochemical reaction.

If the addition of the SAOS does not change the bulk activity of the reaction substance ($a_{Ox}$ = const) and does not change the mechanism of the electrode process ($k^0_S$ = const and $\alpha$ = const), it follows from Eqn.(18) that

$$i_{\theta=0} = nFk^0_s a_{Ox} \cdot \exp\left\{\frac{(1-\alpha)g_{Ox} + \alpha g_{Red} + (\alpha n - z_{Ox})F\psi_{1(\theta=0)} - \alpha nF(\varphi_0 - \varphi^0_0)}{RT}\right\} \qquad (19)$$

Thus for a given $\phi_0$ = const, the following expression is obtained:

$$\frac{i_\theta}{i_{\theta=0}} = (1-\theta)^r \exp\left\{\frac{(\alpha n - z_{Ox})F[\psi_{1(\theta)} - \psi_{1(\theta=0)}]}{RT} + rA\theta\right\} \qquad (20)$$

It is convenient to break down the $\psi_1$-potential into two terms:

$$\psi_1 = \psi_0 + \psi_a \qquad (21)$$

where $\psi_0$ is the potential of the outer Helmholtz plane, which can be calculated from the Gouy–Chapman equation using the experimentally established dependence of the charge on the electrode $q$ on $\theta$. For the quantity $\psi_a$, in a first approximation, a linear dependence on $\theta$ is postulated:

$$\psi_{a(\theta)} = \psi_{a(\theta=0)} - k'\theta \qquad (22)$$

where $k'$ is a constant determined by the position of the activated complex in the compact layer and by the dielectric properties of the latter.

With allowance for Eqns.(21) and (22), Eqn.(20) can be transferred to

$$\frac{i_\theta \cdot \exp[-(\alpha n - z_{Ox})F\psi_{0(\theta)}/RT]}{i_{\theta=0} \cdot \exp[-(\alpha n - z_{Ox})F\psi_{0(\theta=0)}/RT]} = (1-\theta)^r \exp(-s\theta) \qquad (23)$$

where $s$ is the inhibition parameter, equal to

$$s = k'(\alpha n - z_{Ox})F/RT - rA$$

The parameter $s$ reflects both the electrostatic and the "chemical" interaction of the activated complex with the adsorption layer. The other inhibition parameter, $r$, is related to the change in the configurational entropy of

activation $\Delta s^{\neq}$:

$$r \ln(1-\theta) = \Delta(\Delta S^{\neq}/R)$$

Thus examination of the derivation of the fundamental equation of the theory of retarded discharge under the conditions of SAOS adsorption gives Eqn.(23), the right-hand side of which has the form proposed in Ref.35. As shown by the present authors, however, the left-hand side should contain not the usual values of the discharge currents $i_\theta$ and $i_{\theta=0}$ but the corresponding quantities with a correction for the change in the potential of the outer Helmholtz plane in the presence of SAOS. This correction is easily introduced by means of the Gouy–Chapman equation using the experimentally determined dependence of $q$ on $\theta$. Thus for example in the case of a solution containing an excess of a surface-inactive 1,1-valent electrolyte with a concentration $c_{el}$,

$$\psi_0 = (2RT/F)\,\mathrm{arcsh}[q/(8\varepsilon_0\varepsilon RT c_{el})^{1/2}]$$

where $\varepsilon_0$ is the dielectric constant of a vacuum, and $\varepsilon$ the dielectric constant of the solvent.

## III. LOCALISED ADSORPTION OF IONS AND DIPOLAR MOLECULES

In this section, the statistical-mechanical theory of irreversible electrochemical processes complicated by the localised adsorption of inactive ions and molecules is discussed. A central problem in the development of a statistical-mechanical theory describing the influence of SAS on the kinetics of electrochemical processes is the development of an adequate approach to the statistical averaging of the probability of the elementary act of electron transfer over the entire ensemble of "heavy" species in the system. The principles of this approach were described in papers[41,42] dealing with allowance for the influence of the local electric field of the double layer in the equations for the statistical averaging of the probability of the elementary act. In particular, it was shown that the problem of finding the statistically averaged density of the current generated in the elementary act of an electrochemical process can be solved satisfactorily only in two cases: 1) when the electrochemical process does not break down the statistical equilibrium either with respect to the reactants or with respect to the ions of the inactive electrolyte, and 2) when there is no equilibrium with respect to the reacting species, but the reaction takes place in an excess of an electrochemically indifferent electrolyte. The latter should be distributed in space in a quasi-equilibrium fashion, in the sense that its local concentration at each fixed moment of time should be described by the Boltzmann equation, and the magnitude of the field is determined by the instantaneous (not necessarily equilibrium) value of the electrode potential.

The extension of these methods to systems with specific adsorption of ionic and dipolar components of the solution, including the adsorption of reactant species, pointed the way to the development of a quantitative theory of electrochemical kinetics in the presence of SAS.[43–57,60,63,71] This theory takes unified account of inter-particle interaction in an adsorption layer, the influence of the fine structure of the electrical double layer and the influence of the discrete nature of adsorbed ionic or dipolar charges, etc. on the averaged kinetic characteristics of the process.

To illustrate the essential features of the present theory, the irreversible electrochemical reaction of one-electron transfer (6) for $n = 1$, that is the reaction $Ox_z + e \to Red_{z-1}$, where the indices $z$ and $z-1$ of Ox and Red denote the charges of the corresponding ions†, can be considered. It is assumed below that this reaction takes place under conditions in which the centres of specifically adsorbed electrochemically inactive ions are situated within the Helmholtz layer or, more accurately, the reaction layer ($-\beta \leqslant x \leqslant \gamma$ and $\delta = \beta + \gamma$, where $\delta$ is the thickness of this layer).

It will be assumed that the positions of the centres of the adsorbed ions are characterised by the coordinates $\mathbf{r}_1, \ldots, \mathbf{r}_M$ (in the general case, $\mathbf{r}_K$ also denotes all other degrees of freedom of the particles, so that, for example, for dipolar molecules, it includes the orientational and other degrees of freedom of the given particles). The positions of all other species of the solution, including the reactant ions, will be denoted $\mathbf{R}_1, \ldots, \mathbf{R}_N$.

According to the general principles of the theory of the kinetics of heterogeneous processes, the probability $W$ of the elementary act of interphase electron transfer is an exponential function of the activation energy of the process $E_a$:

$$W(\mathbf{R}_1, \ldots, \mathbf{R}_N, \mathbf{r}_1, \ldots, \mathbf{r}_M) = \bar{O}x(\mathbf{R}_1)\cdot\exp(-E_a/kT) \qquad (24)$$

where $\bar{O}x(\mathbf{R}_1)$ is a function which includes the transmission coefficient for the given process. The factor $\bar{O}x = \bar{O}x_z$ is specially distinguished here, since the probability being considered is that of electron transfer to the ion $Ox = Ox_z$ situated at the point $\mathbf{R}_1$, and this factor contains the strongest dependence of $W$ on $\mathbf{R}_1$. The dependence of $E_a$ on the heat of reaction $\Delta I$, however, can be described either strictly quantum-mechanically[58,59] or using the Bronsted relationship. In the general case, the Bronsted relationship is non-linear $E_a = E_a(\Delta I)$, but there is often a linear relationship between $E_a$ and $\Delta I$, that is $E_a = E_a^0 + \alpha\cdot\Delta I$, where $\alpha$ is the transfer coefficient.

From $\Delta I$ it is appropriate to separate the quantity $\Delta I_0$, which is defined by the relationship

$$\Delta I_0(\varphi_0, \mathbf{R}_1) = E_{Ox} - E_m + E_{Red}^{(solv)} - E_{Ox}^{(solv)} + e\varphi_0 + U_{Red}^{(im)}(\mathbf{R}_1) - U_{Ox}^{(im)}(\mathbf{R}_1) \qquad (25)$$

and which takes specific account of the stage of electron transfer from the energy level $E_m$ in the metal to the level $E_{Ox}$ in the ion $Ox = Ox_z$. Thus the total heat of the reaction is written as:

$$\begin{aligned}\Delta I(\mathbf{R}_1, \ldots, \mathbf{R}_N, \mathbf{r}_1, \ldots, \mathbf{r}_M) &= \Delta I_0(\varphi_0, \mathbf{R}_1) + \\ &+ [V_{Red}(\mathbf{R}_1, \ldots, \mathbf{R}_N) - V_{Ox}(\mathbf{R}_1, \ldots, \mathbf{R}_N)] + \\ &+ [\Omega_{Red}(\mathbf{R}_1, \mathbf{r}_1, \ldots, \mathbf{r}_M) - \Omega_{Ox}(\mathbf{R}_1, \mathbf{r}_1, \ldots, \mathbf{r}_M)]\end{aligned} \qquad (26)$$

In Eqns.(25) and (26), the quantities $E_{Red}^{(solv)}$ and $E_{Ox}^{(solv)}$ are the solvation energies of the ions Red and Ox, $\phi_0$ the electrode potential (relative to the bulk of the solution it can be taken as zero), $U_{Red}^{(im)}$ and $U_{Ox}^{(im)}$ the energies of the interactions of the ions Red and Ox with the "electrostatic images" of these ions in the metal and in the electrolyte solution, and $V_{Red}$ and $V_{Ox}$ the energies of the interactions of the ions Red and Ox with the adsorbed ions and the "electrostatic images" of the latter in the metal and solution.

---

†Here and subsequently, for uniformity of indexing, this method will be used to represent the reaction which in Refs.43–57 and subsequent papers is represented as $A^z + e \to B^{z-1}$, that is, subsequently, $Ox = Ox_z$ will be written throughout instead of $A^z$, and $Red = Red_{z-1}$ instead of $B^{z-1}$.

The probability of the elementary act $W$ is related to the current density $i$ passing through the system by the expression

$$i = e[\mathrm{Ox}]f\langle W\rangle \qquad (27)$$

where [Ox] is the total number of reactant ions in the solution, and $f = f(\theta)$ a factor which allows for the "effective area" of the electrode surface on which the reaction can take place. The angle brackets denote the operation of statistical averaging of the quantity $W$ over the entire system of "heavy" species present in the solution, including specifically adsorbed species. For the general case of an arbitrary non-linear dependence of $E_a$ on $\Delta I$, the quantity $\langle W\rangle$ is conveniently represented[50] as a contour integral in the complex plane, which in a number of cases is effectively calculated by the method of steepest descent.

It should be emphasised that the averaging of the quantity $W$ depends to a significant extent on the form of the distribution function $D_{N+M}$ of all $N + M$ "heavy" species in the system. At a low concentration of reactant ions, the function $D_{N+M}$ can be written as $D_{N+M} = \Phi_Z(\mathbf{R}_1).D_{N-1,M}$, where $\Phi_Z(\mathbf{R}_1)$ is the one-particle distribution function of the ions $\mathrm{Ox}_Z$, and $D_{N-1,M}$ the distribution function of all other species, with the condition that the reactant ion Ox is situated at the point $\mathbf{R}_1$. The form of the function $D_{N-1,M}$ in turn depends on the nature of the adsorption. The following three physical situations are possible in principle:[50] a) during the characteristic time of the electrochemical reaction, the adsorbed ions remain at the points where they are localised on the electrode surface, that is they act as sources of an additional external field; (b) adsorption is reversible, and in the characteristic time of the electrochemical reaction, equilibrium can be established between the adsorbed ions and the ions in the bulk of the solution; c) in the characteristic time of the electrochemical process, the adsorbed ions are unable to exchange with the ions in the bulk of the solution.

The results for case (a) are given below. In this case

$$\langle W\rangle = \int W(\mathbf{R}_1, \ldots, \mathbf{R}_N, \mathbf{r}_1, \ldots, \mathbf{r}_M)\, D_{N+M}(\mathbf{R}_1, \ldots, \mathbf{R}_N, \mathbf{r}_1, \ldots, \mathbf{r}_M) \times \times \mathrm{d}\mathbf{R}_1 \ldots \mathrm{d}\mathbf{R}_N \qquad (28)$$

and the final result can be represented as

$$i = i_{z-\alpha}(\varphi_0, \theta) \cdot f(\theta) \cdot \exp\{-\Omega_{z-\alpha}(\theta)/kT\} \qquad (29)$$

$$_{-\alpha}(\varphi_0, \theta) = \mathrm{const} \cdot \exp\left\{-\frac{E_a^{(0)} + \alpha e\varphi_0}{kT}\right\} \cdot \exp\left(\frac{\Delta U^{(*)} + F_z - F_{z-\alpha}}{kT}\right) \Phi_{z-\alpha}(x_0) \qquad (30)$$

$$\Omega_{z-\alpha}(\theta) = \frac{e^2 z_0 (z-\alpha)}{\epsilon_{\mathrm{pl}}} \sum_{(m,n)} \int_0^\infty \chi(\lambda) \cdot \exp(-\lambda x_0) \cdot J_0(\lambda R_{mn})\, \mathrm{d}\lambda \qquad (31)$$

here $z_0$ is the charge of the adsorbed ion, $\varepsilon_{\mathrm{pl}}$ the effective dielectric constant of the reaction region, $J_0(x)$ the Bessel unction of the first kind of zeroth order, $R_{mn}$ the distance rom the centre of the ion Ox (in the adsorption plane) to n arbitrary ion having coordinates ($\xi_{mn}$, $\eta_{mn}$) in this lane, $\chi(\lambda)$ a definite function of the integration variable , and the summation is carried out over the entire system adsorbed ions. The plane $x = x_0$ corresponds to the stance of the most probable point for the discharge of the ns from the electrode, and the quantity $\Delta U^{(*)}$ is a mbination of the quantities $U_{\mathrm{Ox}}^{(\mathrm{im})}$ and $U_{\mathrm{Red}}^{(\mathrm{im})}$ at the point . The quantities $F_Z$ and $F_{Z-\alpha}$ are the partial free ergies of the system of ions present in the solution, nus the energy of the interaction of an ion having a harge $ez$ or $e(z - \alpha)$ respectively with the "intrinsic ectrostatic image" in the metal and the solution, $\Phi_{Z-\alpha}(x_0)$ the paired distribution function of the ions; and $\Omega_{Z-\alpha}(\theta)$ e energy of the interaction of the discharging ion with all the adsorbed ions (and their "electrostatic images" in the metal and the solution), which is calculated for the transition state of the discharging ion, characterised by the "effective charge" $e(z - \alpha)$. Under the conditions of the localised adsorption of ions it is necessary to examine in principle both the regular distribution of their adsorption centres (for example the ionic lattice model) and random distribution of the adsorption centres. In a number of cases, the calculations of $\Omega_{z-\alpha}$ are simplified by using the so-called "cut-out disc model"[77] and replacing the summation, for example in Eqn.(31), by integration according to the scheme:

$$\sum_{m,n} J_0(\lambda R_{mn}) \to 2\pi\Gamma_\infty\theta \int_{r_0}^\infty \rho J_0(\lambda\rho)\, \mathrm{d}\rho \qquad (32)$$

where $r_0$ is the radius of the cut-out disc, which depends on the degree of coverage $\theta$, and $\Gamma_\infty$ is the limiting coverage of the adsorption layer. This model is naturally an approximation to the real situation.

A specific calculation based on the above procedure, carried out in Refs.46 and 47, with the condition that there is a linear relationship between $E_a$ and $\Delta I$, gives the following expression for the rate of the electrochemical process:

$$i = \mathrm{const} \cdot f(\theta) \cdot \exp\left\{-\frac{\alpha e[\varphi_0 - \varphi(x_0, \theta)] + \Omega_{z-\alpha}(\theta)}{kT}\right\} \qquad (33)$$

It was assumed that the discharge takes place from the compact part of the electrical double layer, and that the solution contains an excess of a background electrolyte, so that the diffuse character of the double layer can be neglected (the last assumption is more justified, the smaller the ratio $\varepsilon_{\mathrm{pl}}/\varepsilon_0$, where $\varepsilon_0$ is the dielectric constant of the diffuse region of the double layer). In Eqn.(33), $k$ is the Boltzmann constant, and $\phi(x_0, \theta)$ is the potential of the plane in which the ion Ox is situated, and depends on the degree of coverage of the layer $\theta$ by adsorbed ions. The latter are situated in the adsorption plane $x = 0$; ($\xi_{mn}$, $\eta_{mn}$) are the coordinates of the adsorbed ions in this plane.

The physical significance of the quantity $\Omega_{z-\alpha}$ in Eqn.(33) was explained above, and the next task is the specific calculation of this quantity. In Ref.56 it was calculated with allowance for the effect of the penetration of the electric field into the metal (that is the double layer in the metal itself, or in other words the "electron condenser" factor together with the "molecular dipole condenser" in the solution phase of this interphase boundary):

$$\Omega_{z-\alpha}(\theta) = \frac{e^2 z_0 (z-\alpha)}{\epsilon_{\mathrm{pl}}} \cdot \sum_{m,n} \left\{(R_{mn}^2 + x_0^2)^{-1/2} - \right.$$
$$\left. - [R_{mn}^2 + (x_0 - 2\gamma)^2]^{-1/2} - \int_0^\infty \Lambda(x_0, \lambda) \cdot J_0(\lambda, R_{mn})\, \mathrm{d}\lambda\right\} \qquad (34)$$

Here, $R_{mn} = (\xi_{mn}^2 + \eta_{mn}^2)^{1/2}$, and the function $\Lambda(x_0, \lambda)$ under the integral sign has the form

$$\Lambda(x_0, \lambda) = \frac{[\exp(2\lambda\gamma) - 1] \cdot \{\exp[\lambda(x_0 - 2\gamma)] - \exp(-\lambda x_0)\}}{\left[1 + \left(\frac{2}{\nu} - 1\right) \cdot \exp(2\lambda\delta)\right]} \qquad (35)$$

and

$$\nu = \nu(\lambda) = 1 - (\epsilon_{\mathrm{pl}}\lambda)^{-1} \varepsilon_s (\lambda^2 + \kappa_{\mathrm{m}}^2)^{1/2} \qquad (36)$$

$$\Delta\varphi_s - \kappa_{\mathrm{m}}^2 \phi_s = 0 \qquad (37)$$

In the derivation of Eqns.(34)–(36), the electron density distribution in the region of the metal next to the surface was described in the Thomas–Fermi linear approximation (37); $\varepsilon_S$ is the short-wave ("optical") dielectric constant of the metal, characterising the polarisability of the valence electrons of the ionic core of the metal; $\kappa_{\mathrm{m}}^{-1}$ the Thomas–Fermi length for the electrons of the metal (for

a number of metals, the value of $\varepsilon_s$ is close to 1, and the value of $\kappa_m^{-1}$ is ~1 Å). The Thomas–Fermi distribution of electrons in the metal is the simplest model of the double layer in the metal, but it makes it possible to reveal the principal physical aspects of the phenomenon. A more rigorous but mathematically much more complex approach to this problem involves taking account of collective effects in the shielding, allowance for the discrete nature of the ion charge in the metal itself, and other factors.

In Refs. 46 and 47, the following equation was obtained for calculating the quantity $\Omega_{z-\alpha}$ in Eqn. (33) for the inactive ion adsorption conditions being considered:

$$\Omega_{z-\alpha}(\theta) = \frac{e^2 z_0 (z-\alpha)}{\varepsilon_{pl} x_0} - \frac{e^2 z_0 (z-\alpha)}{\varepsilon_{pl}\delta}\left[\Psi\left(\frac{2\delta - x_0}{2\delta}\right) + \Psi\left(\frac{2\delta + x_0}{2\delta}\right) - \Psi\left(\frac{2\gamma - x_0}{2\delta}\right) - \Psi\left(\frac{2\beta + x_0}{2\delta}\right)\right] + \frac{4e^2 z_0 (z-\alpha)}{\varepsilon_{pl}\delta} \sum_{m,n} \sum_{p=1}^{\infty} \sin\left(\frac{\pi p \beta}{\delta}\right) \cdot \sin\left[\frac{\pi p (x_0 + \beta)}{\delta}\right] \cdot K_0\left(\frac{\pi p}{\delta} R_{mn}\right) \quad (38)$$

Here, $\Psi$ is the Euler psi-function, and $K_0(x)$ the zeroth-order McDonald function, which, as in higher orders, has an exponential asymptote at large values of the argument.

The statistical-mechanical theory developed in Refs. 41 to 47 reveals the mechanism of the influence of the electric field, created by specifically adsorbed ions, on the rate of electrode processes. In Eqn. (38) the local electric field appearing in the statistically averaged probability of electron transfer corresponds to the effective configuration of the ionic components of the solution close to the given reactant ion which would be in equilibrium with the reactant if the charge on the latter were $e(z - \alpha)$. The ion with charge $e(z - \alpha)$ is in a certain sense the analogue of the activated complex appearing in the theory of absolute reaction rates. Contrary to the conclusions of this theory, however, the resulting rate of the electrode process is determined by the local electric potential, and not by the average potential corresponding to continuously distributed ionic charges.

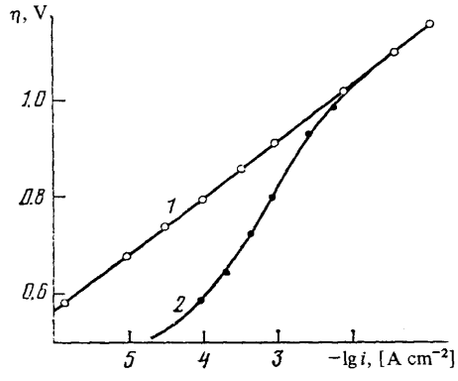

**Figure 2.** Polarisation curves for the discharge of hydrogen ions on mercury from aqueous solutions of 1 M HCl + 2 M KCl (*1*) and 1 M HCl + 2 M KI (*2*); continuous lines—result of the theoretical calculation.[46,47]

In Refs. 46 and 47, the results of calculations based on Eqns. (33) and (38) were used to describe the experimental data from Refs. 1 and 64 on the kinetics of the discharge of hydrogen ions on mercury from mixed aqueous HCl + KCl and HCl + KI solutions. The pre-exponential constant appearing in Eqn. (33) was determined by combining the experimental and theoretical curves in the range of the desorption of the iodide ions. The quantity $x_0$ was used as the fitting parameter of the theory. Quantitative agreement between theory and the experimental data was achieved for the following values of the remaining parameters: $\alpha = 0.5$, $\beta = \gamma = 2.3$ Å, $\Gamma_\infty = 6 \times 10^{14}$ cm$^{-2}$, $\varepsilon_{pl} = 8$, $x_0 = 1.5$ Å (see Fig. 2).

A more detailed analysis of the applicability of Eqns. (33) and (38) for interpreting published data on the influence of the adsorption of ions on the rates of electrochemical reactions were carried out in Refs. 65 and 66. In particular, it was shown that Eqn. (38) gives good agreement between theory and experimental data when the charges on the inactive adsorbed ions and the reactant ions have the same sign. It should be noted, however, that the agreement between theory and experimental data obtained in Refs. 65 and 66 was achieved using additional model representations not present initially in the theoretical equations (33) and (38).

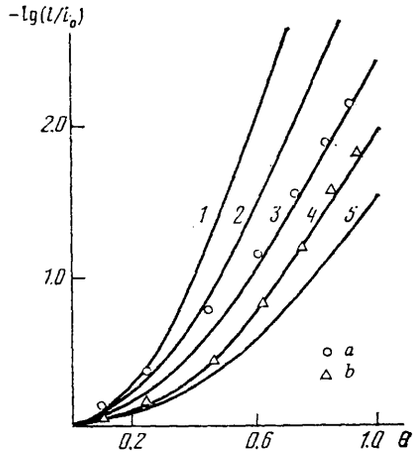

**Figure 3.** Inhibition of the electroreduction of cadmium cations in the presence of t-butylamine (*a*) and t-butyl alcohol (*b*); the continuous lines give the results of the calculation with the following fixed values of the parameters: $\alpha = 0.5$, $\delta = 3$ Å, $\Gamma_\infty = 1.5 \times 10^{14}$ cm$^{-2}$, $x^0 = 1.5$ Å, $z = 2$, $z_0 = 1$, $\varepsilon_{pl} = 8$ and different $x_a = 0.5$, 1.0, 1.5, 2.0, and 2.5 Å (curves *1*–*5* respectively).

Fig. 3 gives the experimental data obtained[67] by measuring the currents for the electrochemical reduction of cadmium cations at a mercury electrode from concentrated aqueous $HClO_4$ solution in the presence of added t-butylamine and t-butyl alcohol. Since these surface-active substances can be adsorbed on mercury from an acidic medium in two forms, neutral and cationic, the rates of the electroreduction were calculated using Eqns. (33) and (38), which take account of the ionic nature of the adsorbed species. Since the theoretical equations contain several parameters for which no reliable experimental values exist (these parameters are, for example $\varepsilon_{pl}$, $\delta$, $\alpha$, $x_0$, $x_a$), the calculations are qualitative. The main aim was to establish the general trend in the influence of cationic SAS in relation to their

position relative to the electrode surface. This problem was solved by constructing a series of curves corresponding to a fixed distance $x_0$ (for constant values of all other parameters of the theory) for varying distances $x_a$. The results of the calculations (see curves *1–5* in Fig. 3) indicate that the inhibition effect increases with decrease in $x_a$. A qualitatively different dependence of the rate of electrolytic reduction on the degree of coverage is observed when the charges on the ions of the adsorbate and the depolariser have different signs.[66,68] This case is examined theoretically in the next section.

The physical principles on which the derivation of Eqn. (33) was based have been used[48,49] to describe the kinetics of electrochemical reactions in the presence of adsorbed inactive dipolar molecules. In the case of the localised adsorption of dipolar molecules, the rate of the electrochemical process is described by Eqn. (39), which is analogous to Eqn. (33):

$$i = i_0(1-\theta)\cdot\exp\left\{\frac{1}{kT}\left[\frac{4\pi e(z-\alpha)\mu x_0\Gamma_\infty\theta}{\epsilon_{pl}\delta} - \Omega_{z-\alpha}(\theta)\right]\right\} \qquad (39)$$

where

$$\Omega_{z-\alpha}(\theta) = \frac{4\pi e(z-\alpha)\mu}{\epsilon_{pl}\delta^2}\sum_{m,n}\cos\sigma_{mn}\sum_{p=1}^{\infty} p\sin\left(\frac{\pi p x_0}{\delta}\right)\times$$
$$\times\cos\left(\frac{\pi p x_a}{\delta}\right)K_0\left(\frac{\pi p}{\delta}\cdot R_{mn}\right) + \frac{4\pi e(z-\alpha)\mu}{\epsilon_{pl}\delta^2}\sum_{m,n}\sin\sigma_{mn}\times$$
$$\times\cos\gamma_{mn}\sum_{p=1}^{\infty} p\cdot\sin\left(\frac{\pi p x_0}{\delta}\right)\cdot\sin\left(\frac{\pi p x_a}{\delta}\right)\cdot K_1\left(\frac{\pi p}{\delta}R_{mn}\right) \qquad (40)$$

The current density $i_0$ corresponds to the absence of adsorbed dipoles. $\mu$ denotes the dipole moment of the adsorbed molecule, and $\mu > 0$ if the dipole is oriented with its negative pole towards the electrode surface; $\sigma_{mn}$ and $\gamma_{mn}$ are the angles characterising the orientation of the dipole with respect to the electrode surface and the reactant ion; and $x_0$ and $x_a$ the positions of the planes in which the centres of the reactant ion and the adsorbed dipoles are localised.

As expected, in the theories adopted for the structure of the adsorption layer, the functional dependence $i(\theta)$ contains in explicit form the values of the angles of orientation of the adsorbed dipoles relative to the electrode surface.[48,49] To determine the influence of the spatial orientation of the adsorbed dipolar molecules on the rate of discharge of the cations, Eqns. (39) and (40) were used to construct two series of curves. The following parameters were unchanged in all the calculations: $\alpha = 0.5$, $\delta = 4$ Å, $x_a = 3$ Å, $x_0 = 2$ Å, $\varepsilon = 8$, $\mu = -1.6$ D, $\Gamma_\infty = 1.5\times10^{14}$ cm$^{-2}$, $z = 2$. Fig. 4*a* gives three curves corresponding to the fixed angle $\sigma_{mn} = 45°$ and three different angles $\gamma_{mn}$: 120°, 90°, and 60° (curves *1*, *2*, and *3* respectively). The influence of the angle $\sigma_{mn}$ (for a fixed angle $\gamma_{mn} = 90°$) is shown in Fig. 4*b*, where curves *1–5* correspond to the angles $\sigma_{mn} = 15°$, 30°, 45°, 60°, and 90°. In the calculation it was assumed that the centres of the adsorbed molecules form a regular two-dimensional hexagonal lattice and that the reactant ion is situated at the centre of an equilateral triangle formed by three adjacent dipoles. Comparison of the two series of curves in Figs. 4*a* and 4*b* shows that the influence of the orientation of the dipoles relative to the reactant ion is stronger than the influence of the angle of inclination to the plane of the electrode.

As in the case of adsorbed inactive ions examined above, the aim of the authors cited[48,49] was not a quantitative comparison of theory with available experimental data (a comparison of this kind has been carried out,[48,51] and gave positive results). It appears much more important and useful to demonstrate the fundamental predictive possibilities of the theory and to analyse the sensitivity of the analytical relationships obtained above to change in the model parameters. The qualitative analysis carried out shows that a satisfactory description of the experimental data can be obtained with completely realistic values of the parameters. In particular, data on the kinetics of the discharge of cadmium and zinc ions in the presence of n-butanol[6,69,70] agree well with the results of a calculation based on Eqns. (39) and (40) and using the values of $\delta$, $\alpha$, $\varepsilon$, $x_0$, and $x_a$ most frequently encountered in the literature for systems of this kind (see Refs. 48 and 51).

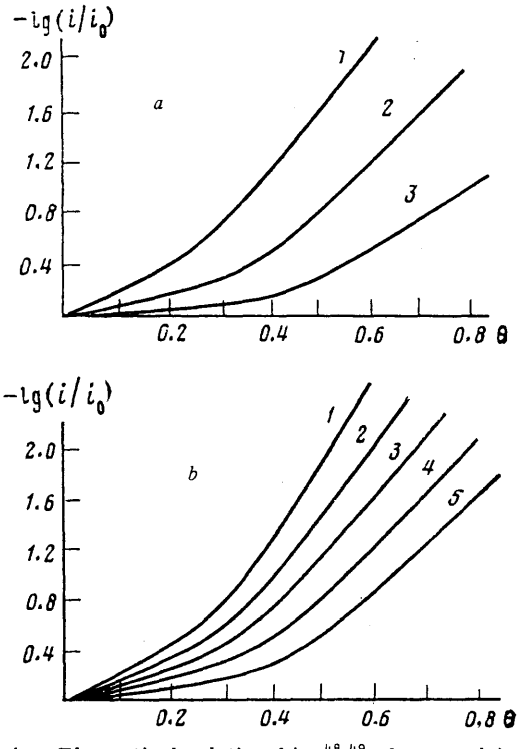

**Figure 4.** Theoretical relationships[48,49] characterising the effect of the inhibition of an electrode process by adsorbed dipolar molecules (the reduction of doubly-charged cations on mercury in the presence of molecules with $\mu = -1.6$ D, oriented mainly with the positive pole towards the electrode): *a*) influence of the orientation of the dipole relative to the reactant ion; *b*) influence of the orientation of the dipole relative to the electrode surface.

Analysis of Eqn. (39) shows that in those cases where the contribution of the interaction described by the term $\Omega_{z-\alpha}(\theta)$ predominates, an increase in the rate of the electrode process by adsorbed SAS is possible.[71] This effect should increase in systems in which the structure of the compact part of the double layer is such that the discharge plane of the ions is situated closer to the poles of the dipoles whose sign is the opposite of that of the charge on the discharging ions. A double-layer structure of this kind is apparently characteristic of the system studied in Ref. 72, where a considerable increase in the rate of the discharge of europium ions on mercury from aqueous N,N-dimethylformamide solutions was observed. A number of other systems in which

the adsorption of organic molecules leads to an increase in the rate of electrochemical processes have been described.[33,73–75]

To explain the experimental data,[72] the authors cited obtained the following equation describing the kinetics of the discharge of the ions $ez$ in this system:

$$i = i_0(1-\theta)\exp\left\{-\frac{e(z-\alpha)\Delta\varphi_{ads}+\Omega_{z-\alpha}(\theta_1,\theta_2)}{kT}\right\} \quad (41)$$

Here, $\theta = \theta_1 + \theta_2$ is the total degree of coverage, and $\Delta\phi_{ads}$ the adsorption potential jump, given by:

$$\Delta\varphi_{ads} = -\frac{4\pi}{\epsilon_{pl}\delta}[\mu_1\Gamma_{1,\infty}(\delta - x_0)\theta_1 - \mu_2\Gamma_{2,\infty}x_0\theta_2] \quad (42)$$

The energy of the electrostatic interaction of the reactant ion in the transition state, corresponding to the charge $e(z-\alpha)$, and the adsorbed species is given by the expression:

$$\Omega_{z-\alpha}(\theta_1,\theta_2) = \frac{4\pi e(z-\alpha)}{\epsilon_{pl}\delta^2}\sum_{p=1}^{\infty} p\cdot\sin\left(\frac{\pi p x_0}{\delta}\right)\left\{\mu_1\cdot\cos\left(\frac{\pi p x_1}{\delta}\right)\sum_{m_1,n_1}K_0\left(\frac{\pi p}{\delta}R_{m_1n_1}\right) + \right.$$
$$\left. + \mu_2\cdot\cos\left(\frac{\pi p x_2}{\delta}\right)\sum_{m_2,n_2}K_0\left(\frac{\pi p}{\delta}R_{m_2n_2}\right)\right\} \quad (43)$$

where the summation with respect to the indices $m_k$, $n_k$ should be carried out in the corresponding adsorption plane ($x = x_1$ or $x = x_2$). With allowance for these results, Eqns.(41)–(43) were used to calculate the dependence of the ratio $i/i_0$ on the relative concentration of the organic phase in the water–organic solvent system.

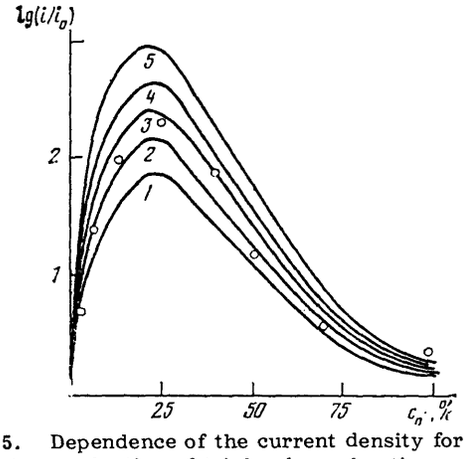

**Figure 5.** Dependence of the current density for the one-electron reduction of triply-charged cations on the relative composition of the mixed solvent, calculated from Eqns.(39) and (40) ($c_0$ is the concentration of the organic solvent); curves *1–3* correspond to values of the dipole moment $\mu$ equal to −2.5, −3.2, −3.9, −4.6, and −5.3 D; the experimental points were taken from Ref.72.

In the calculations it was assumed that in the adsorbed state the dipole moments of the molecules of both solvents are oriented at right angles to the electrode surface (the water molecules with their negative poles towards the electrode, and the organic molecules with their positive poles) and are fixed at the points of a rigid hexagonal lattice. In addition, it was assumed that $\alpha = 0.5$, $x_1 = 1$ Å, $x_0 = 2$ Å, $x_2 = 3$ Å, $\delta = 5$ Å, $\Gamma_{1,\infty} = 5.5 \times 10^{14}$ cm$^{-2}$, $\Gamma_{2,\infty} = 1.2 \times 10^{14}$ cm$^{-2}$, $\mu_2 = 1.8$ D; the value of $\mu_1$ (the dipole moment of the molecule of the organic solvent) was varied from −2.5 D to −5.3 D. The results of the calculations[48,49] are given in Fig.5, which also gives the experimental points obtained for the water–N,N-dimethylformamide system in Ref.72. The simplified character of the picture of the structure of the electrical double layer assumed in the calculations, and the extremely approximate nature of the parameters used, do not provide a basis for a quantitative comparison of the results of the calculation with experimental data. Qualitative agreement can be seen, however, between the theoretical curves in Fig.5 and the experimental data.[72]

The general statistical-mechanical approach described above can be used to calculate the rates of electrochemical processes with allowance for the combined adsorption of several different SAS. Effects of this kind are reflected in the form of the curves giving the dependence of the current density on the degree of coverage.[78] With an adequate quantitative theory, the form of these curves can be used to obtain information on the composition of the adsorption layers next to the electrode.

A method has been proposed[57] for including the effects of the combined adsorption of two surface-active substances in the description of the kinetics of an electrode reaction. A model of the structure of the adsorption layer with two planes ($x = x_1$ and $x = x_2$) in which the centres of the adsorbed species (ions or dipolar molecules) are localised, and a discharge plane $x = x_0$ was examined. This model was used to derive a kinetic equation analogous to Eqn.(41). Cases of the combined adsorption of two different ions or two different dipoles, and also of individual ions with charge $ez_1$, and dipoles (for which the projection of the dipole moment on the perpendicular to the plane of the electrode was $\mu = \mu_1$) were examined. For the last case, in particular, the energy $\Omega_{z-\alpha}(\theta_1, \theta_2)$ is given by the expression:

$$\Omega_{z-\alpha}(\theta_1,\theta_2) = \frac{4\pi e(z-\alpha)\mu}{\epsilon_{pl}\delta^2}\sum_{m_1,n_1}\sum_{p=1}^{\infty} p\cdot\sin\left(\frac{\pi p x_0}{\delta}\right)\cdot\cos\left(\frac{\pi p x_1}{\delta}\right)\cdot K_0\left(\frac{\pi p}{\delta}R_{m_1n_1}\right) +$$
$$+ \frac{4\pi e^2 z_1(z-\alpha)}{\epsilon_{pl}\delta}\sum_{m_2,n_2}\sum_{p=1}^{\infty}\sin\left(\frac{\pi p x_0}{\delta}\right)\cdot\sin\left(\frac{\pi p x_2}{\delta}\right)K_0\left(\frac{\pi p}{\delta}R_{m_2n_2}\right) \quad (44)$$

In the case of the adsorption of two different dipolar molecules with dipole moments $\mu_1$ and $\mu_2$, the corresponding expression for $\Omega_{z-\alpha}(\theta_1, \theta_2)$ has the form (43). To determine the nature of the kinetic curves corresponding to an electrochemical process complicated by the influence of the adsorption of different combinations of SAS, numerical calculations were carried out[57] to determine the dependence of the ratio $i/i_0$ on $\theta$ for the discharge of doubly-charged cations in the presence of two dipolar electrochemically inert SAS, oriented in different ways. The following values were selected for the parameters: $\delta = 5$ Å, $x_0 = 1$ Å, $x_1 = 2$ Å, $x_2 = 3$ Å, $\alpha = 0.5$, $\Gamma_{1,\infty} = \Gamma_{2,\infty} = 1.5 \times 10^{14}$ cm$^{-2}$; the dipole moments $\mu_1$ and $\mu_2$ were assumed to be 1 CGSE unit. The energy $\Omega_{z-\alpha}(\theta_1, \theta_2)$ was calculated from Eqn.(43), but in contrast to the analysis represented by the graphs in Fig.6, the relationship $\theta_1 = f(\theta_2)$ was not determined; it was assumed that $\theta_2 = 1$, and $\theta_1$ was varied. The results of the calculation are given in Fig.6. Qualitative agreement is observed between the calculated graphs for the degree of inhibition and the experimental curves obtained in Ref.78.

## IV. NON-LOCALISED ADSORPTION OF INACTIVE IONS AND MOLECULES AT AN ELECTRODE/SOLUTION INTERFACE

In the examination of the case of the non-localised adsorption of ions and molecules at an electrode/solution interface it is also necessary to carry out statistical averaging of the

probability of the elementary act over the entire ensemble of adsorbed species. A procedure for this averaging has been developed,[52,53] and on the basis of the previously described general approach the authors cited obtained the following expression for the rate of a one-electron reduction:

$$i = \text{const} \cdot (1 - \theta) \cdot \exp\left\{-\frac{\alpha e [\varphi_0 - \varphi(x_0, \theta)] - \Delta F}{kT}\right\} \qquad (45)$$

where $\phi(x_0, \theta)$ is the potential at the point $\xi_0 = \eta_0 = 0$ of the plane $x = x_0$ from which the discharge of the reactant ion takes place, and the quantity $\Delta F = F_z(T, \theta) - F_{z-\alpha}(T, \theta)$ is the difference in the free energies of the system for a charge $ez$ on the ion Ox and an "effective charge" $e(z - \alpha)$ on this ion.

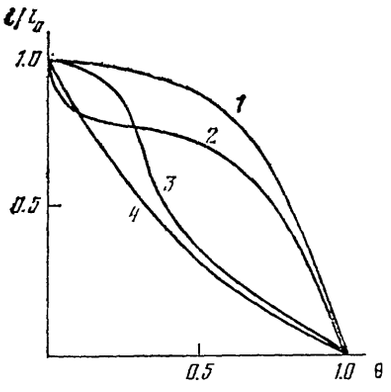

**Figure 6.** Dependence of the current for the electroreduction of doubly-charged cations on the degree of coverage θ under the conditions of the combined adsorption of dipolar molecules of two kinds[57] with the following values of the dipole moments: *1*) $\mu_1 = \mu_2 = 1$; *2*) $\mu_1 = 1$, $\mu_2 = -1$; *3*) $\mu_1 = -1$, $\mu_2 = 1$; *4*) $\mu_1 = \mu_2 = -1$ CGSE unit.

Since $F_z$ and $F_{z-\alpha}$ are related to the corresponding mean-statistical values of $\bar{E}_z$ and $\bar{E}_{z-\alpha}$ of the energies of the system by the Gibbs–Helmholtz thermodynamic relationship, these last quantities are first found by the method of correlative functions (or distribution functions):[79]

$$\frac{\partial \Phi_1(\rho_1)}{\partial \xi_1} + \frac{1}{kT}\frac{\partial U_1(x_0, \rho_1)}{\partial \xi_1}\Phi_1(\rho_1) + \frac{1}{v_s kT}\int \frac{\partial U_2(\rho_1, \rho_2)}{\partial \xi_1}\Phi_2(\rho_1, \rho_2)\,d\rho_2 = 0 \qquad (46)$$

etc., where $\Phi_1$, $\Phi_2$, ... are the unary, binary, etc. distribution functions, $U_1$ and $U_2$ represent respectively the unary and binary (paired) species interaction potentials; and $v_S = \Gamma^{-1} = (\Gamma_\infty \theta)^{-1}$. Relationships (46) represent an infinite system of coupled equations[79] or "chain of equations", and an analogous system of equations is written for the component $\eta_1$ of the two-dimensional vector $\rho_1 = (\xi_1, \eta_1)$ in the adsorption plane $x_a = \text{const}$. The main task is to find an effective method for "terminating" the chain of interrelated equations (46).

Specific results have been obtained[52,53] by introducing "two-dimensional expansions" (with the condition that $\theta < 1$ and that the corresponding integrals converge), that is by expansion of all the distribution functions and thermodynamic quantities being sought in power series with respect to θ; in particular, for $\Delta F(T, \theta)$:

$$\Delta F(T, \theta) = \theta \Delta F_1(T) + \theta^2 \Delta F_2(T) + \ldots \qquad (47)$$

In Eqn.(47), $\Delta F_p$ represents the expansion coefficients which do not depend on θ. For $\Delta F_1$, for example, this method gave the expression

$$\Delta F_1(T) = 2\pi kT\Gamma_\infty \int_0^\infty \{\exp[-U_1^{(z-\alpha)}(x_0, \rho_1)/kT] - \exp[-U_1^{(z)}(x_0, \rho_1)/kT]\}\,\rho_1 d\rho_1 \qquad (48)$$

where $U_1$ is the potential of the interaction of the reactant ion with an arbitrary adsorbed species (with allowance for the interactions of the species with their "electrostatic images" in the metal and the solution). The superscripts on $U_1$ indicate that the reactant ion has the corresponding charge $ez$ or $e(z - \alpha)$.

It follows from Eqns.(47) and (48) that for the non-localised adsorption of the species, the exponent in the expression for the current (45) (with the condition that integral (48) converges) contains a term linear with respect to θ. This is predicted by the theory of the relationship and is apparently reflected in the nature of the behaviour of the experimental $i$, θ curves for systems with adsorption of organic ions.

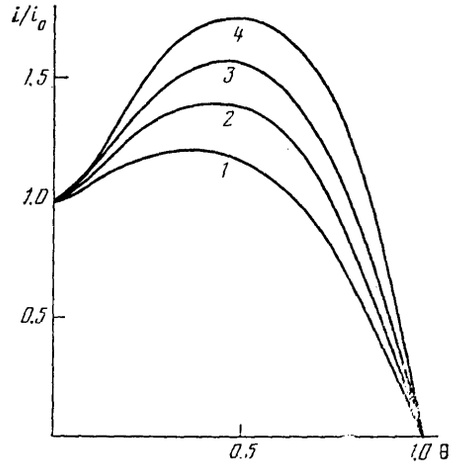

**Figure 7.** Dependence of the current for the electroreduction of doubly-charged cations on the degree of coverage of the electrode surface by inactive singly-charged organic anions.[52,53]

Thus the dependence of the current density on the degree of coverage has been studied[68] under the conditions of the electroreduction of cadmium ions at a mercury electrode in the presence of decyl, nonyl, and octyl sulphate anions. For all the systems studied, the $i$, θ curves show two regions: a region of initial increase and a region of subsequent decrease in the rate of the electrochemical process. According to the theory developed in the present section, these regular features are explained by the different arrangements of the planes in which the centres of the adsorbed ions are localised relative to the plane of the electrode: the closer the localisation of the adsorbed organic anions to the electrode, the more clearly defined the initial region of increase in the current. This effect is illustrated in Fig.7 by four

curves constructed using Eqns.(45)–(48). The common parameters for all four curves were: $z = 2$, $z_0 = -1$, $\alpha = 0.5$, $\varepsilon_{pl} = 8$, $x_0 = 1.5$ Å. The parameters $\Gamma_\infty$ and $x_a$ were varied; curves *1*–*4* in Fig.7 correspond to the following pairs of values of $\Gamma_\infty$ and $x_a$ (in units of $10^{-10}\Gamma_\infty$ and $10^8 x_a$): 4.0 and 2.0 (*1*), 3.0 and 2.5 (*2*), 2.0 and 3.0 (*3*), and 1.0 and 3.5 (*4*). The same trend in the behaviour of the $i$, $\theta$-curves when one organic anion is replaced by another was observed experimentally.[68]

## V. THE INFLUENCE OF THE ADSORPTION OF IONIC REAGENTS ON THE KINETICS OF ELECTROCHEMICAL PROCESSES

A large number of experiments (see for example Refs.9, 10, 29, 32, 33, 80, 81) have established that many electrochemical reactions take place with the reactants in the adsorbed state. The most typical example of reactions of this kind is the discharge of hydrogen ions at a mercury electrode.[1,64] Systems in which even slight adsorption of the reactants can completely change the mechanism of an electrode process have been described. At the same time there have been insufficient quantitative studies of kinetics complicated by adsorption of the reactants. The reason for this is the additional experimental difficulties associated with the need to measure simultaneously, at a given electrode potential, the reaction rate and the concentration of the reacting substance next to the electrode. The first attempts to carry out a theoretical analysis of the influence of adsorption on kinetics were made[33,37] for the reduction of organic substances at a mercury electrode. The analysis was based on the activated-complex method.

A statistical-mechanical approach to the description of the kinetics of electron transfer reactions accompanied by adsorption of the reactants was recently proposed.[53–56] Because of the complexity of the problem, in the initial approximation of the equation for the current $i$ it was assumed that the rate of the process is proportional to the activity $g^*_{ads}$ of the reactant ions in the adsorbed state and the statistically averaged probability $\langle W \rangle$ of the elementary act of electron transfer:

$$i = \text{const} \cdot g^*_{ads} \langle W \rangle \qquad (49)$$

It should be emphasised that completely rigorous and systematic averaging on the right-hand side of Eqn.(49) under the conditions being considered should include the simultaneous determination of both the probability of the given configuration of the system and the probability of the elementary act of the electrode process. This formulation of the problem is extremely complex from both the quantum-mechanical and statistical viewpoints, and its general "analytical" solution (at least without the introduction of any numerically miscalculable model systems) is not yet possible. Eqn.(49) has a factorised (multiplicative) structure, and this is only a definite approximation, whose accuracy cannot be estimated beforehand within a completely rigorous theory.

At the same time, the multiplicative form of the approximation of the equation for the current from Eqn.(49) makes it possible, at least in a whole series of particular cases, to take the solution of this problem to a conclusion.[56] The quantity $g^*_{ads}$ is found from the adsorption isotherms of the species.[53–56] In the works cited, this gave the following equation for the current with adsorption of the ionic depolariser:

$$i = \text{const} \cdot \frac{\theta}{(1-\theta)} \exp\left\{\frac{\mu^{(e)}(\theta) - e[\phi_0 + (z-\alpha)Q(x_1)] - \Omega_{z-\alpha}(\theta)}{kT}\right\} \qquad (50)$$

where the following notation has been introduced:

$$Q(x_1) = \begin{cases} \varphi_0\left(1 - \frac{x_1}{\delta}\right) + \frac{4\pi e z \Gamma_\infty \theta}{\epsilon_{pl}\theta} x_1(\delta - x_0), & \text{for } 0 \leqslant x_1 < x_0 \\ \varphi_0\left(1 - \frac{x_1}{\delta}\right) + \frac{4\pi e z \Gamma_\infty \theta}{\epsilon_{pl}\theta} x_0(\delta - x_1), & \text{for } x_0 \leqslant x_1 \leqslant \delta \end{cases} \qquad (51)$$

Here, $x_0$ is the position of the plane of the adsorption of the reactants in the "inactive adsorbed" state, and $x_1$ the position of the plane from which the discharge of the adsorbed ion takes place; the quantity $\mu^{(e)}(\theta)$ is the electrostatic component of the electrochemical potential of the adsorbed ions. The calculation equations for $\Omega_{z-\alpha}$ are given in the works cited. With allowance for the effect of the penetration of the field into the metal (that is the influence of the "electronic condenser"), it is necessary to modify the quantity $\Omega_{z-\alpha}$ in Eqn.(50) in accordance with Eqns.(34)–(37). Ref.56 also gives an equation for $U_{z,\mu}$, that is the energy of the reaction of the ion with a dipolar molecule with allowance for the penetration of the field into the metal. This quantity is necessary for calculations for conditions in which an organic depolariser is adsorbed.

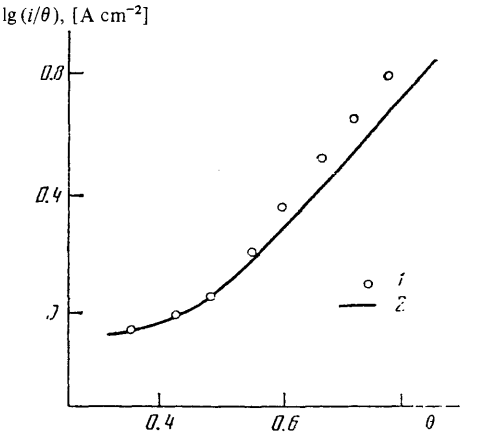

Figure 8. Dependence of the current for the electroreduction of the cationic complex *cis*-Cr(en)(NCS)$^+$ on the degree of coverage of the mercury electrode surface: *1*) experimental points, *2*) results of the calculation using Eqns.(50) and (51).

Eqns.(50) and (51) have been used[55] to calculate the dependence of the current density on the degree of coverage at a constant potential. The numerical values of the parameters were selected for the specific system formed by mercury with the isothiocyanato-complex of chromium *cis*-Cr(en)$_2$(NCS)$_2^+$, where en = ethylenediamine. The kinetics of the discharge of complexes in this system have been studied experimentally.[82] The values of $\Gamma_\infty$ and $\alpha$ measured in this study were $1.5 \times 10^{14}$ cm$^{-2}$ and 0.8 respectively. The following values were taken for the other parameters in the calculations: $\delta = 5$ Å, $x_0 = 3$ Å, $x_1 = 2$ Å, $\varepsilon_{pl} = 6$, $z = 1$. The results of the calculations are compared with the experimental data in Fig.8. It can be seen that at sufficiently low degrees of coverage, the agreement between theory and experiment is satisfactory. The appreciable discrepancy at high degrees of coverage

is apparently related to the fact that at high values of $\theta$ it is not physically justified to regard the discharging complex as a point charge. It would be more adequate to examine the discrete structure of the charges within the actual complex. Another reason for the lack of agreement between the results of the calculation and the experimental data may be the neglect of the contribution from the effects of the penetration of the electric field into the metal, although, as noted above, it is possible in principle to take account of these effects on the basis of the equations given in the present review.

## VI. SUMMARY

Studies directly in the field of the theory of the electrical double layer and the theory of the adsorption of SAS and SAOS on electrodes and also in the field of the theory of the kinetics of electrode processes are now being intensively developed to solve a number of problems in theoretical and applied electrochemistry. These fields of present-day theoretical electrochemistry are organically related and interact naturally with one another, and this interaction process is gradually becoming more interpenetrating and requiring the development of theoretical correlations and self-consistency. An example is provided by the aspects, examined in the present review, of the theory of electrochemical processes complicated by adsorption phenomena at the interface between the electrode and the electrolyte solution.

It should be emphasised that progress in the first two fields naturally provides a basis for the further development of the theory of the kinetics of electrode reactions. In this connection, there is no doubt that recent developments in the theory of the equilibrium double layer, such as the "three state" model or the "cluster" model, the concept of condensed adsorption layers on electrodes with the interpretation of the reorientation of adsorbed molecules as a two-dimensional phase transformation, the representation of two electronic "parts" of the total charge of an electrode (the part of the charge "spread" uniformly over the metal surface and the other part which is the sum of the electronic counter-charges localised close to specifically adsorbed ions) may be reflected in the theory of the kinetics of electrochemical reactions (a bibliography) of relevant work can be found, for example, in a published review).[62]

The present review has dealt partly with the kinetic aspects of the penetration of the electric field into a metal. As has been pointed out,[52] however, it is also necessary to take account of the effect of the shielding of the field of the metal by the "outer" electrons, that is the electrons of the metal penetrating into the effective range of the "compact" layer adjoining the metal (the so-called "electron tails"). These electrons interact with the solvent molecules and adsorbed species, and in this connection it has been emphasised[52] that under these conditions the actual concept of "compact layer" (or "reaction region" in the kinetic aspect) requires physically more correct and electrochemically constructice definitions (concepts), and also definition of the concept of the phase interface (thus for example the theory of the "capacity of the double layer" should include a factor associated with the "electron condenser", etc.).

In addition to these factors, other characteristic features such as the specific structure of the region of the solvent next to the surface (in particular, the influence on its structure of the "outer" electrons of the metal[52] and the possibility in principle of hydrogen bond formation between water molecules in the solvent monolayer [83,84]), the effects of the spatial dispersion of the dielectric constant of the two phases in contact, the questions of "partial charge transfer" in the adsorption of species on electrodes, and a number of other questions will undoubtedly be reflected in the theory of electrode kinetics.

The problem of the statistical averaging of the probability of the elementary act of an electrochemical process accompanied by the adsorption of electrochemically inert species or the reactants themselves was analysed in detail above, and it was shown, in particular, that the interaction between the reactants and adsorbed species is determined by the fine structure of the electrical double layer at the electrode/solution interface. A unique type of electrochemical system is provided by systems in which electrode reactions take place with the reactants in the adsorbed state. In this case, in the averaging of the probability of the elementary act, it is necessary to take into account both the contribution made to the free energy of adsorption of the reactants by the electric field created by these reactants, and the entropy factor, which influences the production of the ionic adsorption isotherm. In the theory of the kinetics of reactions complicated by adsorption, it is also necessary to take account of the structure and parameters of the electronic spectrum of the metals. Thus it is obvious that from the physical viewpoint also, the further development of the theory of the kinetics of electrode reactions complicated by adsorption phenomena at the metal/solution interface is an extremely urgent task.

# Reactions in Organic Crystals

V.E.Shklover, T.V.Timofeeva, and Yu.T.Struchkov

Structural studies on the following types of chemical reactions in organic crystals published after 1977 are considered: dimerisation, redimerisation, polymerisation, asymmetric synthesis, chemical reactions in clathrate compounds, topotactic redox reactions in intercalation systems, and crystal-gas reactions. A common feature of all the processes examined is the influence of the crystal environment of the molecules of the initial substance on the mechanism of the reaction and the character of its product (the topochemical factor).
The bibliography includes 241 references.

## I. INTRODUCTION

Solid-phase reactions are attracting increasing attention at the present time for a number of reasons. Firstly, the limited mobility of the reacting molecules in the crystal makes it possible to carry out a well-founded structural investigation of the entire chain of molecular transformations, i.e. of the reaction mechanism. Secondly, with the aid of solid-phase reactions, it is possible to obtain polymers with a regular structure, enantiomerically pure products with the configuration of the chiral centres specified beforehand, large defect-free single crystals, which are especially suitable for electrophysical measurements, etc. All these features have led to the appearance and development of a new field of scientific research—crystal engineering, whose aim is to investigate the principles and rules governing the construction of different types of packing of potentially reactive molecules and crystals such that favourable conditions are created for the involvement of the molecules in particular chemical reactions and rearrangements not requiring diffusion and accompanied by only a slight rearrangement when the process is subject to topochemical control.[1]

This review surveys the principal results of structural studies on chemical reactions in organic crystals published after 1977 and not included in our previous review,[1] which dealt with the intramolecular rearrangements and reactions involving the formation of low-molecular-weight products in the solid phase.

The dimerisation and polymerisation reactions, to which the greatest number of structural investigations have been devoted, are discussed in greatest detail. With the aid of these reactions, it is possible to obtain in some cases the final product in the form of a single crystal, which is nowadays of practical importance.

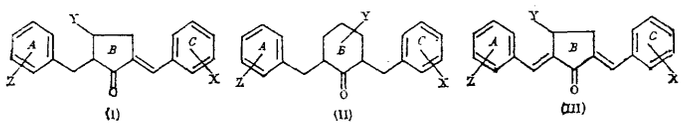
The reactions in clathrate compounds and topotactic redox reactions in intercalation systems, which are intermediates between topochemical transformations in organic crystals and charge-transfer processes in low-dimensional binary systems, are also fairly close to practical application. However, in view of the limited space available in the review, these processes are considered only briefly, although topochemical analysis of the charge-transfer conditions in organic systems, considered as a solid-phase chemical reaction, is fruitful.

The classification of solid-phase reactions employed in this review is somewhat arbitrary, but it makes it possible to differentiate the main types of processes and the directions of further development of this interesting field at the junction between organic chemistry, crystal chemistry, and physical chemistry.

## II. DIMERISATION

Dimerisation belongs to one of the most thoroughly investigated types of solid-phase chemical reactions. In essence, the strategy used in crystal engineering†[2] has been developed in relation to the solid-phase synthesis of optically active olefin dimers (and polymers)[3-9] by cycloaddition with formation of cyclobutane derivatives.

It has been established that the occurrence of these processes requires the type of packing in the crystal where the reacting double bonds are parallel and separated from one another by not more than 4.1 Å.[2] If these conditions are met, the overall geometry of the atomic environment of the reacting double bonds persists in the cyclobutane product, i.e. these processes are subject to topochemical control.#



### 1. Benzylidene Derivatives of Cyclopentanones and Cyclohexanones

Compounds based on 2-benzyl-5-benzylidenecyclopentanone (I), 2-benzyl-6-benzylidenecyclohexanone (II), and 2,5-dibenzylidenecyclopentanone (III) are extremely promising for the study of solid-phase dimerisation and topotaxy of crystals as well as crystal engineering. Derivatives of these compounds (substituted in the *A*, *B*, and *C* rings) have been investigated in the dimerisation reaction in the crystalline state under UV irradiation.[11]

---

†Solid-phase chemical reactions are controlled by specific types of organisation or by varying the character of the packing in the crystals of the initial compound.

#This rule agrees with a general topochemical principle, according to which reactions in organic crystals proceed with minimal atomic and molecular shifts.[10]

(I) (II) (III)

These systems are of considerable interest, because, in principle, it is possible to follow with their aid the non-diffusional rearrangement of atoms directly in the course of the chemical reaction.[5,12]

Table 1. The capacity for solid-phase dimerisation of the benzylidene derivatives of cyclopentanone and cyclohexanone whose structures have been investigated.[11]

| Compound | X | Y | Z |

*Has the ability to dimerise.

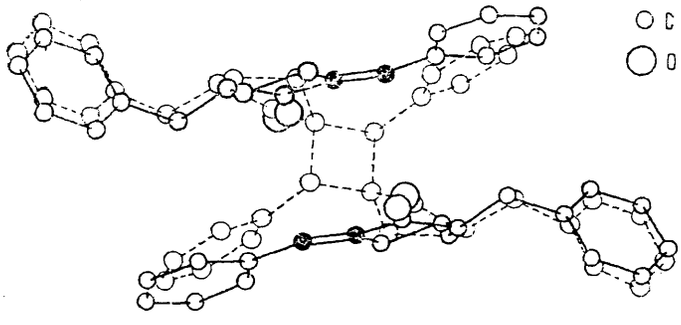

Figure 1. Schematic illustration of the dimerisation of compound (IIa) on irradiation with u.v. light in the crystal. The bold lines represent the monomer molecules and the dashed lines the centrosymmetric dimer molecule; the C atoms linked by a C=C bond are shown shaded. The insignificant shift of the benzene rings on dimerisation is worthy of note.[5]

The majority of reactive compounds of series (I), (II), and (III) (Table 1) crystallise in such a way that the nearest molecules are linked via their centres of symmetry and they therefore form centrosymmetric dimers in the solid-phase reaction (Fig.1). The double bonds in the crystals of compounds (Ia), (Ib), (Ii), and (II), whose structures have been investigated, are separated by distances of 4.2, 3.8, 4.0, and 3.8 Å respectively. The photostability of the remaining series (I) compounds can be accounted for by the larger distance between the double bonds [for example 6.2 and 4.7 Å in the crystal of compound (Ie) for molecules linked by glancing reflection planes]. The crystals of compounds (IIIb) and (IIIc), in which an asymmetric centre arises in the 3-position as a result of the introduction of the methyl substituent into the *B* ring constitutes an exception: the racemate (IIIb) is photostable and the crystals of the individual (IIIc) enantiomers are reactive. In the topotactic dimerisation of compound (Ia) (a single crystal–single crystal transition) the maximum change in the unit cell parameters is 0.7%.[5] However, by controlling carefully the rate of dimerisation, it is possible to achieve a homogeneous single crystal–single crystal transition for compound (Ib) and also for relatively large changes in the unit cell parameters (3.8, 5.6, and 6.5% for periods *a*, *b*, and *c* respectively).

Systems (I)–(III) open up completely new prospects in solid-state chemistry, namely the possibility of investigating the mechanism of a photochemical reaction in the crystal. The first step in this direction was the investigation of the variation of the unit cell parameters with increasing degree of conversion for a crystal of compound (Ia) in which the distance between the reacting double bonds is 4.166 Å, while the distance between the planes in which these bonds are located is 3.80 Å.[11]

The molecules in the crystal (Ii)[13] form around the centres of symmetry predimers in which the distance between the planes incorporating the C=O and C=C double bonds in each molecule is 4.036 Å, as well as the unsubstituted benzene ring. The intermolecular distance between the double bonds in such a predimer (4.027 Å) allows [2 + 2]-cyclodimerisation.[2] For this reason, on photoexcitation, these bonds can interact topochemically to form a cyclobutane ring, which has in fact been observed experimentally.

In order to elucidate the causes of the conversion of compound (II) into an amorphous form in its solid-phase photodimerisation reaction, its crystal structure was determined.[13] The molecules in the crystal of compound (II) also form predimers around the centres of symmetry with a distance of 3.028 Å between the planes incorporating (within each molecule) both double bonds and the unsubstituted benzene ring, which indicates a strong intermolecular interaction between the conjugated π-electron systems of the molecules. The shortest distance between the atoms involved in the C=C double bonds in the predimer is 3.792 Å. The loss of crystallinity by compound (II) as a result of photodimerisation[14] is probably associated with the necessity for an appreciable displacement of the dimer molecules due to the very close relative positions of the molecules in the predimer. In fact, in the crystal of compound (Ib), whose photodimerisation involves a single crystal–single crystal transition, the distance between the planes of the conjugated molecular systems in the predimer is 4.174 Å,[12] which is much greater than in compound (II). Furthermore, the decrease of crystallinity on photodimerisation can be caused by the low melting point of the product. The decrease of the melting point on formation of the new phase can induce the removal of the topochemical control over the solid phase reaction.[15]

Ideas concerning the possibility of topochemical interaction in crystals of types (I)–(III) have been developed[16] from an X-ray diffraction study of compounds (IIIa) and (IIIb) as well as the product of the solid-phase dimerisation of compound (IIIa).

The reactive C=C bonds of the neighbouring molecules in the photoactive crystal of compound (IIIa) and in the photostable crystal of compound (IIIb) have approached one another to distances of 3.720 and 3.871 Å respectively, permitting a topochemical interaction. However, these bonds

are not parallel, i.e. the condition necessary for topochemical interaction is infringed.[2,10,17] Nevertheless, photochemical dimerisation is observed in the crystal of compound (IIIa). The explanation is that, despite the lack of a parallel arrangement of the reacting double bonds (they form an angle of 56°), the axes of the $p_z$ orbitals of the carbon atoms in compound (IIIa) are parallel. This is not observed in the crystal of compound (IIIb), which accounts for its photostability.

According to X-ray diffraction data,[16] the dimerisation of compound (IIIa) leads to the formation of precisely the isomer which should be obtained, i.e. the topochemical reaction proceeds via a defect-free mechanism. However, in contrast to the dimerisation of compound (Ia), the crystal structure of compound (IIIa) breaks down as a result of dimerisation and an amorphous product is formed. The transition to the amorphous state can be caused by the greater rigidity of the molecule of compound (IIIa) [i.e. its smaller ability, compared with compound (Ia), to "become adjusted" to the lattice of the new phase] and also by the necessity for the rotation of the molecules of compound (IIIa), because the formation of the dimer still requires that the double bonds of the interacting molecules be parallel.

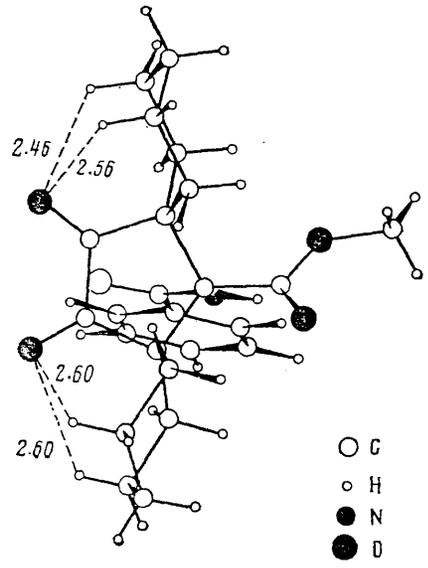
The phenomenon of "structural mimicry" (the ability of molecules to change their conformation on becoming incorporated in the crystal lattice of the "host") has been used successfully[18] to ensure the reactivity of compound (Im), which is inert in the crystalline state, as a result of the formation of its solid solution with the reactive compound (II). The molecules of compound (II) have a planar conformation in the crystal, while those of compound (Im) have a bent conformation. This difference between the conformations, caused by the electronic and steric influence of the chloro-substituent,[18] changes the character of the molecular packing in these crystals. The mixed crystal having the composition (II) : (Im) = 7 : 3 is isostructural with the crystal of compound (II) and is photoactive, while the disposition of the double bonds satisfies the conditions for topochemical dimerisation. Whereas the distance between the double bonds in the photostable crystal of compound (Im) is 4.65 Å, in the photoactive crystal of compound (II) the C=C bonds of the molecules, linked via the centre of symmetry, are parallel and separated by 3.92 Å. In the mixed crystal the molecules of compound (Im) are forced to assume an extended conformation and the distance between the C=C bonds diminishes to 3.87 Å.[18] Thus Jones et al.[18] expanded the range of available tools in crystal engineering, previously restricted to the use of various "controlling" groups,[2,3,6,19] having used "structural mimicry" to convert the inactive molecules into a reactive form (conformation) by distributing them within a specified "active" packing.

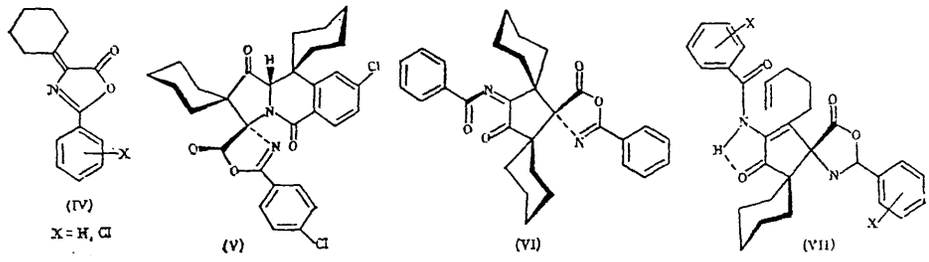
## 2. Cyclohexylidenephenyl-5(4*H*)-oxazolones

In the course of the solid-phase photolysis of cyclohexylidenephenyl-5(4*H*)-oxazolones (IV), asymmetric dimers of three types, (V)–(VII), are formed.[20–23]

The structures of compounds of type (IV) with X = H[21] and Cl[22] the crystals are isomorphous), (V) (colourless main product with X = Cl[21]), and (VI) (yellow main product with X = H[20]) have been determined.

The crystal of compound (IV) has a layer structure with shortened distances between the molecules linked via the glancing reflection plane *b* (space group *Pbcn*). The formation of trispiropyrroloisoquinoline (V) in the crystal of compound (IV) not only as a result of asymmetric dimerisation but also due to the formation of two new C–N and C–C bonds between neighbouring molecules requires the transfer of one of the hydrogen atoms of the benzene ring to the nitrogen atom and the formation of a C–C bond between the benzene and cyclohexane rings. The geometry and relative orientations of the molecules in the predimer (IV) favour such a rearrangement.[21]





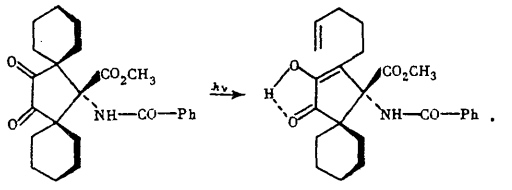


Figure 2. The structure of the diketoester (VIII) molecule. The short γ-H...O contacts are indicated by dashed lines.[20]

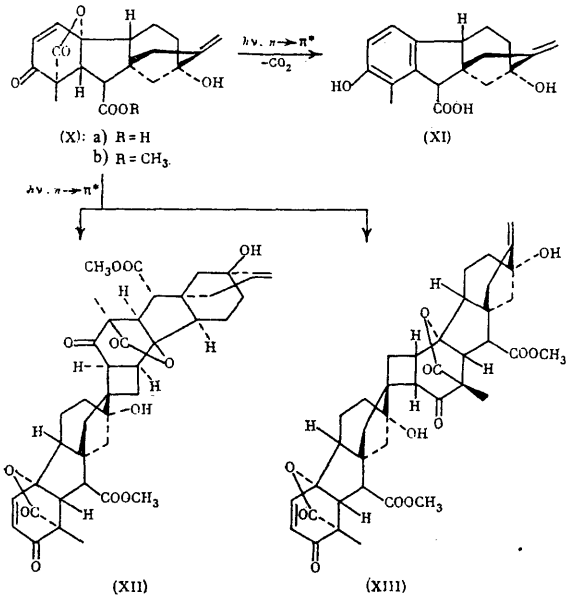
The formation of a dimer of type (VI) can be formally represented as asymmetric ($\pi^2 + \pi^2 + \pi^2 + \sigma^2$)-dimerisation of two molecules of the oxazolone (IV) linked by the plane *b*. The dimer having the presumed structure (VII) is not the primary solid-phase dimerisation product but is formed from the yellow dimer (VI) as a result of a Norrish fragmentation of the second type[20] with transfer of a H atom to the N atom.

Specific hypotheses concerning the mechanism of the γ-H transition are difficult to formulate in view of the disordered nature of the structure of compound (VI) in the region where the *N*-benzoylimino-group is located. However, fragmentation of the second type is characteristic not only of *N*-benzoyl-1,2-diketoimine (VI) but also of dispiro[5,1,5,2]pentadecane-14,15-diones obtained from the dimer (VI, X = H). For example, the yellow diketoester (VIII) gives rise to the colourless fragmentation product (IX).



(VIII) (IX)

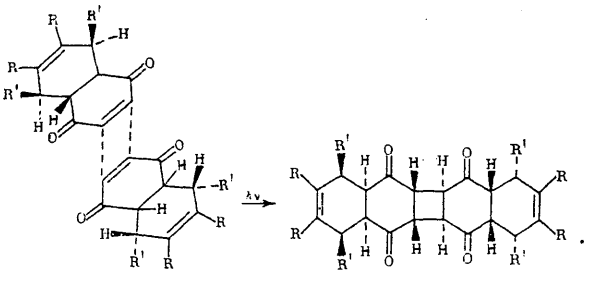
In the crystal of compound (VIII)[20] the four axial γ-hydrogen atoms are involved in intramolecular contact with the corresponding oxygen atoms of the keto-groups over distances of 2.46–2.60 Å, which favour the interaction (Fig. 2).

### 3. Derivatives of 3-Dehydrogibberellin $A_3$

The high photoactivity of 3-dehydrogibberellin $A_3$ (X) in the crystalline phase and the marked dependence of the pathway followed in this reaction on the character of the substituent R have been established.[24,25]

(X): a) R = H
b) R = $CH_3$

(XI)



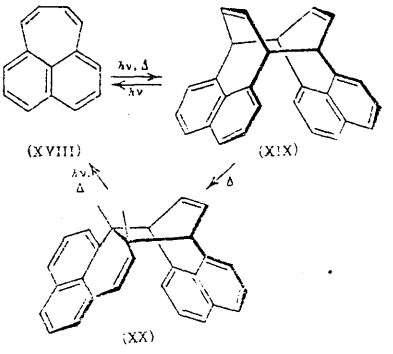
(XII) (XIII)

The enone acid (Xa) is decarboxylated as a result of the $n \rightarrow \pi^*$ excitation of the enone chromophore and is converted into the phenolic acid (XI) in a high yield,[26] while the corresponding methyl ester (Xb) dimerises with formation of compounds (XII) and (XIII) as a result of the intermolecular [2 + 2]-photocycloaddition of the C=C bond of the excited $\Delta^1$-enone ring to the terminal double bond of a neighbouring molecule. The molecular geometries of the ester (Xb)[27] and the acid (Xa)[28] are very similar. Fig. 3 illustrates the relative dispositions of the molecules of compound (Xb), involved in the solid-phase dimerisation reaction, which are packed "head to tail" into infinite chains around the $4_1$ axes (space group $P4_12_12_1$). The distance between the centres of the C(16)=C(17) and C(1′)=C(2′) double bonds in the neighbouring reacting molecules (3.71 Å) is favourable for topochemical reactions of this type.[2,29] The π orbitals of the double bonds of neighbouring molecules are located in approximately the same plane and are directed towards one another. The dihedral angle between the C(13)C(15)C(16)C(17) and C(1′)C(2′)C(3′)C(10′) planes is 19.7° and the torsional angle C(17)–[centre of C(16)–C(17) bond]–[centre of the C(1)–C(2) bond]–C(1) is 31.2°. Thus all the requirements for topochemical [2 + 2]-cycloaddition are met in the crystal of compound (Xb),[30] which makes it possible to predict the structure and stereochemistry of the main dimeric product (XIII) formed in 40% yield. The formation of the dimer (XII) as a side product is difficult to explain within the framework of the ideal topochemical model. Apparently this is a result of non-topochemical photodimerisation[29] caused by the imperfections of the initial crystal of compound (Xb).[2,30,31] It is believed[32,33] that the monomer molecules are able to rotate in the defective regions of this crystal in the intermediate excimeric state.

The different character of the solid-phase reactions on photoexcitation of compounds (Xa) and (Xb) has been explained by the different types of molecular packing in these crystals. In contrast to compound (Xa), in the crystal of compound (Xb)[28] the molecules are combined by hydrogen bonds into layers where the distance between the centres of the potentially active C(16)=C(17) and C(1)=C(2) double bonds is 4.5 Å and their π orbitals are oriented approximately at right angles, as a result of which only intramolecular photochemical reactions are possible.[27]

### 4. Derivatives of Naphthoquinone

Of the nine tetrahydronaphthoquinone systems whose structures have been investigated, only three [compounds (XVIa)–(XVIc)] are involved in topochemically controlled intermolecular reactions, forming the explosive dimers (XVIIa)–(XVIIc) via the [2 + 2]-photocycloaddition of the enedione double bonds of neighbouring molecules (the distances between the centres of their C=C double bonds are ≤4.04 Å).[34,35]



However, according to X-ray diffraction data, solid-phase intermolecular transfer of a hydrogen atom is also possible in compound (XVIb) (the $H_\beta$...O distances are 2.42 and 2.49 Å with the angles $\tau_O$ = 4° and 3° and $\Delta_O$ = 80.8° and

79.5°).§ Nevertheless, in the given instance the effect of the crystal packing, which favours a bimolecular reaction, predominates over the entropy factors, which usually promote a unimolecular reaction. This conclusion emphasises yet again how important it is to take into account the characteristics of the molecular packing in the crystal in formulating hypotheses about the course of photochemical reactions.[36]

### 5. 1,8-Naphthobicyclo[3.2.0]hepta-2,6-diene

Whereas prolonged irradiation of a solution of 1,8-naphthobicyclo[3.2.0]hepta-2,6-diene (XVIII) with ultraviolet light leads to the formation of a polymer and a small amount of naphthobicyclobutane, irradiation of the crystal with light in the visible region results in the appearance of the dimer (XIX):[37]

When the temperature is reduced to −195 °C, dimerisation ceases. On heating *in vacuo* to 150 °C, compound (XIX) isomerises quantitatively to the asymmetric dimer (XX), whose structure has been demonstrated by infrared spectroscopy and NMR. On irradiation with UV light at $\lambda = 313$ nm in solution, both dimers are readily converted into the initial monomer (XVIII).

In the crystal of compound (XVIII) at −196 °C the molecules are packed "head to tail" in pairs. On raising the temperature, the structure becomes disordered and the "head to head" arrangement appears within pairs of molecules, which leads to the formation of the dimer (XIX) for intermolecular distances permitting reaction in the solid phase. A decrease of temperature to −195 °C prevents the disordering and photodimerisation does not take place.

The molecule of compound (XIX) has a strained structure: the naphthalene fragments are not entirely non-planar, the valence angles at the peri-carbon atoms have been reduced to 113.2°, and the C–C bridging bonds have been extended on average to 1.626 Å. The strain energy of the molecule of compound (XIX), which was estimated by comparing the enthalpy of activation $\Delta H^{\neq}$ for the reaction (XIX) → (XX) with the enthalpy of dissociation of compound (XIX), is ~60 kJ mol$^{-1}$.[37]

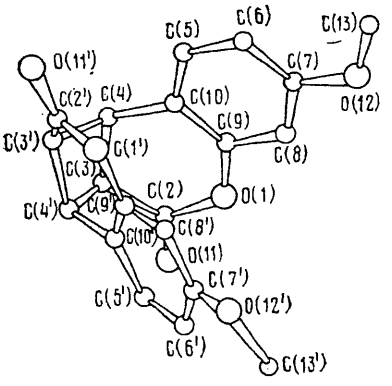


Figure 4. The structure of the 7-methoxycoumarin dimer (XXI); C(3)C(4)C(3′)C(4′) is the cyclobutane ring.[17]

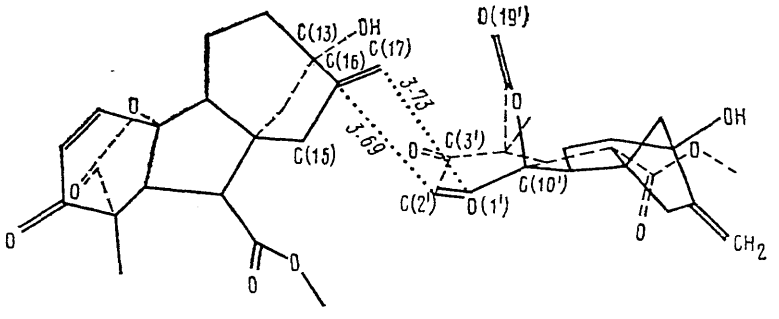

Figure 3. The relative disposition of the molecules linked by the $4_1$ axis in the crystal of compound (Xb).[28]

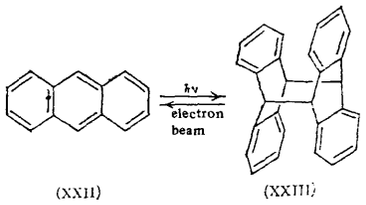
§ The crystal of compound (XVIb) is constructed from two symmetrically independent molecules; $\tau_0$ is the deviation of the atom $H_\beta$ from the plane of the carbonyl group and $\Delta_0$ is the $C(=O)H_\beta$ angle.



### 6. Coumarin Derivatives

Systematic crystallographic and photochemical studies have been made of the solid-phase dimerisation of ten coumarin derivatives.[17] The unsubstituted coumarin is photostable in the crystal, although it dimerises in solution.[38] On irradiation of the crystal with UV light, only 7- and 8-methoxycoumarins and 4-chlorocoumarin dimerise (the yields of the dimers are respectively 90, 50, and 40%). The dimer of 7-methoxycoumarin (XXI) has the *syn*-structure (head to tail arrangement, Fig. 4), but in the crystal of the monomer the orientation of the double bonds of neighbouring molecules, forming an angle of 115°, is topochemically unfavourable. It is suggested that the rotation of the molecules of compound (XXI) essential for their transition to the reactive state is possible at the screw dislocations of the crystal of compound (XXI). The photostability of the non-dimerising crystalline coumarin derivatives is due to the unfavourable relative disposition of the molecules in the crystals[17] and not to their special electronic or steric properties.

### 7. Anthracene Derivatives

The solid-phase dimerisation and dimer dissociation reactions as well as the processes preceding the dimerisation of anthracene and its derivatives have been investigated quite comprehensively. Studies of the crystal structures of anthracene derivatives before dimerisation showed that the final products do not always correspond to compounds whose formation is predicted by the topochemical reaction mechanism. Calculations for the possible local rearrangements in the molecular packing (the appearance of defects and dislocations), responsible for the formation of the final products, are therefore essential in many instances for the modelling of the dimerisation processes.

The anthracene (XXII) dimerises on irradiation and the crystal structure of the monoclinic modification of compound (XXII) does not satisfy the requirements for the occurrence of a topochemical reaction.[39]

(XXII) (XXIII)

It has been suggested that the relative orientation of the molecules of (XXII) convenient for dimerisation can arise at structural defects. Calculation of the energy of the displacement of one half of the crystal relative to the other along the (001), (010), (0$\bar{1}$0), (100), and (20$\bar{1}$) planes (atom–atom approximation) showed[40] that the displacement along the (010) plane should take place most readily, which corresponds to the direction of the dislocations most frequently observed in the anthracene crystal.[41] Analysis of the intermolecular distances changing as a result of the displacement showed that local molecular arrangements, favourable for dimerisation, can arise at the interface. However, Mirsky and Cohen[40] failed to take into account the changes in the disposition of the molecules (relaxation) near the defect, which led to unduly high displacement energies and to clearly unduly low interatomic distances.

The stabilities of point defects arising on the surface and in the bulk of the crystal of compound (XXII) on the removal of one molecule or on replacement of five molecules in the lattice by the more "freely" distributed four molecules have been estimated.[42] This calculation, carried out taking into account the relaxation of the molecular environment around the defect, showed that a defect can be thermodynamically stable and favourable for the subsequent rearrangement with participation of excited molecules.

The metastable triclinic phase of the anthracene (XXII) is formed when the monoclinic crystal is compressed in the direction at right angles to the basal plane. Its structure has been determined by electronic transmission microscopy and has been confirmed by the calculation of the molecular packing by the method of atom–atom potentials. It was found that the atoms interacting on dimerisation in the triclinic structure of compound (XXII) are closer together than in the monoclinic phase (the distance between them has been reduced from 4.5 to 4.2 Å). Calculation for the possible rearrangement of the two modifications on excitation of their molecules[43] failed to reveal changes sufficient to ensure the topotactic formation of the dimer. Consequently the occurrence of the reaction at structural defects is extremely probable.

A similar picture has been observed also for anthracene derivatives. Thus, when 1,5-dichloroanthracene is irradiated in solution with UV light, it is converted into a mixture of "head to head" (HH) and "head to tail" (HT) isomers in proportions of 40:60.[32] The solid-phase dimerisation of the monoclinic form leads to the formation of a dimer of the HH type (the reacting atoms of neighbouring molecules are at a distance of 4.05 Å).[30] The crystalline structure of the triclinic modification formed on dimerisation of a mixture of 80% of the HH isomer and 20% of the HT isomer has been determined by the method of atom–atom potentials.[30] A distance of 4.0 Å between the translationally linked molecules in this structure corresponds to the topochemical mechanism of the formation of the HH isomer. The study of the planar or linear defects showed that the symmetry of the given lattice makes it impossible to find a displacement which would lead to the formation of a dimer of the HT type. Presumably some of the molecules acquired an orientation favouring the formation of the HT dimer on rotation during the crystallisation process, i.e. a point defect appeared. Calculation of the energy of such defects, which is defined as the difference between the energies of the interaction with the environment of the "defect" molecule and the molecule in the ideal lattice has shown[44] that it amounts to ~4 kJ mole$^{-1}$ in the triclinic structure and ~100 kJ mol$^{-1}$ in the monoclinic structure. These differences explain the ease of formation of defects and the appearance of two dimeric products in the triclinic structure.

Dimerisation in the crystals of 1,8-dichloro-9-methylanthracene (XXIV)[45] and 1,8-dichloro-10-methylanthracene (XXV)[30] entails the formation of *cis*-products which are not due to a topochemical reaction. Energy calculation for compound (XXIV)[45] has shown that the appearance of planar defects "preparing" for the formation of the *trans*-dimers is possible. Modelling and electron microscope study of the dislocations in the crystal of compound (XXV)[46] made it possible to explain analogously the formation of dimeric products in this case also. Processes involving the formation of excimers and rearrangements occurring in the crystal lattice under these conditions have been examined in fair detail for anthracene and its derivatives both experimentally and with the aid of computational models. The results of studies devoted to these questions are discussed in the next Section.

### 8. Excimers in Crystals

Excimers were first detected in concentrated pyrene solutions, which exhibited unusual spectroscopic properties on irradiation compared with dilute solutions.[47] Later excimers were found also in pyrene crystals.[48] Experiment showed that excimers are formed throughout the bulk of the crystal and not only at structural defects. The molecular planes are almost fully overlapped to the maximum extent and approach one another. The formation of excimers is most probable when such overlap obtains already in the initial crystal structure.

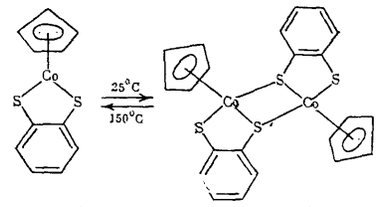
Various computational models have been used to describe the geometry and spectroscopic characteristics of excimers (excimer emission).[49-51] The interactions of the pair of molecules in the excimer are usually assessed semi-empirically by quantum-chemical methods, while the interactions with the environment in the crystal are assessed in terms of the atom–atom approximation. Other parameters, characterising the dispersion interactions, which change as a result of the polarisation or excitation of the molecule, are sometimes specified (within the framework of the atom–atom approximation) for the excited molecule.

In the free pyrene excimer the molecular planes overlap fully and the distance between them becomes 3.2 Å. For such mutual approach of the molecules in the crystal, it is essential to displace them by approximately 0.7 Å, which involves the overcoming of an energy barrier of ~15–20 kJ mole$^{-1}$.[50] Analogous results have also been obtained in the calculation for the α-form of perylene.[51]

Many compounds, in the crystals of which excimers arise on irradiation, tend to undergo photodimerisation reactions. Since the formation of the excimer involves the mutual approach of two molecules and an increase of the degree of overlap of their planes, the excimer can be regarded as a dimerisation intermediate. This has been demonstrated in relation to a series of anthracene derivatives[51-53] which have three types of characteristic packing in the crystal: (1) "herring bone" packing without the overlap of the planes of the nearest molecules (type A) (both anthracene modifications); (2) stacked packing with a "head to head" arrangement—type B1 (9-cyano-, 9-chloro-, 9,10-dichloro-, and 9-carboxy-anthracene); (3) packing with a "head to tail" arrangement of molecules in pairs—type B2 (9-methyl- and 9-amino-anthracene). Emission of the monomer type only is observed in type A crystals,[52] while in crystals of types B1 and B2 the overlap of the molecular planes is significantly greater, excimers and dimers being formed in them; the frequencies change to the greatest extent in type B2 compounds on transition to the excited state.

The possible changes in the relative disposition of the molecules in crystals following the appearance of an excited molecule in the latter have been calculated by the method of atom–atom potentials[54] for two modifications of anthracene and its derivatives—9-cyanoanthracene (XXVI) and 9-methylanthracene (XXVII), which are characterised by different types of packing. Following the appearance of an excited molecule in the crystal of compound (XXII), the disposition of the molecules surrounding it hardly changes, which agrees with the absence of excimer emission. Dimers apparently are not formed in the bulk of the crystal, which does not rule out dimerisation on the surface and on defects.[54] In crystals of compound (XXVI) the excited molecule approaches one of the neighbouring molecules in the stack and the surrounding molecules are "drawn" towards this pair. Since in the given instance the dimerisation products contain only the *trans*-dimer (and not the *cis*-dimer, which corresponds to a topochemical mechanism), presumably the excitation energy of the *cis*-excimers is transferred to structural defects, where the *trans*-dimer is formed. In crystals of compound (XXVII) (type B2), the excited molecules are appreciably displaced towards one of the molecules in its environment, while the positions of the remaining surrounding molecules change little. The absence of steric hindrance and the antiparallel directions of the molecular dipole moments, as in the second modification of 9-chloroanthracene (likewise type B2), permit dimerisation throughout the bulk of the crystal.[54]

The most striking examples of the intermediate formation of excimers are provided by the decomposition and redimerisation in the crystal of dianthracene (XXIII).[44] If a single crystal of compound (XXIII) is subjected to high-energy irradiation, some of the dimer molecules are cleaved into pairs of monomers. Exposure to low-energy irradiation leads to excimer emission and the redimerisation of the monomer molecules. The quantum yields of both processes depend on temperature. Thus, together with dimerisation, the excimer emission serves as a pathway leading to the deactivation of the excimer.



Calculations carried out in terms of the atom–atom approximation, which models the processes described above, have shown[55] that the formation of dianthracene crystals incorporating pairs of anthracene molecules is energetically more favourable than the formation of crystals of dianthracene alone as a result of the increase of the intensity of the non-valence interactions in pairs of molecules compared with the dimer.[55] In our view, a special physical significance should not be attributed to the energy differences observed, but it is clear that the dissociation of the dimer does not induce a significant steric hindrance in the lattice. According to the calculation, the disposition of a pair of molecules of compound (XXII) in the dianthracene matrix is such that their planes do not overlap fully. Hence one can understand the necessity for the expenditure of energy in order to overcome the barrier to the formation of the excimer or to redimerisation.[55]

Excimers are also formed in crystals made up of planar aromatic molecules. Thus excimer emission and photodimerisation are characteristic of two crystalline forms of 2,4-dichloro-3-methylstilbene.[56] In one of the modifications with a stacked molecular arrangement *cis*-excimers and dimers with *m* symmetry are formed. In the other modification, with molecules which have approached one another in pairs, *trans*-excimers and centrosymmetric dimers arise. Thus, in the given instance the structure of the dimer is determined by the same characteristics of the crystal packing as the structure of the excimer.

The formation of excimers in a crystal made up of non-rigid molecules (analogous to those mentioned above) is a more complex process than for rigid aromatic molecules. According to calculations, the photodimerisation of 1-(2,6-dichlorophenyl)-4-phenylbutadiene is accompanied not only by the mutual approach of the molecules but also by a change in their conformation.[57,58] It has been shown that the excimer can be obtained in two ways presupposing the approach to one of two neighbouring molecules in the stack, requiring approximately identical energy expenditures. At any rate, it follows from the results of the calculation taking into account the molecular relaxation that the excimer has an asymmetric environment. The real pathway followed in the dimerisation reaction can be deduced only by determining the structure of the monomer and the products formed by X-ray diffraction. Calculation for 1-(2,6-dichlorophenyl)-4-phenylbutadiene does not rule out the appearance in the crystal not only of excited dimers but also of trimers.

### 9. Cyclopentadienyl(*o*-phenylenedithio)cobalt

The dimerisation of cyclopentadienyl(*o*-phenylenedithio)-cobalt is an example of a rarely encountered reversible solid-phase process (XXVIII).[48]

(XXVIII) (XXIX)

In the crystal of compound (XXVIII) the molecules are arranged "head to tail" and, although the Co...S intermolecular distances [4.702 and 4.325(1), Å] are fairly large, the relative disposition of the "heavy" atoms (Co and S) resembles that observed in the crystal of the dimer (XXIX). In the course of the solid-phase transition the coordination of the cobalt atom changes from the "two-legged" type in compound (XXVIII) to the "three-legged" piano stool type in compound (XXIX). The slope of the plane of the $\eta^5$-$C_5H_5$ ring relative to the S–Co–S plane changes by 45° on passing from compound (XXIII) to compound (XXIX). Whereas the metal-containing ring in compound (XXVIII) is almost planar (the maximum deviation is 0.02 Å), in compound (XXIX) the ring is bent along the S...S line by 20.9°.

The solid-phase dimerisation of compound (XXVIII) takes place as a result of the mutual approach of its molecules (predominantly in the direction of the *b* axis) and increases the density of the crystal by 6%. The orientation of the axes in the crystals of compounds (XXVIII) and (XXIX) (which belong to the same space group $P2_1/c$) is not the same and the reaction is not topotactic. At 25 °C the dimerisation is fairly slow owing to the relatively high "rigidity" of the potential energy surface of the crystal. Furthermore, the development of the reaction requires defects—nucleation centres. The rate of the reverse reaction (XXIX) → (XXVIII), which depends on the particle size, is low at 150 °C but rapidly increases at higher temperatures. The small enthalpy of monomerisation ($\Delta H$ = 18.9 kJ mol$^{-1}$ at 150–160 °C) found from data obtained by differential scanning calorimetry is consistent with data indicating the occurrence of conformational polymorphism and is insufficient for the occurrence of the reversible solid-phase reaction despite the considerable displacements of the atoms.[48]

The examples examined show that the combination of experiment (X-ray diffraction and spectroscopic methods) and calculation makes it possible to investigate various stages in the formation of dimers in the crystal. It may be that subsequently this approach will be applied also to the consideration of more complex solid-state reactions.

## III. REDIMERISATION

The redimerisation process in the crystal has been most thoroughly investigated for anthracene derivatives (see also above). It has been shown that the *trans*-dimer (XXX) of 9-cyanoanthracene (XXXI), formed by the solid-phase dimerisation on irradiation with UV light,[59] is capable of being reconverted into the monomeric form in the crystal on thermal or photochemical initiation,[60] which imparts practical importance to this reversible process, for example, for the reversible absorption of solar energy.[61] The study of crystals by differential scanning calorimetry has revealed the presence of two exothermic peaks, the second of which corresponds to the complete conversion into the monomeric form and the first (at 152 °C) corresponds to a homogeneous topotactic single crystal → single crystal phase transition of the colourless triclinic crystal of compound (XXX) into the yellow, also triclinic, crystal of compound (XXX'). The driving force of this polymorphic transformation is partial conversion into the monomeric form [the admixture of the monomer (XXXI) in the crystal of compound (XXX') amounts to 8%].[60]

Pyrimidines and their *N*-methyl derivatives dimerise on UV irradiation in the solid phase via their double bonds in the 5- and 6-positions. Depending on the disposition of the dihydropyrimidine rings relative to the cyclobutane ring formed on dimerisation, four stereoisomeric forms of the dimer are possible: *cis, syn-*, *cis, anti-*, *trans, syn-*, and *trans, anti-*.[62] The structures of ten dimers of all four types have been determined,[63] including the *cis, syn*-form encountered in DNA[64] and two dimers (of the *trans, anti*-type) of thymine and 1-methylthymine.[65]

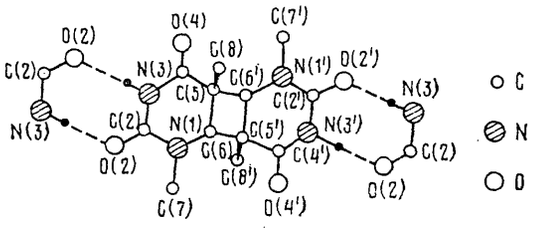


Figure 5. A fragment of the crystal structure of compound (XXXII); the N–H...O hydrogen bonds linking the molecules of compound (XXXII) into infinite chains in the [110] direction are shown dashed.[66]

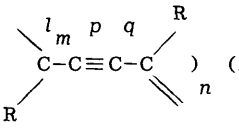
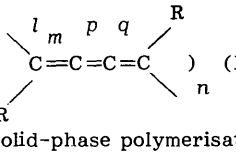
The thymine dimers are cleaved in solution on irradiation with UV light[66] or X-rays.[67] The solid-phase conversion into the monomeric form on exposure to $^{60}$Co γ-rays of the crystals of all four stereoisomers of the *NN*-dimethylthymine dimer[68] or in the course of X-ray measurements on three dimers of the *cis, syn*-type[69] is also possible. X-Ray diffraction study of the 1,1'-trimethylenethymine dimer revealed the presence of ~10% of monomeric molecules incorporated in the dimer crystal.[70] The possibility of the conversion into the monomeric form has been reported by the investigators of the structure of the 1,3-dimethylthymine dimer (a sharp increase in the length of one of the interpyrimidine bonds to 1.66 Å), but the monomeric molecules could not be located.[71] A third example is provided by the sodium salt of the thymine dimer, in the crystal of which monomer molecules were found.[72]

We shall consider the structure of the *trans, anti*-dimer of 1-methylthymine (XXXII).[66] The molecules of compound (XXXII), combined in the crystal into infinite chains along the [110] direction by N(3)–H...O(2) bonds (Fig.5), show no signs of the steric strain observed in the dimers of the *cis, syn*-type, which also associate in the crystal on irradiation with X-rays [the steric strain is shown by the shortened intramolecular distances between the methyl groups at the C(5) and C(5') atoms[70–72]]. Nevertheless the crystal of compound (XXXII) contains ~4% of the monomer molecules

formed as a result of the solid-phase dissociation on irradiation with X-rays in the course of the structural study. This result confirms data[64] indicating the possibility of the solid-phase dissociation on irradiation of unstrained stereoisomeric dimethylthymine dimers with X-rays.

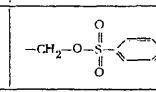


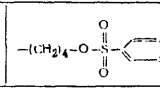


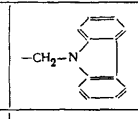
## IV. POLYMERISATION

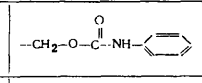
The greatest advances have been made in the field of topochemical solid-phase non-diffusional polymerisation of diacetylenes, which proceeds via 1,4-addition. Reports about these processes appeared a long time ago (the crystals of diacetylenedicarboxylic acid darken on illumination and irradiation with X-rays[73]), while the most important results were obtained approximately 15 years ago by Wegner[74-76] and Baughman.[77] The second field involved the study of solid-phase topochemical polymerisation reactions of diolefins. The investigations began after the report of the ability of the α-modification of 2,5-distyrylpyrazine to polymerise as a result of the photoinduced [2 + 2]-polycycloaddition[78,79] although data concerning the possibility of the occurrence of the process had appeared considerably earlier.[80]

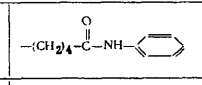
A number of other systems which polymerise in the crystal subject to more or less vigorous topochemical control are also known.[80] Compared with the first two systems (diacetylenes and diolefins), they are less important. Among them, mention should be made in the first place of the cyclic oligomers of formaldehyde, which are capable of polymerisation with the opening of the ring. Although a distinct topotactic interrelation is observed between the starting materials and final product in this process, the latter is not topochemical. This reaction has been considered in detail in a review.[80]

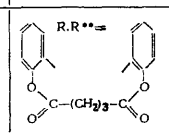












### 1. 1,4-Addition of Diacetylenes

The solid-phase polymerisation of diacetylenes (DA), which makes it possible to obtain large single crystals of polydiacetylenes (PDA), is a fairly thoroughly investigated reaction (see the relevant reviews[80-83]). Nevertheless studies in this field still remain timely, mainly in connection with the vigorous development of research in the field of conducting organic systems.

The solid-phase polymerisation of the diacetylene R–C≡C–C≡C–R, which is initiated either by heating to temperatures below the melting point, or by irradiation with γ-rays or UV light, or by other influences, constitutes poly-1,4-addition. The products of this reaction consist of quasi-one-dimensional macromolecules with a conjugated skeleton fully in the *trans*-configuration.[74-77] Two limiting structures of PDA are possible: the ene-yne (ethylene–acetylene structure  (A) and the butatriene (cumulene) structure  (B); in the real PDA, obtained by the solid-phase polymerisation of DA (Table 2), both structures have been detected, although structure (A) predominates.[78,84-88]

Numerous studies have been devoted to the physicochemical properties of PDA (see, for example, Yee and Chance[82]). The thermal stability of PDA can be both low [compound (XXXIIIp) decomposes at temperatures not

Table 2. Principal structural parameters of PDA obtained by the solid-phase polymerisation of R–C≡C–C≡C–R.

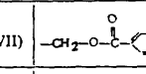
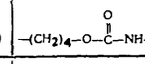
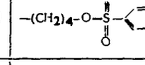
*Literature data not available.

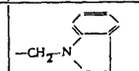
**The monomer unit has a cyclic structure.



***The repeat period of the polymer chain is greater by a factor of approximately two than for (XXXIIIp)–(XXXVIp) in connection with the different (*trans*) disposition of the cyclic substituents relative to the PDA chain.







exceeding 70 °C[89]] and very high [the weight loss of compound (XXXVIIp) is 2.5% at 300 °C,[90] while compound (XXXVp) is stable up to 300 °C and at 400 °C its weight loss does not exceed 6.5%]. Whereas the thermal stability of compound (XXXVIIIp) has been accounted for by the stabilising effect of bisphenylglutaric chains forming a ring on the polymer chain, the thermal stability of compound (XXXVp) is associated with the stability of the carbazolyl substituent [furthermore, a high mechanical strength is characteristic of compound (XXXVp)[82]].

The electrophysical properties of PDA are of special interest. Although these polymers remain insulators under the usual conditions[91–95] [for example the average conductivity of compound (XXXIIIp) is $\sigma = 10^{-15}\ \Omega^{-1}\ cm^{-1}$ [82]], the PDA crystals exhibit anisotropic conductivity.[81] At the same time, by doping the DA crystals with iodine and by subsequent solid-phase polymerisation under the influence of γ-irradiation, it is possible to obtain PDA with metallic lustre and $\sigma = 10^{-4}\ \Omega^{-1}\ cm^{-1}$.[93] The photoconductivity of PDA has been investigated.[82,94] The lowest optical transition energy (1.89 eV) is that of the crystals of compound (XXXIIIp).[82] The appreciable hypsochromic shift of the photoconductivity spectra of PDA relative to the optical absorption spectra is consistent with the exciton mechanism of the optical transitions with the minimum energy in PDA.[82]

The study of the structure of PDA is of special interest for two reasons. Firstly, the polymerisation of DA is possible only under lattice control and is not observed in the melt, in the gas phase, or in solution.[81] Secondly, data for the structure of PDA are important in connection with the similarity of these polymers to polyacetylenes—an important class of organic metals, the elucidation of the structure of which (particularly in doped systems) is fairly difficult.[95]

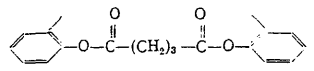


Table 3. The principal data on the reactivities in solid- phase polymerisation and molecular packing in crystals of the structurally investigated diacetylenes of the type R–C≡C–C≡C–R (for the significance of the parameters $S_1$, $\gamma_1$, and $d_1$, see Fig. 6).

*******Cyclic DA.

Apart from the linear DA (XXXIX)–(LVII), the solid-phase polymerisation of the cyclic DA (LVIII) (Table 3) with formation of a fully stereoregular polymer (XXXVIIIp), whose skeleton is threaded by ring-forming *oo*-bisphenylglutarate groups, has also been investigated:[90,112,113]

The capacity for solid-phase polymerisation of the even more complex macrocyclic DA $[-(CH_2)_2-C\equiv C-C\equiv C-(CH_2)_2-]_4$ (LIX) has been observed. As a result of the 1,4-addition via all four diacetylenic groups, this compound is converted into an ordered polymer with a "cylindrical" structure.[114]

The conditions governing the formation of large defect-free crystals of PDA by the solid-phase polymerisation of DA have been analysed.[115]

1. The free energy barrier to cooperative displacements of the DA molecules, necessary for their polymerisation, increases (i.e. the capacity for polymerisation diminishes) with increase of the displacement of the interacting molecules necessary for the reaction.

2. The polymeric molecules must be capable of forming solid solutions in the crystal of the polymerising matrix at any degree of conversion (single-phase or homogeneous polymerisation).

3. The symmetry of the crystal environment of the monomer molecules must correspond to the symmetry of the environment of the monomeric unit of the polymer molecule.

By varying the reaction conditions, it is in many instances possible to promote single-phase polymerisation, in particular, by imposing an external force field it is possible to alter the symmetry of the monomer crystal.[115] However, only polycrystalline PDA are formed in the polymerisation of certain DA. This happens in those cases where the nucleation of the new phase (the solid-phase polymerisation can be regarded as a special type of phase transition) occurs on defects, surfaces, or impurities in the monomer crystal.[81] In principle, such processes can lead to the formation of large PDA crystals (when the polymerisation and crystallisation take place simultaneously). On the other hand, the topotaxy in the initial and final phases does not necessarily indicate the topochemical character of the solid-phase transition.[81]

We shall consider the mechanism of chain propagation in the monomer crystal matrix. The following scheme has been proposed for this process: thermal (or radiation-induced) excitation of the conjugated triple bonds with transition to intermediates of the dicarbene type, combination of the dicarbenes with formation of double bonds, and growth of the macromolecule as a result of further addition of excited molecules to the carbene-like end of the chain.[81] The formation of biradical dimeric, trimeric, and tetrameric, etc. intermediate compounds has been detected by EPR[116–119] and optical spectroscopic[120,121] methods in the study of the solid-phase transition (LIII) → (XXXIVp). The most probable chain length of the PDA macromolecules in the polymerised crystal of compound (XXXIVp) has been estimated by gel-permeation chromatography. It amounts to 1600 monomeric units when the polymerisation is carried out at 7 °C and to 400 units at −263 °C. The difference is attributed to the different mechanisms of the polymer chain propagation.[85]

The condition governing the solid-phase reactivity (the Schmidt condition[2,10,122]), which has been extended in a general form to polymerisation by Kargin and Kabanov,[123] has been formulated by Wegner (see, for example, Shklover et al.[80]) and Baughman (see, for example, Ref.77) on the basis of the analysis of the crystal structures of DA active and inactive with respect to solid-phase polymerisation. This condition reduces to the following limiting values of the parameters $S_1$ and $\gamma_1$ of the molecular packing of DA, generating ladder (stacked) motifs in the crystals: $3.4 \leq S_1 \leq 4.0$ Å; $\gamma_1 \cong 45°$ (Fig.6). In the polymer, $d_2 = 4.9(1)$ Å and $\gamma_2 = 13.5°$.[77,80]

The rates of the solid-phase polymerisation of the chemically very similar compounds (XLVII) and (XLVIII) differ sharply: compound (XLIV) reacts much faster.[104,105] In the crystal of compound (XLIV), the values of $S_1$ (3.36 Å) and $\gamma_1$ (42.4°) satisfy the Wegner–Baughman conditions. In the crystal of compound (XLVIII) two types of relative dispositions of the molecules have been distinguished: the δ-type ($S_1 = 3.817$ Å and $\gamma_1 = 67.54°$) and the δ′-type ($S_1 = 4.643$ Å and $\gamma_1 = 63.44°$). In the former case the solid-phase interaction is significantly hindered, while in the latter case it is impossible.[104,105]

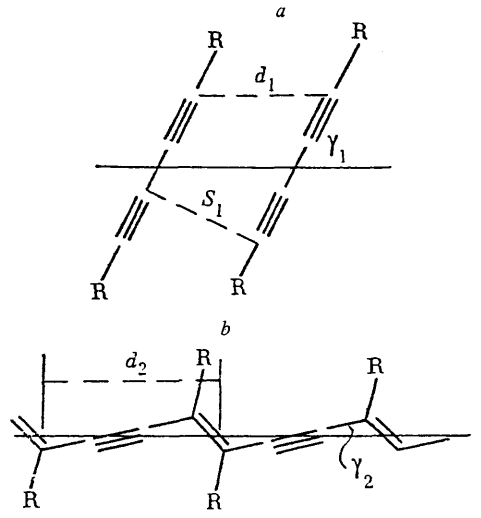

Figure 6. Schematic illustration of the packing of DA crystals with a ladder disposition of the molecules (*a*) and the structure (fragment) of the PDA molecules formed on polymerisation of DA via the "scissors" mechanism (*b*).[77,80]

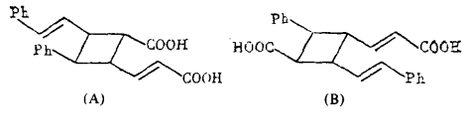
It is of interest that an appreciable infringement of the "scissors" mechanism of the polymerisation of DA has been observed for the solid-phase reaction (LIII) → (XXXIVp) (Fig.6): the centre of gravity of the DA fragment shifts on polymerisation by 0.97 Å.[85] The possibility of such a shift without the breakdown of the crystal lattice structure can be explained by the fact that the toluene-β-sulphonate groups occupy pseudocentrosymmetric positions in the crystal, i.e. they retain their positions on transition to the centrosymmetric crystal of compound (XXXIVp).

The solid-phase polymerisation of the monomer (L), the only reactive DA in the crystal of which the DA "rods" are not parallel but are arranged at an angle of 72°, may constitute an exception to the "scissors" mechanism. The solid-phase transition of the monomer (L) on treatment with dioxan vapour to a very rapidly polymerising modification containing dioxan of crystallisation is also unusual.[106]

## 2. Polymerisation of Olefins

The topochemically controlled solid-phase polymerisation has found many applications in the past years. The synthesis from achiral precursors of chiral polymers, which are new materials for optical devices,[127] has been reported.[9,124-126] Goldanski[128] discovered reactions at extremely low temperatures whose rate is independent of temperature. However, the mechanism of the topochemical polymerisation has not so far been elucidated. In particular, it is not clear whether the crystal structure of the monomer controls all or only some of the three main processes: initiation of polymerisation, propagation of the polymer chain, and crystallisation. The role of the microstructure, in particular of the imperfections of the monomer crystal, has been inadequately investigated. A review[129] has been devoted to the discussion of these questions in terms of the results of X-ray diffraction and electron microscopy experiments. The crystallographic data for monomer–polymer pairs and the crystal structures of 11 diolefinic monomers are considered in this review.



The main conclusion is that the principle of topochemical control formulated by Schmidt[2] plays a decisive role in the four-centre polymerisation of diolefins. In contrast to diacetylenes, many diolefins are available for X-ray diffraction study in both monomeric and polymeric states,[77,130] which makes it possible to determine the topotactic relation between the initial phase and the polymerisation product.[5] Three types of systems have been discovered: (a) all three crystallographic axes of the polymer and monomer crystals coincide (the difference between the volumes of the unit cells is small); (b) the directions of only one axis, along the polymer chain, coincide; (c) the directions of all three axes do not coincide. Although the changes in the unit cell parameters of all the systems investigated are fairly significant on polymerisation [up to 13% for 2,5-distyrylpyrazine (LIX)], the change in the unit cell is small [less than 2% for compound (LIX)].[129] The space group of the monomer crystal is as a rule retained on polymerisation. The solid-phase polymerisation of diolefins always occurs with topochemical control but the strains induced by this process in the lattice of the initial compound lead in all the cases investigated to the fragmentation of the monomer single crystal and the formation of a polycrystalline product.[129]

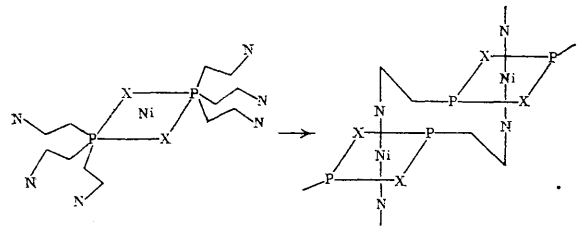
The role of the rigid lattice in solid-phase polymerisation has been confirmed by data for the reaction of diethyl *p*-phenylenebisacrylate (LX), whose polymerising centrosymmetric modification has a melting point of 96 °C. After the irradiation of crystals of compound (LX) at temperatures close to the melting point, an amorphous oligomer is formed; if the process is carried out at 0 °C, it is possible to obtain a crystalline polymer.[131] Thus, even if the initial reaction stages occur in the crystal lattice of the monomer, the topochemical control over the subsequent reaction stages is lost when the thermal energy evolved is comparable to the crystal lattice energy.[129]

Amorphous oligomers appear in the solid-phase reactions of diolefins in those cases where the translationally linked molecules react topochemically with formation of cyclobutane rings having the *m* symmetry. However, the primary products, the V-shaped dimers, disrupt the initial crystal lattice to such an extent that the distances between the reacting double bonds become too great. In other words, the monomer lattice breaks down at the dimerisation stage and the subsequent formation of the amorphous oligomer is not subject to rules of any kind.[130,131] It has been found that the solid-phase oligomerisation of dimethyl 4(2-carboxyvinyl)-α-cyanocinnamate (LXI) takes place in this way.[132]

The molecules in the crystal of compound (LXI) are packed in stacks along the $c = 3.956(1)$ Å axis, in contrast to the crystals of photo-diolefins, where the lattice period along the stacks, formed by molecules displaced by one half of the molecular length, is ~7 Å.[133] Thus the translation of *c* in the crystal of compound (LXI) corresponds to the shortest distance between the reactive double bonds, which is close to that found in photopolymerising crystals (on average 3.94 Å)[132] and differs from the crystals in photostable crystals (for example 4.187 and 4.369 Å[15]). The next distance in terms of magnitude between the double bonds of the molecules of different stacks in the crystal of compound (LXI) exceeds 5 Å. The molecules of compound (LXI) apparently interact within the stacks with formation of cyclobutane derivatives having the mirror symmetry. Such a reaction infringes the ordered arrangement of the molecules in the rest of the monomer crystal and for this reason only an amorphous oligomer is produced.[132]

Kashino and Haisa[134] investigated the geometrical conditions governing the solid-phase reactivity in crystals of two noncentrosymmetric diolefins: 5-phenylpenta-2,5-dienoic acid (LXII) and 1,5-diphenylpenta-2,4-dien-1-one (LXIII), of which the first exhibits solid-phase reactivity. The molecules in the crystal of compound (LXII) are combined via O–H...O hydrogen bonds into dimers whose axes are approximately parallel to the [0$\bar{1}$4] direction. The dimers are in their turn combined into broad strips. The distances between the approximately parallel double bonds (4.07 and 4.42 Å) are favourable for the formation of a type (A) dimer on irradiation of crystals of compound (LXII).[135]

(A) (B)



The angle between the interacting double bonds, which is 28°, can be reduced as a result of thermal movement. In the crystal of compound (LXII) it is also possible to distinguish pairs of molecules in which the mutual orientation of the double bonds promotes the preferential formation of the dimers (B).[135] However, in this case the distance between the double bonds (4.56 and 4.62 Å) is somewhat greater than in photopolymerising crystals.[2] On the other hand, it is possible to distinguish pairs of molecules in which the distance between the double bonds does in fact allow interaction (3.60 and 4.46 Å), but their inclination at an angle of 87° rules out the possibility of reaction in this direction according to the authors.[135]

In the crystal of compound (LXIII) the double bonds in neighbouring overlapping molecules have not approached one another and are not parallel, in contrast to, for example, the photopolymerising crystals of *trans*-cinnamic acid[136] and diphenyl *p*-phenylenediacrylate.[134] The gap of 5.31 Å between the nearest parallel C(4)...C(5) bonds greatly exceeds 4 Å, i.e. the distance necessary for dimerisation.[2]

An attempt has been made to interpret the solid-phase polymerisation process in relation to model crystals of ethylene[137-140] and formaldehyde.[141] Using quantum-chemical methods and the method of atom–atom potentials, calculations have been made of individual sections of the potential energy surface which suggested that the nuclei of the polymer chain are located in non-equilibrium positions between the crystal lattice sites; chain propagation takes place as a result of the migration of the chain nucleus in the crystal, which does not require an energy expenditure. Unfortunately, the alternative dislocation mechanism of the process was not considered in the above studies.

### 3. Thermal Polymerisation of the $NiHal_2L_2$ Complexes

The red square monomeric complexes $NiHal_2L_2$ [Hal = Cl or Br; L = $P(CH_2CH_2CN)_3$] are converted on standing into the blue polymers $(NiHal_2L_2)_x$ with the octahedral coordination of the Ni atom.[142]

Only one of the three cyanoethyl groups of each ligand L participates in the polymerisation. X-Ray diffraction study of the monomer, the polymer (its crystals were grown in solution), and also partly polymerised monomer crystals established that the volume of the unit cell of the complex $NiBr_2L_2$ changes only slightly on polymerisation (2459 and 2467 Å$^3$ for the monomer and polymer respectively) and the length of the lattice period *c* hardly changes at all (8.49 and 8.50 Å).[142] The reaction is heterogeneous and the monomer and polymer are not isomorphous. The topotactic relation between the crystal lattices of the monomer and polymer and the crystallographic direction of the propagation of the polymer chain, namely [101], have been determined. The identity of the polymers obtained by polymerisation in the crystal and in solution has been demonstrated.[142,143]

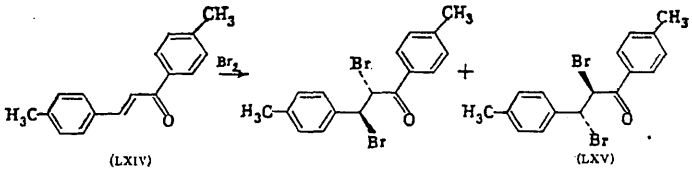
The monomer $NiCl_2L_2$ exhibits the lowest reactivity. Thermal depolymerisation before fusion is characteristic of the polymer formed. The volume of the monomer unit cell is smaller than that of the polymer (2386 and 2402 Å$^3$ respectively). The changes in the lattice identity period are somewhat greater than for the bromo-complex. Furthermore, not one direction of the propagation of the polymer chain, as in $NiBr_2L_2$, but two such directions, namely [101] and [10$\bar{1}$] have been observed for $NiCl_2L_2$ crystals, which leads to a different orientation of the polymer macromolecules in the crystal produced.[142]

The directions of growth of the macromolecules in the doped $NiBr_{1.84}I_{0.16}L_2$ {the [201] direction} and initial $NiBrL_2$ crystals are different, the difference being attributed,[142] in particular, to the character of the disposition of the dopant atoms and of the defects introduced by them approximately in planes perpendicular to the [201] direction.

The complexes $Ni(SCN)_2L_2$, $Ni(CN)_2L_2$, and $NiI_2L_2$ do not polymerise either in the solid phase or in solution. On the other hand, the $Ni(NCS)_2L_2$ crystals exhibit other interesting properties: conformational polymorphism and capacity for martensite-like phase transitions.[142]

## V. ASYMMETRIC SYNTHESIS

Topochemically controlled reactions lead to new possibilities for asymmetric synthesis, frequently with a quantitative yield and in systems "convenient for control".[9,125,144] Furthermore, optically active compounds can be sometimes obtained as a result of the crystallisation of solutions of achiral starting materials and subsequent solid-phase reactions without any external asymmetric influence.[124,126] Studies on these lines, justly referred to as "absolute asymmetric synthesis", can bring us nearer to the solution of the more general problem of the appearance and spread of optically active compounds in biological systems.[124]



Asymmetric synthesis in the crystal has two aspects: the formation of chiral crystals and topochemically controlled solid-phase reactions with formation of chiral products. The very crystallisation process can be regarded as the simplest form of reaction, because the molecules in solution or in the melt usually assume an infinite number of conformations, while in crystallisation they have one or (more rarely) two conformations. Thus asymmetric induction is completed already in the crystallisation stage in the chiral structure; it only remains to transfer this chirality to the configurationally more stable form via a solid-phase reaction.[9]

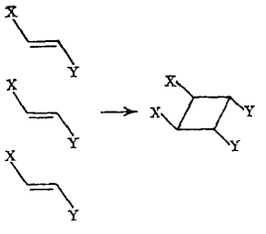
Chiral crystal structures with definite intermolecular and intramolecular characteristics are essential for the systematic study of solid-phase asymmetric synthesis. This problem, which is part of the more general problem of crystal structure "engineering", so far has not had a general solution and studies on these lines are frequently heuristic.

A number of simple qualitative procedures for the synthesis of optically active products as a result of solid-phase reactions are known. For example, carboxylic acids and their primary and secondary amides tend to form centrosymmetric hydrogen-bonded dimers, i.e. they crystallise in centrosymmetric achiral space groups.[146,147] On the other hand, if the molecule contains a second functional group forming hydrogen bonds (−OH, >NH, S=O, etc), then, instead of centrosymmetric dimers, helical chains arise in the crystal, which increases the probability of the formation of crystals with a chiral structure.[148,149] Molecules with an intrinsic $C_2$ symmetry[150] and especially $C_3$ symmetry[9] tend to crystallise in chiral space groups. Clathrates, for example, those of urea and tri-*o*-thymotide, which form chiral crystals with incorporated achiral "guest" molecules, can be conveniently used to construct chiral crystal matrices.[151] The introduction of stable chiral groups into the molecule is believed nowadays to be the most reliable method for the synthesis of an achiral structure.[8]

We shall consider initially achiral or rapidly racemising molecules, which crystallise to give chiral crystals. If the inversion of the configuration is faster than crystallisation, there is a possibility of the formation of unequal amounts of enantiomorphic crystals with excess of one of the enantiomers. It is sometimes possible to obtain the entire substance in the form of a single enantiomorphic homochiral cyrstal.[152,156] The second case is one where the chirality of the crystal is determined by the molecular chirality. Asymmetric synthesis in such systems can be carried out in polycrystalline specimens, since asymmetric induction depends not only on the chirality of the molecules but also on the chirality of their environment in the crystal.

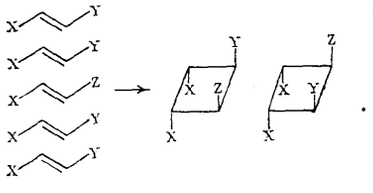
The first experimental confirmation of the possibility of the solid-phase asymmetric synthesis was provided by the interaction of the chiral 4,4′-dimethylchalcone single crystal with gaseous (or liquid) bromine.[157]

(LXIV) (LXV)



The choice of this particular system was made on the basis of earlier data for gas–crystal reactions and crystallographic studies on olefinic systems; 1,2-asymmetrically substituted crystalline *trans*-olefins interact with bromine vapour to form *erythro*-dibromides as a result of *anti*-addition.[158] Chalcones (αβ-unsaturated ketones) are capable of forming chiral crystals, because their molecules assume highly

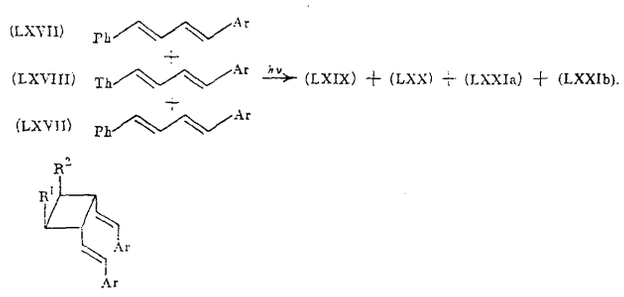
twisted conformations in the crystalline state (i.e. the deviation from the achiral planar conformation is large).[159]



It has indeed been found that the molecules of compound (LXIV), which crystallises in the chiral space group $P2_12_12_1$ have a significantly non-planar structure in the crystal.[160] When ground (in order to increase the area of the exposed surface) crystals of compound (LXIV) are treated with bromine vapour, the dibromide (LXV) is formed with an excess of one of the enantiomers. The optical yield varies from 6 to 25%.[9,157] The determination of the absolute configuration of compound (LXIV)[161] makes it possible to relate the configuration of the initial molecule in the given single crystal to the configuration of the product (LXV) obtained in excess by brominating this single crystal.

It must be emphasised that the optical yield of these gas–crystal reactions depends on the degree of deviation of the molecular conformation from the planar form. This is confirmed by the formation of the racemic dibromide on interaction of bromine with the 4-methoxychalcone (LXVI).[9] Although the crystal of compound (LXVI) is chiral, in this case its molecules deviate less from planarity than in the crystal of compound (LXIV). Studies of the chemical properties and structures of the compounds involved in reactions where bromine adds to racemic crystalline cinnamoyl- and *o*-chlorocinnamoyl-alanines, and of the same compounds after resolution into the individual enantiomers, have also confirmed that the molecular conformation is the principal factor determining the course of these reactions.[9] The optically active dihalides have also been obtained by the addition of chlorine or bromine in the form of monohalogeno-derivatives to compound (LXIV).[9]

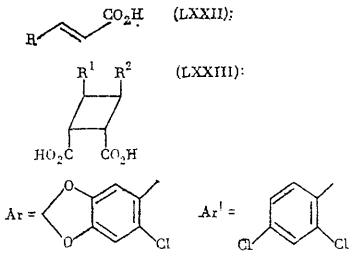
We shall consider in greater detail the mechanism of the solid-phase chemical reactions in olefin crystals. When a chiral crystalline olefin, whose molecules are separated by a distance of ~4 Å (β-structure), are irradiated, cyclobutane dimers with *m* symmetry are formed:



In order to disturb the mirror symmetry, suitable "guest" molecules can be introduced into the "host" lattice. When the correspondence between the molecular geometries of the two components is adequate (solid solutions, mixed crystals), irradiation results in the formation of two enantiomeric "heterodimers" in addition to the two "homodimers", which makes it possible to use these systems for asymmetric synthesis:[9]

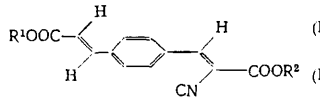
To test these hypotheses, phenyl-substituted olefins (stilbenes, 1,4-diarylbutadienes), which form chiral structures, have been used. It has been noted that the necessary intermolecular distance of ~4 Å is attained by the introduction of two chlorosubstituents into the molecules.[3] It is also known that thienyl and phenyl derivatives frequently form mixed crystals.[162,164] In addition, the ability of the thiophen ring to undergo selective excitation in such mixed crystals has been established.[165]

Whereas the crystals of 4-aryl-1-phenylbutadienes (LXVII) and 4-aryl-1-thienylbutadienes (LXVIII) are converted on irradiation into the achiral cyclobutane dimers (LXIX) and (LXX) respectively, having the *m* symmetry, in the (LXVII) + (LXVIII) mixed crystal the enantiomeric heterodimers (LXXIa) and (LXXIb) are formed in addition to the meso-homodimers (LXIX) and (LXX):



From the standpoint of the elucidation of the influence of the chirality of the crystal structure on the ratio of the enantiomers of compound (LXXI), it is important to excite selectively thienylbutadienes, which absorb in the region of longer wavelengths than the molecules of phenyl derivatives. For small ratios of the concentrations of the thienyl and phenyl derivatives, the selective excitation of the thienyl component suppresses the formation of the achiral dimers (LXIX) and (LXX).

When a light filter is used, irradiation of mixed crystals containing 15% of compound (LXVIII) and 85% of compound (LXVII) at a wavelength of 400 nm leads to a high yield of heterodimers; the filter reduces the absorption by the phenyl derivatives, which prevents the formation of compound (LXIX) and the homogeneous distribution of the thienyl monomer (LXVIII) in the mixed crystal inhibits the formation of the homodimer (LXX). When large homochiral single crystals are irradiated, an optically active dimer is obtained.[57] Dextrorotatory heterodimers are formed in some crystals, while laevorotatory heterodimers are produced in others; the optical yield of these reactions is ~70%. Irradiation at a shorter wavelength ($\lambda < 350$ nm) leads to a decrease of the optical yield, which might have been foreseen by assuming the possibility of absorption by phenyl fragments. This result confirms the preferential propagation of the reaction in stacks, where the distances between the active double bonds are 4 Å.

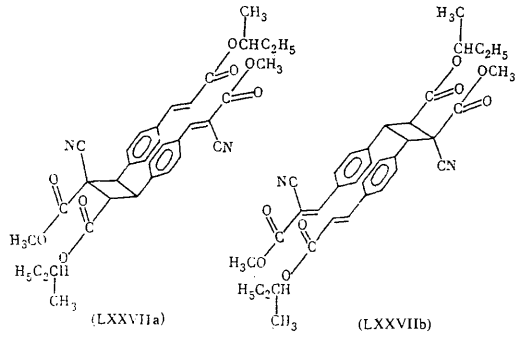


The optical yield of the reaction in the mixed crystal with the ratio (LXVII) : (LXVIII) ≅ 72 : 28[166] is determined by the rate of excitation of the thienyl derivative (LXVIII). Although the translational symmetry of the crystal has been infringed by the substitution of the phenyl group by the thienyl group, the extent of such infringement is slight, as can be seen from X-ray diffraction data, and the intermolecular distances between the olefinic groups in the direction of the ~4 Å translation, are almost identical. The photoexcitation of the thienyl groups can therefore lead to the formation of identical amounts of the enantiomers (LXXIa) and (LXXIb). However, the thiophen fragment is deformed on excitation and the different interactions of the photoexcited compounds (LXVIII) with two nearest neighbours occurring under these conditions induce the appearance of two diastereoisomeric transition states, which explains the observed asymmetry of the synthesis.

The solid-phase reactivity of alkoxyarylchloro-olefins, which also form β-structures, has been investigated.[167] For example, by irradiating at $\lambda \cong 350$ nm the substituted cinnamic acids (LXXIIa) and (LXXIIb), crystallising with formation of the β-structure, it is possible to obtain, as a result of topochemical solid-phase dimerisation, the β-truxillic acids (LXXIIIa) and (LXXIIIb) (with maximum yields of 70 and 90% respectively), compound (LXXIIIb) dimerising much more slowly.[168]

Cyclobutane derivatives of three types [compounds (LXXIIIa), (LXXIIIb), and the chiral compound (LXXIIIc)] are formed on dimerisation in the mixed crystal (LXXIV) made up of compounds (LXXIII) and (LXXII) (in proportions of 1 : 2). The ratios of these reaction products (4 : 1 : 4) agree with the statistical distribution of the molecules of compounds (LXXIIa) and (LXXIIb) in the stack of a (LXXIV) crystal.

Another method of asymmetric synthesis (see above—the chirality of the crystal is determined by the chirality of the molecules of the substance crystallising) requires that the molecules having two different optically active centres be stacked in the chiral crystal in a specific manner—the non-equivalent double bonds must have a favourable disposition (it is required that they be parallel and that the centre–centre distance be ~4 Å) for photocycloaddition with formation of only one of the two possible enantiomers. Among the large number of compounds investigated, 1,4-phenylene diacrylates [for example compounds (LXXV) and (LXXVI)] were selected, since these symmetrically disubstituted compounds are known to be capable of photopolymerisation,[169,170] while chiral s-butyl groups can induce the formation of chiral crystals and can then be readily removed from the product isolated:



In addition, s-butyl groups ensure a relative disposition of the reacting double bonds at a distance of 4 Å, while the cyano-groups ensure the chirality of the product after the removal of the ester groups.

Two enantiomers of compound (LXXV) [the (*S*)-(+)- and (*R*)-(−)-forms] crystallise in two possible diastereoisomeric forms *A* and $\bar{A}$.[144] The reactions in these crystals lead to the formation of cyclobutane dimers, trimers, and oligomers with identical environments of the $C_4$ rings but with opposite chiralities. The absolute configuration of the molecules in the monomer crystal has been established by X-ray diffraction and the configurations of the dimer, trimer, and oligomers have been determined from the configurations of the molecules of the reacting crystal.

The molecular packing in the crystal of compound (LXXV) agrees with the mechanism of the synthesis examined above. The double bonds of neighbouring translationally linked molecules are separated by 4.04 Å. If one begins with the optically pure (*S*)-(+)-enantiomer of compound (LXXV), then the absolute configurations of its reaction product will be 1*S*, 2*S*, 3*S*, and 4*S*. According to the requirements for the packing of the initial enantiomer, under the conditions of topochemical control, only one diastereoisomer of the dimer, trimer, and the oligomers can be formed. Since the energy difference between structures *A* and $\bar{A}$ is not known beforehand, an independent determination of the diastereoisomeric yield of the products is necessary. Diastereoisomers of type $\bar{A}$ were specially synthesised for this purpose and it was shown that they are absent from the reaction mixture. The dimerising chromophoric groups in the racemate are distributed in the same way as in the enantiomeric crystal.

In the second example of asymmetric induction in an enantiomerically pure monomer, we shall consider the photochemical reaction in the crystal of compound (LXXVI) (space group $P2_1$).[144] The enantiomer of compound (LXXVI) is dimorphous: the α-form is stable under illumination, while irradiation of the (*S*)-(+)-monomer in the β-form, with $[\alpha]_D = +23°$, yields, as a result of the topochemical reaction, the dimer with $[\alpha]_D = +12°$ and the structure (LXXVII).

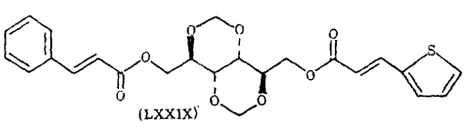
On the basis of the characteristic features of the packing in the crystal of compound (LXXVI), one may expect the formation of both diastereoisomers—(LXXVIIa) and (LXXVIIb).

It follows from the examples examined that the presence or absence of appreciable asymmetric induction depends on the chiral environment of the reaction centre in the crystal and not on the influence of the chiral s-butyl groups. The quantitative diastereoisomeric yield can be achieved even in the polymerisation of polycrystalline specimens of compound (LXXV) with a low optical purity.[144] The limiting case is the racemic mixture isomorphous with the pure enantiomer but made up of crystals of opposite chirality. Under certain conditions, one may expect the formation of a product having predominantly one chirality and specific rotations up to 30° have indeed been achieved in a number of experiments[126,172] by irradiating large crystals with racemic composition.

These considerations can be extended to any achiral compound belonging to the class of asymmetrically substituted dienes, which crystallise with the same chiral structure as compound (LXXV). The absolute configuration of the products must vary depending on which of the isoenergetic enantiomeric structures is formed on crystallisation. The absolute configuration of the product of the reaction of the enantiomerically enriched monomer (LXXV) is dictated by the chirality of the excess s-butyl groups. Since there is a possibility of the formation of solid solutions of enantiomers, it has been suggested[144] that the system investigated can be used as a solid matrix for the induction of crystallisation of other compounds of this class to give chiral structures.

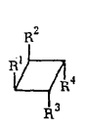
Irradiation of a solution of 1,6-di-*trans*-cinnamate of (+)-2,3:4,5-di-*O*-methylene-D-mannitol (LXXVIII) leads to the formation of isomeric cyclobutane derivatives as a result of cycloaddition, which can be converted into the stereoisomeric truxillic esters on treatment with methanol. When a crystal of compound (LXXVIII) is irradiated, only intermolecular cycloaddition takes place and dimers, trimers, tetramers, pentamers, and higher oligomers with the α-truxillate cyclobutane unit are formed.[173,174]

The molecule of compound (LXXVIII) has a symmetry close to $C_2$ and the centre of gravity of the molecule has been displaced by 0.3 Å relative to that of the bicyclic fragment.[174] The distance of 3.98 Å between the centres of gravity of parallel C(13)=C(14) and C(17)=C(18) double bonds in the molecules linked by the *b* translation indicates that the condition governing topochemical reactivity is fulfilled for the crystal of compound (LXXVIII).[2]



There are no distances permitting interaction between the molecules in the crystal of compound (LXXVIII) extended along the *b* axis, which means that the solid-phase oligomerisation of compound (LXXVIII) should lead to the formation of linear products.[174]

Before the study of Bernstein et al.,[174] the solid-phase di- and oligomerisation was observed only for molecules where two reactive olefinic groups are separated by strictly or approximately planar aromatic ester or amide groups and also by short aliphatic chains.[144,175,176] Bulky groups, such as the tetraoxa-*cis*-decalin group in compound (LXXVIII), had not been used earlier as "spacers" between the reaction centres of solid-phase oligomerisation, just as instances of the presence of 11 covalent bonds between two reactive groups (the distance between the centres of the active double bonds is 13.6 Å) had been unknown. The solid-phase reactivity of compound (LXXVIII) shows that photo-oligomerisation is possible for a much greater number of "spacers" than had been supposed previously. However, it is difficult to predict whether or not the conditions governing the presence of solid-phase reactivity will be maintained: among the six derivatives of D-mannitol with cinnamate end-groups, only compound (LXXVIII) proved to be reactive.[175]



Oligomers (up to octamers) have been isolated chromatographically from the products of the solid-phase photo-oligomerisation of compound (LXXVIII). The proportions of the oligomers depend on the duration of the treatment: brief irradiation promotes the formation of a dimer and short oligomers, while more prolonged exposure entails the appearance of insoluble products, which contain (according to chromatographic data) ten and more monomer units.[174] There exist data indicating further intermolecular photocycloaddition in solutions of oligomers with five and more monomer units.[174,177,178]

In contrast to the crystal, where the molecules of compound (LXXVIII) have the approximate $C_2$ symmetry, in solution this type of symmetry is not characteristic of them according to NMR data and the cinnamate groups are structurally equivalent. Solid-phase photo-oligomerisation enhances the asymmetry and the signals of the cinnamate groups in the NMR spectra of the oligomers are different.[174]

In order to investigate the solid-phase asymmetric synthesis, an attempt has been made to carry out the photo-oligomerisation of compound (LXXIX) tentatively assumed to be isostructural with compound (LXXVIII):[57]

(LXXIX)

(LXXX).

Depending on the relative positions of the molecules in the crystal of compound (LXXIX), the formation of either the enantiomerically pure oligomer (LXXXa) or (LXXXb) [if the structure (LXXIX) is fully ordered] or of the (LXXXa) + (LXXXb) racemate and the achiral product (LXXXc) [for the statistical orientation of the molecules of compound (LXXIX)] might have been expected. However, although the crystals of compound (LXXIX) did exhibit solid-phase activity, they were found to be not isostructural with compound (LXXVIII) and the products of the reactions of compounds (LXXVIII) and (LXXIX) were different. Further work directed towards the investigation of solid-phase solutions of compounds (LXXVIII) and (LXXIX) is being continued.[174]

Racemic derivatives of anthracene frequently crystallise with formation of close-packed enantiomeric pairs of molecules manifesting a characteristic excimer emission and undergoing rapid photodimerisation. The crystals of individual enantiomers have a completely different type of packing, also exhibit a characteristic monomer emission, and are stable as regards the action of light. Esterification with 1-arylethanol of 9-anthroic acid, partly resolved into optical isomers, makes it possible to obtain a mixture of racemic and chiral crystals. On irradiation, the dimer is formed exclusively from racemic crystals. The soluble chiral monomer which failed to react is separated from the insoluble meso-dimer by extraction with hexane; the optical yield reaches 95%.[179]

Optically active products can be obtained from racemic single crystals with the aid of a solid-phase reaction. In principle, it is possible to carry out the reaction only on the upper (or lower) face of such a crystal. The reaction on one face results in the formation of one enantiomer, that on the other affording the other optical isomer. The usefulness of studies on these lines has been confirmed by the difference in the proportions of the reaction products obtained on different single crystal faces[180] and also by the anisotropy of the rate of reaction[181] observed in certain gas–crystal reactions.

The future of the chemistry of organic chiral crystals is associated with the progress in organic solid-state chemistry in general and also with a more profound investigation of the ways in which molecules are packed in crystals. Just as chiral groups are important in the study of many reactions of organic and inorganic compounds in solutions, chiral crystals make it possible to obtain detailed information about solid-phase reactions.

## VI. OTHER REACTIONS

### 1. Chemical Reactions in Clathrate Compounds

Chemical reactions in clathrate compounds are well known (see, for example, Shklover et al.[80]). We shall consider several examples of such reactions. Alkylammonium cations can be incorporated in an inorganic matrix and can form hydrogen bonds with the latter.[182] For example, the intercalation in layer silicates[183] and the formation of mixed crystals by alkylammonium salts with transition metal halides $MX_2$, the so-called "layer perovskites" $(C_nH_{2n+1}NH_3)_2MX_4$, is known.[184,185] There exist numerous data on the magnetic properties and phase transitions in these systems.[186–188] However, until the study of Tieke and Wegner, the possibility of using them as matrices for chemical reactions in the crystal had not been investigated. Tieke and Wegner[182] demonstrated the ability of ω-aminoacids and n-alkylamines to crystallise in "layer perovskites" and also the ability of 6-aminohexa-2,4-dienoic acid, incorporated in $CoCl_2$, $MnCl_2$,

and $FeCl_3$, to polymerise to the *trans*-polyene structure (LXXXI) as a result of solid-phase reactions on irradiation with UV light ($\lambda$ = 254 nm) or $\gamma$-rays:

$$n\,CHR^1{=}CH{-}CH{=}CHR^2 \rightarrow -(-CHR^1{-}CH{=}CH{-}CHR^2{-})_n\ ; \quad (LXXXI)$$

$$R^1{=}CH_2NH_2,\ R^2{=}COOH\ .$$

The polymerisation of *trans,trans*-dienes as a result of 1,4-additon had not been known previously either in the solid phase or in clathrate compounds.[189,190] According to NMR data, the *erythro*-diisotactic disposition of the substituents is postulated in the polymer (LXXXI), which is a racemate. On polymerisation in the clathrate compound in $CoCl_2$, the distance between the layers of metal ions (17.9 Å) increases only by 0.9 Å. The stereoregularity of the products, the insignificance of the structural changes, and the dependence of the reactivity of the monomer on the ionic character of the matrix indicate the possibility of the topochemical control of the reaction.[182] The polymer chains formed as a result of the 1,4-addition of diene groups are extended in the plane parallel to one of the crystallographic directions of the inorganic matrix. The separation of the polymer with an average molecular weight of ~35 000 from the matrix presents no difficulties.[182]

The use of chiral crystals as the medium for asymmetric synthesis is of great interest. This approach makes it possible to "convert" the chirality of the "host" crystal into the chirality of the reaction product.[129,192-195] Among the most successful attempts to carry out such reactions, mention may be made of the solid-phase asymmetric polymerisation of *trans*-penta-1,3-diene (LXXXII) incorporated in the chiral matrix of the crystal of (+)-perhydrotriphenylene.[196,197] $\gamma$-Irradiation results in the formation of an optically active pentadiene polymer, although the molecules of compound (LXXXII) are fixed in the matrix only via van der Waals forces. The same reaction has been carried out in the deoxyfolic acid matrix.[198]

## 2. Topotactic Redox Reactions in Intercalation Systems

Yet another important type of solid-phase reactions involves the formation of intercalation compounds (IC) as a result of the incorporation of "guest" molecules, atoms, and ions in the "host" crystal, which has a suitable structure.[199] Apart from the well known layer systems, for example, graphite, $MoS_2$, and others, both inorganic systems with a skeletal structure (for example $WO_3$) and organic molecular conducting crystals are used for intercalation.[200] The character of the intercalated "guest", ranging from small ions ($H^+$, transition and non-transition metal ions) to large molecular ions (metal complexions, dye, and heterocyclic ions), is also varied.[200]

Direct intercalation can be regarded as a reversible redox electron-ion transfer reaction, which makes it possible to treat from the general standpoint the intercalation processes involving both ions and neutral molecules of the "guest".[200]

Among the fairly varied topotactic redox intercalation processes,[200] the intercalation of organic compounds of the type of Lewis bases (hydrazines, amines, heterocycles, acid amides, *N*-oxides, etc.) in layer dichalcogenides on heating[201,202] as well as the formation of intercalation compounds with molecular "host" crystals[200] are relevant to the subject of the present review.

The interaction of the "host" lattice with the "guest" molecule is usually considered in terms of charge transfer from the donor "guest" molecule to the acceptor—the "host" lattice.[203-206] However, according to latest data, direct intercalation of Lewis bases takes place as a result of topotactic redox reactions with phases having an ionic structure.[207-209] This conclusion has been confirmed by a study of the mechanism of the intercalation of inorganic matrices by ammonia and pyridine. In contrast to the earlier model,[201,211] the $^1H$ NMR data for $TaS_2(NH_3)_x$ and $TiS_2(NH_3)_x$, where $x \cong 1$, indicate the parallel orientation of the $C_3$ axis of the $NH_3$ molecule in the interlayer space of the "host" crystal.[205,206] Such orientation is favourable for interaction with charge transfer between the unshared electron pair of nitrogen and the layers of the $MX_2$ crystal. The study of the mechanism of the intercalation of $NH_3$ has shown that the redox process accompanying this reaction involves the oxidation of some of the "guest" molecules with formation of $N_2$.[209] Electrons pass to the $TaS_2$ layers, while protons are bound to $NH_3$ molecules:

$$2NH_3 \rightarrow N_2 + 6H^+ + 6e^-\ ,$$
$$xe^- + TaS_2 \rightarrow [TaS_2]^{x-}\ ,$$
$$H^+ + NH_3 \rightarrow NH_4^+\ .$$

The intercalated compound $(NH_4^+)_x(NH_3)_{1-x}[TaS_2]^{x-}$ with $x \cong 0.1$ formed has an ionic structure; the $NH_4^+$ cations are "solvated" by neutral $NH_3$ molecules. This scheme accounts for the unusual orientation of the $NH_3$ molecules by the ion–dipole interaction. The thermal intercalation of pyridine (PyH) in $TaS_2$ also takes place as a result of a redox process involving the disproportionation of some of the "guest" molecules with formation of bipyridyl (Py–Py):

$$x\,PyH \rightarrow x/2(Py{-}Py) + xH^+ + xe^-\ ,$$
$$x\,PyH + xH^+ \rightarrow x(PyH_2^+)\ ,$$
$$xe^- + TaS_2 \rightarrow [TaS_2]^{x-}\ .$$

The reaction product also has an ionic structure, namely $(PyH)_{0.5-2x}(PyH_2^+)_x(Py{-}Py)_{x/2}[TaS_2]^{x-}$, where $x \cong 0.2$; the planes of the heterocycles are perpendicular to the six-fold *c* axis of the "host" crystal.[207,210,212]

In the case of compounds with a low ionisation potential, for example, aromatic Lewis bases capable of forming stable radical-cations, the reaction mechanism is simpler; indirect data for this intercalation process involving phenylenediamine have been published.[211] Direct ionisation has been postulated for the thermal intercalation of metallocenes[214,215] as a result of the cathodic reduction of $MX_2$ in electrolytes containing metallocenium cations.[216]

The low electrical conductivity and the low lattice energy prevent the occurrence of topotactic redox processes in molecular crystals. Three cases are exceptions: (a) appreciable intermolecular delocalisation of electrons, for example, as a result of charge transfer or the interaction of the *d* electrons of metals;[217,218] (b) the small size of the "guest" molecules, which leads to an insignificant steric change in the "host" lattice; (c) the presence of convenient ways for the intracrystal diffusion of "guest" ions with low activation energies. The electron-proton transfer is most probable in organic crystals.[200]

Oxygen-transferring metal chelates, for example, [2,2′-ethylenebis-(nitrilomethylidyne)diphenolato]cobalt(2+) and its derivatives have been investigated in greatest detail. These compounds form red-brown crystals, which blacken in air owing to reversible saturation by molecular oxygen.[219-222] Depending on the ligand environment of the cobalt atom, the $Co:O_2$ ratio may be 2:1 or 1:1. Planar chelate complex molecules are packed in such a way that in the crystal there exist large channels open to one-dimensional diffusion of $O_2$ molecules. The $Co^{2+}$ ions are oxidised by oxygen, but the degree of their oxidation has not been established. The chelate complexes of cobalt are used in welding as a source of pure atmospheric oxygen.[200]

Numerous planar metal chelates having an analogous structure with a stacked arrangement of complex molecules are known; their conductivity along the stacks increases sharply on oxidation of the metal ions owing to the interaction with the partly filled *d* orbitals (one-dimensional metals and superconductors). The bis(benzil dioximato)-complexes of nickel(II) and palladium(II) are converted by oxidation with halogens into compounds having the composition $[MR_2]Y$ (Y = Br or I) and a tetragonal structure, characterised by a stacked packing and intermolecular metal–metal interactions; halide ions are distributed in channels parallel to the stack of complex molecules and apparently exist predominantly in the form of the anions $Y_3^-$. The halogen is partly eliminated from the bromo-derivatives, while the tetragonal structure persists over a wide non-stoichiometric range ($z_{max} = 0.8$):[223]

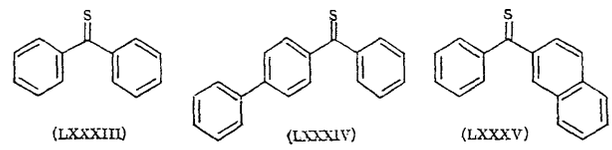
$$[MR_2]^{n+}(Y)^{n-} \rightleftarrows [MR_2]^{(n-x)+}(Y_{1-z})^{(n-x)-} + z/2Y_2\,Y_2 + Y^- \rightleftarrows Y_3^- .$$

Analogous processes are apparently characteristic of partly oxidised phthalocyanines.[224] Phthalocyanines and related metal chelates exhibit an appreciable electrocatalytic oxidative activity in the presence of oxygen,[225,226] which is apparently associated with topotactic redox processes.

Topotactic electron-proton transfer processes have been investigated for tantalum halide clusters and chloroammine-platinum complexes.[227] Reversible electron-proton transfer can occur in crystals of the quinolinium salts of tetracyanoquinodimethane (TCNQ):[228]

$$(C_9H_7NH)^+[(TCNQ)_2]^- + x\,e^- + x\,H^+ \rightleftarrows (C_9H_7NH)^+(H^+)_x[(TCNQ)_2]^{(1+x)-} .$$

Organic molecular crystals with semiconducting properties and an extensive system of π-interactions, for example, dyes and aromatic radical-cations, can be used as electrochromic materials for display purposes.[229–232] Since electron-proton transfer reactions are characteristic of these compounds in solutions,[233] it has been suggested[197] that such processes occur also in the crystalline state. Topotactic doping by oxidants leads to a sharp increase of the conductivity of crystalline polyacetylenes.[234,235]



### 3. The Crystal–Gas Interaction

This extremely common type of solid-phase chemical reactions, which hinder the X-ray diffraction of hydrolysable or oxidisable compounds, has been inadequately investigated as regards structure.

One of the examples of the structural investigation of solid-phase reactions of this type, the interaction of chiral single crystals with gaseous bromine leading to chiral products, was examined above (Section V).

Another example of the chemical crystal–gas interaction is provided by topotactic redox reactions in the formation of intercalated systems (see above).

The ability of thioketones to be readily oxidised in solution to the corresponding *S*-oxides or ketones, the rate of oxidation and the proportions of the products being determined by the electronic and steric characteristics of the molecules, is also known.[236] The capacity of thioketones for oxidation in the solid phase is determined by the packing of their molecules in the crystals. The molecules of the aromatic thioketones (V)–(VII), which undergo solid-phase photochemical oxidation, are stacked in such a way that the thiocarbonyl chromophoric groups C=S are oriented in an antiparallel manner (the intermolecular S...S distances vary from 3.70 to 3.90 Å) and form channels along the shortest period of the unit cell.

(LXXXIII) (LXXXIV) (LXXXV)

The cross-sectional area of the channels is ~8.3 Å$^2$ in contrast to the crystals of stable diarylthioketones whose channels are much smaller (~2.3 Å$^2$).[237] The solid-phase reactivity of compounds (LXXXIII)–(LXXXV) can be accounted for by the diffusion of $O_2$ molecules in the channels and by the subsequent oxidation of the C=S groups.[238,239]

The C=S distances in compounds (LXXXIII)–(LXXXV) are 1.61–1.63 Å and are close to the standard C=S bond length in crystals which are stable as regards the photochemical oxidation of thioketones.[237] The solid-phase reactivity of thioketones is apparently not linked directly to changes in the C=S bond length.

---o0o---

Thus the structural aspect of the solid-phase dimerisation, polymerisation, redimerisation, and other reactions has been investigated for a fairly wide variety of organic compounds. The dimerisation of certain derivatives of 2-benzyl-5-benzylidenecyclopentanone derivatives and the solid-phase polymerisation of diacetylene derivatives take place with rigorous topochemical control at all stages of the reaction with a single crystal → single crystal transition.

At the present time the ideas of crystal engineering have been developed in studies of crystalline low-dimensional semiconductors, metals, and superconductors.[240,241] Crystal engineering merits special consideration as a method of seeking and investigating the properties of this promising class of organic materials (the construction of molecular "corridors" for the preferential migration of electrons, the use of heteroatoms to ensure the overlap of neighbouring molecules, the elimination of the spatial modulation of charge density by altering intermolecular distances, etc.).

# Surface Phenomena in Nematic Liquid Crystals

V.N.Matveenko and E.A.Kirsanov

The characteristic features of the surface tension, adhesion, and ordering of the molecules, and their orientation in the surface layers of the liquid-crystal phases of nematogenic compounds in relation to the anisotropic intermolecular interaction have been examined.
The bibliography contains 95 references.

## I. INTRODUCTION

An understanding of the mechanism of the production of a given orientation of the molecules of liquid crystals between specially treated supports is of considerable practical importance for creating improved electro- and thermo-optical devices based on liquid crystals. The problem has been dealt with to some extent in familiar monographs.[1-5] Most studies, however, have been predominantly experimental and empirical in character, and the discussion of the results has been restricted to general physicochemical considerations, borrowed from the physics of the surface phenomena of ordinary liquids. The few theoretical studies have been devoted to specific chemical compounds, and do not claim to be general in their approach.

It therefore seems appropriate to examine the available experimental results (often contradictory) and various existing theoretical models.

## II. BASIC THEORIES OF THE LIQUID-CRYSTAL STATE

Liquid crystals (LC), or anisotropic liquids, are formed by the molecules of organic compounds which have an elongated shape. Like ordinary liquids, nematic LC are characterised by short-range translational order, but there is no long-range translational order; they can form droplets, and can be drawn into capillaries; and different types of flow are produced in them. At the same time, the long-range orientational order in the arrangement of the long axes of the molecules of nematic LC is preserved, although thermal fluctuations partly deflect the molecules from the predominant direction (denoted by the unit vector **n**, which has been called the "director").

The present examination will be restricted to nematic LC (NLC or nematics). For these, the order parameter

$$Q = {}^1/_2(3\langle\cos^2\theta\rangle - 1),$$

has been introduced, where $\theta$ is the angle of inclination of an individual molecule to the director **n**, and the brackets denote averaging over all possible orientations of the molecules in the macroscopic volume of the material. If the long axes of the molecules are arranged randomly, as in an isotropic phase (or in an ordinary organic liquid), $\langle\cos^2\theta\rangle = 1/3$ and $Q = 0$. The value $Q = 1$ corresponds to 100% parallel mutual orientation of the molecules. In practice, $Q$ can take values of 0.3–0.4 at a temperature close to the transition point from the nematic to the isotropic phase $T \cong T_c$.

The order parameter $Q$ appears in the expression for the total free energy of the liquid-crystal phase, and it is used to describe phase transformations and the changes in the optical, electrical, and magnetic properties of LC with change in temperature. The parameter $Q$ naturally retains its importance in the description of surface phenomena. A typical curve giving the temperature dependence of $Q$, obtained from magnetic susceptibility measurements, is shown in Fig.1.

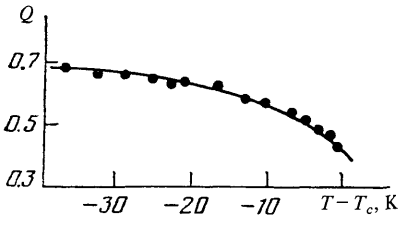

Figure 1. Temperature dependence of the order parameter in the nematic phase of p-azoxyanisole.[4]

In addition to the nematic phase, there exist a large number of other liquid-crystal phases, of which the smectic *A* phase must be mentioned. In it, the molecules are grouped in layers, and the long axes of the molecules are approximately perpendicular to the plane of the layer. The layers can move relative to one another, and the molecules within a layer have short-range translational order. In a nematic phase obtained after heating a smectic LC, clusters with smectic order (or cybotactic groups) are preserved.

For experimental studies, an LC specimen is placed between two glass plates subjected to special treatment. The molecules in the thin layers of the LC are oriented under the influence of the walls of the cell, leading to the formation of the required structures. Rubbing the glass (with paper or diamond paste), the production of a special relief on the glass by applying coatings with an obliquely incident beam, or the deposition of a stepped lattice (by photolithography) create a unique direction in the NLC layer, along which the director **n** is oriented. This direction is called the axis of easy orientation, or the "easy" axis. The methods of treating the support described above lead to the orientation of the director **n** parallel to the support (for example in the direction of rubbing). In the case of thoroughly cleaned glass surfaces or plates covered with surface-active substances, the axis of easy orientation is arranged at right angles to the surface of the support. Thus the orientation of the director close to the support depends on its treatment; the influence of the support extends into the bulk of the specimen, creating a uniform "single-crystal" state (from the viewpoint of optics, nematic crystals behave as monoaxial crystals, whose optical axis coincides with the director **n**). As a result, in a thin layer of LC between treated plates, one of three possible uniform textures is produced: planar with parallel orientation of the molecules with respect to the support, homeotropic with normal orientation of the molecules, or tangential with sloping orientation; the latter exists in the case of a complex relief on the support. The orientation of the director **n** within a specimen relative to the support is generally described using a system of coordinates with the $z$ axis at right angles to the plane of the plates; the $x$ axis is usually directed along the projection of the director **n** (for parallel and sloping orientations).

Table 1. The surface tension of various nematic LC.[10]

| Compound | $\gamma$, erg cm$^{-2}$ | $T$, °C | Method | Refs. |
|---|---|---|---|---|
| MBBA | 38 | 23 | — | [11] |
| MBBA | 35.8 | — | I | [12] |
| MBBA | 30 | — | II | [13] |
| MBBA | 35.3 | — | — | [14] |
| PAA | 38 | 125 | III | [15] |
| PAA | 37 | 120 | — | [14] |
| PAP | 31.2 | 145 | III | [15] |
| 5CB | 28.1 | 31.5 | II | [8] |
| 5CB | 27.9 | 20 | II | [8] |
| 8CB | 26.2 | 41 | II | [8] |

Notes: I—pendant drop method, II—measurements using a Wilhelmy plate, III—capillary rise method; the dash indicates that the method or the temperature of the specimen were not given. Compounds: MBBA = methoxybenzylidenebutylaniline, PAA = *p*-azoxyanisole, PAP = *p*-azoxyphenetol, 5CB = 4-pentyl-4′-cyanobiphenyl, 8CB = 4-octyl-4′-cyanobiphenyl.

Various external influences bring about orientational deformation, associated with the rotation of the local director $\mathbf{n}(x, y, z)$, leading to an increase in the elastic component of the free energy $F_d$. In a magnetic field, for example, the molecules are oriented in the direction of the field **H**. The orientation in an electric field **E** depends on the sign of the dielectric anisotropy $\varepsilon_a$ of the specific LC. Various forms of orientational deformation have been described in detail.[1-5]

Close to the free surface of a liquid-crystal layer (in the case of a freely suspended film or drop on a support), different orientations of the director relative to the normal **N** to the free surface are produced for different substances. For example, for nematic *p*-azoxyanisole (PAA), the angle $\psi$ between the normal **N** and the director **n** on the free surface is 90°,[6,7] whereas for nematic materials of the series of 4-$C_nH_{2n+1}$-4′-cyanobiphenyls, $\psi = 0$.[8] For methoxybenzylidenebutylaniline (MBBA) and ethoxybenzylidenebutylaniline (EBBA), the angle $\psi$ changes with change in temperature.[6,9]

## III. THE SURFACE TENSION OF LIQUID-CRYSTAL MATERIALS

### 1. Experimental Data

The magnitude of the surface tension $\gamma$ for the free surface of the nematic and isotropic phases of liquid-crystal compounds has been measured by different methods at various temperatures. The values of $\gamma$ for individual temperatures are given in Table 1.

The temperature dependence of the surface tension for a given substance, obtained by different authors, often shows lack of agreement, and differences are observed not only in the magnitude of the surface tension, measured at the same temperature by different methods, but also in the nature of the change in $\gamma$ in the region of the phase transformation from the nematic to the isotropic phase (Fig. 2).

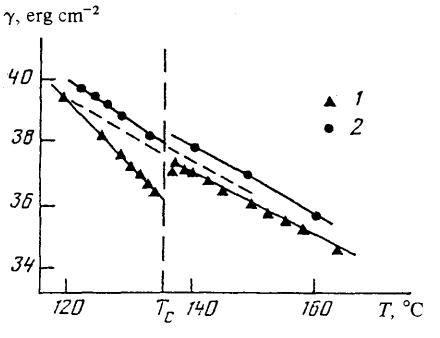

Figure 2. Temperature dependence of the surface tension of PAA, measured by the capillary rise method (*1*),[15] the ring lifting method (*2*),[16] and the maximum gas-bubble pressure method (broken line).[17]

The observed differences in the experimental data are apparently due to differences in the degree of purification of the materials, but the choice of the method used to determine the surface tension also has an extremely significant influence on the results of the experiments; this can be seen, in particular, for the case of PAA (see Fig. 2). In spite of the considerable differences, the curves nevertheless demonstrate important characteristic features of the $\gamma(T)$ relationship for PAA; at a distance from the transition point $T_c$, $\gamma$ changes approximately linearly with increase in the temperature of both the nematic and the isotropic phases; in the region of the transition, the linearity of $\gamma(T)$ breaks down to some extent (depending on the method of measurement); $\gamma$ increases smoothly or abruptly. A

similar non-smooth $\gamma(T)$ relationship in the region of the phase transformation was obtained by the pendant drop method under equilibrium conditions for PAA (Fig. 3*a*) and *p*-anisaldazine (Fig. 3*b*), and also for MBBA.[18]

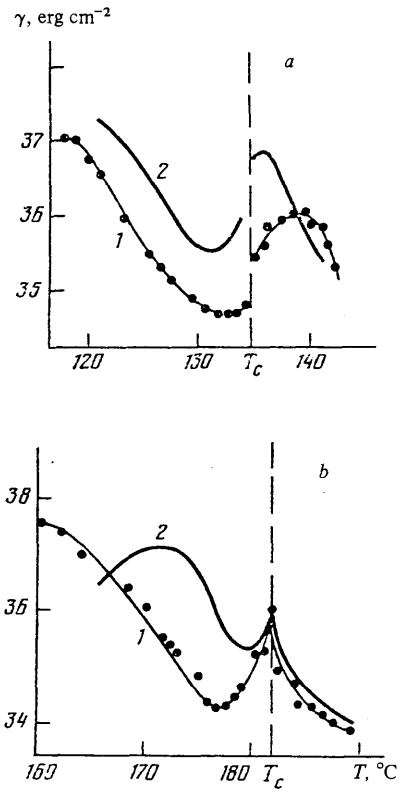

**Figure 3.** Temperature dependence of the surface tension of *p*-azoxyanisole (*a*) and *p*-anisaldazine (*b*):[18] *1*) experiment (pendant drop method), *2*) theoretical curves.[34]

For both MBBA [19] and PAA,[17] the maximum gas-bubble pressure method gives a linear decrease in $\gamma$ with increase in temperature in both phases; on going from the nematic to the isotropic phase, $\gamma$ undergoes a positive jump for both substances.

When the method of detachment (of a plate or ring) from the free surface is used for PAA [16] and MBBA,[20] a linear decrease in $\gamma$ with increase in $T$ is observed, and there is no unique feature (jump) in the region of the transition. Measurements by the Wilhelmy method in an experiment of the continuous type gave $\gamma = 35.0 \pm 0.2$ erg cm$^{-2}$ for MBBA at $T = T_c$.

The same method (Wilhelmy plate), however, gave an appreciably non-linear $\gamma(T)$ relationship close to $T_c$ for 5CB and 8CB.[8] The measurements were made under conditions close to equilibrium, and the rate of displacement was 5–50 mdyne cm$^{-1}$ per day. Measurements with a good accuracy were achieved in this way; for example, for 6CB, $\gamma = 28.1 \pm 0.3$ erg cm$^{-2}$ at 31.5 °C. $\gamma$ increases with increase in temperature, both below and above $T_c$ (Fig. 4). The slope of the $\gamma(T)$ curve is positive close to $T_c$ in both phases (Fig. 4*a*). The maximum on the curve (Fig. 4*b*) was calculated theoretically.[8]

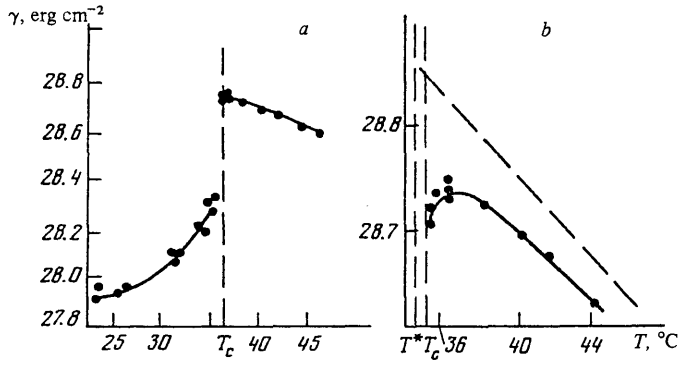

**Figure 4.** Temperature dependence of the surface tension for 5CB in the nematic and isotropic phases (*a*) and in the isotropic phase on an expanded scale (*b*).[8] The thick line gives the theoretical curve, and the broken line the values of $\gamma(0)$, extrapolated from the distant isotropic range.

The fundamental importance of ensuring equilibrium conditions for the reliable determination of $\gamma(T)$ can be proved indirectly for the method involving light scattering from the free surface, in which the shear viscosity and the surface tension are measured simultaneously by generating surface waves and studying their characteristics. The scattering of light from the thermal fluctuations (~10 kHz) of the free surface of MBBA made it possible to calculate $\gamma$ with a relatively low accuracy[21] (Fig. 5*a*). Low-frequency ($\lesssim$1 kHz) running surface waves with a relatively high amplitude (~100 Å) have been used;[22] the temperature dependence of $\gamma$ obtained for the nematic and smectic phases of *p*-cyanobenzylidene-*p*-octyloxyaniline (CBOOA) is shown in Fig. 5*b*. Similar values for the nematic phase of CBOOA were obtained from an experiment on light scattering on the thermal fluctuations of the free surface.[23] It was concluded that within experimental error, $\gamma$ remains constant within the nematic phase; this does not agree with other data.[17,18,34]

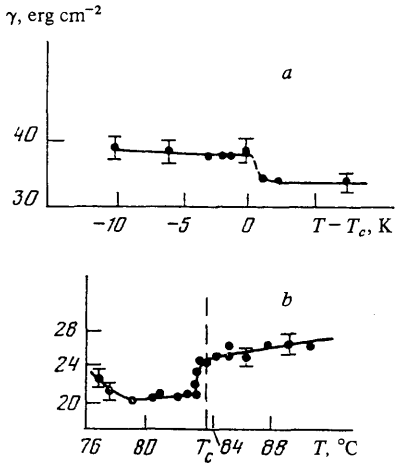

**Figure 5.** Temperature dependence of the surface tension, obtained by light scattering on surface waves: *a*) MBBA in the region of the transition from the nematic to the isotropic phase,[21] *b*) CBOOA in the region of the transition from the nematic to the smectic phase.[22]

The spectra of the autocorrelation functions of surface waves of low amplitude were recently studied and used to calculate the surface tension of PAA.[24] The large scatter in the experimental points (uncertainty ±1 erg cm$^{-2}$) makes possible only a crude estimate, $\gamma \cong 36$ erg cm$^{-2}$, throughout the range of existence of the nematic phase studied.

Thus the non-equilibrium surface-wave method gives values of $\gamma$ with a fairly high uncertainty, so that it is practically impossible to determine the temperature dependence of $\gamma$.

## 2. Theoretical Models of the Surface Tension of Liquid Crystals

Existing calculations of the surface tension $\gamma$ and its temperature dependence have been carried out only for the limiting cases of the orientation of the director next to the phase interface, that is for $\psi = \pi/2$ and $\psi = 0$.

The surface tension $\gamma$ at the free surface of a liquid-crystal material whose molecules are joined by van der Waals interaction has been calculated.[25] The degree of order $Q$ and the angle of inclination of the director $\psi$ do not appear in explicit form in the expression for the interaction potential. In the macroscopic approximation, in which the material is regarded as a continuous medium, it was assumed[25] that two semi-circumferential volumes of the given substance interact with one another through a vacuum gap of thickness $l$. The specific (per unit area of the surface) additional energy of the system due to the van der Waals interaction will then have the form:

$$U(l) = \frac{\hbar}{4\pi}\int_0^{\infty} d\omega \int_0^{k_c} k\, dk \ln[1 - \Delta^2(i\omega)] \exp(-2kl)$$

Here, $k$ is the wavenumber; $\omega$ the frequency of the electromagnetic field; $k_C$ the limiting wavenumber of the fluctuating electric field, directed parallel to the surface; and

$$\Delta(\omega) = [\varepsilon(\omega) - 1]/[\varepsilon(\omega) + 1],$$

where $\varepsilon(\omega)$ is the complex dielectric constant of the liquid.

It is assumed that the free energy $U(\infty) = 0$. Decrease in the gap $l$ to zero gives the quantity $U(0)$, which is equal to the work of cohesion with sign reversed. Thus the free energy of each of the two surfaces is equal to

$$\gamma = -{}^1/_2 U(0)$$

A calculation carried out according to this scheme for the free energy of an isotropic liquid[26,27] gave the following expression:

$$\gamma = -\frac{\hbar}{16\pi^2} k_c^2 \int_0^{\infty} d\omega \ln[1 - \Delta^2(i\omega)]$$

This method can be extended to nematic liquids, taking account of the fact that the dielectric constant of the interacting media is an anisotropic quantity. A rectangular system of coordinates with $z$ axis perpendicular to the surface is used. The dielectric constant of the NLC will then be described by the tensor:

$$\varepsilon(\omega) = \begin{pmatrix} \varepsilon_x(\omega) & 0 & 0 \\ 0 & \varepsilon_y(\omega) & 0 \\ 0 & 0 & \varepsilon_z(\omega) \end{pmatrix}$$

The components of the complex dielectric constant parallel to and perpendicular to the director will be denoted $\varepsilon_\parallel(\omega)$ and $\varepsilon_\perp(\omega)$. In this case, for parallel orientation of the director on the free surface,

$$\gamma_\parallel = -\frac{1}{2}\frac{\hbar}{16\pi^3} k_c^2 \int_0^{\infty} d\omega \int_0^{2\pi} d\varphi \ln \frac{4[\varepsilon_\parallel \varepsilon_\perp \cos^2\varphi + \varepsilon_\perp^2 \sin^2\varphi]^{1/2}}{[\varepsilon_\parallel \varepsilon_\perp \cos^2\varphi + \varepsilon_\perp^2 \sin^2\varphi]^{1/2} + 1} \qquad (1)$$

where $\phi$ is the azimuthal angle of the orientation of the director relative to the $x$ axis. For the orientation of the director normal to the surface, the oscillating electromagnetic field is directed at right angles to the director, and in Eqn.(1) the angle $\phi$ can be put equal to zero. Thus:

$$\gamma_\perp = -\frac{1}{1}\frac{\hbar}{8\pi^2} k_c^2 \int_0^{\infty} d\omega \ln \frac{4(\varepsilon_\parallel \varepsilon_\perp)^{1/2}}{(\varepsilon_\parallel \varepsilon_\perp)^{1/2} + 1} \qquad (2)$$

In the calculation in Ref.25, the boundary wavenumber was taken as $k_C = 2\pi/10$ Å$^{-1}$. Published data[28] on the complex dielectric constant of PAA, and Eqns.(1) and (2), were used to calculate the values $\gamma_\parallel = 37.8$ erg cm$^{-2}$ and $\gamma_\perp = 44.6$ erg cm$^{-2}$.[25] It can be seen that the lowest surface energy corresponds to the parallel orientation of the director on the free surface. Experiment has in fact shown that PAA molecules are arranged in the surface layer parallel to the free surface,[6,7] and the experimental values of $\gamma$ lie in the range 38–39 erg cm$^{-2}$.[15,17] The surface tension $\gamma$ at the boundary between nematic PAA and glass has been calculated similarly; the value

$$\Delta\gamma_{LS} = \gamma_{LS}(\pi/2) - \gamma_{LS}(0) = 0.36 \text{ erg cm}^{-2}$$

was obtained,[25] that is on a clean glass surface the PAA molecules tend to adopt the perpendicular orientation, in agreement with experiment.[29]

A molecular-statistical theory of the surface tension of liquid crystals was developed[30] by examining the anisotropic paired interaction between the LC molecules. It used a general expression for the surface tension of a polyatomic liquid, previously obtained[31] in a calculation of the dipole–dipole contribution to the surface tension of water at a low vapour pressure. If the interaction potential of a pair of molecules $U_{12}$ depends only on the vector of the centres of mass $\mathbf{R} = \mathbf{r}_2 - \mathbf{r}_1$ ($\mathbf{r}_1$ and $\mathbf{r}_2$ are the coordinates of the centres of mass of molecules *1* and *2*) and the orientation of the molecules relative to the direction of the director $\mathbf{n}$, given by the unit vectors $\mathbf{e}_1$ and $\mathbf{e}_2$, the expression for the surface tension has the form:

$$\gamma = -\frac{1}{2}\int_{-\infty}^{+\infty} dz \int d^3R\, d^3e_1 d^3e_2 \left(Z\frac{\partial U_{12}}{\partial Z} - X\frac{\partial U_{12}}{\partial X}\right)\rho^{(2)}(\mathbf{r}_1, \mathbf{r}_2, \mathbf{e}_1, \mathbf{e}_2) \qquad (3)$$

(in the system of coordinates $x$, $y$, $z$ where the plane $xy$ coincides with the free surface, and the $z$ axis is directed into the depth of the LC layer). In Eqn.(3), $Z$ and $X$ are the coordinates appearing in the expression for the potentials $U$, and $\rho^{(2)}$ is the binary distribution function, defined in such a way that the quantity $\rho^{(2)}(\mathbf{r}_1, \mathbf{r}_2, \mathbf{e}_1, \mathbf{e}_2) \cdot d^3\mathbf{r}_1 d^3\mathbf{r}_2$ gives the average number of pairs of molecules present in the corresponding states *1* and *2*. Instead of $\rho^{(2)}$ it is more convenient to introduce the distribution function $g^{(2)}$, such that $\rho^{(2)} = \rho^{(2)} g^{(2)}(\mathbf{r}_1, \mathbf{r}_2, \mathbf{e}_1, \mathbf{e}_2)$, where $\rho$ is the density of the liquid.

For the calculation of the surface energy of a nematic LC,[30] $U_{12}$ was taken as the van der Waals interaction potential in the form used[32] to describe the phase transformation from the nematic to isotropic phase, with the assumption that the molecules are monoaxial and rod-shaped, and that the induced dipole moments are produced along the long axes of the molecules. For a pair of molecules it is possible to introduce the polar angles $\theta_1$ and $\theta_2$ relative to the director $\mathbf{n}$ in a spherical system of coordinates. All the azimuthal angles of these molecules are equally probable, so that the first averaging is carried out with respect to the azimuthal angles. In accordance with the monoaxial symmetry of the nematic phase, it is possible to introduce an order parameter $Q$ from the distribution function $f(\theta)$ of the single molecule:

$$\theta = {}^1/_2 \int_0^{\pi/2} (3\cos^2\theta - 1)\sin\theta \cdot f(\theta)\, d\theta$$

In the average-field approximation, the distribution function of two molecules with respect to the corresponding angles is $f(\theta_1, \theta_2) = f(\theta_1)f(\theta_2)$. Under these conditions, the binary function $g^{(2)}$ takes the form:

$$g^{(2)}(\mathbf{R}, \mathbf{e}_1, \mathbf{e}_2) = g^{(2)}(R)f(\theta_1)f(\theta_2)$$

Thus Parsons' approach[30] includes the following assumptions: the vectors of the centres of mass **R** are distributed isotropically within the meso-phase, the local correlation between the orientations of the molecules can be neglected, and the distribution function $f(\theta)$ is independent of $z$, that is the order parameter $Q$ has the same value in the bulk and on the surface. The calculation gives the expression

$$\gamma = \rho^2/2 \int\limits_{z>0} d^3R Z g^{(2)}(R) \left[ Z \frac{\partial}{\partial Z} - X \frac{\partial}{\partial X} \right] \langle W \rangle \qquad (4)$$

The quantity $\langle W \rangle$ represents the averaging of the Maier–Saupe potential[32] over all azimuthal and polar angles of the vectors **R** under conditions of cylindrical symmetry (the $z$ axis coincides with the director **n**). Thus

$$\langle W \rangle_{\mathbf{e}_1, \mathbf{e}_2, \mathbf{R}} = -\frac{2\nu}{3R^6} \left[ 1 + \frac{Q^2}{5} \right]$$

where $\nu$ is a constant.

Parsons' calculation leads to the following expressions for the parallel and perpendicular orientations of the director relative to the free surface:

$$\gamma_\parallel = \gamma_0 \left( 1 - \frac{4}{9} Q + \frac{8}{27} Q^2 \right) \qquad (5)$$

$$\gamma_\perp = \gamma_0 \left( 1 + \frac{2}{3} Q + \frac{1}{6} Q^2 \right) \qquad (6)$$

where

$$\gamma_0 = (3\pi\rho^3\nu/4) \int\limits_0^\infty \frac{dR}{R^3} g^{(2)}(R) \qquad (7)$$

According to Eqns.(5) and (6), $\gamma_\parallel < \gamma_\perp$ for all values of $Q$ usually realised in the nematic phase.[30] This means that the molecules of the surface layer should be oriented parallel to the surface. The magnitude of the abrupt change in the surface tension at the temperature of the phase transformation $T_C$ is readily determined from Eqns.(5)–(7):

$$(\gamma_0 - \gamma_\parallel)/\gamma_0 = \frac{4}{9} Q_c - \frac{8}{27} Q_c^2$$

where $Q_C$ is the value of the order parameter of the nematic phase at the transition point. For a typical value $Q_C \cong 0.44$,[2] Parsons' model[30] predicts an abrupt increase in $\gamma$ on going to the isotropic phase, in agreement with the experimental data.[15–17]

An obvious merit of Parsons' calculation[30] is that an analytical expression is obtained for the dependence of the surface tension $\gamma$ on the order parameter $Q$. However, it describes sufficiently correctly only the case of rigorously parallel orientation of the director on the free surface, realised, for example, for PAA.

A theory of surface tension for a nematic liquid has been proposed,[34] taking account of the continuous change in the density of the liquid $\rho(z)$ and in the order parameter $Q(z)$ with increase in the distance from the interphase surface along the $z$ axis (coinciding with the normal to the surface N). The theory[34] is not associated with any dependence of $\gamma$ on the orientation of the director on the free surface. The local order parameter $Q(z)$ reaches the value of the bulk order parameter $Q_\nu$ at a sufficient distance from the surface of the liquid. Because of the mathematical difficulty of the problem, only qualitative $\gamma(T)$ relationships were obtained.[34] Variation of some of the parameters appearing in the theoretical equations makes it possible to obtain satisfactory agreement between the theoretical curves and the experimental data in the region of the phase transformation (see Fig.3). At a distance from the transition point $T_C$, the $\gamma(T)$ curves have a negative slope, and close to $T_C$ the quantity $d\gamma/dT$ may be positive. The model of Ref.34 is described in more detail in Ref.2.

To describe the nematic liquids 5CB and 8CB, for which the long axes of the molecules are perpendicular to the free surface, a theory was proposed[8] in which two order parameters were introduced: in the bulk ($Q_0$) and on the free surface ($Q_1$), and $Q_1 - Q_0 \ll 1$. The surface energy is introduced in the form of an expansion with respect to powers of $(Q_1 - Q_0)$ and $(dQ/dz)$ with coefficients $A$ and $B$ which depend on temperature:

$$\gamma = \gamma_0(Q_0) + \left( \frac{\partial \gamma_0}{\partial Q} \right)(Q_1 - Q_0) + \int\limits_0^\infty \left[ A(Q - Q_0)^2 + B \left( \frac{dQ}{dz} \right)^2 \right] dz$$

The minimisation of $\gamma$ with respect to $Q$ and $Q_1$ leads to the expression

$$\gamma = \gamma_0(Q_0) - (\xi/4B)(\partial\gamma_0/\partial Q)^2$$

where $\xi = (B/A)^{1/2}$. Since no detailed microscopic theory exists, the authors cited[8] introduced a simple linear relationship of the form $\gamma_0(Q) = \gamma_0(0) - \alpha Q$, where $\alpha$ is independent of temperature. This gives the expression

$$\gamma = \gamma_0(0) - \alpha Q_0 - (\alpha^2\xi/4B) \qquad (8)$$

which includes only the "bulk" order parameter $Q_0$.

