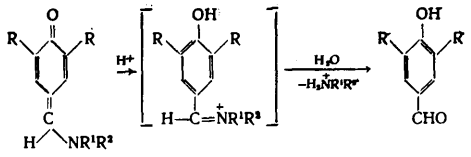
The mode of reaction of methylenequinone homologues with nucleophiles is associated primarily with the characteristic features of the initial step in the interaction of the reagent with the electrophilic centre of the methylene quinone molecule and the character of the decomposition of the intermediate complex formed under these conditions. The reaction of α-alkyl-2,6-t-butyl methylenequinones with amines affords high yields of the corresponding derivatives of *p*-hydroxybenzylamines.[126,127] Organomagnesium compounds also add to the 1,6-positions of the conjugated methylenequinone system with formation of 2,4,6-trialkylphenols; this method has found an application in the synthesis of alkylphenols containing a branched alkyl group in the *para*-position which are difficult to obtain otherwise:[128]

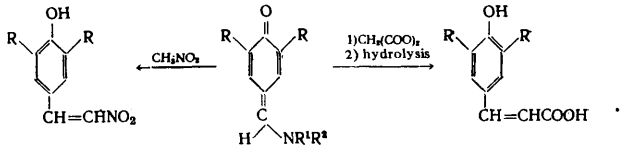
The mechanism of this reaction has not been studied in detail but one can assume that in this instance the addition of the organomagnesium compound takes place synchronously.

In the reaction of the methylenequinone (XVIII) with hydroxide ion (pH 12.3 – 14), 2,6-di-t-butyl-4-vinylphenol is obtained simultaneously with 3,5-di-t-butyl-4-hydroxy-α-methylbenzyl alcohol. The reaction involving the addition of the hydroxide ion to the compound (XVIII) is reversible:[119]



(XVIII)

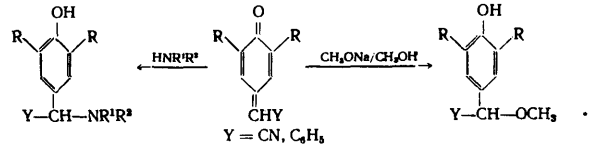
The rate of the 1,6-addition of water to compound (XVIII) depends on the pH of the medium and is approximately 20 times faster at pH 12.4 – 14 than in neutral media. The reactivity of αα-dialkylmethylenequinones is significantly lower than that of α-alkylmethylenequinones, which is apparently associated with steric factors hindering the attack by the reagent on the electrophilic centre of the methylenequinone molecule.



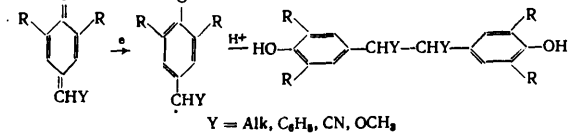
2. Methylenequinones with α-Functional Group Substituents

The electronegative properties of the α-substituent and its capacity to become conjugated with the π-system of the molecule affect directly the reactivity of methylenequinones and this influence is shown most clearly in methylenequinones with α-functional group substituents. Under the influence of the electronic effects of the substituent in the methylene group, the reactivity of the electrophilic and nucleophilic centres of the molecule can alter sharply, which leads in its turn to a change in the behaviour of different α-substituted methylenequinones in the reaction with the same reagent. In the general case in acid media, a proton adding to the carbonyl oxygen atom can induce a bond redistribution with formation of an aromatic system. Naturally, the proton-accepting possibilities of the carbonyl group, which determine the reactivity of methylenequinones in reactions with electrophiles, depend on the degree of conjugation of the π-bond system of the methylenequinone with the α-substituent. αα-(*NN*-dialkylamino)methylenequinones react most readily with acids. The presence of the amino-group in the α-position not only increases the reactivity of the carbonyl group as a result of the high polarisability of the molecule (λ_{max} = 380 nm) but also promotes the aromatisation of the system as a whole by virtue of the possibility of the formation of the azomethine bond system in the transition state. For this reason, αα-(*NN*-dialkylamino)methylene-

quinones are capable of reacting with weak acid reagents, although their reactions in an aqueous medium terminate with the formation of the corresponding *p*-hydroxybenzaldehydes:[30]

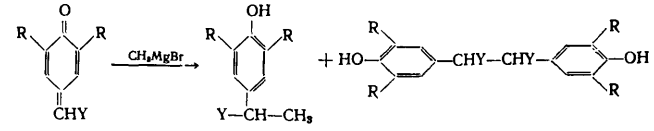


In non-aqueous media, α-(*NN*-dialkylamino)-2,6-di-t-butyl methylenequinones behave as effective *C*-alkylating agents. For example, they react with nitromethane and malonic acid:[30]



α-Alkoxymethylenequinones behave analogously in the presence of acid reagents. By virtue of the lower nucleophilicity of the oxygen atom at the carbonyl group, α-alkoxymethylenequinones interact only with inorganic or carboxylic acids and do not react with nitromethane, but they do react vigorously with alcohols, amines, and alkalis.[30]

Electron-accepting substituents in the α-position (Y = C_6H_5, COOR, or CN) stabilise the quinonoid bond system of the methylenequinone and the reactions of such methylenequinones with acids beome less typical. However, their reactions with nucleophiles proceed fairly readily with formation of phenolic compounds:[30,69,129]

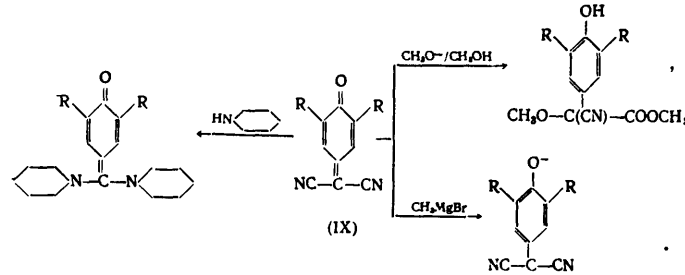


Consequently, in methylenequinones of this kind the carbon atom of the methylene group is fairly reactive with respect to nucleophilic attack.

The most general and typical property of methylenequinones is their ability to participate in oxidation-reduction reactions: a classical example is electrochemical reduction.[108,130,131] The characteristic features of the polarographic reduction of methylenequinones are similar to those of the reduction of quinones. The first polarographic wave of α-substituted 2,6-di-t-butyl methylenequinones in aprotic solvents corresponds to the reversible one-electron reduction, $E'_{1/2}$ depending mainly on the nature of the α-substituent. The main contribution of the electronic effects due to the α-substituent on $E'_{1/2}$ is achieved via the inductive mechanism.[131] The spin density in the radical-anions formed in the one-electron reduction of α-substituted methylenequinones is localised preferentially at the carbon atom of the methylene unit, which determines their ability to undergo spontaneous dimerisation reactions:[102,130]

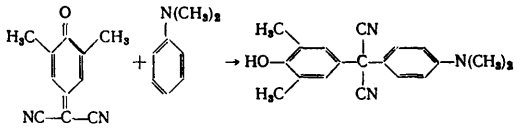
The dimerisation also occurs under the conditions of the polarographic reduction of α-substituted methylenequinones at a concentration of 10^{-4} M in connection with the high reactivity of the radical-anions produced.

In certain chemical reactions of α-substituted methylenequinones containing electron-accepting substituents, oxidation-reduction processes also take place. For example, the reaction of 2,6-di-t-butyl-α-phenyl- or 2,6-di-t-butyl-α-cyano-methylenequinones with Grignard reagents results in the formation of the corresponding dimers as well as products of the 1,6-addition to the double bond:[56,69]



Thus, in the interaction of strong nucleophiles with methylenequinones, a one-electron transfer can take place simultaneously with the main nucleophilic addition reaction.

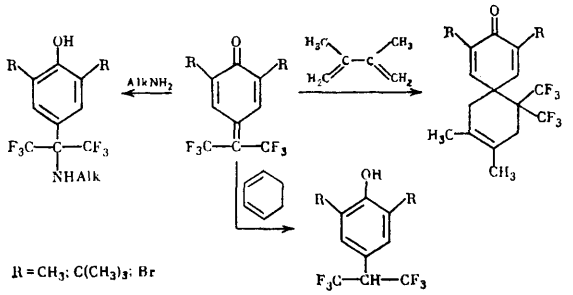
3. αα-Disubstituted Methylenequinones



The differences between the properties, chemical behaviour and reactivity of αα-disubstituted methylenequinones containing substituents of different nature are expressed more clearly than for the mono-α-substituted derivatives. In this case, the nature of the functional groups of substituents, their electronegativity, and their capacity for conjugation cause a more marked alteration of the properties characteristic of the unsubstituted methylenequinone and its homologues and new specific properties, characteristic only of the methylenequinones αα-disubstituted by functional groups, appear under these conditions. The fundamental difference in the chemical behaviour of such methylenequinones follows also from the analysis of their physicochemical properties (see above). Thus, on the basis of UV and IR spectroscopic data alone, one can conclude that the "amide" conjugation is so pronounced in αα-(*NN*-dialkylamino)-2,6-di-t-butylmethylenequinones that they virtually lose the properties characteristic of the structure of the mono-α-substituted methylenequinones and that they should be regarded as compounds having a zwitter-ionic structure. These compounds hardly dissolve in organic solvents and are characterised by a high melting point and a high dipole moment (10.8 D).[24]

On the other hand, the quinonoid bond system becomes stable in methylenequinones with electronegative substituents. Such methylenequinones are inert in relation to protic acids and only reactions with nucleophiles become characteristic of them. For example, compound (IX) exhibits very pronounced electron-accepting properties and is capable of forming donor–acceptor complexes with amines and alkoxides. The interaction of the methylenequinone (IX) with a Grignard reagent results in the appearance of a stable radical-anion.[69] The final product of the reaction of the methylenequinone (IX) with piperidine is 2,6-di-t-butyl-αα-dipiperidinomethylenequinone, while its reaction with sodium methoxide leads to the formation of the product of the addition of methanol with partial alcoholysis of one of the nitrile groups:[56]

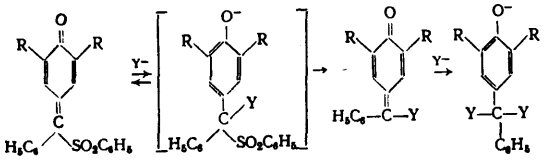
2,6-Disubstituted αα-dicyanomethylenequinones are stable in acid media, although 1,6-addition reactions are possible under the influence of nucleophiles. In this sense, data concerning the use of



αα-dicyano-2,6-di-methylmethylenequinone as an alkylating agent for dimethylaniline are of definite interest:[18,132]

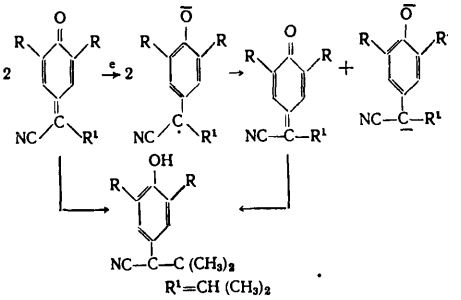
The majority of αα-disubstituted methylenequinones with electronegative substituents are stable compounds whose stability is almost independent of the presence of substituents in the six-membered ring, which is apparently associated with the sharp decrease of the mobility of the *p*-electrons of the carbonyl group and the consequent loss of capacity for protonation in acid media.

The electron-accepting properties and the electron affinities of αα-diphenylmethylenequinone are almost independent of the character of the substituents in the six-membered ring, their polarographic reduction potentials are similar, and the 1,6-addition reactions take place only under the conditions of base catalysis. For example, the methylenequinone (XIII) does not react with amines and sodium methoxide, but, in the presence of potassium t-butoxide, acetonitrile adds to it.[133,134] 2,6-Dialkyl-αα-diphenylmethylenequinones are capable of forming complexes with phenols and the enthalpy of formation of a hydrogen bond in these complexes increases sharply with decrease in the steric effect generated by the alkyl substituents in the initial methylenequinones.[135]



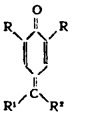
Other examples confirming the similarity of the influence of electronegative α-substituents on the properties of αα-disubstituted methylenequinone are the reactions of 2,6-dialkyl-αα-bis(trifluoromethyl)methylenequinones, which interact with amines and unsaturated compounds but are stable in relation to acids:[136]

R = CH_3; $C(CH_3)_3$; Br



Finally, the reactivity of 2,6-di-t-butyl-α-chloro-α-trifluoromethylmethylenequinone is reduced so much that it has become inert in relation to nucleophiles and is even stable in the presence of alkali metal hydrides.[137]

Reactions leading to the replacement of one of the α-substituents are also characteristic of compounds of the type considered. The characteristic features of the substitution reactions involving αα-disubstituted methylenequinones depend on the thermodynamic stability of the intermediate phenoxide ion and on the strength of the bonds between the α-substituents and the carbon atpm of the methylene unit. An example of such reactions is provided by the substitution of a α-benzenesulphonyl group when 2,6-di-t-butyl-α-phenyl-α-benzenesulphonylmethylenequinone is acted upon by nucleophiles:[138]



Reactions of this type, involving nucleophilic substitution and subsequent addition, have been investigated under conditions where the above methylenequinone was acted upon by alkalis, alkoxides, thiophenoxides, and cyanides. The method has found an application in the synthesis of derivatives of sterically hindered phenols which are otherwise difficult to obtain.

Quantitative data characterising the influence of α-substituents of different nature on the reactivity of αα-disubstituted 2,6-di-t-butylmethylene quinones in the reaction with the simplest nucleophile (the electron) have been obtained as a result of polarographic measurements and electrochemical studies (Table 4). In this series, the greatest electron affinity is shown by the methylenequinone (IX), whose electrochemical reduction takes place in two stages, a stable radical-anion being formed at the potential of the first polarographic wave $E'_{1/2}$. This method makes it possible to estimate the reactivity of methylenequinones containing in the α-positions simultaneously electron-accepting and electron-donating substituents. Furthermore, it has been possible to establish the characteristic features of the electrochemical reduction of 2,6-di-t-butyl-α-cyano-α-isopropyl methylenequinone associated with the phenomena involving the disproportionation of the intermediate radical-anion and the isomerisation of the initial methylenequinone to vinylphenol under electrochemical reduction conditions:[56]

The EPR spectrum of the radical-anion has been recorded in the course of the reduction of 2,6-di-t-butyl-α-cyano-α-isopropylmethylenequinone by metallic potassium in tetrahydrofuran.[56]

Table 4. The half-wave potentials (relative to the saturated calomel electrode) for the polarographic reduction of αα-disubstituted 2,6-di-t-butyl methylenequinones (in dimethylformamide with tetrabutylammonium perchlorate as the supporting electrolyte).[56]

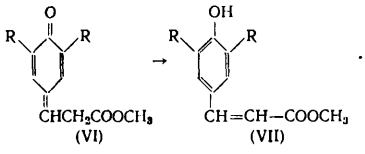
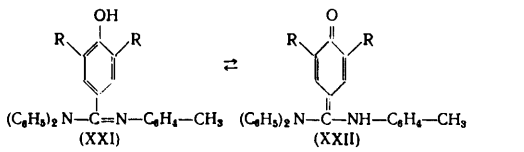
VI. ISOMERISATION OF METHYLENEQUINONES



The high reactivity of methylenequinones is associated with thermodynamic factors and the possibility of a rearrangement of the bond system of the methylenequinone to the aromatic bond system of a phenol. This possibility is manifested clearly in the isomerisation of methylenequinone homologues to vinylphenols. The isomerisation of alkylmethylenequinones to vinylphenols is irreversible,

so that many reactions of the methylenequinones are accompanied by the formation of vinylphenol derivatives. Thus in an aqueous medium at pH 8.2 the isomerisation of the methylenequinone (XVIII) to 2,6-di-t-butyl-4-vinylphenol (XX) takes place simultaneously with its hydration, both reactions proceeding at similar rates under the conditions indicated (k_2/k_3 = 2.8):[119]

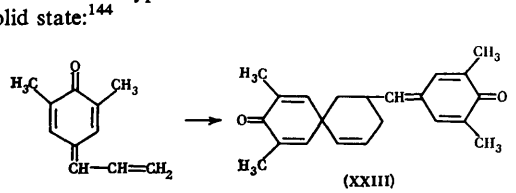
(XVIII) (XX)



In acid or alkaline media, the rate of the 1,6-addition reaction is significantly higher than the rate of isomerisation, but, with increase in the reaction time, the yield of the phenol (XX) increases because of the irreversibility of the isomerisation stage. At 70–75 °C the irreversible isomerisation of α-alkylmethylenequinones takes place in the presence of alumina.[139] Vinylphenols are obtained in substitution reactions with participation of benzyl derivatives of phenol. Many of these reactions proceed via a stage involving the formation of the corresponding methylenequinones, whose isomerisation actually leads to the vinylphenols.[140,141] The functional-group substituents in the α-position promote the isomerisation of methylenequinone to vinylphenol, the process actually occurring spontaneously at room temperature, for example:[56]

(VI) (VII)

The pure methylenequinone (VI) rearranges quantitatively to a cinnamic acid derivative after two days at 20 °C.



Under the influence of functional-group substituents in the α-position, the thermodynamic stability of the methylenequinone structure increases and tautomeric transformations are observed in the case of α-aminomethylenequinones.[142] For example, the prototropism of 3,5-di-t-butyl-4-hydroxy-*NN*-diphenyl-*N'*-tolybenzamidine (XXI) is observed in solution and leads to the establishment of thermodynamic equilibrium with the corresponding αα-diaminomethylenequinone (XXII):

(XXI) (XXII)

Both tautomers, (XXI) and (XXII), have been isolated in a pure state. At 25 °C, the ratio of compunds (XXI) and (XXII) is 42 : 58, $\Delta G^{\ddagger}_{298}$ = 70.8 kJ mole^{-1}, and $\Delta S^{\ddagger}$ = −16.4 e.u. The solvent polarity affects the ratio of the tautomers in solution and hence the nature of the solvent is one of the factors influencing the stability of the methylenequinone bond system.[143]

Methylenequinones containing vinyl substituents in the α-position undergo Diels-Alder-type dimerisations in concentrated solutions or in the solid state:[144]

(XXIII)

The cyclohexadiene structure is retained in reactions of this type and a methylenequinone (XXIII) derivative having a more complex structure is formed. The dimerisation reaction is irreversible.

—o0o—

The interest in the chemistry of methylenequinones has not weakened for a long time. In our day, they remain convenient objects for the investigation of various aspects of theoretical and synthetic organic chemistry and photochemistry and also for the study of the pathways leading to the biogenesis of natural products.

The structure of methylenequinones is labile, which is the reason for their high reactivity. Both homolytic and heterolytic reactions are characteristic of them. Being vinylogues of ketones, methylenequinones possess also many of their properties, but these are manifested more strikingly and are more varied.

Carcinogenic *N*-Nitrosamines. Formation, Properties, and Analysis

Ya.L.Kostyukovskii and D.B.Melamed

Literature data on the formation of carcinogenic *N*-nitrosamines in the environment, their physicochemical properties, their action on the human organism, the methods for their microanalysis, and also their content in the atmosphere, water sources, soil, and industrial agricultural and food products are described systematically and surveyed. The principal features of this comparatively new class of powerful chemical carcinogens are indicated.
The bibliography includes 284 references.

I. INTRODUCTION

A distinct tendency towards an increase in the pollution of the environment as a consequence of the intense technological activity by man can be traced during the last decade. A constant increase in the amount of bound nitrogen in the biosphere as a result of the increase in the scale of industrial manufacture, the consumption of fuel, the use of nitrogen-containing fertilisers and pesticides, the ejection into the atmosphere of nitrogen oxides, ammonia, amines, etc. has been noted.

The pollution of various objects by compounds with a high toxicity and carcinogenic and mutagenic properties is especially undesirable. Among substances of this type, the large group of *N*-nitroso-compounds, in which aliphatic and certain cyclic *N*-nitrosamines (NA) exhibit a high carcinogenic activity, can be distinguished. These compounds have been known for more than 100 years but due attention has not been paid to their investigation. Certain NA have been used in industry as solvents, intermediates for the synthesis of substituted hydrazines, etc. In the middle of the 1950's, it was observed that *N*-nitrosodimethylamine induces liver tumours in animals and in subsequent years it was established that about 200 different nitroso-compounds exhibit a carcinogenic activity.[1-5] About 1500 publications annually have been devoted recently to the study of the properties of this comparatively new class of carcinogens and especially of their biological activity.[6]

NA are fairly stable and are capable of circulating for a long time in the environment, which results in the pollution of various objects. It has been established that NA are contained in water, air, soil, food and industrial products, agricultural pesticides and herbicides, medicinal drugs, etc. and that the compounds most often detected are *N*-nitrosodimethylamine (NDMA), *N*-nitrosodiethylamine (NDEA), *N*-nitrosopyrrolidine (NPyr), and *N*-nitrosopiperidine (NPip). *N*-Nitrosodipropylamine (NDPA), *N*-nitrosodibutylamine (NDBA), *N*-nitrosoethylmethylamine (NEMA), *N*-nitrosomorpholine (NMor), *N*-nitrosothiazolidine (NThia), etc. are more rarely encountered.[3-5,7-11]

An important feature of NA compared with other classes of carcinogens is the possibility of their ready formation directly in various objects as a result of nitrosation. Amines and many other nitrogen-containing substances as well as different nitrosating agents are widely distributed in water, air, food products etc.

Data on the biological activity of NA and their presence in objects in the environment have been published in a series of reviews and monographs.[2-4,8,12-20] This review deals with processes leading to the formation of NA, the chemical reactions determining their properties and transformations, and methods for their analysis and surveys data on the content of these compounds in various objects.

II. METHODS OF SYNTHESIS OF *N*-NITROSAMINES

The main process leading to the formation of NA is nitrosation. The compounds nitrosated can be various mono-, di- and polyamines as well as other nitrogen-containing compounds. Secondary and tertiary amines as well as other compounds containing the $(CH_3)_2N$ and $(C_2H_5)_2N$ groups are most readily and rapidly nitrosated. The nitrosating agents are usually nitrous acid derivatives XNO (X = halogen, NO_2, NO_3 OH_2^+, or OR) as well as the nitrosonium cation, etc.[21-25] The nitrite ion and free HNO_2 are converted into active nitrosating agents in an acid medium:[21,23,25-30]

$$2NO_2^- \xrightarrow{H^+} 2HNO_2 \rightleftarrows H_2ONO^+ + NO_2^- \rightleftarrows N_2O_3 + H_2O\,.$$

At low pH, there is a possibility of the formation of the nitrosonium cation:

$$N_2O_3 + 3H_2SO_4 \rightarrow 2NO^+ + 3HSO_4^- + H_3O^+\,.$$

In the presence of nitrogen halides, HNO_2 is capable of giving rise to the corresponding nitrosyl halides;[21,31]

$$HNO_2 + HCl \rightleftarrows NOCl + H_2O\,.$$

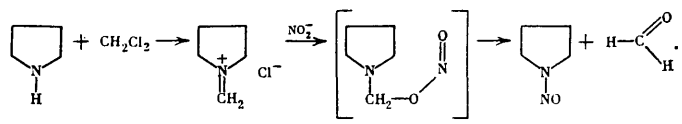
Nitrosating agents can be arranged in the following sequence in order of the decrease in their activity: $NO^+ > H_2ONO^+ > NOCl > N_2O_3$.[21,25,32] In aqueous solutions of nitrites and nitrous acid at pH below 5, various nitrosating agents and their mixtures can be present.[21,23,33]

1. Nitrosation of Amines

The nitrosation of secondary amines is usually used for the synthesis of NA and is the main cause of their formation in various objects.[12,21,22,26,29,34] Nitrosation by various agents takes place in water, mixtures of water with organic solvents, in organic solvents, in the gas phase, and also directly in various objects over a wide temperature range.[4,17,22,29,30,33-39] In solutions, this reaction ensures a high yield of NA:[21,22,29,36,40,41]

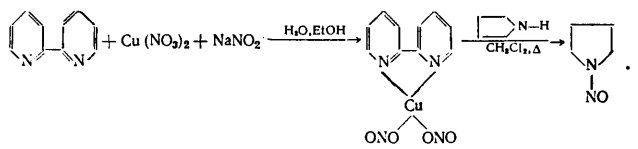
$$\begin{matrix} R \\ R' \end{matrix}\!\!>\!NH + NOY \rightarrow \left[\begin{matrix} R \\ R' \end{matrix}\!\!>\!NHNO\right]^+ Y^- \rightarrow \begin{matrix} R \\ R' \end{matrix}\!\!>\!NNO + HY\,.$$

Under certain conditions, secondary amines are capable of being converted into the corresponding NA on treatment with not only active nitrosating substances but even sodium nitrite. In aqueous solutions of $NaNO_2$ and a secondary amine, the following reactions are possible under the influence of sunlight, UV light, or γ-radiation:[42-45]



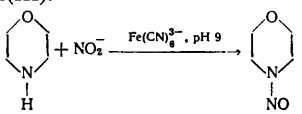
$$2NO_2^- + H_2O \rightarrow N_2O_3 + 2HO^-,$$

$$N_2O_3 + \underset{R'}{\overset{R}{>}}NH \xrightarrow{HO^-} \underset{R'}{\overset{R}{>}}N{-}NO + H_2O + NO_2^-,$$



$$2NO_2^- + 2H_2O \rightarrow N_2O_4 + 2HO^- + 2HO^-,$$

$$N_2O_4 + \underset{R'}{\overset{R}{>}}NH \xrightarrow{HO^-} \underset{R'}{\overset{R}{>}}N{-}NO + H_2O + NO_3^-.$$



Certain secondary amines are nitrosated in methylene chloride with sodium nitrite,[30,35,46] for example:[35,46,47]

A series of metal salts promote the reaction of secondary amines and nitrites in neutral and basic media.[22,29,47-49] Thus pyrrolidine interacts fairly readily with $NaNO_2$, 2,2′-bipyridyl, and copper nitrate:[49]

Instead of 2,2′-bipyridyl, it is possible to use pyridine although with less success.[49] The reaction of morpholine with $NaNO_2$ is promoted by hexacyanoferrate(III):[21,49]

Secondary amines interact analogously with sodium nitroprusside:[22,50,51]

$$\underset{R'}{\overset{R}{>}}NH + Fe(CN)_5NO^{2-} \xrightarrow{OH^-} \underset{R'}{\overset{R}{>}}NNO.$$

Presumably the promoting action of hexacyanoferrate(III) on the nitrosation reaction is caused by the preliminary formation of the nitroprusside ion. This has been confirmed to some extent by the interaction of hexacyanoferrate(II) with nitrite:[49]

$$Fe(CN)_6^{4-} + NO_2^- \rightarrow Fe(CN)_5NO_2^{4-} + CN^-,$$

$$Fe(CN)_5NO_2^{4-} + 2H^+ \rightarrow Fe(CN)_5NO^{2-} + H_2O.$$

The nitrosation of secondary amines in the presence of certain aldehydes, for example, formaldehyde takes place in an alkaline medium.[4,28,47,52]

The nitrosation of secondary amines by gaseous nitrogen oxide is of practical interest from the standpoint of the formation of NA in various objects. Air usually contains N_2O_3 and N_2O_4 which are capable of interacting with secondary amines dissolved in water or organic solvents and also those present in various objects:[29,36,27,42,53]

$$2\,\underset{R'}{\overset{R}{>}}NH + 2N_2O_4 \rightarrow \underset{R'}{\overset{R}{>}}N{-}NO + \underset{R'}{\overset{R}{>}}N{-}NO_2 + HNO_3 + HNO_2.$$

On treatment with gaseous N_2O_3 nd N_2O_4, NA are formed in aqueous solutions over a wide pH range, even at pH > 5, which can be explained by the high rate of nitrosation of secondary amines compared with hydrolytic reactions.[29,36,42] Analogous results have been obtained in the nitrosation with gaseous nitrosyl chloride.[21,36,42] NA are also formed in air from secondary amines and gaseous nitrogen oxides.[36,37,54-57] It is believed that this reaction is initiated by photodissociation and takes place via a radical mechanism:[36,37,42,56,58]

$$HONO \xrightarrow{h\nu} NO^{\cdot} + HO^{\cdot} \xrightarrow{\underset{R'}{\overset{R}{>}}NH} H_2O + \underset{R'}{\overset{R}{>}}N^{\cdot} \xrightarrow{NO^{\cdot}} \underset{R'}{\overset{R}{>}}N{-}NO.$$

Certain organic compounds containing the NO_2 or ONO groups are also capable of nitrosating secondary amines. Aliphatic polynitro-compounds are known to be capable of acting as "NO_2-producing substances".[32,50] It has been shown that tetranitromethane, 2,2-dinitropropanol, and 2-bromo-2-nitropropane-1,3-diol afford NMor on heating with morpholine.[59] The mechanism of this reaction has been inadequately elucidated.

The nitrosating activity of nitrous acid esters has been more fully investigated:[31,42,60-65]

$$R''{-}ONO + HY \rightarrow \left[R''{-}\underset{H}{\overset{|}{O}}NO\right]^+ Y^- \rightarrow R''{-}OH + Y{-}NO,$$

$$\underset{R'}{\overset{R}{>}}NH + Y{-}NO \rightarrow \underset{R'}{\overset{R}{>}}N{-}NO + HY.$$

On exposure to UV irradiation, this reaction can have a radical mechanism.[12,31,61] The thioesters of nitrous acid react analogously.[60,62,65-68]

The transnitrosation reaction, which is not used for the synthesis of NA but can occur in various objects and in the organism, is of significant interest. Various nitroso-compounds, especially those which have no carcinogenic activity or their carcinogenic activity is weak, can act as nitrosating agents and transnitrosation can result in the formation of active carcinogens.[69-72] A series of nitroso-compounds which are quite effective in this reaction, including heterocyclic and aromatic compounds and substituted ureas and urethanes, have been discovered. As a rule, they are all readily obtained by nitrosating substances containing $\rangle$NH group and have a fairly labile NO group.[69,72,73] The nitrosation reactions with participation of the non-carcinogenic nitrosodiphenylamine (NDPhA), used in the rubber industry, have been studied in fair detail. The conditions for the occurrence of this reaction both in various solutions and in the organism have been discovered and a probable process mechanism has been proposed:[70,71,73]

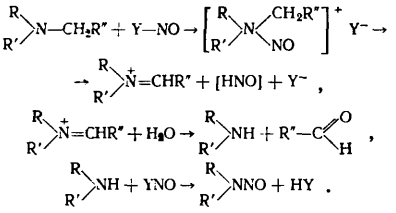
$$(C_6H_5)_2N{-}NO + HY \rightarrow \left[(C_6H_5)_2N\underset{NO}{\overset{H}{<}}\right]^+ Y^- \rightarrow (C_6H_5)_2NH + Y{-}NO,$$

$$\underset{R'}{\overset{R}{>}}NH + Y{-}NO \rightarrow \underset{R'}{\overset{R}{>}}N{-}NO + HY.$$

The reaction is accelerated in the presence of SCN^- and I^- ions.[70,73] When solutions of NDPhA are heated, the following reactions occur:[21,71]

$$2\,(C_6H_5)_2N{-}NO \xrightarrow{\Delta} (C_6H_5)_2N{-}N(C_6H_5)_2 + 2NO,$$

$$\underset{R'}{\overset{R}{>}}NH + NO \xrightarrow{O_2 \text{ or catalyst}} \underset{R'}{\overset{R}{>}}N{-}NO.$$

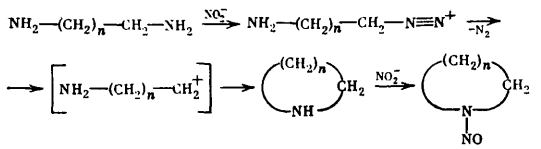


The reaction of NDPhA with dibutylamine results in the formation of NDPA, that with morpholine affords NMor and that with tetramethylthiuran disulphide gives rise to NDMA.[71] Mono- and di-isonitrosopiperazines are also effective in transnitrosation reactions.[41,73]

Transnitrosation with nitrosoaminoacids, which are readily formed in various objects and in the organism, has been investigated.[70-73] Thus the interaction of nitrosoproline or hydroxynitrosoproline with morpholine in animal organisms has led to the detection of NMor.[69]

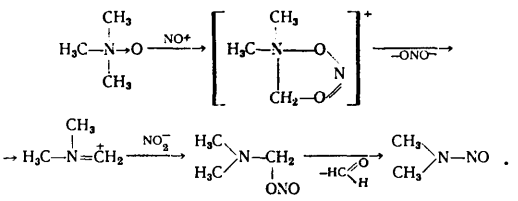
The possibility of nitrosating secondary amines by nitrates after the conversion of the latter into NO_2^-, NO_2, or NO is of practical interest. The microbiological and chemical reduction of nitrates occurs widely both in objects in the environment and in the organism.[7,13,18,33,34,42,45,47,74,75] The presence of high concentrations of nitrates in the soil, in water, in mineral fertilisers, in food products, in various types of animal feed, etc. makes a significant contribution to the pollution of various objects by nitrosamines.

Numerous studies have demonstrated that NA are formed from secondary amines and various nitrosating agents directly in human and animal organisms.[8,12,17,18,53,76-82]



The nitrosation of various tertiary amines, which takes place in a complex manner, has been fairly widely investigated. The majority of workers believe that the nitrosation is preceded by a cleavage stage:[27,34,41,63,83,87]

This mechanism has been demonstrated by isolating the reaction mixture and identifying the NA, the corresponding aldehyde, and the [HNO] conversion product—nitrous oxide.[41,84] Tertiary amines are nitrosated with more difficulty than secondary amines; even under optimum conditions, the yield of NA is significantly lower and rarely reaches 40–50%.[32,41,83,84,87,88] However, it has been noted that trimethylamine and also trimethylamine oxide form NDMA fairly rapidly.[27,41,84,89,90] The ease of nitrosation of tertiary amines decreases appreciably with increase in the number of carbon atoms in the amine.[21,41,84,87,89,90] As a rule, a series of side products are formed together with the NA under severe conditions.[41,83,87,88] The formation of NA from tertiary amines has been demonstrated in various objects and also directly in the organism.[13,34,41,76,84,89,90]

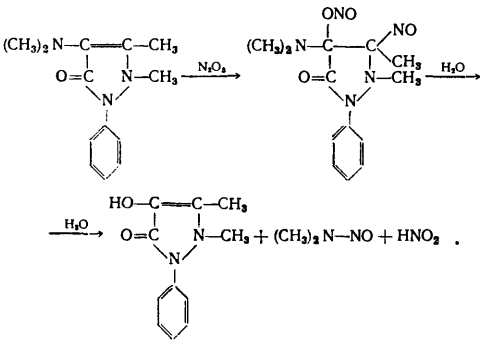


The interaction of nitrosating agents with primary amines has been less thoroughly investigated. These reactions proceed via various fairly complex mechanisms and the yield of the NA is in most cases insignificant.[12,21,32,91,92]

Certain primary di- and poly-amines, including biologically active compounds such as putrescine, cadaverine, spermine, and spermidine can give rise to cyclic NA on nitrosation:[4,5,91,93]

Putrescine reactions with nitrous acid to produce NPyr in yields up to 1.6%.[92-94] For comparison, we may note that the yield of NDBA in the nitrosation of n-butylamine under the same conditions is only 0.01%.[92,94] The nitrosation of primary amines in various objects and in the organism is possible, but this gives rise to only small amounts of NA.[4,91-93]

The nitrosation of quaternary ammonium compounds takes place at elevated temperatures and high concentrations of the starting materials, the yield of the NA being insignificant.[95-97] The mechanism of these processes has been inadequately investigated. It is assumed that tetramethylammonium salts are less capable of being nitrosated than dimethylamine oxide:[84,85,95,97]

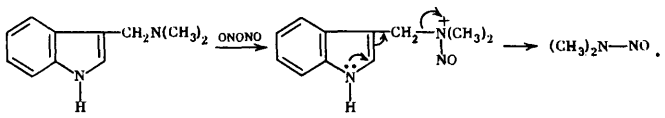


Tetra-alkylammonium compounds can be nitrosated in heterogeneous media on treatment with gaseous nitrogen oxides.[89,90] This reaction leads to pollution with nitrosamines of the products in which high concentrations of trimethylamine, acetylcholine chloride, choline chloride, etc. have been detected.[84,89,90,96,97]

2. Nitrosation of Other Nitrogen-containing Substances

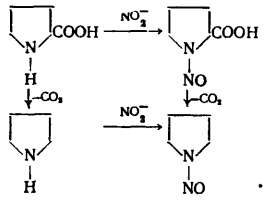
The nitrosation of a series of nitrogen-containing substances with formation of NA can occur in two ways: the insertion of the NO-group in the molecule and the formation of complex nitroso-compounds or the cleavage of the nitrogen-carbon bonds and the interaction of the amino-groups with nitrosating agents. Reactions of the first type have been described in a number of studies.[4,12,27,95,98,99] We shall consider processes which result in the formation of volatile NA—the "nitrosative deamination" reactions.[21,24,100-102]

Certain nitrogen-containing substances are capable of reacting with nitrosating agents at unexpectedly high rates. Thus aminopyrine (2,3-dimethyl-4-dimethylamino-1-phenyl-3-pyrazolin-5-one) is rapidly nitrosated in homogeneous and heterogeneous media during manufacture and storage and also in the organism:[14,58,100,102-109]



It is assumed that the high rate of this reaction is caused by the presence in the molecule of the "active" dimethylamino-group.[21,15,104] In the medicinal forms of amidopyrine, especially in tablets, the distribution of NDMA is not homogeneous: the greatest amounts are contained on the surface, which can be explained by the action of nitrogen oxide present in air within industrial and storage buildings.[58,104,110] Even the introduction of nitrosation inhibitors does not fully prevent the formation of NDMA.[58,104,106]

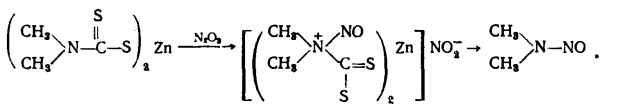
Tetracycline, penicillin, etc. react vigorously with nitrosating agents.[86,102,103,109] Other medicinal drugs and metabolities, for example, phenacetine, imizine, and aminazin, are also capable of "nitrosative deamination".[14,100,102,106-111]



Alkaloids containing the dimethylamino-group can be a source for the formation of NA. This process has been studied in detail in relation to gramine and hordenine—the alkaloids present in barley malt used in the manufacture of beer.[23,27,101] The rate of reaction, which proceeds in accordance with the mechanism proposed by the authors, is close to the rate of nitrosation of dimethylamine, which

can be explained by the presence of the active dimethylamino-group in the gramine molecule:[27,101]

Hordenine is nitrosated much more slowly.[27,110]



It is also possible to obtain NA from certain aminoacids and the reaction can occur via two main pathways:

In the nitrosation and decarboxylation of aminoacids such as arginine and ornithine, NPyr and NPip have been detected. The ease of formation of NA from aminoacids is attributed to the capacity of the latter for decarboxylation; for example, proline and its derivatives are effectively nitrosated.[24,93,112]

NA are formed also from certain insecticides, pesticides, and herbicides. The dimethylammonium salts of various acids, for example, 2,4-D (2,4-dichlorophenoxyacetic acid), 2,4-DB (2,4-dichlorophenoxybutyric acid), 2,3,6-TCBA (trichlorobenzoic acid), MCP (4-chlorotolyloxyacetic acid), MCPP [2-(4-chloro-2-methylphenoxy)propionic acid], etc., are especially readily nitrosated.[96,103,107,113-115]

The "nitrosative deamination" of a series of pesticides and herbicides containing dialkylamino-group leads to the formation of NA:[95]

NDMA has been isolated from the products of the nitrosation of thiram(tetramethylthiuram disulphide) and ferbam [tris(dimethylcarbamodithioato-*SS'*)iron], NDPA has been isolated from trifluralin (ααα-trifluoro-2,6-dinitro-*NN*-dipropyl-*p*-toluidine), isopropalin (2,6-dinitro-4,*NN*-tripropylaniline), and nitrosobutylethylamine has been obtained from benefin (*N*-butyl-*N*-ethyl-ααα-trifluoro-2,6-dinitro-*p*-toluidine).[95,96,103,113,115,116] The pesticides which are quaternary ammonium compounds and derivatives of morpholine afford NA on interaction with nitrites.[96,103,107,114,117]

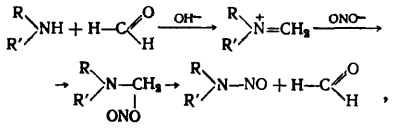
Certain products, widely used in the rubber industry, for example, vulcanisation accelerators and stabilisers, are capable of "nitrosative deamination". This applies mainly to substances containing the dialkylamino-group and to derivatives of morpholine.[38,71,99,118-121]

3. Catalysis and Inhibition of the Nitrosation Reaction

The rate of nitrosation depends on a number of factors among which the structure, basicity, and concentration of the nitrogen-containing compounds to be nitrosated, the properties and concentration of the nitrosating agent, the pH of the medium, temperature, the homogeneity of the reaction mixture, the nature of the solvent, and also the presence of catalysts or reaction inhibitors are important. The rate of reaction of various aliphatic amines with nitrites in weakly acid aqueous solutions is proportional to the concentration of the amine and the square of the concentration of nitrous acid. The kinetics of such reactions have been examined in detail.[21,32,34] The concentrations of the non-protonated form of the amine and of free nitrous acid are of decisive importance for the rapid occurrence of the reaction. The maximum rate of nitrosation of secondary amines with a high or moderate basicity, from which carcinogenic NA are usually formed, has been noted at pH close to 3.4, which corresponds to the dissociation constant of nitrous acid.[21,34,122-124] With increase in pH, the rate of reaction falls (approximately by an order of magnitude for each pH unit), but the NA are formed also at pH 5–6, while in the presence of promoting agents and certain micro-organisms, they are formed at pH > 7.[22,29,34,47-49,123] At low pH, a decrease in the rate of nitrosation was observed as a consequence of the fall in the concentration of the non-protonated form of the amine. For weakly basic amines, a decrease in pH affects less markedly the rate of their nitrosation since under these conditions the concentration of the non-protonated form of the amine is also considerable.[21,34,102]

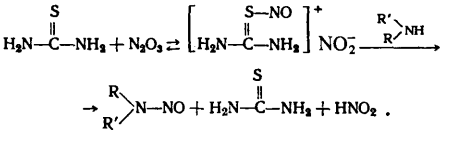
The rate of formation of NA from amines decreases in the following sequence: morpholine > pyrrolidine ⩾ piperidine > dimethylamine > diethylamine > di-n-propylamine ⩾ di-isopropylamine.[23,33,34,102]

In real objects and in the organism, the conditions for the occurrence of nitrosation are less favourable than in solution but prolonged interaction of the reactants can lead to the accumulation of significant amounts of the NA. In this case the presence of a catalyst or inhibitors of the nitrosation reaction in the reaction medium acquires decisive importance.[5,6,10,81,125-127] The accelerating or retarding effect depends on the reaction medium; certain compounds, for example, phenols, can exhibit the opposite influence under different conditions.



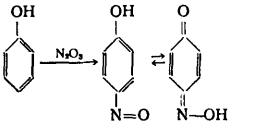
(a) Catalysts. A considerable number of compounds catalysing nitrosation are known.[4,5,10,47,59,115,125,126,128,129] Nucleophilic anions such as thiocyanates and halides are capable of accelerating this reaction significantly.[47,125,126,129-131] In terms of their activities, they can be arranged in the sequence $SCN^- > I^- \geqslant Br^- > Cl^-$.[21,126,131] In the case of SCN^-, the reaction proceeds via the formation of the fairly stable nitrosyl thiocyanate:[55,59,69,126,129,130,132]

$$HONO + SCN^- + H^+ \rightleftarrows SCN{-}NO + H_2O,$$

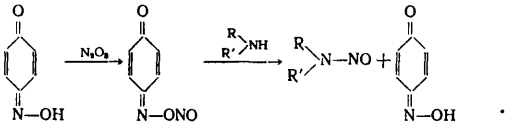


The thiocyanate accelerates this reaction at low pH in solution and also in various objects and in the organism.[47,126,130,132] The I^- ion is an effective nitrosation catalyst; its activity is manifested under different conditions, including heterogeneous nitrosation with nitric oxide.[42,47,126,131] In the presence of I^- and also Br^- and Cl^-, nitrosation proceeds via the formation of nitrosyl halides.[31,47,131]

A number of carbonyl compounds accelerate the synthesis of NA. Formaldehyde shows the highest efficiency; chloral, benzaldehyde derivatives, pyridoxal, mabnodialdehyde, hexachloro- and hexafluoro-acetones, etc. are also active.[28,47,52,125,133] The proposed mechanism of the reactions occurring with participation of carbonyl compounds at pH ⩾ 7 includes the formation of iminium ions:[4,47,52,133]

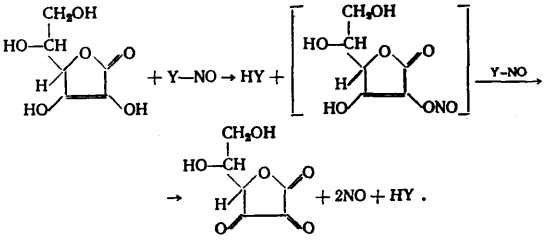


Other substances evolving formaldehyde or reacting analogously probably also catalyse the nitrosation reaction.

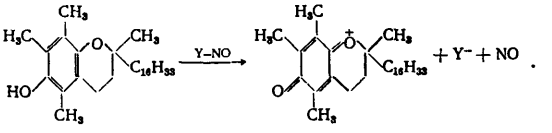


The compounds capable of accelerating this reaction include thiourea and certain thiols.[47,66,130,134] In the case of thiourea, which catalyses the nitrosation of secondary amines at a pH of about 4.0, the reaction proceeds via the *S*-nitroso-adduct:[47,134]

The situation is more complicated with phenols and certain other OH-containing substances which are capable of exerting both catalytic and inhibiting influences on the nitrosation reaction depending on the structure, the pH of the medium, etc.[42,47,66,69,80,135-138] Phenol reacts rapidly with nitrosating agents, for example, with HNO_2, at pH < 4:[47,135]

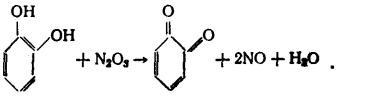


Quinone monoxime is rapidly nitrosated, probably affording the *O*-nitro-derivative, which reacts with the amine:[47,66,135-137]



The catalytic action of resorcinol can be explained analogously.[80,135,139] In principle, under certain coditions catechol and hydroquinone can exhibit an accelerating effect;[47,138] however, the probability of their nitrosation is low, since they show a greater tendency to form the corresponding benzoquinones under these conditions.[80,135,138] Other compounds containing the OH group, for example gallic and chlorogenic acids, camphorol, and quercetin, can likewise catalyse the formation of NA.[32,135]

The ability to accelerate the nitrosation reaction has also been discovered in certain unsaturated compounds, surfactants, conjugate bases of bile acids, etc.[32,140] We may note that certain species of micro-organisms are able to accelerate significantly the formation of NA.[47,74]



(b) Inhibitors. A large number of compounds able to inhibit the formation of NA have been described.[4,5,12,21,47,106,115,125,126] Naturally, the retardation of the reaction is achieved most simply by altering the conditions and in the first place the pH. This is difficult to achieve in various objects and in the organism. For this reason, much attention has been devoted to the search for effective inhibitors and the determination of the mechanism of their action. Virtually all the compounds proposed for this purpose show an inhibiting influence on the reaction as a result of the inactivation of nitrosating agents, but this can be achieved in different ways. Many substances inhibiting the formation of NA react with nitrosating agents, reducing them to the relatively inactive nitric oxide. Most studies have probably been devoted to ascorbic acid and its derivatives, which are able to inhibit effectively in this way the nitrosation reaction over a wide pH range:[6,46,47,55,68,81,106,115,140-144]

Ascorbic acid is especially active in hydrophilic media. The use of α-tocopherol in hydrophobic media has been recommended:[47,81,115,140,142,143,145]

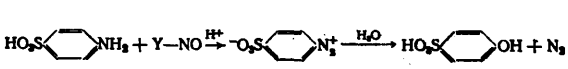
Together with α-tocopherol, one can also use ethoxyquin (6-ethoxy-1,2-dihydro-2,2,4-trimethylquinoline) and dihydroethoxyquin.[146] The oxidation of catechol, hydroquinone, and derivatives of gallic acid and polyphenols, which have been proposed as inhibitors, capable for forming *o*- and *p*-benzoquinones, proceeds via the same pathway:[47,55,69,80,120,135,138,139]

Sulphur dioxide and the bisulphite ion reduce the nitrosating agents to nitric or nitrous oxide:[32,115]

$$SO_2+N_2O_3+H_2O\rightarrow 2NO+H_2SO_4,$$
$$SO_2+2NO+H_2O\rightarrow N_2O+H_2SO_4.$$

Hydroxylamine, various hydrazines, sodium azide, and certain other reductants retard analogously:[33,47,115,147,148]

$$NH_2OH+Y{-}NO\rightarrow N_2O+H_2O+HY,$$
$$NH_2NH_2+Y{-}NO\xrightarrow{H^+}N_2O+NH_4^++HY,$$
$$N_3^-+Y{-}NO\rightarrow N_2O+N_2+Y^-.$$



Certain alcohols, for example, ethanol and ethylene glycol, carbohydrates (glucose, sucrose), and other compounds containing the OH group inhibit the formation of NA, being converted into the corresponding alkyl nitrites:[42,78,144,149-152]

$$ROH+Y{-}NO\rightarrow RONO+HY.$$

Thiols react analogously but more vigorously:[57,144,149,150]

$$RSH+Y{-}NO\rightarrow RSNO+HY.$$

The substances examined inactivate nitrosating agents, converting them into the less reactive esters (thioesters) of nitrous acid or nitric (nitrous) oxide. In order to prevent the reactivation of nitric and nitrous oxides, it is essential to use high concentrations of the inhibitors, in particular ascorbic acid and tocopherol.[141,145,153] It is more useful to seek inhibitors converting active nitrosating agents into substances incapable of reacting with amines. The possibility of using derivatives of primary aromatic amines, for example, sulphanilic acid and sulphanilamide, which give rise to diazo-compounds on reaction with nitrosating agents, has been established:[118,141,154,155]

There is no doubt that new effective nitrosation inhibitors can be found among other readily diazotising compounds.

Urea and sulphamic acid, proposed for the retardation of the formation of NA, also lead to the decomposition of nitrosating agents;[47,81,106,115,144,147]

$$O{=}C(NH_2)_2+2Y{-}NO\rightarrow 2N_2+CO_2+H_2O+2HY,$$
$$NH_2SO_3H+Y{-}NO\rightarrow N_2+H_2SO_4+HY.$$

The use of ammonia, tannin, vanillin, thymol, squalene, pyrrole, glutathione, indole, etc. as inhibitors has also been indicated.[6,21,47,69,126,139,153]

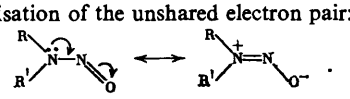
It is useful to employ inhibitors to prevent the pollution of various objects by nitrosamines and the formation of these carcinogens in the organism.

III. PROPERTIES OF *N*-NITROSAMINES

1. Physical Properties

The NA considered are oily liquids or solids which are moderately soluble in water and readily soluble in many organic solvents: methylene chloride, chloroform, carbon tetrachloride, ether, alcohols, acetone, dimethyl sulphoxide, dimethylformamide, etc.; they are highly volatile and can be steam-distilled.[1,3,8,32]

The IR spectra of NA have characteristic absorption bands. Thus $\nu(N{=}O)$ for a series of dialkylnitrosamines is in the range 1425 to 1470 cm^{-1}, while $\nu(N{-}N)$ is in the range 1010–1150 cm^{-1}.[3,32,50]

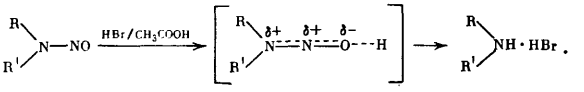


Two maxima, which in the case of aqueous solutions are in the ranges 230–235 nm ($\varepsilon \cong 7000{-}8100$) and 330–350 nm ($\varepsilon \cong 100$), have been found in the UV spectra of NA.[1,3,8,50] It has been noted that the positions of the bands in the IR and UV spectra of NA depend significantly on the nature of the solvent.[32,50]

Fairly intense ions have been observed in the mass spectra of NA obtained on electron impact: the molecular M^+ ion and the fragment ions $M^+ - 17$ (OH split off), $M^+ - 30$ and $M^+ - 31$ (NO or NOH split off), and also an ion with m/z 30 (NO^+). In the mass spectra obtained on chemical ionisation, the maximum content is that of the $(M+1)^+$ ion.[9,156-158]

The bond lengths in aliphatic NA have been determined. Thus in NDMA the length of the N–O bond is 123 nm, while N–N bond length is 134 nm instead of 145 nm, which is the N–N in compounds where both nitrogen atoms are linked to carbon.[31,32] The N–N bond dissociation energy in NDMA is about 55 kcal $mole^{-1}$, which is higher than in nitrodimethylamine.[3,32,50]

The stability of NA is fairly high, exceeding that of nitrodialkylamines. They are not cleaved with solutions of alkalies and dilute acids and are hardly decomposed by scattered light.[3,22,32] These properties of NA predetermine the duration of their presence in the environment.[7,10,13]



The dipole moments of many aliphatic NA are 3.9–4.4 D, which indicates the polarity of their molecules, determined by the possibility of the delocalisation of the unshared electron pair:[32,50,159]

2. Chemical Properties

The structure and the comparatively high mobility of the π electrons in the molecules are responsible for the fairly high reactivity of NA. They can be protonated, can form hydrogen bonds with alcohols and phenol, can combine with certain substances, for example, alkyl halides, can form complexes with various salts, etc.[22,32,50,159] Many of these processes are of not only theoretical but also practical interest. In principle, all the reactions of NA can be divided into two large groups—occurring with and without the cleavage of the N–N bond. In many cases the interaction of NA with a particular reactant can proceed via both these pathways depending on the conditions.

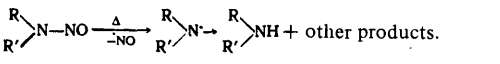
(a) Denitrosation of NA by inorganic acids. This reaction has attracted much attention by investigators, since the products of the denitrosation of NA are non-toxic and the amines formed have been used to develop methods for the analysis of NA. As already mentioned, dilute solutions of inorganic acids interact with NA very slowly. Thus NA distil from 0.1–0.2 M sulphuric acid almost without decomposition.[9,22,141,155,160,161] With increase in acid concentration cleavage of the N–N bond is accelerated; its completion requires heating of the reaction mixture or the use of catalysts, for example, Cl^-, Br^-, and SCN^-.[22,162,163] NA are most readily denitrosated by HBr solutions in glacial acetic acid; at room temperature, a virtually quantitative yield of the corresponding secondary amines is attained after several minutes:[12,163-166]

In the presence of small amounts of water or alcohol, the rate of denitrosation decreases significantly.[166,167] An excess of glacial acetic acid with phosphoric (or sulphuric) acid, containing I^- or Br^-, and also HBr solutions in acetic anhydride can denitrosate NA in the presence of water.[167,168]

Various inorganic acids as well as their derivatives, for example, acetyl, oxalyl, and thionyl chlorides are less effective when HBr is the denitrosating agent.[163,164]

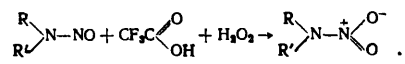
(b) The effect of UV light, γ-radiation, and heat. It is possible to cleave to cleave the N–N bond on treatment with UV light or γ-radiation. These reactions proceed via a fairly complex mechanism and not all the intermediates have yet been identified reliably.[124,169-174] It has been noted that the reaction takes place comparatively slowly.[43,171]

Acids and oxidants have an accelerating effect on the cleavage of NA by irradiation with UV light. Several possible pathways leading to the denitrosation of NA on treatment with UV light and acid have been proposed,[165,170,171,175-177] for example:



Under certain conditions, this reaction can afford high yields of secondary amines and NO (NO_2^-).[172,175] Account must be taken of the fact that the presence of high NO_2^- or NO_3^- concentrations in the reaction mixture creates favourable conditions for the denitrosation of secondary amines.[170,171]

The action of UV light on NA solutions in the presence of bases also leads to the dissociation of the N–N bond.[165,169]



When aqueous solutions of NPip are exposed to the action of γ-radiation in the presence of added acids or alkalies, the cleavage is hindered in the presence of high concentrations of nitrates or nitrites.[42,44,45,178,179]

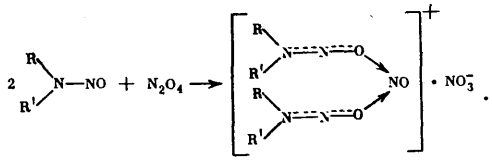
γ-Irradiation of food products leads to the partial decomposition of the NA contained in them.[45,178,179]

NA are hardly decomposed on heating to 200–250 °C. However, their pyrolysis takes place at 450–500 °C:[124,180-182]

(c) Oxidation and reduction. The interaction of NA with oxidants or reductants can lead to the formation of the corresponding nitramines and asymmetric hydrazines or to the cleavage of the N–N bond. The oxidation of NA without dissociation of the N–N bond is achieved mainly with the aid of peracids, among which CF_3COOH is the most convenient. It is usually obtained directly in the reaction mixture from trifluoroacetic acid and hydrogen peroxide:[165,166,180,181,183]

Treatment with pentafluorobenzoic acid and with a mixture of ammonium persulphate and nitric acid, as well as electrochemical oxidation, etc. lead to analogous results.[22,184,185] On treatment of NA with $K_2Cr_2O_7$ or $KMnO_4$ in concentrated sulphuric acid, ozone, etc., the N–N bond is cleaved.[165,166,176]

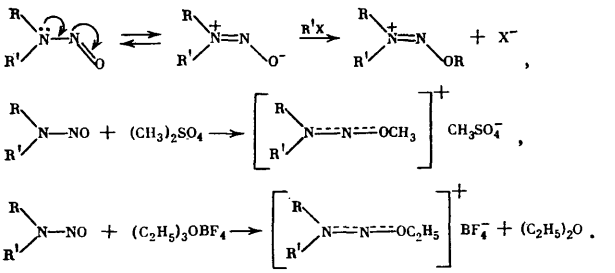
The reduction of NA with zinc in acetic acid to the corresponding dialkylhydrazines has been known for a long time,[50] the same compound being obtained on treatment with $LiAlH_4$, KOH + Al, titanium trichloride, sodium amalgam, etc.[50,186-188] and on electrochemical reduction:[165,186,187]



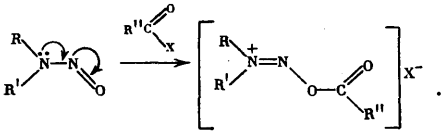
When other reductants are used and the conditions are altered, NA can be converted into mixtures of the corresponding asymmetric hydrazines and secondary amines or mainly into secondary amines. The latter are formed in fairly high yields in the presence of Raney nickel, in an acid solution of copper monochloride or iron dichloride, in the presence of a mixture of nickel, aluminium, and potassium hydroxide, aluminium amalgam, azide, etc.:[165,187]

The reduction of NA results in the formation of tetra-alkyltetrazenes in addition to hydrazines and secondary amines:[165]

(d) Complex formation and addition reactions. The delocalisation of the electron pair >N=N=O characteristic of NA predetermines their tendency towards reactions involving the formation of *O*-complexes on treatment with BF_3, PCl_5, $SbCl_5$, $AlCl_3$, etc.[32,50,159] The interaction of NA with nitrogen tetroxide probably proceeds via the mechanism[50,87]



NA can combine with various metal salts, for example $CuCl_2$, $ZnBr_2$, $PdCl_2$, etc. A stable complex is formed as a result of the reaction of NA with bis(trinitromethyl)mercury:[32,50]



Complexes of NA with bromoplatinic acid and certain other compounds have been described.[32,50]

NA react with many alkylating agents—alkyl halides, dimethyl sulphamate, triethyloxonium fluoroborate, etc.:[159,165,166]

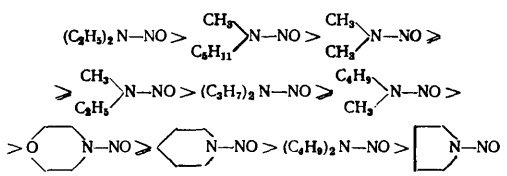
The last reaction proceeds very readily; the resulting salt is involatile and is decomposed by potassium hydroxide, which is used to decompose NA.[165]

NA react with acylating agents:[32]

Certain reactions of NA with organometallic compounds—a Grignard reagent or CH_3LI—have been described:[22,32,165]

The interaction of NA with phenylcopper takes place with dissociation at the N–N bond:[22,32]

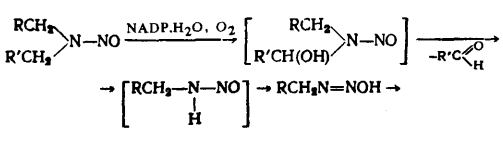
3. Effect on the Organism



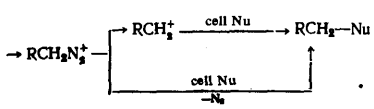
NA exhibit a pronounced toxicity, in the first place in relation to the liver and kidneys, and can give rise to haemorrhagic centrilobular necroses accompanied by blood effusions, the proliferation of bile ducts, disturbance of the renal function, etc.[1-5,8,15,17]

NDMA is the most toxic, its LD_{50} value amounting to about 30 mg kg^{-1} of body weight after single administration to rats. Other NA are less toxic; thus the LD_{50} for NPip, NDEA, and NDPA are respectively 200, 220, and 480 mg kg^{-1}.[1-4,8] Many NA exhibit pronounced mutagenic and carcinogenic activities.[1-4,8,10,14,102,189-192]

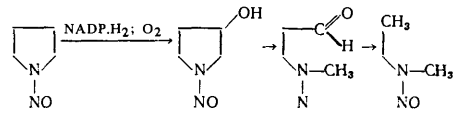
According to Shabad's classification,[193] NA are powerful carcinogens. The blastomogenic properties of NA have been investigated extremely widely and have been demonstrated on 40 different animal species: monkeys, dogs, rabbits, pigs, hamsters, rats, mice, guinea pigs, etc. and also on various birds, amphibia, and fish.[1-4,8,10,16] Despite the considerable species differences, the character of the tumours induced by the corresponding NA is similar as regards location and morphological structure. For example, NDMA and NDEA induce liver tumours—cholangio- and haepato-cellular carcinomas. The species-specific blastomogenic activity of NA is much wider than that of all other known chemical carcinogens, which is important indirect evidence for the carcinogenic activity of NA in relation to man.[2-6,8,10,14,102,189,194-198]



NA exhibit a broad spectrum of carcinogenic activity and can induce the formation of tumours in the liver, kidneys, stomach, alimentary tract, lungs, bladder, trachaea, throat, nasal cavity, etc.[1-5,8,10,17,20,102,199] It is significant that tumours arise both on treatment with NA and when their non-carcinogenic precursors—amines and many nitrogen-containing substances—enter the organism together with nitrosating agents.[3-6,8,10,13,14,16,102,197,200] The formation of NA from precursors has been demonstrated by chemical analysis.[76-79,100,102,105,106,114,200] Micro-organisms capable of converting nitrates and various nitrogen-containing substances into amines and of promoting the formation of NA over a wide pH range including pH $\geqslant$ 7 play an appreciable role in the endogenic synthesis of NA.[3-5,8,10,16,47,199]

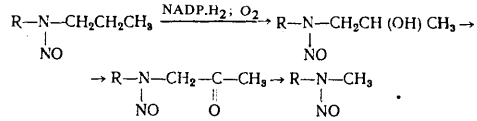


A direct dependence of the blastomogenic effect on the size of the dose and on the duration of its action on the organism has been discovered for NA.[1-5,20,201] It has been suggested that the minimum carcinogenic dose of NDMA for rats is about 0.1 mg per kilogram of body weight per day.[1,10,181] Relatively small frequently non-toxic doses of NA can induce the formation of tumours in various organs in animals and the majority of NA have a carcinogenic effect after a single administration.[1,3,16,20] The relative carcinogenic activities of NA have been calculated from determinations of the NA dose used in the formation of tumours in 50% of animals:[32,194]



It has been shown that carcinogenic activity is exhibited not by the NA themselves but by the products of their metabolic activation under the influence of enzymes—non-specific microsomal demethylases and oxidases located in the membrane of the endoplasmic reticulum of the cell and catalysing the conversions of NA in the organism, especially in the liver.[1-3,10,16,82,192,202-208]

The metabolism of NA, in the first place NDMA and NDEA, has been investigated and the relation between the products of the biotransformation and the carcinogenic activity has been discovered. These are usually multistage processes which lead to the formation of a number of intermediate and final carcinogens.[2-4,10,14,82,195,196,202,207,209] Although the nature of all the products has not been fully elucidated, it has been suggested that the carcinogenic activity is due to the presence of active centres capable of acting on DNA, RNA, protein, etc. macromolecules in the cell.[4,10,14,16,195,196,204,205,207,209] From the chemical point of view, the reactions of NA in the organism are processes involving oxidative hydroxylation and the cleavage of the hydroxyalkyl derivatives formed under these conditions.[2,3,204,205] It is assumed that the hydroxy-group can be incorporated in various positions, for example, in the α-, β-, and ω-positions in the alkyl groups of the NA. The following mechanism has been proposed for the primary activation of NA by α-hydroxylation:[4,192,202-205]



The electrophilic compounds $RCH_2N_2^+$ and RCH_2^+ interact actively with various nucleophiles, in particular with DNA. It has been suggested that the enzymic activation of cyclic NA begins with the cleavage of the ring and the formation of the dialkyl-NA:[205,210,211]

Enzymic β-hydroxylation can proceed as follows:[203-205,210]

Together with processes involving the metabolic activation of the NA, their inactivation reactions also takes place in the organism.[4,16,202,205] The action of the NA on the organism is determined mainly by the alkylation of DNA by the products of their metabolism, which can lead to the breakdown of the functioning of the cell genome. The *N*(7)-, *N*(3)-, and *O*(6)-positions in guanine, and the *N*(7)-, *N*(3)-, and *N*(1)-positions in adenine are most often alkylated.[3,4,14,189,195,196,203-208,212,213] It is believed that the alkylation of the DNA guanine in the *O*(6)-position is significant for the appearance of tumours and the mutagenic effect. Such alkylation damages DNA and disturbs the transfer of genetic information.[4,82,189,195,196,21

Data demonstrating the accelerating or retarding effect of a number of substances, for example, ethanol, hydroxybutylanisoles, and luminal on the NA metabolism have been obtained.[152,201,206,213,214]

It has been shown that there is a clear-cut correlation between the carcinogenic and mutagenic activities of the products of the NA metabolism, but a relation between toxicity and carcinogenic activity has not been established.[14,102,189-192] It has been suggested that the formation of NA from precursors directly in the organism is important in the genesis of cancer.[4,10,14,153,197,215] It is therefore essential to take into account the circulation in the environment and the possibility of the entry into the organism of not only the NA themselves but also of the precursors.[7,216]

IV. PRINCIPAL METHODS OF MICROANALYSIS

The determination of carcinogenic NA in objects within the environment at the microgram and nanogram level is an extremely complex analytical problem, because such objects can contain an extremely large number of substances. For example, thousands of main and hundreds of thousands of minor components have been detected in food products.[198,217]

The main requirements which must be met by the analytical methods for NA are high sensitivity, satisfactory selectivity, and reliability of the results. The determination of NA in objects usually includes all or the majority of the following stages: isolation, preliminary purification, concentration, additional purification, preparation of derivatives, analysis and confirmation of the results. The isolation and purification are the decisive stages ensuring to a large extent the success of the analysis. The methods used to carry out these stages have been examined in a number of studies.[124,141,160,161,180,181,196,218-221]

The methods for the determination of NA makes it possible to analyse them directly or on the basis of their rection products. Spectrophotometric, fluorimetric, polarographic, chromatographic, chromato-spectrometric, and certain other methods have been

proposed for the analysis of NA in solutions and extracts from various objects.[5,12,180,181,186,218] As a rule, methods involving chromatographic separation are used nowadays.

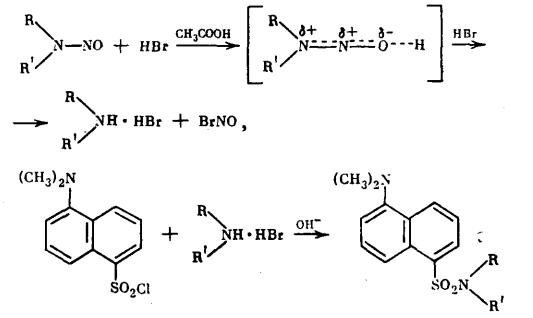
Gas–liquid chromatography (GLC) with different columns, phases, and detectors is frequently employed to identify and determine quantitatively NA. Although NA can be analysed with the aid of flame-ionisation detectors, it is more desirable to use nitrogen-sensitive detectors—thermoionic, conductimetric, and microcoulometric.[12,160,161,180,186,218,222,223] Packed and capillary columns filled with various stationary phases, for example, 10–15% Carbowax 20 M on Chromosorb G or W, 5% Carbowax 20 MTPA on Supelcoport, 2–3% OV-1 on Chromosorb G or W, 5% SE-20 on Chromosorb G or W, and UCON-HB 5100 CPWAX57CB are used for the separation. Chromatography under isothermal conditions is rarely used, the temperature being usually programmed in the range 50–200 °C at a rate of 2–10 K min^{-1}. The quantitative determination is carried out as a rule with an intenal standard; the detection limit is at the level of several nanograms.[9,180,186,218,219,221,224-227]

The retention times of NA, especially NDMA and NDEA are short, and their peaks are distributed in the region of the chromatogram with a high content of peaks due to various volatile substances from the object analysed, which hinders their identification. The NA isolated from the object must therefore be carefully purified before the GLC. In a number of cases, even under the conditions of thorough purification, the agreement involving the retention times does not yet guarantee the reliability of the results of the determination.[9,180,186,218,225]

A novel chemiluminescence method for the analysis of NA was proposed in 1975 and a special apparatus—a thermoenergetic analyser (TEA)—was constructed.[55,99,114,117,124,181,182,196,219,220,228-231] Its operation is based on the decomposition of the NA in a catalytic pyrolyser at a temperature in excess of 450 °C. The NO· radical formed under these conditions interacts with ozone. The reaction results in the appearance of an excited NO_2^*, which passes to the ground state with emission of the characteristic radiation in the IR part of the spectrum, after which it is recorded with a photoelectron multiplier:

$$\mathrm{R_2N{-}NO} \xrightarrow{\Delta} \mathrm{R_2N^{\cdot}} + \mathrm{NO^{\cdot}},$$

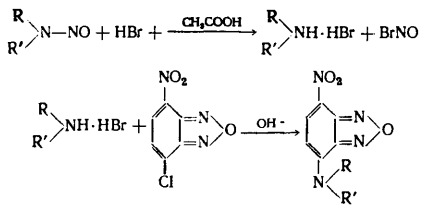
$$\mathrm{NO} + \mathrm{O_3} \rightarrow \mathrm{NO_2^*} + \mathrm{O_2},$$



$$\mathrm{NO_2^*} \rightarrow \mathrm{NO_2} + h\nu .$$

In the main TEA is used as a specific detector for NA in combination with various chromatographs. In terms of its analytical parameters, the TEA method is greatly superior to other detection methods in GLC; the detection limit on the TEA is less than 1 ng.[38,55,99,124,180-182,196,219,220,226,232-235] This has ensured a wide-scale application of GLC with TEA for the determination of NA in various objects within the environment despite the fact that certain other NO- and NO_2-containing substances, for example, *C*-nitroso- and *C*-nitro-compounds as well as *O*-nitroso- and *O*-nitro-compounds, can give rise to false positive results.[124,180,181,196,218-220,225,228,235,236] NA have been determined most reliably in different objects by the chromato-mass-spectrometric method.[9,12,158,172,173,186,224,235,237-239] The application of a high-resolution mass-spectrometer with electron impact ionisation makes it possible to record one, most specific ion. In NA analysis, this ion is as a rule M^+ or NO^+.[157,181,183,219,235,237] It is somewhat more difficult to identify NA on the basis of low-resolution mass spectra. In this case selected ions are monitored. The presence of NA is regarded as established if the mass spectrum of the chromatographic peak with the corresponding retention times contains all the selected ions characteristic of the given NA and their intensity ratios are close to the ratios in the mass spectrum of the standard.[9,157,180,181,183,219,224,235,237] Chromato-mass-spectrometric methods of determination, especially at low resolution, require careful purification of the extracts, since the selected ions are in the region of low masses mixed with fragments of other compounds present in the extract.[9,141,218,219,224] The use of mass spectrometry with chemical ionisation is effective in the determination of NA.[9,156,157,240]

A series of GLC and chromato-mass-spectrometric methods have been proposed for the analysis of NA on the basis of their reaction products. The determination of NA after their oxidation to the corresponding nitramines, having longer retention times than the NA with detection based on electron capture or mass spectrometrically with the aid of TEA has been described.[12,180,181,183,186,219,225] The method is used rarely because of its inadequate reproducibility. Chromatographs with an electron impact detector and chromato-mass-spectrometers are used to determine NA after their conversion into halogeno-derivatives, which are frequently obtained on treatment with heptafluorobutyryl chloride or heptafluorobutyric anhydride:[12,122,180,181,183,184,186,219,223,225,241]



$$\mathrm{R_2N{-}NO} + \left(\mathrm{C_3F_7C}\overset{\mathrm{O}}{\diagup}\right)_2\mathrm{O} \xrightarrow{\text{pyridine}} \mathrm{R_2N{-}C(O){-}C_3F_7}.$$

A method based on the use of dansylamides, obtained from NA by treatment with 1-dimethylaminonaphthalene-5-sulphonyl chloride, is effective for the analysis of NA in various objects:[9,155,225,237,242]

The mass spectra of the dansylamides obtained from various NA contain intense molecular and fragment ions which are either common to all the derivatives, for example the $(NH_3)_2NC_{10}H_7^+$ ion with *m/z* 171 or are characteristic of individual compounds (formed on dissociation of the S–N bond), which makes it possible to identify and determine the NA.[9,155,237,242] The monitoring of selected ions has proved optimal for the detection of dansylamides. The recording of a chromatogram based on several such ions, the retention times as well as the ratios of the intensities of the mass-spectral lines and the areas of the corresponding peaks ensure a reliable identification of the compound analysed; the detection limit is less than 1 ng.[9,155,237,242] The selected ions in the mass spectra of dansylamides are in the region relatively free from ions of impurities present in the NA extract, which makes it possible to employ low-resolution mass-spectrometers and does not necessitate a careful purification of the extract.[9,141,237,242] The adequacy of the standards obtained from the NA and the corresponding secondary amines has been established; the use of the latter simplifies the analysis and makes it safer.[141,155,237,242-244]

The chromato-mass-spectrometric method based on the preparation of NBD-amines by treatment with 7-chloro-4-nitrobenzo-2,1,3-oxadizole is entirely suitable for the analysis of NA:[155,225,243,245]

The mass spectra of NBD-amines contain intense molecular and characteristic fragment ions which can be effectively determined by monitoring the selected ions. The possibilities of this method are analogous to the method involving the use of dansylamides.[155,225,245] The chromato-mass-spectrometric methods for the determination of NA on the basis of their derivatives—dansylamides and NBD amines—can be used also to confirm the results obtained by other methods.[9,141,155,225,237,242,245]

High performance liquid chromatography is used more rarely for the analysis of volatile NA than GLC. The analysis is performed on sorbents: Lichrosorb Si 60, Microporasil, Spherisorb 3SW, Sorbax CN, etc.: the elution is carried out with mixtures of organic solvents, for example, chloroform – cyclohexane – methanol, isopropyl alcohol – hexane, and chloroform – hexane.[124,220,225,229,246] The reversed-phase version on Microbondapak C_{18}, Sorbax ODS, silica gel C_{18}, etc. with mobile phases containing acetonitrile, methanol or ethanol, water, or buffer systems is also used.[173,177,225,227] TEA, photoconductimetric, electrochemical, and UV detectors are used to detect the separated NA; the NA are frequently subjected to preliminary cleavage and are treated with the Griess reagent.[227-229,243,246,247] The detection limit is about 1 ng.[124,173,177,181,220,225] There are data concerning the analysis of NA by the high performance liquid chromatographic method in the form of derivatives.[225,243,247]

A series of simple methods for the determination of NA using thin layer chromatography (TLC) have been proposed. The methods described earlier—involving irradiation with UV light and detection on the basis of the $NO(NO_2^-)$ or R_2NH formed in the form of coloured compounds, are inadequately sensitive and selective.[12,180,186,218,223,225] The methods based on the denitrosation of the NA with HBr and the preparation of fluorescent derivatives of secondary amines have much better characteristics. In principle, different reagents are suitable for this purpose[243,248] but dansyl chloride and NBD chloride are mainly used for the analysis of NA in various objects.[9,141,155,168,218,225,243,244,249] The analysis is performed directly on a plate, visually and densitometrically, or the corresponding spots are eluted and the fluorescence intensity is measured. The detection limit is 1 – 10 ng in the spot.[141,155,168,244,248,249] Compared with dansylamides, the determination of NA in the form of NBD-derivatives is more effective, since the latter not only fluoresce but are also coloured yellow, orange, or pink, while NBD chloride itself does not fluoresce and does not form fluorescent compounds with phenols and alcohols.[141,155,218,241,243,244,248,250] An analogous method has been proposed for the determination of NA in the form of fluorescent derivatives, obtained by the interaction of secondary amines with *N*-(8-methoxyqinoline-5-sulphonyl)aziridine,[251] but in terms of a number of characteristics it is inferior (inadequate separation of derivatives, complexity of the chromatography, etc.) to the method with NBD chloride.

The usefulness of carrying out the TLC in the presence of a control sample from part of the extract after the removal of the NA has been demonstrated. The use of such control samples, which hardly differ in terms of the composition of the impurities from the experimental sample, ensures the reliability of the analysis.[141,155,225,250] The use of comparison samples, prepared by introducing the corresponding standards into the control samples, is even more effective.[252] This procedure simplifies significantly the identification of NA, accelerates the analysis by eliminating the additional purification, and increases the reliability of the determination by reducing the probability of obtaining false results.[252]

It is thought essential to confirm the results of the determination of nanogram and microgram amounts of NA in objects within the environment. Chromato-mass-spectrometric methods are used for this purpose or the analysis is carried out by two different methods.[124,155,172,180,181,184,186,218,219,224,225,233,239,253]

V. THE CONTENT OF *N*-NITROSAMINES IN OBJECTS IN THE ENVIRONMENT

1. Air

Extremely complex processes involving the formation and decomposition of NA take place in the atmosphere. The concentration of nitrogen oxides plays a significant role in the formation of NA. It is believed that the NA content in air is a problem associated with the waste from industrial undertakings, transport, and the pollution of the atmosphere by nitrogen-containing substances.[7,10,54-57,114,216,230] This is confirmed to some extent by the finding that, under conditions remote from large industrial and agricultural manufacturing undertakings, the air contains hardly any NA ($\leqslant 0.01$ μg litre^{-1}).[56,103,114,254] Up to 0.05 μg litre^{-1} of NDMA has been found in the atmosphere over non-industral towns, while the content over industrial towns is 0.76 – 1 μg litre^{-1}.[56,103,114,255] Higher NA concentrations have been observed in chemical, leather, and rubber manufacturing plants: up to 36, 47, and 140 μg litre^{-1} of NDMA and up to 46,20, and 250 μg litre^{-1} of NMor respectively.[55,56,103,114,119,230,254,256] This can be explained by the presence in the above undertakings of a series of readily nitrosated substances, for example, amines and vulcanisation accelerators.[71,99,114,119,121,230,254-257] Other NA may be present in the air within these factories at lower concentrations.[56,99,254,256,258]

The air in showrooms for new automobiles contains the following amounts of NA (in μg kg^{-1}): NDMA $\geqslant$ 1.0, NDEA $\geqslant$ 0.4, and NMor $\geqslant$ 2.5, which can be explained by their evolution from rubber components.[119,121,254,256,259] A series of NA have been found in air within smoking rooms and kitchens, which has been attributed to their presence in tobacco smoke and their evolution in the frying and cooking of food.[55,98,114,183,200]

It is noteworthy that in the atmospheres of towns domestic and tobacco smoke contains significant amounts of nitrogen oxides.[56,78,98,161,255,260]

2. Water

Comparatively little attention has been devoted to the determination of NA in water possibly because they are either absent from purified drinking water or their concentration is extremely low ($\leqslant 0.01$ μg litre^{-1}).[8,13,114,117,241,261,262] Relatively larger amounts are present in chlorinated water (NDMA $\leqslant$ 1.0 μg litre^{-1}) and deionised water (NDMA $\leqslant$ 0.5 μg litre^{-1} and NDEA $\leqslant$ 0.8 μg litre^{-1}).[35,103,114,117,261] NA have been detected in various types of waste water. Thus up to 2 μg litre^{-1} of NDMA has been found in sea water in the vicinity of waste discarding points in a fish processing plant, the discarded water containing NDMA ($\geqslant$3 μg litre^{-1}) and NDEA ($\geqslant$0.2 μg litre^{-1}).[5,114,117,255,261] The waste water from various factories contains up to 10 μg litre^{-1} of NDMA, 5.5 μg litre^{-1} of NDEA,

and certain other NA,[103,114,183,223] while in individual types of water containing slime the content of NA is up to 940 μg litre^{-1}.[128,223] The concentration of NA in waste water containing amines is usually enhanced.[182,252]

In order to prevent the pollution of the environment by nitrosamines, it is essential to purify the waste water, since these carcinogens can pass from water into plants.[7,10,216,222,223,262] Nitrites and nitrates have been detected in natural waters, the concentration of the latter being high.[10,55,255,261]

3. Soil

The turnover of NA in the soil has been inadequately investigated. NA and their precursors can enter the soil from the atmosphere, together with fertilisers and pesticides, with waste water, etc. Although many different amines, other nitrogen-containing bases, nitrates, and nitrites are present in the soil, NA do not usually accumulate in the soil.[5,10,216,262] This can be explained by the occurrence of NA degradation processes under the influence of light, temperature, and the microflora, evaporation into the atmosphere, transfer to water, sorption by plants, etc.[7,10,13,75,216,222,255,262]

4. Inorganic Nitrogen-containing Fertilisers and Pesticides

High concentrations of NA, sometimes exceeding 1000 μg kg^{-1} have been found in a number of pesticides.[8,12,39,96,103,113,114,116,117,183] There is a high content of NDMA in dimethylammonium salts of 2,4-D, 2,4-DB, MCPP, MCP, and TCBA, alkylbenzyldimethylammonium chlorides, cetylethyldimethylammonium bromide, thiram, etc.[96,103,107,115] NMor is present at high concentrations in *N*-alkyl-*N*-ethylmorpholinium ethyl sulphate and NDPA is present in trifluralin (treflan), isopropalin, etc.[96,103,107,114,117]

The presence of NA in inorganic nitrogen-containing fertilisers has not been reported but they are a most important source from which nitrates enter the soil, natural water basins, and plants.[7,10,75,216,263]

5. Products of the Chemical and Rubber Industry

NA have been detected in products produced on a large scale such as amines and solvents. The amines contain the corresponding NA; thus dimethylamine contains up to 17 300 μg kg^{-1} of NDMA, pyrrolidine contains up to 53 000 μg kg^{-1} of NPyr, and dipropylamine contains up to 13 000 μg of NDPA; the concentrations of NA are somewhat lower in other secondary and tertiary amines.[12,183,257]

NMor has been detected in chloroform and methylene chloride at concentrations reaching 376 and 32 μg kg^{-1} respectively. Small amounts of NDMA and NDEA have been found in a number of other solvents. NA are as a rule not detected in these products after purification.[58,264] NDMA, NDEA, and other NA have been found in certain types of synthetic detergents.[14]

Rubber vulcanisation accelerators contain considerable amounts of NA, for example, NDMA (4–800 μg kg^{-1}) in tetramethylthiuram disulphide, (NDEA 10–100 μg kg^{-1}) in tetraethylthiuram disulphide, and zinc diethyldithiocarbamate, NMor (60–3500 μg kg^{-1}) in various morpholine derivatives, etc.[38,71,99,118,119,121,232,253] NA have been discovered also in various rubber articles, including those designed for medical and food related purposes. The contents of NDMA, NDEA, and NMor are 50.3, 2.2, and 120 μg kg^{-1} respectively in medical tourniquets, rubber hose for the milk industry, and certain rubber articles for the food industry prepared by the continuous vulcanisation method.[38,40,118,154,253,259,265] In the rubber teats for babies' bottles, babies' dummies, stoppers for bottles with babies' food, rubber toys, and rubber gloves, the maximum concentrations of NDMA, NDEA, NDBA, NPip, and NMor are 200, 100, 2796, 180, and 86 μg kg^{-1} respectively.[38,40,71,99,118,121,229,232,253,265,266] NA are capable of diffusing from rubber into liquids in contact with it—milk, milk product, fruit juices, etc.[11,38,99,232,253,266] This made it necessary to pay significant attention to reducing the NA content in rubber for food and medical purposes. The introduction of inhibitors into rubber mixtures and the improvement of the technology made it possible to solve this problem.[118,154,174,265]

6. Medicinal Preparations

NA, usually NDMA, have been found in a number of medicinal preparations. For example, amidopyrine contains 1–371 μg kg^{-1} of NDMA, while the content in individual specimens is up to 980 μg kg^{-1} of this NA; there is up to 68 μg kg^{-1} in imizine, up to 40 μg in nitrofurantoin, and up to 7 μg kg^{-1} in oxytetracycline.[12,58,86,102,104,110,183,230] NA have been detected in medicines which incorporate amidopyrine, piperazine, phenacetin, ephedrine, imizine, pipolphen, aminazin, tetracycline, pencillin, analgin, and many others.[14,102,104-106,109-111,230]

It has been shown that many medicinal preparations can be nitrosated directly in the human stomach.[102,106,108]

7. Animal Feed

NA and their precursors are encountered in various types of animal feed. Nitrates, sometimes nitrites, and (only in individual specimens) small amounts of NA have been detected in meadow grass.[231,263,267] Up to 150 mg kg^{-1} of NDMA together with precursors have been found in mixtures of juicy feed together with concentrates and in feed for birds and rabbits.[5,8,102,268]

Various concentrates, including fish meal, in which the NDMA and NDEA concentrations can reach 417–2000 and 36 μg kg^{-1} respectively are used as additives to feeds.[8,128,268,269] NDMA (2 and 85 μg kg^{-1}), NDEA (24 and 512 μg kg^{-1}), and certain other NA have been found in grass and maize silos.[270-272] NA have been discovered in the milk of cows and goats and the eggs of birds receiving feed with a high content of NA and their precursors.[263,268,271] Significant amounts of NDMA, NDEA, NPip, and NPir (up to 79, 65, 300, and 26 μg kg^{-1} respectively) have been detected in the diet of laboratory animals.[8,58,127,231,269]

8. Food Products

The most important food products, prepared dishes and drinks, have now been analysed and in a number of countries systematic monitoring of the NA content in such products has been introduced. NA precursors, in the first place nitrates and nitrites, are determined in many products;[5,7,10,19,40,122,218,273] account must be taken of the fact that the technology of the preparation of many meat products and cheeses provides for the introduction into them of definite amounts of nitrates and nitrites.[11,107,122,127,198,218,274] Much attention has been devoted to the study of the content of amines in food products, although the presence of a broad spectrum of these substances and the necessity for their determination together with nitrates and nitrites was demonstrated as early as 1976.[275] Data

characterising the degree of contamination of food products and drinks by NA and their precursors have been published in a series of monographs and reviews.[3,5,8,10,12,19,23,39,75,122,125,128,148,183,200,215,218,220,276]

As a rule, NA are encountered much more rarely at relatively lower concentrations in raw and cooked products then in fried, smoked, salted, and preserved products. Thus the overall content of NDMA and NDEA can reach 5 μg kg^{-1} only in individual specimens of fresh, freshly frozen, and cooked meat, while the content in cooked sausages can be 10 μg kg^{-1}.[9,122,125,127,160,161,217,233,260,277,278] NA are frequently detected in various types of bacon, large smoked sausages, small smoked sausages, smoked pork products, and preserves, the maximum NDMA, NDEA, NDBA, NPyr, and NPip concentrations amounting to 84, 16, 4, 207, and 50 μg kg^{-1} respectively.[9,40,114,122,125,127,148,160,233,236,265] The amount of NPip increases sharply, sometimes up to 1600 μg kg^{-1}, in smoked products prepared with an excess of spice.[125,127,183,220,279] Nitrosothiazolidine (in an amount of the order of 20 μg kg^{-1}) has been found in bacon and in fried, smoked, and preserved meat. NMor is encountered extremely rarely in food products.[11,236,276,278,280,281] There is a fairly high content of nitrates and nitrites—up to 145 and 750 μg kg^{-1}—in meat products, especially smoked, salted, and preserved products.[40,122,127,148,160,215,233,236,273]

Fish products and sea food are less often found to contain NDMA—up to 9 μg kg^{-1} in individual fresh species. The maximum NDMA, NDEA, NPyr, and NPip concentrations in salt-dried, pickled, smoked, and fried fish can reach 84, 51, 37, and 19 μg kg^{-1} respectively, the frequency of their detection being very high.[3,125,148,160,161,220,234,253,260,265,282] Up to 400 μg kg^{-1} of NDMA [125,128] has been found in salted and salt-dried fish prepared using technical common salt containing nitrates, while hot-smoked fish, obtained using the smoke from wood chips, may contain up to 206.5 μg kg^{-1} of NDMA.[234] Much NDMA (up to 12 600 μg kg^{-1}) has been found in sauces made of sea food (prawns etc.) especially those containing nitrates and nitrites.[183] Apart from nitrites and nitrates, whose concentrations are 30 and 100 mg kg^{-1}, fish and fish products contain amines.[148,160,260]

Milk and plant products are much less contaminated by NA and they contain as a rule only NDMA. NA are almost absent from milk, acid milk products, and curd cheese. However, NDMA and NDEA have been found in dried milk and individual varieties of cheese, for example, Gouda, Cheddar, and wine cheese—up to 68 and 20 μg kg^{-1} respectively.[5,58,122,161,183,215,218,238,250,272,274,277,279] It is noteworthy that the content of nitrites and nitrates in milk and cheeses can reach 1.6 and 76 μg kg^{-1}.[122,218,238,274]

NA are absent from most cereals, vegetables, and fruit; NDMA (2–5 μg kg^{-1}) has been found in stored vegetable and fruit preserves, but the levels of NDMA and NPyr in salt-pickled vegetables reach 63 and 32 μg kg^{-1} respectively.[125,141,148,244,282] As a rule, fruit and vegetables contain a fairly large amount of nitrates, for example, lettuce and beetroot contain up to 8000 mg kg^{-1}.[55,75,148,200,244,282]

NDMA have been found in beer and alcoholic drinks (up to 68 μg $litre^{-1}$ in dark varieties of beer).[6,39,122,148,200,246,277,279,282] It is believed that the NA concentration in beer depends on the quality of the malt.[40,101,233,246,260,277]

Like water, drinks contain nitrates.[55,200] It has been noted that the content of NA, nitrites, and nitrates in the same type of product vary within considerable limits depending on the conditions of their manufacture and storage.[125,127,183,218]

The amount of NA entering daily the human organism together with the diet has been calculated. Naturally, it is different for different countries but it does not usually exceed 2.3 μg per day for man.[3,5,6,10,55,122,148,200,220,277] Significant amounts of nitrates and nitrites enter the human organism together with food products.[6,10,39,55,122,148,200]

Hygienic norms, according to which the limiting permissible NDMA and NDEA concentrations (overall) in various food products must not exceed 2–4 μg kg^{-1} have been specified.†

One of the ways in which food products are contaminated by NA is circulation in food chains. The circulation of NA is a complex process in which account must be taken not only of the transfer of the NA themselves but also of their precursors, capable of forming these carcinogens readily and directly in the given objects. The total NA and their precursors passing from the environment into plants and food products, the formation of NA, and the various reactions of these compounds and their denitrosation determine ultimately their concentration in the given object.[7,126]

Circulation in food chains begins with the contamination of plants by NA and their precursors.[7,10,193,216] It has been shown that NA, nitrites, and nitrates are capable of passing from water and soil and also from residues of inorganic nitrogen-containing fertilisers, pesticides, and industrial and agricultural waste contained in them into plant products and accumulating there.[7,10,216,222,263,267]

Together with various types of feed and water, NA, nitrites, and nitrates enter the organisms of animals and pass into the products of animal husbandry—milk, meat, and eggs.[7,10,216,263,268,271] When various products, especially those with high concentrations of NA precursors, are stored, NA are formed in them.[122,125,128,244,284] Together with food, drinks, and water, NA and their precursors enter the human organism; NA are formed from their precursors in the gastrointestinal tract.[3-5,10,102] It has also been shown that NA can pass into food products from packing materials.[11,281]

The second way in which food products are contaminated is technological treatment: smoking, frying, salting, drying, dry-curing, etc.[40,127,216,233,234,260,284] Much evidence has been obtained showing that high NA concentrations are then observed in products containing considerable amounts of nitrites and nitrates.[10,40,122,127,233,260,273] Smoking using smoke containing nitrogen oxides results in a significant increase of NA levels.[10,160,234,260] It has been shown that a decrease in the concentration of nitrates, nitrites, and nitrogen oxides and also the introduction of inhibitors and the improvement of technology make it possible to obtain smoked, salted, fried, etc. products with a low NA content.[5,40,122,127,198,233,234,273,277]

A decrease in the amount of NA in various nitrogen-containing substances entering the environment as a result of the effective purification of industrial and transport waste and strict regulation of the use of nitrogen-containing inorganic fertilisers, pesticides, etc. is important for the reduction of the degree of contamination of food products by NA.[7,10,216]

- - - o0o - - -

Thus carcinogenic NA are capable of being formed from a wide range of nitrogen-containing substances and nitrosating agents directly in various objects and living organisms. The ease of formation and the fairly high reactivity and stability of NA are responsible for their wide distribution in the environment and the possibility of their undesirable influence on man.