In the Landau–de Gennes theory,[1] the free energy of a nematic is decomposed in powers of $Q$. A critical temperature $T^*$, corresponding to a phase transformation of the second kind, is introduced, with $T_C > T^*$. Using the average-field approximation and the Landau–de Gennes phenomenological model, the authors cited[8] obtained for the isotropic phase ($T > T_C$):

$$\xi = \xi_c [(T_c - T^*)/(T - T^*)]^{1/2} \qquad (9)$$

For the nematic phase ($T < T_C$) the following relationship was obtained:

$$\xi = \xi_c [(T^{**} - T_c)/(T^{**} - T)]^{1/2} \qquad (10)$$

where

$$T^{**} = T_c + {}^1/_8 (T_c - T^*).$$

Substituting Eqns.(9) and (10) in Eqn.(8) gives the following expressions for the surface energy: in the isotropic phase:

$$\gamma \approx \gamma_0(0) - \beta [(T_c - T^*)/(T - T^*)]^{1/2} \qquad (11)$$

and in the nematic phase:

$$\gamma \approx \gamma_0(0) - \alpha Q_0 - \beta [(T^{**} - T_c)/(T^{**} - T)]^{1/2}$$

where

$$\beta = ({}^1/_2)\alpha(Q_1 - Q_0)_{T=T_c} = \alpha^2\xi_c/4B.$$

The relationship

$$\gamma_0(0) = 28.86 - 0.0023\,(T - T_c)$$

was obtained by extrapolating the values from the range of high temperatures of the isotropic phase (broken line in Fig.4*b*). To calculate the value of $\gamma(T)$ in the isotropic phase from Eqn.(11), the value $T_C - T^* = 0.7$ K [35] was used, and the value of $\beta/\alpha^2$ was taken as 0.65 dyne$^{-1}$ cm [8] (Fig.4*b*). Good agreement was obtained between the experimental values and theoretical curve, but it should be noted that $\beta/\alpha^2$ is essentially an arbitrary parameter. It is also

not clear why the authors cited[8] did not carry out a comparison with experiment for the nematic phase, although the temperature dependence of the order parameter $Q_0(T)$ for 5CB is known.

## IV. THE ENERGY OF ADHESION OF A LIQUID CRYSTAL TO A SOLID SUPPORT

Treatment of the surface of glass supports in different ways leads to the production of different liquid-crystal textures (homeotropic and planar).[29,36,37]

In the examination of the orientational deformation of a liquid-crystal specimen, it is usually assumed[1-4] that the orientation of the director n on the supports remains constant, in spite of the change in the orientation of n in the bulk of the specimen. These boundary conditions correspond to so-called strong or rigid anchoring to the support (infinite energy of anchoring of the LC to the support). In the case of a finite energy of anchoring $W_S$, the molecules on the surface of the support change their orientation, and this is expressed in a rotation of the director (weak anchoring). In the simplest case, the potential of the anchoring forces is introduced[37-40] in the form $W_\theta = B\sin^2\theta_0$, where $B = \frac{1}{2}W_S$.

A fairly large number of studies in which the energy of anchoring was determined experimentally by various methods have now been published. For greater clarity, the orientational effects in LC cells whose nature is influenced by the quantity $W_S$ will be examined separately.

### 1. The Frederiks Transition in an External Field

The Frederiks transition involves the reorientation of LC molecules, having dielectric $\varepsilon_\alpha$ or diamagnetic $\chi_a$ anisotropy, under the influence of an external electric E or magnetic H field.[1-3] Orientational deformation of the entire LC specimen takes place. In the general case, the expression for the elastic orientational energy of the specimen per unit volume has the form:[1]

$$F_d = {}^1/_2K_{11}(\mathrm{div}\,\mathbf{n})^2 + {}^1/_2K_{22}(\mathbf{n}\times\mathrm{rot}\,\mathbf{n})^2 + {}^1/_2K_{33}(\mathbf{n}\times\mathrm{rot}\,\mathbf{n})^2$$

where $K_{11}$, $K_{22}$, and $K_{33}$ are the Frank elastic constants for transverse bending, twisting, and longitudinal bending respectively.

The free energy of an original homeotropic specimen is the sum of the bulk elastic energy, the surface anchoring energy, and the energy due to the influence of an external electric or magnetic field of the following form (in the one-dimensional approximation):[38]

$$F = 2B_\theta\sin^2\theta_0 + {}^1/_2\int_{-d/2}^{+d/2}[K_{11}\sin^2\theta + K_{33}\cos^2\theta]\left(\frac{d\theta}{dz}\right)^2 dz - {}^1/_2\int_{-d/2}^{+d/2}\chi_a H^2\sin^2\theta\,dz$$

Here, $\theta$ is the angle between the director n at an arbitrary point of the specimen and the normal to the supports (the $z$ axis), and d the thickness of the specimen. For strong anchoring, the threshold of the Frederiks transition is given by:[1]

$$H_c' = \frac{\pi}{d}\left(\frac{K_{33}}{\chi_a}\right)^{1/2}$$

The existence of a finite anchoring energy, as calculated in Refs. 38–41, leads to a decrease in the threshold $H_C$, and the $H_C(d^{-1})$ relationship becomes non-linear. For MBBA, the following values were obtained[38,41] for $W_S \times 10^{-3}$ (erg cm$^{-2}$): 11.0 for surface-active substances on glass covered with $In_2O_3$ and 6.1 on clean glass; 5.9 for lecithin on glass covered with $In_2O_3$ and 3.1 on cleaned glass.

In the one-constant approximation ($K_{11} = K_{33} = K$), the calculation of the orientational deformation is simplified,[40] and $H_C$ for the Frederiks transition becomes directly proportional to the quantity $(d + 2\xi)^{-1}$, where $\xi = 2K/B_\theta$ has been called the extrapolation length. The Frederiks threshold in an electric field for weak anchoring of the molecules to the walls of the cell is described by the following equation:[42]

$$V_c = V_c'(1 + 2K_u/W_s d)^{-1}$$

where the threshold for strong anchoring is

$$V_c' = 2\pi(\pi K_u/\varepsilon_a)^{1/2}.$$

The Frederiks transition in an electric field has been studied for 5CB. When ordinary glass supports covered with a layer of lecithin were used, strong anchoring of the LC to the support was detected.[43]

The phase difference of polarised light passing through a cell containing an NLC deformed by a magnetic field has been calculated and determined experimentally.[44] To obtain better agreement between the theoretical curves and the experimental data, a new potential of the anchoring forces was introduced, namely:[44,45]

$$W_\theta = C\cos^2\theta_0 + C_4\cos^4\theta_0$$

In an attempt to reconcile the results obtained experimentally in studies of the Frederiks transition and the flexoelectric effect, a potential for the anchoring forces was introduced[46] in the form of the square of the elliptical sine, where the argument $0 \leq k \leq 1$:

$$W_\theta = \frac{1}{2}W_s\mathrm{Sn}^2(\theta_0, k)$$

Table 2. Coefficients of azimuthal anchoring $B_\phi$ of nematic MBBA to a support.[10]

| Method of producing the relief | $B'_\varphi$, J m$^{-2}$ | $B_\varphi$, J m$^{-2}$ |
|---|---|---|
| Rubbing with diamond paste | $8\cdot10^{-5}$ | $7\cdot10^{-6}$ |
| Depositing $SiO_2$ at an angle of 30° | $5\cdot10^{-4}$ | $10^{-3}$ |
| Depositing a film of trimethylchlorosilane | — | $5\cdot10^{-6}$ |

Notes: $B'_\phi$—calculated from Eqn. (12), $B_\phi$—measured experimentally from the Frederiks transition.

The case of the orientational deformation of an NLC on rotation of the director in the plane $xy$ parallel to the walls of the cell can be considered. In this case the potential of the anchoring forces is given by the expression

$$W_\varphi = B_\varphi\sin^2\varphi_0$$

where $\phi_0$ is the angle of deviation of the director from the axis of easy orientation (the $y$ axis). Rubbing of the glass support, and the oblique deposition of $SiO_2$, were used to obtain a planar texture.[10,47] The magnitude of the azimuthal anchoring coefficient $B_\phi$ was determined from measurements of the rotation of the molecules in a magnetic field oriented parallel to the support.[10] The orientation of the molecules along the direction of rubbing is usually attributed to the geometric factor, that is it is assumed that the orientation of the rod-shaped molecules along the grooves is energetically favourable, since elastic orientational deformation does not take place. For the simplest case of a sinusoidal surface relief with wave vector $q$, rotation of the director in a

position perpendicular to the grooves increases the elastic energy by an amount[47]

$$W(\varphi) = {}^1/_4 KAq^3 \sin^2 \varphi_0 \qquad (12)$$

The experimental values of $B_\phi$ and the values calculated from this equation are given in Table 2. The lack of agreement between the experimental and theoretical values is apparently related to the simplification of describing the surface by a sinusoidal function.

## 2. The Flexoelectric Effect

The flexoelectric effect (FE) is related to the asymmetry of the shape of the molecule (for example the "banana-shaped" MBBA) and its constant dipole moment. When an external electric field is applied, polarisation is produced in the specimen as a result of the deformation of the bend, leading to the stabilisation of the orientational deformation in the cell.[1,2] Since the greatest deviation of the director is observed close to the walls of the cell, the flexoelectric effect is very sensitive to the magnitude of the energy of anchoring of the LC to the support.

The fullest theoretical description of the uniform flexoelectric effect is given in Ref. 48. For symmetrical boundary conditions, the value of the angle $\theta$ (between the director n and the $z$ axis) is equal to

$$\theta = (e_3 + p) E \left( W_s \operatorname{sh} \frac{d}{2\zeta} + \frac{K_{33}}{\zeta} \operatorname{ch} \frac{d}{2\zeta} \right)^{-1} \operatorname{sh} \frac{z}{\zeta}$$

where $e_3$ is the flexoelectric coefficient for the geometry of the experiment described above and the "banana-shaped" molecules of MBBA,

$$\zeta = E^{-1} (4\pi K_{33} / |\varepsilon_a|)^{1/2}$$

the dielectric coherence length, and $p$ the surface polarisation at the boundary between the solid support and the LC (possibly produced as a result of the difference in the values of the interaction of the support with the two different ends of the elongated LC molecule). The induced birefringence of the specimen is calculated from the equation:[49]

$$\Delta n = \frac{1}{4d} n_0 \left( 1 - \frac{n_0^2}{n_e^2} \right) \left( \frac{e_3 + p}{K_{33}} \right)^2 E^2 \zeta^3 \left( \operatorname{sh} \frac{d}{\zeta} - \frac{d}{\zeta} \right) \times \times \left\{ \operatorname{ch}^2 \frac{d}{2\zeta} \left[ 1 - \frac{\zeta W_s}{K_{33}} \operatorname{th} \frac{d}{2\zeta} \right]^2 \right\}^{-1} \qquad (13)$$

In most experimental studies,[49-51] the calculations were carried out using different simplified versions of Eqn. (13); thus $W_S$, $p$, and $\varepsilon_a$ (in different combinations) were neglected; the expansion of the hyperbolic functions in a series with respect to powers of $(d/\xi)$ was carried out only as far as the first or second order of smallness. In fact, the experimental $\Delta n(d, E^2)$ relationship gave the effective flexoelectric coefficient $e_3^*$:

$$e_3^* = \frac{e_3 + p}{1 + dW_s / 2K_{33}} \qquad (14)$$

Eqns. (13) and (14) were used to determine the energy of adhesion between MBBA molecules and a support treated with an aqueous solution of decyltrimethylammonium bromide.[49] The value was $3.74 \times 10^{-3}$ erg cm$^{-2}$ in a cell with a thickness of 30 μm for $T_C - T = 16$ K and $2.48 \times 10^{-5}$ erg cm$^{-2}$ for a thickness of 90 μm and $T_C - T = 4.5$ K.

These results indicate that the energy of anchoring depends markedly on the temperature of the specimen. Nevertheless, order of magnitude agreement ($10^{-3}$ erg cm$^{-2}$) is observed with the data obtained from the Frederiks transition.[38,41]

## 3. The Spontaneous Frederiks Transition

In nematics with negative dielectric anisotropy ($\varepsilon_a < 0$), the effect of spontaneous breakdown of the homeotropic orientation at a certain critical thickness of the layer is observed.[52] This effect can be attributed[53] to polarisation in the regions of the homeotropic nematic next to the surface, and hence to an electric field $E_S$ existing in a region of thickness $\delta$ next to the surface. A new term is therefore introduced into the expression for the free energy of the specimen to take account of the energy next to the surface

$$(\varepsilon_a E^2 \delta / 4\pi) \sin^2 \theta_0.$$

Solution of the corresponding equations[53,54] shows that there exists a certain critical cell thickness

$$d_c = 2K | W_s + \varepsilon_a E_\delta^2 / 4\pi |^{-1}.$$

For $d < d_C$, the layer is energetically more favourable in the non-deformed state; for $d > d_C$, on the other hand, the layer is deformed according to the law $\theta = \theta_C = (z - d/2)$. Thus the mechanism of the spontaneous transition is attributed[54] to competition between electric forces of different character next to the surface, facilitating planar orientation of the nematic with $\varepsilon_a < 0$, and the elastic energy of the NLC, which favours the homeotropic orientation. This effect obviously decreases the threshold of the ordinary Frederiks transition.

The orientation of an NLC is influenced considerably by long-range dispersion forces,[46,55] which often stabilise the homeotropic orientation of the director. A theoretical examination of a one-dimensional stabilising field has been carried out.[56] At a layer thickness $d < d_1$, the predominating van der Waals forces lead to homeotropic orientation on the surface of the nematic layer; for $d_1 < d < d_2$ the planar orientation on the surface is ensured by short-range surface forces with a potential $\gamma \cos^2 \theta_0$; for $d > d_2$, the most important role is played by the elastic energy of orientational deformation.[55]

Theoretical calculations[57,58] have shown that shielding of the supports by amorphous films with thickness $l$ leads to a local Frederiks transition in the NLC close to the boundary with a support. The moment of the van der Waals forces is described by the expression

$$\lambda c \sin \theta_0 \cos \theta_0 / (\lambda + z + l)(z + l)^2,$$

where $c$ is a constant, and $\lambda \cong 1000$ Å, and the moment of the short-range surface forces has the form $W_S \sin \theta_0 \cos \theta_0$. An experimental study of a local Frederiks transition was carried out[59] on fragments of crystalline mica with a shielding covering in the form of stepped monolayers of stearic acid. The mica support produces planar orientation of the NLC, and the Langmuir layers produce homeotropic orientation, so that for a Langmuir film of sufficient thickness, a change from planar to homeotropic texture is observed experimentally for liquid-crystal droplets of MBBA and 5CB.

# V. THE SURFACE ORDER PARAMETER

The order parameter $Q$ is an important characteristic of the meso-phase, and is widely used to describe the temperature dependence of various physical characteristics of LC.[2,4] It may be assumed that the values of $Q$ in the volume of a specimen ($Q_V$) and close to a solid support ($Q_S$) are different. This assumption has a significant effect on the calculation of the surface properties of liquid crystals, so that a number of attempts have been made to determine the surface order parameter experimentally.

The first estimates of $Q_S$ and $Q_V$ for planar nematic textures[60,61] were made by multiple-wave interferometry.[62] It was assumed[60] that in the region of solid supports, surface forces produce layers with a surface order parameter $Q_S$ (and corresponding refractive index $n_S$), which have a thickness of the order of the wavelength of light. The cell therefore forms a Fabry–Perot interferometer, but with a three-layer optical medium ($n_S$, $n_V$, $n_S$). The ratio of the intensities of the emergent and incident light beams is given by:[60]

$$\frac{I}{I_0}=\frac{8n_p^2n_s^2}{(n_p^4+6n_p^2n_s^2+n_s^4)-(n_p^4-2n_p^2n_s^2+n_s^4)\cos^2\beta}$$

where $\beta = \pi\bar{n}d/\chi$, $\bar{n}$ is the average value of the refractive index in the volume of the specimen, and $n_p$ the refractive index of the glass plate supports. Increase in temperature leads to changes in the values of both $n_S$ and $\bar{n}$, so that the periodic change in $(I/I_0)$ with increase in temperature makes it possible to determine the value of $\bar{n}$ from the phase, and of $n_S$ from the amplitude of the graph.

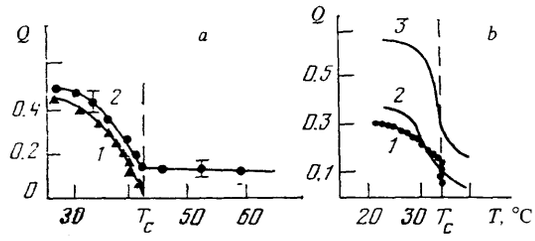

Figure 6. Temperature dependence of the bulk (curves *1*) and surface (curves *2* and *3*) parameters, measured for 7CB [60] (*a*) and 5CB [61] (*b*). Curves *2* were obtained for a support with a layer of $SiO_2$ deposited at an angle of 60°, and curve *3* for a profiled support with a rectangular lattice period of 0.5 μm.

The temperature dependence of $Q_V$ and $Q_S$ obtained by this method[60,61] is shown in Fig. 6. For a specimen of 7CB in a cell with a coating of $SiO_2$, applied at an angle of 60° to the normal, the value of $Q_S$ is slightly greater than $Q_V$, but does not become zero after the phase transformation into the isotropic phase (where $Q_S \cong 0.1$).[60] A much higher value of $Q_S$ compared with $Q_V$ is observed for 5CB for a surface with a profile in the form of a grid with rectangular projections.[61] The authors themselves[61] mention the experimental difficulties associated with this type of interference method for determining $Q_S$. Measurements of the refractive indices $n_\perp$ in planar cells containing MBBA and 5CB have been carried out[63] by two methods: by total internal reflection and by multiple-wave interferometry, and the results obtained by the two methods agreed within the experimental error. This indicates an extremely small difference between $Q_S$ and $Q_V$ in these experiments or a small thickness of the boundary layer ($\xi \ll \lambda$).

A number of published papers[64–68] describe the birefringence in the isotropic phase of nematic compounds, produced by the influence of previously treated supports. To obtain planar orientation of the molecules, the glass plates were rubbed with paper, or covered with surface-active substances (for example polyvinyl alcohol) or with a layer of $SiO_2$. The phase difference $\delta$ of the ordinary and extraordinary waves was determined directly by measuring the intensity of the light passing through the cell, placed between two polaroids. The $\delta(T)$ relationships obtained for a number of specimens are shown in Fig. 7.

The values of the phase difference measured in this way make it possible to determine the briefringence $\Delta n$ and then to calculate the parameter $Q_S$. For this purpose, the Landau–de Gennes approximation was used[65,66] to expand the free energy of the system in a series with respect to the order parameter $Q$:

$$F = F_0 + \frac{a}{2}(T-T^*)Q^2 - \frac{b}{3}Q^3 + \frac{c}{4}Q^4 + \frac{L}{2}|\nabla Q|^2$$

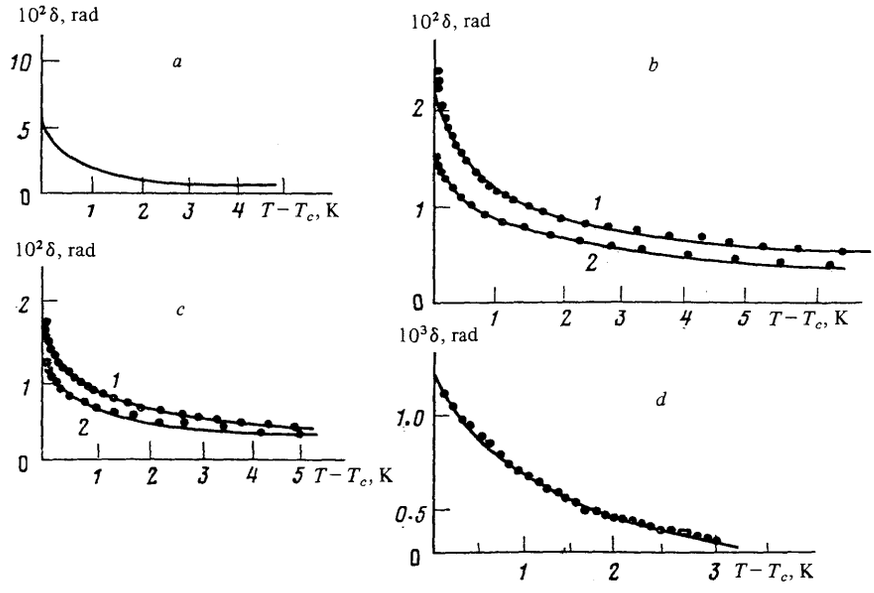

Figure 7. Experimental phase difference relationships $\delta(T)$ in specimens of isotropic nematogenic compounds: *a*) MBBA on glass covered with a rubbed layer of PVA; [66] *b*) 5CB on rubbed glass (*1*) and on a rubbed layer of MAP (*2*); [65] *c*) 5CB on glass covered with HTAB (*1*) and MOAP (*2*); [65] *d*) 7CB on rubbed glass (Pyrex) [67] (the notation for the SAS is explained in the notes to Table 3).

where the coefficients of the expansion $a$, $b$, $c$ are the critical temperature of the virtual phase transformation of the second kind; $T^*$ were estimated for the compounds studied.[67-69] It was assumed that the order parameter $Q$ in the isotropic phase has a finite value at the boundary with the support $Q_{z=0} = Q_S$ and $Q_{z=\infty} = 0$. Minimisation of the free energy with respect to $Q$ incorporating these boundary conditions gives an equation in $Q(z)$:

$$\frac{L}{aT^*}\left(\frac{dQ}{dz}\right)^2 = 2\left[\frac{a}{2}(T-T^*)Q^2 - \frac{b}{3}Q^3 + \frac{c}{4}Q^4\right]/dT^*$$

This equation is solved numerically for various known[67-69] values of $a$, $b$, $c$, and $T^*$ and a reasonable value of $L$. The $Q(z)$ graph obtained is used to calculate $Q_S$. The area under the curve is equated to the value of the birefringence $\Delta n$ induced by the support. The values of $\Delta n$ calculated for different values of $Q_S$ are compared with the experimental value to obtain the order parameter $Q_S$ "next to the wall" for each experiment (see Table 3).

Table 3. Order parameter $Q_S$ "next to the wall"[65,66] in an isotropic phase.

| Method of treating the surface | MBBA | 5CB |
|---|---|---|
| Cleaning | 0 | 0 |
| Cleaning and rubbing | 0.052 | 0.22 |
| Coating of HTAB | 0.321 | 0.32 |
| Coating of MAP and rubbing | 0.063 | 0.18 |
| Coating of DMOAP | 0.054 | 0.17 |
| Depositing $SiO_2$ at an angle of 60° to the normal | — | 0 |
| Coating of PVA and rubbing | 0.364 | 0.172 |

Note. The following substances were used as surface-active substances for treating the surface of the glass support: for the normal orientation—hexadecyltrimethylammonium bromide and its 0.2% solution in chloroform (HTAB) and dimethyl-n-octadecyl-3-aminopropyltrimethoxysilane chloride (DMOAP); for the parallel orientation—N-methyl-3-aminopropyltrimethoxysilane (MAP), polyvinyl alcohol (PVA). Rubbing the surface already covered with SAS gave the planar orientation required to produce an axis of easy orientation in the plane of the support.

Experimental studies in the same direction were continued[67,68] by measuring $\delta(T - T_C)$ in 7CB (see Fig.7d). The values obtained were $Q_S = 0.1$ for rubbed glass, and $Q_S = 0$ for a layer of $SiO_2$ deposited at an angle of 60°. Without treatment of the glass, in the presence of a magnetic field $H$ parallel to the glass surface, birefringence appears as a result of the orientation of the molecules of the isotropic phase by the magnetic field. When the magnetic field is switched off, the birefringence is preserved, that is the field plays the same role as rubbing; a direction of easy orientation is created in the plane of the support.

The birefringence induced by a support was measured[70] in the isotropic phase for a mixture of 5CB with the organic compound hexamethylbenzene (2.5 mole %) on supports covered with a rubbed film of PVA and a deposited layer of $SiO_2$. The surface order parameter $Q_S$ had the values 0.27 and 0.005 respectively.[70] In those cases where the planar orientation of the nematic phase is induced by geometric factors (deposition of $SiO_2$), there is practically no birefringence in the isotropic phase close to the support.

Similarly, when the homeotropic texture of an NLC is produced by thorough cleaning of the glass, birefringence is not produced in the isotropic phase. Thus the birefringence (and hence the ordering) induced by the walls is apparently due to an anisotropic physicochemical interaction between the molecules of the nematogenic material and the support. The absence of ordering in the isotropic phase detected[65-68] when $SiO_2$ was deposited does not agree with other studies[60,61] in which a high value of $Q_S$ on supports of this kind was reported.

Birefringence is also produced in strongly polar organic liquids close to the solid walls of the cell, and the optical axis is perpendicular to the surface of the glass supports. This birefringence is related to an order parameter $Q_S$, in spite of the fact that the liquids studied (nitrobenzene, etc.) do not have a liquid-crystal phase. It has been suggested that a layer of ordered liquid with properties similar to those of a nematic phase is produced close to the surface of the support.†

## VI. ORIENTATION OF THE DIRECTOR ON THE FREE SURFACE OF A NEMATIC LIQUID CRYSTAL

Various optical methods have established that the director **n** on the free surface of an NLC is directed parallel to the surface in PAA,[6,7] and perpendicular to it in cyanobiphenyls,[8,9] and that the angle $\psi$ between the director **n** and the normal **N** to the surface changes with change in temperature in MBBA and EBBA.[6,9] Thus the direction of the axis of easy orientation on the free surface depends on the nature of the liquid-crystal compound.

Accurate measurements of the angle $\psi$ are possible only in uniform specimens: this is usually achieved by applying a magnetic field **H** at a small angle to the free surface. The axis of easy orientation then lies in a plane parallel to **H** and **N**. The magnitude of the relative coefficient of reflection of polarised light incident at small angles (~0.2°) to the normal has been determined experimentally:

$$R = (\rho_\parallel - \rho_\perp)/\rho_\perp$$

where $\rho_\parallel$ and $\rho_\perp$ are the reflection coefficients of light polarised parallel to and perpendicular to the plane of incidence of the light:[7]

$$\rho_\perp = \left(\frac{n_\perp - 1}{n_\perp + 1}\right)^2$$

$$\rho_\parallel = \left(\frac{n(\psi) - 1)}{n(\psi) + 1}\right)^2$$

$\psi$ has been calculated[9] using the following expressions:

$$\rho_\parallel = \left[\frac{(n_\perp^2 \sin^2\psi + n_\parallel^2 \cos^2\psi)^{1/2} - n_\perp n_\parallel}{(n_\perp^2 \sin^2\psi + n_\parallel^2 \cos^2\psi)^{1/2} + n_\perp n_\parallel}\right]^2 \qquad (15)$$

$$\rho_\perp = \left[\frac{n_\perp - 1}{n_\perp + 1}\right]^2$$

It was found that throughout the entire range of existence of nematic PAA, the molecules are arranged so that their long axes are parallel to the free surface, to within 3%.[7] For MBBA and EBBA, Eqns.(15) were used to calculate the temperature dependence of the angle $\psi$ (Fig.8). In a short temperature range close to the phase transformation (from $T_C$ to $T_C$ + 2 °C), the following relationship holds well:[9]

$$\psi = C(T_0 - T)^\beta$$

†See B.V.Deryagin, Yu.M.Popovskii, and B.A.Altoiz, J.Coll.Interface Sci., 1983, **96**, 492.

where for MBBA, $T_0 - T_C = -(0.9 \pm 0.3°)$, $\beta = 0.50 \pm 0.04$, $C = 14.5 \pm 0.6$ degree$^{-1/2}$; for EBBA, $T_0 - T_C = -(1.2 \pm 0.3)$ °C, $\beta = 0.51 \pm 0.1$, $C = 11.8 \pm 1.6$ degree$^{-1/2}$. Above the critical temperature $T_0$ (but below the point of the transition to the isotropic phase $T_C$), the angle $\psi = 0$.

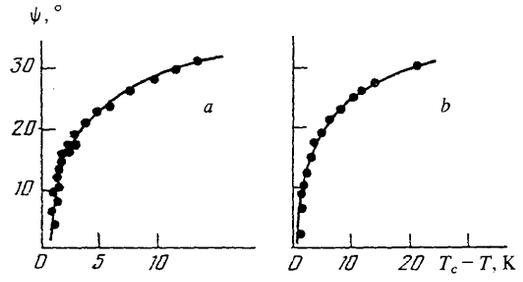

Figure 8. Temperature dependence of the polar angle $\psi$ at the free surface of MBBA (*a*) and EBBA (*b*).[9]

Qualitatively similar results were obtained for free MBBA films[71] in the absence of a magnetic field. The angle of inclination $\psi$ was measured from the conoscopic picture of individual uniform regions of the film; a convergent beam of laser radiation was passed through the specimen and the analyser. At a thickness $d > 70$ μm, the specimen was non-uniform; decrease in the thickness led to the production of a homeotropic texture, after which, at $d < 10$ μm, a schlieren texture typical of nematics with an oblique orientation of the director at the boundaries was produced. The angle $\psi$ decreased with increase in temperature, becoming zero at $T_0$ slightly lower than $T_C$.

The temperature dependence of $\psi$ can be explained using the equation proposed by Parsons[30,33,72] for the surface tension:

$$\gamma = \gamma_0 + \frac{1}{2}\gamma_Q (\mathbf{nN})^2 - \gamma_P \mathbf{nN}$$

where the second term describes the increase in the surface tension on the inclination of a director lying parallel to the surface, and the third term describes its simultaneous decrease as a result of the interaction of the dipole moments of the molecules close to the surface. Thus there exists an equilibrium state of the director, determined by the condition for a surface tension minimum:

$$\frac{d\gamma}{d\psi} = -\gamma_Q \sin\psi\cos\psi + \gamma_P \sin\psi = 0$$

from which

$$\cos\psi = \gamma_P/\gamma_Q \quad \text{for } \gamma_P < \gamma_Q$$
$$\cos\psi = 1 \quad \text{for } \gamma_P > \gamma_Q$$

Since $\gamma_P$ and $\gamma_Q$, generally speaking, change in different ways with change in temperature, $\cos\psi$ is a function of temperature, and with the condition $\gamma_P = \gamma_Q$ the oblique texture is converted smoothly into a homeotropic structure. The temperature for this equality apparently corresponds to the experimental value of $T_0$.

In the direct proximity of $T_0$, the surface tension can be represented as a series with respect to powers of $\psi$:[9]

$$\gamma = \gamma_0 + {}^1/_2 A (T - T_0)\psi^2 + (B/4)\psi^4 \qquad (16)$$

For $T < T_0$, $A/B > 0$, and the minimisation of Eqn.(16) gives:

$$\psi = (A/B)^{1/2}(T_0 - T)^{1/2}$$

On the other hand, for $T_0 < T < T_C$, $\psi = 0$. These elementary estimates agree well with experimental data.[9]

The question of the orientation of the director on a free surface has been studied theoretically.[73,74] The specific energy of the oriented layer on the surface was written in a form analogous to that for the energy of an electric or magnetic field:

$$\Lambda_e = -\frac{1}{2}\Delta\pi\left[(\mathbf{nN})^2 - \frac{1}{3}\right]$$

where $\Delta\pi$ plays the role of the anchoring coefficient of the LC to the free surface. It was assumed[73,74] that $\Delta\pi = \Delta\beta Q$, where $Q$ is the nematic order parameter, and $\Delta\beta$ was called the anisotropy of the ordering. High values of $\Delta\pi$ correspond to a strong orienting influence of the surface. The elastic orientational energy of the surface layer was then introduced, where the moduli of elasticity $\bar{K}_1$ and $\bar{K}_2$ differ from the bulk values $K_{11}$ and $K_{22}$. The propagation of this deformation into the depth of the layer leads to an increase in the bulk elastic energy. From these considerations, the author cited[74] obtained an equation for the moments of the forces acting on the director on the free surface, and calculated the temperature dependence of the angle $\psi$ (Fig.9).

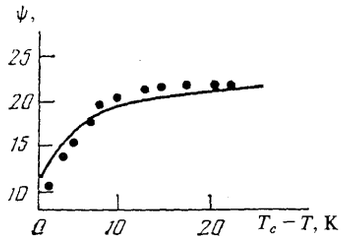

Figure 9. Temperature dependence of the angle between the director **n** and the free surface of MBBA: experiment[6] (points) and calculation (continuous curve).[74]

In all the above studies, $\psi$ was assumed to be independent of the magnitude of $H$, which corresponds to "strong anchoring" of the LC on the free surface. At high values of $H$, however, and at a temperature close to $T_0$, the angle $\psi$ increases with increase in the magnetic field strength.[75] For rotation through an angle $(\psi - \psi_0)$ relative to the original position $\psi_0$ it is necessary to expend the energy of the magnetic field corresponding to the sum of the energy of anchoring of the molecules to the free surface and the energy of elastic deformation in the volume of the NLC adjoining the surface. Thus the total free energy of the surface layer of the LC consists of three terms, and its minimisation with respect to variation of the polar angle $\theta(z)$ in the volume and $\psi$ on the surface gives the equation:[75]

$$\psi \approx \psi_0 + (K_{33}\chi_a)^{1/2}\left(1 + \frac{(K_{11} - K_{33})\sin^2\psi}{K_{33}}\right)^{1/2}\frac{H\cos\psi}{2B_d} \qquad (17)$$

The quantity $\psi(H)$ is calculated from the coefficients of reflection of light $\rho_\parallel$ and $\rho_\perp$. If the temperature dependence of $\psi$, $K_{ii}$, and $\chi_a$ are known, it is possible to obtain from

Eqn.(17) the temperature dependence of the coefficient of adhesion $B_\sigma$ of the NLC molecules to the free surface (Fig.10).

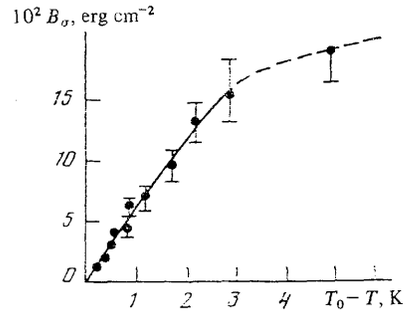

**Figure 10.** Temperature dependence of the coefficient of adhesion $B_\sigma$ to the free surface of MBBA.[75]

## VII. CRITERIA FOR DETERMINING THE NATURE OF THE ORIENTATION OF LIQUID CRYSTALS ON SUPPORTS

The relationship between the surface energy at the phase boundary and the molecular ordering of LC was first explained as follows.[68] For a sufficiently low surface energy of the support $\gamma_S$, the intermolecular forces within the LC are stronger than the forces acting at the phase boundary. As a result, the arrangement of the long axes of the NLC molecules perpendicular to the surface is energetically more favourable. When the surface energy of the solid support $\gamma_S$ is high, the forces of inter-phase interaction predominate, and the NLC molecules are oriented parallel to the support.

Since it is difficult to determine the value $\gamma_S$, for crude estimates it is replaced by the value of the critical surface tension of the support $\gamma_C$, which can be determined by Zisman's method.[76] The procedure for determining $\gamma_C$ by the published method[77] can be described. It is assumed that a drop of liquid with surface tension $\gamma_L$ forms a drop with a contact angle $\alpha$ on a support with energy $\gamma_S$. In this case

$$\gamma_s - \gamma_{sL} = \gamma_L \cos\alpha$$

where $\gamma_{SL}$ is the interfacial surface energy at the boundary between the liquid and the support. Zisman[76] showed experimentally that $\cos\alpha$ decreases linearly with increase in $\gamma_L$ for homologous series of organic liquids. By selecting a series of different liquids with $\gamma_L > \gamma_S$, it is possible to construct the dependence of $\cos\alpha$ on $\gamma_L$ for each support. By extrapolating $\alpha \to 0$ and $\cos\alpha \to 1$, the previous equation is transformed to

$$\gamma_s - \gamma_{sL} = \gamma_c$$

where $\gamma_C$ is determined from the graph for $\cos\alpha = 1$.

The quantity $\gamma_C$ has been called the critical surface tension of the support.

The simple assumption[36,78] that the homeotropic orientation is produced when $\gamma_L > \gamma_C$, and the planar orientation when $\gamma_L < \gamma_C$ gave satisfactory results for MBBA,[12] but was not confirmed for a large number of different NLC on supports covered with surface-active substances (SAS).[79] The molecular ordering was studied in LC of six types on five types of polymer support with $\gamma_C$ in the range 22–40.5 erg cm$^{-2}$. It was found that the lower $\gamma_C$ for the support, the greater the number of LC compounds that undergo homeotropic orientation. For very high values of $\gamma_C$, the planar texture of LC is observed most frequently.[77] For various types of LC and SAS, the ordering can be related to the value of the contact angle of the LC drop: a homeotropic texture is produced for $\alpha \geq 36°$, and a planar texture for $\alpha \leq 36°$.

The surface tension of liquid crystals $\gamma_L$ has been measured at the same temperatures, and amounted to 34.4 erg cm$^{-2}$ for 5CB, 34.2 erg cm$^{-2}$ for MBBA, and 32.6 erg cm$^{-2}$ for dibutyloxyazoxybenzene. Table 4 shows that the condition $\gamma_L > \gamma_C$ is not necessary for the production of a homeotropic texture. Other experiments, however, did not show any characteristic relationship between the ordering and the magnitude of the contact angle[79] (see Table 4).

Table 4. Critical surface tension of the support $\gamma_C$, the contact angles of wetting, and the orientations of the director in liquid crystals on glass supports treated with a solution of 0.5 mass % alkoxysilanes.[79]

| Alkoxysilanes | $\gamma_C$, erg cm$^{-2}$ | 5CB | | MBBA | | Dibutyloxyazoxybenzene | |
|---|---|---|---|---|---|---|---|
| | | $\alpha$, ° | orientation | $\alpha$, ° | orientation | $\alpha$, ° | orientation |
| GMS | 38.5 | 0 | ∥ | 0 | ∥ | 0 | ∥ |
| AAMS | 36.0 | 0 | ⊥ | 0 | ∥ | 0 | ∥ |
| PHES | 32.0 | 16 | ∥ | 15 | ∥ | 8 | ∥ |
| MAP | 29.0 | 16 | ⊥ | 15 | ∥ | 12 | ∥ |
| DMOAP | 23.0 | 55 | ⊥ | 56 | ⊥ | 46 | ⊥ |

Another method of introducing a criterion for the orientation of LC is by representing the surface energy as a function of the angle of orientation $\theta$ at the phase boundary.[13] The work of adhesion of the LC to the support is given by the expression

$$W_a(\theta) = \gamma_L(\theta) + \gamma_s - \gamma_{Ls}[\theta]$$

When there are dispersion forces between the LC and the support, the equation for the work of adhesion becomes:

$$W_a(\theta) = 2[\gamma_L(\theta)\gamma_s]^{1/2}$$

From this it follows that

$$\gamma_{Ls}(\theta) = \gamma_s + \gamma_L(\theta) - 2[\gamma_L(\theta)\gamma_s]^{1/2}$$

Assuming that the LC orientation produced corresponds to a minimum interfacial surface energy $\gamma_{Ls}$ gives:

$$\frac{\partial\gamma_{Ls}(\theta)}{\partial\theta} = \frac{\partial\gamma_L(\theta)}{\partial\theta}\left[1 - \left(\frac{\gamma_s}{\gamma_L(\theta)}\right)^{1/2}\right] = 0$$

and the following typical cases[79] of homeotropic orientation on a support with $\gamma_S < \gamma_L(0)$, oblique on a support with

$$\gamma_L(0) < \gamma_s < \gamma_L(\pi/2)$$

and planar on a support with $\gamma_L(\pi/2) < \gamma_S$.

A systematic physicochemical interpretation of surface orientation has been proposed.[80] The values of the surface energy and the work of adhesion are written as the sum of dispersion and polar components:

$$\gamma_s = \gamma_s^d + \gamma_s^p$$
$$\gamma_L = \gamma_L^d + \gamma_L^p$$
$$W_a = W_a^d + W_a^p$$

where the indices $d$ and $p$ correspond to the dispersion and polar components of the interaction. $W_a$ can be represented as:[81]

$$W_a^d = 2\,[\gamma_s^d \gamma_L^d(\theta)]^{1/2}$$

The total interfacial surface energy is then written as:[80]

$$\gamma_{Ls}(\theta) = \{(\gamma_s^d)^{1/2} - [\gamma_L^d(\theta)]^{1/2}\}^2 + \{(\gamma_s^p)^{1/2} - [\gamma_L^p(\theta)]^{1/2}\}^2$$

For the dispersion part of the surface tension it is possible to write[72]

$$\gamma_L^d(\theta) = (\gamma_L^d)_0 + \Delta\gamma_L^d \sin^2\theta$$

and for the polar part:[33]

$$\gamma_L^p(\theta) = (\gamma_L^p)_0 + \Delta\gamma_L^p \sin^2(\theta - \theta_p)$$

where the angle $\theta_p$ is introduced to take account of the spontaneous polarisation of the surface layer. If the characteristics of the support $\gamma_s^d$ and $\gamma_s^p$ and the characteristics of the LC $(\gamma_L^d)_0$, $\Delta\gamma_L^d$, $(\gamma_L^p)_0$, $\Delta\gamma_L^p$, and $\theta_p$ are known, the condition for a minimum $\theta_{Ls}(\theta)$ can be used to calculate the value of the angle $\theta$ between the director and the normal to the support. This method was used[80] to construct a diagram showing the orienting influence of supports of different kinds (Fig.11).

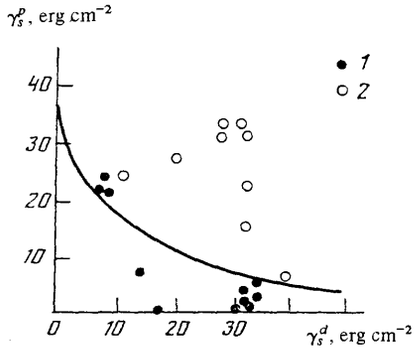

**Figure 11.** Diagram for determining the orientation of MBBA on supports (below the continuous theoretical curve, normal orientation of MBBA is assumed). The experimental points correspond to the known values of $\gamma_s^p$ and $\gamma_s^d$ for different supports; *1*) observed homeotropic orientation, *2*) oblique or planar.[80]

The polar and dispersion contributions to the surface energy have been determined[82] for two types of LC and supports treated with Chromolan solutions of different concentration. The polar $\gamma_s^p$ and dispersion $\gamma_s^d$ contributions to the surface energy of the supports were calculated by the least-squares method using the equation

$$1 + \cos\alpha = 2\,[(\gamma_s^d \gamma_L^d)^{1/2} + (\gamma_s^p \gamma_L^p)^{1/2}]/\gamma_L \qquad (18)$$

where $\alpha$ is the experimentally determined contact angle of wetting of the surface being studied by an isotropic liquid with known values of the polar $\gamma_L^p$ and dispersion $\gamma_L^d$ contributions to $\gamma_L$. The contact angles of wetting of these supports by the liquid-crystal material were then measured, and Eqn.(18) was used to determine $\gamma_L^p$ and $\gamma_L^d$ for the liquid crystal. Decrease in both the polar and the dispersion components of $\gamma_S$ facilitates the homeotropic orientation of the LC.

## VIII. INFLUENCE OF THE AZIMUTHAL ANISOTROPY OF THE SUPPORT ON SURFACE PHENOMENA

The characteristic features of the orientation of specific LC between two treated plates, and different methods of depositing coatings, have been described in detail.[29,36,37] The question of the extent to which the relief of the treated support and its anisotropy influence the orientation of the director and the contact angles of liquid-crystal droplets can be considered.

Rubbing a support always produces an axis of easy orientation in the plane of the support. This can be explained from purely geometric considerations.[1,47] Rubbed polymer films such as polyvinyl alcohol (PVA), polyamides, polyesters, polysiloxanes, etc. produce uniform ordering with a very small angle of inclination of the director to the plane of the support.[83] Rubbing glass with diamond paste produces well-formed grooves, along which the rod-shaped NLC molecules are arranged. Rubbing polymer coatings leads to local fusion of the polymers and orientation of the polymer chains along the direction of rubbing. Rubbing a glass plate with paper produces regions with a high temperature, leading to local fusion of the cellulose and subsequent orientation of the polymeric cellulose molecules along the direction of rubbing. Thus the orientation of NLC molecules is determined by the combined effect of the geometric (steric) factor and the anisotropic dispersion interaction between the oriented polymer and the NLC molecules.[83]

Coatings of pure metals, for example Al and Au,[84] facilitate planar orientation of LC. Depositing $SiO_2$ or metals on supports at different angles gives different angles of inclination of the director to the support.[10,36,83–88]

Experiments to determine the influence of the anisotropy of a support on the orientation of NLC have been carried out using the SAS hexadecyltrimethylammonium bromide (STAB).[20,89] The STAB molecules were adsorbed on the glass surface from solutions with different concentrations, so that monomolecular layers with different (parallel or perpendicular) orientations of the long axes of the STAB molecules were produced. In the first case, MBBA molecules are also oriented parallel to the surface of the support and the direction in which the plate was withdrawn from the STAB solution. In the second case, the homeotropic MBBA texture was produced. The role of rubbing in this experiment is played by the flow of the STAB solution along the glass plate, creating the required anisotropy of the support. Plates covered with STAB were used to measure the flow angles $\alpha_f$ and the wetting angles (established) $\alpha$ of droplets of nematic and isotropic MBBA at different temperatures (Fig.12). No break was observed for the angles $\alpha_f$ and $\alpha$ at the phase transformation from the nematic to the isotropic phase if the MBBA was oriented homeotropically on the support. On a support producing planar orientation, only the angle $\alpha_f$ changed smoothly, and on going to the nematic temperature range the NLC wet the support completely ($\alpha = 0$). The experimentally determined $\gamma_L(T)$ relationship did not show any unique features close to $T_c$. The measured values of the angles $\alpha$ were used to calculate the work of adhesion. The observations described above show that the orientation of the SAS molecules on the support has a significant influence on the orientation of NLC molecules.

Thus SAS which bring about the homeotropic orientation of NLC have their long molecular axes arranged at right angles to the surface, and the molecules of SAS which bring about planar orientation of NLC are usually arranged parallel to the surface of the support.[36,90,91] Two examples of the orientation of SAS on a support are shown in Fig. 13.

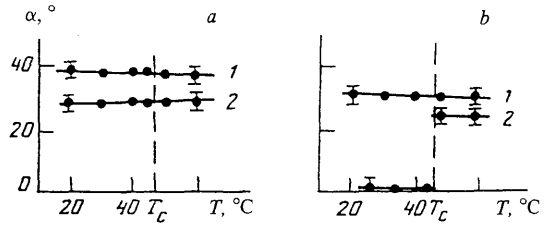

**Figure 12.** Temperature dependence of the angles of flow $\alpha_f$ (*1*) and the contact angles of wetting $\alpha$ (*2*) of drops of MBBA in the nematic and isotropic phases with homeotropic (*a*) and planar (*b*) orientation on STAB supports.[20]

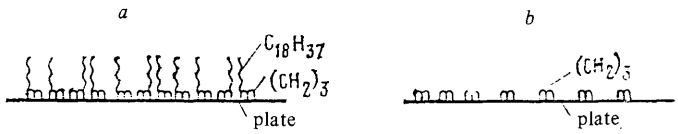

**Figure 13.** Diagram showing the arrangement of the molecules of the alkoxysilanes DMOAP (*a*) and MAP (*b*) on the surface of a support.[90]

Both thermodynamic considerations (minimisation of the inter-phase surface energy) and the steric factor (that is the surface relief) are used to explain the homeotropic texture. The orienting influence of the amphiphilic films studied[92,93] decreases with increase in the density of packing of the molecules. The contact wetting angles $\alpha$ decrease with increase in the area $A$ corresponding to one molecule of the SAS layer (Fig. 14). At the same time the contact angles are independent of temperature in the range 25–50 °C when the angle is measured to within ±1°. The work of adhesion $W_a$ increases smoothly with increase in $A$. These results were explained by the steric mechanism of orientation,[93] where the long NLC molecules are arranged in the depressions between the molecules of the amphiphilic monolayer, adopting the corresponding orientation, which is then propagated into the bulk of the NLC.

On anisotropic supports, the contact angles of wetting should depend on the azimuthal orientation of the cross-section of the drop, that is the measured angles $\alpha$ depend on the angle $\phi$ measured from the direction distinguished on the support. The anisotropy of the critical surface tension $\gamma_c$ on a support with a deposited layer of $SiO_2$ for two mutually perpendicular directions on the support has been described. The value of $\gamma_c(\phi)$ was determined by Zisman's method, by measuring the contact angles of a series of organic liquids: the values obtained were $\gamma_c(0) \cong 37$ erg cm$^{-2}$, $\gamma_c(\pi/2) \cong 39$ erg cm$^{-2}$.[94]

The wetting angles of liquid-crystal drops on supports whose anisotropy was produced by rubbing have been measured.[95] It was assumed that the interaction of the LC with the support involves dispersion forces (index $d$) and hydrogen bonding (index $h$), so that the surface tension at the LC–support boundary is written as

$$\gamma_{Ls} = \gamma_s + \gamma_L - 2(\gamma_s^d \gamma_L^d)^{1/2} - 2(\gamma_s^h \gamma_L^h)^{1/2} \qquad (19)$$

and the wetting angle is given by the expression

$$1 + \cos\alpha = 2[(\gamma_L^d \gamma_s^d)^{1/2} + (\gamma_L^h \gamma_s^h)^{1/2}]/(\gamma_L^d + \gamma_L^h) \qquad (20)$$

in which all the parameters depend on the azimuthal orientation of the cross-section of the drop. The wetting angles of an ethanol–water mixture with known values of $\gamma_L^d$ and $\gamma_L^h$ were first measured, and used to determine the parameters $\gamma_s^d$ and $\gamma_s^h$ for different supports; these parameters and the measured wetting angles of nematic 7CB were then used to calculate the surface tension of the latter.[95]

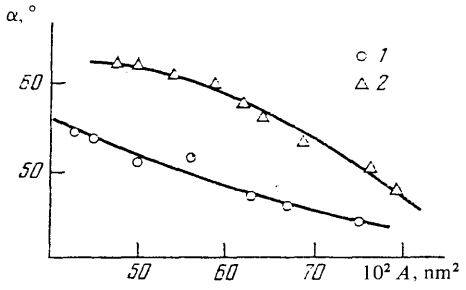

**Figure 14.** Dependence of the wetting angles $\alpha$ of drops of MBBA on supports covered with a layer of *DL*-γ-palmitoylisolecithin (*1*) and *DL*-β,γ-dilauroyl-α-lecithin (*2*) on the area $A$ at 35 °C.[92]

The contact angles were measured in two vertical cross-sections of the drop: one section was parallel to the orientation of the director on glass with a deposited layer of $SiO_2$ ($\alpha_\parallel$), and the other perpendicular to the axis of easy orientation ($\alpha_\perp$). The corresponding values of $\gamma_{s_\parallel}$, $\gamma_{s_\perp}$, $\gamma_{L_\parallel}$, and $\gamma_{L_\perp}$ were calculated using Eqns. (19) and (20).

---o0o---

Thus available experimental data on the surface tension of the nematic and isotropic phases of nematogenic compounds are often contradictory, and are clearly inadequate for developing a general model of the surface tension of liquid-crystal compounds. Existing theories have proved to be applicable only for individual substances (Okano and Murakami,[25] Gannon and Faber[8]), or to explain experimental phenomena at a qualitative level (Parsons,[30] Croxton[34]).

The anchoring of liquid crystals to a support has been studied in more detail, undoubtedly because of the interest in the practical applications of liquid crystals. The surface energy of adhesion is introduced in a form convenient for calculation, and makes possible a satisfactory description of the experimental results, but the physical nature of the energy of adhesion has not yet been sufficiently fully studied.

Studies of texture transformations induced by a surface have been published comparatively recently, and are predominantly theoretical. In spite of some contradictions, a number of serious experimental studies have proved the existence of a nematic order parameter induced by the support in the isotropic phase of an LC. The theoretical interpretation of these phenomena, however, is restricted to the Landau–de Gennes phenomenological explanation.

The experimental temperature dependence of the angle of inclination of the director to the free surface gives sufficient material for the development of a theoretical model. Neither the simplest thermodynamic considerations (Faetti and Fronzoni[9]), nor the extensive assumptions of the calculation of the moments of the forces on the surface (Mada[73,74]) are satisfactory, however.

The calculation of the dispersion and polar components of the surface energy, and attempts to introduce the orientation of the director into the calculations, are necessary steps in the development of theories of the mechanism of the orientation of LC. Nevertheless, up to the present these calculations have been based on phenomenological arguments and have not been related to models of the anisotropic interaction potential.

Practical requirements (the production of displays, radiant energy indicators, etc.) are making it necessary for research workers to learn to predict the characteristics of developed liquid-crystal elements. The large number of studies describing practical methods for producing stable LC textures show clearly the variety of orienting factors, including physicochemical interaction and the three-dimensional structure of the support and the oriented LC layer. The attempts which have been made, however, to formulate the conditions which would make it possible to predict the orientation of the director from the physicochemical characteristics of a liquid crystal and a support have not yet led to the development of criteria suitable for all LC–support pairs studied. Success will probably be achieved by a combined study of the physicochemical parameters of the surface of the support, the surface of the liquid crystal, and various phenomena associated with the interaction of the LC with the support.

# Stereochemical Aspects of the Dimerisation of Phosphazo-compounds

A.S.Tarasevich, I.E.Boldeskul, and V.P.Kukhar'

The review considers the influence of the electronic and steric structures of phosphazo-compounds on the position of their monomer-dimer equilibrium in solution. It is shown that, for acyclic phosphazo-compounds, the decisive factors are, together with steric factors, the apicophilicity of the substituents at the phosphorus atom and the donor-acceptor properties of the substituents at the nitrogen atom of the phosphazo-group. The shift of the equilibrium towards the dimers observed for phosphazo-compounds with strained five-membered phosphorus-containing heterocycles can be accounted for by the increased apicophilicity of the endocyclic substituents at the phosphorus atom. Other characteristic features of the dimerisation of cyclic phosphazo-compounds are also discussed.
The bibliography includes 62 references.

## I. INTRODUCTION

The first monomeric phosphazo-compounds (PAC) $R'_3P{=}NR$, where R = alkyl, aryl, or ArCO and R' = alkyl or aryl, were synthesised in 1919.[1] The dimeric PAC $(PhN = PCl_3)_2$ had been described even earlier.[2] However, serious studies on the physical and chemical properties of compounds of this kind and especially on the relation between their monomeric and dimeric forms did not begin until 1959 when Zhmurova and Kirsanov obtained a whole series of trichlorophosphazo-arenes (TCPA-arenes) and showed that they are almost all dimeric under normal conditions.[3] In the subsequent studies[4-10] it was shown that dimerisation is a specific feature of trichloro- and certain phenyldichloro-phosphazo-hydrocarbons.

The mechanism of the reaction leading to the formation of dimers was discussed by Zhmurova and Kirsanov[11] in relation to the interaction of phosphorus pentachloride with aromatic amines in benzene:

$$PCl_5 + 2ArNH_2 \rightarrow ArNHPCl_4 + ArNHCl$$

$$\underset{1}{\downarrow} \qquad \underset{2}{\downarrow}$$

$$HCl + {}^1/_2\,(ArNPCl_3)_2 \xrightarrow{\text{refluxing}} ArNPCl_3 + HCl.$$

The study of the infrared spectra of the reaction mixture at room temperature demonstrated the presence of an absorption in the range 3310–3320 $cm^{-1}$, which is characteristic of the N–H bond. From this, the authors assumed that the existence in solution of the unstable intermediate arylamino-tetrachlorophosphoranes $ArNHPCl_4$ had been demonstrated; on heating and also *in vacuo* at room temperature, these substances split off hydrogen chloride and are immediately converted into the dimeric TCPA-arenes (pathway *1*). The cryoscopic determination of the molecular weights of the TCPA-arenes obtained (when these are sufficiently soluble in benzene) yields values corresponding to twice the molecular weights of the monomeric forms.[3] Pathway *2* is rejected owing to the lack of absorption in the range at 1320–1380 $cm^{-1}$, attributed to the P=N bond. This absorption, indicating the presence of monomeric TCPA-arenes, appears only after refluxing a benzene solution.

On the other hand, in a later study[12] it is claimed that the reaction considered leads to the monomeric compounds $ArNPCl_3$, which are in many cases capable of dimerising. The existence of arylaminotetrachlorophosphoranes was not confirmed. The $^{31}P$ NMR spectra obtained by the authors for the reaction mixture in different solvents (including benzene) demonstrated the presence of monomeric forms, characterised by signals in the vicinity of −50 p.p.m. In certain cases yet another higher-field signal in the region of −80 p.p.m. was present in the spectrum. The relative rarity of this signal, which is due to the dimeric product $(ArNPCl_3)_2$ readily isolated on evaporating the solution, is usually caused by the inadequate solubility of the dimer and not by its absence from the reaction mixture.

The existence of dynamic equilibrium between the monomeric and dimeric forms of the TCPA-compounds in solution has also been confirmed by a study[13] of the dependence of this equilibrium on various factors. It was noted that an increase of temperature increases the fraction of the monomer in solution. The influence of the solvent is frequently decisive, although it has still not been explained. Despite the large number of experiments and the wide variety of the solvents employed, no direct relation has been found between the dielectric constants or dipole moments of the solvents and the monomer : dimer ratio. The dependence of this ratio on the solution concentration also remains unexplained.

The principal empirical criteria determining the conditions for the existence of the dimeric PAC as a function of the type of substituents at the phosphorus and nitrogen atoms of the phosphazo-group (the PA-group) were first formulated by Zhmurova and Kirsanov,[3] who established that the observed dimers are characterised by the presence at the phosphorus atom of three strong acceptors—fluorine or chlorine atoms. The replacement of even one of these by a more electron-donating group, for example, the phenyl group, leads to the complete or partial conversion into the monomeric form. Alkoxy- and aryloxy-dihalogenophosphazo-arenes were found to exist only in the monomeric form and this also applies to the PA-acyl derivatives. Hydrocarbon residues, unbranched alkyl or aryl groups, must be present

at the nitrogen atom in the dimeric PAC. Steric factors play a major role in the dimerisation process. An increase in the bulk of the substituents both at the phosphorus and nitrogen atoms hinders dimerisation, displacing the equilibrium towards the monomeric form.

The greater or lesser tendency of the TCPA-arenes towards dimerisation depends to a large extent on the basicity of the initial anilines.[3-12] Trichlorophosphazoarenes derived from anilines with $pK_a \leq 0$ exist only as monomers. The presence in solution of an equilibrium mixture of the monomeric and dimeric species is characteristic of derivatives of anilines with $pK_a \cong 0-2$. Only dimeric PAC have been obtained from anilines with $pK_a > 4$.

Unfortunately empirical rules of this kind hold only for a limited series of compounds. In the present review attention is concentrated on a more general theoretical approach which makes it possible to relate clearly the state of the monomer–dimer equilibrium to the electronic and steric structures of a wide variety of PAC (including cyclic compounds).

## II. GEOMETRICAL STRUCTURE AND CERTAIN PHYSICOCHEMICAL PROPERTIES OF PHOSPHAZO-COMPOUNDS

Monomeric PA-hydrocarbons are reactive low-melting crystalline substances or liquids, which readily dissolve in non-polar organic solvents. With increase of temperature, the $^{31}P$ NMR signal undergoes an appreciable upfield shift.[13] The geometrical parameters of a series of structurally investigated monomeric PAC have been published.[14] The correlation, found previously,[15] between the length of the P=N double bond and the valence angle at the nitrogen atom was noted. With increase of this angle, the P=N bond is shortened owing to the improvement of the conditions for the overlap of the orbital of the lone electron pair (LEP) of the nitrogen atom and the phosphorus orbital and the decrease of the covalent radius of the nitrogen atom. A typical feature of monomeric PAC in the crystal is their preferential existence in the uneclipsed conformation, as shown in Fig. 1*a* for $Ph_2PF{=}NMe$.[16] The eclipsed conformation has been observed only for $Cl_3P{=}NCCl(CCl_3)_2$.[14]

The barrier to rotation about the P=N double bond is unusually low. The paper quoted by Romanenko and Povolotskii[17] indicates values in the range 8.8–29.7 kJ mol$^{-1}$, i.e. of the same order of magnitude as the barriers to rotation about single P=N bonds, which ensures the stability of rotation (albeit hindered) about the P=N bond.

In contrast to the monomeric PAC, their dimeric analogues melt at fairly high temperatures and are much less soluble.[18] Many chemical reactions involving dimeric PA-hydrocarbons are much slower than those of the monomers or do not occur at all. The shielding of the phosphorus nuclei in the dimers is almost independent of temperature.[13]

The energy of the PN bond in the $(MeNPCl_3)_2$ dimer proved to be 311.1 kJ mol$^{-1}$,[4,5] which is appreciably higher than the 279.7 kJ mol$^{-1}$ characteristic of $P(NEt_2)_3$ and is close to the values of 302.7 and 303.6 kJ mol$^{-1}$ corresponding to the trimeric and tetrameric cyclophosphazenes. From this, Zhmurova and Kirsanov[3] proposed a cyclic structure for dimeric PA-hydrocarbons with four equalised endocyclic PN bonds, characterised by a considerable proportion of double bond character, as the most probable. X-Ray diffraction studies on the dimeric structures in the crystalline state[19-23] made it possible to refine this picture. As an example, Fig. 1*b* presents the molecular structure of the dimer $(Ph_2.PFNMe)_2$.[23]

In the dimeric PAC the configuration of both phosphorus atoms approaches the trigonal bipyramidal configuration with the F atoms at the apices of the pyramid. On the grounds that the equatorial P=N bonds are appreciably shorter than the single P–N bond in $[H_3^+NPO_3^{2-}]Na^+$, whose length is 1.77 Å,[24] it was concluded that the LEP of the nitrogen atoms in these bonds are delocalised.[25] A correlation has been noted[23] between the increase in the length of the P–N bonds and the decrease of the electronegativity (EO) of the ligand R in the series $(RPF_2NMe)_2$, where R = F, $CCl_3$, $C_6F_5$, or Ph. The spin–spin coupling constant $^2J_{PP}$ is also determined by the EO of the residue R: 125 Hz for $CCl_3$, 111 Hz for $C_6F_5$, and 80 Hz for Ph. The lowest value $^2J_{PP}$ = 28 Hz, found for $(Ph_2PFNMe)_2$, can be explained by the effect of the replacement of F by Ph at the phosphorus atom. A satisfactory correlation is observed between the intramolecular P...P distance $l$ and the constant $^2J_{PP}$ in the series $(R^1R^2PFNMe)_2$; $l$ = 2.579 Å for $R^1$ = F and $R^2$ = $CCl_3$, $l$ = 1.594 Å for $R^1$ = F and $R^2$ = $C_6H_5$, $l$ = 2.61 Å for $R^1$ = F and $R^2$ = Ph, and $l$ = 2.659 Å for $R^1 = R^2$ = Ph.

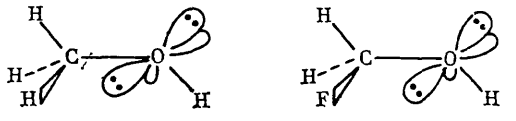
## III. ELECTRONIC STRUCTURE OF PHOSPHAZO-COMPOUNDS

A discussion of the nature of the P=N bond in phosphazines may be found, for example, in Allcock's monograph,[26] where numerous references to the relevant communications are given. In considering the characteristic features of the P=N double bond, which determines the reactivity of the PA group, it is sufficient to compare in terms of the same $s$, $p$ valence orbitals the formally analogous P=N and C=N bonds in the model compounds $H_3P{=}NH$ and $H_2C{=}NH$ respectively.

The localised molecular orbitals (LMO) of the σ and π types can be readily constructed for the C=N bond in the azomethine from the valence orbitals of the C and N atoms:



The polarity of the bond is determined by the difference between the EO of carbon and nitrogen. An analogous covalent structure of the P=N bond is impossible owing to the deficiency of the atomic orbitals (AO) of phosphorus. The formation of $H_3P{=}NH$ can be represented as a result of the σ-dative interaction of the phosphorus LEP in the phosphine ($H_3P$) molecule with the valence $sp^2$-hybridised nitrogen AO of the NH directed towards it:

The disposition of all three electrons in the LMO corresponding to the constituent of the P–N bond is unfavourable, since one of them must be located in the high-energy antibonding σ* LMO. The migration of this electron to another valence AO of nitrogen with formation of a new LEP of the π type is more probable. The PN bond is then found to be highly polarised, much more than would follow from the EO of the P and N atoms. The reverse transfer of electron density from the nitrogen atom to the $H_3P$ group via a hyperconjugation mechanism leads to some redistribution of such electron density from the LEP of nitrogen mainly over the H atoms. Thus, in contrast to the C=N bond, the formally double P=N bond is characterised by a dominant contribution of the $P^+{-}N^-$ structure, which ensures a relatively low barrier to rotation about this bond and the high reactivity of the atoms of the PA group. The use of the 3*d* AO of phosphorus which are unoccupied in the ground state leads to some decrease of the excess positive charge on phosphorus owing to its $p_\pi{-}d_\pi$ bonding to the nitrogen atom. However, this compensation cannot be effective because of the much higher energy level of the 3*d* AO compared with other (valence) phosphorus orbitals.

The analogous structures of methanol ($H_3C{-}OH$) and its substituted derivatives, which have been thoroughly investigated, may be adopted as models of the electronic and steric structures of the monomeric PAC:[27]

(I) (II)

As for $H_3P{=}NH$,[28] the uneclipsed conformation of methanol (I) is the most stable, which can be accounted for by the destabilising effect of the repulsion of the occupied σ constituents of the LMO corresponding to the CH and OH bonds. The replacement of one of the H atoms attached to carbon by an electronegative substituent such as F leads to the preferential *gauche*-conformation (II) stabilised by the interaction of the $p_\pi$ LEP of the oxygen atom with a vacant σ* LMO of the C–F bond. The other oxygen LEP has an appreciable *s* character and cannot participate quite so actively in π bonding to the $CH_2F$ group. As we have seen, a similar situation is observed for $Ph_2PF{=}NMe$.

The electronic structure of dimeric PAC can also be modelled using *s*, *p* valence orbitals. The apical substituents in the trigonal bipyramid (TBP) of phosphorus are distinguished by longer (and weaker) bonds with the central atom compared with the equatorial bonds. Both σ bonds at the phosphorus atom of this type can be described in terms of the three MO of a single three-centre four-electron bond in which only one of the 3*p* AO of phosphorus is involved and is directed along the axis. With increase of the EO of the apical substituents, the stability of such a system also increases.[29] The more electron-donating substituents therefore prefer equatorial positions in the TBP. The presence of the LEP at the bonding atom of such a substituent is responsible for its destabilising interaction with the occupied σ MO of the axial bonds as a result of which the LEP is located in the equatorial plane. Conversely, the presence of an unoccupied orbital in the bonding atom of the substituent increases its chance of occupying an apical position.

The greater or smaller ability of two different substituents to occupy apical positions in the TBP of phosphorus is characterised by their relative apicophilicities. The latter can be estimated from the energy change when the above substituents are exchanged between the apical and equatorial positions. Series of substituents in terms of decreasing apicophilicities have now been established, for example:[29]

$$F{>}H{>}Cl{\sim}C(O)R{>}Br{\sim}CN{>}OPh{\sim}SPh{>}OR{>}NR_2{>}Me{>}Ph.$$

These are only approximate and, as we shall see below, may break down under certain conditions. Nevertheless, in discussing the stability of any TBP, be it the transition state in the nucleophilic substitution reaction at a tetracoordinate phosphorus atom or a stable phosphorane structure, the concept of the apicophilicity of the substituent is much more convenient than, for example, the concept of its EO.

## IV. THE MECHANISM OF DIMERISATION

The observed tendency of PAC towards cyclodimerisation is due to the enhanced electrophilicity of the positively charged phosphorus atom and the enhanced nucleophilicity of the negatively charged atom in the PA group. In principle, two mechanisms are possible for the dimerisation of the PAC $XY_2P{=}NR$—stepwise and synchronous. The former can be formulated on the basis of the existence of the monomers in the most stable (uneclipsed) conformation (Fig.2). The reaction begins with the attack by the $N^1$ atom of one of the monomers via its LEP on the $P^2$ phosphorus atom of another monomer molecule from the side opposite to the direction of the bond between $P^2$ and the most apicophilic of its substituents ($X^2$). The formation of the new bond leads to the transition of the $P^2$ atom from the tetrahedral to the TBP configuration and is accompanied by the transfer of one electron from the first monomer to the second. The tendency of the π-LEP of the negatively charged $N^2$ atom to be located in the equatorial plane of the TBP promotes the rotation of the $N^2{-}R^2$ group about the $P^2{-}N^2$ bond, which places the $sp^2$-hybridised LEP of $N^2$ in the position most favourable for the formation of a dative σ-bond with the positively charged $P^1$ atom. The rotation of the $P^1X^1Y_2^1$ group about the $N^1{-}P^1$ bond is also essential for the closure of the four-membered diazadiphosphetidine ring.

However, it is entirely possible that the barriers to rotation about the $P^2{-}N^2$ and $N^1{-}P^1$ bonds are relatively large and the energy of the $P^2{-}X^2$ axial bond is fairly small. In this case the attack by $N^1$ on $P^2$ can terminate via the mechanism of the usual nucleophilic $S_N2$ substitution: by the elimination of the

apical substituent $X^2$ in the form of an anion and the formation of a more or less stable linear cation $[X^1Y^1_2P^1{-}N^1(R^1){-}P^2(Y^2_2){=}N^2R^2]^+$.

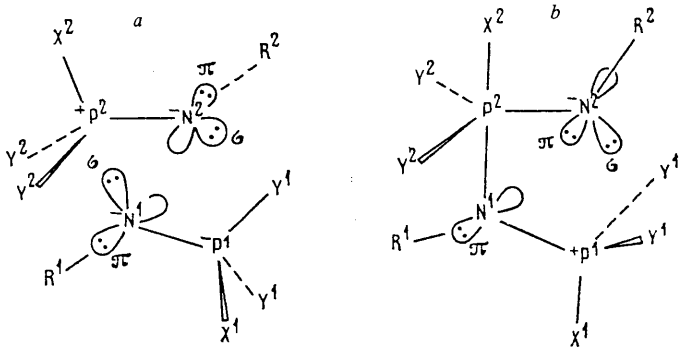


Figure 2. The mechanism of the stepwise dimerisation of phosphazo-compounds: *a*) disposition of the monomers in the formation of the first "dimeric" NP bond; *b*) conformation of the intermediate linear dimer most suitable for ring closure.

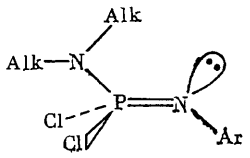
For the second mechanism to operate (synchronous dimerisation), the rotation about the $N^1{=}P^1$ and $N^2{=}P^2$ bonds in the monomers must take place beforehand, i.e. the monomers must be in the eclipsed conformation with a *cis*-disposition of the N–P and P–X bonds, which is energetically unfavourable but is more favourable for dimerisation. After this, both pairs of atoms ($N^1$, $P^2$ and $P^1$, $N^2$) can form the corresponding dative σ-bonds simultaneously. The problem of the possible preference for one of the dimerisation mechanisms discussed has not as yet been finally solved. It is also possible that everything depends on the reaction conditions: the presence of a specific solvent, the relative initial positions of the monomers, etc. Even the P=N–R valence angle apparently affects the dimerisation mechanism.[28] In the subsequent exposition we shall therefore confine ourselves to the synchronous reaction mechanism, since it is simpler.

## V. THE INFLUENCE OF THE ELECTRONIC AND STERIC STRUCTURES OF ACYCLIC PHOSPHAZO-COMPOUNDS ON THE POSITION OF THEIR MONOMER–DIMER EQUILIBRIUM



We shall now consider in greater detail the factors which determine the greater or smaller tendency of PAC to dimerise. They can be arbitrarily divided into two groups—electronic and steric. The former include those which influence the electrophilicity of the phosphorus atom and (or) the nucleophilicity of the nitrogen atom of the PA group and also ensure the stability of the trigonal bipyramidal configuration of the P atoms in the dimers. The most important of these factors is the apicophilicity of the substituents at the phosphorus atom already considered.

Despite the fact that in the nucleophilic attack on the phosphorus atom only one of its three substituents in the PA group enters an apical position in the TBP group formed, a high EO of the remaining substituents is also desirable for dimerisation. An increase in the EO of these substituents not only increases the relative contribution of the AO of phosphorus to the unoccupied MO of the monomer but also leads to a greater decrease of the energy levels of these MO compared with the occupied orbitals. Both these factors intensify the interaction between the monomers, which leads to their dimerisation.[28,30]

A similar effect is induced also by the enhancement of the electron-donating properties of the substituent R at the nitrogen atom, which leads to an increase of the negative charge on the nitrogen AO and to a greater rise of the energy levels of the occupied MO of the PA group compared with the levels of the unoccupied MO. The width of the energy gap between these MO diminishes and the interaction between the monomers is correspondingly intensified.[28]

Speaking of the steric factors influencing the dimerisation of PAC, one should note in the first place the steric factors already mentioned. The presence of hindrance interfering with the disposition of the monomers at a distance necessary for the onset of dimerisation or their most favourable orientation relative to one another shifts the monomer–dimer equilibrium towards the monomer. Many instances of precisely such influence of very bulky substituents in the PA group are available in the literature (see, for example, Kozlov et al.[31]).

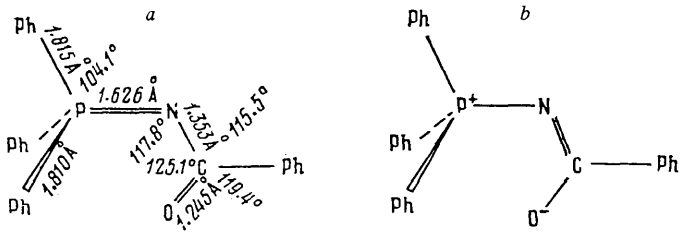
Since the different conformations of the monomeric PAC are not equally favourable for dimerisation, the factors stabilising one of them can play an appreciable and sometimes even a decisive role in the equilibrium considered. As an example, one may quote the effect of the replacement of one of the chlorine atoms in TCPA-arenes by the dimethylamino-group. The atomic EO of nitrogen and chlorine on Pauling's scale are approximately the same. In contrast to chlorine, the $NAlk_2$ group with an $sp^2$-hybridised nitrogen atom has a plane of symmetry and not an axis of symmetry, which is not only responsible for the presence of a barrier to rotation about the P–N single bond but also influences the barrier to rotation about the P=N double bond. The conformation (III) is energetically most favourable.

(III)

Other possible conformations, obtained by rotation about the P=N bond, are characterised by an increase of the total energy of the molecule both as a result of the breakdown of the conjugation of the LEP of the nitrogen atom in the dialkylamino-group with the rest of the molecule and as a consequence of the increasing repulsion between this LEP and the $sp^2$-hybridised LEP of the imino-nitrogen atom. Thus the presence of the dialkylamino-group as a substituent at the phosphorus atom of the PA group stabilises the conformation unfavourable for dimerisation. Ultimately the tendency of the PAC to dimerise diminishes.[18]

Cases where the difference between the monomer–dimer equilibrium positions can be explained by a change in only one factor are very rare. Usually several different factors change simultaneously and in the explanation of the observed shift of the equilibrium it is essential to take into account the effects of each. As an example of the situation where the replacement of only one substituent leads to an extremely marked shift of the equilibrium, induced by the superposition of several effects acting in one direction, it is sufficient to compare the capacities for dimerisation of PA-arenes and PA-acyl derivatives

The triphenylphosphazoacyl derivative $Ph_3P{=}N{-}C(O)Ph$ investigated by Bar and Bernstein[32] is characterised by the eclipsed conformation typical for PAC with an almost planar disposition of the P=N–C=O fragment (Fig. 3*a*). The appreciable contribution of the limiting structure illustrates in Fig. 3*b* the increase of the stability of this conformation. The formation of a weak non-valence bond between the charged $P^+$ and $O^-$ atoms entails a change in which the tetrahedral configuration of the phosphorus atom approaches the trigonal bipyramidal configuration. Despite the corresponding decrease of the P=N bond order, the barrier to rotation about this bond should increase.



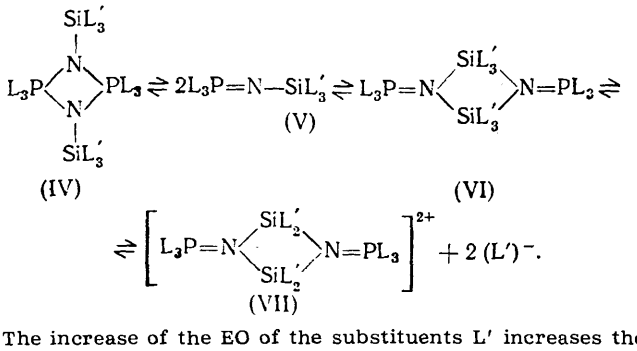


Figure 3. The molecular structure of $Ph_3P{=}N{-}C(O)Ph$: *a*) principal geometrical parameters; *b*) the limiting structure whose contribution increases the stability of the monomeric form [32]

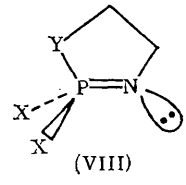
The electrophilicity of the phosphorus atom diminishes on passing to the TBP configuration. As a consequence of the migration of the negative charge from phosphorus to oxygen and not nitrogen, the latter also becomes less nucleophilic. All these factors explain why, in contrast to PA-arenes, the PA-acyl derivatives do not dimerise under any conditions.

In conclusion of this Section, we shall consider the dimerisation of *N*-silyl-substituted PAC $L_3P{=}NSiL'_3$, described by Wolfsberger,[33,34] whose course is extremely unusual. When L′ = alkyl, they become like the usual PAC as regards dimerisation—the tendency to dimerise increases with increasing EO of the substituents L and the dimers themselves are diazadiphosphetidine rings with pentacoordinate phosphorus atoms:

The increase of the EO of the substituents L′ increases the positive charge on the Si atom, promoting an increase of its coordination and saturation. For this reason, in the presence of electron-donating substituents at the phosphorus atom (for example, L = alkyl) and of electron-accepting substituents at Si (for example, L′ = halogen), the Si atom may be more electrophilic than the phosphorus atom of the PA group. In this case the dimerisation takes place with formation of the four-membered ring $(NSi)_2$ with pentacoordinate Si atoms, as has been observed for L′ = F [structure (VI)]. In the pure state such substances are dimeric at room temperature. They are monomeric in solution, but, with decrease of temperature, they dimerise. The pentacoordinate nature of the silicon atom ensures a higher Si–F bonding energy. When the F atoms at the silicon atom are replaced by other halogens, the heterolytic elimination of the latter leads to the more stable dicationic structure (VII) in which the silicon atoms are tetracoordinate.



It is also noteworthy that, whereas the transition from the monomer (VI) to the dimeric structure (IV) is accompanied by the usual upfield shift of the $^{31}P$ NMR signal, the transition to structures (VI) and (VII) is characterised by downfield chemical shifts.

## VI. THE EFFECT OF THE FIVE-MEMBERED PHOSPHORUS-CONTAINING HETEROCYCLE

The chemistry of small (four- and five-membered) phosphorus-containing heterocycles has been developing vigorously in recent times. The characteristic features of their behaviour in chemical reactions have led to the differentiation of this group from other phosphorus compounds. The effect of the five-membered ring is manifested also in the monomer–dimer equilibrium considered here, shifting its position much further towards the dimer than is characteristic of, for example, acyclic PAC. The nature of this effect can be explained on the basis of the general ideas concerning the factors determining the tendency of PAC to dimerise described above.

### 1. Phosphazo-compounds with an Endocyclic P=N Bond

We shall consider initially 1,2-azaphospholes in which the P=N double bond is endocyclic:

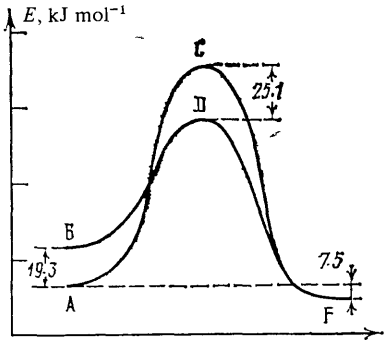
(VIII)

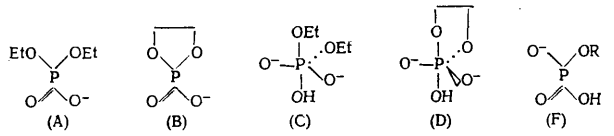
Compared with acyclic PAC, these compounds have a whole series of characteristic features, which affect the reactivity of the PA group. Firstly, the presence of the almost planar five-membered ring is responsible for the unique eclipsed conformation (VIII) which is favourable for dimerisation. Secondly, the enhanced *p* character of the phosphorus atom in the P–Y and P=N bonds corresponds to a relatively small endocyclic Y–P=N angle (~90°), which is equivalent to a decrease of the EO of the phosphorus atom relative to its endocyclic substituents. The lengths of these bonds and the electron densities at the Y and N atoms increase. The *trans*-antiperiplanar disposition of the $sp^2$-hybridised LEP of the nitrogen atom relative to the P–Y bond causes an additional weakening of this bond as a consequence of the so-called stereoelectronic effect (see, for example, Gorenstein et al.[35] and the references therein).

The interaction of this LEP with the unoccupied σ* LMO of the P–Y bond reduces the overlap population between P and Y and its electrostatic (dipole) influence on the occupied σ LMO shifts the electron density from P to Y.[27] The changes

described are equivalent to an increase of the effective potential apicophilicity of the substituent Y and increase the probability of nucleophilic attack on the phosphorus atom along the P–Y bond on the opposite side.

Similar effects have been considered in detail in relation to the hydrolytic reactions of diethyl and ethylene phosphates.[35] The reaction profiles of the above reactions are compared in Fig. 4.[36]





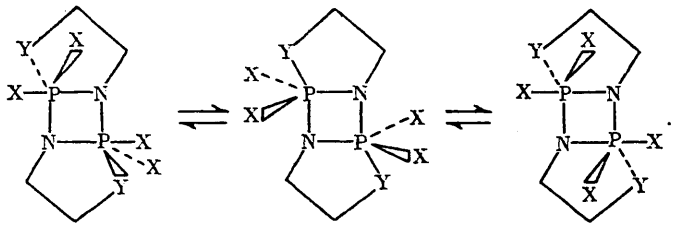


Figure 4. Reaction profiles of the hydrolytic reactions of diethyl phosphate (A) and ethylene phosphates (B) demonstrating the role of the five-membered ring in the energy relations of the transition from tetracoordinate to pentacoordinate phosphorus:[36]

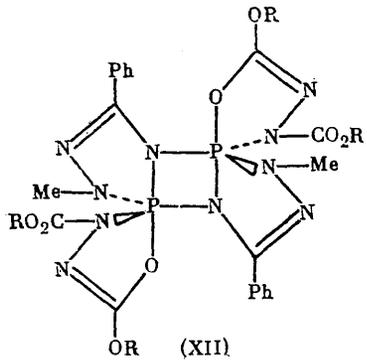
Evidently the activation energy is much lower for the cyclic phosphate than for the acyclic phosphate. This difference is caused both by the angular strain in ethylene phosphate, which increases its energy by 19.3 kJ mol$^{-1}$ compared with diethyl phosphate, where the hybridisation of the tetracoordinate phosphorus atom is closer to equilibrium tetrahedral hybridisation, and by the stereoelectronic effect, which causes additional stabilisation of the apical-equatorial disposition of the five-membered ring in the trigonal bipyramidal transition state (25.1 kJ mol$^{-1}$).[35] The $p_\pi$ LEP of the endocyclic equatorial oxygen atom is orthogonal with respect to the three-centre axial O–P–O bond and the repulsion between the hybridised σ-LEP of this atom and the occupied O–P–O MO is weakened as a consequence of the *trans*-disposition of the corresponding dipoles.[27]

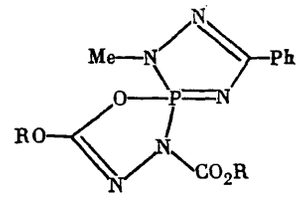
The energy balance in the dimerisation of PAC can be represented by two contributions of comparable magnitude with opposite signs: the energy expenditure on the transition of both phosphorus atoms from the tetrahedral to the TBP configuration and the energy gain on formation of two new P–N bonds.[37] It follows from the above that the energy expenditure on the rehybridisation of the phosphorus atom in the cyclic PAC is much smaller than in the acyclic compounds.

It has been noted[38] in relation to azaphospholes with Y = S or O that, on passing from the acyclic phosphorane to the phosphorane with a planar five-membered heterocycle, the length of the axial P–Y bond increases. Hence it follows that the "dimeric" P–N σ-bond, located approximately on the same axis as the P–Y bond, is stronger (and energetically more favourable), for example, in the tricyclic structure (IX) than in the analogous compound with opened five-membered rings.



All this explains why the presence of the five-membered ring predetermines the enhanced tendency of 1,2λ$^5$-azaphospholes to add to the P=N bond and in particular their tendency to dimerise.[38–40] The electronic properties of the endocyclic substituent Y are then found to exert a decisive influence on the position of the monomer–dimer equilibrium.[41]

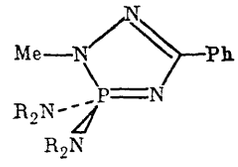
The structure of the dimer formed initially with a trigonal-bipyramidal coordination of the phosphorus atoms and the axial-equatorial dispositions of all three rings is characterised by the so-called meridional form (IX) in which all the bonds of the nitrogen atoms lie in the same plane.[42] The synchronous Berry pseudo-rotations[43] can convert the structure (IX) into any of the two facial forms (X) or (XI) with the nitrogen atoms in the pyramidal configuration. There is equilibrium between these forms in solutions, while in crystals one of them occurs (which particular one occurs depends on the relative apicophilicities of the substituents at the phosphorus atom). Experiments have shown that, for Y = O or S (and for the apicophilicity of X lower than that of Y), the form (IX) is observed,[38] while in the case where Y = N the position of the monomer–dimer equilibrium depends on the apicophilic properties of the exocyclic substituent X at the phosphorus atom. Dimeric forms of type (XI) are realised for 1,2,4,3λ$^5$-triazaphospholes, for example, with X = F, Cl, or Br, whereas in the case where X = OR, OAr, $NR_2$, or Ph only the monomeric forms obtain.[41] The absence of dimerisation for Y = C and apicophilic exocyclic substituents can be explained by the extremely high activation energy for the transition of phosphorus atoms from the tetrahedral to the TBP configuration with a diequatorial disposition of the five-membered ring.



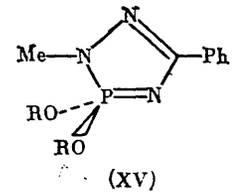
The dimeric form (X) has not as yet been observed in a pure form. Its presence as an admixture to the distorted form (IX) has been noted for dimeric 1,3,4,2λ$^5$-thiadiazaphospholes.[38] The distortion is caused by the angles at the phosphorus atom in the five- and four-membered ring being much smaller than 90°, which leads to the "fracture" of the TBP axis in the direction which is the opposite of that usually observed in acyclic phosphoranes. The decrease of the angle between the exocyclic equatorial substituents at the phosphorus atom to 110° corresponds to the "anti-Berry distortion" indicated.

In conclusion we shall consider the case where the exocyclic substituents at the phosphorus atom in 1,2-azaphospholes have been replaced by a second five-membered heterocycle. The synthesis of the four dimeric compound (XII),

where R = Me, Et, $CHMe_2$, and $CH_2Ph$, has been reported:[44]

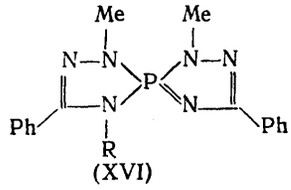


(XII)



(XIII)

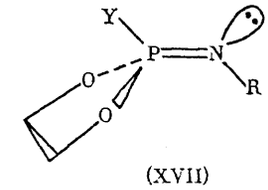
By hypothesis, they are formed as a result of the dimerisation of the spirocyclic intermediate (XIII). By comparing these unstable PAC with the similar monocyclic structures (XIV) and (XV), which exist in the monomeric form only,[41] we can see that the presence of the second five-membered heterocycle clearly enhances the tendency of the azophospholes to dimerise.



(XIV)

(XV)

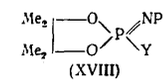
The point is that the bicyclic structure (XIII) with a tetracoordinate phosphorus atom is subject to angular strain to a greater extent than the corresponding monocyclic structure. Although the oxadiazophosphole ring in the TBP of the dimer formed initially is in the diequatorial position, the synchronous Berry pseudorotations lead to the energetically more favourable structure (XII), where both five-membered heterocycles are located in the axial-equatorial positions and the most apicophilic substituent (the oxygen atom) occupies the apical position.



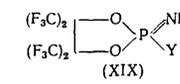
The analogous spiro-bi(triazaphospholes) (XIV) proved to be monomeric.[44] This can be explained both by the lower apicophilicity of nitrogen compared with oxygen and by the decrease of the electrophilicity of the phosphorus atom when oxygen is replaced by nitrogen:

(XVI)

## 2. Phosphazo-compounds with an Exocyclic P=N Bond



We shall now proceed to the consideration of 2-imino-1,3,2-dioxaphospholans and their derivatives—compounds with a five-membered phosphorus-containing heterocycle and an exocyclic P=N bond:

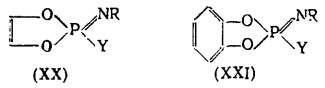


(XVII)

As in the acyclic PAC, the most stable conformation (XVII) is unsuitable for synchronous dimerisation. As a result of the decrease of the O—P—O angle and the increase of the P—O bond length on formation of the dioxaphospholan ring, the apicophilicity of the endocyclic oxygen atoms increases, while that of the exocyclic Y and N atoms correspondingly decreases. Thus, in contrast to azaphospholes, the presence of the ring induces a shortening and not a lengthening of the P=N bond. The stereoelectronic effect considered above obtains also in the dioxaphospholan ring. The hybridised LEP of one of the endocyclic oxygen atoms destabilises the antiperiplanar σ-bond of the other oxygen atom with phosphorus, which also contributes to the overall increase of the apicophilicity of these atoms. The phosphorus atom becomes more electrophilic overall and the basicity of the nitrogen atom falls somewhat. The relative probability of nucleophilic attack on the phosphorus atom from the side opposite to that of any one of the P—O bonds increases. Taking into account all these factors, one may conclude that, in terms of their tendency to dimerise, iminophospholans should occupy an intermediate position between azaphospholes and acyclic PAC with analogous substituents in the PA group. Experiments[45] agree satisfactorily with this conclusion.

The weak electron-donating effect of the alkyl substituents in the 4- and 5-positions in the heterocycle (XVIII) shifts the monomer–dimer equilibrium towards the monomer,[46] while the electron-accepting effect of the trifluoromethyl groups in the structure (XIX) causes a shift towards the dimer:[47,48]

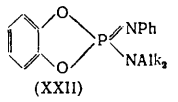
(XVIII)



(XIX)

Compared with acyclic PAC, the influence of the steric factor of the substituent at the imino-nitrogen atom on the dimerisation is clearly reduced. Dimerisation is not interfered with even by the bulky groups at the nitrogen atom such as the trimethylsilyl or t-butyl groups. The role of the EO of the substituent Y is also weakened. X-Ray diffraction analysis of the dimer (XIX) with Y = F demonstrated the equatorial disposition of this substituent in the TBP of phosphorus,[47] which indicates a weaker apicophilicity of fluorine compared with the endocyclic oxygen atom—a result of which is improbable for acyclic phosphorane structures. On the other hand, the effect of the EO of the substituent at the nitrogen atom, which determines the nucleophilic properties of the latter, remains in force. The replacement of R = Ph by the $SO_2Ar$ group shifts the equilibrium towards the monomer.[46] An analogous situation obtains when R = Et is replaced by Ph even if Y = OMe is substituted simultaneously by the dimethylamino-group.

On passing from the dioxaphospholan ring (XVII) to the dioxaphospholen ring (XX), the shortening of the endocyclic C—C bond, caused by the increase of its multiplicity, is accompanied by a further decrease of the O—P—O angle and the increase of the P—O bond length. In addition, the LEP of the oxygen atoms are able to be conjugated with the

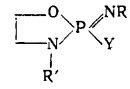


π-component of the C=C bond. Ultimately, the electron-accepting capacity of the ring and its tendency to dimerise increase.[49]

(XX) (XXI)

The replacement of the dioxaphospholan ring (XVII) by the benzodioxaphosphole ring (XXI) has an analogous effect. To demonstrate this, it is sufficient to compare data for the dimerisation of such compounds with R = Ph and Y = $NBu_2$, published by Gilyarov et al.[45] and Kukhar' et al.[50]

The influence of the electronic and steric factors on the dimerisation of *N*-arylimino-4,5-benzo-1,3,2-dioxaphospholes has been studied in detail.[51] The effect of the $NAlk_2$ group, which stabilises the monomeric form in iminodioxaphospholans,[45] is more than compensated in 2-dialkylamino-2-phenylimino-4,5-benzo-1,3,2-dioxaphospholes (XXII) by the increased apicophilicity of the endocyclic oxygen atoms:



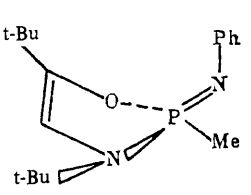
(XXII)

The compounds with Alk = Me or Bu exist only in the form of dimers. On the other hand, when Alk = Et, the monomer is detected in solution together with the dimer.[50] This difference can be accounted for by other, more refined effects of the stabilisation of the conformation of the PA group, which is unfavourable for dimerisation. For the analogous acyclic PAC, which exist only in the form of monomers, such effects can be neglected. The point is that, despite their low acidity, the hydrogen atoms in the C–H bonds are quite capable, under certain conditions, of interacting with the LEP of a powerful nucleophile such as the nitrogen atom of the PA group. Among compounds (XXII) with Alk = Me, Et, and Bu, the corresponding steric conditions for the formation of a weak intramolecular hydrogen bond can be realised only in the last two. The probability of a sufficiently close approach to the imino-nitrogen atom by one of the two β-methylene hydrogen atoms in the butyl group is smaller than for one of the three methyl groups when Alk = Et. Furthermore, the acidity of the methylene protons is smaller than that of the methyl protons.[52] As a result of all these factors, when Alk = Et, the stability of the hypothetical six-membered ring with the H...N hydrogen bond (and the "bonding" of the LEP of the imino-hydrogen in this bond) is a maximum and so is the probability of the existence of this compound in the monomeric form.

The replacement of the endocyclic oxygen atoms in the structure (XVII) by sulphur atoms, which are approximately equivalent as regards their apicophilic properties (although they are much less electronegative), should not be reflected in the monomer–dimer equilibrium. Indeed, like the analogous dioxaphospholans, 2-dimethylamino-2-phenylimino-1,3,2-dithiaphospholan is monomeric,[53] while 2-chloro-2-phenyl-imino-1,3,2-dithiaphospholan has a dimeric structure.[54] Hence it is clearly seen that the change in the electron-accepting properties of the ring does not by itself play a decisive role in the equilibrium considered and is reflected in the latter only in so far as the equilibrium is usually associated with the corresponding change in the apicophilicity of the endocyclic substituents at the phosphorus atom.

The effect of replacing one and even more so two endocyclic oxygen atoms by nitrogen atoms is interesting. Such compounds no longer exhibit a tendency to dimerise.[46,54–56]

It follows from the series based on the decreasing apicophilicity presented above that, for example, the apicophilicity of OR is greater than that of $NR_2$. For this reason, nucleophilic attack on phosphorus in the structure (XXIII) should proceed from the opposite side of the P–O bond.



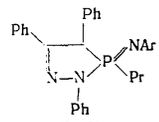
(XXIII)

However, it is noteworthy that the fixation of the O and N atoms in the almost planar oxazaphospholan ring entails some mutual approach of their apicophilicities. The stereoelectronic effect of the σ-LEP of the O atom weakens the endocyclic P–N bond, while the analogous effect for the P–O bond is absent owing to the orthogonality of the LEP of the N atom. The apicophilicity of the oxygen atom in the structure (XXIII) is therefore smaller than its apicophilicity in the dioxaphospholan ring, while the apicophilicity of the endocyclic nitrogen atom is greater than in the diazaphospholan ring, where the stereoelectronic effects are almost absent.

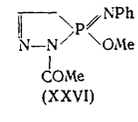
Furthermore, it has been shown[57,58] that the rupture of the endocyclic P–N bond in 1,3,2-oxazaphospholidines following nucleophilic attack on the phosphorus atom occurs with inversion of the configuration of the latter, which agrees with the hypothesis that the apical position in the TBP formed initially in the intermediate is occupied by nitrogen and not oxygen. The concept of the apicophilic capacity of the ligand, describing the probability of finding it on the same axis as the nucleophile during the attack of the latter on a tetracoordinate phosphorus atom, was therefore introduced. The apicophilic capacity of any ligand is assumed to depend on other substituents at the phosphorus atom, the nature of the nucleophile and the solvent, the presence of metal ions, and many other factors.[59]

Thus, although the endocyclic nitrogen atom is less apicophilic than the oxygen atom in the imino-derivatives of 1,3,2-oxazaphospholans (XXIII), it has a greater apicophilic capacity. This is caused by the presence of the bulky R′ substituent at this atom, located approximately in the O–P–N plane, as a result of which nucleophilic attack on the phosphorus atom along the P–O bond is hindered and the analogous attack from the opposite side of the P–N bond becomes more probable. A necessary condition for synchronous dimerisation is in this case the *cis*-disposition of the P–N and N–R bonds, which may be unattainable in the presence of bulky substituents at both nitrogen atoms. All these factors explain why PAC with oxaza- or diaza-phospholan rings lose their tendency to dimerise which is so characteristic of the dioxaphospholan ring.

3,5-Di(t-butyl)-2-methyl-2-phenylimino-1,3,2λ⁴-oxazaphospholine (XXIV) with the pseudoaxial disposition of the P=N bond is very characteristic in this sense:[56]



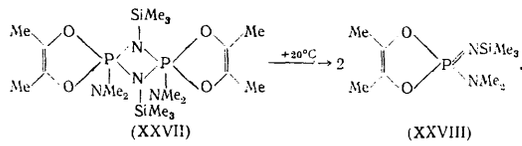
(XXIV)



Even the presence of the endocyclic C=C double bond cannot ensure a stable dimeric structure of the above compound. The bulky t-butyl group in the 3- and 5-positions in the ring does not allow any of the endocyclic heteroatoms

to occupy the apical position in the phosphorus TBP of the hypothetical dimer. These causes, let alone the electron-donating properties of the exocyclic substituents at the phosphorus atom, are entirely sufficient to account for the exclusively monomeric structure of compound (XXIV).

In conformity with the principles described above, 1,2,3-diazaphospholine (XXV) [60] proved to be monomeric:



(XXV)

(XXVI)

This is caused by the low apicophilicity of the endocyclic nitrogen atom and the inadequate EO of the phenyl group at the phosphorus atom. On the other hand, compound (XXVI) with the analogous diazaphospholine ring is formed at the instant of synthesis together with its dimer, [61] which can be explained by the greater apicophilicity of the corresponding nitrogen atom as a consequence of the $\pi$-acceptor character of the exocyclic substituent at this atom, the greater apicophilic capacity of the latter, caused by the absence of the cumbersome phenyl group at the carbon atom in the 4-position in the ring, and also by the greater EO of the methoxy-group at the P atom compared with the phenyl group. Admittedly, the location of the most apicophilic substituent (OMe) in the apical position of the phosphorus TBP requires the energetically unfavourable diequatorial disposition of the diazaphospholine ring. For this reason, only the monomeric form remains after five days storage in the form of a solution in bromoform.

An analogous situation has been described by Zeiss. [62] The crystalline diazadiphosphetidine (XXVII) isolated at a low temperature (−78 °C) is fully converted into the monomeric form (XXVIII) after dissolution in acetonitrile and storage for 24 h at room temperature:

(XXVII) (XXVIII)

At +20 °C the dioxaphospholen (XXVIII) is a colourless liquid, which crystallises at −27 °C, but cannot be reconverted into the dimeric form (XXVII). The thermodynamic stability of the dimer (XXVII) in relation to the monomer (XXVIII) can be explained both by the bulky nature of the trimethylsilyl group at the imino-nitrogen atom and by the electron-donating capacity of the exocyclic dimethylamino- and methyl groups in the five-membered ring. [62]

---o0o---

Summarising, one should note that all the main factors determining the dimerisation of PAC and influencing the position of the monomer–dimer equilibrium are now well known. The so-called phospholan effect, which until recently had an aura of being "unexplained", can be accounted for on the basis of general ideas about the reactivity of the tetracoordinate phosphorus atom and about the electronic nature of the PA group.

All this makes it possible not only to explain but also to shift in the required direction the monomer–dimer equilibrium involving the PAC synthesised by altering appropriately the electronic and (or) steric properties of the substituents at the P and N atoms in the PA group. [26]

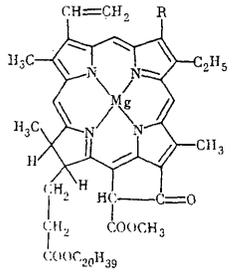
# Applied Aspects of the Chemistry of the Porphyrins

O.A.Golubchikov and B.D.Berezin



The review deals with the prospects for the practical application of porphyrins as catalysts and reactants in various chemical, electrochemical, and photochemical processes.
The bibliography includes 347 references.

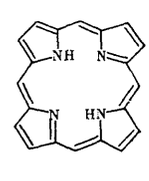
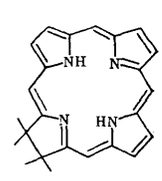
## I. INTRODUCTION

Porphyrin complexes play an important role in nature. It is sufficient to quote the example of chlorophyll [MgChl (I)], which, forming part of the composition of chloroplasts, effects photosynthesis, and haem [FePP (II)], which, as a component of haemoglobin, transports oxygen to animal tissues, as a component of myoglobin, it ensures its storage, and, as a component of cytochromes, it catalyses biochemical oxidation–reduction reactions. There is no doubt that the primary stimulus which led to the investigation of porphyrins and their metal complexes was provided precisely by the biocatalytic properties of metalloporphyrins. This stimulus still remains important.

chlorophyll *a*, with R = $CH_3$;
chlorophyll *b*, with R = CHO
(I)

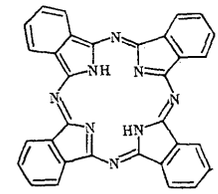


protohaem (II)

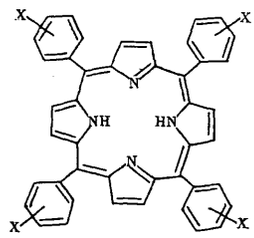


During the last 20–25 years, there has been a sharp growth of interest in porphyrins. Together with fundamental theoretical investigations, numerous applied studies have been made. Porphyrins proved to be universal catalysts of many chemical, electrochemical, and photochemical reactions.

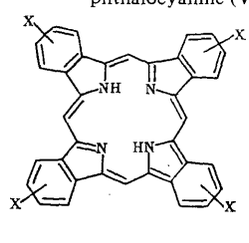
The high catalytic activity of porphyrins is due to the aromatic character of the conjugated π-system of the macroring, the conjugation of the coordinated metal atom to the π-system of the ligand, and the ease with which the oxidation state of the central metal atoms, for example, those of Co, Fe, Mn, and others, changes. It is also important that the extensive π-electron systems of porphyrins have a distinct electron-buffer character. Depending on the other reactant, porphyrins can exhibit both electron-donating and electron-accepting properties. It is significant that porphyrins are chemically stable in the ground and photoexcited states and also in the form of radical-cations and radical-anions. The unique properties of the porphyrins can serve as a basis for the solution of many problems of practical importance.



In this review the term porphyrin is used in a wide sense. Porphyrins ($H_2P$) are assumed to include porphin ($H_2Po$) (III), chlorin ($H_2Ch$) (IV), phthalocyanine ($H_2Phc$) (V), and their derivatives and metal complexes (MP). Tetraphenylporphins ($H_2TPhPo$) ($X_4$) (VI) and tetrabenzoporphins $H_2TBPo$ ($X_4$) (VII) are important among the $H_2Po$ derivatives.



porphin (III)



chlorin (IV)

phthalocyanine (V)

tetraphenylporphin (VI, X = H)
and its derivatives

tetrabenzoporphin (VII, X = H)
and its derivatives

The principle applications of the porphyrin are listed in Table 1.

## II. CATALYSIS OF ELECTROCHEMICAL PROCESSES

Metalloporphyrins are widely investigated and used as catalysts of electrochemical oxidation-reduction reactions. Most studies in this field concern the catalysis of the reduction of molecular oxygen in low-temperature fuel cells. The catalytic activity of metal complexes of porphyrins in the cathodic reduction of oxygen was first observed by Jasinski:[1-3]

$$O_2+4H^++4e^-\rightarrow 2H_2O\ . \qquad (1)$$

A large number of publications on this topic soon appeared.[4-59] There are two reviews on the cathodic reduction of oxygen.[10,11]

Table 1. Practical applications of porphyrins

Oxygen is usually reduced in fuel cells in a highly acidic or highly alkaline medium under the conditions of an appreciable polarisation of the cathode. For this reason, one of the central problems in the development of catalysts for the electrochemical reduction of oxygen is the problem of corrosion resistance.

The investigations have shown[1-59] that, apart from noble metals, whose applicability is limited, metalloporphyrins can serve as active and stable catalysts of reaction (1). The catalytic activity of MP depends on a number of factors, among which the nature of the coordinated metal atom proved to be the most important. Among tens of MP investigated, iron,[10,11,30,35,37] cobalt,[11,25,55] and ruthenium and iridium[45] complexes exhibit the greatest activity. The nature of the porphyrin ligand has a smaller effect on the catalytic activity. However, the increase of the activity of the catalyst with increase of the size of the conjugated $\pi$-bond system of the porphyrin has been demonstrated. Polymeric phthalocyanines $(MPhc)_i$ are less active than the monomeric compounds.[11,15-17,25,33,35,36,43] There exist contradictory views about the electronic effect of the substituents in porphyrins. It was concluded[10,11,25,59] that electron-donating substituents activate the catalyst, while Been et al.[45] claimed that they deactivate it.

In the practical application of reaction (1) in fuel cells, the MP, whose electrical conductivity is low, are deposited on various conducting carriers. Metals and carbonaceous materials (graphite, carbon black, activated charcoal) have been investigated as carriers. Metalloporphyrins deposited on carbonaceous materials show the highest activity.

The catalytic activity of MP in reaction (1) is closely related to their ability to bind oxygen reversibly. The extracoordination of $O_2$ to MP entails partial transfer of electron density from the central metal atom to the antibonding $\pi$ orbital of oxygen. Thus the extracoordination constitutes the initial stage in the reduction of $O_2$. The stability of oxygen extracomplexes of MP is determined by the nature of the second, *trans*-extraligand L:

(2)

Analogous phenomena apparently obtain also in the electrochemical reduction of $O_2$. The functional groups on the surface of the carrier fulfill the role of the extraligand. Chemical modification of the surfaces of carbonaceous carriers therefore constitutes one of the most promising ways of increasing the activity of porphyrin catalysts of the cathodic reduction of molecular oxygen.

One of the most important applications of porphyrins is catalysis of the anodic oxidation of sulphur dioxide. Studies in this field have begun to develop during the last 5–7 years in connection with the research into the problems of atomic-hydrogen power engineering.[60-65]

There exist various projects for the manufacture of hydrogen from water. The thermoelectrochemical sulphuric acid method, in which hydrogen is obtained in two stages, is closest to practical realisation. In the first stage, sulphuric acid is subjected to catalytic thermal dissociation by the heat of a nuclear reactor:

$$2H_2SO_4\rightarrow O_2+2H_2O+2SO_2\ . \qquad (3)$$

In the second stage sulphur dioxide is electrochemically oxidised after its separation from oxygen and water. Hydrogen is evolved at the cathode and is used as the fuel:

$$SO_2+2H_2O-2e^-\rightarrow H_2SO_4+2H^+\ ; \qquad (4)$$

$$2H^++2e^-\rightarrow H_2\ . \qquad (5)$$

The normal electrode potential of reaction (4) is 0.17 V, which makes it possible, in principle, to obtain fairly cheap hydrogen. However, under real conditions, the sulphur dioxide oxidation reaction is accompanied by intense anodic polarisation. For example, the oxidation of $SO_2$ on carbonaceous materials proceeds at an appreciable rate only at potentials in excess of 0.8 V.[64] Reaction (4) takes place under very severe conditions: in concentrated sulphuric acid at an elevated temperature and under the conditions of appreciable anodic polarisation. Thus fuel hydrogen can be obtained in the thermoelectrochemical sulphuric acid cycle subject to the condition that highly active catalysts of the anodic oxidation of sulphur dioxide, which at the same time possess a high chemical stability, are found. Until recently, only one catalyst meeting the above requirements was known: metallic platinum in a pure state or deposited on carbonaceous carriers.[60] Investigations[61-65] have shown that metalloporphyrins deposited on carbonaceous carriers are effective catalysts of the anodic oxidation of $SO_2$. Fig. 1 presents the polarisation curves for the oxidation of sulphur

dioxide. Evidently, the activity of CoTPhPo(p-$OCH_3$)$_4$ is comparable to that of the platinum catalyst. It is significant that the activity and stability of MP-based catalysts increase sharply as a result of heat treatment at 900–1000 K.

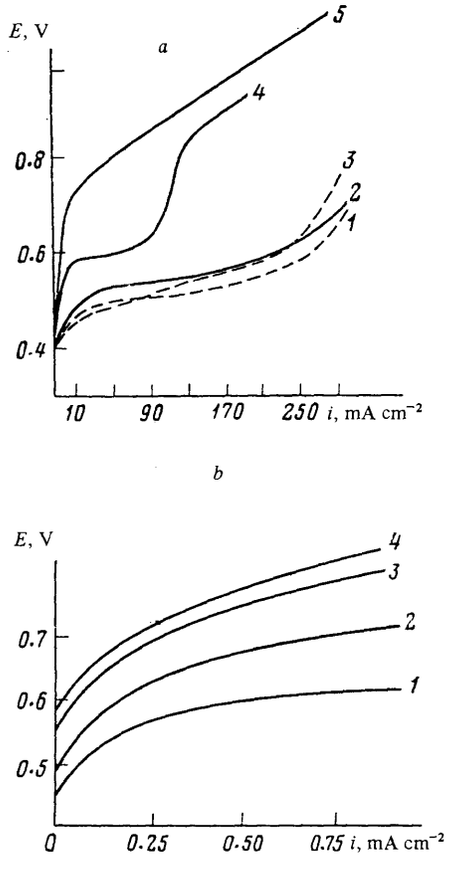

**Figure 1.** Polarisation curves for the oxidation of $SO_2$ in sulphuric acid electrolytes: *a*) on porous PG-50 graphite anodes heat-treated at 1020 K and activated by different substances [*1*) CoTPhPo(*p*-$OCH_3$)$_4$; *2*) Pt; *3*) NiTPhPo.(*p*-$OCH_3$); *4*) FeTPhPo(*p*-$OCH_3$); *5*) without catalyst[64]]; *b*) pyrographite anodes activated by different substances [*1*) CoTPhPo; *2*) CoTPhPo(*p*-$OCH_3$)$_4$; *3*) CoPhc; *4*) without catalyst[65]].

The catalytic activity of MP in the anodic oxidation of sulphur dioxide is determined by the nature of the porphyrin ligand and the metal atom. Metal-free porphyrins are inactive in the oxidation of $SO_2$. The copper complexes and other metalloporphyrins are almost inactive. The catalytic activity of the heat-treated CoTPhPo(*p*-$OCH_3$)$_4$ is higher than that of CoTPhPo.

It is noteworthy that the catalysis of the electrochemical oxidation of $SO_2$ has been investigated for heat-treated specimens. The nature of the chemical transformations of $H_2P$ and MP in the high-temperature treatment is insufficiently clear. It is therefore impossible to formulate at present unambiguous conclusions about the effect of the structure of the porphyrin ligands on the catalytic activity of the MP in the anodic oxidation of sulphur dioxide.

Among other electrocatalytic processes occurring with participation of MP, mention may be made of the cathodic reduction of hydrogen peroxide,[11,66] carbon dioxide,[67,68] nitrous oxide,[69] and organohalogen derivatives.[70,71] The study of the cathodic reduction of hydrogen peroxide is important in connection with the development of oxygen and air electrodes, since hydrogen peroxide is an intermediate in the reduction of oxygen. It has been established that in alkaline electrolytes iron- and cobalt-phthalocyanines exhibits a high activity, which increase in the sequence CoPhc < FePhc < $(CoPhc)_i$.[11] Protohaem is an effective catalyst of the cathodic reduction of $H_2O_2$.[66]

Metalloporphyrins catalyse the electrochemical reduction of carbon dioxide.[67,68] Methanol, formic and oxalic acids, and other valuable compounds have been found among the reduction products. The practical application of this reaction is a matter for the remote future, since the reduction process requires a large energy expenditure.

The catalytic activities of several cyclophan dimers of cobalt-porphyrins in the cathodic reduction of nitrous oxide have been investigated.[69] The reduction proceeds with formation of molecular nitrogen. The dimers investigated are much more active than the monomeric complexes. The authors[69] suggest that the reduction proceeds via a two-electron concerted mechanism.

The catalysis of the electrochemical synthesis of organic compounds may be a promising application of MP.

Methods have been developed[70,71] for the chemical modification of the surfaces of electrodes made of carbonaceous materials by the covalent binding of MP based on $H_2$TPhPo.(*p*-$NH_2$)$_4$. It has been shown that the cathodic reduction potentials of a series of halogeno-derivatives of organic compounds on the modified electrodes are lower by approximately 1 V than on the unmodified electrodes.

## III. CATALYSIS OF OXIDATION-REDUCTION REACTIONS

A very important practical application of porphyrins is the catalysis of the oxidation of hydrogen sulphide and mercaptans (RSH) by atmospheric oxygen. This process is used to purify the waste water from petroleum distilleries and non-ferrous metallurgical undertakings and for the removal of sulphur from petroleum products and natural gas. Mercaptans and similar compounds are oxidised to dialkyl disulphides:

$$4RSH+O_2 \rightarrow 2RSSR+2H_2O \quad . \qquad (6)$$

At the end of the 1950s and the beginning of the 1960s it was observed[72] that the porphyrin complexes of cobalt and vanadium as well as their sulphonate and carboxylate derivatives catalyse the oxidation of mercaptan sulphur by atmospheric oxygen in aqueous alkaline solutions. This process has been used to purify petroleum distillates. Mercaptans are oxidised under the conditions of homogeneous catalysis. In the homogeneous-catalytic oxidation, the hydrocarbon distillate is treated with an aqueous solution of alkali (2–50% NaOH) containing ~0.5% of the catalyst, usually the CoPhc sulphonate. After the extraction of the mercaptans and separation of the aqueous and organic phases, the mercaptides are oxidised by blowing atmospheric oxygen into the aqueous solution. The dialkyl disulphides rising to the surface are separated and the regenerated solution of the alkali and the catalyst is again directed to the extraction of mercaptans. The heterogeneous version of the purification

process differs from that described above by the use of a catalyst adsorbed on an appropriate carrier, usually on activated charcoal.

The catalysis of the oxidation of hydrogen sulphide, mercaptans, and similar compounds has been investigated mainly on metallophthalocyanines. Metalloporphyrins have been investigated in this reaction to a lesser extent, although it is known[72,76] that derivatives of CoTPhPo are catalytically active. The catalytic activity of MPhc depends in many respects on the nature of the central atom. For example, the effectiveness of the catalysis in the oxidation of hydrogen sulphide by atmospheric oxygen increases in the following sequence:[73]

$$\underset{0.30}{\text{ZnPhcTS}} < \underset{0.46}{\text{CuPhcTS}} < \underset{2.9}{\text{V(O)PhcTS}} < \underset{17.3}{\text{NiPhcTs}} < \underset{140}{\text{FePhcTS}} < \underset{5600}{\text{CoPhcTS}}.$$

Here MPhcTS is the tetrasulphonic acid of the metallophthalocyanine. The catalytic activities, measured in moles of absorbed $O_2$ per mole of the catalyst per minute, are indicated under the formulae. A series close to that quoted above has been obtained[77] in the homogeneous oxidation of propanethiol:

$$\text{Cr(Cl)PhcDS} < \text{ZnPhcDS} < \text{Al(Cl)PhcDS} < \text{Sb(Cl)PhcDS} < \text{NiPhcDS} < \\ < \text{FePhcDS} < \text{CuPhcDS} < \text{CoPhcDS}.$$

Here MPhcDS is the disulphonic acid of the metallophthalocyanine. The cobalt complexes show the highest activity in aqueous solutions of alkalis.

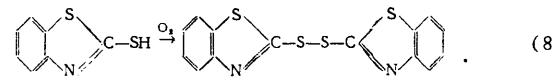
The structure of the ligand also has a significant effect on the rate of oxidation of mercaptans and hydrogen sulphide. The following catalytic activity series has been obtained for CoPhc derivatives:[74]

$$\underset{1.67\ (2.74)}{\text{CoPhc}(SO_3Na)_4Cl_4} > \underset{1\ (1)}{\text{CoPhc}(SO_3Na)_4} > \underset{0.2\ (0.5)}{\text{CoPhc}(SO_3Na)} > \underset{0.07\ (0.23)}{\text{CoPhc}(SO_3Na)_8} > \\ > \underset{0.02\ (0.062)}{\text{CoPhc}(SO_3Na)_4(COOH)_4}.$$

The relative rate constants for the oxidation of cysteine and hydrogen sulphide are indicated under the formulae, the values in brackets referring to the latter; the rate constants for the reactions on $CoPhc(SO_3Na)_4$ were assumed to be unity. It has been established in recent years[77-80] that the catalytic activity of the cobalt-phthalocyanine-sulphonic acids increases greatly when strongly electron-donating (OH, $NH_2$) and electron-accepting ($NO_2$) substituents are introduced into the catalyst molecule. For example, the following series has been quoted.[77]

$$\text{CoPhc}(SO_3Na)_2 < \text{CoPhc}(SO_3Na)_2(NO_2)_4 < (\text{CoPhc})_i < [\text{CoPhc}(SO_3Na)_2]_i < \\ < \text{CoPhc}(SO_3Na)_2(OH)_4 < \text{CoPhc}(SO_3Na)_2(NH_2)_4.$$

Further progress in this field is expected in three directions. Firstly, studies on the structural modification of porphyrin ligands in order to increase the catalytic activity of their metal complexes are promising. Secondly, the development of methods for the activation of heterogeneous catalysts for the oxidation of mercaptans constitutes an urgent problem. In this connection interesting patents have been taken out.[81-85] These describe procedures in which the activation of the MPhc adsorbed on activated charcoal is attained by modifying the carrier with the aid of tetraalkylammonium salts $(R_4N)^+X^-$ containing bulky organic groups R. Methods have also been developed for the immobilisation of complexes of $H_2$TPhPo and its derivatives[76] and MPhc[90] on the surfaces of polymeric carriers. The catalytic activity of the modified polymers[76,90] in the oxidation of alkanethiols has been demonstrated. Thirdly, the replacement of aqueous solutions by non-aqueous solutions may prove to be promising in the field of the elimination of sulphur. Thus, when dimethylformamide (DMF) was used as the solvent, it was possible to achieve the selective oxidation of hydrogen sulphide to elemental sulphur.[88] In aqueous solutions the most active catalysts of the oxidation of mercaptans and hydrogen sulphide are the cobalt complexes, whereas in organic solvents the porphyrin complexes of iron are more effective. The following catalytic activity series has been established for phthalocyaninetetrasulphonic acid derivatives:[88] Fe > Co > Zn > Cu > Al > Cr.



In toluene solution Fe(Cl)TPhPo catalyses the oxidation of alkanethiols by atmospheric oxygen, the addition of pyridine having an appreciable activating effect on the catalyst.[89]

The sulphonic acids of CoPhc and their derivatives with substituents in the benzene ring can be used in the synthesis of certain sulphur-containing accelerators of the vulcanisation of raw rubber. The catalytic activity of CoPhc derivatives in the oxidation of *NN*-dimethyldithiocarbamate has been demonstrated:[78,80]

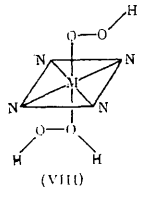
(7)

The catalytic oxidation of 2-mercaptobenzothiazole has been investigated:[79]

(8)

It has been shown[78,79] that the tetrahydroxy-, tetra-amino-, and tetranitro-derivatives exhibit a high catalytic activity among phthalocyaninedisulphonic acids.

In conclusion one should note that the oxidation of hydrogen sulphide and mercaptans by atmospheric oxygen can take place in the gas phase at temperatures in the range 470–620 K.[86,87] The metal complexes of phthalocyanine catalyse this process. In the oxidation of hydrogen sulphide the catalytic activity of polymeric phthalocyanines varies in the following sequence as a function of the nature of the metal: Fe > Co > Cu > Mn.[86] The activity series of the monomeric complexes has been obtained in the oxidation reaction of isopropanethiol: Fe > Cu > Mn > Co > Zn > Ni.[87]



Numerous studies[91-103] have been devoted to the catalytic activity of MP in the disproportionation of hydrogen peroxide:

$$2H_2O_2 \rightarrow 2H_2O + O_2 . \qquad (9)$$

These investigations are important for the protection of plants and animals against the $H_2O_2$ formed as a result of their vital activity. In living organisms hydrogen peroxide is decomposed with the aid of haem-containing enzymes—catalases. The structure, properties, and the mechanism of the activity of catalases have been discussed in detail in a monograph.[104] The catalase activity of MP has also been investigated in connection with the development of oxygen cells in which $H_2O_2$ is formed as an intermediate in the cathodic reduction of molecular oxygen.[11]

MP exhibits a catalase activity under both homogeneous and heterogeneous conditions. The catalytic activity is determined mainly by the nature of the metal atom. It has been established[92] that, under the conditions of heterogeneous catalysis, the highest activity is shown by the osmium, ruthenium, and iron complexes of $H_2$Phc. The catalytic activity of MPhc with other metals is lower by at least two orders of magnitude. The catalysis of reaction (9) by metal complexes of phthalocyanine deposited on carbonaceous carriers has been investigated[100] and it has been shown that the catalytic activity depends significantly on

the nature of the carbonaceous carrier. Depending on the nature of the central metal atom in the monomeric phthalocyanines adsorbed on the carbonaceous carriers, the activity falls in the sequence: Os ≫ Fe > Ru > Pt > Rh > Pd, Ir whereas for polymeric phthalocyanines under the same conditions we have: Fe > Os > Pt, Ru > Ir, Rh, Pd; Fe > Co ≫ Ni > Cu.[100] It is important to note that, when individual heterogeneous phthalocyanine catalysts are used, the polymeric complexes have no advantages over the monomeric complexes.[94,105] On the other hand, the metallophthalocyanine polymers adsorbed on carriers are significantly more active than the monomers.[100] The fact that the activities of both homogeneous and heterogeneous catalysts change on formation of extracomplexes of metallophthalocyanines is important for the development of ideas about the mechanism of the catalytic decomposition of hydrogen peroxide. Small amounts of added extraligands such as pyridine, imidazole, and triphenylphosphine activate the catalyst[11] evidently as a result of the formation of pentacoordinated complexes. An appreciable excess of the extraligand suppresses the catalytic activity,[92] apparently as a consequence of the formation of hexacoordinated extracomplexes. The facts listed above are inconsistent with the mechanism of the catalytic decomposition of hydrogen peroxide based on the hypothesis that hexacoordinated extracomplexes of metalloporphyrin (VIII) with two hydrogen peroxide molecules are formed.[101,103]

(VIII)

Metalloporphyrins catalyse the decomposition of organic hydroperoxides ROOH.[106–113] This reaction constitutes an important link in the catalytic oxidation of hydrocarbons on MP and is therefore considered to some extent in all studies devoted to this question. In contrast to the hydrogen peroxide disproportionation reaction, which apparently takes place without the formation of free radicals, organic hydroperoxides are decomposed via a radical mechanism. The porphyrin and phthalocyanine complexes of metals such as cobalt, iron, nickel, and manganese are effective catalysts of the decomposition of the peroxides. In discussing the reaction mechanism, the authors[108–111] assume that the central metal atom is the active centre of the catalyst. On the other hand, in other studies[106,112] it has been suggested that the hydroperoxide decomposition reaction can take place on the periphery of the MPhc molecule, for example, via the formation of a hydrogen bond between the molecule and one of the peripheral nitrogen atoms. The second reaction pathway appears less likely, since it is known that the complexes of porphyrins themselves, which have no peripheral nitrogen atoms, exhibit a high catalytic activity in the reaction considered. It has been established[113] that organic peroxides form fairly stable extracomplexes with CoTPhPo. The authors[113] noted a significant role of the extracoordination in the decomposition of ROOH.

Extensive studies have been made on the utilisation of MP as the catalysts of the oxidation of hydrocarbons by atmospheric oxygen. The catalytic activities of MP and MPhc in the oxidation reactions of cumene, ethylbenzene, propene, cyclohexane, tetralin, indoles, and other compounds have been studied. A review has been published on this subject.[114] Hydrocarbons are oxidised via a radical chain mechanism and the reaction involves the intermediate formation of hydroperoxides which serve as autocatalysts of the oxidation process. Systematic investigations of the autocatalytic oxidation of cumene and certain other hydrocarbons have been described.[115–120] It has been established that below 370 K the main cumene oxidation product on the phthalocyanine complexes of copper, nickel, magnesium, and tin is the hydroperoxide, whose yield exceeds 90% under these conditions. Hydrocarbon hydroperoxides decompose catalytically on iron and cobalt complexes at the usual temperatures and on virtually all the MPhc investigated at high temperatures (420 K and above) with formation of the final oxidation products.

The catalytic activity of MPhc has been explained[115–120] by the activation of molecular oxygen as a result of extracoordination. The extracoordination of oxygen is accompanied by the transfer of electron and spin density from the central metal atom of the catalyst to oxygen:

$$\mathrm{MPhc} + \mathrm{O_2} \rightarrow \mathrm{MPhc}^{\delta+} \ldots \mathrm{O}^{\delta-} \quad . \tag{10}$$

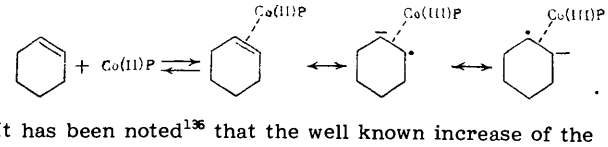
The coordinated oxygen has radical properties and is therefore capable of abstracting a hydrogen atom from the hydrocarbon molecule:

$$\mathrm{RH} + \mathrm{MPhc}^{\delta+} \ldots \mathrm{O_2^{\delta-}} \rightarrow \mathrm{R^{\cdot}} + \mathrm{HO_2^{\cdot}} + \mathrm{MPhc}; \tag{11}$$

$$\mathrm{R^{\cdot}} + \mathrm{O_2} \rightarrow \mathrm{ROO^{\cdot}} \quad ; \tag{12}$$

$$\mathrm{ROO^{\cdot}} + \mathrm{RH} \rightarrow \mathrm{ROOH} + \mathrm{R^{\cdot}} \; ; \tag{13}$$

$$\mathrm{ROO^{\cdot}} \rightarrow \text{other oxidation products.} \tag{14}$$



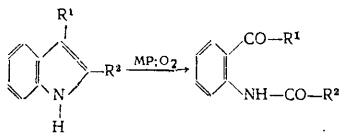
At high temperatures the oxidation of hydrocarbons proceeds autocatalytically. The catalytic decomposition products of the hydroperoxides serve as the source of free radicals:

$$\mathrm{MPhc} + \mathrm{ROOH} \rightarrow \mathrm{MPhc^{+}} + \mathrm{RO^{\cdot}} + \mathrm{OH^{-}}; \tag{15}$$

$$\mathrm{MPhc^{+}} + \mathrm{ROOH} \rightarrow \mathrm{MPhc} + \mathrm{ROO^{\cdot}} + \mathrm{H^{+}}; \tag{16}$$

$$\mathrm{RO^{\cdot}} + \mathrm{RH} \rightarrow \mathrm{ROH} + \mathrm{R^{\cdot}} \; . \tag{17}$$

Next the oxidation reaction proceeds in accordance with Eqns.(12)–(14). It is noteworthy that a careful study of the kinetics of the oxidation of cumene containing minimal amounts of hydroperoxides has led to the conclusion[134] that the Cu, Zn, Ni, V, and Mg complexes of tetra-t-butylphthalocyanine at 330–350 K catalyse the oxidation of cumene via the decomposition of cumenyl hydroperoxide and not via the activation of oxygen. The activation of oxygen has also been ruled out in studies[122,124,125] of the catalytic oxidation of cyclohexene and squalene on iron(II), cobalt(II), and cobalt(III) complexes of protoporphyrin and octaethylporphin. It has been suggested[122,123,125] that the catalytic activity of the MP is due to the activation of the double bond via the transfer of spin density from the central metal atom to the double bond of the extracoordinated alkene, for example:

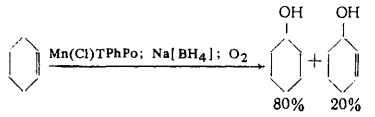


(18)

It has been noted[136] that the well known increase of the selectivity of the oxidation of alkenes in the presence of MPhc with a simultaneous increase of the induction period

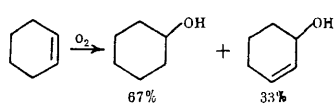
of the reaction indicates unambiguously that the mechanism of the catalytic activity consists in the catalysis of the interaction of hydroperoxides or hydroperoxy-radicals with the olefin.

As a consequence of the radical mechanism, the autoxidation reactions of hydrocarbons have a low selectivity. For example, the liquid-phase oxidation of propene on the phthalocyanine complexes of Mo, V, Sn, and Ru (individual and adsorbed on various carriers) involves the formation, together with the target product (epoxypropane), also of acetaldehyde, isopropyl alcohol, acetone, methyl formate, and other products.[136] The yield of epoxypropane does not exceed 45%. In the oxidation of cyclohexene, the main products are the corresponding epoxy-derivative, cyclohexenol, and cyclohexenone. In some cases the oxidation proceeds with a fairly high selectivity. Thus the oxidation of substituted indoles on the cobalt(II), cobalt(III), and manganese(III) complexes of $H_2TPhPo$ and deuterioporphyrin ($H_2DPo$) affords a satisfactory yield of the corresponding ketoamides:[126,127]



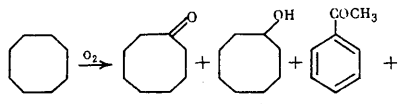
(19)

The catalytic activity series has been established in the oxidation reaction of skatole: CoDPo > CoTPhPo ≫ CuTPhPo ≫ NiTPhPo ≅ 0.[126]

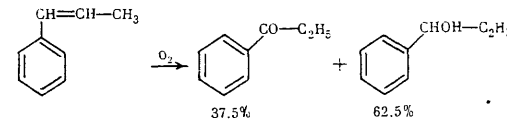


The practical employment of MP for the oxidation of hydrocarbons is complicated by the rapid poisoning of the catalyst as a result of the irreversible oxidation of the MP by alkylperoxy-radicals. Studies where a significant stabilisation of porphyrin catalysts after approximately equimolar amounts (relative to the MP) of copper acetylacetonate had been added are of interest in this respect.[122,124]

An interesting reaction involving the selective oxidation of alkenes to alcohols on treatment with molecular oxygen, tetrahydroborate, and the Mn(Cl)TPhPo catalyst has been discovered recently.[128,130,131,133] The oxidation of cyclohexene has been studied:[133]



(20)



The mechanism of this reaction differs from the usual radical autoxidation, since the reaction has no induction period and is not inhibited by 2,6-di-t-butylphenol. It is noteworthy that the oxidation process proceeds under very mild conditions: at room temperature and normal pressure, and is much faster than radical autoxidation. It has been concluded[133] that the main reaction pathway involves the formation of epoxycyclohexane, which is then reduced by the excess tetrahydroborate to cyclohexanol. The study of the oxidation of alkenes in the Mn(Cl)TPhPo–$[Bu_4N]^+[BH_4]^-$–$O_2$ ternary system[130] yielded the following results:

(21)

(22)

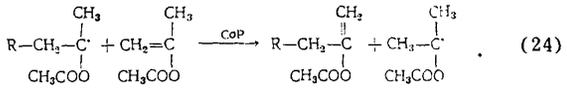
(23)

It was concluded that under these conditions the alkenes are oxidised selectively with formation of ketones and the latter are reduced by the excess tetrahydroborate to alcohols. In their study of the oxidation of alkenes of different structure by atmospheric oxygen in the presence of Mn(Cl)TPhPo and $NaBH_4$, Enikolopov and co-workers[128,131] established that the rate of reaction increases as the alkyl substituents at the double bond accumulate. The oxidation proceeds selectively with respect to the most substituted hydrogen atom. The data obtained for the oxidation of steroids demonstrate unambiguously that neither ketones nor epoxides can be intermediates in the oxidation reaction. The authors[128,131] suggest that the oxidation intermediate is a complex of the olefin, the activated oxygen, and Mn(II).TPhPo. Depending on the nature of the olefin, the complex can disproportionate to a ketone or can be reduced by the tetrahydroborate to the alcohol.

The metal complexes catalyse the autoxidation of alcohols with phenols,[98,99,135,139–151] aldehydes, and carboxylic acids.[99,129,137,148,149,153–157] The reaction has a radical chain mechanism. The aldehyde oxidation products are peracids or carboxylic acids. Phenols are oxidised to the corresponding quinones and other products. Carboxylic acids undergo oxidative decarboxylation. Studies in this field have been surveyed in monographs.[11,112]

The method of synthesis of aromatic aldehydes RCHO from a wide variety of compounds of the type $RCH_2X$ (X = OH, OR, $NH_2$, etc.), described by Tabushi and Koga,[145] is of great interest to organic chemists concerned with synthesis. Manganese(IV) complexes of haematoporphyrin ($H_2HaePo$) or $H_2TPhPo$, obtained directly in the reaction system by the oxidation of manganese(III) complexes with sodium hypochlorite, are used as the oxidants. The reaction can be carried out also in a catalytic version. With the aid of Mn(IV)P, the oxidative cleavage of the ether linkage, for example in benzyl methyl ether, goes to completion at room temperature in 1 min, after which the oxidation proceeds selectively to give benzaldehyde.

A method of synthesis of MPhc, dispersed unimolecularly in zeolite matrices, has been developed.[151] With the aid of catalysts of this type based on CuPhc, CoPhc, and NiPhc, it is possible to carry out a very interesting reaction involving the oxidation of carbon monoxide by atmospheric oxygen. It is significant that the oxidation proceeds very rapidly even at 195 K.[158] The importance of this process for the protection of the environment is evident. However, the proposed catalysts[158] are very rapidly poisoned, apparently by carbon dioxide or carbonate ions.



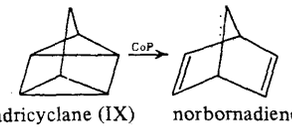
The catalysis of the electrochemical oxidation of carbon monoxide on metal complexes of octaethylporphin ($H_2OEPo$), $H_2TPhPo$, $H_2TBPo$, and $H_2Phc$ has been studied[159] and it has been established that IrTPhPo and RhTPhPo are active in acid and alkaline media. The iron and cobalt complexes exhibit an appreciable activity in alkaline solutions. It has been noted[159] that the catalytic activities of the iron complexes increase in the sequence FeTBPo < FeOEPo < FeTPhPo.

MP exhibit a catalytic activity not only in oxidation reactions but also in the reduction and photochemical reduction of organic compounds. The catalytic activity of CoTPhPo.$(p\text{-}SO_3H)_4$ in the hydrogenation of acetylene[160] and of the MPhc radical anions in the hydrogenation of alkenes[161–163] has been demonstrated. The high-temperature (373–573 K) hydrogenation–dehydrogenation reactions of alcohols and aldehydes in the presence of MPhc have been investigated.[141]

A number of studies of the catalytic oxidation–reduction reactions of nitrogen-containing compounds have been described in the literature. The report[160] of the catalytic activity of $CoTPhPo(SO_3H)_4$ in the reduction of molecular nitrogen by sodium tetrahydroborate is the most interesting in this field. The catalytic activity of MP in the oxidation of hydrazine and hydroxylamine by atmospheric oxygen,[164,165] in the reduction of nitric oxide by hydrogen,[142,166] and in the photochemical reduction of nitro-compounds[167] has been demonstrated. The catalytic activity of MPhc in the electrochemical oxidation of hydrazine has also been established.[168,169] Depending on the nature of the metal, the catalytic activity increases in the sequence NiPhc ≅ CuPhc < CoPhc < FePhc.

## IV. CATALYSTS OF ISOMERISATION AND POLYMERISATION REACTIONS

Studies have shown[170–180] that cobalt-porphyrins are unique regulators of the degree of polymerisation of acrylates and it has been established that CoP catalyses the reaction involving chain transfer to the monomer:

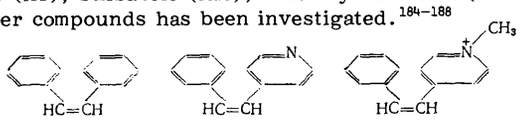


(24)

The degree of polymerisation is regulated by the simple alteration of the concentration of the CoP introduced into the initial monomer. The efficiency of the catalyst in the reaction involving chain transfer to the monomer can be inferred from the following example:[176] the polymerisation of methyl methacrylate in bulk at 233 K and at an initiator (azobisisobutyronitrile) concentration of $2 \times 10^{-2}$ M without added regulator yielded a polymer with an average degree of polymerisation of $4 \times 10^3$. Under the same conditions but with addition of $6 \times 10^{-4}$ M CoHaeP to the initial mixture, the average degree of polymerisation fell to 8.1.

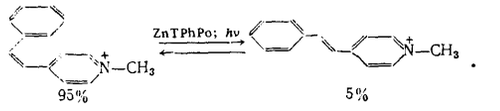
The catalytic activity in the chain transfer to the monomer is shown only by the cobalt complexes of the porphyrins proper. The Ni, Cu, Zn, Cr, Mn, Pd, and TiO complexes as well as MPhc inhibit the polymerisation of methyl methacrylate.[177] The nature of the side groups in the porphyrins is relatively insignificant. The phenomenon described is observed in the polymerisation of acrylates and styrene. Catalytic chain transfer to the monomer with the aid of MP has not been observed for other monomers. It has been established[180] that the mechanism of the chain transfer to the monomer involves the transfer of a hydrogen atom from the methyl group of the growing chain to the cobalt atom of the catalyst with its subsequent transfer to the monomer. Catalysts grafted to a heterogeneous carrier have been synthesised and investigated in order to achieve the practical realisation of the method described above for the regulation of the degree of polymerisation of acrylates.[178]

Certain MP are able to catalyse the dark and photochemical isomerisation of unsaturated compounds. For example, the catalytic activity of CoP in the isomerisation of quadricyclane to norbornadiene has been established:[181–183]



quadricyclane (IX) norbornadiene (X) (25)

In conformity with the Woodward–Hoffman rules, this reaction is symmetry-prohibited and therefore proceeds at a very low rate. The complexes of $H_2TPhPo$ with Co(II) and Co(III) increase sharply the rate of isomerisation probably via the extracoordination of quadricyclane. The catalytic activity of Co(III)TPhPo is greater by two orders of magnitude than that of Co(II)TPhPo. The reaction rate depends strongly on the nature of the organic solvent.



## V. CATALYSIS OF PHOTOCHEMICAL AND PHOTOELECTROCHEMICAL REACTIONS

The metalloporphyrin-sensitised photoisomerisation of stilbene (XI), stilbazole (XII), *N*-methylstilbazole (XIII), and other compounds has been investigated.[184–188]

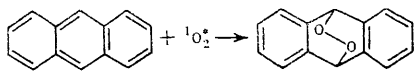
*cis*-stilbene (X) *cis*-stilbazole (XII) *cis*-*N*-methyl-4(β-styryl)-pyridinium (XIII)

It has been shown that under photostationary conditions the N-methyl-4-(β-styryl)pyridinium salt forms an equilibrium mixture of *cis*- and *trans*-isomers enriched in the *cis*-isomer:

(26)

It must be emphasised that, in the absence of metalloporphyrins [ZnTPhPo or Sn(Cl)TPhPo], the *cis*- and *trans*-isomers of *N*-methyl-4-(β-styryl)-pyridinium are completely stable in the dark. The authors[188] concluded that the isomerisation proceeds via electron transfer from the photoexcited MTPhPo molecule to the substrate.

The photoisomerisation of stilbene, stilbazole, and related compounds is observed in the presence of zinc and magnesium[185,187] as well as platinum and palladium[184] complexes of the porphyrins. Under photostationary conditions, the *trans*-isomers of the compounds accumulate. Thus, in the isomerisation of stilbene the content of the *trans*-isomer can reach 85%; stilbazole is converted under photostationary conditions into the *trans*-isomer in 95–99% yield. It was of interest that, in the presence of the zinc complex of aetioporphyrin (ZnAePo), stilbene undergoes *cis–trans* isomerisation with a quantum yield of 0.01, while the analogous reactions of stilbazole and its derivatives have a quantum yield up to 6.6. This means that the absorption of one quantum of light by the ZnAePo molecule leads to the conversion on average of 6.6 *cis*-stilbazole molecules into *trans*-stilbazole. In the discussion of the reaction mechanism, the authors[185] suggested the formation of an extracomplex of stilbazole with MP in an excited triplet state.



The unique photophysical and photochemical properties of porphyrins have been used in the development of new light-sensitive materials for three-dimensional phase holography. The proposed[189,190] light-sensitive materials consist of a polymer matrix in which substituted anthracene and a porphyrin sensitiser, for example, mesoporphyrin ($H_2MPo$) are dispersed. Before recording the hologram, the polymer matrix is saturated with oxygen at a pressure of 80–140 atm. Next, the holographic image is recorded in the usual way. On irradiation with light, porphyrin passes to an excited state, initially singlet and then triplet. The porphyrin in the excited triplet state undergoes a bimolecular reaction with molecular oxygen and leads to the transition of the latter from the ground triplet state to the excited singlet state:

$$H_2P + h\nu \rightarrow {}^1H_2P^* \; ; \qquad (27)$$

$$^1H_2P^* \rightarrow {}^3H_2P^* \; ; \qquad (28)$$

$$^3H_2P^* + {}^3O_2 \rightarrow H_2P + {}^1O_2^* . \quad (29)$$

Singlet oxygen is a powerful oxidant which oxidises anthracene, the reaction being controlled by the rate of diffusion:

(30)

The endoperoxide formed has a refractive index which differs from the initial anthracene. Thus, when a hologram is recorded, regions with different refractive indices are generated in the polymer matrix. The image is then fixed. For this purpose, the hologram is kept in the dark at normal pressure in order to remove the oxygen dissolved in the matrix. In order to reproduce the holographic image, visible light is passed through the hologram. The interference pattern, giving rise to the effect of a three-dimensional image, arises as a result of the different phase shifts in the electromagnetic vibrations of the visible light which has passed through regions with different refractive indices.

One of the possible practical applications of porphyrins in the future may be catalysis of the photochemical decomposition of water in order to utilise solar energy. Comparatively recently, Shilov[191] showed that irradiation of a system comprising ethylenediaminetetra-acetic acid, methylviologen ($MV^{2+}$) (XIV) (an acridine dye), and a colloidal solution of platinum results in the evolution of hydrogen:

methylviologen (XIV) .

The acridine dyes used in the first studies in order to sensitise the photochemical reduction of water utilise only a limited proportion of the sun's rays. Porphyrins, whose absorption spectra cover an appreciable proportion of the spectrum of the sunlight reaching the surface of the Earth, are of great interest in this respect. For example, $H_2$TPhPo can absorb 46% of the energy of the sun's rays, while ZnTPhPo and PdTPhPo can absorb 40 and 25% respectively.[192] One must bear in mind that many $H_2P$ and MP exhibit a very high photochemical stability.

Studies have shown that the metal complexes of phthalocyanine and its derivatives are relatively ineffective sensitisers of the photochemical decomposition of water.[193–195] This can be accounted for by the low energy level of the triplet excited states of MPhc. The porphyrin complexes, particularly those which have positively charged functional groups, for example, the complexes of tetra(*N*-methylpyridyl)-porphin ($MTMePyPo^{4+}$) are more promising. The quantum yield in the evolution of hydrogen on reduction of water in the $ZnTMePyPo^{4+}$/EDTA/$MV^{2+}$/Pt system reaches 0.3.[196–200]

The sequence of reactions in the photochemical reduction of water can be represented as follows:

$$MP \xrightarrow{h\nu} MP^* ; \quad (31)$$

$$MP^* + MV^{2+} \rightarrow MP^+ + MV^+ ; \quad (32)$$

$$MV^+ + H_2O \xrightarrow{Pt} MV^{2+} + {}^1/_2H_2 + OH^- ; \quad (33)$$

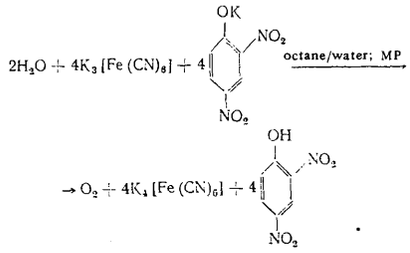
$$MP^+ + EDTA \rightarrow MP + EDTA^+ . \quad (34)$$

The first stage involves the photoexcitation of the metalloporphyrin, which then reduces methylviologen. When colloidal platinum is used as the cocatalyst, the accumulation in solution of the reduced form of methylviologen is a sufficient condition for the evolution of hydrogen from water. Without methylviologen, the quantum yield in the photochemical reduction of water on a MP is $10^{-4}$–$10^{-3}$.[198,200,201]

Methylviologen is an effective quenching agent for the singlet and triplet states of porphyrins. However, one must bear in mind that $MV^+$ can recombine with the oxidised form of the sensitiser:

$$MV^+ + MP^+ \rightarrow MV^{2+} + MP . \quad (35)$$

Thus the yield of hydrogen in the reduction of water depends on the ratio of the rates of the competing reactions (33) and (35).



The rate of recombination can be diminished, firstly, by employing a sensitiser in the triplet excited state as the reductant in reaction (32). The recombination reaction is then spin-prohibited, since the reverse electron transfer from $MV^+$ to $MP^+$ requires a change in the spin state of the system:

$$^3(MP^+ \ldots MV^+) \rightarrow {}^1MP + {}^1MV^{2+} .$$

Secondly, in order to suppress the recombination process, it is useful to employ positively charged sensitisers, for example, complexes of tetra-(*N*-methylpyridyl)porphin. In this case the electrostatic repulsion of the reactants $MTMePyPo^{5+}$ and $MV^+$ prevents their recombination. The rate of reduction of methylviologen [reaction (32)] diminishes at the same time. However, experiment has shown that the introduction of positively charged functional groups into the molecule of the porphyrin sensitiser sharply increases the yield of hydrogen.[196–200] When negatively charged sensitisers are used, for example, the complexes $H_2TPhPo(SO_3^-)_4$, the quantum yield in the photogeneration of hydrogen does not exceed several tenths per cent.[199] Thirdly, in order to eliminate reaction (35) and the regeneration of the initial form of the sensitiser, the so-called sacrificial donors (EDTA, cysteine, amines) are used. The role of these compounds is to reduce the oxidised sensitiser [reaction (34)]. The oxidised donor, for example $EDTA^+$, does not react with $MV^+$ and is irreversibly consumed in the reduction of water. Hydroquinone, which can be, in principle, regenerated in the photochemical oxidation of water to molecular oxygen, has been proposed as a reductant of this kind.[202]

Mainly zinc complexes have been used in the study of the porphyrin sensitisers of the photochemical reduction of water. However, it is known that magnesium,[202,203] tin,[204] ruthenium,[205] and metal-free haematoporphyrin[337] exhibit a high activity in this process. It has been shown[202,203,206–209] that, together with water-soluble sensitisers, complexes of neutral porphyrins dispersed in micelles can be used in the reduction of water. A review of studies on the photodissociation of water sensitised by porphyrins has been published.[192]

The systems described can be used, in principle, to obtain hydrogen subject to the obligatory condition that the process can be combined with the photochemical oxidation of water, i.e. the reaction involving the irreversible consumption of the sacrificial donor is eliminated. Studies[213,214] where it has been shown that metalloporphyrins, for example, chlorophyll, can sensitise the photochemical oxidation of water to oxygen in two-phase systems of the type of water–octane, are interesting in this respect. For the reaction to be carried out, it is essential that oxidants [potassium hexacyanoferrate(III), etc.] and weak proton acceptors, for example, potassium 2,4-dinitrophenoxide, are present:

(36)

The oxidation of water in these systems involves the photoexcitation of the MP with its subsequent oxidation by a weak oxidant:

$$MP^{*}+[Fe(CN)_6]^{3-}\rightarrow MP^{+}+[Fe(CN)_6]^{4-}. \quad (37)$$

The products of reaction (37) do not recombine, because the reactants are in different phases: MP is in octane while the reduced form of the oxidant is in water. Next, water is oxidised by the metalloporphyrin radical-cation. Together with chlorophyll, the iron complex of coproporphyrin exhibits a fairly high photocatalytic activity in this reaction. This is extremely remarkable, because FeP do not have long-lived triplet states.

The photocatalytic systems described above suffer from two significant disadvantages. Firstly, they are complex and, secondly, the water photochemical oxidation and reduction reactions cannot as yet be combined in a single process. The comparatively simple photoelectrochemical method for the decomposition of water into hydrogen and oxygen is attractive in this respect.[216,221]

It has been established[215,218–221] that, when the electrochemical cell $Pt|(MgChl\alpha.2H_2O)_n|H_2O|Pt$ is irradiated with red light, a photocurrent flows through it and water is cleaved into hydrogen and oxygen. The electrophotodissociation of water can be described as follows:

$$Pt|(MgChl\alpha.2H_2O)_n(\text{photocathode}):\ 2H_2O + 2e^- \rightarrow H_2 + 2OH^-; \quad (38)$$

$$Pt(\text{photoanode}):\ 2H_2O \rightarrow 4H^+ + O_2\ 4e^-. \quad (39)$$

The photoelectrochemical reduction of water apparently takes place on chlorophyll *a* dihydrate dimers $[MgChl\alpha.2H_2O]_2$. The quantum yield of hydrogen on irradiation of the above cell with light at a wavelength of 735 nm is 0.88%.[221] A photoelectrolytic apparatus based on a platinised polycrystalline chlorophyll *a* dihydrate deposited on a platinised metallic support has been described in a patent.[219] This apparatus makes it possible to photodissociate water with a quantum yield up to 0.2. It has been shown[217] that polycrystalline chlorophyll *a* dihydrate can be used as the photoanode in the electrochemical cell. However, the activity of such anodes is greatly inferior to that of the platinum anode.

The photoelectrochemical oxidation-reduction reactions catalysed by $H_2P$ and MP have been widely investigated in order to devise converters of solar energy into electrical energy.[222–236] The pigmented electrode serves as the photocathode in almost all photoelectrochemical cells of the type electrode |MP (or $H_2P$)|electrolyte|electrode. The charge carriers are generated in most cases at the MP|electrolyte interface and in some cases at the electrode|MP interface. The mechanism of the generation of the photocurrent as a rule involves the formation of an excited triplet state of the sensitiser, the migration of the triplet exciton state to the MP|electrolyte interface, the generation of charges on this interface as a result of electron transfer from the photoexcited sensitiser to $H^+$, $O_2$, or to an oxidant specially introduced into the electrolyte, and finally the migration of the charges to the current measuring devices. In agreement with this mechanism, the photocurrent flowing through photoelectrochemical cells increases sharply when oxidants such as methylviologen,[224,233] potassium hexacyanoferrate-(III),[222] etc. are introduced into the electrolyte. An appreciable increase of the photocurrent quantum yield is observed when the thickness of the pigment layer is decreased to approximately 3 nm.[222,223,233] Ilatovskii[223] states that, for a greater thickness of the porphyrin sensitiser layer, the exciton states formed in the bulk of the film cannot reach the MP|electrolyte interface. Furthermore, with increase of the thickness of the pigmented film, its ohmic resistance and the probability of the recombination of the charge carriers also increase.

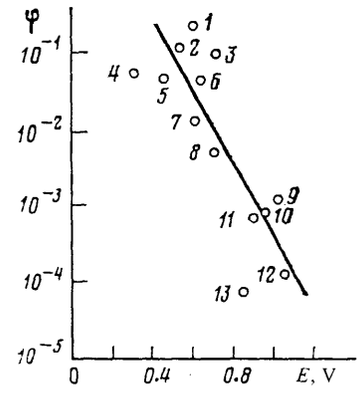


**Figure 2.** Dependence of the photocurrent quantum yields $\phi$ of the cells $Al|MP|[Fe(CN)_6]^{3-}, [Fe(CN)_6]^{4-}|Pt$ on the first oxidation potentials of the porphyrins:[236] *1*) MgPo; *2*) MgTPhPo; *3*) ZnPo; *4*) ZnTPhIBCh; *5*) CdTPhPo; *6*) CdTPhPo; *7*) ZnTPhCh; *8*) ZnTPhPo; *9*) CdTPhPo; *10*) $H_2$TPhPo; *11*) CuTPhPo; *12*) CoTPhPo; *13*) PtTPhPo ($H_2$TPhIBCh = tetraphenylisobacteriochlorin; $H_2$TPhCh = tetraphenylchlorin).

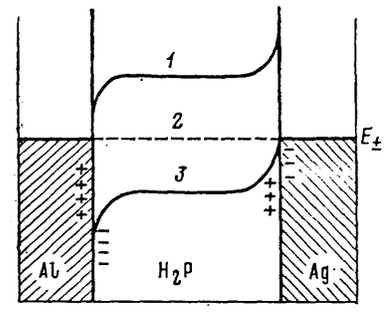

**Figure 3.** Schematic illustration of the energy levels in the cell $Al|H_2P|Ag$:[266] *1*) conductivity level; *2*) Fermi level; *3*) valence level.

The photocurrent quantum yield depends significantly on the nature of the porphyrin sensitiser and in the first place on its reducing properties. The photoelectrochemical

properties of 30 porphyrins and metalloporphyrins have been investigated[236] with the aid of the cell Al|porphyrin|[(Fe.$(CN)_6]^{3-}$, $[Fe(CN)_6]^{4-}$|Pt and it has been established (Fig.2) that the photocurrent quantum yield increases with decrease of the oxidation potential of the porphyrin sensitiser. The most active sensitisers MgPo, ZnTPhPo, and ZnPo ensure a photocurrent quantum yield up to 0.2. Certain MPhc exhibit a high electrochemical activity. Thin-film converters of solar energy, ensuring a photocurrent quantum yield up to 0.15 and an energy efficiency up to 2% have been developed on their basis.[222,223] The photoelectrochemical activity of complexes of tetra(*N*-methylpyridyl)porphin,[225] tetra(*N*-stearylpyridyl)porphin,[226,227] chlorophyll,[216–221,232] and other porphyrins[236] has also been demonstrated.

## VI. SEMICONDUCTORS AND PHOTOCONDUCTORS

Porphyrins possess semiconducting properties and their electrical and photoelectrical properties have been investigated vigorously.[222–224,236,240–292] They are known to possess intrinsic hole conductivity.[212,225,256,279,283] Sandwich cells with two different electrodes, for example Al|$H_2$P(MP)|Ag, have voltage-current characteristics typical for barrier diodes. The blocking layer in the cells is formed as a consequence of the flow of electrons from an aluminium or another electrode with a low electron work function to the porphyrin. This results in the formation of a zone depleted in charge carriers. Its size is 1.5–3 nm depending on the nature of the $H_2$P. At the $H_2$P|Ag interface, electrons pass from the porphyrin cell to the electrode (Fig.3). The resulting distortion in the valence and conductivity levels ensures the migration of the charge carriers photogenerated in the porphyrin film to the electrodes: positive ones to the silver electrode and negative ones to the aluminium electrode.

Porphyrins have a molecular crystal lattice and a low intermolecular interaction energy. The absorption of light results in their intramolecular excitation. The high-lying conductivity band is not then populated. The generation of charge carriers is achieved in the interaction of excited $H_2$P molecules with acceptor centres, which may consist of molecules of oxygen,[222,223,243,283] iodine,[283] or other doping additives. In the sandwich cells Al|$H_2$P|M (M = Ag, Pt, etc) charges are generated in the acceptor traps on the Al|$H_2$P interface, or more precisely on Al|$Al_2O_3$|$H_2$P.[225,256,285] In agreement with the hole character of the conductivity of $H_2$P and MP, the efficiency of the operation of the photocells is related directly to the ability of the porphyrins to be converted into radical-cations. Indeed, the photocurrent quantum yield increases with decrease of the oxidation potentials of the porphyrins.[225–283]

An evident way of increasing the concentration of charge carriers in semiconductors, namely by the introduction of doping admixtures, has only limited applicability to $H_2$P and MP. If the amount of admixture exceeds a specific level (~1%), the quality of the pigment films and hence the quality of the operation of the photocells are sharply impaired. A possible solution of this problem consists in the employment of MP with highly charged cations which contain donor or acceptor groups as the extraligands. For example, it has been established[241] that Al(Cl)Phc and In(Cl)Phc have specific conductances higher by 3–5 orders of magnitude than MgPhc and CuPhc, while their photosensitivity is higher by 2 orders of magnitude.

The specific conductances of $H_2$P and MP are usually in the range from $10^{-15}$ to $10^{-3}$ S m$^{-1}$. Studies[288–292] where it has been shown that, on application of a high pressure (h.p.) and on shear deformation (s.d.), the specific conductances of certain $H_2$P increase by 5–6 orders of magnitude are therefore of great interest. For example, the specific conductance of $H_2$TPhCo increases from $10^{-5}$ to 10–100 S m$^{-1}$ following the application of a pressure of 2–4 GPa and of s.d., while the activation energy for electrical conduction diminishes by a factor of ten.[288] The increase of electrical conductivity and the joint influence of high pressure and shear deformation depend on the nature of the side substituents in porphyrins,[289] on the nature of the central metal atom,[289,290] and on the size and structure of the conjugated system of π-bonds in polymeric phthalocyanines.[292] The increase of electrical conductivity following the application of high pressure and shear deformation has been explained[288–292] by the decrease of the potential barrier to the intermolecular jump of the charge carriers as a result of the mutual approach in space of neighbouring molecules in porphyrin crystals and the increase of the intermolecular overlap of their π orbitals.

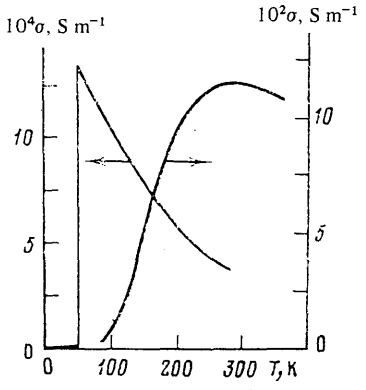

Figure 4. Temperature variation of the specific conductances of organic metals based on different porphyrin derivatives: *1*) NiOMTBPo$(I_3^-)_{0.35}$;[272] *2*) NiPhc$(I_3^-)_{0.33}$.[273]

Metal complexes of phthalocyanine and octamethyltetrabenzoporphin (MOMTBP) have been used[268–274,293] to synthesise organic metals of a new type. Compared with the initial MP, the organic metals obtained on their basis have specific conductances higher by 11–13 orders of magnitude. The increase of conductivity is achieved by treating crystailine MP with iodine vapour or solutions. Iodine plays the role of the oxidant and is converted into the anions $I_3^-$, which are arranged in chains within long narrow channels in the crystal lattice formed via stacks of parallel MP molecules. A fundamental feature of such crystals is the fractional positive charge per MP molecule. As a result, neutral and positively charged MP species alternate in the stack. There is also a possibility of structures with alternation of porphyrin mono- and di-cations. It is of interest that the electrical properties of $MP_n^{m+}(I_3^-)_m$ crystals depend very little on the average fractional positive charge per MP species. The organic metals based on MPhc exhibit metallic electrical conductivity, i.e. their conductivity diminishes with increase of temperature. The temperature dependence of the electrical conductivity of partly oxidised NiOMTBP is represented by a curve with a maximum at 260–330 K (Fig.4).

In conclusion, one should note that materials with a high electrical conductivity can apparently be obtained not only from partly oxidised but also from partly reduced MP.[294]

## VII. ELECTROCHROMIC MATERIALS

By splitting off or combining with one or several electrons, $H_2P$ readily form radical-ion species.[295] The porphyrin radical-ions are very stable and can be generated by chemical or electrochemical methods. It is significant that different radical-ion species have different spectroscopic characteristics. The electrochemical method for the generation of porphyrin radical-ions deposited on optically transparent electrodes, for example, $SnO_2$ or $In_2O_3$ electrodes, is of special interest from the practical point of view. The colour of such electrodes is determined by the applied electrical potential and this can be used in a wide variety of electrochromic devices. The phthalocyanine complexes of Co, Mo, Fe, Mn, Zn, and the lanthanides possess electrochromic properties.[296–299]

Compared with liquid crystals, which are used widely as electrochromic materials, MP have the advantage that they can repeatedly change their colour depending on the sign and magnitude of the polarising potential. The diphthalocyanine complexes of the lanthanides are of particular interest in this respect. For example, as the electrical potential varies, the diphthalocyanine complex of lutetium changes colour five times;[299] its colour can be red, green, blue, and violet. The electrochromic materials based on MP are very durable in use, permitting not less than 100000 colour change cycles.[298]

## VIII. PIGMENTS, DYES, AND FOOD DYES

Tens of thousands of tonnes of MPhc are produced annually as pigments and dyes in industrially developed countries.[268] The interest in these dyes is due to their high photostability, chemical and migrational stability, and the purity of colour tones. Hundreds of publications, mainly patents, have been devoted to phthalocyanine pigments and dyes. Porphyrins proper can also be used as technical dyes. They have all the advantages of the phthalocyanine dyes and have a very wide colour range. However, the practical use of porphyrin pigments and dyes is possible only when their cost is sharply reduced.

Certain readily available porphyrins have found applications as food dyes.[300,301] Thus chlorophylls (a + b), their copper analogues, and the copper complexes of phaeophorbide (a + b) are permitted food colourants in almost all the major foreign countries. As early as 1926, about 20 tonnes of chlorophyll were processed in the U.S.A. for the colouring of food products.[301]

It has been suggested[300] that the cobalt complex of the disodium salt of haematoporphyrin be used to impart a red colour to sausage products. Sodium nitrate is used at present for this purpose. The addition of $(3–5) \times 10^{-3}$ wt.% of the cobalt complex makes it possible to reduce greatly the amount of nitrite introduced into the sausage meat and to eliminate the appearance of residual nitrite and nitrosamines.

## IX. ENRICHMENT OF RADIOISOTOPES

Phthalocyanines are used to synthesise and enrich radioisotopes by the Szilard–Chalmers method,[302–325] which consists of bombarding MPhc specimens with thermal neutrons. Isotopes with higher mass numbers are formed as a result of neutron capture by the nuclei of the coordinated metals. The nuclear reaction is terminated by the emission of a $\gamma$-quantum. Recoil results in the decomposition of the MPhc and the liberated isotope forms a new chemical compound. For the successful application of the Szilard–Chalmers method, the initial coordination compound must have high chemical, thermal, and radiation stabilities. Metalloporphyrins satisfy these requirements. Phthalocyanine complexes have been used to obtain Cu, Zn,[99] Co,[303,306] Ro,[305] and lanthanide[315] isotopes. The yields of radioisotopes obtained by the Szilard–Chalmers method using MPhc are as a rule high. For example the yields of 13 lanthanide isotopes were between 60 and 90%.[315] The enrichment factors were in the range $10^2–10^3$.[99,315]

Table 2. Porphyrins as analytical reagents

| Element to be determined | Analytical reagent | Analytical method | c, M | Refs. |
|---|---|---|---|---|
| Cu(II) | $H_2TPhPo(SO_3H)_3$ | SPPM | $1\cdot10^{-7}–1\cdot10^{-6}$ | [317, 318, 342] |

| | $CaPhc(SO_3H)_4$ | | | |

Notation. SPPM = spectrophotometry; SPPM-CIER = spectrophotometry with preliminary concentration on ion-exchange resins; AD-SPPM = analogue derivative spectrophotometry; TLS = pulsed laser thermal lens spectrophotometry; SPPM-INCE = indirect spectrophotometric determination using Ce(IV); F = fluorimetry; P = polarography; E = extraction–photometric method; C = catalytic method; c = concentration of the element to be determined.

*The metalloporphyrins indicated can be used also to determine Zn, Co, and Mn.

## X. ANALYTICAL REAGENTS

Porphyrins have found applications as analytical reagents in the quantitative analysis of trace amounts of many metals (Table 2). Spectrophotometric analytical methods, based on the use of highly intense absorption bands in the electronic absorption spectra of porphyrins and metalloporphyrins, are mainly employed. The MP formation reactions are highly sensitive, which makes it possible to determine Cu, Zn, Cd, and other metals at concentrations in the range $10^{-7}$–$10^{-6}$ M with an error of 0.5–2%. Preliminary concentration of the salts on ion-exchange resins of the Chelex or Dowex types makes it possible to increase the sensitivity of the reaction by two orders of magnitude.

Selective highly sensitive methods for the catalytic determination of Cd and Hg, whereby it is possible to determine these metals at concentrations of $10^{-9}$ M, have been developed. The methods[334,345] are based on the catalytic acceleration of the coordination of $H_2P$ to Mn(II) salts in the presence of Cd(II) or Hg(II). Porphyrin analytical reagents have been employed to determine Cu and Zn in tap water, in high-purity chemical reagents, hair, etc.

## XI. OTHER APPLICATIONS

MP and MPhc are being studied vigorously as molecular oxygen transferring agents. The ability of the porphyrin complexes of Co, Fe, Mn, Ti, and Mo to fix oxygen reversibly under certain conditions has been demonstrated. These studies are in the main theoretical although patents on this subject have appeared in recent years.

Porphyrins are used in the therapy and early diagnosis of cancer. The ability of $H_2P$ to accumulate selectively in cancer cells is used in this case. On irradiation with u.v. light, the diseased regions exhibit a red fluorescence.

Porphyrins manifest radioprotecting and radiosensitising properties and, depending on the concentration, they can intensify the radiation damge of a living organism and biological objects or can exhibit the opposite effect. Methods have been developed for the local decomposition of cancer cells based on the radiosensitising activity of $H_2P$ and on their ability to accumulate selectively in cancer tumours.

Among other applications, mention may also be made of applications of porphyrins in fields such as the determination of the quality of meat products and their use as inhibitors of the burning of plastics, as antistatic agents, and even as deodorants and stimulants of hair growth.

# Reaction Chromato-mass Spectrometry

A.I.Mikaya and V.G.Zaikin

The principles of the highly effective reaction chromato-mass-spectrometric method, based on the use of chemical reactions of the test specimens directly in the reaction system of a chromato-mass-spectrometer, are examined. The possibilities of the method in the determination of the structures of organic compounds and in the study of the mechanisms of dissociative ionisation, heterogeneous-catalytic reactions, and high-molecular-weight compounds are demonstrated.
The bibliography includes 52 references.

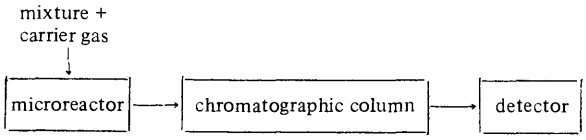
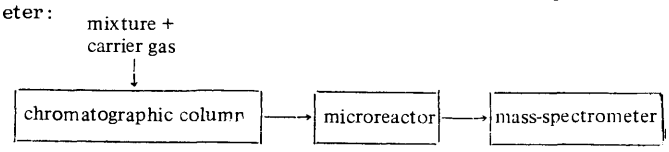
## I. INTRODUCTION



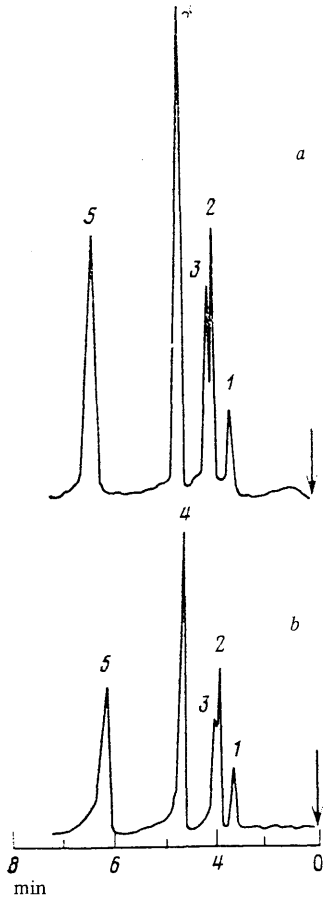
Preliminary chemical transformation of the test specimens is a common methodological procedure in the mass-spectrometric study of organic compounds. Various chemical methods, mainly derivatisation methods, are used in mass spectrometry to increase the volatility and the thermal and catalytic stabilities of the substances analysed, to improve the chromatographic characteristics (in chromato-mass-spectrometric investigations), to obtain additional information about the structure from the mass spectra of the reaction products, and to increase the sensitivity of the method in selective ionic detection.[1,2] The use of degradation methods (hydrolysis, pyrolysis) is extremely effective in mass-spectrometric research.[3,4] The majority of the known chemical modification methods are based on the use of reactions in solution. In such reactions, carried out in separate experiments, much labour and time must be expended on the isolation and separation of the products. In many instances comparatively large (microgramme) amounts of the test specimen are used in the chemical reactions. However, a much more convenient chemical transformation procedure involves gas-phase reactions in a microreaction system incorporated directly into the injection system of the mass spectrometer. Submicrogramme amounts of the test specimens, i.e. amounts sufficient for the mass-spectrometric analysis, can then be transformed. The most important advantage of this method is the possibility of carrying out the reactions directly in the course of the mass-spectrometric study. This creates a basis for the development of high-speed and highly effective research techniques whose possibilities are enhanced still further when chromato-mass spectrometry is employed. This method is called "reaction chromato-mass-spectrometry"[5] because it involves chemical reactions directly in the injection system of the chromato-mass spectrometer.

## II. PRINCIPLES OF REACTION CHROMATO-MASS SPECTROMETRY



In reaction chromato-mass spectrometry (RCMS) the substances analysed or mixture components are modified chemically directly in the injection system of the chromato-mass spectrometer (in microreactors, in reactions on separating columns). This is done in order to alter the physicochemical properties of the substances analysed, in order to obtain from the mass spectra of the reaction product additional or new information about the structures of the starting materials, to investigate dissociative ionisation mechanisms, to study the modes and mechanisms of gas-phase reactions, etc. The familiar reaction gas-chromatographic (RGC) method may be regarded to some extent as a precursor of RCMS,[6] but distinctive features and advantages are characteristic of the RCMS method.

In the first place the value of the information about the structure which can be obtained by the above methods is not the same. Whereas RGC provides for the preparation of products with known chromatographic characteristics or the creation of simpler mixtures from complex mixtures by "subtracting" individual components, the RCMS method provides for specific modification of substances in order to obtain compounds whose mass spectra yield additional information about the structure of the starting materials. The most important advantage of the RCMS method is the possibility of synthesising compounds labelled with stable isotopes (in particular, deuterium) directly in the course of analysis, which is exceptionally promising in the study of the mechanisms of the dissociative ionisation of organic substances and reaction mechanisms. In RGC there is no such possibility.



The microreaction system in RGC is usually placed before the separating chromatographic column:

Only when the subtraction method or the procedure is designed to increase the sensitivity of the analysis (if the detector is insensitive to the given component but is sensitive to its derivative) can the microreactor in RGC be placed between the column and the detector. In contrast to this, the microreaction system in RCMS is best located between the chromatographic column and the mass spectrometer:

The fundamental characteristic of this scheme is that each component eluted after chromatographic separation is subjected to chemical action. The chromatogram recorded under these conditions characterises the initial mixture (which ensures the possibility of a quantitative estimation of its composition), while the mass spectra correspond to the reaction products (which are used for structural assignments). This makes it possible to analyse separately even the isomeric compounds which give rise to identical structures on chemical modification and are naturally not susceptible to analysis by the RGC method.

Chromatogram of the initial mixture of alkenes (*a*) and the same mixture after passage through the hydrogenation microreactor placed between the column and the mass spectrometer (*b*): 1) 2,4,4-trimethylpent-1-ene; 2) oct-1-ene; 3) oct-2-ene; 4) non-1-ene; 5) dec-1-ene.[15]

In certain cases, for example, when it is necessary to decrease the polarity by means of a chemical reaction or to investigate the mechanism of a gas-phase process, the microreactor in the RCMS system can be usefully mounted before the separating column. The "subtraction microreactor" is positioned in the same way when there is a need to simplify the mixture for one reason or another.[7] Sometimes, especially in the analysis of individual substances, the separating column can be altogether disconnected and the microreactor is placed between the evaporator of the chromatograph and the mass-spectrometer.

As in RGC, in investigations by the RCMS method it is very important to select correctly the reactions which ensure the rapid, quantitative, and selective transformation of the substances analysed. Admittedly, a high selectivity is not always obligatory in relation to RCMS; it will be shown below that sometimes side reactions can assist in the determination of the structure.

In the RCMS method which provides for the gas-chromatographic injection of the test substances, gas-phase catalytic reactions are used for the chemical transformation of the compound. The amount of the catalyst required for the complete transformation of the compound depends to a large extent on the degree of its dispersion and on the necessary length of the reaction zone. In order to select the correct amount of the catalyst, the microreactor is placed before the chromatographic column and several experiments are performed varying the length of the catalyst bed and the amount of specimen injected. This also makes it possible to determine the process selectivity at different temperatures.

As stated above, the chemical reactions in RCMS can be achieved in microreactors, reaction columns, or directly in the separating column. A convenient wholly metallic microreactor for RCMS has been described.[8] The minimum number of valves whereby the substance in the stream of carrier gas can be passed either around the catalytic zone (by-pass) or through the catalyst bed are used in this reactor. The system is adequately miniaturised and can be placed within the chromatographic thermostat. The catalyst bed of the required height is placed in the microreactor cartridge between glass wool plugs.

The reaction columns employed in RCMS usually consist of metallic or glass tubes placed directly in the chromatograph thermostat. Such columns are filled with a catalytic packing or an active substance attached to a solid carrier, as in the preparation of packed analytic columns.

It is noteworthy that the RCMS method does not eliminate the need for the usual mass- or chromato-mass-spectrometric analysis of the initial compound. On the contrary, only a combined analysis of the mass spectra of the initial substances and their transformation products permits the most complete solution of structural-analytical problems.[9]

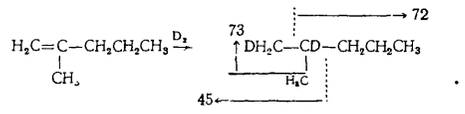
## III. INVESTIGATION OF THE STRUCTURES OF ORGANIC SUBSTANCES

### 1. Olefins

For the general case, in the study of the structures of olefins it is necessary to determine the structure of the carbon skeleton and the position and geometry of the double bond. Mass-spectrometry with ionisation by electron impact (EI) yields relatively little information in the solution of these problems owing to the preferential ionisation of unsaturated molecules at the double bond and the "migration" of the latter along the chain.[10,11] Many methods for the chemical "fixation" of double bonds, permitting the determination of their position and sometimes of their geometry from the mass spectra of the products, have been developed.[2,12] However, the majority of these methods are laborious, do not ensure the determination of the structure

of the carbon skeleton, and are unsuitable for the investigation of mixtures. New possibilities for the solution of these problems are provided by the RCMS.

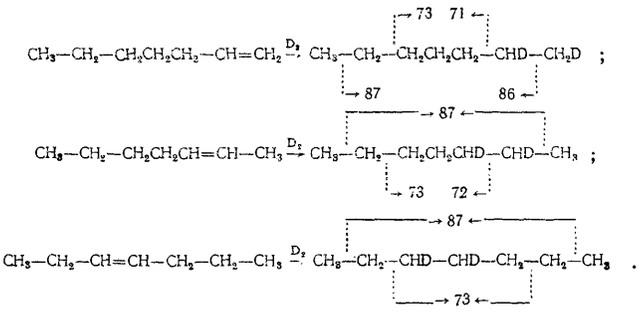
The determination of the structure of the carbon skeleton of olefins is based on the fact that the mass spectra of paraffins, in contrast to those of unsaturated hydrocarbons, have many features from which one can infer the presence and character of branches in their carbon chains. Furthermore, the mass spectra of many alkanes are known and are contained in computer libraries and the structure of alkanes can therefore be sometimes established automatically. Olefins can be successfully hydrogenated in a microreactor placed in the injection system of a chromato-mass spectrometer when hydrogen is used as the carrier gas, serving simultaneously as a reactant. The efficiency of this procedure has been demonstrated in relation to the investigation of mixtures of α-olefins[13] and cyclohexenols.[14] However, the above method was used in these studies only to demonstrate the presence of the double bond and its other structural-analytical possibilities were not discussed. These questions were examined more thoroughly in other investigations.[5,15]



Olefins can be hydrogenated within the framework of the RCMS method using deposited platinum, palladium, or nickel catalysts. The 1-2% Pt/Chromaton and 1% Pd/porous glass catalysts, which ensure quantitative hydrogenation in the temperature range 50–250 °C without inducing undesirable reactions, in particular hydrogenolysis, have been employed for for such purposes.[5,15] The hydrogenation microreactor can be equally successfully placed after both packed and capillary columns and, when the amounts of the catalyst and the reaction temperature have been chosen correctly, an appreciable impairment of the chromatographic separation owing to the possible sorption of hydrocarbons on the catalyst is not observed (Figs. *a* and *b*). Using this method, the molecular weight of each component is established from the mass of the molecular ions ($M^+$) and the structure of the carbon skeleton can be determined from the mass spectra of the hydrogenation products. However, the problem of the determination of the position of the double bond remains. Its solution by the RCMS method can be achieved by the selective deuteriation of olefins at the double bond using deuterium as the carrier gas and the reactant. This approach has been studied in detail.[5,16]

**Table 1.** The isotope distribution (%) in the products of the deuteriation of n-octenes on the Pd/porous glass catalyst (100 °C).[16]

| Initial n-octene | [$D_n$]Octane | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|
| | $D_1$ | $D_2$ | $D_3$ | $D_4$ | $D_5$ | $D_6$ | $D_7$ | $D_8$ | $D_9$ |
| Oct-1-ene | 6 | 34 | 22 | 14 | 10 | 6 | 5 | 3 | — |
| Oct-2-ene | 4 | 20 | 15 | 15 | 12 | 8 | 8 | 6 | 6 |
| Oct-4-ene | 3 | 20 | 13 | 10 | 9 | 9 | 9 | 8 | 7 |



Heterogeneous hydrogenation catalysts based on transition metals are known[17] to ensure the selective deuteriation of olefins because they induce an intense exchange of the substrate hydrogen atoms for deuterium in both liquid-phase and gas-phase processes. However, this exchange proceeds more vigorously at elevated temperatures (>150 °C). It has been shown[5,16] that a decrease of the reaction temperature below 100 °C when the Pt/Chromaton and Pd/porous glass catalysts are used suppresses significantly the deuterium exchange. As an example, Table 1 presents the isotope composition of the products of the deuteriation of isomeric n-octenes. Evidently, in the case of an α-olefin deuterium exchange plays a less important role relative to deuteriation than in the case of olefins with inner double bonds. This finding can be used to differentiate olefins with terminal and inner positions of the double bond.

The deuterium exchange accompanying the addition of deuterium diminishes if the molecule contains a branch at the carbon atom involved in the double bond. This results in an increase of the fraction of vicinal dideuterioalkanes and the determination of the position of the deuterium label and hence of the position of the double bond in the olefin is thereby facilitated. For example, the spectrum of the product of the deuteriation of 2-methylpent-1-ene contains a doublet with equal peaks due to the fragment ions $[M-CH_3]^+$ ($m/z$ 73) and $[M-CH_2D]^+$ ($m/z$ 72) and also an intense peak of the ion with $m/z$ 45, which demonstrates unambiguously the position of the double bond:[5]

The next step in these studies involved the search for a metal complex catalyst which might be used in RCMS for selective deuteriation. Attention was turned to tris(triphenylphosphine)rhodium chloride (Wilkinson's catalyst, which is widely used for such purposes under homogeneous liquid-phase conditions.[18] However, the application of this catalyst in RCMS requires that it be made heterogeneous. Heterogeneous packing based on Wilkinson's catalyst had been obtained earlier by impregnating porous carriers with a solution of $(Ph_3P)_3RhCl$ in comparatively high-boiling liquids. These were used for the gas-phase hydrogenation and hydroformylation of lower olefins (ethylene and propene) at 25 °C.[19] However, this type of packing is unsuitable for RCMS, since the solvent evolved enters the mass spectrometer and creates a strong backgound. It was therefore suggested that the catalyst be converted into a heterogeneous form by depositing it, after dispersion in a stationary liquid phase (Carbowax 20 M), on Chromaton.[20] This catalytic system ensured the selective deuteriation of higher alkenes (up to $C_{12}$) in the gas phase at 50–80 °C under the conditions of heterogeneous catalysis. The column, filled with the catalyst on the carrier, was connected to a mass spectrometer and the substrate in a stream of $D_2$ was passed through it. It was shown[16,21] that the reaction column with an appropriate length ensures the quantitative deuteriation of mono- and di-substituted olefins with substituents attached at the double bond, mass-spectrometric analysis confirming the high isotopic purity of the vicinal dideuterioalkanes formed (>96%).