The development of effective and reliable chromatographic methods for the identification and quantitative determination of these compounds in various objects in microgram and nanogram amounts has played an important role in the study of NA. Systematic analyses made it possible to discover objects with a high NA content and the principal causes of their accumulation and to propose certain measures in order to prevent or sharply reduce the contamination of such objects by these carcinogens.

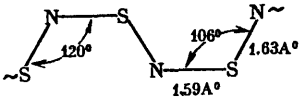
The Preparation, Structure, and Properties of Semiconductor Films Based on Acetylenic Polymers

A.A.Matnishyan



The methods of preparation of organic polymeric semiconducting materials by the catalytic polymerisation of acetylene and its derivatives are described. The characteristics of the catalyst and the influence of the conditions of synthesis on the structure, morphology, stability, and conductivity of the films as well as the questions of the ageing, stabilisation, and doping of the films and the appearance of microheterogeneities (defects) as a result of ageing and oxidation of polyacetylene are considered.
The bibliography includes 196 references.

CONTENTS

I. Introduction 367

V. The oxidation, reduction, doping, and stabilisation of the films 374
VI. The structure and morphology of polyenes 376

I. INTRODUCTION

Organic materials, especially polymers, are already used in electronics, radio engineering, and electrical engineering as electrically conducting and semiconducting elements. After the discovery of semiconducting properties in polymers with a system of conjugated bonds, their investigation has been continuous since the 1950's with continued success.[1-5] The discovery in 1973 of the polymers $(SN)_n$ exhibiting metallic conductivity and not containing metal atoms led to an avalanche of investigations. It was soon found that the polysulphonitrite (polythiazide)

exhibits an intrinsic metallic conductivity and passes to the superconducting state at ~0.3 K.[6] The reports of the first organic polymer capable on doping of the transition from the semiconducting to the metallic state was a well established fact and served as a stimulus for the creation of a series of new conjugated polymers and composites based on polyacetylene, polypyrrole, polythiophen, etc., whose electrophysical properties vary within wide limits during their doping by electron acceptors or donors. However, the high conductivity and effective semiconducting properties of π-electron low-dimensional systems is not their only positive feature; they also manifest various interesting magnetic, optical, and other properties. These materials have begun to play an important role in the development of modern technological systems for the accumulation and storage of information (computers) and the transformation of solar energy,[7] in electronics (field transistors, diodes),[8] and as conductors, electrodes (accumulators, high-capacitance condensers), and as sensors of electromagnetic and acoustic radiation, and also in other branches of engineering.[9,10] The lightness and high strength, characteristic of polymeric materials, their high impact strength, their low cost, and the simplicity of the technology of the preparation of the films, fibres, and articles of complex shape make the new materials advantageous compared with traditional ones.[11]

The synthesis, properties, and applications of polyacetylene have been considered in fair detail in monographs and reviews[1-4,12-18], whose number has increased sharply in recent years.

This paper surveys the results of the latest research into the methods of synthesis and certain properties of polymers of the acetylene series with a regular structure, which are promising as "organic metals" and semiconductors. It deals mainly with the methods which make it possible to obtain films and fibrous materials; it does not include familiar methods such as dehydrogenation, dehydration, and dehydrohalogenation,[19,20] which lead to the formation of films with an irregular structure, exhibiting a low electrical conductivity.

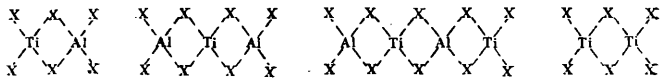
II. THE SYNTHESIS AND PROPERTIES OF POLYACETYLENE

One of the most thoroughly investigated methods of synthesis of polyacetylene (PA) with a regular structure involves the polymerisation of acetylene on a metal complex catalytic system obtained from trialkylaluminium combined with alkoxytitanium. In 1958 Natta and co-workers succeeded in polymerising acetylene in the presence of $Al(C_2H_5)_3-Ti(OC_3H_7)_4$ catalytic system.[21,22] Systematic studies in recent years[23-25] made it possible to find new methods for the synthesis of stereoregular polyacetylene films. The $Al(Et)_3-Ti(OBu)_4$ catalytic system ensures the preparation of PA films with a predominantly (up to 98%) *cis*-structure at temperatures not above 70 °C and with mainly *trans*-structure at +150 °C.[26]

If one disregards the specific requirements which must be met by the conditions in the preparation of the catalytic system (in an inert medium in the absence of traces of moisture), the synthesis of PA itself does not present major difficulties. PA films grow on the surfaces of a concentrated catalyst solution or almost on any support wetted with a catalyst solution (preferably in toluene) in an atmosphere of purified acetylene.[25] The growth of the films can be regulated by altering the temperature and acetylene pressure during the synthesis.[24,27] Before its use, the homogeneous catalytic system is usually maintained at room temperature. The catalyst "ripening" reaction then takes place:[28]

$$Ti(OBu)_4+AlEt_3\rightarrow EtTi(OBu)_3+AlEt_2(OBu),$$
$$2EtTi(OBu)_3\rightarrow 2Ti(OBu)_3+C_2H_4+C_2H_6,$$
$$Ti(OBu)_3+AlEt_3\rightarrow EtTi(OBu)_2+Al(Et)_2OBu,$$
$$EtTi(OBu)_3+AlEt_3\rightarrow EtTi(OBu)_3\cdot Al(Et)_3.$$

The ageing of the catalyst initially increases the activity but after a time the yield PA falls owing to the further reduction of titanium:

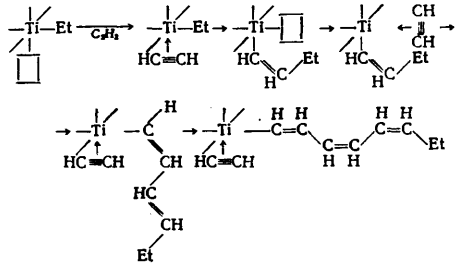


$$EtTi(OBu)_2 + Al(Et)_3 \rightarrow TiOBu + Al(Et)_2(OBu) + C_2H_4 + C_2H_6.$$

If the synthesis is carried out at a low catalyst concentration, a gel-like red product, consisting of tangled fibrils up to 800 Å in diameter, is formed. A foam-like material with a density ranging from 0.04 to 0.4 g cm^{-3} can be obtained from dilute gels by subliming the solvent at a temperature below its freezing point.[29]

The study of the dependence of the rate of formation of PA films on the catalyst concentration and acetylene pressure made it possible to find the optimum ratio of the catalyst components (Al/Ti = 4); the increase of this ratio to 10 increases the size of the fibrils.[30] The fall of the rate of reaction at the end of the process can be explained by the impairment of the diffusion of the monomer through the thickness of the film formed on the catalyst surface.[31] During synthesis, the film is formed simultaneously on the walls of the flask and on the surface of the catalytic solution, the gel accumulating in the upper layer and the PA powder settling on the bottom of the reactor. The molecular weight $\overline{M}_n$ of the powder is lower than that of the gel and decreases with increase in the catalyst concentration to 400–500.[32] The molecular weight of the gel-like PA decreases slightly with increase in the catalyst concentration and rises from 2×10^4 to 3.6×10^4 with increase in temperature from −78 °C to −10 °C. The molecular weight of the PA in the film is a factor of two smaller than in the gel.[33]

The high sensitivity of the catalysts to impurities precludes an unambiguous estimation of the influence of various factors determining $\overline{M}_n$ of polyacetylene. Low-molecular-weight products with $\overline{M}_n \cong 1200$ are formed when the synthesis is carried out in hydrogen.[15] The concentration of acetylene has a considerable influence on $\overline{M}_n$: with increase in its pressure to 760 mmHg, $\overline{M}_n$ increases to 120 000.[28,34] Apparently the inhomogeneity of the substrates, arising from the imperfection of the technique of the synthesis, is the cause of some lack of reproducibility in the properties of the polymers obtained.



It has been suggested that the synthesis takes place on the "surface" of the catalytic clusters. Investigation by the EPR method made it possible to distinguish up to four types of complexes in the catalyst:[35]

(I) (II) (III) (IV)

The highest catalytic activity is shown by the complex (I), while the complexes (II) and (IV) are inactive. The ratios of the complexes in the catalyst depend on the Al/Ti stoichiometric ratio.

The structure of the catalyst suggests that the reaction proceeds via the *cis*-addition mechanism:

This results in the formation of PA with a *cis*-transoid structure. The formation of the *trans*-structure at high temperatures can be explained by the thermal isomerisation preceded by the crystallisation of the chains. An alternative possibility—the *trans*-dissociation of the triple bond in the catalytic complex—is sterically prohibited for the transition state;[35,36] the structure of the complex and the polymerisation kinetics have been examined in greatest detail elsewhere.[28,37]

In all the cases described above the synthesis results in the formation of fibrils[35] and the morphology of the PA films is almost independent of the conditions of synthesis. However, depending on these conditions, the diameter of the fibrils can vary from 200 to 10^4 Å and is usually 220–800 Å.[28,38] When the films are grown on supports, the size of the fibrils diminishes. The same effects have been observed in the synthesis of PA in other polymers. The size of the fibrils is particularly strongly affected by the time during which the catalyst is kept (its ageing); with increase in the ageing time, the size of the fibrils increases.[39] Detailed study of the growth of the fibril on thin films by transmission electron microscopy made it possible to observe microfibrillar branching on the main fibril (30 to 50 Å in size) and thickened regions at its entanglement sites as the presence of rings at the ends of the fibrils.

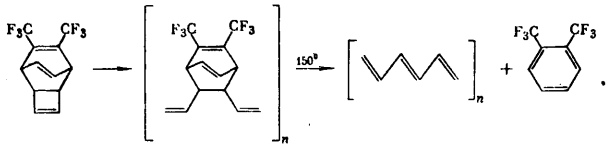
It has been shown that significant changes in the morphology of the film are not observed on isomerisation of PA. The film consists of arbitrarily arranged fibrils which are sometimes collected into larger formations.[36] The formation of the film is apparently a consequence of the interaction of the fibrils with one another via adhesion forces.

The synthesis of PA with fibrils oriented along some axis involves considerable difficulties. The simplest and most readily available method involves the stretching of the film, whereupon the fibrils are oriented predominantly along the stretching axis.[39] Crystalline specimens with a *trans*-structure, which give rise to a diffraction pattern similar to the Debye rings, are formed in the polymerisation of acetylene in a controlled shear field on a Teflon cylinder rotating at a rate of 3×10^3 rev min^{-1}.[40] It has been suggested that the polymer chain in these specimens is not oriented along the axis of the fibre. With increase in the rate of rotation of the cylinder, highly crystalline specimens are obtained in most axes of the fibril and the chains are parallel.[41] A method of preparation of macroscopic ribbon structures in a substrate rotating with a radial velocity of the mixing ring ranging from 10^7 to 10^{10} Å cm^{-1} [sic (Ed.of Translation)] which gives rise to the maximum shear stress in the future microfibrils has been described.[42] In the structures obtained, the molecular axis coincides with the axis of the fibre and the ribbon consists of a bunch of fibres. *trans*-Polyacetylene ribbons are more crystalline and the size of their domains is $(7-10) \times 10^5$ Å. A PA with a molecular weight of ~500, which can give rise to pseudo-lamellar structures, was found in the reaction medium.[42]

Oriented PA films are formed also on a polycrystalline Ziegler–Natta catalyst in solid biphenyl. The technique of deposition of the catalyst is fairly simple: on slow evaporation of the solvent from the mixture, a thin oriented layer of an active complex is produced on which a lustrous silvery PA film grows in the course of 3–5 days at −78 °C; the film is oriented in the direction of the single crystals of the support.[43]

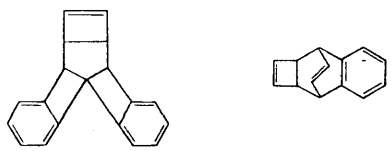
Highly oriented PA films have been obtained by the polymerisation of acetylene which had been epitaxially oriented beforehand on the surface of crystalline benzene.[44] Oriented PA films have been synthesised on the basis of this idea using cyclohexylpropylalkoxybenzene in the liquid crystal state, in the presence of a Ziegler catalytic system at 18 °C.[45] Morphological studies have shown that the fibrils are almost fully oriented in the direction of the liquid crystal domains.[45] Anisotropic PA films have also been obtained by the polymerisation of acetylene in the nematic phase of the MBBA liquid crystal ($C_4H_9C_6H_4N-CHC_6H_4OCH_3$) in a magnetic field with a strength greater than 2500 G, but the orientation is insufficiently

pronounced.[45] Iodine-doped films having the composition $(CH)I_{0.15}$ exhibited appreciable anisotropic properties: their conductivity in the direction of the field was 1235 Ω^{-1} cm^{-1}, while at right angles to this direction it was 300 Ω^{-1} cm^{-1}.[46] X-Ray diffraction studies of the oriented films confirmed that their molecular and fibrillar axes coincide and that they have a high degree of crystallinity (~90%) and made it possible to explain features associated with the lattice parameters and the crystal system. The anisotropy of the electrical conductivity and of the optical properties of oriented films has been investigated in fair detail.[39]



The metal complex catalytic systems are fairly varied. "Mixed systems", for example molybdenum or tungsten compounds combined with trialkylaluminium, have been used to an increasing extent in recent years for the preparation of various semiconducting polymeric materials. Lanthanide (Y, La, Pr, Gd, Tb, Dy) naphthenates or ethyl hexyl phosphates combined with triethylaluminium are effective catalysts of the stereospecific polymerisation of acetylene and its derivatives.[47] A catalyst component ratio of 1 : 5 is optimum. A polyacetylene obtained at a catalyst concentration ranging from 0.03 to 0.7 M at low temperatures contains 70% of the *cis*-isomer; according to the EPR data, there are 10^{17} paramagnetic centres per gram of the substance.[47] The results of X-ray diffraction studies (based on the characteristic $2\theta = 23.3°$ reflection), IR spectroscopic data and the initial conductivities of this specimen correspond to the values obtained for PA synthesised by other methods.[24-27] On the basis of such non-informative data, the not entirely justified conclusion has been reached[47] that the replacement of $Ti(OBu)_4$ by lanthanide compounds does not alter the PA structure.

The $AlR_3-VOCl(neopentyl)_2$ catalytic system is of great practical interest.[48] The PA obtained in its presence at -60 °C has a fibrous structure and can be processed by the usual method adopted in polymer technology. When a "mixed catalyst" is used, the particle size increases from 100 to 500 Å and the density of the film is found to increase. By filtering the suspension, it is possible to obtain a film of any size. Films on different supports, having effective adhesion properties, can be obtained by atomising the gel. The polymer can be readily doped with AsF_5, $FeCl_3$, I_2, and other electron acceptors; preliminary tests demonstrating certain advantages of such materials which are used in accumulators.[48] PA gels with analogous properties, obtained in the presence of other catalytic systems, are of great practical interest.[49] There is information in patent literature[50] about technological procedures for the preparation of PA films from gels with particle diameters in the range 0.01 – 1 mm, obtained in the presence of a "mixed catalyst" in the temperature range from -100° to -48°C. These results indicate the possibility of going over to a very simple and cheap technology involving a continuous process for the preparation of PA films.



WCl_6 and $MoCl_5$, in the presence of which acetylene polymerises at 20 °C and pressures up to 14 atm, are comparatively readily available. However, the polymers obtained contain carbonyl groups, which is apparently due to the presence of oxygen, and have a low molecular weight.[51] Complex systems including tetraphenyltin in addition to WCl_6 or $MoCl_5$ are more promising for the preparation of film materials.[52] A PA film with a predominantly (to the extent of 90%) *trans*-structure and a "fibrous" morphology is formed on the surface of a concentrated solution of a vanadium catalyst. The diameter of the polymer fibrils, obtained in the presence of the $MoCl_5-Ph_4Sn$ catalyst can be varied in the range 300 – 10 000 Å; in the case of the WCl_6-Ph_4Sn catalyst, it reaches 1.2×10^5 Å.[30,52]

The study of the kinetics of the polymerisation of acetylene in the presence of $Ti(OBu)_4-Al(Et)_3$, WCl_6-Ph_4Sn, $MoCl_5-Ph_4Sn$, and $Ti(CH_2C_6H_5)_4$ catalysts showed that the rate of the process decreases in the above sequence.[31,52] Films doped with various acceptors, namely $(CHI_{0.25})_n$, $[CH(SbF_5)_{0.7}]_n$, and $[CH(CF_3SO_3H)_{0.18}]_n$, had a conductivity of 10 – 20 Ω^{-1} cm^{-1} at 20 °C.[53]

A new, novel method of synthesis of PA films in the *trans*-form involves the polymerisation of 7,8-bis(trifluoromethyl)tricyclo[4.2.2.0]-deca-3,7,9-triene (BTFM) with opening of the ring:[54-55]

The polymerisation takes place in the presence of the $WCl_6-Sn(CH_3)_4$ catalytic system and deposits on the reactor surface. The prepolymer film splits off trifluoromethylbenzene with formation of a silvery PA film as a result of heating *in vacuo* at 100 – 150 °C. The density of the polymer reaches 1.1 g cm^{-3} and approaches the flotation density of the PA obtained by other methods. According to Leising et al.[54] and Edwards and Feast,[55] the amorphous PA obtained by this procedure has the fully *trans*-configuration and its structure is not fibrous. According to IR spectroscopic data, 1,2-bis-(trifluoromethylbenzene) residues are present in the polymer. Crystalline PA films with the monoclinic system and $\beta = 91.5°$ are obtained after prolonged heating of the prepolymer on electron microscope grids at 100 °C *in vacuo*.[56] An improvement of the method make it possible to obtain also films of fully oriented crystalline PA.[57] Subsequently methods of synthesis of polymers from other monomers were developed:[58]

On heat treatment of the prepolymer, naphthalene and anthracene are released in the former and latter case. An increase in the heat treatment temperature makes it possible to free the polymer from impurity residues.[58] According to spectroscopic data, the absorption due to the presence of sp^3-hybridised carbon is not observed in the spectra of the films; the absorption in the region of 1480 cm^{-1} in the Raman spectra of the polymers considered, due to the presence of C=C bonds, is displaced compared with the absorption observed for PA obtained by other methods (1460 cm^{-1}). It has been suggested that this is associated with a decrease in the size of the conjugation blocks. The films obtained are doped with difficulty in the gas phase owing to their high density. The conductivity of the initial films is 10^{-7} Ω^{-1} cm^{-1} and reaches 10 – 200 Ω^{-1} cm^{-1} when they are doped with bromine or iodine in solution and 2 Ω^{-1} cm^{-1} when the polymer having the composition $[CH(AsF_5)_{0.03}]_x$ is obtained.[58]

Solutions of ω-($\eta^1:\eta^5$-cyclopentadienyl)tris(η-cyclopentadienyl)-dititanium ($CpTiCl_2TiCp_2$) in hexane[59,60] and the cyclopentadienyl complex of sodium CpNa [61] exhibit a high catalytic activity. By removing the solvent slowly *in vacuo* from the PA gel formed, it is possible to obtain films with a metallic lustre. It has been suggested that the active complex has a tetrahedral structure and that the mechanism of the polymerisation is analogous to the mechanism of the polymerisation of olefins in the presence of a Ziegler – Natta catalyst.[61] The *cis*-polyacetylene films obtained at -80 °C had a conductivity of 240 Ω^{-1} cm^{-1} after doping.[60]

The classical ionic and radical polymerisation methods do not allow the preparation of high-molecular-weight polymers with a system of conjugated bonds (PCB) owing to the isomerisation of the active centres[2] associated with the polyene chain. With increase in the effective degree of conjugation, there is an appreciable change in electron affinity and the ionisation potential.[62] One of the methods

which make it possible to carry out the cationic polymerisation process involves the formation of a complex with the growing polyconjugated chain during synthesis. In practice such a process can be achieved in the presence of a large excess of a strong electron acceptor in the reaction medium. In this case, the electron density on polyene chains falls and there is a corresponding decrease in the probability of electron transfer from the chain to the active centre.

On the basis of these factors, it has been possible to synthesise PA films on the inner surface of the reactor in the temperature range from −78° to −198° when acetylene is added to arsenic pentafluoride. Soga et al.[63] and Kora and Kobayashi[64] identified the absorption band of *cis*-PA in the region of 740 cm^{-1} and of the doped complex in the region of 900 and 1370 cm^{-1}. Doped films having the composition $[CH(AsF_5)_{0.01}]_n$, obtained for the ratio $C_2H_2:AsF_5 \cong 0.1$, have an electrical conductivity of $4.8 \times 10^{-2}\ \Omega^{-1}\ cm^{-1}$.[63,64] Films of analogous composition have been obtained by the gas-phase polymerisation of vinylacetylene in the presence of SbF_5.[65,66] The conductivity of the film increased to $1 \times 10^{-2}\ \Omega^{-1}\ cm^{-1}$ with increase in the SbF_5 concentration, but the metallic state could not be attained.

Soluble polyenes, including soluble PA, have been obtained in solution in AsF_3 in the presence of AsF_5 by cationic polymerisation,[67] which was carried out at the freezing point of acetylene; films having a conductivity of $10^{-6}-10^{-7}\ \Omega^{-1}\ cm^{-1}$, characteristic of weakly doped PA with a molecular weight of $\sim 10^{-3}$, could be cast from the solution obtained. Spectroscopic studies confirmed the presence of the *cis*-structure in the polymer obtained. The possibility, in principle, of the polymerisation of acetylenic monomers (acetylene, methylacetylene, cyanoacetylene, and perfluoroacetylene) with formation of high-molecular-weight products in the presence of Group III, IV, and V metal halides has been indicated.[64] Insoluble polymers with specific conductance of $10^{-3}\ \Omega^{-1}\ cm^{-1}$, obtained at −78 °C by polymerising acetylene in the presence of AsF_5, $NaAsF_5$, SiF_4, AsF_3, BF_3, SbF_5, and PF_6, are of practical interest.[68]

Bivalent mercury compounds or organomercury derivatives are effective cocatalysts of the cationic polymerisation of acetylene and its derivatives.[69] The reactions of mercury oxide or mercury salts with protic and aprotic acids in saturated hydrocarbon media result in the formation of heterogeneous complexes, which effectively polymerise acetylene, vinylacetylene, phenylacetylene, and propargyl alcohol. Polyacetylene mainly with the *trans*-structure and a degree of crystallinity of 70% has been obtained in the form of films in the polymerisation of acetylene on the catalyst surface.[62,69] According to X-ray diffraction data, the principal reflection corresponds to the interplanar spacing $d = 3.22$ Å.[62,69] A homogeneous catalyst, whose active complex with acetylene is stable at low temperatures, has been obtained in the presence of aromatic ligands.[69] In the presence of aromatic solvents (toluene, benzene), the solvent is alkylated and subsequently copolymerises with acetylene, as a result of which the IR spectra of the films show absorption bands corresponding to the aromatic ring. The characteristic features of the polymerisation of acetylenic monomers, the influence of temperature and catalyst composition on the structure, and the properties of the polymers obtained have been investigated.[70,71] A study of the morphology of the films demonstrated the absence of fibrils.

Virtually all the methods of synthesis enumerated above, which make it possible to obtain PA with a high molecular weight, lead to the formation of insoluble polymers. Their insolubility can be explained by the formation of network structures together with the intense intermolecular interaction. The degree of cross-linking of polymers obtained in the presence of Ziegler catalytic systems is 3−5% according to NMR data,[72] which has been confirmed by the results of ozonolysis.[73] Quantum-chemical calculations have confirmed that the isomerisation process results in the formation of intermolecular bonds leading to the appearance of an unpaired electron.[74]

The easiest and most promising method of synthesis of PA with a linear structure involves the polymerisation of acetylene in the presence of Group VIII metals in combination with reductants (Luttinger catalyst).[75-77] Polyacetylene with a high degree of crystallinity has been obtained by polymerising acetylene in the presence of the $Co(NO_3)_2-NaBH_4$ catalytic system with the 1 : 2 component ratio. In order to prevent the destruction of the catalyst, both components are introduced into the substrate containing the monomer. An increase in the temperature and sodium tetrahydroborate concentration leads to the partial reduction of the polymer. The activity of nickel complexes can be greatly increased if the polymerisation is carried out in the preence of $NaBH_4$.[62,77] A crystalline polymer obtained at low temperatures contains no fibrils; the crystallites have dimensions up to 70 Å. The characteristic reflection observed at $2\theta = 23.75°$ ($d = 3.74$ Å) confirms the *trans*-structure of the polymer. Palladium complexes are ineffective in the synthesis of high-molecular-weight polymers.[62,77,78] The Luttinger catalyst makes it possible to obtain linear polymers with the *cis*-structure distinguished by a high crystallinity. The yield of PA reaches 25−30 g per gram of catalyst.

The chlorination of freshly prepared polymers at low temperatures permits the synthesis of soluble chloropolymers with a molecular weight of $(2-5) \times 10^4$.[27,79] Although the authors claim that, in contrast to hydrogenation, at a low chlorination temperature the polymer did not undergo degradation, our data[80] indicate that, when the temperature and the solvent are selected appropriately, the chlorinated polymers obtained have a molecular weight up to 2.5×10^5; the degradation is more appreciable on chlorination in the light and at an elevated temperature. The linear structure of PA is demonstrated by the fact that soluble iodinated polymers are obtained by iodinating a suspension of PA in ethanol.[80]

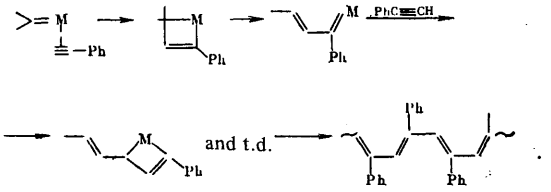
Systematic study of the methods of synthesis of PA made it possible to develop a fairly simple and convenient method for the preparation of films on various supports wetted with an ethereal solution of the catalyst.[79] The disadvantages of these films as well as films obtained by Shirakawa's method[24,25] are the difficulties of freeing them from catalyst residues and the dependence of the properties on the thickness of the surface.[81] The methods for the preparation of PA films by atomising in an inert gas stream PA freed from catalyst residues or by casting homogenised gels are much more practical.[49,82,83] The properties of such films depend on the conditions governing their formation. "Free" films with a thickness up to 2−3 mm are obtained by the filtration under pressure in an inert medium of a homogenised suspension containing 5−10 g $litre^{-1}$ of PA formed in organic media at low temperatures in the presence of the $Co(NO_3)_2-NaBH_4$ catalyst. The films obtained by atomisation in an inert gas stream are homogeneous and exhibit an effective adhesion to metallic, polyurethane, polyester, poly(ethylene terephthalate), polyimide, etc. supports.

The properties of the films have been described as a function of the conditions of synthesis and the composition of the catalyst.[62,84] PA suspensions undergo an appreciable change in their properties in the course of time. In an inert medium at a temperature above −20 °C, cross-linking and aggregation of the fibrils are observed, which lowers the rate of oxidation and chlorination. The morphology of the films changes especially markedly when the suspension is aged in the presence of moisture and oxygen: the diameter of the fibrils increases, their length diminishes, and breaks and nodes are formed. In contrast to this, it has been claimed[85] that a PA suspension undergoes no changes in its properties on being kept for two weeks.

The preparation of soluble polymers with a stream of conjugated bonds and a large molecular weight is especially difficult owing to the strong intermolecular interaction, but a PA with a fairly high molecular weight has been obtained in the form of finely dispersed

particles by carrying out the synthesis in the presence of the Luttinger catalyst and surface-active substances, mainly copolymers of styrene and polyethylene with poly(ethylene oxide).[86] Acetylene was added at −60 °C to the catalyst and the copolymer in solution in the cyclohexane−tetrahydrofuran mixture and the mixture was heated to −30 °C. This resulted in the formation of stable colloidal solutions with spherical particles whose size ranged from 40 to 2000 Å; the density of the films isolated was 1.15 g cm^{-3}. Colloidal PA solutions can be obtained in the presence of other polymers which prevent the aggregation of the PA molecules produced.

Polyacetylene obtained in the presence of Group VIII metals combined with $NaBH_4$ possesses virtually the same morphology as the polymer synthesised by Shirakawa's method.[25] The dimensions of the fibrils are in the range 300−800 Å and depend on the catalyst concentration, the temperature of the synthesis, and the medium.[27,87]



The thermogravimetric curves for the PA have two exothermic peaks at 145° and 325 °C.[16] The first corresponds to irreversible *cis*−*trans* isomerisation. At 325 °C hydrogen migrates, chain termination takes place, and the PA is cross-linked without the formation of volatile products; the polymer acquires a brown colour and a large number of defects appear, which is reflected in the appearance in the IR spectra of absorption bands characteristic of CH_2, CH_3, −C=C−, and C_6H_5 groups.[16] It has been suggested that structure formation takes place in the polymer in the temperature range 280−380 °C. The exothermic peaks in the region of 425° and 440 °C correspond to the partial decomposition of the PA; 72% of the initial mass of the PA is lost at 720 °C. The main products of the decomposition of the PA are benzene, hydrogen, and lower hydrocarbons.[15] When PA is heated in air to 90 °C, the degree of its crystallinity falls after only a few hours and a brown amorphous substance resembling cuprene is obtained when 70 h have elapsed.

III. THE SYNTHESIS AND PROPERTIES OF POLYACETYLENE DERIVATIVES

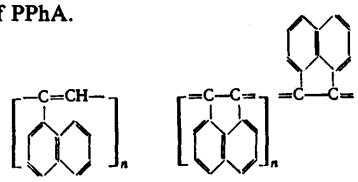
The likely usefulness of PA for the preparation of electrodes in accumulators and new semiconducting materials for the electronic industry stimulated further search for further technological materials. One of the ways in which such search is prosecuted involves the study of the polymerisation of acetylene derivatives and of the properties of the material formed.

The golden-green amorphous films of poly(hepta-1,6-diyne), obtained by the polymerisation of the corresponding monomer in the presence of a Ziegler−Natta catalyst, have the most interesting electrophysical characteristics.[88] In addition to the absorption in the region of 1610 cm^{-1}, characteristic of polyenes, the IR spectrum of this polymer exhibits absorption in the region of 910 and 1430 cm^{-1}, indicating the presence of the methylene group. A cyclic structure has been proposed for the polymer on the basis of these data. The conductivity of the freshly prepared specimens is 10^{-12} Ω^{-1} cm^{-1} and reaches 10 Ω^{-1} cm^{-1} when they are doped with AsF_5. The undoped films have a density of ~1 g cm^{-3}. A transition of the polymer to the vitreous state has been observed by differential scanning calorimetry in the temperature range from −50° to 330 °C; the first exothermic peak, associated with the *cis*−*trans* transition, is observed at 127 °C and the second occurs at 267 °C. The poly(hepta-1,6-diyne) films differ from the polyacetylene films by the fact that they contain no fibrils and are more sensitive to oxygen.[88]

One of the most readily available acetylene derivatives is phenylacetylene (PhA). The method for its polymerisation and the properties of polyphenylacetylene (PPhA) have been studied in fair detail and have been described[12,16,89,90] and we shall therefore consider only certain questions concerning the preparation of semiconducting materials from PhA. The polymerisation of PhA in the presence of $AlEt_3-TiCl_4$ leads to the *cis*-isomer [91] or the *trans*-isomer [92] depending on the conditions of synthesis; the pure *cis*-cisoid PPhA has a bright red colour. The crystalline insoluble *cis*-PPhA is obtained in the presence of iron acetylacetonate and trialkylaluminium.[91] The soluble *cis*-PPhA with $M_n = (1-2) \times 10^4$ is formed in the presence of $MoCl_5$ or WCl_6.[93,94] The kinetics of the polymerisation of PhA in the presence of $MoCl_5$ catalyst fixed on kaolin, talc, and aluminium and magnesium oxides have been investigated[95] and it was found that the carrier influences the structure and properties of PPhA. The molybdenum in the active centre exists in the quadrivalent state.[95] High-molecular-weight PPhA with $M_n \cong 8 \times 10^4$ has been obtained in the form of a yellow soluble powder on UV-initiated polymerisation of the monomer in the presence of tungsten or molybdenum carbonyl in a halogen-containing solvent.[96] It has been suggested that the reaction mechanism involves the elimination of carbon monoxide under the influence of UV irradiation with formation of a coordination complex between the carbonyls of the above metals and PhA. The polymer chain grows in the consecutive stages involving the formation of the metallocarbenes and metallocyclobutenes:

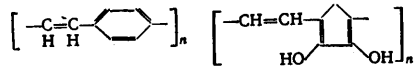
The films can be readily obtained from the polymer solutions.

Although the electron-initiated polymerisation of arylacetylenes is in fact fairly promising, it has been little investigated.[97,98] The PhA polymers obtained in dimethylformamide (DMF), dimethyl sulphoxide (DMSO), and acetonitrile in the presence of tetra-alkylammonium, lithium, potassium, and sodium salts or $NaNO_3$ as electrolytes have a low molecular weight (of the order of 500−3700) and a melting point ranging from 90° to 160 °C. The synthesis takes place in the cathodic space on graphite electrodes; the radical inhibitors do not influence the polymerisation but alcohols retard the process. On the basis of these data, the authors propose an ionic initiation mechanism. The yield of the polymer, in which a large amount of cyclohexadiene structures has been observed, reaches 60%.[97-100]



The PhA polymerises in a homogeneous catalytic system consisting of mercury compounds combined with acids in aprotic solvents.[101] The soluble polymers formed, mainly with the cisoid structure, are distinguished by a high degree of crystallinity. The films obtained from the solution of the polymer weakly doped with boron trifluoride exhibit semiconducting properties and have an electrical conductivity of the order of $10^{-6}-10^{-8}$ Ω^{-1} cm^{-1}; they lose their crystallinity on ageing. It follows from the analysis of the IR and ^1H NMR spectra that, under these conditions, cyclohexa-1,3-diene and cyclohexa-1,4-diene structures, diminishing the effective conjugation, appear in the polymers.[101,102] The stable complexes of PPhA with iodine, which are formed when PhA is polymerised at 100° to 150 °C in the presence of iodine as the catalyst, have an electrical conductivity of the order of $10^{-3}-10^{-5}$ Ω^{-1} cm^{-1}.[103]

The appeciable defects in the conjugation chain in PPhA compared with PA are caused not only by the influence of the benzene ring, which gives rise to steric hindrance to the coplanarity of the fragment of the main chain, but also by the tendency of the PPhA to isomerise. The isomerisation takes place at temperatures up to 130 °C and is accompanied by a slight decrease in the molecular weight; analogous changes have been observed to a large extent after the specimens have been kept for a long time in the light.[104,105] An appreciable decrease in $\overline{M}_n$ and the appearance of cyclohexadiene

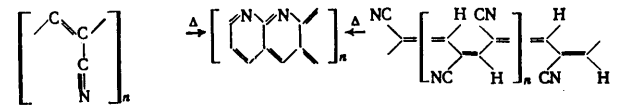


fragments have been observed at 130–280 °C.[106] Further heating leads to weight loss, which is associated with the evaporation of the low-molecular-weight products—mainly triphenylbenzene.[107] These changes result in the complication of the polymer structure, a decrease in the length of the effective conjugation, and hence an impairment of the electrical conductivity.[99] For example, the electrical conductivity of the iodine-doped crystalline *cis*-cisoid PPhA falls by several orders of magnitude after its heat treatment at 120 °C. Apparently this is why a dependence of the electrical conductivity of PPhA on its structure and molecular weight has not been observed in many investigations. On doping with iodine, the electrical conductivity of PPhA reaches 10^{-5} Ω^{-1} cm^{-1}, the *cis*-isomer being doped more readily than the *trans*-isomer. Variation of the molecular weight over the range $(7-10) \times 10^3$ does not affect the reversible incorporation of iodine and the conductivity of PPhA.

Soluble complexes of PPhA with organic electron acceptors have been obtained; their solutions absorb radiation in the range 700 to 900 mm as a function of the nature of the electron acceptor.[108] The electrical conductivity of the polymer increases after the addition of the acceptor, reaching a maximum when the content of the latter is 75 mole per cent and does not then change further. Analogous behaviour has been observed also for polystyrene.[108] The authors suggest that the acceptor forms a complex with the phenyl side groups in the polymer chain. However, a study of the kinetics of the reaction of PPhA with chloroanil and other organic acceptors demonstrated the formation of a charge-transfer complex (CTC) in the first stage of the process and the subsequent complete charge transfer with formation of a polymeric radical-cation.[109] The equilibrium constants for the complex ($K \geqslant 10^3$) have been estimated and its enthalpies have been found ($\triangle H \geqslant 8.6$ kcal $mole^{-1}$) from the activation energies ($E_{eff} = -8.6$ kcal mol^{-1}). Further studies showed that styrene does not form a CTC with iodine.[110]

Methods for the polymerisation of 1-ethynylnaphthalene[89,111] and acenaphthenediylidenes with various substituents[112] have also been investigated. The electrophysical properties of the polymers obtained have been described in fair detail[111,112] and are in the main similar to the properties of PPhA.

Polyarylacetylenes capable of forming films with metallic lustre and having a specific conductance (for undoped specimens) of 10^{-8} Ω^{-1} cm^{-1} each and having the following structure have been obtained by photoreductive condensation:[113]



The synthesis, structures, and properties of polyarylacetylenes have been described in great detail in a review.[90]

Among other polymeric derivatives of acetylenes, poly(3,3,3-trifluoroprop-1-yne) is of interest. Trifluoromethylpropyne is polymerised in solution in DMF in the presence of $PdCl_2$ at 60 °C.[114] Liquid oligomers, which have a polyene structure according to IR and NMR spectroscopic data, are formed. A higher-molecular-weight product with $M_n \cong 10^3$ was obtained at −78 °C in the presence of butyl-lithium.[78] On heat treatment, the brown polymer powder blackens, but its conductivity $\sigma = 10^{-12}$ Ω^{-1} cm^{-1} does not change; specimens doped with iodine have a conductivity of 9.5×10^{-5} Ω^{-1} cm^{-1}. The polymer is resistant to thermal and thermo-oxidative degradation up to 240 °C. In the differential-thermal analysis of the specimen in the temperature range up to 450 °C, three exothermic peaks are observed.[78,114]

A polymer with a conductivity up to 10^{-5} Ω^{-1} cm^{-1}, described previously,[115] has been obtained by the polymerisation of propargyl chloride in the presence of $PdCl_2$.[114] The high conductivity is apparently due to the doping of the polymer by the halogen eliminated. The introduction of an excess of iodine into the polymer powder softens it and a thin film with a conductivity of 2×10^3 Ω^{-1} cm^{-1} can be obtained from it by pressing.

Like cyanoacetylene, propiolonitrile readily polymerises in the presence of various catalysts.[116] In the presence of triethylamine, a black insoluble powder is formed in high yields; in order to obtain films, the reaction is carried out in the gas phase. The BuLi catalyst in THF polymerises cyanoacetylene at −70 °C ($\overline{M}_n \cong 4800$). The effective adhesive properties of the films make it possible to grow them even on the surface of Telfon; splitting into layers on deformation of the support is not observed.[114,117,118] In the presence of $Ti(OBu)_4-AlEt_3$, the reaction involving the formation of a *cis*-transoid polymer takes place in solution in pentane at room temperature but the yield of the polymer is somewhat lower than in the presence of chromium acetylacetonate with an excess of triethylaluminium.[116] A brown polymer with a linear *trans*-transoid structure can also be obtained.

Catalysts based on $MoCl_5$ and $Sn(C_6H_5)_4$ make it possible to obtain linear products from cyanoacetylene at room temperature.[116] The polymer is not doped by electron donors but it is reversibly doped with iodine up to a content of the latter of 40 mole per cent. Its electrical conductivity then changes from 10^{-12} to 10^{-3} Ω^{-1} cm^{-1}. Differential-thermal analysis data indicate the occurrence of processes at 140°, 215°, and 255°C without change in rate. The weight loss at 1110 °C is ~50%. The study of the specimens after the heat treatment suggested that the first stage (280 °C) involves isomerisation, while at higher temperatures cyclic structures appear as a consequence of degradative processes:[114]

linear *trans*-transoid polymer

linear *cis*-transoid polymer

The cyanoacetylene polymers and copolymers exhibit semiconducting properties and are promising materials for the preparation of transistors and solar batteries.[117,118]

Polymethylacetylene has been obtained[119] by the polymerisation of methylacetylene in the presence of a Ziegler–Natta catalyst at 0 °C. The orange powder obtained is sensitive to air and does not give rise to an EPR signal even on heating to 150 °C. The results of thermogravimetric analysis indicate its vigorous decomposition at 180 °C with a weight loss of up to 90%.[119] Polymethylacetylene is doped with iodine and other electron acceptors whereupon $\sigma = 10^{-3}$ Ω^{-1} cm^{-1} is attained. The films are formed on gas-phase polymerisation of methylacetylene on the surface of the catalyst at low temperatures. The polymerisation of ethynylferrocene and methylethynylferrocene takes place readily in the presence of WCl_6-Ph_4Sn.[120]

Other acetylene derivatives containing bulky substituents, capable of fully disturbing the coplanarity of the chain, as a rule polymers with poor electrophysical properties. For example, the polymerisation of t-butyl- or n-butyl-acetylene under the influence of WCl_6 leads to the formation of light-coloured powdered products with $M_n \cong (0.8-5) \times 10^5$ which do not possess the properties of PCB.[121] Table 1 indicates certain acetylenic derivatives used as monomers for the synthesis of PSS.

IV. COPOLYMERS AND COMPOSITES BASED ON POLYACETYLENE

The search for methods of synthesis of polyenes is closely related to the modification of the properties of these polymers in order to obtain materials which are suitable for processing on the technological equipment used in the polymer industry. One of such current procedures is the preparation of copolymers of acetylene and its derivatives with other monomers used in industry and composites. Films containing 2–5% of DA, capable of being doped with electron-acceptors, have been obtained by polymerising acetylene in a matrix comprising polyethylene and copolymers of styrene with butadiene and isoprene using a Ziegler–Natta catalyst.[122,123] The dispersed doped compositions have a high surface conductivity and an improved resistance to the action of air. The number-average molecular weight of the PA composition reaches 2.5×10^4, while the weight-average molecular weight M_w is 10^5, so that we have the ratio $M_w/M_n = 4.26$.[124] The properties of the conducting composites obtained by doping the polymer with iodine and having a PA content up to 3% can be explained by a simple percolation model.[125]

Flexible elastic films can be obtained by pressing PA with ethylene–propene rubbers or by polymerising acetylene in solution in poly(vinyl chloride), polyvinylpyrrolidinone, or polyvinylbutyral; the stretching of the films promotes an increase in electrical conductivity, which can be explained by the orientation effect.[126] The most varied materials, ranging from elastic to rigid, can be obtained by polymerising acetylene in the presence of the $Ti(OBu)_4-AlR_3$ catalyst in a polybutadiene matrix with $\overline{M}_n = 2 \times 10^5$. When they were doped with lithium or iodine, a composite having a conductivity ranging from 10 to 100 Ω^{-1} cm^{-1} was obtained; the conductivity increases on stretching the specimens.[127] The morphology of the composites varies as a function of the PA content from fibrillar (for an 80% PA content) to globular (PA content less than 20%).[128] Electrically conducting compositions have been obtained by the graft polymerisation of acetylene. The addition of PA to the copolymer chain has been demonstrated.[123] The graft block-copolymer of PA and atactic polystyrene with $M_n = 10^5$, obtained in the presence of a Ziegler–Natta catalyst and containing up to 40% of PA, is capable of forming lamellar single crystals which have a hexagonal lattice whose unit cell parameters are $a = 5.12$ Å and $c = 4.8$ Å and whose size ranges from 10^3 to 10^4 Å.[129] With decreased content of the polymer-carrier, the interface necessary for the formation of the crystalline phase diminishes.

A soluble block-copolymer of PA with polyisoprene and polystyrene is obtained for a PA content up to 5% and permits the study of the behaviour of the stable PA chain in solution. Spectroscopic studies[130] have shown that in such copolymers the polyene molecule retains the properties of the homopolymer. However, there are also certain differences. Thus at room temperature rapid *cis–trans* isomerisation takes place in the copolymer. The block-copolymer is more sensitive to oxidation than PA itself and, in contrast to PA or the composite, it is capable of combining quantitatively with bromine at the double bond. NMR data have made it possible to identify segments with PA and to establish that the chain conformation is non-linear. According to electron microscopic data, the graft copolymers are characterised by the presence of separate microphases with microdomains $(1-1.5) \times 10^5$ Å in diameter.[130,131]

The PA and styrene block-copolymers have been obtained from styrene oligomers with $M_n = 10^3$ synthesised in the presence of BuLi. After the treatment of the oligomer with aluminium chloride and the addition of $Ti(OBu)_4$, acetylene was introduced into the system at a pressure of 700 mmHg. This method makes it possible to obtain also copolymers of acetylene with methylacetylene and phenylacetylene.[37] The films made of copolymers with different contents of methylacetylene have also been obtained by polymerising a mixture of monomers on a thin layer of catalyst deposited on a support.[119] The elasticity of the polymer increases with increase in the methylacetylene content whereupon the conductivity of the doped film and its stability in air diminish. With increase in the methylacetylene content in the copolymer, its morphology changes appreciably and the fibrillar structures characteristic of PA disappear.[119]

The reverse process involving the grafting of polystyrene, polyisoprene, poly(methyl methacrylate), and poly(ethylene oxide) blocks to the PA chain is carried out by polymerising the corresponding monomers on polyacetylene doped with sodionaphthalene. Films

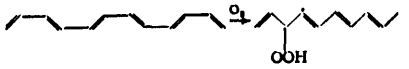
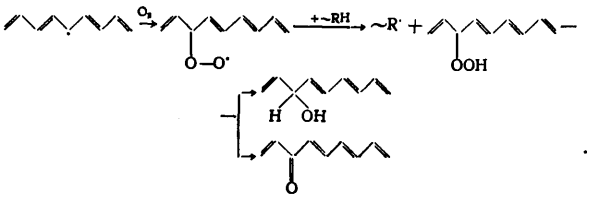
with interesting magnetic properties have been obtained by copolymerising acetylene with carbon monoxide.[131] An amorphous polymer containing up to 15 mole per cent of CO and having molecular weights up to 87×10^4 can be synthesised in the presence of the $Ti(OBu)_4-4AlEt_3$ catalyst. The AsF_5-doped films had conductivities up to 200 Ω^{-1} cm^{-1}.[131] When epoxyethane is used, materials having the properties of solid electrolytes are obtained.[37] In recent years, there has been a marked growth of interest by investigators in composites containing PA. Composites containing graphite, carbon black, charcoals,[132] various network polymers, and, in particular, thermolysed polyacrylonitrile[48] have been produced. Composites obtained by polymerising acetylene on polypyrrole films are of interest; after doping, they have a conductivity of ~ 20 Ω^{-1} cm^{-1} and are fairly stable in air.[133]



V. THE OXIDATION, REDUCTION, DOPING, AND STABILISATION OF THE FILMS

The ability of PA and other PCB to combine with 25–33 wt.% of oxygen in air is evidence of their instability, although the use of this property for special purposes can be of independent practical value. The oxidation of PA alters the chemical and physical characteristics of the material. The electrophysical and mechanical properties of films change particularly markedly.[134] On absorption of oxygen, the material becomes more brittle; the slight modification of the surface of the fibrils in consequence of the adsorption of oxygen or other acceptors greatly influences the formation of films. The films doped with acceptors are oxidised more slowly than the initial films.[135,136] The electrical conductivity of PA films increases after the absorption of oxygen up to 16 wt.% and then falls by several orders of magnitude.



The absorption bands of the oxidised specimens in the region of 1720 and 1670 cm^{-1} correspond to the deformation vibrations of the carbonyl group in the isolated and αβ-unsaturated ketones.[138] Bands at 1109 and 1143 cm^{-1} correspond to the antisymmetric vibrations of the C–O bond in aliphatic ethers. The absorption bands in the range 1000–1300 cm^{-1} and in the region of 3420 cm^{-1} indicate the appearance of hydroperoxy- and hydroxy-groups. The absorption bands at 1370 and 890–900 cm^{-1} appear in the initial stage of the oxidation caused by the doping of the PA with atmospheric oxygen and disappear at high degrees of oxidation; the absorption in the region of 1920 cm^{-1}, attributed to the allene group, vanishes simultaneously.[136-139]

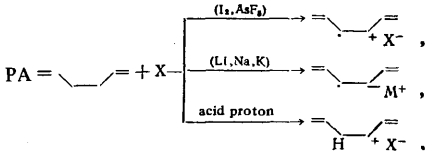
There exist several ways of adding oxygen to polyenes. Singlet oxygen can react with the olefin via the 1,2-addition mechanism with the ultimate formation of cyclic peroxides. In the case of 1,3- and 1,4-addition, other corresponding products appear. Triplet oxygen reacts with the initial radical to form a peroxy-radical capable of being converted into hydroperoxy-, carbonyl-, and hydroxy-groups as a result of further reactions.[136] The oxidation occurring in the absence of UV irradiation is a pseudofirst order reaction.

Visible light does not affect the rate of oxidation; diffusion also does not limit the rate of the process. In the oxidation of the films, an induction period, corresponding to the formation of a CTC, is observed; this is followed by two oxidative processes on the surface and in the bulk of the specimen, which lead to the appearance of an inflection in the kinetic curve. The following reaction scheme has been proposed on the basis of the studies carried out:[136,140]

The oxidation of *cis*-PA begins with the isomerisation and formation of neutral defects:

However, the scheme presented reflects inadequately the specific features of the oxidation process in view of the complex character of the reactions of oxygen with the polyconjugated system. The results of the study of the kinetics of the oxidation of PA indicate the absence of a linear relation between the decrease in the number of double bonds and the accumulation of oxidised groups.[138] The kinetics and mehcanism of the oxidation of PA have been described in detail in other communications.[30,141]

Owing to the preferential consumption of molecules with a *cis*-structure, in the initial stage of the oxidation of PA, the enrichment of the specimen in the *trans*-isomer is observed. If the temperature does not exceed 150 °C, the oxygen content of the polymer can reach 35%. With increase in temperature, thermo-oxidative degradation, in the course of which CO_2 and H_2O are evolved, takes place.[136,138] The rates of oxidation at 70 °C of PA and polymethylacetylene obtained in the presence of a Ziegler–Natta system are respectively 9.16×10^{-7} and 10^{-6} mol g^{-1} s^{-1}, while the activation energies for these processes are 9.6 and 14 kcal mol^{-1}.[142] The activation energies for the oxidation of PA measured by different workers are in the range from 11 to 20 kcal mol^{-1},[136,139,143] which is apparently associated with the different densities of the films employed. The activation energies for the formation of the complex of PA with oxygen and for its decomposition have been found respectively to be 11.52 and 13.45 kcal $mole^{-1}$ and it has been shown that water accelerates the oxidation of PA.



The addition of ozone to polyenes takes place at low temperatures and leads in the case of PA to the formation of an adduct in 98.5% to 99.5% yields whose decomposition results in the formation of oxalic acid diesters.[73] The activation energy for the oxidation of PA by ozone is 19.59 kcal mol^{-1}.[144] The kinetics of the oxidation and doping of polyheptadiene and PA differ somewhat.[145]

Studies of different types of stabiliser have shown that quenching agents for singlet oxygen, for example, dimethylanthracene as well as compounds decomposing peroxides do not affect the rate of oxidation of PA.[142] Sterically hindered phenols and inhibitors of the amine type, which actively capture radicals, inhibit the thermal oxidation of PA. The inhibition of the oxidation of PA also occurs on the addition of mixtures of sterically hindered phenols and peroxide-decomposing compounds which exhibit a synergistic effect. Following an increase in temperature the action of antioxidants weakens; this is believed to be caused by the surface character of the inhibition.[142] In the presence of 2,6-di-t-butylphenol, the stability of PA is retained also after doping. The kinetics of the oxidation of PA have been studied in the presence of inhibitors.[30,136] Analogous results have been obtained in the study of polymethylacetylene synthesised in the presence of a Ziegler–Natta catalyst; stabilisers of the phenolic type are effective if they are used in a complex with systems decomposing peroxides.[146]

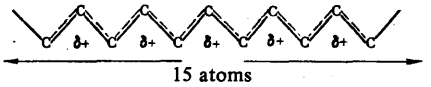
The stability of various polymers of the acetylene series in relation to oxidation in air and UV irradiation increases in the presence of acid esters and thioesters based on Group V and VI elements, especially phosphorus, sulphur, nitrogen, etc.[141] A polyacetylene synthesised in the presence of phenols and phosphines is also less susceptible to oxidation. It is likewise resistant to the action of water, but its doped derivatives, especially those doped with electron

donors, are sensitive to moisture. The PA doped with sodium is readily hydrolysed by water, whereupon its partial hydrogenation takes place.[147] The elecrical conductivity of the films doped with electron acceptors falls in the presence of moisture owing to the hydroxylation of the PA, particularly in alkaline media. Chain protonation takes place in acid media and the stability of the films is higher than in an alkaline medium.[148,149] In strongly acid HBF_4 solutions, it is possible to dope PA irreversibly without the formation of hydroxylation products.[150,151]

Doping of *p*-type includes in essence a PA oxidation step and occurs fairly vigorously with the cooperation of various acceptors. Correspondingly, *n*-type doping includes a reduction process and occurs with the cooperation of electron donors. In early studies, the doping mechanism in the first stage was described by the scheme[36]

Here provision is made for the delocalisation of the cations and anions formed along the conjugation chain. Later this scheme was confirmed by the finding that, following the addition of external oxidants, the rate and degree of doping increase and hydroxy-groups can be detected in the PA structure.[152] As already mentioned, the ability of PA to be doped with an electron acceptor or donor is its most important characteristic, which makes it possible to employ this material as *n*- and *p*-type semiconductors, electrodes, solar energy converters, in the manufacture of accumulators, and in other technological fields. In the vertical stage of the reaction with PA, oxygen acts as an electron acceptor, which entails an increase in the conductivity and the appearance of an interfacial polarisation effect.[139]

One of the most promising methods of doping is electrochemical. The irreversibility of electrochemical doping, investigated in a number of studies,[153,154] made it possible to develop doped polyacetylene electrodes for accumulators.[155,156] In a general form, the equation for the doping process can be written as follows:

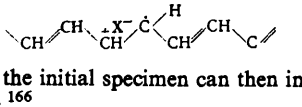


$$CH_x + yA \rightarrow [CH^{y+}(A^-)_y]_x ,$$

$$CH_x + yM \rightarrow [M_y^+(CH)^{y-}]_x ,$$

where A^- and M^+ are the univalent anion and cation respectively.

As in the oxidation reaction, a *cis*–*trans* transition is observed in the PA during the doping process and, depending on the degree of doping, three states of PA arise. In the first, semiconducting state, the concentration of the dopant is less than 1% and the material has semiconducting properties. In the second, metallic state, where the concentration of the dopant exceeds 6%, the material acquires properties characteristic of metals: high conductivity independent of temperature, paramagnetic susceptibility, and low heat capacity; its thermo-e.m.f. begins to vary linearly with temperature, etc. Finally, in the transition state, the material occupies an intermediate position between metals and semiconductors as regards its properties.



At the present time, the high conductivity of doped PA is explained mainly by the mobility of solitons. Neutral solitons, called in the chemical literature "delocalised radicals",[157] exhibit a high mobility in *trans*-PA. Positive and negative solitons (carbonium ions and carbanions) appear as a result of electron transfer to an acceptor (*p*-doping) or from a donor to the polymer (*n*-doping). The unit charge of the solitons is distributed approximately between 15 carbon atoms:

The charge on each CH group diminishes with increase in its distance from the doping ion.[158] Analysis of the IR spectra provides proof of the appearance of solitons. The vibrational models of soliton are observed at 1385 and 900 cm^{-1}, which is consistent with calculated data.[9,105] However, the properties of PA in the initial doping stage can be accounted for differently, with the aid of the theory of the formation of polarons.[159]

The general characteristics of the doping by various electron acceptors are the same. X-Ray diffraction studies on the iodine-doped PA indicate the existence of undoped regions and regions doped on the surface; furthermore, there are also complexes of PA with the dopant exhibiting metallic conductivity.[160] It has been observed by NMR that, together with complex formation, iodine adds to the double bond.[161] The doping of PA films obtained using the $Co(NO_3)_2-NaBH_4$ catalytic system is achieved both by immersing them in solutions of different acceptors and electrochemically until the attainment of a conductivity $\sigma \cong 10^3\ \Omega^{-1}\ cm^{-1}$.[162] In the doping process, the characteristic reflection of *cis*-PA with $d = 3.73$ Å disappears and reflections with $d = 8.35$ Å appear when SbF_5 is used as the dopant and $d = 8.15$ Å when AsF_5 is used; similar reflections have been noted for doped graphite ($d = 8.46$ and 8.15 Å respectively). A layered structure has been proposed for the doped specimens on the basis of these investigations.[162] When the PA film is doped with fluorosulphonic acid in the gas phase, the conductivity increases rapidly with increase in the content of the dopant y up to the critical value $y = 0.02$, after which a tendency towards saturation is observed, occurring at $y = 0.29$, whereupon σ reaches $2 \times 10^4\ \Omega^{-1}\ cm^{-1}$. At low temperatures the conductivity is independent of temperature, which can be explained by the vibrationally-excited tunnelling of the charges between the metal-like sections.[163] Detailed investigation of the doping of PA films indicate a non-uniform occurrence of this process, because the diffusion of the dopant into the relatively dense fibrils is difficult.[164]

A novel doping method involves the implantation of halogens in PA. Treatment of PA with a stream of halide ions at a dose of $10^{11}-10^{17}$ ions cm^{-2} and for an irradiation energy of 10–40 eV generates a uniform ion concentration gradient along the specimen. This film then becomes stable in air and acquires a colour ranging from red to blue depending on the irradiation energy. It has been suggested[165] that complexes having the following structure are formed in the ion implantation process:

The conductivity of the initial specimen can then increase by five orders of magnitude.[166]

The doping of PA by acids, especially those which cannot behave as oxidants is of special interest. The addition of a proton to the polyene chain with formation of a complex is suggested in this case.[167] The doped polymers have a comparatively low electrical conductivity (up to $10^{-3}\ \Omega^{-1}\ cm^{-1}$). This has been explained[167] by the appearance of steric effects, the formation of cross-links, or the addition of HCl to the double bond, which limits the length of the conjugation chain.[168] However, this evidence was in no way confirmed in the above study; furthermore, we have shown† that the addition of HCl to the double bond is not observed.

Doping with alkali metals can be carried out most readily in solution in tetrahydrofuran using sodium naphthalide or benzophenonelithium as the dopant; as in the *p*-doping process, under these conditions absorption bands in the regions of 1090 and 1480 cm^{-1}, characteristic of the *trans*-isomers, appear in the Raman

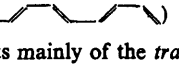
† See A.A.Matnishyan, N.M.Davtyan, and G.R.Martirosyan, Vysokomol.Soed., 1987, **29B**, 728.

spectra of *cis*-PA.[169] Doping with lithium tetrahydroaluminate in solution leads to the formation of a relatively unstable PA anion with a conductivity of 5 Ω^{-1} cm^{-1}.[170,171] In order to prepare elastic *n*-type films, PA is treated with anthraquinone derivatives combined with reductants (KBH_4, $NaHSO_3$, $NaCNBH_3$) in an aqueous medium.[172] Although the stability of the films increases in such treatment, nevertheless doping is accompanied by the partial reduction of the polymer and hence by the destruction of the conjugation regions. PA films treated with biarylyliodonium salts, whose UV irradiation leads to the doping of the exposed sections accompanied by an increase in conductivity, have found a new practical application as photo-sensitive materials.[173] The characteristic features and mechanisms of the doping of PA have been investigated in fair detail in recent years in connection with the prospect of constructing accumulators using PA films as electrodes.

Phenylacetylene is irreversibly doped with iodine, whereupon its conductivity increases from 10^{-14} to 10^{-5} Ω^{-1} cm^{-1}. The dependence of the conductivity on the iodine concentration c is of the form[159]

$$\sigma = \sigma_0 \cdot \exp[\gamma c(1-c) - \gamma/4],$$

where $\gamma \cong E/kT$.[159] An ionic mechanism of electrical conduction involving the thermally activated charge transfer model has been proposed. The current is determined by the number of charge carriers and not by their mobility.[114,174] Complexes of PPhA with various organic and inorganic acceptors were obtained. A mixture of PPhA with dichlorodicyano-*p*-benzoquinone and tetracyano-*p*-quinodimethane exhibits a high conductivity and measurements of the thermo-e.m.f. made it possible to assign it to the *n*-type.[108]



Among other polyenes, doped polyheptadiyne, polymethylacetylene, and certain polyarylacetylenes have been investigated.[112]

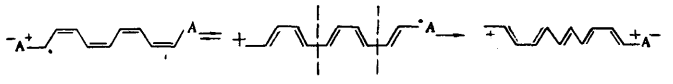
VI. THE STRUCTURE AND MORPHOLOGY OF POLYENES

Studies of PA films obtained both in the presence of Ziegler–Natta catalysts and Group VIII metals led to the conclusion that the *cis*-form of the polymers includes the *cis*-transoid structure

and the *trans*-cisoid structure

while the *trans*-form consists mainly of the *trans*-transoid structure[16,27]

The formation of the *cis*-cisoid structure is not ruled out either. The content of the *cis*-form in the synthesis of the polymer on the support or on the catalyst surface depends on the thickness of the film; as a consequence of the appreciable heat of reaction observed when the films are obtained by the method of Shirakawa and co-workers,[24,25] the fraction of the *cis*-isomers in thick specimens falls to 70–75% owing to their transition to the *trans*-form.[174] However, since the activation energy for the isomerisation reaction increases rapidly as the *trans*-structures accumulate and reaches 21 and 38 kcal $mole^{-1}$ for contents of the *cis*-form of 70 and 20% respectively, this explanation cannot be regarded as exhaustive.[143] If the polymerisation is carried out in the presence of the $Co(NO_3)_2$–$NaBH_4$ catalyst, the *trans*-cisoid structure is formed in appreciable amounts on the supports together with the dominant *cis*-transoid structure;[175] the fraction of the *cis*-cisoid structure is negligible. The ratio of the isomers depends greatly on the composition of the catalyst and the temperature of the synthesis (Table 2). The nature and concentration of the catalyst components also have an appreciable influence on the composition of the PA.



The quantitative ratios of the *cis*- and *trans*-isomers found by different workers differ significantly; this is associated with the use of different methods for the determination of the relative absorption coefficient $K_{trans/cis}$, whose values are 1.05 (Shen et al.[47]), 1.66 (Gibson et al.[176]), etc. The question concerning the mechanism of the *cis*–*trans* isomerisation is not as yet entirely clear. Probably, after the transfer of one electron to the dopant with participation of another electron and a π electron of a neighbouring carbon atom, a new double bond is formed; this process, in which the newly formed unpaired electron is involved, then develops further until the encounter with the dopant or another free electron:[177]

Table 2. The content of the *cis*-isomer (%) of polyacetylene as a function of the nature of the catalyst and the temperature of the synthesis.

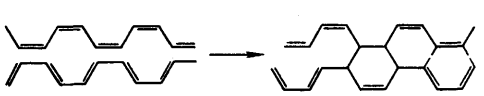
Catalyst	Temperature of the synthesis, °C					Refs.
	−78	−18	0	+20	+100	
$Ti(OBu)_4$–$Al(C_2H_5)_3$	98	95	79	59	7,2	[135]
$Co(NO_3)_2$–$NaBH_4$	94	72	45	30	—	[75, 84]
WCl_6–Ph_4Sn	—	—	—	10	—	[52]
$MoCl_5$–Ph_4Sn	—	—	—	10	—	[52]
$Ti(CH_2$–$C_6H_5)_4$	—	—	—	40	—	[52]

In the presence of an acceptor, in the first stage the *cis*-transoid form is converted into the unstable *trans*-cisoid form, which constitutes an excited state of the initial form and then, as a result of rotation about two single bonds, sections with the *trans*-structures are formed:

The view has been expressed in the literature that the crystal structure of the catalyst produces a planar structure of the PA. The subsequent organisation of the polymer chains depends on the rates of polymerisation and crystallisation, changes in which can lead to sharp changes in the morphology.[38] It has been stated[38] that the concentration of the Ziegler–Natta catalyst has little influence on the PA morphology, while an increase in the ageing time leads to more appeciable changes. The influence of the catalyst on the structure and properties of PA has been investigated in greater detail.[15,16,28] Our studies have shown that the morphology of PA is influenced by the catalyst concentration and the composition of the ligand shell, but especially marked influence is shown by the nature of the metal in the catalytic cluster.[178,179]

The IR spectra of PA contain the following absorption bands: at 440 cm^{-1} (deformation vibrations of the C–C–C fragment), 740 and 1015 cm^{-1} (out-of-plane deformation vibrations of the C–H bond in the *trans*- and *cis*-forms respectively), 1118 cm^{-1} (C–C deformation vibrations), 1249 and 1329 cm^{-1} (in-plane C–H deformation vibrations), 1292 cm^{-1} (out-of-plane C–H vibrations), 3013 cm^{-1} (C–H stretching vibrations characteristic of the *trans*-structure), and 3044 and 3057 cm^{-1} (stretching vibration characteristic of the *cis*-structure).[175] The quality of the spectra increases when thin polymer films, obtained by sputtering the freshly prepared gel onto glass of the KRS type, are investigated. The doped specimens are distinguished by a characteristic absorption due to soliton modes in

the regions of 1370 and 900 cm^{-1}.[147] The photoacoustic IR spectroscopic method (PAIR) makes it possible to investigate PA powders and to detect 1150 and 1920 cm^{-1} absorption regions, which are weakly shown when other methods are used.[137] In combination with Raman spectra, the PAIR method permits a fairly profound investigation of the structures of insoluble and infusible polymers in the form of both powders and films.[17,136-139]



In order to determine the molecular weight and the molecular weight distribution in PA and also in order to characterise quantitatively the cross-links and other features of the structure, it is necessary to hydrogenate or chlorinate the initial polymer. These methods make it possible to convert PA into soluble derivatives. The sodium- or potassium-doped PA is hydrogenated by hydrogen at pressures up to 100 atm.[180] The PA films obtained in the presence of the $Ti(OBu)_4-AlR_3$ catalyst are treated with a solution of potassium naphthalide in THF for 1 h and are then hydrogenated for 20 h at 170–260 °C under pressure of 30 atm. The resulting product with $M_n \cong 10^4$, soluble in tetralin, is polyethylene.[180,181] A residual absorption in the region of 965 cm^{-1}, corresponding to the deformation vibrations of the C–H group and the double bond, is observed in the IR spectra. The presence of a doublet in the regions of 720 and 730 cm^{-1}, corresponding to the vibrations of the CH_2 group, makes it possible to estimate the degree of crystallinity of the specimen, which is approximately 50%. It has been suggested that a linear product is formed in the synthesis of PA in the presence of a Ziegler–Natta catalytic system,[180,182] but the considerable scatter of the yields of the soluble hydrogenation products (from 5 to 80%) suggests the appearance of cross-links in the course of the segregation of the PA.[181]

The melting point of the soluble fraction of the polyethylene obtained is 118–122 °C, the molecular weights are $\overline{M}_w$ = 6000 to 7000 and $\overline{M}_n$ = 14 100–18 700, and the ratio of the number-average and weight-average molecular weights in different specimens varies from 2.4 to 3.14.[124,130,180] Although the form of the molecular weight distribution does not change on hydrogenation of PA in the temperature range 195–260 °C,[180] nevertheless this does not rule out the possibility of cross-linking in the course of the hydrogenation process and also of the degradation of the polymer chain.

According to data obtained by the radioisotope method, the molecular weight of PA varies from 2.2×10^4 to 7.7×10^4 when the temperature of the synthesis is changed from −7° to 25 °C.[34] Polyacetylene with an end group containing tritium or labelled carbon can be obtained by adding an excess of CH_3OT or carbon-labelled CO_2 to the reaction system after the synthesis.[34,183]

Soluble derivatives of PA can be best obtained by chlorinating freshly prepared specimens in suspension in chloroform or carbon tetrachloride at low temperatures.[79] The molecular weight of the chloroform-soluble fraction of the polymer synthesised in the presence of the $Ca(NO_3)_2-NaBH_4$ catalyst is 10^4.[79] Chlorination of the freshly prepared PA suspension at low temperatures makes it possible to reduce the contribution of the possible degradation processes. However, in this case the scatter of the yields of the soluble products is observed, which is a consequence of the occurrence of secondary cross-linking processes in the ageing of the polymer. The soluble fraction of the chlorinated PA diminishes appreciably after the *cis–trans* isomerisation.[74,134]

PA can be cross-linked via the Diels–Alder reaction,[27]

or as a result of the recombination of the radical centres formed in the *cis–trans* isomerisation:

The first process is indicated by a decrease in the amount of the soluble fraction of the chlorinated polymer during the ageing of PA. The probability of the second process increases in thermal or photochemical isomerisation.[79] On oxidation or reduction of the cross-linked polymers, there is a possibility of the formation of structures of the type of Hafner salts.[27,184] The possibility of cross-linking in the course of *cis–trans* isomerisation when unpaired spins appear has been confirmed by quantitative quantum-chemical calculations for a modified diatomic overlap.[74] Attempts have been made to find a correlation between the structural defects in *trans*-PA associated with the cross-links and the vibrational spectra.[38] The attempts to characterise PA in terms of the conjugation length have shown that specimens synthesised in different laboratories have different distributions even when the same method is used. According to Raman or IR spectroscopic data, the breakdown of conjugation is not associated with oxidation in the presence of cross-links.[185] It has been suggested that this is explained by conformational defects (for example, the twisting of the chains) or the inclusion of *cis*-units in the *trans*-chain of the polyene.[185] The appearance of cross-links diminishes the length of the conjugated sections and influences greatly the mechanical and electrophysical properties of PA.[134]

Another defect influencing the properties of PA arises on partial reduction of the double bond. NMR studies using PA enriched in the ^{13}C isotope made it possible to observe a weak signal in the region of 47 p.p.m., which was attributed to methylene groups; the concentration of the latter was 3–4 mole per cent.[15] The possibility of the reduction of double bonds is also indicated by the elemental composition of PA obtained in the presence of Ziegler–Natta catalysts ($CH_{1.03}$): according to different data, the H : C ratio varies in the range from 1.01 to 1.09.[186] The signal due to the CH_2 groups is particularly strong in the ^1H NMR spectra of chlorinated PA in the range 1.2–1.6 p.p.m. Partial reduction of PA can occur even during synthesis in the presence of both Ziegler–Natta catalysts and Group VIII metals. This has also been confirmed by the results of the ozonolysis of *cis*- and *trans*-PA. The final product of the hydrolysis of the *cis*- and *trans*-isomers is the ester $CH_3COO-COOCH_3$ formed in 98.55–99.52% yield, which confirms the linearity of the structure.[73] The presence of the hydrogenated $-CH_2-CH_2-$ units and also of cross-links leads to the formation, after treatment with diazomethane, of additional esters, $CH_3OOCCH_2COOCH_3$ and $CH_3.COOCH_2COOCH_3$, in yields of 0.1–0.5 and 0.23–1.04% respectively.[73] Bearing in mind the high reproducibility of the experimental results, one can assume that an increase in the number of cross-links by a factor of 2–4 occurs during polymerisation. The appearance of defects in the PA structure, including the formation of cross-links and the occurrence of sp^3-hybridisation is indicated also by X-ray diffraction data.[39,187]

The study of electron diffraction and X-ray diffraction analysis of thin oriented PA films have revealed the presence of an orthorhombic unit cell and orientation of the chain axis along the fibrils.[185,188] In the crystalline state, the *cis*- and *trans*-isomeric forms of the chain have different symmetries and repeat distances of 4.36 Å for four CH groups and 2.46 Å two CH groups respectively. It follows from the analysis of the intensity integrals for the powder X-ray diffraction patterns in the crystalline and amorphous regions that the degree of crystallinity of the films is 70–90%. The diffuse halo (at about 4.0 Å) is close to the strong interplanar reflections at 3.81 Å for the *cis*-structures and at 3.72 to 3.56 Å for the *trans*-structures. The disorder in the amorphous region is caused by the chain ends and the sp^3-hybridisation of the carbon atoms. It follows from X-ray diffraction data that the *trans*-cell contain 7% of the structure

of the disordered *cis*-cell and that in the film there are no isolated amorphous or crystalline regions, although a PA structure with single crystals incorporated in the polymer matrix has been proposed.[27]

Doping leads to the formation of new crystal structures inserted between the planes of the initial lattice, whose contribution depends on the diameter of the fibrils, the number of cross-links, the size of the dopant, etc. The inhomogeneity caused by the slow diffusion of the dopant in the fibril also influences the final crystal structure of PA. The distances between the inclusions of the dopant, which is believed to aggregate into packs along the same axis, is between 20 and 60 Å.[187] The interplanar spacings, which are 7.95 Å for I_3^-, 8.3 Å for ClO_4^-, and 9.3 Å for $FeCl_4^-$, can be interpreted as the distances between two dopant-enriched planes separated by PA chains.[187] The X-ray diffraction parameters for different types of PA obtained by the method described above (Table 3) differ somewhat; this is associated with the nature of the catalytic system used and with the method of preparation of the specimens for the investigations. The apparent size of the crystallites, determined from the width of the reflections for PA obtained in the presence of Ziegler catalysts, is 60 Å;[189] for the PA obtained in the presence of Group VIII metals, it reaches 100 Å and more.[178,179]

Table 3. The unit cell parameters of polyacetylene.

Catalyst	Unit cell parameters, Å			Crystal system	Refs.
	a	*b*	*c*

*According to electron diffraction data.
**Block-copolymers of the single crystal.
***Oriented films.

The morphology of PA has been mainly investigated using scanning electron microscopes, but more extensive information has been obtained on high-resolution transmission microscopes.[193] The formation of lamellar particles of irregular shape and with a thickness of 50–100 Å, which, by joining together, form loose fibril-like structures where the chain axes are perpendicular to the fibril axes, has been noted by Wegner and co-workers.[27,79,85,194] However, it was subsequently shown fairly convincingly by electron diffraction and scanning microscope methods that the chain axes in the films are parallel to the axes of the fibrils.[190,191] It is essential to note that the study of the morphology of PA by transmission or scanning electron microscopy makes it necessary to master a fine technique of the preparation of the specimens; the frequently observed "kebab" structures[188] or lamellar formations, thickened regions comprising knots of individual fibres and appearing on doping, as well as the "string of pearls" effect are usually associated with the metal deposition technique (Au : Pd).[195] The conditions leading to photographs in which the initial morphology is masked have been discussed. The size of the fibrils can be diminished by carrying out the polymerisation in the presence of various copolymers, which prevent their formation. The morphology of PA changes in the doping process and a new highly crystalline structure appears. The pattern in the distribution of iodine, used as the dopant, indicates the absence of the segregation of particles.[196]

- - - o0o - - -

The dependence of the PA structure on the composition and concentration of the catalyst, the reaction temperature, and the nature of the monomer gives rise to the hope that the possibilities for the synthesis of polymers of this class are still far from being exhausted. Further development of the synthesis of polymers of the acetylene series will depend on the practical requirements which they will have to meet in the creation of specific instruments or devices

Modern Methods of Synthesis of Modified Glycerophospholipids

O.V.Bogomolov, A.P.Kaplun, and V.I.Shvets

The advances in the synthesis of modified glycerophospholipids of different structure are surveyed. An attempt has been made at a general classification of these compounds. Questions concerning the problem of whether or not various methods of synthesis can be used on a preparative scale are examined.
The bibliography includes 233 references.

CONTENTS

I. Introduction 382
II. Classification and strategy in the synthesis of modified glycerophospholipids 382
III. Modified aliphatic acids 383
IV. General procedures in the synthesis of modified glycerophospholipids 385

I. INTRODUCTION

The vigorous development of bio-organic chemistry during the last decade has led to the creation of preparative methods of synthesis of virtually all principal classes of substances found in living organisms, including glycerophospholipids (PL).[1] However, the tasks faced by investigators have increasingly required the use of modified PL. The applications of modified PL are extensive. They serve as instruments for research into (a) the metabolism of individual representatives of PL,[2] (b) the molecular organisation of submolecular structures whose composition includes PL (membranes, blood plasma lipoproteins, etc.) and the processes incurring in them,[3-15] and (c) enzymes associated with the metabolism of PL;[16-25] furthermore, certain representatives of modified PL are of interest as potential therapeutic agents,[26-31] while a number of PL analogues, which can be immobilised on solid carriers, are of interest as ligands in affinity chromatography for the isolation of various proteins exhibiting an affinity for PL.[32-39]

In principle, traditional methods of synthesis of PL can be used to obtain modified PL,[1] but in most cases special procedures are required, taking into account the specific features of both the label and of the methods used in their subsequent application. The fact that the majority of the labels are relatively difficult to obtain is also reflected in the strategy of the synthesis. It is believed to be preferable to introduce the label in the last stages of the synthesis, which reduces the possibility of the modification of the label (which is as a rule labile) during synthesis and permits an economical utilisation of the labelled intermediates.

II. CLASSIFICATION AND STRATEGY IN THE SYNTHESIS OF MODIFIED GLYCEROPHOSPHOLIPIDS

As the term PL embraces a large group of compounds with extremely varied structures, it is essential to deal with the classification of such PL before considering the methods of their synthesis. PL can be classified in terms of various features: in terms of the aims of the modification (and hence the way in which they are subsequently used), in terms of the site of the modification, and in terms of the type of modification (the type of label).

In terms of the aims of the modification, it is possible to distinguish two types of modified PL: labelled PL (as a rule PL having the natural structure and containing the label or reporter group; they are normally employed as lipid-specific probes or labels closely imitating the corresponding lipids in terms of their properties) and structural analogues of PL (PL in which the structure of the hydrophobic or polar component of the molecule and/or the type of the chemical bond between them has been modified in order to impart to them properties different from those of the natural PL).

Labelled PL can be subdivided further in terms of the type of label into radioisotope-labelled, spin-labelled (those whose composition includes stable nitroxy-radicals), fluorescence-labelled, and photoreactively labelled PL (containing photoreactive groups), PL with NMR-labels (detected with the aid of NMR), and PL with electronically dense labels.

In terms of the site of the modification, all the modified PL can be divided into two classes: (1) derivatives of lipids having the natural structure (this class includes the majority of the labelled PL) and (2) PL with an altered "skeleton". The former are subdivided in their turn into PL modified in the hydrophobic or polar components (Fig.1) and the latter into derivatives of 2-glycerophosphate,[25, 40-42] PL modified in the glycerol residue,[16,20,21,43-54] and PL modified in the phosphoester group.[55-71]

In the general case, the synthesis of modified PL reduces to the synthesis of the initial compounds and their interaction (key stage). The starting materials for the synthesis of the modified PL can be subdivided into two types: structures carrying the label (or the modified fragment), i.e. modifying compounds, and "skeletal" structures which determine the type of the required PL and the site of the label in its molecule.

As regards strategy, the methods of synthesis of modified PL can be arbitrarily divided into synthetic (the assembly of the PL molecule from elementary components: glycerol, aliphatic acids, etc.), semisynthetic (modification of natural PL with the aid of chemical and enzymic reactions), and biological. The semisynthetic methods are the most effective and for this reason they have been used recently with increasing frequency for the modification of PL. However, in a number of instances, for example, in the synthesis of PL modified in the glycerol residue[16,20,21,43-54] and in the phosphoester group[16, 22-24,44,55-72] or isomeric PL,[16,25,40-42,44] total chemical synthesis is essential. The biological methods are more rarely used preparatively[73] and we shall therefore confine ourselves to the consideration of the first two most often used methods for the modification of PL.

To facilitate the use of the present review and to reduce its size, we propose the following procedure for indexing the references. A four-digit number indicating the structure and method of synthesis of the modified PL (see Table 1 and the list of literature references) is assigned to each reference to the synthesis of modified PL (in the list of literature references, it is written at the end of the reference in angular brackets). The first digit indicates the class of the PL, the

second the type of modification (vertical columns in Table 1 with numbers ranging from 0 to 9), and the third the site of the modification (in conformity with Fig.1). We introduce the fourth digit in order to reflect as far as possible the position of the key stage (usually the reaction involving the introduction of the modifying fragment) in the synthesis of the modified PL (Fig.2).

For example, the designation <2044> corresponds to the synthesis of phosphatidylethanolamine (PE) fluorescence-labelled in the polar component, the key stage in the synthesis of which involves a reaction in the polar head (evidently *N*-alkylation or *N*-acylation). Thus it is possible to find readily from Table 1 the reference to a given feature and the list of literature references contains coded information about the contents of a particular communication.

III. MODIFIED ALIPHATIC ACIDS

One of the main types of initial compounds carrying a modified fragment (or label) are modified (labelled) aliphatic acids (ALA). In the synthesis of modified PL, fluorescence-labelled, spin-labelled, and photoreactively labelled ALA (Table 2), as well as isotope-labelled ALA are most widely used.

One of the general and widely employed methods for the introduction of isotope labels (^2H, ^3H) into the hydrocarbon chain of the ALA involves the hydrogenation of unsaturated acids in a $^2H_2$ or $^3H_2$ atmosphere. It is then possible to obtain both saturated ALA [145-147] and fully *cis*-monoene or *cis*-polyene ALA from the corresponding acetylenic acids by hydrogenating the latter in the presence of the Lindlar catalyst.[134-145]

The ^1H atoms can be substituted by the radioactive isotope ^3H also by heterogeneous catalytic isotope exchange with gaseous tritium[148,149] or by the method involving thermal activation of tritium.[132] Randomly tritium-labelled ALA are then obtained. In the case of deuterium, the employment of the heterogeneous catalytic isotope exchange method makes it possible to obtain perdeuteriated ALA with an isotopic purity in excess of 99%.[150,151]

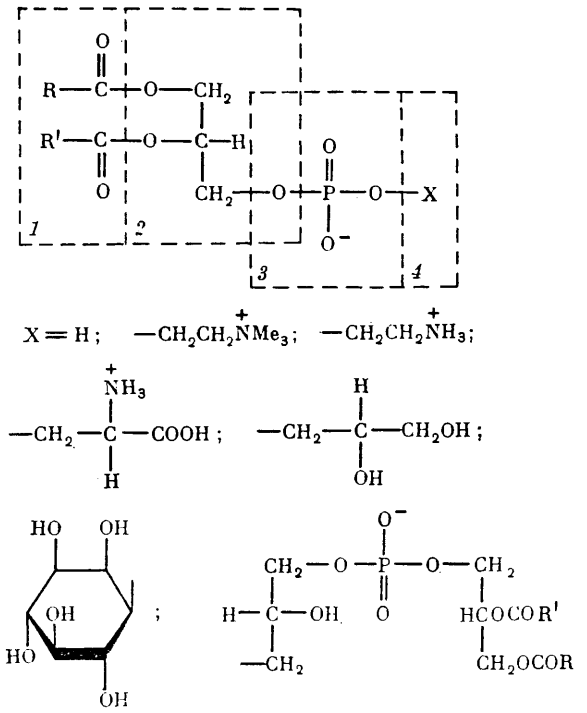

Figure 1. The possible sites of the modification of PL: 1) hydrophobic component (acyl residues); 2) glycerol residue; 3) phosphodiester/phosphomonoester group; 4) polar component.

Apart from the methods listed above, there exist also various procedures which make it possible to introduce the ^{13}C, ^{14}C, ^2H, or ^3H labels at the end,[143,145,152,153] beginning,[154] or middle of the

Table 1. Notation for the references to the synthesis of the modified PL and ALA.

hydrocarbon chain of the ALA [144,153,155] and also to obtain ALA labelled at the carbonyl carbon atom.[142,145,156,157]

Apart from isotope labels, certain heteroatoms, for example ^{19}F, whose chemical shift is sensitive to differences between the outer and inner surfaces of vesicles, can be introduced as NMR-labels.[158-160]

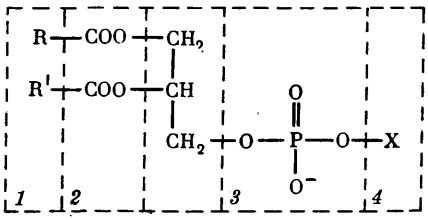

Figure 2. The types of key reactions in the synthesis of modified PL as a function of their location: 1) reactions in the hydrocarbon chains of the acyl residues of the PL; 2) formation of ester (thioester, amide, or others) bonds; 3) phosphorylation and reactions of phosphorus(III) derivatives; 4) reactions in the polar head of the PL.

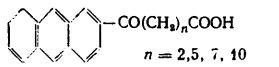
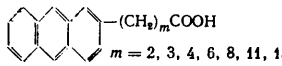
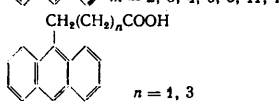
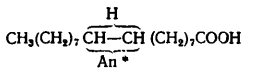
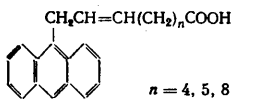
Table 2. Labelled carboxylic acids most promising for the synthesis of modified PL.

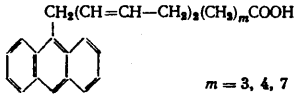


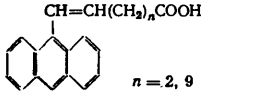


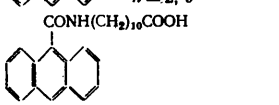


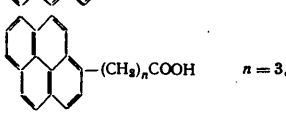












Name	Formula	Refs.
	Fluorescence-labelled	
α-Parinaric		[74–79]

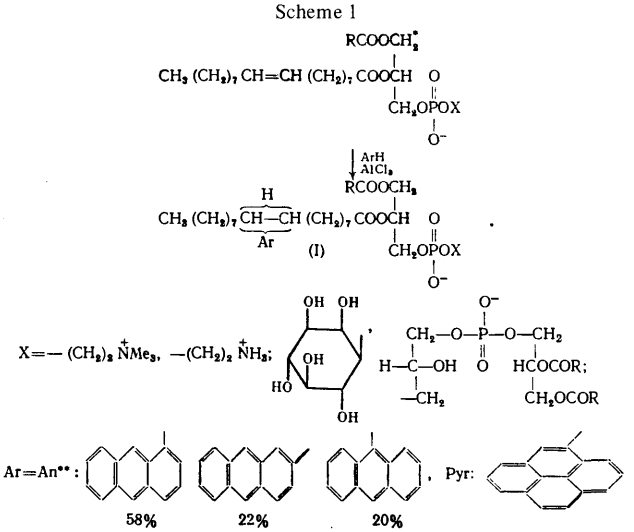
*The significance of the symbol An is indicated in Scheme 1.
**m and n are inter-related.

In order to obtain probes for the investigation of the outer structure of biological membranes by electron microscopy, an organotin analogue of ALA, namely 12,12-dimethyl-12-stannahexadecanoic acid, has been synthesised[161] and introduced into the composition of phosphatidylcholine (PC).

Since 1980, a series of syntheses of photopolymerisable ALA, containing the methacryloyloxy-group[162] or conjugated diacetylene or diene groups,[163-165] have been synthesised. Membranes made up of photopolymerised PL exhibit the properties of both the usual phospholipid double layers and certain properties (for example, resistance to the action of detergents) more characteristic of polymer membranes;[166,167] in 1985, the synthesis of PC incorporating ALA containing the thiol group at the end or beginning of the hydrocarbonchain was reported.[168,169] The liposomes consisting of such PL are capable of reversible polymerisation and depolymerisation via the thiol—disulphide oxidation-reduction cycle.