It is recommended that, for the mass-spectrometric determination of the position of the label in dideuterioalkanes, one should analyse the ions formed as a result of the elimination of the simplest alkyl radicals from molecular ions at the ends of the chain or at branching points. It is shown below how information about the mass numbers of the characteristic fragment ions from isomeric dideuterioheptanes can be used to determine the position of the double bond:

The method described can be employed also for the determination of the position of the double bond in branched alkenes. In the study of mixtures, the individual units of the apparatus are arranged in the following sequence:

separating column → reaction column → mass spectrometer.

It has been suggested that hydrogenation beyond the column, in the chromato-mass spectrometer, be used to determine the configuration of the centre in the 4-position in the stereoisomeric 4-vinyl-*trans*-4-decahydroquinolinols, obtained by the Norman reaction in the form of mixtures. The feasibility of this approach arises from the fact that the mass spectra of the ethyl analogues show intense peaks due to the ions $[M-C_2H_5]^+$, whose intensity depends on the configuration of the centre in the 4-position (the ease of the elimination of the substituent $C_2H_5$ is greater when it is in the axial position), whereas the formation of the ions $[M-CH=CH_2]^+$ is not characteristic of the vinyl analogues. It has been shown[22] that, when the 1–2% Pd/porous glass (150–200 °C) catalyst is used in chromatography in a stream of $H_2$, each component of the mixture of isomeric vinyl alcohols is converted quantitatively into the corresponding ethyl analogue with retention of configuration. The stereospecificity of the fragmentation on electron impact, of the same kind as that observed when the individual stereoisomers of 4-ethyl-substituted alcohols are passed through the direct injection system, is manifested in the mass spectra of the alcohols under these conditions.

Post-column hydrogenation can also be carried out in a tube made of a hydrogen-permeable alloy based on platinum or palladium.[23] After chromatography in a stream of hydrogen, hydrogenation takes place in this case on the walls of the tube and the hydrogen is removed by diffusion through the walls. Such a tube can serve as an effective interface between the chromatograph and the mass spectrometer.

## 2. Alicyclic Compounds

The necessity for the development of additional methods assisting in the determination of the structures of alicyclic compounds arose because their mass spectra frequently resemble the spectra of the isomeric olefins and do not always contain reliable features whereby one could distinguish condensed, bridged, spiran, and jointed systems and also to differentiate cyclopentane and cyclohexane structures.

Cyclic and olefinic structures can be distinguished by means of post-column hydrogenation, because only the mass spectra of the latter are then altered.[5] Further, this method is not applicable to cyclopropane compounds, which undergo ring opening under hydrogenation conditions with formation of aliphatic products. A special method was therefore developed for cyclopropane compounds which increases the diagnostic possibilities of the procedure.[24] The method is based on the use of the hydrogenolysis reaction, which takes place readily in the gas phase in the presence of the Pt/Chromaton, $PtO_2$, and Pd/porous glass catalysts.[25]

It has been shown that the hydrogenolysis of monoalkylcyclopropanes leads to the formation, under these conditions, of a mixture of compounds with branched (A) and linear (B) structures, which can be readily distinguished mass-spectrometrically:

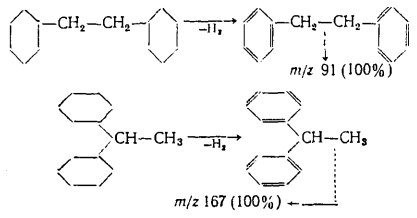
$$\text{>}-R \xrightarrow{H_2} \underset{(A)}{(CH_3)_2CHR} + \underset{(B)}{CH_3CH_2CH_2R} ;$$

$$R = n\text{-}C_8H_{17},\ CH_2CH_2COOCH_3,\ CH_2CH_2COOC_2H_5 .$$

Regardless of the reaction temperature (50–200 °C) and the nature of the substituent R, the ratio of the products (A) and (B) is 94:6. This fact is important, because it allows the microreactor to be placed between the chromatographic column and the mass spectrometer. Indeed, although the measured mass spectrum constitutes the sum of the spectra of both products, it is largely determined by the structure (A). However, a new problem of the differentiation of the cyclopropane compounds and the isomeric branched olefins, which give rise to identical products on interaction with hydrogen, arises under these conditions:

$$\text{>}-R \xrightarrow{H_2} (CH_3)_2CHR \xleftarrow{H_2} H_2C{=}\underset{CH_3}{\underset{|}{C}}R .$$

It has been suggested that the problem be solved by employing deuterium as the carrier gas and the reactant, because deuteriation of cyclopropane and unsaturated compounds gives rise to products with different positions of the label, which can be readily determined from the fragment ions in the mass spectra:



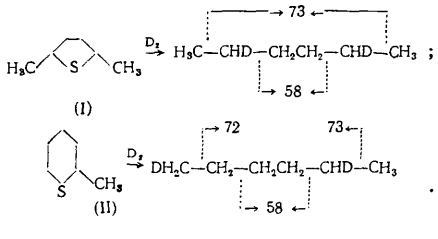
$$\text{>}-R \xrightarrow{D_2} DH_2C-\underset{CH_2D}{\underset{|}{CH}}-R ;$$

$$H_2C{=}\underset{CH_3}{\underset{|}{C}}-R \xrightarrow{D_2} DH_2C-\underset{CH_3}{\underset{|}{CD}}-R .$$

This method may prove to be exceptionally effective in the determination of the structures of cyclopropane derivatives of biological origin.[26]

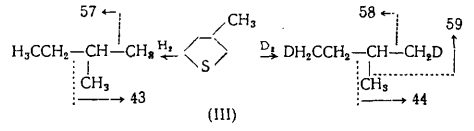
It has been suggested that compounds containing five- and six-membered structures be investigated by means of the dehydrogenation reaction (Pt, C; 320 °C) in a microreactor positioned between the chromatographic column and the mass spectrometer.[27] In this case the process is carried out in a stream of carrier gas which consists of a mixture of 95% of helium and 5% of hydrogen. It has been shown for a large number of mono- and bi-cyclic hydrocarbons with known mass-spectrometric characteristics[28] that the cyclohexane derivatives contained in the mixtures, which do not contain quaternary carbon atoms, or compounds containing a six-membered ring which does not form part of the composition of bridged structures, are dehydrogenated with formation of the corresponding aromatic hydrocarbons. Five-membered cyclic derivatives do not react under these conditions. The number of six-membered rings in the initial molecule and also certain elements of the initial structures can be determined from the mass spectra of the aromatic hydrocarbons produced. The presence of intense $M^+$ peaks in the mass spectra of aromatic hydrocarbons permits a reliable determination of the molecular weight of the parent alicyclic compounds whose spectra do not contain the $M^+$ peaks. The characteristic decomposition of the aromatic hydrocarbons as a result of the benzil dissociation under electron impact makes it possible to detect branching at the

α-carbon atom of the alkyl substituent. In particular, 1,2- and 1,1-dicyclohexylethanes can be readily distinguished by this method:



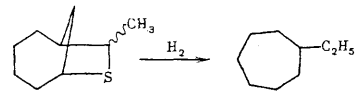
The structure of polycyclic hydrocarbons of the jointed type can also be established from the characteristic mass spectra of the dehydrogenation products.[29,30]

### 3. Cyclic Sulphides



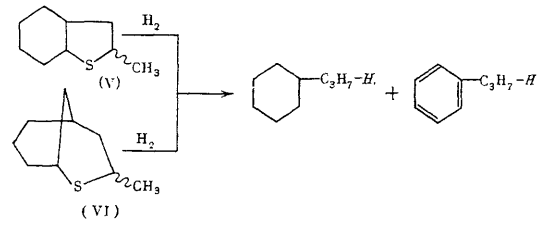
The RCMS method is used to study the structures of cyclic sulphides because EI mass spectrometry yields little information as regards the size of the heterocycle and the positions of its substituents. For a more reliable determination of the structures of monocyclic sulphides in mixtures, it has been suggested that the parallel hydro- and deuteriodesulphurisation of the mixture components in a microreactor placed between the chromatographic column and the mass spectrometer be used.[31] $Pd/Al_2O_3$ or Raney nickel could be used for the reaction, because both these catalysts give rise to effective hydrodesulphurisation in the presence of hydrogen at 150–250 °C. However, in the presence of deuterium, intense deuterium exchange takes place at these temperatures, while at lower temperatures $Pd/Al_2O_3$ becomes inactive. On the other hand, Raney nickel fixed on Chromaton by means of Apiezon is active also at 20–80 °C and at the same time ensures the selective formation of dideuteriohydrocarbons (the deuterium atoms are located at the carbon atoms which are linked to sulphur in the initial sulphides). The mass spectra measured under these conditions can be readily interpreted and make it possible to determine the position of the deuterium label and hence the size of the heterocycle. The positions of the substituents can be established in many cases on the basis of these spectra and also the spectra of the alkanes formed on hydrodesulphurisation.

It is easy to distinguish by this procedure, for example, 2,5-dimethylthiolan (I) and 2-methylthiane (II), whose mass spectra are similar. Although both compounds yield n-hexane on hydrodesulphurisation, the replacement of $H_2$ by $D_2$ leads to the formation of dideuteriohexanes with different positions of the label, which can be readily established mass-spectrometrically:[31]



In the study of the structure of 3-methylthiolan (III), the position of the methyl substituent can be demonstrated already in the hydrodesulphurisation stage, since the recorded mass spectrum corresponds to 2-methylbutane.

The spectrum of the dideuteriohydrocarbon contains in its turn a doublet comprising peaks of equal size due to the ions $[M-CH_3]^+$ and $[M-CH_2D]^+$; this demonstrated unambiguously that the reaction product is 1,4-dideuteriomethylbutane and the initial sulphide therefore has the structure (III):



The employment of the deuteriodesulphurisation reaction in the study of polycyclic sulphides is pointless, since the position of the deuterium label in the naphthenic hydrocarbons formed cannot be determined mass-spectrometrically. Nevertheless, even simple hydrodesulphurisation can yield definite information about the structure of polycyclic sulphides. The qualitative composition of a mixture containing structural and geometrical isomers of methylthiabicyclononanes has been studied in this way.[32] The AP-56 catalyst, ensuring the quantitative hydrodesulphurisation of the test mixture at 300–315 °C, was then used. The desulphurisation microreactor was placed between a capillary column and the mass spectrometer. There was in this instance a risk that the separation of the eluted chromatographic zones would disappear even for small sorption effects of the catalyst. However, it was shown that, for an appropriate thickness of the catalyst bed, the impairment of the separation of the components, achieved with the aid of the capillary chromatographic column, is hardly detectable.

The results of the investigation confirmed the presence in the mixture of stereoisomeric 8-methyl-7-thiabicyclo[4.2.1]nonanes (IV), which gave rise to ethylcycloheptane on hydrodesulphurisation:

The mass spectra of the products of the hydrodesulphurisation of 8-methyl-7-thiabicyclo[4.3.0]nonanes (V), which are components of a mixture, consist of the spectra of the expected product (n-propylcyclohexane) and n-propylbenzene

Analogous mass spectra were recorded after the minor components had been passed through the catalytic zone. The structure of the isomeric 7-methyl-6-thiabicyclo[3.3.1]nonanes (VI) was proposed for such components.

Although the aromatisation of the cyclohexane hydrocarbons reduced the process selectivity and complicated the character of the mass spectra,[32] the latter are easy to interpret. Furthermore, this finding can be used to distinguish thiacyclanes with six-membered carbocycles

from the isomeric compounds with five- and seven-membered carbocycles. The characteristic nature of the mass spectra of aromatic hydrocarbons is also important, yielding additional information about the nature and positions of the substituents in the initial sulphides.

The results quoted by Mikaya et al.[32] are a good illustration of the fact that even those isomeric compounds which give rise to identical products in the reaction can be analysed separately by the RCMS method, which cannot be done by the RGC method.

## 4. Alcohols

Alcohols, especially aliphatic alcohols, are very important products of laboratory and industrial synthesis, frequently obtained in the form of mixtures. A wide variety of alicyclic alcohols (terpene and steroid alcohols) are isolated from biological objects. Thus the complexity of the mixture composition and the limited amount of the biological material available for study suggest that the chromato-mass-spectrometric method is most likely to be useful for their investigation. However, the mass spectra of the alcohols themselves yield insufficient information (or altogether fail to provide it) about their molecular weight and the nature and character of the carbon skeleton.[12] Derivatisation methods, based on liquid-phase reactions, are therefore very widely used for their investigations.[1,2] The RCMS method constitutes a good alternative to these procedures.

The combined RCMS method developed for the study of alcohols is based on the following gas-phase reactions.

1. The dehydrogenation reaction (catalyst—powdered copper; 320 °C)[33,34] carried out in a microreactor using helium as the carrier gas. Under these conditions, primary and secondary alcohols are quantitatively converted into aldehydes and ketones respectively, while tertiary alcohols remain unchanged. The mass spectra of the carbonyl compounds are characterised by the presence of $M^+$ peaks and also the peaks of the acyl ions $RCO^+$ and ions appearing as the result of the McLafferty rearrangement.

2. The reaction involving the exchange for deuterium of the enolysable hydrogen atoms in aldehydes and ketones formed on dehydrogenation of primary and secondary alcohols. This reaction takes place at 20–300 °C in a reaction column containing Chromaton on which dispersed KOD in a stationary SE-30 liquid phase is deposited.[35,36] The number of hydrogen atoms adjoining the carbonyl group exchanged for deuterium is determined from the shift of the $M^+$ peak, the peaks of the acyl ions, and the ions due to the McLafferty rearrangement.

3. The reaction involving the deoxygenation of alcohols to the corresponding hydrocarbons in the presence of a fused iron catalyst (300–320 °C).[37] It takes place in a microreactor in the presence of hydrogen, which serves at the same time as the carrier gas. The structure of the hydrocarbon is established from its mass spectrum by comparison with data in libraries of mass spectra or by analysing the characteristic decomposition under electron impact.

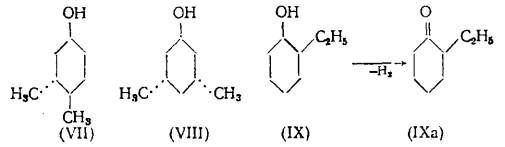
Various systems employed in the analysis of both individual alcohols (*A*–*C*) and their mixtures (*D*–*F*) have been developed on the basis of the reactions indicated:

*A*—dehydrogenation microreactor;
*B*—dehydrogenation microreactor → reaction column;
*C*—deoxygenation microreactor;
*D*—separating column → dehydrogenation microreactor;
*E*—separating column → dehydrogenation microreactor → reaction column;
*F*—separating column → deoxygenation microreactor.

All these systems can be placed in a thermostat of the chromatograph and connected to the inlet of the mass spectrometer.[38]

In the study of mixtures the analysis can be carried out in four stages. The chromatograms and mass spectra of the individual components of the initial mixture bypassing the reactor are recorded initially. The three subsequent stages of the analysis involve chromato-mass-spectrometric study using the *D*, *E*, and *F* systems. At each stage it is possible to obtain the relevant information about the structures of the individual elements of the alcohols investigated, which ultimately makes it possible to reproduce reliably the structure of the latter. Table 2 shows what information can be obtained from the mass spectra of aliphatic alcohols and their reaction products.

Table 2. Information about the structure of the alcohols obtained at different stages of their investigation by the RCMS method.[38]



| Reaction employed | Product analysed | Information obtained |
|---|---|---|
| Without reaction (bypass) | initial alcohol | determination of approximate data on the molecular weight, the nature of the alcohol, and the position of the OH group |
| Dehydrogenation of alcohol | carbonyl compound | reliable determination of molecular weight; differentiation of primary, secondary, and tertiary alcohols and dialkyl ethers; determination of the position of the OH group; determination of approximate (sometimes accurate) data on the character of the branching at the carbon atoms in the α-position relative to the carbonyl group |
| Deuterium exchange involving dehydrogenation products | deuterium-labelled carbonyl compound | determination of the nature and character of the substitution at the carbon atoms in the α-position relative to the carbonyl group |
| Deoxygenation of alcohol | hydrocarbon | determination of the structure of the carbon skeleton of the alcohol |

It is noteworthy that in a number of instances there is no need to carry out all the stages of the investigation and it is sufficient to employ only some of them. Thus in the study of industrial alcohols, only the post-column dehydrogenation and pre-column deoxygenation were used.[39]

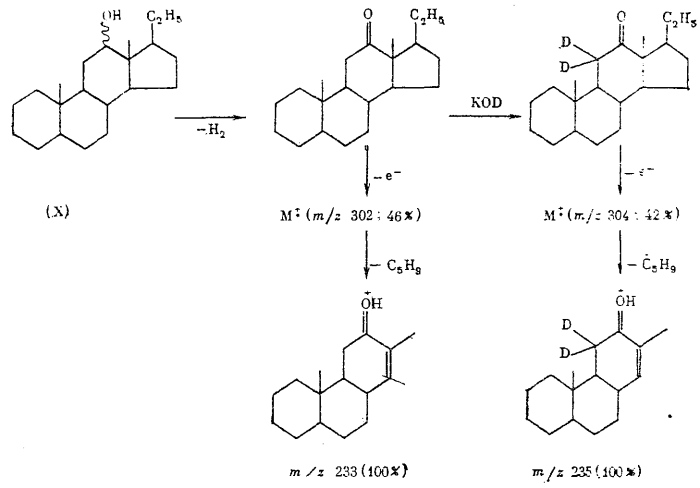
The RCMS method using the above reactions is very useful for the determination of the structures of alicyclic alcohols, whose mass spectra are relatively non-characteristic. The possibilities of the method have been demonstrated[40] in relation to mono- and bi-cyclic alcohols. In particular, it is possible to differentiate 3,4- and 3,5-dimethylcyclohexanols, compounds (VII) and (VIII) respectively, by this method and also to obtain information about their steric structures. After the deoxygenation, the mass spectra of *trans*-1,2-dimethyl- and *cis*-1,3-dimethyl-cyclohexanes respectively were recorded, which demonstrates a specific steric orientation of the $CH_3$ groups in the initial molecules.

When the *A* and *B* systems were used for the analysis of both alcohols, the mass spectra of ketones and their tetradeuterio-analogues were recorded respectively, which indicates the absence of substituents in the α-position relative to the OH groups. The fact that the spectrum of the ketone obtained from one alcohol [compound (VII)] contains peaks due to the ions $CH_3CH{=}CH\overset{+}{C}O$ (*m*/*z* 69) and

$CH_2=CHC\equiv\overset{+}{O}$ ($m/z$ 55), which shift when deuterium is used (the *C* system) to $m/z$ 70 and 56 respectively, while the spectrum of the ketone obtained from the other alcohol [compound (VIII)] contains only the peak of the first ion with $m/z$ 69 indicates the positions of the substituents in these cyclohexanols.

(VII) (VIII) (IX) (IXa)

Even simple dehydrogenation of 2-ethylcyclohexanol (IX) shows that it contains the $C_2H_5$ group in the α-position relative to the carbonyl group, since the maximum peak in the mass-spectrum of the ketone (IXa) is due to the $[M-C_2H_4]^+$ radical-cation, which appears as a result of the McLafferty rearrangement. This is also confirmed by the finding that only three hydrogen atoms in the ketone (IXa) are exchanged for deuterium.



The problem of the mass-spectrometric determination of the position of the OH group is fairly acute in the case of steroid alcohols. The RCMS method gives rise to certain possibilities for the investigation of compounds of this type.[41]

**Table 3.** Composition of the products of the catalytic reactions of steroid alcohols (Cu, 320 °C, total conversion 100%).[41]

| Initial alcohol | Product (content in %) |
|---|---|
| 12α- and 12β-hydroxypregnanes (X) | 12-hydroxypregnane (100%) |
| 3β-Hydroxyandrostan-17-one | androstane-3,17-dione (100%) |
| 17β-Hydroxyandrostan-3-one | androstane-3,17-dione (100%) |
| Cholesterol | cholesta-3,5-diene (20%), cholesta-4,6-dien-3-one (70%), and cholest-4-en-3-one (10%) |
| 6-Methylcholesterol | 6-methylcholesta-3,5-diene (18%), 6-methylcholesta-4,6-diene-3-one (72%), and 6-methylcholest-4-en-3-one (10%) |
| 3β-Hydroxypregn-5-en-20-one | pregna-3,5-dien-20-one (15%), pregna-4,6-diene-3,20-dione (78%), and preg-4-ene-3,20-dione (7%) |

Table 3 presents the results of the investigation of individual steroid alcohols by the RCMS method using the dehydrogenation microreactor → separating column system. In all cases the alcohols react quantitatively. Saturated alcohols (hydroxypregnanes and hydroxyandrostanones) were only dehydrogenated under these conditions with formation of the corresponding ketones. On the other hand, mixtures were obtained from unsaturated alcohols (cholesterol, 6-methylcholesterol, 3β-hydroxypregn-5-en-20-one) in which the expected ketones constituted only an insignificant proportion and the main bulk of the mixture consisted of the products of their further dehydrogenation and also the alcohol dehydrogenation products.

The formation of a mixture of products, noted for unsaturated alcohols, in a microreactor placed between the separating column and the mass spectrometer is undesirable, because the interpretation of the mass spectra of the unresolved mixture gives rise to difficulties. On the other hand, the method can be used effectively for saturated alcohols. For example, the dehydrogenation of 12α- and 12β-hydroxypregnanes (X), whose mass spectra are exceptionally non-characteristic, results in the formation of the same ketone (Xa), the intense peak with $m/z$ 233 in the mass-spectrum of which characterises the 12-oxo-group. As might have been expected, only two hydrogen atoms in this ketone are exchanged for deuterium:

The application of chromato-mass-spectrometry to the study of mixtures of diols and alkoxyalcohols is limited owing to their low volatility, poor chromatographic properties, and the relatively non-characteristic mass spectra. The RCMS methods described above are also unsuitable in this case. On the other hand, the conversion of such compounds into silyl ethers appears definitely promising. In order to increase the speed of the analysis, it is desirable to obtain the silyl ethers directly in the course of the chromato-mass-spectrometric analysis and not in separate experiments.

The method involving direct silylation in the chromatographic column and subsequent mass-spectrometric analysis has been used successfully in the study of a mixture of the aliphatic diols $HO(CH_2)_nOH$ ($n$ = 4–10) obtained synthetically.[42] *N,O*-bis(trimethylsilyl)trifluoroacetamide (BSTFA) with 1% of added $(CH_3)_3SiCl$ was used as the silylating agent. It was added directly 5 s after the injection of the reaction mixture. The volume ratio of the specimen and BSTFA, amounting to approximately 1 : 3, ensured the quantitative silylation of the diols. The mass-spectrometric characteristics of the trimethylsilyl ethers of the diols were established, the molecular weights of the diols were determined, and the character of the alcoholic functions (whether they are primary or secondary) was deduced. Unfortunately, the mass spectra of the silyl ethers have no distinctive features which would make it possible to determine the structure of the carbon skeletons of the diols.

An analogous approach has been used in the study of mixtures of the alkoxyalcohols $RO(CH_2)_nOH$ (R = $CH_3$ or $t$-$C_4H_9$).[43] It was shown that the peaks of the $[M-CH_3]^+$ ions can be used to determine the molecular weights of the methoxyalkanols from the mass spectra of the trimethylsilyl

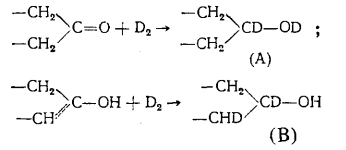
ethers. In the case of t-butoxyalkanols, the peaks of the ions $[M - C_4H_9]^+$ and $[M - C_4H_9O]^+$ can be used for these purposes.

The method of silylation directly in the chromatographic column can be used also for the investigation of other hydroxy-compounds (carbohydrates, steroid and terpene alcohols, lipid diols and triols, and acids).

## IV. INVESTIGATION OF DISSOCIATIVE IONISATION MECHANISMS

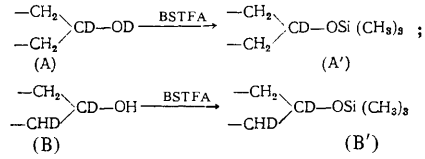
Deuterium-labelled analogues are used widely in the mass-spectrometric study of the mechanisms of the fragmentation of organic compounds. In all the known instances, preparative methods involving the isolation of the required products are used to obtain such derivatives. However, in certain cases the deuteriated analogues can be obtained directly in the injection system of the mass spectrometer without subsequent isolation. This procedure makes it possible to work with submicrogramme amounts of the test substance and sharply reduces the time of the investigation. Naturally, only those deuteriation methods are then permissible which ensure the selective introduction of the label into specific positions in the molecule. These requirements are satisfied by the above method in which reaction columns containing KOD are employed.

The mechanisms of the fragmentation of certain aliphatic ketones under electron impact have been investigated with the aid of a reaction column containing KOD dispersed in a stationary liquid phase and deposited on a solid carrier.[36] The starting materials were not the ketones themselves but the corresponding alcohols, which were subjected to preliminary dehydrogenation in a microreactor placed before the reaction column.



The reaction column, which contained $(Ph_3P)_3RhCl$ dispersed in Carbowax 20M on Chromaton and ensured the selective addition of deuterium to the double bonds of olefins under catalytic conditions, was used to investigate the mechanisms of the fragmentation of cyclobutane hydrocarbons.[44] The initial substrates employed were methylene-, vinyl-, and propylene-cyclobutanes. When these were passed through the above column in a stream of hydrogen or deuterium, the corresponding saturated hydrocarbons and their vicinal dideuterio-analogues were formed according to the mass-spectrometric data. Comparative analysis of the mass spectra permitted the conclusion that the $M^{\ddagger}$ species derived from the alkylcyclobutanes can decompose in both intact cyclic and acyclic forms. The decomposition of the former ensures the characteristic division of the ring "in half" with elimination of the $C_2H_4$ molecule. On the other hand, the elimination of any alkyl radical takes place after the isomerisation of $M^{\ddagger}$ to the open-chain acyclic form. The results obtained also indicate a low probability of the existence of the cyclobutyl cation in the gas phase.

The fragmentation of 1,1-dimethyl-1-silacyclopentane, 1-ethyl-1-methyl-1-silacyclobutane, and ethyltetraethoxysilane was investigated by an analogous procedure. Together with the corresponding dideuterio-analogues, these compounds had been obtained from 1,1-dimethyl-1-silacyclopent-3-ene, 1-methyl-1-vinyl-1-silacyclobutane, and triethoxyvinylsilane respectively.[45]



## V. INVESTIGATION OF HETEROGENEOUS CATALYTIC REACTIONS

The use of the microreaction technique and chromato-mass-spectrometry opens up wide prospects for the investigation of the pathways and mechanisms in heterogeneous catalytic reactions. In the course of a single experiment, it is possible to record by this method the chromatogram of the mixture of products (used for the quantitative estimation of the composition) and to obtain mass spectra permitting the high speed determination of the structures of the products. Although microreactors have been used for a long time in the study of catalytic reactions in combination with gas chromatography, this approach has not yet been as widely adopted in chromato-mass-spectrometry as it should despite its one significant advantage—it permits investigations using labelled compounds. The possibility of investigating by the RCMS method of reactions such as hydrogenation, dehydrogenation, hydrogenolysis, deoxygenation, etc., using deuterium is of undoubted interest. At present one can point to only one study where this method has been used to determine the mechanism of a heterogeneous-catalytic reaction and where its advantages have been fully manifested. It concerned the investigation of the mechanism of the hydrogenation of alicyclic ketones on a fused iron catalyst in a pulse microreactor → separating column → mass-spectrometer system.[46]

The hydrogenation of carbonyl compounds is known to proceed via the addition of hydrogen either to the carbonyl group (the ketone mechanism) or to the double bond of the corresponding enol (the enol mechanism). If the reaction takes place in a deuterium atmosphere, the isotopic forms of the alcohols (A) and (B) should arise respectively when these mechanisms operate:

In a direct mass-spectrometric study of the alcohols formed, it is not possible to establish reliably their isotope composition owing to the low intensity of the $M^{\ddagger}$ peaks, the presence of the peaks of the $[M-H]^+$ ions, and also the reverse D/H exchange of the active hydrogen atoms in the mass spectrometer. It has therefore been suggested[46] that the alcohols be silylated with the aid of BSTFA directly in the separating column. In this case the silyl ethers (A′) and (B′), with different numbers of D atoms which can be readily determined mass-spectrometrically, are then formed from the alcohols (A) and (B):

A special reactor containing an additional inlet for BSTFA was constructed for studies by the above procedure; in order to avoid the poisoning of the catalyst, the silylating agent was introduced into the gas stream beyond the catalyst layer but before the inlet into the chromatographic column.

Calculation of the isotope composition of the silyl ethers of the alcohols taking into account the isotope composition of the unreacted ketone established that the hydrogenation of cyclopentanone and cyclohexanone in the presence of the above catalyst in the temperature range 50–210 °C proceeds with equal probabilities via the enol and ketone mechanisms.

In carrying out such investigations, one must bear in mind that during chromatography different isotopic forms can be eluted in different ways (the forms enriched in deuterium are eluted more readily), although in the general

case the chromatographic zone is not resolved. In order to determine the true isotope composition, it is in this case necessary to scan repeatedly in the course of the elution of the test substance. The calculation is in this case based on the overall mass spectrum.

## VI. PYROLYTIC CHROMATO-MASS-SPECTROMETRY

The combination of pyrolytic methods with chromato-mass-spectrometry (PCMS) can be used for different purposes. In the first place PCMS is an effective procedure for the investigation of the mechanisms of the thermal decomposition of organic compounds.[47,48] From the standpoint of analytic possibilities, the application of the PCMS method to the study of the structures of high-molecular-weight compounds is of greatest interest. For the qualitative analysis of the composition of the pyrolytic reaction mixture, the PCMS method is much more effective than the pyrolytic mass-spectrometric method. However, it is not always suitable for the determination of the quantitative composition, because the volatility of the pyrolysis products may be low and they may not be eluted from the chromatographic column or their molecular weight may exceed the limit of the molecular weights detectable by the mass spectrometer. Nevertheless in some cases it is possible to establish by this method both the qualitative and the quantitative composition of the pyrolytic reaction mixture.[49]

The same pyrolysers (pyrolysers based on the Curie point and filamental and tubular pyrolysers) are used in PCMS as in pyrolytic mass-spectrometry or pyrolytic gas chromatography.[3,4]

In terms of the speed of analysis, PCMS is inferior to pyrolytic mass spectrometry, but the level of structural information obtained in the former case is undoubtedly much greater. The determination of the structures of the pyrolysis products and on that basis also of the structures of high-molecular-weight compounds can be evidently facilitated by using the additional chemical methods discussed above.

The efficiency of the method has been demonstrated in relation to the study of polychloroprene, polyisoprene, a polynitrile, and other industrial elastomers.[50] In the study of the copolymers of acrylonitrile and styrene by this method using a capillary column, the monomers, dimers, and trimers were identified mass-spectrometrically.[51] Analysis of the data obtained made it possible to infer the sequence of units in such polymers.

Very important information, of both theoretical and practical value, has been obtained in the study of coal by the PCMS method.[52] Various saturated and unsaturated hydrocarbons, aromatic hydrocarbons, and phenols were identified among the pyrolysis products.

Although the pyrolytic mass-spectrometric method is used widely in the study of biopolymers, there have been virtually no studies using the PCMS method for this purpose. This is most likely to be due to the high polarity of the pyrolysis products formed, which are poorly eluted in gas-chromatographic separation. Presumably the use of intracolumn derivatisation will render such objects susceptible to analysis also by the PCMS method. In addition, the PCMS method using liquid chromatography may prove to be promising for the investigation of biopolymers.

# Outer-sphere Complexes in Analytical Chemistry

V.V.Kuznetsov

Published data on the use of outer-sphere complexes, formed from coordinatively saturated inner-sphere complexes and ligands, cationic species, or molecules of organic solvents present in the outer sphere, in present-day analytical chemistry have been reviewed. The characteristic features of the outer-sphere complexes, namely their relatively low stability and low activation energy for reactions in the outer sphere, together with their variety, make these complexes effective for the separation, isolation, and more particularly determination of inorganic and organic substances. The consequent improvement in the sensitivity, selectivity, and speed of analytical determinations has been discussed.
The bibliography contains 277 references.

## INTRODUCTION

In recent years there has been a considerable increase in interest in the practical application of outer-sphere complexes (OC) and the concepts of outer-sphere coordination in analytical chemistry. This is related to the need to solve a large number of urgent practical problems, which requires considerable improvement of traditional methods and techniques of analysis, based on non-trivial approaches and new theoretical concepts. Significant improvement of the sensitivity and selectivity, lowering of the detection limits, and decrease in the time taken for analysis can be achieved using the chemical-analytical properties of OC. There are practically no published reviews of the use of OC in analytical chemistry, however. The information in the published review[1] and monographs[2,3] deals mainly with the use of OC only in the photometric analysis of inorganic substances, whereas the role of OC in present-day analytical chemistry is much more significant and varied.[4] Progress in the chemistry of OC[5-11] makes it impossible to re-examine published data on the interesting analytical possibilities provided by this group of compounds.

Outer-sphere complex formation is used to obtain analytical information on the object of analysis not only in photometry[3,12-14] and fluorimetry,[3,13-17] but also in extraction methods,[13,18-20] ionometry,[21-24] and chromatography.[25-28] OC are also used in the trace analysis of elements,[29] in methods for concentrating micro-elements,[30-32] in the chemistry of organic reagents,[3] and in the analysis of various organic substances.[33-35] They are used as analytical forms in crystal-microscopy,[36] qualitative and gravimetric analysis,[37,38] titrimetry,[39,40] work in aqueous-organic solutions,[39-44] automatic analysis,[45-47] and in other situations.[48,49] The analytical use of OC therefore constitutes a fairly

extensive and independent field of application of complex compounds in analytical chemistry. The unique nature of the chemical-analytical properties of OC is determined by the characteristic features of coordination in the outer sphere and by the thermodynamic properties of these compounds. It is therefore appropriate to examine briefly those aspects of the chemistry of OC of greatest importance for analytical purposes.

## II. THE CHARACTERISTIC FEATURES OF OUTER-SPHERE COMPLEXES—THE BASIS OF THEIR ANALYTICAL APPLICATIONS

Published definitions of OC are not unambiguous. Usually, OC are defined as compounds formed by the attachment of electrically neutral[2] or charged[3] ligands to a coordinatively saturated complex. The features emphasised range from the absence of a bond between the outer-sphere ligand and the central atom[5,10,50–53] to the identification of OC with ion pairs.[54–56] The ambiguity of the definition was eliminated in a paper[57] which reflects the many years' experience of the Leningrad school in the study of outer-sphere complex formation. The fundamentally important fact is that an OC is formed by an inner-sphere complex, saturated with respect to its coordination number, and *any* species in the outer sphere. A new direct chemical bond with the central atom of the original reagent is not formed, since the reaction in the outer sphere and the direct chemical bonding take place between the ligands of the inner sphere and the species in the outer sphere. The species of the outer sphere can be described in general terms as ligands—electron pair donors or acceptors[59]—possibly reflecting present-day concepts of the coordinate bond.[60] A characteristic feature of OC is their definite stability towards solvolytic dissociation in polar solvents, characteristic of complex compounds in general.[61]

Ion pairs differ from OC;[53,57–59] ion pairs are produced as a result of the Coulombic interaction of partly or completely solvated ions, whereas OC are formed by a donor–acceptor interaction and show appreciable signs of covalent bonding.[58] The change in the potential energy of the system with change in the distance between the ions in ion pairs is smooth. In the ionisation of OC, however, it is necessary to overcome a potential barrier, whose magnitude is determined by the activation energy,[62] which is low for reactions in the outer sphere.[8,56,57] Thus it is possible in principle for ion pairs and OC to coexist in solution.[53]

The coordinating centre of OC of interest for analytical chemistry are usually inner-sphere cationic or anionic complexes[7,8,10] or neutral chelates.[26,27] The variety of outer-sphere species, which may be anionic complexes[63] or the neutral molecules of organic reagents or solvents,[11] which have electron-donor properties, or the cations of organic bases,[57] which have electron-acceptor properties, is apparently responsible to a large extent for the fairly extensive occurrence of OC. The characteristic features of these compounds used in analysis cannot be attributed entirely to electrostatic interaction. OC also differ from anisotropic[2,10] and mixed-ligand[3] complexes, although this is not always taken into account in the examination of their analytical applications.[1] The anionic complexes of metals, forming the coordination centres of the corresponding OC, do not always contain the number of acido-ligands specified by the coordination number of the metal ion.[5,57] Outer-sphere complexes containing complex forms of the same metal in the inner and outer coordination spheres have been called polycomplexes.[64] The inclusion of OC among the so-called "super-complexes"[65] has been regarded as inappropriate.[10]

The problem of the nature of the chemical bond in the outer sphere is complex. Donor–acceptance interaction makes the most important contribution, and the electrostatic contribution constitutes only part of the outer-sphere forces.[8,11,53,56–59,66] In general, it is recommended that account be taken of ion–dipole interaction, hydrogen bonding, covalent bonding, forces of structure formation in the solvent, dispersion forces, and the influence of external electric fields.[56] Problems of outer-sphere coordination and its experimentally detectable effects in solutions and crystals have been examined.[8–11,14,56–59,66,67]

The three-dimensional delocalisation of one-electron states, a characteristic of the coordinate bond,[60] is revealed by the fact that the points of contact between the outer-sphere ligands and the inner-sphere complexes are usually the points with the highest effective charges of the interacting species.[10] The appearance of or a change in a charge-transfer band in the electronic spectra of OC are regarded as fairly clear signs of outer-sphere coordination.[8,10,57,58] Charge transfer is due to the mixing of the wavefunctions of closely situated excited and ground states, so that in the systems being considered it corresponds to a greater or lesser covalent contribution to the chemical bonding in the outer sphere. This phenomenon has been described, for example, for a large number of OC based on metal–phenanthroline complexes[3] and the OC of hexammineruthenium(III) with various substituted pentacyanoferrates.[68]

The stereoselectivity of outer-sphere complex formation by Λ-(+)- and Δ-(−)-tris(ethylenediamine)cobalt(III) with the Δ-(glycinato)bis(oxalato) cobaltate(III) anion,[69] the localised attachment of fluoride and chloride ions in the outer sphere of hexasolvates of aluminium in methanol and ethanol,[70] and the outer-sphere coordination of pyridine molecules to the hexasolvate of cobalt(II) in deuteriated methanol, established by spin–lattice relaxation,[71] can also be related to the appearance of covalent interaction in the outer sphere. The specific nature of the outer-sphere forces, associated with charge transfer to antibonding orbitals of the inner-sphere complex and with dispersion interaction, is also confirmed by the explanation for the increase in the stability of the OC of tris(2,2′-bipyridyl)cobalt(II) with ammonia, methylamine, and ethylamine with increase in the complexity of the ligand.[72] The three-dimensional oriented solvation of the molecules of coordinatively saturated transition metal chelates by organic solvents determines the energetically most favourable position of the ligands in the outer sphere of these OC.[11] The calculated effects of the redistribution of electron density in hexakis(dimethylformamide)iron(III) and hexakis(dimethylthioformamide)iron(III) perchlorates differ considerably.[73]

Among OC with an electron-acceptor species in the outer sphere, the compounds of greatest interest for analytical chemistry are those formed by metal acido-complexes with the outer-sphere cations of onium compounds and basic organic dyes, referred to in the literature as ionic associates. Recent papers[67,74–76] indicate that electrostatic theories cannot explain the properties of these compounds. The covalent contribution to the bonding in the outer sphere in these systems is indicated, in particular, by the interpretation of the charge-transfer bands in their electronic spectra.[67] Data of this kind have been published, for example, for the compounds formed by anionic halogeno-complexes of copper(II), iron(II), cobalt(II), mercury(II), palladium(II), and silver with the doubly-charged cation of N,N′-dimethyl-4,4′-bipyridyl,[74] for the OC of hexacyanoferrate(II) ions with the cations of various heterocyclic

amines,[75] for the OC of pentacyanoferrate with coordinated dimethyl sulphoxide and pyridine molecules[76] and for other similar complexes.[77] The outer-sphere coordination of electron-pair acceptors by hexacyanoferrate(II,III) ions is indicated by the displacement of the half-wave potential to more positive values.[53] The specific nature of the inter-ionic interaction of 2-octylpyridine with various anions is revealed by the decrease in the polarisation of the π-electron cloud of the aromatic cation and the formation of hydrogen bonds with them, in particular with the tetrachlorogallate ion.[67]

There is practically no corresponding published information on compounds with the acceptor species of a basic dye in the outer sphere. It has been suggested that there are localised contacts between the cations of these dyes and anions as a result of the irregularity of the electron density distribution in the former and the increase in the contribution of ion–dipole interaction to the chemical bonding.[3] Other factors possibly of importance are the type of hybridisation of the atomic orbitals in the acido-complex, which determines its geometry; the difference in the electronegativities of the central metal atom and the donor atom of the inner-sphere ligand, which determines the distribution of the atomic charges in these anions;[78] and the increase in the stability of the OC as a result of the forces of structure formation in the solvent.[79] This is consistent with data on the stability of compounds of $BF_4^-$ (calculated charge on the fluorine atom −0.63[78]) with the cations of basic dyes. The stability constants (lg β) of OC increase in the order Methyl Green, Fuchsine, Malachite Green, Brilliant Green, Crystal Violet: 1.8, 2.0, 2.0, 2.6, and 3.2 respectively.[80] The OC with the most symmetrical species in the outer sphere has the highest stability. The stability of the OC of $SbCl_6^-$ with the cation of Crystal Violet is noteworthy; this complex is decomposed completely only in concentrated ammonia.[13]

The stability constants of the outer-sphere compounds of cationic complexes of metal ions with various ligands have been systematised.[10] Most of the data relate to compounds based on inert inner-sphere complexes of $Co^{III}$ and $Cr^{III}$. There is much less published information on the OC of iron(II,III), nickel(II), and the platinum metals,[10] and for OC formed by neutral chelates with the molecules of organic solvents in the outer sphere.[11] The literature on analytical chemistry contains no examples of the practical application of the tabulated stability constants of OC.

The concentration stability constants of various OC formed by the aquo-ions of the alkali and alkaline earth metals with polyatomic anions in aqueous-organic solutions[81] are provisional, since they were calculated without allowance for side reactions. In these systems, because of the lability of the coordination centre, it is particularly important to distinguish the effects of outer-sphere and inner-sphere complex formation; this is an extremely complex problem, which has not been fully resolved.[8]

The specific nature of the properties of OC as chemical compounds determines their practical importance in analytical chemistry.

## III. THE CHEMICAL-ANALYTICAL PROPERTIES OF OUTER-SPHERE COMPLEXES

In analytical chemistry, outer-sphere complex formation reactions and OC themselves are used in various methods for the qualitative detection, quantitative determination, isolation, and separation of inorganic ions and organic substances.

### 1. Principal Fields of Application of Outer-Sphere Complexes

The analytical application of OC depends on processes in solution in which these complexes are reaction products or, less frequently, the starting materials. The use of OC in analysis is determined by their characteristic properties, which enable these compounds to be the material carriers of analytical signals. These characteristic properties are low solubility in water and higher solubility in organic solvents; characteristic crystal shape; the ability of OC, containing the element being determined, to be coprecipitated; intense absorption in the visible or ultraviolet ranges of the spectrum or bright fluorescence; and the ability of OC to undergo flotation at the interface between two immiscible solvents or extraction into an organic phase. Another form of application of OC involves the production of an indirect analytical signal by a change in the concentration of the ions forming the OC, or its fulfilment of a "transmitting" function with respect to this signal by the selective ionisation of the OC in the outer sphere, often in conjunction with a dynamic process. This becomes possible because of the low thermodynamic stability of OC and the low activation energy of ligand replacement processes in the outer sphere. OC and the reactions involved in their formation are therefore used to produce indirect analytical signals in titrimetric methods with different techniques for establishing the end point—photometric,[39–44,82] amperometric,[83,84] conductometric,[85] potentiometric,[82] and others.[86,87] These characteristic features of OC play an important role in their use as electrode-active materials in the membranes of liquid ion-selective electrodes, in extensively repeated sorption and desorption processes in chromatographic separation systems, and in the rapid formation of OC in flow-type automatic analysers.

An intense analytical signal resulting from the formation of OC, for example their strong absorption or bright fluorescence, makes it possible to achieve a fairly low detection limit.[12–17] The marked dependence of the properties of OC on the nature of the metal ion and the inner- and outer-sphere species often makes it possible to achieve a high selectivity in the determination. Examples can be found in various fields of application of OC—ionometry,[21–24] ligand-exchange[25,88] and other forms of liquid chromatography,[26–28,69,89,90] and titrimetry in aqueous-organic solutions.[39–44]

OC with inert and labile inner coordination spheres have different chemical-analytical properties, and this must be taken into account in analytical practice. The situation is simpler in the first case, since in the analytical determination the OC dissociates only in the outer sphere. In the second case, dissociation of the OC in the inner sphere is also possible, and to suppress this and to ensure the maximum yield of the analytical form, an excess of the inner-sphere ligand is added to the solution.

Dilute aqueous solutions of most salts of *s*-, *p*-, and *d*-block elements, in which the anions are most frequently singly charged, contain only OC at concentrations below the limit of complete solvation.[8] Many reactions, therefore, for example complex formation[2,8,57,91] and redox reactions,[92,93] pass through a stage involving the decomposition of the OC of the aquo-ions of the metals and (or) the formation of intermediate OC. The formation of these OC as sources of analytical signals has no practical value, so that the kinetic role of OC is not examined in the present review.

The analysis of published data on the analytical applications of OC makes possible their systematisation, apparently for the first time. The results are given in Table 1, which shows the great variety of types of OC finding practical applications, although their use is not equally important in different analytical methods. Specific examples are examined below.

### 2. The Precipitation of Sparingly Soluble Outer-Sphere Complexes

The inner-sphere complexes of metals have low hydration energies, so that they can react with fairly large outer-sphere counter-ions to form neutral OC which are relatively sparingly soluble in water. This characteristic feature of OC was apparently first used by Bjerrum to separate thiocyanate complexes of chromium(III) by precipitating with quinolinium sulphate.[94]

Table 1. Fields of application of outer-sphere complexes in analytical chemistry.[1-4,12-28,30-35]

| Outer-sphere complex | | outer-sphere species |
|---|---|---|
| Fields of application | coordinating centre | |
| $ML_n^{x+}$, $ML_{n-k}L_k^{*x+}$ | $A^{y-}$, $R^{y-}$ | ph, e.ph, fl, e.fl, p, g, e, c, i.ch |
| » | $M^*X_m^{y-}$, $M^*X_{m-k}A_k^{y-}$ | ph, e.ph, p, g, lig.ch |
| $MQ_q^{x+}$ | $A^{y-}$, $R^{y-}$, $M^*X_m^{y-}$, $M^*R_n^{y-}$ | ph, e.ph, fl, e.fl, c, i, flot, p, g, i.ch |
| $MQ_q$ | *m*Solv, HO—Si≡ | e, liq.ch |
| $M(OH_g)_n^{x+}$ | $A^{y-}$, $M^*X_m^{y-}$, $\mathscr{M}-A^{y-}$ | aq-org, i.ch |
| $M^{x+}\cdot$Solv | $A^{y-}$, $M^*X_m^{y-}$ | e, aq-org |
| $MX_m^{y-}$, $MX_{m-k}X_k^{*y-}$ | $D^{x+}$ | e.ph, e.fl, flot. c, i |
| » | $B^{x+}$, $Z^{x+}$ | e, flot, c, i |
| » | $\mathscr{M}-B^{x+}$ | i.ch, lig.ch |

Notation: M = metal, L and Q = unidentate and multidentate ligands, A = outer-sphere ligand, R = anion of coloured reagent, X = acido-ligand, $D^{x+}$, $B^{x+}$, $Z^{x+}$ = cations of a basic dye, an organic base, and an onium compound respectively, ≡ = ion-exchanger matrix, HO—Si = silica gel, Solv = organic solvent; ph = photometry, e.ph and e.fl = extraction photometry and extraction fluorimetry, fl = fluorimetry, p = precipitation, g = gravimetry, e = extraction, c = coprecipitation, flot = flotation, i = ionometry, aq-org = reactions in aqueous organic solvents, lig.ch, i.ch, and liq.ch = ligand-exchange, ion-exchange, and liquid chromatography.

Quantitative data on the solubility of sparingly soluble OC, usually in the range $10^{-3}$–$10^{-5}$ M, are rarely used as a basis for their analytical application. They are most frequently determined by studying the OC equilibrium by the solubility method,[95,96] or the thermodynamics of transfer.[97,98] The least soluble OC are important in analysis. The solubility of OC in water is lower, the larger their component fragments. For example, at 25° the solubility of hexamminecobalt(III) oxalate is $3.9 \times 10^{-4}$ M,[99] and that of octammine-μ-aminohydroxodicobalt(III) chloride sulphate is $10^{-7}$ M.[100] The solubility of OC can be calculated from the solubility product;[95,96,101,102] more accurate determination requires allowance for the stability of the OC in solution and the contribution of side reactions of the coordinating centre and the outer-sphere ligands.[102] With increase in the ionic strength of the solution, the solubility of OC increases slightly.[95,96,102] The compounds of metal acido-complexes with outer-sphere organic cations, containing larger species, are less soluble. For example, the solubility of the OC of $CdI_4^{2-}$ with Chromopyrazole is $0.87 \times 10^{-3}$ M, and that with Chromopyrazole II is $7.2 \times 10^{-6}$ M.[103] The more hydrophobic the inner- and (or) outer-sphere species, the greater the solubility of the OC in an aqueous-organic solvent.[98]

The precipitation of OC is widely used in the identification of ions[37,38] and pharmaceutical products,[33] crystal-microscopy,[36] gravimetric analysis, and different forms of precipitation titration, and to separate elements. A particular field of application is the concentration of micro-elements by coprecipitation and flotation.

The element being determined is most frequently present in OC in the inner-sphere complex, and less frequently as the outer-sphere species. Data on OC used as gravimetric forms are given in various sources, including a series of monographs.[49,82,84,86,104-124] The directed selection of the ligands or species of the outer and inner coordination spheres makes it possible to achieve the required analytical effect relatively easily. Thus hexamminecobalt(III) is used for the gravimetric determination of anionic forms of beryllium,[107] cobalt,[82] chromium(III),[110] indium,[111] phosphorus,[115] rhodium(III),[86] and uranium,[122] and the outer-sphere coordination of organic bases by the anionic complexes of elements makes it possible to determine silver,[104] gold,[105] cadmium,[109] mercury,[84] zinc,[124] and other metals.[86,117,121,123] The use of OC in gravimetric analysis extends the possibilities provided by the method and makes it possible to obtain gravimetric forms with a high molecular mass, decreasing the conversion factor and increasing the accuracy of the analysis, particularly in the determination of small quantities of elements. For example, it is possible to determine down to 5 mg of silver or molybdenum as $[Co(en)_2 \cdot (SCN)_2][Ag(SCN)_2]$ (en = ethylenediamine) and $[Cr(NH_3)_5 \cdot Cl](MoS_4)$ respectively[104,114] or down to 2 mg of palladium as $[Pd(SCN)_4][(C_4H_9)_4N]_2$.[116] In qualitative reactions the detection limit is fairly low, amounting to fractions of a microgram.[36-38]

The precipitation of OC is in general not very selective. It is possible to achieve selective precipitation by using different combinations of ligands in complex inner- and outer-sphere species. For example, nickel, copper, iron(III), zinc, and cobalt do not interfere in the determination of gold as bis(trimethyl)hexamethylenediammonium bromoaurate.[105] The gravimetric determination of uranium as $[Co(NH_3)_6]_2[UO_2(CO_3)_2](H_2O)_3(NO_3)_2$ is highly selective.[122] Selective precipitation is used to isolate and separate various elements; for example the precipitation of sulphates by octammine-μ-aminohydroxodicobalt(III) chloride for their indirect photometric determination,[100] the separation of tellurium from selenium as $[Te(phen)_3]X_4$ (phen = 1,10-phenanthroline, X = $Cl^-$, $Br^-$),[125] tantalum from niobium as $[Fe(phen)_3](TaF_7)$,[126] and niobium from tantalum by precipitating $[Fe(phen)_3][NbO_2(C_4H_5O_5)_2]$ from tartrate solution.[127]

Precipitation titration methods based on the formation of sparingly soluble OC, with different means of establishing the end point, are widely used, for example to determine cobalt,[82] silver,[85,104] platinum,[86] anionic complexes of cadmium,[109] tin,[119] mercury,[84] boron, iron(III), gold, and other elements using quaternary ammonium bases[87] and onium salts.[128] High sensitivity in the determination is achieved in the amperometric titration of $BiI_4^-$ with the protonated 8-quinolinol cation[83] and of zinc with thiocyanate ions in the presence of diantipyrinylmethane and its analogues, and even in the visual titration of $Zn(SCN)_4^{2-}$ with Chromopyrazole.[124]

Indirect titrimetric methods based on the preliminary precipitation of OC[108,109,112] have now lost their importance. It is possible, however, to determine down to 15 μg bismuth by precipitating as $[Bi(SCN)_6][(C_4H_9)_4N]_3$ after treating

the precipitate with hydrogen carbonate and titrating thiocyanate ions in an amplification reaction which gives 114 moles of iodine per mole of metal.[129]

OC are effective for concentrating elements. The marked structural similarity between various sparingly soluble OC and the corresponding organic collectors[31] ensures a high degree of coprecipitation of elements in the outer or inner coordination spheres. For example, 90% plutonium(IV) is coprecipitated as the OC of $Pu(NO_3)_6^{2-}$ with the Butylrhodamine cation using Butylrhodamine nitrate as collector; the detection limit is 0.02 μg Pu in 200 ml of solution. The same degree of separation is achieved for silver as the OC formed by its dithizone chelate with azo-dye anions in the outer sphere, and also for other elements as various OC.[31] In the coprecipitation of cobalt, molybdenum, zinc, and lanthanides with salts of antipyrine dyes in the presence of thiocyanate ions, competition between the ligands for a place in the inner sphere, and the formation of two types of coprecipitated OC, are possible.[130,131] The OC of metal–phenanthroline complexes with singly-charged anions in the outer sphere are effectively coprecipitated with AgX (X = $Cl^-$, $Br^-$, $I^-$, $SCN^-$), making it possible to achieve an absolute concentration enrichment coefficient of $10^3$.[132]

Various OC with hydrophobic species in the inner or outer spheres have amphiphilic properties, so that they can be concentrated by flotation, usually with photometric analysis in the final stage. The flotation of OC based on metal–phenanthroline complexes has been examined in a monograph.[3] By carrying out this process at the interface between water and a mixture of toluene and carbon tetrachloride, using the bismuth–Alizarin Red–Brilliant Green system, it is possible to determine down to $10^{-4}$% bismuth in arsenic salts with a detection limit of 0.5 μg Bi in 25 ml of solution.[133]

Examples of the use of sparingly soluble OC in analytical chemistry are given in Table 2.[49,86,110,112,130–136]

### 3. Outer-Sphere Complexes in Photometry and Fluorimetry

The OC used in photometric and chemical luminescent analysis are extremely varied, because of the ready production, on the basis of these compounds, of analytical forms (see Table 1) showing strong absorption in the visible and ultraviolet ranges of the spectrum, or bright fluorescence. The absorbing centre in these OC may be the inner-sphere complexes (the coordination unit of the OC), the outer-sphere species, or both partners of the photometric reaction. Fluorescence is most frequently produced in outer-sphere cations. The element being determined is usually in the inner-sphere complex, and is less frequently a component of the outer-sphere species. Coloured and fluorescent OC are usually extracted by organic solvents, and this makes it possible to carry out multiple extraction-photometric and extraction-fluorimetric determinations.[1–3,12–17,33,34,137–142] The compounds formed are usually ionic associates. The inadequacy of traditional views of these compounds has been noted in an examination of the properties of the OC of metal–phenanthroline complexes with various outer-sphere ligands.[2,3] In recent years there has been a greater tendency to regard the production of the analytical forms being considered here as the result of the interaction of complex electronic systems, and not individual oppositely charged ions.

In photometry and fluorimetry, extensive use is made of OC with the molecules of heterocyclic polyamines in the inner sphere; the wide range of outer-sphere ligands in these complexes makes it possible to develop an extremely large number of methods for determining various elements.[3,14] The nature of the outer-sphere ligands in these OC is important, since it determines the ability of the analytical form to undergo extraction, and the selectivity of the determination. The high extractability of $[Fe(phen)_3]X_2$ (X = $BF_4^-$, $ClO_4^-$), which in the case of the perchlorate ion correlates with the stability of the OC,[143] has been used to determine these anions.[49,85] The detection limit for various elements, achieved using OC, is fairly low, for example 0.07 μg Co in 6 ml of solution in the determination of cobalt as the OC of its phenanthroline complex with hydroxyxanthene dyes[144] or $10^{-5}$ μg Ru in 1 ml of solution in the determination of ruthenium(II) as $[Ru(phen)_2]Cl_2$ by a luminescent method.[145] In the last case the covalent hydration of the inner-sphere ligand, leading to the formation of the carbinolamine, increases the fluorescence of this OC. The possibility of cooperation (that is outer-sphere coordination of ligands in the OC of metal–phenanthroline complexes with dye anions, which excludes the mutual displacement of ligands, has been examined.[146] The inner coordination sphere of a coloured OC may be more complex, as observed, for example, in the extraction-photometric determination of iron(III), bismuth, indium, gallium, and various other elements as $[M(PAR)(ANT)_3]ClO_4.nCHCl_3$ (PAR = pyridylazoresorcinol, ANT = antipyrine). The dependence of the extractability of these OC, the optical characteristics of the extract, and the solvation number on the nature of the anion of the outer sphere has been determined.[142] The outer-sphere complexes $[ReO(thur)_3Cl_2]Cl$ and $[ReO(thur)_4.Cl]Cl_2$ (thur = thiourea) have been used as analytical forms in the determination of rhenium;[117] the compound $[BiSO_4.(oxin)_3]X_4$ (oxin = 8-quinolinol; X = $Cl^-$, $Br^-$, $I^-$, $ClO_4^-$, etc.) in the precipitation-photometric determination of bismuth;[147] and $[Co(NH_3)_2(NO_2)_4][(C_6H_{13})_4N]$ in the indirect determination of perchlorates by exchange extraction (from the decrease in the intensity of the colour of the organic phase).[85]

In extraction photometry and fluorimetry, extensive use has been made of associates of anionic complexes of elements with outer-sphere coloured or fluorescent cations of aryl-, diaryl-, and triarylmethane, xanthene, acridine, arylamine, antipyrine, azo, cyanine, and other dyes.[12–17,137–142] The selectivity of the determination depends on the nature of the outer-sphere anionic complex of the element, and its sensitivity on the intensity of the colour of the outer-sphere species. For example, gallium in zinc was determined by converting the element being estimated into an anionic complex with pyrocatechol, followed by extraction as the OC with basic dyes.[148] The detection limits achieved in these methods are extremely low,[8,12–17] for example 0.03 μg $ml^{-1}$ for uranium(VI),[149] 0.02 μg $ml^{-1}$ for scandium,[150] 24 μg $ml^{-1}$ for magnesium,[151] and $10^{-4}$ μg $ml^{-1}$ for gallium (extraction-fluorimetric method).[160,161] Examples of the use of other OC which make it possible to improve considerably the analytical characteristics of reactions[149–167] are given in Table 2.

A correlation is observed between the stability constants of OC and the molecular refraction of the inner-sphere ligands, which is a function of their average polarisability. This confirms the possibility of the outer-sphere coordination of the cations of Rhodamine S by anionic complexes of the lanthanides with substituted salicylic acid and 8-quinolinol,[152] and also other basic dyes in similar systems.[148–153] The displacement of the absorption band in the spectra of these OC is attributed to the difference in their stabilities in the ground and excited states.[15] The hypsochromic shift of 10–20 nm in the spectra of the outer-sphere cations of antipyrine dyes in compounds with $AuCl_4^-$ [158] and of

**Table 2.** Principal fields of application of outer-sphere complexes in analytical chemistry.

| Species being determined | Coordinating centre of the OC | Outer-sphere species | Method of determination* | Refs |
|---|---|---|---|---|

acridine in compounds with $TeBr_6^{2-}$ [134] can then be regarded as proof of outer-sphere association.

The irregular distribution of electron density in dye cations,[3,165,168] which influences the stability of the corresponding OC by non-Coulombic interaction,[85,152] apparently opens up the possibility of a search for the optimum outer-sphere cations for use in the determination of metals as OC based on acido-complexes. For example, in the extraction-photometric determination of lead, best results were obtained using OC formed by the halogeno-complexes of this element with Brilliant Green and Malachite Green ($PbCl_3^-$) or Victoria Blue 4R ($PbBr_3^-$).[156] Examples of increase in the complexity of the outer-sphere species of OC used as analytical forms are provided by the compounds of $BiI_4^-$ with the phenylhydrazone-1,3,3'-trimethyl-2-formylindolinium cation,[164] of $SbCl_6^-$ with Phenosafrazo Blue,[165] and other compounds.[141]

The anionic coordinating centre of OC, in addition to acido-ligands, may sometimes also contain other species contributing to its coordination saturation. Examples of such systems are the OC of $AuCl_3(OH)^-$ with Chromopyrazole,[158] of $SbCl_5(OH)^-$ with the cations of triarylmethane dyes,[3] of $PdX_3(H_2O)^-$ (X = $SCN^-$, $I^-$, $Br^-$, $Cl^-$) with the cation of Brilliant Green,[155] and of $PbX_3^-$.Solv (X = $Cl^-$, $Br^-$; Solv = benzene, toluene, pentyl acetate) with the cations of triphenylmethane dyes.[156] The OC of $AlF_2F_2^{3-}$ (R = Xylenol Orange) with tri-n-octylamine has been used for the extraction-photometric determination of fluorine.[169]

The difference in the stabilities of labile OC makes exchange of outer-sphere species possible. For example, exchange between the cation of Crystal Violet in its OC with $SbCl_6^-$ and the cations of antipyrine, diantipyrinylmethane, and its analogues, and also trioctylamine, has been used for their determination.[13]

An original type of coloured OC is represented by the compounds of anionic complexes of elements with organic reagents and with the outer-sphere cations of surface-active substances (SAS). In this case a marked improvement in the analytical characteristics of the reactions in aqueous solution is achieved by the complex effects of hydrophobic interaction.[170,171] The outer-sphere complexes formed by the anionic compounds of disulphodecylfluorene with molybdenum(VI), tungsten(VI), germanium, titanium(IV), and tin(IV) with outer-sphere cations of the N-cetylpyridinium type have been characterised as outer-sphere chelates.[172] The sensitivity and selectivity of the reactions in these systems are much better than in those examined above. For example, in nickel and its alloys it is possible to determine $3 \times 10^{-5}$% antimony as the OC of its trihydroxyfluoronate with the N-cetylpyridinium cation in the outer sphere.[173]

The stability of OC towards ultraviolet radiation has not been specially studied, but the ability of iron(III) as $[Fe(phen)_3X_n]$ (X = $ClO_4^-$, $C_2O_4^{2-}$) to undergo photochemical reduction has been used for its determination.[48] The photometric study of mercury-catalysed ligand exchange in $Fe(CN)_6^{4-}$ to give OC based on iron(II)–phenanthroline complexes has made it possible to determine down to 200 ng $ml^{-1}$ of the catalyst element.[29]

Examples of the use of OC in photometry and fluorimetry[174–185] are given in Table 2.

## 4. Outer-Sphere Complexes in Extraction

The extraction of OC is used to isolate or separate elements and in mixed methods of analysis. In general it is possible to draw a parallel between the coordinative unsaturation of the compound extracted, the necessity of which is one of the basic postulates of extraction theory,[186] and the state of the metal ion in the coordinating centre of the OC, when the inner-sphere ligand occupies the energy gap between the central atom and the outer-sphere ligand. This makes it possible to formally compare the properties of the OC being considered in this section with the properties of other extractable compounds. The lack of data on the stability of extractable OC towards solvolytic dissociation in polar solvents creates certain difficulties in applying the concepts of outer-sphere coordination in extraction chemistry, but the available experimental data[67] indicate that this approach is promising.

The use of OC in extraction can be examined on the basis of the type of compound transferred to the organic phase[18,30,32] or on the basis of the characteristics of the extraction process.[19] In the first case, the OC may be various coordinatively non-solvated salts, that is compounds of the type $[Fe(phen)_3](ClO_4)_2$, $[Ca(TBP)_m](SCN)_2$, $[Tl(TBP)_3(H_2O)]Cl_4$ (TBP = tributyl phosphate); compounds of metal solvates, for example $(Mg.Solv)Cl_2$, $(Ca.Solv)(SCN)_2$; and the compounds of acidocomplexes with organic cations, examined above.[18,30,32] The significant covalent contribution to the chemical bond in the outer sphere is revealed by the anomalously high distribution coefficients, as for example in the extraction of tetrachlorogallate by 2-octylaminopyridine.[67] Many extractable compounds of anionic complexes of metals—halide and thiocyanate,[13,14,18,19,187] less frequently nitrate,[20] carbonate,[188] and others[14,110,113]—with the cations of organic bases, of considerable importance in analytical chemistry, are apparently OC.

In the second case it is possible to consider from the viewpoint of outer-sphere complex formation the processes involved in the cation- and anion-exchange extraction of cationic and anionic inner-sphere coordinatively saturated complexes respectively.[19] The outer-sphere coordination of the molecules of organic solvents by neutral metal chelates, distinguished by its orientational specificity and discrete character,[11] makes it possible to relate their extraction, and also the forms of various adducts used in analytical chemistry,[3] to these phenomena.

Synergic extraction in various systems can also be related to the formation of OC. Thus the formation of stable adducts, essentially OC, observed in the extraction of europium by thenoyltrifluoroacetone in the presence of quinolinium cations in cyclohexane, benzene, carbon tetrachloride, and chloroform, increased the extraction constant by a factor of about $10^5$.[189] The formation of a compound containing the inner-sphere complex of uranyl ions with di-(2-ethylhexyl) phosphate and a molecule of a crown ether in the outer sphere made possible the synergic extraction of the element into nitrobenzene.[190]

Competing processes in the outer sphere can explain the suppression, usually interpreted in terms of the "common ion" mechanism, of the extraction of indium from bromide solutions containing the cations of Brilliant Green into benzene in the presence of thallium(III), or the decrease in the extraction of thallium(III) from chloride solutions into chloroform with Crystal Violet in the presence of mercury.[191]

The extraction of OC is used for the effective separation of elements,[30,32,192] including platinum metays with similar properties.[193,194] Various analytical methods are used to determine the elements after their separation or extraction, for example titrimetric (after the separation of zinc and cadmium by extraction from halide solutions by dipyrazolonylmethane[195]), atomic emission (after the extraction of gold(III) and thallium(III) by Chlorex[196]), flameless atomic absorption (in the determination of thallium(III) in sedimentary rocks[197]), and radiometrically (after concentrating iridium and rhodium

by 2-octylaminopyridine,[198] thallium(III) by alkyldiamines,[199] and other elements by methyltrioctylammonium chloride[200]). Small quantities of silver can be determined by an extraction-catalytic method based on the catalytic oxidation of Bromopyrogallol Red (BPR) by persulphate in the presence of 1,10-phenanthroline and extraction of the catalyst [Ag.$(phen)_2$]BPR by nitrobenzene.[29] Examples of the use of OC in extraction[49,195–202] are given in Table 2.

### 5. Outer-Sphere Complexes in Ionometry

The properties of various OC correspond effectively to the requirements to be satisfied by electrode-active materials in membrane liquid ion-selective electrodes (ISE). These requirements include low solubility in water, ready extractability into an organic solvent, ensuring that the OC is in the membrane phase of the liquid ISE, and the ability of the OC to undergo selective ionisation in the outer sphere, resulting from the low activation energy of this process.

These properties are shown by, for example, the OC, dissolved in nitrobenzene, of the phenanthroline complexes of iron(II), nickel, and various other metals with different anionic outer-sphere ligands. Depending on the nature of the outer-sphere ligand, it is possible to prepare ISE for determining $NO_3^-$, $BF_4^-$, $ClO_3^-$, $ClO_4^-$, $IO_4^-$, $ReO_4^-$, and various other anions.[21–24] Since the rate of exchange of a transition metal on a membrane surface is much lower than the rate of anion exchange, the potential of the ISE is determined by the activity of the corresponding outer-sphere ions in the solution. The selectivity of ISE of this type generally decreases in the order $PF_6^- > ClO_4^- > SCN^- > I^- > BF_4^- > NO_3^- > Br^- > Cl^-$, and this can be related to the change in the stability of the OC.[21] A large number of examples of ISE with membranes containing compounds of this type have been described.[203–206]

Electrode-active properties are shown by solutions of the dimethylphenanthroline complex of copper(I) with sulphate and picrate ions in the outer sphere in dibutyl phthalate. This made it possible to develop ISE for the determination of these cationic complexes of copper(I).[24,207] Similar properties are shown by solutions of OC based on thiourea complexes of silver and gold(I) in nitrobenzene, chlorobenzene, and 1,2-dichloroethane.[24,206,208] An electrode with a membrane based on a silver complex can also show an electrode function with respect to phosphate ions.[203]

Electrode-active properties are shown by various OC of anionic halide and pseudohalide complexes of metals with different organic anions in the outer sphere, capable of undergoing solvolytic dissociation in polar organic solvents such as *o*-dichlorobenzene, decan-1-ol, etc.[21,24,204,209–216] ISE of this type are used in flow injection methods in automatic chemical analysis.[46,47]

Additional information on the use of OC with different coordinating centres as electrode-active substances in membrane liquid ISE are given in Table 2.

### 6. Outer-sphere Complexes in Chromatography

The low activation energy of the replacement of outer-sphere ligands in OC makes it possible to carry out this process under the dynamic conditions of various forms of liquid chromatography with extensive repetition of sorption and desorption processes in new layers of sorbent. In different specific cases the stationary phase may be associated either with the coordinating centre of the OC (inner-sphere complex) or with the outer-sphere ligand. The concepts of outer-sphere coordination can be used in ion-exchange, ligand-exchange, and extraction chromatography and in the liquid chromatography of coordinatively saturated metal chelates. The possibility of carrying out "fine" separations of mixtures of substances and concentrating elements is of practical importance. An infrared spectroscopic study of the characteristic features of cation-exchange resins with sulphonate functional groups showed that during ion-exchange sorption on a sulphonic acid cation exchange resin, characteristic OC of the metal aquo-ions with the solid polyelectrolyte in the outer sphere are formed.[217] The formation of OC is also the first stage of the exchange of metal ions in complex-forming ion exchangers.[28] The anion exchange of halide, pseudohalide, nitrate, and other complexes of various metals on anion exchange resins involves the formation of OC.[218,219] In this case the anionic complexes react with the cationic groups of the quaternary ammonium bases of the ion exchange resin, that is with outer-sphere species fixed in the stationary phase. Ion-exchange processes have proved to be effective for the group concentration of micro-quantities of transition metals[220] as their phenanthroline complexes on a polyfunctional outer-sphere ligand (KU-2 cation exchange resin), and is also a convenient method for separating the phenanthroline complexes of nickel, iron(II), and ruthenium(II) on modified silica.[221]

The difference in the stability of OC based on $[Co(en)_3]^{3+}$ with anionic ligands leads to differences in their retention times in the anion exchanger phase, and this has made it possible to separate mixtures of oxalates and sulphates[222] and fumarate and maleate ions.[223]

An even finer chromatographic separation can be achieved by the highly selective method of ligand-exchange chromatography, based on outer-sphere ligand exchange.[25] This makes it possible to separate mixtures of compounds with very similar properties, for example the optical isomers of kinetically inert complexes of chromium(III) and cobalt(III) and various other metals by chromatography on dissymmetric sorbents, or racemates of the tris(oxalato)-compounds of cobalt(III) and chromium(III) as their OC with the cations of brucine, quinine, or cinchonine by electrophoresis.[25] Optically active metal complexes can be used for the enantioselective coordination of asymmetric species in the outer sphere, and this makes it possible, for example on silica gel modified by N-aminoethylaminopropyl groups and Λ-(+)-$[Co(en)_2(NO_2)_2]^+$, to separate respectively the racemates of organic acids and the tris(oxalato)-compounds of cobalt(III) and chromium(III).[224] The modification of silica gel by chloroamine complexes of cobalt(III) makes possible the chromatographic separation of dinucleotides and cephalosporins.[225] The stereoselectivity of outer-sphere complex formation on Sephadex A-25 has been used to separate the racemates of (glycinato)bis(oxalato)cobaltates(III).[69]

The concepts of outer-sphere coordination are actively used in the interpretation of the mechanism of the separation of neutral coordinatively saturated metal chelates by liquid adsorption chromatography in chloroform, di-isopropyl ether, and other solvents with medium polarity.[26,27,89,226–229] The chromatographic properties of the chelates of metals with acetylacetone, benzoylacetone, dibenzoylmethane, dibutyldithiophosphinate, and other multidentate ligands depend on the structure of the ligand fragment peripheral to the chelate unit. The difference in the mobility of these chelates is attributed to the formation of hydrogen bonds between a peripheral electronegative atom of the ligand and the surface

hydroxide groups of the sorbent,[26,27] that is outer-sphere coordination.

Since in organic solvents neutral metal chelates are present as OC,[11] the chromatographic process being considered can be regarded as a characteristic ligand exchange of the outer-sphere molecules of organic solvents with the surface groups of the sorbent.

The concepts of OC formation can also be used in the extraction chromatography of anionic metal complexes,[90,230] as in the case of anion-exchange extraction.[19] The formation of outer-sphere compounds of anionic chloro-complexes of iron(III), copper, cobalt, and other elements in the trioctylamine in toluene—Fluoroplast system has made possible the selective concentration of micro-quantities of these elements. They were determined with a detection limit of $10^{-6}$–$2 \times 10^{-5}$% by flame atomic absorption or emission spectroscopy.[231] The use of high-pressure liquid chromatography for complex analytical purposes has been examined.[232]

## 7. Outer-Sphere Complexes in Organic Analysis

The electron-donor or electron-acceptor properties of the molecules or ions of organic compounds make it possible to attach them as outer-sphere species to coordinatively saturated metal complexes to give OC used as analytical forms. Since the organic compounds considered here have an anionic or cationic function in solution, the pH must be selected to obtain OC. For analytical purposes, use is generally made of the low solubility of OC in water, or their ability to be extracted into an organic solvent. The actual determination is carried out by titrimetric, photometric, atomic absorption, radiometric, and other methods. An example is the determination of aliphatic and aromatic sulphonates.[233]

The outer-sphere compounds of iron(II) chelates with heterocyclic diamines and alkyl sulphates have been used for the sensitive determination of small quantities of these outer-sphere anions.[234] Even greater sensitivity and variety are shown by methods for the extraction-atomic absorption determination of organic substances with an anionic function, such as sulphonates, aminoacids, carboxylic acids, antibiotics, and other compounds from the atomic absorption by copper(II), cobalt(II), cadmium, and nickel[35] in the coordinating centre of the OC.

Various organic compounds with a cationic function can be determined as OC containing anionic inner-sphere metal complexes. OC of this kind are formed in the detection of xanthene dyes by precipitating their cations with $SbCl_6^-$, $AuBr_4^-$, and other anionic complexes; in the detection by extraction of higher aliphatic acids in paraffin wax and vaseline from the formation of coloured compounds of $[UO_2(RCOO)_3]^-$ with the cations of basic dyes;[235] and in the identification of biotin by the reaction with $PtI_6^{2-}$, of thiamine and Vitamin B with $HgCl_4^{2-}$, of the hexamethonium cation with $CdI_4^{2-}$ and other similar compounds.[33] The low solubility of complexes of $[Cr(SCN)_4(NH_3)_2]^-$ with outer-sphere cations has been used to detect pyridostigmine and carbocholine,[33] and also in the photometric determination of aniline, betaine, brucine, caffeine, morphine, pilocarpine, and other compounds as the corresponding OC, dissolved in acetone after precipitation and filtration.[34] It is more convenient to carry out the extraction-photometric determination of various amines as their OC with $Co(SCN)_4^{2-}$.[34] The quantitative determination of alkaloids, aminoquinoline, cationic surfactants, and other organic compounds of similar character by atomic absorption after extraction of their OC with Reinecke's salt or $Co(SCN)_4^{2-}$ appears promising.[35]

In some specific cases the method of analysis in the final stage may be simpler, for example titrimetry in the determination of thiamine as its OC with $BiI_4^-$.[236] The outer-sphere coordination of alcohols by vanadium(V) 8-quinolinolate in chloroform or benzene has been used for their photometric determination.[34] Down to 2 μg of albumin can be determined by making use of its ability to lower the catalytic activity of $[Co(NH_3)_4(H_2O)_2]_2(SO_4)_3$ in the chemiluminescent reaction of luminol with hydrogen peroxide.[237]

## 8. Outer-Sphere Complexes in Aqueous-Organic Solutions

Aqueous-organic solvents are binary systems which have complex compositions and in which the influence on the solute is complex.[56] In aqueous-organic solutions, metal aquo-ions can hold various outer-sphere ligands more firmly than in water, as a result of hydrogen bonding, and this is of considerable importance for analytical practice.[39,40,44,238,239] In some cases the selection of the metal aquo-ions acting as the coordinating centre of the OC can be based on the concept of localised hydrolysis.[44,238,239] From general considerations,[8] superposition of the effects of outer-sphere and inner-sphere coordination is possible in this case, but this does not influence the analytical results achieved.

The formation of outer-sphere complexes by metal aquo-ions with anionic ligands in aqueous-organic solutions is used to mask interfering reactions, in the indirect photometric determination of sulphates,[239] sulphites, and hydrogen phosphates,[240] and, most effectively, in indicator spectrophotometric titration.[42,241,242]

The masking of the reaction of barium with bis(azo)-derivatives of chromotropic acid as a result of the formation of stable OC $[Ba(OH_2)_6]SO_4$ [239] in aqueous acetone and aqueous ethanol solutions can be used to improve the selectivity of the photometric determination of the alkaline earth metals.[243] The same method is used to mask barium in the photometric determination of strontium in barium salts.[244] The formation of OC of this type is particular widely used in methods for the indirect photometric determination of sulphates,[245,246] in their spectrophotometric titration,[247–249] and also in the indicator spectrophotometric titration of mixtures of microgram quantities of barium and strontium.[250] The high rate of formation of these OC makes the corresponding reactions suitable for the sensitive automatic determination of sulphates. The productivity of this analysis reaches 60 specimens per hour,[45] and the information efficiency is very high, 433 byte $h^{-1}$.[239]

Outer-sphere complexes of similar type, formed by barium aquo-ions in aqueous-organic solutions, can also apparently contain the structural analogues of sulphate ions—selenate, chromate, molybdate, fluoroberyllate, and other complex anions of elements of groups IV–VI. This makes possible the selective spectrophotometric titration of micro-quantities of these elements by barium salts in aqueous acetone and aqueous acetonitrile solutions.[241,251–255]

The formation of neutral OC by barium aquo-ions with the anions of various aromatic sulphonic acids, aliphatic sulphonates, and sulphates in aqueous acetone solutions opens up extensive possibilities for the determination of organic compounds containing the corresponding functional groups, by indicator spectrophotometric titration with barium salts.[39,42,44] Of particular interest are methods for the selective determination of various sulphonates of the benzene,[256] naphthalene,[238,257–259] and anthraquinone[260] series, which also make it possible to analyse mixtures of sulphates with any sulphonates, and the mixtures of isomeric products obtained in industrial processes, and this is of considerable

practical importance.[42] Sensitivity and selectivity are also shown by similar methods for determining alkyl and alkylaryl sulphonates and alkyl sulphates,[261,262] and also substances containing a thiol group, for example cystine, cysteine, Captax, and others, after their oxidation to sulphonates by hydrogen peroxide in an alkaline medium.[263] Aromatic sulphonates can be titrated without interference from sulphate ions using solutions of potassium salts in aqueous acetone,[264] where the formation of neutral OC by aquo-ions of potassium with the sulphonates is possible. The aquo-ions of other alkaline earth metals can be used to determine alkyl phosphates, aryl arsenates, and carboxylates by this method.[265]

The solvated potassium ion can undergo outer-sphere coordination with various polyatomic and complex anions in aqueous dimethyl sulphoxide solutions.[40,43,266] This has been shown by spectroscopic and polarographic studies of fluorocomplexes of group V elements.[41] In general, the formation of OC of this type is related to the characteristic features of the behaviour of the dimethyl sulphoxide molecule in the solvate layer of the potassium ion. The coordination of the dimethyl sulphoxide molecule to metal ions through the oxygen atom leads to an increase in the strength of the $S^+ \rightarrow O^-$ $\sigma$-bond and to slight polarisation of this bond. This increases the ability of the coordinated dimethyl sulphoxide molecules to undergo ion–dipole interaction with outer-sphere anionic ligands, and leads to the formation of relatively stable outer-sphere associates, suitable for titrimetric determinations.

The materials determined by spectrophotometric titration with potassium salts in aqueous dimethyl sulphoxide solutions are outer-sphere ligands consisting of the anionic fluorocomplexes of the elements of groups III,[266,268–270] IV,[271] and V[41,272–274] of the periodic system, perrhenates,[275] chlorates, perchlorates,[276] chloro-complexes of palladium(II), platinum(IV),[43,277] and ruthenium(IV),[267] and other polyatomic anions.[242]

The methods developed are highly selective in the analysis of mixtures of elements with similar properties, for example tantalum and niobium,[272,273] uranium and thorium,[270] and palladium and platinum,[43,277] for the determination of chlorates and perchlorates,[276] and in other cases.[242] The absence of interference from hydrolysis, hydrolytic polymerisation, and masking reagents makes these methods convenient in practice. These methods have found practical application in the analysis of minerals,[254] glasses,[253] alloys,[43,268,271] fertilisers,[269] electroplating bath electrolytes,[266] and other materials.[248,274]

The use of OC formation in spectrophotometric titration is illustrated in Table 2.

## IV. SUMMARY

The material presented indicates the intensive development of the application of OC in various fields of present-day analytical chemistry, associated with their flexibility and variety in the production of appropriate analytical signals. The achievements have been most significant in the development of new sensitive and selective methods of analysis associated with the direct use of OC or the reactions involved in their formation. Examples are provided by interesting applications in analytical concentration, extraction-photometric and extraction-fluorimetric methods, ionometry, titrimetry in aqueous organic solutions, and ligand-exchange chromatography. The further development of the analytical applications of OC should lead to new methods for determining elements and organic compounds, showing a high selectivity combined with the necessary sensitivity. These may be, for example, original photometric and fluorimetric methods, ion-selective electrodes for doubly-charged anionic complexes of elements and organic ionophores, methods for the spectrophotometric titration of elements as anionic pseudohalide complexes, "fine" effects of separation in ligand-exchange chromatography, and new methods for the automatic analysis of solutions.

A characteristic feature of the present state of the analytical chemistry of OC is the practical absence of, and hence urgent need for, quantitative data on the stability of these compounds; this is to a considerable extent preventing the possible achievement of maximum pragmatic effects in the development of new methods. The problem of estimating the contribution of outer-sphere interaction to complex-formation equilibrium in labile analytical systems, particularly in aqueous-organic solutions, is most complex. Further studies in this field should apparently find an adequate solution.

# Polyiodo-iodates Containing Five or More Iodine Atoms

B.D.Stepin and S.B.Stepina

The results of theoretical and experimental studies of the chemistry of polyiodo-iodates—complexes of iodine containing five or more iodine atoms in the anion—have been reviewed. The molecules of heterocyclic compounds with a planar configuration, chelates of *d* elements with macrocyclic planar ligands, and organic and inorganic polymers containing cavities and channels, on oxidation with iodine, tend to form compounds with polymeric anions in the form of quasi-one-dimensional chains. New ideas on iodine as a complex-forming species have been examined.
The bibliography contains 222 references.

## I. INTRODUCTION

Polyiodo-iodates containing five or more iodine atoms not only may be discrete, $[I_5]^-$, $[I_7]^-$, $[I_9]^-$, and $[I_8]^-$ but also may form chains containing as units the anions $[I_3]^-$ and $[I_5]^-$.[1-7] The study of the correlation between the interatomic distances and valence angles in polyiodo-iodate anions, and the analysis of vibrational and rotational spectroscopic data, indicate that there is a genetic relationship between the structures of these anions and the structure of the $[I_3]^-$ anion.[4,6] Aqueous and non-aqueous solutions contain chiefly anions with composition $[I_3]^-$, whose formation constants have been determined fairly accurately. The formation of $[I_5]^-$ anions in non-aqueous solutions has been assumed. The existence in solution of hepta-iodide and nona-iodide anions and anions with a chain structure has not been reliably established, however. These anions are apparently formed in the layer next to the surface in a crystallising substance during the establishment of the most stable structures, involving repeated transfer of the cations and anions from lattice sites to the solution and back again. The stability of the anions decreases from $[I_5]^-$ to $[I_9]^-$, the external conditions remaining constant.[8] Polyiodo-iodate anions readily undergo changes in structure and composition under the influence of even slight changes in the environment.

Subsequent sections examine present-day ideas on the nature of polyiodo-iodate anions.

## II. PENTA-IODIDES

Penta-iodides contain the $[I_5]^-$ anion.[1] An anion with this composition has been detected in tetra-alkylammonium[9-15] and quinuclidine[16] compounds, in the iron complexes $[Fe(Et_2S_2.CN)_3][I_5]$,[17] $\{[Fe(C_5H_5)(C_5H_4)]_2Se\}[I_5]$,[18] and $[Fe(C_{10}H_9)].[I_5]$,[19] and in various ammines[20-22] and ethylenediamine complexes,[23] although in the last two groups of compound the composition of the anion was established only by chemical analysis, and not always qualitatively.[20-23]

A study[3] of the reaction of dithizone with molecular iodine showed that the crystal structure of the polyiodo-iodate formed contains dimers with the composition $[(\text{dithizone})I]^+-[I_5]^--I_2-[I_5]^-[(\text{dithizone})I]^+$ with an angular (85.5°) $[I_5]^-$ anion.

In all the systems, studied up to the present, of the type $MI-I_2$ and $MI-I_2$–solvent at 0–25 °C (M = K, Rb, or Cs), an $M[I_5]$ phase was not detected.[24-31] A very small region corresponding to the crystallisation of the incongruently melting (+9.8 °C) $(NH_4)[I_5]$ was detected only in the $NH_4I-I_2-H_2O$ system at 0 °C.[32] In the systems $(NR_4)I-I_2-C_6H_6$ (or $C_6H_6CH_3$) at 6 °C and 25 °C, the phase $(NMe_4)[I_5]$ is formed.[33] This compound also crystallises in the $(NMe_4)I-I_2$ system.[34]

The evidence[35] for the possible formation of the incongruently melting compounds with the composition $[M(NH_3)_4][I_5]_2$ (M = Zn or Cd) in $[M(NH_3)_4]I_2-I_2$ system is not unambiguous.[4] The logarithms of the formation constants (lg β) of the $[I_5]^-$ anion in the reaction:

$$[I_3]^- + I_2 \rightleftarrows [I_5]^-$$

for different solvents at 25 °C and activity coefficients of the components of the system close to 1 were: $H_2O$ 0.95,[36] $C_2H_5OH$ 1.8,[37,38] $CH_3NO_2$ 1.51, $C_6H_5NO_2$ 2.3–2.8,[8,39] propylene carbonate 1.9.[40] The temperature dependence ($t$ in °C) $\lg \beta = 0.954 + 0.0308(t - 25)$ for aqueous solutions gives for this reaction the values $\Delta G^0_T = -5.4$ kJ mole$^{-1}$ and $\Delta H^0_T = 50.1$ kJ mole$^{-1}$.[36] The thermodynamic characteristics of the reaction

$$(NMe_4)[I_3]\,(\text{crystalline}) + I_2(\text{crystalline}) = (NMe_4)[I_5]$$

are: $\Delta G^0_{298} = -13.4 \pm 0.03$ kJ mole$^{-1}$, $\Delta H^0_{298} = -9.2 \pm 0.4$ kJ mole$^{-1}$, $\Delta S^0_{298} = 13.4 \pm 1.7$ kJ mole$^{-1}$ K$^{-1}$.[41]

The structure of the bis(di-iodine)iodate(−1) anion $[I_5]^-$ is given in Fig.1. The anion has an almost planar (±0.12 Å) *V*-shaped configuration with an angle of 88.2–96.5°. The complex-forming species in the anion is the $I^-$ ion, and the ligands are polarised iodine molecules with an interatomic distance of 2.75–2.93 Å. The $I^--I_2$ bond is weak, and its length is 3.01–3.31 Å.[3,16,17,42-46] The force constant of the

vibrations of the complex-forming species is low ($0.15 \times 10^5$ dyne $cm^{-1}$), and the ion is readily deformed in an unsymmetrical crystal field, forming chain and cyclic structures (Fig.2).[3,16,18,44,45,47]

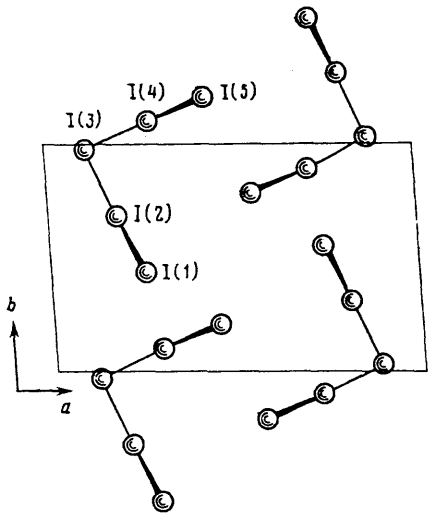

**Figure 1.** Projection of the $[I_5]^-$ anions of the compound $[Fe(Et_2S_2CN)_3][I_5]$ on the *ab* plane:[17] angles: I(1)–I(2)–I(3) = 176.2°; I(2)–I(3)–I(4) = 88.2°; interatomic distances (Å): I(1)–I(2) = 2.799; I(2)–I(3) = 3.148; I(3)–I(4) = 3.015; I(4)–I(5) = 2.837.

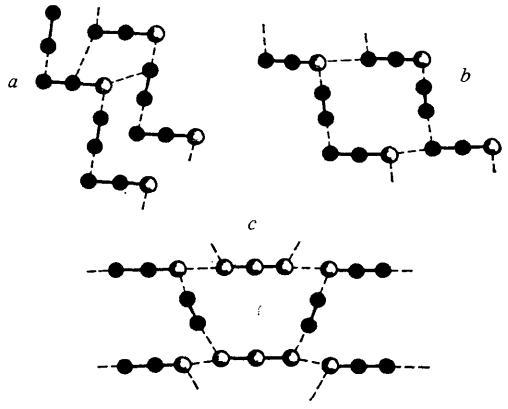

**Figure 2.** Schematic representation of the polyiodo-iodates in various bis(di-iodine)iodates:[18,44] *a*) [(phenacetin)$_2$H][$I_5$]; *b*) [bis(ferrocenyl)selenium][$I_5$].0.5$CH_2Cl_2$; *c*) [(quinuclidine)H][$I_5$]; the black circles denote the iodine atoms of the coordinated iodine molecules.

A calculation[48] of the energies of formation of the $[I_5]^-$ anion in the reaction

$$I^- + 2I_2 = [I_5]^-$$

confirmed its *V*-shaped configuration. The energy for this structure is lower than the energies of formation of the linear, square-planar, and *T*-shaped configurations.

The chemical shifts in the $[I_5]^-$ anion have been examined in terms of six-electron MO, of which the three MO of lowest energy (two bonding and one non-bonding) are completely occupied by electrons. The complex-forming species has an effective charge of −0.5e, and the terminal atoms of the ligands from −0.13e to −0.26e. The iodine atoms directly attached to the complex-forming atom, however, carry positive charges of from 0.08e to 0.11e (from different calculations).[49]

The existence of the $[I_5]^-$ anion as a structural unit is confirmed by data obtained by vibrational spectroscopy,[14] analysis of the nuclear quadrupole resonance spectra,[50] Mössbauer spectroscopy,[51] and X-ray spectroscopy.[52]

The electronic spectra of solutions of compounds containing $[I_5]^-$ anions in acetonitrile and 1,2-dichloroethane ($\lambda_{max}$ = 295 nm, lg ε = 4.65–4.68 and $\lambda_{max}$ = 365 nm, lg ε = 4.40 to 4.42 respectively[10,15]) are identical to those of polyiodo-iodates containing the anions $[I_3]^-$, $[I_7]^-$, and $[I_9]^-$.

The existence of $[I_6]^{2-}$ anions in aqueous solutions[36] and of $[I_6]^-$ anions in the crystalline phase[19] is unlikely.

## III. HEPTA-IODIDES

Hepta-iodides contain the $[I_7]^-$ anion.[1] This anion has been detected in tetra-alkylammonium polyiodo-iodates[14,15,53,54] and various ammines,[20–22] and in dilute solutions containing iodine and lanthanide iodides in molar ratios close to $I^- : 3I_2$.[55,56] Unfortunately, in almost all the works cited the compositions of the bis(di-iodine)tri-iodates obtained by preparative methods were established only from an incomplete chemical analysis, and the formation of the $[I_7]^-$ anion in solution was established using the spectrophotometric version of the Ostromyslenskii–Job method, not applicable in this case.

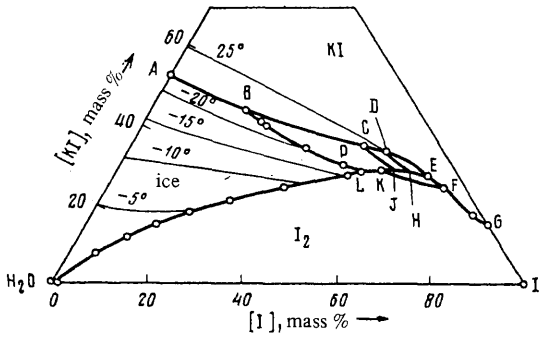

**Figure 3.** Triangular projection of the polythermal equilibrium diagram of the KI–$I_2$–$H_2O$ system;[25] crystallisation fields: K[$I_3$].$H_2O$—DEHD; K[$I_7$].$H_2O$—KJHEFK; α-K[$I_3$].2$H_2O$—BCJKLPB; β-K[$I_3$].2$H_2O$—CDHJC.

The results obtained in a study of a number of systems in which the formation of bis(di-iodine)tri-iodates has been detected are contradictory. Thus in the purely eutectic KI–$I_2$ system, the formation of K[$I_7$] was established erroneously[29] (because of poor experimental technique, part of

the solidus line was taken as an extremely flat liquidus curve). A number of papers describe the study of $KI-I_2-H_2O$ systems,[24,25,27,29–31,57] but the only apparently reliable data are those in Refs.25, 31, and 57 on the existence of $K[I_7].H_2O$ (Fig.3), although in this case also the individuality of the new phases was not confirmed by chemical methods of analysis.

Studies of $MI-I_2-C_6H_6$ systems (6 °C and 25 °C, M = K or Rb) have shown that phases containing the $[I_7]^-$ anion always crystallise as the following solvates, which decompose readily in air: $K[I_7].2C_6H_6$,[29,57] $Rb[I_7].4C_6H_6$, and $Rb[I_7].2C_6H_6$ (Fig.4). This apparently explains the contradictory conclusions regarding the existence of the solvate $K[I_7].2C_6H_6$.[26,28,29,33,57] Compounds containing the $[I_7]^-$ anion were not detected in the systems containing CsI.[28,58] The reasons for the non-existence of regions corresponding to the crystallisation of the phases $M[I_5].xC_6H_6$ (M = Rb or Cs) in the above systems, and the appearance of the non-solvated phase $Cs_2[I_8]$ when RbI is replaced by CsI, have not yet been established.

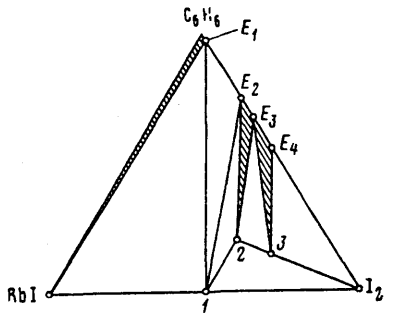

Figure 4. Equilibrium diagram of the $RbI-I_2-C_6H_6$ system, 25 °C:[28] *1*) $Rb[I_3]$; *2*) $Rb[I_7].2C_6H_6$; *3*) $Rb[I_9].2C_6H_6$; compositions of the eutonic points ($I_2$, M): $E_1 = 0.01325$; $E_2 = 0.3425$; $E_3 = 0.393$; $E_4 = 0.545$.

The structure of the $[I_7]^-$ anion is given in Fig.5.[53] The $[I_7]^-$ anion can be represented as the bis(di-iodine)tri-iodate ion $[(I_3)(I_2)_2]^-$, in which the unusual complex-forming species is the symmetrical $[I_3]^-$ anion, to which are coordinated two iodine molecules, which are situated at equal distances (3.43 Å) from the terminal atoms of the central ion and which are weakly bonded to it.[59] The $[I_3]^- - I_2$ distance is slightly less than $I_2-I_2$ distance in crystalline iodine (3.56 Å). The structure of polymeric polyiodo-iodate anions is beginning to form in this anion. The thermodynamic characteristics of the reaction

$$(NEt_4)[I_3]\,(\text{crystalline}) + 2I_2 = (NEt_4)[I_7]\,(\text{crystalline})$$

are $\Delta G^0_{298} = -22.0 \pm 0.6$ kJ mole$^{-1}$, $\Delta H^0_{298} = -23 \pm 1.2$ kJ mole$^{-1}$, and $\Delta S^0_{298} = -3.8 \pm 3$ J mole$^{-1}$ K$^{-1}$.[41]

## IV. OCTA-IODIDES

Octa-iodides are polyiodo-iodates containing the doubly-charged $[I_8]^{2-}$ anion. The following compounds containing this anion have been synthesised: $Cs_2[I_8]$,[28,33,58,60–62] $[(DMX)_2H_2][I_8]$,† [44] $[M(TACD)][I_8]$# (M = Ni, Pd, Pt),[63–65] $[Co(en)_2X_2][I_8]$§ (X = $Cl^-$, $I^-$, $NO_2^-$, and NCS),[66] and $[Ni(en)_3][I_8]$, crystallised from methanol.[67]

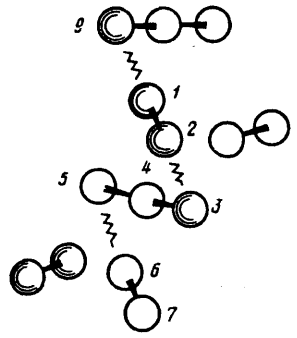

Figure 5. Fragment of the structure of the $[I_7]^-$ anion of the polyiodo-iodate $(NEt_4)[I_7]$ at −175 °C;[53] the hatched iodine atoms are in the same plane; *1*–*7*) iodine atoms in the anion; interatomic distances (Å): I(1)–I(2) = 2.73; I(2)–I(3) = 3.43; I(3)–I(4) = 2.90; I(4)–(I(5) = 2.90; I(5)–I(6) = 3.43; I(6)–I(7) = 2.73.

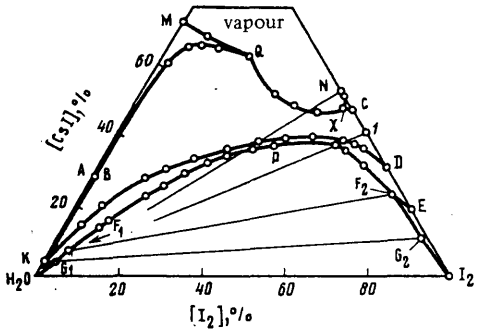

Figure 6. Polythermal equilibrium diagram of the $CsI-I_2-H_2O$ system[62] (pressure 740–750 mmHg, temperature from −5 °C to +305 °C); crystallisation fields: CsI—MQBAM; $I_2$—$EF_2G_2$; $Cs[I_3]$—CXQBKDC; $Cs_2[I_8]$—KDEFPF$_1$K; point N—$Cs[I_3]$; *1*—$Cs_2[I_8]$.

In the $CsI-I_2-H_2O$ system in the temperature range from −5 °C to +305 °C, only two new phases are formed: $Cs[I_3]$ and $Cs_2[I_8]$ (Fig.6). With increase in temperature, the range of crystallisation of the incongruently soluble $Cs_2[I_8]$ decreases, and at 80 °C, a range of separation into layers in the liquid phase appears. The temperature range of the congruent solution of $Cs_2[I_8]$ is very narrow, from 79.5 °C (curve $PF_2$) to 89.0 °C (curve KD). In the range from

† DMX = 3,7-dimethylxanthine.

# TACD = 1,3,5,13-tetra-azocyclohexadecine.

§ en = ethylenediamine.

51.5 °C (isotherm $F_1F_2$) to 79.5 °C (isotherm $PF_2$), $Cs_3[I_8]$ dissolves to give two liquid phases. The field $F_1PF_2$ is the range of the phase equilibrium between $Cs_2[I_8]$ crystals and two liquid phases. According to Ref.68, caesium octa-iodide (but not $Cs[I_5]$) is also formed in the $CsI-I_2$ system (Fig.7), crystallising from the melt below 136 °C. In the $CsI-I_2-C_6H_6(C_6H_5CH_3)$ systems, the largest crystallisation range corresponds to $Cs_2[I_8]$.[28,33,58]

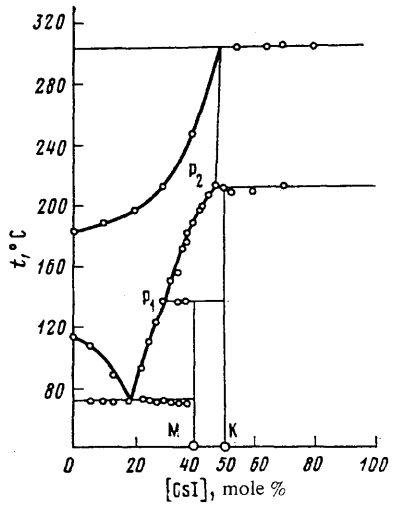

Figure 7. $CsI-I_2$ system (pressure 745 mmHg);[60] coordinates of the point $P_1$: 136 °C (or 141.2 °C [82]) and 30 mole % CsI; M—$Cs_2[I_8]$; K—$Cs[I_3]$.

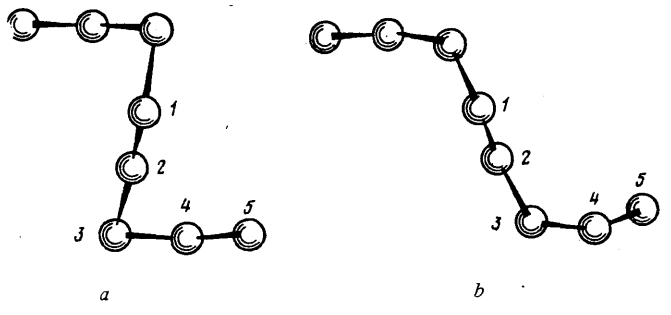

Figure 8. Structure of the $[I_8]^{2-}$ anion;[70,71] *a*) $Cs_2[I_8]$, *b*) $[(CH_2)_6N_4(CH_3)]_2[I_8]$; interatomic distances (Å): *a*) 1–2 = 2.83; 2–3 = 3.42; 3–4 = 3.00; 4–5 = 2.84; *b*) 1–2 = 2.773; 2–3 = 3.386; 3–4 = 3.038; 4–5 = 2.830.

The structure of the $[I_8]^{2-}$ anion is shown in Fig.8. In all polyiodo-iodates studied, the $[I_8]^{2-}$ anion does not have a centre of symmetry and is not planar.[69–71] The complex-forming species in the anion is the strongly polarised iodine molecule, and the ligands are $[I_3]^-$ anions. The $[I_8]^{2-}$ anion is apparently bis(tri-iodido)di-iodate $[(I_2)(I_3)_2]^{2-}$. The representation of the structure of these anions and the separation of their functional parts depend to a large extent on the interpretation of the data on interatomic distances and symmetry. The $[I_8]^{2-}$ anions, when combined with heterocyclic arene cations, can form $[I_{16}]^{4-}$ dimers (Fig.9).[44,63,71] Data on the configurations of polyiodo-iodate anions have been reviewed.[4,72]

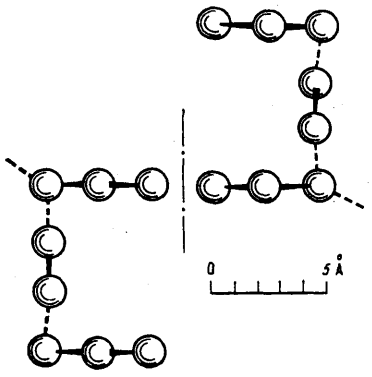

Figure 9. Structure of the $[I_8]^{2-}$ anion in the compound $[(DMX)_2H_2][I_8]$.[44]

The effective charges are +0.08e on the central atoms of the ligands of the $[I_8]^{2-}$ anion, −0.38e on the atoms directly joined to the central iodine molecule, and −0.71e on the terminal atoms.[73,74] Each atom of the central iodine molecule carries a charge of −0.06e.

Studies[75,76] of the thermal stability of $Cs_2[I_8]$ confirmed the results of the structural studies. At 137 °C (or 139° to 140 °C [69]), caesium octa-iodide undergoes incongruent fusion:

$$Cs_2[I_8] \rightarrow \text{melt}\P + Cs[I_3]\,(\text{crystalline}) + I_2(\text{gas})$$

Further heating leads to an increase in the solubility of $Cs[I_3]$ in the melt and hence to a change in the slope of the $\lg p = f(1/T)$ curves, where $p$ is the dissociation pressure, and to the appearance of an inflection at 170 °C. At about 205 °C in the melt, $Cs[I_5]$ decomposes to CsI(crystalline) and iodine. The system after 205 °C is in the same state as in the incongruent fusion of $Cs[I_3]$ (Fig.10), and this explains why the enthalpy changes for the volatilisation of iodine from the two melts practically coincide (46.9 kJ $mole^{-1}$).[75]

The thermal analysis curves for $Cs_2[I_8]$ indicate that the complex decomposes in two stages when heated in air under conditions allowing the free removal of the dissociation products:

$$Cs_2[I_8]\,(\text{crystalline}) = 2Cs[I_3]\,(\text{crystalline}) + I_2(\text{gas})$$

(the start of the inflection on the DTG curve corresponds to 42 °C, and the maximum to 96 °C) and

$$Cs[I_3]\,(\text{crystalline}) = CsI(\text{crystalline}) + I_2(\text{gas})$$

(start of the inflection 107 °C, maximum 158 °C).

---

¶ The melt presumably contains CsI and $I_2$ in the ratio corresponding to the composition $Cs[I_5]$.

Thus the rupture of the chemical bonds in the $[(I_3)-I_2-(I_3)]^{2-}$ anion can take place in two ways: the two bonds may break simultaneously, or only one of them may break to give the ions $[I_5]^-$(liquid) + $[I_3]^-$(crystalline).

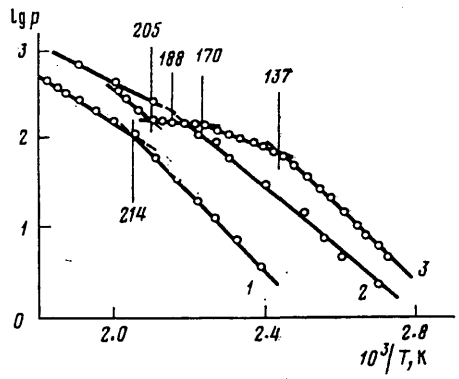

Figure 10. Temperature dependence of the dissociation pressure of polyiodo-iodates:[75,76] *1*) $Cs[I_3]$; *2*) $Rb[I_3]$; *3*) $Cs_2[I_8]$; the temperatures of the phase transformations are given in °C.

The kinetics of the first stage of the thermal dissociation of $Cs_2[I_8]$ in air, described by the equations $dm/d\sigma = km^n$ and $k = Z_0 \exp(-E/RT)$, where $m$ is the mass of the specimen, $\tau$ the time, $k$ the reaction rate constant, $n$ the order of the reaction, $E$ the apparent activation energy, and $Z_0$ the pre-exponential term, are characterised by the quantities $E = 79.1 \pm 1.2$ kJ mole$^{-1}$, $Z_0 = (1.3 \pm 0.4) \times 10^{11}$ min$^{-1}$, $\lg k = 11.114 - 4130/T$ (for $n = 1$).[77,78] Thus the rate of the thermal dissociation is determined by the rate of the diffusion of iodine through the interface. Increase in the decomposition temperature displaces the process into the kinetic range ($n \geq 1$). The dependence of the frequency factor $Z$ on the order of the reaction is given by the equation $Z = Z_0 m_0^{1-n}$, where $Z_0$ is the frequency factor for $n = 1$, and $m_0$ the original number of moles of $Cs_2[I_8]$.

The thermodynamic characteristics of the reaction

$$Cs_2[I_8]\text{(crystalline)} = 2Cs[I_3]\text{(crystalline)} + I_2\text{(crystalline)}$$

are: $\Delta G^0_{298} = 2.6$ kJ mole$^{-1}$, $\Delta H^0_{298} = 3.3$ kJ mole$^{-1}$, and $\Delta S^0_{298} = 2.5$ kJ mole$^{-1}$ K$^{-1}$.[79]

## V. NONA-IODIDES

Nona-iodides are polyiodo-iodates containing the $[I_9]^-$ anion. The appearance of phases with this anion has been established only in the study of non-aqueous systems: $(NMe_4)I-I_2-C_6H_6(C_6H_5CH_3)$ at 6 °C and 25 °C [33] and $MI-I_2-C_6H_6$, where M = K, Rb, or Cs at 25 °C [26,28,29] (the phases $K[I_9].3C_6H_6$, $Rb[I_9].2C_6H_6$, and $2Cs(I_9].3C_6H_6$). In the opinion of Popov and co-workers,[15] in certain organic solvents, for example acetonitrile, the formation of $[I_9]^-$ anions is impossible, because of their complete electrolytic dissociation.

In the $(NMe_4)I-I_2$ [34] and $[Ni(NH_3)_6]I_2-I_2$ [80] systems, the formation of phases with the compositions $(NMe_4)[I_9]$ and $[Ni(NH_3)_6][I_9]_2$ has been established. The conclusion[28,81] that the phase $Rb[I_9]$ may be formed in the $RbI-I_2$ system appears doubtful.[82,83] A large number of syntheses of tetra-alkylammonium nona-iodates has been carried out.[10,11,14,54,84] The data given in Refs.54 and 84 on the compositions of the complexes appear doubtful, however, because of the unsatisfactory methods of chemical analysis.

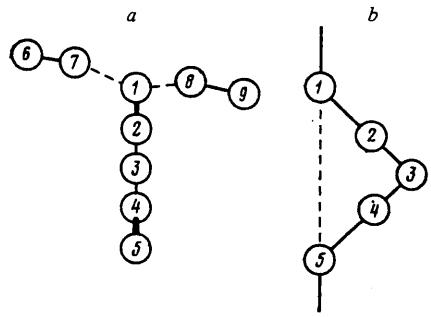

Figure 11. Structure of the $[I_9]^-$ anion in the complex $(NMe_4)[I_9]$;[85] *a*) view from above; *b*) view from the side; interatomic distances (Å): 1–2 = 3.18; 2–3 = 2.90; 3–4 = 3.24; 4–5 = 2.91; 6–7 = 2.67; 8–9 = 2.67; 7–1 = 3.43; 8–1 = 3.24; angle 2–3–4 = 86.5°.

Up to the present, only the structure of $(NMe_4)[I_9]$ (Fig.11) has been studied in detail.[85] The anion contains as complex-forming species the $[I_3]^-$ ion, which coordinates three iodine molecules, two of which lie in the same plane and have interatomic distances which are almost the same as in crystalline iodine. The third iodine molecule is strongly polarised. The unusual arrangement of the ligands is also apparently responsible for the asymmetry and bending of the complex-forming species. This anion can be provisionally regarded as the tris(di-iodine)tri-iodate anion $[(I_3)(I_2)_3]^-$. The thermodynamic characteristics of the reaction

$$(NMe_4)[I_5]\text{(crystalline)} + 2I_2\text{(crystalline)} = (NMe_4)[I_9]\text{(crystalline)}$$

are $\Delta G^0_{298} = -8.9 \pm 0.4$ kJ mole$^{-1}$, $\Delta H^0_{298} = -1.3 \pm 0.8$ kJ mole$^{-1}$, and $\Delta S^0_{298} = 25.9 \pm 2.5$ J mole$^{-1}$ K$^{-1}$.[41]

The reported existence of the polyiodo-iodate $(NMe_4)[I_{10}]$ [33] in the $(NMe_4)I-I_2-C_6H_5Me$ system at 6 °C appears doubtful.

## VI. UNDECA-IODIDES

The possible formation of a polyiodo-iodate containing the $[I_{11}]^-$ anion has been demonstrated in only one paper,[33] describing a study of the $(NMe_4)I-I_2-C_6H_5Me$ system at 6–25 °C. According to these data,[33] a phase with the composition $(NMe_4)[I_{11}]$ crystallises over a fairly wide iodine concentration range: 2.27–9.41 mass % at 6 °C, and 3.53–14.7 mass % at 25 °C. In aqueous ethanol (95%) solutions, tetramethylammonium undeca-iodide is stable only in an extremely narrow iodine concentration range.

The structure of the $[I_{11}]^-$ anion has not been determined, but it may be assumed that it is similar to that of the $[I_9]^-$ anion, except that the inner sphere contains four iodine molecules, two on each end of the $[I_3]^-$ ion.

A study of the $[Ln(ur)_5]I_3-I_2-H_2O$ † systems (0 °C and 25 °C), where Ln represents various lanthanides, detected [85–88] the formation of only one new phase, with the composition $[Ln(ur)_5]I_3.4I_2.10H_2O$, which separated as large acicular hexagonal crystals, incongruently soluble in water. The suggestion that this compound contains the $[I_{11}]^-$ anion has not been confirmed. The new phase apparently contains either the $[I_5]^-$ ion ($[Ln(ur)_5I][I_5]_2.10H_2O$) or chain anions built into the cation matrix.

Anions with the composition $[I_{13}]^-$ have not been detected in any of the polyiodo-iodates synthesised. The preparation of substances with anions containing more than 13 iodine atoms is even less likely. The reaction of iodine with ferrocene in acetone or chloroform gives a black powder with the composition $[Fe(C_5H_5)_2].10I_2$, which decomposes when heated to 170 °C to give iodine and ferrocene, [19] but the actual nature of this substance is still not known.

Thus discrete polyiodo-iodate anions contain not more than 5–7 iodine atoms. The $[I_9]^-$ and $[I_{11}]^-$ anions are rather oligomeric chain anions. If conditions are created for a further increase in the number of iodine atoms in the anion, the latter becomes polymeric, and consists chiefly of $[I_3]^-$ and $[I_5]^-$ ions.

## VII. POLYIODO-IODATES WITH CHAIN ANIONS

The tendency for iodine molecules to form chain polyiodo-iodate anions $[I_x]^-_\infty$ ($x$ = 3, 5, or 7) is often observed when the molecules of substances reacting with iodine have a planar configuration and are able, after oxidation, to form a "stacked" structure containing cavities and channels with dimensions and geometry comparable with those of the polyiodo-iodate chain. [89]

When the chains are not commensurate with the framework of the substance, the latter contains solvent molecules in its channels, as established [90] for the crystals of [(TMA).0.09H][$I_5$].0.7$H_2O$.# The polyiodo-iodate chains in this complex consist of $[I_5]^-$ ions (Fig.12), and do not have a fixed position. In other polyiodo-iodates, some of the channels are occupied by iodine chains, and some by solvent molecules, for example $[Pd(bqd)_2][I_x].0.5C_6H_4Cl_2$.§ [91]

In various organic and inorganic polymers containing cavities of appropriate size, the cavities can be occupied by quasi-one-dimensional chains of iodine atoms.

A polyiodo-iodate chain generally consists of $[I_3]^-$ or $[I_5]^-$ ions or their various combinations. Less frequently, the chains contain $[I_7]^-$ ions. If the chains containing $[I_3]^-$ ions are represented as ...I(1)–I(2)–I(3)...I(1)–I(2)–I(3)..., it may be assumed that the distance I(1)–I(2) and I(2)–I(3) vary in the range $R - \delta$, and the distances I(3)...I(1) in the range $R + 2\delta$, where $R$ = 2.95–3.28 Å, and $\delta$ = 0.15–0.35 Å. The most stable structure is that with linear chains, in which $R$ = 3.2 Å and $\delta$ = 0.15 Å. [92] For linear chains containing $[I_5]^-$ ions, ...I(1)–I(2)–I(3)–I(4)–I(5).....I(1)–I(2)–....., the interatomic distances I(1)–I(2) are $R - \varepsilon$, and the distances I(2)–I(3) and I(3)–I(4) are $R + \delta$, and the most stable structure is that with $\varepsilon$ = 0.5 Å. [92]

The channels of the stacked structures are not always completely filled by the chain anions. For example, in (TTF)[$I_x$]¶ they occupy only 40–50% of the volume, [93] so that the chain anions have little influence on one another.

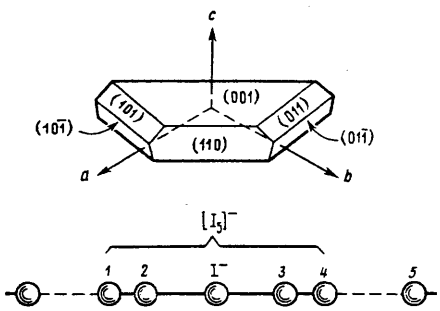

Figure 12. Crystal habit of [(TMA).0.09H][$I_5$].0.7$H_2O$ and a fragment of a polyiodo-iodate chain; [90] interatomic distances (Å): 1–2 = 2.74; 2–I$^-$ = 3.26; I$^-$–3 = 3.26; 3–4 = 2.74; 4–5 = 3.50; 1–5 = 15.5.

Ordered regions ($[I_3]^-$ and $[I_5]^-$ ions) and disordered regions (the intermediate regions between the chains) alternate in the quasi-one-dimensional polyiodo-iodate chains. The disordered regions can be regarded as amorphous one-dimensional formations. [51,94–97]

Phase transformation to a completely ordered structure throughout the chain is not observed above 20 K. [95,98]

Three types of polyiodo-iodate with polymeric anions are examined below: polyiodo-iodates of heterocyclic compounds (mainly aromatic), coordination compounds of *d* elements with macrocyclic ligands, and polymeric carbohydrates.

### 1. Polyiodo-iodates of Heterocyclic Compounds

Many heterocyclic compounds react with iodine or its mixtures with KI in inorganic solvents or aqueous solutions: tetrathiofulvalene, tetrathiotetracene, tetraselenotetracene, tetracyanoquinodimethane, thiopyranylidene, phenazine, thiophenazine, etc. The reaction products are isolated by isohydric or isothermal crystallisation as acicular crystals containing polyiodo-iodate chains.

In the compound $(TTT)_2[I_3]_{1+x}$ † ($x$ = 0.012–0.1), [99–114] the stacked cations with an interplanar distance of 3.32 Å [103,109,110] contain channels occupied by linear chains of symmetric $[I_3]^-$ ions joined to one another; the interionic distance is 3.00–3.64 Å (Fig.13). The non-stiochiometry of the compound is due to the appearance of iodine molecules in the chain. The greatest non-stoichiometry of the polyiodo-iodate chain is observed when $(TTT)_2[I_3]_{1+x}$ is recrystallised from a solution, heated to 95 °C, in nitrobenzene containing $3 \times 10^{-3}$ M TTT at a molar ratio iodine/TTT = 1 and a cooling rate of 3 K $h^{-1}$. [101] Crystals with the stoichio-

† ur = urea.

# TMA = trimesic acid, $C_6H_3(COOH)_3$.

§ bqd = o-benzoquinone dioximate.

¶ TTF = tetrathiofulvalene.

† TTT = tetrathiotetracene.

metric composition can be obtained by decreasing the TTT concentration, the molar ratio iodine/TTT, and the cooling rate.

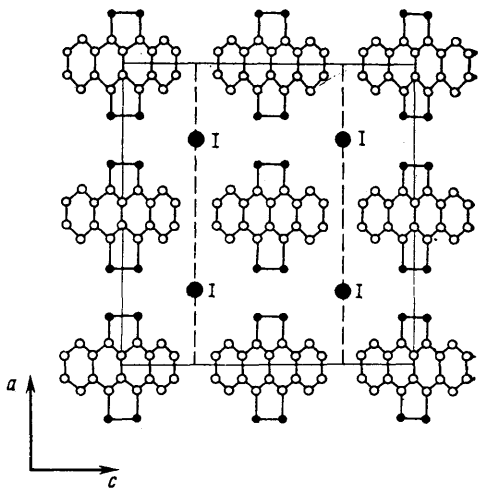

**Figure 13.** [010] projection of the compound $(TTT)_2[I_3]$;[102, 110] the small black and open circles represent the atoms of sulphur and carbon respectively; the polyiodo-iodate chains lie at right angles to the plane of the Figure and are denoted by large black circles.

To obtain single crystals of $(TTT)_2[I_3]$, it is recommended[114] that the substance be crystallised from a gaseous mixture of TTT and iodine, passed in separate streams into a special crystallisation vessel.

In another method, aqueous solutions of TTT acetate and potassium or sodium iodide are mixed.[113]

When the sulphur atoms in the TTT molecule are replaced by selenium atoms (tetraselenotetracene, TSeT), the structure of the polyiodo-iodate chain is altered; in addition to $[I_3]^-$ ions, it also contains $[I_5]^-$ ions.[108,115–119] Three homogeneity ranges have been detected for the compound $(TSeT)_2[I_3]_x$ ($x = 0.17–0.40$):[118] a phase (A) ($x = 0.17$), a phase (B) ($x = 0.24$), and a phase (C) ($x = 0.26$). It is considered[118] that only the phases (B) and (C) contain $[I_3]^-$ and $[I_5]^-$ ions in the chains. Complete charge transfer to the polymeric anion has been established for the phase (A), which is also the phase with the highest electrical conductivity.

The reaction of iodine with tetrathiofulvalene (TTF) in benzene or acetonitrile gives four new phases, depending on the original component ratio: two stoichiometric, $(TTF)_3.[I_3]_2$ and $(TTF)[I_3]$, and two non-stoichiometric, $(TTF).[I_3]_x$ ($x = 0.24–0.26$) and $(TTF)[I_3]_x$ ($x = 0.77–0.87$).[120–128] The syntheses almost always give a mixture of these phases, which are difficult to separate. In the solid-phase synthesis, the number of new phases formed decreases to two: $(TTF)[I_3]$ and $(TTF)[I_3]_x$ ($x = 0.23$).[129]

In all TTF polyiodo-iodates, the stacked structure of the cation contains zigzag chains consisting of $[I_3]^-$, $[I_5]^-$, and $I^-$ ions and iodine molecules.[120,122,124,126] This non-uniform composition of the chains is apparently due to the presence in the new phases of an appreciable number of different trace components and to the difficulty of separating the reaction products.

For the reaction

$$(TTF)(\text{crystalline}) + 3/2\ I_2(\text{crystalline}) = (TTF)[I_3]\,(\text{crystalline})$$

the quantities $\Delta G^0_{298}$, $\Delta H^0_{298}$, and $\Delta S^0_{298}$ are $-5.4 \pm 0.4$ kJ mole$^{-1}$, $-15.1 \pm 0.8$ kJ mole$^{-1}$, and $32 \pm 1.3$ J mole$^{-1}$ K$^{-1}$ respectively.[130]

Tetraselenofulvalene polyiodo-iodates $(TSeF)[I_3]_x$ have been synthesised, but the chain structure of the anions has not yet been studied in detail.[131]

Quasi-one-dimensional polyiodo-iodate chains have been detected in (TPDTP)[$I_x$]# ($x = 2.2–3.4$).[132,133] The polymeric anions consist of either $[I_3]^-$ ions ($x = 2.2$) or a combination of $[I_3]^-$ and $[I_5]^-$ ions ($x = 3.4$). The interionic distances in the $[I_3]^-...[I_3]^-$ chains are 5.49 Å.[132] in the reaction with iodine, the TPDTP molecule loses 0.76–0.90e.

Phenazine (P), phenothiazine (PT), and their derivatives can be oxidised by iodine either in solution in benzene or ether or by thoroughly grinding the starting materials in small quantities of these solvents.[94,95,133–136] The oxidation products have the composition P[$I_x$] ($x = 1.5–1.6$) and $(PT)[I_3]$, and have polyiodo-iodate chains containing asymmetric $[I_3]^-$ ions and $[I_5]^-$ ions.[134,136] The distance between the $[I_3]^-$ ions in the chain is 3.7–3.9 Å.[95]

Quasi-one-dimensional chains consisting of $[I_3]^-$ anions, with an interionic distance of 3.68 Å,[133] have been detected in the crystal structure of $(NMe_4)^+(TCNQ)^{-2/3}[I_3]^-_{1/3}$ § and its derivatives.[137–141] When the tetramethylammonium cation is replaced by the isopentyldimethylammonium cation, the chains acquire quasi-three-dimensional character.[133] The phase transformation of $(NMe_3H)(TCNQ)[I_3]$ at 150 K does not influence the structure of the polyiodo-iodate chains, and alters only the order in which they are arranged.[141]

All the above polyiodo-iodates have cations with a stacked structure, and belong to the group of radical-cation salts.

### 2. Polyiodo-iodates of Polymeric Carbohydrates and Hydrocarbons

Macromolecular carbohydrates (amylose, cyclodextrins, polyvinyl alcohol) and hydrocarbon (polyacetylene, etc.) react in aqueous solution with iodine or its mixtures with KI to form strongly coloured products containing chains of $[I_3]^-$, $[I_5]^-$, and $[I_7]^-$ ions in the channels and cavities of their matrices.

In the channels of amylose (Am), the chains consist chiefly of $[I_5]^-$ ions.[49,142–155] When the solid complexes $Am[I_5]_\infty$ are heated slightly, partial decomposition of the anions to $[I_3]^-$ and iodine takes place.[150] The interionic distance in the chain (3.1–3.5 Å) indicates appreciable interaction of the anions along the chain. The complex with the composition $Am[I_5]_\infty$ contains 50–500 iodine atoms, if there are 3.9 glucose units for every iodine atom.[148,151] Depending on the degree of polymerisation of amylose (the length of its spirals), the concentrations of iodine and iodide ions in the chain may include other ions: $[I_7]^-$, $[I_8]^{2-}$, and $[I_6]^{2-}$. With increase in the length of the chains,

---

# TPDTP = tetraphenyldithiopyranylidene.

§ TCNQ = 7,7,7,6-tetracyanoquinodimethane.

the maximum of the absorption band in the electronic spectra at 580 nm is displaced to 630 nm with a simultaneous increase in the molar absorptivity.[146]

The average decrease in enthalpy in the formation of $Am[I_5]_\infty$, calculated for one glucose structural unit and one mole of combined iodine, is −5.2 kJ mole$^{-1}$.[149]

The polyiodo-iodates of cyclodextrins (CD) have different compositions, depending on the synthesis conditions: $(\alpha\text{-CD})_2M[I_5].8H_2O$ (M = Li, Na, Tl), $(\alpha\text{-CD})_2M[I_5].27H_2O$ (M = K, $NH_4$, Ca, Sr, Zn, Cd), $(\alpha\text{-CD})_2M[I_5].(12–19)H_2O$ (M = K, $NH_4$, Rb, Cs).[149,143,150,156–158] The units of the almost linear polyiodo-iodate chain are $[I_5]^-$ ions.

The central $I^-$ atom of each ion of this type is situated between the dimeric molecules of (α-CD) and does not occupy a definite structural position; the amplitude of its movement is about 1.7 Å.[155,156,159]

The metal cations and water molecules are situated outside the channels of the (α-CD) structure, and are separated from the $[I_5]^-$ anions by a distance of about 6 Å, so that their influence on the polyiodo-iodate anion is slight.[45,143]

In the (β-CD)–iodine complexes, the channels of diameter 6.2 Å are occupied by zigzag chains of $[I_7]^-$ ions.[156]

When iodine is added to polyacetylene during its formation in n-hexane, black polymers with the composition *cis*-$(CHI_{0.06})_\infty$ and *trans*-$(CHI_{0.22})_\infty$ separate. The *trans*-isomer was isolated by heating the mixture of polymers in a vacuum or in argon at 180 °C.[160,161] Polyacetylene film is iodinated by treating it with iodine vapour[161] or by immersing it in $CCl_4$ saturated with iodine.[162,163]

Polyacetylene polyiodo-iodates with other compositions, for example $(CHI_x)_\infty$, where $x$ = 0.12–0.23, can also be obtained.[164–168]

According to Ref.168, the surface layer of the polymer fibres contains $[I_7]^-_\infty$ ions. In a vacuum, these ions decompose, leaving only $[I_5]^-$ ions in the chains, and the composition of the polymer approaches $(CHI_{0.15})_\infty$.

Thus each $[I_5]^-$ ion of the linear chain accepts one electron per 33 carbon atoms of the polyacetylene. Other charge-transfer ratios are also observed.

The polyiodo-iodate chains are arranged between the fibres of the polymer[169] in different ways.[168–171]

The chains of *cis*-$(CHI_{0.23})_\infty$ contain 93% $[I_5]^-$ ions and 7% $[I_3]^-$ ions;[162] the $[I_5]^-$ ion is linear, with a symmetrical charge distribution. When the substance is kept for a long time in a vacuum, the concentration of $[I_3]^-$ ions in the chain increases. An interesting feature is that the ratio of $[I_3]^-$ and $[I_5]^-$ ions in the chains alters when the polyacetylene films are stretched.[98] According to Ref.163, the ions predominating in the polymer $(CHI_x)_\infty$ are $[I_3]^-$ and $[I_5]^-$ at $x \leq 0.1$, $[I_5]^-$ at $x \geq 0.12$, and $[I_7]^-$ at $x > 0.3$.

In the spiral structure of polyvinyl alcohol, the polyiodo-iodate chains consist of $[I_3]^-$ ions.[172–175]

The iodination of polycyclic aromatic compounds (perylene, pyrene, flavone, etc.) gives chain polyiodo-iodates.[176,177] The nature of the chain anions in this case has not been finally established, although the presence of $[I_7]^-$ ions has been assumed.[178,179]

### 3. Polyiodo-iodates of *d* Elements with Macrocyclic Ligands

Polyiodo-iodate chains may be formed in a large number of complex compounds of *d* elements with chelating macrocyclic ligands with a planar configuration (phthalocyanines, tetrabenzoporphyrinates, diphenylglyoximates, benzoquinone dioximates, ethylenediamine complexes of metals, etc.) when these compounds are oxidised by iodine.

Polyiodo-iodate chains are formed in the stacked structure of the cations only when the complex-forming metals are arranged above one another at a relatively short distance of 3.15–3.40 Å.[180] The influence of the iodine atoms on the production of the channels in the stacked structure of the cations has not been proved.

In most cases these polyiodo-iodates are charge-transfer complexes.

The following six groups of complex have been studied in detail: I) diphenylglyoximates with the composition $[M(Hdpg)_2][I_x]$,¶ where $x$ = 0.58–0.68, and M = Ni and Pd;[51,91,181–184] II) benzoquinone dioximates with the composition $[M(Hbqd)_2][I_x]$, where $x$ = 0.5–0.7, and M = Ni and Pd;[91,96,185–188] III) phthalocyanines with the composition $[M(pc)_n][I_x]_n$,† where $x \geq 3$, and M = Cu, Zn, Al, Ga, Si, Cr, Fe, Co, Ni, Pt;[188–195] IV) ethylenediamine complexes with the composition $[M(en)_2][I_3]_2$, where M = Zn, Cd, Ni, Co, Pd;[23,67,89,196–198] V) tetrabenzoporphyrinates with the composition $[Ni(tbp)_2]_2.[Ni(tbp)]^+[I_3]^-$; #[199–201] VI) tetra-azoazulenes with the composition $[M(taa)][I_x]$,§ where $x$ = 0.8–1.9, and M = Cu, Co, Ni, Pd.[202–204]

Polyiodo-iodates with macrocyclic ligands are usually prepared by the same method: the metal chelate and iodine are dissolved in an organic solvent (toluene, dichlorobenzene) with heating, sometimes in the presence of small quantities of KI, followed by slow isohydric crystallisation.[91,185,190,205]

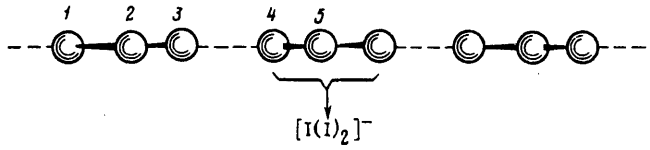

Figure 14. Structure of the polyiodo-iodate anion in $[Ni(Hbqd)_2][I_{0.5-0.7}]$; interatomic distances (Å): 1–2 = 2.96; 2–3 = 2.90; 3–4 = 3.80; 4–5 = 2.90.[96,186]

$[I_5]^-$ anions predominate in the polyiodo-iodate chains of the complexes of the first group, and $[I_3]^-$ ions in the complexes of the second group (Fig.14). Group III also includes the polyiodo-iodates of phthalocyanines with partly oxidised metal-containing macro-rings with the composition $[M(pc)O][I_x]$, where $x$ = 0.5–5.5, and M = Sn, Ge, and Si.[206,207] These substances are stable in air, and lose iodine only when heated above 100°. The anions of the phthalocyanines contain symmetrical $[I_3]^-$ ions with an interionic distance of 3.72 Å.

---

¶ dpg = 1,2-diphenylglyoximate.

† pc = phthalocyanine.

# tbp = tetrabenzoporphyrinate.

§ taa = tetra-azoazulene.

The energy characteristics of the formation of phthalocyanine polyiodo-iodates in the reaction

$$[M(pc)]\,(crystalline) + 1/2\,I_2(crystalline) = [M(pc)]\,[I]\,(crystalline)$$

are, for M = Cu, Co, and Ni, $\Delta H^0_{298} = -13.0$, $-16.7$, and $-18.8$ kJ mole$^{-1}$ respectively, and $\Delta S^0_{298} = -24.3$, $-15.5$, and $-33.9$ J mole$^{-1}$ K$^{-1}$ respectively.[130]

Thus the thermodynamic stability of the phthalocyanine polyiodoiodates decreases with increase in the atomic number of the complex-forming element.

In polyiodo-iodates containing ligands with large rings (pc, tbp, tmp,¶ etc.), the chain anion consists of $[I_3]^-$ ions; when the ligands contain small rings, however, the chains contain $[I_5]^-$ ions, for example in the compounds of Ni and Cu with oep.†[208]

Partial oxidation of the metal-containing macro-rings does not alter the nature of the polyiodo-iodate chains. $[I_5]^-$ ions appear in the chains only at a high iodine concentration.[206,207]

In the complexes of groups IV and V, the chains contain asymmetric $[I_3]^-$ ions with an interionic distance of 3.598 Å.[89] Analysis of the Raman and Mössbauer spectra showed that the chains in the compounds of these groups do not contain iodine molecules or $[I_5]^-$ ions.[181,187,199,200]

In recent years, another class of chain polyiodo-iodates has appeared, namely inorganic polymers. Treatment of the polymer $(SN)_\infty$ with iodine vapour (20 mmHg, 350 °C) gives $(SNI_{0.14})_\infty$. In this product, the polyiodo-iodate chains consist of $[I_3]^-$ and $[I_5]^-$ ions, and also strongly polarised iodine molecules.[209,210]

## VIII. SUMMARY

The above data show that the size, configuration, and composition of the polyiodo-iodate anion are determined not only by the cation environment but also by the synthesis conditions.

Sodium, potassium, and rubidium polyiodo-iodates containing more than five iodine atoms are extremely unstable, and it has not yet been possible to isolate them from aqueous solutions as individual solid phases, although a complex with the composition $(NH_4)[I_5]$ has been obtained. This branch of the chemistry of the alkali metal polyiodo-iodates requires further study.

In $(NR_4)I-I_2-H_2O$–organic solvent systems, polyiodo-iodates with all anions from $[I_5]^-$ to $[I_{11}]^-$ may be formed, but there is no system containing tetra-alkylammonium iodides in which a range of crystallisation of octa-iodides has been detected, or in which the crystallisation ranges of all other polyiodo-iodates coexist.

Non-aqueous solvents often stabilise polyiodo-iodate anions and convert the adducts into ionic compounds, but nevertheless, in the $RbI-I_2-C_6H_6$ system, only the tri-iodide, hepta-iodide, and nona-iodide crystallise, but there is no penta-iodide crystallisation range (see Fig.4). If rubidium iodide in this system is replaced by caesium iodide, the hepta-iodide crystallisation range disappears, but a penta-iodide crystallisation range does not appear.

The fact that the number of iodine atoms in the anions of most polyiodo-iodates is odd is noteworthy. This anion composition is determined by the fact that the complex-forming species is always either an iodine atom with positive, negative, or zero charge, or the tri-iodide ion $[I_3]^-$, and the ligands are iodine molecules or iodide ions. In the $[I_8]^{2-}$ anion, the complex-forming species is an iodine molecule. The coordination number in the polyiodo-iodates is 2. The appearance of coordination numbers of 3 in the $[I_9]^-$ ion and 4 in the $[I_{11}]^-$ ion is unusual, and the distorted chain structure of these anions does not agree with the usual ideas about the conformation of ions with analogous coordination numbers. Nona-iodides and undeca-iodides are rather oligomers.

The influence of the crystal field on the geometry, bond order, and charge distribution in the anions is slight. The stability of the anions is greater when the crystal lattice contains large cations. In an asymmetric crystal field, with a rigid non-deformable cation environment, the anions become angular and asymmetric. For example, the $[I_5]^-$ anion is linear only in a vacuum and in the polyacetylene–iodine system, and in other cases it is V-shaped.

The polyiodo-iodate anions being considered are apparently stereochemically non-rigid structures. The determination of their conformation requires allowance for interatomic vibrations which may bring about rearrangement of the nuclei in the chain. The concepts of "equilibrium structure" and "point symmetry of the nuclear configuration" are therefore inapplicable to these anions.

Polyiodo-iodate chains are ordered only in one direction, and even in this case there are appreciably extended disordered regions (the regions between the anions), as is typical of liquids or amorphous solids. Thus these chains are sometimes regarded[94,95] as one-dimensional liquids. The ordered range along the chains increases with decrease in temperature, but complete ordering is not achieved even at 10–30 K.[94]

All chain polyiodo-iodates can be divided into three types. In compounds of the first type, the chains are stabilised by the presence of spiral and cyclic organic molecules with a closed configuration (amylose, α-cyclodextrin, etc.). The channels in compounds of this type may contain two chains, with different interionic distances.[211] In polyiodo-iodates of the second type, the chains are situated in the channels of stacked cations with an open atom configuration (TTT, TTF, etc.). The chains are stabilised by the planar aromatic system containing donor molecules with π electrons, α-pyrone rings, etc. In compounds of the third type, in which the structure of the cations somewhat resembles that of the polyiodo-iodates of the second type, the chains are stabilised by the oxidation of different functional parts of the inner sphere, and by the arrangement of the chelates in a "stack", in which the complex-forming species form a quasi-one-dimensional chain with the minimum possible interionic distance.

In any case, the presence of a stacked cation structure does not necessarily mean that chains of iodine atoms can be produced in it.[212–215]

Polyiodo-iodates have recently been attracting considerable attention. They include substances with metallic conductivity, some of which may be promising for the product of new semiconductors and high-temperature superconductors.[121,184,185,216] Polyiodo-iodates are being tested as components of future hydrogen energy systems[217,218] and opto-electronic devices,[158] and for the production of organic polymers with controllable composition-dependent electrical properties.[219] Polyiodo-iodates are used in medicinal and antimicrobial preparations,[220] in analytical chemistry,[221] and in the separation

¶ tmp = 5,10,15,20-tetramethylporphyrinate.

† oep = 2,3,7,8,12,13,17,18-octaethylporphyrinate.

of materials and the preparation of extremely pure substances.[222]

# Cluster and Polynuclear Heterogeneous Metal Complex Catalysts

A.Ya.Yuffa and G.V.Lisichkin

The present state of the problem of catalysis by cluster and polynuclear transition metal complexes attached to the surfaces of mineral and organic polymers is analysed. The principal methods of preparation of heterogenised clusters and the possible ways of transforming them on the surfaces of carriers are examined and the influence of the nuclearity of the clusters on the catalytic activity and selectivity in the conversion of CO is discussed. The prospects for the employment of immobilised clusters in catalysis are considered.
The bibliography includes 166 references.

## I. INTRODUCTION

Heterogeneous metal complex catlaysis is a new rapidly developing field of catalytic chemistry. In the first review and monographs,[1-3] the likely usefulness of heterogeneous metal complex catalysts (HMC), containing cluster and polynuclear transition metal complexes attached to a carrier, was already pointed out. During the last 7–8 years, methods of synthesis have been developed and the properties of such catalysts have been investigated. It has been suggested that the cluster HMC manifest a high activity and selectivity in many-electron and multistage chemical reactions as a result of the activation of inert molecules on polynuclear active centres. It is therefore not surprising that the main tests for the catalytic activity of clusters have been reactions involving the simultaneous activation of CO and $H_2$. Some results of these studies are discussed in our previous review.[4]

Numerous investigations of the methods of synthesis of cluster HMC with different nuclearities and of the reactions of the clusters on the surfaces of carriers during catalysis have been published recently. A series of interesting results have been obtained in the investigation of the catalytic activities of these systems and of the influence of the nature of the carrier surface on their catalytic properties. This review is devoted to the analysis of these studies.

Since the terminology in the field of chemistry of cluster and polynuclear compounds has not as yet been finally formulated, we shall explain certain terms employed in this review. A transition metal cluster in catalysis is the name given to a group of $n$ metal atoms ($n \geq 2$) bound to one another. Polynuclear transition metal complexes are compounds whose composition includes two or more metal atoms not linked directly to one another. The nuclearity of the cluster is characterised by the number of metal atoms in its skeleton. The nuclearity of a polynuclear complex is determined by the number of metal atoms in its composition. Homonuclear complexes contain the atoms of only one metal, while heteronuclear complexes contain the atoms of several metals. The interaction of transition metal complexes with the surfaces of carriers, carried out in order to synthesise heterogeneous catalysts, is called heterogenisation. This process can include both pure adsorption interaction and chemical reactions on the surface.

## II. HETEROGENISATION OF CLUSTER CARBONYL COMPLEXES ON UNMODIFIED MINERAL CARRIERS

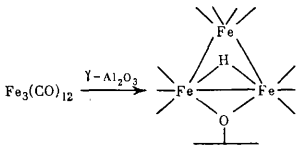
One of the simplest and most widely used methods for the heterogenisation of cluster and polynuclear complexes is adsorption from solution. Hydroxy-groups and acid and basic Lewis centres are distributed on the surfaces of mineral carriers, so that the interaction between the complex and the carrier may be due not only to weak adsorption forces but also to the formation of strong chemical bonds. The chemical interaction of the complex with the surface usually leads to one of three possible consequences: (1) the cluster skeleton and the oxidation state of the constituent transition metal atoms of the cluster remain unchanged; (2) the skeleton of the complex is preserved, but the oxidation state of the metal atoms changes; (3) the cluster skeleton breaks down. In the last case there is a possibility of both the dispersion of the cluster compound with formation of mononuclear centres on the carrier surface and of an increase in the nuclearity of the cluster up to the formation of the metallic phase. Unfortunately the possibility of the occurrence of the processes enumerated above on the carrier surface is by no means taken into account in all the studies devoted to catalysis by heterogenised cluster and polynuclear complexes. Since problems associated with the reactions of complexes on the surface are of key importance for the interpretation of the nature of the activity of heterogeneous cluster catalysts (HCC), studies in which the changes in the complexes on heterogenisation were investigated specially are considered below.

Carbonyl complexes, for example, $Mo(CO)_6$, can interact with the surfaces of mineral carriers in accordance with the following schemes:[5]

$$Mo(CO)_6 + |{-}O^- \rightarrow Mo(CO)_5(O^- {-}|);$$
$$[Mo(CO)_3]_{ads} + 2|{-}OH \rightarrow (|{-}O^-)_2Mo^{2+} + H_2 + 3CO.$$

Thus there is a possibility of the strong chemisorption of metal carbonyls on the carrier surface containing basic groups or acid Lewis centres.[6-8] In the heterogenisation of th iron carbonyls $Fe(CO)_5$, $Fe_2(CO)_9$, and $Fe_3(CO)_{12}$ on $Al_2O_3$, analogous reactions were observed.[9] At 150 °C the so-called sub-carbonyl species $[Fe(CO)_2]_{ads}$ are formed on the surface.[9,10]

It has been suggested[11,12] that the carbonyl ligand may be attacked by the surface hydroxy-group in the first stage of the interaction of $Fe(CO)_5$ and $Fe_5(CO)_{12}$ with $Al_2O_3$ and MgO and the ionic hydride $[HFe_3(CO)_{11}]^-$ is formed:



$$Fe_3(CO)_{12} + M-OH- \begin{cases} \longrightarrow (CO_2)_{ads}\ ; \\ \longrightarrow [HFe_3(CO)_{11}]^- M^+\ ; \end{cases}$$

$$3Fe(CO)_5 + M-OH- \begin{cases} \longrightarrow [HFe_3(CO)_{11}]^- M^+\ ; \\ \longrightarrow 3CO + (CO_2)_{ads}\ ; \end{cases}$$

$M=Al^{3+}, Mg^{2+}$.

The rate of reaction of the mononuclear complex with surface hydroxyls is lower than that of the cluster complex. The addition of HCl to the product leads to the regeneration of $Fe_3(CO)_{12}$ according to the authors' data.[11]

On the basis of EXAFS, infrared, and ultraviolet spectroscopic and thermal desorption data, Iwasawa et al.[13] arrived at conclusions differing somewhat from those of Brenner and Hucul[10] and Hugues et al.[11] They showed that a covalently bound $Fe_3$ cluster is formed when $Fe_3(CO)_{12}$ is adsorbed on the surface of $Al_2O_3$ at 40 °C:

$Fe_3(CO)_{12}$ does not interact with an $SiO_2$ surface.[13]

The anionic complex $[Fe_3(CO)_{11}H]^-$ is more stable on an $Al_2O_3$ surface than its covalently bound analogue, which is readily oxidised by atmospheric oxygen even at room temperature.[13] Presumably both structures considered may be formed on $Al_2O_3$ and the predominance of one of them depends on the acid–base properties of the carrier and the concentration of the surface OH groups.

This hypothesis has been to a large extent confirmed by the results of the study of the heterogenisation of $Fe_3(CO)_{12}$ on magnesium oxide dehydrated under mild and severe conditions.[12] The liberation of hydrogen and the appearance of $Fe^{2+}$ are characteristic of a carrier with a high concentration of OH groups on heating to a temperature above 80 °C. At 110 °C the cluster decomposes fully. The complex is fully decarbonylated without evolution of $H_2$ on the surface of MgO dehydrated at a high temperature, and zerovalent iron is oxidised to $Fe^{2+}$. It is assumed[12] that the $[HFe_3.(CO)_{11}]^-$ ions and possibly the compound $Fe(CO)_4(CO_2Mg)$ are formed on the surface with a low concentration of OH groups.

All three iron carbonyls have been heterogenised on the NaY and HY zeolites in order to synthesise catalysts of the Fischer–Tropsch reaction.[14,15] Behaviour analogous to that described above was then observed: when $Fe_3(CO)_{12}$/HY is heated to 60 °C, $H_2Fe_3(CO)_{11}$ is formed on the surface and decomposes on further increase of temperature to 200 °C giving rise to $Fe^{2+}$ ions attached to the zeolite.

The stabilisation of the metal in a low oxidation state has been observed on the NaY zeolite.[16]

The mononuclear carbonyl $Fe(CO)_5$ adsorbed on the HY zeolite is converted into cluster structures on heating:[15]

$$|\text{--OH} + Fe(CO)_5 \xrightarrow{25°C} [Fe(CO)_5]_{ads} + CO +$$

$$+ [|\text{—O}\cdots Fe(CO)_4] \underset{25°C,+CO}{\overset{60°C,-CO}{\rightleftharpoons}} [(|\text{—OH})_3\cdots F_3(CO)_{12}]\ ;$$

$|$—OH= zeolite HY.

Unfortunately specimens obtained to date by the interaction of iron carbonyls with zeolites are inferior as regards the selectivity of the formation of olefins in the Fischer–Tropsch reaction to the analogous HCC based on $Al_2O_3$.

In a study[17] of the heterogenisation of $Ru_3(CO)_{12}$ on $SiO_2$, it was established by the infrared spectroscopic, thermal desorption (25–170 °C), and radiochemical methods that the physical adsorption is followed by the formation of the subcarbonyl species:

$$|\text{—OH} + Ru_3(CO)_{12} \rightarrow (|\text{—O})_xH_yRu_3(CO)_5\ .$$

The resulting catalyst was active in the isomerisation and hydrogenation of olefins at 353–415 K.

On the other hand, Goodwin and Naccache[18] suggest that, although the cluster–carrier interaction, characterised by the appearance of new absorption bands in the infrared spectrum (2134, 2110, and 2119 $cm^{-1}$), is observed in heterogenisation of $Ru_3(CO)_{12}$ on $Al_2O_3$, $SiO_2$, and NaY, the composition and structure of the initial cluster do not change and hydride complexes are formed. The increase in sensitivity of the heterogenised $Ru_3(CO)_{12}$ to oxygen has been explained[18] by the ease of the oxidation reaction

$$Ru_3(CO)_{12} + 6O_2 \rightarrow Ru_3(O)_6(CO)_6 + 6CO_2$$

on the carrier surface.

In a number of instances a distinct tendency towards the formation on the carrier surface of clusters with a rigorously defined nuclearity, regardless of the nuclearity of the initial complex. Thus, when $Rh_4(CO)_{12}$ was attached to the $SiO_2$ and $Al_2O_3$ surfaces at room temperature,[19] a $Rh_6$ cluster was obtained:

$$3Rh_4(CO)_{12} \rightarrow 2Rh_6(CO)_{16} + 4CO\ .$$

The same cluster is formed on the $Al_2O_3$ surface from $Rh_4(CO)_{12}$ and $Rh_2(CO)_4Cl_2$ when the latter are initially decarbonylated and then again brought into contact with CO.[20]

The high stability of $Rh_6$ structures on the carrier surfaces is indicated by the results of a study by Conrad et al.[21] It has been shown by infrared spectroscopy that $SiO_2$ has no influence on the structure of the cluster and that $Rh_6(CO)_{16}$ may be reversibly decarbonylated on the surface of this carrier.

According to spectroscopic data, the interaction of $Rh_6(CO)_{16}/SiO_2$ with water vapour or hydrogen and the adsorption of CO on metallic rhodium lead to the formation of identical structures on the surface:[22]

$$[Rh_6(CO)_{16}]_{ads} \rightarrow \left[\begin{array}{c} CO\ CO\ CO\ CO\ CO \\ |\ \ \ |\ \ \ |\ \ \ |\ \ \ | \\ \text{—Rh—}\ \ Rh\ \ \text{—Rh—} \end{array}\right],$$

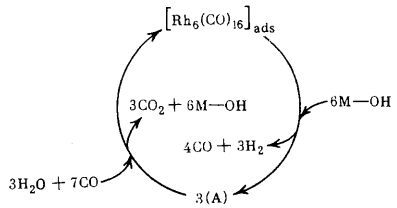
When the $Rh_4(CO)_{12}$ and $Rh_6(CO)_{16}$ clusters heterogenised on $Al_2O_3$, $SiO_2$, and MgO are heat-treated, the polynuclear centre decomposes, the $[Rh(CO)_2]$ fragments are formed, and the metal is oxidised:[19,22,23]

$$Rh_6(CO)_{16} + 6X-OH \xrightarrow{100°C} 3\left[\begin{array}{c} (CO)_2\ \ (CO)_2 \\ Rh\ldots\ Rh \\ \diagdown\ \ \diagup \\ O\ \ \ O\ \ \ O \\ |\ \ \ |\ \ \ | \\ X\ \ \ X\ \ \ X \end{array}\right] + 4CO + 3H_2\ ;$$

(A)

X=Al, Mg, Si.

Spectroscopic studies have shown that the metal–metal interaction in the dimer formed is very weak.[19,23]



The initial cluster structures can be regenerated by a reductive treatment of the specimens with a mixture of water vapour and CO:[19]

$$2[Rh^I(CO)_2] \rightarrow 2[Rh^0(CO)_n] - \begin{cases} \longrightarrow Rh_x(CO)_y\ ; \\ \longrightarrow Rh_4(CO)_{12} \rightarrow Rh_6(CO)_{16}\ . \end{cases}$$

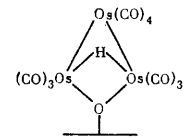
A highly dispersed metallic phase is formed in the absence of CO.

The regeneration of $Rh_6(CO)_{16}$ on the $Al_2O_3$ surface takes place simultaneously with the regeneration of the hydroxyl coating on the carrier with liberation of $CO_2$.[23]

The extremely high stability of the $Rh_6(CO)_{16}$ cluster makes it possible to set up a closed cycle for the Fischer–Tropsch reaction and the conversion of water vapour:[23]

The same behaviour has been observed for the $Rh_6(CO)_{16}$ cluster heterogenised on the NaY and HY zeolites and for the rhodium clusters immobilised on other mineral carriers.[24] Decarbonylation leads to the fragmentation to rhodium(I) complexes, but the initial structures may be subsequently regenerated.

As already mentioned previously,[12] the character of the interaction of the cluster with the carrier depends significantly on the properties of the surface, which are in many respects determined by the dehydration temperature the infrared spectra of $Rh_4(CO)_{12}$ on lanthanum oxide and $Rh_6(CO)_{16}$ on $\gamma$-$Al_2O_3$ (carriers dehydrated at 600 °C) corresponded to the spectra of the individual clusters.[25–27]



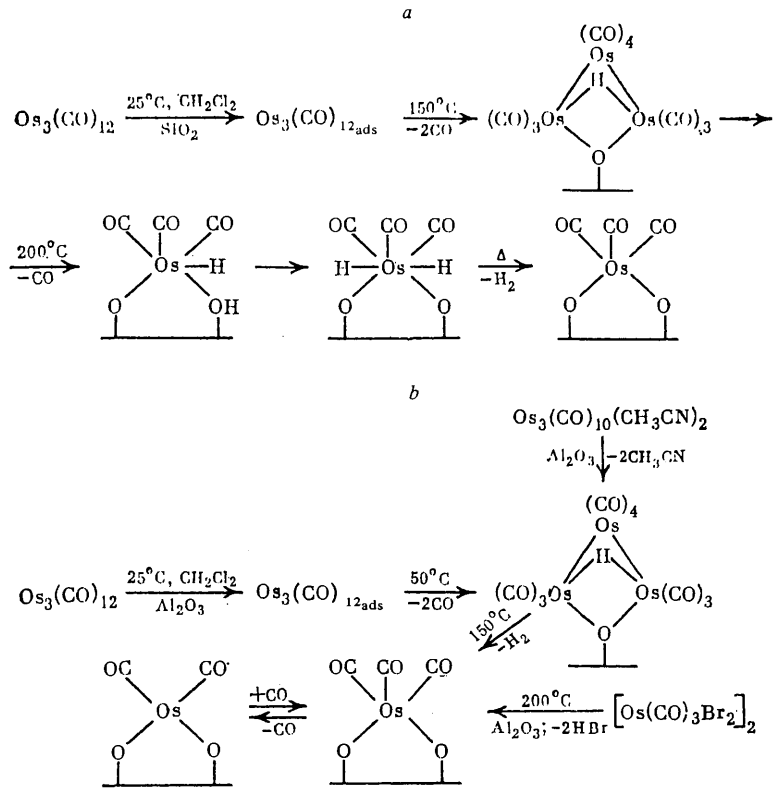
On the other hand, the adsorption of $Rh_6(CO)_{10}$ from solution in chloroform on $Al_2O_3$ dehydrated at a low temperature (200 °C) was accompanied by the partial oxidation of rhodium [the bands of the CO group at 2090 and 2015 $cm^{-1}$, characteristic of $Rh^I(CO)_2$, appeared in the infrared spectrum]. The more reactive $Rh_4(CO)_{12}$ is oxidised even on the carrier dehydrated at 600 °C.

It is essential to bear in mind that the chemical reactivity of the clusters may change on heterogenisation.[20] Thus, $Rh_6(CO)_{16}$, which is stable in air, decomposes partly on the $Al_2O_3$ surface even at room temperature, with evolution of $CO_2$:

$$Rh_6(CO)_{16}/Al_2O_3 + \left(m + n\frac{1}{2}\right)O_2 \rightarrow Rh_6(CO)_{16-n}(O_2)_m/Al_2O_3 + n\,CO_2 \ .$$

On the more inert $SiO_2$ carrier, this type of reaction does not occur.

Much attention has been devoted to the study of the sorption heterogenisation of osmium clusters differing in the nuclearity and nature of the ligands. In the study of the heterogenisation of the osmium clusters $Os_3(CO)_{12}$ and $Os_3(CO)_{10}(MeCN)_2$ on the $SiO_2$ surface at 150° and 25 °C respectively, Besson et al.[28] observed the formation of cluster structures having the composition



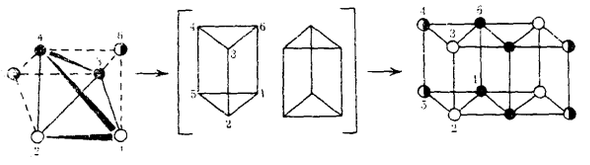


Figure 1. The transformations of the osmium clusters in the course of their heterogenisation on $SiO_2$ and $Al_2O_3$.[29]

The Os–Os distance in the immobilised cluster (2.68 Å) is shorter than in the initial $Os_3(CO)_{12}$ (2.88 Å). Fig. 1 presents the mechanism of the reactions of the osmium clusters heterogenised on $SiO_2$ and $Al_2O_3$ surfaces under the conditions of different types of treatment.[29]

Another rearrangement of the cluster structure has been suggested by Collier et al.,[30] who investigated the heterogenisation of $Os_3(CO)_{12}$ and $Os_6(CO)_{18}$ on the $Al_2O_3$, $SiO_2$, and $TiO_2$ surfaces.[30] When $Os_3(CO)_{12}$ is adsorbed, absorption bands at 442 and 595 nm, characteristic of the $Os_6(CO)_{18}$ cluster, are observed in the diffuse reflection spectra. Three bands in the region of the CO group vibrations have been found in the infrared spectra of the osmium complexes on all three carriers investigated. On the other hand, the spectrum of the initial osmium cluster contains 16 absorption bands in this region. It had been suggested earlier[31] that such simplification of the spectrum is associated with the formation of the mononuclear $Os(CO)_2$ and $Os(CO)_3$ complexes. However, it has been possible to demonstrate[30] that the three absorption bands mentioned above correspond to the vibrations of the CO groups bound to osmium atoms which are partly in negative (1950 $cm^{-1}$), partly positive (2120 $cm^{-1}$), and partly zero (2030 $cm^{-1}$) formal oxidation states. It has been shown for vanadium, chromium, manganese, iron, cobalt, and nickel carbonyls that a ±100 $cm^{-1}$ vibration frequency shift is characteristic of a ±1 change in the oxidation state.[32] Bearing in mind the weakly basic character of the carriers employed, the authors[30] suggested the possibility of the dimerisation of the $Os_6(CO)_{18}$ cluster:

○ – $Os^0$; ◑ – $Os^{+1}$; ● – $Os^{+2}$

The differences between the results of different investigations[29–31] can probably be explained by the fact that their authors used carriers differing in the degree of hydroxylation of the surface and in the reactivity of the hydroxy-groups. In addition, the surface concentrations of osmium were likewise not identical. Unfortunately it is not possible to take into account the effect of these factors quantitatively.

The study of the heterogenisation of clusters on the surfaces of mineral carriers has shown that the strength of the complex–carrier bond depends both on the nature of the transition metal atoms forming part of the composition of the cluster [for example, $Co_2Rh_2(CO)_{12}$, $Co_3Rh(CO)_{12}$, $Co_4(CO)_{12}$> $Ir_4(CO)_{12}$ > $Rh_6(CO)_{16}$ > $Ru_3(CO)_{12}$] and on the nature of the carrier (the adsorption on $\gamma$-$Al_2O_3$ is much stronger than on $SiO_2$).[33] It is significant that the adsorption of the molecules of cluster metal carbonyls containing bridging CO groups on $Al_2O_3$ is accompanied by the elimination of these groups. Decarbonylation is promoted by the dissolved oxygen. As a result, a stronger complex–carrier bond arises than might have been expected for adsorption heterogenisation via van der Waals forces.

The transformations of the clusters on the carrier surfaces are extremely complex. Thus, according to infrared spectroscopic data, the structure of the cluster does not change on heterogenisation of $Ru_3(CO)_{12}$ on the surface of $\gamma$-$Al_2O_3$.[34] On the other hand, two anionic complexes are formed on MgO:

$$3Ru_3(CO)_{12} + 2MgO \rightarrow [HRu_3(CO)_{11}]^-/MgO + [Ru_6(CO)_{18}]^{2-}/MgO \ .$$

In this case MgO exhibits "alkaline" properties.[35,36]

The dependence of the adsorption of the $Ru_3(CO)_{12}$, $H_4Ru_4(CO)_{12}$, and $Ru_6C(CO)_{17}$ on the $\gamma$-$Al_2O_3$ dehydration temperature has been investigated by infrared spectroscopy.[7] Under the conditions of weak dehydration (at temperatures below 300 °C), the absorption bands of the CO groups of the adsorbed $Ru_3(CO)_{12}$ undergo a bathochromic shift, which indicates the appearance of a negative charge in the cluster skeleton as a result of the interaction with the hydroxy-groups of the carrier:

$$Ru{-}CO + \begin{matrix}\diagdown\\ -Al-OH\\ \diagup\end{matrix} \rightarrow \begin{matrix}\diagdown\\ -Al^{\delta+}RuH^{\delta-}\\ \diagup\end{matrix} + CO_2 \ .$$

Under the conditions of vigorous dehydration (at temperatures above 500 °C), the fraction of adsorbed molecules of the complex varies in parallel with the concentration of the Lewis acid centres of the carrier, indicating an interaction of the type $M{-}C{\equiv}O \rightarrow Al^{3+}$. Similar surface compounds have been recorded by infrared spectroscopy in the adsorption of mononuclear nickel,[37] molybdenum,[38] and tungsten[39] carbonyls on $Al_2O_3$.

The hydride carbonyl clusters $H_4Ru_4(CO)_{12}$ [7] and $H_2Fe_3(CO)_{11}$ [40] also form surface anionic complexes by interacting with the hydroxy-groups on the $Al_2O_3$ surface. Some of them proved to be unstable, being transformed in accordance with the mechanism examined with the simultaneous oxidation of the metal and the evolution of CO and $H_2$.[23,25] The transformations of the clusters on $Al_2O_3$ examined above are characteristic also of other oxide carriers.[6,41,42]

In the examples presented above, the coordinated carbonyl ligand is attacked by surface OH groups. Clusters containing acid hydrogen atoms may be deprotonated. For example, the interaction of $H_4Ru_4(CO)_{12}$ ($pK_a$ = 11.7) with $Al_2O_3$ and MgO [43] results in the formation of the anionic cluster $[H_3Ru_4(CO)_{12}]^-$. However, the above feature is not general. In particular, the nucleophilic attack described above, leading to the anion $[H_3RuOs_3(CO)_{12}]^-$, is observed on heterogenisation of the mixed cluster $[H_2RuOs_3(CO)_{13}]$ on $Al_2O_3$.[44] It is noteworthy that the cluster skeleton of the complex obtained is not decomposed by the synthesis gas even at 200 °C.

Thus examination of the studies on the heterogenisation of the carbonyl clusters on the surfaces of mineral carriers leads to the conclusion that it is difficult to predict the state of the complex on the carrier. The composition and structure of the form stabilised on the surface depend on many factors, among which the following may be distinguished: (1) the nuclearity of a cluster; (2) its chemical nature: (3) the nature of the ligands in the coordination sphere; (4) the chemical nature of the carrier; (5) the density of the hydroxyl coating; (6) the heterogenisation conditions.

In addition, analysis of published studies has shown that, even when all the factors enumerated are virtually identical, results may be obtained which lead to different conclusions (see, for example, Refs. 29–31 and 45 and 46).

## III. CATALYTIC ACTIVITY OF THE ADSORPTION-HETEROGENISED CLUSTER AND POLYNUCLEAR TRANSITION METAL COMPLEXES

A general characteristic of processes involving the participation of carbon monoxide (the Fischer–Tropsch reaction, hydroformylation, and carbonylation) is their relatively high exothermicity, i.e. the equilibrium in these reactions is strongly displaced towards the formation of products at room temperature. Nevertheless, real processes are carried out at elevated temperatures, since the activity of industrial catalysts is insufficient for reactions under mild conditions.

It is also known that the selectivity of these reactions is small. For this reason, the application of heterogenised transition metal clusters, which have a fairly uniform set of active centres and promote the many-electron activation of CO, has aroused interest. However, one should bear in mind that, under the conditions of catalysis, the heterogenised clusters as a rule undergo further transformations and their structure frequently differs from the initial structure.

Before being introduced into the catalytic reaction, the heterogenised clusters are usually activated thermally or chemically. The heat treatment is carried out both *in vacuo* and in an atmosphere of CO or the synthesis gas. We may note that even the rate of heating can influence significantly the degree of dispersion of the particles formed. Thus it has been established[47–49] that, on rapid heating (50 K $min^{-1}$) of $Co_2(CO)_8$ specimens on $TiO_2$, $Al_2O_3$, $ZrO_2$, and $SiO_2$, "superparamagnetic" cobalt species are formed and are characterised by a narrow signal in the ferromagnetic resonance (FR) spectrum. When the temperature is raised slowly, relatively large particles, giving rise to a broad signal in the spectrum, are produced.

Chemical activation usually reduces to the oxidation-reduction treatment of the heterogenised clusters. It has been noted[8] that preliminary oxidation of the carbonyl clusters or their decomposition in a stream of inert gas leads to the formation of more dispersed metal particles on the surface of the carrier than direct reduction with hydrogen.[50,51]

When heterogeneous catalysts are employed, it is essential to take into account the texture of the carrier. The effect of the carrier structure on the selectivity of the Fischer–Tropsch reaction has been noted.[52] The catalyst obtained as a result of the heterogenisation of $Co_2(CO)_8$ on $Al_2O_3$ and decomposed at 200 °C is active in the conversion of the synthesis gas into a mixture of linear $C_2$–$C_{20}$ paraffins ($CO:H_2 = 1:2$; 200 °C; 0.1 MPa). The average molecular weight of the paraffin fraction then depends on the effective radius of the carrier pores $r$: 80% of $C_3$–$C_{10}$ paraffins is formed on a narrow-pore carrier ($r = 65$ Å), whereas 80% of the $C_{14}$–$C_{21}$ paraffins are formed on the specimen with $r = 3000$ Å). It may be that the difference between the selectivities is caused by the different degrees of dispersion of cobalt on the two carriers.

The possibility of regulating the selectivity of the Fischer–Tropsch process by altering the nuclearity and composition of the cluster and also of the nature of the carrier has been examined.[53–58] An important result of these investigations is the direct preparation of ethanol from the synthesis gas under relatively mild conditions, which leads to the prospect for the synthesis of ethylene from coal via a process with a small number of stages. The dependence of the yield of ethanol (per atom of rhodium) on the nature of the cluster (with $La_2O_3$ as the carrier) can be represented by the series $[Rh_4(CO)_{12}] > [Rh_6(CO)_{16}] > [Rh_7(CO)_{16}](NEt_4)_3 > [Rh_{13}.(CO)_{23}H_{2-3}](NBu_4)_2$. The following rules have been established:[55] mainly ethanol is formed at temperatures above 200 °C, while at lower temperatures the product is methanol; highly basic carriers (ZnO and MgO) promote the formation of methanol, while basic carriers with weak acidity ($CeO_2$, $La_2O_3$, $TiO_2$, $ZrO_2$, and $ThO_2$) promote the formation of ethanol; weakly acid oxides ($\gamma$-$Al_2O_3$, $V_2O_5$, $WO_3$, and $Al_2O_3$–$SiO_2$) lead to the preferential formation of methane and higher hydrocarbons; the heterogenisation of the $Rh_2$–$Rh_6$ clusters leads to an increase of the selectivity of the conversion into ethanol, while in the presence of the $Rh_7$–$Rh_{13}$ clusters mainly methane and the $C_2$–$C_4$ hydrocarbons are formed.

The synthesis of methanol from CO and $H_2$ (mixture with the ratio $CO:H_2 = 1:2$) in the presence of catalysts obtained as a result of the adsorption heterogenisation of the platinum cluster $[Pt_{15}(CO)_{30}](NEt_4)_2$ on Group IIA, IIB, IIIA, and IVA metal oxides has been described.[54] The highest selectivity of the conversion into methanol, reaching 98%, has been observed for the catalyst on MgO.

Naturally, the process selectivity is greatly influenced also by the nature of the metal: the rhodium clusters immobilised on lanthanum and zirconium oxides promote the selective formation of ethanol, whereas only methane was obtained in the presence of platinum and iridium complexes under identical conditions.[53]

$Ru_3(CO)_{12}$, $H_4Ru_4(CO)_{12}$, $Ru_6C(CO)_{17}$, and $RuCl_3$ deposited on $\gamma$-$Al_2O_3$ have been used in the Fischer–Tropsch reaction.[59,60] It has been established that, with increase of the degree of dispersion of the metallic particles, the specific catalytic activity falls and the fraction of light hydrocarbons in the product increases. The authors explain this effect by the strong interaction of the metal with the carrier. It is believed[59,60] that only the centres coordinating one CO molecule are active. The surface subcarbonyl $Ru(CO)_2$ species are stable at the reaction temperature in an atmosphere of hydrogen, which is probably the cause of their catalytic inertness.

In the previous Section it was shown that the nature of the carrier can influence strongly the structure of the product of the heterogenisation of the clusters. It is therefore also not surprising that, when the same cluster complex is deposited on different carriers, active centres of different composition and structure are produced. Thus, when $Ru_3(CO)_{12}$ is heterogenised on $\gamma$-$Al_2O_3$, microcrystalline metallic ruthenium exhibits catalytic activity, which is confirmed by the composition of the products of the Fischer–Tropsch reaction.[34] The anionic complex $[Ru_6C(CO)_{16}]^{2-}$ proved to be responsible for catalysis on MgO. The same complexes were obtained also when $H_4Ru_4(CO)_{12}$ was heterogenised on $Al_2O_3$ and MgO. However, an active catalysis could not be synthesised by adsorbing $K_2[Ru_6C(CO)_{16}]$ on $Al_2O_3$. The authors[34] explained this by the fact that the interaction of $[Ru_6C(CO)_{16}]^{2-}$, formed when the neutral complexes $Ru_3(CO)_{12}$ and $H_4Ru_4(CO)_{12}$ are heterogenised on $Al_2O_3$, differs from the interaction of $K_2[Ru_6C(CO)_{16}]$. We may note that the compositions of the products of the Fischer–Tropsch reaction on $Ru_3(CO)_{12}/MgO$ and $Ru_3(CO)_{12}/Al_2O_3$ differ markedly. The experimental results described show that it is difficult to predict the catalytic properties of heterogeneous cluster catalysts.

Together with the cluster complexes of noble metals, catalytic activity in the Fischer–Tropsch reaction is shown also, as already mentioned above, by the cluster and polynuclear complexes of other Group VIII metals immobilised by adsorption on the surfaces of mineral carriers, for example by $Fe_3(CO)_{12}$ on a type HY or NaY zeolite.[56] The activity of this catalysis is relatively low: liquid hydrocarbons are formed only at 250 °C and 2 MPa (the degree of conversion is 85% after 15 h). The catalysts based on the dinuclear cobalt complex $Co_2(CO)_8$ immobilised on mineral carriers of different nature was active in the conversion of the synthesis gas into a mixture of liquid hydrocarbons only after reduction in a stream of hydrogen at 150 °C.[57,58] n-Alkanes are formed preferentially on the least active carrier, while isoparaffins are formed on strongly acid carriers. Although hydrocarbons ranging from $C_5$ to $C_{22}$ were detected in the mixture, the bulk of the latter consisted of $C_9$–$C_{13}$ paraffins. In analysing the results of this study,[57,58] one cannot rule out the possibility of structural isomerisation of hydrocarbons on a strongly acid carrier.

It is noteworthy that metallic catalysis obtained on the basis of heterogenised iron clusters are active in the hydrogenation of olefins.[61]

Linear hydrocarbons are mainly formed in the hydrogenation of CO on cobalt catalysis prepared by the thermal decomposition of $Co_2(CO)_8$,[62,63] the distribution of their molecular weights obeying the Schultz–Flory equation.[64] The catalysts obtained by the rapid decomposition of the deposited metal carbonyl are 2–10 times more active than the traditional cobalt catalysts.

The same rules hold for the heterogenised cobalt catalytic systems[65] as for the ruthenium systems:[59,60] an increase in the degree of dispersion of the metallic particles lowers the specific catalytic activity; with increase of the metallic particle size, the relative yield of higher hydrocarbons rises, the maximum yield being obtained using $TiO_2$ and $ZrO_2$ as the carriers.[63,66] The $Co_2(CO)_8$ clusters deposited on $SiO_2$ and $TiO_2$ showed the maximum activity.[65]

Pyrolysis of $Fe(CO)_5$ and $Fe_3(CO)_{12}$ on the $\gamma$-$Al_2O_3$ surface yielded selective catalysts of the synthesis of light olefins.[67] However, in the course of the reaction the finely dispersed metallic particles increases in size and methane became the main product. By using the salt-like heteroatomic cluster $(NEt_4[[Fe_2Mn(CO)_{12}]$ as the initial complex, it is possible to increase the stability of the action of the catalyst and to reduce the yield of methane.[69] An attempt to synthesise an active and stable catalyst from the cobalt carbonyl and manganese compounds taken separately was unsuccessful.

In conclusion of this Section, we shall consider the catalytic properties of heterogeneous clusters in the hydroformylation and hydrogenation of olefins and in the dehydrocyclisation of alkanes and the hydrogenation of benzene. Ichikawa[70,71] hydroformylated ethylene and propene on $Co_4(CO)_{12}$/ZnO. Although this catalyst showed a lower activity than the rhodium and rhodium-cobalt clusters, the selectivity of the formation of the linear aldehyde proved to be higher.

The study of the dehydrocyclisation and the structural isomerisation of n-hexane on platinum clusters[72–75] showed that the reaction pathway depends on the number of transition metal atoms in the heterogenised complexes (Table 1). The complexes were deposited on $Al_2O_3$ and $SiO_2$ from solution in tetrahydrofuran. Stoichiometric amounts of CO and triethylamine were evolved on heat treatment of the heterogenised complexes *in vacuo*, in helium, or in hydrogen at 150 to 170 °C and platinum clusters, whose particle size did not exceed 1 nm, were immobilised on the carrier surface.

Table 1. The conversion of n-hexane on heterogenised platinum clusters.[75]

| Cluster | $c^{**}$, wt.% | $T$, °C | Reaction products, mole % | | | |
|---|---|---|---|---|---|---|
| | | | 2-methylpentane | 3-methylpentane | methylcyclopentane | cyclohexane + $C_6H_6$ |
| $[Pt_{15}(CO)_{30}][NEt_4]_2/\gamma$-$Al_2O_3$ | 0.69 | 295 | 17.2 | 8.2 | 61.7 | 12.9 |
| $[Pt_{15}(CO)_{30}][NEt_4]_2/\gamma$-$Al_2O_3$ | 0.69 | 320 | 15.6 | 6.4 | 65.7 | 12.3 |
| $[Pt_{15}(CO)_{30}][NEt_4]_2/SiO_2$ | 0.15 | 320 | 21.4 | 12.5 | 58.5 | 7.6 |
| $[Pt_{12}(CO)_{24}][NEt_4]_2/\gamma$-$Al_2O_3$ | 0.54 | 275 | 1.25 | 6.8 | 64.1 | 13.9 |
| $[Pt_9(CO)_{18}][NEt_4]_2/\gamma$-$Al_2O_3$ | 0.26 | 320 | 9.6 | 6.4 | 72.8 | 11.2 |
| $[Pt_9(CO)_{18}][NEt_4]_2/\gamma$-$Al_2O_3$ | 0.50 | 320 | 11.4 | 5.2 | 74.4 | 9.0 |
| $[Pt_6(CO)_{12}][NEt_4]_2/\gamma$-$Al_2O_3$ | 0.18 | 320 | 5.4 | 3.7 | 83.6 | 7.3 |
| $[Pt_6(CO)_{12}][NEt_4]_2/\gamma$-$Al_2O_3$ | 0.25 | 325 | 5.2 | 2.6 | 87.0 | 5.2 |
| $[Pt_3(CO)_3(PPh_3)_4]/\gamma$-$Al_2O_3$ | 0.45 | 325 | 3.7 | 1.7 | 92.6 | 2.0 |

*After the heterogenisation of the complexes, the specimens were heat-treated at 350 °C (the last row—at 250 °C) in a stream of hydrogen for 5 h.
**The content of metallic platinum.

It follows from Table 1 that the last catalyst is characterised by a high selectivity in the dehydrocyclisation reaction. It may be that structural correspondence, as defined by Balandin, is manifested in this case and that the multiplet made up of three platinum atoms is the most suitable for this reaction.

An anlogous dependence of the selectivity of the reaction on the number of platinum atoms in the heterogenised cluster has been observed in antoher study by Ichikawa.[76] It was found that the catalysts based on the $Pt_{15}$ and $Pt_{12}$ clusters are active both in structural isomerisation and in hydrogenolysis of neopentane, while the $Pt_6$ and $Pt_5$ clusters lead mainly to hydrogenolysis products.

The influence of the nuclearity of the clusters on the activity and selectivity has also been demonstrated.[77] The complexes $Cp_2Ni$, $Cp_2Ni_2(CO)_2$, and $Cp_3Ni_3(CO)_2$ deposited on the silica gel surface from solution in THF showed different catalytic activities after heterogenisation on the carrier and heat treatment *in vacuo* or hydrogen at 120 °C. Thus it was found that acetylene was readily converted into benzene at room temperature (degree of conversion 75% after 2 h) on the nickel catalyst obtained from $Cp_2Ni$, whereas the cluster catalyst proved to be inactive. Under the same conditions, acetylene was firmly adsorbed on the latter (1 mole of $C_2H_2$ per mole of $Ni_3$ or $Ni_2$). On the other hand, the ethylene and benzene hydrogenation reactions, dueterium–hydrogen exchange, and hydroformylation of ethylene occurred only on the cluster catalyst.

## IV. HETEROGENISATION OF POLYNUCLEAR π-ALLYL COMPLEXES

The π-allyl complexes of transition metals are significantly less stable than the carbonyl complexes. Despite the difficulties arising from this fact, the heterogenisation of the π-allyl complexes has been quite widely investigated.[2]

This Section presents the results of the latest studies on the heterogenisation of polynuclear π-allyl complexes and the catalysts based on them.

Detailed studies have been made[78–83] of the heterogenisation of mono- and di-nuclear π-allyl complexes of molybdenum and chromium, which are of a similar chemical nature. The authors endeavoured to elucidate the following questions:

(1) is the structure of the dinuclear centre preserved on heterogenisation; (2) are there differences between the activities of the catalysts obtained by the heterogenisation of the mono- and di-nuclear complexes; (3) does the nature of the mineral matrix influence the character of the immobilisation. The authors established that the Mo–Mo distance in the complex $Mo_2(\pi\text{-allyl})_4$, which amounts to 2.183 Å, increases to 3.1–3.2 Å after heterogenisation. The bond between the molybdenum atoms in this structure is preserved, which has been confirmed by the study of the catalysts using the atomic radial distribution method. The average distance between the $Mo_2 \ldots Mo_2$ pairs in $Al_2O_3$ with a surface concentration of hydroxy-groups of 2.6 $nm^{-2}$ is 23 Å.

Figs. 2 and 3 present schemes for the heterogenisation of $Mo_2(\pi\text{-}C_3H_5)_4$ and $Cr_2(\pi\text{-}C_3H_5)_4$ on five carriers with different specific surfaces and different densities of the hydroxy-groups.