IV. GENERAL PROCEDURES IN THE SYNTHESIS OF MODIFIED GLYCEROPHOSPHOLIPIDS

The synthesis of modified PL can be conveniently considered in most cases in accordance with the site of the modification of the PL, which makes it possible to differentiate the general methods of synthesis regardless of the type of modification.



1. Synthesis of Glycerophospholipids Modified in the Hydrophobic Component

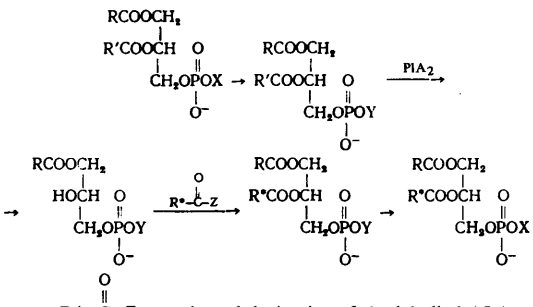
The most general feature influencing the properties of modified PL is the location of the label (modified fragment)—the hydrophobic or polar part of the molecule. Since the polar part of the molecule as a rule determines the majority of the physicochemical properties of the PL, its modification can alter significantly the behaviour of the PL molecule. For example, acylation of PE or phosphatidylserine (PS) at the amino-group[131,170-181] alters the charge and size of the polar head of the lipid molecule. Therefore, in the synthesis of labelled PL which should possess properties close to those of the corresponding natural PL, it is more desirable to modify the aliphatic acid part of the PL molecule; this is particularly justified in view of the fact that this region is relatively large and introduction of the label in this way therefore has less effect on the behaviour of the PL molecule.

(a) Addition to the C=C Bonds of the Acyl Residues in Glycerophospholipids

The introduction of the label at the double bonds of the acyl residues of the PL is the simplest method of obtaining PL modified in the hydrophobic component. The interaction of natural PL with polynuclear aromatic hydrocarbons (anthracene or pyrene) under the conditions of the Friedel—Crafts reaction yields in a single stage PL fluorescence-labelled in the hydrophobic component[85,87,88] (Scheme 1). The label in the PL (I) is then located mainly in the 2-position in the glycerol residue of the molecule (in conformity with the distribution of unsaturated ALA in natural PL).[87,88]

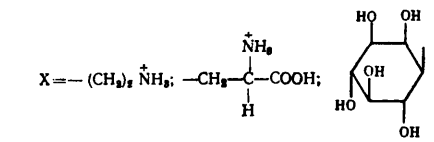
Scheme 1

*Oleic acid is indicated in the 2-position of the glycerol residue, since it represents more than 50% of the unsaturated acids contained in the majority of natural PL.[182]
**The ratio of the anthracene isomers was determined by ^{1}H NMR.[86]



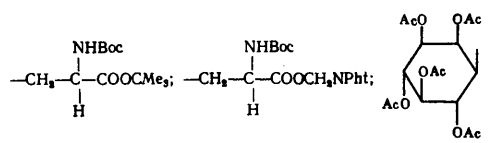
An undoubted advantage of this method is its universality: aromatic fluorophores can be introduced into the majority of natural PL.

Addition to the double bonds of the acyl residues of PL is also used to introduce isotope labels (^2H, ^3H) and certain heteroatomic labels (Br) into PL.[147,183]



(b) Acylation of Glycerophosphates and Lysophospholipids

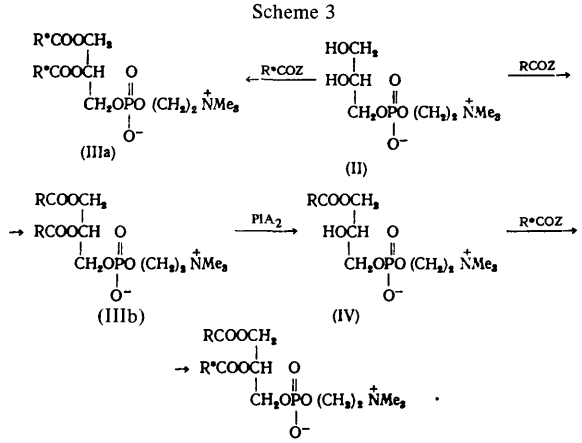
The commonest version of the semisynthetic method involves the introduction of a labelled ALA into lyso-PL, which is obtained by the enzymic hydrolysis of the PL using phospholipase A_2(Pl A_2) [74-79,81,90,92-95,99,101,102] (Scheme 2):



Scheme 2

R*-C-Z = activated derivative of the labelled ALA

Y = — $(CH_2)_2$NHNPS; —$(CH_2)_2$NHBoc; —$(CH_2)_2$NPht;

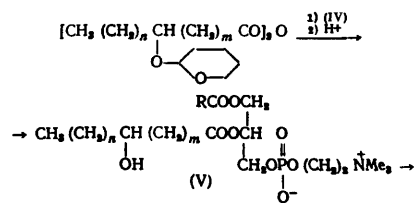


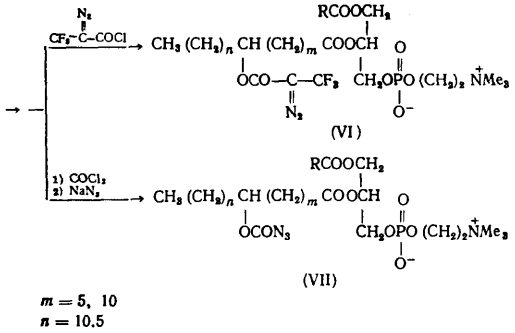
NPS = *o*-nitrobenzenesulphenyl; Boc = t-butoxycarbonyl; Pht = phthaloyl

For all the PL, except PC, it is then as a rule necessary to carry out a preliminary blocking of the functional groups in the polar component of the PL and their deblocking after the acylation of the lyso-PL (Scheme 2). The amino-groups of PE and PS are blocked by *o*-nitrobenzenesulphenyl, t-butoxycarbonyl, and phthaloyl protecting groups,[1,115,116,118,119] the carboxy-group of the PS is blocked by t-butyl and phthalimidomethyl groups,[1] the hydroxy-groups of myoinositol are protected by acetylation,[1,77,99,120] while the hydroxy-group of the glycerol residue of diphosphatidylglycerol (DPG) is not as a rule blocked[123,184] because of its insignificant reactivity.

The labelled PL obtained by this method consist of a mixture of molecular types differing in the acids in the 1-position in the glycerol residue. A procedure consisting in the alkaline hydrolysis of PC and the subsequent acylation of the ALA-labelled glycerophosphocholine (II) is used for the synthesis of the individual substances[79,80,96,135,140,158,162] (Scheme 3):

Scheme 3



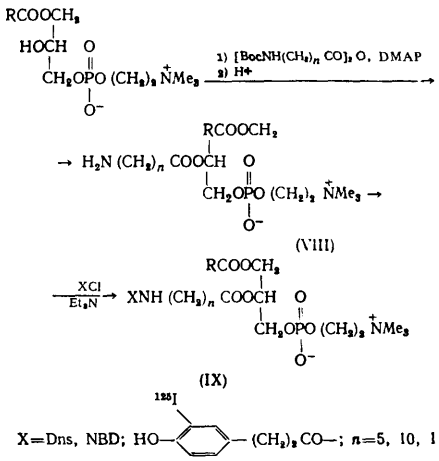


In order to obtain heteroacid PL, glycerophosphocholine (II) is acylated initially with the natural ALA, after which compound (IIIb) is hydrolysed by Pl A_2 and the lyso-PC (IV) is acylated with the labelled ALA [18,99,135,142,144,162] (Scheme 3), the reverse acylation sequence leading to PC with the label in the first acyl residue.[79,80,140,158,162]

Lyso-PL (IV) and the glycerophosphates (II) are acylated by traditional methods in the chemistry of PL.[1] The acylating agents employed are the chlorides of the modified acids[77,92,93,95,96,99,133] and also the more effective (especially in the case of ALA which are difficult to obtain and labile labelled ALA) anhydrides of the ALA in the presence of readily dissociating alkali metal salts of the ALA,[74,102,115,119,158,185] alkali metal oxides,[113,114,123,161,186,188] 4-*NN*-dimethylaminopyridine (DMAP),[79,90,99,110,111,132,135,137,140,142,144,162,189,190] or 4-pyrrolidinopyridine;[106] also used are ALA in the presence of dicyclohexylcarbodiimide (DCC) and DMAP [94,101,138,139,168] or trifluoroacetic anhydride and pyridine,[191] as well as ALA imidazolides.[80,81,93,104,105,116-118,120-122,125,127,129,136]

In many cases (especially when labile labels are used), it is useful to obtain initially the PL containing in one of the acyl residues (and sometimes in both) an active functional group (usually the hydroxy- or amino-group)[103,104,106,107,140,189] with the subsequent introduction of the label into the resulting PL molecule. Thus the photoreactively labelled PC (VI) and (VII) have been obtained by acylating the hydroxylated PC (V) with 2-diazo-3,3,3-trifluoropropionyl chloride or chloroformylated phosgene with subsequent replacement of the chlorine atom by the azido-group[140] (Scheme 4):

Scheme 4



(VI)

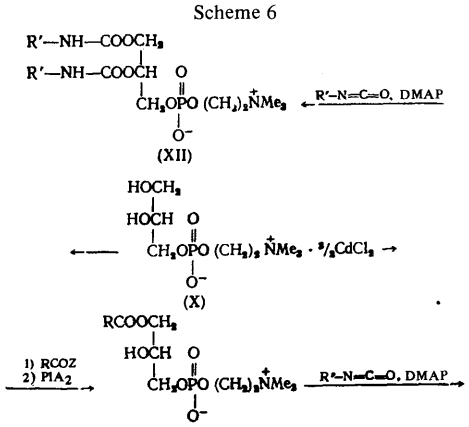
(VII)

$m = 5, 10$
$n = 10.5$

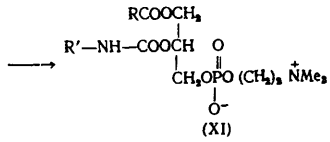
Fluorescence-labelled PC [103,104,106,107] as well a a PC analogue containing the ^{125}I isotope (IX) [189] have been obtained by acylating (or alkylating) the amino-groups in the ω-aminoacyl residues of PC (VIII) (Scheme 5):

Scheme 5

(VIII)



(IX)

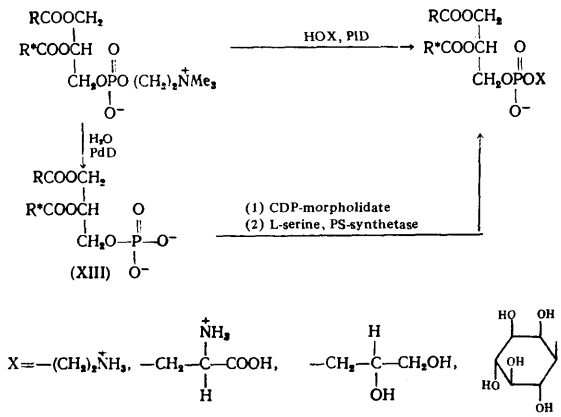


X=Dns, NBD; HO—C$_6$H$_4$—(CH$_2$)$_2$CO—; n=5, 10, 11;

Dns = 5-dimethylaminonaphthalene-1-sulphonyl (dansyl);
NBD = 7-nitrobenzo-2-oxa-1,3-diazol-4-yl

The interaction of lyso-PC (IV) or the cadmium complex of glycerophosphocholine (X) with alkyl isocyanates results in the formation of PC analogues non-hydrolysable by phospholipase A_2, in which the ester group at the C(2) atom of the glycerol residue [as in compound (XI)] or both ester groups, at C(1) and C(2) [as in compound (XII)], have been substituted by the carbamoyloxy-group[192] (Scheme 6):

Scheme 6



(XI)

(c) Transphosphatidylation of PC by phospholipase D

In connection with the discovery of the reaction involving the transfer of the phosphatidyl residue from one alcohol component to another, catalysed by phospholipase D, the possibilities in the synthesis of modified PL have expanded greatly. Thus conditions have been found in which phospholipase D effects the exchange of the choline group in PC for ethanolamine,[20,63,78,99,129,137,188,189,193] glycerol,[7,99,188,194] serine,[99,189] and myoinositol.[195,196] This makes it possible to unify the scheme for the preparation of modified PL: the synthesis of the labelled PC and its transphosphatidylation by phospholipase D in the presence of ethanolamine, serine, glycerol, and myoinositol or hydrolysis with formation of phosphatidic acid (PA) (Scheme 7):

Scheme 7

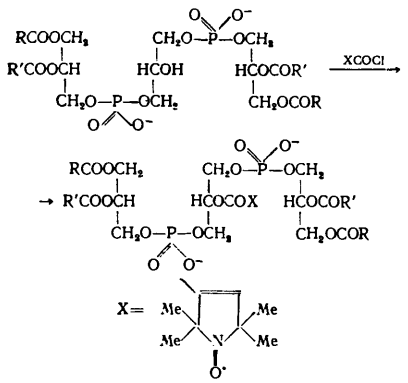
CDP = cytidine diphosphate

Fluorescene-labelled PE, PS, phosphatidylglycerol (PG), phosphatidylinositol (PI), and PA,[7,99,193,195,196] spin-labelled PE, PS, PG, PI, and PA,[129,186,188] photoreactively labelled PE and PG,[137,194] and also radioactive analogues of PE, PS, and PA labelled with ^{125}I [189] have been obtained by this method.

Another version of enzymic synthesis has been used to obtain PS spin-labelled in the hydrophobic component[187] or radioisotope-labelled in the polar component:[197] the conversion of PA (XIII) into CDP-diglyceride followed by its interaction with L-serine in the presence of PS-synthetase (Scheme 7).

2. The Synthesis of Glycerophospholipids Modified in the Polar Head Groups

The presence in the polar components of many PL of active functional groups (hydroxy- or amino-groups) has led to a convenient and relatively simple way of modifying them.[131,170-181,198-204] However, at the same time taditional synthetic methods have continued to be used for the preparation of PL modified in the polar component.[1,28,31,58,59,94,205-223]

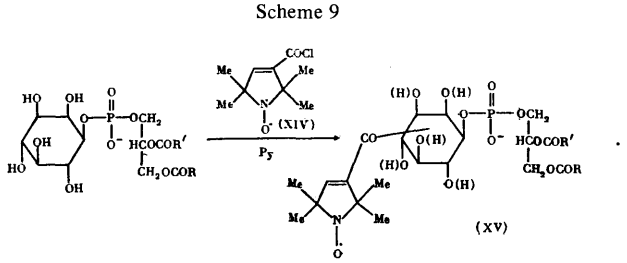


The modification of PL in the polar head groups is used to obtain not only membrane probes[131,170-178,180,198-213] but in recent years has been employed with increasing frequency for the synthesis of various lipophilic physiologically active substances, for example, antioxidants

(phosphatidylhydroquinones),[58,59] the antiviral preparation acyclovir,[31] immunologically active PL analogues containing various haptens in the polar component,[179,181,220,221] nucleotido-PL with antitumour activity,[28-30] etc.

(a) Acylation of the Hydroxy-groups in the Polar Head of the PL

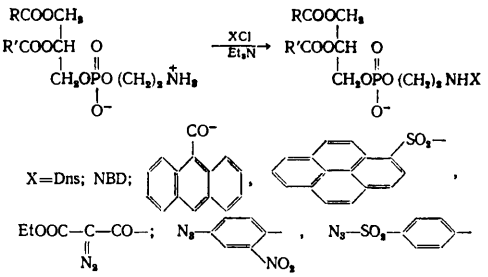
Only a few examples of the direct introduction of the label into the polar component of DPG and PI are known. In the former case,[198] the natural DPG was acylated with the chloride of 2,2,5,5-tetramethyl-*N*-oxypyrroline-3-carboxylic acid in the presence of pyridine (Scheme 8):



Scheme 8

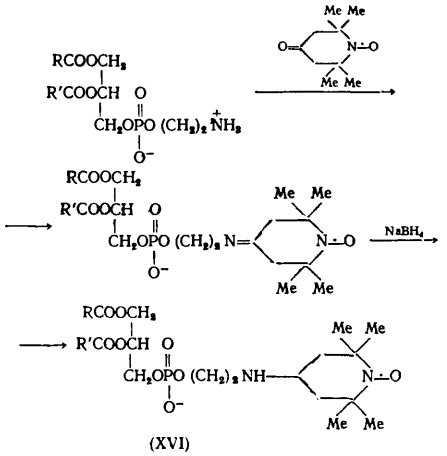
However, it is known that the hydroxy-group of DPG is difficult to acylate under these conditions[123] and the attainment of high yields in the acylation reaction is therefore unlikely in the given instance. The synthesis of photoreactive analogues of DPG containing the 4-azido-2-nitrophenyl group in the polar component of the molecule has also been reported.[203]

The acylation of PI with an equimolar amount of the acid chloride (XIV) yielded compound (XV) with an indefinite position of the label in the cyclitol ring[175] (Scheme 9):



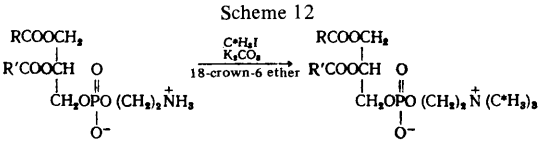
Scheme 9

(b) N-Acylation and N-Alkylation of PE and PS



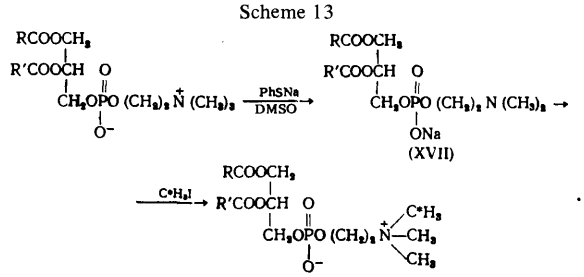
The reactions involving the acylation and alkylation of the amino-groups are used very often for the direct introduction of the label into the polar component of PE or PS. *N*-Dns-PE,[170-173] *N*-NBD-PE,[200] *N*-(9-anthroyl)-PE,[174] *N*-(1-pyrenesulphonyl)-PE,[177] *N*-(ethyl-2-diazomalonyl)-PE,[131,178] *N*-(azido-2-nitrophenyl)-PE,[131] and *N*-(4-sulphonylazidophenyl)-PE [202] (Scheme 10), as well as *N*-Dns-PS,[173] *N*-NBD-PS,[18] and *N*-biotinyl-PE and *N*-biotinyl-PS [176] have been obtained by this method:

Scheme 10



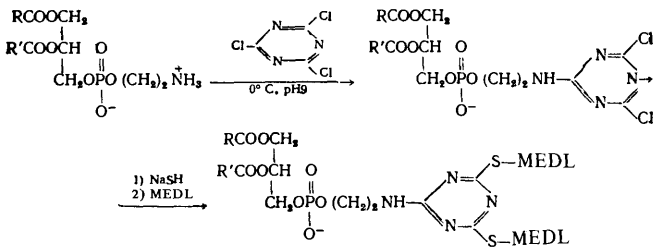
The method involving the reductive alkylation of the amino-group in PE has also been used to obtain the paramagnetic analogue (XVI) of PE [199] (Scheme 11):

Scheme 11



One of the methods of synthesis of PC, isotopically-labelled in the choline group, consists in the *N*-methylation of PE with labelled methyl iodide in the presence of crown-ether and anhydrous potassium carbonate[224] (Scheme 12):

Scheme 12

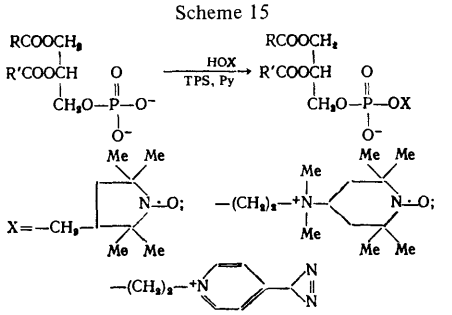


Partial demethylation of PC in the presence of sodium thiophenoxide in dimethyl sulphoxide (DMSO) followed by the methylation of the dimethylamino-derivatives (XVII) with labelled methyl iodide likewise leads to isotope-labelled PC [225-228] (Scheme 13):

Scheme 13

One of the few examples of the synthesis of PL with an electronically dense label is based on the arylation of PE with cyanuric chloride and subsequent replacement of the Cl atoms by SH groups and the reaction with MEDL† [204] (Scheme 14):

Scheme 14

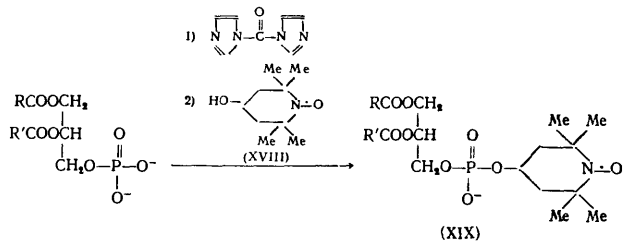


(c) Phosphorylation

PL modified in the polar component are frequently obtained using classical methods for the phosphorylation of glycerol derivatives (1,2-diglycerides, 1,2-*O*-isopropylidene-*sn*-glycerol, or halogenohydrins of 1,2-diglycerides): the phosphorochlorinate method, the silver salt method, and the interaction of phosphomonoester derivatives (usually PA) with the alcohol components in the presence of various activating agents.[28,31,205-223]

Thus, PC, PE, *N*-methyl-PE, and *NN*-dimethyl-PE analogues with different distances between the P and N atoms have been obtained by the phosphorochloridate method;[217-219] the silver salt method has been used to obtain a fluorescent analogue of PC containing the 2-[3,6-bis(dimethylamino)-10-acridino]ethyl group,[213] two immunoactive analogues of PL containing 3β-cholesterol and 3β-hydroxynorpregnen-5-ene,[220,221] several isotope-labelled PL,[211] and a series of PE analogues with different distances between P and N atoms.[214,215]

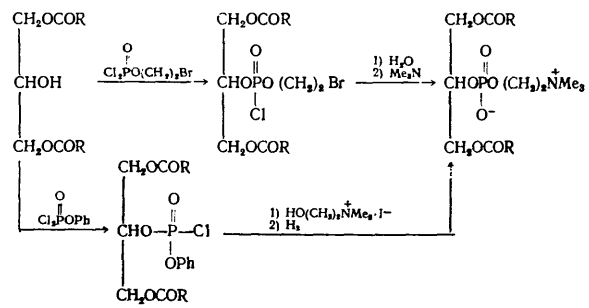
In the method using activating agents, the phosphomonoester component is usually activated with 2,4,6-triisopropylbenzenesulphonyl chloride (TPS).[109,142,205-210] The free-radical analogues of PA [205,207] and PC,[208] the photoreactive analogue of PC [142] (Scheme 15), and a series of isotope-labelled PC [209] and PS [210] have been obtained by this method:



Scheme 15

†MEDL is the electron-dense mercarbide label (organomercury compound having not less than four C—Hg—X groups, where X is an acid anion).[204]

In the interaction of PA with secondary alcohols, this method proved to be relatively unsuitable owing to the low reactivity of these compounds under phosphorylation conditions, which in fact accounts for the difficulty of obtaining the nitroxy-derivative of PA of type (XIX).[205] In order to increase the efficiency of the phosphorylation of secondary alcohols, in particular of the alcohol (XVIII) with an iminoxy-group, use was made of the highly reactive PA imidazolides obtained without isolation by treating the reaction mixtures with carbonyl bisimidazole[206] (Scheme 16):



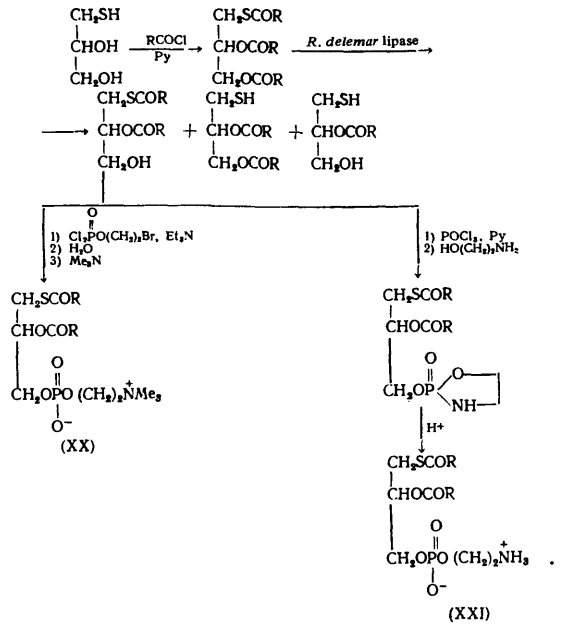
Scheme 16

3. Synthesis of Isomeric PL—Derivatives of 2-Glycerophosphate

A general method of synthesis of structural isomers of PL involves the phosphorylation of 1,3-diacylglycerols[40] by the phosphorylating agents used in the synthesis of PL having the natural structure[41,42] (Scheme 17)

Scheme 17

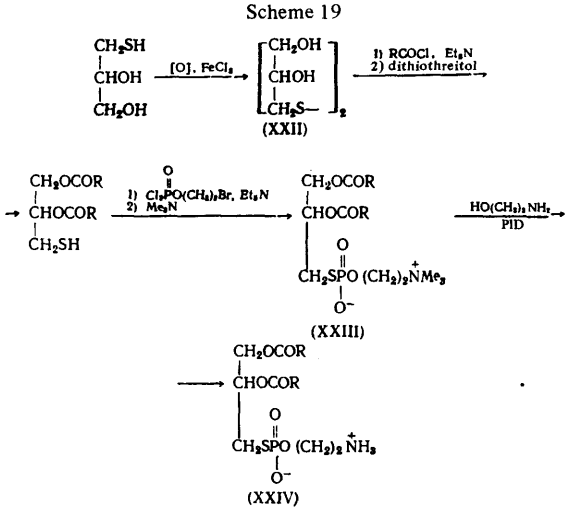
Isomeric PC and PE have been obtained in this way,[40-42] but the yields are as a rule lower in this instance than in the phosphorylation of the primary hydroxy-group.[40]



Isomeric PL are analogues of substrates of phospholipases which are hydrolysed much more slowly than the natural PL.[16]

4. Synthesis of PL Modified in the Glycerol Residue

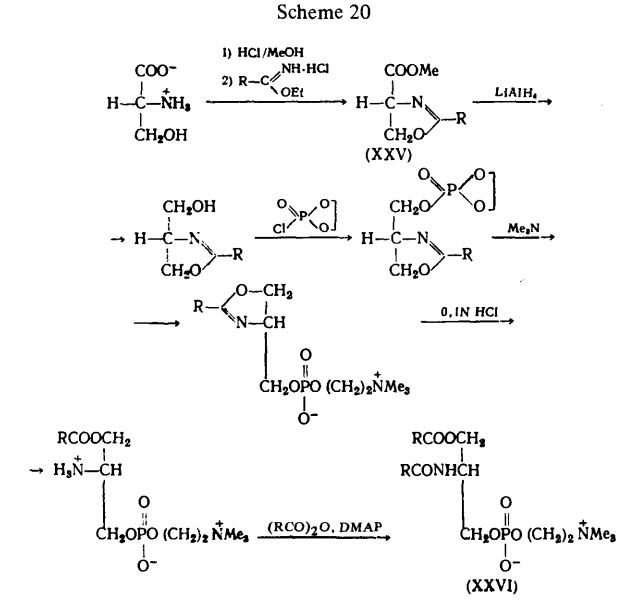
PL analogues in which the ester linkage in one of the positions in the glycerol residue of the molecule has been replaced by the thioester linkage[21] or a phosphoester linkage has been replaced by a thiophosphoester linkage[20-43] are convenient substrates for spectrophotometric studies on phospholipases.



The thioester analogues of PC [compound (XX)] and PE [compound (XXI)] [21] have been obtained from 1-mercapto-*rac*-glycerol[229] by classical methods for the synthesis of PL [230] (Scheme 18):

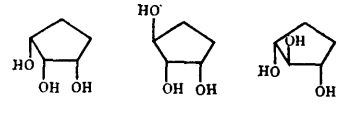
Scheme 18

In the synthesis of the thio-PL (XXIII) and (XXIV), the temporary protection of the mercapto-group in the acylation of mercaptoglycerol was achieved by oxidising it in air in the presence of iron(III) chloride to the disulphide (XXII) and its subsequent reduction with dithiothreitol[20] (Scheme 19):



Scheme 19

In the ^{31}P NMR spectra, the chemical shifts of the ^{31}P nuclei in the thio-PL (XXIII) and (XXIV) and in the PL having the natural structure differ by 19 p.p.m.,[43] which makes it possible to observe separately, with the aid of the selective saturation method, the signals of the thio-PL forming part of the composition of liposomal membranes.

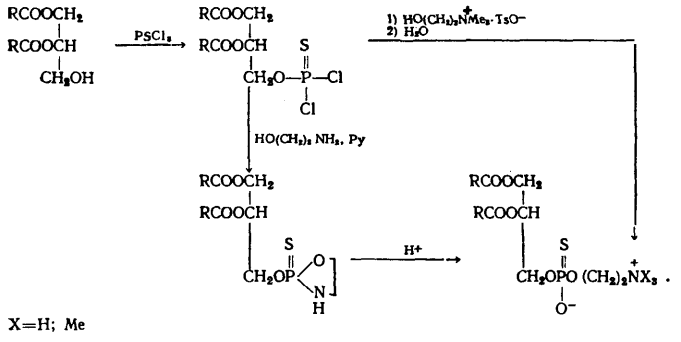


PC analogues non-hydrolysable by phospholipase A_2 have been obtained by replacing the ester linkage in the 2-position in the glycerol residue of PC by the amide linkage. The first synthesis of the acylamide analogue of PC, carried out starting with L-serine,[16,44] led to a racemic compound. Later methods based on the use of D-serine[46] or L-serine[47] were developed and made it possible to obtain the optically active compound. In both cases the key stage of the synthesis is the formation of the oxazoline (XXV) which which makes it possible to reduce the ester group to the hydroxy-group and blocks the amino- and hydroxy-groups in the stages involving the phosphorylation and subsequent alkylation of trimethylamine by the phosphate obtained[46,47] (Scheme 20):

Scheme 20

The amido-PC (XXVI) is a specific inhibitor of phospholipase A_2, exhibiting an even greater affinity for the enzyme than the natural substrate.[46]

PL analogues in which the glycerol residue has been replaced by another triol residue—an alkanetriol (1,2,4-butanetriol[44] or 1,2,5-pentanetriol[48]) or one of the three diastereoisomeric cyclopentane-1,2,3-triols (XXVII)–(XXIX)[49-54]—have been synthesised by traditional methods:

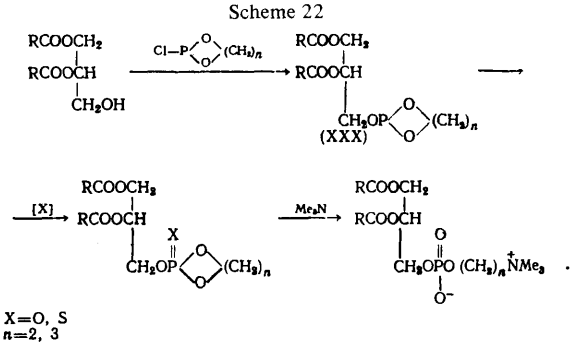


(XXVII) (XXVIII) (XXIX)

5. Synthesis of PL Modified in the Phosphoester Group

The thiono-analogues of PL containing the thiophosphoryl group instead of the phosphoryl group are convenient objects for the study of the behaviour of individual classes of PL in membranes by ^{31}P NMR, since the chemical shifts of the ^{31}P nuclei in thiono-PL and PL having the natural structure differ by 57 p.p.m.,[15,231] which makes it possible to differentiate the thiono-PL using ^{31}P NMR even when these substances are part of the composition of liposomal and biological membranes where the difference in chemical shift reaches 50 p.p.m.[231]

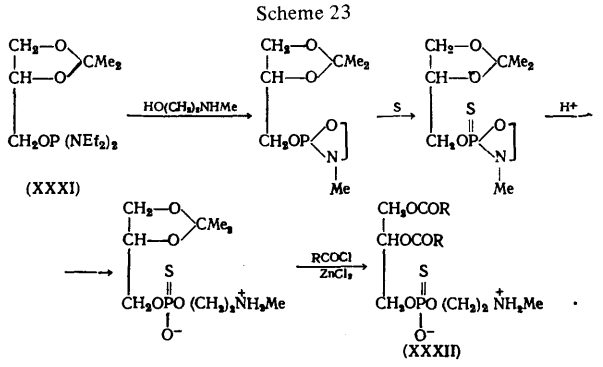
One of the methods for the introduction of the phosphorothioate group into the PL molecule involves the phosphorylation of 1,2-diacyl-*sn*(or *rac*)-glycerol with thiophosphoryl trichloride[62,63] (Scheme 21):



Scheme 21

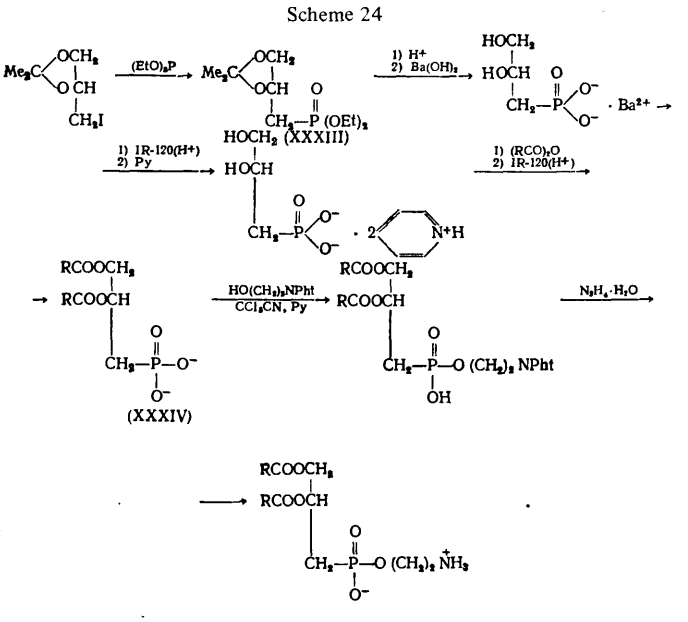
X=H; Me

Another convenient method of synthesis of thiono-analogues of PC as well as PC analogues with different distances between the P and N atoms involves the oxidation (or sulphurisation) of alkylene phosphites derived from glycerol (XXX) and the subsequent interaction of the cyclic phosphates or phosphonothioates with triethylamine[55,61,232] (Scheme 22):



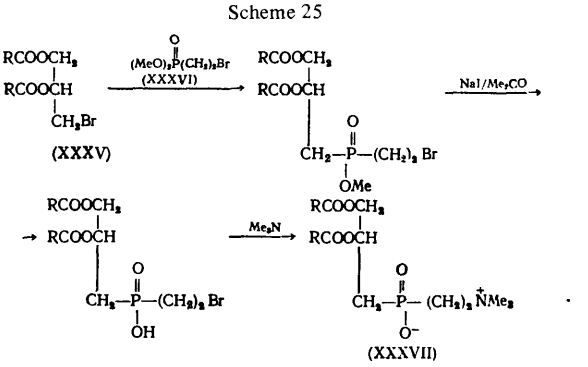
Scheme 22

X=O, S
n=2, 3



N-Methylthio-PE (XXXII) [60] (Scheme 23), thio-PA,[56,57] and also thiono-analogues of phosphatidylhydroquinones[58,59] have been obtained using various phosphoramidites derived from 1,2-*O*-isopropylidene-*rac*-glycerol (XXXI):

Scheme 23

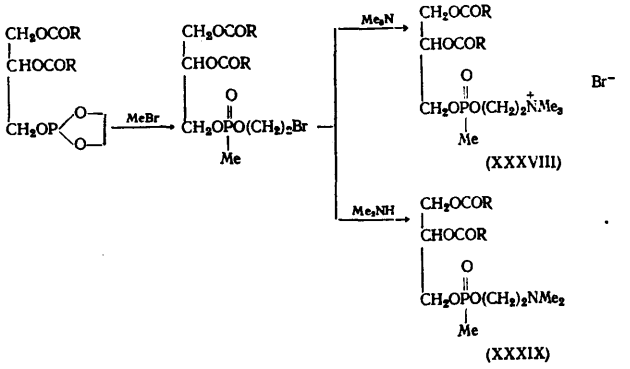


The reaction of the halides of 1,2-disubstituted glycerols with phosphorous acid triesters (Arbuzov alkylation) has been used to synthesise PL analogues in which the polyol is linked to the phosphorus atom by a C–P bond[64,65,67-69] (Scheme 24). The hydrolysis of the resulting diester by the substituted dihydroxypropylphosphonic acid (XXXIII) and subsequent acylation lead to the phosphonic analogue of PA (XXXIV), which can be readily converted into the analogues of other PL [66,67] (Scheme 24):

Scheme 24

The PC analogue (XXXVIII), in which the phosphodiester group has been replaced by the C–P–C linkages (the phosphine analogue of PC), has been obtained by the Arbuzov reaction between the bromohydrin of 1,2-dipalmitoyl-*sn*-glycerol (XXXV) and dimethyl 2-bromoethylphosphonate (XXXVI) with subsequent elimination of the methyl group and quaternisation by reaction with triethylamine[70]‡ (Scheme 25):

Scheme 25



Analogues of PC (XXXVIII) and *NN*-dimethyl-PE (XXXIX), which are neutral esters of methylphosphonic acid, have been obtained by the analogous reaction of ethylene phosphites derived

‡See also Rosenthal.[67]

from 1,2-disubstituted glycerols with methyl bromide[71] (Scheme 26):

Scheme 26

The phosphonic and phosphinic analogues of PL are used as inhibitors of various phospholipases.[16,44]

Thus the modern methods of synthesis of modified PL considered in the review§ make it possible to obtain substances with virtually any structure, necessary both for the study of the structures and functioning of model and biological membranes and for the solution of the ever expanding range of other problems in molecular biology and biochemistry.

Application of Quantum-chemical Methods to the Diels-Alder Reaction

S.S.Babichev, V.A.Kovtunenko, Z.V.Voitenko, and A.K.Tyltin

The quantum-chemical reactivity indices, used to estimate the relative reactivities of dienes and dienophiles in the Diels-Alder reaction, are analysed and certain problems associated with the use of quantum-chemical methods for the interpretation of cycloaddition selectivity, the reaction mechanism, and the influence of catalysts are discussed.
The bibliography includes 118 references.

I. INTRODUCTION

One of the most interesting reactions in organic chemistry is the Diels–Alder reaction. Many ideas concerning synthesis and profound theoretical concepts, sometimes going beyond the framework of the description of the reaction itself, are associated with it. Wasserman[1] and Woodward and Hoffmann[2] must be regarded as the founders of the theoretical interpretation of the Diels–Alder reaction. Wasserman's kinetic studies showed that the reaction is characterised by a low enthalpy of activation (less than 105 kJ mol^{-1}) and a negative activation entropy which is fairly large in absolute magnitude (on average $\sim$35 e.u.). These estimates lead to the conclusion that, firstly, in the transition state the initial molecules must retain their configuration and, secondly, that the structure of the transition state must resemble the configuration of the adduct formed. Wasserman suggested for the first time that the bond formed between the diene and dienophile arises as a result of the overlap of the molecular π orbitals in the direction of the terminal fragments of the system and not as a result of the lateral overlap of the corresponding *p* orbitals. Woodward and Hoffmann devised the elegant theory of "symmetry allowed" processes, which makes it possible to predict whether or not concerted reactions have a low or high activation energy at an elevated temperature or on exposure to UV light. Reactions for which a low activation energy has been predicted are symmetry-allowed, while reactions with a high activation energy are forbidden. In terms of this classification, the Diels–Alder reaction is a thermally allowed process; on the basis of the ideas described above, it should be regarded as a stereospecific suprafacial process with a concerted synchronous mechanism.

The use of asymmetric reagents, complex and specific dienes and dienophiles, non-standard reaction conditions, and catalysts led very rapidly to the application of this reaction which was popular even without these factors. More profound and detailed experimental studies demonstrated the possibility of also carrying out processes

which are "not allowed" according to the Woodward–Hoffmann hypothesis[3] and also the possibility of a two-stage mechanism,[4,5] in contrast to the classical single-stage synchronous mechanism. New views, showing that even this elegant theory has specific and relative aspects, have appeared.[6]

Many workers have now analysed various aspects of the Diels–Alder reaction. In particular, we may mention reviews in which the reactivity and reaction mechanism,[7–10] the activity and selectivity ratios,[11] the influence of substituents,[9] the regioselectivity and stereoselectivity,[9,11] the symmetry of the transition state,[7] and the possibility of applying perturbation theory[8,9] and frontier orbital theory[10,12] to the description of the characteristic features of the cycloaddition reaction are discussed.

The aim of the present review is the analysis of various quantum-chemical approaches used to investigate the Diels–Alder reaction and also a survey of the characteristic features of this reaction deduced from calculated data.

II. THE USE OF QUANTUM-CHEMICAL INDICES FOR THE DETERMINATION OF THE REACTIVITY OF DIENES AND DIENOPHILES. ALLOWANCE FOR THE INFLUENCE OF SUBSTITUENTS

The first attempts to use quantum-chemical methods for the quantitative description of the reactivities of dienes were based on Brown's hypothesis.[13–18] Its essential feature is the assumption that, in the formation of an adduct, one π electron is localised at each of two terminal carbon atoms of the diene system having a favourable conformation for the addition of the dienophile. Such localisation is a precondition for the formation of two new σ-bonds. The energy necessary for the localisation of two electrons [the *para*-localisation energy (PLE)] was calculated by the LCAO-MO method and was related to the reactivity of the diene—the lower the value of the PLE, the lower the activation energy for the reaction.

PLE has been calculated by the free electron method for polycyclic aromatic hydrocarbons (28 compounds in all).[19] The values obtained were compared with Brown's data. For all the compounds considered, the predictions by the two methods concerning the ability of aromatic hydrocarbons to combine with maleic anhydride generally agree. In certain cases the course of the reaction is influenced significantly by the steric hindrance due to the substituents. For example, according to Brown's calculation, 1,2,3,4-tetraphenylbutadiene should react with maleic anhydride somewhat more slowly than anthracene; in fact the reaction does not occur at all.[18]

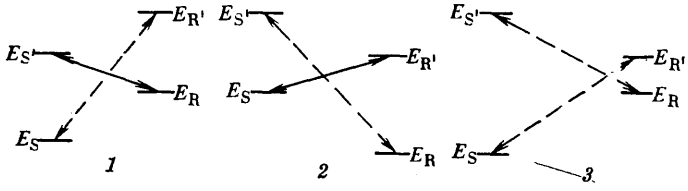
In the case of *o*-benzoquinones, the PLE has been used to characterise their dual ability to react as dienes and dienophiles.[20] It was found that these compounds behave as dienes when the *para*-localisation energy is less than a certain value.

For dienes having several possible addition sites, the Diels–Alder reaction proceeds at sites with the lowest value of PLE[20,21] and the highest localisation of charge.[22] The site at which maleic anhydride adds to Klar's hydrocarbon (centrine) has in fact been determined by calculating the PLE.[21]

On the basis of Brown's idea, Sofer et al.[23] introduced various types of indices (ρ) for dienes and dienophiles: indices of the "ethylene", "butadiene", and "benzene" character, which describe the reactivities of the test systems. For the set of polycyclic aromatic structures, the values obtained are compared with the PLE. It has been found that the character of the correlation between ρ and PLE is different for different types of reaction centre. According to Sofer et al.,[23] this permits conclusions about the reaction mechanism. Indices with the "benzene" character ρ_b were used by the same workers to estimate the relative reactivities of different rings in linear polyacenes.[24] It was assumed that $\rho_b = 1$ for benzene; the value of ρ_b is correlated with the PLE, diminishing with increase in the size of the system. The minimum value ($\rho_b = 0.8$) has been obtained analytically for the middle ring in the infinite polyacene; in practice, it is attained when the number of rings is ten.

Epstein[25] used the orders of the bonds between the carbon atoms in the 1- and 2-positions and 3- and 4-positions in the diene as the static reactivity indices. Benzene, 13 polyacenes containing between two and five condensed rings, 10 even polyenes, and 4 heterocyclic systems were considered. It is stated that a correlation was observed between the bond order and the PLE for each type of molecules listed above, but the correlation breaks down when the molecules of different types are considered jointly. This has also been noted by Raghavan and Narasimhan.[20]

Correlations of different reactivity indices should be treated with caution,[26,27] since they depend on the structure of the compounds, i.e. are functions of the "structural variable" s. Within the limits of a given reaction series, two reactivity indices, say A and B, are functions of s: $A(s)$ and $B(s)$. It would seem at first sight that it is sufficient to eliminate the dependence on s and to find the relations $A = A(B)$. However, this cannot be done because s is not a variable in the fundamental sense but depends in its turn on the nature of the substituent. The correlation of the indices is therefore always some kind of approximation.[26,27] It was shown in the same investigation that the correlation of the reactivity indices is impaired when charge transfer takes place in the transition state between the reactants, which is highly characteristic of the Diels–Alder reaction.[7]



In the PLE, as in other static reactivity indices, no account is taken of the influence of the substituents on the dienophile. Calculation of this kind can then therefore serve only for the description of the relative reactivities of dienes. The change in the π-electron conjugation energy on formation of an adduct from aromatic hydrocarbons has been calculated by the free electron method and related to the relative yields of the reaction products.[28] It was found that a reaction is observed when the losses in the conjugation energy are $< 1.7 \mid \beta \mid$, where β is the resonance integral.

The results of studies on the Diels–Alder reaction involving a series of methyl-substituted 1-ethoxybutadienes (I) and 2-ethoxybutadienes (II) have been analysed.[29] The dienophiles employed were substituted ethylenic compounds $H_2C = CHX$, where X = CHO, CO_2H, $COCH_3$, CO_2CH_3, or CN. Comparison of the experimental data with calculation showed that the logarithms of the rate constants lg k for the reactions considered are linearly correlated with the ionisation potentials of the diene in the series (I) and (II) considered separately. A linear correlation has also been observed between lg k and the electron affinity of the dienophile. The electron density in the frontier MO is also used to account for the reactivity of dienes.[30,31]

We shall consider a series of studies in which account was taken of the influence of substituents.[9,32–35] It is noteworthy that the majority of investigators turn to perturbation theory and to the frontier orbital (FO) approximation in the solution of this problem. Electron-donating substituents increase the energy of both FO's, the energy of the highest occupied molecular orbital E_{HOMO} changing more markedly than the energy of the lowest unoccupied molecular orbital E_{LUMO}. Electron-accepting substituents reduce the energies of both FO's, E_{LUMO} varying more markedly than E_{HOMO}. Depending on the difference between the FO energies of the diene and dienophile, it is formally possible to formulate three types of Diels–Alder reactions: "normal" (*1*), "reverse" (*2*), and "neutral" (*3*) (see Figure).[7,9] The continuous arrow indicates the decisive interaction; such interaction is not observed for reactions of the "neutral" type.

Taking into account the influence of substituents on the FO energy levels in the reactants and the type of decisive interaction, it is possible to predict how these substituents, introduced into the 2π

or 4π system, affect the rate of reaction, since the rate should increase with decrease in the difference between the frontier orbital energies responsible for the interaction.[7,9,32] The theoretical predictions stating that there is a difference between the activation parameters for reactions which obey the forward and reverse Alder rules, that the reactivity of *trans*-disubstituted ethylene, behaving as the dienophile, is higher than that of the *cis*-isomer, and that the introduction of the carbonyl group into the dienophile influences the rate of reaction and predictions concerning the disposition of the orbitals in the reactants, put forward on the basis of calculations by the CNDO/2 method using the perturbation theory, agree with experimental results.[32]

Types of Diels–Alder reactions as a function of the difference between the FO energies of the diene and the dienophile: *1*) "normal" reaction; *2*) "reverse" reaction; *3*) "neutral" reaction; R = diene index; S = dienophile index; E_R, E_S = HOMO energies; E'_R, E'_S = LUMO energies.

The concept of active orbitals has been introduced.[36] Active orbitals comprise the occupied bonding orbital of one of the reactants and the unoccupied antibonding orbital of another. These orbitals describe the bonds formed and broken on cycloaddition. For the "normal" Diels–Alder reaction, the HOMO of the diene and the LUMO of the dienophile are active, whilst the opposite situation obtains for the "reverse" reaction. The experimental activation energy ΔE_{act} obeys the correlation $\Delta E_{act} = \alpha\Delta\varepsilon$, where α is a dimensionless empirical constant for the given reaction (for the Diels–Alder reaction, $\alpha = 0.18$) and $\Delta\varepsilon$ is the difference between the energies of the active orbitals. The quantity $\Delta\varepsilon$ was calculated by the extended Hückel method. The authors[36] believe that the influence of the substituents is associated with the stabilisation and/or destabilisation of the active orbitals.

The influence of electron-donating and electron-accepting substituents on the energies of the HOMO and LUMO of the diene and dienophile has been examined.[37] The rule has been formulated according to which the maximum increase in the rate of the thermal symmetry-allowed cycloaddition reaction of alicyclic reactants is promoted by the introduction of electron-donating substituents into the reactant molecule having the HOMO with the highest energy. This rule is more general than the familiar Alder rule.

It has been shown[38] that the inertness of certain five-membered cyclic chloro-substituted dienophiles in the reaction with cyclopentadiene is associated with the low electron affinities of the test molecules and the low stabilisation energies of the transition state E_s. It has been suggested that there exists a limiting value of E_s, below which the reaction does not occur. The amount of informa-tion contained in certain quantum-chemical reactivity indices of dienophiles was estimated in the same study. The electron affinities calculated by the simple and extended Hückel methods can be useful in the first stage of the study of the reactivity. The reac-tivities of dienophiles in the Diels–Alder reaction are described more adequately by Dewar's MO perturbation method (MOP) and Salem's intermolecular orbital method (IMO). Fukei's frontier orbital method proved unsuitable for the study of compounds of this series. (The frontier orbital approximation cannot be used for heterodienophiles either.[39]) The dependence of the reactivities of dienophiles (ethylenes, benzoquinones, and naphthoquinones) on the nature of the substituents has been considered in a number of studies.[40,41]

The relative reactivities of heterocyclic compounds, namely furan (III), thiophen (IV), and thiophen 1,1-dioxide (V), have been investigated[43] by a modified CNDO/2 method.[42] The stabilising influence of symmetrical (S_π) and antisymmetric (A_π) orbitals of the heteroatom and the SO_2 group on the S_π and A_π MO of the diene and the product was considered as a perturbation of the diene fragment. In furan the 2*p* AO of oxygen have approximately the same stabilising effect on the MO of the product and the reactant and in this case a thermal reaction is possible. The influence of the 3*d* AO of oxygen in furan is insignificant. On the other hand, in thiophen the 3*d* AO of sulphur exert the greatest influence on the A_π MO of the diene, while their influence on the MO of the product is insignificant and the equilibrium in this reaction is strongly displaced towards the reactant. The stabilisation in compound (V) is less marked than in thiophen and the equilibrium is less displaced towards the reactants. The diene reactivity series (IV) < (V) < (III) has been confirmed experimentally.

III. PREDICTIONS BASED ON CALCULATIONS OF THE SELECTIVITY OF THE CYCLOADDITION

The question of selectivity is very important in the Diels–Alder reaction.[9,11] Three types of selectivity are distinguished: chemoselectivity (competition between processes), regioselectivity (competition between the orientations of the reactant leading to positional isomers), and stereoselectivity (competition between the orientations of the reactants leading to geometrical isomers).[44] Special attention is devoted in the literature to the last two types of selectivity. However, competitive processes, for example [2 + 2]-cycloaddition, Michael addition, and the interaction of functional groups, can also arise with the Diels–Alder reaction. The computational method for the prediction of chemoselectivity in the relevant processes has been used very rarely. The chemoselectivity in the reaction of α-dimethylaminostyrene with various dienophiles has been predicted by the MINDO/3 method.[45] Depending on the polarity of the bond in the reactant (the authors introduced a special parameter, equal to the ratio of the difference between the charges on the bonds involved in the multiple bond to its length), one can establish which reaction takes place: [2 + 2]- or [2 + 4]-cycloaddition or the interaction of the amino-group. On the other hand, if several potentially possible Diels–Alder reactions compete, then the more reactive reactants are found to be more selective. This view, derived from the theory of orbital interaction is opposed to the concept put forward previously stating that the less active reactant is the more selective. This means that the processes in which donor–acceptor interactions play a significant role and the relative reactivity is controlled by the frontier orbital energies constitute exceptions to the general rule.[7,12,39] The chemoselectivities and regioselectivities for the radical-cation cycloaddition reactions have been considered.[46]

A general theoretical approach to questions of regioselectivity and stereoselectivity in the Diels–Alder reaction has been described.[9,47–49] Quantum-chemical methods for the determination of the regioselectivity of the process have been used in Refs.50–72 and those for the determination of stereoselectivity have been used in Refs.73–82.

In order to account for the high regiospecificity in the interaction of asymmetric components, the perturbation energies have been calculated by Dewar's method for substituted butadienes (the 1-methyl, 2-methyl, 1-phenyl, and 2-phenyl derivatives) in their reactions with acrylonitrile, methacrylate, and styrene.[50] The coefficients

of the frontier orbitals of the dienes and dienophiles were calculated in terms of the Hückel approximation. The interaction between the atoms of the reacting molecules was taken into account only in the region of bond formation. The calculated perturbation energies for the *o*-, *m*-, and *p*-derivatives were compared with the relative reaction yields. It thus proved possible to predict the preferred orientation in the addition reaction in all the cases examined.

Calculations have been carried out[51] by the PPP method for methyl vinyl ketone and a series of substituted buta-1,3-dienes: 2-methoxy-1-phenylthiobuta-1,3-diene (VI); 2-methoxyphenylthiobuta-1,3-diene (VII); 2-acetoxy-3-(*p*-hydroxyphenylthio)buta-1,3-diene (VIII); 1-acetoxy-4-phenylthiobuta-1,3-diene (IX), and 3-methoxy-3-(2-pyrimidylthio)-buta-1,3-diene (X). The structures of frontier molecular orbitals have been analysed and the regioselectivity in the Diels–Alder reaction has been investigated on the basis of the MOP theory. For all the dienes examined, the transfer of electron density is determined by the primary interaction of their HOMO with the LUMO of the dienophile. The differences between the HOMO coefficients for the corresponding carbon atoms for compounds (VI) and (VII) are small. The regioselectivity of the addition is therefore determined by the character of the LUMO of these compounds, i.e. by the secondary interaction of the LUMO of the diene and the HOMO of the dienophile. The difference between the HOMO coefficients for compound (VIII) is large and the regioselectivity of its addition to methyl vinyl ketone is determined by the primary interaction, in conformity with experimental data. A characteristic feature of 1-acetoxy-4-phenylthiobuta-1,3-diene is that the weak directing effect of the primary interaction is enhanced by the secondary orbital interaction acting in the same direction.

The orientational phenomena in the Diels–Alder reactions of 2R-butadienes with methyl methacrylate have been investigated by the IMO method. A comparison has been made with other methods: the simple perturbation theory and the FO method.[52] The regioselectivity in the reactions of substituted butadienes has also been investigated in other studies.[29,53,54] Analysis within the framework of the perturbation theory in terms of the approximation of F whose coefficients were calculated by the CNDO/S and the Hückel MO method made it possible to account for the regioselectivity in the reactions of methyl-substituted 1- and 2-ethoxybutadienes with substituted ethylenes.[29]

The mode of cycloaddition to various vinylpyridines[55,56] and oxazoles[56] and also of the cyclodimerisation of vinyl pyridines[57] has been correctly predicted and explained on the basis of the formation energies of the regioisomers. If the vinylpyridines function as the dienes, then in their structures it is possible to distinguish formally two pseudodiene fragments: N=C–C=C and C=C–C=C, which must be taken into account in the calculations.[55,57] The formation energies of the regioisomers were estimated in the above studies from

$$\Delta E_\pi = 2\left[\frac{(C_{R_n}C'_{S_m}\beta_{mn} + C_{R_p}C'_{S_q}\beta_{pq})^2}{|E_R - E_{S'}|} + \frac{(C'_{R_n}C_{S_m}\beta_{mn} + C'_{R_p}C_{S_q}\beta_{pq})^2}{|E_{R'} - E_S|}\right],$$

where C and C' are the coefficients of the atomic orbitals of the directly interacting atoms n and p (diene index R) and m and q (dienophile index S) involved in the corresponding HOMO and LUMO, E_R, $E_{R'}$, E_S, and $E_{S'}$ are the frontier orbital energies of the diene and dienophile, and β_{mn} and β_{pq} are the corresponding resonance integrals of the *mn* and *pq* bonds formed in the combined RS system. The coefficients of the AO and the FO energies were calculated by the MINDO/3 method. The experimental data on the stereochemistry of the reaction of 5-ethoxyoxazole with β-acetylacrylic acid and its ethyl ester as well as the reactions of vinylpyridines with azodicarboxylic acid ester and the cyclodimerisation of vinylpyridines agree with the calculations. Similar studies, demonstrating that the observed changes in the reactivity correspond to the stabilisation energies arising as a consequence of the interaction of the frontier orbitals, have been carried out also for the Diels–Alder reaction of the "neutral" type.[58,59]

The π-electon density at the atoms of 5-ethoxyoxazole and acrylic acid and its ethyl ester has been calculated by the Hückel method taking into account the hyperconjugation effects generated by the methyl group. A two-stage mechanism with charge distribution in the transition state has been proposed on the basis of the results of the calculation and the regioisomer formed has been predicted correctly.[60]

The FO theory has been used to account for the isomeric composition of the products of the Diels–Alder reaction.[61] It was postulated that the reaction takes place in two stages and that a weak bond between centres is formed in the first stage. In the special case where the HOMO energy of one molecule and the LUMO energy of the other are close to the energy of the nonbonding orbital, such centres are atoms with the highest, in terms of absolute magnitude, coefficients of the HOMO of the first molecule and LUMO of the second. More than 100 reactions have been investigated within the framework of the Hückel method with various sets of parameters. In all cases the structure of the main product was predicted correctly.

Summarising, one may say that the regioselectivity of the concerted cycloaddition reactions is determined by the orbital effects favouring the formation of bonds between two atoms, to which correspond the coefficients in the expressions for the FO, and between two atoms for which the coefficients for the FO are minimal.[9] On the other hand, Ioffe et al.[62] believe that the relation between the regioselectivity of the reaction and the structure of its transition state is closer and classify the regioselectivity into short-range and long-range components. It follows from the analysis of the structure of the potential energy surface for a reaction leading to two regioisomeric products that the regioselectivity of such a reaction is determined not only by the relative stabilisation of the transition states but also by the height of the ridge separating two valleys on the potential energy surface. If this ridge is low, then a redistribution of the reaction complexes, in conformity with the relative stabilities, can occur during the reaction. In this case the regioselectivity is of the short-range variety and is high when there are significant differences between the stabilisation energies of the transition states. On the other hand, the existence of a high ridge between the valleys prevents the redistribution of the reaction complexes. In other words, in such reactions the regioselectivity is of the long-range kind and is less pronounced, because it is predetermined already in the early stages where the secondary orbital interactions are insignificant.

Ioffe et al.[62] note that, although the calculation of the total potential energy surface is extremely complex, the height of the potential barrier for concerted cycloaddition can be estimated from considerations involving orbital symmetry. On the grounds that the regioisomeric adducts are formed in the Diels–Alder reaction from different transition states and interconversion is difficult, the concerted *supra-supra*-cycloaddition is classified as a process with long-range comparatively low regioselectivity. Different methods of predicting regioselectivities have been compared by Chen.[63]

Quantum-chemical calculations which explain the stereoselectivity in the Diels–Alder reaction have been used for the solution of the problem of both the *endo, exo*-specificity and the *syn, anti*-specificity. On the basis of experimental data obtained in the study of the reaction of cyclopentadiene with maleic anhydride, Alder and Stein concluded that differential *endo*-orientation obtains and explained it by the "maximum accumulation of unsaturation".[1] Woodward and Hoffmann[2] explained this rule by the fact that the FO of the secondary centres, i.e. atoms which are not linked to one another in the adduct (the interaction of the orbitals of the secondary centres is

referred to as secondary orbital interaction), may overlap for the *endo*-adduct. This electronic effect lowers the activation energy for the reaction and hence the *endo*-adduct is formed faster. The study of the reaction of cyclopentadiene with various dienophiles within the framework of the Hückel method showed that the delocalisation energy of the *endo*-configuration is always greater than that of the *exo*-isomer,[73,74] which conforms to the Alder–Stein rule. A model calculation for the coplanar *endo*-oriented complex in the reactions of cyclopentadiene with acrolein, crotonaldehyde, butadiene, isoprene, and piperylene has been carried out by the Hückel method including Madelung's correction to the energy.[75] The distance between the plane of the diene and the dienophile was varied in the range 2.6–4.0 Å. It was found that in the range investigated the *endo*-orientation is always energetically more favourable than the *exo*-orientation and that the charge transfer from the diene to the dienophile in the case of the *endo*-orientation exceeds that for the *exo*-orientation.

However, experimental data have shown that the Alder–Stein rule is not absolute. A mixture of isomers is usually formed, their ratio depending on the nature of the initial compounds, the electronic and steric effects, and also the reaction conditions. Under conditions of thermodynamic control, there is a possibility of the preferential formation of the more stable *exo*-adduct. Such uncertainty in the prediction of the expected stereoisomer can be explained by the fact that the secondary orbital interactions responsible for the stereoselectivity have low energies and the influence of other factors is therefore extremely important. For this reason, in contrast to the problem of the regiospecificity of the Diels–Alder reaction, it is much more difficult to solve the problem of the stereoselectivity by computational methods.

Mazzoechi et al.[76] investigated the π-surface stereoselectivity of the cycloaddition of hexachlorocyclopentadiene to 7R-norbornadienes (R = H, t-BuO, $PhCO_2$, *p*-$MeOC_6H_4$, *p*-MeC_6H_4, Ph, *p*-FC_6H_4, Cl, CH_3CO_2, or Me). Non-empirical *ab initio* MO calculations have shown that the substituents in the 7-position influence the reorientation of the π-bonds in space, the ease of the displacement of the olefinic protons from the plane, and probably the very planarity of alkenes. The substituents investigated increase the electron density at one of the two bonds of the ring. The dependence of the partial reaction rate factors on the electronegativity ε of the substituent *R* can be satisfactorily explained for *anti, exo*-attack. In the case of *syn, endo*-attack, a significant acceleration of the latter has been demonstrated for 7-t-butoxynorbornadiene. However, the slight variation of the partial rate factor as a function of ε for *syn, endo*- and *anti, endo*-attack could not be fully explained.

In a study of the stereochemistry of cycloaddition to substituted acetylenic and ethylenic compounds,[77] it was found that a dienophile adds stereospecifically to the endocyclic diene fragment of fulvenes from the side opposite the CH_2 bridge. In order to explain this phenomenon, calculations were carried out by the MINDO/3 and INDO methods. On the basis of the perturbation theory, the authors[77] believe that such stereospecificity of the cycloaddition is caused by the fact that, when the dienophile is attacked from the side of the methylene bridge, a strong antibonding interaction takes place between the HOMO of the dienophile and the LUMO of the diene (especially in the *exo*-oriented transition state), because the π orbitals of the terminal atoms of the diene are turned inwards towards the π orbitals of the dienophile. On the other hand, one must take into account the fact that the four-electron four-centre interaction considered weakens under the conditions of the *endo*-attack, since the corresponding π orbitals of the diene fragments are turned away from the dienophile. Analysis of the calculated data and photoeletron spectra also permits conclusions concerning the role of the σ–π interactions of the orbitals in the test systems.

In order to account for the experimental observation of the formation of the *exo* or *endo*-configuration with the *syn*-position of the nitrile group in the reactions of cyclopropenes with various dienophiles, the qualitative perturbation theory has been used.[78] The authors based their conclusions on the fact that the steric structure of the transition state is determined by the maximum overlap of the frontier MO of the adducts.

The study by the INDO method of the influence of the methyl groups on the rate and stereochemistry of the cycloaddition and the use of kinetic data for a series of tricyclo[5.2.1.$0^{2,6}$]decadienes and trienes[34] showed that electronic effects play the main role in determining the selectivity (for the majority of compounds). It is believed[34] that one of the main factors determining the reaction selectivity is the character of the distortion of the MO. For norbornyl-condensed spirocyclic cyclopentadiene systems, the mixing of the σ and π orbitals of the dienes plays the most significant role. It is responsible for minimising the antibonding interactions for the observed stereochemistry of the cycloaddition, which has been demonstrated with the aid of the INDO method.[79] The *syn,anti*-stereoselectivity has been investigated as a function of the geometry of the transition state.[80]

The factors influencing the stereoselectivity of the cycloaddition reactions have been examined in a review.[81] It was concluded that the stereoselectivity is determined mainly by the orbital interaction. The application of perturbation theory to the determination of the selectivity of processes has been discussed in detail in a number of studies.[9,83,84]

IV. THE MECHANISM OF THE DIELS–ALDER REACTION

For a long time, the Diels–Alder reaction was assumed to be a concerted suprafacial process with a single-stage synchronous mechanism. This idea was based on the Woodward–Hoffmann theory of orbital symmetry. However, certain experimental and calculated data obtained in recent years make it necessary to consider the following question: is the classical mechanism in the Diels–Alder reaction the rule or an exception. On the basis of the results of kinetic studies by Dewar,[4] one may conclude that the transition state is asymmetric in the reactions of furan derivatives with maleic anhydride. According to the results of the same worker, obtained by the MINDO/3 and MNDO methods, any synchronous processes involving the participation of more than one bond have unduly large activation energies and therefore can hardly occur.[5] Our experimental studies on isoindoles also confirm the possibility of non-synchronous cycloaddition.[85,86]

Nevertheless, from our point of view, the complete neglect of the orbital symmetry theory is unjustified at the present stage. This theory has provided too many explanations for organic chemists to be abandoned without adequate justification. In the general case one must therefore take into account the possibility of both a many-centre synchronous mechanism and a two-stage mechanism with the intermediate formation of a zwitterion or a biradical. A concerted but non-synchronous mechanism, i.e. one where two new bonds are formed at different rates, is also theoretically feasible.

The structure of the transition state of the reaction depends on the proposed mechanism. In the theoretical analysis of this process with the aid of MO methods, one must therefore use different approaches.[87]

Quantum-chemical calculations have been applied most often to the study of the mechanism of the cycloaddition of ethylene to butadiene. It has been demonstrated by the CNDO/2 method that the approach of the ethylene molecule from "above" and not from the plane of butadiene is most favourable.[88] The reaction takes place in such a way that the principle of the maximum overlap of the $2p_\pi$ orbitals of ethylene and the analogous orbitals of the

terminal carbon atoms of butadiene is obeyed. Significant changes in the structure of the reacting molecules, in bond lengths, and in the hybridisation of the atoms take place only when the distance between the carbon atoms of the ethylene and the terminal carbon atoms of butadiene is less than 2 Å. It has been noted that the $\sigma-\pi$ interaction plays a significant role in estimations of the energy characteristics of the reaction. In the case of substituted ethylenes and butadienes,[82] the $\sigma-\pi$ interaction is also very important as a factor controlling the selectivity of the addition.

It has been observed[74] that the stability of the complexes formed between the *cis*-butadiene and dienophile (ethylene or *p*-benzoquinone) components is low if the distance between the components is ~3.0 Å. The stabilisation energy of the charge-transfer complexes in the reaction with ethylene is 16.76 kJ mol^{-1} and that for the reaction with benzoquinone is 37.71 kJ mole^{-1}. It has been noted[88,89] that charge transfer takes place from butadiene to ethylene in the course of the formation of the activated complex. It has been demonstrated[90] that, in the analysis of the dependence of the rate of reaction on the nature of the dienophile, it is likewise necessary to take into account the charge transfer between the components of the diene synthesis.

The non-empirical method for the calculation of the reaction pathway in the cycloaddition of ethylene to butadiene within the framework of the Roothaan method makes it possible to establish that during the reaction the planes of the molecules are disposed at an angle of 70° relative to one another.[89] In the same study an attempt was made to determine the heat of reaction and to estimate the electronic and geometrical structures of the transition state. However, it was found that an unsuccessful method had been used for the optimisation of the geometrical parameters.[91]

An interesting method has been proposed[92] for the description of the reactivity (including that in the Diels–Alder reaction), in which the state of each atom involved in the reaction is described by a parameter called the reaction angle. Two computational schemes, based on the PPP and Hückel MO approximations have been developed. The first has been called the method of topological molecular orbitals (TMO) with configuration interaction (TMO-CI) and the second TMO scheme is a simplified version of the first in which the intermolecular repulsion integrals were disregarded. The total energy of the system is described as a function of the reaction angles. This function describes a topological hypersurface; the reaction mechanisms are discussed in terms of stationary points on the hypersurface. A detailed analysis has been carried out for the reaction of butadiene with ethylene.[92] Minima corresponding to the reactants and products (cyclohexene) and two saddle points, corresponding to the *supra, supra-* and supra, antara-cycloadditions were found on the hypersurface for this reaction. However, only the former corresponds to the true activated complex (the gradient at this point is zero and the Hess matrix has only one negative eigenvalue). The activation energy for the reaction, amounting to 101 kJ mol^{-1} (Hückel MO) and 112 kJ mol^{-1} (PPP), was calculated for the *supra, supra*-cycloaddition. An additional saddle point corresponds to the singlet biradical, but the reaction pathway, linking the reactants to this biradical, passes through a stationary point at which Hess's matrix has two negative eigenvalues. The two stage mechanism is therefore prohibited owing to infringement of the Murrell–Laidler rules. On the other hand, the biradical can be obtained from the reaction products. This is a possible mechanism in cases where the stereoselectivity of the reaction diminishes.

The biradical transition state of the Diels–Alder retroreaction cyclohexene → butadiene + ethylene is supported by the results of the study of the fragments of the potential energy surface carried out in terms of the MINDO/3 approximation with full optimisation of the geometry.[93] The calculations were performed taking into account the configuration interaction. The transition state found was consistent with an asymmetric biradical to which corresponds an activation energy of 428.9 kJ mol^{-1} (experimental value 268.8 kJ mol^{-1}). According to the author,[93] the unrestricted SCF method provides a more correct description of potential energy surfaces, making it possible to distinguish two stages in the retroreaction investigated: the first, rate-limiting stage involving the formation of an asymmetric biradical intermediate with an activation energy of 365.4 kJ mol^{-1} and the second stage involving the decomposition of the intermediate to ethylene and butadiene with an activation energy of 79.9 kJ mol^{-1}. The activation entropies for the first and second stages as well as the kinetic isotope effects were calculated and it was concluded that the latter cannot serve as a criterion for the choice between the synchronous and non-synchronous mechanisms of the Diels–Alder reaction.

Bazilevskii[26] and Tikhomirov[27] suggested that corrections be introduced into the semiempirical π-electron PPP theory in order to take into account the non-orthogonality of the basis AO and the electronic correlation. The correction for the non-orthogonality (exchange repulsion) together with allowance for the Coulombic interaction of the atoms leads to the appearance of a new contribution in the expression for the energy of the system. The potential surface for the Diels–Alder reaction in the ethylene–butadiene system is constructed taking into account this contribution and using the hybrid orbitals. It has been noted that, for a fixed method of calculation of the energy taking into account an incomplete set of degrees of freedom (which is frequently done), one can obtain only the upper limit to the activation barrier (because the crossing point is an extremum).

The results of calculations of the energy of π electrons in terms of the PPP approximation established that the pathway involving the consecutive formation of σ-bonds requires a higher activation energy.[94] The reaction of butadiene with ethylene has been investigated also in other studies,[95–98] whose results do not conflict with these ideas. The possibility of a single-stage mechanism with a pericyclic transition state and of a two-stage mechanism with the intermediate formation of a biradical has been discussed.[99]

Thus one may conclude that the results of quantum-chemical calculations for the forward Diels–Alder reaction between butadiene and ethylene indicate a single-stage synchronous mechanism with the intermediate formation of a charge-transfer complex. However, the retroreaction is characterised by a two-stage mechanism with the intermediate formation of a biradical (or by a single-stage mechanism with a biradical transition state).

A number of studies have been devoted to the mechanism of the reactions of substituted butadienes and ethylenes. The parameters of the transition states for the Diels–Alder reactions of 1- and 2-ethoxybutadienes with acrolein have been calculated by the MINDO/2 method for two reaction mechanisms: the concerted synchronous mechanism and a non-synchronous mechanism.[98] The geometrical parameters were optimised by minimising the energy using Rinaldi's method. The calculated potential barriers to the reaction led to the conclusion that 2-ethoxybutadiene reacts preferentially via the concerted mechanism, while 1-ethoxybutadiene reacts via a non-synchronous mechanism. The calculated activation energies (163 and 119.5 kJ mol^{-1} respectively) agree with the observed rate constants for the reactions of these isomers with acrolein at 65 °C.[98] Evidence supporting the single-stage mechanism for substituted butadienes has also been obtained in other studies.[29,100]

Calculations for the transition state[101] in a reaction involving the cyclodimerisation of buta-1,3-diene to 4-vinylcyclohexene by various methods, (FO, MINDO/3 and *ab initio* SCF MO) showed that the activation energy is reduced when a radical-cation is formed as an intermediate, which is inconsistent with the synchronous mechanism. The authors[101] suggest that the Diels–Alder reaction between

buta-1,3-diene and the butadiene cation proceeds in accordance with a concerted but non-synchronous mechanism via a bisallyl radical-cation in which the pericyclic interaction is relatively weak.

We shall now return to the study mentioned previously[29] in which the mechanism of the reaction of ethoxybutadienes with various dienophiles is discussed (see above). The calculations were performed within the framework of the perturbation theory in terms of the FO approximation and the frontier orbital coefficients were calculated by the CNDO/S and the Hückel MO methods. Comparison of the calculated interaction energies of the frontier orbitals with the logarithm of the reaction rate constant with the aid of correlation analysis leads to the conclusion that a synchronous mechanism operates in the series of compounds II and a non-synchronous mechanism in the series of compounds I. However, the CNDO/S and Hückel MO methods yield opposite answers to the question as to which of the two bonds is formed earlier.

An interesting approach to the study of the reaction mechanism has been proposed.[102] On the basis of the FO theory, the role of the donor–acceptor interaction in two systems is considered qualitatively: (1) with the diene as the donor and the dienophile as the acceptor; (2) with the dienophile as the donor and the diene as the acceptor. The objects of study are not specified exactly. It follows from the analysis in the above investigation[102] that the simultaneous formation of two bonds is possible if the interaction between antisymmetric MO predominates. On the other hand if the interaction between symmetrical MO is decisive, the probability of the formation of a cyclic transition state diminishes.

In relation to the interaction of cyclopentadiene with various dienophiles and of maleic anhydride with various dienes, it has been shown[74] that the diene and the dienophile are charged positively and negatively respectively in the intermediate complex. The degree of polarisation is correlated with the delocalisation energy of the corresponding complex, which is linearly related to Brown's *para*-localisation energy.[74]

The distribution of electron density in the π-complexes between the diene and the dienophile, which have been identified with the activated complexes in the Diels–Alder reaction to simplify the procedure, has been studied with the aid of a modified version of the Hückel method.[103] The π-complexes of cyclopentadiene with ethylene, acroleine, *p*-benzoquinone, and 1,4-naphthoquinone and the π-complexes of maleic anhydride with benzene, napthalene, anthracene, phenanthrene, pyrene, benzanthracene, dibenzanthacene, benzophenanthrene, pentacene, and hexacene were examined. The distance between the molecular planes was assumed to be 1.87 Å. The resonance integrals arising when the molecular interaction was considered were assumed to be proportional to the overlap integrals. In all the π complexes investigated, the diene component is the electron donor. The magnitude of the transferred charge increases with increasing delocalisation of the π complex. It was found that the degree of conjugation in the π complexes corresponding to the endothermic reactions is greater than in the π complexes in the exothermic reactions.

The reactivity of dienophiles having different structures in their reactions with cyclopentadiene has been investigated by the method of intermolecular orbitals (IMO) using a coplanar model of the transition state (TS).[104] Such calculation presupposes the equality of the overlap integrals between different atoms. The interaction energy E_{in}, equal to the stabilisation energy, is used as a characteristic of the of the reactivity for various kinds of mutual approach of the molecules. Within the limits of three reaction series of dienophiles (A—cyanoethylenes, B—maleic anhydride derivatives, C—quinones), the values of E_{in} were calculated for two types of coplanar TS: *endo* and *exo*. It was shown that the IMO method is applicable to the description of the reactivities of symmetrical dienophiles (series B and C), and leads to unsatisfactory results for asymmetrical dienophiles (series A). The authors[104] therefore suggest that the IMO-2 method, in which it is assumed that the primary overlap integrals are not equal, be used. The E_{in} surface, plotted in terms of the coordinates of the overlap integrals, has a saddle point at the origin of coordinates. On the basis of this approach (IMO-2), the authors introduced a new reactivity index, equal to the maximum positive curvature of the interaction energy surface (f_{max}), whose value is independent of hypotheses concerning the structure of the transition state (the TS can be non-coplanar). In the same study, it was also shown that in many instances the index f_{max} contains more information than E_{in}. In particular, the use of this index makes it possible to describe satisfactorily both symmetrical and antisymmetric TS (for example in the reactions of cyclopentadiene with series A dienophiles).

The transition states in the reactions of butadiene with ethylene, cyclopropene, and cyclopropenone have been investigated by the IMO-2 method.[94] The molecular geometry was assumed to be unchanged during the reaction. Variation of the geometrical parameters characterising the mutual disposition of the molecules and the structure of different sections of the potential surface for the reaction led to the conclusion that the non-coplanar mutual approach of the molecule is preferred. It was shown that the molecular planes of the diene and the dienophile in the TS are disposed at an angle whose value is intermediate between the angles in the coplanar model and in the adducts. The use of the IMO-2 method also leads to more correct results in the study of the reactivity of the dienophiles, of the *endo*/*exo* ratio for the products, and of other features of the Diels–Alder reaction.

The calculation of the stabilisation energy of the transition state has been used to characterise the reactivity.[105] The application of the extended Hückel method to the determination of the TS energies in the reaction of maleic anhydride with cyclopentadiene yields a correct view of the relative reaction rates, in agreement with experimental data.

Calculations have been performed[106] for the π-complexes of maleic anhydride with various polycyclic aromatic compounds (32 structures in all). The complex of maleic anhydride with naphthalene was chosen as the model. It was shown that the overlap integral $2p_\pi$–AO for σ interactions passes through a maximum with decrease in the distance R between the diene and the dienophile, which corresponds to a minimum on the potential curve for the two π-systems. The value of R corresponding to the minimum potential energy (R_0) depends on the effective charges at the ends of the diene system of the polycyclic hydrocarbon. It has been suggested that the formation of the π-complex determines the rate of the diene synthesis. For many of the systems considered, the delocalisation energy of the π-complexes is correlated with the PLE.

The stabilisation energy of the transition state has been calculated also in other studies.[31,107,108] The influence of energetic, geometrical, and electronic characteristics on the cycloaddition mechanism has been discussed.[109] The mechanisms of cycloaddition have been described in terms of orbital symmetry.[110–114]

V. EXAMPLES OF THE STUDY OF CATALYTIC REACTIONS

Computational methods have also been applied to the study of catalytic Diels–Alder reactions.[30,44,57,98,99] It has been noted[51] that catalysis by Lewis acid diminishes the role of the secondary orbital interaction involving participation of the LUMO of the diene, which reduces the selectivity of the reactions of methyl vinyl ketone with thio-derivatives of buta-1,3-diene. The experimental data on the regioselectivity of the thermal and catalytic addition of 2-methoxy-1-phenylthio- and 2-methoxy-3-phenylthio-buta-1,3-dienes confirm this conclusion. The boundary electron densities of isoquinolinequinone and of its complexes with BF_3 and acids have been calculated by the

MNDO method; the regioselectivity in the Diels–Alder reaction with asymmetric dienophiles has been predicted.[115]

It has been noted[69] that protonation reduces the LUMO energy of acrolein, which should increase the interaction energy of the frontier orbitals and increase the rate of reaction. Furthermore, the reaction of acid catalysts increases the difference between the LUMO coefficients of the corresponding carbon atoms, which increases the process selectivity, since the latter becomes more marked with increasing difference between these coefficients (other conditions being equal).

The potential barriers and the charge distribution have been calculated by the MINDO/3 method for the Diels–Alder reaction between 1-hydroxybutadiene and acrolein and a study has been made of the influence of catalysts on this reaction.[108] In the case of a non-catalytic reaction, the activation energies for *o*-endo-, *o*-exo-*m*-endo-, and *m*-exo-additions are respectively (in kJ mol^{-1}) 124.15, 124.28, 205.6 and 207.74. In the presence of BF_3 and NH_4^+, the activation energy for the *m*-addition decreases slightly (by 25 to 42 kJ mol^{-1}), whereas the activation energies for the *o-endo-* and *o-exo*-additions are respectively 62.77 and 64.57 (in the presence of BF_3) and 46.93 and 52.04 (in the presence of NH_4^+). These data explain the experimentally observed influence of Lewis acids on regioselectivity and stereoselectivity. The transition state corresponds to the most pronounced charge transfer from the diene to the dienophile and from the reactants to the catalysts. Other studies have also been devoted to the regioselectivity and stereoselectivity in catalytic Diels–Alder reactions.[117,118]

It is noteworthy that calculations for the catalytic cycloaddition reactions are undoubtedly more complex and that a correlation between the presence of a catalyst and change in process selectivity does not always occur.

Metal-carboxylic Acids and Their Derivatives

I.S.Kolomnikov, T.V.Lysyak, S.L.Rusakov, and Yu.Ya.Kharitonov

Questions connected with the synthesis of metal-carboxylic acids, compounds incorporating [M] -COOH fragments with a metal-carbon bond in which M is a transition metal complex, and their derivatives (salts, esters, and amides) are considered. The bibliography includes 189 references.

CONTENTS

I. Introduction 406
II. Metal-carboxylic acids 407
III. Metal-carboxylic acid salts and polynuclear transition metal complexes of carbon dioxide 410
IV. Esters of metal-carboxylic acids (alkoxycarbonyl complexes of transition metals) 410
V. Amides of metal-carboxylic acids (carbamoyl complexes of transition metals) 412

I. INTRODUCTION

Metal-carboxylic acids (MCA) [M]−COOH constitute a new type of organometallic compound. The interest in complexes of this type is associated with studies on the formation of complexes by carbon dioxide with transition metal compounds.[1-7] The formation of MCA and their derivatives is also encountered in the study of various reactions in the presence of transition metal complexes. A review on MCA and their derivatives appeared in 1972.[8]

In the present review, covering the literature up to 1985, attention has been concentrated on the preparation of MCA and their derivatives and the literature on catalytic processes with the intermediate formation of [M]−COOH, [M]−COOR, or [M]−$CONR_2$ groups is covered only fragmentarily. The review also hardly reflects data on the synthesis of unstable MCA esters and amides by the usual methods.

The formation of MCA and their derivatives (esters and amides) in intermediates has been postulated in various catalytic processes with participation of carbon monoxide and carbon dioxide, although their involvement in the catalytic step has not been rigorously demonstrated. At any rate, one of the possible pathways in the majority of these processes may involve the intermediate formation of [M]−COOH, [M]−COOR, or [M]−$CONR_2$. The synthesis of higher carboxylic acids and their esters from unsaturated compounds, carbon monoxide, and an alcohol (or water) in the presence of transition metal compounds (the Reppe synthesis) can also be assigned to reactions of this type:[9-15]

$$H_2O + [M] \rightleftarrows H[M]OH ,$$
$$H[M]OH + CO \rightleftarrows H[M]CO_2H ,$$
$$H[M]CO_2H + \underset{|\ |}{\overset{|\ |}{C{=}C}} \rightarrow \underset{|\ |}{\overset{|\ |}{HC{-}CCO_2H}} + [M] ,$$
$$\text{or } H[M]OR + CO \rightleftarrows H[M]COOR ,$$
$$H[M]COOR + \underset{|\ |}{\overset{|\ |}{C{=}C}} \rightleftarrows \underset{|\ |}{\overset{|\ |}{HC{-}CCOOR}} + [M] ,$$

where [M] is a fragment of the transition metal complex.

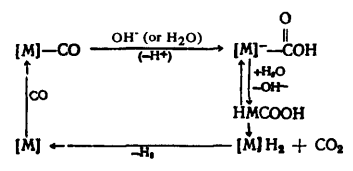
The formation of MCA esters as intermediates has been put forward also in the reaction involving the carbonylation of alkyl halides by carbon monoxide in the presence of transition metal complexes (see Fracalanci et al.[16] and the literature quoted therein). Although the metal-carboxylic acid can be isolated in a pure state from the reaction mixture under the conditions of the reaction involving the addition of formic acid and its esters to unsaturated compounds,[1,17] the question of the character of the transfer of the carboxy-group to the olefin with formation of H[M]COOH remains open; one of the possible pathways is as follows:

$$HCO_2H + [M] \rightarrow H[M]CO_2H ,$$
$$H[M]CO_2H + \underset{|\ |}{\overset{|\ |}{C{=}C}} \rightarrow \underset{|\ |}{\overset{|\ |}{HC{-}CCO_2H}} + [M] .$$

It is entirely possible that the esters of palladium-carboxylic acid are formed as intermediates in the carboxylation of unsaturated compounds in the presence of palladium salts[18] and in the synthesis of oxalic and carbonic acid esters by the reaction of carbon monoxide with alcohols:[19-21]

$$2CO + 2ROH \xrightarrow{PdCl_2} RCO_2CO_2R .$$

One cannot rule out the possibility that the electrocatalytic carboxylation of olefins in alcohols in the presence of platinum complexes proceeds, as postulated by Inoue and Tsutsumi,[22] with formation of a platinum-carboxylic acid ester, while the electro-chemical reduction of carbon dioxide at a platinum electrode results in the formation of the $[Pt]CO_2H$ fragment.[23] A reaction mechanism involving stages with participation of metal-carboxylic acids has been proposed for the electrocatalytic reduction of CO_2 to carbon monoxide in the presence of cobalt and nickel complexes:[24]



$$[LM^{III}CO_2Na]^{n+} + H_2O \overset{fast}{\rightleftarrows} [LM^{III}CO_2H]^{n+} + NaOH ,$$
$$[LM^{III}CO_2H]^{n+} + e \rightarrow [LM^{II}CO_2H]^{(n-1)+} ,$$
$$[LM^{II}CO_2H]^{(n-1)+} \xrightarrow{slow} [LM^{II}]^{n+} + CO + OH^- .$$

where M is the metal and L an N-containing ligand.

In connection with this study, one should note that much attention has been devoted recently to the investigation of the reactions involving the oxidation of CO by water in the presence of transition metal complexes:[25-32]

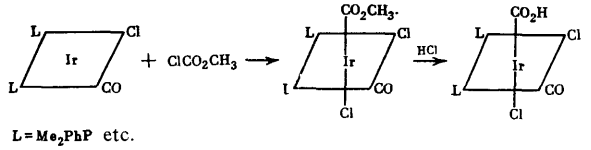
$$CO_2 + H_2O \overset{[M]}{\rightleftarrows} H_2 + CO_2 .$$

This reaction takes place via a general mechanism involving as one of the stages the formation of an unstable metal-carboxylic acid[31] (see also Vol'pin and Kolomnikov[25] and the literature quoted therein):

There is no doubt that metal-carboxylic acids or their esters are formed in all the reactions quoted above, although the transfer of the carboxy-group to the olefin remains in many respects obscure. Therefore the synthesis and study of the properties of metal-carboxylic acids and their derivatives will promote in many ways the elucidation of this complex process.

A fair amount of attention has also been devoted in the literature to the synthesis of carbamoyl compounds of transition metals (metal-carboxylic acid amides), which are intermediates in catalytic processes.[8] The synthesis of metal-carboxylic amides and the study of their properties are of undoubted interest for the understanding of the mechanism of carbonylation of amines in the presence of transition metal complexes.[33,34]

To conclude this, by no means complete, list of reactions in which the formation of metal-carboxylic acids and their derivatives as intermediates plays a major role, one must emphasise the importance of the chemistry of these compounds, because they constitute an independent class of organometallic compounds. Syntheses based on them extend the possibilities of coordination and organometallic chemistry. On the other hand, platinum(or gold)-carboxylic acids and their derivatives can be of interest from the practical point of view as antitumour medicinal preparations.[35]



II. METAL-CARBOXYLIC ACIDS

1. Stable Metal-carboxylic Acids

Although the intermediate formation of MCA is frequently postulated, their preparation in a pure state involves considerable difficulties. The number of stable metal-carboxylic acids described in the literature is small. The synthesis of such acids would make it possible to obtain their various derivatives by analogy with the chemistry of carboxylic acids. On the other hand, as already mentioned above, metal-carboxylic acids are of great interest for preparative coordination chemistry, because specific synthesis of transition metal complexes with carbon dioxide via the following pathways is possible with their aid:

$$[M]OH + [M']CO_2H \rightarrow [M']CO_2[M] + H_2O\ ,$$
$$[M]HCO_3\ (\text{or}\ [M]_2CO_3) + [M']CO_2H \rightarrow [M']CO_2[M] + CO_2 + H_2O\ .$$

A stable metal-carboxylic acid was first described in 1969:[36]

L = Me_2PhP etc.

According to the data of these workers, the iridium-carboxylic acid is formed as colourless crystals stable in air. The IR spectrum of the resulting compound contains the intense ν(CO) = 1663 cm^{-1} (KBr) absorption band as well as the distinct ν(OH) = 3313 cm^{-1} (dry deuteriochloroform) absorption band. Titration of the iridium-carboxylic acid in aqueous acetone after the addition of one equivalent of alkali led to the observation of the evolution of carbon dioxide and the formation of the initial complex $L_2Ir(CO)Cl$. Carbon dioxide is also evolved on thermolysis of the acid with formation of the iridium hydride complex $L_2Ir(CO)HCl_2$.

The question of the formation of an iridium-carboxylic acid on hydrolysis of the complex $L_2Ir(CO)Cl_2(COOCH_3)$ has been investigated using the methods proposed by Deeming and Shaw;[36] when gaseous HCl is passed through a benzene solution of the iridium-carboxylic acid ester, only a mixture of the acid with the initial ester can be isolated from the reaction mixture in all cases.[37] The lack of information about this acid in later literature is probably associated with this finding.

Iridium-carboxylic acids of the above type have also been obtained on treating phosphine complexes of tervalent iridium with formic acid.[38] However, in view of the insignificant yields of the acids, this procedure cannot be regarded as preparative.