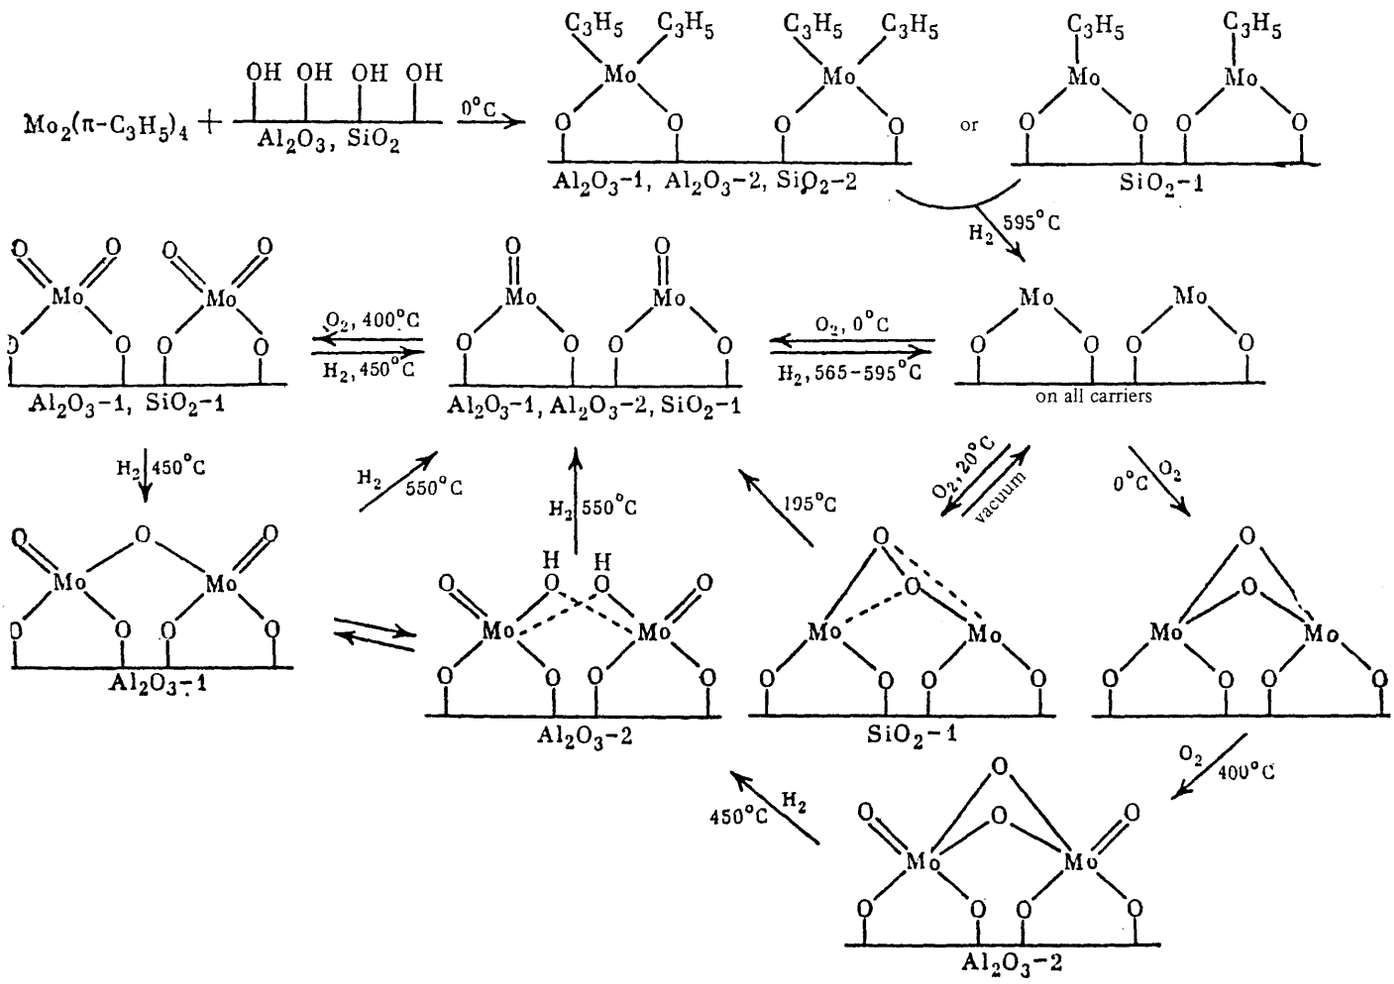
Comparison of the structures obtained by the heterogenisation of mononuclear complexes with the structures derived from their dinuclear analogues shows that the dinuclear molybdenum structures are produced with much more difficulty than the mononuclear structures (Fig. 4). Furthermore, whereas the reduction reaction proceeds in accordance with the scheme $Mo^{6+} \rightarrow Mo^{4+} \rightarrow Mo^{2+}$ for the mononuclear centre, in the case of the dinuclear centre it is possible to detect also the 5+ oxidation state. The $Mo^{3+}$ state was not observed in either case.[83] The variation of the stability of the surface dinuclear structures on $SiO_2$ with the surface

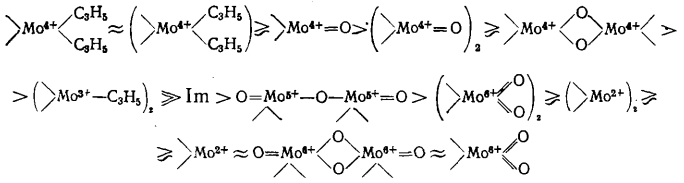
concentration of the immobilised complexes has also been noted: with increase of the concentration, the stability of the structures falls.[83]

The catalytic activities of the immobilised di- and mononuclear complexes differ appreciably. Thus in the oxidative dehydrogenation of ethanol the activity of the mononuclear catalyst is proportional to the concentration of the $Mo^{6+}$ centres, while that of the dinuclear catalyst is proportional to the number of $Mo^{6+}$ pairs (Fig.5). This makes it possible to speak of the cooperative effect of the $Mo^{6+}$ pairs in the catalyst obtained as a result of the immobilisation of the dinuclear π-allyl complex of molybdenum; in other words, this result agrees with Balandin's hypothesis that the dehydrogenation reaction proceeds via a doublet mechanism.

The catalytic properties of the mononuclear and dinuclear molybdenym complexes in a low oxidation state ($Mo^{2+}$) in the hydrogenation of butadiene also proved to be different[83] (Fig.6). Thus, in the presence of the catalyst obtained by the heterogenisation of the mononuclear cluster $Mo(\pi\text{-}C_3H_5)_4$, buta-1,3-diene is mainly converted into a mixture of *cis*- and *trans*-but-2-enes, while in the case of the dinuclear complex but-1-ene is formed in 60% yield. The hydrogenating activity of the dinuclear centre at 0 °C is 5 times greater than that of the mononuclear centre and 3280 times greater than the activity of the traditional impregnated catalyst.

By altering the nuclearity of the active centre and the oxidation state of the transition metal atom forming part of the composition of this centre, it is sometimes possible to





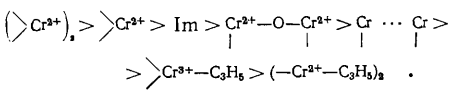


Figure 2. The structures of the surface centres formed as a result of the oxidation-reduction reactions of the dinuclear complex $Mo_2(\pi\text{-}C_3H_5)_4$ heterogenised on carriers of different nature. Carriers: $Al_2O_3$-1 (190 $m^2\ g^{-1}$, 2.6 OH group $nm^{-2}$); $Al_2O_3$-2 (385 $m^2\ g^{-1}$, 4.5 OH group $nm^{-2}$); $SiO_2$-1 (120 $m^2\ g^{-1}$, 3.5 OH group $nm^{-2}$); $SiO_2$-2 (285 $m^2\ g^{-1}$, 4.6 OH group $nm^{-2}$); $SiO_2$-3 (510 $m^2\ g^{-1}$, 1.3 OH group $nm^{-2}$).[78]

discover the structure of the centre which is optimal for the reaction of the given type. This problem has been solved[83] for the disproportionation of propene. The activities of different surface centres, illustrated in Fig.2, diminish in the sequence

where Im is the impregnated catalyst. The activities of the immobilised di- and mono-nuclear π-allyl complexes of chromium in the hydrogenation of propene at −35 °C vary in the analogous sequence:[83]

In this case too the dinuclear centre is more active than the mononuclear centre. This may be explained by the fact that the doublet (as defined by Balandin) is preferable for the hydrogenation reaction.

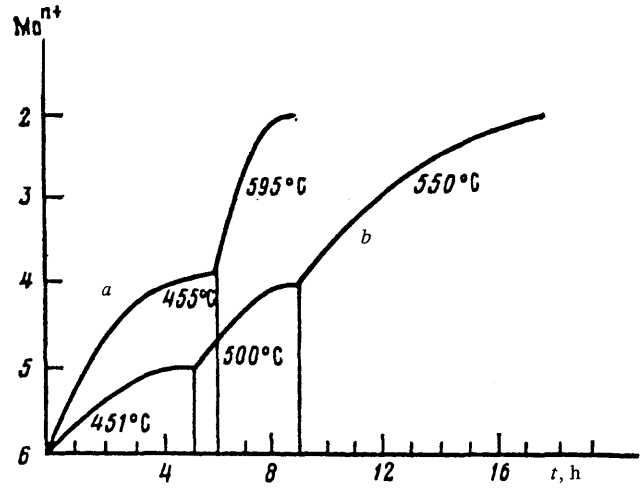

**Figure 4.** Kinetics of the reduction with hydrogen of immobilised mononuclear (*a*) and dinuclear (*b*) π-allyl complexes of molybdenum ($p_{H_2}$ = 64 mmHg).[83]

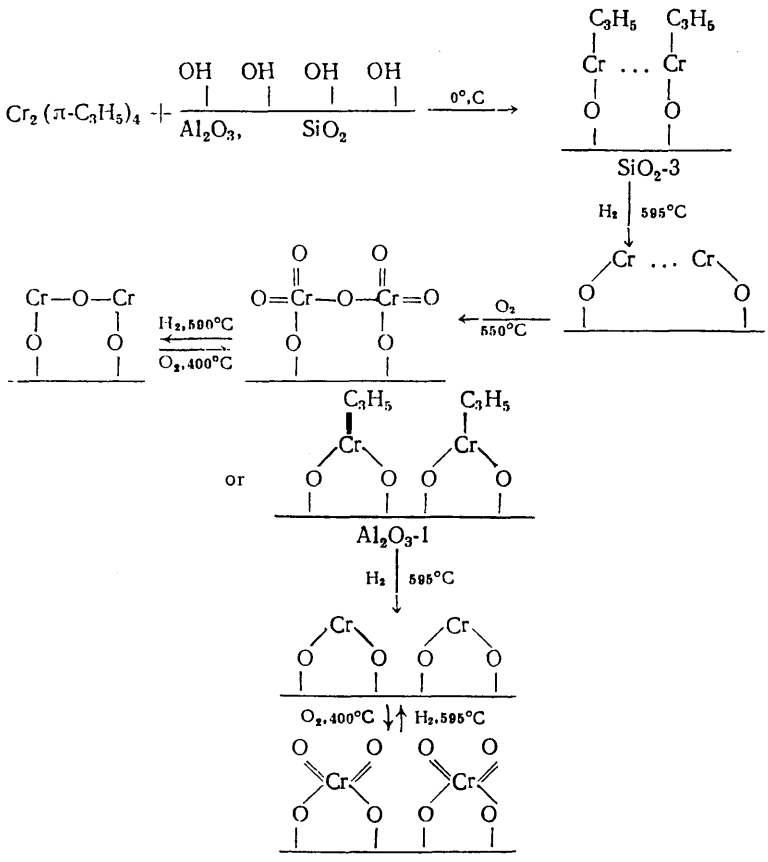

**Figure 3.** The structures of the surface centres formed as a result of the oxidation-reduction reactions of the dinuclear complex $Cr_2(\pi\text{-}C_3H_5)_4$ heterogenised on carriers of different nature; carriers—see the legend to Fig.2.[78]

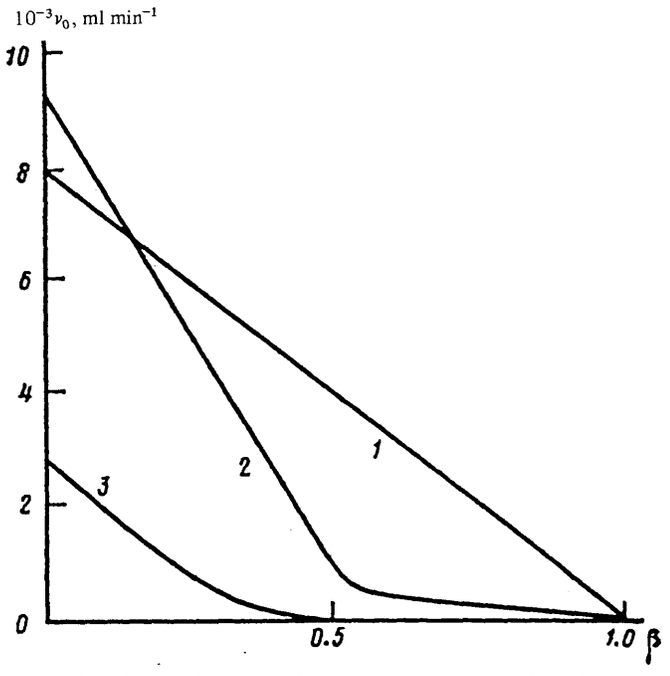

Figure 5. Dependence of the initial rate of the dehydrogenation reaction of ethanol ($v_0$) on the relative content of $Mo^{6+}$ ions ($\beta$) in the oxidised specimens of the immobilised $Mo(\pi\text{-}C_3H_5)_4$ (line *1*) and $Mo_2(\pi\text{-}C_3H_5)_4$ (line *2*) complexes; (*3*) impregnated catalyst based on $(NH_4)_2MoO_4$ ($7.85 \times 10^{18}$ Mo atoms, 148 °C).[83]

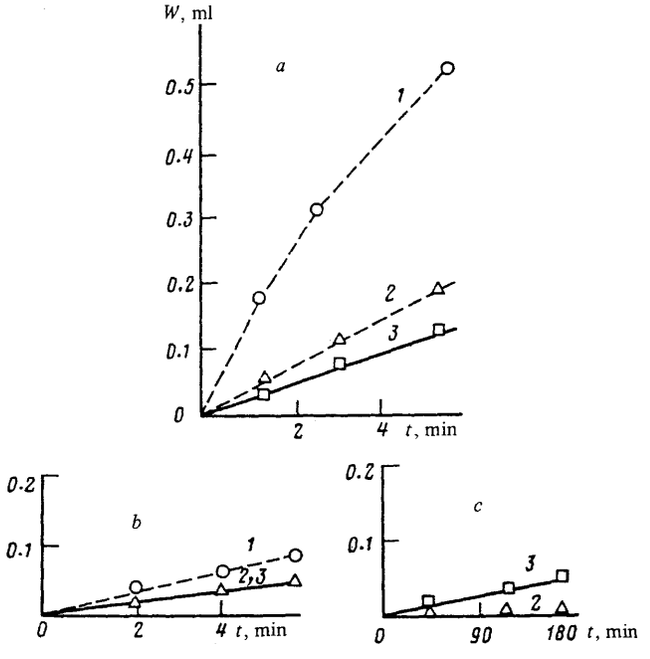

Figure 6. Hydrogenation of buta-1,3-diene on $Mo_2/Al_2O_3$ (*a*), $Mo/Al_2O_3$ (*b*), and the impregnated catalyst based on $(NH_4)_2$. $.MoO_4$ (*c*); molybdenum content (atoms): *a*) and *b*) $5.37 \times 10^{18}$; *c*) $3.16 \times 10^{19}$; 1) but-1-ene; 2) *trans*-but-2-ene; 3) *cis*-but-2-ene ($p_{C_4H_8} : p_{H_2} = 2:1$; 0 °C).[83]

An even greater difference has been obtained in the study of the catalytic activities of the mono- and di-nuclear centres based on the allyl complexes of molybdenum immobilised on the surfaces of aluminium and silicon oxides in the hydrogenation of ethylene (Fig.7).[83] It is of interest that, whereas no differences between the activities of the mono- and di-nuclear centres were observed on $Al_2O_3$, on $SiO_2$ only the immobilised dinuclear complexes were activie. The influence of the nature of the carrier is difficult to explain in this instance. The possible causes are the conversion of the dinuclear complexes into the monomeric form on the surface of $Al_2O_3$ and the lack of a difference between the structures of the mono- and di-nuclear centres. The significantly higher activity of the catalyst based on $Al_2O_3$ is also noteworthy.

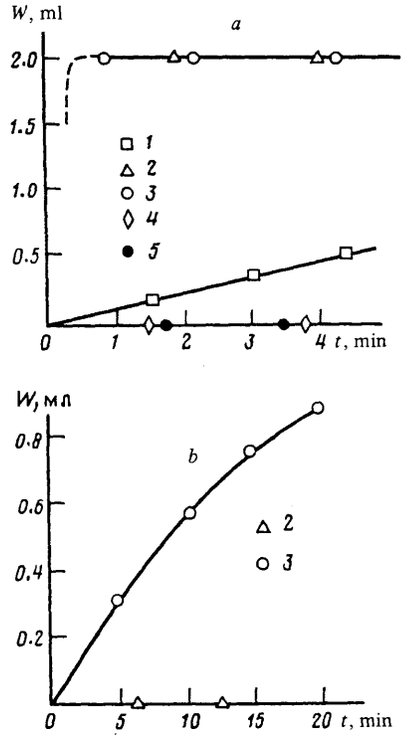

Figure 7. The influence of the structure of the surface centres formed in the oxidation-reduction treatment of the complexes $Mo(\pi\text{-}C_3H_5)_4$ and $Mo_2(\pi\text{-}C_3H_5)_4$, immobilised on $Al_2O_3$ and $SiO_2$, on the yield of ethane in the ethylene hydrogenation reaction ($p_{H_2} = 48$ mmHg; $p_{C_2H_4} = 12$ mmHg). Reaction conditions: *a*) for $TMC/Al_2O_3$, temperature 73 °C, sample size 0.1 g; *b*) for $TMC/SiO_2$, temperature 20 °C, sample size 0.28 g; 1) reduced impregnated catalyst based on $(NH_4)_2MoO_4$; 2) $(|\text{-}O)_2Mo$; 3) $[(|\text{-}O)_2Mo]_2$; 4) $[(|\text{-}O)_2Mo{=}O]_2$; 5) $(|\text{-}O)_2Mo{=}O$.[83]

Thus the nuclearity and the skeleton of the immobilised centre can be frequently preserved in the heterogenisation of transition metal complexes on mineral carriers. However, this does not guarantee that the immobilised structures remain unchanged under these conditions of the catalytic reaction. Unfortunately, very little attention has been devoted to this question in the literature.

## V. THE "ASSEMBLY" OF CLUSTER CENTRES ON THE SURFACES OF CARRIERS

All the methods of synthesis of cluster and polynuclear heterogeneous catalysts described above are based on the same procedure for the immobilisation of the complex obtained beforehand and containing several metal atoms. However, catalysts containing centres with a higher nuclearity can be synthesised also in a different way—from mononuclear complexes, i.e. by "assembling" the cluster or polynuclear active centres directly on the carrier surface.

Two main trends in the application of this method of synthesis of heterogeneous metal complex catalysts have come to be most widely used at the present time. The first may be referred to as the method of statistical assembly and the second the method of programmed assembly on the surface. The first method consists in the preliminary immobilisation on the carrier surface of mononuclear centres which can be converted by further chemical treatment into polynuclear formations stable under given conditions. Naturally, when this method is employed, the structure of the active centre is unknown and the species formed are non-uniform as regards size. This is caused by the statistical nature of the process involving the formation of the structure of the centres and the energetic and geometrical non-uniformity of the carrier surface.

The method of programmed assembly on the surface involves a series of consecutive chemical reactions leading to an increase in the complexity of the structures of the immobilised mononuclear complexes. In this case the degree of uncertainty in the structures of the centres formed on the surface is diminished but the element of uncertainty persists, because the number of different types of centre which may be superimposed on the surface is equal to the number of stages of the reaction occurring on the surface.

Examples of the employment of these two varieties of the surface assembly methods for the synthesis of polynuclear, cluster, and highly dispersed metallic catalysts are presented below. We may note that it is difficult to draw a clear-cut boundary between these types of catalysts, at any rate so long as the particle size does not exceed 30–50 Å.

### 1. Statistical Assembly

The statistical method of surface assembly of highly dispersed metallic catalysts consists in the preliminary immobilisation on the carrier surface of mononuclear complexes (for example, π-allyl complexes) which are reduced with hydrogen at elevated temperatures:

$$\left|\!-\mathrm{OH}\xrightarrow[-\mathrm{HL}]{\mathrm{ML}_n}\left|\!-\mathrm{OML}_{n-1}\xrightarrow{\mathrm{H_2}}\right.\right.\text{microcrystallites of the dispersed metal on the carrier surface.}$$

This method of synthesis of the highly dispersed catalyst as a result of the preliminary heterogenisation of π-allyl complexes of transition metals on $SiO_2$ and $Al_2O_3$ has been developed and studied in detail at the Institute of Catalysis of the Siberian Division of the USSR Academy of Sciences.[2]

After the reduction of the immobilised π-allyl complexes of nickel, palladium, and platinum, it was suggested that the atomically dispersed metallic phase be produced on the surface. However, the low energy of the migration of atoms on the carrier surface (12.6 kJ $mol^{-1}$), which, amounts to half the energy of the interaction with the surface according to Anderson,[84] prevents the aggregation of metal atoms. The stabilisation of the highly dispersed state is achieved as a result of the preliminary immobilisation of Group VI metal ions in low oxidation states on the surface.[85,86] These atoms serve as "energy traps" and prevent the migration and the increase in the size of the surface particles as a result of the high energy of the $M^{VIII}$–$M^{VI}$ bond. It has been noted[87] that the increase in the interaction energy to 84 kJ $mol^{-1}$ increases the probability of the localisation of the surface atoms by a factor of $10^4$. The metal–metal bond energies in different complexes have been published;[88] these data make it possible to limit the range of atoms whose hydrogenation would promote the stabilisation of the state of the catalytic active centres based on noble and certain transition metals corresponding to the maximum degree of dispersion.

A method has been developed[89,90] for the preparation of highly dispersed palladium and platinum catalysts stabilised by the doubly charged molybdenum and tungsten ions previously immobilised:

$$2\left(\left|\!-\mathrm{OH}\right.\right)+\mathrm{MR_4}\rightarrow\left(\left|\!-\mathrm{O}\right.\right)_2\mathrm{MR_2}\xrightarrow[\mathrm{H_2}]{500\text{–}600^\circ\mathrm{C}}\left(\left|\!-\mathrm{O}\right.\right)_2\mathrm{M}\rightarrow$$

$$\rightarrow\xrightarrow{1)\ \mathrm{PtR_2};\ 2)\ \mathrm{H_2}}\begin{cases}\longrightarrow \underline{\mathrm{M_xPt_n}}\ (\mathrm{I})\ ;\\ \longrightarrow \left|\!\begin{matrix}-\mathrm{O}\\-\mathrm{O}\end{matrix}\right\rangle\mathrm{M}\!-\!\mathrm{Pt}_n\ (\mathrm{II})\ ;\end{cases}$$

$R=\pi\text{-}C_3H_5$; M=Mo, W.

So far it is difficult to state that one of the proposed structures is preferable.[91]

The catalysts obtained by this method had a series of unusual properties compared with the unmodified molybdenum and tungsten catalysts: (1) a high thermodynamic stability of surface centres over a wide temperature range, which is characterised by the constancy of the ratio O : Pt = 1 (at 300–700 °C) in the chemisorption of oxygen; (2) a higher activity in benzene hydrogenation (by a factor of 2–5) and ethane hydrogenolysis (by a factor of $10^4$) reactions (Table 2); (3) a higher stability of the catalytic activity; (4) a change in the kinetic parameters of the hydrogenolysis of ethane (the activation energy is reduced and the order of the reaction with respect to hydrogen is altered).

**Table 2.** The activity of platinum catalysts in the hydrogenation of benzene (25 °C; $H_2 : C_6H_6 = 8 : 1$; 0.53 MPa).[91]

| Catalyst | $c$, wt.% | $T_r$, °C | $a$, mol $g^{-2}$ | $b$, $s^{-1}$ |
|---|---|---|---|---|
| $Pt/SiO_2$ | 3.5% Pt | 500 | 0.21 | 18 |
| $Pt/SiO_2$ | 3.1% Pt | 700 | 0.18 | 20 |
| $(Mo\div Pt)/SiO_2$ | 1.5% Mo; 4.4% Pt | 500 | 1.20 | 64 |
| $(Mo\div Pt)/SiO_2$ | 1.5% Mo; 4.4% Pt | 500* | 2.00 | 110 |
| $(W\div Pt)/SiO_2$ | 4% W; 2.9% Pt | 700 | 0.80 | 46 |
| $(W\div Pt)/SiO_2$ | 6% W; 3.0% Pt | 700 | 1.25 | 67 |

Notation: $c$ is the content of surface elements, $T_r$ the reduction temperature, $a$ the amount of benzene which has reacted per gram of platinum in 1 h, $b$ the amount of benzene (in moles) which has reacted per mole of the surface platinum atoms in 1 s (the turnover number).

*The catalyst was oxidised before reduction.

The study of platinum catalysts by X-ray photoelectron spectroscopy showed that the presence of a Group VI metal ion with a low charge leads to a redistribution of electron density and the appearance of an electron deficiency at the platinum atom. This entails an increase of the binding energy of the $4f_{7/2}$ level, which can be explained, according to the authors,[87] by the transfer of electrons to the oxygen atoms of the mineral matrix, the molybdenum and tungsten

ions with a low charge playing the role of a bridge. If this interpretation is correct, the active centre should have the structure (II) (see Scheme).

## 2. Programmed Assembly

A novel version of the method of the programmed surface assembly has been developed by Semikolenov and co-workers.[92,93] Its essential feature consists in the controllable growth of the catalytic centre, which is immobilised on $SiO_2$ by means of a chemically modified chelating ligand:

$$\text{Si}\begin{matrix}\diagup\ \text{CH}_2\text{CH}_2\text{CH}_2\text{PPh}_2\\ \diagdown\ \text{CH}_2\text{CH}(\text{CH}_3)\,\text{CH}_2\text{PPh}_2\end{matrix}\ \left(\left|\text{—Si—P}_2\right.\right):$$

$$\left|\text{—Si—P}_2\xrightarrow[(a)]{\text{Pd(OAc)}_2}\left|\text{—Si—P}_2\text{Pd(OAc)}_2\xrightarrow[(b)]{\text{HCOOH}}\right.\right.$$

$$\rightarrow\left|\text{—Si—P}_2\text{Pd(OCOH)}_2\xrightarrow[-\text{CO}_2,-\text{CO},-\text{H}_2\text{O};(c)]{\text{Pd(OAc)}_2}\left|\text{—Si—P}_2\text{Pd}_2\text{(OAc)}_2\xrightarrow[(b)]{\text{HCOOH}}\right.\right.$$

$$\rightarrow\left|\text{—Si—P}_2\text{Pd}_2\text{(OCOH)}_2\xrightarrow[-\text{CO}_2,-\text{CO},-\text{H}_2\text{O};(c)]{\text{Pd(OAc)}_2}\left|\text{—Si—P}_2\text{Pd}_3\text{(OAc)}_2\right.\right.\ \text{etc.}$$

According to the authors' data, by alternating stages ($b$) and ($c$) several ($n$) times, it is possible to obtain a cluster containing $n + 1$ palladium atoms. In order to regulate the stoichiometry of the interaction and the degree of reduction of the $Pd^{2+}$ ions, the process leading to the assembly of the surface cluster was carried out in the presence of a ligand (the formate ion), which possessed, apart from reducing properties, also the ability to immobilise beforehand a new metal ion on the complex already immobilised, as a result of the formation of bridge bonds.

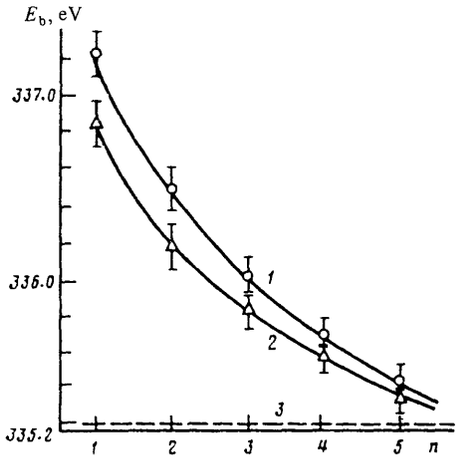

Figure 8. Dependence of the binding energy of the electrons of the Pd atom in the $3d_{5/2}$ level on the number of Pd atoms in the cluster: 1) initial $\left|\text{—P}_2\text{Pd}n(\text{OCHQ})_2\right.$ specimens; 2) the same specimens heated *in vacuo* at 110 °C for 1 h; 3) metallic palladium foil.[92]

The successive formation of surface polynuclear structures with a nuclearity varying from 2 to 5 is demonstrated by the parallel decrease of the binding energy of the electrons in the $3d_{5/2}$ level and the increase of the number of palladium atoms immobilised on the surface of the matrix (Fig. 8).

We may note that the binding energy of the electrons in the $3d_{5/2}$ level for a pentanuclear cluster is very close to the binding energy of the electrons in the same level for the compact metal.

The catalytic properties of the cluster palladium catalysts with $1 \leqslant n \leqslant 5$ have been investigated in the cyclopentadiene hydrogenation reaction and in Zelinskii's irreversible catalytic reaction. The dependence of the catalytic activity on $n$ has been demonstrated. Specimens with $n = 1$ or 2 did not exhibit activity in the disproportionation of cyclohexene. It is extremely probably that the surface of these catalysts contains no palladium microcrystals, because it is known that palladium on $SiO_2$ is an active catalyst in this reaction. For $n = 3$–5, cyclohexene is converted into cyclohexane and benzene with a high yield (Fig. 9). In the cyclopentadienes hydrogenation reaction the catalysts containing monatomic centres were inactive.

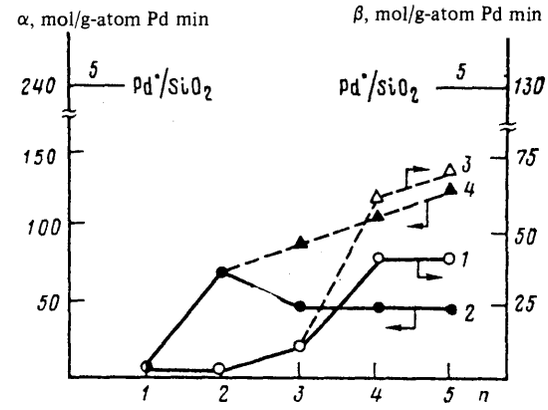

Figure 9. The influence of the nuclearities $n$ of the palladium clusters on their catalytic properties: 1) disproportionation of cyclohexene (β); 2) hydrogenation of cyclopentadiene (α); 3) and 4) calculated dependences of the catalytic activity in the same reactions respectively plotted on the assumption that the active centres for the disproportionation and hydrogenation reactions are the $Pd_3$ and $Pd_2$ fragments respectively; 5) the level of activity of the impregnated $Pd/SiO_2$ catalyst in the same reactions.[93]

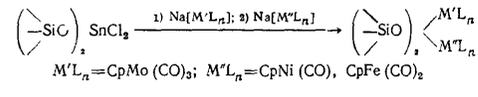


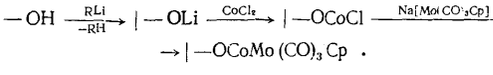
The results of the above studies[92,93] enabled the authors to conclude that the reactions considered proceed only on active centres with a definite structure: the hydrogenation reaction takes place on a diatomic active centre, whereas the cyclohexene disproportionation reaction occurs on a triatomic centre. These conclusions are consistent with the principle of structural correspondence in the multiplet theory of catalysis, to which this composition of the centres for the above reactions corresponds precisely.

Yet another version of the surface assembly method consists of the following operations:[94,95]

$$\left|\text{—OH} + \text{SnCl}_4 \rightarrow \left(\left|\text{—O}\right.\right)_2\text{SnCl}_2\xrightarrow{a\ \text{NaML}_n}\left(\left|\text{—O}\right.\right)_2\text{SnCl}_x(\text{ML}_n)_{2-x}\right.$$

$\text{ML}_n$=CpCr(CO)$_3$, Cr(CO)$_5$, CpMo(CO)$_3$, CpW(CO)$_3$, CpNi(CO); $x = 0, 1$ .

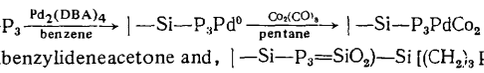
The same approach can be used to synthesise heteroatomic dinuclear complexes:[96]



$M'L_n$=CpMo(CO)$_3$; $M''L_n$=CpNi(CO), CpFe(CO)$_2$

The Group IV non-transition element fulfills several functions: (1) it abolishes the non-uniformity of the carrier surface; (2) it serves as an "anchoring microsupport" for the transition metal atom (the fairly high $M^{VIII}$–$M^{IV}$ bond energy, amounting to 220–300 kJ mol$^{-1}$, gives rise to the hope that the atomically disperse metallic phase will be stable even under the conditions of a fairly high surface concentration of the complex); (3) it modifies the properties of the transition metal; (4) it makes it possible to obtain both homonuclear and heteronuclear immobilised active centres of different nuclearity.

It is noteworthy that this version of the surface assembly method also does not allow the preparation of a sufficiently homogeneous set of active centres on the surface. Thus, in the synthesis of heteronuclear dinuclear complexes, homonuclear as well as heteronuclear active centres may be formed on the surface. Furthermore, mononuclear active centres will persist on the surface, particularly at sites to which access is difficult (for example, within the narrow pores of the carriers). All these factors subsequently introduce an ambiguity into the interpretation of the results obtained. Despite these remarks, one should note that the required active centres are mainly formed on the surface, which is indicated by the almost complete identity of the infrared spectra of the heterogenised complexes and their low-molecular-weight analogues.[97]



The possibility of employing an analogous approach to the synthesis of heteronuclear surface complexes with a $M^{VI}$–$M^{VIII}$ bond has been demonstrated:[97]

A method of synthesis of bimetallic cluster catalysts has been proposed by Ermakov et al.[98] It is based on the idea of the oxidative addition of a zerovalent palladium complex to the Co–Co bond by analogy with the reaction considered in the book of Nesmeyanov and Kocheshkov:[99]

The heterogeneous catalyst was synthesised in accordance with the scheme

DBA = dibenzylideneacetone and, 

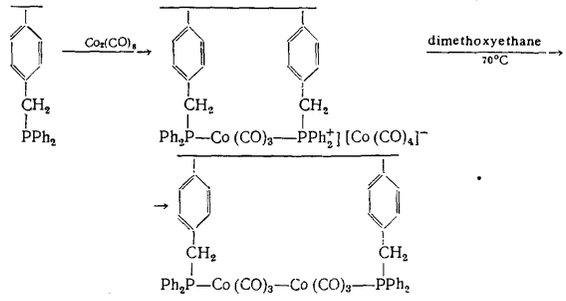
It was found that the infrared spectrum of the specimen obtained is analogous to the spectrum of the complex ($PPh_2$.$CH_2CH_2PPh_2$)Pd[Co(CO)$_4$]$_2$.[100] Together with the results of elemental analysis, these data show that the ratios P : Pd : Co = 3 : 1 : 2, and the results of the study of the heterogenised homonuclear palladium complex $Pd_2(DBA)_4$ and $Co_2(CO)_8$ on the analogous phosphinated $SiO_2$ [101,102] enabled the authors to suggest the formation of the heteronuclear complex |–Si–$P_3$Pd$Co_2$(CO)$_x$, where $x$ = 6–8.

The heteronuclear HMC exhibits an appreciable activity in the hydroformylation of propene even at 40–60 °C, i.e. under conditions where homonuclear HMC are almost inactive. In the course of the reaction the activity of the heteronuclear catalyst fell and the relative yield of the products with the normal structure increased. Thus the introduction of palladium into the composition of the phosphine cobalt carbonyl complex leads to the appearance of a synergistic effect, which is most pronounced at 40–60 °C.

The heterogenisation of the mononuclear iridium complex [Ir(CO)$_2$ (*p*-toluidine) Cl] on polystyrene containing phosphine and diphosphine groups (DIOP) in the presence of zinc leads to the formation of surface clusters.[103–106] Thus the complex containing one phosphine group is formed on polystyrene with phosphine groups in the presence of a low phosphorus content (0.69 wt.%); at higher phosphorus concentrations (1.28 wt.%) the cluster centres linked to the carrier surface via monodentate and chelate bonds are superimposed. On polystyrene containing diphosphine groups, a set of surface compounds is produced. At a low phosphorus concentration in the polymer, |–DIOP[$Ir_4(CO)_{11}$]$_2$ is formed. With increase in the phosphorus concentration, the diphosphine groups begin to behave as chelating ligands and the surface complexes |–DIOP[$Ir_4(CO)_{10}$] are produced. All the immobilised cluster structures exhibit a fairly stable activity in the hydrogenation of ethylene and cyclohexene under mild conditions (40 °C, $10^5$ N m$^{-2}$). Thus, under the reaction conditions mentioned above, the turnover number on the catalyst formed after the heat treatment of |–$PPh_2$.$Ir_4(CO)_{11}$ at 80 °C in helium was 5000. Heat treatment at higher temperatures (120 °C) leads to complete decarbonylation, aggregation of the metal, and an appreciable decrease in catalytic activity.[103,104]

The procedure examined above has been used[107] for the assembly of an iridium cluster on the surface of $SiO_2$ modified by phosphine groups. The reaction was carried out under the conditions of the synthesis of a cluster having the composition [$Ir_4(CO)_nPPh_3$] from the low-molecular-weight complex [Ir(CO)$_2$(*p*-toluidine) Cl] at 90 °C and a 5 atm CO pressure.[108] The authors suggested that the surface phosphine groups play the role of a monodentate ligand.[107]

After decarbonylation, the tetrairidium cluster heterogenised on $SiO_2$ proved to be active in the hydrogenation of ethylene at 30–90 °C. On the basis of the data obtained by Studer and Schrader,[107] one may postulate that the structure of the cluster breaks down in the course of the preliminary treatment and catalysis, and that the reaction proceeds on metallic microcrystals.



## VI. HETEROGENISATION OF POLYNUCLEAR AND CLUSTER COMPLEXES ON MODIFIED CARRIERS

The application of chemically modified carriers for the heterogenisation of complexes is based on the fact that with their aid it is possible to immobilise complexes on the surface via a chemical reaction specified beforehand, i.e. the use of modified carriers makes it possible to increase the probability of the retention of the initial structure of the transition metal complex. At the same time, chemical modification of the carrier constitutes an additional and frequently fairly laborious stage in the preparation of the catalyst.

### 1. Catalysts on Modified Organic Polymers

The synthesis of a cluster ruthenium catalyst on the surface of the phosphinated styrene–divinylbenzene copolymer, which is active in the hydrogenation of ethylene (52 to 95 °C), has been described.[109]

The heterogeneous metal complex catalyst, active under milder conditions than its homogeneous analogue, has been obtained in accordance with the scheme[110]

The catalyst exhibited a high stability in the hydroformylation reaction: after washing with a solvent, its activity hardly differed from the initial activity. The authors[110] believe that the active centre in this instance is not a dinuclear complex but a mononuclear hydride formed on hydrogenolysis of the Co–Co bond.

The reduction of $Rh_4(CO)_{12}$ and $Rh_6(CO)_{16}$ heterogenised on phosphinated polystyrene yielded an active metallic catalyst for the hydrogenation of arenes at room temperature under normal pressure.[111,112] In contrast to the industrial $Rh/Al_2O_3$ catalyst, the rhodium deposited on the polymer is in a more dispersed state. The authors quote data concerning the extraction of rhodium from the catalyst with the aid of CO as evidence in support of this hypothesis. When the polymer catalyst is treated with carbon monoxide, it is possible to regenerate 50% of the rhodium, while the metal is hardly removed from the $Al_2O_3$ surface.[113]

It has been shown[114,115] that the olefin hydrogenation catalyst obtained by the heterogenisation of $Rh_6(CO)_{16}$ on phosphinated polystyrene contains no carbonyl ligands and the surface phosphine groups play the role of polydentate ligands stabilising the small rhodium clusters on the surface. Carbon monoxide poisons the catalyst and in the presence of traces of oxygen the surface phosphine groups are oxidised, which promotes the agglomeration of rhodium;[115] the activity of the catalyst remains stable at 75 h.

The heterogenisation of $Rh_6(CO)_{16}$ on polystyrene containing *NN*-dimethylbenzylaniline groups led to the synthesis of an active catalyst of the reduction of nitrobenzene and the conversion of water vapour.[116] However, it is somewhat less active and more sensitive to oxygen than its homogeneous analogue.

Studies of the heterogenisation of bimetallic clusters on the surface of phosphinated polystyrene established[117,118] that the clusters $[ClAuOs_3(CO)_{10}Ph_2P-|]$ and $[Co_2Pt_2(CO)_8.(Ph_2P-|)_2]$ with an open structure of the "butterfly" type are active in the hydrogenation of ethylene (<100 °C, $1 \times 10^5$ N $m^{-2}$) in contrast to polymers which contain clusters with a closed tetrahedral structure—for example, $[HAuOs_3(CO)_{10}.Ph_2P-|]$ and $[H_2PtOs_3(CO)_{10}(Ph_2P-|)_2]$.[115] This difference is due to the presence in clusters of the first type of coordination-saturated metal atoms. In order to impart catalytic activity to these clusters, it is essential to rupture the metal–metal bond.

The clusters $[RuPt_2(CO)_5(Pt_2P-|)_3]$ and $[Fe_2Pt(CO)_8.(Ph_2P-|)_2]$ immobilised on phosphinated polystyrene are active in the hydrogenation of ethylene (70–100 °C, $1 \times 10^5$ N $m^{-2}$). However, whereas the first complex is stable (turnover number ~4400), the second decomposes with formation of mononuclear complexes and the metallic phase.[118]

## 2. Catalysts on Modified Silicas

Bilhou et al.[119] heterogenised the rhodium cluster $Rh_6(CO)_{16}$ on the surface of phosphinated silica $\equiv Si(CH_2)_2PPh_2$ (grafting density 1.6 groups per $nm^2$) at room temperature and observed that the cluster is decarbonylated, which is characterised by the disappearance of the absorption bands of the carbonyl groups from the infrared spectrum. Treatment of the specimens with carbon monoxide is accompanied by the appearance of the corresponding bands in the infrared spectrum. This finding as well as the similarity of the stretching vibration frequencies for a series of rhodium carbonyl and phosphinerhodium clusters (Table 6) [Table 6 of Bilhou et al.[119]? (Ed. of Translation)] enabled the authors to suggest that the structure and skeleton of the cluster are retained after its heterogenisation on the mineral carrier.

The partly decarbonylated $Rh_6$ clusters exhibit a low activity in the benzene hydrogenation reaction at room temperature (25 °C). It has also been noted that phosphine-containing clusters, with the exception of that heterogenised on $SiO_2$, exhibit a higher (up to 150 °C) thermal stability than purely carbonyl clusters.

Other results have been obtained from the study of Thornton et al.[120] Two types of $SiO_2$ carriers were used as the matrix for the heterogenisation of the $Rh_6(CO)_{16}$ cluster: $SiO_2$ modified by a phosphine group $-(CH_2)_3PPh_2$ and $SiO_2$ modified by an amine group $-(CH_2)_3NHC_6H_{11}$. The density of the grafting of the functional group on the two carriers was the same (1.1 $nm^{-2}$) and the rhodium contents[119] were 0.24 and 0.66 wt.% respectively.

It has been shown that the interaction of rhodium clusters with aminated $SiO_2$ yields a specimen in the infrared spectrum of which vibrations appear at 2085 and 2003 $cm^{-1}$. These were characterised as symmetric and antisymmetric vibrations of the CO groups of a mononuclear rhodium carbonyl complex containing the $Rh(CO)_2$ fragment. The formula $L_nRh(CO)_2$, where $n$ is the number of amine ligands bound to the surface, may be attributed to this complex. The decarbonylation of the complex diminishes the intensity of the two CO absorption bands mentioned above and leads to the appearance of a new single absorption band at 1943 $cm^{-1}$, which can be assigned[121] to the vibration of the terminal CO group in the complex $L_nRhCO$. The decarbonylation–carbonylation processes

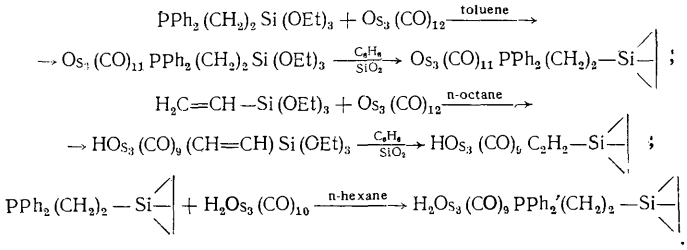
$$L_nRh(CO)_2 \underset{+CO}{\overset{-CO}{\rightleftharpoons}} L_nRhCO$$

are fully reversible up to 157 °C. At this temperature the amine ligand grafted to the surface begins to decompose. The reduction with hydrogen at the temperature above 117 °C is accompanied by the aggregation of the mononuclear rhodium centres, which is indicated by the darkening of the initial brown colour of the specimen and by the appearance in the infrared spectrum of an absorption band at 2020 $cm^{-1}$.

The same band has been observed after the adsorption of CO on the $Rh/Al_2O_3$ deposited catalyst and on thin rhodium films[122,125] (the CO group on 1.5–2.0 nm rhodium crystallites, formed as a result of the agglomeration of rhodium clusters immobilised on phosphinated polystyrene, absorbs at 2045 $cm^{-1}$ [113]). The hypothesis of the formation of the metallic rhodium phase has been confirmed by electron microscopy—the particle size is 1.6–1.7 nm.

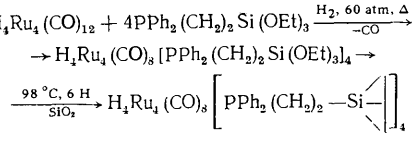
During the ethylene hydrogenation reaction at 56 °C, the activity of the rhodium catalyst increased: the degree of conversion rose from 0.3% to 87% during 54 h; the authors explain this finding by the agglomeration of the metal in the course of the catalytic reaction.[120]

A more complex picture is observed in the heterogenisation of $Rh_6(CO)_{16}$ on phosphinated $SiO_2$,[121] but, as in heterogenisation on aminated $SiO_2$, it indicates, according to the authors,[121] the breakdown of the octahedral skeleton. As in the previous case, the surface mononuclear centres agglomerate during the catalytic process, which leads to the



formation of 1.2–1.5 nm crystallites. The process is accelerated in a hydrogen atmosphere and on the phosphine-modified $SiO_2$ the rate of agglomeration of the metal is lower than on aminated $SiO_2$.

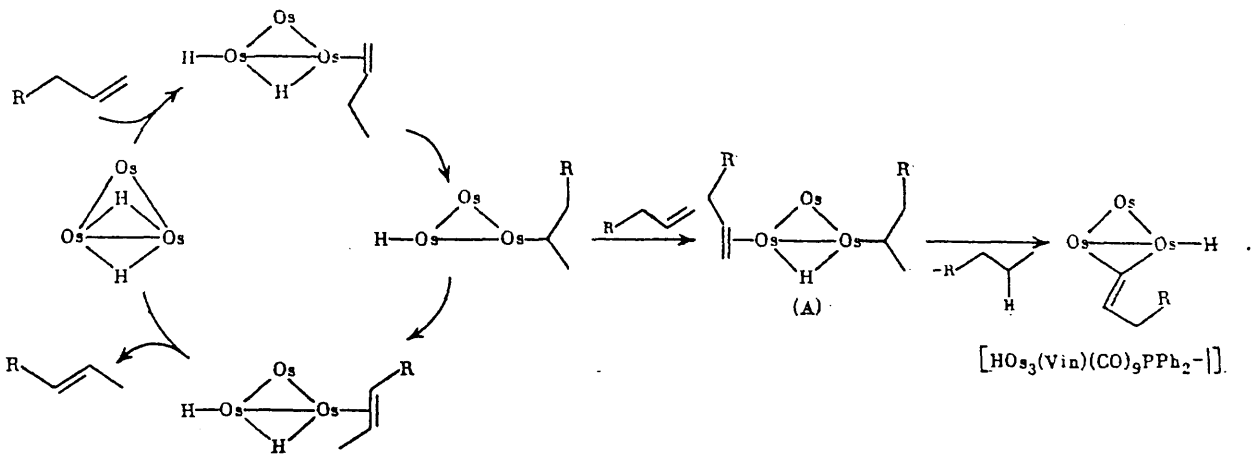
The heterogenisation of $Rh_6(CO)_{16}$ on $SiO_2$ modified by phosphine groups has also been investigated.[126,127] If the reaction is carried out at 80 °C in a boiling benzene solution, then, according to the authors, two types of complexes are formed on the surface. One complex contains structures of indefinite nuclearity comprising $Rh^+$ and two terminal CO ligands (in agreement with other data[121,128]). The second complex also consists of metal clusters whose nuclearity is unknown, but, after carbonylation, the infrared spectra of this complex correspond to those of $Ph_6(CO)_{16}/SiO_2$.[19] In the heterogenisation at room temperature hexa-atomic metallic clusters were formed on the surface.[127] The following structure was attributed to their carbonylation products:



It has been noted that the catalysts obtained from boiling benzene solution are 10 times more active in the hydrogenation of aromatic hydrocarbons than those prepared at room temperature.

Several methods have been described for the heterogenisation of osmium clusters on chemically modified silicas:[128–130]

An analogous approach has been used also in the heterogenisation of the $H_4Ru_4(CO)_{12}$ cluster on $SiO_2$:[131]



The activity of this catalyst in the ethylene hydrogenation reaction at 70 °C and a $C_2H_4$ and $H_2$ pressure of 100 mmHg is higher by an order of magnitude than the activity of the homogeneous complex $H_4Ru_4(CO)_{12}$ and the $H_4Ru_4(CO)_{12}/SiO_2$ catalyst. According to Doi et al.,[131] the cluster skeleton of the heterogenised complex is retained in the catalytic reaction and the cluster is not washed off into the solution, whereas in the case of $H_4Ru_4(CO)_{12}/SiO_2$ 30–40% of the clusters are transferred to the solution in heptane. This catalyst is regenerated by washing with heptane.

The preparation of heterogenised cluster catalysts by immobilising $[H_2Os_3(CO)_{10}]$ on the surface of $SiO_2$ modified with $[PPh_2(CH_2CH_2)Si(OEt)_3]$ has been reported.[130] An analogous system has been obtained also using phosphinated polystyrene cross-linked by divinylbenzene (3%). The results of an infrared spectroscopic study of the heterogenised clusters and their homogeneous analogues presented in the above communication indicate the retention of the cluster skeleton of the complex on heterogenisation.

The $[H_2Os_3(CO)_{10}]$ cluster is a 46-electron coordination-unsaturated complex, which exhibits a tendency towards conversion into a 48-electron complex in the presence of electron-donating ligands. Consequently, one might have expected that coordination-saturated complexes without catalytic activity would be formed as a result of immobilisation on a phosphinated matrix. A coordination-saturated catalytically inactive complex $[H_2Os_3(CO)_{10}PPh_2/carrier]$ was indeed obtained in the first stage as a result of immobilisation on a phosphinated matrix, which was demonstrated by the similarity of the infrared spectra of the homogeneous and heterogenised compounds.[130] Only after decarbonylation on boiling in hexane was a coordination-unsaturated cluster obtained, exhibiting catalytic activity in the isomerisation of pent-1-ene.

An important feature of the heterogenised clusters compared with the homogeneous analogue $[H_2Os_3(CO)_9PPh_3]$ is their high stability. Thus the homogeneous triosmium cluster decomposed during the reaction with formation of disproportionation products and mononuclear complexes, while the heterogeneous analogues promoted the isomerisation of pent-1-ene with an efficiency equivalent to $10^3$ moles of the olefin per mole of the cluster. The decrease of the activity of the cluster is attributed to the formation of a coordination-saturated complex containing a bridging vinyl ligand. The formation of the 48-electron vinyl cluster is reflected in the mechanism of the isomerisation reaction presented below (the carbonyl and phosphine ligands have been omitted):

It is noteworthy that the activity of the heterogenised triosmium cluster is twice as high as that of another homogenous analogue $[H_2Os_3(CO)_{10}]$. The authors[130] explained this finding by the steric hindrance arising at the stage involving the formation of the product (A), which requires the simultaneous coordination of two olefin molecules and this is responsible for the higher stability of the heterogeneous catalyst. The specific activities of the cluster heterogenised on $SiO_2$ and of its active homogeneous analogue proved to be identical. Bearing in mind the difference between the rate constants for the homogeneous ($k_1 = 0.026 \pm 0.005$ litre $mol^{-1}$ $s^{-1}$) and heterogeneous ($k_2 = 0.08 \pm 0.02$ litre $mol^{-1}$ $s^{-1}$) reactions, the authors[130] suggested that the promoting effect of the phosphine group on the surface is abolished by the influence of the carrier.

The complete analogy between the catalytic behaviour of the heterogeneous cluster and its homogeneous analogue is indicated also by the composition of the reaction products. Thus 19% of hexane and 79% of olefins with inner double bonds are formed in the presence of the triosmium cluster heterogenised on $SiO_2$ (in 45 h at 75 °C and a 4 atm $H_2$ pressure). Analogous results have been obtained[132] under the same conditions in the presence of the $[H_2Os_3(CO)_{10}]$ cluster (19 and 81% respectively).

---o0o---

As can be seen from the literature data presented in this review, the heterogeneous cluster and polynuclear complex catalysts have attracted the attention of many investigators. However, despite the abundance of studies in this field, so far there have been no reports of qualitatively new results. Nevertheless data have been obtained which suggest that catalytic systems of the class considered are promising. In the first place this applies to cluster HMC for the selective synthesis of alcohols and ethylene glycol by the Fischer–Tropsch reaction.

The experience accumulated in the field of the synthesis, structure, and properties of cluster HMC has shown that these objects undergo changes during preparation, preliminary treatment, and catalysis. In the heterogenisation of cluster and polynuclear complexes, it is therefore necessary to pay special attention to the preservation of their structure.

As an example of an unsuccessful application of the immobilisation method in the preparation of cluster HMC, one may quote the study of Pierantozzi et al.[133] The heterogenisation of the cluster $[H_2FeRu_3(CO)_{13}]$ on phosphinated $SiO_2$ led, according to the authors' results, to the formation of mononuclear centres of the type $[Ru(CO)_4PPh_2-Si\equiv|]$ on the surface. The heterogenisation of the cluster $[Fe_2Pt.(CO)_8(PPh_3)_2]$ on the same carrier was accompanied by the decomposition of the cluster and the aggregation of the metal.

The complexity of the synthesis of the transition metal cluster and polynuclear complexes as well as their instability in the course of the preparation of heterogeneous catalysts necessitate the conclusion that in industrial analysis one should apparently favour the method involving the assembly of the cluster centres on the carrier surface, because relatively simple and accessible initial compounds are immobilised in this process.

For theoretical predictions of catalytic activity, important results can be obtained in the study of the influence of the nuclearity and the geometrical structure of the clusters on the catalytic activity and selectivity of the catalyst. Despite the large number of studies on catalysis by clusters and cluster HMC, many fundamental processes remain open. These include the influence of the nuclearity of the cluster on many-electron and structure-sensitive reactions, the synergistic effect in the above reactions on heteroatomic clusters, and the formation of cluster HMC with an asymmetric activity (both as a result of the presence of chiral ligands and the chirality of the cluster skeleton, arising either as a result of the asymmetry of the metal lattice or as a result of the skeletal asymmetry caused by the form of the cluster[134–137]). Presumably catalysts of the latter type will make it possible to synthesise selectively complex optically active compounds from CO and $H_2$.

During the preparation of the review for the press, a number of other review articles[138–145] and original papers[146–163] devoted to the preparation and application of catalysts based on heterogenised transition metal clusters were published.

Basset and Choplin[138] examined in detail the reactions of cluster compounds on the surfaces of mineral carriers. A mechanism has been proposed for the hydrogenation of olefins on the immobilised cluster $[HOs_3(CO)_{10}(O-|)]$. The results of an investigation of the Fischer–Tropsch reaction in the presence of carbonyl clusters on carriers have been described.[146,163] The reactions of clusters accompanying the Fischer–Tropsch reaction have been considered.

Another study has also been devoted to this topic.[147]

Using the EXAFS method, the interaction of the $[HFe(C).(CO)_{12}]^-$ cluster with the surface of a partly dehydroxylated alumina has been investigated.[148] A study has been made of the activity of the resulting catalyst in the CO and benzene hydrogenation reactions. The processes accompanying the heterogenisation of heteroatomic clusters on mineral carriers have been described in two communications.[149,150]

A simple geometrical model of the kinetics of the aggregation of clusters has been described.[151] Interesting results have been obtained in the study of the properties of catlaysts based on immobilised heteronuclear transition metal clusters.[152,153] Much attention has been devoted to the spectroscopic study of the products of the reaction of the clusters on the surfaces of carriers;[154–156,160,161] special mention should be made of studies[155,160] in which the EXAFS method was used to investigate the immediate environment of the metal ions.

Questions concerning catalysis by immobilised transition metal clusters have been considered at the IInd All-Union Conference on the Chemistry of Clusters (Odessa, May 1985). In addition they have been dealt with in a number of books.[164–166]

# The Dehydrofluorination of Complexes of Silicon Tetrafluoride with Nitrogen- and Oxygen-containing Donor Ligands

A.A.Ennan, L.A.Gavrilova, and V.O.Gel'mbol'dt

Data on the dehydrofluorination of complexes of silicon tetrafluoride with N- and O-donor ligands in the absence of a solvent and in benzene, and on the alcoholysis and hydrolysis of silicon tetrafluoride, have been reviewed. The probable mechanism of dehydrofluorination has been discussed.
The bibliography contains 88 references.

CONTENTS

I. Introduction 843
II. The dehydrofluorination of amine complexes of silicon tetrafluoride in the absence of a solvent and in benzene 843
III. The dehydrofluorination of alcohol complexes of silicon tetrafluoride. The hydrolysis of silicon tetrafluoride 847
IV. The mechanism of the dehydrofluorination of complexes of silicon tetrafluoride 848

## I. INTRODUCTION

Earlier reviews[1-5] and a monograph[6] summarised data on the properties and structures of the complexes of silicon tetrafluoride with organic bases, but do not give sufficient information on the dehydrofluorination of these complexes. These processes, however, form the basis for the preparation of various fluoro-organosilicon compounds with covalent Si–N and Si–O bonds, of practical interest (fluorosilylamines, hexafluorodisilazanes, oligomeric and polymeric cyclic and linear fluorosilazanes, and alkoxysilanes). Dehydrofluorination reactions are also of undoubted theoretical interest in the study of the relationship between the type of coordination polyhedron of the mixed-ligand fluorocomplex of silicon and the nature of the ligands present. The pioneers in the study of the dehydrofluorination of complexes of silicon tetrafluoride with alkylamines were the group of English workers in London University headed by Aylett, who published their first papers in the mid-sixties. Their success was largely due to their experience with related silicon–nitrogen monomers and polymers.[7,8]

The present review systematises and summarises the results of studies of the dehydrofluorination of complexes of silicon tetrafluoride with nitrogen- and oxygen-containing donor ligands, published up to and including 1984.

## II. THE DEHYDROFLUORINATION OF AMINE COMPLEXES OF SILICON TETRAFLUORIDE IN THE ABSENCE OF A SOLVENT AND IN BENZENE

The high strength of Si–F bonds and the stability of the complexes of silicon tetrafluoride with alkylamines[9] made it necessary to use fairly severe conditions to achieve dehydrofluorination: the complexes, or stoichiometric $SiF_4$–amine mixtures, were heated for a long time at a comparatively high temperature in the presence of special dehydrofluorinating agents, such as $LiAlH_4$, $NaBH_4$, $NaNH_2$, $B_2H_6$, LiH, Na, Al, and Mg.[10-13]

Heating the complexes of $SiF_4$ with secondary or primary amines in the presence of hydrogen fluoride acceptors to 180–220° leads to the removal of one or two molecules of hydrogen fluoride to give tri- and difluorosilylamines or hexafluorodisilazanes:[10,11]

$$SiF_4(R_2NH)_2 \rightarrow R_2NSiF_3 + HF + R_2NH$$
$$SiF_4(R_2NH)_2 \rightarrow (R_2N)_2SiF_2 + 2HF$$
$$2SiF_4(RNH_2)_2 \rightarrow RH(SiF_3)_2 + 2HF + 3RNH_2 .$$

The composition of the dehydrofluorination products is determined not only by the number of hydrocarbon groups in the molecules of the amine ligands but also by the characteristics of the dehydrofluorinating agent used. Thus the reaction of silicon tetrafluoride with dimethylamine in the presence of $LiAlH_4$ or $B_2H_6$ (190–200°) gives dimethylaminotrifluorosilane and bis(dimethylamino)difluorosilane; with Na (25°) or Al (350°), bis(dimethylamino)difluorosilane is obtained; and traces of tris(dimethylamino)fluorosilane $(Me_2N)_3SiF$ are obtained only on prolonged heating (340 h) in the presence of Na (25°). The complexes with ammonia or with primary amines give substituted hexafluorodisilazanes $RN(SiF_3)_2$ (R = H, Me, Et, Ph), unstable aminotrifluorosilanes ($EtNHSiF_3$,[12] $PhNHSiF_3$,[11] or condensed products of the disproportionation of the hexafluorodisilazanes. An increased tendency to form the last compounds was observed for the derivatives $RN(SiF_3)_2$ with R = H, Ph:

$$n\,RN(SiF_3)_2 \begin{cases} \longrightarrow SiF_3NR(SiF_2NR)_{n-1}SiF_3 + (n-1)SiF_4 \\ \longrightarrow (RNSiF_2)_n + n\,SiF_4 \end{cases},$$

The disproportionation of N-alkylhexafluorodisilazanes $RN(SiF_3)_2$ (R = Me, Et) has also been described;[13] the intermediate products $SiF_3NRSiF_2NRSiF_3$ were isolated.

A number of suggestions have been made[11] about the role of different acceptors in the binding of hydrogen fluoride by the dehydrofluorinating agents. Thus $LiAlH_4$ reacts with silicon tetrafluoride and methylamine according to the scheme:

$$4SiF_4 + 2MeNH_2 + LiAlH_4 \rightarrow 2MeN(SiF_3)_2 + LiF + AlF_3 + 4H_2$$

and with secondary amines (R = Me, Et) according to the scheme:

$$(6-2n)SiF_4 + 4R_2NH + LiAlH_4 \rightarrow (6-2n)(R_2N)_nSiF_{4-n} + LiF + AlF_3 + 4H_2 .$$

The thermal decomposition of lithium aluminium hydride in turn is accompanied by the transformations:[14]

$$3LiAlH_4 \rightarrow Li_3AlH_6 + 3H_2 + 2Al$$
$$Li_3AlH_6 \rightarrow 3LiH + {}^3/_2H_2 + Al .$$

The LiH and Al formed have an increased reactivity, and can react with amines and $SiF_4$. The possible reaction of $LiAlH_4$ with amines to give $LiAlH_{4-n}(NR_2)_n$ at increased temperatures is not excluded; under these conditions, the complexes $SiF_4(R_2NH)_2$ can dissociate, and the partial pressure of the amine becomes considerable, and $LiAlH_4$ does not decompose. Dehydrofluorination can evidently take place with the participation of both $LiAlH_4$ and the products of its thermochemical transformations (including organometallic compounds with Li–N[15] and Al–N[11] bonds); however, the contribution of these reactions is not known.

In dehydrofluorination, sodium hydroborate behaves like $LiAlH_4$, but the yield of dehydrofluorination products is slightly lower. The main reaction is complicated by the decomposition of $NaBH_4$ to give borazoles or aminoboranes. When diborane is used as dehydrofluorinating agent, boron trifluoride complexes which are much more stable than the corresponding silicon tetrafluoride derivatives are formed, and the boron trifluoride complexes, for the same reason, are present in the reaction products even in an appreciable excess of $SiF_4$:

$$6SiF_4 + B_2H_6 + (3n + 2)\,R_nNH_{3-n} \rightarrow 3n\,R_nN(SiF_3)_{3-n} + 6H_2 + 2BF_3 \cdot R_nNH_{3-n}.$$

The complexes of primary amines, depending on the type of hydrocarbon group, either give low yields of silazanes (R = Me) or do not form silicon–nitrogen compounds at all (R = H, Pr, Ph). In the latter case, borazoles are formed.

Aluminium, magnesium, and zinc powders, in contact with gaseous mixtures of $SiF_4$ and $MeNH_2$ at increased temperatures, can bind HF:

$$M + nHF + MF_n + n/2\,H_2.$$

The intensification of dehydrofluorination using metals at comparatively high temperatures (>300°) is evidently due to the breakdown of the oxide film on the metal surface.

As already noted, sodium under mild conditions reacts extremely slowly according to the scheme:

$$SiF_4 + n\,Me_2NH + n\,Na \rightarrow (Me_2N)_n\,SiF_{4-n} + n\,NaF + \frac{n}{2}\,H_2$$

An excess of dimethylamine brings about the disproportionation of the initially formed $Me_2NSiF_3$ (base catalysis), so that $(Me_2N)_2SiF_2$ predominates in the dehydrofluorination products:

$$2Me_2NSiF_3 \rightarrow (Me_2N)_2SiF_2 + SiF_4$$

The addition of an excess of methylamine to the reaction gives volatile oligomeric silazanes, which tend to lose silicon tetrafluoride to give cyclosilazanes $(MeNSiF_2)_n$.[11]

With increase in temperature (300–400 °C), more extensive thermochemical transformations of the complexes take place to give polymers containing the $-RNSiF_2-$ fragment. A method for synthesising polymeric silicon–nitrogen compounds by the thermal decomposition of adducts or stoichiometric mixtures of $SiF_4$ with primary or secondary amines in sealed ampoules in the presence of bases such as $NaNH_2$ or $LiAlH_4$ has been patented.[16,17] In a typical example, the thermal decomposition of the complex $SiF_4(MeNH_2)_2$ in the presence of sodamide (350°, 10 h) gives a brown polymer powder:

$$SiF_4(MeNH_2)_2 + 2NaNH_2 \rightarrow 1/n\,(MeNSiF_2)_n + 2NaF + 2NH_3 + MeNH_2.$$

The process can be carried out in two stages: the first stage gives N-methylhexafluorodisilazane (250°, 2 h), which is purified by fractional vacuum distillation and which undergoes further thermal decomposition (100°, 6 h):

$$4SiF_4 + 2MeNH_2 + LiAlH_4 \rightarrow 2MeN(SiF_3)_2 + LiF + AlF_3 + 4H_2$$
$$MeN(SiF_3)_2 \rightarrow SiF_4 + 1/n\,(MeNSiF_2)_n.$$

Selection of the thermal decomposition conditions and the dehydrofluorinating agents makes it possible to vary the mechanical characteristics of the polymeric products from soft to elastic and hard. The polymers with a high molecular mass have a high thermal stability (they do not melt or decompose when heated to 500°), are insoluble in most organic solvents, and are stable to hydrolysis (including the action of aqueous alkali solutions), but decompose in contact with solid alkali.

Published data[10,11,16,17] strengthened the view that in dehydrofluorination it is necessary to use hydrogen fluoride acceptors of basic character. In 1970,[18] however, the ability of silicon tetrafluoride complexes (by themselves or in an excess of $SiF_4$) to undergo "spontaneous dehydrofluorination" was observed. Similar results were obtained in Ref. 19; heating silicon tetrafluoride with trimethylhydrazine or unsymmetrical dimethylhydrazine gave $Me_2NN(Me)SiF_3$ and $Me_2NNHSiF_3$ respectively. The term "spontaneous dehydrofluorination"[18] (that is dehydrofluorination in the absence of special dehydrofluorinating agents) apparently does not fully reflect the essential features of the processes taking place, since no account is taken of the ability of the complexes to act as HF acceptors:

$$SiF_4(R_nNH_{3-n})_2 + 2HF \rightarrow (R_nNH_{4-n})_2SiF_6.$$

Trifluorosilylamines and hexafluorodisilazanes can be obtained by the thermal decomposition of complexes of silicon tetrafluoride with primary and secondary amines in sealed ampoules;[18,20] the presence of an excess of silicon tetrafluoride leads to an increase in the yield of the desired products. The complexes of secondary amines are converted fairly rapidly (1.5–8 h) into the corresponding trifluorosilylamines, and silicon tetrafluoride in turn combines with the dialkylammonium fluoride formed:

$$SiF_4(R_2NH)_2 \rightleftarrows R_2NSiF_3 + R_2NH_2F$$
$$SiF_4 + 2R_2NH_2F \rightleftarrows (R_2NH_2)_2SiF_6.$$

Experiments with the complexes of diethylamine and pyridine proved that the first reaction is reversible.[20] The thermal decomposition of these compounds in a melt gave the corresponding trifluorosilylamines; the original complexes were formed when the products of each reaction were kept at room temperature for several days.

Table 1. Reaction conditions and yields of products in the thermal decomposition of the complexes of silicon tetrafluoride with secondary amines.[20]

| Complex | $t$, °C | $\tau$*, h | Product | Yield, % |
|---|---|---|---|---|
| $SiF_4(Me_2NH)_2$ (liquid) | 175 | 1.5 | $Me_3NSiF_3$ | 52 |
| $SiF_4(Et_2NH)_2$ (solid) | 40 | 21.5 | $Et_3NSiF_3$ | 10 |
| $SiF_4(Et_2NH)_2$ (liquid) | 110–120 | 4.5 | $Et_3NSiF_3$ | 100 |
| $SiF_4(Et_2NH)_2$ (gas) | 175–190 | 7.5 | — | 0 |
| $SiF_4(Pr_2NH)_2$ (solid) | 100 | 3 | $Pr_3NSiF_3$ | 100 |
| $SiF_4(Bu_2NH)_2$ (solid) | 120 | 3.5 | $Bu_3NSiF_3$ | 100 |
| $SiF_4(C_4H_8NH)_2$ (liquid) | 145 | 6 | $C_4H_8NSiF_3$ | 1 |
| $SiF_4(C_5H_{10}NH)_2$ (solid) | 120 | 8 | $C_5H_{10}NSiF_3$ | traces |
| $SiF_4(C_5H_{10}NH)_2$ (liquid) | 175–185 | 3.8 | $C_5H_{10}NSiF_3$ | 16 |

*$\tau$ is the reaction time.

The data in Table 1 show that the yields of trifluorosilylamines increase with increase in the length of the hydrocarbon groups in the amine molecule, and are very low for derivatives of cyclic amines $(CH_2)_nNSiF_3$ ($n$ = 4, 5).

Unfortunately, an objective estimation of the yield of the dehydrofluorination products is difficult, since the time and temperature conditions for different syntheses vary over wide ranges. No justification has been given for the selection of the conditions for carrying out a given reaction.

A combination of differential thermal analysis, differential thermogravimetric analysis, infrared spectroscopy, and elemental analysis made it possible to refine the dehydrofluorination scheme[21–23] and to establish the temperature ranges for achieving it (Table 2) in the thermal decomposition of the complexes of secondary amines:

$$SiF_4(R_2NH)_2(\text{solid}) \rightarrow SiF_4(R_2NH)_2(\text{liquid}) \rightarrow R_2NSiF_3(\text{gas}) + HF(\text{gas}) + R_2NH(\text{gas, liquid})$$

$$\frac{SiF_4(R_2NH)_2(\text{liquid}) + 2HF(\text{gas}) \rightarrow (R_2NH_2)_2SiF_6(\text{liquid})}{3SiF_4(R_2NH)_2(\text{liquid}) \rightarrow 2R_2NSiF_3(\text{gas}) + (R_2NH_2)_2SiF_6(\text{liquid}) + 2R_2NH(\text{gas})}$$

**Table 2.** Thermal analysis of the complexes of silicon tetrafluoride with secondary alkylamines.[22,23]

| Complex | Endothermic effects | | Mass loss, % | | Assignment* |
|---|---|---|---|---|---|
| | $t_0$, °C | $t_{max}$, °C | found | calculated | |
| $SiF_4(Et_2NH)_2$ | 200 | 220 | 15 | 0 | *a* |
| | — | 255 | 65 | 61 | *b* |
| | — | 275 | 100 | 100 | *c* |
| $SiF_4(Bu_2NH)_2$ | 165 | 180 | 7 | 0 | *a* |
| | 220 | 250 | 68 | 63 | *b* |
| | — | 270 | 98 | 100 | *c* |
| $SiF_4 2(C_{10}H_{21})_2NH$ | 160 | 180 | 3 | 0 | *a* |
| | 220 | 235 | 28 | 36 | *b* |
| | — | 275 | 95 | 100 | *c* |
| $SiF_4(C_5H_{10}NH)_2$ | 175 | 210 | 5 | 0 | *a* |
| | — | 265 | 56 | 62 | *b* |
| | — | 280 | 100 | 100 | *c* |
| $SiF_4 2(PhCH_2)_2NH$ | 200 | 215 | 3 | 0 | *a* |
| | 235 | 260 | 52 | 40 | *b* |
| | — | 285 | — | — | *c* |
| | — | 305 | 100 | 100 | *d* |

*$a$ = fusion, $b$ = dehydrofluorination, $c$ = dissociation, $d$ = boiling of the amine.

Thus the silicon tetrafluoride complex itself acts as a dehydrofluorinating agent. The possible use of a silicon tetrafluoride complex as dehydrofluorinating agent was reported earlier.[24]

**Table 3.** Reaction conditions and yields of products in the thermal decomposition of complexes of silicon tetrafluoride with primary amines.[20]

| Complex | $t$, °C | $\tau$, h | Product | Yield, % |
|---|---|---|---|---|
| $SiF_4(MeNH_2)_2$(gas) | 220 | 2.5 | — | 0 |
| $SiF_4(EtNH_2)_2$(gas) | 190—200 | 10 | — | 0 |
| $SiF_4(PrNH_2)_2$(solid) | 200 | 8.2 | $PrN(SiF_3)_2$ | 3 |
| $SiF_4(PrNH_2)_2$(gas) | 190—200 | 10 | — | 0 |
| $SiF_4(BuNH_2)_2$(solid) | 190—200 | 8.2 | $BuN(SiF_3)_2$ | 6 |
| $SiF_4$(i-$BuNH_2)_2$(solid) | 190—200 | 8 | i-$BuN(SiF_3)_2$ | 30 |
| $SiF_4$(i-$BuNH_2)_2$(liquid) | 220—240 | 24 | i-$BuN(SiF_3)_2$ | 75 |
| $SiF_4$(t-$BuNH_2)_2$(solid) | 190—200 | 8 | t-$BuNHSiF_3$ | 60 |
| $SiF_4$(t-$BuNH_2)_2$(liquid) | 220—240 | 24 | t-$BuNHSiF_3$ | 86 |
| $SiF_4$(t-$BuNH_2)_2$(solid) | 180—200 | 12 | — | 0 |

Complexes of primary amines undergo dehydrofluorination in sealed ampoules over a longer period (8–24 h) (Table 3). The process is complicated by the ability of the trifluorosilylamines formed in the first stage to be transformed into the more stable hexafluorodisilazanes:

$$SiF_4(RNH_2)_2 \rightarrow RNHSiF_3 + RNH_3F$$

$$SiF_4 + 2RNHSiF_3 + SiF_4(RNH_2)_2 \rightarrow 2RN(SiF_3)_2 + 2RNH_3F \ .$$

Thermogravimetric data[22,23] (Table 4) give grounds for modifying the scheme for the thermal decomposition of the complexes of primary amines as follows:

$$2SiF_4(RNH_2)_2(\text{solid}) \rightarrow RN(SiF_3)_2(\text{gas}) + 2HF(\text{gas}) + 3RNH_2(\text{gas})$$

$$\frac{SiF_4(RNH_2)_2(\text{solid}) + 2HF(\text{gas}) \rightarrow (RNH_3)_2SiF_6(\text{solid})}{3SiF_4(RNH_2)_2(\text{solid}) \rightarrow RN(SiF_3)_2(\text{gas}) + 3RNH_2(\text{gas}) + (RNH_3)_2SiF_6(\text{solid})} \ .$$

**Table 4.** Thermal analysis of complexes of silicon tetrafluoride with primary alkylamines.[22,23]

| Complex | Endothermic effects | | Mass loss, % | | Assignment |
|---|---|---|---|---|---|
| | $t_0$, °C | $t_{max}$, °C | found | calculated | |
| $SiF_4(EtNH_2)_2$ | 140 | 170 | 53 | 59 | *b* |
| | 250 | 280 | 100 | 100 | *c* |
| $SiF_4(PrNH_2)_2$ | 150 | 178 | 57 | 61 | *b* |
| | 245 | 280 | 100 | 100 | *c* |
| $SiF_4$(i-$PrNH_2)_2$ | 120 | 165 | 55 | 61 | *b* |
| | 250 | 270 | 100 | 100 | *c* |
| $SiF_4(BuNH_2)_2$ | 175 | 195 | 58 | 61 | *b* |
| | 250 | 278 | 100 | 100 | *c* |
| $SiF_4$(i-$BuNH_2)_2$ | 110 | 145 | 57 | 61 | *b* |
| | 230 | 275 | 100 | 100 | *c* |
| $SiF_4(C_7H_{15}NH_2)_2$ | 135 | 165 | 59 | 62 | *b* |
| | 245 | 280 | 100 | 100 | *c* |
| $SiF_4(C_8H_{17}NH_2)_2$ | 140 | 175 | 57 | 62 | *b* |
| | 235 | 280 | 100 | 100 | *c* |
| $SiF_4(PhCH_2NH_2)_2$ | 205 | 230 | 56 | 62 | *b* |
| | 260 | 285 | 100 | 100 | *c* |

The structure of the amine determines not only the yield but also the composition of the dehydrofluorination products.[20] Thus for the complex $SiF_4$(t-$BuNH_2)_2$ containing the bulky t-butyl group, the reaction is complete with the formation of t-$BuNHSiF_4$, whereas the dehydrofluorination of the complexes $SiF_4(BuNH_2)_2$ and $SiF_4$(i-$BuNH_2)_2$ gives N-butylhexafluorodisilazanes. The formation of N-alkylhexafluorodisilazanes is represented as the stepwise replacement of the hydrogen atoms on the nitrogen by trifluorosilyl groups. In the thermal decomposition of the complex $SiF_4$(i-$BuNH_2)_2$ with an excess of $SiF_4$, the products included, in addition to hexafluorodisilazane, an oligomeric oil formed by the disproportionation of the primary product:

$$\text{i-}BuN(SiF_3)_2 \rightarrow SiF_4 + 1/n\,(\text{i-}BuNSiF_2)_n \ .$$

The prolonged thermal decomposition of the complexes $SiF_4(RNH_2)_2$ (R = H, Me, Bu, Ph) at comparatively high temperatures in a nitrogen atmosphere (Table 5)[25] is accompanied by more extensive dehydrofluorination to give stable solid polymeric products: white $(NSiF)_n$, yellow-brown $(MeNSiF_2)_n$, and dark violet $(PhNSiF_2)_n$. Poly-(n-butyldifluorosilazane) was isolated as a high-boiling (350–400°) oligomeric oil and a white waxy non-volatile powder:

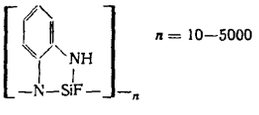
$$2SiF_4(NH_3)_2 \rightarrow NH_4F + (NH_4)_2SiF_6 + 1/n\,(NSiF)_n$$

$$2SiF_4(RNH_2)_2 \rightarrow 2RNH_3F + (RNH_3)_2SiF_6 + 1/n\,(RNSiF_2)_n \ .$$

Polymeric fluorosilazanes remain unchanged when heated in a stream of dry nitrogen to 500°, but they can be hydrolysed by strong alkalis. The reaction of dry oxygen with $(NSiF)_n$ at 500° gives silicon dioxide and an unidentified compound containing nitrogen, oxygen, and fluorine.

Table 5. Reaction conditions and the yield of polymeric products in the thermal decomposition of complexes of silicon tetrafluoride with ammonia and primary amines.[25]

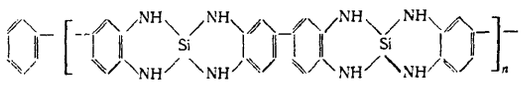
| Complex | $t$, °C | $\tau$, h | Product | Yield, % |
|---|---|---|---|---|
| $SiF_4(NH_3)_2$ | 160–170 | 162 | $(NSiF)_n$ | 21 |
| $SiF_4(NH_3)_2$ | 290–310 | 21 | $(NSiF)_n$ | 20 |
| $SiF_4(NH_3)_2$ | 290–310 | 44 | $(NSiF)_n$ | 14 |
| $SiF_4(NH_3)_2$ | 250–280 | 66 | $(NSiF)_n$ | 18 |
| $SiF_4(MeNH_2)_2$ | 250–280 | 84 | $(MeNSiF_2)_n$ | 38 |
| $SiF_4(BuNH_2)_2$ | 250–280 | 72 | $(BuNSiF_2)_n$ | 37 |
| $SiF_4(PhNH_2)_2$ | 250–280 | 72 | $(PhNSiF_2)_n$ | 37 |



Thermogravimetric, infrared spectroscopic, chemical analysis, and X-ray diffraction data have been used to propose a scheme for the thermal decomposition of the complex $SiF_4(NH_3)_2$ [26] differing from that in Ref. 25. It was shown that the thermal decomposition takes place in stages to give ammonium hexafluorosilicate and a polymer with the composition $(NHSiF_2)_n$ (identified from the similarity of its infrared spectrum to the published spectrum[27]); $HN(SiF_3)_2$ was detected as an intermediate product. Ammonium fluoride was not detected among the thermal decomposition products, as confirmed indirectly in Ref. 28. Thermodynamic calculations for the thermal decomposition of the complex $SiF_4(NH_3)_2$ ($\Delta H^\circ_{decomp} = 2.5$ kJ mole$^{-1}$, $\Delta S_{decomp} =$ 12 kJ mole$^{-1}$ K$^{-1}$) show that the extremely high thermal stability of the complexes is due mainly to kinetic factors.[25]

Harris and Rudner[29,30] were the first to show that the complexes of $SiF_4$ with primary amines can be dehydrofluorinated in the presence of tertiary amines: trimethylamine, triethylamine, or di-isopropylethylamine; trimethylphosphine can also be used.[29] The syntheses were carried out in benzene at room temperature, that is under much milder conditions than dehydrofluorination by thermal decomposition:

$$3SiF_4 + RNH_2 + 2R_3N \rightleftarrows 1/n\,(RNSiF_2)_n + 2\,(R_3NH)\,SiF_5$$



$$(m+1)\,SiF_4 + RNH_2 + 2R_3N \rightleftarrows 1/n\,(RNSiF_2)_n + \frac{2}{m-1}\,(R_3NH)_{m-1}\,Si_nF_{5m+1}^{-(m+1)} .$$

The possibility of the process taking place according to one of the above schemes is determined by the nature of the tertiary amine. The dehydrofluorination of the complexes of methylamine, aniline, and 2-amino-4-chlorotoluene gave mixtures of cyclofluorosilazanes ($n = 3$–5). The oligomer $(MeNSiF_2)_n$ could not be converted[30] into a heat- and water-resistant polymeric product of the type described by Aylett and co-workers.[16,17] The dehydrofluorination of complexes of silicon tetrafluoride with multidentate amines (*o*-phenylenediamine, 3,3',4,4'-tetra-aminobiphenyl) in the presence of triethylamine fairly easily yields the silazane polymers

$n = 10$–5000

and

$n = 2$–1000

which react with a side product of the reaction, trimethylammonium fluorosilicate, to give an oil insoluble in benzene.

Somewhat later, the "spontaneous dehydrofluorination" of complexes of $SiF_4$ with primary and secondary alkylamines under mild conditions was described.[21,23,31,32] Complex formation by silicon tetrafluoride with ethylamine is accompanied by dehydrofluorination even at 25°;[21] in an excess of $SiF_4$, the dehydrofluorination of $SiF_4(EtNH_2)_2$ is complete:

$$SiF_4 + 2EtNH_2 \rightarrow SiF_4(EtNH_2)_2$$

$$2SiF_4(EtNH_2)_2 + SiF_4 \rightarrow EtN(SiF_3)_2 + (EtNH_3)_2SiF_6 .$$

Similarly, in boiling benzene (80°) in the presence of silicon tetrafluoride, the complex $SiF_4(Et_2NH)_2$ undergoes dehydrofluorination according to the scheme:

$$2SiF_4(Et_2NH)_2 + SiF_4 \rightarrow 2Et_2NSiF_3 + (Et_2NH_2)_2SiF_6 .$$

In general, the dehydrofluorination of complexes $SiF_4(RNH_2)_2$ (R represents a group with the normal structure $C_nH_{2n+1}$, $n = 2$–4) is favoured by heating the reaction mixture and an excess of silicon tetrafluoride; with increase in the length of the hydrocarbon group in the amine ligands ($n > 4$), the dehydrofluorination takes place at room temperature and at all $SiF_4$ : amine ratios. Increase in the degree of branching (and hence in the steric effect) of the hydrocarbon group gives the same effect. Thus the dehydrofluorination of the complex $SiF_4(i\text{-}BuNH_2)_2$ takes place at 25° in an excess of the amine. The dehydrofluorination of t-$BuNH_2$ is so vigorous that it is practically impossible to isolate the complex $SiF_4(t\text{-}BuNH_2)_2$ in pure form even with cooling of the reaction medium. Under these conditions, t-butylammonium hexafluorosilicate is precipitated, and t-$BuNHSiF_3$ was identified in the solution by infrared spectroscopy. In boiling benzene, hexafluorodisilazane accumulates in the liquid phase, and is probably produced by the disproportionation of the initially formed t-butyltrifluorosilylamine:

$$2t\text{-}BuNHSiF_3 \rightarrow t\text{-}BuN(SiF_3)_2 + t\text{-}BuNH_2 .$$

As in the thermal decomposition of the complexes of silicon tetrafluoride with the isomeric butylamines,[18,20] the structure of the amine (the steric effect of the substituents on the nitrogen atom, $E_N$ [33]) influences the dehydrofluorination rate and the composition of the reaction products. In particular, the complexes of primary amines with groups having a normal structure, and also isopropylamine and isobutylamine ($E_N = -0.93$ and $-1.10$ respectively) form hexafluorodisilazanes; with t-butylamine, where the substituent has a greater steric effect ($E_N = -1.54$), trifluorosilylamine is formed. It is reasonable to assume that the complexes $SiF_4(RNH_2)_2$ with ligands having a normal structure, in the first stage of the dehydrofluorination, also give unstable $RNHSiF_3$, which rapidly disproportionate to give more stable hexafluorodisilazanes. The stabilisation of products of t-$BuNHSiF_3$ type is most probably due to the sharp increase in interligand interactions in the fragment  [34] on going from t-$RNHSiF_3$ to t-$R_2NSiF_3$.

The dehydrofluorination of the complexes $SiF_4(R_2NH)_2$ (R represents a group with a normal structure $C_nH_{2n+1}$, $n = 2$, 4, 10, 18; R = $CH_2Ph$; $R_2NH = C_5H_{10}NH$) in benzene solution generally takes place under milder conditions than the corresponding transformations of the complexes of primary amines: at room temperature and in an excess of

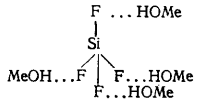
$SiF_4$, or even at molar ratios $SiF_4$ : amine < 2.[23] As with the complexes of primary amines, increase in the length of the hydrocarbon group R in the ligand molecules intensifies the dehydrofluorination of the complexes $SiF_4(R_2NH)_2$. Thus elemental analysis and infrared spectroscopy show that the reaction of silicon tetrafluoride with dibutylamine in benzene gives a precipitate containing not only $SiF_4(Bu_2NH)$ but also the hexafluorosilicate $(Bu_2NH_2)_2SiF_6$, and in the products of the reaction of $SiF_4$ with $(C_{10}H_{21})_2NH$ and $(C_{18}H_{37})_2NH$, the corresponding dialkylammonium hexafluorosilicates predominate.

The possibility of carrying out the above reactions of "mild" dehydrofluorination (in contrast to the "severe" thermal decomposition processes) is most likely due to the specific properties of benzene as reaction medium.[35] The energy capacity of the benzene molecules[35] gives their large number the function of a buffer; by absorbing the excess energy, liquid benzene prevents elastic collisions of the reagent molecules and increases the probability of reactive collisions, that is it facilitates the formation of activated complexes.

Finally, mention may be made of the problems of identifying dehydrofluorination products; the novel character of the experimental material and the difficulty of isolating the individual compounds, which tend to undergo hydrolysis and disproportionation, complicate their analysis. Nevertheless, spectroscopic methods have been used successfully to identify monomeric, oligomeric, and polymeric fluorosilyl and fluorosilazane derivatives. The strong bands in the infrared spectra of trifluorosilylamines at about 850 $cm^{-1}$ and 960 $cm^{-1}$ are assigned[20] to the symmetric and antisymmetric $\nu(SiF)$ vibrations, and the splitting of the $\nu_{as}$ band into two components (958 $cm^{-1}$ and 980 $cm^{-1}$ for $Me_2NSiF_3$) is attributed to a decrease in the symmetry of the $R_2NSiF_3$ molecule as a result of restricted rotation about the Si–N bond. For trifluorosilylamines, the series of fairly strong bands in the range 1000–1300 $cm^{-1}$ (1051, 1172, and 1221 $cm^{-1}$ for $Et_2NSiF_3$) has been assigned to the CNC fragment stretches.[20,23]

The hexafluorodisilazanes $RN(SiF_3)_2$ give $\nu_{as}(SiF)$ and $\nu_{as}(Si_2N)$ bands in the range 910–1030 $cm^{-1}$, and $\nu_s(SiF)$ bands in the range 790–845 $cm^{-1}$.[11,20,23,36]

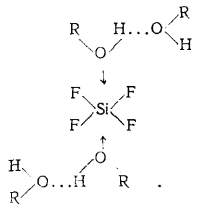
For linear and cyclic fluorosilazanes $(RNSiF_2)_n$ and related compounds, the most informative range is 800–1060 $cm^{-1}$, in which the Si–F and Si–N bond vibrations appear. As with the compounds of the previous class, the interpretation of the spectra is complicated by the similarity in the Si–F and Si–N bond stretching frequencies and by overlapping and splitting of the bands. In the spectra of linear fluorosilazanes, the bands have been tentatively assigned as follows: $\nu_{as}(Si_2N)$ 930–980, $\nu_s(Si_2N)$ 600–620 $cm^{-1}$, $\nu_{as}(SiF)$ and $\nu_s(SiF)$ 800–900 $cm^{-1}$.[15,17]



The parameters of the $^1H$ and $^{19}F$ NMR spectra of various trifluorosilylamines, and also $MeN(SiF_3)_2$, $(Me_2N)_2SiF_2$, and $(MeNSiF_2)_3$, have been published.[38,39] The values of the constants $J(^{29}Si–^{19}F)$ are highly characteristic for each type of compound containing the groups $SiF_3$ and $-SiF_2-$ (202–206 Hz and 218–219 Hz respectively).[39]

The parameters of the infrared and $^{19}F$ NMR spectra of "complex" trialkylammonium fluorosilicates with the stoichiometric composition $(R_3NH)_3Si_2F_{11}$ and $(R_3NH)_4Si_3F_{16}$, which are side products of the dehydrofluorination, have been discussed.[30,40–43] In the absence of structural data, these compounds with anions having the empirical formula $Si_nF_{5n+1}^{-(n+1)}$ ($n$ = 2 or 3) can be regarded as double salts $(R_3NH)_2SiF_6.n(R_3NH)SiF_5$ or as salts of polymeric octahedral ions with bridging fluorine atoms. The spectral parameters of the "complex" fluorosilicates (infrared: bands at 720, 790, and 880 $cm^{-1}$ $\nu(SiF)$ and 450 and 480 $cm^{-1}$ $\delta(SiF)$; $^{19}F$ NMR: two singlet signals with chemical shifts of 126–128 p.p.m. and 135–136 p.p.m. relative to $CFCl_3$) do not provide any evidence for a polymeric anion structure with Si–F–Si fragments, and are consistent with the alternative structures $(R_3NH)_2SiF_6.n(R_3NH)SiF_5$. The data in Refs. 38–43 illustrate clearly the value of spectroscopic methods in the identification of dehydrofluorination products. The $^{19}F$ NMR spectra may be particularly useful in the study of the structure and the quantitative estimation of the yields of fluorine-containing products when mixtures of substances difficult to separate are formed.

## III. THE DEHYDROFLUORINATION OF ALCOHOL COMPLEXES OF SILICON TETRAFLUORIDE. THE HYDROLYSIS OF SILICON TETRAFLUORIDE



The state of silicon tetrafluoride in solution in aliphatic alcohols, and the question of the possible alcoholysis of $SiF_4$ in these systems, have been the subject of prolonged discussion.[4] Alcohols, which are bases of medium strength, absorb silicon tetrafluoride to give unstable complexes with the composition $SiF_4.4ROH$.[44,45] This stoichiometry of the complexes was confirmed[46] in detailed experiments on the tensimetric titration of silicon tetrafluoride with methanol and of methanol with silicon tetrafluoride. The reported preparation of complexes with the compositions $SiF_4.6MeOH$ and $SiF_4.8MeOH$[47] is apparently erroneous.

A tetrahedral structure has been proposed[46] for the complex $SiF_4.4MeOH$ with four strong hydrogen bonds between fluorine atoms and methanol molecules:

The spectral characteristics (infrared, $^1H$ NMR) of the complex given in Ref. 46, however, can be interpreted as providing evidence for alternative structures. Since silicon tetrafluoride shows appreciable Lewis acidity,[3] its reaction with alcohols only by hydrogen bond formation is unlikely. In fact, analysis of the low-temperature $^{19}F$ NMR spectra of solutions of $SiF_4$ in alcohols ROH (R = Me, Et, Pr, Bu, i-Bu) showed the presence of the complexes *trans*-$SiF_4.(ROH)_2$, *trans*-$SiF_4(ROH)(H_2O)$, and *trans*-$SiF_4(H_2O)_2$.[48,49] The concentrations of the complexes of the last two types were much lower than that of the purely alcohol complexes; the appearance of hydrated forms in the solutions is attributed to dehydration of the alcohols, catalysed by silicon tetrafluoride.[45,46]

$^{19}F$ NMR established the nature of the coordination of only the inner-sphere alcohol ligands forming the $SiF_4O_2$ coordination sphere. Later, however, infrared spectroscopic data for saturated solutions of $SiF_4$ in methanol, ethanol, and isopropyl alcohol[50] confirmed the proposed[48,49] *trans*-octahedral structure of the alcohol complexes. The splitting of the $\nu(CO)$ band into two components in the infrared spectra of alcoholic solutions of silicon tetrafluoride is due to the structural non-equivalence of the alcohol molecules in the complex: two molecules form Si ← O coordinate bonds, and the other two are in the outer sphere. The bonding between the outer-sphere alcohol molecules and the first coordination sphere involves intermolecular hydrogen bonds, where the proton donors are the coordinated alcohol molecules:

It has been claimed[51] that, unlike other silicon tetrahalides, $SiF_4$ in alcoholic solutions does not undergo alcoholysis. Later measurements[46] of the electrical conductivity of methanol solutions of $SiF_4$.MeOH showed that the complex is a very weak electrolyte, that is the inner-sphere alcohol molecules show little tendency to lose protons. The reported[52] rapid dehydrofluorination in the $SiF_4$–MeOH system to give $MeOSiF_3$ and small quantities of $(MeO)_2SiF_2$

$$MeOH+SiF_4\rightarrow MeOSiF_3+HF$$

$$MeOSiF_3+MeOH\rightarrow (MeO)_2SiF_2+HF$$

is somewhat surprising. The reaction conditions were not given,[52] however. Other data[46,48–51] indicate that under ordinary conditions the solvolysis of silicon tetrafluoride in alcohols is not accompanied by appreciable dehydrofluorination, that is the equilibrium

$$SiF_4+n\mathrm{ROH}\rightleftarrows SiF_{4-n}(OR)_n+n\mathrm{HF}$$

is displaced to the left. This is evidently due both to the high strength of the Si–F bond (539–564 kJ $mole^{-1}$) compared with, for example, the Si–Cl (359–380 kJ $mole^{-1}$)[53] and to the inability of alcohols to form stable oxonium complexes with HF. As already noted, the last factor (that is the presence of a hydrogen fluoride acceptor) has a decisive influence on the course of the dehydrofluorination.

The dehydrofluorination of alcohol complexes of silicon tetrafluoride is readily carried out in the presence of strong bases—ammonia or aliphatic amines. Alcohol complexes of $SiF_4$ undergo dehydrofluorination under the influence of trialkylamines to give alkoxysilanes and trialkylammonium fluorosilicates:[30]

$$5SiF_4+4\mathrm{ROH}+4R_3N\rightarrow Si(OR)_4+4(R_3NH)SiF_5 .$$

The bulky di-isopropylethylamine forms a stable pentafluorosilicate, and triethylammonium pentafluorosilicate is stable in benzene and acetonitrile solutions, but when the solvent is removed it loses $SiF_4$ to give the doube salt $(Et_3NH)_2SiF_6.2(Et_3NH)SiF_5$.[43] Similarly, all attempts to isolate trimethylammonium pentafluorosilicate gave a product with the composition $(Me_3NH)_3Si_2F_{11}$, probably the double salt $(Me_3NH)_2SiF_6.(Me_3NH)SiF_5$. To investigate the influence of the nature of the amine on the composition of the dehydrofluorination products, $SiF_4$–EtOH–(primary, secondary, or tertiary amine) systems were studied.[54] The dehydrofluorination in these systems can be described by the equations:

$$3SiF_4+4R_{3-n}NH_n+4\mathrm{EtOH}\rightarrow Si(OEt)_4+2(R_{3-n}NH_{n+1})_2SiF_6$$

$$11SiF_4+12R_3N+12\mathrm{EtOH}\rightarrow 3Si(OEt)_4+4(R_3NH_3)_3Si_2F_{11} .$$

The reaction takes place according to the first scheme when primary and secondary amines are used ($n = 1, 2$); with tertiary amines ($n = 0$), the reaction takes place according to both schemes.

The behaviour of aliphatic diamines,[55,56] 2,2′-iminodi(ethanol), 2,2′,2″-nitrilotri(ethanol),[57] and highly basic N-containing heterocyclic compounds (imidazole, benzimidazole, and its derivatives)[58] in the dehydrofluorination of alcohol complexes of $SiF_4$ is analogous to that of aliphatic monoamines.

A reaction related to the dehydrofluorination of alcohol complexes of silicon tetrafluoride is the hydrolysis of $SiF_4$, usually described[59] by the scheme:

$$2SiF_4+2H_2O\rightarrow SiO_2+SiF_6^{2-}+2H^++2\mathrm{HF} .$$

This is an overall equation, and does not reflect the complex set of equilibria in the $SiF_4$–$H_2O$ system.[4] In acidic silicon–fluoride solutions, various methods have established the existence of the complex $SiF_4(H_2O)_2$,[60–62] whose formation can be regarded as the primary stage of the dehydrofluorination in the reaction of silicon tetrafluoride with water.

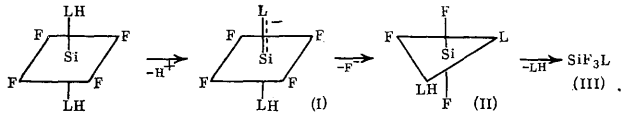
Dehydrofluorination in the $SiF_4$–ROH–amine and $SiF_4$–$H_2O$ systems is of interest for the utilisation of silicon tetrafluoride, of which a large tonnage is produced as a waste product in the manufacture of phosphorus fertilisers.[6] According to patents,[63–65] the dehydrofluorination of alcohol complexes takes place according to the scheme:

$$3SiF_4+4\mathrm{ROH}+4NH_3\rightarrow Si(OR)_4+2(NH_4)_2SiF_6 .$$

The yields of tetra-alkoxysilanes are 70–95%. Tetra-alkoxysilanes are used in the synthesis of organosiloxane oligomers and polymers. Silicon tetrafluoride reacts with alcohols in the presence of Zn or Fe;[66] the zinc and iron hexafluorosilicates formed in addition to $Si(OR)_4$ have been proposed for the protection of constructional materials. A method for preparing tetra-alkoxysilanes by the reaction of alcoholic solutions of $SiF_4$ with alkali and alkaline earth metal sulphides, oxides, carbides, chlorides, carbonates, and cyanides has been patented.[67,68] The reaction is described by the scheme:

$$SiF_4+4\mathrm{ROH}+4\mathrm{MA}\rightarrow Si(OR)_4+4\mathrm{MF}+4\mathrm{HA} ,$$

and is accompanied by the formation of the metal fluoride or hexafluorosilicate and the volatile compound HA, for example $H_2S$, $C_2H_2$, etc.



Schemes have now been developed on the industrial scale for utilising silicon tetrafluoride, based on its hydrolysis[69] to give finely dispersed silicon dioxide, $H_2SiF_6$, and $Na_2SiF_6$. The last of these is used on an increasing scale to obtain synthetic cryolite and aluminium fluoride. $SiF_4$ is hydrolysed by water vapour or in the flame obtained by burning hydrogen or a hydrocarbon mixture.[70] Silicon dioxide is separated from the gas mixture on ceramic filters, and the HF is adsorbed on solid sodium fluoride, followed by its thermal regeneration. A patent[71] has proposed a rapid flow method for depositing a film of silicon dioxide on silicon semiconducting devices; a mixture of $SiF_4$, water vapour, and a carrier gas at temperatures of 700–1000 °C is passed over the semiconducting wafer.

## IV. THE MECHANISM OF THE DEHYDROFLUORINATION OF COMPLEXES OF SILICON TETRAFLUORIDE

It has been suggested that the dehydrofluorination of amine and alcohol complexes of silicon tetrafluoride and the hydrolysis of $SiF_4$ should be regarded from the viewpoint of a single mechanism[4,46,49,72] taking account of the specific nature of the bonds in the fluoro-complexes of non-transition elements. Traditional views of the nature of the bonds in compounds of the type $SiF_4X_2$ and $SiF_4X$ [1–3] assume that the 3*d* AO of silicon take part in the bonding and have integral populations. As noted in Ref. 73, however, for five-coordinate fluoro-complexes of silicon it is possible to put forward a counter-argument to practically all the evidence for the participation of the 3*d* AO of silicon in bond formation. According to Williams,[74] the exaggeration of the role

of the outer *nd* AO in the chemistry of non-transition elements results from a historically determined tendency to interpret the octahedral structure of complexes taking account of only two-centre two-electron bonds ($sp^3d^2$ hybridisation of the AO of the central atom), and not delocalised multi-centre bonds. Recently, Musher's alternative hypervalent bond model has been used increasingly to describe the electronic and geometric structure of fluoro-complexes of *p* elements.[75] This model is based on Rundle's postulate[76] that the complex-forming element A with a restricted *ns*, *np* valence basis set, in addition to ordinary two-electron two-centre bonds A–F, also forms three-centre four-electron bonds F–A–F. This model has been used successfully[77–79] to analyse the characteristic features of the structure of silatranes, (aroyloxymethyl)trifluorosilanes with a five-coordinate silicon(IV) atom, and pseudo-octahedral complexes of tin(IV).

By analogy with published data,[79] the structure of the original complexes $SiF_4(LH)_2$ (L = RNH, $R_2N$, RO, HO) with *trans*-orientation of the ligands can be regarded as based on two three-centre hypervalent fragments F–Si–F with almost pure *p* character in the equatorial plane; the axial fragment LH–Si–LH is formed by two ordinary bonds with the participation of $sp_z$-hybrid orbitals of the silicon atom. Dehydrofluorination takes place as a result of the protonic dissociation of one inner-sphere ligand, brought about by the base:

The appearance in the coordination polyhedron of silicon of the π-donor acido-ligand L, which requires the participation of the corresponding equatorial p orbital of silicon for the formation of the π-component of the Si–L bond, leads to a decrease in the strength of the Si–F σ-bonds (*cis*-weakening[80,81]). This favours the removal of one fluoride ion from the coordination sphere of the intermediate (I). The five-coordinate intermediate (II) in turn loses the weakly bonded molecular ligand LH and is transformed into the four-coordinate reaction product (III).

The dehydrofluorination reactions examined in the present review illustrate the configurational lability of fluoro-complexes of silicon(IV), that is the ability of the silicon atom to adopt different coordination numbers (CN) from 4 to 6, depending on the nature of the ligands co-existing in the complex. The phenomenon of configurational lability is due to the orbital-deficient nature of the silicon atom as a non-transition element, and is revealed by the ready decrease in the CN of silicon and increase in the multiplicity of the bond with the ligand as a result of its deprotonation. Dehydrofluorination reactions with a decrease in the CN of the central atom are also extremely typical of the analogous fluoro-complexes of phosphorus(V).[82–86] On the other hand, dehydrofluorination reactions are less characteristic of the fluoro-complexes of the heavier analogues of silicon and phosphorus, that is germanium(IV) and antimony(V).[30,87] The relative stabilisation of the six-coordinate fluoro-complexes of these elements is evidently due to the increase in the valence basis set of the central atoms.[49,88]

# 1,3-Dipolar Cycloaddition—A General Method of Synthesis of Five-membered Nitrogen-containing Heterocycles with Organoelemental Substituents

O.V.Drygina and A.D.Garnovskii

The review deals with the possibilities and advances in the application of the method of 1,3-dipolar cycloaddition to the synthesis of five-membered nitrogen-containing heterocycles with organoelemental substituents.
The bibliography includes 203 references.

## I. INTRODUCTION

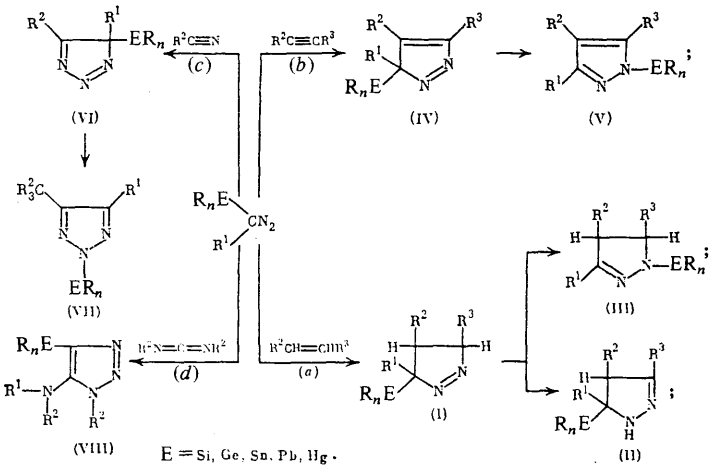
Heterocyclic compounds with organoelemental substituents play a significant role in modern chemistry: they serve as monomers for the synthesis of heterochain metal-containing oligomers and polymers,[1-5] as ligands for complex formation,[1,2,6,7] and as models for the solution of important theoretical problems, for example in the study of elementotropic processes in the series of five-membered nitrogen-containing heterocycles.[8-14] They are of interest as biologically active compounds[15-19] and are also used for other purposes.[15]

The most widely used methods of synthesis of heterocycles with organoelements substituents are based on the introduction of organometallic fragements into complete heterocyclic systems by direct[20-26] or covalent[27-29] metallation, as a result of the exchange of a halogen for the metal,[21,23,25,26] by the interaction of organometallic derivatives of heterocycles with metal salts,[30-33] via the reaction of the carbonylmetallate anion with halogeno-derivatives of heterocycles,[34-39] etc.

At the same time it is known that heterocycles can be synthesised by constructing the ring from simpler starting materials.[40-44] Methods such as different types of condensations and cyclisations[42-48] or recyclisation[49-51] are therefore applicable also to the synthesis of heterocycles with organoelemental substituents. Such procedures include also the 1,3-dipole addition (1,3-DCA),[52-66] which takes place on addition of two addends: a 1,3-dipole and a dipolarophile. The organoelemental groups can enter into the composition of 1,3-dipoles (diazoalkanes, azides, nitrile oxides, nitrones, nitrile imines, etc.) and dipolarophiles (olefins, acetylenes, nitriles, isonitriles, and heterocumulenes).[56,57,63-66] The general principle governing the construction of five-membered heterocycles by the 1,3-DCA method can be represented as follows on the basis of Huigen's ideas:[52-55]

Thus the type of heterocycle formed in the 1,3-DCA reaction is determined mainly by the nature of the 1,3-dipole ($\overset{+}{a}-\ddot{b}-\bar{c}$), while the dipolarophile (d = e or d ≡ e) determines the degree of saturation of the heterocyclic system. This is why we thought it useful to arrange the description of the data relevant to the present review by taking into account primarily the character of the 1,3-dipole. At the same time one should bear in mind that, when dipolarophiles with heteroatoms are used, the latter can enter into the composition of the heterocycle and hence can alter its type.[56,57,64]

1,3-DCA makes it possible to obtain a wide variety of heterocyclic systems containing the N and O heteroatoms and organoelemental substituents. Since the latter can enter into the composition of the molecules of 1,3-dipole and dipolarophiles, wide prospects arise for the synthesis of N- and C-substituted heterocycles. Whereas the syntheses of heterocycles with organoelemental substituents at the nitrogen atom from complete heterocyclic systems are comparatively easy processes (see, for example, Refs.1, 2, 21, 23, 25, 26), the syntheses of the analogous C-substituted heterocycles give rise to serious difficulties.[67,68] This is why 1,3-DCA is especially useful for the preparation of C-organoelemental derivatives of heterocycles and also of a series of heterocyclic systems with organoelemental substituents in exocyclic fragments which are difficult to obtain.



## II. SYNTHESES WITH PARTICIPATION OF DIAZOALKANES

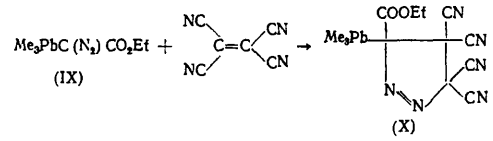
### 1. Synthesis of Heterocycles from Diazoalkanes with Organoelemental Substituents

In order to obtain five-membered nitrogen-containing heterocycles, diazoalkanes with organoelemental substituents are widely used[54-56,63,69,70] (Scheme 1). These make it possible to obtain $R_nEN$- and $R_n$-EC-substituted pyrazolines (on interaction with olefins—pathway a), pyrazolenines and

pyrazoles (in reactions with acetylene—pathway *b*), and triazoles (in reactions with participation of nitriles—pathway *c*, or when nitrogen-containing heterocumulenes, for example carbodiimide, are used as the dipolarophile—pathway *d*).

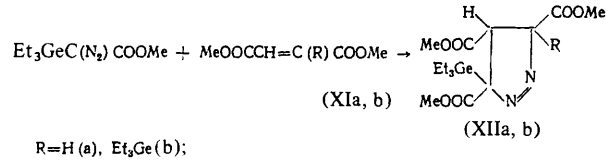
Scheme 1

*(a) Pyrazolines*



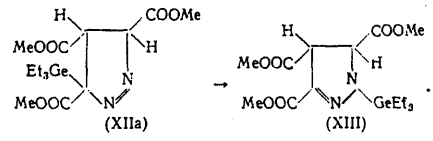
The 1,3-DCA of α-silyldiazoalkanes to acrylonitrile, methyl acrylate, ethyl fumarate, and other dipolarophiles with an activated ethylenic bond has been studied systematically.[63,71-76] The 1,3-DCA reactions considered proceed via intermediate products detected in a whole series of instances. Thus it has been shown from $^1$H NMR spectra[74,76] that the primary products in Scheme 1 (pathway *a*) are 3-organosilyl-$\Delta^1$-pyrazolines (I). Since the majority of $\Delta^1$-pyrazolines readily isomerise to $\Delta^2$-pyrazolines,[77] the isomerisation of the heterocycles (I) leads to compounds (II), if the process is accompanied by the 1,3-transfer of a proton, or to compounds (III) as a result of the 1,3-migration of $R_3Si$. A rearrangement of the first type is characteristic of diazoalkanes $R_3SiC(N_2)R^1$ for $R^1$ = H or Me and one of the second types occurs when $R^1$ = Ph or COOEt.[73,74,76] It has been established for diethyl fumarate[76] that the relative rate of cycloaddition of a diazoalkane diminishes in the sequence

$$\underset{1}{Me_3SiC(N_2)Me} > \underset{2\cdot10^{-2}}{Me_2SiC(N_2)Ph} > \underset{2,5\cdot10^{-3}}{Ph_2SiC(N_2)Me} > \underset{2,5\cdot10^{-4}}{Ph_2SiC(N_2)Ph} > \underset{2,5\cdot10^{-7}}{Me_3SiC(N_2)COOEt}$$



It is believed that the rate of such reactions depends on the degree of $p_\pi, d_\pi$ conjugation of the silicon atoms and the diazo-group in silyl diazoalkanes and on steric factors in the transition state of the cycloaddition reaction.[76]

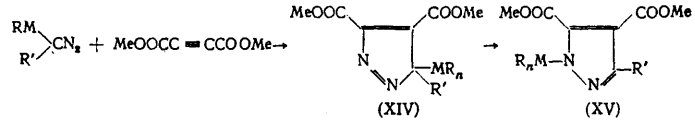
It has also been shown[74,76] that (1) the 1,3-migration of a hydrogen atom [(I)–(II)] is accelerated by electron-accepting groups $R^3$ and is catalysed by traces of water or amines and (2) that the rate of isomerisation reaction (I) → (II) diminishes as the electron-accepting character of the substituent $R^1$ becomes more pronounced: Me ≥ Ph > COOEt.



The 1,3-DCA of ethyl trimethylplumbyldiazoacetate (IX) to a wide variety of alkenedipolarophiles, namely acrylonitrile, acetylenedicarboxylic acid, dimethyl maleate, and tetracyanoethylene takes place in accordance with Scheme 1 (pathway *a*).[78] For example, the 1,3-DCA involving tetracyanoethylene (in ether at −20 °C) results in the formation of a derivative of tetracyanotrimethylplumbylpyrazoline (X) in 52% yield:

The 1,3-DCA of methyl triethylgermyldiazoacetate to dimethyl fumarate and 1-triethylgermyl-1,2-ethylenedicarboxylic acids (XIa, c) leads to the $\Delta^1$-pyrazolines (XIIa, b).[79] Among them, the monogermylated adduct (XIIa) isomerises to the $\Delta^2$-pyrazoline (XIII) as a result of the 1,3-migration of the $Et_3Ge$ group. It has been noted that the ester (XIb) is a mixture of the *Z*- and *E*-isomers and that the adduct (XIIb) is therefore also a mixture of isomeric $\Delta^2$-pyrazolines:

R=H (a), $Et_3Ge$ (b);

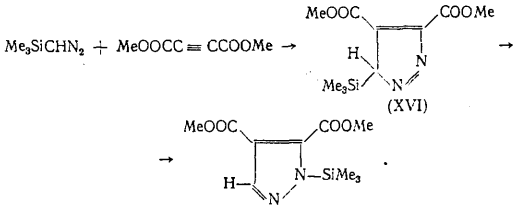


Previously the same authors[80] had obtained bis(triethylgermyl)pyrazolines by the joint thermolysis of ethyl triethylgermyldiazoacetate and ethyl diazoacetate.

*(b) Pyrazolenines and Pyrazoles*

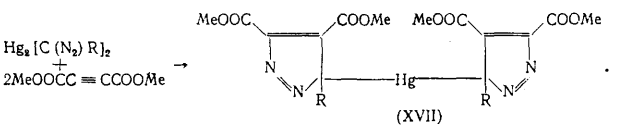
Organoelemental diazomethanes reacting as 1,3-dipoles in interactions involving dipolarophiles containing the acetylenic bond can give rise in the first stage to a pyrazolenine (IV) (Scheme 1, pathway *b*), which is converted into the pyrazole (V) in the course of the sigmatropic rearrangement.

Progress in the development of the methods of synthesis of a wide variety of organometallic diazoalkanes (derivatives of tin,[81] germanium, lead, Group IIB elements,[82] mercury,[83] Group VB elements,[84] thallium,[85] etc.[63,70]) made it possible to introduce them into the 1,3-DCA reaction. For example, the reactions of metallated diazoalkanes $R_nMC(N_2)R'$ with dimethyl acetylenedicarboxylate have been investigated:



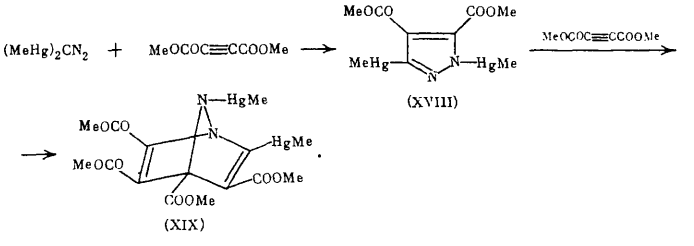
$R_nM$=$Me_2Sn$, $Me_3Pb$, $Me_2Sb$, $Me_3Bi$, MeHg, $HgC(N_2)COOEt$, $HgC(N_2)COMe$; R′=$R_nM$, COOEt, COMe, COPh.

The pyrazolenine (XIV), which readily isomerises to the pyrazole (XV) with 1,3-migration of the $R_nM$ fragments, is formed in the course of the reaction.



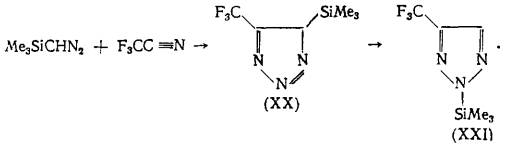
However, it has been found that not all the organometallic diazoalkanes described enter into the 1,3-DCA reaction with acetylenic dipolarophiles: the amount of ionic character of the bond and the bulk of the substituents in the 1,3-dipoles play a significant role in these reactions. Thus, whereas the organoelemental diazoalkanes of the type $R_nEC(N_2)R^1$, where E = Si,[63,70,71,75,86] Sn,[63,87] Pb,[78] Hg,[87] etc.,[63] react with alkynes, the analogous arsenic derivatives do not enter into the 1,3-DCA reaction due to steric hindrance[63] and the

thallium derivative, namely bis(dimethylthallium)diazomethane, does not react because it has an ionic structure.[85]

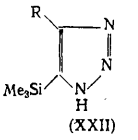


It has also been shown that sigmatropic rearrangements of the type (IV) → (V) are observed also for the 1,3-DCA of $(Me_3Sn)_2CN_2$ and $Me_3SiC(N_2)R$ to MeOOCC≡CCOOMe and are characterised by a decrease of the capacity of the group R for migration in the sequence $Me_3Sn$ > $Me_3Si$ > H > COOEt. For example, the isomerisation of the pyrazolenine (XVI) is accompanied by the migration of $Me_3Si$ and not of a hydrogen atom as had been suggested earlier:[75]

When organoelemental bisdiazoalkanes were involved in the reactions considered above bisheterocyclic systems were isolated. For example, the mercuribisdiazoalkane $Hg[C(N_2)R]_2$, in which R = COOEt or COMe, reacts with dimethyl acetylenedicarboxylate to form the dipyrazoleninemercury derivatives (XVII):[87]

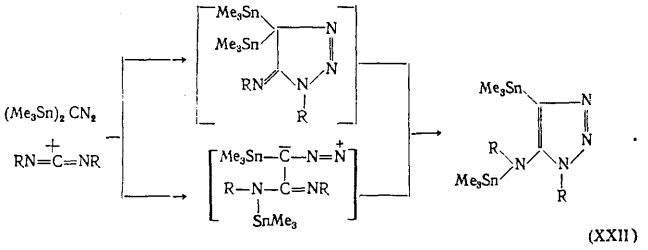


In an analogous reaction bis(methylmercuri)diazomethane is converted into the 1,3-bis(methylmercuri)pyrazole (XVIII), which gives rise to the *CN*-bis(methylmercuri)-derivative of diazanorbornadiene (XIX) on interaction with a second molecule of MeOCOC≡CCOOMe:[87]

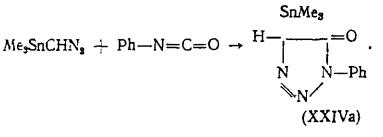


α-Metallated diazoalkanes hardly react with phenylacetylene, diphenylacetylene, sodium acetylenedicarboxylate and bis(trimethylstannyl)acetylene.[63] The causes of such behaviour of the above dipolarophiles are obscure.

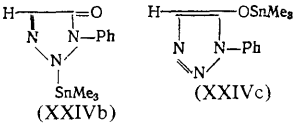
*(c) Triazoles*



The 1,3-DCA of organoelemental diazoalkanes to nitriles (Scheme 1, pathway *c*) and carbodiimide (Scheme 1, pathway *d*) results in the formation of the triazoles (VI)–(VIII). In particular, it has been established[88] that the interaction of trimethylsilyldiazomethane with trifluoroacetonitrile produces the adduct (XX) which is readily converted into 5-trifluoromethyl-2-trimethylsilyl-1,2,3-triazole (XXI):



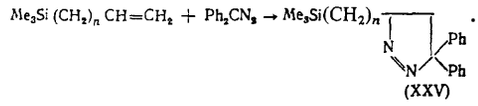
In contrast to the *N*-trimethylsilyltriazoles (XXI) indicated above, the C-substituted triazoles (XXII) with R = Pr, t-Bu, Ph, $PhCH_2$, 1-naphthyl, 2-pyridyl, 1-isoquinolinyl, EtS, and PhO have been obtained via the 1,3-DCA reaction from the lithium salts of trimethylsilyldiazomethane and nitriles.[89–91]



Thus the data presented show that 1,3-DCA can be used for the specific synthesis of *C*- and *N*-organoelemental derivatives of triazoles. Triazole systems with organoelemental substituents are also formed on interaction of organoelemental derivatives of diazomethane with heterocumulene dipolarophiles (Scheme 1, pathway *d*). Thus the dimetallated triazole (XXIII) is formed in the reaction of bis(trimethylstannyl)diazomethane with carbodiimide:[70]

1,3-DCA apparently proceeds analogously in the case of trimethylstannyldiazomethane and phenyl isocyanate.[81] The authors[81] believe that the reaction leads to the formation of the triazolone (XXIVa):

However, a further two isomeric structures, (XXIVb) and (XXIVc), may be proposed for the reaction product taking into account the data presented above, and of these we believe that (XXIVb) is the most probable:

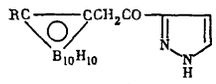


The elucidation of the mechanism of 1,3-DCA with participation of heterocumulene dipolarophiles and of the structure of the products formed therefore requires additional investigation.

## 2. The Synthesis of Heterocycles from Diazoalkanes and Organoelemental Dipolarophiles

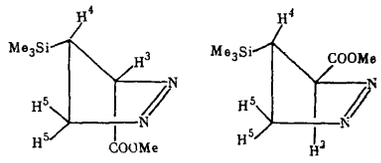
Pyrazolines, pyrazolenines, and pyrazoles with organoelemental substituents are formed from diazoalkanes and organoelemental dipolarophiles in the course of 1,3-DCA reactions.[56,57,92–111]

*(a) Pyrazolines*



Silylolefins react with diphenyldiazomethane (in proportions of 3 : 1 at +5 °C) to form trimethylsilylpyrazolines (XXV):[92]

(XXV)

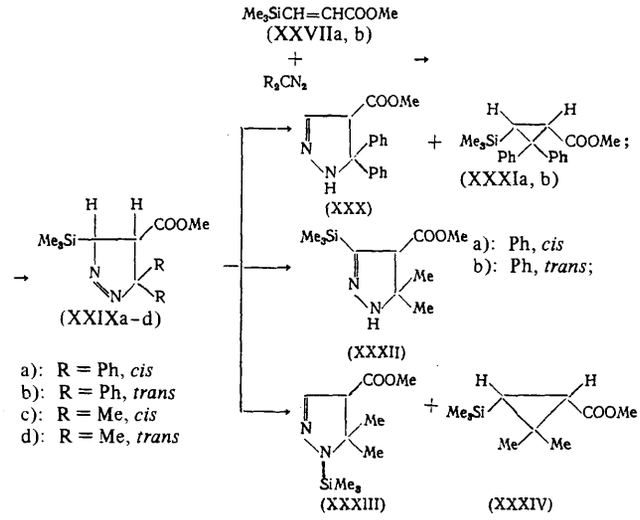


In particular, 3,3-diphenyl-5-trimethylsilyl-$\Delta^1$-pyrazoline (XXV, $n = 0$) has been synthesised in this way. We may note that the same reaction in the presence of copper sulphate as the catalyst leads to silyl derivatives of cyclopropane.

The interaction of carbaboranylmethyl β-chlorovinyl ketones with diazomethane affords the pyrazoles (XXVI).[93]

(XXVI)

The 1,3-DCA of diazoalkanes to alkenes with organoelemental substituents has been studied in detail in relation to the methyl esters of 3-methylsilylpropenoic acid.[94] The *cis*- and *trans*-isomers of $Me_3Si-CH=CHCOOMe$ (XXVIIa, b). obtained by the reduction of $Me_3SiC\equiv CCOOMe$, give rise to high yields of the isomeric *cis*- and *trans*-3-methoxycarbonyl-4-methylsilyl-1-pyrazolines (XXVIIIa, b) on 1,3-DCA to diazomethane (in ether and a nitrogen atmosphere):



(XXVIIIa) (XXVIIIb)

The pyrazolines (XXVIIIa, b) whose structure has been demonstrated by $^1H$ NMR, subsequently rearrange with elimination of a nitrogen molecule, the migration of the $Me_3Si$ substituent from the C(4) to the C(5) atom of the pyrazoline ring, and the formation of a series of *cis*(*trans*)-isomeric silicon-containing ethylene derivative. The reaction involving monosubstituted diazomethanes proceeds analogously.[94]

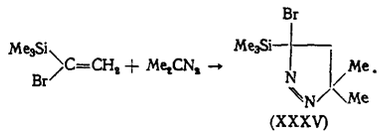
The cycloaddition of diphenyldiazomethane to the *cis*-isomer of the methyl ester (XXVIIa) gives rise to *cis*-4-methoxycarbonyl-3,3-diphenyl-5-trimethylsilylpyrazoline (XXIXa) in 71% yield, while its addition to the *trans*-isomer of the methyl ester (XXVIIb) results in the formation of *trans*-4-methoxycarbonyl-3,3-diphenyl-5-trimethylsilyl-1-pyrazoline (XXIXb). Heating of the pyrazoline (XXIXa) in protic solvents leads to disilylation and the formation of compound (XXX), while prolonged thermolysis in boiling hexane produces *cis*- and *trans*-2,2-diphenyl-3-trimethylsilylcyclopropanecarboxylates (XXXIa, b) in proportions of 2 : 3. The thermal stability of the pyrazoline (XXIXa) is higher than that of compound (XXIXb), but it eliminates nitrogen in boiling octane, forming the *cis*- and *trans*-carboxylates (XXXIa, b) in proportions of 1 : 4.

The reaction of the *cis*-isomer of the methyl ester (XXVIIa) with 2-diazopropane leads to the formation of 4-methoxycarbonyl-5,5-dimethyl-3-trimethylsilyl-2-pyrazoline (XXXII) in 75% yield, which has been demonstrated by the $^1H$ NMR spectrum of the reaction mixture before its further treatment. Other results have been obtained for the reaction of 2-diazopropane with the *trans*-isomer of the methyl ester (XXVIIb). In this case analysis by the GLC method demonstrated the presence in the reaction mixture of 4-methoxycarbonyl-5,5-dimethyl-1-trimethylsilyl-2-pyrazoline (XXIII) and the *trans*-cyclopropanecarboxylate (XXXIV) in proportions of 1 : 1. However, the signals which could be assigned to compounds (XXXIII) and (XXXIV) are absent from the $^1H$ NMR spectrum of the above mixture, but signals due to the pyrazoline (XXIXd) are present. The authors point out that, under the GLC conditions, compound (XXIXd) is the starting material in the formation of compounds (XXXIII) and (XXXIV). The dimethylpyrazoline (XXIXd) is sensitive to the action of water, like the diphenylpyrazoline (XXIXa), and when moist 2-diazopropane is employed in this case, the desilylated 4-methoxycarbonyl-5,5-dimethyl-2-pyrazoline is formed in a high yield:

(XXIXa-d)

a): R = Ph, *cis*
b): R = Ph, *trans*
c): R = Me, *cis*
d): R = Me, *trans*

(XXX) (XXXIa, b)

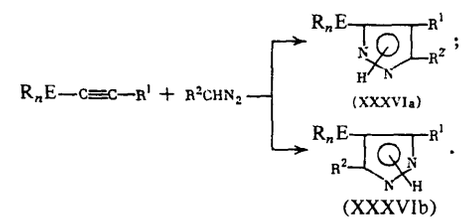


(XXXII)

a): Ph, *cis*
b): Ph, *trans*;

(XXXIII) (XXXIV)

It was then shown that the 1,3-DCA is stereospecific and is sensitive to the nature of the 1,3-dipole, namely to the character of the substituents R, and makes it possible to synthesise specifically the isomeric forms of pyrazolines.

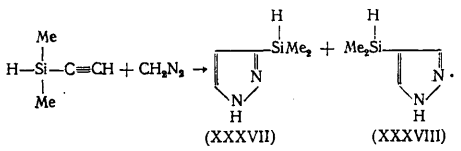


Treatment of an ethereal solution of dimethyldiazomethane with α-bromovinylsilane at 0 °C leads to the formation of 3-bromo-5,5-dimethyl-3-trimethylsilylpyrazoline (XXXV) in 63% yield:[95]

(XXXV)

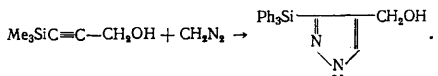
*(b) Pyrazoles*

The addition of diazoalkanes to acetylenes with organoelemental substituents has been studied fairly completely.[56,57] It proceeds in accordance with the 1,3-DCA principle and leads to the formation of two isomeric pyrazoles (XXXVIa, b):



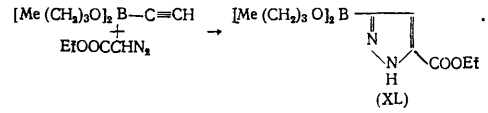
(XXXVIa)

(XXXVIb)



E usually represents Group IV elements (Si, Ge, Sn, and Pb), although similar syntheses of pyrazoles with other organoelemental substituents are known.[56,57] R, $R^1$, and $R^2$ are usually aliphatic or aromatic substituents, $R^1$ representing not only hydrocarbon groups but also a wide variety of functional groups ($CH_2OH$, $-C(=O)P$, etc.). Thus the interaction of diazomethane ($R^2$ = H) and its monosubstituted derivatives ($R^2$ = alkyl or aryl) with trialkyl derivatives of silicon[96,97] or tin[98,99] leads to the formation of pyrazoles containing the substituents $R_3E$ (E = Si or Sn) in the 3- or 5-position.

In the course of its 1,3-DCA to diazomethane in absolute ether at 0–5 °C (three weeks), ethynyldimethylsilane gives rise to a mixture of approximately equal amounts of 3- and 4-dimethylsilylpyrazoles (XXXVII) and (XXXVIII):[100]

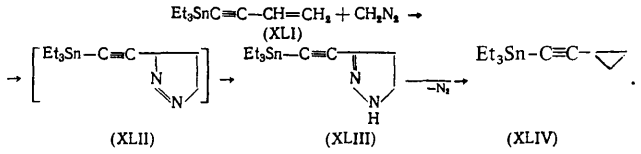


(XXXVII) (XXXVIII)

Triphenylsilylpropargyl alcohols enter into the 1,3-DCA reaction,[99,101] producing mainly compound (XXXIX):

(XXXIX)

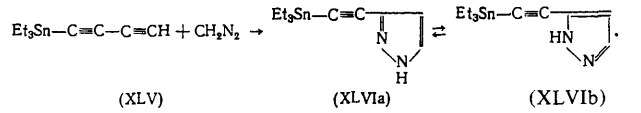
Reaction specificity has been observed also in the addition of diazoacetic ester to dibutyl ethynylboronate[102] with formation of a boron-substituted pyrazole (XL):



(XL)

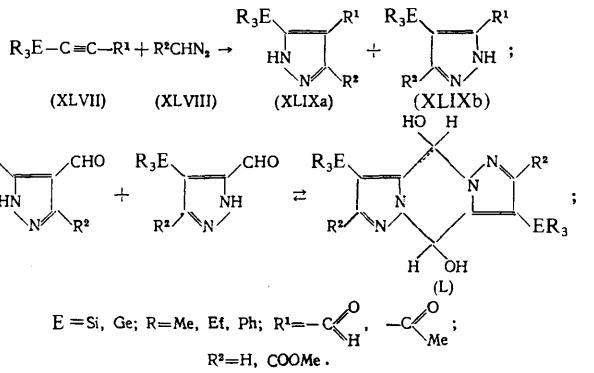
Ethyl diazoacetate enters into an analogous reaction with dibutyl ethynylboronate.

The 1,3-DCA reaction with participation of bi- and polyfunctional dipolarophiles is of considerable interest; heterocycles not only with organoelemental but also with active functional groups have been obtained in the course of this process. Polyheterocyclic systems with organoelemental substituents are frequently formed as a result of this type of 1,3-DCA.



Systematic studies of the competitive reactivities of difunctional dipolarophiles[64,103] have shown that, in the presence of two reaction centres, αβ-unsaturated heteroatomic compounds can react in two ways: with participation of the multiple bond, i.e. [3 + 2]-cycloaddition, or via the heteroatom. Furthermore, it has been established in studies by the same authors that, in the presence of two multiple bonds in the dipolarophile molecule, the most electrophilic of these enters into the 1,3-DCA reaction.[104,105] The data presented above clearly illustrate this behaviour.

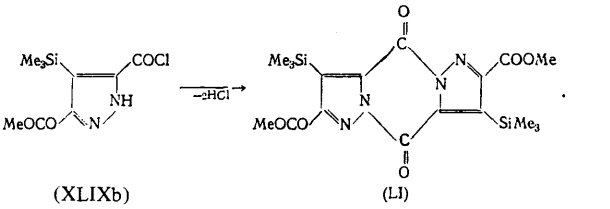
Metallated vinylacetylenes combine with diazo-compounds at the more electrophilic double bond with formation of the corresponding pyrazolines. In particular, triethylstannylfinylacetylene (XLI) reacts in this way with diazomethane to form the $\Delta^1$-pyrazoline (XLII), which readily isomerises to $\Delta^2$-pyrazoline (XLIII). On heating to 120 °C, the latter is fully converted into cyclopropyltriethylstannylacetylene (XLIV) with evolution of a nitrogen molecule:



(XLII) (XLIII) (XLIV)

1,3-DCA takes place analogously at the more electrophilic carbon atom of the terminal acetylenic bond in the case of triethylstannyldiacetylene (XLV) with formation of 3(5)-(triethylstannylethynyl)pyrazoles (XLVIa, b):

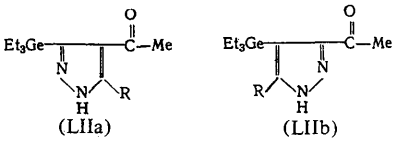
(XLV) (XLVIa) (XLVIb)



The reactions of triorganylgermanium- or triorganylsilicon-containing carbonyl derivatives (XLVII) with diazoalkanes[106] or with methyl esters of diazoacetic acid (XLVIII)[107–112] lead to the formation of the isomeric pyrazoles (XLIXa, b) and also of the tricyclic hemiaminal (L, $R^1$ = CHO):

(XLVII) (XLVIII) (XLIXa) (XLIXb) (L)

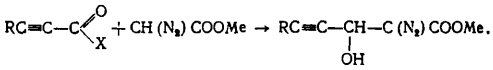
E = Si, Ge; R = Me, Et, Ph; $R^1$ = –C(=O)H, –C(=O)Me; $R^2$ = H, COOMe.



The interaction of trimethylsilylpropiolic acid chloride (XLVII, E = Si, R = Me, R' = COCl) and methyl diazoacetate (XLVIII, $R^2$ = COOMe)[112] proceeds analogously. However, the dioxopiperazine (LI) and not a heminal of type (L) is then formed from the pyrazole (XLIXb) on dehydrohalogenation:

(XLIXb) (LI)

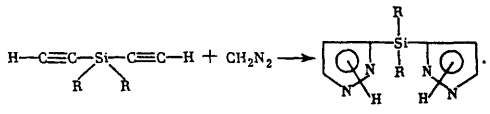
The 1,3-DCA reaction described above proceeds under mild conditions at room temperature or on cooling in absolute ether, albeit over a long period (from 1 to 60 days). The character of the adducts formed, whose structure has been demonstrated on the basis of 1R and $^1$H NMR spectra, and the ratio of the isomeric pyrazoles depend on the substituent $R^2$ in the diazoalkane and on the nature of the solvent.



It has been shown[105] that only a mixture of the isomeric pyrazoles (LIIa, b) is formed from methyl triethylgermylethynyl ketone.

(LIIa) (LIIb)

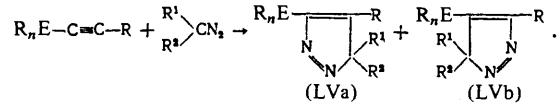
The ratio of the isomers depends on the composition of the 1,3-dipole: an equilibrium mixture of the isomers (LIIa, b) is obtained from diazomethane, in the reaction involving diazoacetic ester the isomer (LIIb) greatly predominates, and in the reaction of diazoacetone the isomer (LIIa) is obtained preferentially.



The 1,3-DCA reaction with participation of organoelemental propynals as 1,3-dipoles leads to the formation, apart from pyrazoles, of cyclic hemiaminals (L)[106–110] and also of element-containing diazoesters (LIII) as a result of addition to the aldehyde group:[108]

(LIII)

The nature of the solvent has a significant effect on the content of the dimeric form (L) and the monomeric form (XLIX): according to $^1$H NMR data, the equilibrium in weakly polar solvents (THF, $CHCl_3$, and dioxan) is displaced towards the dimer, while in more polar solvents [MeOH and dimethyl sulphoxide (DMSO)] it is shifted towards the monomeric formylpyrazole.[108,109]



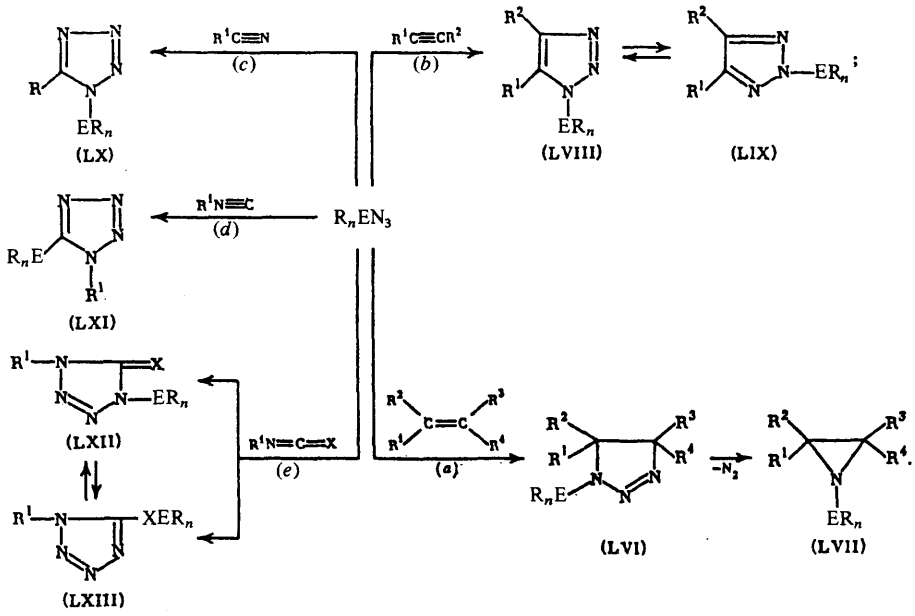
Here we may also note that the 1,3-DCA of diazomethane to bisacetylenic derivatives with equally electrophilic dipolarophile groups, for example, $R_2Si(C{\equiv}CH)_2$, is accompanied by the reaction involving both triple bonds and leads to silylenebispyrazole systems (LIV):[56]

(LIV)

*(c) Pyrazolenines*

The 1,3-DCA method makes it possible to obtain pyrazole isomers which are otherwise difficult to synthesis—the pyrazolenines,[113] their formation being promoted by the use of disubstituted diazo-compounds and disubstituted acetylenes. Thus pyrazolenines have been obtained in the form of two isomers (LVa, b) by the reaction of metallated acetylenes with disubstituted diazoalkanes:[101]

(LVa) (LVb)



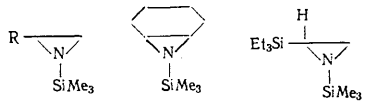
The data presented in Section II suggests the conclusion that 1,3-DCA makes it possible not only to obtain a wide variety of *C*- and *N*-derivatives of pyrazolines, pyrazoles, pyrazolenines, triazoles, and complex polycyclic systems but also to direct the reaction towards the preferential formation of specific isomers.

## III. SYNTHESES WITH PARTICIPATION OF AZIDES

### 1. Syntheses of Heterocycles Based on Organoelemental Azides

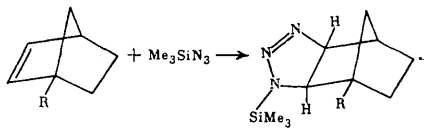
The common instances of syntheses based on organoelemental azides are presented in Scheme 2:

Scheme 2



(LXII), (LXIII) X = O, S; E = Cu, Au, Hg, Si, Sn, Pb, Pt, Pd, Ru

*(a) Triazolines and Azirdines*

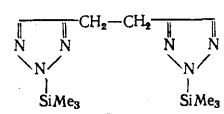


The interaction of organoelemental azides with alkenes (Scheme 2, pathway *a*) leads to the unstable triazolines (LVI), which are converted, as a result of the elimination of a nitrogen molecule, into the N-substituted aziridines (LVII) which are comparatively difficult to obtain.

Thus the interaction of trialkylsilyl azide with the corresponding olefin, which takes place after the reactants have been allowed to stand for a long time (up to 85 days), makes it possible to obtain a series of aziridines (LXIV)–(LXVI),[114] including the formation of the bistrialkylsilyl derivatives (LXVI) from a silylated olefin:

(LXIV) (LXV) (LXVI)

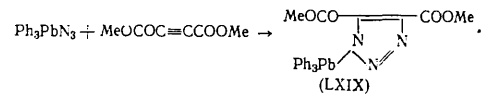
A fairly stable triazoline (LXVII) can be isolated after the interaction of trimethylsilyl azide with a bridge bicyclic olefin:[115]



(LXVII)

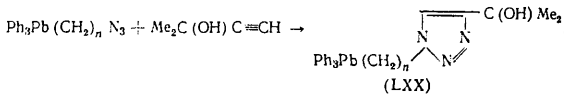
*(b) Triazoles*

1,3-DCA with participation of organoelemental azides and acetylenic dipolarophiles (Scheme 2, pathway *b*) was first used to obtain organoelemental derivatives of 1,2,3-triazoles by Birkofer and co-workers:[116–120] after prolonged heating of mixtures of trimethylsilyl azide and substituted acetylenes, high yields of *N*-trimethylsilyl-1,2,3-triazoles were obtained. It was established by the method of dipole moments that the $R_3Si$-substituted 1,2,3-triazoles exist in the form of isomers and it has been suggested that the $R_3Si$ substituent migrates rapidly between the N(1) and N(2) atoms of the triazole ring. This was evidently the first case of elementotropism among heterocyclic compounds, which was later demonstrated convincingly in a whole series of tautomeric systems,[7–13] including pyrazole[8,10] and triazole[11,13] derivatives containing organoelemental substituents.



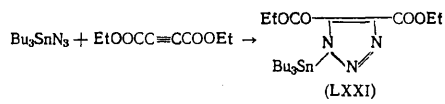
The bisheterocyclic systems (LXVIII) was also synthesised by means of the reactions indicated above; the reaction was carried out in an autoclave at 120–150 °C and the yield of the product was 80%.[119]

(LXVIII)



The interaction of trimethylsilyl azide with substituted acetylene RC≡CR′ leads to the formation of 1-trimethylsilylmethyl-4-R-5-R′-1,2,3-triazoles.[121]

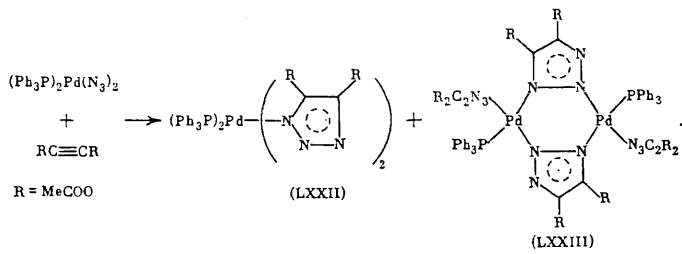
Triphenylplumbyl azide,[122–125] was made to react with a large number of olefinic and acetylenic compounds.[126] However, the reaction does not take place with maleic anhydride, dimethyl maleate, ethyl vinyl ether, morpholinocyclopentene, diphenylacetylene, phenylacetylene, propargyl alcohol or 2-methylbut-2-en-2-ol. 4,5-Dimethoxycarbonyl-1-triphenylplumbyl-1,2,3-ditrazole (LXIX) is formed only in the reaction with dimethylacetylenedicarboxylate, which is a very powerful dipolarophile:



(LXIX)

In contrast to triphenylplumbyl azide, triphenylplumbylalkyl azides readily enter into 1,3-DCA even with weak dipolarophiles such as 2-methylbut-3-en-2-ol, forming the corresponding triazoles (LXX):

(LXX)



Heterocycles with a N–Sn bond [compounds (LXXI)] can be synthesised from organotin azides and substituted acetylenes as described, for example, by Leijten and van der Kerk:[127]

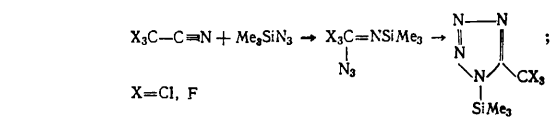
(LXXI)

We may note that the structures of compounds (LXIX)–(LXXI) quoted in the studies considered above are open to doubt: they have not been demonstrated and, when account is taken of the possibility of the metallotropic N(1)–N(2) migrations of the organoelemental groups, structures of type (LIX) appear to be more probable.

Unusual products are obtained on 1,3-DCA of palladium-substituted organophosphorus azides to dimethyl acetylenedicarboxylate: apart from N-palladium derivatives of the bispyrazoles (LXXII), the highly symmetric dimers (LXXIII) are produced:[128]

(LXXII) (LXXIII)

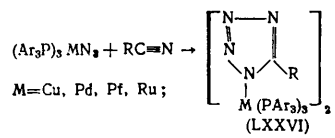
*(c) Tetrazoles, Tetrazolones, and Their Thio-analogues*



Organoelemental derivatives of the tetrazoles (LX) and (LXI) are formed as a result of the 1,3-DCA of organoelemental azides to nitriles (Scheme 2, pathway *c*) and isonitriles (Scheme 2, pathway *d*).[129–147] The reactions of these azides with heterocumulenes lead to the tetrazolones (LXII) (Scheme 2, pathway *e*) and their thio-analogues.[128,133,135]

Using Scheme 2 (pathways *c*, *d*, and *e*), it is possible to synthesise specifically *N*-substituted [compounds (LX) and (LXII)] or *C*-substituted [compounds (LXI) and (LXIII)] derivatives respectively.

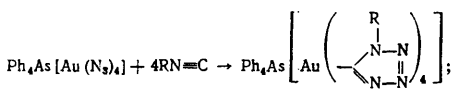
The addition of trimethysilyl azide to benzonitrile takes place in the presence of catalytic amounts of $AlCl_3$ or other Lewis acids.[135]



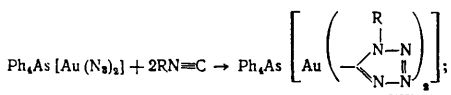
It has been found[136] that trimethylsilyl azide adds to the C≡N bond also in the presence of catalytic amounts of triethylamine. Thus the interaction of $Me_3SiN_3$ with trichloro- or trifluoroacetonitrile with participation of the

above catalyst leads to trihalogenomethyl-1-trimethylsilyltetrazoles (LXXV). It has been shown that aluminium chloride is ineffective in this reaction, since it induces the polymerisation of the nitriles. The 1,3-DCA proceeds in this case via the stage involving the formation of 1-azido-2,2,2-trihalogeno-1-(trimethyl-silylimino)ethanes (LXXIV):

(LXXIV) (LXXV)

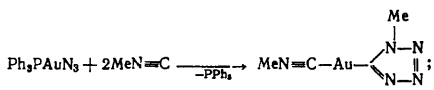


Bistetra-azotriarylphosphine complexes of copper, palladium, platinum, and ruthenium (LXXVI) have been obtained [75,131,138,141,147]† by the interaction of metal azides with nitriles:

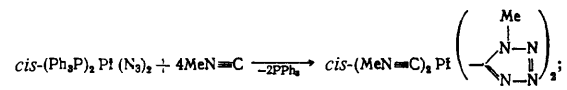


(LXXVI)

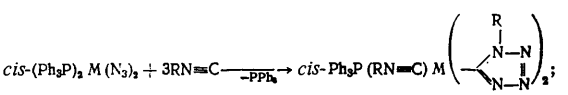
The 1,3-DCA involving azidotriphenylphosphinoisonitrile complex on platinum, leading to Pt–N-derivatives of tetrazoles, proceeds analogously.[141]



The azide-containing complexes $Ph_4As[Au(N_3)_4]$, $Ph_4As.[Au(N_3)_2]$, $Ph_3PAuN_3$, and $(Ph_3P)_2M(N_3)_2$ (M = Pd, Pt, or Hg) react with isonitriles under very mild conditions, forming tetrazolate complexes[132,140] in which the organometallic substituents are bound to a carbon atom of the tetrazole ring [compounds LXXVII)–LXXXIII)]:

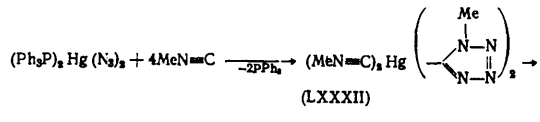


(LXXVII)

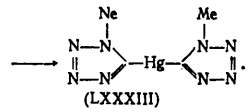


(LXXVIII)

(LXXIX)

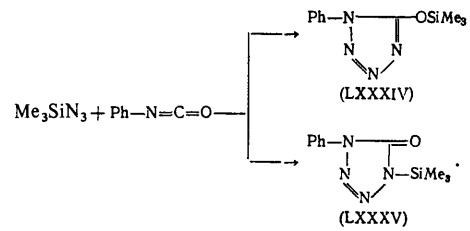


(LXXX)



(LXXXI) M=Hg, Pd, Pt

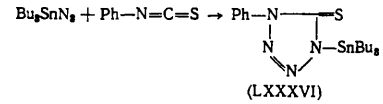
† A whole series of communications[128,144–147] concerning the 1,3-DCA of organoelemental azides to nitriles, isonitriles, and other dipolarophiles, leading to N- and C-substituted tetrazoles, have been published. The examination of all these studies is outside the framework of the present review. In most cases the above investigations were concerned with the reactions of the azides of various metals and provided no fundamental information. We therefore considered the most important and latest studies of this series.



(LXXXII)

(LXXXIII)

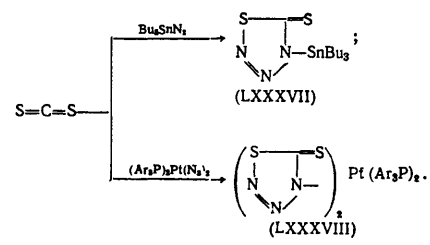
Other methods, which are difficult to apply, have been suggested for the synthesis of the complexes (LXXXII)–(LXXXIII).



The synthesis of the tetrazolones (LXII, X = O)[128,135] and their thio-analogues (LXII, X = S)[128,131] in accordance with Scheme 2 (pathway *e* usually take place under fairly severe conditions in the presence of catalysts. Thus the 1,3-DCA of trimethylsilyl azide to phenyl isocyanate, which takes place on heating to 140 °C for 12 h in the presence of $AlCl_3$, leads to the silyloxytetrazole (LXXIV) and the *N*-silyltetrazole (LXXXV):[135]

(LXXXIV)

(LXXXV)



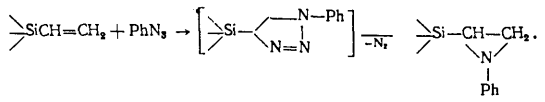
A reaction involving tributylstannyl azide and phenyl isothiocyanate has also been described,[131] although the authors postulate only one structure for the 1,3-DCA product—that of the thionotetrazole (LXXXVI):

(LXXXVI)

The 1,3-DCA reactions of platinum- and palladium-substituted bistriphenylphosphine azides proceed in accordance with analogous mechanisms.[128]

Carbon disulphide has also been used as the heterocumulene dipolarophile:[128,131–133] the 1,3-DCA leads to extremely unusual heterocycles—the thionotriatriazoles (LXXXVII) and (LXXXVIII), the possibility of the synthesis of which by other methods is obscure:[40–43]

(LXXXVII)



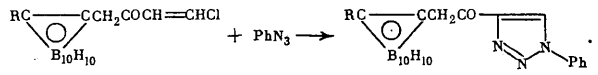
(LXXXVIII)

## 2. The Syntheses of Heterocycles Based on Azides and Organoelemental Dipolarophiles

### *(a) Triazolines and Aziridines*

*C*-Organosilicon derivatives of aziridine have been obtained[148–150] by the interaction of vinylsilanes with phenyl azide at room temperature[149–150] or of alkenylmethylsiloxanes

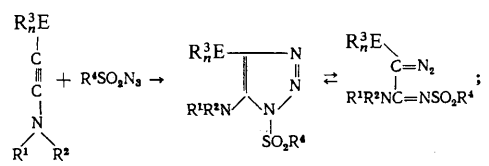
with benzoyl azide at 60–80 °C.[148] The first stage of this reaction is apparently the addition of the azide to the vinyl group with formation of a five-membered ring, which eliminates a nitrogen molecule and is converted into the *N*-phenylaziridine derivatives (LXXXIX):



(LXXXIX)

The yields of *C*-aziridinyl derivatives after a 40-day reaction of vinylheptamethylcyclotetrasilane or 3-vinylheptamethyltrisiloxane with phenyl azide did not exceed 11%. The reaction of allylsilanes with $PhN_3$, is even more difficult,[150] while phenyl azide adds somewhat more readily to 3-vinylheptamethyltrisilane;[150] the yield of the reaction product in petroleum ether after ten days at 30–40 °C reaches 40.5%.[148]

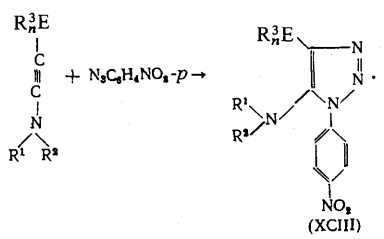
When the alkenylsilanes RCH=CHSiR′ are used in the reaction with *p*-bromophenyl azide, 1-*p*-bromophenyl-2-trimethylsilyl-3-R-aziridines are formed.[151] On heating $PhCH{=}CHSiMe_3$ with $p\text{-}BrC_6H_4N_3$ in $CCl_4$ for 24 h, it is possible to isolate 1-*p*-bromophenyl-5-phenyl-4-trimethylsilyl-$\Delta^2$-1,2,3-triazoline in 10% yield. On further heating in the course of 4 days, the triazoline is converted into an aziridine and a 1 : 1 mixture of $Me_3SiCHN_2$ and $PhCH{=}NC_6H_4.Br\text{-}p$.



*(b) Triazoles*

4-(*o*-Carbaboranylacetyl)-1-phenyltriazoles (XC) are formed after prolonged heating of carbaboranylmethyl β-chlorovinyl ketone with phenyl azide in benzene solution:[152]

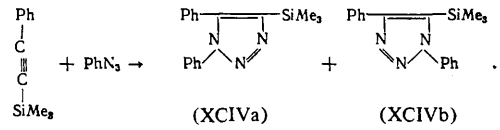
(XC)



The reactions of sulphonyl azides with organometallic ynamines are regiospecific[153,154] and lead to 5-amino-1,2,3-triazoles (XCI), which, depending on the nature of the substituents $R^1$, $R^2$, $R^3$, and $R^4$, either isomerise wholly to the α-metallated diazoacetamidines (XCII) or are involved in a tautomeric equilibrium with the latter:

(XCI) (XCII)

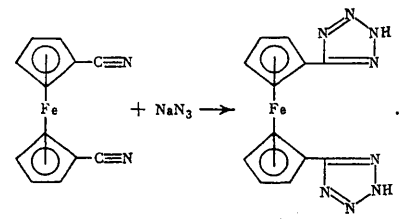
$R^1$, $R^2$, $R^4$=alkyl, aryl; $R_n^3E = R_2^1As$, $R_2^1Sb$, $R_3^1Si$, $R_3^1Ge$, $R_3^1Sn$, $Ph_2P(O)-$, $Ph_2P(S)-$.



The analogous triazoles (XCIII) with *N*-*p*-nitrophenyl substituents instead of the sulpho-group are more stable:[155]

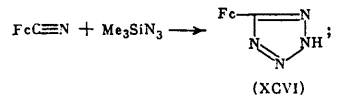
(XCIII)

We may note that tolyl azide does not react with phenylacetylene itself but does react with its sodium salt.[153] There are also data indicating the condensation of various lithium and magnesium acetylides with azides.[156,157]



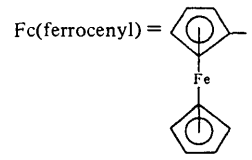
In contrast to the 1,3-DCA with participation of diazoalkanes, which exhibits an appreciable structural specificity in reactions with alkynes, in the case of azides, such specificity is not always marked. However, an appreciable selectivity of the addition reaction, leading to the preferential formation of one isomer, for example (XCIVa), has been sometimes noted; the second isomer (XCIVb) has been obtained in a yield of only 3%:[117,120]

(XCIVa) (XCIVb)



*(c) Tetrazoles*

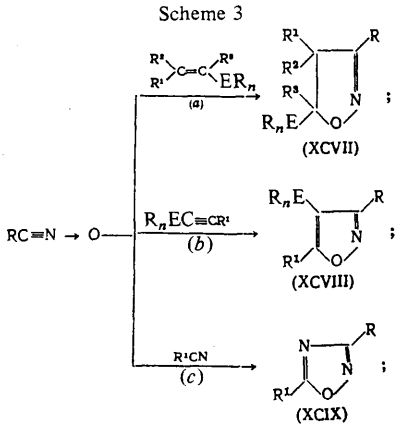
The interaction of 1,1′-dicyanoferrocene with $NaN_3$ in THF in the presence of $AlCl_3$ leads to the formation of 1,1-di(5-tetrazolyl)ferrocene (XCV):[158]



(XCV)

The *C*-ferrocenyltetrazole (XCVI) is formed in the reaction of 1-cyanoferrocene and trimethylsilyl azide in *o*-dichlorobenzene in the presence of $AlCl_3$:[159]

(XCVI)



We must emphasise that, so far as we are aware, organoelemental derivatives of heterocumulenes have not been introduced into this type of 1,3-DCA, although the dipolarophiles have been fairly thoroughly investigated (see, for example, Refs.160–162).

## IV. SYNTHESES WITH PARTICIPATION OF NITRILE *N*-OXIDES

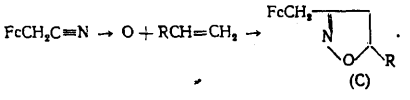
1,3-DCA with participation of nitrile *N*-oxides as dipolarophiles, which arise in the course of the reaction and react *in situ*, have been used fairly widely in the synthesis of heterocycles with organoelemental substituents.[95,163–173] The reactions lead to the formation of *NO*-heterocyclic systems—isoxazolines (XCVII), isoxazoles (XCVIII), and oxadiazoles

(XCIX), the methods of synthesis of which are illustrated in Scheme 3:

Scheme 3

(XCVII)

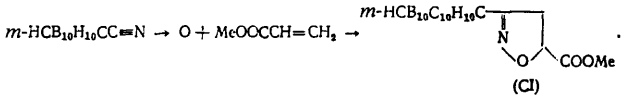
(XCVIII)



(XCIX)

*a*) and *b*) $R_nE$ = carbaborane- and ferrocene-containing groups, R = Ar, and $R^1$, $R^2$, $R^3$ = alkyl or aryl; *c*) R = $FcCH_2$ and R = Me.

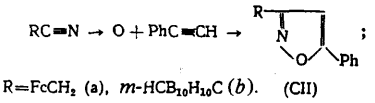
## 1. The Syntheses of Heterocycles from Organoelemental Nitrile *N*-oxides



### *(a) Isoxazolines*

Ferrocenylacetonitrile *N*-oxide, formed from ferrocenylnitroethane, reacts *in situ* with a series of olefinic dipolarophiles—hept-1-ene, styrene, acrylonitrile, or trimethylsilylethylene, forming isoxazolines (C):[163]

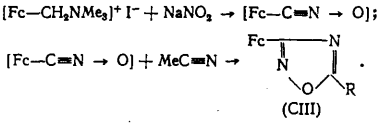
(C)



*m*-Carbaboranylnitrile *N*-oxide has been synthesised.[164] Its reaction *in situ* with methyl acrylate leads to an isoxazoline having a *m*-carbaboranyl substituent (CI):

(CI)

### *(b) Isoxazoles*

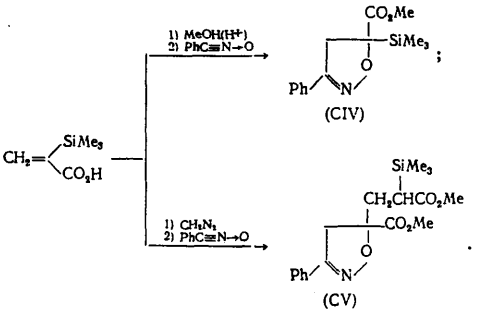


The interaction of phenylacetylene with ferrocenylacetonitrile *N*-oxide or with *m*-carbaboranylnitrile *N*-oxide, obtained *in situ*, results in the formation of the corresponding isoxazoles (CII):[163,164]

R=$FcCH_2$ (a), *m*-$HCB_{10}H_{10}C$ (*b*). (CII)

### *(c) Oxadiazoles*

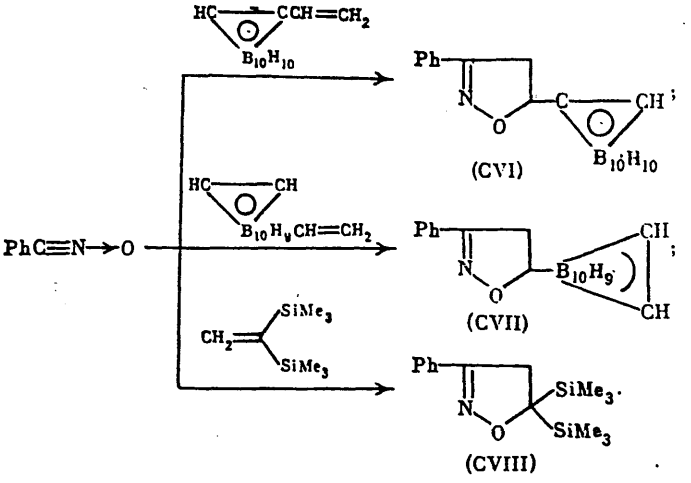
The reaction of ferrocenylmethyltrimethylammonium iodide with sodium nitrite and acetonitrile, which entails the formation of ferrocenyloxadiazole (CIII),[165] probably involves a stage in which ferrocenylacetonitrile *N*-oxide is formed *in situ*:



(CIII)

## 2. The Synthesis of Heterocycles from Nitrile *N*-oxides and Organoelemental Dipolarophiles

### *(a) Isoxazolines*

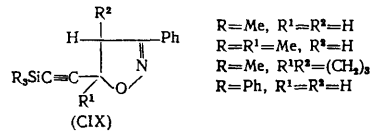


Isoxazolines (XCVII) are formed in the course of 1,3-DCA of nitrile *N*-oxides to dipolarophiles containing a double bond (Scheme 3, pathway *a*). Thus treatment of benzonitrile with methyl α-trimethylsilylacrylate affords the isoisoxazoline (CIV). The interaction of 2-trimethylsilylacrylic acid with benzonitrile oxide leads mainly to the product (CV):[95,166]

(CIV)

(CV)

The 1,3-DCA of benzonitrile oxide to unsaturated *o*-carbaborane derivatives gives rise to the isoxazolines (CVI) and (CVII) with a *o*-carboboranyl substituent, while the interaction of 1,1-bis(trimethylsilyl)ethylene results in the formation of the disilylated isoxazoline (CVIII):[164,166]

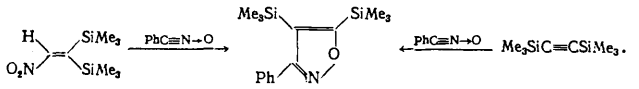


(CVI)

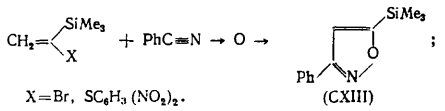
(CVII)

(CVIII)

The study of the competitive reactions of benzonitrile *N*-oxide with dipolarophiles containing double and triple bonds established that the 1,3-DCA is exclusive to the new reaction centre and leads to isoxazolines with silylethynyl substituents.[167,168] Thus the interaction of 1,3-enyne silylhydrocarbons (1-trimethylsilylbut-3-en-1-yne, 1-trimethylsilyl-3-methylbut-3-en-1-yne, 1-trimethylsilylethynylcyclopentene, and 1-triphenylsilylbut-3-en-1-yne) with

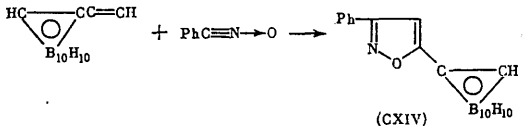


benzonitrile oxide results in the formation of compound (CIX) in satisfactory yields:[168]



(CIX)

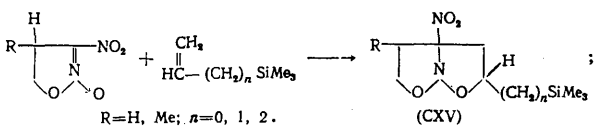
*(b) Isoxazoles*



Disilylated isoxazoles of the type of compound (CXI) are obtained instead of the expected isoxazolines (Scheme 3, pathway *a*) in the interaction of nitrovinylidenebistrimethylsilane (CX) with benzonitrile oxide.[95,166] There is in general no doubt about the structure of the isoxazole (CXI), since it has been obtained by specific synthesis from bis(trimethylsilylacetylene). The isoxazole (CXI) had been obtained earlier from benzonitrile oxide and bis(trimethylsilyl)acetylene:[169]

(CX) (CXI) (CXII)

The isoxazole (CXIII) is formed analogously instead of isoxazolines on interaction of α-bromovinyltrimethylsilane or α-(2,4-dinitriphenylthio)vinyltrimethylsilane with benzonitrile oxide:[166]



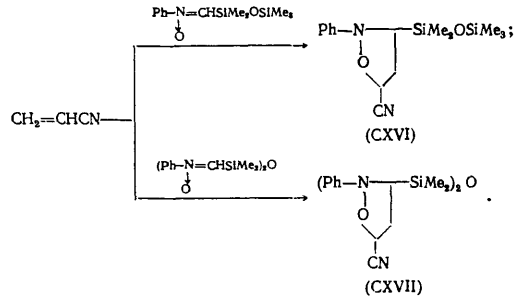
X=Br, $SC_6H_3(NO_2)_2$. (CXIII)

The 1,3-DCA of 1-ethynyl-*o*-carbaborane to benzonitrile oxide leads to the formation, as was to be expected, of the *o*-carbaboranylisoxazole (CXIV):[164]

(CXIV)

*(c) Isoxazolidines*

3-Nitroisoxazoline *N*-oxides react with silylolefins to form the bicyclic isoxazolidines (CXV):[170]

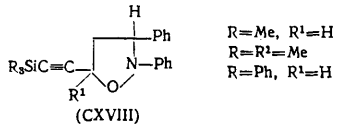


R=H, Me; *n*=0, 1, 2. (CXV)

## V. SYNTHESES WITH PARTICIPATION OF NITRONES

### 1. The Synthesis of Heterocycles from Organoelemental Nitrones

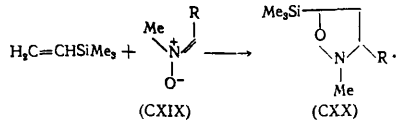
*(a) Isoxazolidines*



The 1,3-DCA of organosilicon nitrones to compounds containing a double bond results in the formation of derivatives of fully saturated *NO*-heterocycles—isoxazolidines. However, these 1,3-dipoles exhibit a weak affinity for olefins—the cycloaddition products (CXVI) and (CXVII) are obtained in low yields only after the reactants have been allowed to stand for a long time:[171]

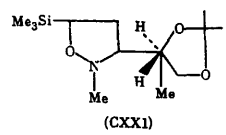
(CXVI) (CXVII)

### 2. The Synthesis of Heterocycles from Nitrones and Organoelemental Dipolarophiles



*(a) Isoxazolidines*

The addition of α*N*-diphenylnitrone to silylethynylalkenes (1-trimethylsilylbut-3-en-1-yne, 1-trimethylsilyl-3-methylbut-3-en-1-yne, and 1-triphenylsilylbut-3-en-1-yne) takes place at the double bond with formation of 5-organylsilylethynyl-2,3-diphenyloxazolidines (CXVIII):[168]



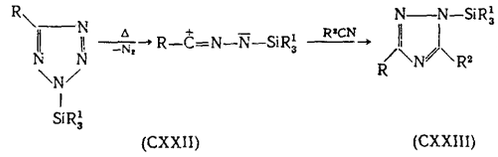
(CXVIII)

The reaction of trimethylvinylsilane with the nitrone (CXIX) affords 5-trimethylsilylisoxazolidine (CXX):[172,173]

(CXIX) (CXX)

The demonstration of the possibility of this reaction enabled the authors[173] to employ the principle in the synthesis of two stereoisomeric isoxazolidines (CXXI) which are deoxysugar derivatives:

(CXXI)



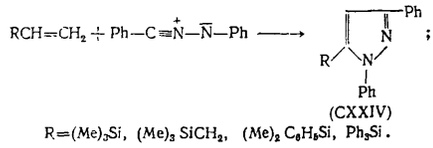
## VI. SYNTHESES WITH PARTICIPATION OF NITRILE IMINES

Nitrile imines are 1,3-dipoles which react exclusively *in situ*. Their 1,3-DCA reactions lead to the formation of pyrazolines (in reactions with olefins)[168,174] or 1,3,4-triazoles (in reactions with nitriles as dipolarophiles).[114]

### 1. The Synthesis of Heterocycles from Organoelemental Nitrile Imines

#### *(a) Triazoles*

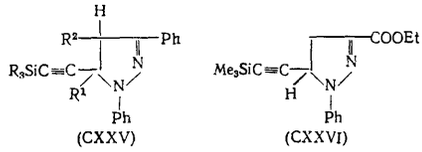
Silylated nitrile imines (CXXII) are formed when *N*-silyltetrazoles are heated, the 1,3-DCA to the nitrile resulting in the formation of 2-trimethylsilyl-1,2,4-triazoles (CXXIII):[114]



(CXXII) (CXXIII)

### 2. The Synthesis of Heterocycles from Nitrile Imines and Organoelemental Dipolarophiles

#### *(a) Pyrazolines*



The reactions of dimethylvinylsilane, trimethylvinylsilane, and triphenylvinylsilane with diphenylnitrile imine give satisfactory yields of derivatives of 1,3-diphenyl-2-pyrazoline with organosilicon substituents in the 5-position of the heterocycle as in compound (CXXIV).[174] The dipolarophile activity of the double bond in allyltrimethylsilane is much lower and the 2-pyrazolines are formed in lower yields:

(CXXIV)

R=$(Me)_3Si$, $(Me)_3SiCH_2$, $(Me)_2C_6H_5Si$, $Ph_3Si$.

2,3-Enyne silylhydrocarbons (1-trimethylsilylbut-3-en-1-yne, 1-trimethylsilyl-3-methylbut-3-en-1-yne, 1-trimethylsilylethynylcyclopentene, and 1-triphenylsilylbut-3-en-1-yne) also react with diphenyl nitrile imine as the double bond with formation of 2-pyrazolidines (CXXV).[168] *C*-ethoxycarbonyl-*N*-phenylnitrile imine adds to 1-trimethylsilylbut-3-en-1-yne to form 3-ethoxycarbonyl-1-phenyl-5-trimethylsilylethynyl-2-pyrazoline (CXXVI):[168]

(CXXV) (CXXVI)

## VII. CONCLUSION

The data presented in this review clearly indicate the extensive possibilities for the use of 1,3-DCA in the synthesis of heterocycles with organoelemental substituents. This aspect is important for the chemistry of heterocyclic compounds, since it enables one to avoid the use of complete heterocycles, whose preparation frequently involves multistage syntheses or the application of initial reactants which are difficult to obtain.[40-43]

This review was devoted to 1,3-DCA, but it is already clear[42,66] that other types of cycloaddition used to construct heterocyclic systems can also be regarded as universal methods of synthesis of heterocycles with organoelemental substituents: "2 + 1 = 3", "2 + 2 = 4", and "4 + 2 = 6" additions in the syntheses of three-membered, four-membered, and six-membered heterocycles. Examples of such reactions are available in the literature for organoelemental reagents. Thus the [2 + 2]-cycloaddition of heterocumulenes to a cobalt complex led to the synthesis of metallocyclic compounds.[175,176]

The [2 + 2]-cycloaddition of triphenylstibazosulphonylarenes to diethyl acetylenedicarboxylate gives rise to a four-membered stiba-azaheterocycle.[177]

In addition, one should bear in mind that five-membered heterocyclic systems with organoelemental substituents can be obtained, by analogy with the data quoted by Paquette,[42] Grimmett,[44] and Grüning and Lorberth,[178] as a result of [4 + 1]-cycloaddition, while condensed heterocycles can be produced by intramolecular 1,3-cycloaddition.[66]

In connection with the above, it appears useful to modify both 1,3-dipoles and dipolarophiles by introducing organoelemental substituents and also to employ other types of cycloaddition in order to extend the number of types of heterocycles with organoelemental fragments. The development of new methods of synthesis of organoelemental dipoles and dipolarophiles is also useful in this connection (see, for example, Refs. 179–186).

In our view, the study of the physicochemical properties, structure, and reactivity of heterocycles with organoelemental substituents may be of considerable interest; this field of the chemistry of heterocyclic and organoelemental compounds has been little studied and this is why some of the data presented above concerning the structures of heterocycles with organoelemental substituents are open to doubt. In particular, such heterocycles with organometallic substituents contain simultaneously electron-donating (the N, O, and S heteroatoms) and electron-accepting (M = Ge, Sn, Pb, etc.) centres. Most of them should therefore[1,2] have oligomeric or polymeric structures. This question so far remains open, since in the studies examined above the molecular weights of the heterocycles synthesised were frequently not measured and no mass-spectrometric investigations were made. In this connection, we may note that the dimers (L) described in a series of studies,[107-111] especially the dimers of germylpyrazoles, can also have a different structure (with involvement of the Ge and N atoms of the pyrazole ring), which is extremely characteristic of boron, aluminium, and other organoelemental derivatives of azoles.[1,2,6]

The extensive possibilities for the synthesis of heterocycles with organoelemental substituents with the aid of 1,3-DCA and other types of cycloaddition and the investigation of the nature of this process can be considered also in terms of another aspect, associated with the study of the mechanisms of the reactions of organometallic compounds,[187] including also a wide variety of different types of elementotropic processes.[7-13] The influence of the nature of elements entering into the composition of the fragments of 1,3-dipoles and dipolarophiles considered in this review on the 1,3-DCA mechanism therefore appears to have been inadequately investigated.[61,65,188,189]

Finally, both for a deeper investigation of 1,3-DCA and from the standpoint of the synthesis of heterocycles incorporating different elements in the ring, the study of

the corresponding silyl[190–196] and other organoelemental reagents[175–177,197–201] is of interest. Definite advances in this little investigated field have been made. The first examples of the synthesis of heterocycles by 1,3-DCA with participation of a dipolarophile having a silicon atom in the reaction centre has been described,[190] namely the reaction of 1,1-dimethyl-2,2-bis(trimethylsilyl)-1-silaethylene and trimethylsilyl azide. However, the formation of a silatriazole ring requires more rigorous proof, as has been done in the synthesis of cobalt-containing[175] and arsenic-containing[177] heterocycles.

After the synthesis of silylenes,[191–196] it was natural to attempt to introduce them as dipolarophiles into the 1,3-DCA reaction (see, for example, Masuune et al.).[194] However, it was shown that the cycloaddition product formed in this reaction is unstable; disilacyclopropane was formed as a result.[194]

We believe that the aspects indicated above are promising and can assist in the progess of both theoretical chemistry and the chemistry of heterocyclic and organoelemental compounds.

We emphasise that monographs thematically related to the present review have been published recently.[202,203] However, the aspects of the 1,3-DCA as a general method of synthesis of heterocyclic compounds which we examined are not adequately dealt with in these publications.

# Catalytic Properties of Hydrogenases

A.A.Karyakin and S.D.Varfolomeev

The review considers the most general physicochemical properties of hydrogenases, the structure of their active centres, and the characteristics of the catalytic reactions in which they participate. It has been suggested that the hydrogenases be divided into one- and many-centre types in terms of the content of the iron-sulphur clusters in the protein molecule. The hydrogenases in these groups differ in their activity and physical and kinetic properties. Much attention has been devoted to the kinetic characteristics of hydrogenases, a scheme for the catalytic reaction has been deduced, and hypotheses have been put forward about the molecular mechanism of the action of these enzymes.
The bibliography includes 145 references.

## I. INTRODUCTION

Processes involving the absorption and formation of molecular hydrogen in biological systems proceed as a rule with participation of a specific class of enzymes for which the trivial name "hydrogenases" has been proposed.[1] The general scientific and practical interest in these enzymes has been stimulated by a number of their features. Firstly, detailed study of the mechanism of the activation of hydrogen by biological catalysts makes possible a significant progress in our understanding of the physicochemical principles governing the enzyme catalysis of oxidation-reduction reactions as a whole. Secondly, the understanding of the mechanism of these enzymes should greatly facilitate the search for catalysts of the hydrogenation–dehydrogenation reactions of organic compounds which have found extensive practical applications. Furthermore, direct practical use of hydrogenases in reactions involving the oxidation or formation of hydrogen is of great interest. Thirdly, hydrogenases are terminal enzymes in the formation of hydrogen by micro-organisms,[2-4] which can be used, in particular for the utilisation of solar energy for the industrial preparation of hydrogen (the biophotolysis of water).[5] Furthermore, there is a possibility of creating model biochemical systems which effect the photodecomposition of water into hydrogen and oxygen.[6] Fourthly, the possibility of using enzymes in systems for the bioconversion of energy is extremely promising. The bioelectrocatalysis by hydrogenases can serve as the basis for the creation of fuel electrodes in electrochemical converters (biofuel cells).[7-11]

Hydrogenases are fairly common enzymes, which ensure the energy supply for many organisms by the oxidation of hydrogen. The metabolic pathways in micro-organisms exhibiting hydrogenase activity as well as the location and the functions of the hydrogenases themselves have now been thoroughly investigated. There are also numerous data on the biochemistry of these enzymes.[12-15] However, no general views about the catalytic properties of hydrogenases can be found in the literature and the kinetic characteristics of the individual enzymes are dealt with extremely incompletely and in a contradictory manner.

The aim of the present review is to give a systematic account of data on the catalytic functions of hydrogenases. The authors did not attempt to include all the available literature information about enzymes of this class and their aim was to seek the most general features.

## II. CERTAIN PHYSICOCHEMICAL PROPERTIES OF IRON–SULPHUR PROTEINS

### 1. Hydrogenases as Iron–Sulphur Proteins

The first hypotheses concerning the presence of iron in the active centres of hydrogenases were based on the dependence of the activities of the enzymes on the concentration of iron in the culture medium of the micro-organism.[16] The direct radiochemical determination of the iron content in the fractions exhibiting hydrogenase activity at different stages of the purification of the preparation confirmed the presence of iron in the hydrogenases.[17] In addition, all the investigators, starting from 1943,[18] noted the influence of iron complexones on the activity of hydrogenases. Finally, direct determination by atomic-absorption spectroscopy demonstrated that the active centres of hydrogenases contain non-haem iron.[15]

At the same time a large series of studies devoted to the inhibitor analysis of hydrogenases with the aid of specific reagents for SH groups have been successful. It was established in the 1960's that *p*-chloromercuribenzoate, iodoacetamide, and mersalyl suppress hydrogenase activity.[19,20] However, the latter can be restored by incubation with reducing agents.[20-22] It has been shown[23] that, when the hydrogenase from *Clostridium pasterianum* is inhibited by mersalyl, the mercury ions interact with sulphur atoms, leading to the removal of iron from the active centre. The presence of the so-called "acid-labile" sulphur, which is evolved in the form of hydrogen sulphide on strong acidification of the preparations, has been established independently.[24-26]

At the beginning of the 1970's the presence of 12 iron atoms and 12 acid-labile sulphur atoms in the active centre of the enzyme was observed in a study of the hydrogenase from *Cl. pasterianum*.[24] Subsequent investigations confirmed that iron and sulphur are present in hydrogenases in equimolar amounts. The investigation of the optical spectra of hydrogenases made it possible to discover a chromophoric group, corresponding to an iron–sulphur cluster, in the active centre. The development of quantitative extrusion methods[27] made it possible to establish the identity of the structures of the clusters in the active centres of hydrogenases and low-molecular-weight iron–sulphur proteins. The structure and properties of the latter have been studied much more fully compared with hydrogenases. The characteristic features of the behaviour of the iron–sulphur clusters, which are extremely important for the analysis of the catalytic properties of hydrogenases, can be conveniently considered in relation to ferredoxins.

## 2. The Structure of the Active Centre and the Oxidation–Reduction Properties of Low-Molecular-Weight Iron–Sulphur Proteins

Vigorous study of iron–sulphur proteins began in 1962 when the ferredoxin from *Cl. pasterianum* was discovered.[28] One of the distinctive properties of the metalloproteins of this class is the presence of non-haem iron in the active centre.[29,30] Ferredoxins have a relatively low molecular weight (6000–30000).[29] They differ mainly in the structure of the active centre. The 1Fe proteins of rubredoxins contain one iron atom bound to four sulphur atoms in amino-acid cysteine residues. Apart from the two iron atoms, the 2Fe–2S ferredoxins contain two atoms of acid labile sulphur. The class of 4Fe–4S proteins is of greatest interest. It incorporates both ferredoxins and high potential iron proteins or HIPIP differing in the potentials of oxidation–reduction transitions. The proteins of the 8Fe–8S class and more complex ones do not have independent structures, their active centre being formed from the 2Fe–2S and 4Fe–4S clusters.

The iron–sulphur proteins have come to be divided into two groups in terms of the oxidation-reduction potential. The class incorporating the 2Fe–2S and 4Fe–4S proteins, whose potentials are negative (−0.3–−0.4 V), is largest. Here and henceforth the potential is quoted relative to the normal hydrogen electrode. The 4Fe–4S proteins with potentials of about +0.3 V belong exclusively to the group of high-potential proteins. In order to explain the above difference, the hypothesis of "three states" has been put forward,[31] according to which the transitions in ferredoxins and HIPIP take place between different electronic states of the clusters determined by the ratio of the $Fe^{2+}$ and $Fe^{3+}$ atoms. The discovery of superoxidised ferredoxins ($Fd_{S-ox}$) and super-reduced HIPIP ($HP_{S-red}$) suggested the model of "three states" and the final scheme for the oxidation-reduction transitions in the 4Fe–4S proteins:[32]

$$\begin{array}{ccccc} 4Fe^{2+} & Fe^{3+}+3Fe & 2Fe^{3+}+2Fe^{2+} & 3Fe^{3+}+Fe^{2+} & \\ [Fe_4S]^0 & \leftrightarrow [Fe_4S_4]^{1+} & \leftrightarrow [Fe_4S_4]^{2+} & \leftrightarrow [Fe_4S_4]^{3+} & \\ & Fd_{red} & Fd_{ox} & Fd_{s-ox} & \\ & HP_{s-red} & HP_{red} & HP_{ox} & . \end{array}$$

Here and henceforth the charge on the cluster corresponds to the sum of the charges on the iron and acid–labile sulphur atoms.

The study of the physical properties also led to the elucidation of the nature of the ferredoxin transition in the 2Fe–2S proteins. It was established that in the oxidised cluster both iron atoms are in the +3 oxidation state; the reduction of the cluster leads to the transition of one of the atoms to a bivalent state.[33]

The fact that the iron–sulphur cluster constitutes a single electronic structure is remarkable. Numerous investigations have shown that the iron atoms within the cluster are indistinguishable.[30] In order to account for this effect, the hypothesis of the "antiferromagnetic interaction", based on the valence bond method, has been put forward.[33]

Many investigators (for example, Sweeney and Rabinowitz[34]) have pointed out that the spectroscopic characteristics of the 2Fe–2S and 4Fe–4S clusters are extremely similar and sometimes it is impossible to identify the type of cluster. This is caused by the binding of other chromophores and frequently by the influence of the polypeptide chain itself. These difficulties can be overcome by applying the magnetic circular dichroism method[35] and the effect of the linear electric field, which alters the EPR spectrum.[36] However, the simplest method consists in the study of the EPR spectra in 80% dimethyl sulphoxide at different temperatures.[37]

The number of iron atoms in the active centres of hydrogenases is a multiple of four. The application of the quantitative extrusion method to the 12Fe hydrogenases from *Cl. pasterianum*[27] and *Desulfovibrio vulgaris*[38] demonstrated the presence of only the 4Fe–4S clusters in the active centre. In addition there exists a whole series of enzymes containing one 4Fe–4S cluster per protein molecule. However, two 2Fe–2S clusters were detected together with two 4Fe–4S clusters in a study of the EPR spectra of the 12Fe hydrogenases from *Alcaligenes eutrophus* H16.[39,40] Such detailed studies have not been made for other multicluster hydrogenases, but the presence of the 4Fe–4S cluster in the active centre of the enzyme is apparently always essential for hydrogen catalysis. We shall consider briefly the properties of such clusters.

## 3. The Physical Properties of the 4Fe–4S clusters in Low-Molecular-Weight Proteins

(a) *Optical Properties.* The absorption spectra in the visible region of the iron–sulphur proteins containing clusters in the same oxidation states are identical. The absorption at 400 nm diminishes in the sequence

$$[Fe_4S_4]^{3+} > [Fe_4S_4]^{2+} > [Fe_4S_4]^{1+}.$$

The ratio of the absorptions at 400 and 280 nm is a measure of the ratio of the chromophore and the peptide and is usually employed as an indicator of the purity of the iron–sulphur protein.[34]

(b) *Magnetic Properties.* An even number of unpaired electrons in the cluster predetermines the absence of EPR signals. Thus the $[Fe_4S_4]^{2+}$ state is undetectable by EPR.

The $[Fe_4S_4]^{+}$ clusters have a characteristic EPR spectrum which depends relatively weakly on the polypeptide environment. An axial or orthorhombic signal is observed and the $g$-factor is about 1.96. If one excludes the influence of the peptide by recording the spectrum in 80% dimethyl sulphoxide (DMSO),[27] one can obtain an axial signal with the parameters $g_\perp = 1.94$ and $g_\parallel = 2.05$. Ferredoxins

containing two and more iron–sulphur clusters in the $[Fe_4S_4]^+$ state give rise to a more complex EPR signal, which can be accounted for by spin–spin coupling.[34]

The EPR spectra of the $[Fe_4S_4]^{3+}$ clusters are much more sensitive to the polypeptide environment. They are characterised by the factor $g > 2$ (one unpaired electron per four iron atoms).

(c) *The influence of the protein globule.* The protein globule can have a twofold effect on the properties of the cluster. Firstly, it influences on the choice of the optimum oxidation-reduction transitions (ferredoxins and HIPIP). Secondly, depending on the protein, a fairly wide variation of the oxidation-reduction potential is possible for the same reaction. It has been noted[34] that the potentials of the ferredoxin transition $[Fe_4S_4]^{2+} \leftrightarrow [Fe_4S_4]^+$ vary within the limits of 650 mV, while those of the HIPIP transition $[Fe_4S_4]^{3+} \leftrightarrow [Fe_4S_4]^{2+}$ vary up to 750 mV. The conformational changes of the ferredoxin from *C. acidiurici* in the course of the reduction have been recorded.[41] Carter et al. observed in their study of the high-potential proteins from *Chromatium sp.* by X-ray diffraction[42] that the symmetry of the iron–sulphur cluster changes in the oxidation-reduction transition. The protein globule can stabilise or destabilise a particular state of the cluster by its conformational influence, by acting upon the choice of the optimum transition, on the one hand, and by shifting the thermodynamic equilibrium of the oxidation-reduction reaction and hence its potential, on the other.

It has also been stated in the literature that two 4Fe + 4S clusters, greatly differing in the potential of the same electronic transition $[Fe_4S_4]^{3+} \leftrightarrow [Fe_4S_4]^{2+}$ may be present in the iron–sulphur proteins. Ferredoxin I from *Azotobacter vinelandii*[43] has potentials of −420 and +320 mV, the corresponding potentials of ferredoxin IV from *Rhodospirillium rubrum*[44] are respectively −380 and +355 mV, and those of ferredoxin I from *Myobacterium flavum*[45] are −420 and +230 mV.

The ability of the iron–sulphur protein to be degraded by atmospheric oxygen can be accounted for mainly by the lability of the cluster. It has been shown[46] that the interaction of the 4Fe–4S cluster with $O_2$ leads to the transfer of one iron atom to the solution. The discovery of clusters of the type 3Fe–*n*S confirms this conclusion.

### 4. The 3Fe–*n*S Clusters

The 3Fe–*n*S cluster was first detected in ferredoxin II from *Desulfovibrio gigas*.[47] Then it was shown that the ferredoxin from *Cl. pasterianum* is also converted into a form containing a similar cluster on oxidation with hexacyanoferrate(III).[48]

On reconstructing ferredoxin II from *D. gigas* containing initially one each of the 4Fe–4S and 3Fe–*n*S clusters,[49] it was found that an excess of bivalent iron and $S^{2-}$ leads to the formation of clusters of the first type exclusively. An increase of ionic strength or a decrease of the iron concentration in solution has the same effect involving the appearance of a considerable proportion of the 3Fe–*n*S cluster. Furthermore, there is a possibility of the direct interconversion 4Fe–4S ↔ 3Fe–*n*S.[49] Under severe oxidation conditions [in the presence of hexacyanoferrate(III) and oxygen] the 4Fe–4S clusters are converted into the 3Fe–*n*S form, liberating one bivalent iron atom to the solution. It was found possible to carry out also the reverse process under oxidative conditions, the 3Fe–*n*S clusters are capable of being converted into 4Fe–4S under the influence of dithiothreitol and iron salts.

## III. PHYSICOCHEMICAL PROPERTIES OF HYDROGENASES

### 1. Oxidation-reduction Properties

Hydrogenases are capable of both activating molecular hydrogen and of catalysing its evolution. Numerous experiments designed to isolate and store enzymes under various conditions have shown that, under the influence of atmospheric oxygen, the hydrogenase is converted into an inactive form, which, however, may be reactivated by incubation with reductants. It is of interest to determine the influence of the oxidation-reduction state of the enzyme on its activity.

However, serious errors have been made in some studies of this phenomenon. In the course of the measurement of the activity of the hydrogenase on the basis of the rate of evolution of $H_2$, a number of workers[50–53] determined in essence the potential dependence of the hydrogen electrode (see, for example, Damaskin and Petrii[54]), i.e. the potential of the equilibrium evolution of hydrogen from water. Nevertheless, the loss of activity of the enzyme at potentials less than −480 mV under strongly reductive conditions has been reliably established.[51]

The oxidation-reduction titration of the hydrogenase from *Thiocapsa roseopersicina* using various electron donors made it possible to determine the activation potential ($E = -276 \pm 8$ mV).[55]

Although reduction promotes the activation of hydrogenases, nevertheless the direct reduction of the active centre also leads to the loss of activity. There is no doubt about the inhibiting effect of reducing agents, especially sodium dithionite, on the activity of hydrogenases.[13] Together with the irreversible loss of activity,[56] many investigators point out either a weak effect or the possibility of reactivation[20,55,57,58]). The inactivation of the hydrogenase from *Cl. pasterianum* at potentials below −480 mV was noted above.[51] At low concentrations, sodium dithionite does not affect the rate of evolution of hydrogen which takes place with participation of the enzyme from *D. vulgaris*;[59] an increase of the concentration of the reductant leads to a fall of the activity of the hydrogenase to zero.

Together with the usual "two-sided" hydrogenases, there exist a number of hydrogenases capable mainly of absorbing hydrogen. They are all located in the cells of microorganisms together with nitrogenase, which is apparently a factor determining their physiological function. The activity of the "one-sided" hydrogenases as regards the evolution of hydrogen is usually lower by two orders of magnitude than the activity measured on the basis of the absorption of $H_2$ under the same conditions. The rate of evolution for *Rhodopseudomonas capsulata*,[60] *Cl. pasterianum*,[52] and *Rhizobium japonicum*[61] is 1–3% of the rate of absorption of $H_2$; the corresponding activities of the "one-sided" hydrogenase from *Azotobacter chroococcum*[62] differ by a factor of 200.

It has been suggested[63] that the reduction of "one-sided" hydrogenases takes place even in the positive range of potentials relative to the hydrogen electrode in the same solution. Thus, under conditions thermodynamically favourable for the evolution of hydrogen, the hydrogenase becomes inactive. The inactivating reduction potential for the enzyme from *Rh. capsulata*[63] at pH 7.0 was found to be 340 mV. This quantity depends on the pH: $\partial E/\partial \mathrm{pH} \approx -30$ mV. At pH 5.0 the rates of evolution and absorption of hydrogen are approximately the same.

## 2. Optical Properties

Hydrogenases have optical spectra characteristic of iron–sulphur proteins. An absorption maximum at a wavelength of approximately 400 nm is observed in the visible region. The extinction coefficients of hydrogenases calculated per iron atom are usually 4000 litre $mol^{-1}$ $cm^{-1}$, but may deviate significantly from this value.[14,15] When hydrogenases are reduced to the active state by various agents (including sodium dithionite and hydrogen), the absorption at 400 nm diminishes by 10–20%.[14]

## 3. EPR Spectra

Hydrogenases give rise to EPR signals characteristic of iron–sulhpur proteins. In terms of the character of the changes in the EPR spectra during the oxidation–reduction of the active centre, hydrogenases can be divided into two groups. The one-centre enzymes, i.e. those containing one 4Fe–4S cluster, have in the oxidised state an EPR spectrum with $g > 2$, which is extremely similar to the spectrum of the high-potential proteins in the oxidised state, i.e. the spectrum of the $[Fe_4S_4]^{3+}$ cluster. When these hydrogenases are reduced, the EPR signal vanishes. Consequently the oxidation-reduction transition in the enzymes of this group corresponds to the transformation $[Fe_4S_4]^{3+} \leftrightarrow [Fe_4S_4]^{2+}$. Such data have been obtained for the hydrogenases from *Th. roseopersicina* and *Rh. capsulata*,[63] *Rhodospirillium rubrum*,[64,66] *Chromatium vinosum*,[67] and *Chromatium sp.*[68] The authors of the last investigation noted, like Zorin et al,[63] that carbon monoxide does not affect the EPR signals of hydrogenases either in the oxidised or reduced states.

Many-centre hydrogenases (containing more than four iron atoms in the active centre) behave in a significantly different manner. Whereas in the oxidised state they too give rise to EPR signals resembling the $[Fe_4S_4]^{3+}$ signal, after reduction, spectra characteristic of reduced ferredoxins are observed, i.e. characteristic of the state of the $[Fe_4S_4]^{+}$ cluster with the typical $g = 1.94$. The hydrogenase from *Megasphaera elsdenii*, containing three clusters per molecule, has an EPR signal with $g > 2$ in the oxidised state, which is somewhat atypical for HIPIP; when it is reduced, the characteristic ferredoxin spectrum is manifested.[69] Conversely, the hydrogenase from *Cl. pasterianum*, containing 12 iron atoms in the centre, is characterised in the reduced state by the presence of an additional "extraordinary" signal in the ferredoxin spectrum.[70] The authors believe that in the oxidised state only the $[Fe_4S_4]^{3+}$ signal is observed. The number of 4Fe–4S clusters in the hydrogenase from *D. vulgaris* is three.[38,71,72] The EPR spectra of this hydrogenase are typical for many-centre hydrogenases.[38,73]

The oxidation-reduction titration of the enzyme from *A. eutrophus* H16, containing 12 iron atoms per molecule, at different temperatures in 80% DMSO made it possible to distinguish the EPR signals of the two 4Fe–4S and two 2Fe–2S centres.[39,40] The electronic transitions take place at potentials of −445 and −325 mV respectively.

Thus the one-centre hydrogenases in the oxidised state contain the $[Fe_4S_4]^{3+}$ cluster. On reduction, they pass to an active state corresponding to the $[Fe_4S_4]^{2+}$ form. The oxidation-reduction potentials of the above electronic transitions lie mainly in the negative region (for example, at −276 mV for *Th. roseopersicina*[55]). Consequently, the hydrogenases of this type have the properties of low-potential HIPIP proteins. Re-reduction leads apparently to a transition to the $[Fe_4S_4]^{+}$ state in which the enzymes are inactive.

The situation is more complex for many-centre hydrogenases. In the reduced state the EPR spectra resemble those of the $[Fe_4S_4]^{+}$ clusters, while in the oxidised state they resemble the spectra of $[Fe_4S_4]^{3+}$. Chen suggested that in the hydrogenase from *Cl. pasterianum*,[52] containing three 4Fe–4S centres,[27] there are two $[Fe_4S_4]^{2+}$ clusters and one $[Fe_4S_4]^{+}$ cluster in the oxidised state and two $[Fe_4S_4]^{+}$ clusters and one $[Fe_4S_4]^{2+}$ cluster in the reduced state. However, the simultaneous transfer of three electrons (in the potential range 50–60 mV) is possible only for vigorously isolated clusters, while the available data indicate the interaction of the latter. It has been shown[38] that the three-centre hydrogenase (incorporating three clusters of the 4Fe–4S type) from *D. vulgaris* contains no $[Fe_4S_4]^{3+}$ clusters in the oxidised state. The form of the spectrum of this hydrogenase, resembling the HIPIP spectrum, is apparently due to the spin–spin coupling of the clusters in other oxidation states, namely $[Fe_4S_4]^{2+}$ and $[Fe_4S_4]^{+}$. Unfortunately, it was not possible to determine the electronic structure of the active centre of the hydrogenase in greater detail.

## 4. The Relation between the Physical and Catalytic Properties of Hydrogenases

It is of interest to compare not only the physical but also the catalytic properties of the one-centre and many-centre hydrogenases. The Table shows that the activity of the latter, as regards the absorption and evolution of hydrogen, is on average higher by two orders of magnitude than that of the one-centre enzymes. It will be shown below that the cleavage of the hydrogen molecule and the proton exchange with the solvent are not rate-limiting in the $H_2$ activation and evolution reactions.

On this basis, one can put forward two hypotheses concerning the role of the iron–sulphur clusters in catalysis. According to the first, the cluster is an electronic structure stabilising the transition state and hence reducing the height of the activation barrier (see, for example, Berezin and Martinek[77]). The hydrogen oxidation pathway via the intermediate formation of the charged forms of the enzyme ($E^-$ and $E^{2-}$), of the kind suggested, for example, by Chen[52] is unlikely. On the other hand, the undue stabilisation of the intermediate complex leads to an increase of the height of the activation barrier.[77]

According to the second hypothesis, the change in the symmetry of the iron–sulphur clusters in oxidation–reduction transitions (see above) can entail an enforced stabilisation or destabilisation of one of the electronic states under the influence of the thermal movement of the protein globule, which decreases the activation energy via the entropy term.

However, the presence of iron–sulphur clusters in the protein molecule is insufficient for the manifestation of the hydrogenase activity. In contrast to one-centre hydrogenases, the low-potential HIPIP catalyse neither the evolution nor the absorption of hydrogen. An example has been provided by the ferredoxins from *D. gigas*[78] and *M. flavum*,[45] containing four iron atoms per molecule and having oxidation-reduction potentials of −130 and −420 mV respectively, as well as the 6Fe ferredoxins from *T. thermophilis*,[79] whose potential is −250 mV.

## 5. The Role of Nickel in the Hydrogenase Catalysis

The studies in recent years have shown that the presence of nickel in the active centre is extremely important for the manifestation of the hydrogenase activity. This conclusion originated from experiments concerning the effect of the nickel content of the culture medium on the synthesis of hydrogenases during the growth of the micro-organism. It has been shown[80] that the addition of EDTA (at a concentration of 150 μM) to the propagation media of three different cultures (*Azospirillium brasilense*, *A.lipoberum*, and *Derxia gummosa*) suppresses the synthesis of the hydrogenase without influencing significantly the activity and only the introduction of catalytic amounts of bivalent nickel ions (10 μM) makes it possible to abolish the inhibiting effect of EDTA. A correlation has been found[81] between the absorption of radioactive $^{63}Ni^{2+}$ by the cells of *Azotobacter chroococcum* and their hydrogenase activity. The addition of bivalent nickel ions to the culture medium of *Chromatium vinosum*[82] increases the activity of the hydrogenase by a factor of 3–6 without affecting the rate of growth of the micro-organism.

It has been observed that, during the purification of the hydrogenase from *Vibrio succinogenes*,[83] nickel is washed out of the preparation. The authors state that the dependence of the activity of the enzyme on the $Ni^{2+}$ concentration is represented by a straight line passing through the origin of coordinates. Admittedly, individual points on this straight line corresponded to specimens of the enzymes with different degrees of purity.

The involvement of nickel in the hydrogenase catalysis has been confirmed by physicochemical data. The EPR spectrum of the enzyme from *Chromatium vinosum*[82,84,85] shows that the 4Fe–4S cluster interacts with the nickel centre. The effect of the latter is not manifested in a hydrogen atmosphere. The unperturbed spectrum of the cluster can be observed when it is converted into the 3Fe–*n*S form, which, as stated by the authors, is catalytically inactive. Nickel has also been detected by EPR in the hydrogenases from *M.thermoautotrophicum*,[86] *D.gigas*,[87] and *D.vulgaris*.[38]

The EPR spectra of the nickel present in the hydrogenase from *D.gigas* have been studied for different oxidation-reduction states of the enzyme.[87–89] It has been shown that the nickel centre is capable of entering into a one-electron exchange reaction, altering the oxidation state. The potential of this transition is −220 mV at pH 8.5 [88] and depends greatly on the pH ($\partial E/\partial pH = -60$ mV).[89] Thus the reaction is proton-dependent, the $Ni^{3+}$ form being singly protonated:

$$Ni^{3+}+H^{+}+\bar{e}\rightleftharpoons Ni^{2+}H^{+} \qquad (1)$$

Bearing in mind the character of the oxidation-reduction transition (1), we normalise the potentials at pH 7.0. Very close values are obtained for the many-centre enzyme from *D.gigas*[88,89] and the one-centre enzyme from *Chromatium vinosum*[85] (−140 and −150 mV respectively). In the active state of the hydrogenase (in the vicinity of the hydrogen electrode potential) the nickel exists in a bivalent state.

It has been suggested[85] that the nickel centre is the primary acceptor of the hydrogen molecule. It is believed that the Ni atom has an octahedral environment with five occupied coordination centres and one centre capable of being substituted. According to EPR data the minimum distance between the iron and nickel atoms in the hydrogenase from *Chromatium vinosum* does not exceed 12 Å.

Comparative characteristics of the physical and catalytic properties of certain hydrogenases.

### 6. Characteristics of the Catalysis by the Hydrogenase from *A. eutrophus*

The hydrogenase from *A. eutrophus* includes yet another group involved in hydrogen catalysis, namely the flavin mononucleotide (FMN),[57] which is responsible for its NADH-dehydrogenase activity. The enzyme molecule (molecular weight 180000–200000) contains 12 atoms of iron and acid-labile sulphur each, combined in two 4Fe–4S and two 2Fe-2S clusters,[39,40] and two FMN molecules.[90] The enzyme consists of four subunits, the hydrogenase activity being manifested solely by the complete molecule,[91] while the NADH-dehydrogenase activity is retained in subunits with molecular weights up to 60000. The enzyme from *A. eutrophus* has unique properties, behaving simultaneously as a hydrogenase and a NADH-dehydrogenase. During the oxidation of hydrogen, the electron density acceptor (via intermolecular electron transfer), is FMN which is capable of reacting subsequently with NAD, reducing it to NADH. It has been shown[92] that methylviologen is able to "intercept" the electron density on the way to the FMN molecule. We may note that the reduced FMN is weakly oxidised by oxygen, like NADH. As a result, NAD should react with FMNH even under aerobic conditions. Indeed, the rate of reduction of NAD by hydrogen, catalysed by the hydrogenase from *A. eutrophus* Z1, is virtually the same in an open cuvette and under anaerobic conditions.[93] The competitive inhibition of the enzyme from *A. eutrophus* H16 [94] by oxygen with respect to $H_2$ has been noted. In the subsequent stages the electron density remains inaccessible to $O_2$. Thus the unique characteristic of the hydrogenase of *A. eutrophus* consists in the fact that this enzyme is capable of oxidising hydrogen with subsequent reduction of the acceptor, which has a low negative potential, almost independently of the presence of oxygen. This is so far impossible on any other catalyst.

## IV. THE INFLUENCE OF VARIOUS EFFECTS ON THE ACTIVITY OF HYDROGENASES

### 1. The Role of the Ionic Strength of the Solution

Contradictory data concerning the influence of the ionic strength of the solution on the activity of hydrogenases have been quoted in the literature. For example, a high ionic strength has an inhibiting effect on the enzymes from *Paracoccus denitrificans*[95,96] and *D. vulgaris*.[71] The activity of the hydrogenase from *Chromatium vinosum*[67] falls appreciably in the presence of cobalt sulphate and chloride. The enzymes from *Chromatium sp.*[22] are inhibited by heavy metal ions.

On the other hand, the activity of the hydrogenase from *Megasphaera elsdenii*[69,71] increases with increase of the ionic strength of the solution. The stabilising effect of chlorides at concentrations in excess of 0.7 M on the enzyme from *Rh. rubrum* has been noted.[97] The hydrogenase from *Spirilina maxima*[98] is inactivated by copper and zinc ions, but the presence of iron, manganese, magnesium, and calcium leads to a slight activation.

The contradictory nature of the above data gives some indication of the mechanism of the effects. The ionic strength apparently acts on the protein globule. Evidently the proteins of even a single micro-organism, located in different places within the cell, can show significant differences. In conclusion, we may mention the retention of the activity of the hydrogenase from *D. vulgaris*[99] in the lyophilised state.

### 2. The Effect of Iron Complexones

At the beginning of the 1970's many workers observed a strong inhibition of the activity of hydrogenases by iron complexones: αα′-bipyridyl, *o*-phenanthroline, EDTA, $CN^-$, and $N_3^-$ (see, for example, Bone[20] and Hashke and Campbell[100]). However, it was found subsequently that the above reagents have only a weak effect on the activity of the enzymes from *Chromatium sp.*[22] and *D. vulgaris*.[101] The hydrogenases from *Anabaena cylindrica*[102] and *E. coli*[103] are not inhibited by αα′-bipyridyl, while the enzyme from *Chromatium vinosum*[67] is unaffected by $CN^-$ and $N_3^-$. Furthermore, EDTA, αα′-bipyridyl, and *o*-phenanthroline have a prolonged effect against the inactivation of the hydrogenase from *Cl. pasterianum* by oxygen,[104] while $CN^-$, $N_3^-$, and $F^-$ do not affect its activity at concentrations up to $10^{-2}$ M.[105]

Although it has been recognised that the above iron complexones are not inhibitors of hydrogenases,[14,15] studies are still being published in which a decrease of their activity in the presence of EDTA, $CN^-$, and $N_3^-$ has been noted.[98] The effect of these reagents is apparently associated with the partial degradation of the iron–sulphur cluster and should therefore depend on the stability of the latter. Indeed, the stability of the hydrogenase from *A. cylindrica* with respect to inactivation by oxygen has been noted in a study[102] where the absence of an effect by αα′-bipyridyl on the activity of the enzyme was observed. The unusual stability of the clusters from *Chromatium sp.* with respect to extrusion[106] agrees well with their insensitivity to iron complexones.[22]

The effect of carbon monoxide should be considered specially. The inhibiting action of CO has been found in all studies in which its influence on the activity of hydrogenases has been investigated. It is difficult to suppose that this entails any changes in the electronic structure of the iron–sulphur cluster, because CO shows no effect on its EPR spectrum.[67,68] It has been established that one CO molecule is adsorbed on the active centre of the enzyme.[67,102] In the hydrogen oxidation reaction the inhibition by carbon monoxide is competitive with respect to $H_2$ [105,107–109] and non-competitive with respect to the electron acceptor.[107,108] Thus, within the framework of the hypothesis that the nickel centre is an acceptor of the $H_2$ molecule while the iron–sulphur cluster stabilises the intermediate state in electron transfer, the inhibiting effect of CO can be readily accounted for. Carbon monoxide evidently blocks the free coordination site in the nickel centre which is inaccessible to larger complexones. The hydrogen molecule is also adsorbed at this coordination site.

### 3. The Mechanisms of the Inactivation of Hydrogenases by Oxygen

The high sensitivity of hydrogenases to oxygen is well known. Attempts have therefore been sometimes made to extract the enzymes from strict anaerobes under the conditions of the controlled absence of $O_2$.[24,100,110] Subsequent studies led to the abandonment of this complication in biological techniques. Two mechanisms for the action of oxygen on the activity of hydrogenases have been discovered: (1) reversible oxidation of the active centre in which the possibility of its reactivation by a reductant remains; (2) slow irreversible inactivation. The occurrence of the latter has been demonstrated.[111]

The slow irreversible inactivation in air is characteristic of all hydrogenases. Nevertheless the enzymes of *A.eutrophus* Z1 proved to be more stable on storage in air than in an atmosphere of a pure inert gas or hydrogen.[93] The stabilising effect of oxidants has also been noted in other studies.[39,40] The kinetics of the irreversible inactivation of hydrogenases by oxygen indicate a distinct two-phase character of the process,[93,112,114] the reduced form of the enzyme being labile and the oxidised form stable.[93] The conclusion that the oxidised hydrogenase is more resistant to $O_2$ than the reduced form has been confirmed also by other data.[39,71,113]

The attempts to stabilise hydrogenases in air are associated in the first place with immobilisation. The two-phase character of the inactivation of the enzyme from *Cl.pasterianum*[114] persisted also after immobilisation on glass, but its stabilisation was then achieved. The degree of blocking of the active centre of the enzyme, determined from the ratio of its activity in the presence of low-molecular-weight (methylviologen) and high-molecular-weight (ferredoxin) electron transferring agents, is satisfactorily correlated with the stabilising effect.

A novel method for protecting against $O_2$ has been proposed.[115] By immobilising the protein on the charged surface of a polyanionic adsorbent, it is possible to create a microenvironment in which "gasses are salted out". The adsorption of the hydrogenase from *Cl.pasterianum* on DEAE-cellulose or Dowex 1-X2 increased the stability of the enzyme in air by a factor of 20–25. It was noted that at a low ionic strength hydrogen was also no longer in contact with the hydrogenase. Consequently, when this method is used, the reaction can be effected only in the direction of $H_2$ evolution.

However, another stabilisation procedure, which throws light on the mechanism of the inactivating effect of oxygen, is the most interesting. It has been found that iron complexones (EDTA, αα′-bipyridyl, *o*-phenanthroline, and Chelex-100) at concentrations in the range 0.01–0.5 M have a prolonged effect on the hydrogenase from *Cl.pasterianum*,[104] while αα′-bipyridyl and benzylviologen[103] lower the rate of the oxygen inactivation of the enzyme from *E.coli*. Finally, the protecting effect of carbon monoxide against the action of $O_2$ has been observed and it has been shown that the hydrogenase from *Chlamydomonas reinhardi* reacts with one oxygen molecule at the rate-limiting stage of the inactivation process.[116]

It has been reported that the reduction of the reduced enzyme from *A.eutrophus* H16 with $O_2$ leads to the appearance in solution of the superoxide radical-ions $O_2^{\cdot-}$.[117] Like hydrogen peroxide, the latter inactivate the hydrogenases from *E.coli*, *Cl.pasterianum*,[103] *Th.roseopersicina*, and *Rh.capsulata*[118] more strongly than does molecular oxygen. It may be that this is one of the factors determining the relative lability of the reduced forms of the enzymes. However, the superoxide radical-ions had no effect on the hydrogenase from *A.eutrophus H*16.[94]

The degradation of the iron–sulphur clusters in hydrogenases by oxygen is to some extent analogous to the interconversion in ferredoxins. The 4Fe–4S cluster is capable of being converted into the 3Fe–*n*S form with liberation of an iron atom into the solution, especially under the influence of $O_2$.[49] The 3Fe–*n*S cluster is believed to be inactive in hydrogen catalysis.[82,84,85,87] Furthermore, in studies[84,85] of the EPR spectra of the hydrogenase from *Chromatium vinosum* it was found that the interconversion interferes with the electronic interaction of the iron–sulphur and nickel centres, which is also important for catalysis. It has been suggested that the iron atom nearest to nickel is liberated from the cluster. However, the attempts to reconstruct the hydrogenases by analogy with ferredoxins[49] led to the recovery of only traces of activity for *D.vulgaris*[119] and were unsuccessful in many instances. However, there exists an indirect confirmation of the proposed hypothesis. The fact that bivalent iron ions stabilise the hydrogenase from *Azotobacter chroococcum* and prevent the loss of its activity[62] can be interpreted as a consequence of their effect on the kinetics of the degradation of the 4Fe–4S cluster, which takes place with the evolution of a bivalent ion into the solution.

Another consequence of the effect of oxygen on hydrogenases is rapid reversible inhibition. As already stated, the enzymes isolated and stored in air are in an inactive state. They can be reactivated by adding reducing agents. Furthermore, in the oxidation of $H_2$ or in deuterium exchange there is a possibility of an autocatalytic acceleration of the reaction after an induction period.[20,57,120–122]

The phenomenon of autocatalysis has been studied in detail in relation to the enzymes from *Th.roseopersicina*[120] and *A.eutrophus*.[93] It was shown that the induction period decreases or is completely eliminated after the addition of reducing agents, for example sodium dithionite, or very small amounts of the product, i.e. the reduced form of the electron acceptor. The lag period is shortened also after increasing the concentrations of the enzyme[93,120,122,123] and the electron acceptor,[120] which is extremely characteristic of reactions under autocatalytic conditions.[120] However, the opposite variation has been observed in the reduction of NAD by hydrogen, which is catalysed by the hydrogenase from *A.eutrophus* Z1: the induction period increases with increase of the NAD concentration.[93] We may recall that NADH inhibits the hydrogenase from *A.eutrophus* Z1 [91] by cleaving it into subunits. The superposition of the inhibition by the product does in fact lead to this type of extraordinary variation.

The question of the mechanism of the activation of hydrogenases is of fundamental importance: does it occur under the influence of hydrogen, in the reduced electron acceptor, or as a result of a proenzyme–enzyme interaction. Data on autocatalysis have shown that there is no direct activation of the enzyme by hydrogen. In the oxidation of hydrogen by methylviologen,[120] the hydrogenase from *Th.roseopersicina* is activated solely by the interaction of the inactive enzyme with the reduced methylviologen. However, one should note that the concentration of $MV^{2+}$ in this reaction was much higher than in the enzyme concentration.

The study of the deuterium exchange involving the hydrogenase from *A.eutrophus H*16 [123] showed that in solution the enzyme can be activated also in the absence of an electron transferring agent, while in the immobilised state the free electron transferring agent is essential for this purpose in the absence of the enzyme–enzyme interaction. The impossibility of activating the enzyme directly by hydrogen has also been confirmed in another study.[92] Consequently the activity of the hydrogenase irreversibly inactivated by oxygen can be restored under autocatalytic conditions via the interaction either with the reduced form of the electron transferring agent or with the molecules of the active enzyme.

The "oxygenation" hypothesis was proposed in 1954, according to which[122] the reversible inactivating effect of oxygen reduces to the formation of a complex and not to an oxidation-reduction reaction:

$$E + O_2 \rightleftarrows EO_2,$$

where $EO_2$ and E are the inactive and active forms of the

enzyme. Oxygen can be evolved from the active centre of the enzyme as a result of dissociation. The authors believe[122] that the hydrogenase is activated in this way.

Since this theory has gained fairly wide currency,[13,15] it is essential to consider it in greater detail. The authors[122] believe that the correlation between the "oxygen-absorption" activity of the reductant and the decrease of the induction period for the hydrogenase from *P. vulgaris* constitute proof of "oxygenation". However, the lag period in the oxidation of hydrogen catalysed by the hydrogenase from *A. eutrophus* is eliminated both as a result of the glucose oxidase reaction (glucose + glucose oxidase),[121] which the above authors[122] regard as one of the best "deoxygenants", and after the addition of very small amounts of NADH ($10^{-4}$ M),[93] which interact very weakly with $O_2$. We may note the potential of the oxidation of glucose to gluconate[124] is $-0.42$ V.[7] Oxygen may not be the only oxidant in this reaction. Finally, data for the oxidation-reduction transitions in the active centres of hydrogenases on activation (see above) are entirely inconsistent with the "oxygenation" hypothesis.

Autocatalysis takes place owing to the presence of micro-amounts of the active form of the enzyme, which are inevitably present even at high positive potentials. In the initial stages of the reaction, oxygen is present in solution, so that $O_2$ reacts with the reduced forms of the enzyme and the electron transferring agent. A dependence on the oxygen concentration appears as a result and this has been recorded.[122] The competition between autocatalysis and the inhibition of the reaction by oxygen leads to the appearance, in the general case, of more complex dependences of the rate of acceleration on the specific activity of the hydrogenase, the oxidation-reduction potentials of the enzyme and the electron acceptor, and the concentrations of all the components, including $O_2$. The existence of a threshhold concentration of the enzyme has been indicated.[123]

### 4. The Effect of the pH of the Medium on Catalysis by Hydrogenases

The effect of the concentration of hydrogen ions on the kinetics of reactions with participation of hydrogenases is determined by a large number of factors. Protons are the product of the reaction

$$H_2 \rightleftarrows 2H^+ + 2\bar{e}.$$

Consequently a change in their concentration entails a shift of the thermodynamic equilibrium and it is known that a shift of the equilibrium hydrogen potential per pH unit is 59.2 mV. Thus the activity of electron acceptors in the oxidation of $H_2$ should also depend on the pH. Indeed, the optimum absorption of hydrogen is as a rule attained in the region of alkaline pH, while the optimum evolution occurs in the region of acid pH.[13-15]

However, for certain hydrogenases, for example, those from *Chromatium sp.*,[22] *Th. roseopersicina*,[125] and *Rh. capsulata*,[126] the rate of oxidation of hydrogen by methylviologen in the pH range 7–9 is independent of the proton concentration. The kinetics of the catalysis by hydrogenases will be examined in the next Section.

The proton concentration can influence not only the thermodynamic and kinetic parameters of the reaction itself but also a whole series of other factors. Firstly, one cannot rule out the presence in the protein of ionogenic groups which influence the catalysis. Secondly, the oxidation-reduction transitions in the iron–sulphur clusters and nickel centres also depend on the pH. Thirdly, the proton concentration can influence the properties of the electron transferring and reducing agents. For example, a shift of the pH optimum has been observed[19] in the deuterium exchange reaction catalysed by the hydrogenase from *D. desulfuricans* on activation by various reducing agents.

It is believed that the reduced form of methylviologen is capable of being protonated and decolorised in the range pH < 6.0.[15] Fernandez and co-workers[126] explained the decolorisation of $mV^+$ in acid solutions, observed by other workers, by the loss of the reducing capacity of sodium dithionite, whose oxidation-reduction potential depends on the pH. In the reduction of methylviologen by metallic zinc, the extinction coefficient of the reduced form of the former was independent of the pH up to 5.0.[127]

## V. KINETICS OF THE REACTIONS CATALYSED BY HYDROGENASES

Both in nature and in artificial systems hydrogenases can catalyse reactions of two types. On the one hand, they activate molecular hydrogen for subsequent reactions, including the oxidation of $H_2$. On the other hand, hydrogenases are capable of catalysing the evolution of hydrogen. The deuterium exchange and hydrogen ortho–para conversion reactions include both processes. Overall, these enzymes accelerate the equilibration in the system

$$H_2 \rightleftarrows 2H^+ + 2\bar{e}.$$

The above reactions can be used to measure the hydrogenase activity. The methods involving the evolution of hydrogen should be especially considered. It has been found[128] that, when the reaction mixture is shaken at a frequency greater than 200 cycles per minute, the $H_2$ evolution process is not controlled by diffusion. The above conditions are still used in most investigations. However, judging from the latest data,[63] it is impossible to attain the independence of the rate of evolution of hydrogen of the rate of stirring and of the area of the interface between the liquid and gas phases, i.e. the processes associated with the evolution of $H_2$ are nevertheless complicated by diffusion. The method for the determination of the concentration of hydrogen in solution at the Clark electrode[129] also suffers from a series of disadvantages. Furthermore, the evolution of $H_2$ from the reduced forms of methylviologen and other electron transferring agents can be complicated by the re-reduction of the hydrogenase. We shall therefore concentrate attention on the kinetics of the processes associated with the activation of hydrogen.

### 1. Activation of the Hydrogen Molecule at the Active Centres of Hydrogenases

It has been suggested that the rate-limiting stage of the process is the cleavage of the $H_2$ molecule in the active centres of hydrogenases.[125] However, the order of the reaction involving the oxidation of hydrogen by methylviologen in the presence of hydrogenases from *Th. roseopersicina*[130] and *Rh. capsulata*[126] with respect to $H_2$ is zero. The study of the isotope effects observed when hydrogen is replaced by deuterium in the activation process with participation of the hydrogenases from *A. eutrophus*, *D. desulfuricans*, and *Rh. japonicum*,[92,131,132] confirmed that the cleavage of the $H_2$ molecule is the rate-determining stage in the reaction.

The question of the nature of this cleavage is of fundamental importance for catalysis. There exists the view that the cleavage of hydrogen in the active centres of hydrogenases takes place heterolytically. The view is based, in particular, on a study[133] where only the intermediate HD was detected in the gas phase in the course of an investigation of the hydrogenase-catalysed isotope exchange between $H_2$ and $D_2O$. However, the final exchange product $D_2$ was detected in the same system.[128]

Subsequently it was suggested[22] that the rates of formation of the exchange reaction products HD and $D_2$ be compared. The ratio of the rates $v_{HD}/v_{D_2}$ ($v_{HD}/v_{H_2}$) depends on a whole series of parameters, for example, on the concentration and activity of the enzyme, so that its numerical values cannot serve as a characteristic of the system. Nevertheless, it is noteworthy that, when the exchange reactions with participation of the hydrogenases from *Chromatium sp.*,[22] *D. desulfuricans*,[134] *D. vulgaris*,[128] *Th. roseopersicina*,[135] *A. eutrophus*,[123] and *Rh. japonicum*[132] were carried out, the rates of formation of HD were of the same order of magnitude as the rates of formation of $D_2$ and as a rule were not lower than the latter. According to Gitilitz and Krasna,[22] this must be regarded as undoubted evidence in support of the heterolytic mechanism of the cleavage of the $H_2$ molecule, because at a platinum catalyst the product HD is almost absent, in contrast to $D_2$. However, platinum is a many-centre catalyst, so that each hydrogen atom behaves independently after the dissociation of the molecule, while the active centre of the hydrogenase is an isolated electronic system with rigorously defined oxidation-reduction electronic transitions.

The ratio of the rates of formation of the intermediate and the exchange products falls with increase of the enzyme concentration, which supports, together with the data quoted above, the model

$$H_2 + E \rightleftharpoons EH^- + H^+.$$

It has been found that the ratio $HD/D_2$ is independent of the partial pressure of hydrogen.[128] This finding does not disprove the model (2), because it can be accounted for also within the framework of this scheme, for example, when the orders of the formation reactions of HD and $D_2$ with respect to $H_2$ are the same.

The dependence of the rate of deuterium exchange in the presence of the hydrogenase from *Rh. japonicum*[132] on the pH parallels the influence of the pH on the rate of evolution of hydrogen. On the other hand, the rate of absorption of $H_2$ is relatively independent of the proton concentration within the same limits.

The above results support the mechanism of the activation of hydrogen via the intermediate formation of an enzyme–hydride complex $EH^-$. There are no important facts in the literature in conflict with this mechanism. Furthermore, in a number of studies on the kinetics of reactions with participation of hydrogenases there are direct indications of the possibility that the process occurs via the intermediate formation of $EH^-$.[52,123,128,132]

However, this does not as yet permit conclusions about the mechanism of the activation and cleavage of the hydrogen molecule in the active centres of hydrogenases. It is appropriate to quote at this point the energy cycle for the reaction between $H_2$ and protons[136] (the numerical values are given in kcal $mol^{-1}$):

$$\begin{array}{ccc} H_2 & \xrightarrow{101} & 2H \\ {\scriptstyle 398}\downarrow & & \downarrow{\scriptstyle 2\times 312} \\ H^- + H^+ & \xrightarrow[327]{} & 2H^+ \end{array}.$$

For reactions in an aqueous medium, it is essential to take into account the solvation energy.[137] Thus only 33 kcal $mol^{-1}$ has to be expended on the heterolytic dissociation of the hydrogen molecule in solution.

The active centres of one-centre hydrogenases contain the $[Fe_4S_4]^{2+}$ cluster and $Ni^{2+}$. Nor can one rule out the possibility of the homolytic dissociation of the $H_2$ molecule as a result of the redistribution of the electron density and the formation of a covalent bond. Next, as a result of the rapid intramolecular reaction in the active centre of the hydrogenase, there is a possibility of the liberation of protons and of the formation of the EH form in order to compensate for the energy expenditure.

We shall now proceed to the discussion of the activation of the $H_2$ molecule in the active centres of hydrogenases in the course of its oxidation. We shall consider initially the question of the mutual effect of two substrates: the electron acceptor and $H_2$. As already stated, carbon monoxide is a competitive inhibitor with respect to hydrogen and a non-competitive inhibitor with respect to the electron acceptor. Study of the mutual effect of $H_2$ and the oxidised form of methylviologen showed that, in the case of the hydrogenases from *Cl. pasterianum*,[108,138] *M. thermoautotrophicum*,[109] and *Rh. japonicum*,[107] these substrates react with different sections of the active centres. On the other hand, the electron acceptors whose nature is significantly different, namely the high-molecular-weight cytochrome $c_3$ and the low-molecular-weight methylviologen, interact with the same section of the active centre of the hydrogenase from *D. vulgaris*.[139] Thus the electron acceptor and $H_2$ molecules each add to their own section of the active centres of the hydrogenases in the hydrogen oxidation reaction.

The processes in which hydrogen is activated by hydrogenases are fairly rapid. In the $H_2$ oxidation reaction catalysed by the one-centre enzymes from *Th. roseopersicina*[130] and *Rh. capsulata*,[126] the reaction is of zero order with respect to hydrogen. This finding is fairly unexpected for the kinetics of processes with participation of hydrogenases. The dependence on the hydrogen concentration of the oxidation of $H_2$ by methylviologen had been described earlier for the hydrogenases from *Cl. pasterianum*[108,138] and *D. vulgaris*[140] by the classical Michaelis function. The non-zero reaction order with respect to $H_2$ is manifested also in the oxidation of the latter by Methylene Blue in the presence of the hydrogenase from *Rh. japonicum*.[107]

The difference between the enzymes from *Th. roseopersicina* and *Rh. capsulata*, on the one hand, and the enzymes from *Cl. pasterianum* and *D. vulgaris*, on the other, consists in the fact that the former are one-centre enzymes, while the latter are many-centre hydrogenases (see Table). The physical properties of the enzyme from *Rh. japonicum* have been less thoroughly investigated, but, it has been shown[61] that it contains 12 iron atoms per protein molecule.

The kinetic parameters of the reactions with participation of the hydrogenases in this group depend in different ways on the pH. In the course of the oxidation of hydrogen by methylviologen with participation of the enzyme from *Cl. pasterianum*,[108] the ratio of the maximum rate of reaction to the Michaelis constant ($V_{max}/K_M$) increases with decrease of the concentration of protons in the pH range 8–10. $V_{max}$ does not then change and $K_M$ decreases sharply. This confirms indirectly the conclusion that the oxidised form of methylviologen reacts with the enzyme–hydride complex $EH^-$. Unfortunately, in the remaining cases, it is not possible to discover rigorously the influence of the pH on the reaction kinetics.

In the oxidation of $H_2$ by methylviologen with participation of the one-centre hydrogenases from *Th. roseopersicina*[125] and *Rh. capsulata*[126] in the pH range 7–9, the maximum rate

and the Michaelis constant are independent of the hydrogen ion concentrations. The parameters of the overall kinetic curves remain unchanged when the pH is varied within the same limits.[130]

The fact that the rate of the enzyme reaction can be of zero order with respect to the substrate and the product is misunderstood in the literature. Thus the authors of a review,[15] criticising the results of Varfolomeev et al.,[125] claim from general considerations that the rate of oxidation of hydrogen "must" depend on the pH.

We shall now consider the observed relations taking into account the known rules governing the occurrence of single-pathway catalytic reactions under stationary conditions (see, for example, Karyakin et al.[141]). The concentration of the product does not enter into the rate equations for such reactions if the product formation stage is irreversible. In order to eliminate the influence of the substrate, a further requirement is that its addition should be much faster than the remaining stages of the reaction. Consequently the zero order of the reaction implies that the addition of the hydrogen molecule and the liberation of protons from the active centres of the one-centre hydrogenases from *Th. roseopersicina* and *Rh. capsulata* should be much faster than the remaining stages, including the oxidation-reduction stages.

A detailed study has been made[130] of the kinetics of the oxidation of hydrogen by methylviologen catalysed by the hydrogenase from *Th. roseopersicina*. In order to discover the sequence of the stages, the dependence of $1/V_{max}$ and $K_M/V_{max}$ for both substrates on the pH and the concentration of the second substrate was determined. Kinetic analysis makes it possible to select the unique sequence

$$H_2 \cdot H^+ — MV^{2+} \rightarrow MV^{2+} — H^+ \rightarrow,$$

where the arrow indicates irreversible stages. Thus, according to Karyakin et al.,[130] the electron acceptor reacts with the enzyme–hydride complex $EH^-$; after the elimination of the second acceptor molecule from the active centre, the enzyme remains in the protonated form.

Thus kinetic data confirm the conclusion that the activation of the hydrogen molecule in the active centres of hydrogenases leads to the formation of the enzyme–hydride complex.

The kinetic differences between the many-centre and one-centre hydrogenases can be traced in relation to the enzymes considered. While the kinetic parameters of the hydrogen oxidation reactions in the presence of one-centre hydrogenases are independent of the pH and the $H_2$ concentration, in the presence of many-centre enzymes the reaction can be of zero order with respect to hydrogen and protons. If the rates of the oxidation-reduction stages were comparable for both groups of enzymes, it would follow that the cleavage of the $H_2$ molecule in the presence of many-centre hydrogenases should be slower than in the presence of the one-centre enzymes. However, the opposite behaviour is observed experimentally: the activity of the many-centre hydrogenases is on average higher by two orders of magnitude than that of the one-centre hydrogenases. Thus the rates of the oxidation-reduction stages are much higher for the many-centre hydrogenases than for the one-centre enzymes. This in fact constitutes the main kinetic difference between them.

It would be of interest to compare also the rates of formation of the enzyme–hydride complex for both groups of hydrogenases. However, this would require the knowledge of the dependence of the Michaelis constant (with respect to hydrogen) on the pH. Unfortunately there are no such data in the literature. The hydrogenase from *Th. roseopersicina*[130] forms $EH^-$ at a rate characterised by a constant of the order of $10^5$ $min^{-1}$, which is comparable to the rate constants for reactions catalysed by many-centre hydrogenases (they are calculated from the maximum rates[13,14] see Table), which are of the order of $10^4$–$10^5$ $min^{-1}$. Thus the hydrogen molecule is activated with formation of the enzyme–hydride complex equally fast by both groups of hydrogenases. Since the iron–sulphur clusters of the one-centre and many-centre enzymes have extremely different properties, presumably the hydrogen molecule is not activated at this cluster. This conclusion agrees well with the hypothesis that the nickel centre is the acceptor of the $H_2$ molecule.

The extremely high rate of formation of the enzyme–hydride complex $EH^-$ in the active centres of hydrogenases is noteworthy. The heterolytic dissociation of the $H_2$ molecule under the conditions of the metal complex catalysis[142] is $10^5$–$10^6$ times slower. However, it is as yet not clear what particular mechanism is responsible for such high rates of the enzyme reactions compared with the reactions in the presence of the familiar model catalysts.

## 2. The Oxidation-Reduction Stages

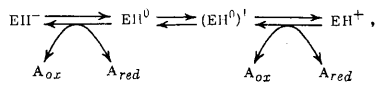
We shall consider the interaction of the enzyme with the electron acceptor in the hydrogen oxidation reaction. Firstly, one should note that a dependence of the catalytic properties of enzymes on numerous factors is characteristic of all enzymes. Thus it has been found that cytochrome $c_3$ appreciably stimulates the activity of the hydrogenase from *D. desulfuricans*.[131] Furthermore, the rate of evolution of hydrogen from the reduced mixture of methylviologen and cytochrome $c_3$ under the influence of this hydrogenase exceeds the sum of the rates of its evolution from methylviologen and the cytochrome taken separately.[139] Inhibitor analysis shows that both acceptors interact with the same section of the active centre in the enzyme.

Secondly, it has been stated by some investigators[108,123] that the deuterium exchange reaction in the active centres of hydrogenases can include oxidation-reduction stages due to the enzyme–enzyme interaction. The addition of an electron acceptor leads to the inhibition of the deuterium exchange with participation of the hydrogenases from *Cl. pasterianum*,[108] *A. eutrophus*,[123] and *Rh. japonicum*.[132] After the complete reduction of the acceptor, the deuterium exchange is renewed. Consequently the pathway associated with the reduction of the electron transferring agent is tentative.

Finally, as established above, the oxidation-reduction stages are rate-limiting in the catalysis of the oxidation of molecular hydrogen by hydrogenases. The dependence of the rate of oxidation of molecular hydrogen catalysed by hydrogenases on the concentration of a one-electron acceptor (methylviologen, benzylviologen) is as a rule described by the Michaelis function. However, in the catalysis by the hydrogenases from *M. elsdenii*[71,76] and *D. vulgaris*[53] the dependence of the reciprocal of the rate of evolution of hydrogen on the reciprocal of the methylviologen concentration is non-linear. This can be accounted for by side effects, for example, by the formation of the dimer of the reduced form of methylviologen,[143] and by the diffusion or re-reduction of the enzyme, because the non-linear dependence of the rate of evolution of hydrogen in terms of the variables of the Lineweaver–Burk equation was found[53,76] to be coupled with a linear dependence of the absorption of hydrogen. Furthermore, it has been discovered[71] that the $H_2$ evolution reaction is of first order with respect to methylviologen for the same hydrogenase from *D. vulgaris* (Hildenborough strain) (cf. Grande et al.[53]).

On the other hand, studies[59,139,140] using the hydrogenase from *D. vulgaris* (Miyazaki strain) led to the discovery of a quadratic dependence of the rates of absorption and evolution of hydrogen on the methylviologen concentration. This contradiction was explained somewhat later.

With rare exceptions, the hydrogen oxidation (and formation) reactions are usually found to be of first order with respect to the electron acceptor. Methylviologen and benzylviologen are one-electron mediators and their interaction with the active centre of the enzyme during the reaction should be separated by an irreversible stage.[130,141]



A detailed study has been made[126,130] of the kinetics of the interaction of the enzyme–hydride complex with the electron acceptor. The rate of the hydrogen oxidation reaction is related to the electron acceptor concentration by an expression of the type of the Michaelis equation and the form of the integral curve depends on the concentration of the reduced form of the acceptor. The apparent Michaelis constant is proportional to the concentration of the reduced form of the electron acceptor. Thus the rate equation for the process is

$$v = \frac{V_{max}[S]}{K_M + [S] + K'_p[P]}, \qquad (2)$$

where [S] and [P] are respectively the concentrations of the substrate and the product and $K'_p$ is the product binding constant.

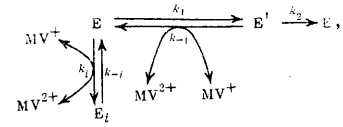
Various possible mechanisms, including the mechanism involving a reversible catalytic stage, the general mechanism with inhibition by the product, and the mechanism with a reversible bimolecular interaction with the substrate have been considered in the course of kinetic analysis. The dependence of the kinetic parameters of Eqn.(3) on the oxidation-reduction potential of the electron acceptor made it possible to give preference to the mechanism with reversible bimolecular interaction:

Scheme 1

where $A_{ox}$ and $A_{red}$ are respectively the oxidised and reduced forms of methylviologen or benzylviologen. Thus a slow intramolecular stage has been discovered in the mechanism of the catalytic reaction.

On the other hand, the $H_2$ oxidation reaction catalysed by the hydrogenase from *Rh. japonicum* is not inhibited by the reduced form of the electron acceptor [Methylene Blue (MB), phenazine metasulphate (PMS)].[107] The oxidation-reduction potentials of the above acceptors are respectively +11 and +80 mV and differ markedly from the potentials of methylviologen and benzylviologen (−440 and −359 mV respectively). Since the "inhibiting" effect is shown to be associated with the reverse reaction, i.e. with the donation of an electron, the behaviour of reduced MB and PMS becomes entirely understandable. Furthermore, Scheme 1 has been derived for a one-electron transferring agent.

In Scheme 1 there is a unimolecular stage between the stages involving interaction with electron acceptors and it is rate-limiting. Its physical significance becomes understandable if account is taken of the fact that the abstraction of the first electron from the hydride ion in the gas phase required approximately twenty times less energy than the abstraction of the second electron. The $\Delta H$ for these processes are respectively 15 and 312 kcal $mol^{-1}$.[136]



The difference between the many-centre and one-centre hydrogenases may consist both in the different degrees of stabilisation of the intermediate forms and hence in the different ratio of the rates in stages (*1*) and (*3*) in the forward and reverse directions (Scheme 1) and in the acceleration of the intramolecular stage (*2*). As a consequence of this, when the most active hydrogenases are employed, the second order of the reaction with respect to the electron acceptor may be observed. The hydrogenase from *D. vulgaris* (see Table) has established a kind of record as regards activity and the second order of the hydrogen absorption and evolution reactions with respect to methylviologen, observed in the presence of this enzyme, is quite readily explicable.

However, it has been shown[126] that the second order of the reaction with respect to methylviologen is also observed in the hydrogen oxidation reaction in the presence of the hydrogenase from *Rh. capsulata*. This enzyme is a striking representative of the group of one-centre hydrogenases (see Table) and there is therefore no analogy with the hydrogenase from *D. vulgaris*. We may recall that the enzyme from *Rh. capsulata* belongs to the group of "one-centre" hydrogenases:[60,75] The question arises what can be the characteristic features of the enzymes of this group.

A catalyst is incapable of shifting the thermodynamic equilibrium of the reaction. Consequently the only possible explanation is the creation of kinetic hindrance: the acceleration of the forward reaction of the catalyst and its "switching off" along the reverse pathway. It has been suggested[63] that the inactivating re-reduction of one-sided hydrogenases occurs even in the range of positive potentials relative to the hydrogen electrode in the same solution. Thus, under conditions which are thermodynamically favourable for the evolution of hydrogen, the hydrogenase becomes inactive. The inactivating re-reduction potential for the enzyme from *Rh. capsulata*[75] proved to be −340 mV at pH 7.0. The change in potential per pH unit is then approximately −30 mV.

Only the reduced electron acceptor can serve as the electron donor for the re-reduction in the hydrogen oxidation reaction. The simplest scheme of the oxidation-reduction stages in the catalysis by the hydrogenase by *Rh. capsulata* is as follows:

Scheme 2

where $E_i$ is the inactive form of the catalyst.

Using the corresponding rate equation, it is possible to calculate from kinetic data the inactivating re-reduction potential ($E_i \cong -387 \pm 5$ mV at pH 8.5). This value agrees well with that found by oxidation-reduction titration ($E_i \cong -385 \pm 5$ mV).[75] Thus the hypothesis of the inactivating re-reduction as the basis for the regulation of "one-sided" hydrogenases has been confirmed in a direct kinetic study. It must be emphasised that the conclusion that common mechanisms of the catalysis operate has been extended also to the group of "one-sided" enzymes. Their only difference from the two-sided hydrogenases from the kinetic standpoint is the presence of the characteristic inactivating re-reduction stage.

In conclusion we present the final scheme for the catalysis by the hydrogenase from *Th. roseopersicina* (Scheme 2 based on the data of Karyakin and co-workers[126,130]), which is fairly general for hydrogenases from different

sources:

Scheme 3

$$E + H_2 \overset{K_1}{\rightleftarrows} EH_2, \quad (1)$$

$$EH_2 \overset{K_2}{\rightleftarrows} EH^- + H^+, \quad (2)$$

$$EH^- + A_{ox} \underset{k_{-3}}{\overset{k_3}{\rightleftarrows}} EH^0 + A_{red}, \quad (3)$$

$$EH^0 \underset{k_{-4}}{\overset{k_4}{\rightleftarrows}} (EH^0)', \quad (4)$$

$$(EH^0)' + A_{ox} \underset{k_{-5}}{\overset{k_5}{\rightleftarrows}} EH^+ + A_{red}, \quad (5)$$

$$EH^+ \underset{K_6}{\rightleftarrows} E + H^+, \quad (6)$$

where E is the hydrogenase and A is methylviologen or benzylviologen. Stages (*1*), (*2*), and (*6*) are of the quasi-equilibrium type. Here the equilibrium is strongly displaced towards the formation of products, so that the occurrence of any kind of irreversibility in the above set of stages is entirely well founded. Stage (*4*) is also irreversible within the framework of the given kinetic conditions. Since the adjoining stages (*3*) and (*5*) can proceed in both forward and reverse directions while stage (*4*) is the slowest, it is reasonable to postulate the simplest type of irreversibility: $[A_{ox}]k_5 \gg k_{-4}$. We may note that the restrictions on the reaction conditions thus obtained involve the concentrations of the reactants. Thus, by changing the process conditions, it is possible to achieve not only reversibility along the sections indicated but also irreversibility in the opposite direction.

## VI. KINETICS OF THE ELECTROCHEMICAL PROCESSES CATALYSED BY HYDROGENASES

The phenomenon of the acceleration of electrode processes by enzymes has been called "bioelectrocatalysis".[7-11] In this case the electrode behaves as one of the reaction substrates, the electron donor, or the electron acceptor. There are two ways of coupling enzyme and electrochemical reactions: the mediator mechanism in which the electron exchange is effected by a transferring agent, capable of reacting both with the electrode and with the active centre of the enzyme, and the direct mechanism in which the enzyme is capable of being directly oxidised or reduced at the electrode.

The mediator bioelectrocatalysis has been achieved using the hydrogenases from *Pr. aestuarii* and *Th. roseopersicina*.[144] It has been shown that the conditions in the oxidation of hydrogen are close to reversibility: depending on the electrode potential, such a system can operate both with absorption and in evolution of hydrogen.

A unique feature of the hydrogenase from *Th. roseopersicina* is its ability to behave as the electrocatalyst of the oxidation-formation of molecular hydrogen in sorption on the surface of a carbon black electrode.[145] It has been shown that, in a $H_2$ atmosphere on an electrode with the immobilised hydrogenase, an equilibrium hydrogen potential is established. In the hydrogen oxidation reaction the current drawn from the electrode is independent of the pH and the partial $H_2$ pressure over the entire overpotential range.[126] The zero order of the electrocatalytic reaction with respect to the substrate and the product permits the conclusion, as in homogeneous reactions, that the addition of a hydrogen molecule and the liberation of protons from the active centre of the enzyme are rapid compared with the oxidation-reduction (in the given instance electrochemical) stages.

The overall polarisation curve for the electrochemical oxidation of $H_2$ is described by the equation corresponding to the occurrence of two consecutive potential-dependent stages involving electron transfer from the active centre of the enzyme to the electrode.[126] It has been shown that the electrochemical stages must follow one after another, i.e. cannot be separated by addition–dissociation processes. The mechanism of the homogeneous reaction includes, in addition, an intramolecular stage separating two oxidation-reduction stages. Evidently in electrocatalysis this stage is concealed in the electrochemical stages; one can only observe that the second electron is transferred to the electrode more slowly than the first.

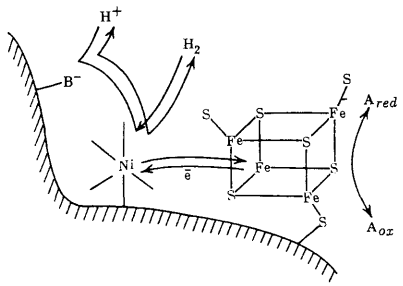
The parameters of the positive branch of the polarisation curve make it possible to predict the kinetics of the reverse reaction, i.e. of the electroevolution of hydrogen. The negative branch has inferior current characteristics compared with the positive component. Thus the use of the hydrogenase electrode is most justified in the $H_2$ oxidation reaction. Furthermore, the inactivating re-reduction of the active centre of the hydrogenase has been detected in the electrochemical system, which constitutes evidence for the occurrence of this phenomenon, since the possibility of the effect by any other inactivating factors has been ruled out experimentally.

Thus the study of the kinetics of the electrochemical reaction with participation of the hydrogenase from *Th. roseopersicina* not only confirms but also supplements the conclusions concerning the characteristic features of the homogeneous kinetics and the catalytic properties of hydrogenases reached in the previous Section.

## VII. CONCLUSIONS

This review has dealt with the most general physicochemical properties of hydrogenases, the structure of their active centres, and the characteristic features of the catalysis. In conclusion we should like to put forward the hypothesis that the action of these enzymes has a molecular mechanism.

We have been able to divide hydrogenases into two groups differing in their physical properties, activities, and kinetic parameters in the hydrogen oxidation reaction. The one-centre hydrogenases contain one 4Fe–4S cluster. Their activity is on average lower by two orders of magnitude than that of the many-centre hydrogenases containing several iron–sulphur clusters in the active centre. While the addition of a hydrogen molecule and the liberation of protons are effected equally rapidly by both groups of hydrogenases, an appreciable difference is observed in the rates of the oxidation-reduction stages. The latter evidently proceed with participation of the iron–sulphur structures in the active centre.



Furthermore, it has been possible to elucidate the kinetic scheme for the hydrogenase catalysis. The activation of the hydrogen molecule in the active centres of hydrogenases leads to the formation of the enzyme–hydride complex $EH^-$. In the $H_2$ oxidation reaction the interaction of the one-electron acceptor with the active centre is a reversible bimolecular process. The addition of the second acceptor molecule is preceded by a slow intramolecular stage.

The involvement of nickel in hydrogenase catalysis is indisputable. This has been confirmed, firstly, by the overlap of the electron orbitals of the nickel and iron–sulphur centres. Secondly, inhibitor analysis and the character of the mutual influence of substrates indicate that the $H_2$ and electron acceptor molecules interact with different sections of the active centre. Furthermore, a parallel has been

traced between the relative equality of the rates of activation of the hydrogen molecule by the one-centre and many-centre hydrogenases and the identity of the oxidation-reduction potentials of their nickel centres, while the properties of the iron–sulphur cluster structures in these two types of hydrogenases differ significantly. Finally, the one-electron reduction of $Ni^{3+}$ to $Ni^{2+}$ requires the participation of a proton acceptor. All these factors support the view that the nickel centre is the initial acceptor of the $H_2$ molecule.

The molecular mechanism of the catalysis by hydrogenases of the hydrogen oxidation reaction can be described with the aid of a two-centre model:

Scheme 3

The $H_2$ molecule is sorbed on a "free" coordination site of nickel, substituting, for example, a water molecule. This is followed by heterolytic dissociation with formation of the enzyme–hydride complex apparently without the involvement of the electron density of the iron–sulphur cluster. The latter is also able to accept one of the electrons of the hydride rapidly and reversibly. The iron–sulphur cluster interacts with the acceptor, giving up the "superfluous" electron, also rapidly and reversibly. The abstraction of the second electron from the hydride ion is known to require the expenditure of more energy by 300 kcal $mol^{-1}$ than the abstraction of the first electron. Consequently, the transfer of the second electron between the nickel and iron–sulphur centres is much slower. This stage is in fact manifested in the kinetics as the slow intramolecular stage. It is also followed by the rapid interaction with the acceptor and by deprotonation. As a result of the superior organisation of the iron–sulphur clusters, many-centre hydrogenases are capable of effecting the intramolecular transfer of the second electron at a higher rate. Overall, the role of the iron–sulphur clusters in hydrogenases consists in the stabilisation of the intermediate electronic states, as in other enzymes, for example, in nitrogenase. The presence of a spatially branched structure is essential for the abolition of the change in the ambient medium when the oxidation state is altered, which leads to a decrease of the activation energy for the electron transfer according to the solvent reorganisation theory.

In the oxidised state, hydrogenases are inactive in the hydrogen oxidation reaction and the possibility of the activation of the $H_2$ molecule is lost. It would appear that the electric field of $Ni^{3+}$ should promote the heterolytic dissociation of the $H_2$ molecule to a greater extent than the $Ni^{2+}$ field. The first step in the activation of the $H_2$ molecule apparently consists in the transfer of an electron to the latter from the active centre of the hydrogenase, which appreciably weakens the H–H bond. The potential of the $Ni^{3+} \leftrightarrow Ni^{2+}$ transition (−150 mV) allows fully the possibility of such donation. If this were followed by the reduction of $Ni^{3+}$ to $Ni^{2+}$, for example, as a result of the reduction of the iron–sulphur cluster $[Fe_4S_4]^{2+}$, then a proton-acceptor group would appear in the coordination sphere of $Ni^{2+}$. Thus the following conditions for the dissociation of the $H_2$ molecule arise in the transition state obtained: (1) the weakening of the H–H bond as a result of the appearance of an electron in the antibonding orbital of the molecule; (2) the presence of a bivalent nickel atom capable of accepting a hydride ion; (3) the appearance of a proton acceptor in the coordination sphere of the nickel centre; (4) the formation of an oxidised iron–sulphur cluster capable of accepting an electron.

As already mentioned, hydrogenases activate the hydrogen molecule and effect the formation of the enzyme–hydride complex at extremely high rates compared with metal complex catalysts. The hydrogenase from *A.eutrophus* is capable of hydrogenating NAD to NADH. Thus specific modification of the active centres of hydrogenases or their modelling leads to a way of creating more effective catalysts of the hydrogenation and dehydrogenation of organic compounds.

# Geminal Sulphones

V.M.Neplyuev, I.M.Bazarova, and M.O.Lozinskii

The literature data on the method of synthesis, structures, and chemical properties of compounds containing geminal sulphonyl groups are surveyed and described systematically. The available information about the thermodynamic and kinetic acidities of the compounds and the stability and reactivity of the carbanions stabilised by two (and more) sulphonyl groups is discussed. The bibliography includes 222 references.

## I. INTRODUCTION

Compounds containing geminal sulphonyl groups were first synthesised at the end of the last century but for a long time their number was small, they were difficult to obtain, and they were inadequately investigated. The first representatives of geminal sulphones (GS) were β-disulphones (DS). Subsequently numerous publications were devoted to the chemistry of DS and at the present time these are the most thoroughly investigated representatives of GS. Studies have developed mainly in two directions during the last three decades on the basis of these compounds: (1) investigation of the thermodynamic and kinetic acidity of GS and the problems of the formation, stabilisation, and reactivity of the corresponding carbanions associated with it; (2) the search for methods of synthesis of various types of GS.

The first direction is represented by studies in which, together with the investigation of the acid properties of GS and of the factors influencing the stabilisation of carbanions and their reactivity (hybridisation of the carbon atom, configuration, conformation, and $2p,3d$-orbital interaction), problems concerning the proton-donating activity of certain representatives of GS in the formation of hydrogen bonds with electron donors were solved.

The second direction developed rapidly in recent years when appreciable advances were achieved in the synthesis of unsaturated GS, in the use of GS for the introduction of sulphonyl groups into heterocyclic compounds, and also in the synthesis of new organophosphorus and organofluorine compounds. It was found that unsaturated GS have specific properties characteristic only of these compounds.

The amount of available information in the literature and the synthesis of properties of GS is sufficient for its survey and systematic treatment. Nevertheless there has so far been no review on the chemistry of GS. Even in the familiar monograph of Oae[1] and the review by Magnus[2] little attention has been devoted to GS.

In the present review the first attempt is made to fill this gap. The data dealt with in the review are described in the following order: we start with the chemistry of β-disulphones and then proceed to unsaturated compounds and more complex structures containing geminal sulphonyl groups.

Information which appeared in the literature during the last forty years, up to July, 1984, has been used in the review. Earlier studies are quoted only when necessary. In considering the theoretical problems concerning the thermodynamic acidity of GS and the stabilisation of the corresponding carbanions, certain aspects of the chemistry of monosulphones are discussed to achieve a fuller description of the problem. Compounds containing geminal sulphonamide groups are not considered in this review.

## II. METHODS OF SYNTHESIS

The methods of preparation of aliphatic GS containing an unsubstituted methylene or methylidyne group reduce to the following fundamental schemes with rare exceptions: (1) synthesis and subsequent oxidation of the geminal bis-sulphides (thioacetals) or tris-sulphides (trithioorthoesters); (2) the introduction of $SO_2R$ groups (or SR groups with subsequent oxidation) in the α-position in compounds containing two geminal electron-accepting groups, one of which is the sulphonyl group. Both methods lead to the formation of methane derivatives. Higher homologues of aliphatic GS are obtained from DS or geminal trisulphones (TS) by alkylation with alkyl halides or via the Michael reaction.

The higher reactivity of the methylene group in DS makes it possible to employ a wide variety of DS for the synthesis of certain unsaturated GS.

### 1. Linear and Cyclic Disulphones

Linear symmetrical GS with a free methylene group (1) were obtained for the first time by condensing formaldehyde[3,4] or its trimer[5,6] with thiophenols or merceptans in the presence of acids with subsequent oxidation of the bis-sulphide formed. These reactions proceed as a rule with satisfactory yields and the availability of the DS is therefore determined by the availability of the corresponding thiol. Methylene chloride[7] or bromide[8] in the presence of alkali metal alkoxides is used much more rarely in the synthesis of bis-sulphides instead of formaldehyde:

$$RSH \xrightarrow[CH_2X_2,\ EtONa]{CH_2O,\ H^+} \xrightarrow{[O]} \underset{(I)}{(RSO_2)_2CH_2}\ ;$$

$$R = Alk, Ar;\ X = Cl, Br\ .$$

A wide variety of oxidants are used in the oxidation stage, among which nitric acid,[9] hydrogen peroxide,[6,10] chromium trioxide,[11,12] peracids,[13] hydroperoxides,[14] and potassium permanganate[15] are most common.

Various aromatic and aliphatic DS have been synthesised by the method which is based on the oxidation-reduction cleavage of arene- or alkane-sulphinylacetic acids obtained from S-substituted mercaptoacetic acid:[16]

$$RSCH_2COOH \xrightarrow[HAc]{H_2O_2} [RSOCH_2COOH] \xrightarrow{H^+} (RS)_2CHCOOH \xrightarrow{H_2O_2} (I)\ ;$$
$$R = Alk, Ar\ .$$

Disulphones with an unsubstituted methylene group (I) have also been synthesised by nucleophilic substitution of halogen atoms in α-halogenosulphones by treating them with alkali metal thiolates and oxidising the resulting sulphone sulphides,[17,18] by chlorinating aryl methyl sulphides with subsequent disproportionation of aryl chloromethyl sulphides on alumina and oxidation of the resulting bis-sulphide,[19] and by oxidising the bis-sulphides formed in the radical reaction of a monochloromethyl ether in the presence of thiols.[20]

Symmetrical DS (II), in which the hydrogen atoms of the methylene group have been substituted by various aliphatic groups, are usually obtained by alkylating unsubstituted DS (see below), although the synthesis by the oxidation of substituted thioacetals and thioketals is also known:[21]

$$RR^1C(SR^2)_2 \rightarrow RR^1C(SO_2R^2)_2\ ;$$
$$(II)$$
$$R, R^1 = Alk;\ R^2 = Alk, Ar\ .$$

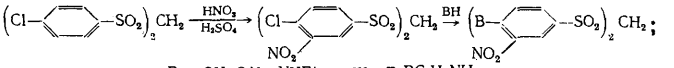
A universal method of synthesis of both symmetrical and asymmetric DS has been proposed by Gibson,[22,23] who obtained various DS in high yields by making use of the availability of various alkane- and arene-sulphonyl acetones, the high reactivity of the methylene group in these compounds in thioalkylation and thioarylation reactions, and also the ready heterolytic abstraction of the acetyl group (sometimes even in the oxidation process):

$$RSO_2CH_2COMe \xrightarrow[EtONa]{R^1SX} RSO_2CH(SR^1)COMe \xrightarrow[HAc]{H_2O_2} RSO_2CH_2SO_2R^1\ ;$$
$$R, R^1 = Alk, Ar;\ X = Hal, SO_2Alk, SO_2Ar\ .$$

Substituted DS containing a third electron-accepting substituent at the carbon atom are synthesised by introducing a second sulphonyl group (or SR group with subsequent oxidation) at the methylene carbon atom in compounds of the type $RSO_2CH_2S$. As a rule, the reaction proceeds only with the most reactive sulphonyl chlorides:[24]

$$\left.\begin{array}{l} MeSO_2CH_2CN + PhSO_2Cl \xrightarrow{(>3\%)} \\ PhSO_2CH_2CN + MeSO_2Cl \xrightarrow{(70\%)} \end{array}\right\} \rightarrow PhSO_2CH(CN)SO_2Me\ .$$
$$(III)$$

Owing to the low reactivity of aromatic sulphonyl chlorides, DS substituted by two aromatic groups are synthesised using the corresponding aryl thioesters of sulphinic acid or arenesulphenyl chlorides:[24]



$$PhSO_2CH_2CN \xrightarrow{PSO_2SPh} PhSO_2CH(SPh)CN \xrightarrow{[O]} (PhSO_2)_2CHCN\ .$$
$$(IV)$$

Substituted DS of type (III) substituted by aliphatic and aromatic groups are obtained by employing methanesulphonyl chlorides, which makes it possible to shorten the synthesis by one stage. Asymmetric DS with electron-accepting substituents (CN, COOMe, COOEt, COMe, and COPh) at the methylidyne carbon atom have been synthesised in this way.[25]

Bis(benzenesulphonyl)ethoxycarbonylmethane (V) has been obtained from ethyl dichloroacetate and thiophenol with subsequent oxidation of the reaction product:[26]

$$PhSH + Cl_2CHCOOEt \xrightarrow{EtONa} (PhS)_2CHCOOEt \xrightarrow{[O]} (PhSO_2)_2CHCOOEt\ .$$
$$(V)$$

Nitrodisulphones cannot be obtained by the direct nitration of the methylene group. Nitration of bis(benzenesulphonyl)-methane leads to bis(3-nitrobenzenesulphonyl)methane.[27] Bis(4-chlorobenzenesulphonyl)methane is converted into bis(4-chloro-3-nitrobenzenesulphonyl)methane on nitration.[28] A series of DS containing various substituents in the aromatic ring have been obtained by the nucleophilic substitution of chlorine atoms of the last compound:[28]

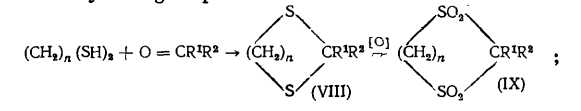
$$B = OH, OMe, NHEt, o\text{-}, m\text{-}, p\text{-}RC_6H_4NH.$$

A disulphone with the nitro-group at the methylene carbon atom has been obtained by the alkaline cleavage of tris-(methanesulphonyl)nitromethane:[29]

$$(MeSO_2)_3CNO_2 \xrightarrow{NaOH} (MeSO_2)_2CHNO_2 + MeSO_3Na\ .$$
$$(VI)$$

The synthesis of DS with the $CF_3SO_2$ group has been described.[30] The authors used the usual method for the preparation of the bis-sulphide and oxidised the latter to DS with chromium trioxide in acetic acid:

$$p\text{-}XC_6H_4SNa \xrightarrow{ClCH_2SCF_3} p\text{-}XC_6H_4SCH_2SCF_3 \xrightarrow[HAc]{CrO_3} p\text{-}XC_6H_4SO_2CH_2SO_2CF_3\ ;$$
$$X = H, Cl, NO_2\ .$$



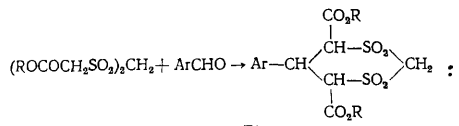
Disulphones with two perfluoroalkyl groups have been obtained from perfluorinated sulphonyl fluoride and Grignard reagents.[31,32] The reaction takes place in several stages and makes it possible to obtain a DS with an unsubstituted or substituted methylene group:

$$R_FSO_2F + RCH_2MgX \xrightarrow[25°C]{THF} (R_FSO_2)_2CHR\ ;$$
$$R = H, Me;\ R_F = CF_3, C_4F_9, C_8F_{17}\ .$$

Methanedisulphonyl fluoride has been synthesised by the reaction of methionic acid chloride (methanedisulphonyl chloride) with anhydrous zinc fluoride:[33,34]

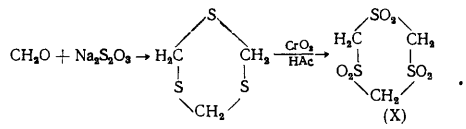
$$CH_2(SO_2Cl) + ZnF_2 \rightarrow CH_2(SO_2F)_2\ .$$
$$(VII)$$

Cyclic DS are usually obtained by oxidising 1,3-dithiacycloalkanes, which are in their turn synthesised from the corresponding αω-dithiol and a carbonyl compound (an aldehyde or ketone). The use of formaldehyde or its trimer with subsequent oxidation lead to cyclic 1,3-disulphones with a free methylene group:[35]



$$R^1, R^2 = H, Alk;\ n = 2-4\ .$$

The reaction of αω-dihalogenoalkanes with sodium thiosulphate is a convenient method of synthesis of 1,3-dithiacycloalkanes.[36] The polymethylenebisthiosulphonate formed as an intermediate reacts with carbonyl compounds to form 1,3-dithiacycloalkanes, which are then oxidised by hydrogen peroxide to cyclic 1,3-disulphones:[37]



$$X-(CH_2)_n-X + Na_2S_2O_3 \rightarrow (CH_2)_n(SSO_2ONa)_2 \xrightarrow{R^1COR^2} (VIII) \xrightarrow{[O]} (IX)\ ;$$
$$R^1, R^2 = Alk;\ X = Cl, Br;\ n = 2-4\ .$$

Cyclic 1,3-disulphones containing oxygen atoms in the ring have been synthesised by an analogous procedure.[38] A method of synthesis of ring-substituted 1,3-dithiane 1,1,3,3-tetroxides with a free methylene group by the condensation of bis(alkoxycarbonylmethanesulphonyl)methane with various aldehydes in the presence of ammonium acetate has been published recently:[39]

R = Me, Et .

*sym*-Trithianes, which are products of the interaction of aldehydes or ketones with hydrogen sulphide,[40,41] are readily oxidised to cyclic trisulphones containing three free or substituted methylene groups. 2,4,6-Trimethylene-1,3,5-trisulphone (TTS) (X) has been most thoroughly investigated. It is usually synthesised by the reaction of formaldehyde with sodium thiosulphate[42,43] and the oxidation of the tris-sulphide formed by chromium trioxide in acetic acid:

2,4,6-Tri(methylmethylene)-1,3,5-trisulphone (TMTS) has been synthesised by the same method.[45]

## 2. Geminal Trisulphones

Two methods of synthesis of geminal trisulphones have been described in the literature. Symmetrical aliphatic and aromatic TS are obtained by oxidising orthothioesters:[46]

$$3RSH \xrightarrow{HCOOH} CH(SR)_3 \xrightarrow{[O]} CH(SO_2R)_3 ;$$
$$R = Alk, Ar . \qquad (XI)$$

The orthothioesters are synthesised by the Houben method.[47] Owing to their high tendency to hydrolyse, the oxidation is carried out very cautiously using peracetic[48] and perphthalic[22] acids or an alkaline solution of potassium permanganate[48] as oxidants.

Owing to the low yields of the TS, this method of their synthesis has not been widely employed. A more convenient procedure for the synthesis of TS, both symmetrical and mixed, involves the introduction of an alkylthio- or arylthio-group into the molecule of bis(alkanesulphonyl)- or bis-(arenesulphonyl)-methane and its subsequent oxidation:[22,49,50]

$$(I) \xrightarrow{R^1SCl(RSO_2SR^1)} (RSO_2)_2CHSR^1 \xrightarrow{[O]} (RSO_2)_2CHSO_2R^1 ;$$
$$(XII)$$
$$R, R^1 = Alk, Ar .$$

The reaction of alkanesulphonyl chlorides with TS in the presence of alkali metal alkoxides is a convenient method of synthesis of TS:[8,22,25,51]

$$(I) \xrightarrow[EtONa]{AlkSO_2Cl} (XII) ;$$
$$Alk = Me, Et, PhCH_2 .$$

Many of the TS described in the literature, including those with a chiral carbon atom in the methylidyne group, have been synthesised by this method in satisfactory yields.[22,51] A limitation of this method consists in the impossibility of synthesising TS with three aromatic substituents, since arenesulphonyl chlorides do not enter into this reaction being weak electrophiles.

Methanetrisulphonyl fluoride has been obtained by treating methanetrisulphonic acid with sulphur tetrafluoride:[34]

$$HC(SO_3H)_3 \xrightarrow[50\,^\circ C,\ 2\ h]{SF_4,CH_2Cl_2} HC(SO_2F)_3$$
$$(XIII) .$$

## 3. Other Alkanes with Geminal Sulphonyl Groups

Alkanes (ethane, propane, etc.) containing geminal sulphonyl groups (GSG) at one end of the chain are obtained by alkylating DS having the necessary set of alkane- or arene-sulphonyl groups:[23,52]

$$(I) + R^1X \xrightarrow[EtOH]{EtONa} (RSO_2)_2CHR^1 ;$$
$$(XIV)$$
$$R = Me, Ph; R^1 = Me, Et; X = Hal, p\text{-}MeC_6H_4SO_3 .$$

The ease of the alkylation of the DS makes it possible to synthesise alkanes containing GSG in the middle of the aliphatic chain by this procedure:[52]

$$(I) + 2Me(CH_2)_nX \xrightarrow[EtOH]{EtONa} Me(CH_2)_nC(SO_2R)_2(CH_2)_nMe ;$$
$$X = Hal, n = 0, 1, 2 .$$

Certain ethane derivatives containing GSG are obtained analogously to disulphonylethane (I) by employing acetaldehyde instead of formaldehyde:[22]

$$2RSH + MeCHO \xrightarrow{H^+} (RS)_2CHMe \xrightarrow[HAc]{H_2O_2} (XIV) ;$$
$$R^1 = Me$$
$$R = Me, Ph .$$

1,1,2,2-Tetrakis(methanesulphonyl)-1,2-bis(methanesulphonylthio)ethane has been obtained by the reaction of thiophosgene with sodium methanesulphinate.[53]

The Michael reactions of DS and TS with methyl vinyl sulphone[54] or 1,1-bis(arenesulphonyl)ethylenes lead to polysulphonylpropanes (XV)–(XVII). Compounds (XVII) have also been obtained by the reaction of DS with paraformaldehyde in the presence of bases:[55–59]

$$\underset{(I)}{(ArSO_2)_2CH_2} + CH_3SO_2CH{=}CH_2 \xrightarrow{EtONa} \underset{(XV)}{(ArSO_2)_2CHCH_2SO_2Me} ;$$
$$\underset{(XII)}{(ArSO_2)_2CHSO_2Me} + \underset{}{(ArSO_2)_2C{=}CH_2} \xrightarrow{F^-} \underset{(XVI)}{(ArSO_2)_2CHCH_2C(SO_2Ar)_2SO_2Me};$$
$$\underset{(I)}{(ArSO_2)_2CH_2} \xrightarrow[CH_2O]{F^-} \underset{(XVII)}{[(ArSO_2)_2CH]_2CH_2} .$$

A pentane containing four benzenesulphonyl groups at the C(1) and C(5) atoms has been described.[57]

## 4. Unsaturated Compounds

Ethylenes with GSG have been described comparatively recently.[56,58,60,61] They were obtained by the thermal decomposition of Mannich bases obtained by condensing DS, formaldehyde, and a secondary amine (usually piperidine or pyrrolidine):

$$(I) + CH_2O + HNC_5H_{10} \rightarrow (RSO_2)_2CHCH_2NC_5H_{10} \xrightarrow[80\,^\circ C,\ 3\ h]{HCl} (RSO_2)_2C{=}CH_2 ;$$
$$(XVIII)$$
$$R = Alk, Ar.$$

The condensation of aromatic DS with aromatic aldehydes usually leads to 1,1,2-trisubstituted ethylenes:[60]

$$(PhSO_2)_2CH_2 \xrightarrow{PhCHO} (PhSO_2)_2C{=}CHPh .$$
$$(XIX)$$

Aliphatic aldehydes condensed in this way give rise to isomerisation products together with normal products.[60] The reaction of bis(ethanesulphonyl)methane with benzaldehyde is accompanied by a rearrangement with degradation of the geminal functional group.[62]

The fluorine-containing 1,1-bis(ethanesulphonyl)-2,2-bis(trifluoromethyl)ethylene has been obtained by oxidising a fluorine-containing thioketal with trifluoroperacetic acid:[63]

$$(CF_3)_2C{=}C(SEt)_2 \xrightarrow{CF_3COOOH} (CF_3)_2C{=}C(SO_2Et)_2 .$$

The majority of ethylenes with 2,2-GSG containing reactive functional groups at C(1) were discovered after the successful development of the reaction of DS with ethyl orthoformate, which made available 2,2-disulphonyl-substituted ethyl vinyl ethers (XX):[62,64,65]

$$(I) + CH(OEt)_3 \xrightarrow[Ac_2O]{ZnCl_2} \underset{(XX)}{(RSO_2)_2C{=}CHOEt} ;$$
$$R = Alk, Ar .$$

The nucleophilic exchange of the ethoxy-groups, which takes place readily in these compounds, makes it possible to synthesise a wide variety of functional derivatives of ethylenes with 2,2-GSG.[64,65]

Polysulphonylethylenes were unknown until recently despite repeated attempts at their synthesis.[66-68] The report[69] of the synthesis of tetrakis(2-chloroethylsulphonyl)-ethylene [69] proved to be erroneous. Even the synthesis of the intermediate tetrakis(alkylthio)- and tetrakis(arylthio)-ethylenes presented considerable difficulties.[70,71] It was not until the end of the 1970's that a convenient and highly effective method was proposed for the synthesis of unsaturated tetrakis-sulphides from tetrachloroethane and thiolates in aprotic solvents (DMF, DMSO, HMP, etc.), significantly accelerating nucleophilic exchange, which made compounds of this class available:[72,73]

$$Cl_2C{=}CCl_2 \xrightarrow[DMF,\ DMSO,\ HMP]{RS^-} (RS)_2C{=}C(SR)_2 ;$$
$$R = Alk, Ar .$$

This reaction as a rule involves the formation of 10–15% of tris-derivatives. Tris- and tetrakis-sulphonylethylenes (TSE) were obtained by the same investigators[74] by oxidising the corresponding tetrakis-sulphides with trifluoroperacetic acid in methylene chloride:

$$(RS)_2C{=}C(SR)_2 \xrightarrow[CH_2Cl_2]{CF_3CO_3H} \underset{(XXI)}{(RSO_2)_2C{=}C(SO_2R)_2} .$$

Propenes with GSG have been synthesised[64,75,76] by condensing ethyl vinyl ethers containing geminal electron-accepting groups (one of which is the sulphonyl group) with DS in the presence of sodium alkoxide:

$$(I) + \begin{matrix} ArSO_2 \\ X \end{matrix}\!\!>\!C{=}CHCOEt \xrightarrow[EtOH]{EtONa} \begin{matrix} ArSO_2 \\ X \end{matrix}\!\!>\!C{=}CHCH(SO_2R)_2 ;$$
$$(XXII)$$
$$X = COPh, CN, R = Alk, Ar .$$

It is striking that the synthesis of 1,1,3,3-tetrasulphonylpropenes (XXII, X = $RSO_2$) by this procedure using 2,2-disulphonyl-substituted ethyl vinyl ethers is unsuccessful because of the high rate of the competing reaction involving the dissociation of the electron-deficient double bond in these ethers.

## III. STRUCTURE AND PHYSICAL PROPERTIES

Geminal sulphones are high-melting colourless crystalline substances. They are insoluble in water; DS and TS with an unsubstituted methylidyne group dissolve in aqueous solutions of alkali or sodium carbonate.

The structure of tris(methanesulphonyl)methane has been determined by X-ray diffraction. The S–C–S angles (110.8 ± 0.4°) proved to be close to the tetrahedral value. The central C–S bonds are formally single with a length of 1.83 + 0.01 Å. The lengths of the other bonds are 1.43 ± 0.01 Å for S=O and 1.73 ± 0.02 Å for S–$CH_3$.[77,78] The structures of bis(*p*-bromobenzenesulphonyl)methane [79] and 2-(3-piperidinopropyl)-1,3-dithiane 1,1,3,3-tetraoxide [80] have been determined by X-ray diffraction.

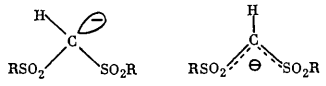
The nature of the S=O bonds and the character of the interaction of the sulphonyl group with the rest of the molecule remain the most controversial questions in the chemistry of sulphones. The hypothesis that, apart from the σ-bond, there is additional $d_\pi$,$p_\pi$ bonding between the S and O atoms so that S=O should be regarded as a (σ + π)-bond and not a semipolar bond has nowadays received increasing confirmation.[81-84] The dipole moments of a series of aromatic DS [85] suggest that the transoid conformation of these compounds is most stable, but their values (4.7–5.8 Å) preclude an unambiguous conclusion about the character of the sulphur–oxygen bond. The dipole moments of a series of aromatic unsubstituted aliphatic DS have been investigated.[86,87]

The question of the character of the interaction of the $SO_2$ group with aromatic and unsaturated groups in sulphones is insufficiently clear. Analysis of the IR spectra of a large number of different diaryl sulphones led to the conclusion that there is a weak interaction between the π electrons of the rings and the S=O bonds.[88] Raman spectroscopic data for aryl cyclopropyl sulphones revealed the presence of a barrier to electronic conduction generated by $SO_2$ groups as a result, according to the authors, of the absence of free electrons in such groups.[89] A marked weakening of the electronic influence of the substituent on the absorption frequency of the $CF_3$ group has also been observed in a series of *p*-substituted trifluoromethylthiobenzenes [90] and in *m*-trifluoromethylthiostyrene on oxidation of the sulphide sulphur atom to the $SO_2$ group.[90,91] The study of the photoelectron spectra of dimethyl, methyl vinyl, and divinyl sulphones showed that in the last two compounds there is conjugation between the π MO of the vinyl group and the MO of the $SO_2$ group. The conjugation effect is insignificant (0.2–0.3 eV) and the $SO_2$ group exhibits a strong inductive effect (~1 eV).[92] The inductive constants of alkane- or arenesulphonyl substituents (σ* = 0.57–0.60), determined by Charton[93] from the $pK_a$ of aliphatic acids, also indicate a strong inductive effect of these groups. The constants σ*($SO_2CF_3$) = 0.64 and σ*($SO_2F$) = 0.86 are close to σ*[$N^+(Me)_3$] = 0.92.[94]

By virtue of the presence of characteristic intense absorption bands,[88] GS can be reliably identified with the aid of IR spectroscopy. The spectra of these compounds contain absorption bands characteristic of the S=O bond in the region of symmetrical (1120–1180 $cm^{-1}$) and asymmetric (1300–1380 $cm^{-1}$) stretching vibrations. Substituents of different nature in the rings of aromatic DS cause hardly any shift of the absorption bands of the $SO_2$ group.[28] The absorption bands of such groups in a series of unsaturated GS are in the same region.[58,63,65] The stretching vibration frequencies of the $SO_2$ groups are sensitive to the state of aggregation; they are higher by 10–20 $cm^{-1}$ for the substances in solution than in the crystalline state. The solvent as a rule removes the band splitting which is frequently observed. The study of the IR spectra of 2,2-bis(arenesulphonyl)vinyl ethyl ethers[62,65] and 1,1-bis(arenesulphonyl)ethylenes [57] yielded direct evidence for the absence of conjugation of the $SO_2$ groups with the C=C double bond. The $^1H$ NMR spectra of a series of aromatic DS have been investigated.[95] The signals of the methylene protons are manifested by a narrow unresolved peak in the range 4–4.5 p.p.m. ($CDCl_3$) or 6–6.5 p.p.m. (DMSO). The downfield shift of the signals in DMSO can be accounted for by the formation of intermolecular hydrogen bonds between the substrate and the solvent (for a more detailed discussion of this problem, see Section IV). The effective correlation of the chemical shifts of the methylene protons with the Hammett σ constants led the authors to the conclusion, without ruling out the

possibility of the transmission of the substituent effect through space, that the electronic influence is transmitted via the $SO_2$ group with the possible participation of the 3*d* orbitals of sulphur in the formation of the S=O bond and that $d_\pi, p_\pi$ conjugation is present. The $^1$H NMR spectra of polysulphonylpropanes,[55] 1,1-bis(benzenesulphonyl)-ethylene,[58] and propenes containing GSG [75] have been published. The $^{13}$C NMR spectrum of tetrakis(benzene-sulphonyl)ethylene has been published by Petukhova et al.[74]

α-Alkylated aromatic [96] and cyclic [97] DS have been used as convenient subjects for the study by $^1$H NMR of the possibility of the formation of an intramolecular hydrogen bond between the hydrogen atom of the methylidyne group and the electron-donating group in the ω-position in the aliphatic chain. The OMe, $N(Me)_2$, $N(Et)_2$, piperidino-, and morpholino-groups were used as electron donors. The presence of an intermolecular hydrogen bond in compounds with two and three carbon atoms in the aliphatic chain has been demonstrated from the shift of the methylidyne proton signal.



The mass-spectra of $PhCH_2SO_2CH_2SO_2Me$ have been investigated in order to confirm the mechanism of the rearrangement, analogous to the Ramberg–Bäcklund reaction of α-halogenosulphones, which takes place in compounds of this series.[98] The rearrangements of monosulphones induced by electron impact have been discussed in a review.[99]

## IV. CH ACID PROPERTIES

The acid properties of DS and some of their derivatives were noted already in the first publications. Subsequently the acid properties of compounds activated by two (and more) sulphonyl groups as well as the study of factors influencing the stabilisation of the corresponding carbanions and their reactivity attracted much attention among investigators. The thermodynamic acidities of numerous DS and TS were determined experimentally, methods were developed for the generation of carbanions, and a study was made of the dependence of the reactivity of carbanions with GSG on the configuration of the carbon atom of the methylene or methylidyne group, on the molecular conformation, and on the 2*p*, 3*d* orbital interaction. The proton-donating activities of certain GS and the formation of hydrogen bonds with electron donors and their kinetic acidity were investigated.

### 1. Thermodynamic Acidity and Stabilisation of Carbanions

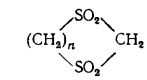
The reactivities of DS or TS as CH acids are determined by the ease of deprotonation (thermodynamic factor) and the rate of reaction of the carbanions formed (kinetic factor). Two extreme structures can be put forward for carbanions generated from DS–(A), where the charge is localised at the carbon atom, and (B), where the charge is fully delocalised over the sulphonyl groups:

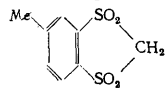
(A) (B)

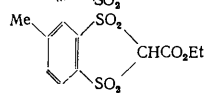
The nature of the $RSO_2$ substituents in the molecule of the initial CH acid and its geometry determine the degree of delocalisation of the charge in the carbanion. According to the molecular orbital perturbation theory, an increase in the degree of charge delocalisation entails a decrease of the energy of the highest occupied molecular orbital, an increase of the stability of the carbanion, a decrease of its nucleophilicity, and an increase of the acidity of the CH acid.

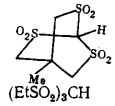
Titrimetric determination of the dissociation constants of DS have become part of the practical research routine after the introduction of electrochemical titration methods in non-aqueous media (potentiometry and conductimetry). Owing to the inadequate solubility in water of the majority of GS, the dissociation constants of many of them have been determined by potentiometric titration in organic solvents. The available literature data and the experimental acidity constants of DS in aqueous solutions are limited (Table 1).

Table 1. The acidity constants of DS ($H_2O$, 25 °C).









| Compound | $pK_a$ | Refs. |
|---|---|---|

The principal relations between the conformation, configuration, and stability of the α-sulphonyl carbanion have been formulated in Cram's well known monograph[105] on the basis of the conformations of the α-sulphonyl-carbanion calculated by the molecular orbital method[104] and also the analysis of the thermodynamic stabilities of

sulphones (Table 1) and certain phenols with the $SO_2R$ group.[100]

The acidity constants of GS have been determined by potentiometric titration in DMF [106,107] (Table 2). The $pK_a$ values (compounds 1–4 and 5–9, Table 2) are satisfactorily correlated with the $\sigma$ constants of the substituent ($\rho = 2.094$ and 2.557, $r = 0.995$ and 0.996, and $s = 0.192$ and 0.100 respectively).

Table 3. The acidity constants of substituted DS and TS (96% alcohol, 25 °C).[25]

| Me | $p$-$MeC_6H_4$ | −0.49 | — |
| Cl | $p$-$ClC_6H_4$ | −1.29 | 2.79 |
| Cl | $p$-$MeC_6H_4$ | −1.00 | — |

The character of the change in the acid properties of asymmetric DS when the hydrogen atom of the methylene group is substituted by a third electron-accepting group has been investigated[25] (Table 3) and the authors established that the electronic nature of the substituents in the $p$-position in the aromatic ring of the $SO_2Ar$ group has little influence on the acidity of the compound, while the introduction of a third electron-accepting substituent at the methylidyne carbon atom greatly increases it. In terms of their effect on the acidity of $MeSO_2CH(R)SO_2Ph$, the substituents at the α-carbon atom can be arranged in the sequence $CN \geq SO_2Ph \gg COPh > COOEt > CONH_2$. The acid properties of propenes with GSG (Table 4) have been studied in order to compare them with the acidity of DS containing electron-accepting substituents in the α-position (Table 3) and in order to elucidate the nature of the activating effect of the vinyl group with two electron-accepting substituents at the β-carbon atom.[75,76] The propenes (Table 4) are strong CH acids. The delocalisation of the charge and the stabilisation of the corresponding carbanions are achieved by virtue of the $-I$ effects of the arene- or alkane-sulphonyl groups and the $-M$ effect of other electron-accepting substituents.

The first quantitative study of the selective solvation of aliphatic DS by $^1H$ NMR in mixed aqueous binary systems (1,4-dioxan–$H_2O$, 1,3-dioxan–$H_2O$, and dimethoxyethane–$H_2O$) was carried out by Remerie and Engberts.[108]

## 2. The Proton-Donating Capacity and Kinetic Acidity

Studies carried out during the last decades have shown that the C–H groups polarised by strong electron-accepting substituents form hydrogen bonds (HB) as proton donors.

Table 5. Thermodynamic characteristics of the hydrogen bonds with DMSO, acetone, and pyridine.[109,110]

| No. | Compound | DMSO | | Acetone | | |
|---|---|---|---|---|---|---|
| | | $-\Delta H$, kJ mol$^{-1}$ | $-\Delta S$, J mol$^{-1}$K$^{-1}$ | $-\Delta H$, kJ mol$^{-1}$ | $-\Delta S$, J mol$^{-1}$K$^{-1}$ | $pK_a$ |
| 1 | $(PhSO_2)_2CH_2$ | 9.2 | 20.9 | 12.6* | 31.0* | 11.2 |
| 2 | $p$-$ClC_6H_4SO_2CH(COPh)SO_2Me$ | 13.8 | 23.0 | 10.5 | 20.9 | 4.77 |
| 3 | $PhSO_2CH(COPh)SO_2Me$ | 14.2 | 25.5 | 9.6 | 18.0 | 5.32 |
| 4 | $p$-$MeC_6H_4SO_2CH(COPh)SO_2Me$ | 12.6 | 21.3 | 10.0 | 21.3 | 5.81 |

| 7 | $p$-$CH_3C_6H_4SO_2CH(COOEt)SO_2Me$ | 10.9 | 19.2 | 10.5 | 22.2 | 6.36 |

*In pyridine.

The strength of the $R_nCH_{4-n}\ldots B$ bonds depends both on the nature and number of substituents R and on the electron-donating capacity of the base B. The proton donating capacity of bis(benzenesulphonyl)methane in the formation of HB with DMSO and pyridine and also of the trisubstituted methanes ($MeSO_2$) ($p$-$XC_6H_2SO_2$)CHR in similar reactions with acetone and DMSO has been studied by $^1H$ NMR in the series of GS.[110] It follows from the results presented in Table 5 that the enthalpy of the HB formed by the compounds investigated with DMSO is in the range 9.2–14.2 kJ mol$^{-1}$. The strength of the HB between trisubstituted methanes and DMSO is higher, in conformity with their more acid character, than for bis(benzenesulphonyl)methane. However, in the series of trisubstituted methanes there is no general relation between the quantities $K_a$ and $\Delta H$ embracing all the compounds investigated. The kinetics and thermodynamics of proton transfer from trisubstituted methane to γ-collidine have been investigated by $^1H$ NMR in $CD_2Cl_2$ by Pogorelyi et al.[111,112], while the kinetics of the proton exchange in the trisubstituted methane–triethylamine systems have been investigated by the same workers in Ref. 113. According to their data,[111] the proton transfer to γ-collidine is preceded by the formation of hydrogen-bonded complexes:

$$\geq CH + N \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} \geq CH \ldots N \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} \geq C^- \ldots HN^+ \diagup$$

The proton transfer is completed by the formation of an ion pair which does not dissociate in $CD_2Cl_2$ (having a low dielectric constant ε) and is a kinetically independent species. The results of calculations of the kinetic and thermodynamic characteristics are presented in Table 6.

According to Table 6, the activation energies for deprotonation $E_+$ are significantly smaller for all the compounds investigated than the values of $E_-$ characterising

the reverse process; this shows that the proton abstraction reaction is exothermic ($\Delta Q < 0$). The characteristics of the equilibrium ($\lg K$ and $\Delta Q$) vary in parallel with the equilibrium acidity ($pK_a$). The authors[111] believe that, since the degree of delocalisation of the free electron pair in the carbanion is high in the DS investigated, the transition state of the reaction is reactant-like according to Hammond's postulate, i.e. the degree of proton transfer in the transition state is low. The conjugation effect is therefore manifested mainly in the anion and not in the transition state of the deprotonation reaction of the CH acid, which induces an increase of $E_-$. The small change in $E_+$ in the series of compounds investigated is evidence for an insignificant difference in the effect of the substituents PhCO and COOEt on the polarity and strength of the C–H bond. On the other hand, in conformity with their mesomeric effects, these substituents affect significantly the protonation energy of the carbanion $E_-$. In the series of compounds with identical R, the substituents X also have a greater effect on $E_-$ than on $E_+$. Consequently substituents influence mainly the kinetic characteristics of the protonation of the carbanion and have a very weak effect on the rate of deprotonation of the acid. Analysis of the relations between $pK_a$, $E_+$, $E_-$, and $k_+$ (the kinetic acidity of $R_3CH$) or $k_-$ (the kinetic basicity of $R_3C^-$), carried out in the above study,[111] permits the conclusion that the equilibrium acidity of $R_3CH^-$ is determined mainly by the stability of the carbanion and depends to a much lesser extent on the strength and polarity of the C–H bonds.

Table 6. Thermodynamic and kinetic characteristics of the proton transfer from the DS $p$-$XC_6H_4SO_2CH(R)SO_2Me$ to $\gamma$-collidine.[111]

| No. | X | $pK_a$ (alcohol) | $\lg K^{293}$ | $-\Delta Q$, kJ mol$^{-1}$ | $-\Delta S$, J mol$^{-1}$K$^{-1}$ | $\lg k_+^{293}$ | $E_+$, kJ mol$^{-1}$ | $\lg A_+$ | $\lg k_-^{293}$ | $E_-$, kJ mol$^{-1}$ | $\lg A_-$ |
|---|---|---|---|---|---|---|---|---|---|---|---|
| 1 | PhCOCl | 4.77 | 2.8 | 52 | 120 | 3.8 | 22 | 8 | 1.0 | 74 | 14 |
| 2 | PhCOMe | 5.81 | 1.7 | 37 | 92 | 3.3 | 27 | 8 | 1.6 | 63 | 13 |
| 3 | COOEtCl | 5.24 | 1.9 | 32 | 76 | 5.7 | 18 | 9 | 3.8 | 51 | 13 |
| 4 | COOEtMe | 6.36 | 0.9 | 24 | 62 | 5.1 | 17 | 8 | 4.2 | 41 | 12 |

The observed relations were interpreted by the same workers[112] in terms of the Bell–Evans–Polanyi potential curves, which confirmed that there is no general relation between the thermodynamic or kinetic acidity and the strength of the HB with DMSO ($\Delta H$) in the series of trisubstituted methanes with GSG.

The experimental data obtained in the study of the kinetics of proton exchange in the $(MeSO_2)(p\text{-}XC_6H_4SO_2)CHR$–triethylamine (R = COPh or COOEt) systems by $^1H$ NMR in $CD_2Cl_2$ made it possible to establish the mechanism of the process.[113]

## V. REACTIVITY

The reactivities of the majority of GS are determined by the activating influence of the sulphonyl groups. DS and TS as well as certain higher alkanes activated by GSG as CH acids are involved in the chemical reactions as a rule in the form of the conjugated bases (carbanions), so that electrophilic substitution reactions are characteristic of the compounds enumerated above. The activation of the double bond in unsaturated GS is responsible for the ease of the nucleophilic substitution and addition reactions in the series of these compounds.

### 1. Electrophilic Substitution Reactions

(*a*) *Salts and complex formation.* Alkali metal salts are formed when DS are treated with the corresponding hydroxides or alkoxides:[12,52,114]

$$\underset{\text{(I)}}{} + MOH \rightarrow \underset{\text{(XXIII)}}{(RSO_2)_2\bar{C}HM^+} + H_2O\ ;$$

$$R = Alk, Ar;\ M = Li, Na, K, NH_4\ .$$

In the series of DS the second hydrogen atom of the methylene group is not substituted by a metal even when strong bases (BuLi) are used.[115] The silver salt of methanedisulphonyl fluoride was isolated after prolonged refluxing of the latter with silver oxide in anhydrous ether in the presence of a zeolite.[34] Bis(benzenesulphonyl)-methylmagnesium bromide has been obtained by the reaction of the corresponding DS with butenylmagnesium bromide in ether.[115] The salt-forming reaction between bis(benzenesulphonyl)methane and monoethanolamine has been investigated.[117]

Being stronger CH acids, trisulphones form salts with alkali metal or alkaline earth metal hydroxides, alkoxides, and carbonates[118] and also with organic bases.[119] The salts of tris(methanesulphonyl)methane with the $NH_4^+$, $Li^+$, $K^+$, $Rb^+$, $Cs^+$, and $Tl^+$ anions have been obtained for crystallographic analysis.[120] The salts $M[C(SO_2Et)_3]_2.6H_2O$ (M = $Mn^{2+}$, $Co^{2+}$, $Ni^{2+}$, $Zn^{2+}$, or $Cd^{2+}$) have been prepared by heating aqueous suspensions of the metal carbonate and the TS. The manganese and cobalt salts react with pyridine (Py) and phenanthroline (L) to form the complexes $M(Py)_2.[C(SO_2Et)_3]_2$ and $[ML]_3.[C(SO_2Et)_3]_2$.[121]

In order to investigate the reactivities of the metal cation–carbanion ion pairs, the complexes of the sodium salts of TS with 15-crown-5-ether and of the potassium salt of bis-(benzenesulphonyl)methane with 18-crown-6-ether were synthesised.[122] These complexes proved to be relatively unreactive; this can be explained by the formation of a close ion pair comprising the anion and a complex cation, which creates steric hindrance to attack by the electrophile. TS give rise to high yields of tetra-alkylammonium salts on interaction with tetra-alkylammonium halides in the $CH_2Cl_2$–$H_2O$ two phase system in the presence of alkali.[123]

(*b*) *Alkylation and sulphenylation.* The ion pair comprising aromatic and aliphatic DS $(RSO_2)_2CH^-M^+$ (XXIII) (M = alkali metal) is readily alkylated by alkyl halides to form mono- and di-alkyl derivatives:

$$\text{(XXIII)} \xrightarrow{R^1X} \underset{\text{(XIV)}}{(RSO_2)_2CHR^1}\ ;$$

$$\text{(XXIII)} \xrightarrow{2R^1X} (RSO_2)_2CR^1_2\ ;$$

$$R^1 = Alk;\ X = Cl, Br, I\ .$$

2,2-Bis(benzenesulphonyl)propane has been isolated after the alkylation of bis(benzenesulphonyl)methane with methyl iodide in absolute alcohol in the presence of sodium ethoxide:[52] the analogous reaction with benzyl chloride (THF–hexane, BuLi) yields the monoalkylation product.[115] The silver salts of methanedisulphonyl fluoride[34] and bis-(trifluoromethanesulphonyl)methane[32] react with one molecule of the alkylating agent, while cyclic trimethylene

trisulphone (X) reacts with alkyl iodides in an aqueous-alcoholic alkaline solution to form hexa-alkyl-substituted derivatives.[45,124]

Cyclic alkylation products, derivatives of cyclopentane, have been obtained by the reaction of the sodium salts of aromatic, aliphatic, and cyclic DS with dimethylvinylsulphonium bromide in anhydrous methanol:[125]

$$(XXIII) + CH_2{=}CH\overset{+}{S}Me_2Br^- \rightarrow \left|\begin{array}{l}SO_2R\\SO_2R\end{array}\right. \xrightarrow{HI} (RSO_2)_2CH(CH_2)_2I \ ;$$

57%

R = Me, Et, Ph or R, R = $-CH_2CH_2-$ .

When cyclopropanes are refluxed with hydriodic acid, 1,1-disubstituted 3-iodopropanes are formed. 1,1-Bis(benzenesulphonyl)cyclopropane reacts as the 1,3-dipolar ion:[126]

$$\left|\begin{array}{l}SO_2Ph\\SO_2Ph\end{array}\right. \rightarrow [\overset{+}{C}H_2CH_2\overline{C}(SO_2Ph)_2] \ ;$$

$$RXH + \left|\begin{array}{l}SO_2Ph\\SO_2Ph\end{array}\right. \xrightarrow{DMF} RXCH_2CH_2CH(SO_2Ph)_2 \rightarrow$$

$$\xrightarrow[NaH]{R^1Hal} RXCH_2CH_2C(R^1)(SO_2Ph)_2 \ ;$$

R = Ar, $R^1$ = Alk, X = S, O .

In the presence of sodium alkoxide, methylthiobis(methanesulphonyl)methane is alkylated by allyl bromide:[120]

$$(MeSO_2)_2CHSMe \xrightarrow[EtONa]{CH_2{=}CHCH_2Br} (MeSO_2)_2C(SMe)CH_2CH{=}CH_2 \ .$$

The alkylation of bis(benzenesulphonyl)methane by dienes in the presence of catalysts has been investigated.[127]

In the study of the reaction of phenylmethanesulphonyl fluoride with phenyl-lithium, Shirota et al.[128] isolated α-benzenesulphonyl-α-phenylmethanesulphonyltoluene, whose formation can be explained by the competition of two processes occurring in this reaction: nucleophilic substitution at the sulphur atom and metallation of the methylene group:

$$PhCH_2SO_2F \xrightarrow{PhLi} PhCH_2SO_2Ph + PhCHLiSO_2F \ ;$$

$$PhCH_2SO_2Ph \xrightarrow{PhLi} PhCHLiSO_2Ch \xrightarrow{PhCH_2SO_2F} PhCH_2SO_2CH(Ph)SO_2Ph.$$

Disulphones are readily alkylated by αβ-unsaturated compounds under the conditions of the Michael reaction. Aliphatic DS combine with two molecules of an αβ-unsaturated compound and aromatic DS combine with one such molecule.[54,129,130] γγ-Bis(arenesulphonyl)butyric and 4,4-bis(ethanesulphonyl)pimelic acid and many of their derivatives have been synthesised[129,130,131] by the reaction involving the addition of acrylonitrile to aromatic DS [129] and bis(ethanesulphonyl)methane.[130] The reactions of trimethylenetrisulphone (X) [132] and its derivatives[133] with acrylonitrile, ethyl acrylate, and 2-vinylbenzothiazole have been investigated. The alkylation of bis(benzenesulphonyl)-methane by the salt of a Mannich base, namely the hydrochloride of 1-dimethylamino-2-(2-thenoyl)ethane, which takes place with elimination of the amine, has been described.[134]

In contrast to DS, trisulphones are alkylated with difficulty, which can apparently be accounted for by the much lower nucleophilicity of their carbanions. The yield of 1,1,1-tris(methanesulphonyl)ethane in the reaction of the sodium salt of tris(methanesulphonyl)methane with methyl iodide is extremely low (3.6%).[120] The interaction of the silver salt of tris(benzenesulphonyl)methane with methyl iodide[118] and bromotris(methanesulphonyl)methane with methylmagnesium bromide[120] does not lead to methylation products. The products of the alkylation of TS are therefore obtained by alkylating alkyl- or aryl-thio-derivatives of DS or by sulphenylating alkylated DS with subsequent oxidation of the reaction products:[120]

$$\left.\begin{array}{l}(MeSO_2)_2CHSMe \xrightarrow{MeI}\\(MeSO_2)_2CHMe \xrightarrow{MeSSO_2Me}\end{array}\right] \rightarrow (MeSO_2)_2C(Me)SMe \rightarrow$$

$$\xrightarrow{H_2O_2} (MeSO_2)_3CMe.$$

An interesting method has been developed for the ethylation of TS with a high yield.[135] It has been observed that, after prolonged heating with ethyl orthoformate in the presence of acetic anhydride and $ZnCl_2$, TS give rise to the diethylacetals of 1,1,1-tris-sulphonylacetaldehydes, which are unstable and are rapidly cleaved to 1,1,1-tris-sulphonylpropanes and ethyl formate:

$$(RSO_2)_3CH \rightarrow [(RSO_2)_3CCH(OEt)_2] \rightarrow (RSO_2)_3CEt + HCOOEt \ ;$$

R = Alk, Ar .

A direct method for the arylation of the methyl group in DS has not been described. Monoaryl derivatives are usually synthesised in accordance with the scheme[29]

$$ArCHO + 2RSH \rightarrow ArCH(SR)_2 \xrightarrow[HAc]{H_2O_2} ArCH(SO_2R)_2 \ ;$$

R = Alk, Ar.

DS and TS are sulphenylated by sulphenyl halides or the thioesters of sulphinic acids in an alkaline medium and the reaction proceeds as a rule more readily (particularly in the series of TS) than alkylation, since sulphenylating agents are stronger electrophiles. The reactions of DS with the thioesters of sulphinic acid[120,136,137] and sulphenyl chlorides[118,120,136] and of the silver salt of methanedisulphonyl fluoride with pentafluorobenzenesulphenyl chloride[34] have been described:

$$(I) \xrightarrow[EtONa]{R^1SCl(R^1SSO_2R^2)} (RSO_2)_2CHSR^1 \ ;$$

(XXIV)

R = Me, Ph; $R^1$ = Me, $PhCH_2$, Ph; $R^2$ = Me, Ph, $(Ph)_2CH$.

DS can be alkane- and arene-sulphenylated in steps with formation of mono- and di-thio-derivatives.[120,137] TS are sulphenylated under the same conditions.[120]

The thioarylation[138] and selenoarylation[139] of bis(benzenesulphonyl)methane has been achieved in alkaline media by treatment with diaryl sulphide selenides (ArSSeAr) and diaryl diselenides (ArSeSeAr):

$$(PhSO_2)_2CH_2 + RC_6H_4XSeC_6H_4R \xrightarrow{EtONa} (PhSO_2)_2CHXC_6H_4R \ ;$$

R = H, *m*- or *p*-Me, *o*- or *p*-Cl, *m*- or *p*-$NO_2$, *p*-Br, *p*-MeO; X = S, Se.

The alkyl- and aryl-thiomethylation of aliphatic and aromatic DS by condensation with mercaptans and formaldehyde in alkaline media has been described:[140]

$$(I) + CH_2O + R^1SH \xrightarrow{NaOH} (RSO_2)_2CHCH_2SR^1 \ ;$$

R = n-Bu, Ph, cyclohexyl; $R^1$ = alkyl, aryl.

Bis(benzenesulphonyl)methane is more reactive in this reaction than its aliphatic analogue. When the merceptan is replaced by potassium hydrogen sulphide, 1,1,5,5-tetrasulphonyl-3-thiapentanes are formed:[141]

$$(I) \xrightarrow[dioxan,MeOH,H_2O]{CH_2O,KSH} [(RSO_2)_2CHCH_2]S_2 \ ;$$

20°, 12 h, R = alkyl, aryl.

The reaction of bis(methanesulphonyl)methane with carbon disulphide in DMSO in the presence of t-BuOK (20 °C, $N_2$) and subsequent methylation of the reaction product with methyl iodide lead to 1,1-bis(methanesulphonyl)-2,2-bis(methylthio)ethylene:[68]

$$(MeSO_2)_2CH_2 \xrightarrow[t\text{-}BuOK,\ DMSO]{1)CS_2\ 2)MeI} (MeSO_2)_2C{=}C(SMe)_2 \ .$$

The hydrolysis of mono- and di-mercapto-substituted DS in the presence of bases (NaOH, piperidine) and acids (HCl, $H_2SO_4$) proceeds with successive elimination of alkyl- or aryl-thio-groups. Sulphinic acids, diaryl and dimethyl thiocarbonates, thioesters of sulphinic acids, and dialkyl disulphides have been found among the reaction products:[142]

Tris(methanesulphonyl)methanes with a substituent at the carbon atom of the methylidyne group split off one $MeSO_2$ group on heating in an alkaline medium:[120]

$$(MeSO_2)_3CX \xrightarrow{H_2O,NaOH} (MeSO_2)_2CHX + MeSO_3Na\ ;$$
$$X = Me, Ph, MeS, NO_2\ .$$

The hydrolysis of substituted tris(methanesulphonyl)-methanes in the presence of organic bases has been investigated.[143]

(c) *Halogenation. Properties of halogeno-derivatives.* In aqueous alkaline media DS and TS are halogenated by freshly prepared hypohalites,[32,46,114,118,130,144,145] while in organic solvents ($CCl_4$–$CHCl_3$ mixture,[144] acetic acid[146]) they are halogenated by elemental halogens ($Cl_2$, $Br_2$). In a series of DS the ease of the halogenation reaction creates appreciable difficulties in the synthesis of the monohalides. They are obtained by treating the substrate in dilute aqueous alkaline solutions with an equimolar amount of a hypohalite[114,130] and by halogenating a DS salt with elemental halogen in an organic solvent.[32] The monohalides of DS have also been synthesised by halogenating the esters of bis(sulphonyl)acetic acids:[26]

$$\underset{(V)}{(RSO_2)_2CHCOOR^1} \xrightarrow{Hal_2} (RSO_2)_2CHalCOOR^1 \xrightarrow[-R^1OH]{H_2O} \rightarrow (RSO_2)_2CHalCOOH \xrightarrow[-CO_2]{} \underset{(XXV)}{(RSO_2)_2CHHal}\ ;$$
$$R = Alk, Ar; Hal = Cl, Br\ .$$

The halogenation of trimethylenetrisulphone (X) in aqueous alkaline media leads to the formation of hexahalogeno-derivatives.[124,147] Disulphones containing a third electron-accepting substituent ($NO_2$, COMe) at the α-carbon atom are readily hydrogenated by hypohalites,[29,148] but the acetyl group is not then eliminated.[148]

The silver salt of methanetrisulphonyl fluoride (XIII) is brominated and iodinated in Khladon 113 with formation of tris(fluorosulphonyl)halogenomethanes.[134] tris(Fluoro-sulphonyl)iodomethane is the first iodo-derivative of DS and TS described in the literature. Halogenation with hypo-halites in an aqueous alkaline medium is a very rapid process mainly owing to the high concentration of the electrophilic $Br^+$ species and the "carbanionic state" of the substrate. Halogenation in organic solvents with elemental halogens proceed much more slowly. Tris(ethanesulphonyl)methane is brominated in acetic acid much more slowly than its potassium salt;[146] the addition of water accelerates the process.

Certain monobromo-derivatives of DS can be synthesised by disproportionation into the dibromo-derivative of the DS and an unsubstituted compound.[145] Tribromotrimethylene-trisulphone has been obtained by the reaction of TTS hexa-bromide and the unsubstituted TTS.

The equilibrium in the disproportionation reaction of a mixture of $(RSO_2)_2CH_2$ and $(RSO_2)_2CHal_2$ with formation of $(RSO_2)_2CHHal$ (R = alkyl or aryl) has been investigated.[26] It is noted that the disproportionation is reversible and proceeds more readily for the bromo-derivatives than for the chloro-derivatives.

Bromination of bis(ethanesulphonyl)methane by hypo-bromite in an aqueous alkaline medium is a reversible process; the equilibrium at 20 °C is displaced towards the formation of the dibromo-derivative:[130]

$$\underset{10\%}{(EtSO_2)_2CH_2} \underset{OH^-}{\overset{KBrO}{\rightleftarrows}} \underset{30\%}{(EtSO_2)_2CHBr} \underset{OH^-}{\overset{KBrO}{\rightleftarrows}} \underset{60\%}{(EtSO_2)_2CBr_2}\ .$$

The properties of the DS and TS halides are determined by the character of the C–Hal bond in these compounds. By virtue of the strong electron-accepting effect of the sulphonyl groups on the polarisation of the C–Hal bond, the halogen atom becomes the positive end of a dipole, assumes a cationoid character, and is capable of breaking off in the form of a cation. The mono- and di-bromo-derivatives of DS are reduced by iodide ions and can be determined quantitatively by iodometric titration.[114,130,144] The chloro-derivatives of TS also have this property:[144]

$$\rangle C{-}Hal + 2NaI \xrightarrow[25°C]{MeCN} \rangle CNa + I_2 + NaHal\ ;$$
$$Hal = Br, Cl\ .$$

DS and TS bromides are brominating agents which brominate *NN*-dimethylaniline [144] and toluene (in the presence of $AlCl_3$).[32] Hexabromotrimethylenetrisulphone has analogous properties.[149] DS mono- and di-bromides and TS chlorides and bromides react with alkalis to form DS or TS salts and hypohalites.[29,114] The hexachloro- and hexabromo-deriva-tives of trimethylenetrisulphone and the trichloro- and tribromo-derivatives of tris(methylmethylene)trisulphone react with organic bases (pyridine, αα-bipyridyl, quinoline, piperidine, and morpholine) to form complexes having the composition $(CHal_2SO_2)_3.(Nu)_n$ and $(MeCHalSO_2)_3(Nu)_n$ (Nu = organic base, $n$ = 2, 3, 5),[150,151] which have the structure of quaternary ammonium salts according to the authors. The reaction of dibromobis(methanesulphonyl)-methane with copper powder is a radical process among the products of which tris(methanesulphonyl)methane was found.[152] The monohalogeno-derivatives of DS are stronger CH acids than the unsubstituted compounds, although the acidifying effect of chlorine and bromine is small.[26] They are alkylated by diazomethane [26] and in the presence of bases they react with alkyl halides and benzenesulphenyl chloride.[26] The monochloro-derivatives of aromatic DS react in an aqueous alkaline medium with arenediazonium salts to form bis(arenesulphonyl)arylazochloromethanes [114] and they combine with acrylonitrile.[152]

$$\underset{(XXVI)}{(ArSO_2)_2CHCl} \begin{cases} \xrightarrow{ArN_2^+} (ArSO_2)_2CClN{=}NAr\ ; \\ \xrightarrow{CH_2=CHCN} (ArSO_2)_2CClCH_2CH_2CN\ . \end{cases}$$

The bromine atom in bromobis(trifluoromethanesulphonyl)-methane (XXVI) is more mobile than the hydrogen atom of the methylidyne group and is involved in the Michael reaction with αβ-unsaturated compounds instead of the latter:[32]

$$\underset{(XXVI)}{(CF_3SO_2)_2CHBr} + CH_2{=}CHR \rightarrow (CF_3SO_2)_2CHCH_2CHBrR\ ;$$
$$R = CH_2CH_2Cl\ (70\%), CH_2COOH\ (50\%), C_6H_{13}\ (32\%)\ .$$

The interaction of the bromo-derivative (XXVI) with $Na_2CO_3$ at 150 °C leads to the formation of only the sodium salt of the initial CH acid instead of the expected 1,1,2,2-tetrakis-(trifluoromethanesulphonyl)ethylene (by analogy with the reaction of bromomalonic ester).[32]

(d) *Nitration.* As shown above (Section II), DS are not nitrated at the methylene group in sulphuric acid, since a reactive carbanion is absent from such a solution. In the

series of TS, which are stronger CH acids, the carbanionic character of the carbon atom of the methylidyne group is more pronounced and they can be nitrated by the usual nitrating mixture. The low nucleophilicity of TS is compensated by the strength of the electrophile (nitronium cation). Tris-(methanesulphonyl)nitromethane has been obtained in high yields by the nitration of tris(methanesulphonyl)methane (XI) (100 °C, 15 min):[120]

$$(XI) \xrightarrow{HNO_3,H_2SO_4} (MeSO_2)_3CNO_2 .$$

It has been shown that, in the nitration of mixed TS, the aromatic ring of the arenesulphonyl groups are first nitrated, while at elevated temperatures the methylidyne group is also nitrated:[154]

$$(4\text{-}RC_6H_4SO_2)_2CHSO_2Me \xrightarrow[20°C]{HNO_3,H_2SO_4} (4\text{-}R\text{-}3\text{-}O_2NC_6H_4SO_2)_2C(NO_2)SO_2Me \ (XXVII);$$
$$R=H, Me, Cl .$$

Disulphones with a strong electron-accepting substituent at the carbon atom of the methylidyne group have acidities similar to those of TS and are nitrated under analogous conditions:[154]

$$4\text{-}MeC_6H_4SO_2CH(CN)SO_2Me \xrightarrow{HNO_3,H_2SO_4} \rightarrow 4\text{-}Me\text{-}3\text{-}O_2NC_6H_4SO_2C(NO_2)(CN)SO_2Me \ (XXVIII) .$$

The nitromethanes (XXVII) and (XXVIII) undergo hydrolytic cleavage fairly readily. As a consequence of the steric hindrance arising as a result of the repulsion of the non-bonded oxygen atoms of the sulphonyl and nitro-groups, the loss of one of these groups reduces the free energy of the system. Furthermore, the presence of four strong electron-accepting substituents increases the electronegativity of the carbon atom in the molecules of compounds (XXVII) and (XXVIII), since in each of them the substituent is somewhat less electronegative than in compounds not containing additional electron-accepting groups. The least electronegative of the four substituents (in the given case the methanesulphonyl group) can therefore be subjected to nucleophilic attack and, after the elimination of this substituent, a carbanion, stabilised by the three strong electron-accepting substituents, is formed. Even on heating in 8% aqueous $NaHCO_3$ solution, compounds (XXVII) split off the methanesulphonyl group and their treatment with freshly prepared potassium hypobromite in addition to the bromination of the intermediate carbanion.[154] On reaction with KBrO, the nitromethanes (XXVIII) also split off the $MeSO_2$ group with subsequent bromination of arenesulphonylcyanonitromethane.[154]

Hydrolysis of tris(methanesulphonyl)nitromethane in the presence of alkali affords bis(methanesulphonyl)nitromethane,[29] which reacts with chlorine and bromine in an alkaline medium[29] and reacts with $Ag_2CO_3$ as a strong CH acid to form a silver salt, which reacts with methyl iodide to produce 1,1-bis(methanesulphonyl)-1-nitroethane.[153,155]

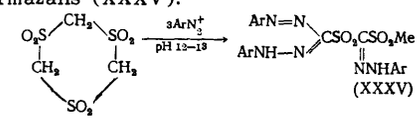
(*e*) *Reactions with arenediazonium salts* Disulphones with a free methylene group interact with arenediazonium salts in alkaline media (pH 8–13). Depending on the structure of the DS and the diazonium salt, the reaction conditions and the reactant ratio, the interaction can proceed with formation of one or several reaction products. In the first studies devoted to this reaction,[156,157] it was already shown that aromatic TS react with diazonium salts to form the azo-coupling product

$$(I) \xrightarrow{ArN_2} (RSO_2)_2CHN{=}NAr \rightleftarrows (RSO_2)_2C{=}NNHAr ;$$
$$(XXIX) \qquad (XXX)$$
$$R=Ph .$$

An unambiguous choice between the two possible structures (XXIX) and (XXX) was not made and it was shown only later that[158] the products of the coupling of DS and other methylene compounds to diazonium salts have the hydrazone structure (XXX). In his study of the reaction of bis-(benzenesulphonyl)methane with *p*-nitrobenzenediazonium tetrafluoroborate in a weakly alkaline medium (pH 8.2), Hunig[159] isolated three reaction products: *p*-nitrophenylhydrazone of bis(benzenesulphonyl)carbonyl (XXXI), *N*-benzenesulphonyl-*N'*-(*p*-nitrophenyl)diimide (XXXII), and 5-hydroxy-1,3-di(*p*-nitrophenyl)tetrazolium betaine (XXXII):

$$(I) \xrightarrow{p\text{-}O_2NC_6H_4N_2^+BF_4^-} (PhSO_2)_2C{=}NNHC_6H_4NO_2\text{-}p + (XXXI)$$
$$+ p\text{-}O_2NC_6H_4N{=}NSO_2Ph + p\text{-}O_2NC_6H_4{-}\overset{+}{N}{-}N$$
$$(XXXII) \qquad (XXXIII)$$

A mechanism of the formation of the betaines (XXXIII) has been proposed[159] on the hypothesis of a higher reactivity of the NH group of the hydrazone (XXXI) which is formed in the first stage and reacts with a second molecule of the diazonium salt to form the "*N*-azo-derivative" (XXXIV). The rapid hydrolysis of the arenesulphonyl groups in the product (XXXIV) and subsequent ring closure lead to the betaine (XXXIII):



$$(XXXI) \xrightarrow{p\text{-}NO_2C_6H_4N_2^+BF_4^-} \left[(PhSO_2)_2C{=}NNC_6H_4NO_2\text{-}p \ \big| \ N{=}NC_6H_4NO_2\text{-}p\right] \rightarrow (XXXIII) + 2PhSO_2^- \ (XXXIV);$$
$$PhSO_2^- + p\text{-}NO_2C_6H_4N_2^+BF_4^- \rightarrow (XXXII) .$$

Subsequently it was shown that aromatic DS form hydrazones in an alkaline medium (pH 8–13) in the presence of an equimolar reactant ratio, while the betaines (XXXIII) are formed under the same conditions when the reaction is carried out with a twofold excess of the diazonium salt containing electron-accepting substituents in the *p*- or *m*-position in the aromatic ring.[12,28,148,160,161] Aliphatic DS are more reactive in this reaction. The interaction of bis(ethanesulphonyl)methane with diazonium salts terminates at the hydrazone stage only when *o*-substituted salts are employed, while *m*- and *p*-substituted salts in both strongly alkaline (pH 11) and weakly alkaline (pH 8.2) media react with formation of betaines (XXXIII).[162] The reactions of arenesulphonyltrifluoromethanesulphonylmethanes with diazonium salts in a weakly alkaline medium (pH 8.3) lead to the formation of hydrazones.[30]

Trimethylenetrisulphone (TTS) reacts with diazonium salts in an alkaline medium (pH 9) to form the TTS trisarylhydrazone,[163] while in a neutral medium (pH 7) TTS bisarylhydrazones were obtained[164] whose structure was demonstrated by spectroscopic methods.[165]

Tris(methylmethylene)trisulphone (TMTS) gives rise to its bisarylazo-derivatives in an alkaline medium (pH 9–10).[166]

In a strongly alkaline medium (pH 12–13) TTS reacts with a threeefold excess of diazonium salts with the opening of the ring, the elimination of one $SO_2$ group, and the formation of formazans (XXXV):[167]

Disulphones with the methanesulphonyl group and electron-accepting substituents at the carbon atom of the methylidyne group (CN, COMe, COOEt) react in anhydrous

DMF,[168] in a weakly alkaline (pH 8.2) aqueous alcoholic medium,[169] or in the form of sodium salts in aqueous solution[170] with diazonium salts containing electron-accepting substituents to form arylazo-derivatives. The elimination of $MeSO_2$ and MeCO groups is not observed under these conditions:

$$ArSO_2CH(R)SO_2Me \xrightarrow{R^1C_6H_4N_2^+} ArSO_2C(R)(SO_2Me)(N{=}NC_6H_4R^1);$$
$$R = CN, COMe, COOEt;\ R^1 = o\text{-}, m\text{-}, p\text{-}Cl, Br, NO_2 .$$

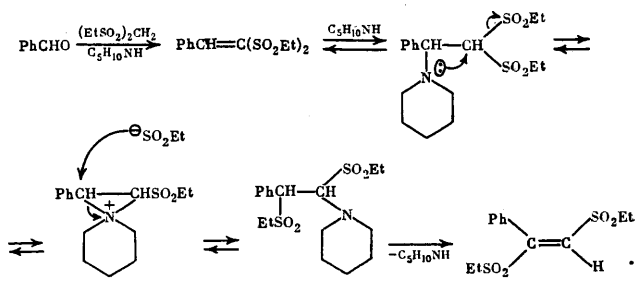
Trisulphones with the methanesulphonyl group interact in an aqueous alkaline medium (pH 8–9) or in anhydrous DMF with diazonium salts containing electron-accepting substituents in the *o*- and *p*-position, forming arenediazonium trisulphonylmethanides $ArN_2^+\,\bar{C}(SO_2R)_3$. On decomposition, the latter give rise to sulphonylazo-compounds of type (XXXII) together with arylhydrazones of type (XXXI) (in DMF) or betaines of type (XXXIII) (in an aqueous alkaline medium).[170]

In their reaction with tris(fluorosulphonyl)methane in water, arenediazonium chloride exchange the anion with formation of water-insoluble arenediazonium tris(fluorosulphonyl)methanides. The decomposition of the latter on heating leads to the *aci*-forms of the aryl esters of tris(fluorosulphonyl)methane:

$$RC_6H_4N_2^+Cl^- + HC(SO_2F)_3 \xrightarrow{H_2O} RC_6H_4N_2^+C^-(SO_2F)_3 \xrightarrow[-N_2]{80-120^\circ C} RC_6H_4OS(F){=}O{=}C(SO_2F)_2;$$
(XIII)
$$R = H, p\text{-}, m\text{-}F, p\text{-}NO_2 .$$

The structure of the latter has been confirmed by chemical reactions, spectroscopic methods (IR, $^1H$ NMR, and $^{19}F$ NMR), and X-ray diffraction analysis.[171] This is the first example of the arylation of the $SO_2$ group by diazonium salts described in the literature.

(*f*) *Arylcarbamoylation and arylthiocarbamoylation.* The interaction of aromatic DS with aryl isocyanates and allyl isothiocyanates was first described in 1966.[172] The potassium salts of DS in anhydrous acetonitrile form salt-like adducts, which are converted, after acidification, into the arylamides of bis-sulphonyl-substituted acetic and thioacetic acids:[172,173]



$$(ArSO_2)_2CHK \xrightarrow[MeCN,\,70-80^\circ C]{Ar^1NCX} (ArSO_2)_2CHC(XK){=}NAr^1 \xrightarrow{HCl} (ArSO_2)_2CHC(X){=}NHAr^1;$$
(XXIII)
$$X = O, S .$$

The reactions of aromatic DS with aryl isothiocyanates were later achieved in absolute alcohol in the presence of sodium ethoxide.[148,174] A novel method for the introduction of arylthio-, heteroarylthio-, and arylalkylthio-carbamoyl groups into the molecule of an aromatic DS has been developed on the basis of the reaction of active methylene groups with the methyl esters of substituted dithiocarbamic acids:[175–178]

$$RNHCSSMe + (ArSO_2)_2CH_2 \xrightarrow[EtOH]{EtONa} (ArSO_2)_2CHCSNHR;$$
$$R = Ar, 2\text{-pyridyl}, PhCH_2 .$$

This method and also the oxidative cyclisation of the arylamides of bis(arenesulphonyl)thioacetic acid by potassium hexacyanoferrate(II) in an aqueous alkaline medium[179] or by bromine in acetic acid[179] made it possible to obtain substituted heterocyclic compounds of the pyridine and benzothiazole series containing GSG in the side chain.

(*g*) *Interaction with aldehydes.* The pyridine-catalysed condensation of bis(ethanesulphonyl)methane with benzaldehyde is accompanied by a stereospecific intermolecular rearrangement with formation of *E*-αβ-bis(ethanesulphonyl)styrene [62] instead of the expected ββ-bis(ethanesulphonyl)styrene, the formation of which in this reaction had been erroneously reported earlier:[180,181]

As mentioned above (Section II), aromatic DS react with aldehydes to form 1,1,2-trisubstituted ethylenes; the interaction with aliphatic aldehydes is then frequently accompanied by the isomerisation of the final product owing to the prototropic allylic rearrangement.[60] In the condensation of bis(benzenesulphonyl)methane with isobutyraldehyde, the yields of the normal and isomerised reaction products were the same.[182] The condensation with other aliphatic aldehydes affords only isomerisation products:[182]

$$(PhSO_2)_2CH_2 \xrightarrow{\text{iso-PrCHO}} (PhSO_2)_2C{=}CHPr\text{-iso} + (PhSO_2)_2CHCH{=}CMe_2$$
$$50\% \qquad 50\%$$
$$\xrightarrow{RCH_2CHO} (PhSO_2)_2CHCH{=}CHR;$$
$$R = Et, Pr .$$

The reaction of DS with furfural yields the expected products—furfurylidenebis(sulphonyl)methanes, but under these conditions bis(benzenesulphonyl)methane and butyraldehyde react to form only the isomerisation product—1,1-bis(benzenesulphonyl)pent-2-ene.[183] Methanedisulphonyl fluoride reacts with *p*-dimethylaminobenzaldehyde in acetic anhydride to form ββ-difluorosulphonyl)-*p*-dimethylaminostyrene.[33] The condensation of DS with formaldehyde in the presence of bases leads to asymmetrically substituted propane with GSG at the terminal carbon atom.[55,57–59] Only the use of a large excess of piperidine and pyrrolidine makes it possible to carry out the Mannich reaction involving DS and to isolate the corresponding bases:[60,61]

$$(I) + CH_2O + HN\langle\rangle \rightarrow (RSO_2)_2CHCH_2N\langle\rangle$$

(*h*) *Reactions with mercury salts.* Organomercury compounds and mercury salts react with DS as electrophiles. Bis(benzenesulphonyl)methane and 1,1-bis(benzenesulphonyl)ethane reacts with *p*-dimethylaminophenylmercury hydroxide to form mercury derivatives of DS which are resistant to spontaneous disproportionation:[184]

$$p\text{-}Me_2NC_6H_4HgOH + (PhSO_2)_2CH_2 \rightarrow (PhSO_2)_2CHHgC_6H_4NMe_2\text{-}p .$$

The interaction with bis(arenesulphonyl)methanes with mercury diacetate affords mono- and di-mercurated products depending on the conditions:[185]

$$(p\text{-}RC_6H_4SO_2)_2CH_2 \xrightarrow{Hg(Ac)_2} \begin{cases} \rightarrow (p\text{-}RC_6H_4SO_2)_2CHHgAc; \\ \quad (XXXVI) \\ \rightarrow (p\text{-}RC_6H_4SO_2)_2C(HgAc)_2; \end{cases}$$
$$R = H, Me, Cl, NO_2 .$$

Bis(arenesulphonyl)methylmercury halides are formed when the potassium salts of bis(arenesulphonyl)methanes or mercuriacetates (XXXVI) interact with mercury or potassium halides respectively:

$$(p\text{-}RC_6H_4SO_2)_2CHK \xrightarrow{HgX_2} (p\text{-}RC_6H_4SO_2)_2CHHgX\ ;$$
$$(XXXVI) \xrightarrow{KX} (XXXVII)$$
$$R=H, Me;\ X=Cl, Br, I\ .$$

The C–H bond in the series of DS is readily cleared by nucleophiles ($Na_2S$) but is comparatively resistant to attack by electrophiles: only prolonged reaction with bromine or hydrogen chloride leads to its cleavage.[185]

The study of the chemical properties and IR spectra of mercurated derivatives[185] established that the C–Hg bond is covalent, is appreciably polarised, and its character is close to that of the C–Br bond in the mono- and di-bromo-derivatives of DS.

(*i*) *Reactions with formation of ylides.* Disulphones are capable of acid-base interactions with phosphines. Tertiary phosphines react with fluorinated DS to form tertiary phosphonium salts. As a result of protonation at the nitrogen atom, aminophosphines form salts which are then converted into the dialkylammonium salts of α-phosphino-substituted DS (XXXVIII):[186]

$$RSO_2CH_2SO_2CF_3 \xrightarrow{R^1_3P} R^1_3P{-}{-}{-}HCH(SO_2R)(SO_2CF_3) \rightleftarrows R^1_3\overset{+}{P}H\ \bar{C}H(SO_2R)(SO_2CF_3)\ ;$$
$$RSO_2CH_2SO_2CF_3 \xrightarrow{R^2_2PNEt_2} R^2_2\overset{+}{P}NHEt_2\ \bar{C}H(SO_2R)(SO_2CF_3) \longrightarrow$$
$$\longrightarrow R^2_2PCH(SO_2R)SO_2CF_3 + HNEt_2 \longrightarrow \underset{(XXXVIII)}{R^2_2P\bar{C}(SO_2R)SO_2CF_3\ H_2\overset{+}{N}Et_2}\ ;$$
$$R=Ph, CF_3;\ R^1=Et;\ R^2=Ph\ .$$

The salts (XXXVIII) are alkylated (with transfer of the reaction centre) at the phosphorus atom with formation of phosphorus ylides.[186]

Halogenophosphoranes react with aromatic DS in the presence of triethylamine to form phosphonium ylides with the halogen atom at the phosphorus atom—*P*-halogenoylides (XXXIX):[187]

$$Ph_nPHal_{5-n} + CH_2(SO_2Ph)_2 \xrightarrow{2NEt_3} \underset{(XXXIX)}{Ph_nPHal_{3-n}{=}C(SO_2Ph)_2}\ ;$$
$$n=2, 4;\ Hal=Cl, Br\ .$$

*P*-Halogenoylides (XXXIX) have also been obtained by treating with carbon tetrahalides the products of the reaction of tervalent phosphorus halides with bis(benzenesulphonyl)methane:[188,189]

$$R_2PCl + CH_2(SO_2Ph)_2 \xrightarrow{NEt_3} R_2P{-}CH(SO_2Ph)_2 \xrightarrow{CHal_4}$$
$$\rightarrow \underset{Hal\ \ldots\ CHal_3}{R_2\overset{\delta+}{P}{-}CH(SO_2Ph)_2} \rightarrow \underset{(XXXIX)}{R_2P(Hal){=}C(SO_2Ph)_2} + CHHal_3\ .$$

Another method of synthesis of the ylides (XXXIX) involves the interaction of chloro- or bromo-bis(benzenesulphonyl)-methanes with chlorodiphenylphosphine in the presence of triethylamine.[190] *P*-Halogenoylides with GSG virtually lack basicity. They do not interact with hydrogen chloride and do not enter into the Wittig reaction with carbonyl compounds. The halogen atom in the ylides (XXXIX) readily undergoes nucleophilic substitution:

$$(XXXIX) \xrightarrow{R^1ONa} \underset{R^1=Me, Ph}{R_2P(OR^1){=}C(SO_2Ph)_2}\ ;$$
$$(XXXIX) \xrightarrow[Et_3N]{H_2O} \underset{(XL)}{R_2P(O)CH(SO_2Ph)_2}\ ;$$
$$(XXXIX) \xrightarrow{2RR^1NH} \underset{R=R^1=H, Alk;\ R=H, R^1=Alk}{R_2P(NR^1_2){=}C(SO_2Ph)_2}\ ;$$
$$(XXXIX) \xrightarrow[Et_3N]{EtSH} R_2P(SEt){=}C(SO_2Ph)_2\ .$$

The strong electron-accepting effect of the two benzenesulphonyl groups in the phosphine oxide (XL) determines the high acidity of the compound ($pK_a = 3.27$ in 95% alcohol), as a result of which reactions involving the oxygen of the phosphoryl group are typical of this compound.[191] The same effect is responsible for the occurrence of the phosphine oxide–hydroxy-ylide tautomerism of these compounds and for the possibility of the existence of phosphonium ylides with the OH group at the phosphorus atom:[192]

$$(XL) \xrightarrow{CH_2N_2(MeI)} Ph_2P(OMe){=}C(SO_2Ph)_2\ ;$$
$$Ph_2\underset{\underset{O}{\|}}{P}{-}CH(SO_2C_6H_4P\text{-}p)_2 \rightleftarrows Ph_2P{=}\underset{\underset{OH}{|}}{C}(SO_2C_6H_4R\text{-}p)_2\ ;$$
$$R=Cl, H, Me, MeO\ .$$

The stable dimethylsulphonium di(fluorosulphonyl)-methylide has been obtained from methanedisulphonyl fluoride in DMSO in the presence of acetic anhydride.[33] When compound (VII) is acted upon by diacetoxyiodobenzene or the corresponding *m*-nitro-derivative, iodine ylides are formed:[33]

$$\underset{(VII)}{CH_2(SO_2F)_2} \xrightarrow[Ac_2O,\ 12\ h,\ 20\ ^\circ C]{Me_2S{=}O} Me_2S{=}C(SO_2F)_2\ ;$$
$$\underset{(VII)}{CH_2(SO_2F)_2} \xrightarrow{RC_6H_4I(OAc)_2} RC_6H_4I{=}C(SO_2F)_2\ ;$$
$$R=H, m\text{-}NO_2$$

(*j*) *Other reactions.* α-Diazo-β-disulphones (XLI) have been obtained by the interaction of tosyl azide with DS in an aqueous alcoholic medium in the presence of a base:[193]

$$(I) \xrightarrow[NaOH]{TsN_3} \underset{(XLI)}{(RSO_2)_2CN_2}\ ;$$
$$R=Ph, 2,4\text{-}Me_2C_6H_3, 2,4,6\text{-}Me_3C_6H_2\ .$$

The coupling reaction between compounds (XLI) and the carbanions of CH acids proceeds with elimination of one arenesulphonyl group.[193] Thermal decomposition of compounds (XLI) and its mechanism have been investigated.[193,194]

Bis(methanesulphonyl)nitromethane reacts with diazomethane to form the *N*-oxide (XLII) and the reaction proceeds via oxathiazole oxide as an intermediate:[119]

$$(MeSO_2)CHNO_2 \xrightarrow{CH_2N_2} (MeSO_2)_2CH{-}\overset{\overset{O}{\uparrow}}{N}{-}{-}O{-}N \xrightarrow{-N_2} \underset{(XLII)}{(MeSO_2)_2CH{-}N\!\!<^{CH_2}_{O}}\ .$$

The final product (XLII) is readily converted to isonitroso-bis(methanesulphonyl)methane (XLIII):

$$(XLII) \xrightarrow[-CH_2O]{H_2O} (MeSO_2)_2CHNO \rightleftarrows \underset{(XLIII)}{(MeSO_2)_2C{=}NOH}\ .$$

The isonitroso-compounds (XLIII) form salts with piperidine and hydrazine and are readily alkylated by dimethyl sulphate and acylated by acetic anhydride with formation of bis-(methanesulphonyl)-methoxyiminomethane or -acetoxyimino-methane.[119] Compound (XLIII) is unstable and it has been suggested that it decomposes via a radical mechanism.[195] On reaction of the isonitrosomethane (XLIII) with diazomethane under anhydrous conditions, 1-hydroxy-2,2-bis-(methanesulphonyl)aziridine was isolated:[196]

$$(XLIII) \xrightarrow[-N_2]{CH_2N_2} (MeSO_2)_2C{-}NOH\ (\text{with } CH_2 \text{ bridge})\ .$$

The synthesis and oxidation of *NN*-bis(arenesulphonyl)-hydroxylamines have been described.[197]

The possibility of using the thiosulphonates $(RSO_2)_2.CHSSO_2R$ for the sulphenylation of aliphatic ketones and other compounds with an active methylene group in an alkaline medium has been reported.[198]

## 2. Chemical Properties of Unsaturated GS

(*a*) *1,1-Bis(arenesulphonyl)ethylenes.* The strong polarisation of the double bonds in 1,1-bis(arenesulphonyl)-ethylenes, caused by the overall electron-accepting effect of the two sulphonyl groups, lowers appreciably the π-electron density at the β-carbon atom, which facilitates the attack by the nucleophile and makes nucleophilic addition reaction characteristic of the given series of compounds. Highly basic nucleophiles promote (particularly in protic media) the competing double bond dissociation reaction. These factors are responsible for the wide variety of the chemical properties of 1,1-bis(arenesulphonyl)ethylenes.

The acid- and base-catalysed addition of water to 1,1-bis-(arenesulphonyl)ethylenes [57] does in fact lead to the formation of 1,1,3,3-tetrakis(arenesulphonyl)propanes (XVII).[57–60,199] A mechanism has been proposed for this reaction:[57]

$$\underset{\text{(XVIII)}}{(RSO_2)_2C{=}CH_2} \underset{}{\overset{H_2O}{\rightleftarrows}} \underset{\text{(C)}}{(RSO_2)_2CHCH_2OH} \rightleftarrows \underset{\text{(D)}}{(RSO_2)_2\bar{C}H} + CH_2O + H^+ ;$$

$$\text{(C)} \overset{H^+}{\rightleftarrows} (RSO_2)_2\overset{+}{C}HCH_2\overset{+}{O}H_2 \xrightarrow[-H_2O]{(D)} \underset{\text{(XVII)}}{[(RSO_2)_2CH]_2CH_2} ;$$

R = Ar .

The C–C bond in compounds (C) is appreciably polarised under the influence of the two arenesulphonyl groups and is capable of hydrolytic cleavage by bases or acids. The formation of the carbanion (D) is apparently the rate-limiting stage in the overall reaction. The final products can be formed both via the pathway indicated in the scheme and via the interaction of the initial olefin with the anion (D). In ahydrous $CCl_4$ the olefin (XVIII) combines with aromatic and heterocyclic thiols, while in the presence of acetic acid it can combine with sulphinates.[57] They are active acceptors in the Michael reaction and in the presence of $F^-$ they readily combine with DS, TS, nitromethane, and arenesulphonylacetonitrile.[57] It has been shown that the reactions of the olefin (XVIII) with TS are also catalysed by a Lewis acid ($BF_3$ etherate),[56] while the interaction with β-diketones (acetylacetone and dibenzoylmethane) proceeds in dioxan in the presence of Triton B (200). ββ-Bis(benzenesulphonyl)styrene combines with malonic ester.[64] The use of 1,1-bis(benzenesulphonyl)ethylene as the dienophile in cycloaddition reactions with cyclopentadiene, cyclohexa-1,3-diene, cycloheptatriene, and other dienes has been described recently.[61] The study of the reactions of 1,1-bis(benzenesulphonyl)ethylene with various amines showed that, depending on the basicity of the amine, the reaction proceeds via two pathways: with formation of adducts (XLIV) or substituted propanes (XVII):[199]

$$(PhSO_2)_2C{=}CH_2 \begin{cases} \xrightarrow{\text{amines } (pK_a\ 1.0\text{–}6.9)} \underset{\text{(XLIV)}}{(PhSO_2)_2CHCH_2NHR} ; \\ \xrightarrow{\text{amines } pK_a\ 9.3\text{–}11.2)} \underset{\text{(XVII)}}{} . \end{cases}$$

A mechanism has been proposed[199] for the reaction of 1,1-bis(benzenesulphonyl)ethylene with highly basic amines:

$$\underset{\text{(XVIII)}}{(PhSO_2)_2C{=}CH_2} \xrightarrow{RNH_2} \text{(XLIV)} \rightleftarrows$$

$$\rightleftarrows (PhSO_2)_2\bar{C}H + [CH_2 \cdots NHR]^+ \xrightarrow{RNH_2} CH_2(NHR)_2$$
$$\downarrow (PhSO_2)_2C{=}CH_2 \qquad (PhSO_2)_2\bar{C}H \downarrow$$
$$(PhSO_2)_2\bar{C}CH_2CH(SO_2Ph)_2 \xrightarrow{H^+} \text{(XVII)} .$$

The rate of heterolysis of the C–C bond in the amine (XLIV) exceed the rate of its formation, as a result of which the DS carbanion can react with both the initial olefin and with the second heterolysis product—the aminal (the nitrogen-containing derivative of formaldehyde), to form the propanes (XVII). The olefins (XVIII) interact with electrophiles only with difficulty. They combine with bromine in acetic acid on heating. Mercury acetate undergoes the Hofmann–Sand reaction with two ethylene molecules and the addition takes place contrary to the Markovnikov rule:[57]

$$(PhSO_2)_2C{=}CH_2 \xrightarrow{Hg(OAc)_2MeOH} [MeOCH_2C(SO_2Ph)_2]_2Hg .$$

ββ-Bis(benzenesulphonyl)styrene reacts with diazomethane to give a substituted pyrazoline, which is converted into 1,1-bis(benzenesulphonyl)-3-phenylprop-3-ene on heating:[64]

$$(PhSO_2)_2C{=}CHPh \xrightarrow{CH_2N_2} (PhSO_2)_2C(\text{—}N{=}N\text{—}CH_2\text{—})CHPh \rightarrow (PhSO_2)_2CHCH{=}CHPh .$$

A thermal stereospecific rearrangement catalysed by ammonium salts has been discovered for the olefins (XVIII). On heating (138–139 °C) in *p*- or *m*-xylene in the presence of catalytic amounts of ammonium salts, the *gem*-substituted olefins (XVIII) rearrange to *E*-1,2-bis(arenesulphonyl)-ethylenes:[201]

$$\text{(XVIII)} \xrightarrow[\text{ammonium salts}]{\Delta} p\text{-}RC_6H_4SO_2\text{—}C(H){=}C(H)\text{—}SO_2C_6H_4R\text{-}p ;$$

R = H, Me, Cl .

A rearrangement in the opposite direction has been observed in the nucleophilic vinyl substitution reaction when 1,2-bis-[alkane(or arene)sulphonyl]-1,2-dichloroethylenes are treated with amines:[202]

$$RSO_2C(Cl){=}C(Cl)SO_2R \xrightarrow{R^1NH_2} (RSO_2)_2C{=}C(NR^1)_2 ;$$

$R = Et, C_8H_{17}, Ph; R^1 = Ph, p\text{-}HOC_6H_4, p\text{-}NO_2C_6H_4$ .

(*b*) *Polysulphonylethylenes.* The presence of four electron-accepting groups in the molecules of tetrasulphonylethylenes (TSE) (XLV) entails a high reactivity of these compounds. In aqueous solutions the TSE are hydrolysed with dissociation of the C=C bond[203] and the formation of disulphonylmethanes. This process proceeds readily in neutral, acid, and basic media. The mechanism of the hydrolysis of TSE [203] is based on a detailed study of the kinetics of the hydrolytic reactions of asymmetric olefins activated by several electron-accepting groups:[204,205]

$$(RSO_2)_2C{=}C(SO_2R)_2 \underset{}{\overset{H_2O}{\rightleftarrows}} (RSO_2)_2C(OH)\text{—}\bar{C}(SO_2R)_2 \overset{H^+}{\rightleftarrows}$$

$$\rightleftarrows (RSO_2)_2C(OH)CH(SO_2R_2) \rightarrow \text{(I)} + [(RSO_2)_2C{=}O] \xrightarrow{H_2O_2} RSO_3H + CO_2 ;$$

R = Et, *n*-Bu .

The extremely ready fragmentation of TSE is the reason why their synthesis is possible only under anhydrous conditions.[74] Alcohols which react readily with TSE do not form fragmentation products. In the presence of urea, the reactions of TSE with alcohols lead to the esters of bis(alkanesulphonyl)acetic acids:[203]

$$\text{(XLV)} \xrightarrow{R^1OH} [(RSO_2)_2C{=}C(OR^1)SO_2R] \xrightarrow{R^1OH} (RSO_2)_2C{=}C(OR^1)_2 + 2RSO_3H ;$$
$$\downarrow H_2O \qquad\qquad (RSO_2)_2CHCOOR^1 \xleftarrow{H_2O} \downarrow$$

$R = Et, R^1 = Me, Et$ .

The ideas concerning the course of the interaction of TSE with alcohols have been confirmed by a study of the reactions of TSE with thiols, where the intermediate thioacetals and their dioxides proved to be stable:[203]

$$(XLV) \xrightarrow{R^1SH} (RSO_2)_2C{=}C(SO_2R)(SR^1) + (RSO_2)_2C{=}C(SR^1)_2 ;$$
(XLVI)
R = Et, *n*-Bu, $R^1$ = Et, Ph .

Thioacetal *SS*-dioxides readily hydrolyse with the elimination of the $SO_2R$ group:

$$(XLVI) \xrightarrow{H_2O} (RSO_2)_2CHCOSR^1 \rightleftarrows (RSO_2)_2C{=}C(OH)SR^1$$
(XLVII) (XLVIII) .

According to IR spectroscopic data, the hydrolysis products exist both in the form of the esters (XLVII, R = n-Bu, $R^1$ = Et) and in the enolic form (XLIII, R = Et, $R^1$ = Ph).

The reactions of TSE with secondary or bulky primary amines take place with formation of bis(sulphonyl)acetamides—the products of the hydrolysis of the unstable 1,1,2-tris-(sulphonyl)-2-(R-amino)methylenes.[206] A mechanism has been proposed for the reactions with amines on the basis of the $Ad_N - E$ nucleophilic substitution mechanism for other electrophilic olefins.[207,208]

Together with the formation of disulphonylacetamides, primary amines give rise to the formation in this reaction of 1,1-bis[alkane(or arene)sulphonyl]-2,2-bis[alkyl(or aryl)amino]ethylenes—the products of the substitution of two sulphonyl groups.[206] Fragmentation has been observed only when highly basic amines were employed, bis-sulphonyl)methanes being apparently formed as a result of the competitive cleavage of the TSE by the amines.

(c) *2,2-Bis(alkanesulphonyl)- and 2,2-bis(arenesulphonyl)-vinyl ethyl ethers.* The different electronic natures of the substituents at C(1) and C(2) in these compounds are responsible for their unusual chemical behaviour. In contrast to unsubstituted ethyl vinyl ethers, 2,2-bis-(sulphonyl)vinyl ethers (VE) do not react with alcohols and do not form acylals on reaction with acetic acid. Addition reactions are not characteristic of these compounds. 2,2-Bis(benzenesulphonyl)vinyl ethyl ether forms a complex mixture of products on heating with bromine in $CCl_4$, from which bis(benzenesulphonyl)bromomethane was isolated (10%).[65] Like TSE, the VE hydrolyse in acid and alkaline media with rupture of the double bond and the formation of bis(arenesulphonyl)methanes.[65] VE react with ammonia to form 2,2-bis[alkane(or arene)sulphonyl]-vinylamines.[62,64,65] The latter are acylated by benzoyl chloride, react with ethyl and phenyl isocyanates to form substituted ureas, react with tosyl chloride (in the presence of BuLi),[62,65] and are reduced by sodium tetrahydroborate to 1,1-bis(alkanesulphonyl)- or 1,1-bis(arenesulphonyl)-ethanes.[58]

2,2-Bis(arenesulphonyl)vinylamines have also been synthesised from the sodium salts of bis(arenesulphonyl)-methanes, DMF, and dimethyl sulphate[58] or by the reaction of bis(arenesulphonyl)methanes with bis(trimethylsilyl)-formamide:[209]

$$(p\text{-}RC_6H_4SO_2)_2CH_2 \xrightarrow[HCON(SiMe_3)_2,\ 120°-140°C]{Me_2SO_4DMF} (p\text{-}RC_6H_4SO_2)_2C{=}CHNH_2 ;$$
R=H, $CH_3$, Cl .

2,2-Bis(toluene-*p*-sulphonyl)vinylamine reacts with phenyl isothiocyanate in the presence of triethylamine to form *N*-[2,2-bis(toluene-*p*-sulphonyl)vinyl]aniline and not a substituted thiourea as was expected:[210]

$$(p\text{-}MeC_6H_4SO_2)_2C{=}CHNH_2 \xrightarrow[Et_3N,120-140°C]{PhNCS} [(p\text{-}MeC_6H_4SO_2)_2C{=}CHNHCSNHPh] \xrightarrow{Et_3N} \rightarrow (p\text{-}MeC_6H_4SO_2)_2C{=}CHNHPh + (Et_3NH)^+SCN^- .$$

Ethyl vinyl ethers containing alkanesulphonyl groups (XLIX) react with aromatic[130] and aliphatic (primary and secondary) amines[62] in the presence of TsOH to form substituted vinylamines:

$$(RSO_2)_2C{=}CHOEt \xrightarrow[TsOH]{R^1R^2NH} (RSO_2)_2C{=}CHNR^1R^2 ;$$
(XLIX)
R = Me, Et; $R^1$ = Ph, $R^2$ = H or $R^1$, $R^2$ = Alk .

The same reaction of VE containing arenesulphonyl groups is accompanied by a competing process—the dissociation of the double bond, which greatly reduces the yield of the required products.[65] Ethyl vinyl ethers (L) react with dihydroresorcinol,[64] 2,4-dinitrophenylhydrazine,[65] and hydroxylamine[62] to form substitution products. Alkaline hydrolysis of the VE (L) at the interface between two phases leads to acetaldehyde with GSG:[64]

$$(ArSO_2)_2C{=}CHOEt \xrightarrow[CHCl_3]{KOH} (ArSO_2)_2CHCHO ;$$
(L)
Ar = Ph .

Nucleophilic substitution of the OEt group in the VE (L) by the carbanions of CH acids results in the formation of 1,1,3,3-tetrasubstituted propenes:[64,75]

$$(ArSO_2)_2C{=}CHOEt \xrightarrow[EtONa/EtOH]{R^1CH_2COOEt} (ArSO_2)_2C{=}CHCH(R^1)COOEt ;$$
$R^1$ = COMe, CN.

(d) *Polysulphonylpropenes.* Propenes with GSG at C(1) or C(3), containing simultaneously two other electron-accepting substituents at the terminal carbon atoms [C(3) and C(1) respectively] have been described.[64,75,76] In solution these compounds are involved in a tautomeric equilibrium:[75,76]

$$R^1R^2C{=}CHCHR^3R^4 \rightleftarrows R^1R^2CHCH{=}CR^3R^4 ,$$
(LI) : $R^1$=$R^2$=$PhSO_2$; $R^3$ = COMe; $R^4$ = COOEt ;
(LII) : $R^1$=$ArSO_2$; $R^2$=CN; $R^3$=$R^4$=$SO_2Et$, $SO_2Ar$ .

The chemical reactions of propenes with GSG are determined mainly by their CH-acid properties (Table 4). The propenes (LII) form salts with alkali metals, react with diazonium salts and bromine, and form products resulting from the substitution of the hydrogen atom at C(1).[76] The propenes (LII, $R^3$ = $R^4$ = $SO_2Ar$) are nitrated with dissociation of the double bond and the formation of bis(4-R-3-nitrobenzene-sulphonyl)methanes.[27] The propene (LI) reacts with diazonium salts to form the product of substitution at C(3),[211] the nitration of compound (LI) is accompanied by the rupture of the double bond and leads to bis(3-nitro-benzenesulphonyl)methane, and nitrosation affords ethyl γγ-bis(benzenesulphonyl)-α-hydroxyiminovinylacetate:[27]

$$(LI) \xrightarrow[pH\ 8,3]{R^1C_6H_4N_2^+} (PhSO_2)_2C{=}CHC(N{=}NC_6H_4R^1)(COMe)COOEt ;$$
$$(LI) \xrightarrow{HNO_3,H_2SO_4} (3\text{-}O_2NC_6H_4SO_2)_2CH_2 ;$$
$$(LI) \xrightarrow{NaNO_2,HAc} (PhSO_2)_2C{=}CHC(COOEt){=}NOH ;$$
$R^1$ = *p*-Cl, *p*-Br, *m*-$NO_2$.

1,1-Bis(benzenesulphonyl)-2-cyano-2-ethoxycarbonylprop-1-ene, which has a similar structure but is much more acid ($pE_a$ = 1.04 in acetone), reacts with diazonium salts in the tautomeric prop-3-ene form with substitution of the hydrogen atom at C(1), the elimination of the EtOCOC(CN) =CH group, and the formation of 1,3-diaryl-5-hydroxytetrazolium betaines (XXXIII).[211]

---oOo---

Thus GS exhibit a varied reactivity. Further investigation of the chemistry of compounds of this class will lead to the discovery of their new practical applications as physiologically active preparations,[212] pesticides,[213] and in the manufacture of polymeric materials.[214–222]

# Non-traditional Oxidants in Preparative Coordination Chemistry

V.Yu.Kukushkin and Yu.N.Kukushkin

The application of nitrosonium and arenediazonium salts, carbenium, silver(I), and mercury(II) ions, protic acids, and amine oxides as oxidants in preparative coordination chemistry is examined. Specific examples illustrate which problems in the field of the synthesis and reactions of coordination compounds can be solved with the aid of these oxidants.
The bibliography includes 158 references.

## I. INTRODUCTION

Many synthetic methods are based on the use of oxidants in preparative coordination chemistry, among which oxidants, one may include the halogens, oxygen, hydrogen peroxide, concentrated nitric acid, permanganates, bromates, persulphates, etc. The choice of oxidants depends on the problem to be solved. It is sometimes required to oxidise the central atom of a complex without affecting the ligand, while in other cases it is necessary to oxidise the ligand without affecting the central atom. The products of the reduction of oxidants are frequently themselves ligands, which is sometimes a decisive factor in the choice of the oxidant. The larger the set of oxidants available to the synthetic chemist, the easier it is to solve specific problems.

In the last 10–15 years the range of oxidants in coordination chemistry has been greatly expanded by the use of non-aqueous solvents. The solvent as a rule influences strongly the oxidation-reduction potential of the system. One of the causes of this behaviour is the different degrees of solvation of the oxidant molecule and its reduction products. For example, the high oxidation potential of chlorine in polar solvents is associated, in particular, with the much higher solvation energy of two chloride ions than that of the $Cl_2$ molecule, which tends to shift the equilibrium to the right in the presence of the solvent. In [weakly] solvating solvents the difference between the solvation energies of the chlorine molecule and chloride ions is smaller and this is reflected in a decrease of the oxidation potential. In practice this amounts to the observation

that chlorine becomes a milder oxidant in a weakly solvating solvent. Thus, attempts[1] to obtain platinum(IV) complexes of hydroxylamine by oxidising $[Pt(NH_2OH)_2X_2]$ (X = Cl or Br) by halogens in an aqueous solution led to the decomposition of the coordinated $NH_2OH$ molecule and the formation of acido- and hydroxo-complexes of platinum(IV). When this reaction was carried out in the weakly solvating $CCl_4$, the corresponding platinum(IV) complexes with coordinated hydroxylamine were obtained.

In recent years oxidants which may be referred to as non-traditional have been introduced into preparative chemistry to an increasing extent. The term "new oxidants" would not be altogether accurate since individual instances of their use have been known for a fairly long time. The fact that the oxidants considered in this review are sometimes fairly specific in the oxidation of particular ligands in coordination compounds is of special interest to synthetic chemists. They make it possible to direct the oxidation process to a specific site in the complex.

## II. NITROSONIUM SALTS

Nitrosonium salts are one-electron oxidants which have been most frequently used during the last decade. According to Mussini[2] and Schmid and Neumann,[3] the redox potential of the $NO^+/NO$ pair in aqueous solution is 1.45 V (1.23 V relative to the Ag/AgCl electrode). When nitrosonium salts are used in non-aqueous solvents with weak electron-donating properties, the difference between the degrees of solvation of $NO^+$ and NO diminishes and the activity in relation to oxidation reactions increases.[4] Indeed, the potential of the $NO^+/NO$ pair in nitromethane relative to the Ag/AgCl electrode is as much as 1.58 V.[5]

Various methods of preparation of the above reagents are known. Nitrosyl chloride NOCl is formed on direct interaction of $Cl_2$ and NO, in the reaction of $NOHSO_4$ or $NaNO_2$ with HCl, and also as one of the products of the reaction of KCl and $NO_2$; NOBr is usually obtained from $Br_2$ and NO.[6] In the same study a method of synthesis of nitrosyl fluoride was also described. Among the different procedures for the preparation of $NO^+BF_4^-$,[7-11] the method based on the reaction of $N_2O_3$ with aqueous $HBF_4$ solution is most often employed:[9-11]

$$N_2O_3 + 2HBF_4 \rightleftarrows 2NO^+BF_4^- + H_2O,$$

$NO^+ClO_4^-$ is obtained analogously.[11-14]

Nitrosonium salts containing large anions with a weak electron-donating capacity are used to synthesise various metal salts and homogeneous solvato-complexes. Thus, one of the first syntheses in which a nitrosonium salt was used as the oxidant was achieved in 1950:[15]

$$Na + NO^+SbCl_6^- \xrightarrow{SO_2} Na[SbCl_6] + NO.$$

Later the oxidation of metals by nitrosonium salts in electron-donating solvents came to be used in the synthesis of homogeneous solvato-complexes. Thus, the complexes $[Cu(MeCN)_4]X$ [16,17] have been obtained by oxidising copper in acetonitrile with $NO^+X^-$ (X = $BF_4$ or $ClO_4$); the perchlorate $NO^+ClO_4^-$ in MeCN is capable of oxidising metallic gold with formation of the complex $[Au(MeCN)_4](ClO_4)$.[18] The solvates $[Eu(MeCN)_n]X_3$ (X = $BF_4$ or $PF_6$),[19] $[Ni(MeCN)_6](ClO_4)_2$,[20] and $[Pd(MeCN)_4](BF_4)_2$ [21,22] have been synthesised by oxidising metals with nitrosonium salts.

The oxidation of the complex $[Re_2Cl_4(PMe_2Ph)_4]$ with metal–metal bonds by one mole of $NO^+PF_6^-$ in acetonitrile led to the formation of $[Re_2Cl_4(PMe_2Ph)_4](PF_6)$ in 73% yield. The complex $[Re_2Cl_4(PMe_2Ph)_4](PF_6)_2$ has been isolated in 90% yield as a result of the interaction of the initial compound with 3.5 moles of $NO^+PF_6^-$.[23]

The oxidation of the complexes $[Cr(NO)(CNCMe_3)_4(PR_3)]X$, where R = Et or Bu, by $NO^+X^-$ salts (X = $BF_4$ or $PF_6$) in acetone is completed after 10 min with the formation of the products $[Cr(NO)(CNCMe_3)_4(PR_3)]X_2$ in approximately 90% yield.[24] The reaction of the zerovalent platinum complex $[Pt(PPh_3)_2(C_2H_4)]$ with nitrosonium tetrafluoroborate in acetonitrile led to the oxidation of the central atom with the simultaneous substitution of the coordinated ethylene by solvent molecules:[25]

$$[Pt(PPh_3)_2(C_2H_4)] + 2NO^+BF_4^- + 2MeCN \rightarrow$$
$$\rightarrow [Pt(PPh_3)_2(MeCN)_2](BF_4)_2 + C_2H_4 + 2NO.$$

The oxidation of the complex $MoL(NO)(CO)_2$ [L = tris(3,5-dimethylpyrazolyl)borate] by nitrosyl chloride is accompanied by substitution of the coordinated carbonyl groups by chloride ions:[26]

$$MoL(NO)(CO)_2 + 2NOCl \xrightarrow{CH_2Cl_2} MoL(NO)Cl_2 + 2CO + 2NO.$$

In the above examples the substitution of the ligands by the nitrosyl group was not noted. However, a series of studies have produced data indicating a dual reactivity of nitrosonium salts towards metal complexes. It has been established that the $NO^+$ cation can react to give either the corresponding nitrosyl derivatives or oxidation products. Sometimes both processes take place simultaneously. It has been shown[27,28] that the product of the reaction of $Mo(CO)_6$ with $NO^+$ in acetonitrile may be different under different experimental conditions. Thus, when the NO formed in the reaction is removed from the reaction mixture, the complex $[Mo(NO)(MeCN)_5]^{2+}$ is obtained, whereas, in the case where the reaction is carried out in the presence of NO, $[Mo(NO)_2(MeCN)_4]^{2+}$ is isolated. When these investigations were continued, it was established[29] that, when the reaction between $[Cr(CO)_4L]$ [L = bis(diphenylphosphino)-methane (Dppm) or 1,2-bis(diphenylphosphino)ethane (Dppe)] and $NO^+BF_4^-$ in $CH_2Cl_2$ is carried out in a closed nitrogen-filled flask, the product is the complex $[Cr(CO)_3(NO)L]^+$. On the other hand, when NO is removed from the reaction sphere by bubbling nitrogen through the reaction mixture, the oxidation product $[Cr(CO)_4L]^+$ is formed. The studies carried out by Connelly's group led to the mechanism

$$[ML_n] + NO^+ \rightarrow [ML_n(NO)]^+ \begin{cases} \rightarrow [ML_n]^+ + NO; \\ \rightarrow [ML_{n-1}(NO)]^+ + L. \end{cases}$$

The mechanism illustrates the fact that a change in reaction conditions can shift the equilibrium and can lead to the possibility of obtaining either the oxidation product $[ML_n]^+$ or the substituted nitrosyl complex $[ML_{n-1}(NO)]^+$. The latter can also be regarded as the oxidation product when the coordinated nitrosyl is converted into the $NO^-$ anion. It has been stressed[29] that the nature of the central atom M and of the coordinated ligand L can appreciably affect the equilibrium position. The ability of the complex $[ML_n]$ to form intermediates of the type $[ML_n(NO)]^+$ with an increased coordination number is also important.

The interaction of the complex $(Et_4N)[V(CO)_6]$ with $NO^+BF_4^-$ in dichloromethane, resulting in the formation of the substituted complex $[V(CO)_5(NO)]$ has been investigated.[30]

It has been shown that the infrared spectra of the products obtained by the interaction of $[V(CO)_6]^-$ with $NO^+$ and of $V(CO)_6$ with NO are identical. The following reaction mechanism has been proposed:[18]

$$V(CO)_6^- + NO^+ \rightarrow V(CO)_6 + NO \rightarrow [V(CO)_6(NO)] \xrightarrow{-CO} [V(CO)_5(NO)].$$

This mechanism does not conflict with Connelly's mechanism and actually supplements it.

We shall quote certain examples illustrating the dual reactivity of nitrosonium salts. When the isonitrile complex of tungsten $W(CNPh)_2$ is mixed with $NO^+PF_6^-$ in tetrahydrofuran (THF), two products are formed:[31]

$$2W(CNPh)_6 + 2NO^+PF_6^- \xrightarrow{THF} [W(NO)(CNPh)_5](PF_6) + [W(CNPh)_7](PF_6) + NO.$$

The oxidation of the osmium complex $[Os(CNR)_4X_2]$ proceeds without the formation of substitution products:[32]

$$[Os(CNR)_4X_2] + NO^+BF_4^- \xrightarrow{MeCN} [Os(CNR)_4X_2](BF_4) + NO;$$
$$R = t\text{-Bu, iso-Pr, } C_6H_{11};\ X = Cl, Br.$$

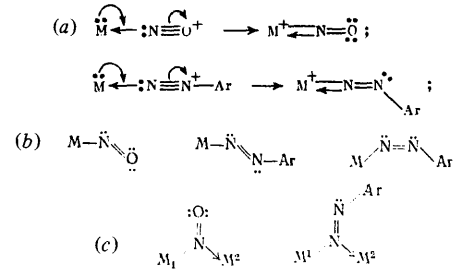
The interaction of a solution of $Mo(CO)_6$ in dichloromethane with $NO^+PF_6^-$ leads to the formation of $Mo(NO)_2(PF_6)$, which has a polymeric structure with a bridging hexafluorophosphate ligand.[33] The corresponding solvates $[Mo(NO)_2S_n].(PF_6)_2$ (S = solvent molecule) are formed from the same reactants in MeCN [34] or $MeNO_2$.[33]

It has been noted[35–38] that nitrosonium salts can react in two ways also with cluster compounds. For example, the oxidation of the anion $[Os_4H_3(CO)_{12}]^-$ by the $NO^+X^-$ salts (X = $BPh_4$ or $PF_6$) in acetonitrile gave rise to the clusters $[Os_4H_3(CO)_{12}(MeCN)_2]X$ in a yield of ~35%. The replacement of acetonitrile by dichloromethane or THF results in the formation of the compound $[Os_4H_3(CO)_{12}(NO)]$ in this reaction.[38]

It has been noted in a review[35] that nitrosyl salts are used as the source from which the nitride ligand is introduced into the carbonyl clusters of various metals.

The ability of nitrosonium salts to oxidise the coordinated azide ion is used in practice in preparative coordination chemistry:

$$[Co(NH_3)_5N_3](ClO_4)_2 + NO^+ClO_4^- \xrightarrow{S} [Co(NH_3)_5S](ClO_4)_3 + N_2O + N_2,$$



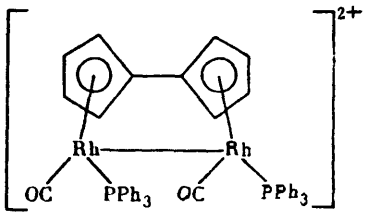
where S = tetramethylene sulphone,[39] triethyl phosphate,[40] or acetonitrile.[41,42] The reaction led to the isolation of gaseous oxidation-reduction products, the vacant site in the coordination sphere being occupied by solvent molecules.

The reaction between the phosphine complexes of nickel(II) $[Ni(PPh_3)_2X_2]$ (X = Cl, Br, or $NO_3$) and NOCl has been investigated[43,44] in a benzene–cyclohexane mixture. Without dwelling on the pathways leading to the formation of the oxidation products, the authors conclude that the reaction results in the formation of the dimers, $[Ni(OPPh_3)XCl]_2$.

## III. ARENEDIAZONIUM SALTS

The classical studies by Nesmeyanov and co-workers[45] were devoted to the oxidation and arylation of organometallic compounds, especially of ferrocene by arenediazonium salts.

Certain aspects of the coordination chemistry of arenediazonium have been examined in a review[46] and an analogy has been drawn between the nitrosyl and arenediazenate complexes of transition metals. This applies in broad outline to the valence structures of the complexes in linear (a), angular (b), and bridged (c) coordination, i.e.



and also to the similarity of the reactivities. The analogy has been extended[29,47] to redox reactions with participation of nitrosonium and arenediazonium salts.