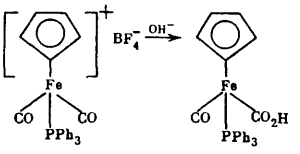
The preparation of a platinum-carboxylic acid via the mechanism

$$\text{dppe}\,Pt(R)OH + CO \rightarrow \text{dppe}\,Pt(R)CO_2H$$
$$R = Me,\ C_6H_5;\ \text{dppe} = Ph_2PCH_2CH_2PPh_2$$

has been reported.[39] However, this communication contains no data on IR spectroscopy, elemental analysis, etc. Analogous platinum-carboxylic acids were obtained later: $(Ph_2PCH=CHPPh_2)Pt(CO_2H).(CH_3CN)$ with m.p. 177–179 °C [ν(OCO) = 1604 cm^{-1} (v.s.) and ν(OH) = 2680 cm^{-1} (v.w.)] and $(Ph_2PCH=CHPPh_2)Pt(CO_2H).(CH_3CF_3)$ with m.p. 188–190 °C [ν(OCO) = 1610 cm^{-1} (v.s.) and ν(OH) = 2685 cm^{-1} (v.w.)].[40] The platinum-carboxylic acid *trans*-$(Et_3P)_2Pt(CO_2H)Cl$, which is unstable in air, has been obtained recently by treating the cationic complex $[(Et_3P)_2Pt(Cl)CO][BF_4]$ with water;[41] the IR spectrum contains the ν(OCO) = 1595 cm^{-1} (v.s.) and 1150 (s.) as well as the ν(OH) = 3140 cm^{-1} (v.w.) absorption bands; the last band shifts to ν(OD) = 2240 cm^{-1} (v.w.) when hydrogen is replaced by deuterium. According to NMR data, the spin–spin coupling constant $J^{195}_{Pt-^{13}C}$ = 1337. It is noteworthy that this method of synthesis of metal-carboxylic acid is the easiest among all those available.

The comparatively stable rhenium-carboxylic acid of the type η^5-CpRe(CO)(NO)COOH has been obtained by treating the cationic complex $[\eta^5\text{-CpRe(CO)NO}]^+$ with aqueous solutions of triethylamine or alkali.[42–44]

The rhenium-carboxylic acid is quantitatively converted into the hydride complex CpRe(CO)(NO)H in absolute tetrahydrofuran (THF). The IR spectrum of the acid in THF contains the 2960 (s., br.) and 1631 (m.) absorption bands, while the ^1H NMR ($CDCl_3$) spectrum contains the δ = 9.47 p.p.m. signal. According to Sweet and Graham,[43] the interaction of a dialkylamine with the rhenium-carboxylic acid in solution results in the formation of the metal complex of carbon dioxide:



$$[Re]COOH + R_2NH \rightarrow [Re]COO^- \ldots H_2NR_2^+\ ,$$
$$[Re]COO^- \rightarrow [Re] + CO_2\ .$$

A rhenium-carboxylic acid of the type $CpRe(CO)(N_2Ar)COOH$ has been obtained recently.[45] The authors failed to observe the ν(OH) frequency both in fluorinated oil and in CH_2Cl_2. However, on treatment with NaOD in D_2O the exchange of hydrogen for deuterium was observed—an absorption band at 2240 cm^{-1} appeared in the IR spectrum.

The rhenium complexes $[\eta^5\text{-CpRe(CO)}_2(p\text{-N}_2C_6H_4R)COOH]$, where R = Me, OMe, or NEt_2, have been obtained in the same way, i.e. by treating cationic rhenium complexes with alkali.[45] A band with δ = 8.9 p.p.m., corresponding to the proton in the carboxy-group, has been observed in the ^1H NMR ($CDCl_3$) spectrum. The IR spectrum (CH_2Cl_2) also contains absorption bands at 1954 (v.s.), 1643 (v.s.), and 1596 (v.s.) cm^{-1}. A rhenium hydride complex as well as $[CpRe(CO)_2(N_2Ar)(CO_2^-)]$ are formed in the presence of an excess of alkali as a consequence of the deprotonation of the metal-carboxylic acid. After the irradiation of rhenium carbonyl with UV light in THF in the presence of cyclo-octatetraene, an insignificant amount of a trirhenium-carboxylic acid having the composition $Re_3(CO)_{14}CO_2H$ was detected among the reaction products.[46] The colourless "$Re(CO)_5OH$" complex, which becomes coloured in the light, has been obtained in a quantitative yield by treating the

cationic complex $(CO)_5ReBF_4$ with alkali.[47] Subsequently, this intermediate, which may be a rhenium-carboxylic acid, is converted into a rhenium complex of carbon dioxide. In comparing the results of the synthesis of the rhenium-carboxylic acid obtained by different workers, one must note that the spectroscopic data for the identification of the rhenium-carboxylic acid quoted by Casey et al.[42] agree qualitatively with the spectroscopic data for the rhenium complex of carbon dioxide.[47] It has therefore been suggested[47] that the adduct having the composition "$(CO)_5ReOH$" is the protonated form of the rhenium complex of carbon dioxide formed ultimately: "$(CO)_5$. .ReOH" $\leftrightarrows$ $(CO)_4ReCO_2H$.

There are also literature data concerning the synthesis of stable iron-carboxylic acids.[48] Thus the interaction of aqueous solutions of alkalies with cationic iron complexes made it possible to obtain an iron-carboxylic acid in a pure state:

The compound synthesised is a yellow substance, fairly stable in the presence of atmospheric oxygen, which decomposes on heating above 130 °C. The IR spectrum contains the ν(OCO) = 1565 (m.) and 2700 (m.) cm^{-1} absorption bands. Treatment of the iron-carboxylic acid with potassium hydroxide leads to the formation of the corresponding potassium salt, which can be converted into the iron-carboxylic acid on acidification with hydrochloric acid.

2. Unstable Metal-carboxylic Acids

As can be seen from the foregoing, the problem of the synthesis in one way or another of stable metal-carboxylic acids has been solved in principle, which made it possible to investigate their chemical and physicochemical properties. On the other hand, the hypotheses concerning the existence of unstable metal-carboxylic acids as intermediates had been put forward even earlier. Studies in which the formation of unstable metal-carboxylic acids as intermediates has been claimed can be divided into two groups:

(a) Oxidation of carbon monoxide with water in the presence of transition metal salts. Only hypotheses concerning the formation of metal-carboxylic acids in one of the stages were put forward in these investigations.

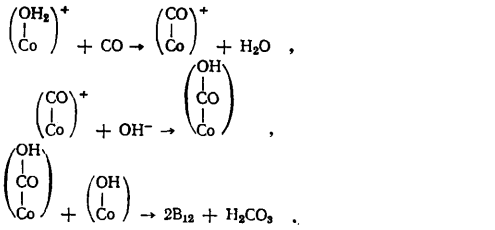
(b) The formation of metal-carboxylic acids in the presence of ligands stabilising the metal–carbon σ-bond, such as CO, phosphines, cyclopentadiene (Cp), and others. Under these conditions, it is sometimes possible to obtain an unstable metal-carboxylic acid or at least to achieve the confirmation of its formation by spectroscopic methods.

The existence of metal-carboxylic acids in aqueous solutions was first reported in 1961.[49,50] The authors suggested the formation of a mercury-carboxylic acid as one of the stages in the oxidation of carbon monoxide by water in the presence of mercury salts:[49]

$$Hg^{2+}OH_2 + CO \rightarrow [-Hg-\overset{\overset{O}{\|}}{C}-OH] + H^+ .$$

By analogy with this reaction, the formation of carbon dioxide and hydrogen when carbon monoxide is passed through a solution of univalent thallium hydroxide permitted the conclusion that unstable thallium-carboxylic acid is formed in aqueous solution:[51]

$$TlOH + CO \rightarrow [TlCO_2H] .$$



It is also stated in the literature that nickel-carboxylic,[48] silver-carboxylic,[50], and copper-carboxylic[52] acids are formed under analogous conditions. It has been shown in relation to iron-carboxylic acids that the nature of the ligand determines in many respects the stability of these derivatives.[48] The formation of unstable iron-carboxylic acids has also been indicated in other investigations.[53,54] When a cationic platinum complex was treated with water, a platinum hydride complex was obtained as an intermediate.[55] The authors suggest that the reaction proceeds via the formation of a platinum-carboxylic acid:

$$[(Et_3P)_2Pt(Cl)CO]BF_4 \xrightarrow[-HBF_4]{H_2O} [(Et_3P)_2Pt(Cl)CO_2H] \rightarrow [(Et_3P)_2Pt(Cl)H] + CO_2 .$$

The interaction of carbon monoxide with water in the presence of phosphine complexes of zerovalent platinum has been studied in fair detail.[26] The complex $[(iso\text{-}Pr)_3P]_3Pt$ proved to be the most active in this process; a hydroxoplatinum complex is formed on treatment with water in the course of the reaction and interacts further with carbon monoxide, being converted into a platinum-carboxylic acid [ν(OCO) = 1575 cm^{-1}].

There are data on the synthesis of unstable manganese- and rhenium-carboxylic acids on interaction of water with the corresponding metal carbonyl derivatives.[56,57] Derivatives labelled with ^{13}C and ^{18}O were used to identify the intermediates in spectroscopic studies.[57] For example, the interaction of the cationic manganese complex $[dppeMn(CO)_4]^+$ (see Table 1 below) with $H_2{}^{18}O$ results in the formation of the manganese-carboxylic acid $dppeMn(CO)_3.CO^{18}OH$ according to spectroscopic data.

Much attention has been devoted in the literature to the formation of cobalt-carboxylic acids in connection with the modelling of the reactions of vitamin B_{12} by various cobalt chelate complexes.[1,56] Thus the formation of a unstable cobalt-carboxylic acid can be represented schematically in the following way:[58]

The study of processes involving the oxidation of $[Co^I(CN)_2(Et_3P)_2.CO]^-$ by hexacyanoferrate(III) $[Fe(CN)_6]^{3-}$ led to the conclusion that the unstable cobalt-carboxylic acid $[(CN)_5Fe^{II}CNCo^{III}(CN)_2(Et_3P)_2.CO_2H]^{4-}$ is formed in solution.[59]

The formation of unstable rhodium-, iridium- and platinum-carboxylic acids has been postulated in the synthesis by indirect methods of transition metal complexes of carbon dioxide involving treatment of the corresponding hydroxo-complexes of the transition metals with carbon monoxide.[60–63] Thus a familiar carbon dioxide complex has been obtained from the complex $(Ph_3P)_2Rh(CO)OH$:[63]

$$(Ph_3P)_2Rh(CO)OH \xrightarrow{CO+C_6H_6} [(Ph_3P)_2Rh(CO)CO_2H] \rightarrow (Ph_3P)_3Rh_2(CO)_2 \cdot CO_2 \cdot C_6H_6 .$$

The formation of unstable rhodium-carboxylic acids has also been indicated in other communications.[64,65]

An unstable palladium-carboxylic acid is apparently formed on carboxylation of aromatic compounds to the corresponding acids with the aid of palladium acetate in a mixture of glacial acetic acid and its anhydride.[20,21] In this connection, we may note that numerous reactions involving the oxidation of carbon monoxide by water to CO_2 in the presence of palladium salts also probably proceed with formation of a palladium-carboxylic acid.[20]

The synthesis of metal-carboxylic acids from CO_2 and transition metal hydride complexes is a fundamentally new procedure.[1,66] Thus, when a cobalt hydride complex is treated with carbon dioxide, an "anomalous" insertion of a CO_2 molecule in the CO–H bond takes place with formation of an unstable cobalt-carboxylic acid, which was identified by means of chemical reactions.[66]

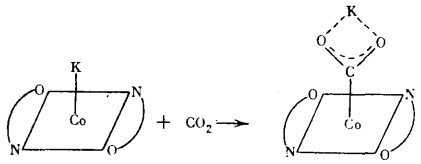
**Characterised by X-ray diffraction.

***The esters of cobalt-carboxylic acids with other *N*-containing ligands have also been obtained.

****Other esters of rhodium-carboxylic acids of the type $[Rh(NO).(Ph_3P)_2(ROH)CO_2R]^+$ as well as rhodium clusters of the type $[Rh_6(CO)_{14}(CO_2Me)_2]^{2-}$ have also been obtained.

Data on the synthesis of a fairly stable chromium-carboxylic acid on radiolysis of tervalent chromium salts in the presence of formic acid in aqueous solutions are also of fundamental importance:[67]

$$[\cdot COOH] + [Cr^{3+}] \rightarrow [CrCO_2H]^{3+},$$



The radical-anion CO_2^- is apparently formed under these conditions and can be stabilised at the metallic centre with subsequent protonation to .COOH. A titanium-carboxylic acid may be formed under analogous conditions.[1] These results are important for the

understanding of the mechanism of the reduction of carbon dioxide to organic compounds in aqueous solutions in the presence of transition metal compounds.

III. METAL-CARBOXYLIC ACID SALTS AND POLYNUCLEAR TRANSITION METAL COMPLEXES OF CARBON DIOXIDE

As already mentioned above, treatment of a platinum-carboxylic acid with potassium hydroxide can yield an equivalent amount of the potassium salt of the platinum-carboxylic acid,[26] which has been characterised by IR and NMR spectroscopic methods.

There have been reports of attempts to obtain salts of metal-carboxylic acids by inserting carbon dioxide in the transition metal–alkali metal (or alkaline earth metal) bond. Thus treatment of the organometallic analogue of a Grignard reagent $C_6H_5(Ph_3P)NiMgBr$ with CO_2 results in the formation of the unstable $Cp(Ph_3P)NiCO_2.MgBr$, the complex $Cp_2Ni(CO)_2$ being formed as the final product on hydrolysis.[68] When carbon dioxide was passed through a solution of the potassium salts of complexes of the type $K(Co)(Salen)_2$ (where Salen = silicylidene-ethylenediamine), the insertion of a CO_2 molecule in the cobalt–potassium bond was observed:[69,70]

When sodium salts of manganese and rhenium hydride carbonyls are treated with carbon dioxide, a CO_2 molecule is also inserted in the transition metal–sodium bond.[71] The product of the interaction of carbon dioxide with the sodium salt of the rhenium compound was then characterised spectroscopically and with the aid of chemical reactions as the sodium salt of a rhenium-carboxylic acid. However, in the light of latest data concerning the synthesis of trirhenium-carboxylic acids,[46,47] further studies on these lines are essential in order to elucidate the question whether or not the compound obtained by Lysak et al.[71] is a rhenium cluster with CO_2.

It has been shown recently that carbon dioxide can be inserted also in the iron–magnesium bond:[72]

$$[(\eta\text{-CpFe(CO)}_2]_2Mg + CO_2 \rightarrow [(\eta\text{-Cp})(CO)_2FeCO_2]_2Mg\,.$$

Alkylation of this salt with methyl iodide yielded the methyl ester of the iron-carboxylic acid.

When aluminium halides interact with the iridium-carboxylic acid ester $(Ph_3P)_2Ir(CO)_2CO_2Me$ in the presence of traces of moisture, a complex of carbon dioxide coordinated simultaneously to iridium and aluminium atoms is formed.[73,74] It has been shown that carbon dioxide is displaced from this compound by triphenylphosphine and carbon monoxide and that, following the replacement of $^{12}CO_2$ by $^{13}CO_2$, the 1725, 1375, and 1220 cm^{-1} bands are displaced to 1700, 1340, and 1210 cm^{-1} respectively.

Overall, the study of reactions in which compounds of CO_2 coordinated to a transition metal atom and to alkali or alkaline earth metals are formed is important for the solution of problems associated with the introduction of CO_2 molecules into catalytic processes (bifunctional catalysis).[75–77]

Considerable difficulties arise in the interpretation of experimental data concerning the nature of these products. It has been shown by X-ray diffraction that the product of the insertion of the CO_2 molecule in the cobalt–potassium bond is in reality not a salt of a cobalt-carboxylic acid but a complex of carbon dioxide.[70] On the other hand, the insertion of a CO_2 molecule in the rhenium–sodium bond is irreversible. Depending on the nature of the metal and the ligand, one can probably expect the formation of metal-carboxylic acid salts in some cases and of transition metal complexes of carbon dioxide in others.

One can assume that the formation of metal-carboxylic acids on interaction of hydroxo-complexes with carbon dioxide can lead to the formation of transition metal complexes of carbon dioxide, for example via the mechanism

$$[M]OH + [M']CO_2H \rightarrow [M']CO_2[M] + H_2O$$

In this case the dinuclear (polynuclear) complexes formed can be regarded as derivatives (salts) of the corresponding metal-carboxylic acids. Indeed, it has been found that the interaction of carbon monoxide with the hydroxorhodium complex $(Ph_3P)_2Rh(CO)OH$ leads to the formation of a rhodium complex of carbon dioxide: $(Ph_3P)_3Rh_2(CO)_2CO_2C_6H_6$.[63] Analogous reactions occur also when hydroxo-complexes of transition metals, namely $[Me_3PtOH]_4$, $(Ph_3P)_2Ir(CO)OH$, etc., are treated with carbon monoxide.[60–62] The formation of the rhenium complex of carbon dioxide $(CO)_5ReCO_2.[Re(CO)_4]_2$ also probably proceeds via the formation of an unstable rhenium-carboxylic acid.[47] The IR spectrum of the resulting compound contains absorption bands characteristic of transition metal complexes of CO_2 [1458 (s.), 1165 (br.), and 1150 (s.) cm^{-1}]. According to X-ray diffraction data, the CO_2 molecule is coordinated to three metal atoms. We may note that the IR spectra of metal-carboxylic acids usually contain one ν(CO) absorption band, while in the case of carbon dioxide complexes the spectra show three absorption bands.[1,2] The data of Casey et al.,[42] demonstrating that the IR spectrum (nujol) of the rhenium-carboxylic acid $CpRe(CO)(NO)CO_2H$ which they obtained contains three intense absorption bands near 1585 (s.), 1145 (s.), and 1135 (s.) cm^{-1}, correspond better to a rhenium complex of carbon dioxide, although they observed also absorption bands corresponding to the vibrations of the hydroxy-group near 2960 (w.), 2860 (w.), 2705 (w.), and 2690 (w.) cm^{-1}.

The ruthenium and osmium complexes of carbon dioxide are probably formed on treatment of the corresponding metal carbonyls with alkalies also via the intermediate formation of metal-carboxylic acids.[78,79] According to X-ray diffraction data, the CO_2 molecule in the osmium complex $[HOs_3(CO)_{10}CO_2Os_6(CO)_{17}]^-$ is linked to three metal atoms.[79]

IV. ESTERS OF METAL-CARBOXYLIC ACIDS (ALKOXY-CARBONYL COMPLEXES OF TRANSITION METALS)

1. Synthesis

The most widely used and convenient methods from the preparative point of view are as follows:[8]

(1) Treatment of the carbonyl group coordinated to the metal with solutions of alkalies in alcohol:

$$[M]CO + OR^- \rightarrow \{[M]CO_2R\}^-\,,$$

Treatment of cationic complexes of metal carbonyl derivatives with alcohols is a modification of this method.

(2) Treatment of halogeno-derivatives of transition metal complexes with alcoholic alkalies in the presence of carbon monoxide, for example:

$$(Ph_3P)_2PtCl_2 + CO + NaOH/ROH \rightarrow (Ph_3P)_2Pt(CO_2R)_2\,,$$

Treatment of alkoxo-complexes of transition metals directly with carbon monoxide leads to the same results.

(3) Exchange reactions between chloroformic acid esters and transition metal hydride salts, for example:

$$NaMn(CO)_5 + ClCO_2CH_3 \rightarrow (CO)_5MnCO_2CH_3 .$$

(4) Reactions involving the oxidative addition of chloroformic acid esters to transition metal complexes, for example:

$$(Ph_3P)_3Pt + ClCO_2R \rightarrow (Ph_3P)_2Pt(Cl)CO_2R .$$

(5) Treatment of transition metal isocyanate complexes with carbon monoxide and alcohol:

$$(Ph_3P)_2Pd(NCO)_2 \xrightarrow{ROH;CO} (Ph_3P)_2Pd(CO_2R)_2 ,$$

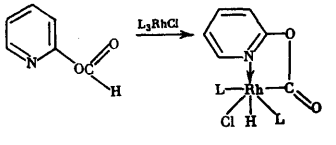
(6) Alkylation of metal-carboxylic acid salts:[72]

$$[(\eta\text{-Cp})Fe(CO)_2CO_2]_2Mg + CH_3I \rightarrow (\eta\text{-Cp})Fe(CO)_2CO_2CH_3 .$$

(7) Transfer of the CO_2R group from an organomercury derivative to a transition metal complex via the oxidative addition mechanism:[80,81]

$$(Ph_3P)_4Pd + ClHgCO_2R \rightarrow (Ph_3P)_2Pd(Cl)CO_2R + Hg .$$

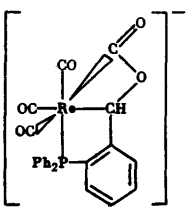
(8) Direct action of carbon dioxide on transition metal complexes containing a metal–carbon σ-bond:[82]



$$M^{\delta-}—R^{\delta+} + CO_2 \rightarrow MCO_2R .$$

(9) Esters of metal-carboxylic acids can be obtained also by esterifying the carbamoyl complexes of transition metals. Table 1 lists the metal-carboxylic acid esters described in the literature.

Esters of metal-carboxylic acids are also formed on decomposition of keto-acids in solution or on their thermolysis:[130]



$$(Ph_3P)_2Pd(Cl)COCO_2R \rightarrow (Ph_3P)_2Pd(Cl)CO_2R + CO .$$

Yet another method of synthesis of metal-carboxylic acid esters is *ortho*-metallation. Thus the interaction of α-pyridyl formate with the complex $[Rh(Ph_3P)_3Cl]$ can yield the ester of a rhodium-carboxylic acid:

The disproportionation of CpRe(CO)(NO)CHO results in the formation of the complex $Cp(CO)(NO)ReCO_2CH_2Re(CO)(NO)Cp$, which can be regarded as a rhenium-carboxylic acid ester.[132] Treatment of the ester with methanol results in the formation of CpRe.(CO)(NO)CO_2Me (m.p. 105–115 °C; IR spectrum: 1626 and 1010 cm^{-1} in nujol).

A rhenium-carboxylic acid ester has been obtained to which the following structure was attributed on the basis of IR and ^1H NMR spectroscopic data:[133]

After alkylating an iridium complex of carbon dioxide with $MeSO_3F$, the methyl ester of an iridium-carboxylic acid was isolated:[110]

$$(dmpe)_2Ir(Cl)CO_2 + MeSO_3F \rightarrow [(dmpe)_2Ir(Cl)CO_2Me][SO_3F],$$

dmpe = dimethylphosphinoethane

The IR spectrum contains absorption bands at 1630 and 1065 cm^{-1}.

2. Investigation by Physicochemical Methods

As can be seen from Table 1, the IR spectroscopic method yields an extremely large amount of information in the study of metal-carboxylic acid esters. The MCA esters have characteristic absorption bands, as a rule with appreciable intensity, corresponding to the ν(OCO) frequencies of the ester group in the range 1600–1700 cm^{-1} and the ν(OR) frequencies in the range 1000–1070 cm^{-1}. A fairly large number of metal-carboxylic acid esters, which cannot be isolated as pure compounds from the reaction mixture, were characterised by this method.

There exist also data obtained by investigating metal-carboxylic acid esters in solutions by UV spectroscopy. Thus studies have been made of the UV spectra of complexes of the type $(Ph_3P)_2Pt(Cl)CO_2.CH_2R$, where R = H, Me, or Ph.[123] The following values of 10^{-4} ε (λ_{max}, nm) were found for R = H: 2.3 (257); 1.6 (268); 1.1 (275). The corresponding values for the ethyl and benzyl esters are close to those for the methyl ester.

The ^1H NMR method is used widely for the identification of metal-carboxylic esters. Data obtained by determining the dipole moments permitted the conclusion that platinum-dicarboxylic acid esters of the type $(Ph_3P)_2Pt(CO_2Me)_2$ have the *trans*-structure.[118]

It is noteworthy that metal-carboxylic acid esters are the *C*-isomers of the corresponding carboxylate complexes of transition metals (*O*-isomers),[134] for example: $Hg(CO_2R)_2$ and $Hg(OCOR)_2$; $(CO)_5ReCO_2R$ and $(CO)_5ReOCOR$; $(Ph_3P)_2Pt(CO_2R)_2$ and $(Ph_3P)_2.Pt(OCOR)_2$; $(Ph_3P)_2Pd(CO_2R)_2$ and $(Ph_3P)_2Pd(OCOR)_2$. The method of X-ray electron spectroscopy has been applied successfully in the solution of the problem of the mode of coordination of carbon dioxide in the complex $(Ph_3P)_2PtCO_2$.[135]

Table 2 lists the bond lengths in metal-carboxylic acid esters determined by X-ray diffraction.

Table 2. X-Ray diffraction data for metal-carboxylic acid esters.

Compound	Bond length, Å			O–C–O angle, deg	Refs.
	M–C	C=O	C–O		
$ClHgCO_2Me$	1.96	1.24	1.26	114	[136]
trans-$(Ph_3P)_2Pt(CO_2Et)_2$	2.059 (7)	1.228 (7)	1.351 (7)	119.5 (6)	[137]
$[(dmpe)_2Ir(Cl)CO_2Me][FSO_3]$	2.073 (8)	1.151 (10)	1.366 (10)	123.0 (8)	[110]

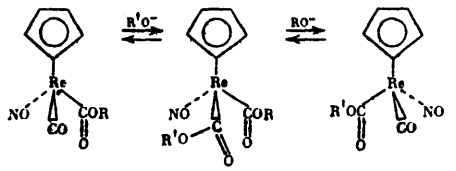
$HOs_3C(CO)_{14}CO_2Et$	2.028 (15)	1.28 (2)	1.34 (3)	—	[94]
$IOs_3C(CO)_{14}CO_2Me$	2.02 (4)	1.28 (5)	1.29 (5)	—	[94]
$[Rh_6(CO)_{15}CO_2Me]^-$	1.96 (2)	1.18 (3)	1.31 (3)	109.2	[139]

3. Reactions



(a) Transesterification. One of the widely investigated reactions of metal-carboxylic acid esters is transesterification:

$$[M]CO_2R + R'OH \rightleftarrows [M]CO_2R' + ROH .$$

It has been shown for an iron-carboxylic acid ester that the ease of this reaction is due to the existence in solution of the equilibrium:[42]

$$Cp(Ph_3P)Fe(CO)CO_2Me \rightleftarrows Cp(Ph_3P)Fe(CO)_2^+ + OMe^- .$$

The existence of such equilibrium has been confirmed by IR and ^1H NMR spectroscopic methods. The compound $CpFe(CO)(Ph_3P).CO_2Me$ [ν(OCO) = 1630 cm^{-1}] has been obtained in an optically inactive form by the transesterification of the (-)$CpFe(CO)(Ph_3P).CO_2C_{10}H_{19}$ [ν(OCO) = 1615 cm^{-1}] diastereoisomers with methyl alcohol.[140] The following mechanism has been proposed for the transesterification of rhenium-carboxylic acid esters:[132]

The interaction of the allyl alcohols $H_2C=C(R)CH_2OH$ with the methyl ester of an iridium-carboxylic acid leads to the formation of cyclic esters of the type $(Ph_3P)_2COIrCO_2CH_2C(R)=CH_2$ as a result of transesterification (Table 1).

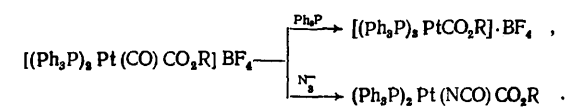
Metal-carboxylic acid esters are formed readily also when carbamoyl complexes of transition metals are treated with alcohols, which can also be regarded as a method of their synthesis. On the other hand, when metal-carboxylic acid esters are treated with amines, the reverse reaction is observed, i.e. metal-carboxylic acid esters are formed.[141,142]

(b) Reactions with alkyl halides. When metal-carboxylic acid esters interact with alkyl halides, the corresponding new esters are formed:[82]

$$[M]CO_2R + R'X \rightarrow R'CO_2R + [M]X .$$

(c) Interaction with acids. In acid hydrolysis of the esters, one observes as a rule the decomposition of the metal-carboxylic ester to the corresponding alcohol and carbon monoxide. As mentioned above, an iridium-carboxylic acid may be obtained by treating the iridium-carboxylic acid $(Me_2PhP)_2Ir(CO)Cl_2(CO_2Me)$ with hydrogen chloride.[36]

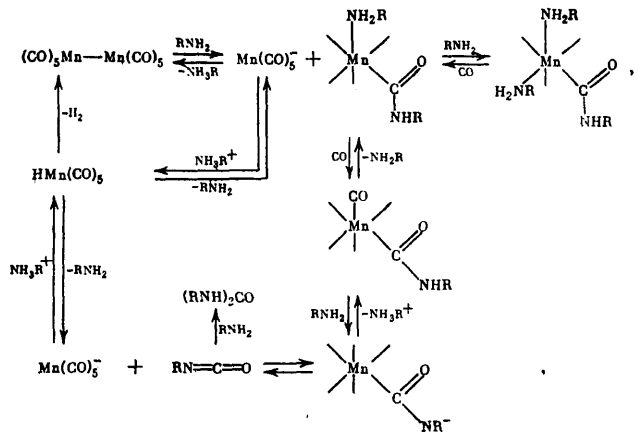
The reactions of cationic complexes with the various reagents, leading to the formation of metal-carboxylic acid esters, have been briefly characterised.[117]



(d) Hydrolysis. When metal-carboxylic acid esters interact with water, carbon dioxide is evolved and a hydride complex is formed. This reaction probably proceeds via the intermediate formation of a metal-carboxylic acid:[143]

$$(Ph_3P)_2Pt(Cl)CO_2R + H_2O \rightarrow [(Ph_3P)_2Pt(Cl)CO_2H] \rightarrow (Ph_3P)_2Pt(H)Cl + CO_2 .$$

(e) Thermal decomposition. Carbon dioxide is evolved in the thermolysis of the methyl ester of an iridium-carboxylic acid and an iridium hydride complex is formed:[36]



$$(Me_2PhP)_2Ir(CO)Cl_2(CO_2Me) \rightarrow (Me_2PhP)_2Ir(CO)(H)Cl_2 + CO_2 .$$

(f) Other reactions. Among other reactions, the interaction of cationic complexes containing the CO_2R group various reagents, leading to the substitution or modification of the ligand, is of some interest:[117]

V. AMIDES OF METAL-CARBOXYLIC ACID (CARBAMOYL COMPLEXES OF TRANSITION METALS)

As already mentioned above, the formation of MCA amides as intermediates is observed in the reactions involving the carbonylation of amines by carbon monoxide in the presence of catalysts. According to Dombek and Angelici,[144] the mechanism of this reaction can be represented schematically in the following manner:

The study of the carbonylation of amines in the presence of iron[145,146] and manganese[144] carbonyls led to the conclusion that the corresponding carbamoyl derivatives are formed in the course of the process, for example, *cis*-$Mn(CO)_4(NH_2R)CONHR$ on carbonylation of n-butylamine.[144] A series of amides of a nickel-carboxylic acid (carbamoyl derivatives) having the general formula $(PNP)Ni(Cl).CONHR$, where PNP is the ligand and R = Ph, *p*-MeC_6H_4, *p*-ClC_6H_4, n-Bu, etc., have been obtained in a study of the carbonylation of amines with carbon monoxide in the presence of nickel chloride and 2,6-bis(diphenylphosphinomethyl)pyridine (PNP) as the ligand.[147]

The alkoxycarbonylation reactions of the amines probably proceed via the intermediate formation of carbamoyl complexes.[148,149]

1. Methods of Synthesis of Metal-carboxylic Acid Amides

The general methods of synthesis of MCA amides (carbamoyl complexes of transition metals) have been described.[8,142] Among the methods of preparation of carbamoyl derivatives, the following may be noted:

(1) Exchange reactions of the type

$$(CO)_nMnNa + ClCONR_2 \rightarrow (CO)_nMnCONR_2 + NaCl .$$

(2) Oxidative addition reactions:

$$(Ph_3P)_3Pd + ClCONR_2 \rightarrow (Ph_3P)_2Pd(Cl)CONR_2 + Ph_3P .$$

(3) Syntheses via mercury-carboxylic acid amides[80] of the oxidative addition type.

(4) Interaction of metal carbonyls or their derivatives with primary and secondary amines:

$$Mn(CO)_5+RNH_2\rightarrow Mn(CO)_4(CONHR)(RNH_2) \text{ etc.}$$

In terms of their reactivity, metal carbonyls can be divided into three groups.[8] It was found that the reactivity can be related to the M–CO bond force constant, which can be obtained from spectroscopic data. Such correlation permits the prediction of the course of these reactions via one pathway or another: the formation of stable carbamoyl complexes, the establishment of equilibrium, and, finally, the absence of any interaction.

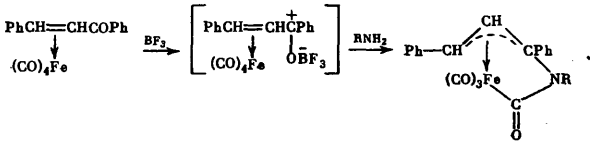
(5) Interaction of cationic complexes of transition metals with NaNRR′, isocyanates or quaternary ammonium salts.[142]

(6) Aminolysis of metal-carboxylic acid esters. The rate of this reaction diminishes with increase in the size of the group at the nitrogen atom:[142] $MeNH_2 \gg EtNH_2 \gg Me_2NH > Me(CH_2)_3NH_2 > Me_2CHNH_2 \geqslant Me_3CNH_2$.

(7) Insertion of alkyl isocyanates in a metal–hydrogen bond, for example:

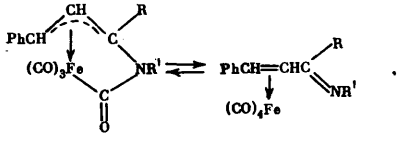
$$CpFe(CO)_2H+MeNCO\rightarrow CpFe(CO)_2CONHMe \ .$$

(8) Interaction of isonitrile complexes of transition metals with alkalies:[150]



$$(Ph_3P)_3Pt(CNMe)_2^{2+}+OH^-\rightarrow(Ph_3P)_2Pt(CNMe)CONHMe^+ \ .$$

(9) Insertion of carbon monoxide in the $M-NR_2$ bond. This reaction proceeds under mild conditions in the case of coordination compounds of the actinides:[151]



$$M(\eta\text{-}C_5Me_5)_2NR_2(Cl)+CO\rightarrow M(\eta\text{-}C_5Me_5)_2(\eta^2\text{-}CONR_2)Cl \ .$$

The reaction is extremely important as one of the stages in the carbonylation of amines by carbon monoxide in the presence of catalysts.

Stable carbamoyl complexes of iron are formed from the adduct of (*C*-chalcone)$Fe(CO)_4$ with boron trifluoride, its formation being followed by treatment with primary amines:[152–154]

The carbamoyl derivatives with the R = Me and C_6H_{11} groups obtained in this way consist of yellow crystals which are extremely stable in air and have distinct melting points. The equilibrium

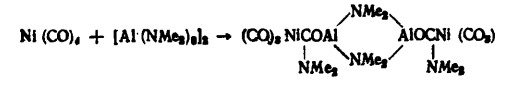
has been investigated by IR spectroscopy.[154] It was shown that, when the group R is large, the equilibrium is displaced to the left, while in the case where the group R′ at the nitrogen atom is large the equilibrium is displaced to the right.

Anionic complexes constitute a special type of compound incorporating the carbamoyl group. Thus the interaction of tetrakis(dimethylamino)methane with iron or nickel carbonyl [155] results in the formation of stable carbamoyl complexes:

$$M(CO)_n+C(NMe_2)_4\rightarrow[C(NMe_2)_3][(CO)_{n-1}MCONMe_2]\xrightarrow{R_2NH}[C(NMe_2)_3][(CO)_{n-1}MCONR_2]$$

M=Fe, Ni

When an anionic iron complex containing the carbamoyl group is treated with a nickel salt, a complex is formed in which the carbamoyl group plays the role of the bridging ligand (η^2-coordination):[156]



$$[C(NMe_2)_4][(CO)_4FeCONR_2]+NiBr_2\rightarrow[(CO)_4FeCONR_2]_2Ni \ .$$

R=Me_2, $(CH_2)_4$, $(CH_2)_5$

The interaction of nickel carbonyl with lithium dimethylamide leads to the formation of a carbamoyl complex of nickel:[157]

$$Ni(CO)_4+LiNMe_2\rightarrow Li[(CO)_3NiCONMe_2] \ .$$

An analogous reaction takes place also between nickel carbonyl and $[Al(NMe_2)_3]_2$ [158] or $Ti(NMe_2)_4$:[159]

The results obtained in the syntheses of stable metal-carboxylic acid amides are summarised in Table 3.

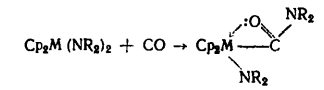
*Characterised by X-ray diffraction analysis.

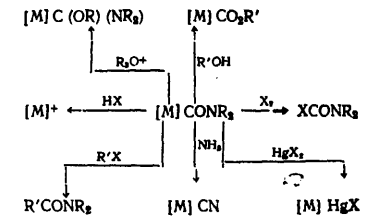
2. Investigation of Metal-Carboxylic Acid Amides by Physicochemical Methods



One of the principal physicochemical methods used to study MCA amides is IR spectroscopy. With the aid of this method, it is possible to identify in most cases the CO and NH groups, although in many instances the identification of the vibration frequencies of the carbonyl group may be difficult owing to the superposition of the broad band due to the deformation vibrations of the NH group.[8] The bands of the carbonyl group are observed over a fairly wide range and are sensitive to the solvent employed in the measurement.[163]

The ^{1}H NMR methods yields much information for the identification of substituents at the nitrogen atom (see, for example, Refs.147, 165, and 179). This method has been used successfully also in the study of the reactions involving the transformation of the carbamoyl group into the amidine group.[163] The signal of the carbon atom of the carbamoyl group can also be identified by NMR. In the case of cobalt-carboxylic acid amides it is located within a fairly wide range of values of δ (183—213 p.p.m).[180]

The mass-spectrometric method has also been used to identify metal-carboxylic amides (see, for example, Angelici and Blacik[168]).



A study in which the structure of the complex $Mn(CO)_4(MeNH_2)$. .CONHMe had been established by X-ray diffraction[8] was for a long time the only structural study available. However, recently X-ray diffraction data have been published on the coordination of the carbamoyl group with other metals. It has been established that the carbamoyl group can function both as a monodentate ligand, for example, in *trans*-$(Et_3P_2)Ni(I)CONEt_2$,[181] and a bidentate ligand. In the latter case, the carbon and oxygen atoms of the carbamoyl group can be linked to a single metal atom, for example, in $(\eta\text{-}C_5Me_5)_2Th$. .$(\eta^2\text{-}CONEt_2)Cl$ [151] or can function as a bridge between two metal atoms as in $HRu_3(CO)_{10}CONMe_2$.[182] It has been noted[151] that on η^2-coordination the C—O bond is lengthened compared with the usual coordination of this group to a metal. The pronounced shortening of the metal—oxygen bond in the uranium complex compared with the uranium—carbon bond was attributed by the authors to the high affinity of uranium for oxygen. Table 4 presents data obtained in X-ray diffraction studies on the carbamoyl complexes.

Clearly the results of X-ray diffraction analysis have posed a number of problems in this field which can be solved with the aid of IR and NMR spectroscopic methods. Indeed, data concerning the mode of coordination of the carbamoyl group can be obtained with the aid of IR spectra. Furthermore, it is apparently possible to estimate by NMR the contribution of a particular structure in the reaction, as shown by Fagan et al.:[151]

3. Reactions of Metal-Carboxylic Acid Amides (Carbamoyl Derivatives)

The chemical reactions of carbamoyl complexes of transition metals have been considered in a review:[8]

The thermal stability of the isostructural iron, ruthenium, and osmium carbamoyls has been investigated.[184] The authors showed that the stability of these compounds increases in the sequence Fe < Ru < Os. A study,[185] in which the interaction of a cationic manganese complex with amines, namely

$$Mn(CO)_4(MeCN)_2^+ + MeNH_2 \rightarrow Mn(CO)_3(CONHMe)(MeCN)_2 ,$$

was investigated, should also be mentioned. It is remarkable that, after a long reaction time, the amidine complex (CO_4). .$\overline{MnC(R'NMeCNHR)}$ is formed; the course of this reaction depends on the nature of the amine.

A comparatively stable carbamoyl complex of nickel, active in the carbonylation reaction, has been obtained recently:[186]

$$(Et_3NH)_2NiI_2 + CO \xrightarrow[THF]{Et_2NH} (Et_2NH)_2Ni(I)CONEt_2$$

It has been suggested that an unstable biscarbamoyl complex of nickel is formed on further treatment of the above compound with CO and Et_2NH.

Other questions associated with the formation and chemical reactions of carbamoyl complexes (metal-carboxylic acid amides) have been examined in reviews[187–189] (see the references therein); in the last study, certain aspects of the formation of alkoxycarbonyl complexes (metal-carboxylic acid esters) are examined in addition.

---o0o---

As can be seen from the present review, metal-carboxylic acids and their derivatives constitute a fairly broad class of organometallic compounds. The interest in the synthesis of these complexes has increased still further in connection with the advances made in the field of the fixation of carbon dioxide in the presence of transition metal compounds. One of the aims of the present review was to attempt to demonstrate as far as possible the relation between these two trends in modern coordination chemistry.

Coordination Compounds of Transition Metals in the Chemistry of Aromatic Nitro-compounds

E.N.Izakovich and M.L.Khidekel'

The catalytic possibilities of coordination compounds of transition metals in the chemistry of aromatic nitro-compounds are discussed. The catalytic (including enzymic) reduction of aromatic nitro-compounds by various reductants, namely molecular hydrogen, alkali metal tetrahydroborates, CO + H_2O and CO + H_2 mixtures, alcohols, secondary amines, etc., is considered. The interaction of aromatic nitro-compounds with transition metal complexes, leading either to complexes containing the aromatic nitro-compound or to reduction products, is discussed. The structures of these complexes are classified. The bibliography includes 236 references.

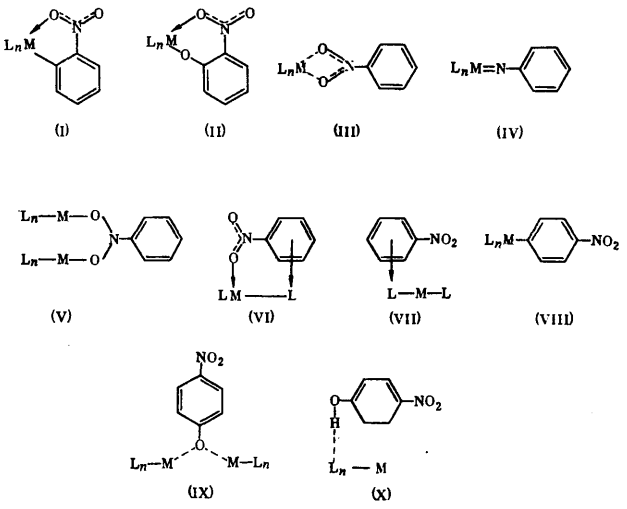
I. INTRODUCTION

The chemistry of aromatic nitro-compounds is one of the traditional branches of organic chemistry in which considerable theoretical and practical advances have been achieved. Methods and technological processes, based on aromatic nitro-compounds, for the preparation of dyes, explosives, and medicinal preparations have been devised, considerable numbers of molecular complexes have been obtained, etc. At the present time an increased interest in compounds of this class has arisen. A characteristic feature in this instance is the invocation of ideas taken from coordination chemistry: the synthesis of new transition metal complexes incorporating aromatic compounds, the use of coordination compounds as catalysts in the reactions of aromatic nitro-compounds, etc. In this connection, it is useful to discuss new aspects arising in the interrelations between the chemistry of aromatic nitro-compounds and coordination chemistry.

Analysis of the literature has shown that the field of metal complex catalysis has been most fully investigated in relation to catalytic reactions such as the carbonylation and reduction of unsaturated hydrocarbons, deuterium–hydrogen exchange, and free-radical chain oxidation of aromatic compounds. The data on the interaction of aromatic nitro-compounds with transition metal complexes are scattered and have not been surveyed and there is no information about the reaction mechanism. Two recent reviews,[1,2] have been devoted to the reductive amination of aromatic nitro-compounds and their carbonylation with carbon monoxide,[1,2] data on their catalytic hydrogenation can be found in Refs.3–9, and those on their reduction by alkali metal tetrahydroborates have been published by Okushi.[10]



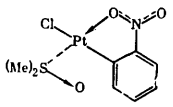
This review discusses the reactions of aromatic nitro-compounds with coordination compounds of transition metals and also the catalytic reduction of aromatic nitro-compounds by various reductants.

II. INTERACTION OF AROMATIC NITRO-COMPOUNDS WITH TRANSITION METAL COMPLEXES

The interaction of aromatic nitro-compounds with non-transition metal complexes (Al, Ga, Hg, etc.) leading to the formation of molecular complexes has long been known and has been investigated in fair detail.[11,18] In the main, the coordination of the metal to the oxygen (one or two atoms) of the nitro-group is postulated.

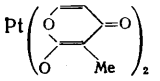
During the last several years, there has been an appreciable growth of interest in the reactions of aromatic nitro-compounds with transition metal complexes in connection with the elucidation of the mechanism of their catalytic action. Depending on the complex-forming ion, the ligand, and the reaction conditions, the interaction of aromatic nitro-compounds with transition metal complexes leads to the formation of either new stable complexes containing the aromatic nitro-compound (or its reaction product) in the coordination sphere or to organometallic compounds (metallation reaction).