It has been noted[47] that there are no literature data on the oxidation potentials of nitrosonium and diazonium in any one non-aqueous solvent, i.e. under comparable conditions. However, it follows from the available potentials that $NO^+$ (1.58 V, nitromethane, Ag/AgCl electrode) is a stronger oxidant than $ArN_2^+$ (0.295 V, sulpholan, saturated calomel electrode), although strictly speaking the potentials quoted are not directly comparable. A comparative study has been made of the interaction of the complexes $[Cr(CO)_2L.(\eta\text{-}C_6Me_6)]$ [L = $PPh_3$, $PMePh_2$, $PMe_2Ph$, $P(OPh)_3$, or $P(OMe)_3$] with $NO^+PF_6^-$ and $PhN_2^+PF_6^-$ in PhMe–MeOH and $CH_2Cl_2$ respectively.[47] It has been established that nitrosonium salts give rise only to the products of substitution of CO or L, i.e. $[Cr(CO)(NO)L(\eta\text{-}C_6Me_6)](PF_6)$ and $[Cr(CO)_2(NO)(\eta\text{-}C_6Me_6)](PF_6)$. The interaction with a diazonium salt leads to the formation, together with the substitution products $[Cr(CO)(N_2Ph)L(\eta\text{-}C_6Me_6)](PF_6)$ and $[Cr(CO)_2(N_2Ph)(\eta\text{-}C_6Me_6)](PF_6)$, also of the one-electron oxidation product $[Cr(CO)_2L(\eta\text{-}C_6Me_6)](PF_6)$. In order to account for this finding, the authors[29,47] turned to the mechanism of the interaction of carbonyl complexes with nitrosonium salts which they proposed (see previous Section). On the basis of the similarity between the reactivities of $NO^+X^-$ and $ArN_2^+X^-$, they extended the scheme to the reactions of complexes of the type $[ML_n]$ with $ArN_2^+X^-$. Analysis showed, despite the more negative potential of the $ArN_2^+/ArN_2$ pair compared with that of the $NO^+/NO$ pair, diazonium salts are more reactive one-electron oxidants. On the one hand, this can be explained by the greater steric hindrance by the $ArN_2^+$ ligand to the formation of the intermediate $[ML_n(ArN_2)]^+$ and on the other, the formation of the oxidation product $[ML_n]^+$ is favoured by the irreversible formation of $N_2$ and biaryl:

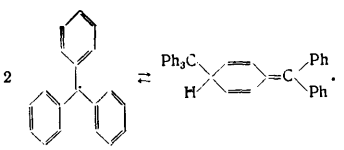
$$2ArN_2^+ + 2e \rightarrow 2N_2 + Ar\text{—}Ar.$$

The oxidising capacity of diazonium salts can be used in preparative coordination chemistry. Thus the complex $[Mo(NO)(MeCN)(Dppe)_2](PF_6)$ has been oxidised by the stoichiometric amount of $[p\text{-}FC_6H_4N_2]^+(PF_6)^-$ in dichloromethane.[48] The reaction is completed in 30 min; $[Mo(NO).(MeCN)(Dppe)_2](PF_6)_2$ was isolated from the reaction mixture in 92% yield. The one-electron oxidation product $[Co(Salen)(H_2O)](BF_4)$ ($H_2Salen$ is the Schiff base prepared from one mole of ethylenediamine and two moles of salicylaldehyde) has been obtained by the reaction of [Co(Salen)] with $[p\text{-}XC_6H_4N_2]^+(BF_4)^-$ (X = H, OMe, or $NO_2$) in $CH_2Cl_2$ or $Me_2CO$ containing traces of water.[49] It has been stated[50] that diazonium salts in acetonitrile are capable of oxidising metallic copper or silver with formation of the corresponding homogeneous solvato-complexes. The oxidation can involve also coordinated ligands. Thus the interaction of $[Rh(CO)(PPh_3)(\eta\text{-}Cp)$ (Cp = cyclopentadienyl)

with $[p\text{-}FC_6H_4N_2]^+(BF_4)^-$ in dichloromethane leads to the formation of the fulvalene complex:[51]

## IV. TRIPHENYLCARBENIUM SALTS

In 1958 it was suggested[52] that triphenylcarbenium salts (the $Ph_3C^+$ cation is frequently referred to as the trityl cation in the literature) be used as powerful acceptors of hydride ions. The employment of $Ph_3C^+X^-$ in preparative coordination chemistry can be considered in terms of at least three aspects. Firstly, trityl is used as a one-electron oxidant. Secondly, it is capable of abstracting the hydride ion from an organic ligand. Thirdly, triphenylcarbenium salts are able to accept a coordinated hydride ion.



Data concerning the synthesis of triphenylmethyl perchlorate and triphenylmethyl tetrafluoroborate have been published.[53,54] The above reagents are obtained by the reaction of triphenylmethylmethanol with 71% $HClO_4$ or 48% $HBF_4$ in the presence of acetic anhydride. The latter is introduced to remove water:

$$Ph_3COH + H^+ \rightarrow Ph_3C^+ + H_2O.$$

The yields are 76 and 92% respectively. The tetrafluoroborate $Ph_3C^+BF_4^-$ has advantages over the perchlorate $Ph_3C^+ClO_4^-$ because of its greater stability.[53]

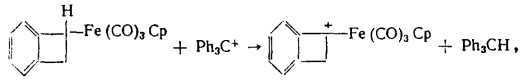
It has been established[50] that $Ph_3C^+BF_4^-$ can function as a one-electron oxidant and is able to oxidise metallic copper with formation of the homogeneous solvato-complex $[Cu(MeCN)_4](BF_4)$. The phosphine complexes of palladium(II) $[Pd(PPh_3)_4]X_2$ (X = $BF_4$ or $PF_6$) and $\{Pd[P(OPh)_3]_4\}.(PF_6)_2$ have been synthesised in 60 and 50% yields respectively by the oxidation of the complexes $[Pd(PPh_3)_4]$ and $\{Pd[P(OPh)_3]_4\}$ by the trityl cation.[55]

The triphenylmethyl radical, formed in the reduction process, dimerises with formation of 1-diphenylmethylene-4-tritylcyclohexa-2,5-diene:[56,57]

The one-electron oxidation of the complex $\{CpW(NO).[P(OMe)_3]\}$ with triphenylcarbenium tetrafluoroborate in $CH_2Cl_2$ in air led to the isolation from the reaction mixture of the already known[59] compound $Ph_3COOCPh_3$ in 13% yield.[58] Cobalt(II) complexes having the general formula $[CoHL_4]X$ [L = $P(OEt)_2Ph$, $P(OMe)_2Ph$, or $P(OPh)_3$; X = $PF_6$ or $BF_4$] have been obtained by the reaction of the corresponding hydrides $[CoHL_4]$ with a stoichiometric amount of the triphenylcarbenium salt.[60] In this case the trityl cation behaves as a one-electron oxidant and not as a hydride ion acceptor. This has been explained[60] by the greater strength of the Co–H bond.

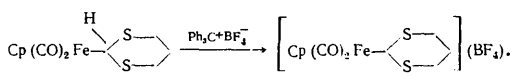
The dependence of the reactivity of the triphenylcarbenium ion on the properties of the solvent has been clearly demonstrated in a study of the reaction of $Ph_3C^+PF_6^-$ with the polyhydride $Re_2H_8(PPh_3)_4$.[61] The abstraction of a hydride ion in acetonitrile results in the formation of a coordination-saturated intermediate, which is stabilised in the form of the solvato-complex $[Re_2H_7(PPh_3)_4(MeCN)](PF_6)$. When the reaction is carried out in dichloromethane, $Ph_3C^+PF_6^-$ functions as a one-electron oxidant, which results in the formation of $[Re_2H_8(PPh_3)_4](PF_6)$.

Other carbenium ions can be used in one-electron oxidation reactions in addition to the triphenylmethyl cation. Thus the complex $\{CpW(NO)[P(OMe)_3]\}$ is oxidised to the corresponding monocationic complex on interaction with $MeOSO_2F$ in accordance with the reaction equation



$$[CpW(NO)\{P(OMe)_3\}] + MeOSO_2F \xrightarrow{CH_2Cl_2} \rightarrow [CpW(NO)\{P(OMe)_3\}](OSO_2F) + {}^1/_2C_2H_6.$$

The ethane evolved was detected by gas–liquid chromatography (GLC).[58]



The one-electron oxidation of the complex $[MoCl_2(Dppe)_2]$ by the compound $[Et_3O]^+(BF_4)^-$ and $MeOSO_2F$ in dichloromethane leads to the formation of the molybdenum(III) complex $[MoCl_2(Dppe)_2]X$ (X = $BF_4$ or $OSO_2F$).[62] Triethyloxonium tetrafluoroborate oxidises $[Re(CO)_3Cl(PPh_3)_2]$ to the corresponding complex $[Re(CO)_3Cl(PPh_3)_2](BF_4)$. Although the reduction products were not identified in the above study,[62] by analogy with other data[58] one can assume that the $Me^+$ and $Et^+$ ions are reduced as a result of the reaction.

A brief survey of the applications of triphenylcarbenium salts in the chemistry of organometallic compounds has been published.[63] We shall quote only a few additional examples.

The reaction

has been carried out.[64] The carbene complex has been isolated analogously in the oxidation of the dithiane derivative:[65]

A μ-methylidyne compound is formed from a complex with a bridging methylene ligand:[66,67]

$$[Cp_2(CO)_2Fe_2(\mu\text{-}CO)(\mu\text{-}CH_2)] + Ph_3C^+PF_6^- \xrightarrow{CH_2Cl_2} \rightarrow [Cp_2(CO)_2Fe_2(\mu\text{-}CO)(\mu\text{-}CH)](PF_6) + Ph_3CH.$$

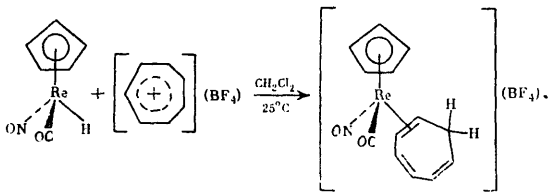
The initial complex can be regenerated by treating the final product with $Li[HBEt_3]$.

The question of the mechanism of hydride shifts has been the subject of a controversy. It has been noted in a monograph[68] that the hydride shift reaction can take place in either one or two steps:

$$B^+ + H{-}A \rightarrow BH + A^+;$$
$$B^+ + H{:}A \rightarrow B^{\cdot} + [HA]^{\cdot+} \rightarrow BH + A^+$$

In several studies the possibility of a hydride shift via a mechanism involving a one-electron transfer has been demonstrated. The question of the extent to which this mechanism occurs has so far remained open.[68]

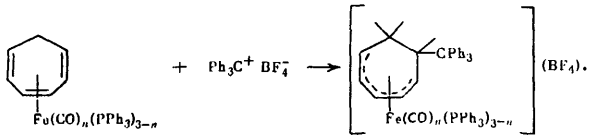
The ability of the trityl cation to interact with an inner-sphere hydride ion can be clearly demonstrated in relation to the complex $[RuH_2(PPh_3)_4]$.[69] Treatment of the complex with a calculated amount of $Ph_3C^+PF_6^-$ yielded $[RuH(PPh_3)_4].(PF_6)$. Oxidation of the hydride ligand can lead to the



formation of the bridged complex[70]

$$2\,(Ph_4As)\,[HCr(CO)_5] + Ph_3C^+BF_4^- \xrightarrow{THF} \rightarrow (Ph_4As)\,[(CO)_5Cr(\mu\text{-}H)Cr(CO)_5] + Ph_3CH + [Ph_4As](BF_4).$$

It has been demonstrated convincingly[71] that the character of the product of the reaction between $Ph_3C^+X^-$ ($X = BF_4$ or $PF_6$) and the hydride compound $[CpW(NO)_2H]$ depends on the electron-donating capacity of the solvent. Thus the solvato-complex $[CpW(NO)_2(MeCN)]X$ is formed in acetonitrile, while the dimer $[Cp_2W_2(NO)_4H]$ is produced in dichloromethane, which has no electron-donating properties. The oxidation of the hydride ligand in the complexes $\{Mn(CO)_3[P(OMe)_3]_2H\}$ [72] and $[Cp(CO)_3MH]$ ($M = Mo$ or W) [73] by $Ph_3C^+PF_6^-$ in $CH_2Cl_2$ leads to the deposition of the compounds $\{Mn(CO)_3[P(OMe)_3]_2(FPF_5)\}$ and $[Cp(CO)_3M.(FPF_5)]$ respectively in the solid phase. These compounds are formed because the solvent cannot compete with the $PF_6^-$ anion for a site in the inner coordination sphere. The reaction of the rhenium complex $[CpRe(CO)(NO)H]$ with triphenylcarbenium tetrafluoroborate in $CH_2Cl_2$ affords $[CpRe(CO)(NO)(\eta_2\text{-}PhCHPh_2)](PF_6)$ as the final product.[74]



Apart from trityl cations, other carbenium ions can also be used as hydride ion acceptors in preparative coordination chemistry. Although the tropylium cation is a much less active hydride ion acceptor than the triphenylcarbenium cation,[68] nevertheless the oxidation of the cluster anion $[Re_3(\mu\text{-}H)_4(CO)_{10}]^-$ by the tropylium ion has been described.[75] This reaction involves the abstraction of the hydride ligand and the formation of the compound $[Re_3(\mu\text{-}H)_3(CO)_{10}L_2]$ in the presence of carbon monoxide ($L = CO$) or an electron-donating solvent ($L = MeCN$). In the absence of electron donors, in the inert dichloromethane, the complex $[Re_3H_2(CO)_{10}(\eta_5\text{-}C_7H_9)]$ is formed in a satisfactory yield.

The interaction of tropylium tetrafluoroborate with the complex $[CpRe(CO)(NO)H]$ leads to the dehydrogenation of the complex and subsequent coordination of the triene formed:[76]

Dehydrogenation of the complex $[CpOs(CO)_2H]$ by tropylium tetrafluoroborate in $CH_2Cl_2$ at 25 °C for 6 days gives rise to $[CpOs(CO)_2(1,2\text{-}\eta_2\text{-}C_7H_8)](BF_4)$ in 80% yield.[77]

In conclusion of this Section, we may note that the trityl cation can alkylate coordinated ligands, for example:[78,79]

## V. PROTIC ACIDS

In studies in non-aqueous solvents the proton can function as a one-electron oxidant. Thus metallic titanium or chromium are oxidised by $HBF_4$ in acetonitrile with formation of $[Ti(MeCN)_6](BF_4)_3$ and $[Cr(MeCN)_x](BF_4)_3$.[80] When zerovalent molybdenum hexacarbonyl $Mo(CO)_6$ was refluxed with anhydrous formic acid for 3 h in diglyme, $Mo_2(O_2CH)_4$ was isolated in 65% yield.[81] The complex $[CpRh(PPh_3).(PhC_2Ph)]$ reacts with an excess of trifluoroacetic acid at 40 °C with displacement of the acetylenic ligand and the formation of the oxidation product $[CpRh(PPh_3)(O_2CCF_3)]$.[82]

The reaction of the dimeric complex $[CpCr(NO_2)]_2$ with two moles of $HBF_4OMe_2$ in dichloromethane leads to oxidative cleavage with formation of the monomeric compound $CpCr(NO)_2BF_4$, which is converted into the stable complex $[CpCr(NO)_2(MeCN)](BF_4)$ on treatment with acetonitrile.[9] Similarly the interaction of the isoelectronic complex $[CpFe(CO)_2]_2$ with toluene-*p*-sulphonic acid in acetonitrile leads to oxidative cleavage of the Fe–Fe bond and formation of the solvato-complex $[CpFe(CO)_2(MeCN)](O_3SC_6H_4Me)$.[84] It was assumed in the above study that the protic acid is in fact responsible for the oxidation of the complex. However, the evolution of free hydrogen was not observed.

Together with triphenylcarbenium and silver salts, protic acids are used to oxidise the $H^-$ ion in hydride complexes. It has been established[85] that $MoH_4(PMePh_2)_4$ reacts with $HBF_4$ or $HBF_6$ in THF to form the cation $[MoH_3(PMePh_2)_3]^+$. The reactions with the weaker acids $CF_3CO_2H$ or $p\text{-}MeC_6H_4SO_3H$ in toluene lead to the formation of the compounds $[MoH_2(CF_3CO_3)_2(PMePh_2)_3]$ and $[MoH_2.(p\text{-}MeC_6H_4SO_3)_2(PMePh_2)_3]$. The complex $[CpW(NO)_2H]$ is oxidised by anhydrous toluene-*p*-sulphonic acid in THF to $[CpW(NO)_2(OSO_2C_6H_4Me)]$.[86] The interaction of the complex $[H_2RhCp(PPr_3)]$ with trifluoroacetic acid in methanol in the presence of $NH_4PF_6$ entails a rapid reaction accompanied by the evolution of hydrogen and the formation of the dinuclear complex $[Cp(PPr_3)Rh(\mu\text{-}H)_3Rh(PPr_3)Cp](PF_6)$.[82] The interaction of tungsten, rhenium, osmium, and iridium polyhydride compounds with $HBF_4.OEt_2$ in acetonitrile has been investigated.[87] The initial compounds and the final products of the syntheses are presented schematically below:[87]

$$WH_6(PMe_2Ph)_3 \rightarrow [WH_2(MeCN)_3(PMe_2Ph)_3]^{2+};$$
$$ReH_5(PMe_2Ph)_3 \rightarrow [ReH(MeCN)_3(PMe_2Ph)_4]^{2+};$$
$$ReH_7(PPh_3)_2 \rightarrow [ReH(MeCN)_4(PPh_3)]^{2+};$$
$$OsH_4(PMe_2Ph)_4 \rightarrow [Os(MeCN)_3(PMe_2Ph)_3]^{2+};$$
$$IrH_5(PPh_3)_2 \rightarrow [IrH_2(MeCN)_2(PPh_3)_2]^+.$$

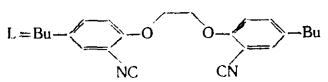
The authors concluded[87] that the central atoms in the complexes $WH_6(PMe_2Ph)_3$ and $ReH_7(PPh_3)_2$ have the $d^0$ electronic configuration. The protonation of the metal ion in such compounds is therefore hardly to be expected. It is most likely that the interaction with $H^+$ leads to the formation of the $M...H...H^+$ linear intermediate. On the other hand, the complexes $OsH_4(PMe_2Ph)_3$, $ReH_5(PMe_2Ph)_3$, and $IrH_5.(PPh_3)_2$ are more likely to be protonated at the metal atom. In all cases the protonated adducts are relatively unstable and decompose at room temperature with evolution of hydrogen and the vacant sites generated in the inner sphere are filled by solvent molecules. In the analysis of their own experimental and literature data on the acidolysis of the polyhydride compounds the authors[87] note that the biscationic complex is frequently stabilised as a result of the reaction. However, the causes of this phenomenon remain unelucidated.

The interaction of $[Mn(CO)_5]^-$ with trifluoromethanesulphonic acid in THF yielded the compound $HMn(CO)_5$,[88] which is a fairly strong acid ($pK_a = 7$).[89] Consequently, the hydrogen in $HMn(CO)_5$ has almost no hydride character. Nevertheless, the interaction of the complex $[(Ph_3P)_2N].[Mn(CO)_5]$ in the absence of a solvent with pure $CF_3SO_3H$ leads to the formation of the complex $Mn(CO)_5(SO_3CF_3)$ and

the evolution of hydrogen.[89] This reaction proceeds via the stage

$$HMn(CO)_5 + CF_3SO_3H \rightarrow Mn(CO)_5(SO_3CF_3) + H_2.$$

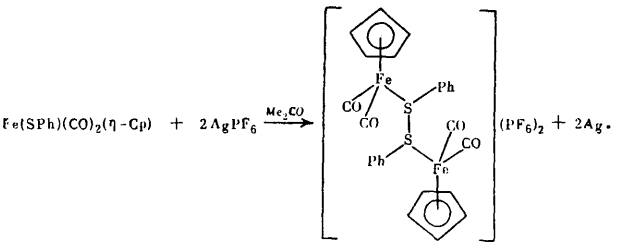
Thus, when the character of the medium is altered, a ligand, which does not exhibit the properties of a hydride in other solutions, is oxidised.



## VI. SILVER AND MERCURY SALTS

The importance of silver salts as dehalogenating agents has been emphasised in a review.[90] However, the salts AgX are also used as one-electron oxidants in syntheses in non-aqueous media. According to Rabinovich and Khavin,[91] the redox potential of the $Ag^+/Ag$ pair in aqueous solution is 0.799 V. There are no literature data on the redox potentials of the $Ag^+/Ag$ pair in weakly electron-donating solvents. This can probably be accounted for by the limited solubility of silver salts in such media.[92] In order to estimate the oxidising capacity of $AgBF_4$ in non-aqueous solvents, its reactions with $N(C_6H_4Br\text{-}p)_3$ ($E$ = 1.16 V), $NPh_3$ ($E$ = 0.88 V), and $Cp_2Fe$ ($E$ = 0.38 V) were investigated[92] in $CH_2Cl_2$, PhMe, MeCN, and THF. In all the solvents, ferrocene is oxidised to $[Cp_2Fe](BF_4)$, whereas amines are oxidised only by a suspension of $AgBF_4$ in dichloromethane. Consequently $AgBF_4$ is a powerful oxidant in $CH_2Cl_2$, but is milder in PhMe, MeCN, and THF, in agreement with their solvating capacities.

An important additional factor responsible for the application of silver salts in synthesis as oxidants is the possibility of the ready separation of the metallic silver formed on reduction from the reaction mixture. As a rule, reactions with participation of $Ag^+$ as the oxidant are rapid, are satisfactorily selective, and do not require an appreciable excess of this reagent.



A manual recommends[53] that silver tetrafluoroborate be obtained from AgF and $BF_3$ by the method of Olah and Quinn.[93] The same compound can also be obtained by dissolving silver oxide in 45% $HBF_4$.[94] Silver perchlorate is obtained by the reaction of $Ag_2CO_3$ with 10% $HClO_4$. The synthesis involves filtration, the removal of water *in vacuo*, and azeotropic drying with benzene.[53]

The $Ag^+$ ion has been used in preparative coordination chemistry for a long time. For example, as early as 1923 Morgan[95] suggested that the complex $[Cu(MeCN)_6](NO_3)$ be prepared by oxidising metallic copper with $AgNO_3$ in acetonitrile. The extensive use of silver salts as oxidants began in the last decade. According to Treichel and Essenmacher,[96] the isonitrile complex of chromium $[Cr(CNPh)_6]$ is instantly oxidised in acetone by one equivalent of $AgPF_6$ with formation of $[Cr(CNPh)_6](PF_6)$. When the latter was allowed to interact with yet another equivalent of $AgPF_6$ or on interaction of the initial complex with two moles of silver hexafluoroborate, $[Cr(CNPh)_6](PF_6)_2$ was obtained. The chelate compounds $[CrL_3](PF_6)$ and $[CrL_3](PF_6)_2$ have been synthesised analogously:[97]

The oxidation of the complex $CpCo(PPh_3)_2$ by silver halides AgX (X = Cl, Br, or I) in THF led to the formation of the compounds $[CpCo(PPh_3)X]$.[98]

The oxidative dimerisation reaction, which proceeds via the oxidation of the ligand, has been investigated:[99]

The authors[99] suggest that the HOMO in the initial complex is localised mainly on the sulphur atom and not on the iron atom. The loss of one electron from this orbital leads to the formation of a radical species with the unpaired electron localised on the ligand. The final dimeric complex is formed from two such species. The central atom in the complexes $Fe(SPh)(CO)L(\eta\text{-}C_5R_5)$ is oxidised:

$$Fe(SPh)(CO)L(\eta\text{-}C_5R_5) + AgX \rightarrow [Fe(SPh)(CO)L(\eta\text{-}C_5R_5)]X + Ag;$$
$$R=Me,\ L=CO,\ PMe_3,\ PMe_2Ph,\ PMePh_2;$$
$$R=H,\ L=PMe_3,\ PMe_2Ph,\ PMePh_2.$$

Numerous examples of the oxidation of organometallic compounds with silver salts have been described in a book.[100]

The possibility of the oxidation of the hydride complexes $[MoH_4L_4]$ (L = $PMe_2Ph$ or $PMePh_2$) by silver tetrafluoroborate in acetonitrile has been demonstrated:[101]

$$[MoH_4L_4] + 2AgBF_4 + 2MeCN \rightarrow [MoH_2L_4(MeCN)_2](BF_4)_2 + H_2 + 2Ag.$$

The reactions reached completion in several minutes and the products were obtained in satisfactory yields.

Mercury salts together with silver salts can be used in experiments in non-aqueous solvents as oxidants. Like the $Ag^+$ ion, the $Hg^{2+}$ ion has a relatively high oxidising capacity. In both cases the reduction products, namely metallic silver and mercury, can be readily separated from the reaction mixture. The oxidation of the lanthanides Sm, Er, Yb,[102] Sc, and Y [103] by $HgCl_2$ in THF yielded the tetrahydrofuranates of the corresponding trichlorides:

$$2Ln + 3HgCl_2 + 6THF \rightarrow 2LnCl_3 \cdot 3THF + 3Hg.$$

The complex $[Cr(CO)_5(O_2CCF_3)]^-$ is formed as a result of oxidative substitution by mercury trifluoroacetate:[104]

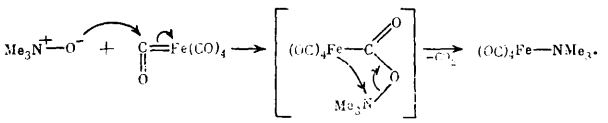
$$[Cr_2(CO)_{10}]^{2-} + Hg(O_2CCF_3)_2 \rightarrow 2[Cr(CO)_5(O_2CCF_3)]^- + Hg.$$

## VII. AMINE OXIDES

The ability of the $CO_2$ molecule to be coordinated to metal ions is known to be appreciably weaker than that of carbon monoxide. For this reason, one of the methods of the specific elimination of CO from metal carbonyl compounds involves the oxidation of a carbonyl ligand to $CO_2$ with subsequent substitution of this molecule by some stronger electron donor (in particular, a solvent molecule). Trimethylamine oxide is nowadays used widely for the oxidation of the coordinated CO molecule.

The above reagent is formed in 95% yield as the dihydrate $Me_3NO.2H_2O$ on oxidation of $Me_3N$ by hydrogen peroxide:[105,106]

$$Me_3N + H_2O_2 + H_2O \rightarrow Me_3NO \cdot 2H_2O.$$



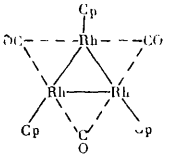
Total dehydration gives rise to the extremely hygroscopic product $Me_3NO$.[106,107] The ability of amine oxides to react with metal carbonyls was first demonstrated by Heiber and Lipp[108] and Alper and Edward.[109] In particular, it has been

established[109] that aliphatic, aromatic, or heterocyclic amine oxides are reduced to the corresponding amines on interaction with $Fe(CO)_5$. The amines have been isolated from the reaction mixture and characterised. Iron oxides have also been obtained in the synthetic reactions. It was suggested in 1974 [110] that the reactions of amine oxides with metal carbonyls be used for the decomposition of the complex and the isolation of the organic ligand. Thus, when the complexes $[LFe(CO)_3]$ [L = $C_8H_8$, norbornadiene,[110] or $C_7H_6NN(H)C_6H_4NO_2$ [111]] in benzene or acetone react with an excess of $Me_3NO$ or $Me_3NO.2H_2O$, complete decarbonylation with decomposition of the complexes takes place. The free ligands L have been isolated in 75–95% yields. The reaction of $Me_3NO$ with $Fe(CO)_5$ in the presence of bidentate diene ligands L yielded substituted complexes $[LFe(CO)_3]$:[112]

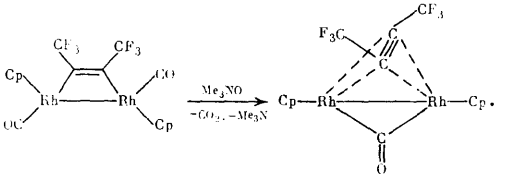
$$Fe(CO)_5 + Me_3NO + L \rightarrow [LFe(CO)_3] + Me_3N + CO_2 + CO.$$

Since then the reactions involving decarbonylation by amine oxides have been used for preparative purposes.

In the interaction of $Fe(CO)_5$ with a twofold excess of $Me_3NO$ in THF at −30 °C, evolution of $CO_2$ was observed; the complex $Fe(CO)_4(NMe_3)$ was obtained from the reaction mixture in 45% yield;[113] a mechanism for the oxidative decarbonylation, involving nucleophilic attack by $Me_3NO$ on the carbon atom of the carbonyl ligand, has been proposed on the basis of the results:[107,113]



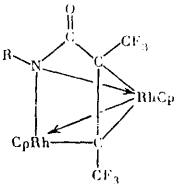
Many instances of oxidative decarbonylation reactions using amine oxides, some of which have been published in a review,[106] are known at present in the literature. It has been noted[107] that these reactions can be carried out in a wide range of solvents such as benzene, dichloromethane, chloroform, THF, acetonitrile, acetone, 2-methoxyethanol, and methanol.



We shall present certain examples of the reactions involving the selective oxidation of CO in metal carbonyls. The interaction of $[W(CO)_5(PPh_3)]$ with $Me_3NO$ in dichloromethane in the presence of $SMe_2$ led to the formation of $[W(CO)_4(PPh_3).(SMe_2)]$.[114] The reaction of $[Ru(CO)_2Cl_2bipy]$ (bipy = 2,2′-bipyridyl) with $Me_3NO$ in molar proportions of 1:5 in pyridine formed the monosubstitution product $[Ru(CO)PyCl_2.bipy]$.[115] The authors of the above study point out that the attempts at the complete decarbonylation of $[Ru(CO)_2.Cl_2bipy]$ were unsuccessful. Refluxing of the homodinuclear complex $[Mn_2H(CN)(CO)_5Dppm]$ with an excess of $Me_3NO.2H_2O$ in a dichloromethane–methanol mixture for 88 h leads to the formation of the complex $[Mn_2H(CN)(CO)_4Dppm]$ in 24% yield; irradiation of the reaction mixture with visible light increases the rate of reaction and the yield of the final product.[116] Data on the oxidative decarbonylation of cluster compounds may be found in a number of publications.[107,117–124]

If the oxidative decarbonylation is carried out in the presence of electron-donating solvents, the reaction can influence the formation of solvato-complexes. For example, the removal of a carbonyl group from the triosmium cluster $Os_3(CO)_{12}$ with the aid of trimethylamine oxide in the presence of acetonitrile leads to the formation of the monosolvate $Os_3(CO)_{11}(MeCN)$. The reaction of $Os_3(CO)_{11}(MeCN)$ with yet another mole of $Me_3NO$ gives rise to a high yield of $Os_3(CO)_{10}(MeCN)_2$.[119,120] The reaction does not proceed further and the trisolvate is not formed. According to the authors, this can be explained by the mutual influence of the ligands, which reduces the tendency of the carbonyl centres to undergo nucleophilic attack.

In the absence of an electron-donating ligand (or an electron-donating solvent) the coordination-unsaturated species formed as a result of the removal of CO can react with the initial compound to form a metal–metal bond.[125] Thus the interaction of $Me_3NO$ with $CpRH(CO)_2$ in benzene leads to the formation of the trimer as the dominant product:



The decarbonylation of the complex $(\eta\text{-}Cp)_2Rh_2(CO)_2.(CF_3C_2CF_3)$ by trimethylamine oxide in dry acetone is accompanied by the rotation of the coordinated alkyne by 90° and the remaining coordinated carbonyl occupies a bridging position:[126–128]

The interaction of $Ru_2(CO)_6(DAB)$ (DAB = 1,4-substituted 1,4-diazabuta-1,3-diene) with trimethylamine oxide in a mixture of non-electron-donating solvents (dichloromethane and toluene) leads to the formation of the compound $Ru_2.(CO)_5(DAB)$.[129] The reaction alters the type of binding of the DAB ligand: instead of the 6e-($\sigma$-N, $\mu^2$-N′, $\eta^2$-C=N′) coordination, we have the coordination 8e($\sigma$-N, $\sigma$-N′, $\eta^2$-C=N, $\eta^2$-C′=N′).

Many chemical properties of inner-sphere organic isocyanides are known to resemble those of coordinated carbon monoxide.[130] In a recently published study,[131] trimethylamine oxide was used to oxidise the isocyanide ligand RNC (R = Me, Bu, Pr, $C_6H_{11}$) coordinated to a rhodium atom in the complex $[(\eta^5\text{-}Cp)_2Rh_2(CO)(CNR)(CF_3C_2CF_3)]$. The oxygen is then transferred from $Me_3NO$ to the isocyanide with formation of the isocyanate RNCO. The subsequent intramolecular rearrangement and evolution of CO results in the formation of a compound which has the following structure according to X-ray diffraction data:

## VIII. OTHER OXIDANTS

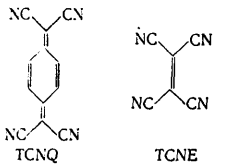
Among other oxidants, mention should be made of the higher halides of Group V elements. Thus the oxidative halogenation of the complex $[Mo(\mu\text{-}C_8Me_8)Cp_2]$ by the mild oxidants $[NPr_4](SbCb_6)$ or $[PhCO](SbCl_6)$ in dichloromethane leads to the formation of the complex $[Mo(\mu\text{-}C_8Me_8).(\mu\text{-}Cl)Cp_2](SbCl_4)$ in a quantitative yield.[132] The authors[132]

suggest that the final product is obtained as a result of oxidation which is followed by the halogenation of the cation formed.

In order to obtain complexes with a coordinated $SO_2$ molecule, $AsF_5$ is widely used.[133-135] Thus the reaction of metallic zinc or cadmium with an excess of arsenic pentafluoride in liquid $SO_2$ leads to the formation of homogeneous solvato-complexes:[134,135]

$$M + 3AsF_5 \xrightarrow{SO_2} [M(SO_2)_2](AsF_6)_2 + AsF_3.$$

The complexes $[M(SO_2)_2(AsF_6)_2]_n$ have been obtained by the interaction of the metal M (M = Mn, Fe, Co, Ni, Cu, Zn, or Mg) and $AsF_5$ in molar proportions of 1:5 in liquid $SO_2$.[133]



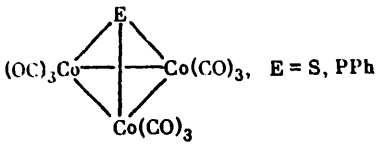
Organic 1,2-dihalides can oxidise certain metals. For example, the slow addition of Sm or Yb to a solution of 1,2-diiodoethane in THF leads to the formation of $SmI_2$ and $YbI_2$ in quantitative yields:[136]

$$M + ICH_2CH_2I \xrightarrow{THF} MI_2 + CH_2CH_2.$$

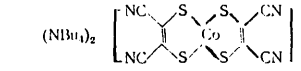
The reaction is rapid at room temperature.

A mixture of $AlCl_3$ and $CH_2Cl_2$ exhibits fairly strong oxidising properties.[137-139] Unfortunately the authors did not consider the oxidation mechanism and did not identify the reduction products. $AlCl_3$ in dichloromethane has been used to oxidise the molybdenum complex $[Mo(CO)_2(bipy)_2]$. After the completion of the reaction, the product was precipitated in the form of the dimer $[Mo(CO)_2(bipy)_2]_2 \cdot (BF_4)_2$ by adding $NaBF_4$ to the reaction mixture.[140]

Tetracyanoquinodimethane (TCNQ) and tetracyanoethylene (TCNE)



TCNQ



TCNE

are known to be fairly strong electron acceptors.[141,142] Stable radical-anions $TCNQ^-$ and $TCNE^-$ are formed in one-electron reduction. The half-wave potentials of the polarographic reduction of these compounds in acetonitrile (0.127 V for TCNQ and 0.152 V for TCNE) show that they are mild oxidants in the given solvents.[142] It has been established in a recently published study[143] that the clusters

react with TCNQ in ethanol, acetone, dichloroethane, THF, or dichloromethane to form the one-electron oxidation product $[ECo_3(CO)_9]^+$. TCNE oxidises the complex

with formation of the dimeric compound $[NBu_4)_2 \cdot [Co(C_4N_2S_2)_2]_2$.[144]

Organic disulphides can oxidise metal carbonyls in a photochemical reaction in accordance with the equation

$$[CpM(CO)_n]_2 + S_2R_2 \xrightarrow{h\nu} 2[CpM(CO)_n SR];$$

M = Fe, R = Me, $n$ = 2 (Ref.145);

M = Ru, R = Me, Ph, Bz, $n$ = 2 (Ref.146);

M = W, R = $Me_2NC(S)$, $n$ = 3 (Ref.147).

The mechanism of processes of this kind involves the formation of extremely reactive metal carbonyl radicals as a result of photolysis, which are oxidised in a dark reaction by the organic disulphide with formation of thiolate complexes.[147]

In conclusion, one should note that many oxidants can be used in both aqueous and non-aqueous solutions. Thus instances of the employment of $PbO_2$ in a mixture of MeCN and $CF_3CO_2H$,[148] of $Cp_2Fe^+$ in acetonitrile[149,150] and THF,[151-153] of $Pb(OAc)_4$ in dichloromethane,[154] of $TiCl_3$ in dichloromethane,[155,156] etc. are known. The procedure involving the modification of "traditional" oxidants in order to impart hydrophobic properties to the latter is of interest. For example, the pyridine analogue of potassium dichromate, namely $(PyH)_2Cr_2O_7$, has been synthesised.[157] This compound is highly soluble in dimethylformamide, diethylacetamide, and dimethyl sulphoxide and is sparingly soluble in dichloromethane and chloroform. An analogue of hydrogen peroxide, namely the compound $(Me_4N)_2O_2$, is used to synthesise complexes in acetonitrile.[158]

# Thermochemistry of Organic and Organohalogen Compounds†

V.P.Kolesov and M.P.Kozina

The advances in the thermochemistry of organic compounds, mainly cyclic and organohalogen derivatives, are examined. Studies on the thermodynamics of the polymerisation reactions of cyclic compounds, the determination of the standard enthalpies of formation of cyclic and organohalogen compounds, and the determination of relations between the standard enthalpies of formation and the strain energies of molecules, on the one hand, and their structure, on the other are analysed in detail.
The bibliography includes 213 references.

## I. INTRODUCTION

Fundamental research into the thermochemical properties of organic compounds is traditional in Russian thermochemistry. The determination of the heats of combustion of organic compounds in a bomb calorimeter was the fundamental experimental method at the Laboratory of Thermochemistry founded at Moscow State University (1891) by V.F.Luginin.[1,2]

After Luginin, his student and collaborator P.V.Zubov continued the research into the thermochemistry of organic compounds.[3-7] M.M.Popov made a major contribution to the development of the methods for the determination of heats of combustion. Together with W.Świętosławski, he proposed in 1914 that a single primary standard, benzoic acid, be used for the calibration of calorimeters.[8] In 1934 Popov and Shirokikh[9] constructed the first calorimeter with a moving bomb and thereby introduced into calorimetric practice a new method, which proved to be exceptionally useful for the investigation of organohalogen, organosulphur, organosilicon, and organometallic compounds as well as many other substances with a relatively complex composition.

The studies of S.M.Skuratov and his co-workers, in the course of which a self-sealing bomb calorimeter was constructed and a new model of a highly sensitive mercury thermometer was used, led to the creation of precision calorimetric apparatus which differed little from modern apparatus.[10,11] The sharp increase in the accuracy of the determination of the heats of combustion made it possible to observe extremely fine energetic effects (the mutual influence of atoms and groups, the differences between the properties of isomers, etc.). Further improvement of the apparatus and methods for stationary bomb calorimeters involved the improvement of the means for the measurement of temperature, the technique of the calorimetric experiment, and the analytical part of the thermochemical experiment.[12-14]

†In 1984, 150 years elapsed since the date of the birth of the famous Russian chemist, V.F.Luginin, who was a student of M.Berthelot and professor of Moscow University. The review has been written to commemorate this jubilee.

The standard enthalpies of formation of gaseous lower fluoro- and chlorofluorohydrocarbons have been determined mainly by two methods: by measuring the enthalpy of reaction with alkali metals ($\Delta H$) [15,16] and by measuring the standard enthalpy of combustion in oxygen ($\Delta H_c^\circ$).[17,18]

Table 1. The specific combustion energies of standard substances at 298 K.

| Substance* | $-\Delta U_c^0/M$, J g$^{-1}$ | | | |
|---|---|---|---|---|
| | data from Laboratory of Thermochemistry at Moscow State University | refs. | data of other workers | refs. |
| Succinic acid (s) | 12638.3±3.4 | [10] | 12638.5±1.5** | [28] |
| *p*-Chlorobenzoic acid (s) | 19569.4±3.8 | [19] | 19566.6±1.9** | [28] |
| α-D-Glucose (s) | 15559.7±3.0 | [26] | 15557.9±1.6 | [29] |
| ααα-Trifluorotoluene (l) | 23058.6±2.9 | [27] | 23064±14 | [30] |
| | | | 23051.2±2.8 | [31] |

*Here and henceforth the state of the substance is indicated in brackets: (l) = liquid, (s) = solid, and (g) = gaseous.
**Values recommended by the Mendeleev All-Union Institute of Metrology.

As the range of substances investigated was extended and the experimental technique improved, the importance of the method of combustion in oxygen increased continuously in view of its universality. The improvement of the method of determining the energies of combustion in rotating bomb calorimeters made it possible to apply it in the study of a whole series of new groups of organohalogen compounds: for substances containing different groups of halogens (for example, $CF_3CHClBr$ and $CF_2BrCHFCl$), for gaseous and volatile Freons (for example, $CF_2ClCFCl_2$, $CF_2ClCCl_3$, and $CF_2ClCF_2Cl$), for perfluoro-compounds, etc.[19-21] The development of methods for the combustion of gaseous substances in the liquefied state in a bomb calorimeter, first used in experiments designed to determine the combustion energy of chlorotrifluoroethylene,[22] occupies a special place.

The validity of the results obtained has been confirmed by the analysis of the literature data.[20,23-25] The method for the determination of the enthalpies of combustion of liquefied gases has led to extensive possibilities for the investigation of the thermochemical properties of substances which are not fully combusted in the gaseous state in the bomb.

The reliability of the methods for the determination of the energies of combustion of organic and organohalogen substances in stationary and rotating bomb calorimeters has been demonstrated by measuring the energies of combustion of secondary standards and highly pure specimens of thoroughly investigated substances (Table 1).

In the present review we were naturally unable to analyse all the available experimental data on the thermochemistry of organic and organohalogen compounds and we were obliged to confine ourselves to the aspects of the field which have been developed at the Laboratory of Thermochemistry at Moscow State University with inclusion of literature data for related thermochemical fields. Almost the entire data in the review can be arranged in terms of three principal branches of thermochemistry: the thermochemistry of the polymerisation reactions of heterocyclic compounds, the thermochemistry of cyclic hydrocarbons and their derivatives, and the thermochemistry of organohalogen compounds. The development of each has been stimulated by the urgent requirements of industry.

## II. UNITS OF MEASUREMENT, AUXILIARY QUANTITIES, AND CALCULATION OF THE STRAIN ENERGY

The enthalpies of formation of organic and organohalogen compounds ($\Delta H_f^\circ$) quoted in this review constitute a system of mutually consistent quantities. In order to ensure this, all the enthalpies of formation have been recalculated on the basis of key quantities selected by the International Commission from the most reliable studies carried out in recent years and recommended by CODATA.[32] Since the values recommended by CODATA for certain key quantities (for example the $\Delta H_f^\circ$ for HF solutions) differ significantly from those adopted earlier,[33,34] the values of $\Delta H_f^\circ$ for organofluorine compounds presented in this review also frequently differ from those published in experimental or review communications.

All the thermochemical quantities in the present review are expressed in Joules in conformity with the international SI system of units. The data quoted in the original communications in calories have been recalculated on the basis of the relation 1 cal = 4.184 J.[35] The atomic weights have been adopted on the basis of IUPAC tables.[36] The enthalpies of dilution of HF and HCl solutions have been taken from Johnson et al.[37] and Cox et al.[38] respectively. The heat capacities of the individual substances have been taken from a handbook[33] and the heat capacities of solutions from Parker.[39]

The strain energies $E_S$ of cyclic compounds, considered in this review, were obtained as differences between the experimental $\Delta H_f^\circ$ and quantities calculated assuming additivity for unstrained acyclic molecules with the same number and character of bonds:

$$E_s = \Delta H^\circ_{f,(g),e} - \Delta H^\circ_{f,(g),c},$$

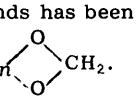
where $\Delta H_f^\circ$, (g), e is the experimental standard enthalpy of formation of the gaseous compound and $\Delta H_f^\circ$, (g), c the calculated value equal to the sum of the corresponding group contributions taken from Benson et al.[40] For certain groups of compounds, the $E_S$ were calculated analogously as the differences between the experimental and calculated enthalpies of combustion. The contribution of the $-CH_2-$ groups to $\Delta H^\circ_{c(g)}$ in these calculations was assumed to be $-658.63$ kJ mol$^{-1}$;[40] the contributions due to other groups are listed in the corresponding Tables in this review. In certain specially stipulated cases it proved possible to calculate the $E_S$ only for the liquid state; in this case the contributions of the $-CH_2-$ group were taken from Prosen and Rossini[41] and Skuratov.[42]

Such calculation yields conventional values of $E_S$, because the result depends on the choice of the additive scheme for the calculation of the $\Delta H_f^\circ$ for the unstrained analogue and in addition the calculation does not take into account the difference between the thermal and zero-point energies and also the difference between the internal energies and the enthalpies for the real cyclic molecule and the hypothetical molecule adopted as the unstrained species. The influence of these energy differences, which have not been allowed for, on $E_S$ has been examined;[43] it is relatively small and is approximately constant in each series of cyclic compounds, so that, when the values of $E_S$ are compared for compounds of a single series, the error arising due to the failure to take them into account is insignificant.

Questions associated with the nature of the strain and the complications arising in the quantitative analysis of the $E_S$ have also been examined in a number of studies.[44-46]. The conventional nature of the $E_S$ does not preclude the comparison and discussion of the reactivities of compounds of a single series[47] and of the dependence of the $\Delta H_f^\circ$ on their structure.[43,48]

The values of $\Delta H_c^\circ$, $\Delta H_f^\circ$, and $E_S$ presented below refer to 298.15 K (except for specified cases). The errors in the thermochemical quantities are expressed in terms of a 95% confidence interval.

## III. THERMOCHEMISTRY OF THE POLYMERISATION REACTIONS OF HETEROCYCLIC COMPOUNDS



The study of the thermodynamic properties of lactams and their *N*-methyl-substituted derivatives is of great interest from the standpoint of the investigation of the capacity of these compounds for polymerisation. The reactivity of heterocyclic compounds is known to depend greatly on the number of members in the ring. This has also been observed for a series of lactams whose capacity for polymerisation diminishes consistently on passing from an eight-membered ring (ζ-enantholactam) to a five-membered ring (α-pyrrolidinone).[49] The ability of lactams to polymerise can be rigorously characterised by the Gibbs free energy of polymerisation at the corresponding temperature. In order to determine this quantity, direct measurement of the enthalpy of polymerisation and the measurement of the absolute entropies of the monomers and polymers are normally required; both sets of measurements are extremely laborious and are not always possible.

However, it is possible to make a significant approach to the solution of this problem by employing the enthalpies of combustion of the monomers. Thus it has been shown[49] that one of the factors determining the different capacities of lactams for polymerisation is the ring strain energy $E_S$. The values of $E_S$ calculated[49] from the experimental enthalpies of combustion of lactams using data[50] for ζ-enantholactam, ε-caprolactam, α-piperidinone, and α-pyrrolidinone at 75 °C are 22.2, 15.9, 9.2, and 4.6 kJ mol$^{-1}$ respectively. The decrease of $E_S$ with decrease in the number of members in the ring ($8 > 7 > 6 > 5$) varies in parallel with the capacity of lactams for polymerisation.

Direct measurement of the enthalpies of polymerisation of caprolactam and enantholactam[42,51] and also the calculation of the enthalpies of polymerisation of these substances from the experimental $\Delta H_c^\circ$ of the polymer and monomer[52] led to values which agreed, within the limits of error, with the $E_S$ taken from Strepikheev et al.[49]. Strepikheev et al.[49] also demonstrated, in relation to 5- and 7-methylcaprolactams, that the substitution of a hydrogen atom in the methylene group by the methyl group does not affect significantly the ring strain.

Substitution at the N atom reduces the capacity of lactams for polymerisation to a greater extent than substitution at a C atom.[53] It has been suggested that N-substituted lactams are in general unable to polymerise, but it was later established that *N*-methylenantholactam nevertheless undergoes the polymerisation reaction.[54] The strain energies of *N*-methyl-lactams have been calculated[55] from the experimental enthalpies of combustion $\Delta H_c^\circ$(liq.); at 298 K they are 16.1, 9.2, −2.6, and −2.7 kJ mol$^{-1}$ for compounds containing between 8 and 5 members in the ring respectively. These data show that *N*-methyl lactams have significantly lower $E_S$ than their unsubstituted analogues. The highest $E_S$ has been observed for *N*-methylenantholactam; it is approximately equal to $E_S$ for the unsubstituted ε-caprolactam. In both series of compounds, at temperatures in the range 200–250 °C and a pressure of 100 kPa, the substances do not polymerise in the presence of activators if $E_S$ < 12 kJ mol$^{-1}$.[55]

For a more accurate description of the ability of substances to polymerise, it is necessary to take into account the entropy of this reaction. Since the entropies for unsubstituted lactams and certain polymers have been measured experimentally,[52] there is a possibility of testing and revising earlier conclusions. Comparison of the thermodynamic functions calculated[52] for the polymerisation reactions of four lactams shows that there is no significant difference between the $\Delta H$ and $\Delta G$ for the polymerisation of caprolactam and enantholactam and that in these cases allowance for the entropy term does not influence the conclusions reached above on the basis of the analysis of the $E_S$ alone. For the polymerisation reactions of α-pyrrolidinone and α-piperidinone, the difference between the enthalpies and Gibbs free energies is appreciably greater, because in this case the entropy of reaction $\Delta S$ is large. However, here too the qualitative conclusions reached from the analysis of the $E_S$ remain in force. Furthermore, since the entropies of α-pyrrolidinone and α-piperidinone are greater than the entropies of the corresponding linear polymers, allowance for the entropy term for the polymerisation reactions of these substances makes the Gibbs free energies of both reactions positive.

The thermochemistry of the polymerisation reactions of oxygen-containing compounds has been studied in relation to the cyclic formals  . The enthalpies of combustion and the strain energies for these substances are presented in Table 2. In the calculation of $E_S$, the contribution of the -O–$CH_2$–O- group to the standard enthalpy of combustion in the gaseous state $\Delta H_c^\circ$(gas) = −395.1 kJ mol$^{-1}$ was calculated as the difference between the values of $\Delta H_c^\circ$(gas) for di-n-butyl formal (Table 2) and n-octane (−5512.05 ± 2.9 kJ mol$^{-1}$ [50]). The enthalpies of evaporation required for the calculation of $\Delta H_c^\circ$(gas) have been calculated[57] from the semiempirical formulae quoted by Heukelom.[60] The standard enthalpies of evaporation $\Delta H_v$ were adjusted to 298 K on the basis of Watson's formula.[61] For comparison, the $E_S$ for cyclanes are also quoted in Table 2; the similarity of the dependences of $E_S$ on *n* for these two series is evident.

It follows from Table 2 that the strain energies of the formals investigated depend greatly on the number of members in the ring and decrease in the sequence 8 > 5 > 7 > 6. The equilibrium polymerisation of cyclic formals at 100–150 °C has been investigated[62] and it follows from the results that the capacity of cyclic formals for polymerisation decreases in the sequence 8 > 7 > 5 > 6 as a function of the number of members in the ring, i.e., as in the case of lactams, is largely determined by the strain energy.

Table 2. The enthalpies of combustion and evaporation and the strain energies of cyclic formals at 298 K (in kJ mol$^{-1}$)**.

| Substance | *n** | $-\Delta H_c^0$(l) | $\Delta H_v^?$ | $-\Delta H_c^0$(g) | $E_S$ | |
|---|---|---|---|---|---|---|
| | | | | | formals | cyclanes |
| Ethylene formal (l) | 5 | 1700.4±4.2 [56] | 35.6±0.4 [56] | — | — | — |
| | 5 | 1704.8±0.5 [57] | 33.5 [57] | 1738.3 | 25.7 | 26.4 |
| Trimethylene formal (l) | 6 | 2322.1±5.8 [56] | 35.6±0.8 [56] | — | — | — |
| | 6 | 2340.8±0.6 [58] | — | — | — | — |
| | 6 | 2331.9±0.8 [59] | — | — | — | — |
| | 6 | 2331.4±0.8 [57] | 38.5 [57] | 2369.9 | −1.1 | 0 |
| Tetramethylene formal (l) | 7 | 3008.8±0.9 [57] | 40.2 [57] | 3049.0 | 19.4 | 26.8 |
| Pentamethylene formal (l) | 8 | 3697.7±1.1 [57] | 43.9 [57] | 3741.6 | 53.3 | 41.4 |
| Di-n-butyl formal (l) | — | 5850.2±1.8 [57] | 56.9 [57] | 5907.1 | — | — |

Note. In this and subsequent tables the references are given to the original studies in which the experimental $\Delta H_c^\circ$ or $\Delta H_v^\circ$ were obtained. The values calculated by the authors of the present review from the tabulated data are quoted without references. When several experimental studies have been made, the $E_S$ were evaluated from the most reliable data and are given in the corresponding row.

The error of the initial experimental quantities is quoted after the original communications. The error of the calculated quantities is given in those cases where they have been obtained from reliable experimental data accompanied by the authors' estimate of the error.

If the experimental data referred to a temperature other than 298 K, we recalculated them for the standard temperature.

*The number of members in the ring.

**Here and henceforth the numerals in square brackets denote references (Ed.of Translation).

Indeed, the $E_S$ for five- and seven-membered rings are similar and the equilibrium yields of polymers also do not differ very greatly. On the other hand, the transposition of the formals with five and seven members in the ring can probably be accounted for by the effect of the entropy of polymerisation. It follows from general considerations that, with decrease of the number of members in the ring, the difference between the entropies of the linear polymer (calculated for the corresponding unit) and the monomer should diminish. The experimental entropies of polymerisation of lactams confirmed this. It has been shown that,[52] with decrease of the number of members in the ring from 8 to 5, $\Delta S$ gradually diminishes, changing sign at the same time. Whereas the entropy change is favourable for the polymerisation process in the case of eight- and seven-membered rings, in the case of five- and six-membered rings, it becomes unfavourable and the polymerisation reaction takes place by virtue of the enthalpy change or, in other words, the strain energy $E_S$. One can assume with

complete justification that the dependence of $\Delta S$ for polymerisation on $n$ has the character as for cyclic formals.

We may note that, although the thermochemistry of heterocyclic compounds has been investigated in order to elucidate and refine our knowledge about their capacity for polymerisation, the measurement of strain energies is of wider importance. It is to be expected that, for comparatively high values of $E_S$, other reactions involving the opening of the ring and the formation of straight-chain products will also take place more readily. Many instances of different reactivities of substances as a function of ring size are known for heterocyclic compounds. Thus tetrahydrofuran is more reactive than tetrahydropyran; five-membered glucosides are more reactive than six-membered glucosides and five-membered γ-monosaccharides are so unstable, in contrast to the six-membered compounds, that they have not even been isolated in a free state.[26]

The enthalpies of combustion of several monosaccharides as well as certain other oxygen-containing cyclic compounds are listed in Table 3. The contribution to the $\Delta H_C^\circ$ by the -O- group, found as the difference between $\Delta H_C^\circ$ for di-*n*-butyl ether (Table 3) and *n*-octane [50] and amounting to 125.0 kJ mol$^{-1}$ in the gaseous state, was used to calculate the $E_S$ for cyclic oxygen-containing compounds. Comparison of data obtained for the simplest oxygen-containing heterocycles (tetrahydrofuran and tetrahydropyran) shows that the strain energy of the six-membered ring is close to zero, while the strain energy of the five-membered ring is ~24 kJ mol$^{-1}$. Similar results are quoted above for cyclic formals and lactams.

Table 3. The enthalpies of combustion and evaporation and the strain energies of certain oxygen-containing cyclic compounds at 298 K (in kJ mol$^{-1}$).

| Substance | *n* | $-\Delta H_C^0$ | $\Delta H_v^\circ$ | $-\Delta H_C^\circ$ (gas) | $E_S$ |
|---|---|---|---|---|---|

*Here and in the subsequent Tables the quantities calculated from insufficiently reliable data or calculated using approximate methods are enclosed in round brackets.

Analysis of the $\Delta H_C^\circ$ for carbohydrates and other oxygen-containing cyclic compounds led to the conclusion[26,68] that the relations characteristic of compounds of other classes are typical also for them. Thus the simplest additive calculation of thermodynamic quantities is entirely feasible for carbohydrates whose molecules contain a large number of polar functional groups. On this basis, the authors[26,68] estimated the $E_S$ for the five-membered methyl β-D-glucofuranoside by comparing its enthalpy of combustion with the $\Delta H_C^\circ$ for the six-membered methyl β-D-glucopyranoside assuming that $E_S \approx 0$ for the latter, by analogy with other six-membered rings. Since the $\Delta H_V^\circ$ for these substances are unknown, the estimate could be carried out only for the liquid state. Table 3 shows that the $\Delta H_C^\circ$ for these two glucosides differ by ~30 kJ mol$^{-1}$ despite their overall formulae being identical. Having taken into account the enthalpy of fusion of methyl α-D-glucopyranoside, the authors[26,68] obtained the strain energy of methyl β-D-glucofuranoside, amounting to ~22 kJ mol$^{-1}$, which is very close to $E_S$ for tetrahydrofuran and other five-membered rings. The higher reactivity of five-membered rings can apparently be also explained by the appreciable strain energy. The polymerisation of γ-monosaccharides as well as other low-molecular-weight cyclic compounds, which is possible by virtue of the high $E_S$, probably plays an appreciable role in the biosynthesis of higher carbohydrates in nature.

The study of the mutual influence of the amino-groups and oxygen-containing groups is closely related to the investigation of cyclic lactams. Measurements have been made[69] of the $\Delta H_C^\circ$ for aliphatic aminoacids and the interaction energies of the amino- and carboxy-groups, amounting to ~13 kJ mol$^{-1}$, have been estimated. The similarity of the $\Delta H_C^\circ$ for different aminocaproic acids with different positions of the amino-group is evidence of the approximate constancy of the energy of this interaction.

## IV. ENTHALPIES OF COMBUSTION OF BRANCHED ALKANES

The measurement of the enthalpies of combustion and formation of branched alkanes made it possible to estimate the contribution of the interaction of hydrogen atoms in close proximity, for example in the methyl groups at quaternary carbon atoms separated by one methylene group. This interaction was not taken into account by the constants of the additive scheme proposed for the calculation of the enthalpies of formation of hydrocarbons.[70] On the other hand, the average difference between the experimental and calculated[70] $\Delta H_C^\circ$ amounted to ±2 kJ mol$^{-1}$; in three cases, namely for 2,2,4-trimethylpentane, 2,2,3,4-tetramethylpentane, and 2,2,4,4-tetramethylpentane, discrepancies between the calculated and experimental values exceeding the experimental error were noted. A prediction has been made[70,71] that the interaction of the methyl groups in such substances may be significant. It has been noted[72] that the distance between the closest hydrogen atoms of the $CH_3$ groups in the 2- and 4-positions in 2,2,4,4-tetramethylpentane, calculated on the assumption of a "staggered" configuration, is 0.0729 nm, whereas, for example, in the methyl group it is 0.1786 nm. Such an anomalous approach of the hydrogen atoms should alter the internal energy, by an amount which remains considerable even if one takes into account the fact that it is reduced somewhat owing to the rotation of methyl groups, which distort the valence angles.

The energy of interaction has been determined quantitatively[73] by measuring the enthalpies of combustion of several branched alkanes. The validity of the determination of the $\Delta H_C^\circ$ for 2,2,4,4-tetramethylpentane [73] has been confirmed by the satisfactory agreement of this value with the results of Johnson et al.[74]. The data obtained were used to calculate the correction which must be taken included in the calculation, by an additive scheme taking into account the first interaction sphere,[70] of the $\Delta H_C^\circ$ for all alkanes containing hydrogen atoms in close proximity, i.e. the C(3)–C–C(4) or C(4)–C–C(4) fragments. Taking into account this correction, the enthalpies of combustion of branched alkanes at 298 K can be calculated from the formula[72]

$$\Delta H_c^0 \text{ (kJ mol}^{-1}) = \sum_{i=1}^{4}\sum_{j=i}^{4} n_{ij} H_{ij(c)} - 10.13k$$

where $k = 1$ for each C(3)–C–C(4) fragment and $k = 2$ for each C(4)–C–C(4) fragment; $j \neq 1$.

## V. THERMOCHEMISTRY OF CYCLIC HYDROCARBONS AND THEIR DERIVATIVES

In recent years much attention has been devoted in the thermochemistry of organic compounds to the study of cyclic hydrocarbons and their simplest derivatives. The special interest in the thermochemistry of cyclic compounds is determined mainly by two causes: (1) the high specific combustion energy of a number of substances belonging to this class; (2) the specific thermochemical relations which are characteristic of cyclic compounds but have so far been little investigated.

Among these substances, compounds with small rings (three- and four-membered) are especially interesting because of their unusual structural and chemical features. For this reason special attention has been devoted to them in this review. We shall not dwell on the analysis of the thermochemical data for other monocyclanes and their derivatives, since they are few in number and in addition are well known.[50,75]

*The enthalpy of evaporation was calculated from the Klages formula.[103]

**The value of $\Delta H_c^\circ$ for hexylcyclopropane, given by Fierens and Nasielski[84] and also quoted by Pedley and Rylance,[50] deviates sharply from the series of $\Delta H_c^\circ$ for other substituted cyclopropanes.

***The $\Delta H_v^\circ$ were estimated from the group contributions quoted by Lebedev and Miroshnichenko.[83] The contribution of the three-membered ring to $\Delta H_v^\circ$, amounting to 3.3 kJ mol$^{-1}$, was obtained from a comparison of the experimental and calculated $\Delta H_v^\circ$ for cyclopropane and 1,1-dimethylcyclopropane.

****Determined by S.M.Pimenova in the Laboratory of Thermochemistry at Moscow State University.

### 1. Three- and Four-Membered Rings

The variation of the strain energy of the three-membered ring in substituted cyclopropanes and cyclopropenes is illustrated in Table 4. The nature of the bonds in cyclopropane and the interaction of the ring with substituents have been the subject of numerous theoretical studies.[76-79] For example, the interaction of the three-membered ring with various substituents, in the first place π-donors and π-acceptors, has been examined[79] within the framework of perturbation methods using molecular orbitals. The effect of the interaction was estimated[79] mainly from the change in the geometry of the ring. However, as can be seen from the same investigation, this criterion is by no means always sufficiently sensitive.

Thermochemical data for cyclopropane derivatives are fairly numerous and are of undoubted interest. The results of the measurements of the $\Delta H_c^\circ$ and $E_S$ for substituted cyclopropanes, presented in Table 4, show that the interaction of the substituent with the three-membered ring is complex and that the effect of the stabilisation (or destabilisation) of the ring does not always agree with the postulated effect. The substitution of hydrogen by one or two methyl groups gives rise to a relatively small effect. An appreciable decrease of $E_S$ has been observed for 1,1,2-trimethylcyclopropane and 1,1,2,2-tetramethylcyclopropane, going far beyond the limits of experimental error. However, this effect has not been noted for 2-n-alkyl-1,1-dimethylcyclopropanes. It has been shown[85] that the presence of the strained three-membered ring in the molecules of compounds of this series does not affect the bond energies in the side chain; this enabled the authors[85] to put forward a formula for the calculation of the $\Delta H_c^\circ$ for liquid 1-n-alkyl-2,2-dimethylcyclopropanes, starting with 1-ethyl-2,2-dimethylcyclopropane:

$$-\Delta H_c^0 \text{ (liq.) (kJ mol}^{-1}) = 4665.2 + (n-7)\,653.7,$$

where $n \geq 7$ is the number of carbon atoms in the molecule.

The strain energies of the *cis*- and *trans*-isomers of 3,3-dichloro-1,2-dimethylcyclopropane proved to be much greater than the $E_S$ for their hydrocarbon analogues. This conclusion must be regarded as preliminary, since the $\Delta H_v^\circ$ for these compounds are approximate estimates and the energy contribution of the $C-(Cl)_2(C)_2$ group (taken from Benson et al.[40]) used in the calculation of $\Delta H_f^\circ$(gas) for the hypothetical unstrained compound is not entirely reliable.

The introduction of an exocyclic double bond appreciably increases the strain energy of the ring, which can be seen in relation to methylenecyclopropane. In the calculation of $E_S$ for trimethylenecyclopropane it was assumed that the contribution of the $C_d-(C_d)_2$ group to $\Delta H_f^\circ$ is equal to the contribution of the $C_d-(C_d)(C)$ group; furthermore, the accuracy of the measurement of $\Delta H_f^\circ$(gas) is low. This makes it necessary to regard the result of the calculation of $E_S$ as approximate. However, the appreciable increase of $E_S$ in this case too can be hardly open to doubt (see Table 4). On the other hand, the strain energies of alkenyl- and alkynyl-cyclopropanes, in which the double (or triple) bond is separated from the ring by a single bond, are close to the $E_S$ for cyclopropane; for the majority of compounds, the difference is within the limits of the experimental error. This indicates the absence in most cases of an appreciable effect of the conjugation of the cyclopropane ring. However, there are also exceptions: the decrease of $E_S$ in cyclopropyl methyl ketone greatly exceeds the experimental error, while the strain energy of dicyclopropyldiacetylene calculated for a single ring is only 91.5 kJ mol$^{-1}$. The conjugation of the triple bonds probably plays a major role in the latter case.

When an endocyclic double bond is introduced, the strain energy of the three-membered ring increases even more than that after the introduction of the exocyclic bond. The same behaviour has been observed for methylcyclopropenes as for methylcyclopropanes: the $E_S$ for methylcyclopropene hardly differs from that for cyclopropene itself and the $E_S$ for 1,3,3-trimethylcyclopropene is significantly lower.

Phenylcyclopropanes have an even lower strain energy compared with the unsubstituted cyclopropane. For phenylcyclopropanes and 1,1-diphenylcyclopropanes, this decrease is approximately the same. The effect of the interaction of the phenyl group with the three-membered ring in 1,2-diphenylcyclopropanes depends on their relative positions: for the *trans*-isomer, $E_S$ is appreciably lower than for the *cis*-isomer. It is of interest that this feature is retained also in oxygen-containing phenyl-substituted derivatives: in phenylcyclopropanoic acids and their ethyl esters.

Comparatively few experimental enthalpies of combustion and strain energies are available for cyclobutane and cyclobutene derivatives (Table 5). So far as can be judged from the few reliable data, features similar to those noted above for cyclopropane and cyclopropene derivatives are characteristic of these compounds. Thus the strain energies of the alkyl-substituted derivatives differ little from the $E_S$ for cyclobutane. When a double bond is introduced, $E_S$ increases but the change in the $E_S$ for the four-membered ring is much smaller than for the three-membered ring.

Table 5. The enthalpies of combustion, formation, and evaporation and the strain energies of cyclobutane, cyclobutene, and their substituted derivatives at 298 K (in kJ mol$^{-1}$).

***Calculated from the Klages formula.[103]

### 2. Bicyclic Hydrocarbons with Separated Rings and Spirans

Table 6 presents the enthalpies of combustion and formation and the strain energies for bicyclic hydrocarbons in which two rings are separated by one or two σ-bonds and also for spirans. As was to be expected, the $E_S$ for the

individual rings in bicyclanes without a common carbon atom hardly differ from the $E_S$ for the corresponding monocyclanes. Thus the strain energy of one three-membered ring in bicyclopropyl is equal to the $E_S$ for cyclopropane within the limits of experimental error. The same feature has been observed also for other bicyclanes with analogous structures. It has been shown[111] that the difference between the enthalpies of combustion of a bicyclane and the corresponding monocyclanes in the liquid state is constant in all the known instances and amounts to $251.5 \pm 1.6$ kJ mol$^{-1}$. Thus the enthalpies of combustion of liquid bicyclanes in the molecules of which the rings are separated by one σ-bond can be calculated from the formula

$$\Delta H_c^0(\text{liq.})\ (\text{kJ mol}^{-1}) = [\Delta H_c^0(\text{liq.})]' + [\Delta H_c^0(\text{liq.})]'' + 251.5,$$

where $[\Delta H_C^\circ(\text{liq.})]'$ and $[\Delta H_C^\circ(\text{liq.})]''$ are the enthalpies of combustion of the corresponding monocyclanes.[11]

The difference between the enthalpies of combustion of dicyclopentylmethane and bicyclopentyl is −649.8 kJ mol$^{-1}$ according to Kozina et al.[11] Using this value and the data quoted above, it is possible to calculate approximately the $\Delta H_C^\circ$ for bicyclanes, in the molecules of which the rings are separated by the $-CH_2-$ group, from the formula

$$\Delta H_c^0(\text{liq.})\ (\text{kJ mol}^{-1}) = [\Delta H_c^0(\text{liq.})]' + [\Delta H_c^0(\text{liq.})]'' - 398.3,$$

where, as in the previous formula, $[\Delta H_C^\circ(\text{liq.})]'$ and $[\Delta H_C^\circ(\text{liq.})]''$ are the enthalpies of combustion of the corresponding monocyclanes. Presumably the interaction between the rings does not affect the thermodynamic quantities also in those cases where the number of rings separated by σ-bonds is greater than two.

*Calculated from the Klages formula.[103]

On the other hand, the strain energies of spiro-hydrocarbons are greater than some of the $E_S$ for the individual rings. For example, the strain energy of one three-membered ring in spiropentane is 132.8 kJ mol$^{-1}$, which exceeds by ~17 kJ mol$^{-1}$ the strain energy of cyclopropane. The increase of $E_S$ relative to the additive value has been observed also for other spiro-hydrocarbons, although the effect for these substances is smaller than for spiropentane (Table 6).

It has been shown[111] that, when the strain energies of individual rings in spiro-hydrocarbons are assumed to be equal to the values of $E_S$ for the corresponding monocyclanes, then the contribution introduced by the quaternary carbon atom to $\Delta H_C^\circ$ and $\Delta H_f^\circ$ is found to be constant for all four spirans investigated by Kozina et al.[111] This contribution naturally differs from that adopted by Benson et al.[40] since account was taken of the thermochemical characteristics of spirans in its calculation. By taking into account the data of Subach and Zvolinski,[112] the following formulae have been obtained for the approximate calculation of $\Delta H_C^\circ$ and $\Delta H_f^\circ$ for spirans (apart from those containing three- and four-membered rings):

$$-\Delta H_c^0(\text{gas})\ (\text{kJ mol}^{-1}) = 406.2 + 658.63n + \Sigma E_s,$$
$$\Delta H_f^0(\text{gas})\ (\text{kJ mol}^{-1}) = 12.8 - 20.71n + \Sigma E_s,$$

where $n$ is the number of $-CH_2-$ groups and $E_S$ the strain energies of the constituent rings of the given molecule according to Benson et al.[40]

### 3. Bridged and Condensed Bicyclic Hydrocarbons

The study of bicyclic hydrocarbons and their simplest derivatives has aroused much interest in recent years. The experimental measurement of the standard enthalpies of formation and of the strain energies calculated from them occupies an important place in such research. The special interest in the strain energies of these compounds is determined, in particular, by the fact that an increase in the rigidity of the molecular skeleton on passing from monocyclic to bicyclic and polycyclic compounds entails a change in the geometry of the individual rings, which greatly affects $E_S$. Thus, measurement of $E_S$ in combination with conformational analysis and electron diffraction and spectroscopic studies makes it possible to investigate the nature of the strain.[114-117] On the other hand, there remains the problem of the empirical study of $\Delta H_f^\circ$ and $E_S$ in order to investigate the influence of substituents, the introduction of a double bond, etc. on the latter with the aim of establishing the thermochemical relations for predicting the thermodynamic properties of compounds which have not been investigated. This Section deals with the results of thermochemical studies on compounds of two classes: bridged bicyclic hydrocarbons and their derivatives, i.e. [*n.m.k*]bicyclic compounds, and condensed bicyclic compounds, i.e. [*n.m.*0]-bicyclic compounds.

The thermochemical data for bridged bicyclic hydrocarbons and their simplest derivatives are presented in Table 7. The greatest number of experimental data are available for derivatives of bicyclo[2.2.1]heptane (norbornane). Table 7 shows that the strain energies of norbornane derivatives depend greatly not only on the number but also on the positions of the substituents. Even when hydrogen atoms are replaced by one or two methyl groups, $E_S$ varies from ~55 to ~80 kJ mol$^{-1}$. The introduction of the $CH_3$ group in the 2-position or even two $CH_3$ groups in the 2- and 3-positions, which are most remote from the "bridge" has comparatively little effect on the strain energy. On the other hand, $E_S$ for 1-methylnorbornane is lower by almost 10 kJ mol$^{-1}$ than for the unsubstituted norbornane. The introduction of two methyl groups at tertiary carbon atoms, i.e. in the 1- and 4-positions stabilises the molecule to an even greater extent. On the other hand, $E_S$ for 7,7-dimethylnorbornane is ~10 kJ mol$^{-1}$ higher than for norbornane.

**Table 7.** The enthalpies of combustion, formation, and evaporation (sublimation) and the strain energies of bridged bicyclic hydrocarbons and their derivatives at 298 K (in kJ $mol^{-1}$).

*Calculated from the Klages formula.[103]

**In the calculation of $\Delta H_f^\circ$ from the enthalpy of hydrogenation, the values of $\Delta H_f^\circ$ for the corresponding saturated compounds, taken from Pedley and Rylance,[50] were used here and henceforth.

***Recalculated by ourselves for 298 K.

The introduction of an endocyclic double bond appreciably increases $E_s$ but not to the extent observed for the three-membered ring. The influence of an exocyclic double bond depends on the position of the methylene group: the strain energy of 2-methylenenorbornane is a little lower and that of 7-methylenenorbornane is significantly higher than the $E_s$ for the initial molecule. $E_s$ is even greater for *cis*- and *trans*-ethylidenenorbornanes. The influence of the substitution of a hydrogen atom by the oxo-group is similar to the influence of the $=CH_2$ group: the oxo-group in the 7-position significantly increases while in the 2-position it slightly diminishes the strain energy. The introduction of the methyl group in the 1-position in the molecule of bicyclo[2.2.1]heptan-2-one, reduces $E_s$ still further, analogously to such substitution in norbornane. The replacement of the $-CH_2-$ group in the bridge by an ether oxygen atom entails some decrease of the $E_s$ for the 7-oxabicyclo[2.2.1]heptane molecule, in contrast to the three-membered ring, whose strain energy $E_s$ remains almost unaltered following such substitution.[40]

Bicyclo[2.2.2]octane is an interesting compound for the investigation of the nature of strain. Its molecule can be imagined as being made up of, as it were, two six-membered rings, but its strain energy proved to be unexpectedly extremely high, amounting to ~40 kJ $mol^{-1}$. It has been suggested[136] that this strain is mainly determined by the presence of three pairs of hydrogen atoms in the "eclipsed" conformation. The influence of the methyl substitution and also of exocyclic and endocyclic double bonds on the $E_s$ for bicyclo[2.2.2]octane is qualitatively similar to that noted above for norbornane derivatives, but is much weaker.

The marked dependence of $E_s$ on the structure of the molecule and on the position of the double bond is evident from the example of certain saturated hydrocarbons (Nos.1, 19, 41, and 42) and three bicyclononene isomers (Nos.20, 21, and 36, Table 7).

**Calculated from the Klages formula.[103]
***The value of $\Delta H_v^\circ$ measured for bicyclo[4.1.0]hept-3-ene is quoted.
****Estimated group contributions taken from Lebedev and Miroshnichenko.[83]

The results of the measurement of the enthalpies of combustion and strain energies of condensed bicyclic hydrocarbons and their derivatives are presented in Table 8. Unsubstituted bicyclo[*n.m.*0]alkanes are also extremely interesting objects for the study of strain in cyclic compounds. The strain energies of condensed rings do not in general consist of the sum of the contributions of the constituent monocyclic moieties of the molecule, but are fairly close to this value. Two factors affecting the strain energy on formation of a bicyclic compound have been noted:[143] the change in the conformation of the rings leading to an increase of $E_S$ and the disappearance of torsional interactions causing a decrease of $E_S$. The effects of these factors approximately cancel out for many real molecules. A more rigorous approach makes it necessary to reconcile data on the enthalpies of formation, molecular geometries, and vibrational frequencies. In many cases it has been possible to calculate fairly accurately the enthalpies of formation of cyclic hydrocarbons,[114–117] but this requires a knowledge of numerous accurately measured parameters, which are in practice not always known.

In relation to unsubstituted cyclic hydrocarbons of different classes, the dependence of the strain energy on the geometrical structure of the molecules has been analysed and correlation equations have been derived.[43] It has been found that the $E_S$ in the given series of compounds is determined mainly by the change of some one structural parameter. For example, in bridged bicyclic compounds $E_S$ is determined by the change of the dihedral angle, while in condensed bicyclic compounds it is determined by the deformation of the angles at the tertiary carbon atom. This may account for the characteristic variation of $E_S$ in each series of cyclic compounds after the introduction of the same substituents.

The empirical dependence of the enthalpies of formation of bicyclo[*n*.1.0]alkanes on their structure has been examined.[46]

The influence of substitution on the strain energy of bicyclo[*n.m.*0]alkanes can be traced in relation to bicyclo-[4.1.0]heptane (norcarane), for the derivatives of which numerous experimental data have been obtained (Table 8). The substitution of a hydrogen atom at the tertiary carbon atom of the methyl group does not affect the $E_S$, in contrast

to norbornane. The introduction of an endocyclic double bond entails an appreciable decrease of $E_S$, i.e. it exerts the opposite effect compared with norbornane and cyclopropane. On the other hand, the effect of an exocyclic double bond is small.

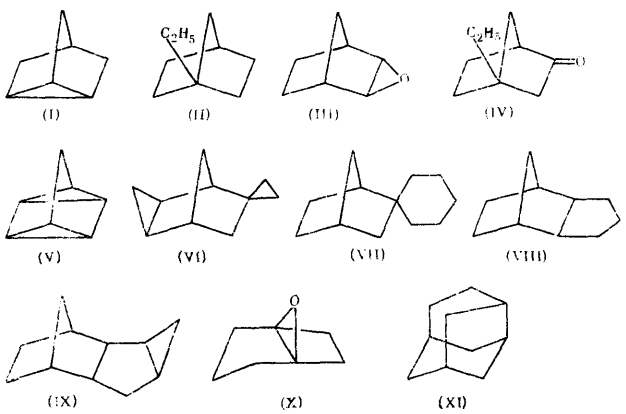

Table 8 shows that the strain energies of carane and carene (trimethyl-substituted derivatives of norcarane and norcarene) are somewhat greater than those of the initial compounds. It is of interest to note that the $E_S$ for 2-carene, whose double bond is conjugated with the three-membered ring, is greater than for 3-carene.

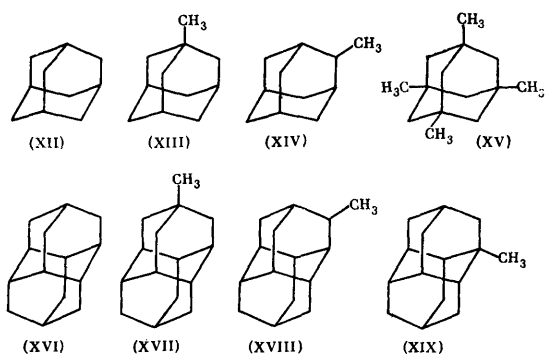
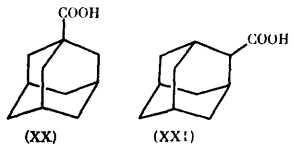
Many of the bicyclic compounds investigated are known only in the *cis*-form. However, in many cases $\Delta H_f^\circ$ and $E_S$ have been determined for the *cis*- and *trans*-isomers. The difference between these quantities for certain bicyclic hydrocarbons proved to be very considerable, amounting to ~10–20 kJ mol$^{-1}$ (Table 8)—see, for example, the strain energies of the *cis*- and *trans*-isomers of bicyclo[3.3.0]-octane, bicyclo[4.4.0]decane, etc.

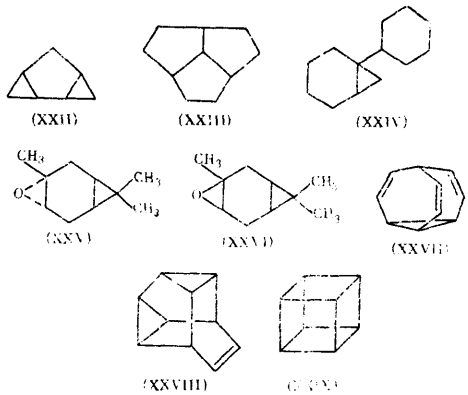


The introduction of oxygen into the three-membered ring of condensed bicyclic hydrocarbons leads to some increase in $E_S$, as in bridged bicyclic compounds. On the other hand, the presence of the OH group in the *cis*-carane structure entails an appreciable change in the strain energy regardless of its position and orientation.



### 4. Polycyclic Hydrocarbons and Their Derivatives

Until recently, the thermochemical properties of polycyclic compounds were little investigated. However, in the last decade a number of studies, mainly of bridged polycyclic compounds (I)–(XI) containing small rings with less than six atoms in the ring have been published.



The bridged polycyclic compounds (XII)–(XXI) containing only six-membered rings (adamantane, diadamantane, and their derivatives) constitute a separate group.

A few data are available for the condensed polycyclic compounds (XXII)–(XXIX) containing different rings, including seven-membered rings.

The study of polycyclic compounds has been partly induced by practical needs, because many of them enter into the composition of petroleum and their physicochemical properties are close to those of components of lubricating oils.[165] These compounds are of even greater interest for the investigation of the influence of the structural features of molecules on the energy properties of the given substance.

Thermochemical data for polycyclic hydrocarbons and their derivatives are presented in Table 9. It has been observed for the compounds investigated that the strain energies of the majority of these molecules are smaller than the sums of the contributions of the strain energies of the individual rings constituting the molecule. In some cases the strain energy may be much higher, for example, in cubane (XXIX) and spiro{tricyclo[3.2.1.0$^{2,4}$]octane-6,1′-cyclopropane} (VI) (Table 9).

It was initially assumed that the adamantane (XII) and diadamantane (XVI) molecules are unstrained, but the experimental determination of $\Delta H_c^\circ$ showed that their strain energies are appreciable (~20–40 kJ mol$^{-1}$). This finding has been explained[115,170] by the presence of angular strain and by the interaction of non-bonded carbon atoms.

It is noteworthy that the substitution of a hydrogen atom at a tertiary carbon atom by an alkyl group in nortricyclene (VII), adamantane, and diadamantane leads to an appreciable decrease in $E_S$. The introduction of the methyl group in the 2-position, causes, on the other hand, an increase in $E_S$. These effects are similar to that of alkyl substitution on the $E_S$ for norbornane (Table 7) and can apparently be accounted for by the same causes.

## VI. THERMOCHEMISTRY OF ORGANOHALOGEN COMPOUNDS

The organohalogen compounds investigated belong to different classes. A considerable proportion of them consist of fluoro-substituted lower hydrocarbons (methane, ethylene, ethane, and propane). The $\Delta H_c^\circ$ and $\Delta H_f^\circ$ have also been determined for many chlorofluoro-derivatives as well as bromine-containing compounds.

It is noteworthy that there are still many obscure problems and even contradictions in the thermochemistry of organohalogen compounds. This can be explained mainly by the methodological difficulties noted above. In recent years determinations of $\Delta H_c^\circ$ and $\Delta H_f^\circ$ for organohalogen compounds have been made in order to establish the thermochemical properties of the compounds of greatest importance for technology, to elucidate and resolve the contradictions in the available data, and also to investigate new promising classes of organohalogen compounds (tertiary perfluoroamines, fluoro- and chlorofluoro-ethers, fluorinated diketones, etc.). For example, the measurement of the $\Delta H_c^\circ$ and $\Delta H_f^\circ$ for 1,2,2-trichloro-1,1,2-trifluoroethane, 1-bromo-2-chloro-1,1,2-trifluoroethane, and chlorotrifluoroethylene made it possible to correct (by 40–50 kJ mol$^{-1}$) the incorrect values present in the literature and to solve one of the most complex problems of the thermochemistry of organohalogen compounds.[22]

Table 9. The enthalpies of combustion, formation, and evaporation (sublimation) and the strain energies of polycyclic compounds at 298 K (in kJ mol$^{-1}$).

*Calculated from the Klages formula.[103]
**The measurements were carried out by L.P.Timofeeva and L.L.Pashchenko in the Laboratory of Thermochemistry at Moscow State University.

The publication of numerous new experimental data made it necessary to revise the entire set of enthalpies of formation of organohalogen compounds. This revision is particularly urgently required also because until recently there has been a considerable lack of coordination in the selection of key quantities for the calculation of $\Delta H_f^\circ$. This virtually precluded the analysis of the experimental data and the search for thermochemical relations on the basis of the results of different workers.

In order to represent and analyse the entire experimental thermochemical data for organohalogen compounds on a modern basis, the $\Delta H_f^\circ$, both those obtained in the Laboratory of Thermochemistry at Moscow State University and the available literature data, were recalculated by ourselves on the basis of a single system of key quantities developed and adopted by CODATA.[32] Analysis of the available experimental data for different groups of organohalogen compounds led Kolesov[171] to the following results. In the case of halogenomethanes, the most reliable $\Delta H_f^\circ$ for 17 compounds were selected and on their basis the $\Delta H_f^\circ$ for all the remaining halogenomethanes were calculated by approximate estimation methods.[171] Among the halogenoethanes, reliable $\Delta H_f^\circ$ were selected for 37 compounds and the $\Delta H_f^\circ$ for all the possible 210 bromochlorofluoroethanes were calculated on the basis of these reference quantities in terms of the approximation of atom–atom pair interactions.[172]

A somewhat greater number of reliable $\Delta H_f^\circ$ values are available in the literature for the halogeno-derivatives of saturated aliphatic compounds. The enthalpies of formation of saturated fluoro- and chlorofluoro-derivatives of organic compounds ($n \geq 3$, where $n$ is the number of carbon atoms) are presented in Table 10, which embraces all the data known at present except the $\Delta H_f^\circ$ for methane and ethane derivatives as well as Swarts's obsolete data.[199] To facilitate the calculation of certain constants entering into computational schemes and to revise their values, Table 10 also includes two compounds without fluorine, namely propyl chloride and 1,1,1,3-tetrachloropropane. The majority of the quantities listed in Table 10 have been obtained experimentally in the Laboratory of Thermochemistry at Moscow State University. The experimental data have been analysed and the choice of the $\Delta H_f^\circ$ for compounds Nos.1–9 and 16–19 has been justified by Kolesov.[200] The numerical differences between the $\Delta H_f^\circ$ for the compounds in Table 10 and those quoted by Kolesov[200] can be due only to the recalculation in terms of the SI system of units and the recalculation in terms of the system of key quantities adopted by CODATA (see above). The details of the experimental determination of all the values of $\Delta H_f^\circ$ are given in the corresponding communications quoted in Table 10. The $\Delta H_v^\circ$ obtained from calorimetric and ebulliometric measurements were used to calculate the $\Delta H_f^\circ$(gas).[201–204] In those cases where the experimental data were lacking, the enthalpies of evaporation were estimated from the Klages[103] and Kistiakowsky[205] equations.

The experimental data were treated by Tatevskii's method.[70,206,207] Preliminary analysis showed[208,209] that at least a scheme taking into account the atoms in the first and second interaction spheres should be adopted as a single computational scheme which would ensure an accuracy of the calculation comparable to the experimental accuracy. However, the experimental data available at present are clearly insufficient for the calculation of all the constants involved in such a scheme. The experimental enthalpies of formation of the organofluorine compounds were therefore treated as follows.[208]

In the first place the constants necessary for the evaluation of the $\Delta H_f^\circ$ in accordance with the scheme involving "atoms in the first interaction sphere" were calculated from the available experimental data. In setting up this computational scheme, we began with the usual classification of structural elements, i.e. we took into account the chemical nature and valence state of the given atom and also the

chemical nature and valence state of the atoms linked directly to the given atom.[72] The structural elements were designated by the system of symbols taken from Benson et al.[40], which is fully consistent with the characteristics of the structural elements in the scheme involving atoms where the first interaction sphere is taken into account. In order to limit reasonably the number of unknowns, the contributions of the structural elements not containing halogens were taken from the same investigation.[40]

The enthalpies $\Delta H_f^\circ$ for 41 compounds (Table 10) were treated by the method of least squares. Comparison of the calculated and experimental $\Delta H_f^\circ$ shows that the computational scheme employed is extremely approximate and that the difference between the calculated and experimental values $\Delta(\Delta H_f^\circ)$ is several times greater than the experimental error in some cases. This comparison makes it possible to discover also groups of compounds for which the deviations $\Delta(\Delta H_f^\circ)$ are a maximum. This applies in the first place to perfluoroalkanes and substances where the perfluoro-group ($CF_3$ or $-CF_2-$) adjoins the $-CH_2-$ group. Appreciable discrepancies have also been observed for certain ethers. For the remaining compounds, the scheme involving atoms and their first environment as a rule yields satisfactory results.

In order to reduce the most serious of the discrepancies noted above, the calculation of $\Delta H_f^\circ$ in accordance with the "atoms in the first interaction sphere" scheme was refined by partial allowance for the second interaction sphere. Since the limited amount of experimental data precluded the complete allowance for the second interaction sphere, account was taken only of the second interaction sphere of the oxygen atom in the ethyl group and the carbon atom in the perfluoro-groups. For this purpose, the structural elements incorporating the second interaction sphere of the oxygen atom in ethers were identified, i.e. $O-(CF_2)(CF_2)$, $O-(CF_2)(CH_2)$, $O-(CF_2)(CCl_2)$, $O-(CF_2)(CCl_3)$, $O-(CF_2)(CH_3)$, and $O-(CF_2)(CF_2Cl)$. The perfluoro-groups were subdivided into two categories: the $C-(F)_3[C_F]$ and $C-(F)_2.[C_F]_2$ groups, adjoining only fluorine-containing groups even though these may not be fully fluorinated ($CF_2H$, $CF_3$, CFH, $CF_2$, CFCl, etc.) and the $C-(F)_3(CH_2)$ and $C-(F)_2(C).(CH_2)$ groups linked to at least one $-CH_2-$ group. Unfortunately a more detailed differentiation of the perfluoro-groups is so far impossible owing to the insufficiency of experimental data.

**Table 10.** Comparison of the experimental and calculated $\Delta H_f^\circ(g)$ for organohalogen compounds (in kJ mol$^{-1}$).

| No. | Substance | $-[\Delta H_f^0(g)]_{exp}$ | $-[\Delta H_f^0(g)]_{c,I}$ | $\Delta[\Delta H_f^0(g)]_I$ | $-[\Delta H_f^0(g)]_{c,II}$ | $\Delta[\Delta H_f^0(g)]_{II}$ |
|---|---|---|---|---|---|---|

Notation. $[\Delta H_f^\circ(g)]_{exp}$ is the experimental standard enthalpy of formation of the gaseous compound, while $[\Delta H_f^\circ(g)]_{c,I}$ and $[\Delta H_f^\circ(g)]_{c,II}$ are the values calculated respectively taking into account the first environment and with partial allowance also for the second environment.

**Table 11.** The contribution of atoms to $\Delta H_f^\circ(g)$ taking into account their first and in some cases also the second interaction sphere (in kJ mol$^{-1}$).

| Atoms and their environment | Contribution to $\Delta H_f^0(g)$ | Atoms and their environment | Contribution to $\Delta H_f^0(g)$ |
|---|---|---|---|
| $C-(F)_3[C_F]$ | −676.5 | $C-(Cl)(H)_2(C)$ | −63.6 |
| $C-(F)_3(CH_2)$ | −696.3 | $O-(CF_3)(CCl_3)$ | −642.8 |
| $C-(F)_2(Cl)(C)$ | −436.8 | $O-(CF_2)(CH_3)$ | −619.1 |
| $C-(F)(Cl)_2(C)$ | −255.9 | $O-(CF_2)(CF_2Cl)$ | −1069.8 |
| $C-(F)_2(H)(C)$ | −428.2 | $O-(CF_2)(CF_2)$ | −985.2 |
| $C-(F)(Cl)(H)(C)$ | −263.2 | $O-(CF_3)(CCl_3)$ | −643.9 |
| $C-(F)(H)_2(C)$ | −216.1 | $O-(CF_2)(CH_2)$ | −602.8 |
| $C-(F)_2[C_F]_2$ | −409.9 | $C-(H)_3(C)$ | −42.2 |
| $C-(F)_2(C)(CH_2)$ | −442.2 | $C-(H)_2(C)_2$ | −20.7 |
| $C-(F)(Cl)(C)_2$ | −207.1 | $C-(O)(C)(H)_2$ | −35.6 |
| $C-(F)(H)(C)_2$ | −201.8 | $O-(H)(C)$ | −158.5 |
| $C-(F)_2(CO)(C)$ | −402.3 | $O-(C)_2$ | −96.5 |
| $C-(F)_3(N)$ | −699.1 | $C-(H)_3(O)$ | −42.2 |
| $C-(F)_2(N)(C)$ | −416.6 | $O-(CO)(C)$ | −172.8 |
| $C-(Cl)_3(C)$ | −82.1 | $CO-(O)(C)$ | −139.7 |
| $C-(Cl)_2(H)(C)$ | −74.3 | $N-(C)_3$ | +102.1 |

Partial allowance for the second environment led to an increase of the constants of the additive scheme from 19 to 23. They were evaluated by the method of least squares in accordance with a standard program. The constants of these, i.e. the energy contributions to the $\Delta H_f^\circ$ from structural elements, are presented in Table 11, which includes also nine contributions taken from Benson et al.[40]. The $\Delta H_f^\circ$ calculated from the contributions in Table 11 are given in the sixth column of Table 10. It is seen from Table 10 that the differences between the calculated and experimental $\Delta H_f^\circ$ as a rule do not exceed the experimental error. Only for a few compounds does the discrepancy $\Delta(\Delta H_f^\circ)$ exceed 10 kJ mol$^{-1}$. These discrepancies can probably be accounted for by the incomplete allowance for the second environment of the atom. On the other hand, overall comparison of the experimental and calculated $\Delta H_f^\circ$ shows that the additive computational scheme, taking into account fully the first environment and partly the second environment of the atoms, is fully applicable in the approximate calculation of the standard enthalpies of formation of fluoro- and chlorofluoro-derivatives of organic compounds.

## VII. CONCLUSION

Thus it follows from the present review that the capacity of lactams, their *N*-methyl derivatives, and cyclic formals for polymerisation can be fairly fully characterised by thermodynamic functions obtained using calorimetric methods. The problem whether or not polymerisation reactions of other cyclic compounds are thermodynamically allowed still remains acute. For this reason, studies of the thermodynamics of the polymerisation reactions of cyclic compounds of different classes are being continued and will apparently continue to develop in the immediate future.[211,212] Studies carried out in recent years made it possible to generalise and refine the earlier conclusions. It has been established that the polymerisation of three-, four-, five-, seven-, eight-, and many six-membered rings of different chemical nature is thermodynamically allowed. On the other hand, the polymerisation reactions of acyclic monomers, leading to the formation of highly structured thermally stable polymers with cyclic fragments, have aroused much interest in recent years. The thermodynamics of reactions of this type, for example, the cyclotrimerisation of aryl cyanates, isocyanates, etc. has been vigorously investigated[213] and these studies will undoubtedly continue to develop.

Despite the fairly extensive experimental data, few reliably established relations are so far available in the thermochemistry of cyclic hydrocarbons and their derivatives. Some of them were noted above in the analysis of the $\Delta H_f^\circ$ for compounds with small rings and also with rings separated by a single bond. For compounds with a more complex structure (bicyclic bridged compounds, condensed bicyclic compounds, etc.), the experimental data obtained show that, as a rule, a characteristic dependence of the $\Delta H_C^\circ$ and $E_S$ on the nature, positions, and numbers of substituents in the molecule has been observed for each series of compounds. Extrapolation of the relations found for any one series of cyclic compound to other groups of compounds can lead to large errors. The study of the energetic and structural characteristics of cyclic compounds is therefore inevitably associated with the need for a fairly large set of reliable experimental data, particularly for methyl- and ethyl-substituted derivatives. They should be regarded as the first series members having unusual properties, which is analogous to the consideration of methane or ethane in the series of n-alkanes.

The numerical values of the strain energy have been used in the present review mainly for the analysis of thermochemical relations for particular groups of compounds. However, they can be useful also for the parametrisation of various empirical force field methods in order to calculate the $\Delta H_f^\circ$(gas) for cyclic compounds.[114-117]

The set of investigations carried out in the thermochemistry of organohalogen compounds has already made it possible to set up a system of thermochemical data by means of which it is possible to calculate approximately the enthalpies of formation of numerous compounds which have not yet been investigated. The accuracy of the calculations for the fluoro- and chlorofluoro-substituted n-alkanes is comparable to the accuracy of the determination of the experimental quantities.[172,208]

The further development of the thermochemistry of organohalogen compounds will apparently be determined by the investigation of new promising classes of substances and the accumulation of reliable experimental data for "reference" compounds.

# The Luminescence-spectroscopic Properties of Aromatic Radicals and Biradicals

V.A.Smirnov and V.G.Plotnikov

The luminescence-spectroscopic characteristics (the parameters of the absorption and luminescence spectra and the lifetimes and conditions in the observation of luminescence) of the radical products of the photolysis of aromatic compounds, namely abstraction radicals, hydro-radicals, radical-ions, and biradicals, are examined.
The bibliography includes 158 references.

## I. INTRODUCTION

The study of the luminescence-spectroscopic properties of polyatomic molecular systems can yield information about the nature and characteristics of the processes involved in the evolution of electronically excited molecular states. A number of problems of practical importance have made such research particularly timely. Among these we may mention the problem of the selection and creation of active media for lasers based on solutions of organic compounds, the development of methods of synthesis of effective organic phosphors and scintillators, the development of systems for the photochemical recording of information, the creation of photostable and radiation-chemically stable systems, etc.

The luminescence-spectroscopic properties of organic molecules have been so far studied in adequate detail and at sufficient depth and the general characteristics of their dependence on the electronic structure of the molecules have been established.[1-5] The principal stages in the development of such investigations are associated with the development of orbital models to describe the electronically excited molecular states, the study of the fine structure of vibronic states, and the development of theoretical ideas about the nature and characteristics of non-radiative conversion processes.

The problem of the determination of a relation between luminescence-spectroscopic properties and the structure of radicals and biradicals derived from organic compounds, which are the primary products of the photochemical and radiation-chemical reactions, has been solved to a much lesser extent. It is essential that they be solved because luminescence (together with EPR) is one of the main procedures whereby the decomposition products of the initial compounds can be detected. Furthermore, a luminescence analysis makes it possible to determine the electronic state in which the decomposition product is formed and hence to understand the mechanism of the process.

We may mention further that at advanced stages of photolytic (or radiolytic) processes, the radicals and biradicals themselves react and the mechanisms of such reactions cannot be understood without the knowledge of the nature of their electronic states.

The present review gives a systematic account of experimental luminescence-spectroscopic data for the radicals, biradicals, and radical-ions derived from aromatic compounds together with their interpretation based on molecular orbital ideas concerning the nature of the electronically excited states and the general characteristics of the processes involved in radiative and non-radiative evolution. Since these ideas and characteristic features have been described in a number of reviews in recent years,[2,4,5] in the present review we will confine ourselves to a brief description.

## II. GENERAL CHARACTERISTICS OF THE LUMINESCENCE OF POLYATOMIC MOLECULAR SYSTEMS

The electronic states of radicals and biradicals, like those of molecules, can be classified in terms of the multiplicity of the given states. The electronic states of molecules and biradicals can be of the singlet ($S$) and triplet ($T$) types, because these systems contain an even number of electrons. In the majority of molecules, the ground state is of the singlet type ($S_0$) and the electronically excited state with the lowest energy is of the triplet type. The ground state of the majority of known biradicals is of the triplet type. In conformity with the fact that radicals contain an odd number of electrons, they can have either doublet ($D$) or quartet ($Q$) electronic states. The ground state of known radicals derived from organic compounds is of the doublet type ($D_0$). The lowest electronically excited state in most cases is a $D$ state, while $Q$ states have a higher energy.

Another important characteristic feature of excited states is their orbital nature. Ideas concerning the orbital nature of the electronic transitions and electronically excited states, which have been developed in detail for planar $\pi$-electron systems, can be used without any changes for planar radicals and biradicals. Accordingly, $S_{\pi\pi^*}$, $S_{n\pi^*}$, $T_{\pi\pi^*}$, $T_{n\pi^*}$, etc. states are possible in biradicals, whereas $D_{\pi\pi^*}$, $D_{n\pi^*}$, $Q_{\pi\pi^*}$, $Q_{n\pi^*}$ states are possible in radicals. For systems

with a non-planar structure, states of the $n\pi^*$ and $\pi\pi^*$ types cannot, strictly speaking, be separated even in terms of the Condon approximation. However, when the deviations of the geometrical structure of the system from planarity are small or when the $\pi$ and $n$ orbitals are separated by large energy gaps, the lowest excited states of the system can be approximately classified as $\pi\pi^*$, $n\pi^*$, etc. states.[6] As for molecules, we shall retain designations of the type $S_0$, $T_0$, and $D_0$ for the ground state, because they are adequate for the description of the luminescence-spectroscopic properties (we may note that they can be specified in greater detail for the purpose of the EPR method). Here we shall also not dwell on the differentiation of the $\pi\pi^*$ and $n\pi^*$ states of molecular systems containing $l$ and $\nu$ orbitals.[4]

Two principal channels leading to the decomposition of electronically excited states of photostable polyatomic systems are known to exist, namely the photon emission process (luminescence) and non-radiative conversion processes in which the energy of the electronic excitation is converted into the vibrational energy of the nuclei of the system. The probability of both is governed significantly by the orbital nature and multiplicity of the combining states and (especially for the conversion processes) by the transition energy. The general features which determine the probability of the radiative processes and the non-radiative conversion processes as a function of the structure of the molecular system have been to a large extent elucidated for $\pi$-electron molecules. Some of them can be transferred to polyatomic radicals and biradicals without significant changes, while others must be somewhat modified taking into account the characteristic features of the structures of these systems and the form of their energy spectra. Here we shall discuss briefly these features emphasising their similarity and differences in the case of molecules, radicals, and biradicals.

### (a) Radiative Transitions

The probability of radiative transitions between states of identical multiplicity (fluorescence in the case of emission) is determined by the orbital nature of the transition. Since the expressions for the probability of a radiative transition in molecules, radicals, and biradicals, contain isotypical matrix elements of the dipole moment of the transition, the features found for molecular systems can be used also for radicals and biradicals. In the case of the symmetry-allowed $\pi \rightarrow \pi^*$ transitions ($D_0 \rightarrow D_{\pi\pi^*}$, $T_0 \rightarrow T_{\pi\pi^*}$, $S_0 \rightarrow S_{\pi\pi^*}$) the dipole moment of the transition $e\langle\pi|\mathbf{r}|\pi^*\rangle$ (where $\mathbf{r}$ is the radius-vector of the electron and $e$ its charge) is approximately 1 a.u., the oscillator strength $f \cong 0.1-1$ and the radiative lifetime $\tau_r$ of the excited state is $\sim 10^{-8} - 10^{-9}$ s. If the $\pi \rightarrow \pi^*$ transition is symmetry-prohibited, its probability may be found to be non-zero only on going outside the framework of the Condon approximation. The oscillator strength is then reduced to approximately $10^{-3} - 10^{-4}$ and $\tau_r$ is increased to $\sim 10^{-6}$ s.[7]

The $n \rightarrow \pi^*$ electronic transition is allowed in terms of the Condon approximation only when the $n$ orbital contains an admixture of an atomic $s$ orbital. The oscillator strength of such a transition is approximately $10^{-3}$ and $\tau_r \cong 10^{-6}$ s.[8] For the symmetry-prohibited $n \rightarrow \pi^*$ transitions, the oscillator strength is $\sim 10^{-4} - 10^{-5}$ and the lifetime is $\sim 10^{-5}$ s.[9] We may note that, when the steric structure of the system deviates from planarity, the $n\pi^*$ and $\pi\pi^*$ states of the corresponding planar configuration are mixed and the probability of a transition genealogically related to the $n \rightarrow \pi^*$ transition increases.

The probability of multiplicity-prohibited transitions depends on the energy of the spin-orbital coupling of states of different multiplicity, which depends in its turn on the orbital nature of the interacting states. The matrix elements for the spin-orbital coupling of states (of identical orbital nature) of planar molecular systems are small, because they contain only the three-centre one-electron integrals and two-electron integrals. They are estimated as approximately 0.1 $cm^{-1}$.[10,11] The matrix elements of the spin–orbital coupling of electronic states of different orbital nature (for example, $n\pi^*$ and $\pi\pi^*$) include one-centre one-electron integrals, which are proportional to $Z^4$, where $Z$ is the effective charge of the atomic nucleus carrying the $n$ electrons. For this reason, the matrix elements $|\langle S_{\pi\pi^*}|\hat{H}_{SO}|T_{n\pi^*}\rangle|$ and $|\langle S_{n\pi^*}|\hat{H}_{SO}|T_{\pi\pi^*}\rangle|$ are relatively large, amounting to approximately 100 $cm^{-1}$.[12] The matrix elements $|\langle D_{n\pi^*}|\hat{H}_{SO}|Q_{\pi\pi^*}\rangle|$ and $|\langle D_{\pi\pi^*}|\hat{H}_{SO}|Q_{n\pi^*}\rangle|$ can reach values of the same order of magnitude. Such a large difference between the coupling energies of states of the same and different orbital nature and the difference between the probabilities of the multiplicity-allowed $\pi \rightarrow \pi^*$ and $n \rightarrow \pi^*$ transitions lead to significant differences between the probabilities of the multiplicity-prohibited $\pi \rightarrow \pi^*$ and $n \rightarrow \pi^*$ transitions.

Since the $T_{n\pi^*}(Q_{n\pi^*})$ states are linked by a comparatively strong spin–orbital coupling with the $S_{\pi\pi^*}(D_{\pi\pi^*})$ states and the probability of the $S_0 \rightarrow S_{\pi\pi^*}$ ($D_0 \rightarrow D_{\pi\pi^*}$) transitions is high, the radiative lifetime of the $T_{n\pi^*}(Q_{n\pi^*})$ states is comparatively short. For molecular systems, it amounts to approximately $10^{-4} - 10^{-3}$ s.[1-4] For reasons which are clear from the foregoing, the radiative lifetime corresponding to the $T_{\pi\pi^*} \rightarrow S_0$ and $Q_{\pi\pi^*} \rightarrow D_0$ transitions is, unlike the previous case, large, amounting to 0.1–10 s.[1-4]

### (b) Non-radiative Conversion Processes

Such processes are understood as processes involving the conversion (total or partial) of the electronic excitation energy of the system into vibrational energy. Two types of conversion processes are distinguished in molecular systems: the internal conversion processes ($S-S$ and $T-T$) and intersystem crossing processes: singlet–triplet ($S-T$) and triplet–singlet ($T-S_0$) (degradation processes). The internal conversion processes take place as a consequence of non-adiabatic interaction, while intersystem crossing processes are possible only with participation of spin–orbital coupling.

The probability of internal conversion processes diminishes exponentially with increase of the transition energy.[13] If the transition energy exceeds approximately 2.5 eV, the probability of this process is less than the probability of emission and intersystem crossing. In this case the contribution of the internal conversion process may be neglected in the description of the evolution of the electronically excited state. Such a situation is observed in reality for many polyatomic aromatic molecules in the transition between the lowest excited $S_1$ state and the ground $S_0$ state.[14] In molecules containing a comparatively small number of atoms (for example, in benzene and its simplest derivatives) the $\pi \rightarrow \pi^*$ electronic excitation entails an appreciable decrease of the lengths of the C–H bonds whose stretching vibrations play the role of promoting vibrations in the internal conversion process. This leads to such a significant increase of the probability of the internal conversion that it becomes close to the probability of emission and $S-T$ conversion even for transitions with energies exceeding approximately 2.5 eV.[13]

If the transition energy is 1.5–2.5 eV, then the probability of internal conversion for polyatomic molecules and molecules with a comparatively small number of atoms is similar to, as regards order of magnitude, or exceeds the probability of emission and $S-T$ conversion. In this case the internal conversion process competes with other processes leading to the decomposition of the excited state and the role of conversion increases with decrease of the transition energy.

Finally, if the transition energy is less than approximately 1 eV, the main pathway to the decomposition of the excited state becomes the internal conversion process whose rate constant exceeds $10^{11}$ $s^{-1}$ and it suppresses the emission process. This energy range is characteristic of transitions between the electronically excited states of molecular systems: the very low (approximately $10^{-4}$) quantum yields of the fluorescence in the highest excited states are due to this factor (Kasha's rule[1]). The internal conversion process is characterised by an isotope effect (H/D) whose magnitude increases sharply (exponentially) with the increase of the transition energy. If the conversion process competes with the emission process, then the isotope effect affects also the fluorescence yield.[15]

Thus, since, as shown below, the energy of the long-wavelength multiplicity-allowed transition is much smaller for radicals and biradicals than for molecules, the internal conversion process ($D_1-D_0$ or $T_1-T_0$) in radicals may compete with the fluorescence process and the fluorescence quantum yield should be sensitive to isotopic H/D substitution; such a situation has indeed been observed experimentally. As for molecules, the yield of the fluorescence from the highest excited states of radicals and biradicals cannot be high.

The probability of the intersystem crossing (degradation) processes depends on the energy of the spin–orbital coupling of the combining states and diminishes exponentially with increase of the transition energy. Since the energy of the spin–orbital coupling of states of different orbital nature is relatively high (see above), the probability of the conversion processes $S_{\pi\pi^*} \rightsquigarrow T_{n\pi^*}$ and $S_{n\pi^*} \rightsquigarrow T_{\pi\pi^*}$ is also high and the rate constant is approximately $10^{10}-10^{11}$ $s^{-1}$ for molecules.[2,4] If there is a possibility of processes of this type, the fluorescence quantum yield is very low, (approximately $10^{-3}-10^{-4}$). In conformity with the fact that the spin–orbital coupling of states of an identical orbital nature is weak, the probability of the $S_{\pi\pi^*} \rightsquigarrow T_{\pi\pi^*}$ and $S_{n\pi^*} \rightsquigarrow T_{n\pi^*}$ conversion processes is appreciably lower and amounts to approximately $10^7-10^9$ $s^{-1}$.[2,4] Consequently processes of this kind can compete with the fluorescence process but do not lead to the complete suppression of the latter. The relations between the processes involved in the evolution of excited states described above serve as a basis for a systematic treatment of molecules in terms of their luminescence-spectroscopic properties.[16,17] These features can be transferred without any changes to the $S \rightarrow T$ and $T \rightarrow S$ transitions in biradicals and the $D \rightarrow Q$ transitions in radicals. In particular, it is shown below that, when there is a possibility of intersystem crossing between the excited states of different orbital nature, the fluorescence yield of biradicals is very low.

In the case of intersystem non-radiative transitions to the ground state where the probability of the transition depends on the spin–orbital coupling, the dependence of such probability on the transition energy, which has been studied in detail both experimentally and theoretically for molecular systems,[2,4,18,19] becomes of primary importance. A sharp decrease of the phosphorescence yield with decrease of the energy of the $T \rightarrow S_0$ transition is a consequence of this dependence. Such behaviour also obtains in the case of radicals and biradicals.

Thus one may expect that, if the energies of the excited states of radicals and biradicals are relatively low, the quantum yield of their luminescence should be smaller than for molecules.

## III. THE BENZYL RADICAL

The luminescence of radicals of the benzyl type (the triphenylmethyl radical) was first observed in 1944.[20] This radical was formed chemically in solution in the ether–isopentane–alcohol (EPA) mixture; on cooling the solution to 90 K, the absorption and luminescence spectra of the radical were recorded.

The benzyl radical is the simplest odd alternant aromatic hydrocarbon and its structure has been thoroughly investigated.[21] It is illustrated in Fig. 1*a*. Three of the four electrons of the methyl carbon atom are located in the hybrid $sp^3$ orbitals forming two C–H bonds and one C–C bond; the fourth electron is involved in $\pi$ conjugation.

Numerous theoretical calculations by various methods[22–25] indicate the occurrence of prohibited electronic transitions in the range 400–500 nm (2.5–3 eV) and of allowed transitions in the ultraviolet region of the spectrum at 250–350 nm (3.5–5 eV).

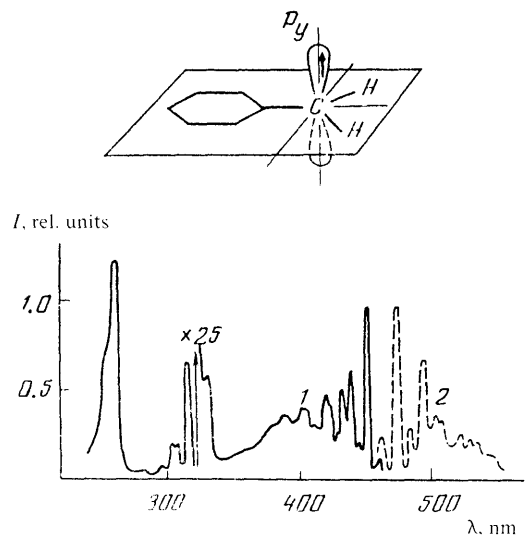

**Figure 1.** *a*) The structure of the benzyl radical; *b*) the excitation (curve *1*) and luminescence (curve *2*) spectra of the benzyl radical in a vitreous solution at 77 K.[41]

The absorption spectrum (the luminescence excitation spectrum) of the benzyl radical (Fig. 1) has three distinct bands in the region of 450, 320, and 250 cm, which correspond to different electronic transitions. The characteristics of these bands are presented in Table 1. The most probable extinction coefficients are $\varepsilon_1 \cong 50$ litre $mol^{-1}$ $cm^{-1}$ in the long-wavelength band, $\varepsilon_2 \cong (1-5) \times 10^3$ litre $mol^{-1}$ $cm^{-1}$ in the region of 320 nm, and $\varepsilon_3 \cong 10^4$ litre $mol^{-1}$ $cm^{-1}$ in the short-wavelength region. The weak absorption band in

the region of 450 nm was first observed in the photolysis of toluene in solution in the isopentane–methylcyclohexane glass at 77 K.[26] It has been noted[27] that the extinction coefficient of the benzyl radical can vary with solvent polarity: with increase of the polarity, the ratio $\varepsilon_{258}/\varepsilon_{318}$ diminishes: at room temperature it is 4.4 in cyclohexane, 3.3 in alcohol, and 2.5 in water.

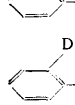
| 21 626 | n-Pn | pc | 77 | [44] |
| 22 007 | neon | — | 4.2 | [45] |

Notation: gl = vitreous state (glass), pc = polycrystalline state, 3-MP = 3-methylpentane, MCH = methylcyclohexane, CP = cyclopentane, MCP = methylcyclopentane, CH = cyclohexane, and n-Pn = n-pentane.



The luminescence of the benzyl radical was first observed in an electric discharge in toluene vapour.[38,39] It was subsequently observed in solutions in glasses[40,41] and in polycrystalline hydrocarbons[42–44] at 77 K and also in a neon matrix at liquid helium temperature.[45] Table 2 presents the energies of the 0–0 transitions of benzyl radicals under different conditions. In the gaseous phase the energy of 22002 cm$^{-1}$ (454.5 nm) appears to be the most likely. The same transition energy has been found also in an inert gas (neon) matrix at 4.2 K. A shift of the 0–0 transition towards lower energies by 300–400 cm$^{-1}$ (~10 nm) has been observed in the condensed phase. Deuteriation of the radical reduces the energy of the 0–0 transition by 90–100 cm$^{-1}$ in both gaseous[48] and condensed[43] phases.

According to theoretical calculations, bands corresponding to two $\pi \rightarrow \pi^*$ electronic transitions, having similar energies but associated with excited electronic levels of different symmetry ($A_2$ and $B_2$), should occur in the long-wavelength part of the spectrum; according to some calculations, the lowest excited level has the $A_2$ symmetry,[49,50] while in other studies the lowest excited state is said to have the $B_2$ symmetry.[24]

A calculation carried out[23] taking into account only singly excited configurations has led to the conclusion that this state has the $B_2$ symmetry; allowance for doubly excited configurations lowers the energy of the states with the $A_2$ symmetry. It is now regarded as established that the lowest excited state has the $A_2$ symmetry both in solid solutions[51] and in the gaseous phase[47,52] and that the splitting between the excited $1^2A_2$ and $2^2B_2$ states is 430–485 cm$^{-1}$ for the benzyl radical and 355–370 cm$^{-1}$ for the perdeuteriobenzyl radical.

Thus the $1^2A_2$–$1^2B_2$ optical transition is responsible for the fluorescence of the benzyl radical. This transition is symmetry-prohibited and the extinction coefficient is approximately 50 litre mol$^{-1}$ cm$^{-1}$ (Table 1) and, when account is taken of the fact that the energy of this transition is ~2.5 eV and that the radical contains relatively few atoms, competition is to be expected between the internal conversion and $D_1 \rightarrow D_0$ fluorescence processes. Experimental data have confirmed this: the fluorescence quantum yield of the benzyl radical is 0.39, while deuteriation increases it to 0.47.[53]

Table 3. The fluorescence lifetimes (μs) of the benzyl radicals in glasses at 77 K and in the gas phase.

| Radical | Matrix | | | | | |

|  | — | — | 1 54 | — | — | — |
|  | 1.73 | — | 1.26 | — | — | — |
|  | 3.21 | — | — | — | — | — |
|  | 3.26 | — | 3.22 | — | — | — |
|  | 3.93 | 2.97 | 3.65 | 3.69 | — | 1.34 |

Notation: EPA = ether–isopentane–alcohol and 3-MH = 3-methylhexane; for the significance of the remaining symbols, see the footnote to Table 2.

Table 3 presents the fluorescence lifetimes of the benzyl radical and its deuteriated analogues in glassy solvents at 77 K. These times are of the order of $10^{-6}$ s, which

corresponds to the symmetry-prohibited $\pi \rightarrow \pi^*$ transition. Estimation of the oscillator strength from the formula $f = 1.5\tau_f^{-1}\nu^{-2}$, where $\nu = 22600$ cm$^{-1}$ is the average transition frequency, yields $f = 8 \times 10^{-4}$;[54] the extinction coefficient estimated from this oscillator strength is 68 litre mol$^{-1}$ cm$^{-1}$.[33]

The quartet states of the benzyl radical lie above the lowest excited doublet states. Theoretical calculations lead to the following energies of the lowest quartet states of the benzyl radical: 3.65 eV (29450 cm$^{-1}$),[23] 3.92 eV (31630 cm$^{-1}$),[24] and 3.89 eV (31380 cm$^{-1}$),[25] while the energy of the doublet–doublet transition is 2.67 eV (21550 cm$^{-1}$). The intersystem doublet–quartet conversion $D_{\pi\pi^*}$–$Q_{\pi\pi^*}$ in the benzyl radical cannot compete with the $D$–$D$ internal conversion process whose rate constant exceeds $10^{11}$ s$^{-1}$ for the energy of the transition between the states less than 1 eV; for this reason, the $Q$–$D$ phosphorescence of the benzyl radical has not been observed.

## IV. RADICALS OF THE BENZYL TYPE

This Section deals with the properties of aromatic radicals containing an unpaired electron at the α-carbon atom of an aliphatic substituent. These include radicals arising from the decomposition of alkylbenzenes and their homologues—radicals of the diphenylmethane and triphenylmethane series. Their luminescence-spectroscopic characteristics are presented in Table 4. The unpaired electrons in these radicals participate in π conjugation and their lowest electronically excited states are ππ* states, although they contain an admixture of the σπ* states in the case of nonplanar systems.

**Table 4.** The 0–0 transition energies and the fluorescence lifetimes ($\tau_f$) of radicals of the benzyl type.

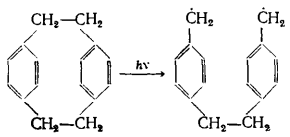
*In the gas phase and for solution No.56 in CH room temperature was used; the temperature for specimens Nos.1–22, 32–47, 56, and 59–66 was 77 K; the temperature for specimen No.57 in argon and No.59 was 20 K; the temperature for specimens Nos.26–31 was 88 K.

**Here R = $CH_3$, $C_2H_5$, or n-$C_3H_7$.

***Thermoluminescence was observed on raising the temperature above 77 K.

It is seen from Table 4 that the introduction of alkyl substituents into the aromatic ring of the benzyl radical reduces the energy of the first excited $D_{\pi\pi^*}$ state; the decrease is 2760 cm$^{-1}$ for hexamethylbenzene. The probability of the radiative transition increases with increase of the number of aliphatic substituents as a consequence of the removal of the symmetry prohibition, which entails an increase of the fluorescence quantum yield[33] and a decrease of the lifetime of the excited state. As for the benzyl radical, the $D_1$–$D_0$ internal conversion process competes with the emission process, which is the reason for the effect of isotope substitution on the fluorescence lifetime.



The photolysis of certain compounds (pentamethylbenzene, ethylmethylbenzenes), in solid matrices gives rise to nonequivalent radicals and at least two sets of vibrational bands appear in the luminescence spectrum, while a doublet with a splitting of 100–200 cm$^{-1}$ corresponds to the 0–0 transition (Table 4). However, only one set of vibrational bands is manifested in a gas discharge regardless of the nature of the second alkyl substituent.[62] This suggests that the radical is formed in the discharge as a result of the dissociation of a C–H with minimal energy. The same result has been obtained also in the condensed phase.[63] It has been shown in relation to reactions involving the abstraction of a halogen atom on electron capture in γ-irradiated frozen solutions[61] that, if a radical with an unpaired valence at the β-carbon atom of the alkyl substituent is formed initially, it rearranges to a more stable radical via the dissociation of the α-C–H bond even in a vitreous solution.

An interesting effect of the dissociated halide ion on the luminescence-spectroscopic properties of benzyl type radicals has been observed.[55,57,61,76] A halide ion adjoining the radical induces a bathochromic shift of the spectrum (by 140 cm$^{-1}$ for $Cl^{-1}$), a change in the vibrational structure of the fluorescence spectrum of the radical, and a decrease of the fluorescence lifetime. New bands due to radical–halide ion charge-transfer complex appear in the absorption spectrum in the region of 265, 362, 413, and 500 nm for $F^-$, $Cl^-$, $Br^-$, and $I^-$ respectively. This effect is absent in polar matrices, since the halide ion is solvated by solvent molecules.

The fluorescence of the diphenylmethyl and triphenylmethyl radicals is displaced to the red region relative to the benzyl radical (Table 4) and the energy of the 0–0 transition for the diphenylmethyl radical (19120 cm$^{-1}$) is smaller than for the triphenylmethyl radical (19400 cm$^{-1}$). This is apparently associated with the fact that the diphenylmethyl radical has a structure closer to planarity. It has been noted[70] that methyl substituents in the *para*-position significantly reduce (by 3000 cm$^{-1}$) the energy of the 0–0 transition for triphenylmethyl radicals. This appears doubtful, since the introduction of even the amino-group shifts the 0–0 transition band by a smaller amount (by 2400 cm$^{-1}$).[71] In the benzyl radical the methyl, hydroxy-, and amino-substituents in the *para*-position lower the 0–0 transition energy by 250, 1500, and 2500 cm$^{-1}$ respectively (Table 4).

The luminescence of other radicals of the benzyl type is known only for methylnaphthalenes.[72–74] In the photolysis of methylnaphthalene in n-paraffin matrices at 77 K, a luminescence, attributed to methylnaphthyl radicals, appears in the red region.[72] Luminescence attributed to methylnaphthyl radicals has also been observed in an electric discharge in ethyl- and dimethyl-naphthalene vapours.[73,74] Both in the gas discharge and in the condensed phase, the energy of the 0–0 transition is in the region of approximately 17000 cm$^{-1}$ (~590 nm), but in the case of the gas discharge the 0–0 transition of the α-methylnaphthyl radicals has a lower energy than for the β-methylnaphthyl radical, while in solid n-hexane the opposite effect has been observed. The results of theoretical calculations are also ambiguous.[82,83] It may be that the experimental results do not provide an unambiguous answer owing to the inaccurate identification of the products, since the hydronaphthyl radicals, examined below, may be present in the specimen.

An interesting example is provided by the product of the photolysis of (2,2)-*p*-cyclophane in vitreous solutions,[81] which was formed via the reaction

It can exist in two configurations, one of which corresponds to a biradical (a radical pair) and the other to two benzyl radicals linked by the $-CH_2-CH_2-$ group. Together with the band characteristic of the benzyl radical, a structureless band in the range 500–700 nm, attributed to the emission from the radical pair, appears in its luminescence spectrum. On decrease of the viscosity of the matrix, the intensity of the long-wavelength band diminishes, because the conformational transformations of the photolysis product are facilitated.

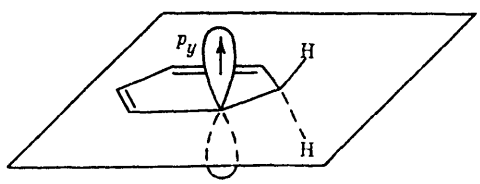
Table 4 presents data for the acenaphthyl and α-styryl radicals (Nos.59 and 60). These hydrocarbon radicals are not of the benzyl type, because their unpaired electron occupies the $sp^2$-hybrid orbital of the carbon atom, i.e. is an *n* electron. The lowest excited states of these radicals are therefore $n\pi^*$ states, have a long radiative lifetime,

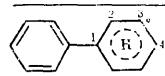
and their fluorescence quantum yield cannot be high. The luminescence in the range 588–640 nm, manifested in the photolysis of the acenaphthene in n-pentane at 20 K, has been observed[79] and has been attributed to the luminescence of the acenaphthyl radical. A luminescence has been observed[80] which the authors attributed to the α-styryl radical, whose absorption bands are in the region of 320 and 480 nm.[84] However, special investigations[65] failed to confirm these observations. Thus there are at present no reliable data on the luminescence of hydrocarbon radicals from $D_{n\pi^*}$ states owing to its low yield, as in the case of the luminescence observed for the $S_{n\pi^*}$ molecular states.

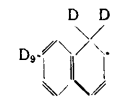
## V. HYDRO-RADICALS

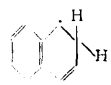
Hydro-radicals are formed by the addition of a hydrogen atom to the aromatic ring of a π-electron molecule. Such radicals have been investigated in detail by EPR.[85] The luminescence of a hydro-radical was first observed in solid solutions.[86,87]

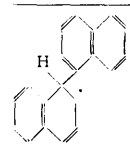
The simplest hydro-radical is the cyclohexadienyl radical arising following the addition of a hydrogen atom to a benzene molecule, its structure being illustrated in Fig. 2. The cyclohexadienyl radical can be regarded as a polyene chain made up of five carbon atoms. Accordingly, its lowest excited state is of the $D_{\pi\pi^*}$ type and the probability of the long-wavelength electronic transition is high.











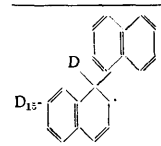


**Figure 2.** The structure of the cyclohexadienyl radical.

The luminescence of the cyclohexadienyl radical was observed after the laser excitation of crystalline benzene subjected to preliminary radiation by fast electrons at liquid helium temperature.[88] Its fluorescence band has undergone a 2500 $cm^{-1}$ bathochromic shift compared with the benzyl radical. In conformity with the fact that the $D_{\pi\pi^*} \to D_0$ transition is allowed, the luminescence lifetime is approximately 2 ns (Table 5). The effect of isotope substitution on the fluorescence lifetime indicates the competition of $D_1$–$D_0$ internal conversion and emission processes; this is consistent with the finding that the transition energy is approximately 2 eV.

The biphenyl and naphthalene molecules contain non-equivalent carbon atoms; for this reason, the hydro-radicals formed by the addition of hydrogen at these positions have different absorption and luminescence spectra. Different 0–0 transition energies of the hydrobiphenyl radical, with maximum differences of 200 $cm^{-1}$, correspond to four different isomers.[89] The 0–0 transition energies of the isomers of the hydrobiphenyl radical have been calculated theoretically,[89] the results being in good agreement with experimental data. The 1-hydrobiphenyl radical has the highest energy of the first excited state. This can be accounted for by the fact that there is no interaction between the benzene rings in this radical.

**Table 5.** The 0–0 transition energies and fluorescence lifetimes of hydro-radicals.

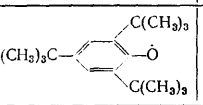
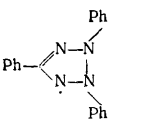
Notation: BA = vitreous boric acid, EE = diethyl ether, and cr = crystal; for the significance of the remaining abbreviations, see the footnotes to Tables 2–4.

In the naphthalene molecule there are two non-equivalent positions to which correspond two isomers: the α- and β-hydronaphthyl radicals,[86,87] differing in the absorption, luminescence, and EPR spectra. A photochromic interconversion of the α- and β-radicals has been observed in solid solutions.[86,87]

In the case of a naphthalene single crystal irradiated by fast electrons, the luminescence of only one α-hydronaphthyl radical was observed. In the crystal field the radical occupies two non-equivalent positions; the splitting between the levels amounts to 27 $cm^{-1}$.[90] Binaphthyl hydro-radicals





having four non-equivalent positions have also been observed in the single crystal; for this reason four vibrational band progressions are manifested in their fluorescence spectra.

The luminescence properties of a small number of hydroradicals, presented in Table 5, have now been investigated.

## VI. HETERORADICALS

Aromatic radicals having an unpaired electron at a heteroatom (heteroradicals) are widely known in the literature and have been investigated both by EPR and by optical absorption spectroscopy. Many of these radicals are stable[93] but the luminescence properties have been investigated only for four types of heteroradicals; thiophenoxy-, phenoxy-, verdazyl, and anilino-radicals (Table 6).

**Table 6.** The 0–0 transition energies and fluorescence lifetimes of heteroradicals.

***Laser generation was achieved with *p*-aminothiophenoxy-radicals (S.Ishizaka and M.Kotani, Chem.Phys.Letters, 1985, 117, 251).

*The thiophenoxy-radical ( the phenylsulphyl radical).* The luminescence of the thiophenoxy-radicals has been investigated after the photolysis of frozen solutions of thiophenol or diphenyl disulphide in EPA or 3-MP at 77 K.[94] A characteristic feature of the luminescence of this radical consists in the fact that emission has been observed in two parts of the spectrum, at 400–500 and 640–700 nm, and is due to two different electronic transitions ($D_2$–$D_0$ and $D_1$–$D_0$). The lifetime of the red fluorescence is 30–50 μs whilst that of the blue fluorescence is 60–70 ps.[95] The opposite shifts of the red and blue fluorescence bands in different solvents show that the long-wavelength fluorescence corresponds to the $D_{n\pi^*}$–$D_0$ transition, while the short-wavelength fluorescence corresponds to the $D_{\pi\pi^*}$–$D_0$ transition. The spectroscopic behaviour of this radical constitutes an instance of the deviation from Kasha's rule, which is rare even for molecules. The deviation is caused by the fact that the rate constant for the $D_2$–$D_1$ internal conversion between the $\pi\pi^*$ and $n\pi^*$ levels is small both as a consequence of the orbital nature of the transition and as a consequence of the relatively large transition energy (1.15 eV).

*The phenoxy-radical.* The luminescence of the 2,4,6-tri-t-butylphenoxy-radical, obtained chemically in solution in benzene, has been observed at room temperature in the range 400–450 nm.[96] However, it is known[97] that, apart from the absorption band in the range 350–400 nm, the phenoxy-radical has a long-wavelength absorption band in the range 500–700 nm and for this reason the fluorescence is apparently caused by a transition of the $\pi\pi^*$ type from the second doublet level. The structure of the phenoxy-radical is illustrated in Fig. 3*a*.

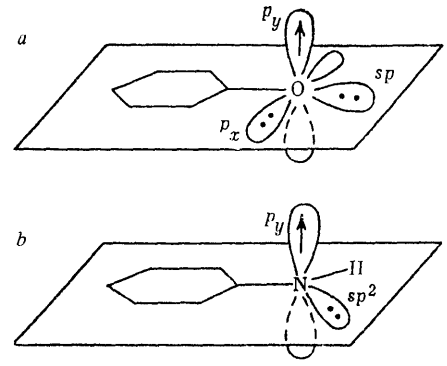

Figure 3. The structure of the phenoxy-radical (*a*) and the phenylaminyl radical (*b*).

*The phenylaminyl radical (the anilino-radical).* The luminescence of the phenylaminyl radical has been observed after the photolysis of aniline in glassy solutions in ether and MCH at 77 K[98] (Fig. 4). The absorption spectrum of this radical has two bands: a weak band in the region of 400 nm and a more intense band in the region of 300 nm.[100] For the sterically hindered 2,4,6-tri-t-butylphenylaminyl radical, obtained photochemically in solution in hexane at room temperature,[101] the extinction coefficients $\varepsilon_{400}$ = 670 litre mol$^{-1}$ cm$^{-1}$ and $\varepsilon_{300}$ = 4700 litre mol$^{-1}$ cm$^{-1}$ have been measured. The short luminescence lifetime of the radical (Table 6) made it possible to assign it to a $D_{\pi\pi^*}$–$D_0$ fluorescence. The phenylaminyl radical is isoelectronic

with the phenoxyradical (Fig. 3*b*), but absorption and emission by the phenylaminyl radical in the long-wavelength region have not so far been observed.

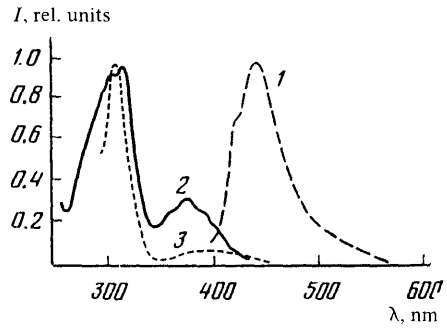

**Figure 4.** The excitation (curve 2) and luminescence (curve 1) spectra of the phenylaminyl radical in ether at 77 K [98] and the absorption spectrum (curve 3) of the phenylaminyl radical in heptane at room temperature.[101]

The phenoxy- and aminyl radicals are isoelectronic with the benzyl radical (cf. Figs. 1 and 3), but their luminescence properties are significantly different (cf. Figs. 1 and 4). This can be explained by the inclination of the axis of the $p_y$ orbital in the heteroradical relative to the plane of the ring or by its strong conjugation with a carbon atom of the ring and the formation of a structure close to one of the quinonoid type.

*The verdazyl radical.* The luminescence of the stable triphenylverdazyl radical (Table 6, No. 3) has been investigated in solution in ethanol, isoctane, diisopropyl ether, benzene, and poly(ethylene glycol) at 77 K.[99] The radical, obtained chemically, has two absorption bands with maxima at 400 and 700 nm, to which correspond two luminescence bands in the region of 485 and 800 nm (in ethanol). In the other solvents enumerated above, the short-wavelength luminescence maxima are at 472, 497, and 478 nm respectively, while in acetonitrile the maximum is at 518 nm.

## VII. RADICAL-IONS

The luminescence of radical-ions was first observed for the radical-cations of triphenylmethane dyes in vitreous solutions at 77 K.[102] The most intense investigations of the luminescence of the radical-ions of aromatic compounds have been carried out recently. The results are presented in Table 7.

*Halogenobenzenes.* The luminescence properties of the radical-cations of halogenobenzenes have been studied in detail in the gas phase. The luminescence spectra were then compared with the photoelectron spectra.

Fig. 5 presents the photoelectron spectrum of 1,2,4-trifluorobenzene on irradiation with light corresponding to the He(I) line.[103] The $\tilde{X}$ band in this spectrum corresponds to the formation of a radical-cation in the ground state, while the $\tilde{A}$, $\tilde{B}$, $\tilde{C}$, etc. bands correspond to excited states of the radical-cation. During photoionisation, the radical-cations are formed in an excited state and their transition to the ground state is accompanied by luminescence. The lowest excited state $\tilde{A}$ is located near $\tilde{X}$ and is due to the splitting of the ground state in asymmetric (with not more than a twofold symmetry axis) halogeno- or alkyl-benzenes. The luminescence (doublet–doublet $\pi \rightarrow \pi^*$ fluorescence) of such radical-cations is observed in the $\tilde{B} \rightarrow (\tilde{X}, \tilde{A})$, $\tilde{C} \rightarrow (\tilde{X}, \tilde{A})$, etc. transitions, but is not observed for the $\tilde{A} \rightarrow \tilde{X}$ transition as a consequence of the smallness of the energy gap. The energies of the electronic levels of certain radical–cations are presented in Fig. 6.[104,106] Using the method based on the coincidences of photoelectrons and luminescence photons,[105] it has now been possible to observe luminescence from the $\tilde{C}$ and $\tilde{D}$ levels and to estimate the lifetimes of the highest electronic states, which proved to be several times shorter than for the $\tilde{B}$ level.

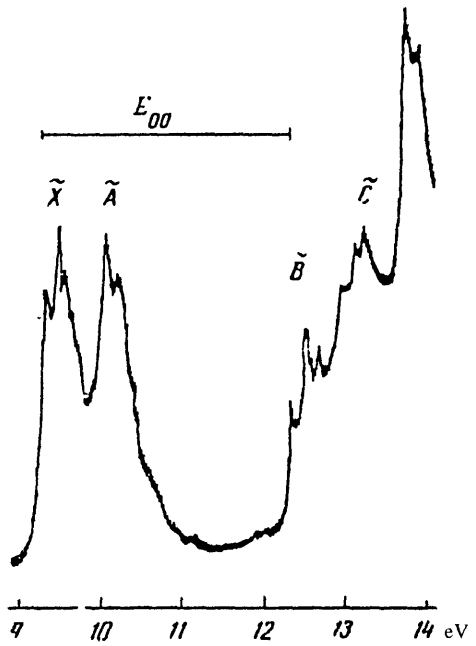

**Figure 5.** Photoelectron spectrum of 1,2,4-trifluorobenzene.[103]

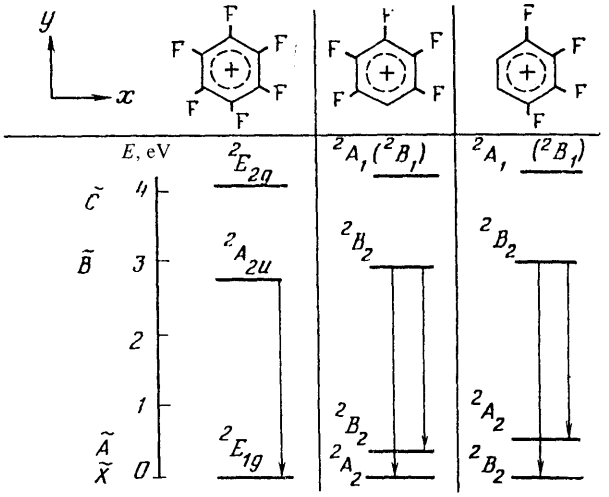
The fluorescence of the radical-cations derived from halogenobenzenes has also been investigated in inert (argon and neon) matrices at temperatures close to liquid helium temperature.[110,111] In solid argon the excitation and luminescence lines of the radical-cations are broader and are displaced towards the red region relative to the neon matrix.[112,113] This is due to the higher energy of the interaction of the radical-cations with the argon atoms than with the neon atoms. The luminescence spectra of the radical-cations obtained in the neon matrix are close to the spectrum in the gas phase. The vibrational structures of the absorption and luminescence are similar, which indicates only a small change in the geometrical parameters of the system on electronic excitation.

Polarisation studies of the fluorescence of the radical-cations in a neon matrix at helium temperatures have been carried out.[114] For molecules with the $D_{6h}$ and $D_{3h}$ symmetries, where the ground state is degenerate, the luminescence is polarised with a degree of polarisation $P = I_{\parallel}/I_{\perp} = 4/3$. For low symmetry radical-cations, for example 1,2,4,5-$C_6H_2F_4^+$, two sets of vibrational bands are observed in the emission spectrum. One set, with a degree of polarisation $P = 3.0$, corresponds to a transition to the lowest non-degenerate state $\tilde{X}^2B_2$. The second system of bands is displaced to the red region and perpendicular polarisation ($P = 0.5$) predominates in it. This system has been attributed to the transition $\tilde{B}^2B_2$–$\tilde{A}^2B_1$.



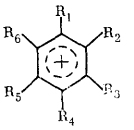


Figure 6. Schematic illustration of the electronic states and the radiative transitions of the radical-cations of fluorobenzenes.[104,106]

The luminescence quantum yield varies from unity in perfluorobenzene to approximately $10^{-2}$ in difluorobenzene, while the luminescence lifetimes amount to tens of nanoseconds, which shows that the transition of the $\pi \rightarrow \pi^*$ type is allowed.[106] Such behaviour of the luminescence yield can be accounted for by the increase of the $D_{\pi\pi^*}$–$D_0$ internal conversion rate constant with increase of the number of C–H oscillators in the system.[13] This is one of the causes of the low luminescence yield of the benzene radical-cation (see below).

The rate constant for the non-radiative decomposition of the excited states increases with increased amount of the vibrational energy in the excited state and with decrease of the transition energy.[105,106] Luminescence investigations have established the following features of the vibrational relaxation in the radical-cations of halogenobenzenes:[114,115] (1) the lifetimes of vibrationally excited states are in the range from 200 ps to less than a picosecond; (2) the rate of relaxation increases with increase in the amount of vibrational energy but not monotonically; (3) the rate of vibrational relaxation increases with decrease in the symmetry of the system. Theoretical studies of the Jahn–Teller effect in symmetrical radical-cations of halogenobenzenes have been made.[117–119]

For a long time it has not been possible to observe the luminescence of the benzene radical-cation. The reason for this is that the lowest excited level has the $^2E_{2g}$ symmetry and the radiative transition $^2E_{2g} \rightarrow {}^2E_{1g}$ is prohibited and non-radiative processes predominate. Luminescence has been observed in an argon matrix at 12 K;[111] it is manifested on laser excitation in the form of three weak peaks at 19770, 19140, and 18290 $cm^{-1}$ (at 19860, 19270, and 18400 $cm^{-1}$ for deuteriobenzene). The luminescence can be accounted for by the fact that in an argon matrix the $^2A_{2u}$ and $^2E_{2g}$ excited levels are inverted, which produces the radiative transition $^2A_{2u} \rightarrow {}^2E_{1g}$. The benzene radical-cations are unstable; on irradiation with light from a mercury lamp, they rapidly decompose and their fluorescence vanishes.

**Table 7.** The 0–0 transition energies and fluorescence lifetimes and quantum yields ($q$) of the radical-cations of substituted benzene derivatives.

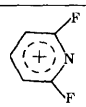
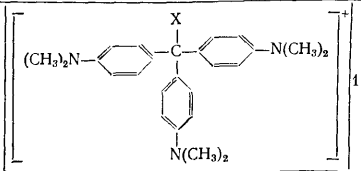
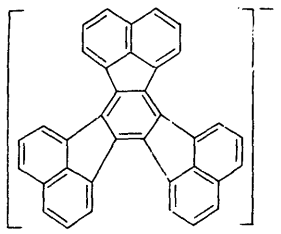
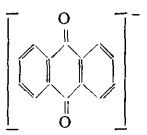
**Fluorescence of the $\tilde{C} \rightarrow \tilde{X}$ transition.









***Only luminescence was noted for the radical-cations Nos. 53–57.

*Other substituted benzenes.* Apart from halogenobenzenes, the luminescence of radical-cations of halogenated alkylbenzenes, alkylphenols, and alkylbenzonitrile derivatives has now been investigated (Table 7). In addition, the luminescence in the gas phase of the radical-cations of pentafluorobenzene with the following substituents has also been reported: $NH_2$, $NO_2$, $OCH_3$, COOH, and CHO,[108] although spectroscopic data have not been presented. The energies of the 0–0 transitions for the radical-cations of phenols and methyl-substituted benzenes lie in the same range as for halogenobenzenes and the luminescence lifetimes are also similar; there are no quantum yield data. The methyl and hydroxy-substituents influence the spectroscopic characteristics similarly to a fluorine atom but their effect on non-radiative processes is apparently significantly

different. It has been noted[108] that the gas-phase luminescence of the radical-cations of xylenes and pentamethylbenzenes has not been observed. The same communication quotes a list of 42 aromatic compounds for which the luminescence of radical-cations could not be observed in the range 300–850 nm on ionisation of these compounds in the gas phase with an electron beam having an energy of 20–40 eV.

*Complex aromatic molecules.* The fluorescence of the radical-cations of molecules more complex than those of substituted benzenes has been observed for the leuco-base of Crystal Violet (Table 8). The study of two-step photoionisation and photodissociation reactions of aromatic amines in solutions in ethanol at 77 K led to the observation[102] of the luminescence of the photolysis product, which was modified on replacement of the methyl hydrogen atom in the leuco-base by the OH or CN group. The luminescence band with a maximum near 17000 $cm^{-1}$ and the absorption band at 21000 $cm^{-1}$, which the authors[102] attributed to the radical-cation of the leuco-base of Crystal Violet, proved to be the most stable under these conditions.

Table 8. The 0–0 transition energies and fluorescence lifetimes and quantum yields of the radical-ions of aromatic compounds.

Notation: 2-MTHF = 2-methyltetrahydrofuran; for the significance of the remaining abbreviations, see the footnotes to Tables 2–5.

*The fluorescence maximum is indicated.
**The helium temperature was used for specimen No.1, while in the remaining cases the temperature was 77 K.

Interesting studies of the luminescence properties of the decacyclene radical-anion (Table 8, No.3) have been carried out.[120,121] The phosphorescence from a quartet level, i.e. a radiative quartet–doublet transition, was observed for the first time in these investigations. The decacyclene radical-anion absorbs intensely in the infrared with a maximum at 4950 $cm^{-1}$ and absorbs in the visible region at 16500 $cm^{-1}$. If a solution of decacyclene radical-anions in 2-methyltetrahydrofuran (in which neutral molecules are also present) at 77 K is excited with light at a wavelength longer than that of the singlet–singlet absorption of the neutral molecule ($E_{S_1}$ = 21 400 $cm^{-1}$), then fluorescence attributed to the $D_2$–$D_0$ transition and phosphorescence with $\tau_p = 2.6 \times 10^{-3}$ s, attributed to the $Q_1$–$D_0$ transition of the radical-anion, are observed. The electronic levels of the decacyclene radical-anion are illustrated schematically in Fig.7 and the main spectroscopic characteristics are listed in Table 8 (No.3).

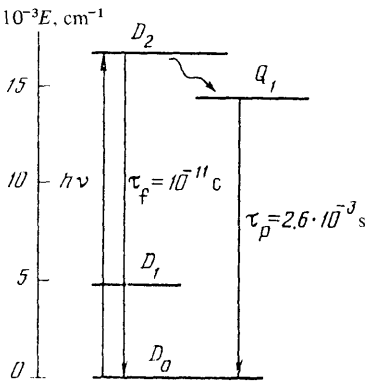

Figure 7. Schematic illustration of the electronic states of the decacyclene radical-anion.[120,121]

The luminescence of the radical-anions has also been observed for anthraquinone.[122] In ethanol to which a 0.1 M KOH solution has been added, anthraquinone is reduced to the radical-anion having a characteristic absorption at 480 nm. A broad luminescence band with a maximum at 540 nm (at room temperature) has been attributed to the fluorescence of the anthraquinone radical-anion, since its excitation spectrum coincided with the absorption spectrum, while the absorption and fluorescence spectra exhibit mirror symmetry. On reducing the temperature to 77 K, the bands undergo a bathochromic shift, which may be associated with dimerisation.

Attention should be drawn to a study[123] whose authors investigated the luminescence of an anthracene solution in a 1:2 mixture of acetic and sulphuric acids. In such a solution it is possible to photoinduce anthracene radical-cations having absorption bands at 315, 352, and 720 nm and an EPR spectrum, which vanish in the dark in the course of several minutes. The luminescence in the range 550–600 nm, excited by light with a wavelength shorter than 500 nm, is correlated with this behaviour. This emission has been attributed to the fluorescence of the anthracene radical-cation. Such interpretation requires further confirmation, because, as noted by the authors

themselves,[123] it has been found that the luminescence spectrum depends on the exciting light wavelength, which means that either different products emit or charge-transfer complexes or exciplexes are formed, so it cannot be regarded as unambiguously established that the observed emission is due to the anthracene radical-cations.

## VIII. BIRADICALS

*Carbenes.* The luminescence of aromatic biradical species was observed for the first time for diphenylcarbene,[134] whose structure is illustrated in Fig. 8*a*.[135] It has been shown by EPR[136] that the benzene rings are located in the same plane and that the angle between them is 140–150°. The unpaired electrons are present in two orbitals, one of which is located in the plane of the rings, while the other is at right angles to this plane. The spins of these electrons are parallel; the ground state of carbene is a triplet, which has been demonstrated by EPR also for other aromatic carbenes.[137] The unpaired electron present in the 2*p* orbital perpendicular to the molecular plane is conjugated to the π-electron system and for this reason the luminescence-spectroscopic properties of diphenylcarbene should resemble those of the benzyl and diphenylmethyl radicals. Indeed the absorption spectrum of diphenylcarbene contains a weak band in the region of 450 nm and a more intense band in the region of 300 nm,[134,138,139] whose extinction coefficients have been estimated[140] as $\varepsilon_{301}$ = 2500 litre mol$^{-1}$ cm$^{-1}$ and $\varepsilon_{465}$ = 300 litre mol$^{-1}$ cm$^{-1}$. The long-wavelength absorption is polarised along the line connecting the benzene rings[139] so that one can claim that they correspond to the $T_0 \rightarrow T_{\pi\pi^*}$ transition.

The luminescence spectrum of diphenylcarbene is presented in Fig. 8*a* (curve 2). Since the carbene has a triplet ground state, the observed luminescence has been identified as triplet–triplet fluorescence, which has been confirmed by the mirror symmetry of the absorption spectrum (or the excitation spectrum) and the luminescence spectrum and also by the short luminescence lifetime.[134,135,140]

The electron present in the orbital in the molecular plane is an *n* electron and can participate in $n \rightarrow \pi^*$ transitions. In the spectra of aromatic aldehydes and ketones the absorption bands corresponding to the $n \rightarrow \pi^*$ transitions are in the region of 300–400 nm[1–4] and the extinction coefficient corresponding to the $n \rightarrow \pi^*$ transitions is small (~100 litre mol$^{-1}$ cm$^{-1}$). In the spectra of carbenes the bands corresponding to the $n \rightarrow \pi^*$ transitions are apparently in the same range 300–400 nm, but the absorption is relatively weak and is masked by the more intense absorption corresponding to the $\pi \rightarrow \pi^*$ transitions, which determine the luminescence properties of aromatic carbenes.

It has not yet been discovered what influence is exerted on the spectroscopic properties of carbenes by the lowest singlet state having the same electronic configuration as the ground triplet state. Direct photolysis of diazodiphenylmethane results in the formation of diphenylcarbene in the lowest singlet state, from which it passes to the ground triplet state after a period of approximately 10$^{-11}$ s.[141] The energy gap $S_1$–$T_0$, estimated from the equilibrium constants of the chemical reactions of diphenylcarbene, is only 3–5 kcal mol$^{-1}$[(1 – 2) × 10$^3$ cm$^{-1}$].[141–143] For such a small energy gap, it is naturally impossible to expect an appreciable yield of the phosphorescence corresponding to the $S_1$–$T_0$ transition. Theoretical estimation of the $S_1$–$T_0$ gap leads to 10–20 kcal mol$^{-1}$ [(3.5–7) × 10$^3$ cm$^{-1}$].[144] Such a large discrepancy between the experimental and theoretical values is associated both with the approximate character of the quantum-chemical methods used in the calculation and the fact that the experimental values do not correspond to the equilibrium configuration of the system.

The lifetime of diphenylcarbene at the $T_{\pi\pi^*}$ excited level at 77 K is approximately 10$^{-7}$ s; the introduction of heavy atoms (in the form of ethyl iodide) into the solution does

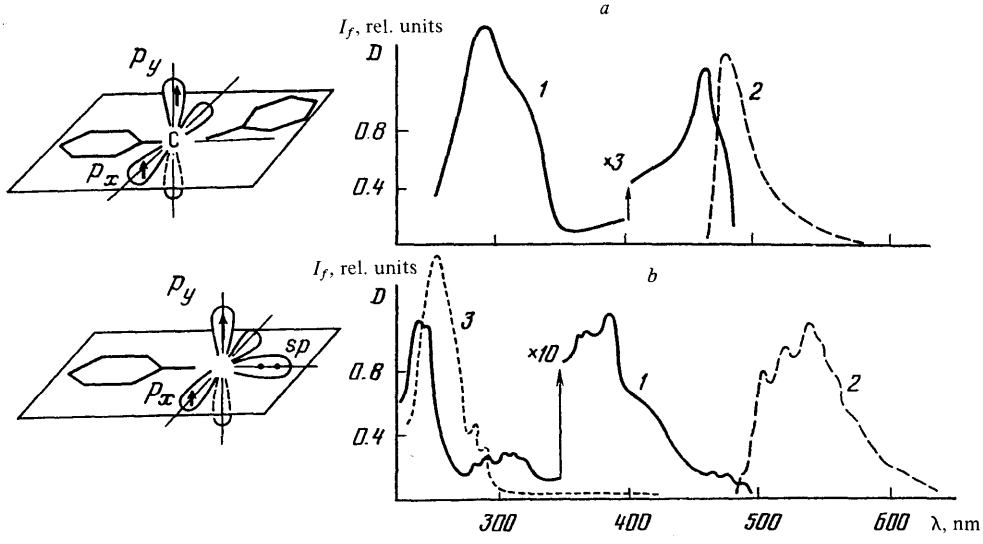

**Figure 8.** a) The structure of the excitation (curve *1*) and the luminescence (curve *2*) spectra of diphenylcarbene;[134,135] b) the structure and the absorption (curve *1*) and luminescence (curve *2*) spectra of phenylnitrene and the absorption spectrum of the initial phenyl azide (curve *3*).[149]

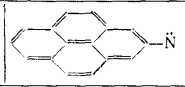

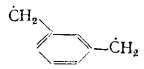

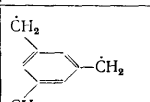

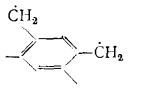

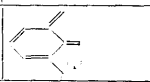

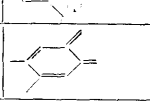

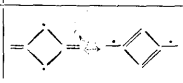

not entail sharp changes in this value. Hence one may conclude that the probability of the intersystem crossing $T_{\pi\pi^*} \rightarrow S_1$ is small because the energy gap is approximately 2.5 eV and the conversion does not compete with the luminescence.

Fluorescence has been observed also for many *para*-substituted dephenylcarbenes (Table 9). If the substituent is a nitro-group, then there is no fluorescence.[135,158] This finding can be accounted for by the fact that in nitro-derivatives the $S_{n\pi^*}$ states lie below the $T_{\pi\pi^*}$ state and the $T_{\pi\pi^*}$–$S_{n\pi^*}$ conversion suppresses the fluorescence, similarly to the situation which obtains in molecules as a consequence of the $S_{\pi\pi^*}$–$T_{n\pi^*}$ conversion.[2-5]

Table 9. The 0–0 transition energies and the fluorescence lifetimes and quantum yields of the biradicals of aromatic compounds at 77 K.

*Room temperature.

Dicarbene (Table 9, No.11), whose luminescence has been observed,[146] constitutes a special case. Formally it should have a sextet ground state, but, as a consequence of π-conjugation, it passes to a triplet state, which corresponds to a quinonoid structure:

For this reason, the luminescence of dicarbene is also $T_{\pi\pi^*} \rightarrow T_0$ fluorescence.

*Nitrenes.* The electronic structure of nitrenes resembles that of carbenes (Fig. 8*b*). The unpaired electrons are in two 2*p* orbitals, one of which ($p_x$) is in the molecular plane, while the other ($p_y$) is perpendicular to this plane. Furthermore, a nitrene contains an unpaired electron pair which

occupies a hybrid *sp* orbital located also in the molecular plane. Aromatic nitrenes are usually formed on photolysis of light-sensitive compounds such as azides and their chemical and certain spectroscopic properties have therefore been surveyed in a number of reviews and monographs,[147,148] but the luminescence properties of nitrenes have been investigated only recently.

The absorption spectrum of phenylnitrene, obtained on photolysis of phenyl azide in a solid solution at 77 K, is illustrated in Fig. 8*b*.[149] As in the spectrum of the benzyl radical, three bands are observed: an intense band in the region of 240 nm, a less intense one in the region of 300 nm, and a weak band in the region of 350–450 nm. As in carbenes, absorption bands in the range 300–400 nm, masked by the absorption due to the $\pi-\pi^*$ transitions, should correspond to the $n \rightarrow \pi^*$ transitions from the $p_x$ and *sp* orbitals. Theoretical estimates of the transition energies in phenylnitrene[150] describe fairly satisfactorily the experimental absorption spectrum.[149–151]

The luminescence spectrum of phenylnitrene is represented by curve *2* in Fig. 8*b*. The fact that the luminescence is due to the corresponding nitrenes has been confirmed by the agreement between the dynamics of the behaviour of the absorption and luminescence spectra, the mirror symmetry of the spectra, and the coincidence of the luminescence excitation spectrum with the absorption spectrum of nitrene.[149] The luminescence lifetime is approximately $10^{-8}$ s and, when account is taken of the fact that nitrenes have a triplet ground state,[141] one may conclude that the observed emission represents the triplet–triplet fluorescence of nitrenes.

Phenylnitrene is isoelectronic with the benzyl radical (cf. Figs. 1 and 8) and their luminescence-spectroscopic properties are very similar, which significantly distinguishes phenylnitrenes from the phenoxy- and aminyl heteroradicals.

The addition of the methyl group to the *para*-position causes a hypsochromic and not a bathochromic shift of the band corresponding to the 0–0 transition in phenylnitrene, in contrast to aromatic molecules. This phenomenon had been observed earlier for radical-ions and had been explained by the inductive effect.[152] The inductive effect is associated with the redistribution of the electron density in the excited state: when it increases at the site of the addition of the substituent, the transition energy rises, i.e. the hypsochromic shift of the 0–0 transition is observed. When alkyl substituents are introduced into simple aromatic molecules, the hyperconjugation effect, which always leads to a bathochromic shift of the absorption band, usually predominates. In this case the inductive effect predominates in the nitrene.

The luminescence properties of aromatic nitrenes are presented in Table 9; in many respects they resemble those of carbenes. Phenylnitrenes with alkyl electron-donating substituents fluoresce, while electron-accepting substituents (the nitro- and acetyl group) quench the fluorescence of nitrene.[149] As in the case of carbenes, the presence of *n* electrons in the substituent gives rise to the possibility of an intense $T_{\pi\pi^*}-S_{n\pi^*}$ conversion and leads to the quenching of the fluorescence.

It follows from Table 9 that a dinitrene with strong conjugation between the nitrene groups (4,4-dinitrenobiphenyl, Table 9, No. 17) also fluoresces, which is due to its biradical quinonoid structure. In the case of weakly conjugated systems, such as triphenylmethanes, the individual molecular fragments make independent contributions to the absorption spectra. However, the fluorescence quantum yield of dinitrenotriphenylmethane (Table 9, No. 20) is an order of magnitude lower than for the mononitrene (Table 9, No. 19), while the fluorescence of trinitrenotriphenylmethane has not been observed at all.[153] This can be explained both by the mutual quenching of the fluorescence due to the individual fragments, analogous to concentration-induced quenching, and by the formation of states with higher multiplicity.

*Xylylenes.* Xylylenes constitute yet another class of biradical species for which luminescence has been observed.[154,155] The photolysis of methylated benzenes in MCH at 77 K [154] led to the observation of the luminescence of the product in the range 400–440 nm, which differs from the luminescence of benzyl radicals and was attributed to *ortho*- and *meta*-xylylenes (such products did not appear for toluene and *p*-xylene). Subsequently xylylenes were synthesised chemically and their luminescence, whose characteristics are presented in Table 9 (Nos. 22–27), was investigated.[155] It is noteworthy that only *meta*-xylylene and its methyl derivatives (Table 9, Nos. 22–24) are true biradical species, while *ortho*-xylylenes (or *para*-xylylenes) have the configuration shown in Table 9 (Nos. 25–27). According to theoretical calculations,[155,156] *meta*-xylylenes have a triplet lowest state so that the observed luminescence can be attributed to triplet–triplet fluorescence. Theoretical estimates of the transition energy agree well with experimental data.[155]

The triplet–triplet fluorescence of the biradical benzene isomer 2,4-dimethylenecyclobutane-1,3-diyl, obtained by the photolysis of an azo-compound, has been observed.[161] This biradical is unstable even at 77 K and decomposes spontaneously; its concentration diminishes by a factor of two over a period of 30 h.

---o0o---

The studies of the luminescence-spectroscopic properties of the radical products of aromatic compounds have shown that all the rules of the luminescence-spectroscopic systematic treatment developed in recent years for molecular systems[1–5] are applicable to them. Apart from the general selection rules as regards multiplicity and symmetry, account must be taken of the influence of the orbital nature of the excited states in the radiative and non-radiative transitions. The characteristics of the structure of certain radical compounds and the development of modern research methods (laser excitation, accumulation of spectra) made it possible to observe interesting phenomena in the luminescence spectra; quartet–doublet phosphorescence, the Jahn–Teller effect, fluorescence from the highest excited states, laser generation based on the fluorescence of radicals, and vibrational structure in luminescence spectra. The luminescence of radicals of the benzyl type has been most fully investigated and described in the literature; the luminescence of radical-ions of complex aromatic systems, such as naphthalene, biphenyl, etc., as well as the luminescence properties of the heteroradicals have been studied to a much lesser extent.

# Nucleophilic Substitution Reactions. Modern Ideas About the Mechanism and Reactivity

M.V.Bazilevskii, S.G.Koldobskii, and V.A.Tikhomirov

The mechanism of $S_N2$ reactions is discussed on the basis of gas-phase experimental data and quantum-chemical calculations: the energy relations, stereochemistry, and the form of the potential energy surface. The results of modern kinetic measurements and calculations are presented. The experimental data for the reactions in solution are discussed at the level of qualitative quantum-chemical concepts. The causes of the strong influence of the solvent on the kinetics of these reactions are analysed and the empirical correlations between the kinetic and thermodynamic characteristics and the link between the correlations and modern theoretical ideas are examined.
The bibliography includes 134 references.

## I. INTRODUCTION

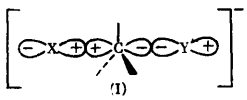
During the last fifteen years, the ideas about the mechanism of nucleophilic substitution in aliphatic compounds have changed beyond recognition. Previous concepts have been revised as a result of studies on the kinetics of gas-phase $S_N2$ reactions with the aid of new mass-spectrometric methods, especially after the experimental results have been confirmed by quantitative quantum-chemical calculations. It was found that the potential energy surface (PES) profile for these reactions is much more complex than had been suggested previously and the mechanisms corresponding to it do not fit within the simplest kinetic schemes which have been generally accepted. The strong influence of the solvent on these reactions has become evident. The mechanism of $S_N2$ processes in a polar medium is much closer to previous schemes than the mechanism of the gas-phase reactions. Elementary theoretical considerations as regards reactivity which ignore fully or almost fully the influence of the medium have paradoxically proved to be applicable only to reactions in a polar solvent, since only such $S_N2$ reactions have the usual PES profile.

In the present review an attempt has been made to summarise and treat systematically the advances in recent years. The familiar nucleophilic substitution reactions have become the subject of the latest experimental and theoretical studies. The principles of the corresponding approaches and research methods are examined in the present review in fair detail. Furthermore, the methods used in the kinetic interpretation of mass-spectrometric experiments, the problems of the theory of chemical reactions in polar media, the correlation between kinetic and thermodynamic characteristics in terms of the Marcus equation, and certain other features of modern theoretical chemistry are also discussed.

## II. THEORETICAL RESEARCH METHODS

### 1. Quantum-Chemical Calculations

Exhaustive information about the mechanism of the reaction of a chemical system can be obtained by calculating the PES. Within the framework of the activated complex theory, it is sufficient to find the geometrical configurations of the minimum corresponding to the reactants and the saddle point corresponding to the transition state (TS) of the reaction and then to estimate the height of the potential barrier from the difference between their absolute energies. In the case of a complex mechanism, one has to investigate complex PES with several minima and saddle points, whereupon the TS with the minimum energy usually corresponds to the preferred reaction pathway. More detailed investigations of PES involve the calculation of reaction pathways, i.e. of multidimensional curves in the internal coordinate space in which energy minima are attained in all the sections orthogonal with respect to their direction. Finally, for simple systems calculations of the dynamics of the movement of the representative point in the PES, classical or quantum, are feasible. This level of theoretical analysis is higher than that involving the calculation of the rate constants in terms of the activated complex theory.



Both semiempirical and non-empirical quantum-chemical methods are used at present for the calculation of the PES. The semiempirical procedures (for example, CNDO/2, MINDO/3, MNDO, etc.) require a moderate expenditure of computer time and are frequently used in studies on complex reactions. Unfortunately they are not immune to uncontrollable errors, which are sometimes serious. In particular the standard semiempirical methods are unsuitable for the calculation of the saddle points of the simplest $S_N2$ reactions.

The non-empirical self-consistent field methods (for example, STO-3G, 3-21G, 4-31G, 6-311G, etc.) are much more laborious (in the incomplete list of non-empirical methods quoted above, the size of the basis set, the labour involved in the calculation, and the quality of the latter increase in the order in which the methods are listed). It has come to be assumed that calculations by the 3-21G or 4-31G method are sufficient for the determination of the geometry of stationary points. In order to achieve reliable energy estimates, it is necessary to expand the basis set and also to take into account electronic correlation. The latter improvement implies going beyond the framework of the self-consistent field procedure. Among the methods whereby correlations can be taken into account, which have been applied successfully to $S_N2$ reactions, mention should be made of the CEPA-PNO scheme (the approximation of interacting electron pairs).

### 2. Qualitative Methods of the Reactivity Theory

The traditional approach, in which the geometrical structures of the transition and initial states are postulated on the basis of intuitive considerations (the validity of the choice of the model can be checked in principle by calculating the PES for the simplest cases), is widely used. For models specified in this way, an elementary quantum-chemical assessment is made of the energy relations, i.e. of the tendency towards a change in the height of the potential barriers in the reaction series.

As an example, we shall consider a model for the TS of an $S_N2$ reaction at a saturated carbon atom. It has the structure (I):

(I)

where X is the nucleophile and Y the leaving group. It is assumed that the atoms X, C, and Y are located on the same axis, which is at right angles to the plane of the trigonal system of the bonds involving the carbon atom. The main element of the electronic structure of such TS is a delocalised three-centre four-electron system made up of three *p* orbitals, which overlap in phase, as shown in Scheme (I). For this system, it is possible to carry out an elementary calculation by the Hückel method or to apply the perturbation theory to the interaction, assuming that the substrate–nucleophile bond (C.X) is much weaker than the "intramolecular" bond C–Y (which is hardly justified). According to the perturbation theory, only the interactions between the occupied and unoccupied molecular orbitals (MO) of the reactants contribute to the energy. Its simplest version, the method of frontier orbitals (FMO), takes into account the contribution to the interaction energy only from a single pair: the highest occupied orbital of the nucleophile (HOMO)—the lowest unoccupied orbital of the substrate (LUMO). Thus it is sometimes possible to predict or explain the characteristics of the variation of the reactivity in reaction series.

In order to analyse the energy of the interaction in the TS, the latter is sometimes subdivided into a series of contributions (several versions of such subdivision are known): Coulombic ($E_{coul}$), polarisation ($E_{pol}$), charge transfer or delocalisation ($E_{ct}$), exchange repulsion ($E_{ex,rep}$), exchange ($E_{exch}$), and dispersion ($E_{disp}$):

$$E = E_{coul} + E_{pol} + E_{ct} + E_{ex,rep} + E_{exch} + E_{disp}. \quad (1)$$

Some of these quantities are combined in a single term. The interaction energy can be calculated by Eqn.(1) using fairly sophisticated quantum-mechanical methods—semiempirical or non-empirical.

### 3. Correlations

In the present review we shall examine only certain aspects of the application of correlations to nuclephilic substitution reactions, namely those for which it is possible to associate the relations with more fundamental approaches. Equations which are strictly speaking empirical can be often derived from a qualitative quantum-chemical analysis or from general geometrical considerations concerning the structure of multidimensional PES. Such derivations sometimes follow simply from the outward similarity of the equations and expansions of the molecular orbital perturbation theory as in the case of linear correlations of the Hammett type. In other cases the considerations are not so trivial. This applies to the Marcus equation, which is now a subject of a vigorous discussion in connection with exchange reactions to which the $S_N2$ reactions belong.

## III. SUBSTITUTION REACTIONS AT A SATURATED CARBON ATOM

### 1. Stereochemical Specificity

The stereochemistry of $S_N2$ reactions has been investigated theoretically already in the course of 50 years at a wide variety of levels: ranging from simple electrostatic

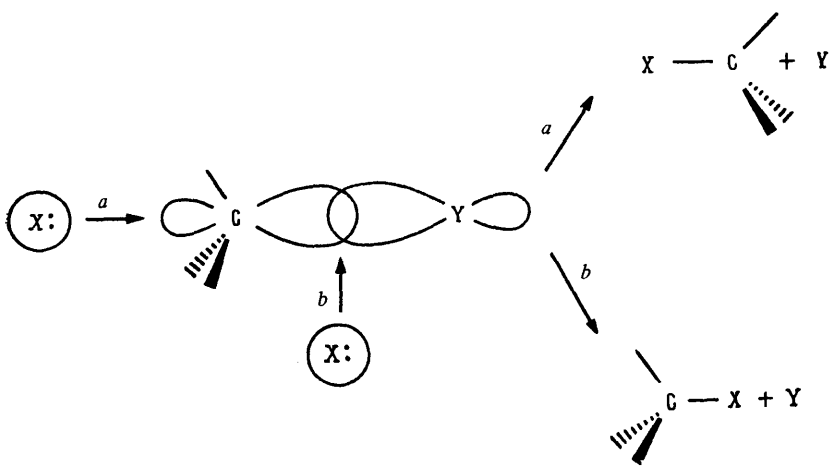


**Figure 1.** The rear (*a*) and frontal (*b*) attack in reactions of the $S_N2$ type.

estimates to modern semiempirical[1-7] and non-empirical[8-13] quantum-chemical calculations. Two directions of attack on the saturated substrate by the nucleophile X, differing in the relative disposition of X and of the leaving group Y, are distinguished (Fig.1): the rear direction, where X attacks the substrate from the side opposite to that of Y, and the frontal direction, where X attacks the substrate from the side of Y. Stereochemically different products correspond to these reaction pathways. Attack from the rear leads to the inversion of configuration (Walden inversion), while frontal attack results in the retention of configuration at the central atom of the substrate.

In the case of a saturated carbon atom, it has been established theoretically that the reaction with inversion of configuration is preferred Thus the search for the TS in the $H^- + CH_4$ system by the STO-3G method without symmetry-dependent limitations led to a configuration with $D_{3h}$ symmetry[13] (Fig.2). The analysis of the form of the MO calculated by the CNDO/2 method for the $F^- + CH_3F$, $H^- + CH_4$, and $NH_3 + CH_3F$ reactions[2] also leads to the conclusion that the configuration is inverted. Analysis of the components of the total energy, calculated by a semiempirical method[3,4] for the $Cl^- + CH_3Cl$ system, shows that the Coulombic and exchange contributions of expansion (1) favour inversion and that the Coulombic component predominates over long distances. The delocalisation contribution is relatively small over long distances but becomes significant when the reactants approach one another and attack from the rear is then also favoured.

Experiment confirms that inversion of configuration is always observed in reactions of the $S_N2$ type at a saturated carbon atom. This fact has been firmly established for reactions both in solution and in the gas phase. In the first gas-phase experiments,[17] it was already shown that the nucleophilic reaction of $Cl^-$ with *cis*- and *trans*-4-bromocyclohexanols takes place with inversion. The stereochemistry of substitution in positively charged intermediates under the influence of water in the gas phase has been investigated by the ion–cyclotron resonance (ICR) method.[18] The substitution takes place via the $S_N2$ mechanism to the extent of 64–98% (depending on the substrate) with inversion of configuration at the carbon atom.

The simplest three-centre four-electron model can be used to compare the electronic structures of the TS corresponding to the rear and frontal attack. The open-chain TS model for attack from the rear was indicated above in Scheme (I). The cyclic TS illustrated in Fig.3 corresponds to frontal attack. The open-chain and cyclic TS structures differ by too many parameters to enable comparison of their energy relations, even at the qualitative level, to be made. However, for each TS it is possible to analyse the conditions favouring the given stereochemical direction of the reaction. For example, the factors which increase the probability of frontal attack can be discovered by the qualitative analysis of the relative stability of the cyclic TS.[7,10,19] We shall examine these considerations in greater detail as a typical example of a qualitative approach to the MO theory. A similar treatment of the open-chain TS is described below.

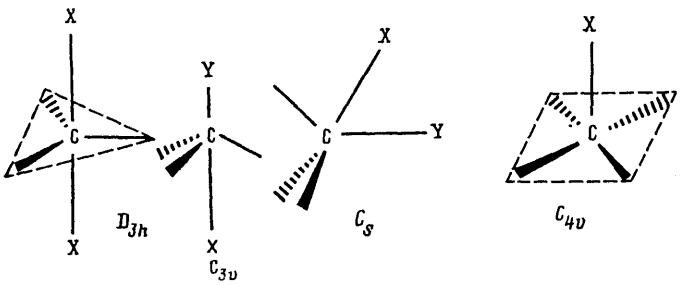

Figure 2. The possible configurations of the TS in $S_N2$ reactions.

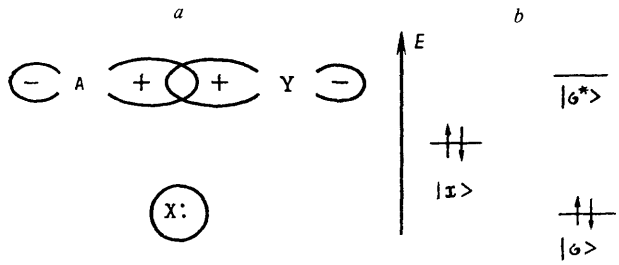

Figure 3. Schematic illustration of the three-centre cyclic TS in reactions of the $S_N2$ type (*a*) and the disposition of the energy levels (*b*).

Direct calculations have shown that the difference between the TS energies for the rear and frontal attack is sufficiently large to assume that the inversion of configuration at the saturated carbon atom is preferred (Table 1 and Fig.2). A high symmetry of the TS corresponding to inversion obtains only if the nucleophile and the leaving group are monatomic anions. For polyatomic nucleophiles and leaving groups and also for asymmetrically substituted substrates, the conclusion that the configuration is inverted remains but the symmetry of the TS is distorted to a greater or lesser extent.[14-16] According to a non-empirical calculation,[14] the angle α(C–X–Y) for X, Y = HO, HOO, $NH_2$, CN, SH, $OCH_3$, or $OC_2H_3$ deviates from 180° by an amount up to 4°. For example, in the $[FCH_3OF]^-$ system the angle α(F–C–O) = 176°, while in the $[HOOCH_3OOH]^-$ system we have α(O–C–O) = 182.4°. In the presence of a methyl substituent at the carbon atom of the substrate, α(X–C–Y) = 150°.[16]

We introduce the following notation: $|x\rangle$ is the HOMO (or AO) of the nucleophile X and $|a\rangle$ and $|y\rangle$ are the AO of the central atom A of the substrate and of the leaving group Y (Fig.3) contributing most to the LUMO $|\sigma^*\rangle$ of the substrate:

$$|\sigma^*\rangle = (|a\rangle - \lambda|y\rangle)(1+\lambda^2)^{-1/2} \cong |a\rangle - \lambda|y\rangle \,. \qquad (2)$$

Within the framework of perturbation theory, the stabilisation of the TS is determined by the interaction of the HOMO $|x\rangle$ of the nucleophile and the LUMO $|\sigma^*\rangle$ of the substrate. The matrix elements of the Hamiltonian *h* will be designated as follows:

$$\langle a|h|a\rangle = \alpha_a; \quad \langle x|h|x\rangle = \alpha_x; \quad \langle y|h|y\rangle = \alpha_y;$$
$$\langle a|h|y\rangle = \beta_{ay}; \quad \langle a|h|x\rangle = \beta_{ax}; \quad \langle x|h|y\rangle = \beta_{xy} \,.$$

It is assumed that they satisfy the relations

$$\alpha_x, \alpha_y \ll \alpha_a < 0; \quad 0 < \lambda \simeq \beta_{ay}/(\alpha_y - \alpha_a) \ll 1; \quad 0 < \lambda' \cong \beta_{ay}/(\alpha_x - \alpha_a) \ll 1. \qquad (3)$$

This means that the electronegativity of the central atom A is much smaller than the electronegativity of the nucleophile X and of the leaving group Y and that on the energy scale the differences between the electronegativities are large compared with the strength of the corresponding bond.

The energy of interaction of the orbitals $|x\rangle$ and $|\sigma^*\rangle$ is

$$\Delta E = 2\langle x|h|\sigma^*\rangle/(\langle x|h|x\rangle - \langle\sigma^*|h|\sigma^*\rangle) < 0 \ .$$

When the higher powers of the small quantities $\lambda$ and $\lambda'$ are neglected, the above expression reduces to

$$\Delta E \simeq -2(\beta_{ax}^2 - 2\lambda\beta_{ax}\beta_{xy})/(\alpha_a - \alpha_x) \ . \qquad (4)$$

It follows from Eqn.(4) that the decrease of the quantity $\lambda$ stabilises the TS. According to Eqn.(3), $\lambda$ (the contribution of the AO $|y\rangle$ to the LUMO $|\sigma^*\rangle$ of the substrate) diminishes with increase of $\alpha_a$ and with decrease of $\alpha_y$. Consequently decrease of the electronegativity of the central atom and increase of that of the leaving group promote frontal attack. This is confirmed by direct calculations and by experiments on nucleophilic substitution at a silicon atom, which is less electronegative than a carbon atom. Calculations of the TS energies for different configurations have shown that, although frontal attack on the silicon atom is energetically less favourable than attack from the rear, it is so to a lesser extent than for a carbon substrate (Table 1). Whereas reactions of the $S_N2$ type at a saturated carbon atom always proceed with inversion, in substitution at a silicon atom configuration is retained[21-24] (in this case frontal attack is preferable to attack from the rear, although the mechanism in the given instance differs from $S_N2$).

Table 1. The relative TS energies with inversion ($D_{3h}$, $C_{3v}$) and retention ($C_s$, $C_{4v}$) of configuration.

| System | $E$, kcal mol$^{-1}$ | | | | Method (basis set) | Refs. |
|---|---|---|---|---|---|---|
| | $C_{3v}$ | $D_{3h}$ | $C_s$ | $C_{4v}$ | | |
| $CH_5^-$ | — | 0 | 56.8 | 54.3 | (7.3/3) → [4.2/2] | [8] |
| $CH_5^-$ | — | 0 | 54.5 | 54.5 | two-exponential function, minimal Slater basis set | [9] |
| $CH_6^-$ | — | 0 | 15 | — | PNDO | [1] |
| $CH_3F_2^-$ | — | 0 | 56.4 | — | 4-31G | [12] |
| $CH_3(CN)_2^-$ | — | 0 | 15 | — | MNDO | [6] |
| $SiH_4F^-$ | 0 | — | 9 | — | STO-3G | [19] |
| $SiH_4Cl^-$ | 0 | — | 33.6 | — | STO-3G | [19] |
| $SiH_5^-$ | — | 0 | — | 2.9 | (12.9/5) → [6.4/2] | [20] |

The increase of the electronegativity of Y within the limits of a single Group of the Periodic System (on replacement of Cl by F or of SR by OR) also favours retention of configuration.[19,24] Furthermore, analysis of the denominator in Eqn.(4) makes it possible to understand the effect of electronegativity of the nucleophile. The conclusion that an increase of $\alpha_x$ facilitates frontal attack is apparently indirectly confirmed by the dependence of the stereochemical specificity of certain $S_N2$ reactions in aprotic solvents on the hardness of the nucleophile.[24] Finally, the inclusion of the central atom of the substrate in the strained cyclopropane ring favours retention of configuration. This result, obtained by calculation using the extended Hückel method (EHM),[7,10] can be explained qualitatively by the fact that the corresponding change in the degree of hybridisation diminishes $\lambda$ by diminishing the absolute value of $\beta_{ay}$. We may note that, even for the reaction with cyclobutane, a similar EHM calculation[5,10] predicts inversion in agreement with a non-empirical calculation[11] and experiment.[25]

The elementary considerations presented above are not faultless even within the framework of the simplest model employed. It is sufficient to point out that a change in the nature of A, X, and Y should influence not only the corresponding quantity $\alpha$ but also $\beta$ in Eqn.(3) or (4) (for example, via a change in the A–X and A–Y bond lengths). In discussing the role of the electronegativity of the atom A, no account was taken of the effect of $\alpha_a$ in the denominator of Eqn.(4), the result of which is the opposite of that of the effect of $\lambda$. Steric effects can be excluded in by no means all the examples examined. Finally, one should consider simultaneously how the above factors influence the stability of the alternative open-chain TS.

## 2. The Mechanism of the Gas-Phase Reactions

Fig. 4 illustrates the complex PES profile along the reaction coordinate of the reaction

$$X^- + CH_3Y \rightarrow XCH_3 + Y^- \ . \qquad (5)$$

It is now generally accepted that the mechanism of the simplest gas-phase reactions (5) is described by a two-well potential curve. The minima correspond to the prereaction complex $[X^-.CH_3Y]$ and the postreaction complex $[XCH_3.Y^-]$ with highly asymmetric structures and localised charges. The bonds represented by dots are mainly electrostatic in nature: the corresponding internuclear distance is still too large for the formation of strong covalent bonds. The bonds in the $CH_3Y$ and $XCH_3$ molecules which enter into the composition of the corresponding complexes are almost undistorted and are largely covalent. The conversion of the first complex into the second proceeds via the saddle point on the PES, to which corresponds the TS $[XCH_3Y]^-$ with a more or less symmetrical structure and a delocalised charge.

The order of magnitude of the stability of the electrostatic complexes can be estimated for the energy of the ion–dipole interaction over the distance corresponding to the sum of the van der Waals radii of the corresponding atoms. Estimates in the range $U \cong 10$–$20$ kcal mol$^{-1}$ are thus obtained. The formation of ion–molecule complexes has been established in a number of gas-phase experiments.[26-31] Their measured formation energies agree with the above estimate. Thus the bond energy of the complex $Cl^-.CH_3CN$ is 16 kcal mol$^{-1}$,[27] while those of the complexes $Hal^-.CH_3Hal$ range from 8.6 to 14.4 kcal mol$^{-1}$.[28-30] The non-equivalence of the X and Y atoms in symmetrical systems (X = Y = Cl) has been demonstrated by isotopic analysis of the reaction products:

$$[^{35}Cl \cdot CH_3^{37}Cl]^- + CH_3CF_3 \rightarrow [^{35}Cl \cdot CH_3CF_3] + CH_3^{37}Cl \ ,$$

where one of the reactants was the complex of the $^{35}Cl^-$ anion with the $CH_3^{37}Cl$ molecule prepared beforehand.[31]

The complexes are apparently not formed in polar solvents. At any rate, liquid-phase experiments provide no evidence for their formation. Up to the beginning of the 1970's, kinetic studies of reactions of type (5) were performed exclusively in the liquid phase and no considerations indicating the possibility of complex mechanisms were put forward. The first convincing piece of evidence was obtained in the theoretical calculation by Dedieu and

Veillard.[32] The main result of this study was the prediction of a two-well PES profile for reaction (5) with X, Y = H, F.

Kinetic studies of gas-phase reactions (5) using the mass-spectrometric technique involving afterglow in a stream,[33–36] the ICR method,[17,37–41] and the pulsating electron beam method[42] yielded final evidence in support of the view that they have a complex mechanism. Approximately 100 kinetic constants have now been measured for such reactions. Table 2 lists the rate constants $k$ for the $X^- + CH_3Y$ reactions; the data for reactions with substituted substrates $CR^1R^2R^3$ are not included. The constants $k$ measured by the afterflow in a stream method are systematically higher than those obtained by the ICR method. The determination of the parameters of a two-well PES from the results of a kinetic experiment presents serious difficulties. Two different procedures for the estimation of the activation barrier $\Delta E$ (Fig. 4), based on different hypotheses concerning the reaction mechanism, were used in Table 2. The Arrhenius equation, in which the pre-exponential factor represents the collision frequency, was employed in the first of these.[36] The large number of $\Delta E$ values close to zero, supporting a complex PES profile, is striking: the reactions for which $\Delta E < 0$ also fell within the group. The second estimate[39–41] is based on the Kassel–Marcus theory (RRKM); for this model, $\Delta E < 0$.

Table 2. The experimental rate constants $k$ ($cm^3$ molecule$^{-1}$ $s^{-1}$), the efficiencies $f$, and the enthalpies $Q_{XY}$ (kcal $mol^{-1}$) of the gas-phase reactions $X^- + CH_3Y \rightarrow XCH_3 + Y^-$ as well as estimates of $\Delta E$ and $E_{XY}$ (kcal $mol^{-1}$) (Fig. 4).

Remarks. The measurements of Bohme and Young[33] and Tanaka et al.[36] were made by the method of afterglow in a stream and the $\Delta E$ were estimated from the Arrhenius equation with the pre-exponential factor equal to the collision frequency; Pellerite and co-workers[39,41] carried out their measurements by the ICR method, $\Delta E$ was estimated by the RRKM method, and $E_{XY}$ was calculated on the assumption that the formation energy of the complex is −9 kcal $mol^{-1}$.

The efficiency $f = k/k_c$ is defined as the ratio of the observed rate constant $k$ to the gas-phase kinetic rate of collision $k_c$. The range of the gas-phase ion–molecule reaction rates is usually small. For example, the proton transfer reactions in systems with a localised charge are rapid and $f \cong 1$ for such processes. The low efficiency and the long range of its variation indicate an unusual character of the reactions quoted in Table 2.

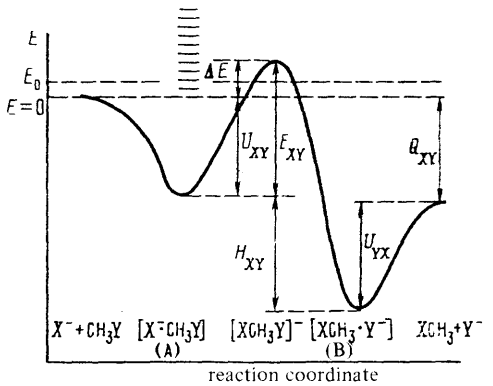

**Figure 4.** The PES profile for a gas-phase reaction of the $S_N2$ type; $E_0$ is the kinetic energy of the reactants and the short horizontal lines represent schematically the energy levels of the "hot" prereaction complex located above the intrinsic energy of the reactants ($E = 0$).

A model kinetic description of a multistage exothermic process with a two-well potential profile has been proposed by Brauman and co-workers[39–41] and is based on the scheme

$$X^- + CH_3Y \underset{k_1}{\overset{k_0}{\rightleftarrows}} [X^- \cdot CH_3Y] \qquad (6)$$

$$[X^- \cdot CH_3Y] \xrightarrow{k_2} \text{products} \qquad (7)$$

to which correspond simple expressions for the observed rate constant and efficiency:

$$k = k_0 k_2/(k_1 + k_2) \ , \qquad f = (1 + k_1/k_2)^{-1} \ . \qquad (8)$$

The relation $k_1/k_2 \gg 1$ corresponds to the data in Table 2. This inequality may be ensured even for negative $\Delta E$ with a not unduly large absolute value (the barrier for the process with $k_2$ is lower than the barrier for the process with $k_1$), because the large distance between the reactants in the TS of the reverse reaction (6) increases the freedom of their relative movement.

The simplest estimate of the $k_1/k_2$ ratio within the framework of the activated complex theory is

$$k_1/k_2 = (A_1/A_2)\exp(\Delta E/RT) \ . \qquad (9)$$

The pre-exponential factors $A_1$ and $A_2$ are calculated by standard methods. Eqn.(9) is valid if the distribution function for the complexes $[X^-.CH_3Y]$ corresponds to equilibrium, i.e. if the rate of deactivation (as a result of collisions) of the "hot" complexes formed via reaction (6) is much higher than the rate of their decomposition defined by the constants $k_1 + k_2$. Experiments[39–41] carried out at a low pressure ($10^{-5}$–$10^{-6}$ mmHg) do not satisfy this relation. The statistical unimolecular decomposition theory (RRKM) was used to estimate $k_1/k_2$ under such conditions. It was assumed that the "hot" complex formed decomposes via one of the possible pathways, without undergoing even a single collision, and that its energy $E = E_0 + U_{XY} = E_0 + E_{XY} - \Delta E$ (Fig.4) is distributed statistically among the internal degrees of freedom. The following approximate expression is valid within the framework of this model:[39]

$$\frac{k_1}{k_2} \cong \frac{\int_{U_{XY}}^{\infty} G_1(E - U_{XY}) \exp(-E/kT)\, dE}{\int_{U_{XY}}^{\infty} G_2(E - E_{XY} - \Delta E_{rot}) \exp(-E/kT)\, dE} \ , \qquad (10)$$

where $G_1(E)$ and $G_2(E)$, i.e. the numbers of the vibrational-rotational states in a microcanonical ensemble with the energy $E$ for the corresponding activated complexes, were calculated by the RRKM method (the energy arguments are indicated in brackets; $\Delta E_{rot}$ is the adiabatic change in the rotational energy in the TS). The independent experimental estimate $U = -9$ kcal mol$^{-1}$ was adopted for the energy of formation of the complexes $U_{XY}$, after which only one unknown parameter remains in Eqn.(10)—the height of the internal barrier $E_{XY}$; this quantity was chosen in such a way that the experimental efficiencies were consistent with Eqn.(8).

Unfortunately the results obtained are not unambiguous because of the arbitrary choice of the activated complex models in the calculation of $G_1$ and $G_2$ (see the scatter of the estimates of $\Delta E$ and $E_{XY}$ in Table 2). In order to refine the model, more detailed experimental information is essential.

A temperature variation of the rate constant $k$ has been investigated[42] in the range 25–390 °C for the reactions

$$Cl^- + RBr \rightarrow ClR + Br^-$$
$$R = CH_3,\ C_2H_5,\ \text{iso-}C_3H_7,\ \text{n-}C_4H_9,\ \text{iso-}C_4H_9.$$

The ratio $k_1/k_2$ was estimated using the activated complex theory [Eqn.(9)] on the grounds that the experiment was performed at a fairly high pressure (~4 mmHg). The estimates of their height proved to be much less ambiguous:

| R | $CH_3$ | $C_2H_5$ | n-$C_4H_9$ | iso-$C_3H_7$ | iso-$C_4H_9$ |
|---|---|---|---|---|---|
| $E_a$, kcal mol$^{-1}$ | −2.5 | 0.8 | −0.5 | 5.1 | 5.7 |

According to Eqn.(9), negative values of $\Delta E$ should lead to a negative observed activation energy $E_a$, which in a rough estimate agrees with $\Delta E$ as regards absolute magnitude (in an exact calculation account is taken of the temperature variation of the pre-exponential factors). The negative value $E_a \cong -2$ kcal mol$^{-1}$ has indeed been observed in the reaction with the $CH_3Br$ substrate.

The validity of such treatment of kinetic experiments is far from evident. In a non-equilibrium situation the very kinetic scheme defined by Eqns.(6) and (7), which ignores the direct mechanism involving the collision of the species, unassociated with the formation of the pre-reaction complex, is doubtful. If an appreciable fraction of the reaction product is formed via the direct mechanism, Eqn.(8) has no significance. Quantum-dynamic calculations have shown[43,44] that the contribution of the direct process to the formation of products is different in different systems. For thermally neutral and endothermic reactions ($Q_{XY} \geq 0$), it is appreciable. On the other hand, for exothermic reactions ($Q_{XY} < 0$), the direct mechanism leads to almost complete reflection (the probability of reflection in the direct process, amounting to 0.998 for $\Delta E = -1.9$ kcal mol$^{-1}$, has been found for $H^- + CH_3F$) and its contribution to the reaction may be neglected. In this case the reaction does indeed proceed

via the formation of the complex $[X^-.CH_3Y]$ and it would be incorrect to calculate the efficiency $f$ by Eqns.(8) and (10). The low efficiency is associated with the low probability of the formation of the complex. It can be calculated from the formula:[45]

$$f = (h/kT)\sum_{\lambda} P_{0\lambda}k_{2\lambda}\exp(-E_\lambda/kT),$$

where $h$ is the Planck constant, $P_{0\lambda}$ the probability of the formation of the "hot" complex in the vibrational state $\lambda$ with the energy $E_\lambda$ (reckoned from the energy of the reactants $E = 0$—see Fig.4), and $k_{2\lambda}$ the rate constant for the decomposition of this state to the products. The quantities $P_{0\lambda}$ and $k_{2\lambda}$ are found in the dynamic calculation.

Table 3. Results of the calculations of the parameters of the complexes or TS of the type $[XCH_3Y]^-$ by various methods.

[a]Complex, there is no saddle point on the PES; all the remaining configurations correspond to saddle points on the PES.

[b]Our results.

[c,d,e]The calculation was performed with addition of polarisation and diffuse functions to the (10,6/5) → [5,4/3] minimal basis set, namely: [c]$d$(C) and $p$(H); [d]$d$(C); [e]$p$(H).

[f]The configuration interaction was taken into account by the CEPA-PNO method in terms of the minimal basis set (8,4/4) → [4,2/2].

Thus the low efficiency of the non-activated ($\Delta E < 0$) reactions under non-equilibrium conditions (low pressure) can be accounted for solely within the framework of a dynamic calculation. It is caused by the marked energy exchange between the reaction coordinate and the transverse vibrational degrees of freedom in the region of the free reaction complex.

## 3. Calculations of the Potential Energy Surfaces

Reactions (5) of the $S_N2$ type at a saturated carbon atom have been investigated vigorously by quantum-chemical methods—mainly non-empirical methods[11-14,32,46-66] and more rarely by semiempirical methods.[1,7,10,15,16,67-73] The complex two-well profile of the potential curves is reproduced satisfactorily only in calculations at a sufficiently high level. Practice has demonstrated that semiempirical methods are as a rule unsuitable for the calculation of the PES for such reactions; this is illustrated in Table 3. Their application has therefore been restricted to the study of qualitative relations (the study of stereochemistry or of the effect of substituents). Methods using the approximation involving the neglect of differential overlap (NDO) yield a qualitatively incorrect potential surface for reaction (5), predicting the formation of a stable pentacoordinate complex (the presence of a minimum on the PES), for example $CH_5^-$ or $CH_3F_2^-$, instead of the saddle point.[67,70] The geometry of these complexes differs considerably from the geometry of the TS calculated by non-empirical methods: the axial bonds in the complex are shorter by ~0.5 Å than in the TS.

The stability of the structures $[XCH_3Y]^-$ is found to be too high in calculations by semiempirical methods for two reasons. Firstly, the form of the valence atomic orbitals of X and Y changes appreciably and their atomic charges are altered in the course of the reaction, which is characteristic of anionic reactions where X and Y are isolated atoms, particularly when X = Y = H. If X and Y are molecular residues, then the errors diminish because of the delocalisation of the excess electron densities.

Secondly, the NDO approximation introduces a significant error. The empirical inclusion of non-orthogonality effects in the parameters of the semiempirical methods is intended for neutral molecules and cations (included in the calibration set in the optimisation of the parameters of the MINDO and MNDO methods). As a result, one of the components of the total energy, namely the contribution of the exchange repulsion, is underestimated if the excess electron populations on the atoms of the reaction centre are large. In calculations for cationic systems, the latter defect is removed. This is confirmed by the result, likely to be correct, obtained in calculations for cationic reactions by the MINDO/3 [71] and MNDO [16] methods. The potential curves for $S_N2$ reactions with neutral nucleophiles, $\ddot{X} + RN_2^+ \rightarrow XR^+ + N_2$ (R = $CH_3$ or $C_2H_5$), calculated by the MNDO method, have a characteristic two-well profile with minima 3–10 kcal mol$^{-1}$ deep and separated by a barrier. However, the parametrisation of the MNDO method successfully models the exchange repulsion also in certain anionic systems. For example, two-well potential curves have been obtained for the following anionic $S_N2$ reactions: $CN^- + CH_3CN$,[6] $Cl^- + RCl$ (R = alkyl or $R'C_6H_4CH_2$), and $X^- + CH_3Cl$ (X = Cl, HO, HS, $CH_3O$, $CH_3S$, $H_2N$, CN, NC, or HCC).[73] The best result was obtained for X = Cl (Table 3). This is because the calibration of the parameters of the Cl atom in the MNDO method reproduces its electron affinity, i.e. is in fact designed for the description of the $Cl^-$ anion. For the majority of other anions with the charge localised on one

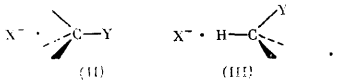
atom, the errors in the heats of formation are now as much as 20–30 kcal mol$^{-1}$ and this affects the calculated energy parameters of the reactions.[73] Calculations with the aid of MNDO, as well as other NDO methods, for the $H^- + CH_4$ reaction yield a false minimum for the symmetrical configuration and the barrier of the $F^- + CH_3F$ reaction is unacceptably high (Table 3).

The semiempirical method based on the explicit allowance for the AO non-orthogonality effects[76,77] has been used successfully in the calculations on the kinetics of a series of $S_N2$ reactions. In this method the integrals are parametrised in terms of an atomic basis set and are then converted to an orthogonal basis set. This procedure eliminates the disadvantages of the NDO approximation and the method yields characteristic two-well curves for reactions (5) with X, Y = H, F, Cl, or OH.[72]

The effect involving a change in the form of the AO following a change in the atomic charges, indicated above, cannot be taken into account in non-empirical methods employing a minimal basis set either. It can be estimated by comparing the results of calculations in terms of the STO-3G basis set and in terms of an extended basis set (Table 3). The axial bonds in a TS of the type of $CH_5^-$ found in terms of the limited STO-3G basis set are too short. A more significant feature is that the forms of the potential curve for the $F^- + CH_3F$ reaction correspond to the formation of a stable complex instead of the TS, as in semiempirical methods.

The electronic correlation contribution in calculations on reactions (5) is weak (Table 3) and, according to the available calculations,[53,66] does not introduce significant changes into the barrier on the PES.

A series of studies[14,32,53,58,59,72] have been devoted to systematic calculations of the PES for reactions (5), including the TS and complexes. The results of the best calculations are presented in Table 4. The majority of the PES have been calculated in terms of the moderate 4-31G basis set with two exponential functions with respect to the valence shell. Table 3 illustrates the effect of the basis set. A reliable geometry of the stationary points is usually obtained at the level of the 4-31G basis set. However, in order to obtain reliable energy parameters, a wider basis set is required. Thus the energies of the TS in the $F^- + CH_3F$, $Cl^- + CH_3Cl$, and $H^- + CH_3F$ systems, calculated in terms of the 4-31G basis set[12,14] and by the CEPA-PNO method {balanced basis set (8,4/4) contracted to [4,2/2] taking into account electron correlation}[53] differ by 20 to 25 kcal mol$^{-1}$ and have opposite signs relative to the energies of the reactants. A saddle point is not obtained in the PES for the $H^- + CH_3Cl$ [56] and $F^- + CH_3Cl$ [14] reactions in the 4-31G method, which conflicts with the calculations in terms of a wider basis set.



Two minima on the potential energy profile correspond to electrostatic ion–molecule complexes. The calculated characteristics of the complexes agree with the experimental data. Their calculated energy of formation is in most cases between −10 and −20 kcal mol$^{-1}$. The complexes are highly asymmetric. When X = Y, the length of one bond (X.C) is more than 2.5 Å, while that of the other (C–X) is close to the equilibrium value in the substrate. The calculated length of the X.C bond sometimes depends significantly on the basis set of the computational method. In [$H^-$.$CH_3F$] the length of the H.C bond, calculated in terms of the 4-31G basis set, is 2.64 Å, whilst that calculated in terms of 6.311G*

Table 4. The geometrical and energy characteristics of the PES for the reactions $X^- + CH_3Y \rightarrow XCH_3 + Y^-$ (bond length, Å; energy, kcal mol$^{-1}$).

[a]Complex of type (III).

basis set is 3.06 Å.[14] The bond in the complex can be formed in two ways, to which correspond two local minima on the PES:[12,14]

(II) (III)

For X = Y = F, the energy of complex (II) is lower by only 0.1 kcal mol$^{-1}$ than that of complex (III) and the barrier to the transformation (II) → (III) is 0.8 kcal mol$^{-1}$.[12] On the other hand, if the substrate is $CH_4$, then the complex of type (III) is more stable.

The configuration of the TS of reactions (5) corresponds to the apex of the internal barrier. The energy of the TS can be not only higher ($\Delta E > 0$) but also lower ($\Delta E < 0$) than those of reactants (Table 4 and Fig. 4). This has apparently been confirmed by experiment.[36,41,42]

The geometry and the changes in the X–C and C–Y distances in the TS compared with equilibrium X–C and C–Y bond lengths are listed in Table 5 for some reactions. The X–C and C–Y bonds in the TS are longer than the equilibrium bonds by 0.3–0.8 Å and differ greatly for a series of reactions based both on the nucleophile and on the leaving group.

Table 5. The geometry of the TS and the energy characteristics of reactions of type (5); the changes in the length of the axial bonds relative to the equilibrium values in the substrates $XCH_3$ and $CH_3Y$ (the bond lengths are in Å, the angles in degrees, and the energy in kcal mol$^{-1}$) (the calculation was performed in terms of the 4-31G basis set using Mitchell's data[14]).

It was noted earlier[14,32,72] that Hammond's postulate holds in the $X_i$ + $CH_3Y$ reactions, which is illustrated in Table 5. This is a familiar, consistent relation between the structure of the TS and the heat of reaction, according to which the position of the TS shifts less along the reaction coordinate the higher the heat change $Q$. The change in the valence angle Δ(H–C–Y) or the increase in the bond length Δ(C–Y) in TS of the type $[XCH_3Y]^-$ compared with the equilibrium values in the substrate $CH_3Y$ can be adopted as measures of the above shift. Table 5 shows that both quantities are correlated with $Q$. This apparently exhausts the simple regularities in gas-phase reactions. The correlation usually postulated between the height of the activation barrier of the reaction $\Delta E$ and the heat of reaction $Q$ is not observed, in agreement with gas-phase experiments, if it is assumed that the measured reaction rate constant characterises the height of the barrier $\Delta E$ (Table 2).

The lack of simple correlations for gas-phase reactions of the $S_N2$ type can be accounted for by two causes. Firstly, for a complex two-well profile of the potential curve, the conditions essential for the derivation of the Bell–Evans–Polanyi principle or Hammond's postulate do not hold (they are considered in Appendix 2). From this standpoint, one is more justified in expecting a correlation between the geometry of the TS and the heat of the "complex → complex" stage, which is equal to $H$.

The estimation of reactivity-nucleophilicity, the mobility of the leaving group (nucleofugacity), etc. from calculated data is also difficult owing to the complex form of the PES. An uncertainty arises because it is not known which of the calculated quantities, $\Delta E$ or $E$, should be used as the measure of the reactivity. Furthermore, as stated in Section III.2, the kinetic models for the description of multistage $S_N2$ processes are not unambiguous and it is not clear whether the characteristics of the potential curve are susceptible to a simple kinetic interpretation.

Secondly the lack of simple relations is associated with the fact that the replacement of X or Y in the reaction centre XCY alters the structure of the TS too drastically. For example, this is manifested in the length of the axial bonds. Table 5 shows that the quantities Δ(C–Y) differ in the range 0.1–0.3 Å even in narrow series. Different TS actually correspond to series in which the nucleophile X or the leaving group Y are altered. This explains why the experimental nucleophilicity series (variation of X) depend on the leaving group Y and the nucleofugacity series (variation of Y) depend on the nucleophile X.[37,72]

### 4. Attempts at a Theoretical Study of Reactions in Solution. Problems Involving Allowance for the Medium

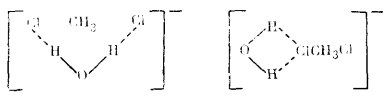
The gas-phase experiments and quantum-chemical calculations examined above refer to reactions of isolated chemical systems. However, $S_N2$ reactions in solution are of direct practical interest. They require special consideration, as can be seen from the following facts:

(1) The rates of typical $S_N2$ reactions decrease by 10–20 orders of magnitude on passing from the gas phase to a polar solvent[36,39,78] [the logarithm of the rate constant for the $F^-$ + $CH_3Cl$ reaction at 25 °C is 11.7 (litre mol$^{-1}$ s$^{-1}$) in the gas phase and −7.8 (litre mol$^{-1}$ s$^{-1}$) in water].

(2) The activity series of nucleophiles can be different in the gas phase and in solution and also vary as a function of the solvent (the gas-phase activity series $F^- > Cl^- > Br^- > I^-$ is inverted on passing to proton-donating media[79]).

(3) The solvent can alter the mechanism of an $S_N2$ reaction: in solution the latter can proceed via a preliminary stage involving the formation of ion pairs up to the change of the mechanism to the $S_N1$ type.

Such a marked influence of the solvent on the chemical process is specific to reactions with participation ions. Strong electrostatic (ion–dipole) interactions arise in these systems. They in fact determine the characteristic features of reactions in polar media. The intensity of the ion–dipole interactions is comparable to that of interactions responsible for the chemical reaction proper in an isolated system. Any theory, quantitative or qualitative, claiming to explain the kinetics of $S_N2$ reactions in solution cannot ignore the presence of the medium.



Attempts at experimental[33,80–83] and theoretical[62] study of the influence of the solvent have been undertaken in relation to $S_N2$ reactions with participation of a small number of solvating molecules. In gas-phase experiments with hydrated nucleophilic species,[80,81] i.e.

$$HO^- \cdot n\,H_2O + CH_3Br \begin{cases} \longrightarrow HOCH_3 + Br^- \cdot n\,H_2O\ , & (11) \\ \longrightarrow HOCH_3 + Br^- + n\,H_2O\ . & (12) \end{cases}$$

measurements were made of the rate constants (in $cm^3$ molecule$^{-1}$ $s^{-1}$) and the following values were obtained at 300 K: $10^{-9}$ ($n = 0$); $(6 \pm 2) \times 10^{-10}$ ($n = 1$); $(2 \pm 1) \times 10^{-12}$ ($n = 2$); $2 \times 10^{-13}$ ($n = 3$); in aqueous solution: $k = 2.3 \times 10^{-25}$ $cm^3$ molecule$^{-1}$ $s^{-1}$.[78] The processes follow pathway (12), which is preferred for thermodynamic reasons: when $n \geq 3$, reaction (11) becomes endothermic. Indeed, it has been found[81] that the ionic ratio in the reaction product $Br^-.H_2O/(Br^- + Br^-.H_2O) = 0.04–0.07$.

Mechanism (12) has also been confirmed by systematic study of the reaction $X^-.nS + CH_3Y \rightarrow XCH_3 + (n-m)Y^- + mS$ (Y = Cl or Br; X = OD, $CH_3O$, $C_2H_5O$, $CH_3COCH_2$, HCOO, or $CH_3COO$).[82] It is of interest to compare with these data the quantum-chemical calculation of the PES for the reaction $Cl^-.nH_2O + CH_3Cl \rightarrow ClCH_3 + Cl^-.nH_2O$ ($n = 0, 1, 2$) by a non-empirical method (3-21G basis set) with complete optimisation of the geometry.[62]

According to the calculation, the prereaction electrostatic complexes are formed also in the case of the solvated nucleophile. Solvation increases their energy and the height of the internal barrier $E$ (Fig.4). The relief of the PES with one and especially two water molecules becomes very much more complex: intermediate structures, corresponding to different mechanisms of the transfer of $H_2O$ molecules from the nucleophile to the leaving group, appear. Two TS with similar energies have been found for $n = 1$:

The first corresponds to the simultaneous occurrence of the chemical and solvation rearrangements, while in the second the solvation rearrangement follows the chemical rearrangement. For $n = 2$, the following consecutive mechanism is energetically preferable: transfer of $H_2O$—chemical rearrangement—transfer of $H_2O$:

$$(H_2O)_2 \cdot Cl^- + CH_3Cl \rightarrow H_2O \cdots Cl^- \cdot CH_3Cl \cdots H_2O \rightarrow$$
$$\rightarrow H_2O \cdots ClCH_3 \cdot Cl^- \cdots H_2O \rightarrow ClCH_3 + Cl^- \cdot (H_2O)_2\ .$$

Several alternative reaction pathways have been observed together with that indicated above. The simultaneous occurrence of the $H_2O$ transfer and of the chemical rearrangement is the least favourable pathway.

Both experiment and calculation demonstrate the importance of solvation effects. On the other hand, it is evident that systems with a small number of solvent molecules are not successful models of reactions in solution. Indeed, although the measured constants did decrease, they remained within the range of "gas-phase" values. The formation of a desolvated anion in the reaction products is a specifically gas-phase mechanism, which does not occur in solution. The complex mechanisms of the transfer of water molecules noted in the calculation also have hardly any bearing on the real mechanisms in solution, where a collective rearrangement of the solvation shell, involving simultaneously many solvent molecules, is most probable.

The necessity to take into account explicitly a large number of solvent molecules is the main problem of the modern theory of chemical reactions in polar media. Two methods for its solution are being developed.[84,85] The so-called supermolecular approach considers the chemical system and the molecules of the medium on an equal basis in a single quantum-chemical calculation of the PES. An example is provided by the calculation described above.[62] It is clear from its consideration that the "supermolecules" for which the calculation is made must be fairly large. An analogous calculation of the solvation energies of ions with model potentials (which is technically incomparably simpler than the calculation of the PES) requires an explicit consideration of at least three coordination spheres, i.e. several hundred solvent molecules. In order to obtain concordant quantitative results, it is essential to optimise their positions and orientations, which are self-consistently determined by the electric field of the entire assembly of species forming the supermolecule and not only by the field of the "parent" ion. If account is taken of the multiplicity of the energy minima and the corresponding multiplicity of the reaction mechanisms, which is inevitable in such an investigation (an indication of this can be seen even in the simplest example discussed), then one can imagine how great are the technical difficulties in the solution of the problem.

Recent calculations for the $Cl^- + CH_3Cl$ reaction in water[75,86] and in dimethylformamide (DMF) [87] have demonstrated the present possibilities of this branch of research. The potential gas-phase reaction profile was calculated by a non-empirical method in terms of the 6-31G basis set. The interaction of the chemical subsystem with solvent molecules was taken into account with the aid of empirical atom–atom potentials calibrated against preliminary non-empirical calculations for simple model systems. This made is possible to take into account 250 water molecules and 180 DMF molecules surrounding the chemical subsystem. The configuration of the solvation shell was optimised by the Monte Carlo method. As a result of the calculation, the minima on the PES, to which correspond the electrostatic complexes found, as usual, for the gas phase, disappeared for the reactions in solution. The observed heights of the potential barriers proved to be 26.3 kcal mol$^{-1}$ for the reaction in water and 19.3 kcal mol$^{-1}$ for the reaction in DMF. The corresponding experimental activation energies are 26.6 and 22.7 kcal mol$^{-1}$.

In the second approach, the medium is regarded as a dielectric continuum in which the chemical system is immersed. For elementary situations, the solvation energy $U$ can be determined from simple formulae. For example, for a spherical ion with a radius $r$ in a medium having a dielectric constant $\varepsilon$, it can be calculated from the Born formula

$$U = e^2(1 - 1/\varepsilon)/2r\ .$$

In order to describe the chemical reaction in the continuous model, it is necessary to calculate the energy of the electrostatic interaction of the chemical system (with a complex distribution of electric charges) with the dielectric medium. The calculation is based on the same principles which lead to the Born formula, but in this case a cumbersome computer computation is required.[88] Ideally the calculation should be self-consistent, i.e. it should take into account the converse effect of the potential of the medium on the structure of the chemical system and the distribution of the electric charge in the latter.[89,90] There exist serious difficulties both in the selection of the dielectric constant (it does not agree with the usual macroscopic value) and in the selection of the size of the cavity in which the reacting system is placed. The

existing methods for the estimation of the size of the cavity, for example from the polarisability,[91] are not unambiguous.

All the foregoing considerations are based on the assumption that the solvation effects can be described within the framework of the activated complex theory. Only in this case is it sufficient to consider the stationary configurations of the initial and transition states of the reacting species + medium system. This is by no means evident. The orientational movements of solvent molecules which optimise the energy may not keep up with the movement of the reacting molecule; non-equilibrium reaction conditions then obtain.[92,93] In the continuous model the effective dielectric constant of the non-equilibrium medium diminishes.

As a consequence of all these problems, the published calculations of the PES for ion–molecule reactions in a polar solvent are usually far from perfect. The frankly empirical approaches employed have been discussed, for example, in the review of Abronin et al.[84] For nucleophilic substitution reactions, the continuous model has been used in calculations for the $X^- + CH_3F$ reactions, where X = OH or CN.[91]

The most elementary approach links the solvation effect to the shift of the energies of the frontier MO. For $S_N2$ reactions, calculations by the STO-3G method showed[94] that the formation of clusters of nucleophilic anions with several water molecules reduces the energies of the HOMO of the nucleophile, the effect increasing in the sequence $I^- < Br^- < Cl^-$. According to perturbation theory, the decrease of the HOMO level of the nucleophile, which increases the difference between this energy and the energy of the LUMO of the substrate, reduces the reactivity of the $Cl^-$ ion to a greater extent than that of $Br^-$ ion and the latter to a greater extent than the reactivity of $I^-$. Hence it follows that the nucleophilicity series $Cl^- > Br^- > I^-$, characteristic of aprotic solvents and the gas phase, can be inverted in a protic solvent.

We shall now consider the main causes of the changes which the PES for gas-phase $S_N2$ reactions undergo in solution. One of them is well known and consists in the fact that the electric charge in the TS is delocalised and the corresponding solvation energy is much smaller than the solvation energy of the nucleophilic ion with a localised charge. The loss of solvation energy has been estimated in several semiempirical calculations for the $F^- + CH_3F$ reaction.[74,95,96] According to the calculation by the MINDO/3 method, it amounts to 31 kcal mol$^{-1}$.[96] Calculation by the CNDO/2 method leads to clearly high values, which vary in the range 62–100 kcal mol$^{-1}$ as a function of the number of water molecules incorporated in the solvation shell.[74] A similar value (105 kcal mol$^{-1}$) has been obtained in the solvation model on the basis of the CNDO/2 method.[95] In the continuous model, the solvation energy differences calculated by the CNDO/2 method for the $X^- + CH_3F$ reaction[91] are 43 (X = OH) and 12.7 kcal mol$^{-1}$ (X = CN).

Although the semiempirical methods used are unsuitable for calculations on gas-phase reactions, the estimated solvation effect, which amounts to several tens of kcal mol$^{-1}$, is likely to be correct in terms of order of magnitude.

The second cause of the change in the form of the potential curve on passing from the gas phase to the solution becomes evident when the energies of the successive desolvation of ions are examined in relation to $F^-.nH_2O$: $\Delta H_{n,\,n-1}$ = −13.2 ($n$ = 5), −13.5 ($n$ = 4), −13.7 ($n$ = 3), −16.6 ($n$ = 2), and −23.3 kcal mol$^{-1}$ ($n$ = 1).[97] The reaction with the substrate is preceded by the formation of a contact ion–molecule pair with partial desolvation of the ion and the substrate in accordance with the idealised scheme

$$X^-\cdot nS + CH_3Y\cdot mS \rightleftarrows [X^-\cdot CH_3Y][(n+m-2)S] + 2S, \qquad (13)$$

where S is a solvent molecule. At this stage the amount of energy expended is approximately equal to the energy of the removal of one $H_2O$ molecule from the complete hydration shell of the nucleophilic ion. Together with the remaining solvation effects, it amounts to ~20 kcal mol$^{-1}$ for $F^-$. This is sufficient to understand why the formation of the electrostatic complexes is not observed in a polar solvent: the energy of their formation in the gas phase is as a rule less than the positive heat of reaction (13). The potential curves for the next, chemical stage proper, i.e.

$$[X^-\cdot CH_3Y][(n+m-2)S] \rightarrow \text{products}, \qquad (14)$$

are smoothed out acquiring the usual profile illustrated in Fig. 5. The barriers indicated by dashed lines correspond to the preliminary reaction (13) in which the solvation shells of the reactant are rearranged. In stage (14) the solvent exerts its influence in the usual way—via the shifts of the energies of the initial and transition states.

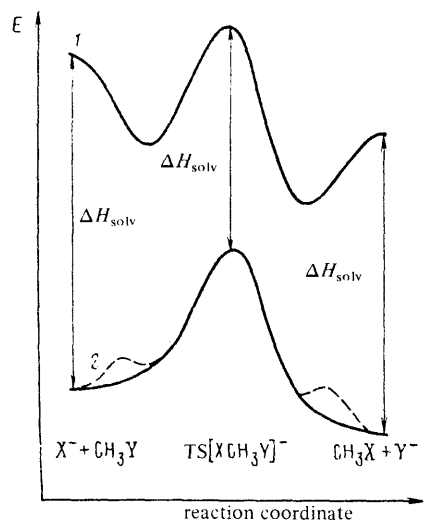


**Figure 5.** The change in the PES profile for an $S_N2$ reaction on passing from the gas phase (curve *1*) to a polar solvent (curve *2*). The dashed lines are explained in the text.

These considerations apply in the model calculation for reaction (14) with X, Y = F, Cl, or H.[98] The water molecules were replaced by point charges, forming dipoles. Their disposition and magnitudes were chosen so as to reduce the observed total solvation energies of the anions and the energies of their partial desolvation. In the calculation for reaction (14), one dipole each was removed from the solvation shell of the nucleophile and the substrate. In each external electric field specified in this way, the PES was calculated by a semiempirical method specially devised for calculations for the corresponding gas-phase reactions.[76,77]

The calculation reproduced the smooth potential profile for the reaction, because postulates designed to achieve this result were incorporated in the basis of the model of solvation shells adopted. The potential barrier found reflects the experimentally observed trends. It is of interest to compare the geometries of the TS found in solution and in

the gas phase for the $F^-$ + $CH_3Cl$ reaction, where these changes are most pronounced: $R(C-F)$ = 2.06 Å in solution and 2.14 Å in the gas phase and $R(C-Cl)$ = 2.35 Å and 2.24 Å in solution and in the gas phase respectively.

Thus, even if we confine ourselves to the description of the reactions in solution with the aid of the activated complex theory and the non-equilibrium character of the solvation effect is neglected, their standard treatment requires a significant revision. The calculation of the energy changes employing the "gas-phase" configurations of the reactants and of the activated complex is inadequate. It is necessary to take into account the distortion of the configuration of the PES in the region of the corresponding points under the influence of the medium. In the example considered, it has the character of a moderate correction in the case of the TS. However, in the region of the initial state the deformation of the PES is so great that one is justified in speaking of a change in the reaction mechanism.

### 5. The Effect of Substituents

The effect of substituents R both in the nucleophile $X(R^1)$ and in the substrate $C(R^2)-Y$ or $C-Y(R^3)$ on the reactivity can be naturally accounted for within the framework of a three-centre four-electron model of the open-chain TS:

$$\underset{\alpha_x}{[X(R^1)} \overset{\beta_{cx}}{---} \underset{\alpha_c}{C(R^2)} \overset{\beta_{cy}}{---} \underset{\alpha_y}{Y(R^3)]^-} \quad ;$$

(IV) (TS)

$$\underset{\alpha_x}{X^-(R^1)} + \underset{\alpha_c}{C(R^2)} \overset{\beta_0}{---} \underset{\alpha_y}{Y(R^3)} \quad \text{(initial state).}$$

(V)

The corresponding Coulombic ($\alpha$) and resonance ($\beta$) integrals are indicated in Schemes (IV) and (V) (the Hückel method).

It was noted above that the variation of the atoms X and Y alters the structure of the reaction centre so much that simple correlations are lacking in the corresponding reaction series. The introduction of substituents R for fixed X and Y makes it possible to construct narrow reaction series in which systematic changes in reactivity are observed.

The corresponding kinetic measurements have been as a rule made in polar aprotic solvents, which makes it possible to to adopt the usual smooth PES profile for the reactions considered. Other aspects of the effect of the solvent are usually ignored in a qualitative treatment.

According to perturbation theory for the interaction ($\beta_{cx}/\beta_0 \ll 1$, although this condition is by no means evident), the interaction of the highest occupied AO (MO) of the nucleophile $|x\rangle$ having the energy $\alpha_x$ with the LUMO of the substrate $|\sigma^*\rangle$ having the energy $\varepsilon_\sigma$ makes the main contribution to the change in the height of the potential barrier. Attempts have sometimes been made to explain the influence of the substituent by its effect on the energies of the corresponding frontier MO (i.e. on $\alpha_x$ or $\varepsilon_\sigma$). According to the Hückel MO theory, the interaction should alter $\alpha_x$ (for the substituent $R^1$ in the nucleophile) or $\varepsilon_\sigma$ (for substituents in the substrate) to a greater or lesser extent depending on the nature of the substituent. The interaction with electron-donating substituents (heteroatom with an electron pair) in the $\alpha$-position induces the greatest effect. It is to be expected that the introduction of such substituents into the nucleophile should increase the relative reactivity (the $\alpha$-effect), while their introduction into the substrate should diminish it. This model presupposes a purely resonance interaction of the substituent with the reaction centre.

The above treatment presupposes, in particular, that the levels of the substituent MO always lie below the level of the nucleophile HOMO. This is not always so and cases are known where direct calculation does not confirm the increase of the HOMO energy level predicted by the Hückel MO theory.[99] The effect is extremely sensitive to the spatial orientation of the substituent or more precisely of its unshared electron pair. This has been demonstrated by a non-empirical calculation of potential barriers for the $H^- + CH_3R \rightarrow CH_3R + H^-$ reactions, where R = OH, $NH_2$, or $BH_2$.[100]

We shall consider a reaction series with variation of a nucleophile of the type $X(R^1)$. In schemes (IV) and (V) it is characterised by the two variable parameters $\alpha_x$ and $\beta_{cx}$. For the standard system with $X(R_0^1)$, we shall designate them by $\alpha_x^0$ and $\beta_{cx}^0$. The energy of system (IV) relative to the standard system is then given by the following expression according to the perturbation theory:

$$\Delta E = E - E_0 = q_x^0(\alpha_x - \alpha_x^0) + 2P_{cx}^0(\beta_{cx} - \beta_{cx}^0) \ , \qquad (15)$$

where $q_x^0$ is the electronic charge on X and $P_{cx}^0$ is the order of the C–X bond in the TS of the standard system. If account is taken of the fact that $\alpha$ is a measure of the effective electronegativity of the atom X and $\beta$ is a measure of the effective capacity for the formation of a bond, then Eqn.(15) can be regarded as an analogue of the two-parameter empirical Edwards or Todesco–Bartoli equation[101,102] [in order to complete the derivation, it is necessary to formulate the analogous equation for the initial state (V) and subtract it from Eqn.(15)].

Suppose that only the substituents $R^1$ at X are varied. One can then fix $\beta_{cx} = \beta_{cx}^0$, which yields a one-parameter equation of the Hammett type. As will be shown below, it is then not essential to apply perturbation theory and $\alpha_x$ can be varied within wide limits.

The variation of the substituents $R^2$ at C or $R^3$ at Y can be treated in the same way by varying the corresponding Coulombic parameters $\alpha_c$ or $\alpha_y$. This corresponds to the induction model of the effect of substituents on reactivity which is an alternative to the resonance model mentioned above.

We shall designate the electronic energies of systems (IV) and (V) by $E(\alpha_i)$ and $E^0(\alpha_i)$ respectively ($i = x, c, y$). Suppose that $q_i$ and $q_i^0$ are the corresponding electronic charges in systems (IV) and (V). Since $q_i = \partial E/\partial\alpha_i$,[103] we have

$$E(\alpha_i + \Delta\alpha) = E(\alpha_i) + \int_{\alpha_i}^{\alpha_i+\Delta\alpha} q_i \, d\alpha \ ;$$

$$E^0(\alpha_i + \Delta\alpha) = E^0(\alpha_i) + \int_{\alpha_i}^{\alpha_i+\Delta\alpha} q_i^0 \, d\alpha \ .$$

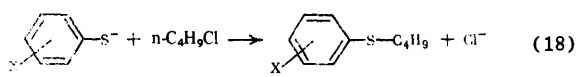
The reactivity is determined by the quantity

$$\Delta_i = \Delta(\alpha_i + \Delta\alpha) - \Delta(\alpha_i) = [E(\alpha_i + \Delta\alpha) - E^0(\alpha_i + \Delta\alpha)] - [E(\alpha_i) - E^0(\alpha_i)] .$$

We thus obtain the expression

$$\Delta_i = \int_{\alpha_i}^{\alpha_i+\Delta\alpha} (q_i - q_i^0) \, d\alpha \ . \qquad (16)$$

If $q_i$ and $q_i^0$ change only slightly, the result obtained agrees with the conclusion reached from perturbation theory:



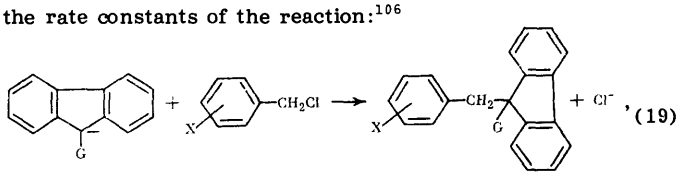
$$\Delta_i \cong (q_i - q_i^0)\Delta\alpha \ . \qquad (17)$$

When $\alpha_i$ changes by $\Delta\alpha$, the system becomes more or less reactive depending on whether the relative stabilisation energy $\Delta_i$ is positive or negative. Consequently analysis of

reactivity for a specified $\Delta\alpha$ reduces to the study of the sign of the difference $q_i - q_i^0$ in Eqn.(16) or (17). In the former case $q_i - q_i^0$ is assumed to be a variable-sign quantity.

The sign of $q_i - q_i^0$ for $\alpha_c \gg \alpha_x, \alpha_y$ is examined in Appendix 1. The results of the analysis are used below.

(1) Substituent in the nucleophile: $q_x - q_x^0 < 0$. The reactivity of the nucleophile (the nucleophilicity) increases if the introduction of the substituent diminishes the electronegativity of the nucleophile: $\Delta_x < 0$ if $\Delta\alpha > 0$. This conclusion is consistent with experiment (and the conclusion reached from the resonance model). An increase in basicity (occurring simultaneously with the decrease of electronegativity) is known to increase the reactivity of the nucleophile as a rule. An analogous conclusion has been reached[104] from thermochemical measurements, with the aid of which it was estimated whether the TS is close to either the reactants or products along the reaction coordinate: the TS moves towards the reactants with increase of the basicity of the nucleophile. The rate constants for the $RO^- + CH_3Cl$ gas-phase reactions with R = alkyl (Table 2) and for heteroatomic substituents are correlated with Taft $\sigma^*$ constants (in this case one should recall that gas-phase two-well potential curves introduce an additional uncertainty into the analysis). The most convincing confirmation of the conclusion concerning the character of the influence of the substituent in the nucleophile is provided by the correlation between the rate constants for the reaction



(18)

and the Hammett $\sigma$ constants for the substituents X [105] (X = $NH_2$, $CH_3O$, $CH_3$, Br, Cl, $CF_3$, OH, or $NO_2$). In this series the reaction rate varies by four orders of magnitude.[105]

(2) Substituent in the leaving group: $q_y - q_y^0 > 0$. In this case $\Delta y > 0$ for $\Delta\alpha > 0$. The reactivity diminishes if the substituent reduces the electronegativity of the leaving group (or increases its basicity), which agrees with the claim[104] that an increase in the basicity of the leaving group shifts the TS towards the products and also with the experimental observation that the nucleofugacity diminishes with increase of the basicity of the leaving group.

(3) Substituent at the central atom of the substrate: $q_c - q_c^0 > 0$ if $\beta_{cy}/\beta_0 > \varepsilon$ and $q_c - q_c^0 < 0$ if $\beta_{cy}/\beta_0 < \varepsilon$. In this case the reactivity series depends on the extent to which the C–Y bond in the TS is loosened compared with that in the initial state. The critical ratio of the resonance parameters is always less than unity. For the symmetrical case (X = Y), $\varepsilon = 2^{-\frac{1}{2}}$ (see Appendix 1). This estimate probably changes little when X ≠ Y if the main condition $\alpha_c \gg \alpha_x, \alpha_y$ remains in force. At any rate it is to be expected that the quantity $q_c - q_c^0$ is small in absolute magnitude, i.e. the effect of substituents must be appreciably weaker than in the first two cases. A linear correlation with the $\sigma$ constants of the substituents X is indeed observed for the rate constants of the reaction:[106]

, (19)

where G = phenyl, 2-benzenesulphonyl, CN, or $CH_3$. The rate constants for different X differ within the limits of 1–2 orders of magnitude. It then follows from the slope of the straight line that $q_c - q_c^0 > 0$. According to calculations by the MNDO method, $q_c - q_c^0 \approx 0.3$ e.s.u. for the $Cl^- + RCl$ systems.[73] The deviation of individual points from the correlation can probably be accounted for both by steric effects and by the inversion of the relation $\beta_{cy}/\beta_c \gtrless \varepsilon$: the lengths of the axial bonds vary within fairly wide limits as a function of the substituent—for example from 1.592 Å for R = F to 1.736 Å for R = OH in the TS $[HCH_2RH]^-$.[14] The reactivities estimated by calculation fit the Hammett correlation. This has been demonstrated in the case of the $Cl^- + XC_6H_4CH_2Cl$ reactions for which calculations were made by the CNDO/2 (X = $NH_2$, $CH_3$, F, $CF_3$, or $NO_2$) [107] and MNDO (X = F, OH, $OCH_3$, $NH_2$ or $NO_2$) [73] methods.

## 6. The Application of Correlation Equations

The relative reactivities of a series of nucleophiles (nucleophilicity) can be more or less satisfactorily described by a four-parameter equation of the Edwards type:[101,102]

$$\lg(k_x/k_{x_0}) = A(P_x - P_{x_0}) + B(H_x - H_{x_0}) , \quad (20)$$

where $P_x$ is a measure of the polarisability of the nucleophile, $H_x$ a measure of its basicity, linked directly to its proton affinity, and $X_0$ the standard nucleophile. More precisely the symbols X and $X_0$ correspond to the "nucleophile + solvent" pair, because the nucleophilicity depends on the solvent. Thus Eqn.(20) is suitable for the correlation of nucleophilicities in different solvents. The parameters *A* and *B* characterise the substrate and can be used in principle to correlate data for the relative mobilities of the leaving group Y (nucleofugacities).[102] Nevertheless, X and Y are involved in Eqn.(20) asymmetrically, i.e. the significance of the parameters *P* and *H* in relation to X is different from the significance of *A* and *B* in relation to Y.

For a complex anionic nucleophile $R^1X^-$ differing in the substituents in $R^-$, a relation of the Brønsted type holds satisfactorily:

$$\lg(k_x/k_{x_0}) = B[pK_a(X) - pK_a(X_0)] , \quad (21)$$

where $pK_a$ are the basicities of the corresponding nucleophiles. Linear correlations of type (21) have been found, for example, for the reactions of substituted fluorenyl and thiophenoxide anions with benzyl and butyl chlorides in DMSO [105,106] [systems (18) and (19)]. Eqn.(21) reduces to Eqn.(20) if the factors associated with the polarisability are constant in the reaction series. Other correlations (the Swain–Scott, Ritchie, etc. correlations) reduce similarly to Eqn.(20) when the reaction series are narrow.[102]

The reactivity in exchange reactions, including those of the $S_N2$ type, has been discussed in recent years on the basis of the Marcus equation:

$$U_{XY}^{\neq} = \lambda_{XY} - Q_{XY}/2 + Q_{XY}^2/16\lambda_{XY}$$
$$\lambda_{XY} = (\lambda_{XX} + \lambda_{YY})/2 \quad (22)$$

where $U_{XY}^{\neq}$ is the height of the potential barrier, identified with the observed activation energy, $Q_{XY}$ the heat of reaction ($Q_{XY} < 0$), and $\lambda_{XX} = U_{XX}^{\neq}$ and $\lambda_{YY} = U_{YY}^{\neq}$ are the barriers for thermally neutral symmetrical reactions. An analogous relation can be formulated also for the free energies $\Delta G_{XY}^{\neq}$, $\Delta G_{XX}^{\neq}$, and $\Delta G_{XY}^{\neq}$. Eqn.(22) was first used to describe the rearrangement of the solvation shells of transition metal ions in electron transfer reactions.[108,109] It was then applied to proton transfer reactions[110,111] and also to the transfer of the methyl group in the gas phase[40,41,112] and in solution.[113–115] Since the heat of reaction can be resolved into increments corresponding to X and Y, i.e. $Q_{XY} = Q_X + Q_Y$ (with an accuracy to within a constant independent of X and Y), it follows that Eqn.(22), like

Eqn.(20), is a four-parameter correlation. The Marcus equation is symmetrical relative to X and Y and, in contrast to Eqn.(20), embraces very wide series, including the variation of both the nucleophile and the leaving group. Its non-linearity makes it possible to explain the deviations from the linear Brønsted relations, which are sometimes observed.

The Marcus parameters differ fundamentally from the parameters of the usual correlations. The latter are normally associated with the electronic structures of the reactants in the spirit of the concept of the influence of the structures of the reactants on the reactivity. The parameters in Eqn.(22) are characteristics of the reactivity (or the PES) and not of the electronic structures of the reactants. From the standpoint of the concept indicated, they themselves require explanation. Nevertheless, they have a clear physical significance and in principle can be determined experimentally. The derivation of the Marcus equation from the overall PES for the exchange reactions is examined in Appendix 2.

For gas-phase $S_N2$ reactions, the Marcus equation has been used in the treatment of kinetic data obtained by the ICR method[40,41,112] and for the systematic treatment of several tens of liquid-phase reactions.[113-115] Its use is restricted by the insufficiency of experimental information about the heats $Q$ (especially in solution) and about the internal barriers $\lambda$. In the studies mentioned above, the quantities $\lambda_{XX}$ and $\lambda_{YY}$ were assumed to be adjustable parameters and were selected empirically ($\Delta G_{XX}$ in Table 6). If X and Y vary in the same series made up of $n$ members, then it is necessary to know $n$ values of the internal barrier $\lambda$ for the description of $n(n-1)/2$ asymmetric reactions. Since kinetic measurements have usually been made for by no means all asymmetric processes, the number of reference points exceeds only slightly the number of parameters. In this case the empirical adjustment of the latter is unreliable and ambiguous.

Table 6. The free energies of activation $\Delta G_{XX}$ in water[103] and the internal barriers $E_{XX}$ (calculation in terms of the 4-31G basis set[14]) for the symmetrical $X^- + CH_3X$ reactions.

| X | $\Delta G_{XX}$, kcal mol$^{-1}$ | $E_{XX}$, kcal mol$^{-1}$ |
|---|---|---|
| H | — | 57.3 |
| I | 23 | — |
| Br | 24 | — |
| Cl | 27 | 5.5 |
| F | 32 | 11.7 |
| $NO_2$ | 27 | — |
| TosO | 35 | — |
| $CH_3SO_3$ | 35 | — |
| $C_6H_5SO_3$ | 36 | — |
| $ClO_4$ | 37 | — |
| OH | 42 | 21.2 |
| CN | 51 | 28.5 |
| HS | — | 15.5 |
| HOO | — | 18 7 |
| FO | — | 18 8 |
| $CH_3O$ | — | 23.5 |
| $H_2N$ | — | 38 |
| NC | — | 43 8 |
| HCC | — | 50.4 |

The contribution of solvation to the activation barrier has been estimated from the Marcus equation in terms of the continuous polar medium model.[116-118] It was postulated that the reaction system moves along the chemical ("gas-phase") reaction coordinate $s$ up to a certain intermediate (not corresponding to a saddle point) value $s_0$. With $s_0$ fixed, the system is then moved along the coordinates of the medium, i.e. the solvent undergoes a rearrangement. The rearrangement is characterised by the reorganisation energy $E_R$ calculated from the electrostatic formula[93,108,109]

$$E_R = (\varkappa/2) \int \mathrm{d}V\,[D_1(s_0) - D_2(s_0)]^2 ,$$

where $\varkappa$ is the effective dielectric constant and $D_1$ and $D_2$ are the vectors of the electrical induction, generated by the charge distribution in the $X^- + CR_3Y$ chemical subsystem, which correspond to the initial and final states of the solvent for the fixed $s_0$. The integration is carried out over the entire space around the cavity occupied by the chemical subsystem. The estimates made for the simplest forms of the cavity[117,118] have shown that, in water with X = I and Y = F, Cl, or Br, the quantity $E_R$ varies from 60 to 80 kcal mol$^{-1}$. In this model the activation energy is

$$U^{\neq} = U(s_0) + [E_R/4 + Q(s_0)/2 + Q(s_0)^2/4E_R] .$$

The expression in square brackets describes the rearrangement of the solvent according to Eqn.(22); here the role of $\lambda_{XY}$ is assumed by the quantity $E_R/4$ and the modified heat $Q(s_0)$ characterises the rearrangement for a fixed $s_0$. Calculations by this formula have been compared with experiment for many $S_N2$ reactions in water and acetone[117,118] and the quantities $U(s_0)$ and $Q(s_0)$ were estimated from thermochemical and spectroscopic data.

Thus the contribution of the solvent to $\lambda_{XY}$ in Eqn.(22) can be expressed in terms of the reorganisation energy $E_R$. The contribution of the chemical rearrangement proper should be added to it, having calculated such contribution in terms of the internal barriers $\lambda_{XX}$ and $\lambda_{YY}$ in Eqn.(22).

Quantum-chemical calculations of the internal barriers are of undoubted interest in this connection (Table 6). Systematic quantum-chemical study of the PES for simple $S_N2$ reactions[14,59] made it possible to check how well the Marcus equation holds by comparing directly its predictions with the calculated potential barriers. For the description of reactions between electrostatic complexes, $[X^-.CH_3Y] \rightarrow [XCH_3.Y^-]$, the agreement proved to be very satisfactory in the case of 11 X,Y reaction pairs: H, NC; H, CN; H, F; H, CCH; H, OH; F, SH; HO, CN; HO, F; HCC, F; F, OOH; $CN^-$, F. The height of the barriers was varied within the limits of 50 kcal mol$^{-1}$. In order to describe the entire two-well potential curve, Eqn.(22) was modified.[14]

It is noteworthy that both the calibration of the Marcus equation and its comparison with the exact calculation have been carried out on the basis of energetically unreliable calculations in terms of the 4-31G basis set. Nevertheless, the fact that this equation describes satisfactorily model quantum-chemical PES over a very wide energy range indicates the possibility of applying it to real $S_N2$ reactions. This is apparently the only way of treating systematically wide reaction series with different X and Y within the framework of a simple correlation scheme.

As already mentioned (Section III), simpler schemes, such as the Bell–Evans–Polanyi equation (linear dependence of the activation energy on the heat of reaction) and the Brønsted equation (the analogous relation for free energies) are applicable to a reaction series with variable X or Y. Satisfactory Brønsted relations can be observed only by varying the substituent with a constant reaction centre. Linear relations (21) reduce to Brønsted relations if it is assumed that the heats of reaction $Q$ are linearly related to the basicities of the nucleophiles. Comparison of the calculated affinities of nucleophiles for the proton and the methyl cation[14] demonstrated the likelihood of this hypothesis. Thus one may conclude that Brønsted correlations exist for systems (18) and (19) in DMSO with the reaction rate

constants varying in the range of 4–5 orders of magnitude[105,106] (~10 kcal mol$^{-1}$ on the energy scale). A similar conclusion was reached in the study of other systems.[119,120] The absence of a visible curvature in the Brønsted plots within the framework of the Marcus equation shows that the role of the quadratic term in Eqn.(22) is small, i.e. that the ratio $Q_{XY}/\lambda_{XY}$ is small. It is of interest that this holds against the background of fairly large systematic changes in the structure of the TS (Table 5). In other words, the derivation of linear relations from equations of type (20), always based on the implicit assumption that the reaction centre is constant, is not convincing.

According to an alternative view,[105] over such a wide range of variation of the reactivity, the Marcus curvature should have been manifested and the linearity of the observed correlations is therefore a special effect whose nature is still obscure and at any rate cannot be accounted for within the framework of the Marcus equation.

It may be that there are systematic deviations from Brønsted correlations. An anomalous increase of reactivity has been observed for a heteroatomic substituent with an unshared electron pair in the nucleophile. The corresponding positive deviations from the Brønsted relation have been called the α-effect.[121–123] In solution the α-effect for $S_N2$ reactions is weak.[123] Measurements in the gas phase for the $X^-$ + $CH_3F$ reactions (X = OH or OOH) led to the conclusion that this effect is absent.[124] Calculation of the heights of the barriers and heats of the $X^-$ + $CH_3F$ reactions (X = HO, $CH_3O$, HOO, FO, or HCOO) in terms of the 4-31G basis set[14,19] yielded ambiguous results: a satisfactory linear relation can be drawn through these five points. The calculation also failed to reveal anomalies in the geometrical structure of the TS for reactions with α-substituted nucleophiles (Tables 4 and 5) and also in the energy relations for symmetrical reactions (Tables 4 and 6). The authors[14,99] are therefore inclined to assume that in the gas phase the α-effect is absent for $S_N2$ reactions and its existence in solution is due to differences between the solvation energies of the normal and α-substituted nucleophiles. Reliable data are apparently still insufficient at the present time for the final solution of this problem.

Attempts to improve the Marcus equation for $S_N2$ reactions have been published.[125,126] The shifts of the TS in the reaction series not only along the reaction coordinate but also at right angles to it have been considered in these models. In other words, a change in the reaction pathway curve for the reaction series is permitted. Additional empirical parameters appear in the corresponding correlation equations which makes the practical application of such equations relatively ineffective.

## IV. APPENDICES

### Appendix 1

Analysis of the sign of the quantity $\Delta q_i = q_i - q_i^0$ subject to the condition $\alpha_c \gg \alpha_x, \alpha_y$.

(1) Substitution at the nucleophile.

Here $q_x^0 = 2$ and $1 < q_x < 2$ [127] as a consequence of the partial delocalisation of the unshared electron pair. Thus, $\Delta q_x > 0$.

(2) Substitution at a carbon atom.

In this case $0 < q_c^0 < 1$ and $0 < q_c < 1$, so that the analysis is more complex. We shall carry it out for the symmetrical X–C–X system assuming that the results do not change greatly for X ≠ Y, provided that $\alpha_c \gg \alpha_x, \alpha_y$.

It is possible to introduce the group orbitals $|x_+\rangle = (|x_1\rangle \pm |x_2\rangle)/2^{1/2}$, where $|x_1\rangle$ and $|x_2\rangle$ are the atomic orbitals of different atoms X. The corresponding matrix elements are equal (for the significance of the notation, see Section III):

$$\langle x_+|h|x_+\rangle = \langle x_-|h|x_-\rangle = \alpha_x \ ;$$
$$\langle x_+|h|c\rangle = 2^{1/2}\langle x|h|c\rangle = 2^{1/2}\beta_{cx} \ ;$$
$$\langle x_-|h|c\rangle = 0 \ .$$

As a consequence of symmetry, only one lowest MO of the X–C–X system is bonding; the MO which follows it is non-bonding and does not contribute to $q_c$. The lowest MO can be formulated thus:

$$\psi_1 = c_{11}|c\rangle + c_{12}|x_+\rangle$$

and the MO which follows it can be written as follows:

$$\psi_2 = c_{21}|c\rangle + c_{22}|x_-\rangle \ .$$

The coefficients of $\psi_1$ are found from the secular equation for a quasi-two-centre "bond":

$$\underset{\alpha_c}{C} \overset{2^{1/2}\beta_{cx}}{\text{———}} \underset{\alpha_x}{X_+} \ .$$

In the initial state a two-centre bond is considered (see Section III):

$$\underset{\alpha_c}{C} \overset{\beta_0}{\text{———}} \underset{\alpha_x}{X} \ .$$

These bonds differ formally only by the value of the resonance integral. We thus obtain

$$\Delta q_c > 0, \quad \text{if} \quad \beta_{cx}/\beta_0 > 1/2^{1/2} \ ;$$
$$\Delta q_c < 0, \quad \text{if} \quad \beta_{cx}/\beta_0 < 1/2^{1/2} \ .$$

(3) Substitution at the leaving group.

An unambiguous conclusion can be reached most simply for the symmetrical situation X = Y examined above. It is sufficient to use the symmetry condition $q_x = q_y$ and the normalisation condition $q_x + q_c + q_y = 4$. Then $q_y = 2 - q_c/2$. In the initial state $q_y^0 = 2 - q_c^0$ according to the normalisation condition. Hence $\Delta q_y = q_c^0 - q_c/2$. This quantity is known to be positive when $\Delta q_c < 0$ (i.e. $\beta_{cx}/\beta_0 < 2^{-1/2}$). In the general case the difference between $q_c$ and $q_c^0$ is small ($q_c/q_c^0 \cong 1$), so that the relation $\Delta q_y > 0$ always holds.

### Appendix 2. The Marcus Equation

The canonical Marcus formula for the height of the chemical reaction barrier has the form of Eqn.(22), where $Q_{XY}$ is the heat of reaction and $\lambda_{XY}$ the so-called "internal barrier". It was obtained for electron transfer reactions,[108,109] whose PES were modelled by two intersecting paraboloids. The derivation of Eqn.(22) has been revised[110] in relation to the usual reactions with rearrangement of chemical bonds, for which the parabolic approximation of the PES is far from realistic. Subsequently it was modified by various investigators.[128–133]

Eqn.(22), which establishes a non-linear relation between the height of the potential barrier and the heat of reaction, can be obtained as a consequence of simple geometrical properties of PES of a specific type. In the derivation given below, this factor is specially emphasised.

Fig.6a illustrates schematically the two-dimensional c curve—the coordinate of a typical exchange reaction. The points $s_1$ and $s_2$, corresponding to the reactants and products, are selected on it (these can be electrostatic or

van der Waals minima; in principle, it is sufficient to choose any points in the asymptotic regions of the reactants or products, where the reaction coordinate becomes a straight line). Suppose that $\sigma$ is the length of the arc $ss_1$ linked to the current coordinate s on the c curve and $\sigma_0$ is the length of the arc $s_2s_1$. The variable $\alpha = \sigma/\sigma_0$ is a natural characteristic of the movement of the system from the reactants to the products on the PES.

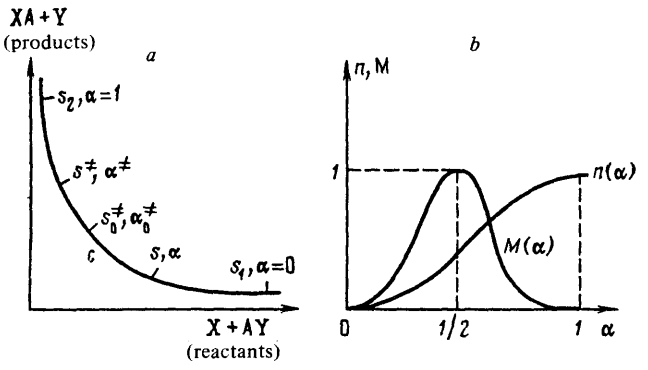


**Figure 6.** Illustration of the derivation of the Marcus equation: *a*) the $S_N2$ reaction coordinate; *b*) kinetic [$M(\alpha)$] and thermodynamic [$n(\alpha)$] interpolation functions; $\alpha = (s - s_1)/(s_2 - s_1)$.

The PES profile $U(\alpha)$ is represented by the relation

$$U(\alpha) = n(\alpha)U(1) + \lambda M(\alpha);\ U(1) = Q \qquad (23)$$

The interpolation functions $n(\alpha)$ and $M(\alpha)$ are specified in the following form (see Fig. 6*b*):

$$\begin{aligned} &0 \leqslant n(\alpha) \leqslant 1;\ n(0) = 0;\ n(1) = 1;\ n(1/2) = 1/2;\ dn/d\alpha > 0 \\ &0 \leqslant M(\alpha) \leqslant 1;\ M(0) = M(1) = 0;\ M(1/2) = 1;\ \frac{dM}{d\alpha}(1/2) = 0; \end{aligned} \qquad (24)$$

$$\frac{d^2M}{d\alpha^2}(1/2) = -k < 0 \qquad (25)$$

According to these definitions, both functions are normalised to unity, $n(\alpha)$ increases monotonically and $M(\alpha)$ has a single maximum at $\alpha = 1/2$. The $U(\alpha)$ potential curve is divided into two components: one component (the "thermodynamic contribution") describes the monotonic evolution of heat and the other (the "kinetic contribution") is responsible for the barrier. The main hypothesis is that $n(\alpha)$ and $M(\alpha)$ are the same in the reaction series, i.e. are the same for all X and Y. Eqns.(24) and (25) do not impose serious limitations on the choice of these functions (with the exception of the symmetrical choice of the value of n at the point $\alpha = 1/2$—a condition which is discussed below). The methods of their detailed specification discussed in the literature[129,130,132] are always arbitrary and are unsuitable for further treatment.

The quantity $U(1)$ is the heat change and $\lambda$ is determined from Eqn.(23) for symmetrical reactions [X = Y: $U_{XX}(1) = 0$]:

$$U_{XX}(1/2) = U^{\neq}_{XX} = \lambda_{XX}\ . \qquad (26)$$

The following approximation has been adopted for asymmetric reactions:[110]

$$\lambda_{XY} = (U^{\neq}_{XX} + U^{\neq}_{YY})/2\ . \qquad (27)$$

Subsequently the function (23) is expanded in Taylor's series in the vicinity of the point $\alpha = 1/2$ and the position of the maximum $\alpha^{\neq}$ is found taking into account the quadratic terms of the expansion on the basis of the condition

$$\left.\frac{dU}{d\alpha}\right|_{\alpha^{\neq}} = 0\ . \qquad (28)$$

Elementary calculations using Eqns.(23)–(25) yield

$$U^{\neq} = U(\alpha^{\neq}) = \lambda + U(1)/2 + (n')^2[U(1)]^2/2k\lambda\ , \qquad (29)$$

where

$$n' = \frac{dn}{d\alpha}(1/2)\ .$$

This is the generalised Marcus formula. The canonical formula (22) is obtained from the latter by putting $(n')^2/k = 1/8$. This result is obtained if the PES profile has the form of two intersecting parabolas.[108] According to the above derivation, the quantity $(n')^2/k$ is a characteristic of the interpolation functions $n(\alpha)$ and $M(\alpha)$, which should be selected in such a way that the PES profile is reproduced most effectively for the given reaction series. In an empirical treatment, $(n')/k$ should be regarded as an adjustable parameter. The special selection of Eqn.(22) usually made has persisted partly because of inertia but mainly because it proved to be fairly apt by chance. The coefficient 1/2 of the linear term in Eqn.(29) is obtained on the assumption that $n(1/2) = 1/2$, which is also non-obligatory. It arose as a consequence of the selection of the symmetrical reaction (X = Y) as the standard around which the expansion in Taylor's series is carried out. If reaction series with highly asymmetric TS are studied, it is more convenient to assume that the quantity $n(1/2)$ is yet another adjustable parameter and to calibrate it against data for any reaction chosen as the standard (the choice $\alpha = 1/2$ is permissible for any standard reaction, which need not necessarily be symmetrical). Such treatment of various series of reactions involving the radical abstraction of hydrogen yielded $n(1/2) = 0.54$–$0.7$.[131]

The non-linearity of Eqn.(29) appeared as a consequence of the variation of the positions of the TS on the reaction coordinate in conformity with the condition for a stationary state [Eqn.(28)]. In linear correlations of the Hammett type, the constancy of the structure of the TS throughout the reaction series is always implied. The same hypothesis is implicit in various approximate quantum-chemical treatments. The fact that the structure of the TS is not postulated but is calculated by a physically well-founded procedure is the fundamental feature distinguishing the Marcus equation among other theories of reactivity.

The shift of the TS along the reaction coordinate is described by the expression

$$\alpha^{\neq} - 1/2 = n'U(1)/k\lambda\ . \qquad (30)$$

For each specific reaction, it is controlled by the ratio of the heat of reaction and the energy of the internal barrier. The shift is appreciable in reaction series with a small force constant *k*—a situation which is characteristic of exchange reactions in which the TS is symmetrical or almost symmetrical and the reaction coordinate is an antisymmetric mode. The application of the Marcus equation to such reactions (these include also the $S_N2$ reactions) is most fruitful. On the other hand, in reactions involving addition to a multiple bond, where the reaction coordinate virtually coincides with the contraction along the newly formed bond, the force constant is large and the shift defined by Eqn.(30) is negligible.[134] In this case Eqn.(29) becomes linear with an unjustifiably rigidly fixed value of 1/2 for the Brønsted coefficient.

According to this derivation, the shifts defined by Eqn.(30) should not be very large. This is why the use of a symmetrical standard reaction [$n(1/2) = 1/2$] for the description of highly asymmetric TS yields unsatisfactory results.

# Kinetics and Mechanism of Electron Transfer in Proteins

J.Kulys

The results of studies on the kinetics of the oxidation-reduction reactions of individual proteins (electron transfer agents and enzymes) are described. Attention has been concentrated on the effect of the nature of the active centres in the protein molecules and of the modification of individual aminoacid residues on the rate of electron transfer in a homogeneous medium. Questions associated with the electrochemical reactions of proteins and with the effect of the state of the interface on the rate of this process are considered in detail. Ideas concerning the theoretical calculation of the rate constants for electron transfer in proteins are described.
The bibliography includes 154 references.

III. Quantitative characteristics of the oxidation-reduction reactions of enzymes 971
IV. The rates of electrochemical reactions of proteins 972

## I. INTRODUCTION

The oxidation-reduction processes involving the synthesis and degradation of substances in living organisms are effected with participation of protein systems in which electron transfer takes place via the oxidation or reduction of active centres in the protein molecules.[1] The success of the practical employment of these reactions, which is now beginning to take shape, in the transformation of organic and inorganic compounds, in energy conversion, and in electrocatalytic systems[2-4] is to a large extent determined by the depth of our understanding of the principal characteristics of electron transfer in individual proteins. The quantitative estimation of the rate of electron transfer in proteins assumes no less importance in the modelling of enzyme catalysis and in the creation of effective low-molecular-weight catalysts.[5] The kinetics of the oxidation-reduction reactions of individual proteins are also of considerable theoretical interest for molecular biology and related fields, because they help in understanding the mechanism of the functioning of oxidation-reduction electron transfer chains in biological membranes.

Kinetic studies occupy at present a permanent place in the research into the mechanism of electron transfer in proteins. The development of preparative methods, which make it possible to obtain individual proteins in amounts necessary for chemical experiments, promoted the rapid accumulation of experimental data concerning the influence of the structure of the protein globule or even of individual aminoacids on the rate of electron transfer. A survey and discussion of these results appear to be extremely timely.

The present review is devoted to the analysis of the kinetic results of studies on the oxidation-reduction reactions of proteins—electron transfer agents and enzymes. It presents data on the chemical and electrochemical reactions of proteins and describes the principal ideas concerning the theoretical calculation of the rate of electron transfer.

## II. OXIDATION-REDUCTION REACTIONS OF ELECTRON TRANSFER AGENTS

### 1. The Formal Kinetic Features of Electron Transfer in Proteins

Oxidation-reduction proteins which are components of the oxidation-reduction electron transfer chains or which participate in oxygen transport processes as a rule have low molecular weights and contain metals, iron–sulphur clusters, flavin-adenine dinucleotide (FAD), flavin mononucleotide (FMN), or other co-factors in the active centre. After isolation in the native state, these proteins are able to react with various compounds and such reactions are bimolecular.

Since protein molecules are charged species, the rate of the process depends on the electrostatic interactions. In order to eliminate this effect, the rate constant is referred to infinite ionic strength of the solution in accordance with the expression:[6]

$$\ln k^{\infty} = \ln k + 3.576 \left[\frac{\exp(-\kappa R_1)}{1+\kappa R_2} + \frac{\exp(-\kappa R_2)}{1+\kappa R_1}\right]\left[\frac{Z_1 Z_2}{R_1+R_2}\right],$$

in which $Z_1$, $Z_2$, $R_1$, and $R_2$ are respectively the charges and radii of the reacting molecules and $\kappa = 3.29\ \mu^{1/2}\ \text{nm}^{-1}$ (25 °C), where $\mu$ is the ionic strength of the solution expressed as a molarity.

The rate constants for the bimolecular reactions of electron transfer agents with complexes vary in the range $10^6$–$10^{-2}$ litre $\text{mol}^{-1}\ \text{s}^{-1}$ and depend on the pH, the ionic strength of the solution, and on the nature of the donor and acceptor. Analysis of the data presented in Table 1 shows that inorganic reactants containing aromatic ligands react at a higher rate than coordination compounds of the same metals without hydrophobic ligands. The reactivity of cobalt oxalate complexes is as a rule low. Low rate constants are also observed for proteins whose physiological function consists in transporting oxygen, namely for haemoglobin and myoglobin.

**Table 1.** The rate constants and certain thermodynamic parameters of the reactions of electron transferring agents with inorganic complexes at 25 °C.

*Electronically excited.

Note. Numbers in square brackets denote references (Ed. of Translation).

The enthalpies and entropies of activation of electron transfer reactions vary from 0 to 352 kJ mol$^{-1}$ and from −185 to 33 J mol$^{-1}$ K$^{-1}$ respectively, which indicates the possibility of appreciable conformational changes in the protein globules on electron transfer, because low activation enthalpies are typical for the formation of simple bimolecular collision complexes, while the activation entropy is −40 J mol$^{-1}$ K$^{-1}$.

A species specificity is also manifested in electron transfer reactions. The high-potential iron-containing protein plastocyanin isolated from various sources reacts with different oxidants at unequal rates. At a low ionic strength, certain transfer agents form complexes with inorganic ions. The stability constant of the complex of azurin with the phenanthroline complex of cobalt is 457 litre mol$^{-1}$, while the rate constant for the reaction is $k$ = 21.3 s$^{-1}$.[28] The reaction between the same copper-containing protein and hexacyanoferrate(III) proceeds in a more complex manner with formation of complexes of both oxidised and reduced azurin.[29] The oxidation of cytochrome *c* with hexacyanoferrate(III) also leads to the formation of a complex whose stability constant is $3.2\times10^4$ litre mol$^{-1}$, while the reaction rate constant is $1.9\times10^3$ s$^{-1}$.[30]

The effect of pH on the rate of the process is determined by the change in the degree of protonation of the aminoacid residues in the region of the centres of proteins. It has been shown that the deprotonated histidine residue His-83 in the azurin molecule decreases the electrostatic repulsion of positively charged ions, so that at pH's above the p$K$ there is an appreciable increase of the reaction rate.[28] In reactions with hexacyanoferrate, His-35 is responsible for the binding of the substrate and its protonation in an acid medium appreciably accelerates the process. In the case of plastocyanin at pH < 5, the rate of reaction is appreciably reduced when the phenanthroline complex of cobalt is used, but is independent of pH when negatively charged complexes are employed.[10] This is because the phenanthroline complex binds to the deprotonated Tyr-83 residue located at a distance of 1 nm from the active centre, while hexacyanoferrate(III) forms a complex with deprotonated His-87 (p$K$ = 5.7) located in the coordination sphere of copper.[31] Since the protonated Lys-72 and Lys-13 residues present near the haem group participate in the reactions of cytochrome *c* with hexacyanoferrate and other negatively charged reagents,[32] the association of cytochrome *c* with polyamines reduces the reaction rate. The rate of reaction is also influenced by the protonation of Tyr-87, which is responsible for conformational changes in the protein globule.[16]

Redox proteins exhibit overall an increased reactivity in relation to organic compounds (Table 2). Particularly large rate constants for the reduction of proteins have been observed in their reactions with the radical-cations of viologens and other radical species. The rate of reaction of flavodoxin, cytochrome *c*, and cytochrome $c_3$ with the methylviologen radical-cation approaches the rate of a diffusion-controlled process. Reduced flavin mononucleotide ($FMNH_2$) and its semiquinone ($FMNH^{\bullet}$) are also highly reactive owing to their low redox potentials.

It has been shown that the electron transfer in the reactions of cytochrome *c* with flavins takes place when the *N*-5-region in the flavin molecules is oriented towards the haem gap, while the *N*-pyrimidine component is oriented in the opposite direction.[34] The rigorous relative disposition of the reactants in the collision complex is responsible for the weak dependence of the reaction rate on the ionic strength of the solution despite the fact that $FMNH^{\bullet}$ and $FMNH_2$ have charges of −2 and −2.8 respectively. The results obtained are important for the theoretical analysis

of the dependence of the rate of electron transfer on the ionic strength of the solution.

The rate of reaction of the solvated electron with cytochrome *c*, myoglobin, and methaemoglobin is determined by diffusion.[41,42] The redox state of the active centre has little influence on the rate of reduction of the protein and only the removal of haem from mylglobin retards the rate of reaction by a factor of two.

Table 2. The rate constants for the interaction of redox proteins with organic compounds (25 °C).

| Protein | Reductant | pH | μ, M | $k_{12}$, litre mol$^{-1}$ s$^{-1}$ | Refs. |

Notation: $MV^+$, $BV^+$, and $PV^+$ are respectively the radical-cations of methylviologen, benzylviologen, and propylviologen; $C_2H_5OH^{\cdot}$ = ethanol radical.

*At 20 °C.

Note. Numbers in square brackets denote references (Ed. of Translation).

The study of the reduction of the acetylated, succinylated, and carboxymethylated cytochrome *c* by solvated electrons and other reductants made it possible to elucidate the role of the electrostatic interaction and of the conformational changes in the redox reactions.[41] It was found that the rate of the reaction involving cytochrome *c* is determined mainly by the conformational change, while electron transfer proceeds in the region of the haem group.

## 2. Quantitative Characteristics of Electron Transfer

The results of studies on the redox reactions of electron transfer agents have been used in the investigation of the possibility of applying outer-sphere transfer theory to protein systems. According to Marcus's ideas,[43] the rate constant for outer-sphere electron transfer $k_{12}$ is related to the reaction equilibrium constant $K$ and the internal exchange rate constants $k_{11}$ and $k_{22}$ for each reactant by the following equation:

$$k_{12}^{\infty} = (k_{11}^{\infty} k_{22}^{\infty} K f)^{1/4},$$

where $\lg f = (\lg K)^2 / 4 \lg (k_{11}^{\infty}/k_{12}^{\infty}/P^2)$ and $P \cong 10^{11}$ litre$^{-1}$ mol$^{-1}$ s$^{-1}$. The above quantity is usually close to unity when $K$ is small. It follows from this equation that the rate of electron transfer depends on the accessibility of the central atom of the complex to individual reactants and also on the difference between the potentials of the reacting compounds, i.e. on the equilibrium constant of the process. If electron transfer at the protein active centre proceeds in the same way as in low-molecular-weight redox compounds, then the internal exchange rate constants for the proteins, calculated for reactions with different reactants, should be identical within the limits of an order of magnitude. Under the conditions of kinetic selectivity, the constants differ by several orders of magnitude.

The study of the rate of reduction of cytochrome *c* by iron complexes containing EDTA derivatives as ligands revealed a satisfactory agreement between the experimental rates and the rates calculated in accordance with outer-sphere transfer theory.[44] A difference is observed only for coordination compounds with an incomplete coordination sphere, which may be due to the increase in the size of the complex owing to the formation of a hydrogen bond between the solvent and a hydroxyl incorporated in this sphere. In the oxidation of cytochrome *c* by substituted ferricenium ions, whose redox potentials ranged over 0.56 V, the calculated and experimental constants were also found to be similar.[45] The enthalpy of activation for the process reaches ~20 kJ mol$^{-1}$ and the entropy varies between −24 and −48 J mol$^{-1}$ K$^{-1}$. These data show that the process does indeed proceed via the formation of a simple bimolecular collision complex without appreciable structural changes in the protein globule.

When coordination compounds of other metals are used instead of isotypical iron complexes, an appreciable scatter of the calculated internal exchange rate constants is observed (Table 3). These constants are almost independent of the nature of the reactant only for two proteins—stellacyanin and rubredoxin. For the remaining proteins investigated, they can differ by more than five orders of magnitude when different reactants are used.

Anomalously high constants are observed in those cases where the interaction between the reactants leads to the formation of complexes, for example the complexes of cytochrome *f* with plastocyanin or cytochrome $c_{551}$ with azurin. Higher and lower constants correspond respectively to reactants incorporating aromatic and hydrophilic ligands, which is associated with the ability of the former to penetrate the hydrophobic region of the active centre. Available data show that iron derivatives containing ethylenediaminetetraacetic acid or its analogues as ligands do not penetrate the protein globule. The constants obtained for these compounds can therefore be used as "reference" values in comparing the reactivities of different proteins. Evidently (Table 3) the internal exchange rate constants obtained using $Fe(EDTA)^{2-}$ are similar for different cytochromes. Stellacyanin and methaemoglobin have the highest and lowest internal exchange rate constants respectively.

In order to eliminate effects associated with the hydrophilic or hydrophobic properties of ligands, an electronically excited ruthenium complex was used (Table 1). Since the

excitation entails a marked increase of the oxidation-reduction capacity of the reactant, this is equivalent to an increase of the driving force of the reaction. The rate constants for bimolecular oxidation-reduction reactions of reduced copper-containing proteins agree well with the theoretical values calculated from the redox potential of the excited complex. This is an important confirmation of the applicability of the outer-sphere electron transfer theory to these metalloproteins. The possibility of applying this theory has been postulated also for other proteins, in particular for flavodoxin.[47]

*$\mu$ = 0.1 M. **$\mu$ = 0.5 M.

Note. Numbers in square brackets denote references (Ed. of Translation).

The relations arising from the outer-sphere transfer theory have been observed also when organic reactants were employed. Thus for cytochrome *c* or cytochrome *f* a linear dependence of the logarithm of the rate constant on the standard potentials of quinones has been observed experimentally with the slope of the resulting linear plot close to the theoretical value.[48] These experimental data show that the rate-limiting stage of the process is a one-electron transfer and that the internal exchange rate constants for the quinones employed do not differ greatly.

In the reactions of electron transferring proteins with organic reactants, the rate of electron transfer was found to approach a limiting value with increase of the free energy of reaction.[49] This is apparently due to the fact that the energy of the reorganisation of the solvent in these processes is lower than in reactions with inorganic charged complexes and the system approaches the "inversion" region,[43] in which the rate diminishes with increase of the free energy of reaction. It is essential to note that the attainment of a limiting rate for a large free energy change has been observed also in reactions involving low-molecular-weight compounds. In order to account for the experimental data, an empirical expression has been put forward[50] for the free energy of activation, which is equal to the free energy of reaction when the reaction is highly exothermic. This expression has been justified theoretically by Scandola and Balzani.[51]

Together with outer-sphere electron transfer theory, the thermally activated tunnel transfer theory has been used to calculate the rate of the process in proteins.[52–54] According to Chien,[55] the tunnel electron transfer rate constant is given by

$$k_1^{\infty} = 0.6023 \cdot k_{\mu} (2\pi\lambda_0^3 r / R_1)$$

$$k_{\mu} = (4\pi^2/h) |T(r)|^2 (4\pi k_B T\Delta)^{-1/2} \exp[-(E_a - E_b - \Delta)^2/4 k_B T\Delta],$$

$$|T(r)| = 2.7 (N_a N_b)^{-1/2} \exp(-7.2\, r),$$

where $\lambda_0$ is the decay constant, $r$ the electron transfer distance, $R_1$ the radius of the protein molecule, $h$ Planck's constant, $k_B$ Boltzmann's constant, $T$ the absolute temperature, $\Delta$ the vibrational synchronisation parameter, $E_a$ and $E_b$ are the standard potentials of the protein and the mediator, $N_a$ and $N_b$ the numbers of distribution sites for the initial and final wave functions, and $T(r)$ is the electron exchange matrix element. The decay constant for protein molecules is usually assumed to be 0.07 nm and the vibrational synchronisation parameter does not exceed 1 eV.

According to the tunnel transfer theory, the enthalpy and entropy of activation are expressed by the equations

$$\Delta H^{\neq} = (E_a - E_b - \Delta)^2/4\Delta - 3RT/2,$$

$$\Delta S^{\neq} = R \ln \left[ \frac{23.8}{k_B T} \left( \frac{2\pi\lambda_0^3 r}{R_1} \right) \left( \frac{1}{4\pi k_B T\Delta} \right)^{1/2} |T(r)|^2 \right] - \frac{3R}{2}.$$

These equations are used to calculate the vibrational synchronisation parameters and decay constants.

For cytochrome *c*, the rate constants calculated within the framework of the outer-sphere and tunnel transfer theories are similar.[44] However, when ferredoxin is reduced by vanadium and europium complexes or the methylviologen radical-cation, the mutual exchange rate constants calculated using the outer-sphere transfer theory are smaller by four orders of magnitude than the constants determined experimentally for model compounds. At the same time, the calculation performed within the framework of the tunnel transfer theory yields values close to the experimental data.[26] It is essential to note that the calculated constants are extremely sensitive to the vibrational synchronisation parameter and the decay constant. The latter can be calculated from thermodynamic data, but in most cases their use in subsequent calculations does not lead to a satisfactory agreement with experimental quantities.

Assuming that the decay constant is invariant for different metalloproteins, Mauk and co-workers[15] proposed a semi-empirical formula relating the electron transfer distance to the mutual exchange rate constant:

$$r = 0.62 - 0.035 \ln k_{11}^{\infty}.$$

After being reduced by the van der Waals radius, this distance corresponds to the depth of the active centre, which is 0.34–0.69 for cytochromes, 0.28 for plastocyanin, and 0.56 for azurin, and 0.58 nm for high-potential iron-containing proteins. The active centre of stellacyanin is located on the surface of the globule and for this reason the mutual exchange rate constant for this protein has been used in the derivation of the last equation. Its application to

electron transfer agents which do not contain metals leads to results which are satisfactorily correlated with X-ray diffraction data.[56]

### 3. Experimental Data for Electron Transfer in Protein Complexes and Structural Ideas

The rate constants for reactions in protein complexes assume values in the range $10^3$–$10^7$ litre $mol^{-1}$ $s^{-1}$ (Table 4). The pairs of proteins forming complexes in electron transport chains (cytochrome c oxidase–cytochrome c, cytochrome c–cytochrome $b_5$, plastocyanin–cytochrome f, azurin–cytochrome $c_{551}$, etc.) react much faster than proteins which do not give rise to such complexes. Similar pairs are produced as a result of the electrostatic interaction of the positive and negative charges on the aminoacid residues, which has been established in relation to complexes of cytochrome c with cytochrome $c_1$ and cytochrome c oxidase,[68] of cytochrome $b_5$ with methaemoglobin,[69] and of cytochrome $b_2$ with cytochrome c.[70] The formation of complexes between proteins which are not physiological partners is possible on interaction of sections bearing both unlike and like charges.[57,70] The hydrophobic interaction forces apparently play an important role in such cases.

Table 4. The rate constants for electron transfer between proteins (pH 6.1–7.6).

| Oxidant | Reductant | T, °C | μ, M | k, litre $mol^{-1}$ $s^{-1}$ | Refs. |

Note. Numbers in square brackets denote references (Ed. of Translation).

The groups involved in the formation of the complexes have been discovered by selective modification. In cytochrome c, the Lys-13, Lys-25, Lys-27, Lys-72, and Lys-79 residues are in the vicinity of haem and interact with the negatively charged Asp-48, Asp-60, Glu-43, Glu-44, and haem propionate in cytochrome $b_5$ in a complementary manner.[63] The carboxy-groups of Asp-112, Glu-114, and Glu-198 participate in the interaction of cytochrome c with cytochrome c oxidase.[71] The electrostatic interaction between the two physiological partners in the cytochrome $b_5$-NADH–cytochrome $b_5$ reductase system takes place between the complementary Glu-47, Glu-48, and Glu-52 residues, haem propionate, and the sixth carboxy-group of cytochrome $b_5$, whose position has not been established.[72] The lysine residues at a distance of 3 nm from the redox centres also participate in the reactions of cytochrome $c_3$ with hydrogenase or ferredoxin.[73]
cytochrome $c_3$ with hydrogenase or ferredoxin.[73]

X-Ray diffraction data for individual proteins made it possible to construct models of the complexes and to put forward a hypothetical electron transfer pathway. In the complex of cytochrome c with cytochrome $b_5$, the prosthetic groups are almost coplanar and the distance between the nearest atoms of the porphyrin ring is 0.85 nm.[74] The structure of the cytochrome c peroxidase–cytochrome c complex has been analysed in greater detail.[75] In this complex the His-13, His-27, His-72, His-86, His-87, Gln-12, and Gln-16 residues of cytochrome c interact with the Asp-79, Asp-216, Asp-37, Asp-37, Asp-34, Asn-87, and Gln-86 residues of the peroxidase. In the complex two haem moieties are parallel, but their planes are separated in the vertical direction by a gap of 0.68 nm. The distance between the iron atoms is 2.46 nm and the minimum distance between the haem moieties is 1.65 nm. It has been assumed[75] that the electron transfer in the complex takes place with migration of the free valence, since it has been suggested[76] that this process proceeds via a tunnel mechanism. The experimental detection of the charge-transfer complex between haem and hexacyanoferrate and also of charge transfer in the cytochrome c–$P_{870}$ complex constitutes an important confirmation of tunnel transfer.[77]

Hypothetical models of the cytochrome $b_5$–methaemoglobin [78] and flavodoxin–cytochrome c complexes have also been constructed.[64] In the complex of cytochrome $b_5$ with methaemoglobin subunits, the negatively charged groups of cytochrome $b_5$ interact with the positively charged groups of methaemoglobin. The haem groups in the complex are arranged in parallel at a distance of 0.7–0.8 nm from one another, while the distance between the iron atoms is 1.6 nm. Since the latter is close to the corresponding distance in the cytochrome c peroxidase–cytochrome c complex, presumably the electron transfer between the haem groups proceeds via tunnelling with active participation of the propionate group of the haem in cytochrome $b_5$.[79]

The Lys-13, Lys-25, Lys-27, and Lys-29 residues of cytochrome c and the Glu-120, Glu-65, Glu-62, and Asp-28 groups in flavodoxin take part in the formation of the flavodoxin–cytochrome c complex.[64] The shortest distance between the sulphide bond of Cys-17 in cytochrome c and the methyl group at C(7) of flavin in flavodoxin is 0.34 nm. The distance between the carbon atoms in the conjugate systems is 0.57 nm. The haem and flavin planes are inclined at an angle of 30°, which ensures a satisfactory overlap of the π orbitals and a high rate of electron transfer within the complex. Analysis of X-ray diffraction data for cytochrome $c_3$ [80] and of kinetic results for cytochrome $cd_1$ [81] confirmed the conclusion that a parallel arrangement of the haem groups is essential in order to ensure a high rate of intramolecular electron transfer.

Experimental rates of electron transfer in protein molecules have been obtained using proteins labelled with ruthenium pentammine.[82–84] It has been found that the rates of electron transfer in cytochrome c 20 and 82 $s^{-1}$ over distances of 1.4 and 1.6 nm respectively. In the azurin molecule the electron transfer to the active centre at a distance of 1.2 nm from the label is slower (1.9 $s^{-1}$).[84] An even greater difference between the rates has been observed for electron transfer between the haemoglobin subunits.[85] In this protein the distance between the metal ions is 2.5 nm and the rate of electron transfer is 60 $s^{-1}$. All these results indicate the specificity of the protein globule and the influence of the nature of the active centre. The spatial orientation of both metal atoms and the ligands is extremely

important. Electron transfer between active centres apparently takes place via tunnelling, but one cannot rule out the possibility of valence transfer and also the involvement in this process of intermediate covalent bonds and aromatic aminoacid residues.

## III. QUANTITATIVE CHARACTERISTICS OF THE OXIDATION–REDUCTION REACTIONS OF ENZYMES

Few quantitative data are available for electron transfer with participation of enzymes, which can be accounted for by the high specificity of enzymes and the complexity of the mechanism of their action. Reaction series have been selected for a few enzymes, which made it possible to obtain kinetic data for the redox reactions of catalytically active proteins.

### 1. Oxidation of the Active Centre of Glucose Oxidase

The oxidation of the active centre of glucose oxidase by quinonoid electron acceptors proceeds at rates ranging from $3.5 \times 10^3$ to $1.5 \times 10^6$ litre $mol^{-1}$ $s^{-1}$.[56] The rate of reaction for compounds having the *p*-quinone structure increases with increase of the redox potential of the electron acceptor. There is a linear relation between the logarithms of the rate constants and the potentials of the acceptors, which is described by a correlation straight line with a slope of 8.4 $V^{-1}$.

Inorganic complexes react with reduced glucose oxidase more slowly despite their high potential, but the rate of oxidation by hexacyanoferrate(III) greatly increases in an acid medium. At a high ionic strength of the solution the phenanthroline or bipyridyl complexes of cobalt react with the above substrate at a rate which is close to the rate of its oxidation by hexacyanoferrate(III), but, when the pH is diminished (to 4), the rate changes much less.

The data obtained led to the following conclusions: (1) the rate-limiting stage of the process is one-electron transfer, because the rates of reactions with participation of one-electron acceptors (tetracyano-*p*-quinodimethane and its radical-anion) obey the Brønsted relation; (2) electron transfer takes place via the outer-sphere mechanism; (3) derivatives of *o*-quinones form an independent group of acceptors, which have a higher reactivity than the *para*-derivatives owing to the *ortho*-effect; (4) the low rate of oxidation of glucose oxidase by inorganic compounds is caused by the specificity of the action of one-electron acceptors, which is determined by the presence of the charge.

The mutual exchange rate constants for glucose oxidase calculated on the basis of the outer-sphere transfer theory are $10^{-2}$–$10^{-9}$ litre $mol^{-1}$ $s^{-1}$ at a high ionic strength and the electron transfer distance for inorganic reagents is 1.1 to 1.3 nm in a neutral medium and 0.8–0.9 nm in the acid region. In the case of hydroquinone the distance is 0.88 nm. These differences in the calculated distances are determined by the degree of penetration of the reagents into the active centre zone, which entails structural changes in the protein globule.

### 2. Reactions of Cytochrome $b_2$ with Electron Acceptors

The rate constants for the oxidation of cytochrome $b_2$ by organic electron acceptors depend on the redox potentials of the compounds and vary in the range $1.2 \times 10^4$–$4.7 \times 10^7$ litre $mol^{-1}$ $s^{-1}$.[86] A linear relation is observed between the logarithm of the rate constant and the redox potential, the slope of the corresponding plot being 8.6 $V^{-1}$. Reduced cytochrome $b_1$ also reacts with inorganic complexes, haem being oxidised, while organic electron acceptors interact with another prosthetic group of the enzyme (FMN). The rate constants for mutual exchange with the complexes, calculated from kinetic data, vary in the range $1 \times 10^1$ to $6.6 \times 10^6$ litre $mol^{-1}$ $s^{-1}$, while the constant for *p*-benzoquinone is $1.6 \times 10^3$ litre $mol^{-1}$ $s^{-1}$. This constant is particularly large for the bipyridyl complex of cobalt, which reacts in the cytochrome *c* binding zone. The electron transfer distance for non-penetrating complexes is 0.31–0.54 nm, while for *p*-benzoquinone it is 0.36 nm. These values agree with those obtained for other cytochromes.

### 3, Characteristics of Electron Transfer in the Peroxidase Process

The formation of active intermediate states of the enzyme (the complexes $E_1$ and $E_2$) is characteristic of the catalysis by peroxidase.[87] It has been suggested that the iron in compound $E_2$ is in the ferryl [$FeO^{2+}$] state. In $E_1$ one of the oxidation equivalents exists in the form of the porphyrin $\pi$-radical-cation, while the other is analogous to the $E_2$ equivalent. In cytochrome *c* peroxidase the free radical is localised at the Trp-51 residue and not on the porphyrin ring.[88] The oxidation-reduction potentials of the two forms of enzymes depend little on the pH and amount to 0.963 V for the $E_2/E$ transition and 0.94 V for the $E_1/E_2$ transition.[87]

Table 5. The rate constants for the reduction of peroxidases at 25 °C.[89–92]

| Peroxidase | Reagent* | pH | $\mu$, M | $k_{12}$, litre $mol^{-1}$ $s^{-1}$ |
|---|---|---|---|---|
| Cytochrome *c* peroxidase ($E_2$ complex) | $Co(tpyr)_2^{2+}$ | 7.0 | 0.1 | $1.1 \cdot 10^5$ |
| ditto | $Ru(NH_3)_5(pyr)^{2+}$ | 7.0 | 0.1 | $9.5 \cdot 10^5$ |
| " | $Fe(CN)_6^{4-}$ | 7.0 | 0.1 | $7.6 \cdot 10^3$ |
| " | $Fe(CN)_6^{4-}$ | 5.26 | 0.1 | $8.1 \cdot 10^3$ |
| " | $Fe(bpyr)_3^{2+}$ | 5.26 | 0.1 | $3.6 \cdot 10^5$ |
| " | $Fe(dmbpyr)_3^{2+}$ | 5.26 | 0.5* | $4.2 \cdot 10^5$ |
| " | $Fe(tmbpyr)_3^{2+}$ | 5.26 | 1.0 | $1.2 \cdot 10^4$ |
| " | $Fe(phen)_2(CN)_2$ | 5.26 | 2.0 | $3.4 \cdot 10^4$ |
| " | $Fe(phen)(CN)_4^{2-}$ | 5.26 | 1.0 | $8.0 \cdot 10^5$ |
| Horseradish peroxidase ($E_1$ complex) | $Fe(CN)_6^{4-}$ | 6.93 | 0.11 | $8.5 \cdot 10^5$ |
| Horseradish peroxidase ($E_2$ complex) | $Fe(CN)_6^{4-}$ | 6.83 | 0.11 | $1.8 \cdot 10^4$ |
| Horseradish peroxidase | $Co(sep)^{2+}$ | 6.3 | 0.15 | $7.0 \cdot 10^4$ |
| ditto | | 6.3 | 0.15 | $5.0 \cdot 10^5$ |
| " | $MV^+$ | 7.0 | $\infty$ | $4.9 \cdot 10^5$ |

Notation: tpyr = terpyridyl; dmbpyr = dimethylbipyridyl; tmbpyr = trimethylbipyridyl.

*At 20 °C.

The reduction of the complex $E_1$ by inorganic compounds proceeds in most cases via a one-electron mechanism with formation of the complex $E_2$. The rate constants for the reduction of the complex $E_1$ are in the range $10^4$–$10^7$ litre $mol^{-1}$ $s^{-1}$ (Table 5). Ruthenium derivatives containing an aromatic compound as the ligand reacts at an exceptionally high rate.[89] Ferriperoxidase is also reduced by powerful reductants to the ferro-form. The standard potential of this transition is −0.25 V.[93] Cobalt sepulchrate, whose

standard potential is −0.3 V, reacts at a rate of $7 \times 10^4$ litre $mol^{-1}$ $s^{-1}$, while dithionite reacts faster almost by an order of magnitude.[92] In the reactions of ferriperoxidase with $MV^+$, a marked dependence of the rate of reduction on the ionic strength of the solution is observed. The charge of peroxidase calculated from these results is −5. It has been shown[90] that, in the reduction of cytochrome *c* peroxidase in the $E_2$ state by iron complexes, a linear relation is observed between the free energies of reaction and activation, which agrees with the outer sphere transfer theory. The mutual exchange rate constant calculated for hexacyanoferrate(II) is $7.5 \times 10^{-5}$ litre $mol^{-1}$ $s^{-1}$ while that calculated for the bis-(terpyridyl)cobalt(II) is $1.3 \times 10^{-4}$ litre $mol^{-1}$ $s^{-1}$. The mutual exchange rate constant for the complex $E_2$ of horseradish peroxidase is almost an order of magnitude smaller ($9 \times 10^{-7}$ litre $mol^{-1}$ $s^{-1}$) when hexacyanoferrate(II) is used. The electron transfer distances calculated from these data are 0.93, 0.95, and 1.1 nm respectively for the above three cases.

The free energies of the reactions of ferriperoxidase with reductants are smaller than for the reactions involving the complexes $E_1$ or $E_2$ and the probability that the system enters the inversion region diminishes. The present authors determined[4] the mutual exchange rate constant for the interaction of $MV^+$ with ferriperoxidase. It amounts to 3.6 litre $mol^{-1}$ $s^{-1}$ and the electron transfer distance is 0.58 nm. Calculation within the framework of tunnel transfer with $\Delta = 0.8$ eV and a decay constant of 0.07 nm, adopted by analogy with ferricytochrome *c*, also yielded an electron transfer distance of 0.58 nm.

### 4. The Oxidation of Electron Donors in the Laccase Reaction

Laccase is one of the few oxidases which reduce molecular oxygen to water in a four-electron process. The active centre of laccase includes copper ions of three types which are in the bivalent state and all participate in the catalytic reduction of oxygen. Laccase is a two-substrate enzyme catalysing the oxidation of the hydroxy-derivatives of benzene or inorganic ions by molecular oxygen. The rate constant for the bimolecular interaction of the laccase active centre with oxygen is $1.6 \times 10^6$ litre $mol^{-1}$ $s^{-1}$ and the rates of oxidation of substrates vary in the range $1.0 \times 10^5$–$2.5 \times 10^6$ litre $mol^{-1}$ $s^{-1}$ and depend on the nature of the enzyme.[94,95] The rate constants for the reduction of the active centre are not correlated with the redox potentials of the donors. However, for one of the laccases investigated,[95] an increased bimolecular constant has been observed for a series of hydroquinones containing substituents with an unshared electron pair despite the fact that the introduction of the substituent increases the redox potential of the electron donor. A similar effect of substituents has likewise been observed in the study of prestationary kinetics of the reduction of copper of the first type in laccase.[96] It has been suggested that this is caused by the additional coordination of the nucleophilic substituent to copper atoms of the third type. This in fact accounts for the appreciable increase of the constant for the inhibition by the fluoride ion of the oxidation of 2,3-dicyanohydroquinone, because the affinity of fluoride for copper of the second type also diminishes on coordination of copper of the third type to the azide.[97]

Kinetic data for the reduction of the active centre of laccase by hydroquinone and hexacyanoferrate(II), obtained by the stopped flow method,[98] permit the conclusion that the reaction proceeds via the outer sphere transfer mechanism. The absence of the Brønsted relation in oxygen reduction processes is due to the complexity of the mechanism and the four-electron reduction of oxygen.[98]

An important question in catalysis by laccase is that of the nature of the high potential of the active centre of the enzyme. Spectroelectrochemical measurements of the redox potential of laccase in the range 7–41 °C yielded the following changes in the thermodynamic parameters and the reduction potential of the active centre: $\Delta S = -58.2$ J $mol^{-1}$ $K^{-1}$, $\Delta H = -92.6$ kJ $mol^{-1}$, and $E$ (25 °C) = 780 mV.[99] Comparison of the entropy and enthalpy parameters with the values known for one-centre metalloproteins permits the conclusion that the high potential of the blue copper is due mainly to stabilisation by ligands, while protein solvation effects play an appreciably smaller role.

## IV. THE RATES OF ELECTROCHEMICAL REACTIONS OF PROTEINS

There exists a profound analogy between electron transfer processes in solution and electrode reactions. Within the framework of the simple isotropic medium models, the outer-sphere transfer theory yields the following expression relating the rates of the processes in the bulk of the solution and on the electrode surface:[43]

$$(k_h/P_h)^{1/2} \geqslant k_s/P_s ,$$

where $k_h$ and $k_s$ are the rate constants for the bimolecular and heterogeneous processes respectively and $P_h$ and $P_s$ are the numbers of the maximum possible collisions in the bulk (~$10^{11}$ litre $mol^{-1}$ $s^{-1}$) and on the surface (~$10^4$ cm $s^{-1}$). With the aid of this equation, it is possible to estimate the rates of electrochemical reactions of proteins on the basis of kinetic results, while the concept of tunnel transfer[100] makes it possible to calculate the rate from structural data for protein molecules.

### 1. The Redox Reactions of Proteins at the Mercury Electrode

In the early investigations the electrochemical properties of proteins were most often studied at dropping and stationary mercury electrodes. Cytochrome *c* was the first protein to be investigated and it has been studied in greatest detail.[101] In the numerous investigations devoted to this protein, different degrees of reversibility of the electrochemical reactions of cytochrome *c* at mercury electrodes were observed. For example, Betso et al.[102] and Scheller et al.[103] believe that the reduction of cytochrome c at low concentrations is reversible. However, other investigators[104,105] have shown that, in contrast to haemin, native cytochrome *c* is reduced with a high overpotential, reaching 0.3 V, while the heterogeneous rate constant for this process is extremely low ($10^{-10}$–$10^{-11}$ cm $s^{-1}$). The observed difference in the electrochemical behaviour of cytochrome c is apparently caused by the different compositions of the medium and by the presence of impurities. Indeed it has been shown recently[101] that, even in highly purified protein preparations, there is an admixture which influences significantly the rate of the electrochemical reaction.

The study of electrochemical properties of cytochrome *c* at the mercury electrode made it possible to formulate the problem of the state of the protein globule on its surface. It has been suggested that the first adsorbed portions of the protein "are flattened" and are irreversibly denatured on the electrode surface.[106,107] According to Kuznetsov,[108] the cytochrome c molecules are discharged within the pores of the monolayer. The adsorption of native globules in such

pores is reversible. The area of the pore is 4 $nm^2$ for cytochrome *c*, which is smaller by a factor of 2.25 than the cross-sectional area of the native protein molecule. It is essential to note that the adsorption of cytochrome *c* on the second and subsequent layers is slower compared with the adsorption on the free mercury surface. For this reason, at a high overpotential, electron transfer may be limited by the exchange of the adsorbed and freely diffusing molecules. As a result, the limiting currents do not reach the values obtained from the Ilkovič equation.

Cytochrome $c_7$, whose structure resembles that of cytochrome *c*, is a three-haem protein. This low-potential haemoprotein is reduced reversibly at −0.17 and −0.22 V.[109] The rate of the process is determined by diffusion and electron transfer not retarded by the adsorption of the protein. Another cytochrome, namely cytochrome $c_{553}$, has a low molecular weight, but its haem environment differs from that in cytochrome *c*. The electrochemical reaction of cytochrome $c_{553}$ is quasi-reversible.[110] The cathodic reduction overpotential of this cytochrome does not exceed 40 mV and the redox potential of the system is 0.02 V. The electrochemical reduction of the four-haem cytochrome $c_3$ is reversible with a low rate constant (>0.1 cm $s^{-1}$) but takes place stepwise owing to the non-equivalence of the haem groups in the protein molecule.[111,112]

Cytochrome $b_5$ partly cleaved by trypsin gives rise to distinct waves under the conditions of classical polarography and the half-wave potential is near its redox potential.[113] The native cytochrome $b_5$, isolated using detergents, is reduced at the mercury electrode with much more difficulty and a much higher overpotential, while cytochrome P-450 is not reduced at all.[113] Other haem-containing proteins, whose natural functions consist in electron transfer, namely metmyoglobin and methaemoglobin, are reduced at the electrode with a high overpotential and irreversibility.[114,115]

Comparison of the electrochemical properties of haem-containing electron transferring proteins shows that only low-molecular proteins with low redox potentials, which are correlated with the degree of accessibility of haem to water, undergo rapid electrochemical reactions.[116] Consequently the structural features of the protein molecule play an appreciable role in electrochemical reactions. There is no doubt that the adsorption and orientation factors also affect the rate of the process. The weak adsorption and (or) aggregation of cytochrome $b_5$ is apparently the cause of the slowness of the reaction, although the active centre has an appreciable area of contact with the aqueous medium.

The electrochemical properties of other proteins have also been investigated at the mercury electrode. The reduction of ferredoxin from higher plants takes place at −0.33 V and that of bacterial ferredoxin occurs at −0.325 V and protons participate in the electrode reaction.[117] The available literature data show that ferredoxins of plant and microbial origin behave differently at the electrode.[118]

Comparative electrochemical studies of five proteins, namely ferredoxin, rubredoxin, flavodoxin, cytochrome $c_3$, and cytochrome *c*, have revealed the following features:[119]

(1) The positively charged cytochrome $c_3$ is reduced readily at the mercury electrode, because the process takes place below the zero-charge potential of mercury, and poly-L-lysine inhibits the process.

(2) Bacterial and plant ferredoxins as well as flavodoxin are negatively charged. Their redox potentials are identical with the zero-charge potential of the electrode. For this reason, a high rate of electrochemical reaction is observed only in the presence of positively charged surfactants.

(3) The positively charged cytochrome c is slowly reduced on the positively charged electrode in the region of the redox reaction of the protein.

All these factors permit the conclusion that electrostatic interaction plays a significant role in the electrochemical reactions of proteins and that the reduction of positively charged proteins is slow at a positive potential higher than the zero-change potential. Similar difficulties arise also in the reduction of negatively charged proteins if the electrode potential is more negative than the charge of the protein [the electrode potential corresponds to a charge more negative than that of the protein?]. A non-uniform distribution of charges on the surfaces of the protein globules can, however, lead to the observation of the effective interaction of like charges on the electrode and the protein or, conversely, the process may not occur despite the fact that they have opposite charges. An example is provided by data for the reduction of the negatively charged rubredoxin and flavodoxin, whose redox reactions do not occur when the mercury electrode is positively charged.[119] Therefore, as in cytochrome *c*, the orientation of the dipole in these proteins is such that it forms an angle with the haem group. Consequently, as the protein molecule approaches the positively charged surface, the side groups interact preferentially and the active centre does not come into direct contact with the electrode.

The electrochemical reduction of enzymes whose molecular weight is higher than that of the electron-transferring proteins proceeds as a rule with dissociation of the co-factor.[114] Even in the case of cholesterol oxidase, in which FAD is bound to the protein by a covalent bond, adsorption leads to the partial liberation of the cofactor and the electrochemical properties of the system are determined by the redox reactions of FAD in the presence of the denatured protein.[120] The catalytically active fragments of glucose oxidase are formed on partial cleavage of the native structure of the enzyme and are reduced at a potential higher by 0.1 V than the reduction potential of FAD.[121] Furthermore, the enzymically reduced enzyme is oxidised electrochemically with a low overpotential. The agreement of the half-wave potential $E_{1/2}$ with the redox potential of the enzyme and the constancy of $E_{1/2}$ as the enzyme concentration is varied show that the glucose oxidase fragment reacts reversibly. Native glucose oxidase reacts quasi-reversibly on platinum electrodes.[122]

Other proteins investigated, including flavoproteins from egg yolk, are denatured when adsorbed on the mercury electrode with liberation of the co-factor, which is reduced in the region of the redox potential.[121] When peroxidase is adsorbed on an amalgamated gold electrode, an oxidation-reduction process is observed, but it is associated with redox reactions of the disulphide bonds.[123]

### 2. Electrochemical Reactions of Proteins on Solid Electrodes

It was shown in early investigations that the electrochemical reaction of cytochrome *c* on gold, platinum, nickel, silver, and other metallic electrodes and on the silicon *p*-type semiconductor electrode is irreversible.[101] A quasi-reversible reaction of cytochrome *c* has been observed on optically transparent electrodes.[124] It has been shown[101] that thoroughly purified cytochrome *c* reacts quasi-reversibly on a tin-doped indium oxide electrode with a heterogeneous rate constant of $4.9 \times 10^{-3}$ cm $s^{-1}$. Detailed investigation of the electrochemical reaction of cytochrome *c* on solid electrodes showed that the rate of the process depends not only on the degree of purification of the protein but also on the method used to prepare the electrode and on the composition of the buffer solution.[125] The available data demonstrate convincingly that cytochrome *c* can exchange electrons with

various electrodes. The rate of the process is then close to that calculated from the mutual exchange rate constant, which amounts to 0.1 cm $s^{-1}$ when account is taken of the steric factor (0.025).[126]

The reduction and oxidation of ferredoxin on pyrolytic graphite electrodes proceeds reversibly only in the presence of magnesium ions.[127,128] The electrochemical reactions of rubredoxin, flavodoxin, and ferredoxin on the same electrodes in the presence of positively charged chromium hexammine ions or magnesium ions are either quasi-reversible or reversible.[129] Ions are not required for the rapid reaction of azurin. The observed phenomena can be accounted for by the fact that all the proteins investigated are negatively charged and have redox potentials in the region of which the graphite surface has a negative capacitive charge. The positively charged ions are concentrated in the outer plane of the Helmholtz layer and thereby diminish the repelling effect of the electrode on rubredoxin, flavodoxin, and ferredoxin. The weak influence of the positively charged ions in the case of azurin is caused by the high degree of charge pairing between side groups.

The electrochemical oxidation of cytochrome $b_5$ at platinum gauze electrodes takes place at 0.9 V, while the reduction of the enzyme is masked by the reduction of water.[130] The data obtained indicate the irreversibility of the electrochemical reaction of the enzyme. However, spectroelectrochemical studies have shown that both cofactors (FMN and haem) exchange electrons via an independent pathway.

The electrochemical reactions of oxygen transporting agents are extremely low. It has been shown[4] that the electrochemical reaction of methaemoglobin at the $SnO_2$ electrode proceeds irreversibly with a heterogeneous constant of $5.2 \times 10^{-8}$ cm $s^{-1}$ and a transport coefficient of 0.29. The adsorption of the tetraethylammonium ion increases the constant by a factor of 3. This may be caused by the change in the potential of the diffuse layer of the electrode following the adsorption of the surface-active cation.

### 3. The Oxidation-Reduction Reactions of Proteins on Modified Electrodes

The results for the electrochemical reactions of proteins on solid electrodes discussed above show that the rate of the process is greatly influenced by the state of the electrode–buffer solution interface. Modifying agents are used to alter it in a specific manner (Table 6). The electrochemical reactions of cytochromes on gold, carbon, or platinum electrodes modified with 4,4′-bipyridyl or its sulphur-containing analogues take place at the equilibrium potential with a high rate constant, which is close to the constant for the thoroughly investigated hexacyanoferrate(III)/hexacyanoferrate(II) pair. Together with these four analogues of 4,4′-bipyridyl, several compounds capable of accelerating the redox reaction of cytochrome *c* are known: 4,4′-azopyridyl, 2,5-di(4-pyridyl)-1,3,4-thiadiazole, and purine and its derivatives.[133,145] The modifying agents each contain as a rule one nitrogen atom at the ends of the molecule, have a definite length, and possess a conjugated electron system. Other compounds which do not meet these requirements but whose structure is close to that of 4,4′-bipyridyl, such as pyridine, pyrazine, 4-phenylpyridine, 2,2′-bipyridyl, and 1,2-di(4-pyridyl)ethane, do not increase the electrochemical activity of cytochromes.

The mechanism of the action of the modifying agents consists in their adsorption on the electrode surface and the formation of a layer on which proteins are absorbed.[146] Positively charged lysine residues participate in the interaction of the protein with the adsorption layer, which promotes the orientation of haem towards the electrode surface.

The mechanism of the action of another modifying agent, polyethyleneimine, apparently also consists in orienting the protein globules.[134] However, the concentration dependence of the potential of the redox reaction of the protein and the dependence of the reaction current on the electrode modification time have shown that polyethyleneimine does not form a continuous coating on the electrode.

Table 6. Electrochemical parameters of proteins determined on chemically modified electrodes.

| Protein | Electrode | Modifying agent | Electrochemical parameters | | Refs. |
|---|---|---|---|---|---|
| | | | $k_s$, cm $s^{-1}$ | $\alpha$ | |
| Cytochrome *c* | Au | 4,4′-Bipyridyl; 1,2-di-(4-pyridyl)ethylene | $1.9 \cdot 10^{-2}$ | — | [131] |
| ditto | Au | di(4-pyridyl) disulphide; di(4-pyridyl) sulphide | $(2.1—8.9) \cdot 10^{-3}$ | — | [132] |
| » | Au | Purine | $1.0 \cdot 10^{-3}$ | — | [133] |
| » | $SnO_2$ | Polyethyleneimide | — | 0.3 | [134] |
| » | C | 4,4′-Bipyridyl | $4.4 \cdot 10^{-4}$ | — | [135] |
| Cytochrome $c_3$ | Au | ditto | $>10^{-2}$ | — | [131] |
| Cytochrome $c\,d_1$ | C | » | $4.0 \cdot 10^{-4}$ | | [135] |
| Cytochrome *c* | Au | Methylviologen | $3.4 \cdot 10^{-5}$ | 0.25 | [136] |
| Myoglobin | Au | ditto | $7.7 \cdot 10^{-5}$ | 0.18 | [136] |
| ditto | Au | » | $3.9 \cdot 10^{-11}$ | 0.18 | [137] |
| Ferredoxin | Au | » | $(59—6.5) \cdot 10^{-5}$ | 0.4—0.6 | [138,139] |
| Peroxidase | Au | *NN*′-Di(2-aminoethyl)bipyridyl; methylviologen; benzylviologen | $(84—1.3) \cdot 10^{-5}$ | 0.31—0.71 | [140] |
| Cytochrome *c* | Au, Pt | *NN*′-Bis[3](trimethoxysilyl)propyl] bipyridyl | $<0.06$ | — | [141] |
| ditto | C | *N*-Vinyl-4,4′-bipyridyl | — | — | [142] |
| » | Pt | Polyalkylated ferrocene | $(2.4—8.7) \cdot 10^{-4}$ | — | [143] |
| » | *n*-Si | | $(1.8—3.5) \cdot 10^{-4}$ | — | [144] |
| Ferredoxin | C | *NN*′-Di(3-aminopropyl)-bipyridyl | $(1.6—4.0) \cdot 10^{-3}$* $>10^{-2}$** | — | [145] |

*For bacterial ferredoxin. **For plant ferredoxin.

Note. Numbers in square brackets denote references (Ed. of Translation).

Viologens polymerised on gold electrodes are also used as modifying agents.[136–140] The constants for the electrochemical reactions of proteins on such electrodes are, however, small and the transfer coefficient $\alpha$ in certain systems is close to unity (Table 6). The action of polyviologens as agents promoting the electrochemical reactions of proteins has a mechanism analogous to that of the action of 4,4′-bipyridyl, which has been confirmed by the electrochemical inertness of the modifying agents as regards the redox reactions of proteins. Furthermore, polyviologens are conjugated molecules whose end groups contain nitrogen atoms, so that they resemble bipyridyl.

Electrodes modified with *NN'*-bis[3-(trimethoxysilyl)-propyl]bipyridyl and related compounds (Table 6) contain immobilised viologens or ferrocene. The electrochemical reactions of proteins on these electrodes proceed via a mediator mechanism.[147] For cytochrome *c*, the process can be represented by the following equations:

$$MV^{2+} + e \xrightarrow{k_S} MV^{+},$$

$$MV^{+} + \text{cytochrome } c \text{ (oxidised)} \rightarrow MV^{2+} + \text{cytochrome } c \text{ (reduced)}.$$

The rate constant for the bimolecular reaction in this process exceeds $10^8$ litre $mol^{-1}$ $s^{-1}$. The rate of the process is limited by the reaction of the protein on the electrode surface and the current is therefore directly proportional to the square root of the rate of potential scan.[141,144]

### 4. Electrochemical Reactions of Covalently Immobilised Enzymes

When glucose oxidase is immobilised on graphite electrodes via cyanuric chloride, the differential pulse voltamperogram shows a peak at −0.31 V.[148] The potential of this peak is displaced by 20 mV towards the cathodic region compared with the enzyme adsorbed on the graphite electrode and by 100 mV into the anodic region compared with the redox reaction of the enzyme in solution. Immobilised L-amino-acid oxidase and xanthine oxidase react at the same potentials.[149] These results demonstrate the possibility of direct electron transfer to flavin oxidases. However, the native state of the immobilised enzymes, i.e. their ability to catalyse the reactions of substrates, remains open to doubt. The point is that the enzymes investigated readily dissociate into the apoenzyme and the co-factor. The fact that the proteins are reduced at a potential differing from the reduction potential of the adsorbed FAD does not fully demonstrate the native state of the enzyme, because it can be due to the reduction of the FAD, which is associated [with the protein? (Ed.of Translation)] in a region other than that of the active centre. Such effects are observed, for example, in the association of FAD within an inert protein.[106]

---o0o---

Thus the electron transfer proteins and oxidation-reduction enzymes react similarly to non-protein redox systems. The specificity of the action of the polypeptide chain consists in regulating the potential of the active centre and its orientation in complexes where electron transfer takes place. One cannot rule out the possibility that the side groups of the aminoacids are directly involved in electron transfer over long distances, as shown for the cytochrome *c* peroxidase–cytochrome *c* complex.[150] Further progress in the study of the mechansim of electron transfer in proteins depends to a large extent on the elucidation of the contribution of the polypeptide chain to the activation energy and the adiabatic nature of the transfer. Extremely interesting results on these lines have been obtained in a number of studies.[151–154]

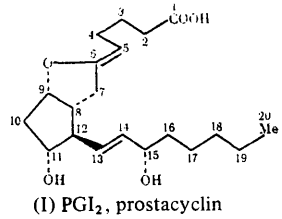
# The Synthesis of Prostacyclin and Its Analogues

V.A.Dombrovskii, E.V.Gracheva, and P.M.Kochergin

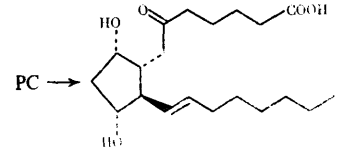
The advances in the synthesis of prostacyclin and its analogues are examined. The bibliography includes 114 references.



CONTENTS

I. Introduction 978
II. The synthesis of prostacyclin and its analogues 978

## I. INTRODUCTION



Much attention is being devoted at present to prostacyclin (PC)—a substance which is tens of times more active than any of the prostaglandins (PG). PC is formed from arachidonic acid in minute amounts in the heart and in the walls of the blood vessels. Investigators have assigned a special place to PC because, in contrast to PG, it does not decompose in the lungs and, circulating in the blood, it tends to reduce the arterial pressure. PC has yet another exceptional property—the ability to prevent the development of atherosclerosis and especially its severe consequence—the formation of clots in the blood vessels.[1]

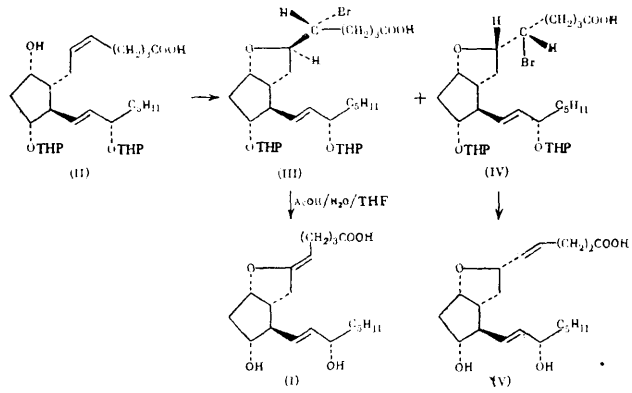
By incubating the endoperoxides $PGG_2$ and $PGH_2$ with the enzyme system of the microsomal fraction of the arterial vessels, Vane and co-workers[2,3] observed in 1976 the formation of an unstable substance which proved to be a powerful inhibitor of the aggregation of platelets. This substance, initially designated by PGX, was subsequently characterised as (5Z)-9-deoxy-6,9α-oxido-$\Delta^5$-$PGF_{1\alpha}$ [4,5] and now bears the trivial name prostacyclin or the abbreviation $PGI_2$ or (I). PC is at the present time the most powerful inhibitor of the aggregation of platelets[6] and possesses strong vasodilating properties.[2,7-9]

(I) $PGI_2$, prostacyclin

The chemistry of PC is determined by characteristic groups, one of which is the vinyl ether group incorporating the C(5)–C(6) atoms and the oxygen atom attached to C(9) in this molecule.[4,5,10] The potential value of PC as a therapeutic agent, particularly when its prolonged action is required, is appreciably reduced owing to the fact that its vinyl ether group is very readily and rapidly hydrolysed (the half-decomposition time is 10 min at pH 7.6 at 25 °C) which leads to the formation of 6-oxo-$PGF_{1\alpha}$.[11,12] The problem therefore arose of the synthesis of chemically stable analogues of PC possessing a high selective activity while retaining, in principle, the structure of PG, since PC, which is ultimately transformed into the usual $PGF_{1\alpha}$ metabolites, reduces the adhesion and sticking together of blood platelets 1000 times more effectively than the stable 6-oxo-$PGF_{1\alpha}$ and 30 times more effectively than $PGE_1$.[2,3] The tactics and strategy used in the synthesis of PG and their analogues, developed between 1960 and 1980,[13-15] helped to solve the problem of the synthesis of PC and its analogues.

6-oxo-$PGF_1$

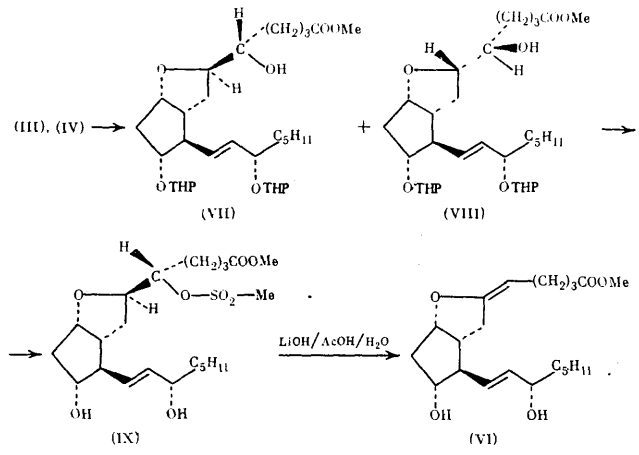
The growing interest in PC analogues led to the publication of numerous studies on the synthesis and pharmacological properties of these compounds. However, the data on their synthesis have been scarcely treated systematically or surveyed. A monograph[16] and a review[17] are mainly devoted to the pharmacological properties of PC and its analogues and in another review[18] the methods of synthesis of PC and thromoboxanes are examined extremely concisely. We therefore thought it useful to review the most important studies on the synthesis of PC and its analogues.



## II. THE SYNTHESIS OF PROSTACYCLIN AND ITS ANALOGUES

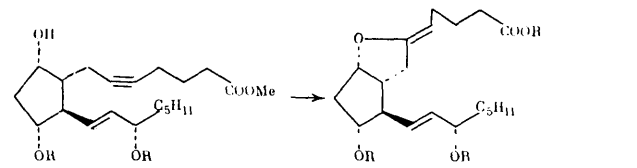
### 1. Synthesis from Natural Prostaglandins and Their Analogues

The simplest and most general method of synthesis of PC and its analogues involves the modification of natural PG or their analogues, including the following series of reactions: (1) intermolecular nucleophilic addition of bromine or iodine to the C(5)–C(6) double bond of PG with the simultaneous formation of the ring; (2) elimination of HBr or HI with alkali or reductive elimination of iodine.



The required stereochemistry of the C(5) atom is retained in all the transformations, since the main processes are the *trans*-addition of the halogen to the double bond and the *trans*-elimination of HBr or HI. For example, the bromination of $PGF_{2\alpha}$ (II) with *N*-bromosuccinimide (NBS) yields a mixture of diastereoisomers of the 5-bromo-substituted $PGI_1$ (III) and (IV) (3 : 1). After the removal of the tetrahydropyranyl (THP) protecting group from the diastereoisomer (III) and the elimination of HBr by treatment with *t*-BuOK/BuOH, PC [compound (I)] is formed. The diastereoisomer (IV), formed as a minor product in the cyclisation stage, gives rise to $\Delta^4$-6α-$PGI_1$ (V) after the same treatment as that described for compound (III) [19,20] (Scheme 1).

Scheme 1

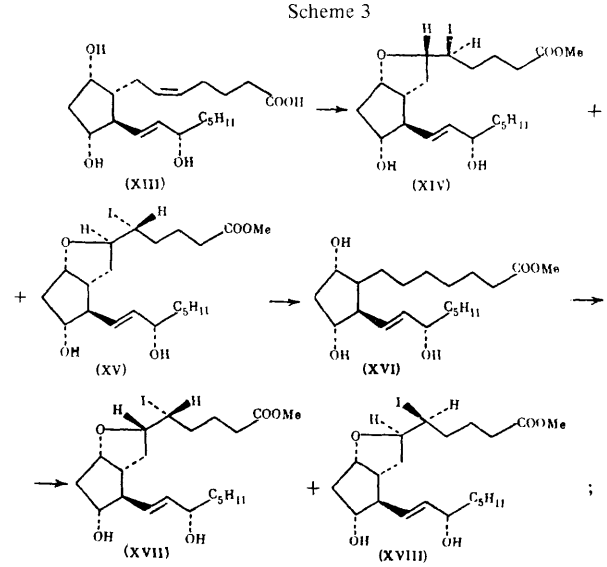


Corey and co-workers described the synthesis of (5*E*)-$PGI_2$ (VI) from the intermediates (III) and (IV),[21] whose treatment with $K_2O$ and 18-crown-6 ether in dimethyl sulphoxide (DMSO) leads to the corresponding mixture of alcohols with inversion at the C(5) atom (85%). The mixture of alcohols is esterfied with diazomethane to compounds (VII) and (VIII), which are then converted into the methanesulphonate (IX) (84%) by reaction with methanesulphonyl chloride and triethylamine. The THP groups in compound (IX) are removed in the usual way and the product is hydrolysed to the corresponding acid, which is then treated with an excess of t-BuOK/BuOH to form compound (VI) (Scheme 2).

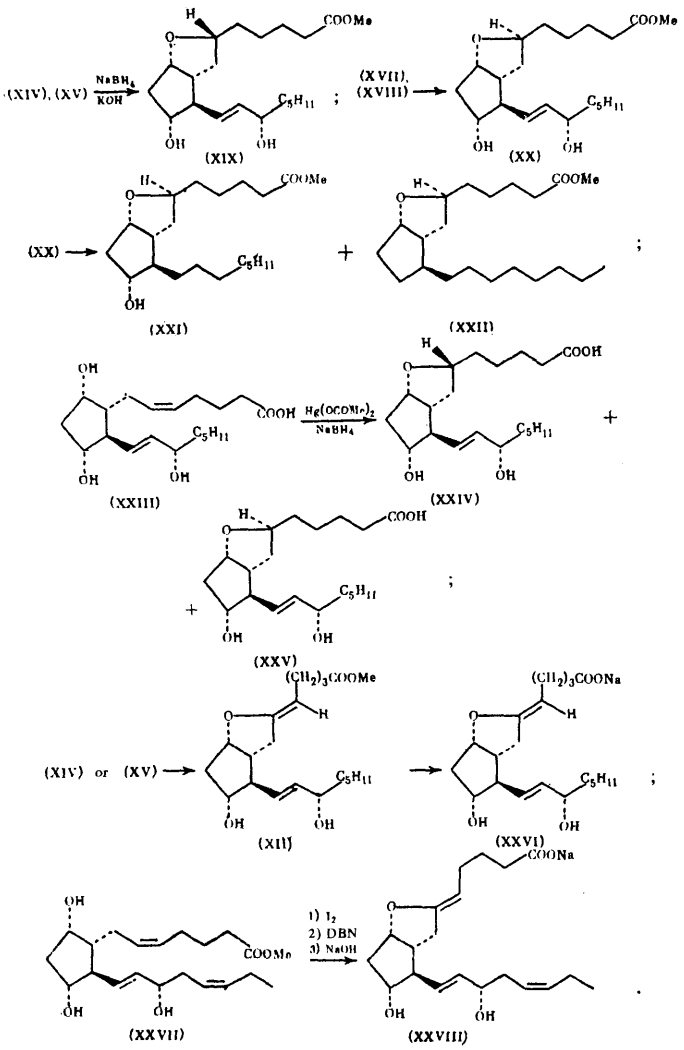
Scheme 2

Suzuki[22] proposed a simple stereospecific synthesis of PC, with a small number of stages, starting from the derivative 5,6-dihydro-$PGF_{2\alpha}$. The chiral acetylenic alcohol (X) is converted into the cyclic product (XI). The removal of the protecting groups in compound (XI) by treatment with tetra-n-butyl ammonium fluoride (TBAF) in tetrahydrofuran (THF) affords the methyl ester of $PGI_2$ (XII) (74%), the alkaline hydrolysis of which leads to $PGI_2$ (I).

(X): R = Si(Me)$_2$-t-Bu



(XI): R = Si(Me)$_2$-t Bu, R$^1$ = Me



(XII): R = H, R$^1$ = Me

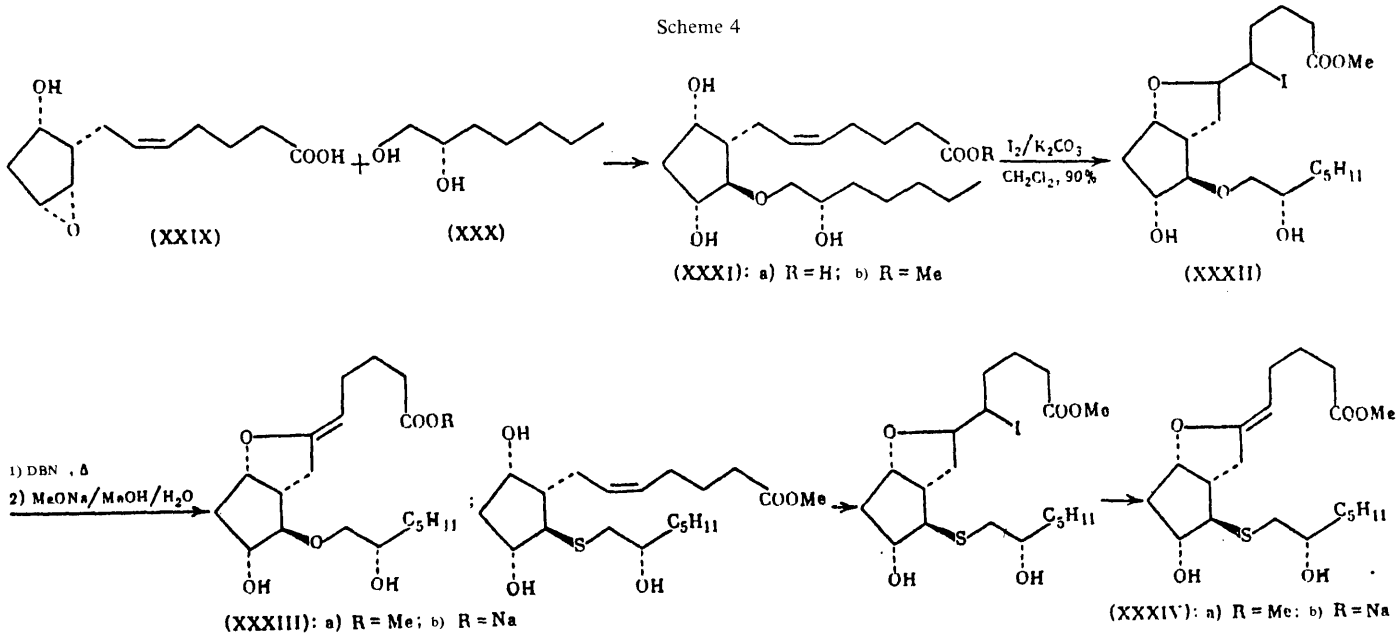
(XIII): R = H, R$^1$ = H

The sodium salts of PC and other compounds with a similar structure, which can be regarded as precursors of PC and its chemically stable analogues, have been synthesised. $PGI_3$ and $\Delta^6$-$PGI_1$ with a double bond in the 6-*endo*-position, have been obtained.[10] The key compounds, the methyl esters of (5*S*, 6*S*)-5-iodo-$PGI_1$ (XIV) and (5*R*, 6*R*)-5-iodo-$PGI_1$ (XV), have been obtained by the reaction of the methyl ester of $PGF_{2\alpha}$ (XIII) with iodine in the presence of sodium carbonate. The diastereoisomeric methyl esters of (5*R*, 6*S*)-5-iodo-$PGI_1$ (XVII) and (5*S*, 6*R*)-5-iodo-$PGI_1$ (XVIII) are formed analogously from the methyl ester of 5-*trans*-$PGF_{2\alpha}$ (XVI). The reductive removal of iodine by treatment with $NaBH_4$ from the esters (XIV) and (XV) or (XVII) and (XVIII) leads to the methyl esters of (6*R*)-$PGI_1$ (XIX) and (6*S*)-$PGI_1$ (XX) respectively. Compounds (XIX) and (XX) can also be obtained by the reaction of compound (XIII) with mercury acetate and subsequent reduction with $NaBH_4$ or from the methyl ester of 6-oxo-$PGF_{2\alpha}$ by treatment with an excess of sodium cyanohydroborate. Catalytic reduction of compound (XX) gives rise to the methyl ester of (6*R*)-13,14-dihydro-$PGI_1$ (XXI) and the methyl ester of (6*S*)-13,14-dihydro-15-deoxy-$PGI_1$ (XXII). The compounds (6*R*)-$PGI_1$ (XXIV) and (6*S*)-$PGI_1$ (XXV), which have structures related to that of $PGI_1$, are obtained by the reaction of $PGF_{2\alpha}$ (XXIII) with mercury acetate and subsequent reduction with $NaBH_4$ or by the hydrolysis of the methyl esters (XIX) and (XX) respectively. The sodium salt of PC (XXVI) can be obtained from the iodo-esters (XIV) and (XV) by reaction with 1,5-diazabicyclo-[4.3.0]non-5-ene (DBN) or with $K_2O$ to form the methyl ester of $PGI_2$ (XII), which gives rise to the sodium salt of $PGI_2$ (XXVI) on treatment with NaOH. Treatment of $PGF_3$ (XXVII) in the same sequence gives rise to the sodium salt of $PGI_3$ (XXVIII) (Scheme 3).

Scheme 3

The racemic 11-deoxy-PC can be obtained analogously from the methyl ester of 11-deoxy-$PGF_{2\alpha}$.[23]

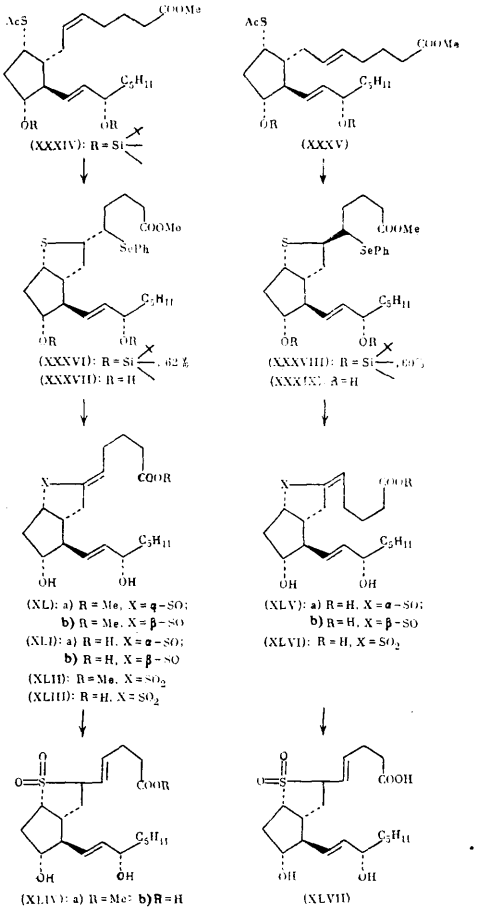
13-Oxa-13,14-dihydro-$PGI_2$ (XXXIII) and 13-thiadihydro-$PGI_2$ have been synthesised from the corresponding $PGF_{2\alpha}$ analogues via the stage involving the formation of the iodoester and subsequent deiodination.[24] The sodium salt (XXXIII) is obtained from the optically active epoxyalcohol (XXIX) whose interaction with the monosodium salt of the diol (XXX) gives rise to 13-oxa-13,14-dihydro-$PGF_{2\alpha}$ (XXXIa). The ester (XXXIb), formed after the esterification of compound (XXXIa), is converted into the iodoester (XXXII). The dehydrohalogenation of compound (XXXII) leads to the methyl ester (XXXIIIa) (90%), whose hydrolysis gives rise to the sodium salt (XXXIIIb).



The same procedure was used to obtained the 13-thia-analogue (Scheme 4).

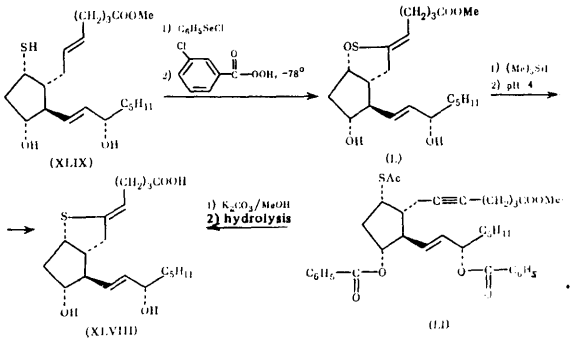
In order to investigate the relation between the reactivity and structure, the sodium salts of native 13-thia-13,14-dihydro-PC and its 15-epi-, 15-methyl-, etc. analogues have been synthesised by a standard method from the corresponding methyl esters of native 13-thia-13,14-dihydro-$PGF_{2\alpha}$ and tested.[25]

A series of sulphur-containing PC have been synthesised stereoselectively by means of the new organoselenium methodology.[26]



It has been observed that the methyl esters of (5*Z*)- and (5*E*)-$PGF_{2\alpha}$, (XXXIV) or (XXXV), cyclise on treatment with organoselenium compounds without the preliminary removal of the substituent protecting the thiol group. Thus compound (XXXIV) or (XXXV) reacts with phenylselenyl chloride at −78 °C to form the individual selenides (XXXVI) or (XXXVIII), which give rise to compounds (XXXVII) and (XXXIX) after the removal of selenium by treatment with TBAF. It is of interest that, when compound (XXXVII) is treated with the first equivalent of *m*-chloroperbenzoic acid (*m*-CPBA) (at −78 °C), only the sulphur atom is oxidised selectively, while after the addition of the second equivalent of *m*-CPBA at −78 °C and then heating to −20 °C, the selenium atom is oxidised effectively. Further heating to 20 °C leads to the formation of the isomeric (5*Z*)-sulphoxides (XLa) (18%) and (XLb) (53%). On the other hand, when a

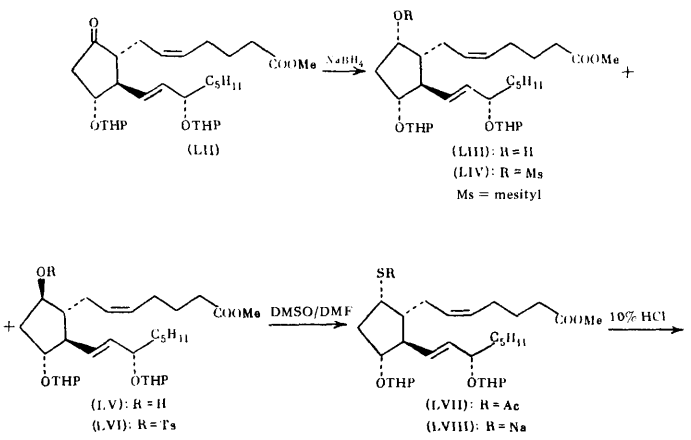
Scheme 4



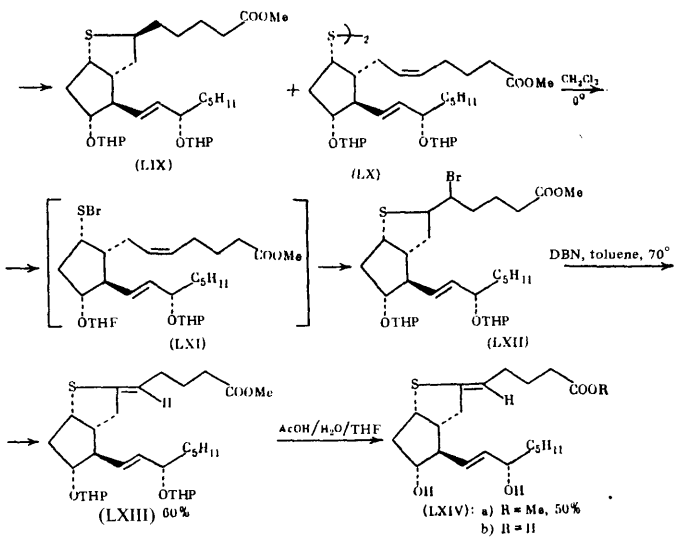
third equivalent of *m*-CPBA is added to the mixture of compounds (XLa, b), the sulphur atom is oxidised further with the exclusive formation of the (5Z)-sulphone (XLII) (86%). This sulphone can be obtained by adding four equivalents of $H_2O_2$ to the reaction mixture of compounds (XLa, b). Finally, the oxidation of the thioselenide (XXXVII) with $H_2O_2$ (8 equivalents, 20 °C) immediately affords the sulphone (XLII) as the main product (75%) together with a small amount of the non-conjugated (4*E*)-sulphone (XLII) (22%). The base hydrolysis of the methyl esters (XLa, b), (XLII), and (XLIVa) leads to the corresponding acids (XLIa, b), (XLIII), and (XLIVb) in satisfactory yields. The acids (XLVa, b), (XLVI), and (XLVII) have been obtained analogously, also in satisfactory yields, from the isomer of the thioselenide (XXXIX) using the oxidation methods described above (Scheme 5).

Scheme 5

The thia-PC (XLVIII) is obtained, like the previous compounds, by the organoselenium method using the methyl ester of 9-thia-5,6-$PGF_{2\alpha}$ (XLIX) as the initial compound. The sulphoxide (L) formed is reduced with iodotrimethylsilane to the corresponding thioether, whose hydrolysis leads to compound (XLVIII).[26-28] The thia-PC (XLVIII) can be obtained in two stages from the prostanoid (LI)[29] (Scheme 6).



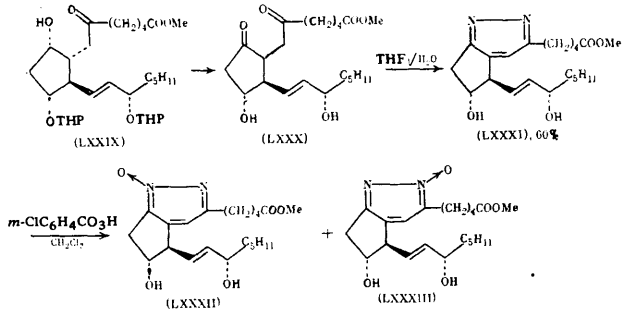
Scheme 6



$\Delta^4$-$PGL_1$ has been synthesised from $PGF_{2\alpha}$ by the method described above using organoselenium compounds.[19,20,30,31]

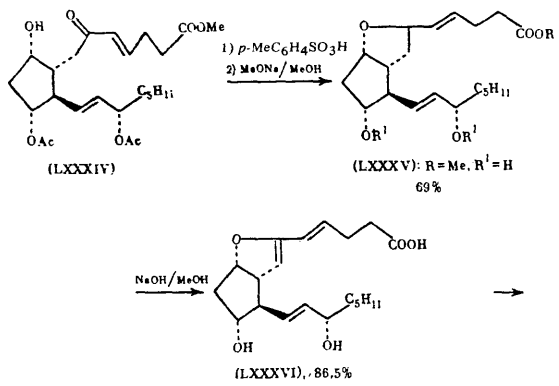
The starting compound in the synthesis of 9(0)-thia-$PGI_2$ is the methyl ester of $PGE_2$ (LII).[32] The reduction of compound (LII) leads to a 1 : 1 mixture of the alcohols (LIII) and (LV). In order to invert the configuration of the 9α-hydroxy-group in compound (LIII), the latter is converted into the methanesulphonate (LIV), the reaction of which with $K_2O$/18-crown-6 ether in DMSO and subsequent esterification with diazomethane afford the 9β-alcohol (LV) (60%). Treatment of the toluene-*p*-sulphonate (LIV) with sodium thioacetate makes it possible to introduce a sulphur atom with simultaneous inversion of the 9β-OH configuration to give the corresponding 9α-derivative (LVII) (55%). Mild hydrolysis of compound (LVII) leads to the cyclic sulphide (LIX) (60%) with a small admixture of the disulphide (LX), formed as a result of oxidation with atmospheric oxygen. The disulphide (LX) is obtained in 80% yield when the mercaptide (LVIII) reaction mixture is kept in atmospheric oxygen. Treatment of compound (LX) with bromine gives rise to the bromosulphide (LVII) and the reaction proceeds via intramolecular cyclisation with the initial formation of the bromosulphide (LXI). Compound (LXII) is then converted into the vinyl sulphide (LXIII) with the required (*syn*, *cis*) geometry). The removal of the protecting group in compound (LXIII) leads to the methyl ester of 9(O)-thia-PC (LXIVa). It is noteworthy that the relatively low yield in the hydrolysis stage indicates the partial decomposition of the final compound (LXIVa). Compound (LXIVa) is converted into compound (LXIVb) by alkaline hydrolysis (Scheme 7).

Scheme 7



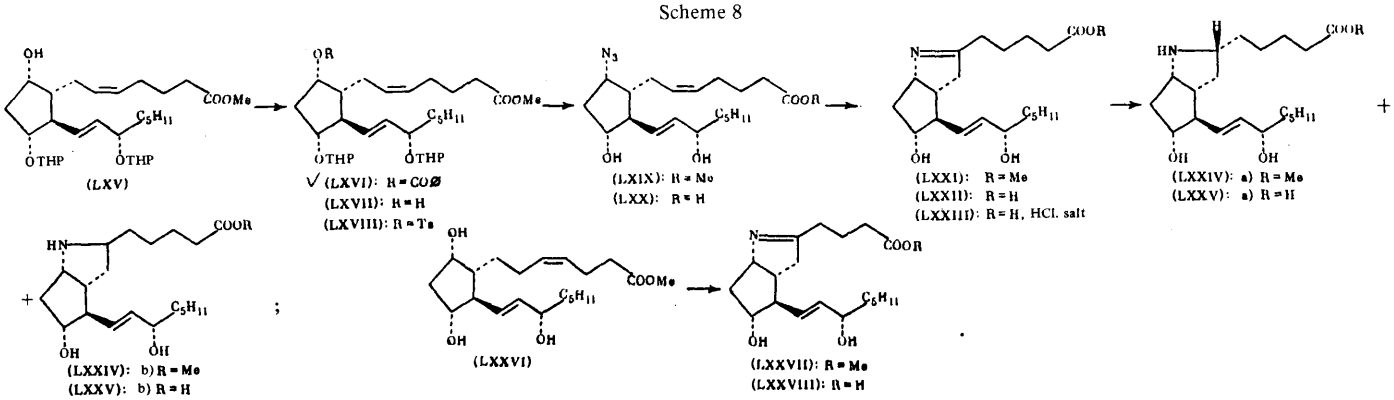
(5Z)- and (5E)-6,9-dithia-PC can be obtained via an analogous scheme from the methyl ester of $PGE_2$.[33]

The synthesis of 9-deoxy-9α,6-nitrilo-$PGF_{1\alpha}$ (LXXII) and of the corresponding cyclic imine in which the oxygen atom has been replaced by nitrogen have been described.[34] The first stage includes the conversion of the methyl ester of $PGF_{2\alpha}$ (LXV) into the 9β-epimer (LXVII) by reaction of compound (LXV) with triphenylphosphine, benzoic acid, and the diethyl ester of azodicarboxylic acid (DEADA) followed by treatment of the resulting 9β-benzoate (LXVI) with MeONa/MeOH. Toluene-*p*-sulphonation of the 9β-hydroxy-group and the removal of the THP protecting groups leads to the derivative monotoluene-*p*-sulphonated at the C(9) atom. Treatment of the 9β-toluene-*p*-sulphonate (LXVIII) with $NaN_3$ affords the 9α-azide (LXIX) which is converted on heating into the cyclic imine (LXXI) (80%). The acid (LXXII) has been obtained by the hydrolysis of the ester (LXXI) or, which is preferable, by the hydrolysis of the ester azide (LXIX) to the acid (LXX) with subsequent cyclisation to the iminoacid (LXXII)—a substance which contains 30% of the zwitter-ionic form. The acid (LXXII) readily gives rise to the hygroscopic hydrochloride (LXXIII), both imines, (LXXI) and (LXXIV), being stable in 1 M HCl solution at 25 °C. The reduction of the iminoester (LXXI) leads to the esters (LXXIVa, b). Both isomers are hydrolysed to the corresponding crystalline iminoacids (LXXVa, b), which exist fully in the zwitter-ionic form. Using the analogous sequence of reactions, the methyl ester of *cis*-$\Delta^4$-$PGF_{1\alpha}$ (LXXVI) was converted in six stages into the 9α,5-nitrilo-analogues (LXXVII) and (LXXVIII) (Scheme 8).

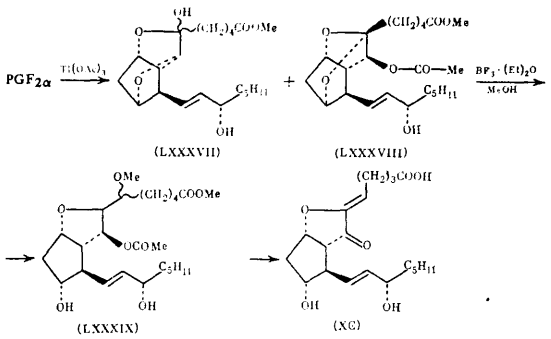


The synthesis of 6,9-pyridazo-PC (LXXXI) and its *N*-oxides (LXXXI), (LXXXII), and (LXXXIII) from the methyl ester of 6-oxo-$PGF_{1\alpha}$ (LXXIX) have been described.[35] Oxidation of compound (LXXIX) with pyridinium chlorochromate of Jones' reagent ($CrO_3$, acetone, −20 °C) and the removal of the THP protecting groups lead to the methyl ester of 6-oxo-$PGE_1$ (LXXX). Treatment of compound (LXXX) with hydrazine and oxidation over $PtO_2$ gives rise to the methyl ester (LXXXI), from which a mixture of the methyl esters (LXXXII) and (LXXXIII) is obtained (Scheme 9).

Scheme 9

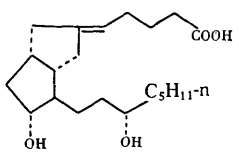


The pyrrole analogue of PC has been obtained from the protected 6-oxo-$PGE_1$ derivative by standard methods.[36]



An analogue of $PGI_2$ has been synthesised in two stages from the readily available enone (LXXXIV).[37] After treating the methyl ester of 11(*O*),15(*O*)-diacetyl-4,5-dihydro-6-oxo-$PGF_{1\alpha}$ (LXXXIV) with toluene-*p*-sulphonic acid and subsequent methanolysis, the diene (LXXXV) is obtained whose hydrolysis leads to the isolation of the acid 4,5,6,7-tetrahydro-$PGI_1$ (LXXXVI):

Scheme 8

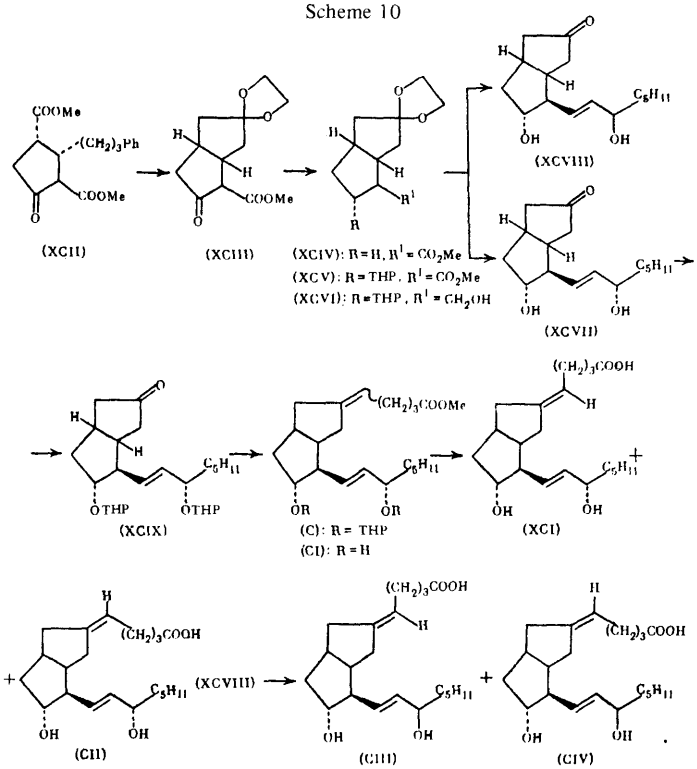


The conversion of the methyl ester of $PGF_{2\alpha}$ into the PC analogue (XC) by the reaction with thallium triacetate, leading to the formation of the hemiacetal (LXXXVII) and the acetate (LXXXVIII), has been described. Transacetylation of compound (LXXXVIII) affords the methyl acetal (LXXXIX), which can be readily converted into 7-oxo-$PGI_2$ (XC) in five stages: [38]

(LXXXVII) (LXXXVIII) (LXXXIX) (XC)

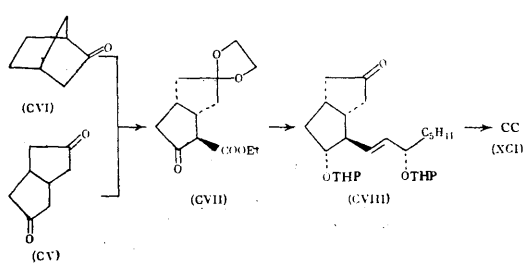
## 2. Synthesis of Carbacyclin

Among the PC analogues, carbacyclin (CC) (XCI) merits special attention. It was reported in 1981 [39] that, when this compound is administered to man intravenously, it causes an appreciable inhibition of platelet aggregation and does not have the side effects observed in the case of PC itself. [16] Carbacyclin can be regarded as a PC derivative in which the ethyl unit in the cyclic enol ether has been replaced by a methylene group:



(XCI). CC

Several syntheses of CC were described almost simultaneously, [40–43] representing to some extent a repetition of the classical scheme for the synthesis of PG.

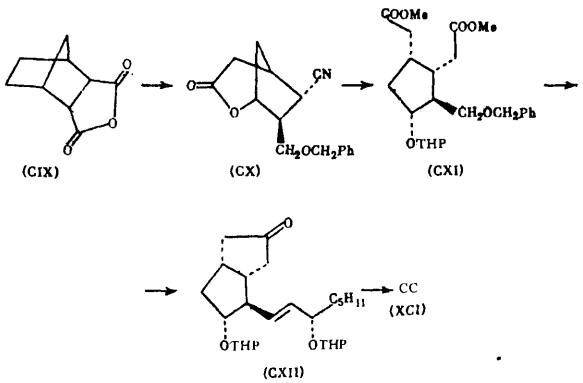


The synthesis of 9(*O*)-methano-PC (XCI) and of its three isomers (CII), (CIII), and (CIV), in which the *trans,cis*-diester (XCII), used in the total synthesis of $PGF_{2\alpha}$, serves as the starting material, has been described. [44] The diester (XCII) is converted in eleven stages into the *cis*-bicyclic ketone (XCIII), whose reduction leads to the basic *trans*-alcohol (XCIV). After protecting the OH group in compound (XCIV) to give a compound (XCV) and after reducing the ester group in the latter with $LiAlH_4$, the alcohol (XCVI) is obtained. The introduction of the allyl alcohol side chain into compound (XCVI) is achieved by standard methods using the diols (XCVII) and (XCVIII): (1) Collins oxidation ($CrO_3$. .$Py/CH_2Cl_2$); (2) condensation with tri-n-butyl-2-oxoheptylidenephosphorane; (3) reduction with $NaBH_4$; (4) the removal of THP protecting groups. After protecting the OH groups in compound (XCVII), the resulting ether (XCIX) is treated with the Wittig reagent obtained from 5-triphenylphosphonopentanoic acid and is then esterified with $CH_2N_2$ to form the ester (C) in the form of a mixture of regioisomers with respect to the C(5) atom. The removal of the protecting groups in compound (C) yields the diol (CI), whose hydrolysis leads to the formation of 9(*O*)-methano-PC (XCI) as the main product and 11α,15α-dihydroxy-6,9α-methyleneprosta-5(*Z*),13(*E*)-dienoic acid (CII); the 5(*E*)-isomer (CIII) and the 5(*Z*)-isomer (CIV) can also be obtained from the diol (XCVIII) by the same sequence of reactions (Scheme 10).

Scheme 10

(XCII) (XCIII) (XCIV): R=H, R¹=CO₂Me (XCV): R=THP, R¹=CO₂Me (XCVI): R=THP, R¹=CH₂OH (XCVII) (XCVIII) (XCIX) (C): R=THP (CI): R=H (XCI) (CII) (CIII) (CIV)

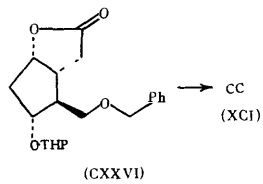
The total synthesis of CC from the readily available *cis*-bicyclo[3.3.0]octane-3,7-dione (CV) in accordance with a similar scheme has been described. [42,44] The most important intermediate in all three syntheses is the monoketal (CVII). In order to prevent the partial hydrolysis of compound (CV) in its conversion to compound (CVII), a method of synthesis of compound (CVII) from 5-norborn-2-enone (CVI) was proposed in 1980. [45] The ester group in compound (CVII) can be converted into an aldehyde whose condensation with the Wittig reagent affords the key ketone (CVIII). It is converted into CC by standard methods:



(CVI) (CVII) (CVIII) (CV) CC (XCI)

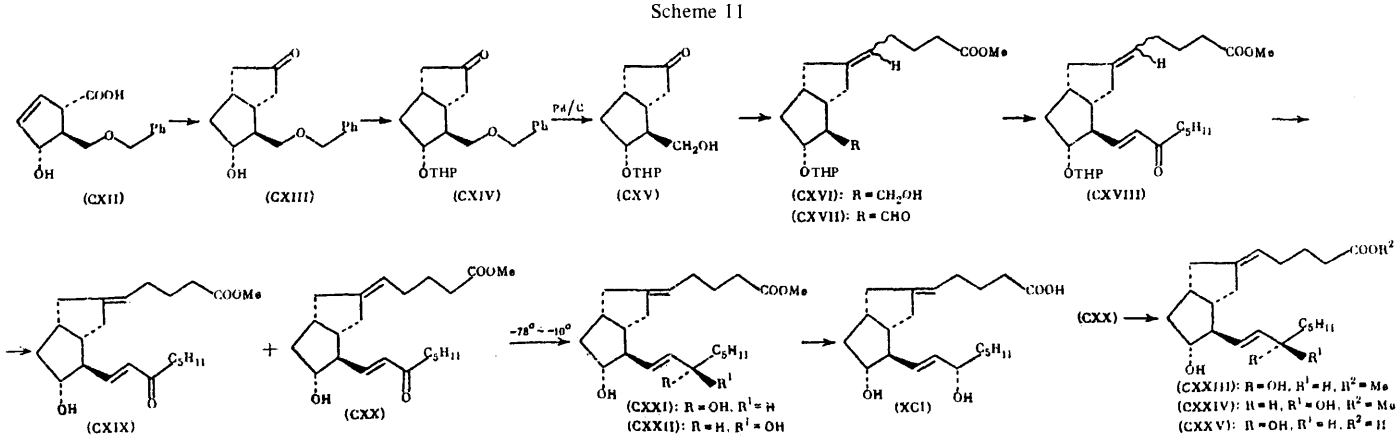
Three other total syntheses of CC [44,46,47] are based on cyclo-octa-1,3-diene and differ only by the stage in which it is converted into a derivative of *cis*-bicyclo[2.3.0]octan-3-one (CVIII).

A stereocontrolled multistage synthesis of CC from the anhydride of norborn-5-ene-2,3-dicarboxylic acid (CIX) using the methods employed in the synthesis of PG has been proposed. [48] The anhydride (CIX) is converted into the lactone (CX), whose alkaline hydrolysis and the subsequent



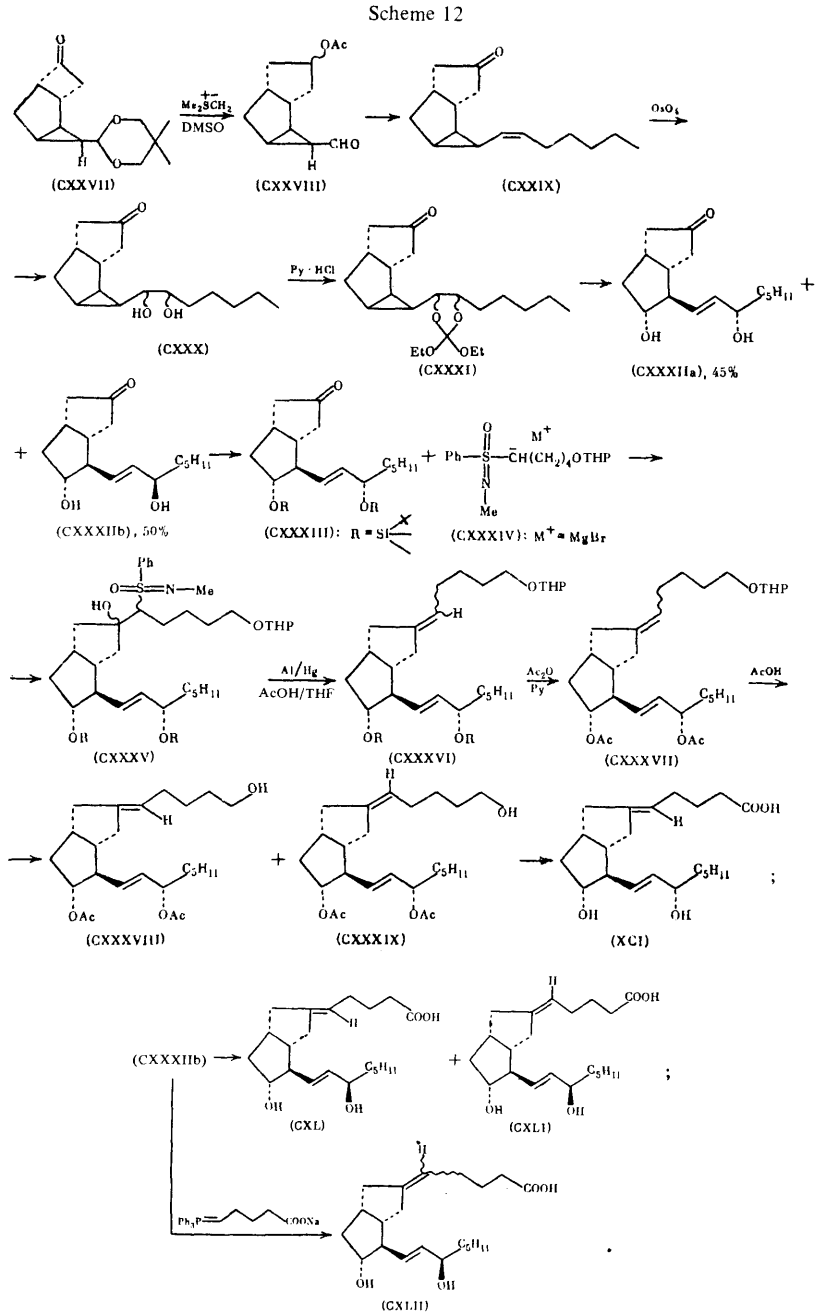
transesterification of the resulting dicarboxylic acid with $CH_2N_2$ lead to the diester (CXI) whose Dieckmann condensation and decarboxylation together with the addition of a side chain at the C(12) atom result in the formation of the CC precursor (CVIII), whose conversion into the CC presents no difficulty. The conversion of compound (CIX) into compound (CVIII) includes 24 stages:

A convenient synthesis of the optically active CC from the hydroxyacid (CXII),[49] which is converted into the cyclic ketone (CXIII), has been described. After protecting the OH group in compound (CXIII), the benzylethyl group in compound (CXIV) is subjected to hydrogenolysis, giving rise to the hydroxyketone (CXV), which is converted into the ester-alcohol (CXVI) (overall yield 77%): protection of the OH group by treatment with 2-methoxypropane, condensation with 4-carboxybutylenetriphenylphosphorane (4-CBTP), selective removal of the 2-methoxypropyl unit, and esterification with $CH_2N_2$. The alcohol (CXVI) is oxidised to the aldehyde (CXVII) using the complex $SO_3$.Py or DMSO-$(COCl)_2$, whose condensation with the phosphonate by the Emmons–Horner method results in the formation of the enone (CXVIII) (99%). After the removal of the THP group in compound (CXVIII), a mixture of the more polar compound (CXIX) and the less polar compound (CXX) is formed (1 : 1, 98%). The selective reduction of the oxo-group at the C(15) atom in compound (CXIX) with diisobutylaluminium 2,6-di-t-butyl-4-methylphenoxide leads to the (15*S*)-alcohol (CXXI) (83%) and the (15*R*)-alcohol (CXXII) (12%). Alkaline hydrolysis of compound (CXXI) gives rise to CC.

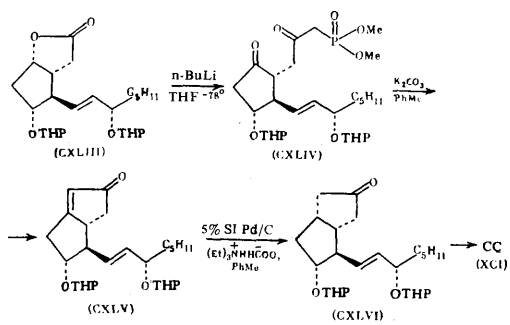


The (5*Z*,15*S*)-isomer (CXXII), the (5*Z*,15*R*)-isomer (CXXIV), and the acid (CXXV) are obtained from the enone (CXX) in the same way (Scheme 11).

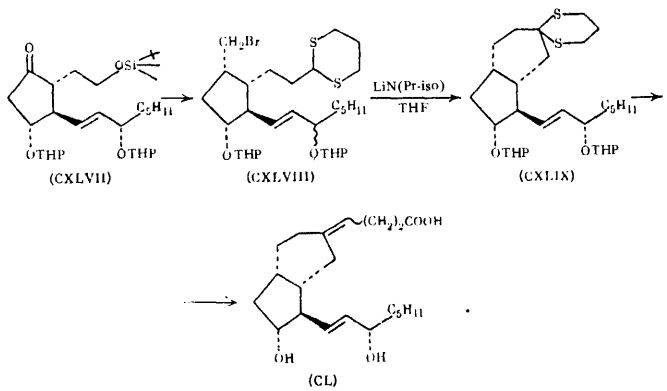
CC can also be obtained from the lactone (CXXVI), which is used in the synthesis of natural PG:[49]



One of the ways of synthesising optically active CC involves the use of the familiar intermediate optically pure ketone (CXXVII),[40] which is converted into the *endo*-aldehyde (CXXVIII) when the latter is successively condensed with n-hexylidenetriphenylphosphorane, hydrolysed, and oxidised by Jones' reagent with formation of the tricyclic intermediate (CXXIX). The ketone (CXXIX) is converted into the isomeric *cis*-glycols (CXXX). The reaction of compound (CXXX) with triethyl orthopropionate affords the isomeric orthoesters (CXXXI), which are converted into the (15*S*)-ketonediol (CXXXIIa) and the (15*R*)-ketonediol (CXXXIIb) after solvolysis in 100% formic acid and alkaline hydrolysis. The condensation of the ketone (CXXXIII) with the anion of the sulphoxyimine (CXXXIV) leads to a mixture of adducts (CXXXV), which give rise to the isomeric [with respect to the C(5) atom] olefins (CXXXVI) on reductive elimination. The silyl groups are removed with TBAF and the diols formed are converted into the isomeric diacetates (CXXXVII). After removing the protecting group at the C(1) atom in compound (CXXXVII), a mixture of the unsaturated alcohols (CXXXVIII) is oxidised by Jones' reagent and hydrolysed with aqueous alkali to CC. Using the same methods, the corresponding (15*R*)-dihydroxy acids (CXL) and (CXLI) were obtained from the (15*R*)-ketonediol (CXXXIIb). Condensation of the ketonediol (CXXXIIb) with the Wittig reagent gives rise to a mixture of the C(5)-isomers and the dihydroxyacids (CXII) (Scheme 12).

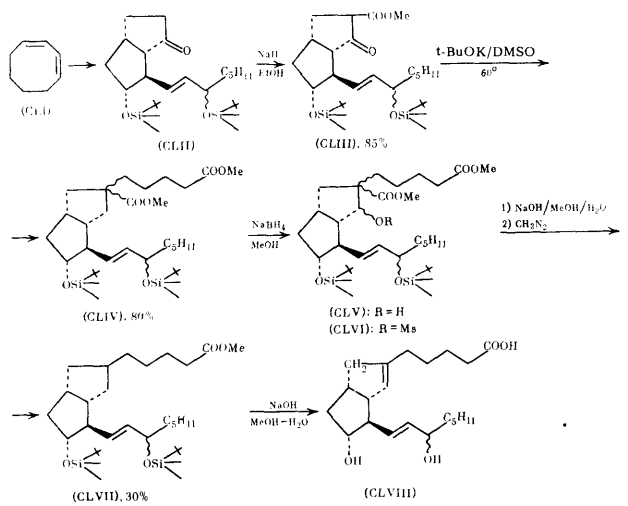


Scheme 11

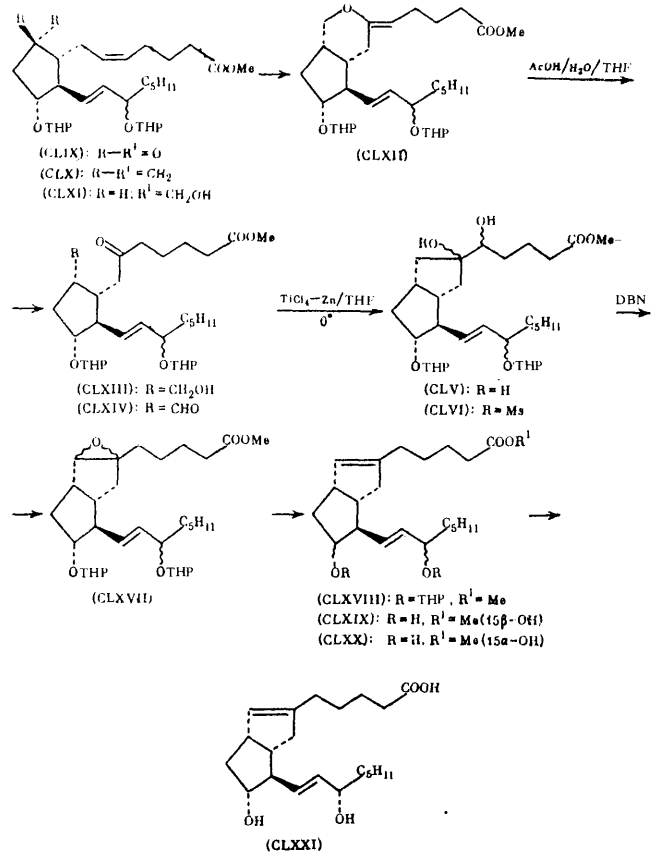


Scheme 12

The synthesis of CC via the key intermediate (CXLIII) has been described.[50,51] The reaction of compound (CXLIII) with the lithio-derivative of dimethyl methylphosphonate leads to a bicyclic alcohol, whose Collins oxidation produces the ketone (CXLIV). A suspension of the latter in 18-crown-6 ether is heated, the enone (CXLV) is obtained and its reduction affords compound (CXLVI). The condensation of the latter with 4-CBTP and subsequent removal of the THP protecting group leads to CC:



The 11-stage synthesis of 6a-carba-$PGI_2$ (CL) from the ketone (CXLVII) has been achieved.[52] The intermolecular alkylation of the dithiane (CXLVIII), obtained from compound (CXLVII) by the usual methods in 7 stages, is the key stage in the formation of the bicyclic compound (CXLIX), which is converted into compound (CL) in three stages:

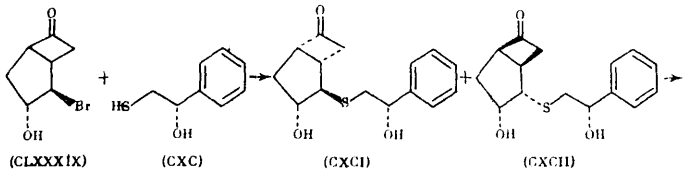


A method of synthesis of the carbon analogue $\Delta^6$-PGI (CLVIII), using cyclo-octa-1,3-diene (CLI) as the starting compound, has been described.[53] The regioselective methoxycarbonylation of the ketone (CLII), obtained in 7 stages from compound (CLI), with dimethyl carbonate leads to the ketoester (CLIII). The reaction of compound (CLIII) with methyl 5-iodoheptanoate yields the alkylated product (CLIV) in the form of a mixture of stereoisomers with respect to the C(6) atom. The reduction of the ketone (CLIV) leads to a mixture of the diastereoisomeric alcohols (CLV) (90%), the methanesulphonation of which affords compound (CLVI). The decarboxylation and subsequent esterification of compound (CLVI) lead to the ester (CLIII). Despite the low yields of compound (CLIII), this synthesis has the advantage that the methoxycarbonyl functional group at the C(6) atom not only makes it possible to carry out successfully the alkylation at the C(6) atom but also promotes the introduction of a double bond between the C(5) and C(6) atoms. After the removal of the protecting groups in compound (CLVII) and hydrolysis, 9(*O*)-methano-$\Delta^6$-$PGI_1$ (CLVIII) is isolated in the form of a mixture of diastereoisomers with respect to the C(15) atom (the 15α- and 15β-isomers) (Scheme 13).

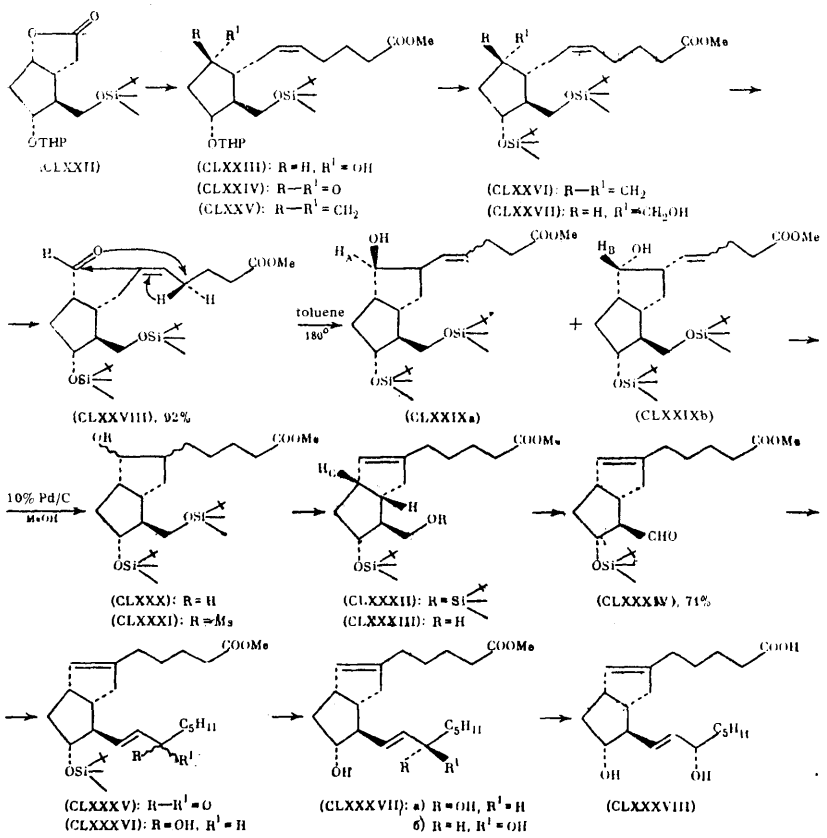
Scheme 13

Using an intermolecular pinacol addition reaction as the key stage, 9(*O*)-methane-$\Delta^{6(9\alpha)}$-$PGI_1$ (CLXXI) was obtained.[54-57] The methylene group in the $PGE_2$ (CLIX) molecule is introduced by treatment with $Zn-CH_2Br_2-TiCl_4$, which results in the formation of compound (CLX) (80%). Cautious hydroboration of compound (CLX) with 9-borabicyclo[3.3.1]nonane (9-BBN) (THF, 0°) followed by treatment with an $H_2O_2$ solution leads to the primary alcohol (CLXI) (64.5%). The iodoesterification of the latter and treatment with DBN yield the enol ether (CLXII) (the main product), which is converted into the ketoalcohol (CLXIII). The oxidation of compound (CLXIII) with the complex $SO_3$.Py leads to the aldehyde (CLXIV), which is immediately introduced into the intermolecular pinacol addition reaction with formation of a mixture of the diastereoisomeric bicyclic diols (CLXV). The crude compound (CLXV) is converted into the methanesulphonate (CLXVI), which is in turn converted into the epoxy-derivative (CLXVII) and then into the *endo*-olefin (CLXVIII). After the removal of the THP protecting groups, a readily separable mixture of alcohols is obtained [the less polar 15β-isomer (CLXIX) and the more polar 15α-isomer (CLXX)]. Alkaline hydrolysis of compound (CLXX) leads to compound (CLXXI) (Scheme 14).

Scheme 14

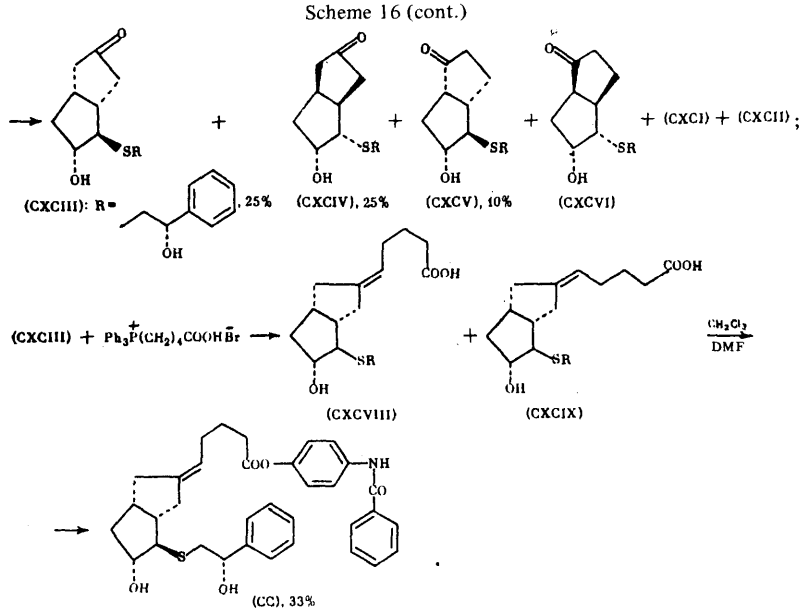


Using the intramolecular thermal ene reaction, (+)-9(*O*)-methano-$\Delta^{6(9\alpha)}$-$PGI_1$ (CLXXXVIII) was synthesised from the Corey lactone.[58] The aldehyde (CLXXVIII), necessary for the ene reaction, is obtained by converting the lactone (CLXXII) into the hydroxyester (CLXXIII) in the usual way: (1) reduction with diisobutylaluminium hydride (DIBAH); (2) condensation with 4-CBTP; 3) esterification with $CH_2N_2$ (overall yield 98%). The subsequent oxidation of compound



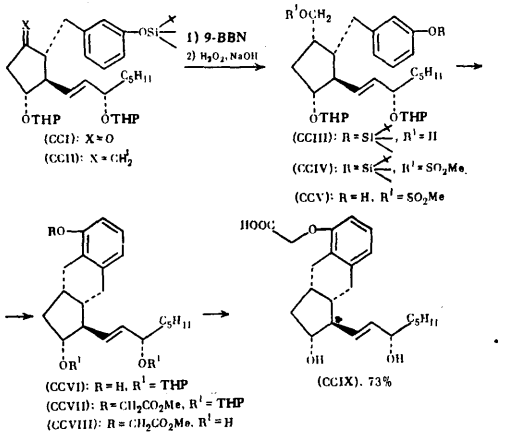
(CLXXIII) with pyridinium chlorochromate gives rise to the ketoester (CLXXIV) (92%). Substitution of the methylene group in the latter by treatment with $Zn-CH_2Br_2-TiCl_4$ leads to the diene (CLXXV) (81%). The thermally unstable THP-ether (CLXXV) is converted in two stages into the disilyl ether (CLXXVI), the hydroboration of which with 9-BBN and subsequent treatment with a solution of $H_2O_2$ produces the primary alcohol (CLXXVII), which is converted by the Collins oxidation into the aldehydes (CLXXVIII). The thermal ene reaction at 180 °C leads to two ene products: (CLXXIXa) (the main more polar isomer) and (CLXXIXb) (the minor less polar isomer). The mixture of these compounds is hydrogenated, which affords compound (CLXXX). On heating with diazabicycloundecene (DBU), the methanesulphonate (CLXXXI) gives rise to compound (CLXXXII). On treatment of the latter with a catalytic amount of pyridinium toluene-*p*-sulphonate, one obtains the key intermediate (CLXXXIII), whose oxidation produces the aldehyde (CLXXXIV), which condenses, without being isolated, with dimethyl 2-oxoheptylphosphonate to form the enone (CLXXXV) (71%). The reduction of compound (CLXXXV) with $NaBH_4$ gives rise to the C(15)-epimeric alcohols (CLXXXVI) and the removal of the protecting group leads to the more polar diol (CLXXXVIIa) (55%) and the less polar diol (CLXXXVIIb) (22%). Alkaline hydrolysis of compound (CLXXXVIIa) results in the formation of compound (CLXXXVIII) (Scheme 15).

An 8-stage synthesis of a CC analogue, namely the benzamidophenyl ester of (CC), has been achieved in 5% yield.[59] The key compounds for the synthesis of this analogue are the bromohydrin (CLXXXIX) and the thiol (CXC), which are in their turn obtained from cyclopentadiene and L-(+)-mandelic acid respectively. The addition of compound (CXC) to the bromohydrin (CLXXXIX) leads to a mixture of the isomers (CXCI) and (CXCII) which is difficult to separate. Treatment of the mixture with $CH_2N_2$ makes it possible to carry out a ring expansion reaction. The resulting mixture of compounds (CXCIII), (CXCIV), (CXCV), and (CXCVI) is readily separated by chromatography on silica gel. The Wittig condensation of compound (CXCIII) with the phosphorane obtained from phosphonium salts (CXCVII) results in the formation of a mixture of the *E*- and *Z*-isomers (CXCVIII) and (CXCIX), which is esterified with *p*-benzamidophenol and compound (CC) is isolated (Scheme 16).

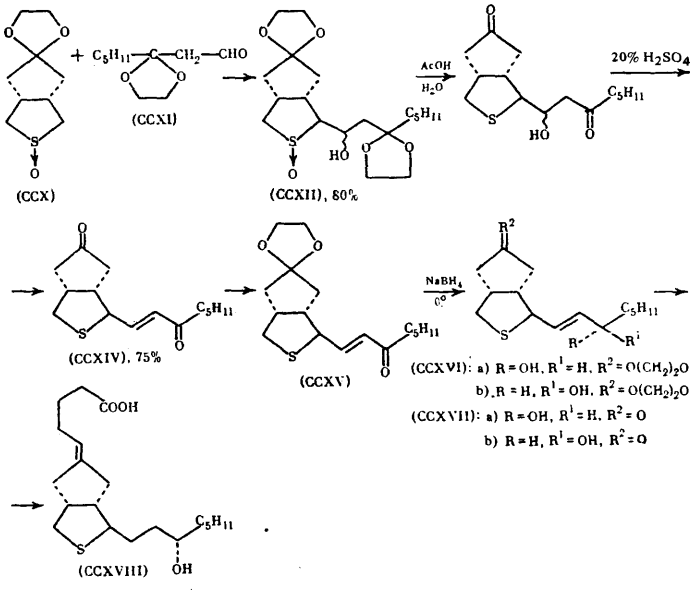


Scheme 16

Scheme 15

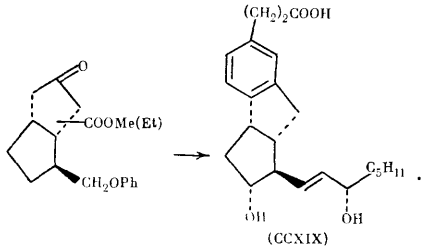


Scheme 16 (cont.)



In order to discover PC analogues which are resistant to hydrolysis, benzoindene derivatives have been synthesised.[60,61] The starting material for the synthesis of such derivatives was compound (CCI), which is used in the synthesis of PG analogues.[62] The methylene group is introduced in two stages: the ketone reacts with the anion of methylphenyl-*N*-methylsulphoxyimine and this is followed by treatment of the adduct with aluminium amalgam ($H_2O$–AcOH–THF) with formation of compound (CCII) (72%), whose hydroboration and subsequent oxidation produce the alcohol (CCIII) (92%). The alcohol (CCIII) is converted into the methanesulphonate (CCIV) (88%), the silyl group in the latter is removed by treatment with TBAF, and compound (CCV) is refluxed with NaH in glyme until the formation of compound (CCVI), which is converted into the ester (CCVII) by treatment with NaH and methyl bromoacetate. After the removal of the THP protecting group, the ester (CCVIII) is formed and its alkaline hydrolysis affords the crystalline acid (CCIX) (Scheme 17).

Scheme 17

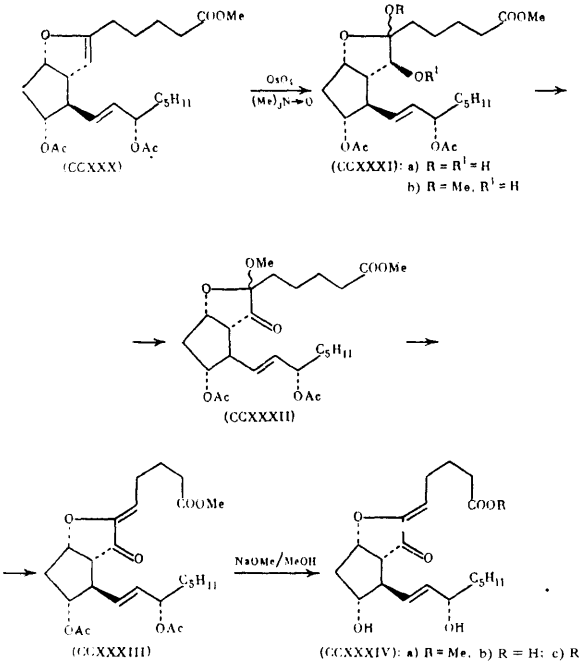


The synthesis of the ethylene ketal of tetrahydrobiscyclopentano[c]thiophen-5-one (CCX) and its conversion into the analogue 11-thia-CC have been described.[63] The synthone (CCX) has two functional groups, which makes it possible to introduce the necessary side chain fairly readily and also has a hydrogen atom activated by the sulphoxide group. The introduction of the ω-chain into the molecule is achieved by the reaction of the carbanion generated from compound (CCX) with the protected aldehyde (CCXI) to form a mixture of the aldols (CCXII), which is not separated. Treatment of the mixture with diborane with subsequent deketalisation leads to the formation of the β-hydroxyketone (CCXIII), whose dehydration affords the αβ-*trans*-enone (CCXIV). The ring carbonyl group is protected by treatment with 2-ethyl-2-methyl-1,3-dioxolan and compound (CCXV) formed is reduced to a mixture of the epimeric alcohols (CCXVIa, b). After the removal of the ketal protecting group, the mixture of compounds (CCXVIIa, b) is separated chromatographically. The condensation of the more polar C(15)-epimer (CCXVIIa) with 4-CBTP leads to compound (CCXVIII) and its (15*R*)-epimer in the form of a mixture of the *cis*,*trans*-isomers (Scheme 18).

Scheme 18

In order to establish the relation between structure and activity for a series of $PGI_2$ analogues, a new aromatic CC analogue (CCXIX), which has no biological PC activity, was obtained by total synthesis (20 stages):[64]

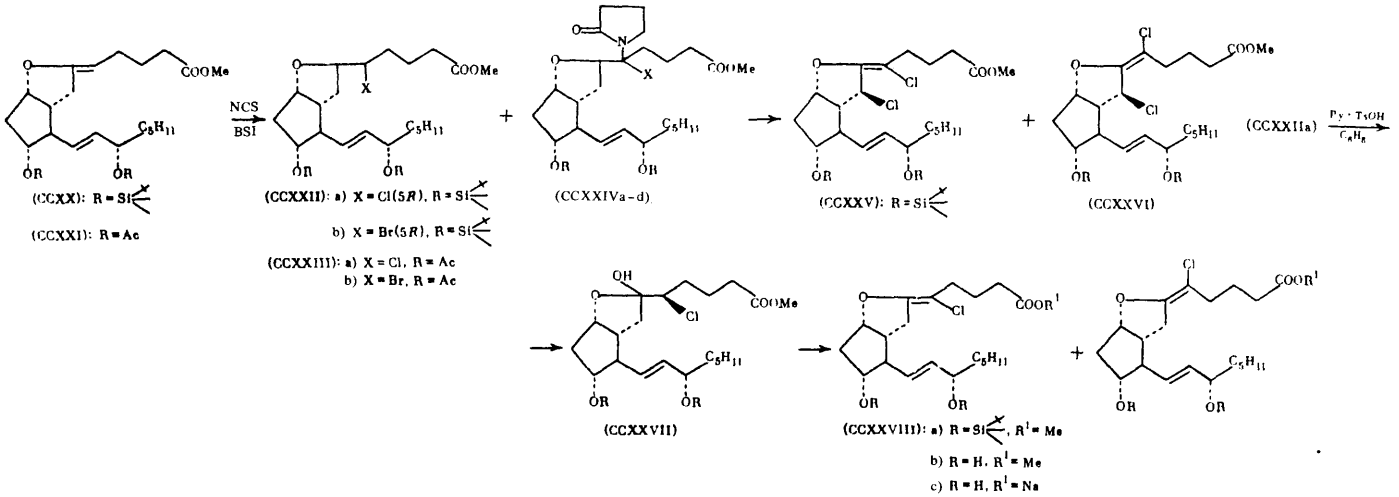
(CCXIX)



### 3. The Synthesis of Prostacyclin Analogues with an Enol Ether Double Bond Resistant to Hydrolysis

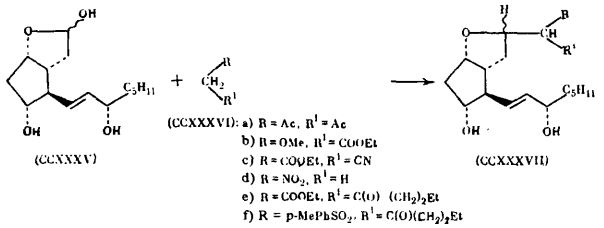
One of the effective ways of stabilising PC involves the introduction of electron-donating and electron-accepting substituents next to the enol ether group sensitive to hydrolysis or its replacement by another ether system.

Thus halogenation of the protected ethyl ester of $PGI_2$ (CCXX) proceeds stereoselectively with formation of the methyl ester of (5*R*)-5-Cl-$\Delta^6$-$PGI_1$ (CCXXIIa) (60%) or the methyl ester of (5*R*)-5-Br-$\Delta^6$-$PGI_1$ (CCXXIIb) (57%) with an admixture of the succinimido-adduct (CCXXIVa) (20%) or compound (CCXXIVb) (20%).[65] On the other hand, the halogenation of the acetyl-substituted methyl ester of $PGI_2$ (CCXXI) under the same conditions gives rise to a mixture of the diastereoisomers of the methyl ester of 5-Cl-$\Delta^6$-$PGI_2$ (CCXIIIa) (58%, 5*R* : 5*S* = 5 : 3) or the methyl ester of 5-Br-$\Delta^6$-$PGI_1$ (CCXXIIIb) (60%, 5*R* : 5*S* = 7 : 3) with the corresponding succinimido-adduct (CCXXIVc) (20%) or (CCXXIVd) (13%). The subsequent chlorination of the (5*R*)-allyl chloride (CCXXIIa) with *N*-chlorosuccinimide NCS leads to a mixture of the methyl esters of (5*E*,7*S*)- and (5*Z*,7*S*)-5,7-dichloro-$PGI_2$ (CCXXV) and (CCXXVI) (15 and 20% respectively). Treatment of the allyl chloride (CCXXIIa) with Py.TsOH leads to the hemiacetal (CCXXVII), whose dehydration with an excess of $MgSO_4$ in benzene results in the formation of the (5*E*)-vinyl chloride (CCXXVIIIa) (20%) and the (5*Z*)-vinyl chloride (CCXXIXa) (28%). The removal of the protecting groups in compounds (CCXXVIIIa) and (CCXXIXa) with TBAF leads to the methyl esters of (5*E*)-5-Cl-$PGI_2$ (CCXXVIIIb) (95%) and (5*Z*)-5-Cl-$PGI_2$ (CCXXIXb) (80%), whose alkaline hydrolysis resulted in the formation of the sodium salts (CCXXVIIIc) and (CCXXIXc) (Scheme 19).



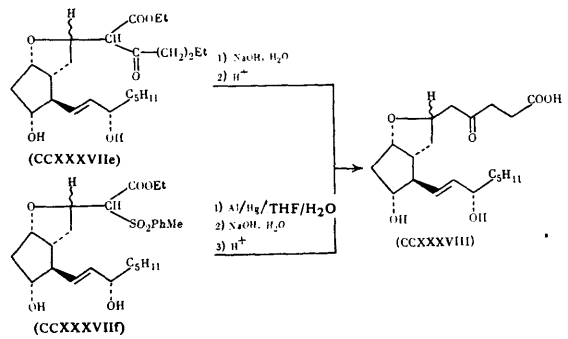
A five-stage synthesis of 7-oxo-$PGI_2$ (CCXXXIV) via the selective hydroxylation of the methyl ester of 11,15-diacetyl-$\Delta^6$-$PGI_1$ (CCXXX) has been described. The stereochemistry of the intermediates has been determined and their conformational analysis has been carried out.[66] Selective hydroxylation of the enol ether double bond in compound (CCXXX) proceeds smoothly with formation of compound (CCXXXIa) (80%), which is converted into the isomeric methyl ketals by appropriate successive treatments (MeOH, $Et_2O.BF_3$); after chromatographic separation one obtains the pure *endo*-isomer (27%) and exo-isomer (51%) of compound (CCXXXIb). Oxidation of both isomers (pyridinium dichromate/DMF or pyridinium chlorochromate/NaOAc/$CH_2Cl_2$) leads to the *endo*- and *exo*-isomers of compound (CCXXXII) respectively, whose thermolysis at 160–170 °C affords compound (CCXXXIII) and deacetylation of the latter results in the formation of compound (CCXXXIV) (Scheme 20).

Scheme 20

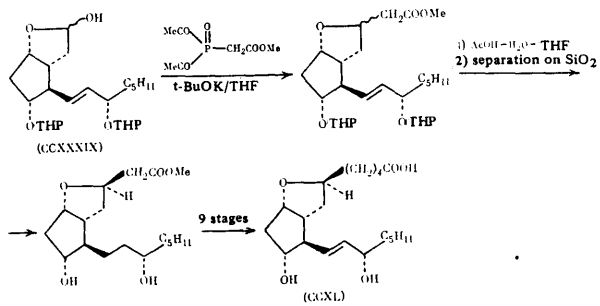


(CCXXX) (CCXXXI): a) R = R¹ = H; b) R = Me, R¹ = H (CCXXXII) (CCXXXIII) (CCXXXIV): a) R = Me, b) R = H; c) R = Na

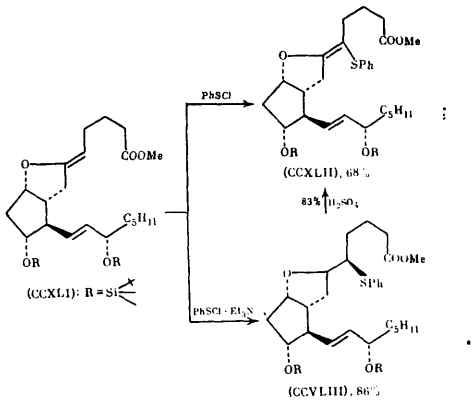
Scheme 19



(CCXX): R = Si (CCXXI): R = Ac (CCXXII): a) X = Cl(5*R*), R = Si; b) X = Br(5*R*), R = Si (CCXXIII): a) X = Cl, R = Ac; b) X = Br, R = Ac (CCXXIVa–d) (CCXXV): R = Si (CCXXVI) (CCXXVII) (CCXXVIII): a) R = Si, R¹ = Me; b) R = H, R¹ = Me; c) R = H, R¹ = Na

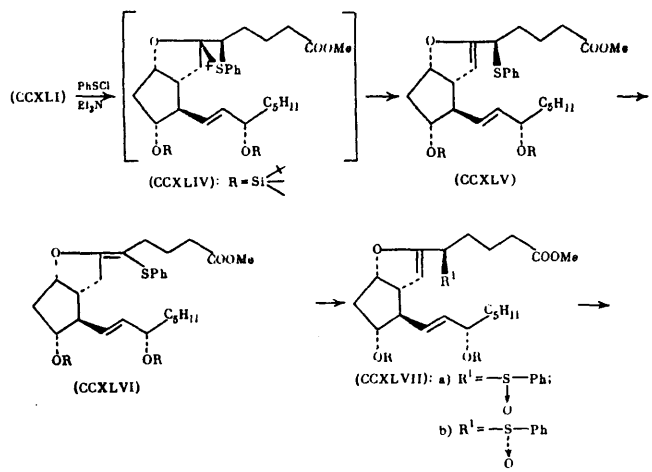


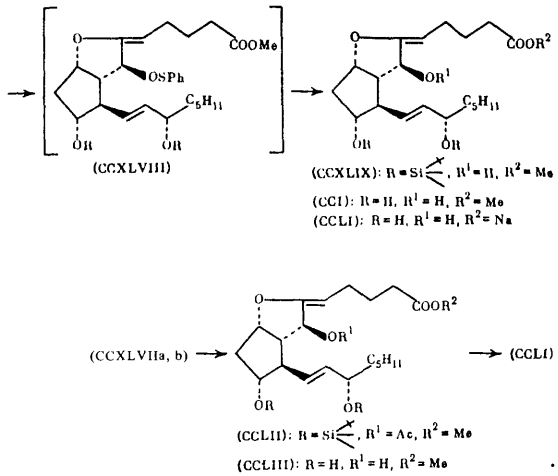
A simple method of synthesising the PC analogues (CCXXXVII) using the hemiacetal (CCXXXV) and a compound with an active methylene group [compounds (CCXXXVIa–f)] under the conditions of the Knoevenagel condensation has been proposed:[67,68]



This method is extremely promising, since many compounds with an active methylene group can be condensed. The reaction can be carried out both with malonic and acetoacetic acid derivatives and with β-oxosulphones and aliphatic nitro-compounds. An advantage of this method is its simplicity, which makes it possible to apply it on an industrial scale. Despite the fact that the reaction results in the formation of all four possible isomers of compound (CCXXXVII), the Knoevenagel condensation has been used successfully as the key stage in the synthesis of the familiar 4-oxo-$PGI_1$ (CCXXXVIII):

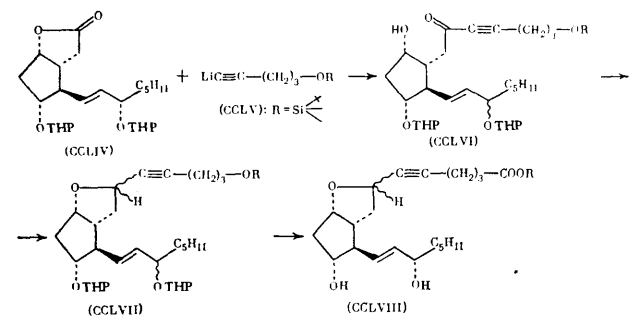
An analogous strategy has been used to convert the lactone (CCXXXIX) into 6β-$PGI_1$ (CCXI), the Wittig condensation being used in the first stage instead of the Knoevenagel condensation:[69]





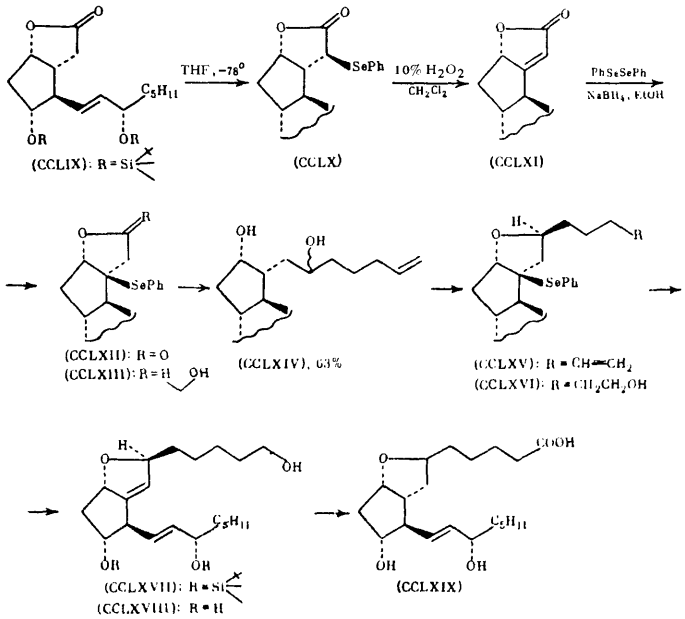
Several stable $PGI_2$ analogues containing electron-accepting substituents at the C(5) or C(7) atoms have been synthesised.[70] The methyl ester of $PGI_2$ (CCXLI) reacts with benzenesulphenyl chloride to form (5*E*)-5-phenylthio-$PGI_2$ (CCXLII) or (5*R*)-5-phenylthio-$\Delta^6$-$PGI_1$ (CCXLIII) depending on the condensation conditions.

The synthesis of the stable analogues 7-hydroxy- and 7-acetoxy-$PGI_2$, the methyl ester of $PGI_2$, using the stereocontrolled sulphoxide–sulphenate rearrangement has been described.[71] The methyl ester (CCXLI) is converted into the allyl sulphide (CCXLV) (86%), the phenylthio-group attacking the less hindered β-side of the $\Delta^5$-double bond with formation of the intermediate episulphonium ion (CCXLIV), in which the proton at the C(7) atom is abstracted with conversion into compound (CCXLV). It is of interest that, when a solution of compound (CCXLV) in $CHCl_3$ is treated with a catalytic amount of $H_2SO_4$, the $\Delta^6$-double bond isomerises rapidly and readily to the (5*E*)-sulphide (CCXLVI) (83%) without the formation of the (5*Z*)-isomer. The oxidation of compound (CCXLVI) with *m*-chloroperbenzoic acid gives rise to an isomeric mixture of the sulphoxides (CCXLVIIa, b) (53%), which is not resolved into the isomers in view of the rapid epimerisation of allyl sulphoxides via the sulphenate ester (CCXLVIII) stage [(CCXLVIIa) ⇌ (CCXLVIII) ⇌ (CCXLVIIb)]. When a mixture of compounds (CCXLVIIa, b) is treated with diethylamine, the rearranged alcohol (CCXLIX) is obtained (68%). The silyl protecting groups in the latter are removed with TBAF to form the methyl ester of (7*S*)-hydroxy-$PGI_2$ (CCL) (87%), the alkaline hydrolysis of which affords the sodium salt of (7*S*)-hydroxy-$PGI_2$ (CCLI). Treatment of compounds (CCXLVIIa, b) with the acetic acid–pyridine mixture yields the acetate (CCLII) (62%). The removal of the protecting groups with TBAF leads to the methyl ester of (7*S*)-acetoxy-$PGI_2$ (CCLIII), whose hydrolysis results in the formation of compound (CCLI) (Scheme 21).



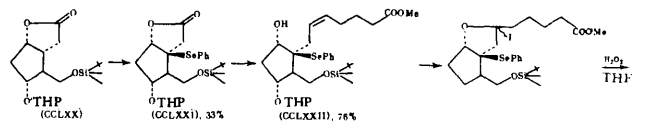
Scheme 21

An interesting synthesis, involving only a few stages, of the 4,4,5,5-tetrahydro-PC analogue (CCLVIII) has been developed.[72] The initial compound employed was the lactone (CCLIV), whose reaction with alkynyl-lithium (CCLV) results in its conversion into the ketone (CCLVI). The reduction of the keto-group with $NaBH_4$ and subsequent cyclisation in the presence of toluene-*p*-sulphonyl chloride in pyridine lead to the bicyclic compound (CCLVII). After the removal of the THP group in the usual way and alkaline hydrolysis, the latter is converted into compound (CCLVIII) (Scheme 22).

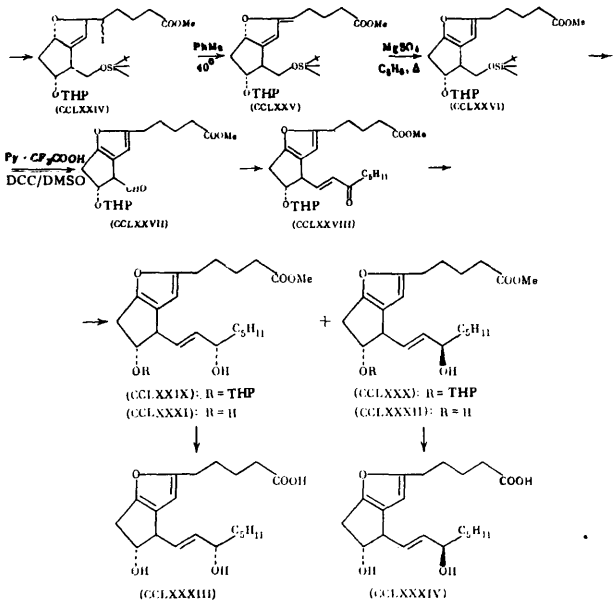


Scheme 22

A similar strategy, based on the use of the lactone (CCLIV), was used in the synthesis of 6β-$\Delta^7$-$PGI_1$.[73]

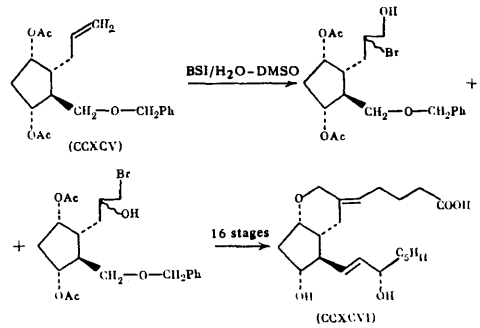


The synthesis of (6*R*)- and (6*S*)-$\Delta^7$-$PGI_1$ (CCLXIX) [74] from the lactone (CCLIX) has been described. The reaction of the lactone with lithium diisopropylamide and treatment of the resulting enolate with PhSeCl yield the 7-phenylselenyl-lactone (CCLX) (90%), which is converted into the αβ-unsaturated lactone (CCLXI) via the phenylselenium oxide elimination stage. The lactone (CCLXI) is converted into the 8-phenylselenolactone (CCLXII), whose reduction with DIBAH gives rise to the lactone (CCLXIII). The alkylation of compound (CCLXIII) with 4-pentylmagnesium bromide leads to the olefin (CCLXIV). The formation of the 6,9-epoxy-unit in compound (CCLXIV) takes place on treatment with toluene-*p*-sulphonyl chloride (pyridine, 40 °C) or methanesulphonyl chloride ($Et_3N$, $CH_2Cl_2$, −78 °C). The conversion of compound (CCLXV) into (6*S*)-$\Delta^7$-$PGI_1$ (CCLXIX) is carried out in four stages: (1) hydroboration of compound (CCLXV) and 9-BBN and subsequent oxidation afford the primary alcohol (CCLXVI); (2) treatment of compound (CCLXVI) with 10% $H_2O_2$ results in the formation of the unsaturated compound (CCLXVII); (3) mild acid hydrolysis of compound (CCLXVII) leads to the C(1) alcohol (CCLXVIII); (4) selective oxidation of compound (CCLXVIII) over $Pt/O_2$ produces compound (CCLXIX) (Scheme 23).

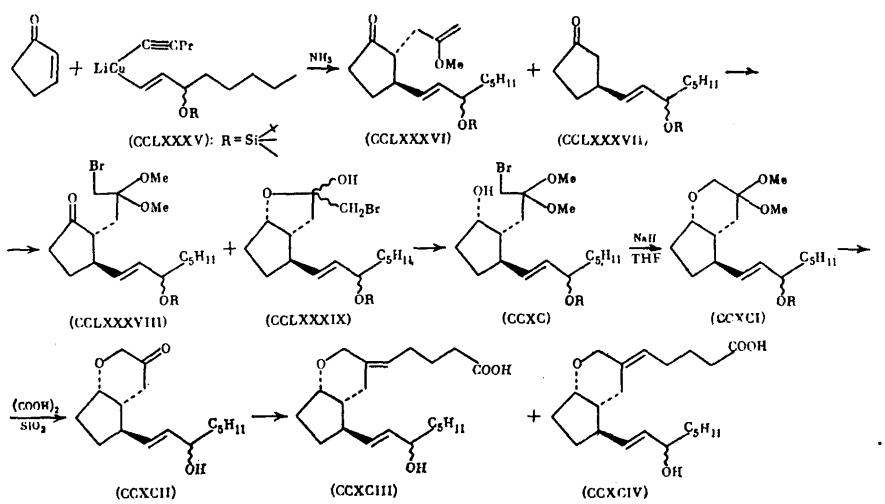


Scheme 23

Stable PC analogues having a furan ring instead of the enolic ether group have been synthesised.[75] The introduction of the phenylseleno-group in the α-position in the lactone (CCLXX) followed by treatment with $(MeSi)_2NLi$ and PhSeCl (THF), −70 °C, the elimination of the phenylseleno-group under oxidation conditions ($H_2O_2$), and the reintroduction of the phenylseleno-group ($NaHB_4$, PhSeSePh, EtOH) result in the formation of the β-phenylselenolactone (CCLXXI). The reduction of the latter with DIBAH (−70 °C), condensation with the lithium salt of 4-CBTP, and treatment of the resulting carboxylic acid with $CH_2N_2$ lead to the ester (CCLXII). The bicyclic iodoester (CCLXXIII) is obtained by treating compound (CCLXXII) with $I_2$ and $NaHCO_3$ with subsequent elimination of the phenylseleno-group and the formation of the dihydrofuran (CCLXXIV). The dehydroiodination of compound (CCLXXIV) with DBU gives rise to the very labile dienol ether (CCLXXV), which immediately isomerises to the furan derivative (CCLXXVI). The protecting group in compound (CCLXXVI) is removed with TBAF and the resulting alcohol is oxidised to the unstable aldehyde (CCLXXVII), which is condensed with dimethyl 2-oxoheptylphosphonate to form the enone (CCLXXVIII). The latter is reduced to $NaBH_4$ in the 15α- and 15β-alcohols (CCLXXIX) and (CCLXXX) (53% and 39% respectively). After removal of the THP protecting group in the usual way, the methyl esters (CCLXXXI) and (CCLXXXII) are obtained and then hydrolysed to the free acids (CCLXXXIII) and (CCLXXXIV) (Scheme 24).

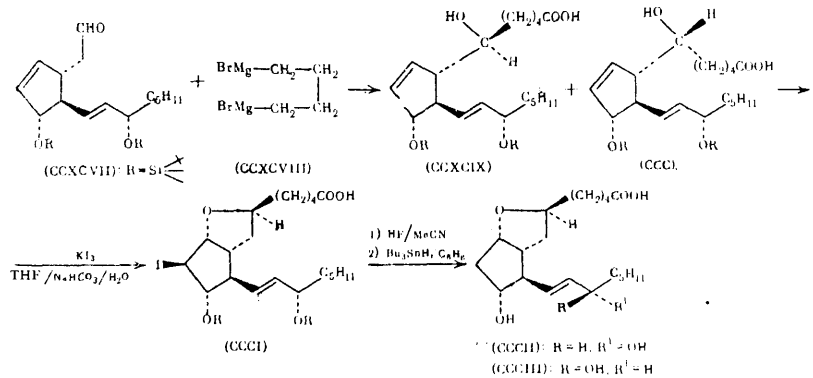


Scheme 24



A synthesis of 11-deoxyhomo-PC analogues with a small number of stages has been proposed. The key stage in the synthesis is the reaction involving the coupled addition of organocuprate and alkylation of the resulting enolate.[76,77] Treatment of cyclopent-2-enone with the mixed cuprate (CCLXXXV) and alkylation of the intermediate enolate with 2-methoxyallyl bromide lead to a mixture of the alkylated product (CCLXXXVI) and the non-alkylated ketone (CCLXXXVII). Bromination of compound (CCLXXXVI) yields the α-bromoketal (CCLXXXVIII) together with the bicyclic acetal (CCLXXXIX). The stereospecific reduction of the keto-group in compound (CCLXXXVIII) with potassium *t*(*s*)-butylhydroborate leads to the α-alcohol (CCXC), which is cyclised to the ketal (CCXCI) with the simultaneous elimination of HBr. The hydrolysis and desilylation of compound (CCXCI) lead to the ketone (CCXCII), whose condensation with 4-CBTP gives rise to a mixture of compounds (CCXCIII) and (CCXCIV), which can be separated chromatographically (Scheme 25).

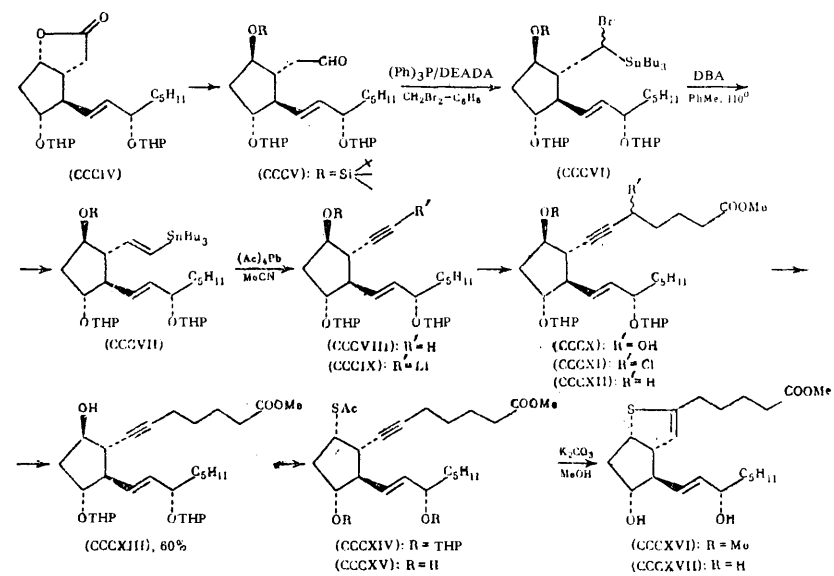
A similar approach to the synthesis of homo-PC (CCXCVI) is based on the use of the alkene (CCXCV). However, in the stage involving the addition of HOBr to the double bond, which precedes cyclisation, a low selectivity is observed:[78]



The stereoselective synthesis of the racemic 6β-$PGI_1$, which is a biologically active stable PC analogue, has been achieved.[79,80] The aldehyde (CCXCVII) reacts with an excess of the bis-Grignard reagent (CCXCVIII) and subsequent carboxylation with gaseous $CO_2$ affords a mixture of the acids (CCXCIX) (6α-OH) and (CCC) (6β-OH). When this mixture is treated with $KI_3$, the esters of 10β-iodo-derivative (CCCI) (34%) and the 6α-hydroxy-derivative (CCXCIX) (40%) are obtained. Compound (CCXCIX) is separated chromatographically, subjected to Collins oxidation, and then reduced with $NaBH_4$ to a mixture of compounds (CCXCIX) and (CCC), which is reused. When compound (CCCI) is treated with HF, (±)-6β-$PGI_1$ (CCCII) and (±)-6β-epi-$PGI_1$ (CCCIII) are obtained and are separated chromatographically (Scheme 26).

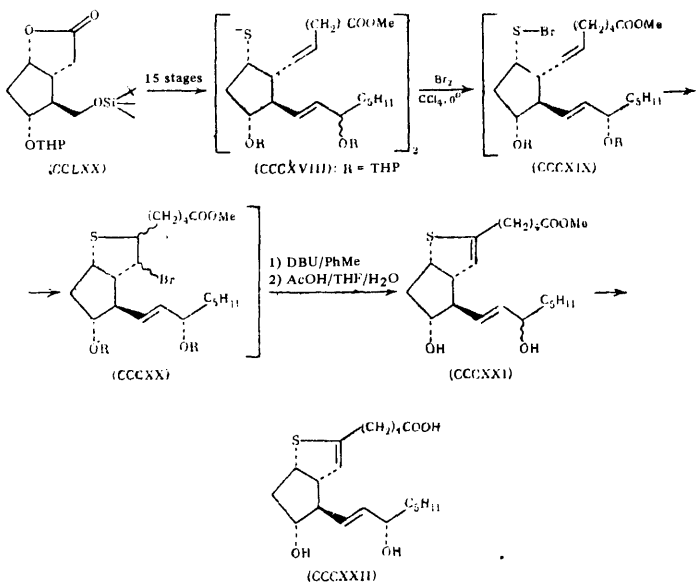
Scheme 25

Scheme 26



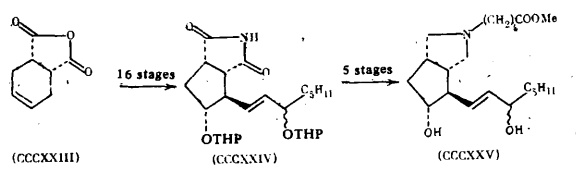
### 4. Prostacyclin Analogues From Which the O Atom in the 9-Position Has Been Replaced by Other Heteroatoms. Prostacyclin Analogues Containing Additional Heteroatoms

In order to elucidate the influence of the replacement of the O(9) atom by other heteroatoms, for example S and N, on the biological properties of PC, a series of syntheses were carried out, as a result of which it was possible to establish that the PC heteroanalogues exhibit a weaker biological activity than PC itself.[21,43]



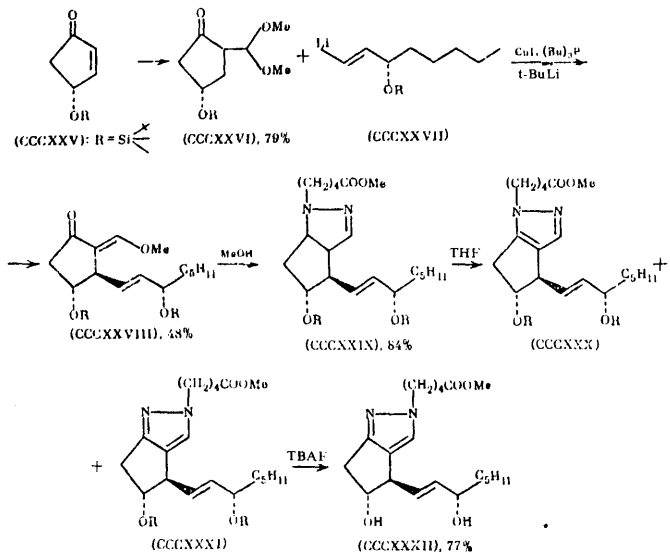
A new method for the conversion of the aldehyde into the acetylenic derivative via 1-alkenyltin was used in the synthesis of 9(*O*)-thia-$\Delta^6$-$PGI_1$ (CCCXVII).[81] The initial aldehyde (CCCV) was obtained from the well known lactone (CCCIV) in six stages (overall yield 57%). The aldehyde is converted in two stages into the α-bromoalkyltin derivative (CCCVI) (54%). The elimination of HBr from compound (CCCVI) gives rise to the vinyltin derivative (CCCVII) in a satisfactory yield. Further treatment of compound (CCCVII) leads to the terminal acetylene (CCCVIII) (63%). The condensation of the lithio-derivative (CCCIX) with methyl 4-formylbutanoate results in the formation of the propargyl alcohol (CCCX). The replacement of the OH group in compound (CCCX) by chlorine leads to compound (CCCXI), whose subsequent treatment with tri-n-butyltin hydride affords the propargyl chloride (CCCXII). After the removal of the protecting group in compound (CCCXII), the 9β-alcohol (CCCXIII) is formed and is then converted into the 9α-thia-acetate (CCCXIV) by Volante's method [$(C_6H_5)_3P$/di-isopropyl azodicarboxylate in the presence of thioloacetic acid]. The removal of the THP group in compound (CCCXIV) yields compound (CCCXV) (83%), the subsequent hydrolysis of which gives rise to the dihydrothiophen derivative (CCCXVI) (endoenol, 66%). Alkaline hydrolysis of compound (CCCXVI) with LiOH in a THF–$H_2O$ mixture followed by the adjustment of the pH to 4.01 with the aid of a buffer solution leads to compound (CCCXVII) (Scheme 27).

Scheme 27



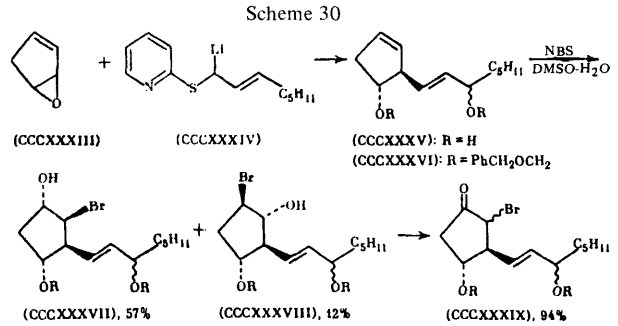
The synthesis of the chemically stable 9(O)-thia-$\Delta^6$-PC (CCCXXII) from Corey's lactone (CCLXX), which is converted in the usual way into the disulphide (CCCXVIII), has been described. The bromination of compound (CCCXVIII), treatment with DBA, and the removal of protecting groups lead to different amounts of the methyl esters of compound (CCCXXI) and its 15-epimer. The conversion of the disulphide (CCCXVIII) into the sulphenyl bromide (CCCXIX) initiates a new intermolecular rearrangement with formation of the halogenotetrahydrothiophen derivative (CCCXX). Alkaline hydrolysis of compound (CCCXXI) affords compound (CCCXXII), which exhibits a high activity in the inhibition of the aggregation of platelets, comparable to the activity of 9(O)-thia-PC [82] (Scheme 28).

Scheme 28

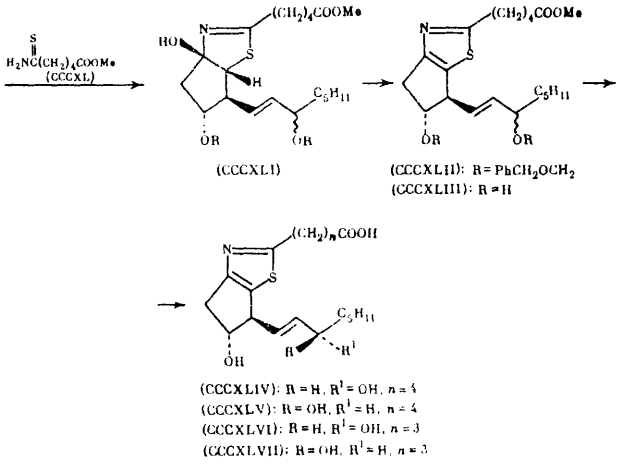


A multistage synthesis of racemic 6-aza-6,9-methano-$PGI_2$ (CCCXXV), which inhibits the aggregation of platelets, has been achieved. The anhydride (CCCXXIII) served as the starting material. It is converted into the imide (CCCXXIV) in 16 stages and the 6-aza-PC analogue (CCCXXV) was obtained from the latter in 5 stages: [83]

A convergent approach to the chiral analogue of the heteroaromatic PC has been proposed. [84] The enone (CCCXXV) is initially converted into the dimethoxymethyl derivative (CCCXXVI): treatment with (1) phenylselenotrimethylsilane and trimethylsilyltrifluoromethanesulphonate, (2) trimethyl orthoformate, (3) pyridine, and (4) 30% $H_2O_2$. The reaction of compound (CCCXXVI) with the organocuprate reagent obtained from copper(I) iodide and the lithium derivative (CCCXXVII) gives rise to the product (CCCXXVIII). Its condensation with hydrazine hydrate affords the pyrazole derivative (CCCXXIX), whose potassium salt is treated with methyl 5-iodopentanoate, which leads to a 1 : 1 mixture of the products (CCCXXX) and (CCCXXXI) (67%). After the removal of the protecting groups in compound (CCCXXXI), compound (CCCXXXII) is obtained (Scheme 29).

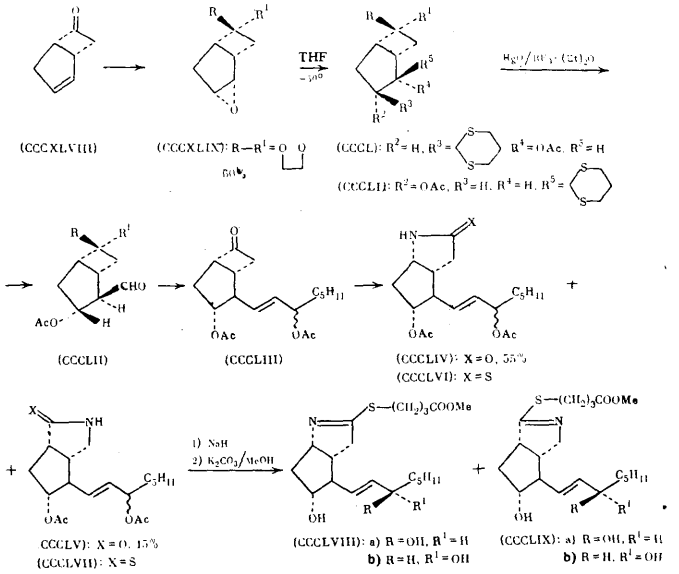


Scheme 29

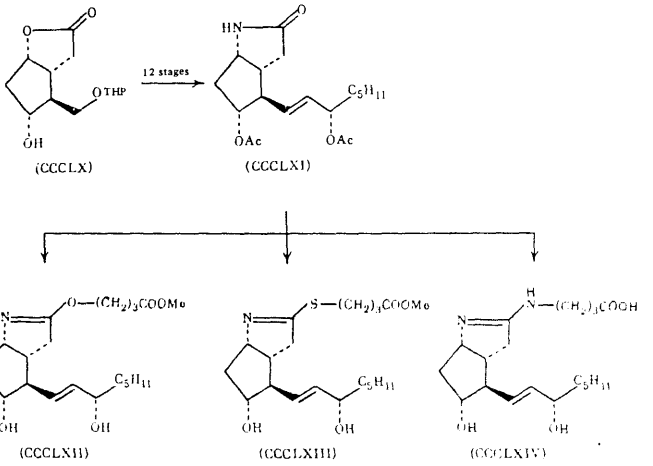


Thiazole analogues of PC are obtained from compound (CCCXXV), synthesised in several stages by the opening of the epoxy-ring in the 3,4-epoxycyclopentene (CCCXXXIII) by treatment with the lithio-derivative (CCCXXXIV). [85] The hydroxy-groups in the diol (CCCXXXV) are protected in the form of the bisbenzyloxymethyl ethers (CCCXXXVI), which give rise to an appreciable steric hindrance to electrophilic attack on the double bond in the side chain.

Treatment of compound (CCCXXXVI) with NBS gives rise to a mixture of two readily separated bromohydrins (CCCXXXVII) and (CCCXXXVIII). Oxidation of the main bromohydrin (CCCXXXVII) with pyridinium chlorochromate yields the bromoketone (CCCXXXIX) in the form of a mixture of epimers at C(8). The reaction of compound (CCCXXXIX) with the thioamide (CCCXL) leads to the hydroxythiazoline (CCCXLI), which is treated, without being isolated, with the complex of $(C_6H_5)_3P$ and DEADA, to give the thiazole (CCCXLII). After the removal of the protecting groups in compound (CCCXLII) and alkaline hydrolysis of the diol (CCCXLIII), the PC analogue (CCCXLIV) and its 15-epimer (CCCXLV) are obtained and are separated chromatographically. The nor-PC analogue (CCCXLVI) and its 15-epimer (CCCXLVII) are obtained analogously from the bromoketone (CCCXXXIX) and a thiazole derivative obtained from the methyl ester of glutaric acid monoamide (Scheme 30).

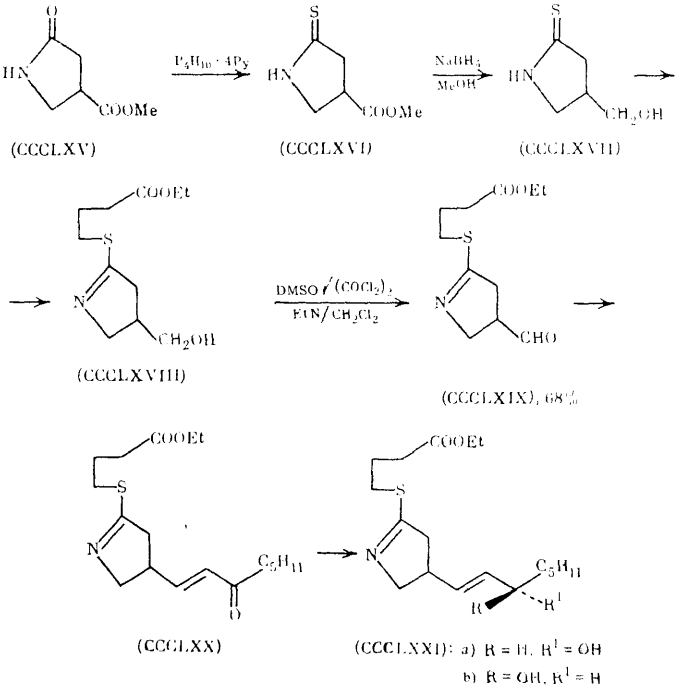


Scheme 30

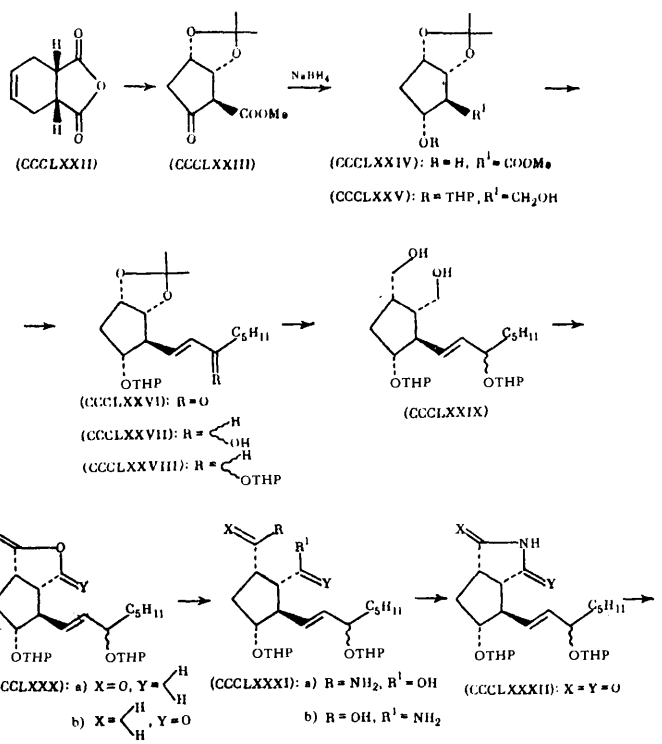


The synthesis of β-thiaimino-PC using bicyclo[3.2.0]hept-2-en-6-one (CCCXLVIII), the intermediate in the synthesis of natural PG, as the starting material has been described.[86] The ketone (CCCXLVIII) is converted by a standard method into the ketal (CCCXLIX) whose treatment with 2-lithiodithiane followed by acylation gives rise to the crystalline acetates (CCCL) and (CCCLI) (2 : 8, 61%), which are readily separated by crystallisation. Selective hydrolysis of the dithiane unit in the acetate (CCCLI) results in the formation of the aldehyde (CCCLII), whose condensation with the corresponding phosphonate, the reduction of the enone produced ($ZnBH_4$, diglyme), acylation, and the removal of the ketal protecting group lead to the ketone (CCCLIII). Treatment of compound (CCCLIII) with *o*-mesitylenesulphonylhydroxylamine yields the crystalline lactam (CCCLIV) and the isomeric lactam (CCCLV). On heating the mixture of lactams ($P_4S_{10}$.Py, toluene), the mixture of the thiolactams (CCCLVI) and (CCCLVII) is obtained (80%), whose alkylation with ethyl γ-bromobutyrate followed by the hydrolysis of the acetate groups affords a mixture of compounds (CCCLVIIIa, b) and (CCCLIXa, b) in an overall yield of 64%, which can be readily separated chromatographically (Scheme 31).

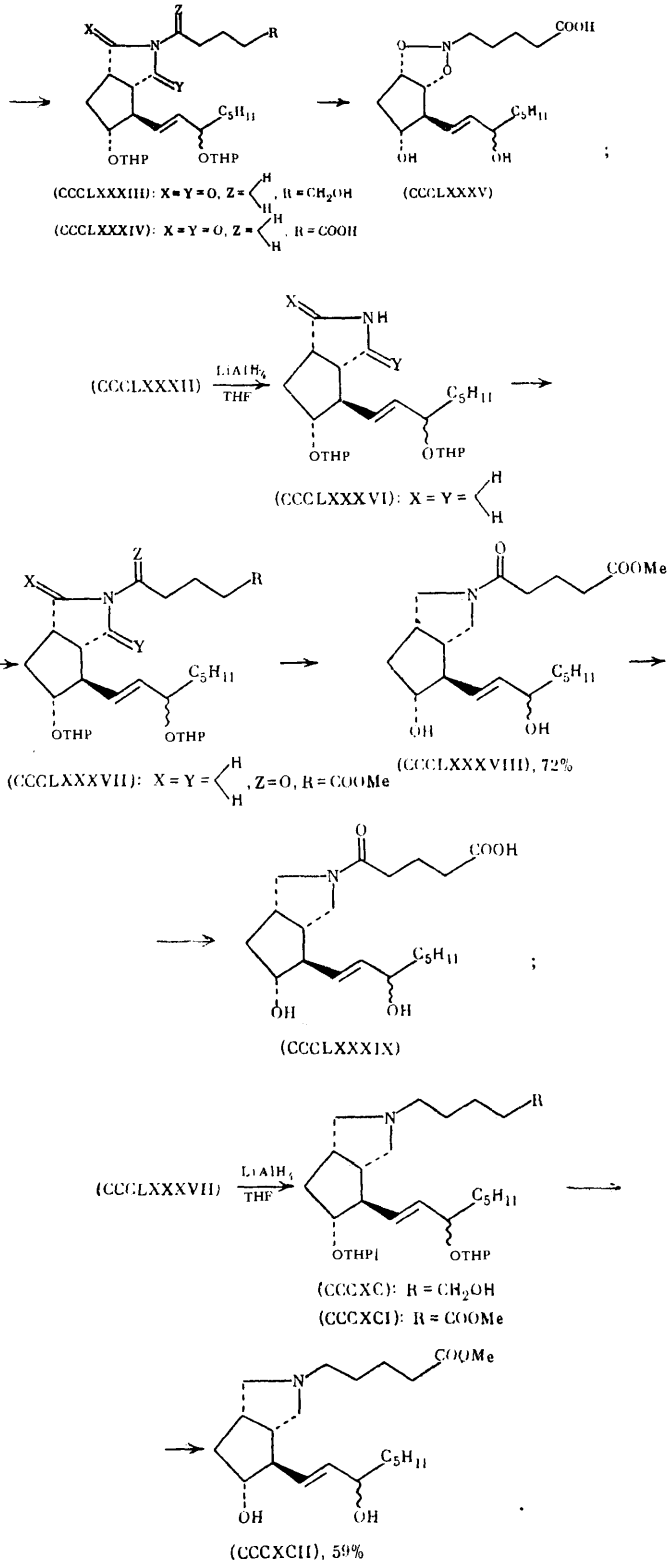
Scheme 31



The lactone (CCCLX) can be converted into the lactam (CCCLXI), which is the key synthone in the synthesis of 4-oxa-9-aza-$PGI_1$ (CCCLXII), 4-thia-9-aza-$PGI_1$ (CCCLXIII), and 4,9-diaza-$PGI_1$ (CCCLXIV).[87]

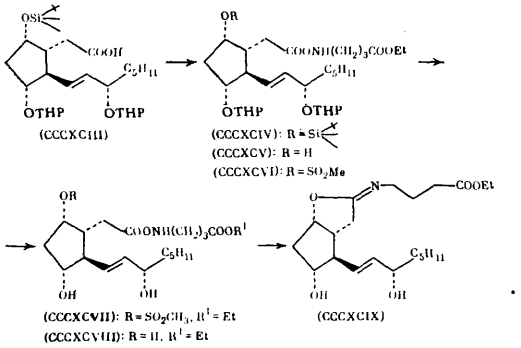


The racemic thiolactam esters (CCCLXXIa, b) are obtained from 4-methoxypyrrolidin-2-one (CCCLXV) via compound (CCCLXVI) and *S*-alkylation of the thiolactam alcohol (CCCLXVII) with ethyl ω-bromobutyrate to the thiaimino-alcohol (CCCLXVIII). After the oxidation of the OH group in compound (CCCLXVIII), the aldehyde (CCCLXIX) is obtained and its condensation with dimethyl 2-oxoheptylphosphonate leads to the enone (CCCLXX). The reduction of the last compound with diisobornyloxyaluminium isopropoxide yields a 1 : 1 mixture of the epimers (CCCLXXIa, b) which can be separated chromatographically (Scheme 32).[88]

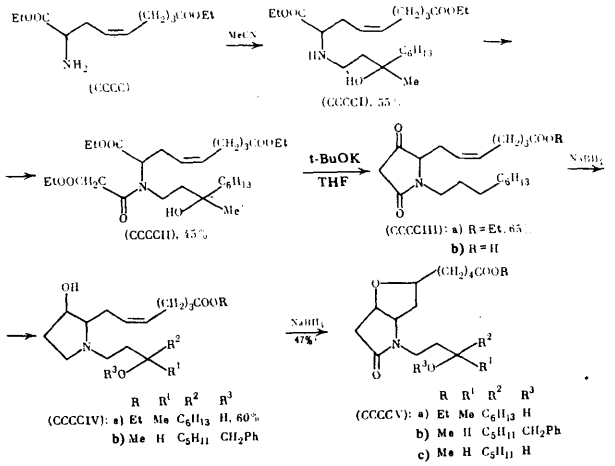


Scheme 32

The synthesis of analogues of *dl*-6-aza-6,9-methano-$PGI_1$ (CCCLXXXV), (CCCLXXXVIII), (CCCLXXXIX), and (CCCXCII) from the anhydride (CCCLXXII), which is converted in 5 stages into the β-ketoester (CCCLXXIII), has been achieved.[89] Reduction of the keto-group makes it possible to obtain compound (CCCLXXIV). By protecting the OH group in compound (CCCLXXIV) and reducing the ester group with DIBAH, one can obtain the alcohol (CCCLXXV), whose oxidation to the aldehyde and subsequent condensation with dimethyl 2-oxoheptylphosphonate give rise to the enone (CCCLXXVI). The reduction of the keto-group in compound (CCCLXXVI) with $NaBH_4$ leads to a mixture of the C(15)-epimers (CCCLXXVII), which is converted, without being isolated, into compound (CCCLXXVIII) and the latter is converted into the diol (CCCLXXIX) by reaction with pyridinium toluene-*p*-sulphonate. The Sarett oxidation of compound (CCCLXXIX) leads to a mixture of two isomeric γ-lactones (CCCLXXXa, b), b) (94%) and their treatment with hydrazine results in the formation of a mixture of the amidoalcohols (CCCLXXXIa, b), whose oxidation gives rise to the imide (CCCLXXXII). The reaction of the imide with 5-aminopentanol leads to the imidoalcohol (CCCLXXXIII), the Sarett oxidation of which affords the imidoacid (CCCLXXXIV). After the removal of the protecting groups in compound (CCCLXXXIV), compound (CCCLXXXV) is obtained. The reduction of compound (CCCLXXXII) leads to the formation of the cyclic amine (CCCLXXXVI), which is converted into the amidoester (CCCLXXXVII) after treatment with glutaric anhydride and esterification with $CH_2N_2$. The removal of the protecting groups in compound (CCCLXXXVII) affords compound (CCCLXXXVIII), whose alkaline hydrolysis leads to compound (CCCLXXXIX). The reduction of compound (CCCLXXXVII) leads to the formation of the aminoalcohol (CCCXC). It is successively oxidised by the Jones' method and esterified with $CH_2N_2$ to the aminoester (CCCXCI) and, after the removal of the protecting groups in the latter, compound (CCCXCII) is obtained (Scheme 33).

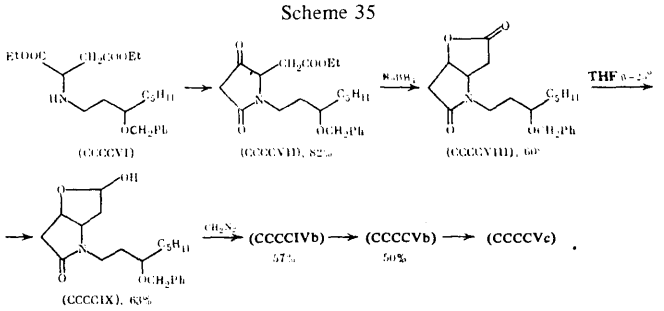


Scheme 33



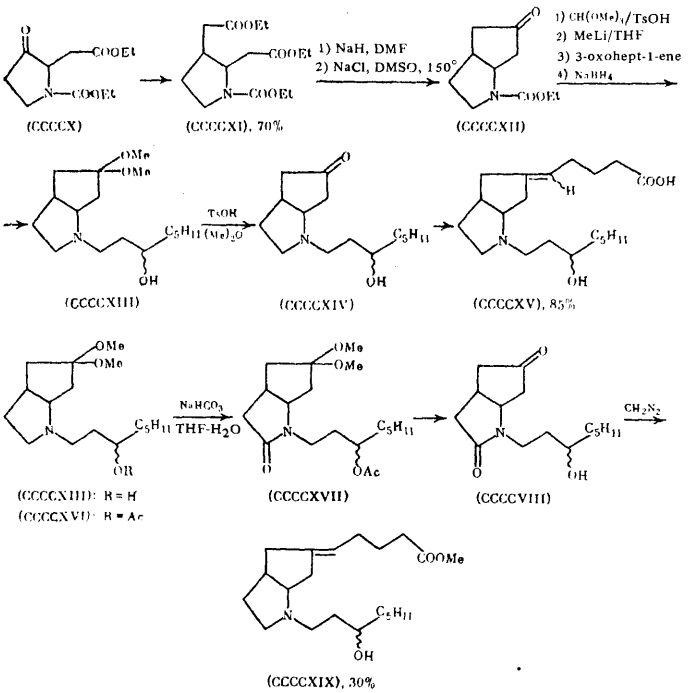
The synthesis of the optically active 5-aza-PC derivative (CCCXCIX) in which the enol ether unit has been replaced by the iminoether system has been described.[90-92] The acid (CCCXCIII) is first converted into a mixture of anhydrides

and the latter are converted by reaction with ethyl 4-aminobutanoate into the amine (CCCXCIV), whose reaction with TBAF produces the alcohol (CCCXCV). Subsequent removal of the protecting groups in the latter leads to the crystalline compound (CCCXCVII) (81%). The interaction of this compound with LiBr ($NaHCO_3$, DMF) leads to a mixture of compounds (CCCXCIX) and (CCCXCVIII), whose separation is the most important stage. Compound (CCCXCVIII) (30%) is isolated from the organic layer by partition between 0.1 *N* citrate buffer (pH 4) and the 4 : 1 ether-dichloroethane mixture. The crystalline compound (CCCXCIX) (51%) is isolated from the aqueous layer by treatment with $Na_2CO_3$ (pH 8) and extraction with $CH_2Cl_2$:



Analogues of 12-aza-PC can be obtained in two ways.[93] The first approach (Scheme 34) is based on the use of the amine (CCCC), whose treatment with 3-methyl-1-(toluene-*p*-sulphonyloxy)nonan-3-ol leads to compound (CCCCI), whose acylation with monoethyl malonate yields compound (CCCCII). The cyclisation of the latter to (CCCCIIIa) and treatment with anhydrous $MgSO_4$ afford compound (CCCCIIIb). Its reduction and treatment of compound (CCCCIVa) with mercury trifluoroacetate followed by reduction make it possible to obtain the 12-aza-PC analogue (CCCCVa).

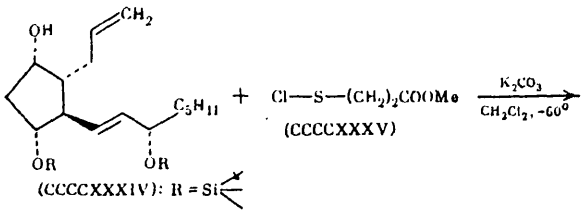
Scheme 34



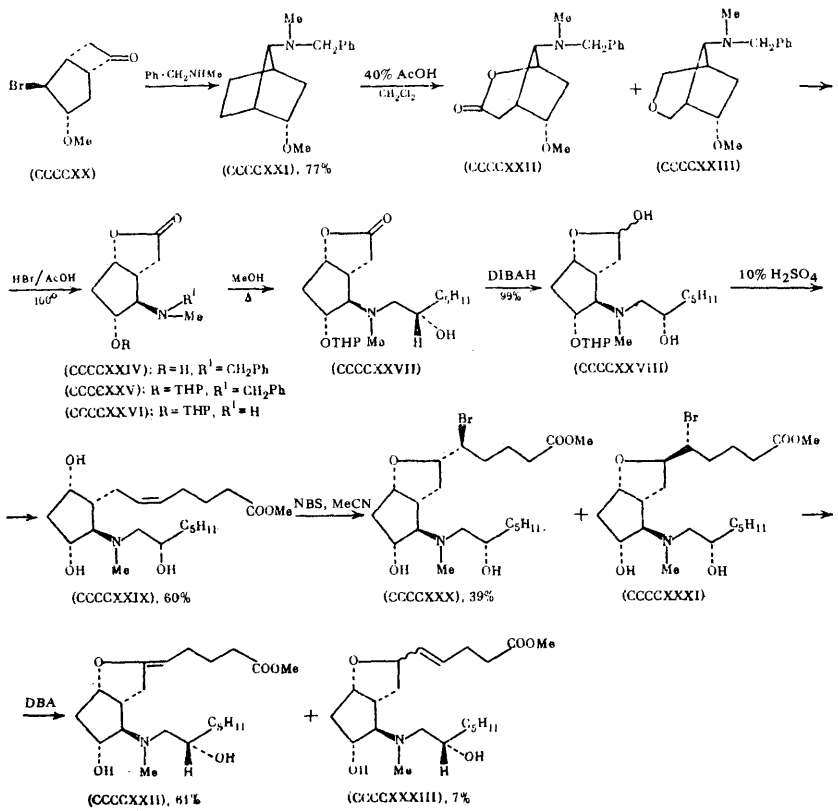
The second approach (Scheme 35) involves the application of the amine (CCCCVI), which is cyclised by the method described above. The potassium salt (CCCCVII) is reduced *in situ* to the bicyclic lactone (CCCCVIII). Its treatment with lithium tri-t-butoxyhydroaluminate leads to the lactol (CCCCIX), whose condensation with 4-CBTP and esterification give rise to compound (CCCIVb). The cyclisation of the latter to compound (CCCCVb) and hydrogenolysis over Pd/C result in the formation of the 12-aza-PC analogue (CCCCVc).

Scheme 35

In the search for anticlotting agents, the 12-azacarba-PC analogues (CCCCXV) and (CCCCXIX) have been synthesised from the common intermediate (CCCCXIII) (Scheme 36).[94] By reaction with $(MeO)_2OPCHNaCOOMe$ and subsequent hydrogenation, compound (CCCCX) is converted into the triester (CCCCXI), which is subjected to Dieckmann cyclisation and decarboxylation to give compound (CCCCXII). The ketone (CCCCXII) is converted into the dimethyl ketal (CCCCXIII) in four stages (overall yield 57%). After the removal of the protecting group in compound (CCCCXIII), the ketone (CCCCXIV) is obtained and condensed with 4-CBTP to form compound (CCCCXV). The intermediates in the synthesis of compound (CCCCXV), necessary for the conversion of the pyrrolidinone ring into a five-membered lactam, are used to synthesise the analogue (CCCCXIX). By protecting the OH group in compound (CCCCXIII) and by oxidising compound (CCCCXVI) with NBS, we obtain the 3-oxo-derivative (CCCCXVII). After the removal of the protecting groups, the hydroxy-ketone (CCCCXVIII) is condensed with the phosphorane to obtain an acid, whose subsequent esterification leads to compound (CCCCXIX).

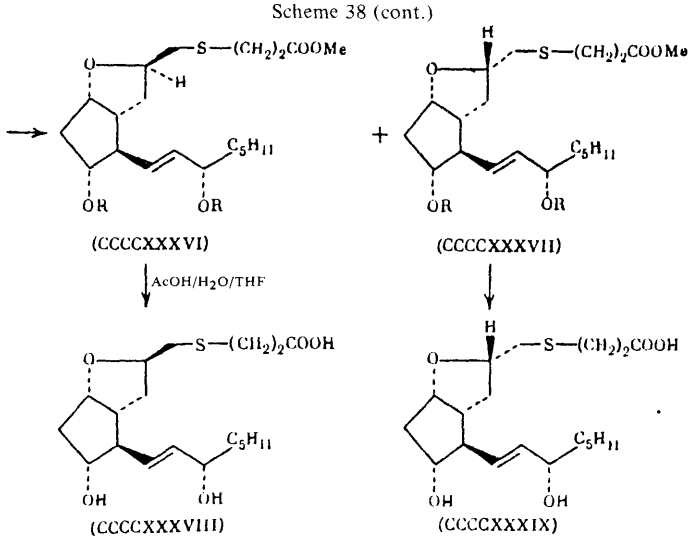


Scheme 36



The stereoselective synthesis of the methyl ester of 13-aza-PC in 10 stages from the readily available 2-*exo*-bromo-3-*endo*-methoxybicyclo[3.2.0]heptan-6-one (CCCCXX) has been described.[95] The heptanone is converted into compound (CCCCXXI) and subjected to Baeyer–Villiger oxidation to give a mixture of the isomeric lactones (CCCCXXII) and (CCCCXXIII). The lactone (CCCCXXII) is kept in a mixture of acids, whereupon the methyl ester is cleaved with the simultaneous rearrangement of the δ-lactone to the γ-lactone (CCCCXXIV) (69%). Compound (CCCCXXIV) is converted via its hydroxy-group into the protected lactone (CCCCXXV). It is then hydrogenated over a Pd catalyst to the secondary amine (CCCCXXVI). The introduction of a ω-chain into this amine is achieved by reaction with (*S*)-pentyl oxide. The reduction of the lactone (CCCCXXVII) to the lactol (CCCCXXVIII), its subsequent condensation with 4-CBTP, and the removal of the protecting groups gives rise to the triol (CCCCXXIX). The hydrochloride of the latter is converted into the bromoesters (CCCCXXX) and (CCCCXXXI) (*endo* : *exo* = 3 : 1, 39%). Dehydrohalogenation of the two isomers after chromatographic separation leads to the methyl ester (CCCCXXXII) and its (4*E*)-isomer (CCCCXXXIII) (Scheme 37).

The addition of the alkanesulphonyl chloride (CCCCXXXV) to the alcohol (CCCCXXXIV) at −60 °C produces the bicyclic thiaesters (CCCCXXXVI) and (CCCCXXXVII). These diaesteroisomers are separated chromatographically and are converted, after the removal of the protecting groups and hydrolysis, into the 4-thia-PCI$_1$ analogues (CCCCXXXVIII) and (CCCCXXXIX) (Scheme 38).[96]



Scheme 38

Scheme 37

Scheme 38 (cont.)

After the review had been prepared for publication, a number of communications on the subject were published. Thus a new method for the construction of the ω-chain, with a stereospecific introduction of the 15α-hydroxy-group, was used in the synthesis of (±)-6,9α-methano-$PGI_3$.[97,98] Corey obtained a satisfactory yield of CC by an intramolecular thermal ene reaction.[99] The synthesis of CC from the key compound 2-(formylmethyl)-1-methylcyclopentane using a rhodium(I) complex has been achieved.[100] A new version of the synthesis of (+)-isocarbacyclin from a chiral substituted Corey's lactone has been developed.[101] In order to investigate biological activity, 6α-carba-$PGI_3$ has been synthesised from (1*S*,2*R*,3*R*,5*R*)-7,7-ethylenedioxy-2-formyl-3-tetrahydropyranyloxybicyclo[3.3.0]octane.[102] A method has been proposed for the synthesis of 13-thia-CC.[103] Cyanocarbacyclins have been synthesised using the stereospecific 1,4-hydrogenation of the corresponding conjugated dienes catalysed by the $ArCr(CO)_3$ complex as the key stage.[104] In the search for new stable and active PC analogues, (5*E*)- and (5*Z*)-(±)-CC were synthesised from cyclopent-2-en-1-one.[105] A synthesis of native (+)-9(*O*)-methano-PC from racemic (1*S**,5*R**)-7,7-ethylenedioxy-3-oxobicyclo[3.3.0]octane has been developed.[106] A simple synthesis of 13,14-didehydro-6,9α-methano-PC via the ethylene ketal of 3-oxotricyclo[$4.3.0.0^{2,4}$]nonan-8-one has been described.[107] A new CC analogue, namely 4,4,5,5-tetradehydro-9(*O*)-methane-$\Delta^{6(9\alpha)}$-$PGI_1$, has been synthesised using the regiocontrolled opening of the β-propyl-lactone ring by reaction with dialkylaluminium acetimide as the key stage.[108] A new synthesis of (+)-6α-CC from *cis*-bicyclo[3.3.0]octane-3,7-dione has been proposed.[109] The methyl ester of (±)-$PGI_2$ and its 15-epimer have been synthesised from 2-(cyclopent-2-enyl)-1-(2-oxocyclopentyl)ethanol.[110] In view of the interest in the antineoplastic properties of PC, the methyl ester of 12,13-didehydro-PC has been synthesised from 7-chloronorbornadiene.[111] A new synthesis of racemic 4-oxo-PC from 7-*endo*-t-butyldimethoxy-6-*exo*[3′(*S**)-butyldimethoxyoct-1′(*E*)-enyl]-3-oxo-2-oxabicyclo[3.3.0]octane† has been described.[112] Synthetic schemes have been devised for imidazoline, furan, thiophen, and pyrrole PC analogues.[113,114]

† The amended name of this compound is tentative since the original authors do not give it a name. The Russian text reads ...7-*endo*-*t*-butyldimethyloxy(BDMS)-6-*exo*-[3′(*S**).(BDMS-oxy)oct-1′(*E*)-enyl]-3-oxo-2-oxabicyclo[3.3.0]-octane [112] [Ed.of Translation].

# Nucleophilic Substitution in β-Heterofunctional αβ-Unsaturated Iminium Salts

V.A.Usov, L.V.Timokhina, and M.G.Voronkov

Data on the hydrolysis, aminolysis, hydrothiolysis, and cyanolysis of β-heterofunctional αβ-unsaturated aliphatic and cyclic iminium salts are described systematically and surveyed. The direction of attack by the nucleophile on the two C-electrophilic centres in these compounds is discussed.
The bibliography includes 81 references.

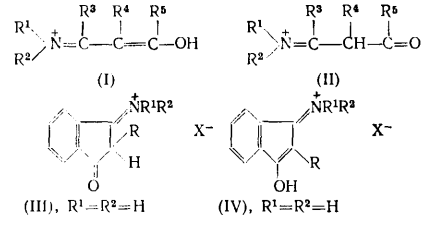
## I. INTRODUCTION

The many-faceted and high reactivity of compounds containing the $Y-\overset{|}{C}=\overset{|}{C}-\overset{|}{C}=\overset{+}{N}\diagdown$ (Y = HO, RO, SH, or Hal) group is of considerable theoretical and practical interest. However, there have been as yet no monographs or reviews devoted to the chemistry of such compounds. There exist only individual publications surveying the methods of synthesis and the properties of certain representatives of this class of substances [Freimanis[1] (p.183) and Liebscher and Hartmann[2]]. This review deals with the available few synthetic studies involving the nucleophilic substitution in β-heterofunctional αβ-unsaturated iminium salts, certain theoretical aspects of these reactions are discussed (in so far as this is allowed by the data obtained), and an attempt is made to assess their preparative importance.

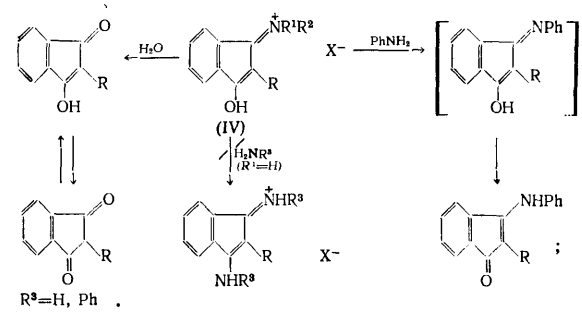
The nucleophilic substitution reactions in activated unsaturated systems proceed in most cases via an "addition–elimination" mechanism.[3-5] Thus, when a charged nucleophile interacts with the $Y-\overset{|}{C}=\overset{|}{C}-\overset{|}{C}=\overset{+}{N}\diagdown X^-$ group, two intermediate adducts, (A) or (B), can be formed depending on the direction of attack [on the C(1) or C(3) atom].



The outcome of the nucleophilic substitution in salts of the given type should apparently be subject to both charge and orbital control and the direction of the reaction should accordingly depend on the "hard–soft" properties of the nucleophile and both electrophilic centres in the substrate. Furthermore, in each specific case one must take into account the influence of the steric and electronic effects of the substituent in the pentad $Y-C(R^1)=C(R^2)-C(R^3)=\overset{+}{N}R^4R^5$, the acid–base properties of the medium, and the effects of solvation, temperature, and reaction time.

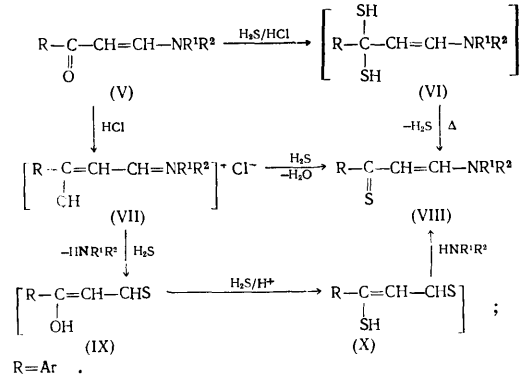
The first attempts to carry out calculations for the cations $Y-\overset{|}{C}=C-C=\overset{+}{N}\diagdown$ by the LCMO PPP method [Freimanis[1] (p.173) and Liebscher and Hartmann[2]] did not permit the elucidation of the specific reactivities of the C(1) and C(3) atoms. In only one investigation[6] was a more far-reaching quantum-mechanical analysis of nucleophilic substitution in 3-hetero-substituted cyclohex-2-ene-1-iminium salts carried out and a conclusion was reached about the preferred direction of the reactions of these salts with nucleophiles from the standpoint of the principle of "hard" and "soft" acids and bases (HSAB). The synthesis of certain new types of organic sulphur compounds became possible on the basis of these ideas.

## II. β-HYDROXY AND β-ALKOXY-IMINIUM SALTS



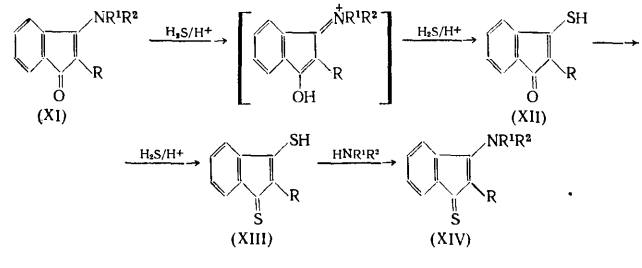
### 1. β-Hydroxyiminium salts

The reactivity of enaminoketones in nucleophilic substitution reactions is fairly low but increases appreciably in the presence of organic[7] or inorganic[8,9] acids. This can be explained by the intermediate formation in acidic media of the corresponding 3-hydroxyprop-2-eneiminium salts (I), which are highly electrophilic. Apart from protonation at the oxygen atom, there is a possibility of the C(2)-protonation with formation of the salt (II) [Freimanis[1] (p.187)]:



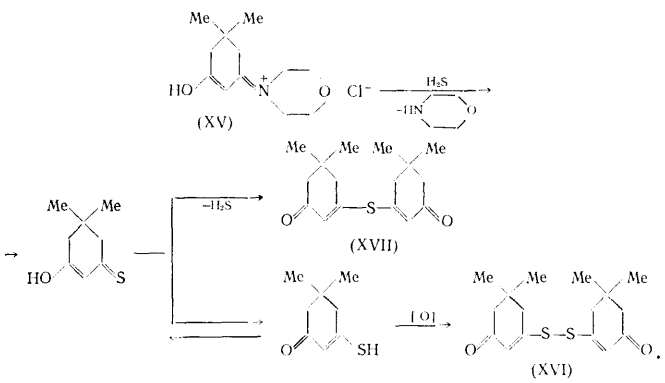
Precisely these two types of salts [compounds (III) and (IV)] were isolated among indene derivatives.[1] The form (III) is the most stable in the crystalline state. However, the reactions of enamines proceed as a rule in highly polar media, i.e. under conditions favourable for the existence of more polar tautomers—3-hydroxyind-2-eneiminium salts (IV).

Their behaviour has been investigated in hydrolysis and aminolysis reactions:[10]



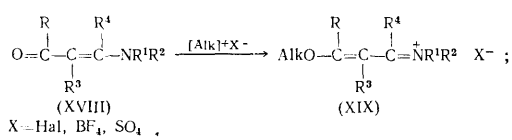
The preferred site of attack by the nucleophile in the salts (IV) is the $C=\overset{+}{N}$ bond. The explanation is that the solvated hydroxy-group is appreciably shielded and the nucleophilic species is directed towards the other electrophilic centre in the molecule.[10]

It has been suggested[1] that the hydrothiolysis of enaminoketones, which is usually carried out in alcoholic media in the presence of HCl, HF, or $H_2SO_4$, also proceeds via the intermediate hydroxypropeneiminium salt (VII). The second possible version of this reaction is believed to involve the intermediate formation of the *gem*-dithiol (VI).[11] Accordingly, the interaction of, for example, 1-aryl-3-(*NN*-dialkylamino)-1-propenones (V) with hydrogen sulphide in an alcoholic HCl solution[11–14] can be represented schematically as follows: (V) → (VI) → (VIII) and (V) → (VII) → (VIII).

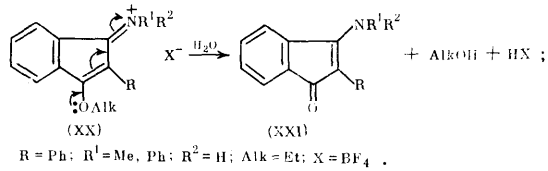


Bearing in mind the ability of various enaminoketones to form iminium salts with protic acids,[1,15,16] preference may be given to the intermediate (VII). However, the direct transformation (VII) → (VIII) is doubtful, since the reaction of 2-aryl-3-(*NN*-dialkylamino)-1-indenones (XI) with hydrogen sulphide in the presence of HCl in alcoholic media is accompanied by the thiolysis of the amino-group with formation of the mercaptoindenones (XII):[17]

Under the same conditions, compounds (XII) are converted into the β-dithiodiketones (XIII),[18] which readily react with highly basic amines to form the enaminothioketones (XIV).[19] For the same reason and also bearing in mind the mode of hydrothiolysis of the iminium salts,[6,20-23] one must postulate the more complex reaction scheme (V) → (VII) → (IX) → (X) → (VIII), which accounts for the low yield of the enaminothioketones (VIII) (3–10%).

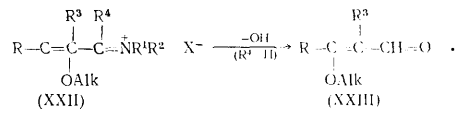


When 3-hydroxy-5,5-dimethylcyclohex-2-ene-1-*N*-morpholinium chloride (XV) reacts with hydrogen sulphide at −60 °C in dimethylformamide (DMF), the disulphide (XVI) and the sulphide (XVII) are present in the reaction mixture. Their formation indicates the attack by the nucleophile on the C=N̊ bond. The process probably proceeds in accordance with the mechanism[24]

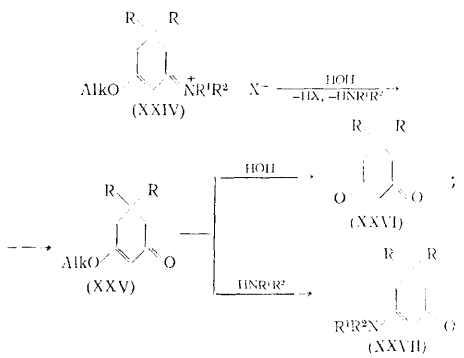


The benzeneiminium analogue of the salt (XV) does not react with hydrogen sulphide in the range from −60 °C to 15 °C, which indicates the low electrophilicity of this salt.

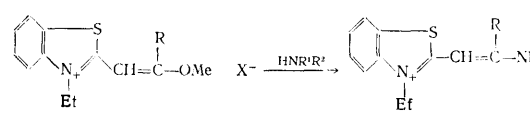
## 2. β-Alkoxyiminium Salts



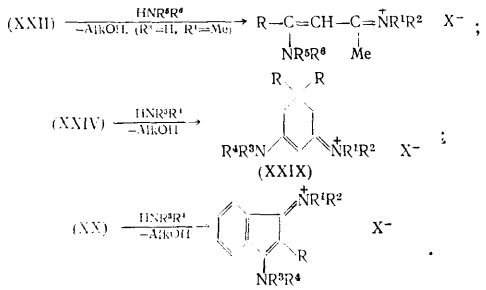
The salts (XIX) containing the β-alkoxypropeneiminium group are obtained by alkylating the corresponding enaminoketones (XVIII) by alkyl halides, dialkyl sulphates, or triethyloxonium tetrafluoroborate:[1]



*Hydrolysis.* The salts containing the β-alkoxypropeneiminium group are much more sensitive to hydrolysis than the corresponding bases. Thus the tetrafluoroborates of 1-imino-3-ethoxyindenes (XX) are converted into the aminoindenones (XXI) even in the presence of traces of moisture.[25] The high lability of the salt (XX) can be explained by the increased electrophilicity of the C(3) atom in the cation induced by the strong electron-accepting effect of the iminium group. With increase of the latter, the stability of compounds (XX) falls. For example, the *N*-methyl-substituted salt (XX) initially dissolves in water and only then the enaminoketone (XXI) is formed. On the other hand, the *N*-phenyl-substituted compound (XX) is very hygroscopic and can be purified only in the form of the hydrolytically more stable free base:

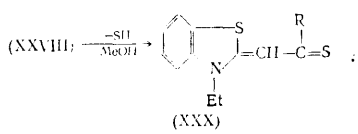


It was believed that salts of type (XX) are hydrolysed exclusively at the C(3)–O bond.[1] However, this is apparently true only for the hydrolysis of such compounds in neutral and acid media. Thus, when the salt (XXII) was treated with aqueous alkali, the aldehyde (XXIII), which is a product of the hydrolysis at the C(1) atom, was isolated:[26]

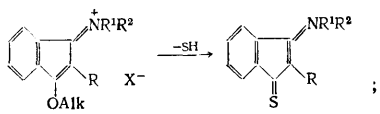


The hydrolysis of 3-alkoxycyclohex-2-ene-1-iminium salts (XXIV) in the presence of triethylamine at 20 °C also takes place at the C(1)=N̊ bond with elimination of amines and the formation of 3-alkoxycyclohex-2-en-1-ones (XXV).[27] After prolonged storage or heating of the reaction mixture, the product of further hydrolysis, namely the diketone (XXVI), and also the enaminoketone (XXVII) are formed. The latter is apparently obtained as a result of the reaction of the alkoxyketone (XXV) with the eliminated amine, which has been confirmed by the reaction of compound (XXV) with piperidine [the aminolysis of dimedone (XXVI) takes place under more severe conditions[28]]:

*Aminolysis.* The reactions of salts containing the β-alkoxypropeneiminium group with amines were first achieved for substituted benzothiazolium salts (XXVIII),[29] this being the only possible mode of reaction:



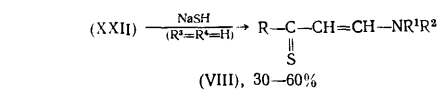
The aminolysis of other salts (aliphatic,[26,29] alicyclic,[23,28,30] and indene[31] salts) also takes place at the C(3)–O bond. These reactions are of great preparative importance for the synthesis of enaminoimines.[1] Other conditions being equal, the indene derivatives react more readily. This can be explained by the increased electrophilicity of the aryl substituent and hence by the greater reactivity of the C(3) atom. The reactions of aliphatic salts (XXII), the cyclohexene salts (XXIV), and the indene salts (XX) with 1,4-phenylenediamine in alcoholic media provide a clear example:[31]



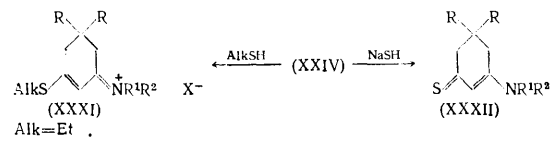
The rate of reaction depends on the basicity of the amine. Thus the reactions of *O*-alkyl derivatives of the cyclohexene enaminoketones (XXIV) with pyrrolidine in methanol take place instantaneously with evolution of heat and lead to the corresponding enaminoimine (XXIX) in a high yield (92%); the interaction of this salt with the less basic diethylamine is slow (48 h).[28]

In the aminolysis of salts with the 3-alkoxypropeneiminium group, the reaction involving the second electrophilic centre, namely the C(1) atom, was not observed. However, the overall data for the reactions of these compounds as well as their thio-analogues[32,33] with nucleophiles do not rule out the possibility of the amine exchange at the C(1) atom under certain conditions.

*Hydrothiolysis and alkanethiolysis.* When substituted benzothiazolium salts (XXVIII) react with alkali metal hydrogen sulphides, the alkoxy-group is readily substituted by the mercapto-group with formation of the enaminothioketones (XXX).[29] Subsequently this reaction became one of the preparative methods for the synthesis of enaminothioketones:

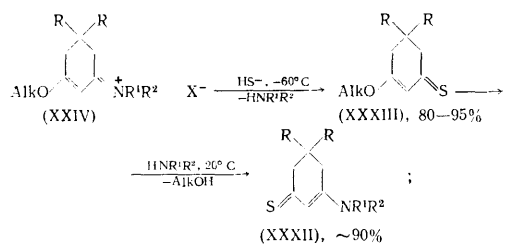


When 2-aryl-3-ethoxyindene-1-iminium tetrafluoroborates (XX) were heated with sodium hydrogen sulphide in methanol, a series of 3-amino-2-arylindene-1-thiones (XIV) were obtained.[34] The *N*-unsubstituted aminothioketones (XIVa–c) are formed in 55–74% yield. The yield of *N*-monoalkyl-substituted 3-amino-2-phenylindene-1-thiones (XIVe, f) is 31 to 38% and that of 2-phenyl-3-piperidinoindene-1-thione (XIVi) is below 30%. These data suggest that the reaction of the tetrafluoroborate (XX) and particularly that of the *NN*-disubstituted derivative (XXi) with sodium hydrogen sulphide can be determined to a large extent also by the attack of the *S*-nucleophile on the C=N bond with a subsequent wide range of different reactions:



a) R=Ph, $R^1$=$R^2$=H; b) R=4-$MeOC_6H_4$, $R^1$=$R^2$=H; c) R=4-$ClC_6H_4$, $R^1$=$R^2$=H; d) R=1-$C_{10}H_7$, $R^1$=$R^2$=H; e) R=Ph, $R^1$=Me, $R^2$=H; f) R=Ph, $R^1$=$PhCH_2$, $R^2$=H; g) R=1-$C_{10}H_7$, $R^1$=Me, $R^2$=H; h) R=1-$C_{10}H_7$, $R^1$=$PhCH_2$, $R^2$=H; i) R=Ph, $R^1R^2$=$(CH_2)_5$;
Alk=Et; X=$BF_4$ .

The reactions of the salts (XXII) with sodium hydrogen sulphide are used to obtain aliphatic enaminothioketones (VIII):[35]



*N*-Monosubstituted 3-ethoxy-5,5-dimethylcyclohex-2-ene-1-iminium salts (XXIV, $R^1$ = H; $R^2$ = Me or Ph; X = $BF_4$) react with sodium hydrogen sulphide in absolute alcohol at 20 °C to form a complex mixture of sulphur compounds, the corresponding enaminothioketones (XXXII) being obtained in a low yield (~9%):[36]

Treatment of 3-ethoxy-5,5-dimethylcyclohex-2-ene-1-pyrrolidinium iodide [XXIV, $R^1R^2$ = $(CH_2)_4$; X = I] with ethanethiol in methanol in the presence of sodium methoxide at 25 °C led to a salt of the ethylthio-derivative (XXXI)† in 66% yield.[30]

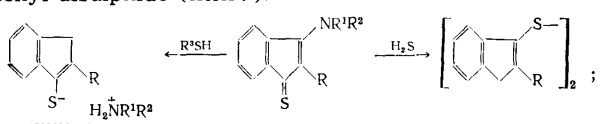
In the instances of hydrothiolysis described above, the attack by the nucleophile on the C(3) atom in the propene fragment predominates. However, a recent systematic investigation of the hydrothiolysis of iminium salts with the cyclohexene skeleton led to a new idea about the mode of nucleophilic substitution in salts containing the 3-alkoxy-, 3-alkylthio-, and 3-chloropropeneiminium groups.[6,20–23] The results cast doubt on the apparently self-evident nature of the reaction of the $HS^-$ anion at the C(3) atom in the compounds investigated.

Thus the study of the interaction of 3-alkoxycyclohex-2-ene-1-iminium salts (XXIV) with hydrogen sulphide or metal hydrogen sulphide at a low temperature established that the conversion of the initial compound (XXIV) into the enaminothioketones (XXXII) is a two-stage process:[23]

R=H, Me; $R^1$=H, Alk, $-(CH_2)_n-$;
$R^2$=H, Alk, $-(CH_2)_n-$, Ar; X=$BF_4$, I .

The first stage, namely the hydrothiolysis of the C(1)=N bond and not the C(3)–O bond as was assumed previously, takes place at −60 to −40 °C and leads to previously unknown 3-alkoxycyclohex-2-ene-1-thiones (XXXIII) in a high yield. The second stage, namely the aminolysis of the stable intermediate (XXXIII), takes place at the C(3)–O bond and at 20 °C leads rapidly to a high yield of the enaminothioketones (XXXII).

The salts (XXIV) react with hydrogen sulphide only in a dipolar aprotic solvent [DMF, dimethyl sulphoxide (DMSO), hexamethylphosphoramide (HMP), and pyridine], known to



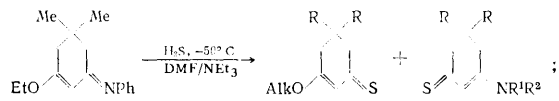
†One must bear in mind that the effective radius of the $EtS^-$ anion is much greater than that of the $HS^-$ anion[6] and that this may be responsible for the attack of the former on the sterically less hindered C–O bond.

be capable[37] of solvating the cations selectively and weakening the $H^+-{}^-SH$ bond, which increases the nucleophilicity of the hydrogen sulphide anion. Furthermore, the rate of nucleophilic substitution reactions is greatly influenced by the specific solvation of the anion.[38] The lower the degree of solvation of the anion, the higher its nucleophilicity and reactivity. Protic solvents solvate anions especially effectively owing to the tendency towards the formation of hydrogen bonds. In dipolar aprotic solvents the anions are less effectively solvated, i.e. here they behave as "true nucleophiles". In view of the necessary reaction temperature, a suitable solvent for the reaction (XXIV) → (XXXIII) is DMF.[6] The addition of a highly basic amine accelerates the process significantly and tends to increase the yield of the required product (XXXIII).

In a protic solvent (methanol, ethanol) the salts (XXIV) do not react with hydrogen sulphide at temperatures between −60° and 20 °C. When triethylamine or piperidine is added to the reaction mixture, only traces of compound (XXXIII) are formed. The salts (XXIV) react with sodium hydrogen sulphide in accordance with the scheme (XXIV) → (XXXIII) → (XXXII) both in DMF and in absolute methanol.[6,23]

At 20 °C, i.e. without the isolation of the intermediate (XXXIII), the reaction (XXIV) → (XXXII) terminates with a relatively low (~10%) yield of the enaminothioketone (XXXII). In this case the amine formed in the first stage is largely bound by the eliminated acid ($HBF_4$, $HClO_4$, HI) and hydrogen sulphide, which prevents the rapid occurrence of the subsequent reaction (XXXIII) → (XXXII).[6]

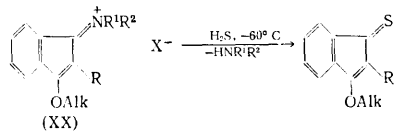
The reaction of 3-ethoxy-5,5-dimethylcyclohex-2-ene-1-*N*-piperidinium tetrafluoroborate [XXIV; R = Me; $R^1R^2$ = $(CH_2)_5$; Alk = Et; X = $BF_4$] with sodium hydrogen sulphide at 20 °C leads to the formation of a mixture of two thioketones (XXXII) and (XXXIII).[6,23] When the reaction is carried out in DMF at −60 °C with equimolar proportions of the initial compounds, the ethoxythioketone (XXXIII; Alk = Et) is formed preferentially, but, in the course of the treatment of the reaction mixture, it is almost fully converted into the enaminothioketone [XXXII; $R^1R^2$ = $(CH_2)_5$]. On the other hand, if acetic acid, which reduces the reactivity of piperidine, is added to the reaction mixture before this happens, it is possible to isolate the ethoxythione (XXXIII) in 54% yield. The yield of the enaminothioketone (XXXII) also depends on the competing reactions of compounds (XXXII) and (XXXIII) with *S*-nucleophiles. For example, the indene analogues (XIV) of compounds (XXXII) are readily reduced by thiols or hydrogen sulphide, forming the thiolates (XXXIV) [39] or bisindenyl disulphide (XXXV):[34]



(XXXIV) (XIV) (XXXV)

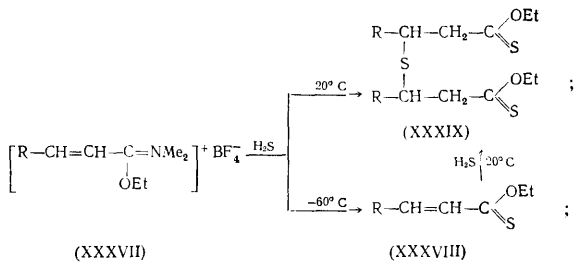
R=Ph; $R^3$=Bu, Ph, H .

The multistage reaction (XXIV) → (XXXIII) → (XXXII) is followed by TLC and spectrometrically. For example, it has been found that, for R = OMe, $R^1R^2$ = $(CH_2)_2O(CH_2)_2$, $R^3$ = Me, and X = I, the above process is accompanied by the consecutive bathochromic and then hypsochromic shifts of the long-wavelength absorption band in the electronic spectrum—the colourless solution becomes raspberry-red and then yellow: $\lambda_{max}$ = 286 nm ($\lg\varepsilon$ = 3.8) → $\lambda_{max}$ = 498 nm ($\lg\varepsilon$ = 4.6) → $\lambda_{max}$ = 386 nm ($\lg\varepsilon$ = 4.4).[6]



It must be emphasised that the hydrothiolysis of only the *NN*-disubstituted iminium salts (XXIV) at a low temperature leads exclusively to compounds (XXXIII).[6] The *N*-monosubstituted salts (XXIV) react with hydrogen sulphide in DMF in the presence of triethylamine to form a mixture of products containing small amounts of the alkoxythioketone (XXXIII) and the corresponding enaminothioketone (XXXII). This can be explained by the fact that in basic media the *N*-monosubstituted salts (XXIV) are deprotonated and are readily converted into the less reactive bases with the RO−C=C−C=N− group. Their hydrothiolysis can take place at the C(1) and (or) C(3) atoms[1] and should require more severe conditions. Thus a long time is required for the completion of the reaction of 3-ethoxy-5,5-dimethyl-1-phenylcyclohex-2-ene (XXXVI) with hydrogen sulphide; ultimately a mixture of products containing the ethoxythioketone (XXXIII) and the N-phenyleneaminothioketone (XXXII) is formed:[23]

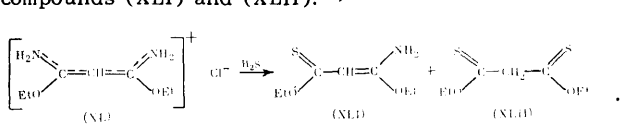
(XXXVI) (XXXIII) (XXXII)



R=Me, $R^1$=H, $R^2$=Ph, Alk=Et .

The results of the hydrothiolysis of the cyclohexeneiminium salts (XXIV) have been confirmed in relation to the indene compond (XX):[40]

(XX)

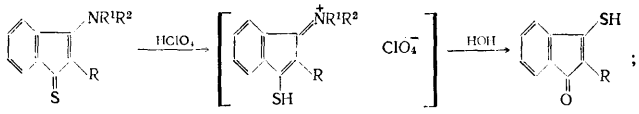


The hydrothiolysis of 1-alkoxyprop-2-eneiminium salts (XXXVII), the structural isomers of substituted cyclohexenes (XXIV), which takes place at −15 °C in a mixture of anhydrous ether and pyridine, is remarkable from this point of view. This reaction proceeds with elimination of the amine and retention of the C−O bond. Whereas at −60 °C the hydrothiolysis of the salt (XXXVII; R = Me) leads to compound (XXXVIII), the sulphide (XXXIX) was isolated at 20 °C. The latter is formed as a result of the addition of hydrogen sulphide to the C=C bond and subsequent intermolecular condensation:[41,42]

(XXXVII) (XXXVIII)

R=Me, Ph .

The reactions of the salts (XL) with hydrogen sulphide in a methanol–pyridine mixture proceed analogously with formation of compounds (XLI) and (XLII):[41,43]

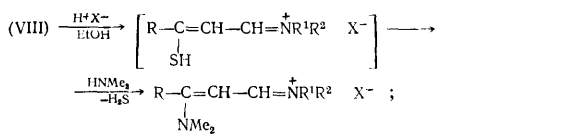


(XL) (XLI) (XLII)

## III. β-MERCAPTO- AND β-ALKYLTHIO-IMINIUM SALTS

### 1. β-Mercaptoiminium Salts

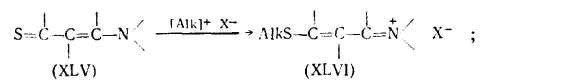
Stable 3-mercaptoprop-2-eneiminium salts and their cyclic analogues are known. It has been shown by $^1$H NMR [44] that 3-(*NN*-dimethylamino)-2-phenyl-1-indenethione (XIV) is



protonated by perchloric acid in acetone with formation of a solution of 3-mercapto-*NN*-dimethyl-2-phenylindene-1-iminium perchlorate (XLIII). The latter hydrolyses at the C=N bond and is converted into 3-mercapto-2-phenyl-1-indenone (XII):

(XIV) (XLIII) (XII), 80%

R=Ph; $R^1=R^2=Me$ .

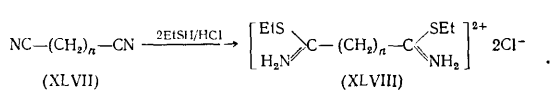


A mechanism has been proposed for the aminolysis of 3-aminoprop-2-enethione (VIII) in an acid medium at 20 °C, in which the intermediate formation of the 3-mercaptoprop-2-eneiminium salt (XLIV) is postulated:[11]

$R^1=R^2=Me$ .

## 2. β-Alkylthioiminium Salts

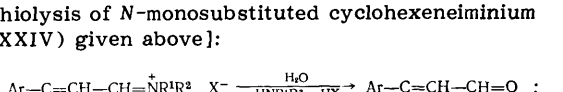
The salts (XLVI), containing the β-alkylthiopropeneiminium group, are obtained from the corresponding enaminothioketone (XLV) using the same alkylating agents as in the synthesis of their 3-alkoxy-analogues (see above). Methyl fluorosulphonate is used for this purpose:[45]



(XLV) (XLVI)

X=Hal, $BF_4$, $FSO_3$, $SO_4$ .

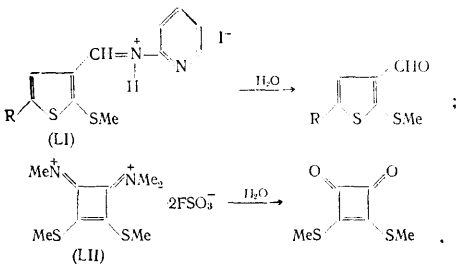
Stable salts of the propene,[46,47] indene[48] and cyclohexene[6] series and the thio- and dithio-esters of squaric[49] and dicarboxylic[43] acids have been synthesised in this way in high yields. Enaminothioketones are alkylated regiospecifically and more readily than enaminoketones.[21,48]



Dicarboxylic acid thioesters (XLVIII) are also obtained by the reaction of the corresponding dinitriles (LXVII) with ethanethiol and hydrogen chloride:[43,50]

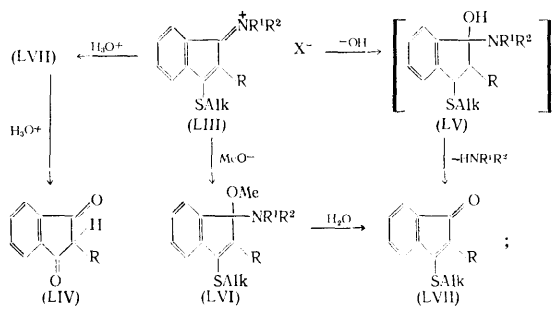
(XLVII) (XLVIII)

*Hydrolysis.* The few studies which have been made on the hydrolysis of β-alkylthio-substituted αβ-unsaturated iminium salts nevertheless embrace compounds of various classes, which makes it possible to discover a general feature of the process—the direction of attack by the hydroxide ion on the C=N bond.



The hydrolysis of *NN*-disubstituted 3-methylthioprop-2-eneiminium salts (XLIX) leads to the corresponding β-alkylthioaldehydes (L).[46,47,51] The *N*-monoaryl-substituted iodides (XLIXb) are hydrolytically stable [cf. data on the hydrothiolysis of *N*-monosubstituted cyclohexeneiminium salts (XXIV) given above]:

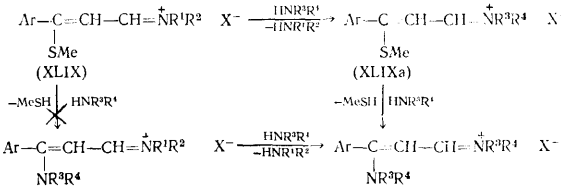
(XLIX) (L)



Ar=Ph, 4-$ClC_6H_4$, 4-$MeOC_6H_4$; $R^1R^2=(CH_2)_4$, $(CH_2)_5$, $(CH_2)_2O(CH_2)_2$ (a); $R^1=H$, $R^2=Ar$ (b); X=I .

The salts of the thiophen series (LI)[52] as well as derivatives of squaric acid (LII) are hydrolysed analogously:[45]

(LI) (LII)

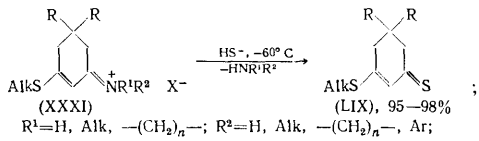


The hydrolysis of 3-alkylthio-2-phenylindene-1-*NN*-dimethyliminium salts (LIII) has been studied in greatest detail.[48] Alkaline hydrolysis in DMF leads to their ready conversion into 3-alkylthio-2-phenyl-1-indenones (LVII). The *gem*-alcohols (LV) are probably intermediates in this reaction, since the corresponding *gem*-methoxyamino-derivatives were isolated on methanolysis of the salt (LIII). Their hydrolysis leads to the alkylthioketones (LVII). The final product of the acid hydrolysis of the salt (LIII), which proceeds via the formation of the alkylthioketones (LVII), is 2-phenyl-1,3-indandione (LIV):[48]

(LIV) (LVI) (LVII)

R = Ph; $R^1=R^2=Me$ .

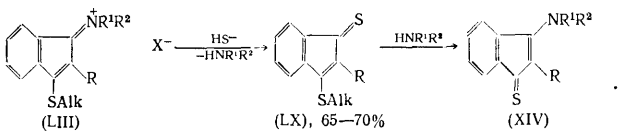
*Aminolysis.* 3-Alkylthiopropeneiminium salts (XLIX) react with alkyl- and aryl-amines to form the salts of enaminoimines with identical substituents at different nitrogen atoms [compounds (LVIIIa)].[32,33] Of the two possible reactions (XLIX) → (LVIII) → (LVIIIa) and (XLIX) → (XLIXa) → (LVIIIa), the latter occurs.[32] The sequence of reaction stages (transamination–substitution) has been demonstrated by the reaction of compound (LVIIIa; Ar = 4-$MeOC_6H_4$; $R^3=R^4=Et$; X = $ClO_4$) with an excess of dimethylamine. It was found that the reaction of the resulting asymmetrically substituted salt [4-$MeOC_6H_4$–$C(NMe_2)$=CH–CH=$NEt_2$]$^+ClO_4^-$ dimethylamine, modelling the stage (LVIII) → (LVIIIa), does not take place:



(XLIX) (XLIXa) (LVIII) (LVIIIa)

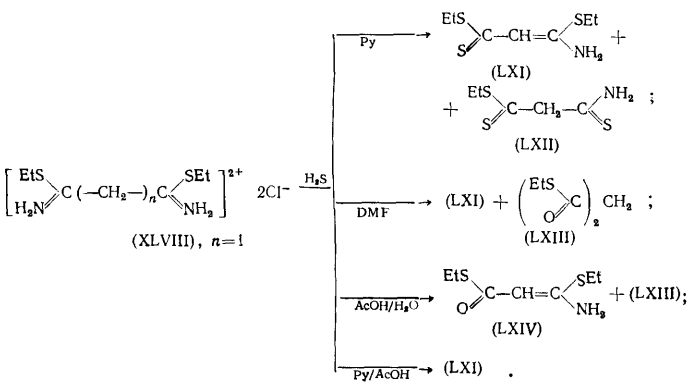
Ar=Ph, 4-$MeOC_6H_4$; $R^1=R^2=Alk$; $R^3=R^4=Alk$ или $R^3$ = H, $R^4$ = Ar; X = $ClO_4$, I .

When the salts (XLIX) are acted upon by arylamines in ethanol, the transamination products (XLIXa) are formed in 90% yield. The methylthio-group is exchanged for the amino-group [(XLIXa) → (LVIIIa)] only in acetic acid.[33] The perchlorates (XLIX; Ar = Ph or 4-$MeOC_6H_4$; X = $ClO_4$) form

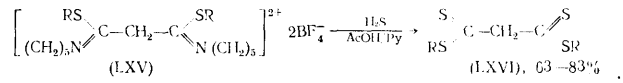


the corresponding enaminoimines (LVIIIa) in a high yield (up to 88%). On the other hand, the enaminoimine salts (LVIIIa) are obtained from the analogous iodides (XLIX) in a yield not exceeding 38%.

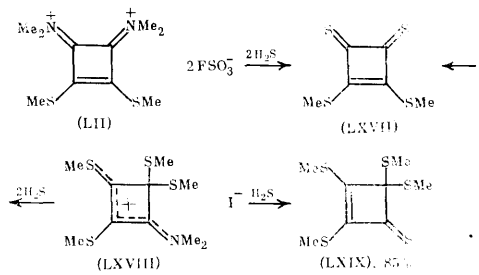
*Hydrothiolysis.* The study of the reactions of β-alkylthio-substituted αβ-unsaturated iminium salts with sulphur-containing nucleophiles was first undertaken in relation to cyclohexene derivatives.[6,21] 3-Alkylthiocyclohex-2-ene-1-iminium salts (XXXI) react with hydrogen sulphide in DMF in the presence of triethylamine at −60 °C via the C=N bond (see above), similarly to the 3-alkoxy-derivatives, forming 3-alkylthiocyclohex-2-ene-1-thiones (LIX). These compounds contain the little known structural fragment AlkS−C=C−C=S:



$R^1$=H, Alk, $-(CH_2)_n-$; $R^2$=H, Alk, $-(CH_2)_n-$, Ar; X=$BF_4$, I .

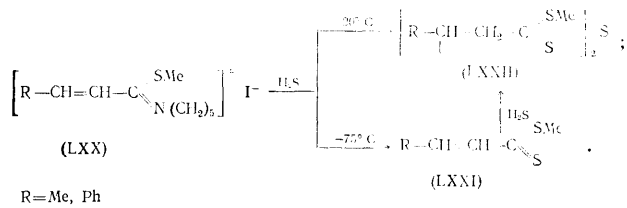


3-Alkylthio-2-arylindene-1-iminium salts (LIII) react with hydrogen sulphide in methanol at 20 °C to form 3-alkylthio-2-arylindene-1-thiones (LX). When the salt (LIII) is treated with sodium hydrogen sulphide, the corresponding enaminothioketones (XIV) are formed rapidly in accordance with the scheme (LIII) → (LX) → (XIV):[48]



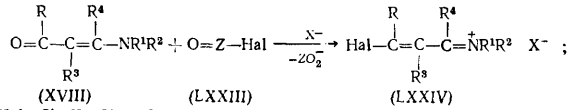
The hydrothiolysis of the dihydrochloride of *SS*-diethylpropanedithiodiimidic acid (XLVIII) has been investigated in detail.[50] This salt does not interact with liquid hydrogen sulphide at −78 °C, while at 20 °C in pyridine, DMF, DMSO, or acetic acid, several compounds (LXI)–(LXIV) are formed in yields ranging from 20 to 40%, which indicates the non-regiospecificity of the hydrothiolysis. The formation of the carbonyl compounds (LXIII) and (LXIV) has been explained[50] by the hydrolysis of the initial dihydrochloride (XLVIII) as a result of the treatment of the reaction mixture with an aqueous solution of sodium bicarbonate:

*N*-Unsubstituted salts (XLVIII) react with hydrogen sulphide in a pyridine–acetic acid mixture, retaining one amino-group, while their piperidine analogues (LXV) lose both amino-groups under these conditions and give rise to the ester of the bisdithiocarboxylic acid (LXVI):[41]



The hydrothiolysis of both dimethylamino-groups in methylthiocyclobut-2-ene-1,4-bis-*NN*-dimethyliminium bisfluorosulphonate (LII) proceeds readily. The product of this reaction is 2,3-bis(methylthio)cyclobut-2-ene-1,4-dithione (LXVII), whose chemical properties have been vigorously investigated:[49,53]

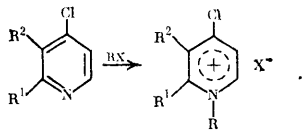
The hydrothiolysis of 2,3,4,4-tetrakis(methylthio)cyclobut-2-ene-1-*NN*-dimethyliminium iodide (LXVIII) either proceeds immediately via two pathways to the dithiodiketone (LXVII) or the reaction involves only the iminium group, which leads to the monothioketone (LXIX).[53]



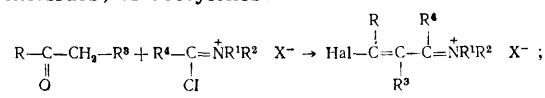
1-Methylthioprop-2-ene-1-piperidinium iodide (LXX), which is a structural isomer of the 3-alkylthioprop-2-ene-1-iminium salts (XLIX), reacts with hydrogen sulphide in a tetrahydrofuran (THF)—pyridine mixture at −75 °C, forming methyl dithiocinnamate (LXXI).[42] The sulphide (LXXII) has been obtained at 20 °C by the reaction of compound (LXX) with hydrogen sulphide (cf. the reaction described in Section III, 2 above):

R=Me, Ph

## IV. β-HALOGENOIMINIUM SALTS



There exist two main synthetic approaches to the preparation of β-halogeno-substituted αβ-unsaturated iminium salts (LXXIV).[2] The first is based on the corresponding modification of the C(1)- and C(3)-structural elements in the initial compound with the propene group. The second involves the construction of the propene skeleton of the salt from suitable components containing the C(1)- and C(2)-, C(3)-fragments of the required compound. Halogenoiminium salts are obtained by the first method as a result of the interaction of β-aminovinylcarbonyl compounds (LXXX) with various chlorinating agents (LXXIII) ($POCl_3$, $COCl_2$, $SO_2Cl_2$, and ClCOCOCl) or even with $PCl_5$. Treatment with the analogous brominating agents leads to the corresponding bromo-substituted salts. Compounds (XVIII) and (LXXIII) vary structurally within relatively wide limits:[28]

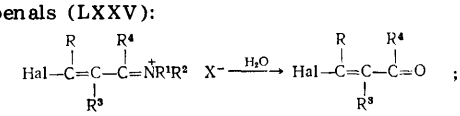


(XVIII) (LXXIII) (LXXIV)

Hal=Cl; X=Cl, $ClO_4$, $OPOCl_2$ .

The first method is also used to synthesise substituted pyridinium salts by alkylating 4-chloropyridines:[2]

In the synthesis of 3-chloroprop-2-eneiminium salts (LXXIV) via the formation of the C(1)–C(2) bond, one uses methyleneketones and the salts of imidoyl chlorides, mainly formimidoyl chloride, or even the phosgeneiminium salt, whose mobile chlorine atom is readily substituted by a nucleophile.[2] The initial methylenecarbonyl compound can be replaced, for example, by enamines, enol ethers, acetals, vinyl chlorides, or acetylenes:[2]

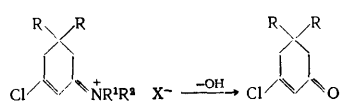


(LXXIV)

$R^4$=H, Cl; Hal=Cl .

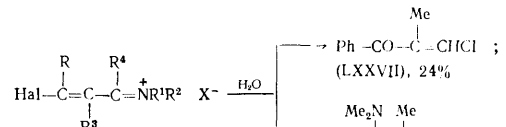
The second method is of the greatest synthetic importance. However, the first method is so far the only one available in many instances, for example, for cyclic derivatives.

*Hydrolysis.* Little information is available about the hydrolysis of 3-halogenoprop-2-eneiminium salts and their cyclic analogues.[54–56] 3-Halogeno-prop-2-ene-1-*NN*-dimethyliminium salts (LXXIV) are hydrolysed with retention of the C–Hal bond, which leads to the formation of 3-halogenopropenals (LXXV):



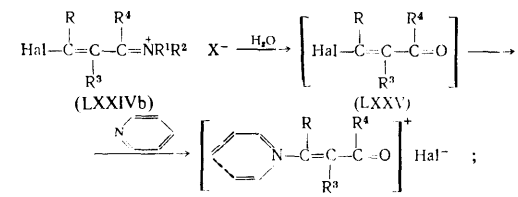
(LXXIV) (LXXV)

$R^4$=H; Hal=Br, Cl; X=Cl, $ClO_4$, $OPOCl_2$, *o*-$MeC_6H_4SO_2O$ .



The nature of the substituents R and $R^3$ has a marked effect on the hydrolytic stability of the salts (LXXIV). The salts (LXXIV; $R^1$ = H or Me; $R^3$ = H), which have no substituents at the central carbon atom, are distinguished by an extremely high stability in aqueous solution, which can be accounted for[56] by the high degree of conjugation in the pentad fragment.

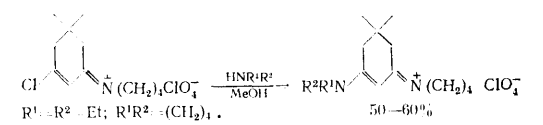
The salts (LXXIV) having substituents R with a large effective volume (R = Ph or t-Bu) and $R^3$ = H are readily hydrolysed on refluxing with an aqueous solution of sodium acetate. 3-Chlorocyclohex-2-ene-1-pyrrolidinium perchlorate (LXXVI) is also hydrolysed at the C=N̂ bond on heating in methanol to which a 10% NaOH solution has been added:[28]



(LXXVI) 95%

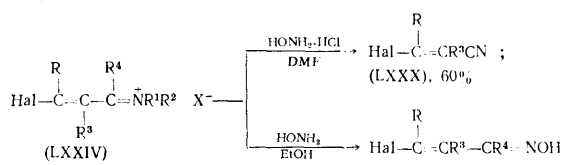
3-Chloro-2-methyl-1-phenylprop-2-ene-1-*NN*-dimethyliminium chloride (LXXIVa) is hydrolysed via two pathways with formation of 3-chloro-2-methyl-1-phenylprop-2-en-1-one (LXXVII) and more than 50% of the aldehyde (LXXVIII). The low yield of the ketone (LXXVII) can be accounted for by steric hindrance, which prevents the hydrolysis of the C=N̂ bond:[54]

(LXXIVa), R=H, $R^1$=$R^2$=$R^3$=Me, $R^4$=Ph, Hal=X=Cl .



Treatment of the 3-chloro-3-(4-tolyl)prop-2-ene-1-iminium salt (LXXIVb) with pyridine in 90% ethanol yielded the chloride (LXXIX).[57] It may be that the first stage of this reaction is the hydrolysis of the salt (LXXIVb) at the C=N̂ bond and the formation of 3-chloropropenal (LXXV), whose aminolysis at the C–Cl bond leads to compound (LXXIX):

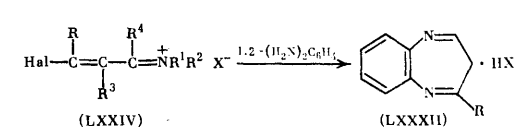
(LXXIVb) (LXXV) (LXXIX)



R=4-$MeC_6H_4$, $R^3$=$R^4$=H, Hal=Cl .

*Aminolysis.* β-Chloro-substituted αβ-unsaturated iminium salts react with amines, substituting the chlorine atom for the amino-group, which leads to salts of enaminoimines,[28,58] for example:

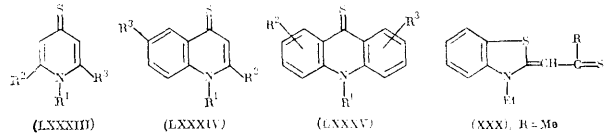
$R^1$=$R^2$=Et; $R^1R^2$=$(CH_2)_4$ . 50–60%



The ability of chloroiminium salts to react with nucleophiles via the C=N̂ bond has attracted much attention by investigators. Thus the reaction of arylpropene derivatives (LXXIV) with hydroxylamine hydrochloride in DMF has led to a simple way of synthesising the corresponding 3-chloropropenyl cyanides (LXXX).[59] Treatment of the salt (LXXIV) in ethanol with a hot aqueous solution of hydroxylamine leads to a high yield of 3-aryl-3-chloroprop-2-ene-1-aldoxime (LXXXI):[60]

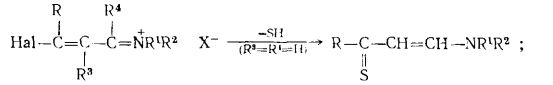
(LXXIV) (LXXX), 60% (LXXXI), 92%

R=4-$MeC_6H_4$, 4-$MeOC_6H_4$; $R^3$=$R^4$=H; Hal=Cl .



When the salts (LXXIV) react with 1,2-phenylenediamine, both electrophilic centres—the C(1) and C(3) atoms—are attacked by the nucleophile and 2-aryl-3*H*-1,5-benzodiazepinium salts (LXXXII) are formed:[61]

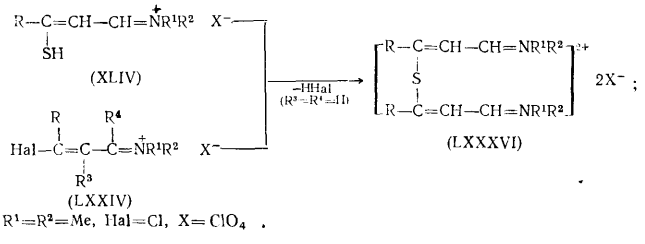
(LXXIV) (LXXXII)



R=Ar, $R^3$=$R^4$=H, Hal=Cl .

*Hydrothiolysis.* The reactions of salts of nitrogen-containing heterocyclic bases incorporating the $Cl-\overset{|}{C}=C-\overset{|}{C}=\overset{+}{N}\diagup X^-$ group with sodium sulphide of hydrogen sulphide in alcohol has been used for a long time to synthesise the corresponding heterocyclic enaminothioketones. Sodium thiosulphate and *NN*-dimethyldithiocarbamate,[62] and thiourea[63] have also been used for the thiolysis of salts of this type. Substituted 4-thiopyridones (LXXXIII),[63,64] 4-thioquinolones (LXXXIV),[64,65] 9-thioacridones (LXXXV),[62,66,67] and 3-ethyl-2-thioacetonylidene-2,3-dihydro-1,3-benzothiazole (XXX)[68] have been obtained in this way in high yields:

(LXXXIII) (LXXXIV) (LXXXV) (XXX), R=Me



The synthesis of the aliphatic enaminothioketones (VIII) is based on the reactions of 3-aryl-3-chloroprop-2-ene-1-*NN*-dimethyliminium salts (LXXIV) with sodium sulphide in aqueous DMF solution or in a DMF–ethylene glycol mixture[69] and also with sodium thiosulphate in alcohols.[70] The temperature (20–60 °C) and the reaction time (2–24 h) are determined by the nature of the aryl substituent:

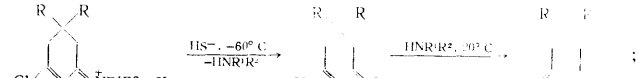
(LXXIV) (VIII), ~80%

R=Ph, 4-$MeC_6H_4$, 4-$BrC_6H_4$, 1-$C_{10}H_7$ etc.; $R^1=R^2=Me$; Hal=Cl .

When the reaction mixture is treated with a primary or secondary amine, amine exchange takes place and leads to the corresponding enaminothioketones $R-C(=S)-CH=CH-NR^1R^2$ (VIII) with a wide variety of nitrogen-containing substituents.[70] If the molar ratio of sodium thiosulphate and the salt (LXXIV) is 1:2, the reaction product is the sulphide compound (LXXXVI) (yield 80%). It is apparently obtained as the final result of the condensation of the initial 3-chloropropeneiminium salt (LXXIV) with the 3-mercaptopropeneiminium salt (XLIV) formed initially:

(XLIV) (LXXXVI)

(LXXIV)

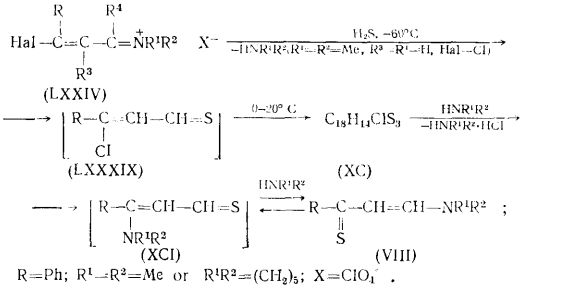


$R^1=R^2=Me$, Hal=Cl, X=$ClO_4$ .

The salts (LXXIV) react with mercaptoacetate esters $HSCH_2COOR$ in the presence of sodium methoxide with elimination of the chlorine atom and the amino-group and the formation of cyclisation products—5-substituted thiophencarboxylates (LXXXVII):[71]

(LXXXVII)

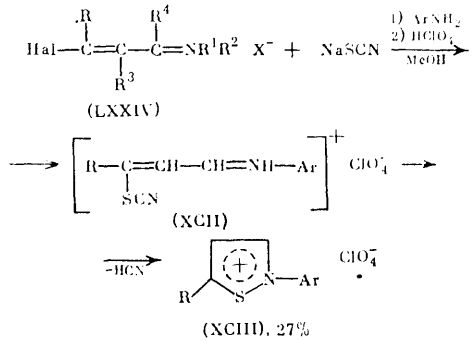
Thus, until recently, the usual pathway in the reaction of compounds containing the $Cl-\overset{|}{C}=\overset{|}{C}-\overset{+}{C}=N\diagup$ group with sulphur-containing nucleophiles was believed to involve the substitution of the chlorine atom. However, it was established in 1979[2] that this reaction can proceed with dissociation of the C=N bond. Thus the interaction of 3-chlorocyclohex-2-ene-1-iminium salts (LXXVI) with hydrogen sulphide in DMF at −60 °C in the presence of triethylamine leads to 3-chlorocyclohex-2-ene-1-thione (LXXXVIII). A compound containing the $Cl-\overset{|}{C}=\overset{|}{C}-\overset{|}{C}=S$ group was obtained in this way for the first time. The chlorothione (LXXXVIII) is a stable intermediate in the hydrothiolysis of the salt (LXXVI), since it interacts instantaneously with amines at 20 °C, forming the enaminothioketones (XXXII):[6,22]



(LXXVI) (LXXXVIII), 87% (XXXII)

$R^1$=H, Alk, $-(CH_2)_n$; $R^2$=H, Alk, $-(CH_2)_n$, Ar; X=$ClO_4$ .

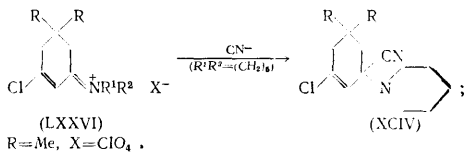
In addition it has been established[6] that the reaction of 3-chloro-3-phenylprop-2-ene-1-*NN*-dimethyliminium perchlorate (LXXIV) with hydrogen sulphide in DMF at −60 °C entails in the first place the elimination of dimethylamine, and not hydrogen chloride, and compound (XC) having the composition $C_{18}H_{14}ClS_3$ is produced. In this case the hydrothiolysis of the iminium group should have led to 3-chloro-3-phenylprop-2-ene-1-thial (LXXXIX), but the latter could not be isolated in a pure state. The absence of resolved signals in the IR, $^{13}C$ NMR, and $^1H$ NMR spectra of the product (XC) indicated its polymeric structure.



The hydrothiolysis product (XC) reacts rapidly with dimethylamine and piperidine at 20 °C.[6] The amine hydrochlorides isolated under these conditions indicate the involvement of the C–Cl bond in the reaction. However, the aminolysis products were not 3-(*NN*-dimethylamino)-(piperidino)-3-phenylprop-2-ene-1-thials (XCI) or the isomeric enaminothioketones (VIII), identical with those described previously.[70] Like their oxygen analogues,[55,72] the thials (XCI) formed initially probably isomerise in the presence of amines, which is the reason for the final outcome of the aminolysis of the product (XC):

(LXXIV) (LXXXIX) (XC) (XCI) (VIII)

R=Ph; $R^1=R^2=Me$ or $R^1R^2=(CH_2)_5$; X=$ClO_4$ .

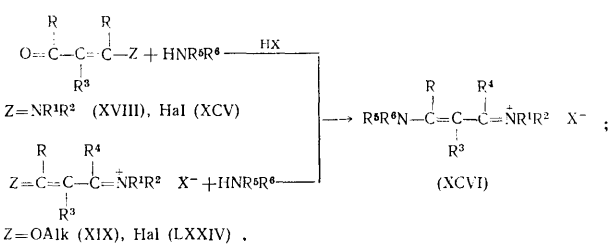


*Reaction with alkali metal thiocyanates.* The successive interaction of 3-chloroprop-2-ene-1-iminium salts (LXXIV) with thiocyanic acid and primary aromatic amines leads to 1,2-thiazolium salts (XCIII).[2] The authors[2] suggest that the reaction proceeds via the intermediate formation of 3-thiocyanatoprop-2-ene-1-iminium salts (XCII):

(LXXIV) (XCII) (XCIII), 27%

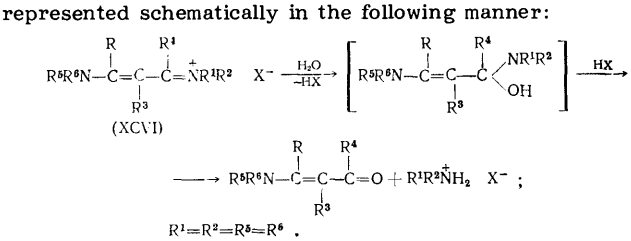
The reactions of the salts $ClCR{=}CH{-}CH{=}\overset{+}{N}R^1R^2\ X^-$ with KSCN (or NaSCN) in acetonitrile or DMF in the presence of catalytic amounts of tetra-alkylammonium iodide or crown-ether lead to 3-thiocyanato-substituted salts $NCSCR{=}CH{-}CH{=}\overset{+}{N}R^1R^2\ X^-$, where R = Ph, Ar, naphthyl, anthryl, heteroaryl, or PhCH = CH, $R^1$, $R^2$ = Alk, Ar or $R^1R^2 = (CH_2)_4$ or $(CH_2)_2O(CH_2)_2$, and X = Cl, $ClO_4$, or $PO_2Cl_2$, in 44–97% yield.[73]

*Cyanolysis.* The product of the reaction of 3-chloro-5,5-dimethylcyclohex-2-ene-1-piperidinium (LXXVI) with potassium cyanide in DMF is 3-chloro-1-cyano-5,5-dimethyl-1-piperidinocyclohex-2-ene (XCIV):[6]



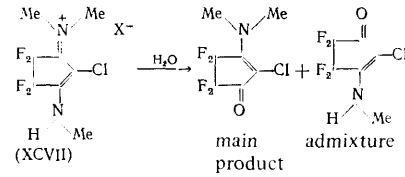
(LXXVI)
R=Me, X=$ClO_4$ .

The formation of the geminal aminonitrile (XCIV) shows that, in the first stage of the overall nucleophilic substitution reaction involving salts of type (LXXVI), the "soft" nucleophile adds to the C(1)=$\overset{+}{N}$ bond and not to the C(2)=C(3) bond.



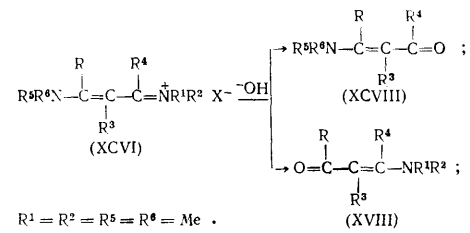
## V. β-AMINOIMINIUM SALTS

The reactions of compounds (XVIII) containing the β-aminovinylketone group or compound (XCV) containing the β-halogenovinylketone groups as well as the reactions of β-heterofunctional αβ-unsaturated iminium salts (XIX) and (LXXIV) with various amines are usually employed for the synthesis of enaminoimine salts (XCVI):[1]



Z=OAlk (XIX), Hal (LXXIV) .

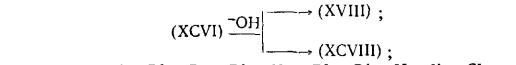
*Hydrolysis.* The hydrolysis of the enaminoimine salts (XCVI) substituted symmetrically at the nitrogen atoms can be represented schematically in the following manner:



Depending on the structure of the salts, this reaction takes place in acid, neutral, or basic media.[1] The *N*-aryl-substituted salts of the indene enaminoimines are more resistant to hydrolysis than those unsubstituted at the nitrogen atom.[74]

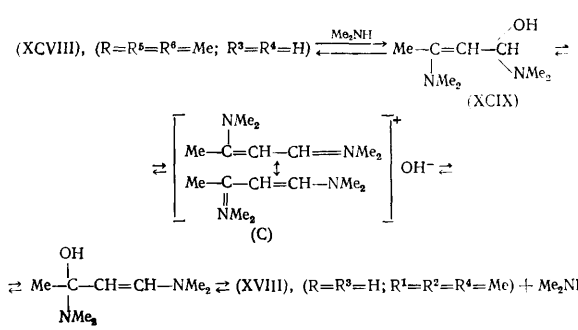
In the case of asymmetrically substituted enaminoimine salts, the question arises of the carbon atoms to which the attack by the nucleophile is directed. The influence of steric factors on the outcome of the hydrolysis has been stressed in a study[75] of the hydrolysis of the 2-chloro-4,4,5,5-tetrafluoro-3-(*N*-methylamino)cyclopent-2-ene-1-*NN*-dimethyliminium salt (XCVII) and also in a review:[1]

(XCVII) main product admixture



The mode of hydrolysis of tetrasubstituted aminopropeneimine salts (XCVI) is treated from the same standpoints:[1]

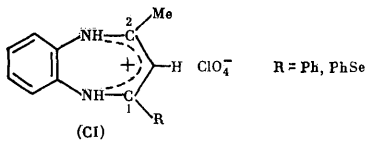
$R^1 = R^2 = R^5 = R^6 = Me$ .



When R = Me or Ph and $R^4$ = H, mainly the enaminoaldehyde (XCVIII) is formed, while the isomer (XVIII) is a side product.

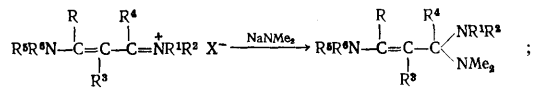
In another study[76] the mechanism of the reactions was treated in a different way. Two isomers, namely 4-(*NN*-dimethylamino)but-3-en-2-one (XVIII) and 3-(*NN*-dimethylamino)but-2-en-1-al (XCVIII), were isolated on hydrolysis of 3-methyl-3-(*NN*-dimethylamino)prop-2-ene-1-*NN*-dimethyliminium chloride (XCVI) with aqueous alkali:

R = $R^1 = R^2 = R^5 = R^6$ = Me; $R^3 = R^4$ = H; X = Cl .



The hydrolysis of the salt (XCVI) at 25 °C and a reduced pressure leads to the aldehyde (XCVIII) in 55% yield. The authors[76] explained the formation of the two isomers (XVIII) and (XCVIII) on hydrolysis of the salt (XCVI) by the ability of the aldehyde (XCVIII) to isomerise readily to the ketone (XVIII) on treatment with dimethylamine. It was suggested that the *gem*-hydroxyamine (XCIX), formed as a result of the addition of dimethylamine to the aldehyde (XCVIII), is in equilibrium with the dissociated form (C). Its mesomeric cation is converted into the aldehyde (XCVIII) or the ketone (XVIII) after recombination with a hydroxide ion and the elimination of dimethylamine:

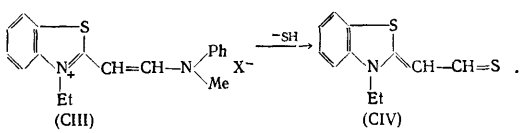
(XCIX)



(C)

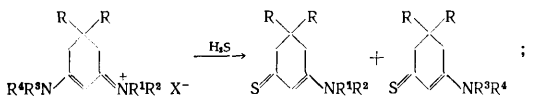
the hydroxide ion attacks the sterically most shielded C(1) atom:

(CI) R = Ph, PhSe



*Aminolysis.* The aminolysis of enaminoimine salts is usually terminated by transamination and has little preparative value.[78] The reaction probably proceeds via the formation of a *gem*-diamine. When 3-(*NN*-dimethylamino)prop-2-ene-1-*NN*-dimethyliminium salts (XCVI) were allowed to react with sodium NN-dimethylamide in benzene, the stable aminal (CII) was obtained:[79]

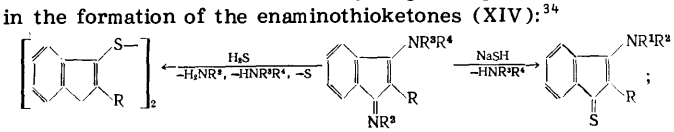
(XCVI) (CII), 62%



$R = R^3 = R^4 = H$; $R^1 = R^2 = R^5 = R^6 = Me$; $X = ClO_4$, $MeSO_4$ .

*Hydrothiolysis.* The hydrothiolysis of enaminoimines was first described in relation to the reaction of a 3-ethyl-2-[2-(*N*-methyl-*N*-phenylamino)vinyl]benzothiazolium salt (CIII) with sodium hydrogen sulphide in methanol, which led to a satisfactory yield of the enaminothial (CIV):[29]

(CIII) (CIV)

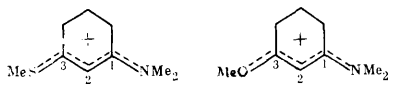


The hydrothiolysis of 3-piperidinocyclohex-2-ene-1-iminium salts (XXIX) does not proceed unambiguously. Their C(1) and C(3) atoms have similar reactivity indices,[23] which is apparently the cause of the simultaneous formation of the two enaminothioketones (XXXII) and (XXXIIa):

(XXIX) (XXXII) (XXXII a)

$R^1R^2 = (CH_2)_5$; $R^3 = H$; $R^4 = CH_2Ph$, Ph, 4-$MeOC_6H_4$ .

The reactions of 3-amino-2-phenylindene-1-imines (CV) with hydrogen sulphide in the presence of piperidine lead to a reduction product—bis(indenyl)disulphide (XXXV), while the reactions with sodium hydrogen sulphide result in the formation of the enaminothioketones (XIV):[34]



(XXXV) (CV) (XIV)

R = Ph, $R^1 = H$ .

## VI. QUANTUM-CHEMICAL ANALYSIS OF NUCLEOPHILIC SUBSTITUTION IN 3-ALKOXY- AND 3-ALKYLTHIO-CYCLOHEX-2-ENE-1-IMINIUM SALTS

Calculations have been carried out for the 3-methylthio- (A) and 3-methoxycyclohex-2-ene-1-*NN*-dimethyliminium (B) cations by the CNDO/2 method using a novel parametrisation.[6] The results of the calculation, which are presented solely for the chemically reactive $X-C=C-C=\overset{+}{N}Me_2$ fragment, are indicated in the molecular diagrams (A) and (B) (see Table) [the initial location of the positive charge on the N atom in the cations (A) and (B) is energetically more favourable to the extent of ~2 eV than its location on the O or S atoms]. Analysis of the molecular diagrams showed that both "soft" and "hard" nucleophiles attack the $C=\overset{+}{N}$ bond preferentially in the 3-methylthio-substituted cation (A)—this reaction pathway is subject to orbital and charge control.

Results of the calculations for the 3-methylthio- (A) and 3-methoxy-cyclohex-2-ene-1-*NN*-dimethyliminium (B) cations.

(A) (B)

| Atom or bond | Form (A) | | | Form (B) | | |
|---|---|---|---|---|---|---|
| | $q_i$, e | $k_i$ | $w$ | $q_i$, e | $k_i$ | $w$ |
| N | −0.063 | — | — | −0.071 | — | — |
| C(1) | 0.275 | 0.36 | — | 0.280 | 0.42 | — |
| C(2) | −0.104 | — | — | −0.191 | — | — |
| C(3) | 0.211 | 0.26 | — | 0.312 | 0.25 | — |
| S | 0.021 | — | — | — | — | — |
| O | — | — | — | −0.182 | — | — |
| $C(1)=\overset{+}{N}$ | — | — | 1.560 | — | — | 1.518 |
| C(1)=C(2) | — | — | 1.420 | — | — | 1.452 |
| C(2)=C(3) | — | — | 1.642 | — | — | 1.588 |
| C(3)—S | — | — | 1.071 | — | — | — |
| C(3)—O | — | — | — | — | — | 1.147 |

Notation: $q_i$ are the atomic charges, $k_i$ are the relative contributions of the atomic $\pi$ orbitals of the lowest unoccupied molecular orbital, and $w$ are the Wiberg bond indices.

In the case of the 3-methoxy-substituted cation (B), "soft" nucleophiles should react preferentially via the $C=\overset{+}{N}$ bond (orbital control predominates), while "hard" nucleophiles should react via the C—O bond (charge control predominates), which can be accounted for by the greater electronegativity of the MeO group compared with MeS.

---o0o---

Thus the problem of the analysis of the reactions considered here is fairly complex, since the aim of the majority of the published studies (which have been very numerous—cf. Hünig[80]) was not a specific investigation of the reactions of unsaturated iminium salts with nucleophiles under comparable conditions. Instances of the hydrolysis, aminolysis, and hydrothiolysis of such salts at the C(1) atom as well as the C(3) atom or at both electrophilic centres are known. It is sometimes difficult to arrive at a correct conclusion about the course of the process owing to the hydrolysis of the final product and the occurrence of other side reactions. However, the practical usefulness of further more extensive investigation of nucleophilic substitution in iminium salts has been demonstrated by recent studies,[6,81] which indicated ways of synthesising new thio-derivatives of cyclohexene and indene on the basis of these reactions.

# Reactions of Organic Compounds with Dissociation of N-N Bonds

M.F.Marshalkin and L.N.Yakhontov

Reactions involving the dissociation of single N-N bonds which have been carried out during the last decade and which are important for organic chemistry are surveyed. New data on the reductive cleavage of such bonds, various rearrangements, N-N bond dissociation reactions with simultaneous *N*-alkylation, and thermal, electrochemical, and photochemical processes are examined. Attention is concentrated on fundamentally new reactions, on studies of the reaction mechanisms, and on the development of methods extending the preparative scope of organic synthesis.
The bibliography includes 118 references.

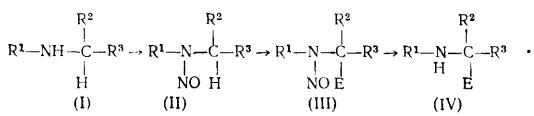
## I. INTRODUCTION

Reactions proceeding with dissociation of N–N bonds in both cyclic and acyclic compounds occupy a major place in organic chemistry. Owing to the repulsion between the *p* orbitals of neighbouring nitrogen atoms, the length of a single N–N bond (1.40 nm) exceeds the sum of the radii of the two nitrogen atoms ($0.53 \times 2 = 1.06$ nm). A characteristic feature of this bond is its very low dissociation energy (37 kcal $mol^{-1}$) compared with other single bonds most frequently encountered in organic compounds (for example, the energy is 80 kcal $mol^{-1}$ for the C–C bond, 66 kcal $mol^{-1}$ for the C–N bond, and 64 kcal $mol^{-1}$ for the S–S bond).

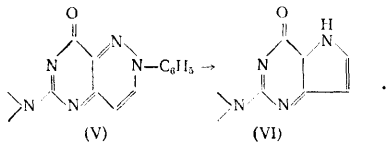


The above features of the N–N bond are responsible, under conditions where there is a possibility of competing reactions, for its preferential dissociation compared with the dissociation of the C–C or C–N bonds. This entails the formation of either the corresponding amino-derivative, or unstable products with an electron sextet at the nitrogen atom of the type of nitrenes, which are stabilised by further addition reactions, rearrangements, etc., or unstable free radicals, which recombine or undergo other radical processes ensuring the stabilisation of the molecule, are generated.

In our earlier review[1] an attempt was made for the first time to give a systematic account of the extensive literature data on the methods for the dissociation of single N–N bonds in organic compounds. The present review describes the advances during the last decade in the studies on organic compounds involving the dissociation of N–N bonds. Attention is concentrated on the examination of fundamentally new reactions, new studies on reaction mechanisms, and on the search for fundamentally new ways of employing processes of this type in preparative organic chemistry rather than on numerous new applications of compounds described previously.

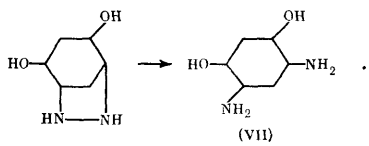
## II. REDUCTIVE CLEAVAGE OF N–N BONDS

The hydrogenolysis of N–N bonds is one of the commonest methods for the conversion of various azines, azides, hydrazines, and their derivatives into the corresponding amines. The methods for the reductive cleavage of N–N bonds published up to 1972 have been examined in detail in the authors' previous review[1] as well as other reviews.[2-6]



A new general method for the introduction of various substituents at the C(1) atom in secondary amines (I), based on their nitrosation, treatment of the nitroso-derivatives (II) with powerful bases and electrophiles, and reductive cleavage of the N–N bond in the nitrosoamine (III) in order to remove the nitroso-group, has been developed during the last decade:[7]

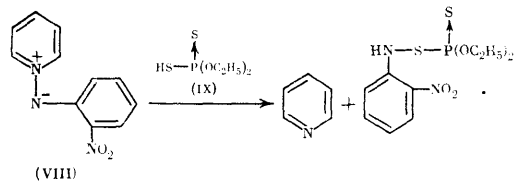
The last stage of the synthesis of compound (IV) is effected on the basis of a specially developed method for the reductive denitrosation of compound (III) with hydrogen in the presence of small amounts of Raney nickel.[8] This method proved to be suitable for compounds which are unstable in acid media, the other functional groups present in the substance (apart from the readily reducible olefinic and β-keto-groups), being unaffected under these conditions, which is the reason for its significant advantages over the earlier method for the denitrosation of amines with cleavage of the N–N bond in acid media.[9]



A method for the hydrogenolysis of the N–N bond in hydrazobenzene with formation of aniline via hydrogen transfer from 2-propanol to hydrazobenzene, catalysed by the triphenylphosphine complexes of rhodium and ruthenium, was published during the same period.[10]

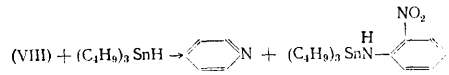
By analogy with the other methods for the reductive cleavage of the N–N bond in pyridazine compounds indicated in the earlier review,[1] which lead to ring contraction, new syntheses have been developed for 5*H*-pyrrolo[3,2-*g*]-pyrimidines (V).[11] They include a stage involving the reduction of pyrimido[5,4-*c*]pyridazines (V) in the presence of a nickel or palladium catalyst.[11] The reductive opening of the pyridazine ring with dissociation of the N–N bond and the subsequent closure of a five-membered ring, the 4,6-diazaindole system (VI), are then observed:

(V) (VI)



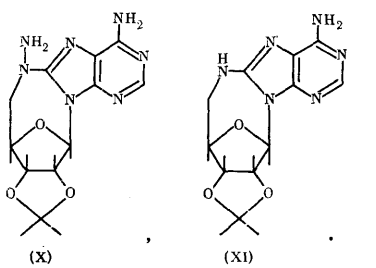
The catalytic reductive cleavage of both exocyclic[12] and endocyclic[13] N–N bonds in the synthesis of aminocyclitols (VII) has acquired considerable importance:

(VII)



In view of the increasing importance of the problem of the protection of the environment, a study[14] in which a general method was proposed whereby various hydrazine compounds, including substances with a carcinogenic activity, can be made harmless by the reductive cleavage of their N–N bond with conversion into the corresponding less dangerous amino-derivatives, has attracted special attention.

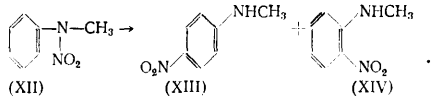
Reduction with dissociation of this bond by a nucleophile, namely diethyl phosphinodithioic acid (IX), has been described for a compound with a semipolar N–N bond of the N-iminopyridinium type, namely the betaine (VIII):[15]



(VIII)

The same type of reaction takes place on treatment of compound (VIII) with tributyltin hydride[16] in the presence of αα′-azobisisobutyronitrile and is believed to be of the radical type:

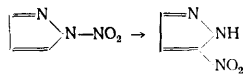
In contrast to the reactions involving the reductive cleavage of N–N bonds described above, the oxidative cleavage of such bonds is also known and can be illustrated in relation to the deamination of the *N*-amino-derivatives (X) to give compound (XI) by oxidants such as iodine pentoxide, lead tetra-acetate, potassium permanganate, and sodium metaperiodate:[17]



(X) (XI)

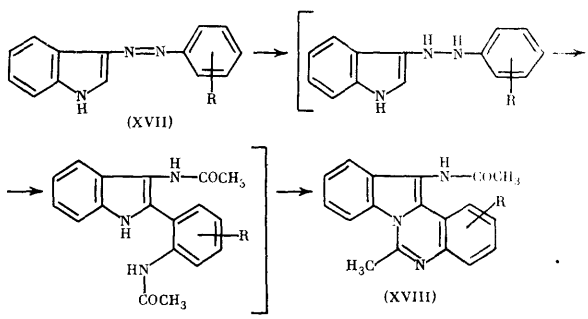
The deamination of 1,1-disubstituted aromatic hydrazines with the aid of nitrous acid, which apparently proceeds via *N*-diazonium salts, has also been studied in detail in recent years.[18]

## III. REARRANGEMENTS INVOLVING THE DISSOCIATION OF N–N BONDS



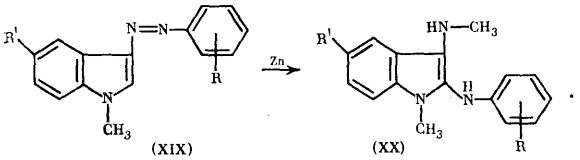
In addition to the sextet rearrangements of the type of the Curtius and Schmidt reactions and nitrile and various aryl-hydrazone rearrangements described in a previous review, publications dealing with new types of reactions, involving the cleavage of the N–N bond, have appeared during the last decade. At the same time, some of the reactions known previously not only came to be used more widely on a preparative scale but also have been the subject of more detailed theoretical and applied research.

For the acid-catalysed nitroamine rearrangement involving *N*-methyl-*N*-nitroaniline (XII), processes occurring in the presence of hydroquinone, which rules out an intermolecular reaction mechanism, were investigated, and it was shown that the yield of the *p*-nitro-isomer (XIII) relative to the *o*-nitro-amino-compound (XIV) increases appreciably with increase of the viscosity of the solution. According to the authors, this indicates the involvement of solvent molecules in the nitro-group migration processes:[19]



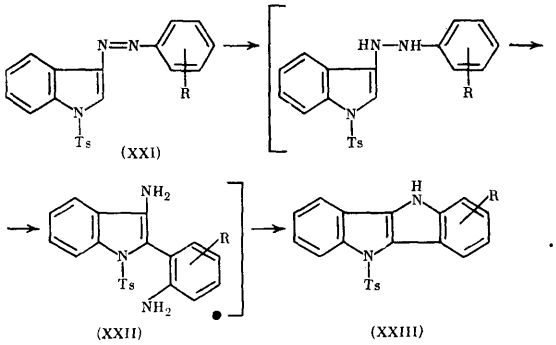
(XII) (XIII) (XIV)

The dissociation of the N–N bond accompanied by the rearrangement of the nitroamine type on thermolysis of 1-nitropyrazole (XV) to give 5-nitropyrazole (XV) and in other analogous reactions has also been described:[20]



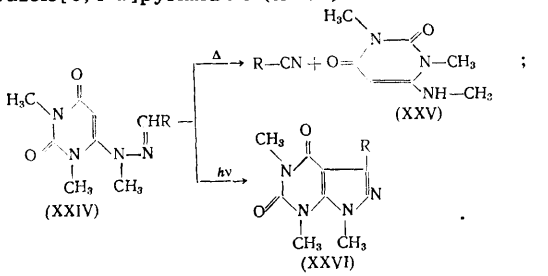
(XV) (XVI)

Vigorous studies on the mechanism of the benzidine rearrangement have continued.[21–27] When 3-arylozoindoles (XVII) were reduced with zinc in acetic acid in the presence of acetic anhydride and sodium acetate, a rearrangement of the *o*-benzidine type, proceeding with dissociation of the N–N bond and the formation, as a result of subsequent *N*-acylation and cyclisation, of derivatives of indolo[1,2-*c*]-quinazoline (XVIII) was observed:



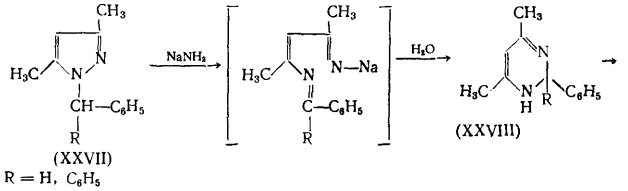
(XVII) (XVIII)

An analogous reaction occurs also for azo-compounds acylated at the pyrrole nitrogen atom[29] and also *N*-acetylin-doxyl arylhydrazones.[30,31] However, in the azo-compounds (XIX), which have a methyl substituent at the indole nitrogen, the dissociation of the N–N bond is accompanied by a semidine rearrangement with formation of 3-acetamido-2-arylamino-1-methylindoles (XX):[31]



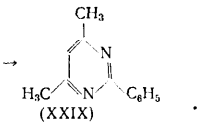
(XIX) (XX)

The reaction involving 3-aryl-1-tosylindoles (XXI) also proceeds with dissociation of the N–N bond accompanied by a rearrangement of the *o*-benzidine type, but the 3-amino-2-(*o*-aminoaryl)indoles (XXII) formed in this process cyclise with elimination of ammonia to give 5-tosylindolo[3,2-*b*]-indoles (XXIII):[32]



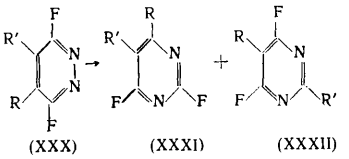
(XXI) (XXII) (XXIII)

Together with the nitrile rearrangement of hydrazones which has been widely investigated in previous studies,[1,33] the thermolysis of 1,3-dimethyl-6-(1-methylhydrazino)uracils (XXIV), which proceeds via a mechanism of the nitrile rearrangement type with dissociation of the N–N bond and the formation of 1,3-dimethyl-6-methylaminouracil (XXV), has been described in the last decade.[34,35] On the other hand, the photolysis of compound (XXIV) takes place without the cleavage of the N–N bond and leads solely to a derivative of pyrazolo[3,4-*d*]pyrimidine (XXVI):[36,37]



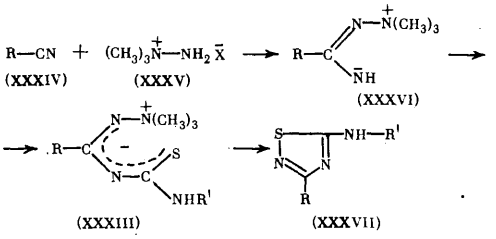
(XXIV) (XXV) (XXVI)

A new rearrangement has been discovered on heating to 155 °C α-benzyl-3,5-dimethylpyrazoles (XVII, R = H or $C_6H_5$) with sodium amide.[38] In this case the N–N bond of the pyrazole ring is broken with subsequent closure of the 1,2-dihydropyrimidine ring (XXVIII). If the reaction with compound (XXVII, R = H) is carried out at 185 °C, a further aromatisation of compound (XXVIII) is observed and the final product is 4,6-dimethyl-2-phenylpyrimidine (XXIX):



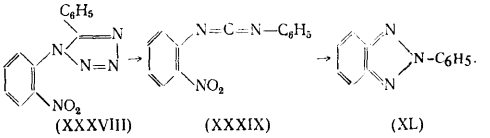
(XXVII) (XXVIII)

R = H, $C_6H_5$



(XXIX)

An interesting thermal rearrangement has been observed for perfluoro-4,5-dialkylpyridazines or 4,5-diperfluoroalkylpyridazines, which are converted at 650 °C into perfluoro-4,5-dialkylpyrimidines (XXXI) and the corresponding diperfluoroalkyl derivatives while in the case of perfluoro-4,5-perfluoroethylpyridazines (XXX) a mixture of perfluoro-4,5-diperfluoroethylpyrimidines (XXXI) and perfluoro-2,5-diperfluoroalkylpyrimidines (XXXII) is obtained:[39,40]

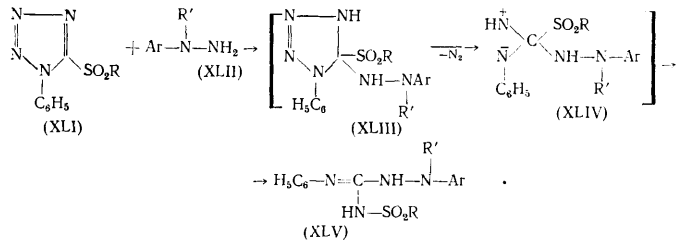


(XXX) (XXXI) (XXXII)

It has been found[41] that the thermolysis of the ylides derived from thiocarbamoylamidrazones (XXXIII) by the reaction of the nitriles (XXXIV) with trimethylhydrazinium chloride of the tosylate (XXXV) and potassium t-butoxide [42] followed by treatment of the ylides of unsubstituted amidrazones (XXXVI) thus produced with aryl or pentyl isocyanates leads to intramolecular nucleophilic attack by the sulphur atom on the N(2) atom with dissociation of the N–N bond, the elimination of triethylamine, and the formation of the corresponding 3-alkyl(aryl)-5-alkyl(aryl)amino-1,2,4-thiadiazoles (XXXVII) in high yields:

(XXXIV) (XXXV) (XXXVI) (XXXIII) (XXXVII)

The thermolysis of 1-(*o*-nitrophenyl)-5-phenyltetrazole (XXXVIII) involves the dissociation of the N–N bonds and the liberation of a nitrogen molecule with subsequent elimination of carbon dioxide from the resulting 1-(*o*-nitrophenyl)-3-phenylcarbodiimide (XXXIX) accompanied by the closure of the triazole ring. 2-Phenylbenzotriazole (XL) is formed in this reaction in yields up to 90%:[43]

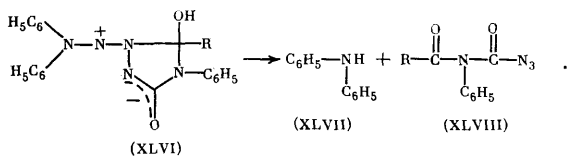


(XXXVIII) (XXXIX) (XL)

The formation of nitrogen and CO in this reaction was confirmed mass-spectrometrically. The corresponding 1-(*p*-nitrophenyl)-5-nitrotetrazole gives rise under these conditions to the thermally stable 1-(*p*-nitrophenyl)-3-phenylcarbodiimide as the main thermolysis product, which confirmed the reaction mechanism postulated by the author.

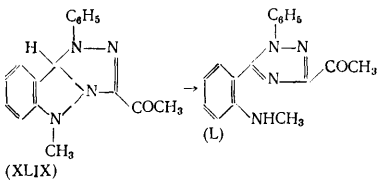
5-(*o*-Methoxyphenyl)-1-(*o*-nitrophenyl)- and (*oo'*-dimethoxyphenyl)-tetrazoles have been converted analogously in high yields into 2-(*o*-methoxyphenyl)- and 2-(*oo'*-dimethoxyphenyl)-benzotriazoles.[44]

Heating of 5-methanesulphonyl-1-phenyltetrazole (XLI) with arylhydrazines (XLII) above 170 °C leads to vigorous evolution of nitrogen as a result of the thermolysis of the



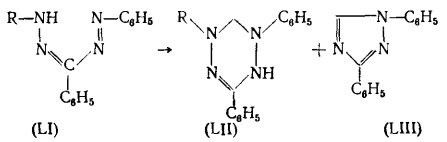
tetrazoline derivatives (XLIII) formed initially. Analogously to the process described previously,[45] the 1,3-dipoles (XLIV) apparently arise under these conditions and in the given instance are stabilised as a result of the migration, via the 2,3-shift mechanism, of the alkanesulphonyl groups from the carbon atom to the vicinal positively charged nitrogen atom with formation of 3-alkanesulphonyl-1-arylamino-2-phenylguanidine (XLV):[46]

(XLI) (XLII) (XLIII) (XLIV) (XLV)



An analogous reaction takes place also when unsubstituted hydrazine is used instead of arylhydrazine.[47]

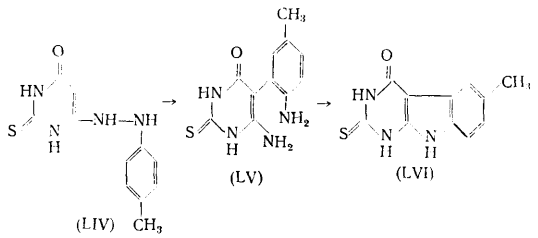
It has been shown that aminoazimines (XLVI) react at room temperature with bases such as ammonia, aliphatic amines, hydrazines, and aqueous alcoholic solutions of alkali metal hydroxides, being converted into the corresponding amines (XLVII) and azides (XLVIII) with dissociation of the N–N bond:[48]



(XLVI) (XLVII) (XLVIII)

Under equally mild conditions, in tetrahydrofuran at room temperature but under the influence of catalytic amounts of concentrated hydrochloric acid, the N–N bond in 3-acetyl-5-methyl-1-phenyl-[1,9*b*]-dihydro-5*H*-1,2,4-triazolo[4,3-*b*]-indazole (XLIX) is broken with formation of 3-acetyl-5-(*o*-methylaminophenyl)-1-phenyl-1,2,4-triazole (L):[49]

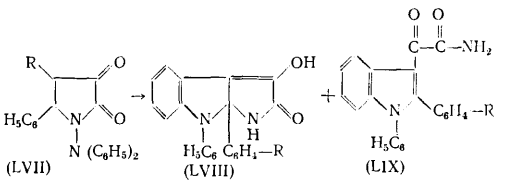
(XLIX) (L)



When 1-(2-methyl-5-tetrazolyl)-3,5-diphenylformazan (LI) was treated with formaldehyde, the cleavage of the N–N bond with formation of 1,3-diphenyl-1,2,4-triazole (LIII) was noted together with the closure of the tetrazine ring (LII):[50]

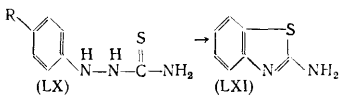
(LI) (LII) (LIII)

Despite its having been studied for a century, the widely known Fischer indole synthesis still continues to be one of the most investigated reactions in the chemistry of heterocyclic compounds. During the last decade alone, a series of new reviews[51–53] and chapters in monographs[6,54] were devoted to this reaction. The development of the concept of the [3,3]sigmatropic shift in the rearrangement stage with cleavage of the N–N bond,[52,56–58] the discovery of the "heterogeneous-catalytic Fischer reaction"[59–63] and its application to the synthesis of unsubstituted indole from acetaldehyde phenylhydrazone,[64] the discovery of the possibility of carrying out the Fischer reaction without acid catalysts ("thermal conversion into indoles",[65,66] conversion into indoles in the presence of bases[67–70] and under the conditions of "extractive base catalysis"[71]), and the discovery of the cationotropic rearrangement of arylhydrazides to 2-aminoindoles[72–77] and of the formation of γ- and δ-halogeno-carboxy-derivatives of indolylalkylamines on conversion of arylhydrazones into indoles[78] must be regarded as the most significant additional advances in the study of the Fischer reaction during this period.



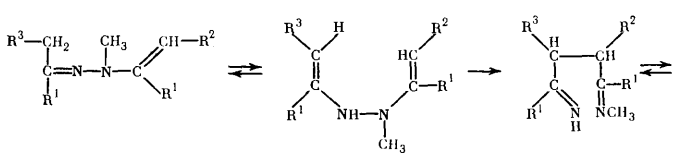
An acid-catalysed [3,3]sigmatropic rearrangement of the type of the Fischer reaction, proceeding with dissociation of the N–N bond, has been discovered for the reaction involving 6-(*p*-tolylhydrazino)-2-thiouracil (LIV). This led to the isolation of 5-(6-amino-3-tolyl)-6-amino-2-thiouracil (LV), which was converted on heating into the corresponding thio-derivative of 9*H*-pyrimido[4,5-*b*]indole-2,4-dione (LVI):[79]

(LIV) (LV) (LVI)

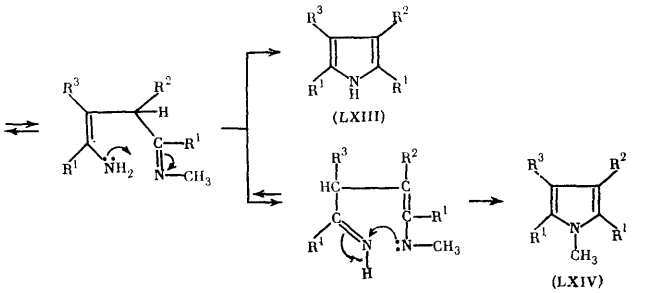


An analogous reaction had been described earlier also for 6-phenylhydrazinouracil.[80,81]

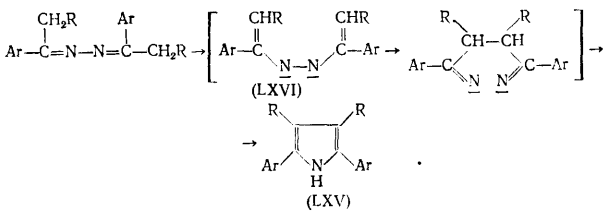
Certain other reactions involving the dissociation of the N–N bond and related to the Fischer indole synthesis have also been investigated. Thus the thermal cyclisation of 1-diphenylamino-2,3-dihydropyrrolidine-2,3-diones (LVII) yielded derivatives of pyrrolo[2,3-*b*]indole (LVIII) and (1,2-diphenyl-3-indolyl)glyoxylic amide (LIX):[82]



(LVII) (LVIII) (LIX)

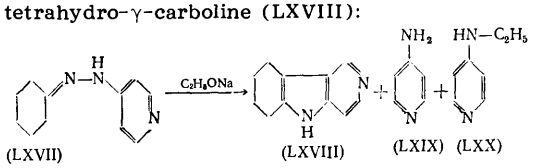


2-Aminobenzothiazoles (LXI) have been isolated in satisfactory yields after the Hugershoff reaction of 1-arylthiosemicarbazides (LX) with alkyl or halogeno-substituents in the benzene ring when these were treated with polyphosphoric acid:[83]



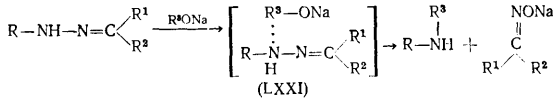
(LX) (LXI)

For the cyclisation of *N*-methylhydrazones of the enolisable ketones (LXII) to substituted pyrroles (LXIII) and (LXIV) under the conditions of the Piloty reaction, using titanium tetrachloride and molecular sieves as catalysts, a mechanism analogous to that of the corresponding reactions of azines has been proposed:[84,85]



A mechanism involving the [3,3]sigmatropic rearrangement has been postulated as the most likely for a new synthesis of pyrroles (LXV) from the ketazine dianion (LXVI), which takes place in the presence of lithium diisopropylamide in tetrahydrofuran and not in an acid medium, in contrast to the Piloty reaction:[86]

## IV. REACTIONS INVOLVING THE DISSOCIATION OF THE N–N BOND WITH SIMULTANEOUS *N*-ALKYLATION

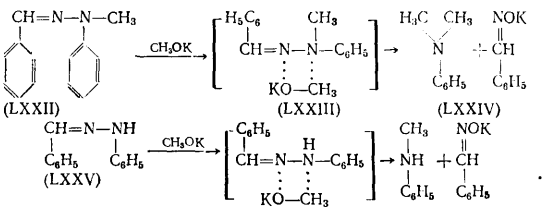


In the course of the study of the Fischer indole synthesis at the beginning of the 1970s, a new type of cleavage of the N–N bond with simultaneous *N*-alkylation was discovered.[87–89] It was found initially that, when cyclohexanone (4-pyridyl)-hydrazone (LVII) is heated with sodium ethoxide, the *N*-unsubstituted 4-aminopyridine (LXV) and 4-(*N*-mono-ethylamino)pyridine (LXX) are formed simultaneously with the occurrence of the normal Fischer reaction, which leads to the tetrahydro-γ-carboline (LXVIII):

It was shown thereby that the presence of acid catalysts is not an essential condition for the Fischer indole synthesis. Two reactions, which proceed under these conditions simultaneously with the indole synthesis, among which the first is associated with the thermal cleavage of the N–N bond in the hydrazone, apparently via a radical mechanism, and leads to the *N*-unsubstituted aminopyridine (LXIX), while the second has a mechanism apparently involving the intermediate formation of a four-membered cyclic transition state (LXXI), in which the synchronous cleavage of the C–O and N–N bonds is completed by the simultaneous formation of 4-(*N*-monoethylamino)pyridine and the sodio-derivative of cyclohexanone oxime, were observed.

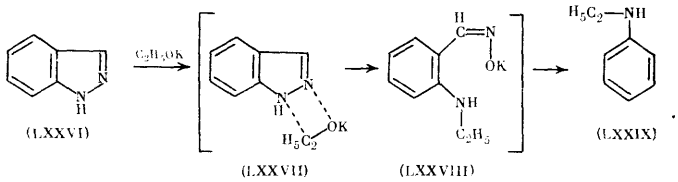
The application of various pyridyl(aryl)hydrazones of aromatic aldehydes in this reaction makes it possible to rule out the possibility of indole synthesis and, by selecting the appropriate temperature, the process can be directed predominantly either towards *N*-unsubstituted or *N*-monoalkyl-substituted pyridyl(aryl)amines.

During the last decade, studies on the N–N bond cleavage reaction with simultaneous *N*-monoalkylation in the reactions of hydrazone and other analogous compounds with alkali metal alkoxides in accordance with the mechanism



were developed further. The use in these reactions of the familiar[90] increase of the amount of ionic character in the oxygen–alkali metal bond in the sequence Li < Na < K < Rb < Cs made it possible to shift the process significantly, in the case of arylhydrazones. towards the formation of *N*-mono-alkylanilines and to achieve 80–90% yields of these compounds in reactions with potassium alkoxides. The analogous reactions with sodium alkoxides take place to an extent not greater than 10% and the main reaction pathway is the thermal decomposition of the arylhydrazones to *N*-unsubstituted anilines.[91,92]

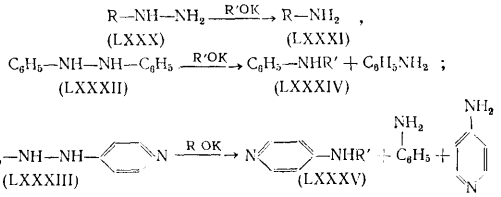
The same influence on the main reaction pathway on passing from sodium to potassium and rubidium alkoxides has also been observed in the synthesis of *N*-monoalkylamino-derivatives of pyrazine, pyridazine, and pyrimidine from the corresponding benzaldehyde diazinylhydrazones and alkali metal alkoxides.[93]



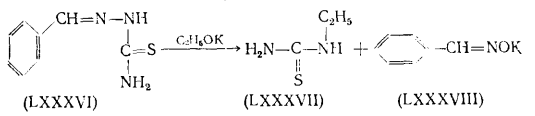
The isolation of 3-aminopyridazine, dibenzylamine, dibenzyl, benzyl alcohol, benzylidene-ethylamine and the products of the reaction of benzaldehyde (3-pyridazinyl)-hydrazone with sodium ethoxide at high temperatures indicates the radical character of the thermal decomposition of the hydrazones. As in other cases, the contribution of this reaction pathway increases with increase of temperature (the yields of the *N*-unsubstituted aminodiazines increase and those of *N*-monoalkylamino-derivatives diminish simultaneously).[93,94]

At the same time special experiments have shown that *N*-unsubstituted heteroaryl(aryl)amines cannot serve as intermediates in the formation of *N*-monoalkylheteroaryl-(aryl)amines, because they do not undergo *N*-alkylation when heated with alkali metal alkoxides at various temperatures.[94]

It is of interest that, when benzaldehyde *N*-methyl-*N*-phenylhydrazone (LXXII) was used as the initial compound in the reaction with potassium methoxide, the formation of a four-membered cyclic transition state (LXXIII) was nevertheless found to be possible despite a definite steric hindrance and the corresponding *NN*-dimethylaniline was obtained in a yield exceeding 20%. The formation of this compound even in trace amounts could not be detected by GLC in the reaction of benzaldehyde phenylhydrazone (LXXV) with potassium methoxide:[94]

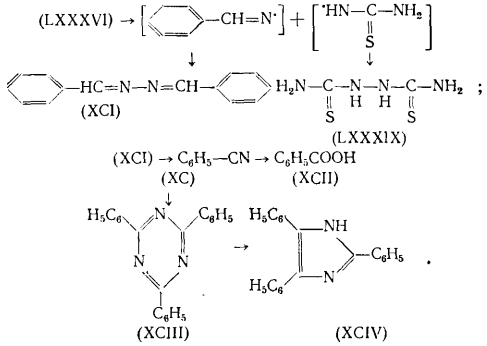


Indazole (LXXVI), which can be regarded as an endocyclic hydrazone, apparently undergoes similar reactions, on heating with potassium ethoxide, via the four-membered (in this instance tricyclic) transition state (LXXVII), in which synchronous dissociation of the C–O and N–N bonds take place. However, the resulting potassium salt of *o*-ethyl-aminobenzaldehyde oxime (LXXVIII) fragments with elimination of potassium cyanate or its elements and gives rise to a fairly high yield (60%) of *N*-monoethylaniline (LXXIX):[95]



(LXXVI) (LXXVII) (LXXVIII) (LXXIX)

In contrast to *N*-monosubstituted hydrazines, which are cleaved at high temperatures by alkali metal alkoxides to give virtually quantitative yields of the primary amines (LXXXI), only[96] *NN'*-disubstituted hydrazines such as hydrazobenzene (LXXXII) and *N*-phenyl-*N'*-(4-pyridyl)-hydrazine (LXXXIII) give rise under analogous conditions to the corresponding *N*-alkylated amines (LXXXIV) and (LXXXV). The pathway involving the dissociation of the N–N bond with simultaneous alkylation is determined by the electron-accepting character of the residues at the hydrazine nitrogen atoms, which influence the polarity and polarisability of the N–N bond. For example, in the reaction of *N*-phenyl-*N'*-(4-pyridyl)hydrazine (LXXXIII), only 4-(*N*-monoalkylamino)pyridines (LXXXV) are formed and not even traces of *N*-monoalkylanilines can be detected:[94]



On passing to benzaldehyde thiosemicarbazone (LXXXVI),[97] the reaction with potassium ethoxide also proceeds via the general mechanism and *N*-ethylthiourea (LXXXVII) and the potassium salt of benzaldehyde oxime (LXXXVIII) are formed:

(LXXXVI) (LXXXVII) (LXXXVIII)

As in other analogous reactions, a thermal decomposition of the radical type takes place simultaneously with this process.