Complexes in which the aromatic nitro-compound is coordinated in a wide variety of ways have been synthesised and to a large extent characterised. The types of compounds are presented below:



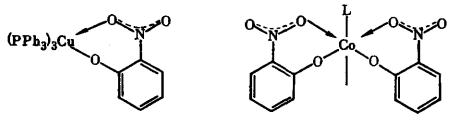
The structures indicated can be subdivided conventionally into two groups—in the first of these the nitro-group is linked to the metal and in the second the nitro-group does not participate in coordination of the aromatic nitro-compound to the metal. We shall not consider the interaction of coordination compounds with aromatic nitro-compounds where the nitro-group is fairly remote from the chelating or strongly accepting centres in the molecule and for this

reason does not participate in complex formation (see, for example, Refs.19–22).

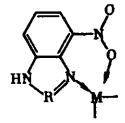


Complexes of type (I) have been formed via the reaction

$$PtCl_2(DMSO)_2 + RC_6H_4NO_2 \xrightarrow{\Delta} PtCl(DMSO)(RC_6H_3NO_2) + HCl + (DMSO).$$
$$R = H, p\text{-Me}, p\text{-Cl}.$$

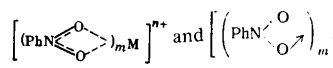


and isolated. The platinum atom has the planar coordination typical of platinum(II) and forms a five-membered ring with a molecule of the nitro-compound in which one of the oxygen atoms of the nitro-group and the carbon atom in the *ortho*-position to the nitro-group coordinate to platinum; the Pt–O and Pt–C bond lengths are 1.96 and 2.06 Å respectively:[23,24]



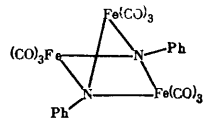
It has been shown by Raman spectroscopy that the nitro-group is coordinated to platinum in nitrobenzene solutions of the complexes[25] $PtCl_2(DMSO)_2$, K_2PtCl_4, and

Complexes of type (II) have been isolated for copper, cobalt, and palladium.[26–29] A six-membered metallocycle is characteristic of these compounds, the metal atom are being linked to the oxygen atoms of the nitro- and hydroxy-groups:



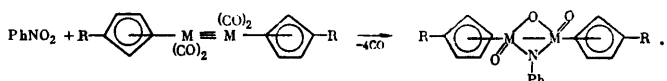
The nickel(II), copper(II), zinc(II), cadmium(II), and mercury(II) complexes of 4(7)-nitrobenzimidazole, investigated by IR, EPR, and electron spectroscopic methods, can be assigned to the same type.[30] It has been shown that these ligands are bidentate; the metal ions are coordinated to the oxygen of the nitro-group and the nitrogen of the imidazole ring with formation of a six-membered metallocycle:

The photolytic or thermal reaction of the pentacarbonylmanganese radicals with aromatic nitro-compounds in the presence of PBu_3 have been investigated by EPR.[31] A cyclic structure in which the manganese atom constitutes a bridge between two oxygen atoms of the nitro-group [type (III)] has been proposed on the basis of the EPR spectra of the stable paramagnetic species:



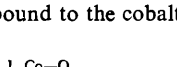
where R = t-butyl, isopropyl, phenyl, 3,5-dichlorophenyl, 2-thienyl, or 3-thienyl. The reactions of transition metal [Fe(III),[32] Co(II), Ni(II), Cu(II), Pd(II), and Mn(II)] chlorides[33] with $SbCl_5$ and aromatic nitro-compounds in an aprotic solvent (CCl_4) lead to the formation of complexes. $Fe(PhNO_2)_6(SbCl_6)_3$, $Fe(PhNO_2)_3(SbCl_6)_3$, and $FeCl(PhNO_2)_2(SbCl_6)_2$ are formed from the iron salt, complexes having the composition $M(PhNO_2)_2(SbCl_6)_2$ are produced from the cobalt, nickel, copper, and palladium salts, and the complex $Mn(Ph.NO_2)_3(SbCl_6)_2$ is formed from the manganese salt. The following structures have been assigned on the basis of spectroscopic studies:

The formation of nitrene derivatives [type (IV)] has been observed in many studies for the Co, Fe, Ru, Pd, Ti, V, Cr, Mo, and W complexes. A crystalline green product, to which the composition $Pd(acac)H(C_6H_5N=)Py$ was assigned on the basis of thermal and spectroscopic analyses, has been isolated.[34] The authors postulate the coordination of palladium to the nitrogen of the nitro-group with formation of a phenylnitrene complex.



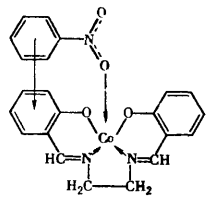
The interaction of nitrobenzene with $Fe_3(CO)_{12}$ in benzene containing methanol [35] or in a mixture of benzene, aqueous alkali, and a phase transfer catalyst,[36] leading to the reduction of nitrobenzene to aniline, has been investigated. A mechanism of the reduction process, involving the formation of intermediate nitrene complexes of iron, has been proposed. The compound

has been isolated and characterised. The authors suggest that the active species is the anion $HFe_3(CO)_{11}^-$. It has been shown that the IR spectra resembling those of the complex described above are observed when nitrobenzene (nitromethane [37]) is added in an He or H_2 atmosphere to the anion $HFe_3(CO)_{11}^-$ on an ion-exchange resin.[38] A similar mechanism has been put forward also for the reaction of nitrobenzene in tetrahydrofuran (THF) with titanium, molybdenum, and iron clusters having the composition $M_xC_4H_8$ ($x \geqslant 2$).[39]



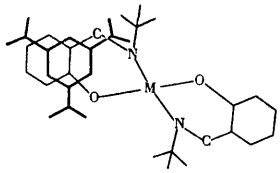
The study of the EPR spectra of the products of the interaction of $[Co(CN)_5]^{3-}$ and [(bis-salicylidene-ethylenediaminato)Co^{2+}] (salen) with an aromatic nitro-compound[40–43] demonstrated the presence of a cobalt nitroxide free radical or radical-anion in which there is a cobalt–nitrogen bond.

In order to investigate the mechanisms of the hydrogenation of aromatic nitro-compounds in the presence of ruthenium complexes, the products of the interaction of nitro-compounds with the complexes in the absence of hydrogen were isolated. Nitrene derivatives, whose structures have been shown to be $Ru_3(CO)_{10}NPh$ and $Ru_3(CO)_9(NPh)_2$ are isolated in an atmosphere of nitrogen after the reaction of nitrobenzene with $Ru_3(CO)_{12}$.[44,45] The same complexes can also be obtained by the reaction of aniline or phenyl isocyanate with ruthenium carbonyl. A reaction has been described in which the complex is fully decarbonylated:[46]

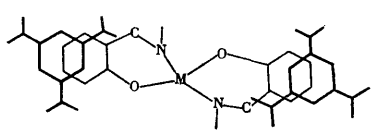


The yield is 40–46%. Hydrogenation of the reaction product under phase transfer conditions leads to the formation of an aromatic amine in a quantitative yield.

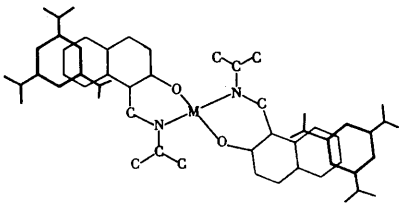
The formation of a dimeric compound on interaction of nitrobenzene with cobaloxime has been suggested,[47] the authors assuming that the nitro-group is bound to the cobalt atom via both oxygen atoms [type (V)]:



Thus stable complexes are obtained when both oxygen atoms of the nitro-group are coordinated to the metal atom. When the nitro-group is coordinated via one oxygen atom, the complexes are stabilised via the formation of a metallocycle incorporating a ring carbon atom in the *ortho*-position relative to the nitro-group or the oxygen atom of the hydroxy-group. Nitrene complexes with a metal–nitrogen bond are stable.

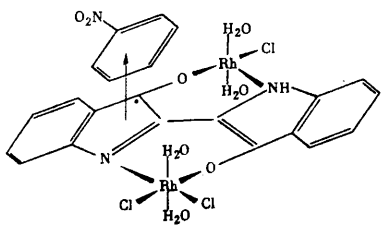


The interaction of aromatic nitro-compounds with cobalt and copper complexes (in which Schiff bases are ligands) has been investigated.[48] It has been shown that the reaction product is characterised by a high-intensity band in the electronic spectra in the range 420–432 nm. A black adduct of Co^{2+}(salen) with nitrobenzene, in which the aromatic ring of nitrobenzene is located above the plane of the ligand and in which the oxygen atom of the nitro-group is linked to the metal [type (VI)], has been isolated:



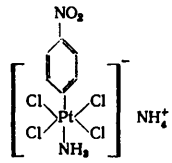
In the complex bis(*N*-*p*-nitrophenylsalicylaldiminato)Cu(II).dioxan, the copper atom is coordinated via four atoms (two oxygen atoms and two nitrogen atoms) of the ligands as a chelate and two monomeric complexes, linked via the centre of symmetry, give rise to a dimer as a result of the formation of a strong axial Cu...O bond. The coordination of the copper atom is built up to a distorted octahedral form via the oxygen atom of the nitro-group, which leads to the formation of an infinite polymer chain.[49]

Many complexes containing highly conjugated ligands—porphyrins, dyes, *o*-hydroxyquinones, and 8-hydroxyquinolines—form donor–acceptor complexes with aromatic nitro-compounds, in which there is no metal–nitro-group bond [type (VII)] ("peripheral mechanism"). The interaction of tetra-*p*-tolylporphyrinatocobalt(II),[50,51] palladium(II), cobalt(II), copper(II), and nickel(II) 5,10,15,20-tetraphenylporphyrinates[52–54] and the dimethyl esters of the meso-porphyrin complexes of cobalt(II) and nickel(II) [55] with 1,3,5-trinitrobenzene and 2,4,7-trinitrofluorenone has been investigated and it has been shown that, under these conditions, the $\pi-\pi$ interaction takes place exclusively on the periphery of the porphyrin and does not involve the metal. X-Ray diffraction studies have demonstrated that *sym*-trinitrobenzene forms 1:1 [56] and 1:2 [57] compounds with M^{2+} complexes of bis-salicylidene-ethylenediamine (salen) and is located exclusively over the π-system of the ligand, the planes of the two ligands being parallel. A similar interaction has been described[58–64] for copper(II) and palladium(II) 8-hydroxyquinolinates with a series of strong acceptors: *sym*-trinitrobenzene, chloranil, etc. In the donor–acceptor complexes formed, the acceptor is localised exclusively over the donor and is not linked to the metal atom:



Molecular complexes of 1,3,5-trinitrobenzene with copper(II), nickel(II), and palladium(II) 1-alkylaminomethyl-2-naphthoxides have been synthesised.[65] The structure of the adduct of palladium(II) 1-isopropylaminomethyl-2-naphthoxide with trinitrobenzene has been investigated by X-ray diffraction. The plane of the nitro-compound is parallel to that of the naphthalene ring and trinitrobenzene is disposed over the terminal naphthalene ring:

The interaction of nitrobenzene, a week acceptor, with coordination compounds of transition metals has been studied in a number of investigations. It has been shown that nitrobenzene reacts with haematoporphyrin to form a weak 1:1 complex.[66] Stoichiometric reduction of nitrobenzene by the rhodium(II)–potassium indigo-sulphonate complex in solution[67] proceeds at the expense of the electrons of both the ligand and rhodium(II). A signal whose intensity corresponds to 2–3% of paramagnetic species relative to the amount of the complex has been detected in the EPR spectrum on interaction of nitrobenzene with this complex bound to alumina. The mechanism of the activation of nitrobenzene involves the intermediate formation of a peripheral complex via the π orbitals of the ligand and nitrobenzene:



The formation of molecular complexes between nitrobenzene and copper(II) bisalizarinate has been demonstrated by ^{1}H NMR.[68] The nitro-group in the molecular complex is oriented towards the side opposite to that of the copper(II) ion. It has been demonstrated by electronic emission spectroscopy[69] that the character of the interaction of alizarin and palladium bisalizarinate with an aromatic nitro-compound is isotypical which led the authors to the conclusion that the interaction of the nitro-compound with a palladium complex has a peripheral mechanism.

In the 1:1 donor–acceptor complex of the tricarbonylchromanisole and *sym*-trinitrobenzene,[70] there is interaction between the aromatic systems of the nitro-compound and the complex. The planes of anisole and trinitrobenzene form a small angle of 3° and the centres of the planes are somewhat displaced relative to one another, so that the interaction in this system is weaker than between the aromatic systems without the metal.

A specific "metal ion–nitrobenzene" interaction via the hydrogen bond of the NH protons has been observed in a study of the electrical conductivity of [Co(acac)$_2$diamine]X in nitrobenzene.[7,72] Furthermore, there is $\pi-\pi$ interaction in this system between the bipyridyl ligand and the nitrobenzene molecule.

As can be seen from the data presented, a strong $\pi-\pi$ interaction between the aromatic system of the nitro-compound and the highly conjugated ligand is characteristic of complexes of this group [types (VI) and (VII)], the nitro-group either not being involved in complex formation or being additionally coordinated to the metal ion via the oxygen atom.

Complexes of type (VIII) have been isolated after the reaction of nitrobenzene or *p*-nitrotoluene with H_2PtCl_6 in $CF_3COOH-H_2O$. The isomers of the *m*- and *p*-σ-aryl complexes of platinum(IV) were obtained in which the nitro-group does not enter the coordination sphere of platinum:[73]

Nitrophenol can serve as a bridge between two copper atoms [type (IX)], the authors indicating that the IR spectra of structures of type (II) and (IX) do not differ.[27] In the 1 : 1 adduct of *p*-nitrophenol and Cu^{2+}(salen), nitrophenol is disposed between the molecules of the chelate.[74] The oxygen atom of the phenol forms a hydrogen bond with the oxygen of the donor and this adduct is linked solely to the ligand and not to the metal atom. The nitrogroup does not participate in the binding to the chelate [type (X)]. A polymeric nitrobenzene complex of nickel stable in air has been isolated:[75]

$$NiO_2(t\text{-BuNC})_2 + PhNO_2 + t\text{-BuNC} \rightarrow Ni(PhNO_2)(t\text{-BuNC})_2.$$

Table 1. Interaction of aromatic nitro-compounds with transition metal complexes.

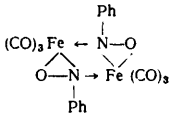
No.	Aromatic nitro-compound	Metal ion	Type of compound	Method of investigation*	Refs.
1	Nitrobenzene, *p*-nitrotoluene, *p*-chloronitrobenzene	Pt(II)	(I)	RRS, XRD	[23—25]
2	*o*-Nitrophenol, Nitrobenzimidazole	Cu(II), Co(II), Pd(II), Ni(II)	(II)	IR, EPR, XRD	[26—30]
3	Nitrobenzene, 3,5-dichloronitrobenzene, α-nitronaphthalene	Mn(II), Fe(III), Co(II), Ni(II), Cu(II), Pd(II)	(III)	IR, EPR	[31—33]
4	Nitrobenzene	Co(II), Fe(III), Ru(II), Pd(II), Mo(II), Cr, Fe	(IV)	XRD, IR, EPR	[34—46]
5	Nitrobenzene	Co(II)	(V)	IR	[47]
6	Nitrobenzene	Co(II), Cu(II)	(VI)	IR	[48, 49]
7	1,3,5-Trinitrobenzene, 2,4,7-trinitrofluorenone	Co(II), Pd(II), Cu(II), Ni(II), Cr(III)	(VII)	^{1}H NMR, XRD	[50—65, 70]
8	Nitrobenzene	Rh(II), Cu(II), Pd(II), Co(II)	(VII)	EPR, ^{1}H NMR, EES	[66—69, 71, 72]
9	Nitrobenzene, *p*-nitrotoluene	Pt(IV)	(VIII)	XRD, ^{1}NMR	[73]
10	*o*-Nitrophenol	Cu(II)	(IX)	IR, XRD	[27]
11	*p*-Nitrophenol	Cu(II)	(X)	XRD	[74]

*RRS = resonance Raman spectroscopy, XRD = X-ray diffraction analysis, and EES = electronic emission spectroscopy.

The complex $Ni(PhNO_2)_2(PPh_3)_2$ has been obtained in the form of crystals.

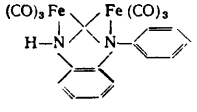
Table 1 compiles data on the formation of complexes by aromatic nitro-compounds with transition metal complexes.

III. REDUCTION OF AROMATIC NITRO-COMPOUNDS



1. Reduction by Transition Metal complexes

Numerous studies have been devoted to the reduction of aromatic nitro-compounds by metal complexes. The iron carbonyl cluster $Fe_3(CO)_{12}$ possesses reducing properties in benzene, hexane, and THF. In methanol-containing benzene, mixing of an equimolar amount of nitrobenzene and $Fe_3(CO)_{12}$ leads to the formation of an aniline.[35] The rate of reaction can be increased by an order of magnitude by introducing a phase transfer catalyst.[36] In a CO atmosphere, an aniline is also the reaction product.[66] The use of this cluster on alumina lowers the selectivity of the reaction; a mixture of an aniline and azobenzene is obtained, the yield of anilines depending on the substituent in the aromatic ring and varying in the range 40—79%, while the yield of azobenzene does not exceed 4—7%.[77] The reducing species is the $HFe_3(CO)_{11}^-$ anion,[78] which can be obtained in its turn by treating $Fe_3(CO)_{12}$ in THF with 1 M tetrabutylammonium fluoride solution. If this reaction is carried out in the presence of *p*-nitrotoluene, *p*-toluidine is detected. Furthermore, this anion can be isolated from the reaction



$$Fe_3(CO)_{12} + KF + 18\text{-crown-6} \rightarrow [HFe_3(CO)_{11}]^-.$$

When manganese pentacarbonyl was treated with $(C_4H_9)_4NF$ or $(C_4H_9)_4NF.3H_2O$, its anion was obtained. It reduces nitrotoluene and nitroanisole to the corresponding anilines in the presence of water in 52—88% yield. The corresponding cobalt compound does not reduce the aromatic nitro-compounds.

Iron pentacarbonyl, in the presence of which aromatic nitro-compounds are reduced to nitroso-compounds, is extremely reactive. The nitroso-compounds subsequently form a complex with the iron. Thus a nitrosoiron complex was isolated from a mixture of 3-chloro-2-methylnitrobenzene with $Fe(CO)_5$ and its structure was determined:[79]

Monomeric or dimeric iron complexes are formed in the reduction of iron pentacarbonyl under the influence of light or ^{60}Co γ-radiation.[80] It has been stated that under other conditions one mole of nitrobenzene can be reduced by one mole of iron pentacarbonyl to azoxybenzene and 1.4 mole is reduced to azobenzene in yields up to 76%. Treatment of nitrobenzene with a large excess of iron pentacarbonyl in hot butanol or with 1.4 mole of iron nonacarbonyl can yield the complex

The reaction of $KHFe(CO)_4$ with nitrobenzene at room temperature takes place exothermically, CO_2 is evolved, and the reaction product is aniline.[81] If bromomagnesioalkyl- or bromomagnesioarylamides are added to the reaction mixture, the reaction products are asymmetric *NN'*-disubstituted ureas (yield 42—99%):[82]

$$R'NHMgBr + Fe(CO)_5 + R^1NO_2 \rightarrow R'NHCONHR^1.$$

It has been suggested that carbamoyltetracarbonylferrate is formed initially and then reacts further with the aromatic nitro-compound.[83]

The interaction of acyltetracarbonylferrates with nitrobenzene[83] leads to anilines. Ferrates are both reducing and acylating agents:

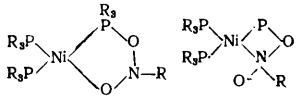
$$R'COFe(CO)_4^- + PhNO_2 \rightarrow R'CONHPh\ .$$

The yield of the target products is 68–86% and the amine R′NHPh is a side product.

The mechanism of the oxidation of the iron-porphyrins by an aromatic nitro-compound has been studied:[84,85]

$$6Fe^{II} + PhNO_2 + 6H^+ \rightarrow 6Fe^{III} + PhNH_2 + 2H_2O\ .$$

The rate of reaction diminishes in the sequence trinitro > dinitro > mononitro. Aromatic nitro-compounds are then reduced to amines, whose yield falls appreciably when various substituents are introduced into the aromatic ring. Comparison of iron-porphyrins with haemoproteins showed that the latter exhibit a very low activity. This effect is associated, according to the authors, with the fact that the rate-limiting stage is the dissociation of the protonated aromatic nitro-compound (by analogy with the mechanism of the oxidation of iron-porphyrins by molecular oxygen[86]). The aromatic nitro-compound interacts directly with the iron atom, although in the presence of a solvent such as pyridine one cannot rule out the possibility of a peripheral mechanism.



The reaction of *o*-nitrophenol with $[Ru(CO)_3(PPh_3)_2]$ (which is a catalyst of the hydrogenation of aromatic nitro-compounds[107]) takes place in an interesting manner. A ruthenium complex has been isolated[87] in which one nitrophenol molecule is bound to ruthenium via the oxygen atom of the OH group while the other has been transformed into a nitroso-derivative and has been coordinated to ruthenium via the nitrogen of the nitroso-group and the oxygen of the OH group. The nitro-group is not coordinated to ruthenium and is not coplanar with the benzene ring. Complexes of zerovalent nickel also reduce aromatic nitro-compounds to the nitroso-derivatives;[88] the reaction takes place rapidly in benzene with a sharp change in colour:

$$PhNO_2 + Ni(PPh_3)_4 \rightarrow (PhNO)Ni(PPh_3)_2 + OPPh_3 + PPh_3\ .$$

In the presence of nickel complexes, oxygen is transferred from the aromatic nitro-compound to the phosphine in accordance with the following scheme:

$$NiL_4 \rightleftharpoons NiL_3 + L\ ,$$
$$NiL_3 + RNO_2 \rightarrow [Ni^{I}L_3 \cdot RNO_2^-]\ ,$$
$$[Ni^{I}L_3 \cdot RNO_2^-] \rightarrow L_2Ni(ONR) + LO\ .$$

The formation of intermediate complexes with nitrobenzene is then postulated:

When 3,4-dichloronitrobenzene is added to a solution of the $NaBH_4$-treated iridium(IV) complex of chloranilic acid, the 3,4-dichloronitrobenzene radical-anion is formed.[89]

Metal-chelated flavins reduce the aromatic nitro-compound, the reducing property depending on the metal ion and increasing in the sequence Mn(II) < Zn(II) < Ni(II) < Co(II).[90]

Table 2 presents data on the reduction of aromatic nitro-compounds by transition metal complexes.

In conclusion we may note general characteristics. Aromatic nitro-compounds are reduced via the formation of the nitro-compound radical-anion with subsequent reduction to the nitroso-compound. Depending on the complex-forming metal, the nitroso-compound can subsequently give rise to a stable complex with the metal (iron, nickel, cobalt, ruthenium) or it can be reduced with formation of various products (iron).

2. Reduction by Molecular Hydrogen

It is known that the reduction of aromatic nitro-compounds can lead to a series of products:

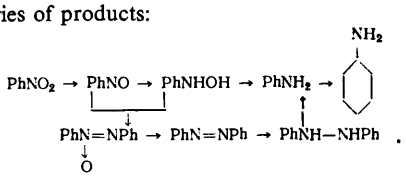


Table 2. Reduction of aromatic nitro-compounds by metal complexes.

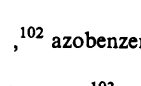
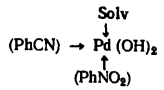
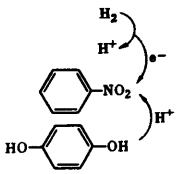


No.	Complex	Aromatic nitro-compound	Reaction products	Remarks	Refs.
1	$Fe_3(CO)_{12}$	Nitrobenzene	Aniline	—	[35,36, 76]
2	$Fe_3(CO)_{12}$	Substituted nitrobenzenes	Substituted anilines, azobenzenes	Complex on Al_2O_3	[77]
3	$Fe_3(CO)_{12}$	*p*-Nitrotoluene	*p*-Toluidine	Addition of tetra-butylammonium fluoride or KF + crown-ether	[78]
4	$Mn_2(CO)_{16}$	ditto	ditto	Ditto	[78]
5	$Fe(CO)_5$	3-Chloro-2-methyl-nitrobenzene	Nitrosoiron complex	—	[79]
6	$Fe(CO)_5$	Substituted nitrobenzenes	Ditto	Under the influence of light or ^{60}Co γ-rays	[80]
7	$Fe(CO)_5$	Substituted nitrobenzenes	*NN*′-disubstituted ureas	Addition of RNHMgBr	[82]
8	$Fe(CO)_4(RCO)$	Nitrobenzene	Amide, amine	—	[83]
9	Iron-porphyrins	Mono-, di-, and tri-nitrobenzenes	Anilines	—	[84, 85]
10	$Ru(CO)_3(PPh_3)_2$	*o*-Nitrophenol	Nitronitroso-ruthenium complex	—	[87]
11	$Ni(PPh_3)_4$	Substituted aromatic nitro-compounds	Nitroso-compounds of nickel	—	[88]
12	Ir(CAA)* + $NaBH_4$	3,4-Dichloro-nitrobenzene	3,4-Dichloronitro-benzene radical-anion	—	[89]
13	Flavin radicals containing manganese, nickel, and cobalt	Substituted aromatic nitro-compounds	Radical-anions of aromatic nitro-compounds	—	[90]



*CAA = chloranilic acid.

The study by Ogata and Sugiyama[91] may be regarded as the first of this kind, but vigorous research has been prosecuted mainly during the last 20 years. One of the first catalysts used in this reaction is cobalt pentacyanide. In aqueous[92] and aqueous alkaline[93,94] solutions close to room temperature, the product of the halogenation of nitrobenzene is azobenzene,[92] while the halogenation of nitrobenzen and *o*-nitroanisole results in a mixture of azo- and hydrazo-compounds,[93] while at elevated H_2 pressures a mixture of an amine and an azo-compound is produced.[94] Complexes of bisdimethylglyoximatocobalt(II) catalyse the hydrogenation of aromatic nitro-com pounds under mild conditions to an aniline and hydrazobenzene an the hydrogenation of methyl *p*-nitrocinnamate to methyl *p*-amino-cinnamate in 78% yield.[95] When nitrobenzene is reduced in the presence of cobalt pentacyanide, the rate of reaction depends on th

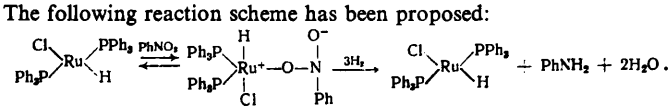


OH^- concentration and the catalyst : substrate ratio; thus, when the ratio of cobalt to nitrobenzene is less than unity, the reaction does not occur. In an aqueous alcoholic medium with added KOH, the reaction products are azo- and azoxy-benzenes.[96]

Cobaloximes having the composition $Co(DMG)_2OAc$ and $[Co(DMG)_2]_2CO_3$, where DMG = dimethylglyoxime, are more active catalysts.[97] The catalytic activity is manifested only in the presence of an amine, for example, morpholine. In a mono-olefin–nitrobenzene mixture, the latter is hydrogenated selectively,[98] while isoprene fully inhibits the reaction. It has been suggested that the hydrogenation proceeds via an intermediate dinuclear complex.[99] The presence of a stronger base (KOH, NaOH) is necessary for the manifestation of catalytic activity by the complex (DMG) $(PPh_3).XCo^I.C_2H_5OH$ (X = Cl or Br).[100] At elevated hydrogen pressures, the reaction takes place also in the absence of a base. In contrast to the previously study, Datta et al.[100] suggest that the hydrogenation takes place via the formation of an intermediate phenylnitrene complex. The copper complex $Cu^IBr(PPh_3)_3$ is active under severe conditions.[101] The nitrobenzene halogenation products are aniline (75–79%), azobenzene (5–10%), and nitrosobenzene (2–7%). It has been shown that in an atmosphere of hydrogen the initial complex is transformed into the hydride complex $[CuHBr(PPh_3)]_2$, while at the end of the reaction the complex $(PhN=NPh)Cu_2(PPh_3)_4Br_2$ was isolated.

Palladium and platinum complexes are more active and selective. Under mild conditions, nitrobenzene was hydrogenated to aniline (98%) in the presence of the $NaBH_4$-treated complex PdL_2Cl_2 (where  , [102] azobenzene, and pyridines[103]). Hydrazobenzene [102] or azobenzene [103] may be present as impurities. A high yield of aniline was obtained also in the presence of the $Pd(PhCN)_2Cl_2$ catalyst.[104] At elevated hydrogen pressure, the yield of aniline falls to 65%.[105] New bands appeared in the electronic and infrared spectra after the addition of nitrobenzene to the complex, which the authors attributed to an intermediate complex having the composition

The mechanism of the reduction of nitrobenzene in an aprotic solvent (DMSO) in the presence of the $PtCl_2(DMSO)_2$ + $NaBH_4$ catalyst and added quinones has been investigated.[106] Under the hydrogenation conditions, the quinones are rapidly and quantitatively reduced to hydroquinones, which facilitates the reduction of nitrobenzene as a result of the protonation of the intermediate reduction products. The function of the catalyst consists in electron transfer from H_2 to nitrobenzene, while the role of the hydroquinone, introduced into the system or formed on hydrogenation of quinone, is to transfer a proton. The formation of donor–acceptor complexes of nitrobenzene with hydroquinone has been postulated:



The reduction of nitrobenzene is described by the scheme

The final hydrogenation product is phenylhydroxylamine.

The ability to catalyse the selective reduction of dinitrobenzenes to the corresponding nitroanilines is a unique feature of ruthenium complexes.[107–109] Substituted nitrobenzenes are hydrogenated only at the nitro-group (in the presence of ruthenium and iron complexes). The following reaction scheme has been proposed:

Here one can imagine that the stage involving the interaction with the nitro-compound is more complex (see, for example, Pizzotti and Crotti[87]). The iron complexes are less active. The complex $RuCl_2.(PPh_3)_3$ exhibits the highest specificity in the hydrogenation of dinitrobenzene to nitroanilines,[107,110] which permitted the selective hydrogenation of mixtures of dinitro- and nitro-compounds. For example, in a mixture of nitrobenzene with *p*-dinitrobenzene, only *p*-dinitrobenzene is reduced (to *p*-nitroaniline).[111] *o*-Substituted nitro-compounds are more effectively hydrogenated in the presence of a quaternary ammonium base and ruthenium(II) and ruthenium-(III) complexes;[112] alcohols, halogenohydrocarbons, or ethers can serve as solvents. The selectivity with respect to reaction products is 85% for a 95% conversion.

The dimeric ruthenium hydride, obtained from $RuCl_2.(\eta^6\text{-}C_6Me_6).(PPh_3)$ and Na_2CO_3 in isopropyl alcohol, shows a low catalytic activity in the hydrogenation of nitrobenzene; the yield of aniline reaches 38% after 36 h at 50 °C and 50 atm.[113]

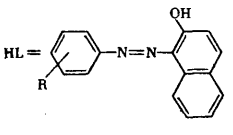
The titanium(III) compounds obtained by reducing the titanium-(IV) compounds $R_nTi^{IV}Cl_{4-n}$ (where R = $MeCOO^-$, PhH_2COO^-, or $\alpha\text{-}C_{10}H_7CH_2COO^-$; n = 0, 1, 2) with hydrogen catalyse the hydrogenation of nitrobenzene to aniline in the presence of heterogeneous catalysts in dimethylformamide (DMF).[11]

Wilkinson's complex $RhCd(PPh_3)_3$ is inert in the hydrogenation of aromatic nitro-compounds. When a phosphine or an amine is added to the reaction medium, nitrobenzene is hydrogenated to aniline at a low rate (0.2–2.6 moles of H_2 per mole of rhodium per minute).[115–117] Under the same conditions, the rhodium complex Rh(hexa-1,5-diene)Cl_2 catalyses the reduction of substituted nitro-compounds, appreciable dehalogenation being observed for halogeno-derivatives.[116] The complex $RhPy_3Cl_2$, which manifests a catalytic activity after treatment with $NaBH_4$ and DMF, has been studied in detail.[115,118,119]. The intermediate catalytically active complex $Py_2.(DMF)RhCl(BH_4)$ was isolated. It was noted that the catalyst decomposes after a time owing to the reduction of the ligand—pyridine. The dinuclear rhodium complexes with a bridging nitrogen heterocycle, namely [(COD)ClRh(μN–N)RhCl(COD)], where COD = cyclo-octa-1,5-diene or *NN'*-bipyridyl, are more stable.[120,121] After treatment with $NaBH_4$, the complexes catalyse the hydrogenation of nitrophenols and nitrobenzoic acid. The authors did not characterise the active species.

The catalytic activity of sulphur-containing rhenium complexes has been investigated in a number of studies. At 95 °C and 1–40 atm H_2, nitrobenzene and *o*-nitrotoluene were hydrogenated to the corresponding anilines in the presence of complexes with thiourea or mercaptobenzimidazole $[ReOL_2X_3].2H_2O$;[122] the rhenium thio-complexes $Re_2S_2L_8$, where L = $CS(NH_2)_2$, Cl^-, or H_2O, catalyse the conversion of nitrobenzene to azoxybenzene in DMF.[123,124]

Metal clusters have been investigated in recent years as catalysts. The palladium cluster $Pd_5(PPh)_2$ in DMF,[125] the complex obtained by the interaction of the platinum cluster $[Pt_3Sn_8Cl_{20}]^{4-}$ with cyclo-octa-1,5-diene and having the composition $(C_6H_{12})_3Pt_3Sn_2Cl_6$,[126] and soluble polynuclear rhenium thio-complexes[124] catalyse the hydrogenation of nitrobenzene under mild condtions. The reaction has been investigated potentiometrically[126] and it has been shown that the platinum is in the zerovalent state. At temperatures in the range 100–130 °C and pressures in the range 100–300 atm, the iron

cluster $[(\eta^5\text{-}C_5H_5)Fe(\eta^3\text{-}CO)]_4$, in which each iron atom is linked to three other iron atoms and three carbonyl ligands, is active; the yield of aniline is 6–31%.[127]



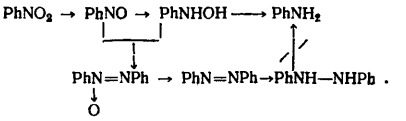
Catalysts obtained by immobilising complexes (mainly palladium and platinum) on carriers have been used successfully. Palladium complexes with polyvinylpyrrolidinone and polyacrylic acid fixed on silica gel,[128] the $Pd(PPh_3)_n^{2+}$ complex on organic and inorganic carriers,[129] the palladium(II) complex on γ-aminopropyl-containing silica gel,[130] and palladium complexes with chloromethylated polystyrene treated with anthranilic acid,[131–133] with a polymeric carrier containing oxime groups,[134,134] with polymeric ligands containing NH groups in the polymer chain,[136–138] etc. have a high activity in the hydrogenation of aromatic nitro-compounds. The main reaction products are the corresponding anilines. Dinitro-compounds can be hydrogenated stepwise with isolation of the mononitro-compounds.[130] It has been noted that the hydrogenation of *p*-chloronitrobenzene is accompanied by dehalogenation.[132] The platinum-nylon catalyst, familiar in the selective hydrogenation of benzene to cyclohexene, hydrogenates nitrobenzene and its derivatives in the liquid phase.[139]

The most active catalysts in the reduction of aromatic nitro-compounds are complexes based on platinum-group metals with highly conjugated ligands (arylazonaphthols, azobenzene, *o*-quinones, *o*-hydroxyquinones, γ-indigoid dyes). The reactivity of the majority of the catalysts which were described is associated with the non-complementary character of the process. The intermediate metal hydride complex is a two-electron reductant, while nitro-compounds are one-electron acceptors.

In complexes incorporating ligands with a branched system of π-bonds, there is a possibility of electron transfer via a peripheral mechanism through the ligand.[5,140] At the beginning of our review, the list of such complexes is given in which donor–acceptor interaction takes place between the aromatic nitro-compounds and the highly conjugated ligand (Table 1). The use of catalysts of this kind made it possible to achieve effective and selective hydrogenation of aromatic nitro-compounds under mild conditions:[141–143]

$$RC_6H_4NO_2 \rightarrow RC_6H_4NHOH\ (96—99\%),$$
$$RC_6H_4NO_2 \rightarrow RC_6H_4NH_2\ (100\%),$$
$$C_6H_4(NO_2)_2 \rightarrow H_2NC_6H_4NO_2\ (95—98\%),$$
$$ClC_6H_4NO_2 \rightarrow ClC_6H_4NH_2\ (99{,}9\%).$$

N-Arylhydroxylamines have been synthesised in 96–99% yield in the presence of the platinum complexes $Pt_2L_3(HL)Cl$, where



R = H, 4-Me, 2,4-$(Me)_2$, or 4-SO_3Na and L are the corresponding benzeneazonaphthoxides [144–148] or PtQ_2 (where Q = *o*-hydroxyquinones).[149] Platinum complexes with azobenzenes exhibit a lower selectivity (the yield of *N*-phenylhydroxylamine is 55%).[150] The corresponding palladium complexes of azobenzenes[151] are more active then the platinum complexes.[57,150] The reaction takes place via the formation of phenylhydroxylamine, but the final product is aniline. Palladium complexes of *o*-hydroxyquinones[152] and platinum complexes of *o*-γ-pyrone and *o*-quinone[103] are effective catalysts of the hydrogenation of aromatic nitro-compounds to anilines. The reduction of dinitrobenzenes to mononitro-derivatives is catalysed by platinum and palladium complexes of *o*-hydroxyquinones[153,154] and the reduction of halogenonitrobenzenes to the corresponding halogenoanilines (without the occurrence of the dehalogenation side reaction) is catalysed by platinum, rhodium, and iridium complexes.[155–159]

Thus the synthesis and use of complex catalysts containing as ligands large conjugated systems with a considerable electron capacity constitutes an extremely fruitful and promising development.

3. Reduction by Alkali Metal Tetrahydroborates

The reduction of aromatic nitro-compounds by alkali metal tetrahydroborates in water and aqueous alcoholic solution of alkali is known to lead to the $PhNO_2^-$ radical-anion,[160] while the reaction in diglyme at elevated temperatures affords azoxybenzene.[161] Transition metal complexes catalyse the reduction process. The cobalt complexes have been most thoroughly investigated.

The reduction of nitrobenzene by $NaBH_4$ in the presence of cobaloxime $H-Co(DMG-H_2)(PPh_3)$ on heating in 50 alcoholic solution was first observed by Sal'nikova and Khidekel'.[162] Nitrobenzene was reduced quantitatively to a mixture of azobenzene (30%), azoxy-benzene (60%), and aniline (10%). The same mixture was obtained in the presence of the complex $H-Co(DMG-H_2)Py$.[151,163] Nitrobenzene and the products of its incomplete reduction have been reduced[164] with sodium and potassium tetrahydroborates in the presence of cobalt(III) complexes—cobalt bisguanide, the cobalt–salen complex, and the cobalt complex of a macrocyclic Schiff base. The complexes were compared with vitamin B_{12} and its model—the cobalt bisdimethylglyoximate complex. The general characteristic of the systems investigated have been discovered: the Co^{3+} ion is reduced to Co^+ or the cobalt(III) hydride; Co^{2+} interacts weakly and Co^+ and the hydride interact strongly with the substrate. The reaction proceeds mainly in the forward direction: nitrobenzene → nitrosobenzene → phenylhydroxylamine → aniline. Among the side products, azoxy- and azo-benzenes were detected, ar increase in the reaction temperature from 40° to 100 °C resulting in an increase in the yield of aniline. The same features have been observed when hydroxycobalamin was used as the catalyst.[165] It has been suggested that the catalytic system involves the formation of an unstable cobalt–nitrogen intermediate compound (nucleophilic addition to an unsaturated system). On the basis of kinetic measurements, the following reaction mechanism has been put forward:[165]

Cobalt(II) compounds are also active. The first stage is probably the reduction by alkali metal tetrahydroborates of cobalt(II) to cobalt(I), which is in fact the active catalytic species. The composition of the product varies markedly as a function of the nature of the ligand and the solvent. Thus in methanol in the presence of $Co(II)-Co(DMG)_2$, $CoCl_2$, $Co(AcO)_2$, etc., hydrazobenzene and aniline were obtained,[166] in the presence of the Co(II)–mesoporphyrin complex the products were phenylhydroxylamine (34%) and azoxybenzene (35%),[167] while in the presence of the complexes $Co(bipy)_3^+$ and $Co(bipy)_3^{3+}$ the products were phenylhydroxylamine and aniline.[168] The last two cobalt complexes react rapidly with the tetrahydroborate to form a cobalt(I) complex. The nitrile group is reduced faster than the nitro-group, which enabled the authors to carry out the selective reduction of *p*-nitrobenzonitrile to *p*-nitrophenylmethylamine at –10 °C in the presence of the $CoCl_2 + NaBH_4$ system.[169] On raising the temperature, the nitro-group is also reduced.

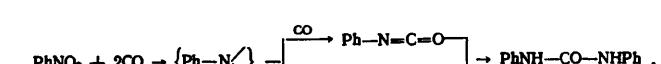
The highest yield of aniline has been achieved in the presence of the $CuCl_2 + NaBH_4$ catalytic system.[170] In the series of metal acetylacetonates, the highest activity is manifested by copper acetylacetonate,[171] in the presence of which the yield of aniline reaches 90%.

Nickel complexes are active in an inert atmosphere. In water at 70 °C in the presence of cyanonickel complexes,[172] nitrobenzene is readily reduced to azoxybenzene. In an alcoholic medium under the

same conditions in the presence of the $Ni(PPh_3)_2Cl_2$ complex, substituted nitrobenzenes are reduced to the corresponding anilines in 80–88% yield.[173] The reaction selectivity changes sharply when nickel complexes fixed on polymers containing PPh_2 or CH_2PPh_2 groups on the surface are used—the main product is azoxybenzene (up to 85%) with an admixture of azobenzene.[174]

Rhodium(III) complexes, which form hydrides, for example, the hydridochlorotriethylenetetra-aminerhodium(III) cation, catalyse the reduction of nitrobenzene to aniline in solution in aqueous methanol.[175] It is noteworthy that the reduction of aromatic nitro-compounds by alkali metal tetrahydroborates has not found extensive application owing to the low activity and selectivity.

4. Reduction by the Synthesis Gas



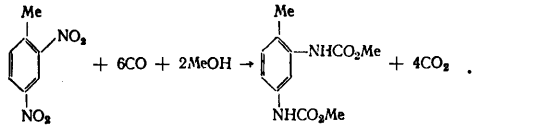
Although the first communication about the reduction of aromatic nitro-compounds by the CO + H_2 mixture in the presence of iron pentacarbonyl appears in 1925,[176] studies in this field were initiated much later. Virtually all the investigations demonstrated that catalytic activity is manifested by transition metal carbanions. The complexes $Rh_4(CO)_{12}$ and $Co_2(CO)_8$ [177,178] in benzene or a benzene–alcohol mixture at 120 °C and 100 atm CO + H_2 catalyse the reduction of nitro-compounds to amines in 94–100% yield:

$$PhNO_2 + 2CO + H_2 \rightarrow PhNH_2 + 2CO_2 .$$

Diphenylurea is a side product (5–6%).

In the presence of cobalt carbonyl, *p*-nitrobenzyl alcohol is reduced to a polymer of *p*-aminebenzyl alcohol (44%), while nitrobenzene is reduced to acetanilide (44%).[179] These results can be explained by the presence of acetic acid (obtained as a result of hydrolysis on synthesis of cobalt carbonyl from cobalt acetate); aniline has not been detected. The reduction of nitrobenzene, *m*-dinitrobenzene, and 2,4-dinitrotoluene under hydroformylation conditions is catalysed by rhodium, iridium, iron, and osmium carbonyls. Iron carbonyl is the least active, while osmium carbonyl is active even in the absence of hydrogen.[180] The yield of the amino-product is 97%. The low activity of iron pentacarbonyl has also been indicated by L'Esplattenier et al.[181]

Ruthenium(III) complexes, namely ruthenium dodecacarbonyl, ruthenium pentacarbonyl, and trisacetylacetonatoruthenium, are active catalysts. Urea was detected among the products for the $C:H_2 > 1$ ratio, its amount increasing with increase in the quantity of CO in the mixture. It has been suggested that a phenylnitrene complex is an intermediate:[181]



The introduction of sodium methoxide into the reaction medium alters the course of the reaction:

$$PhNO_2 + CO + H_2 + NaOMe \xrightarrow{M_x(CO)_y} PhNHCOH + PhNHCOOMe + PhNH_2 + PhNHCONHPh + PhN{=}NPh .$$

where M = Fe or Ru; the main products in the presence of ruthenium carbonyl are PhNHCOH and $PhNH_2$, while the products in the presence of iron cargonyl are PhNHCOOMe and PhNHCO. .NHPh.

The reduction of an aromatic nitro-compound in the presence of carbon monoxide and alcohol is of greater interest; carbamates, usually synthesised via a multistage process, are then obtained.[182] The ruthenium complexes $Ru_3(CO)_{12}$ and $Ru(CO)_3(PPh_3)_2$ are effective catalyst in the presence of tetraethylammonium chloride as the cocatalyst.[183] A monocarbamate has been obtained in 93% yield from the mononitro-compound, while the dinitro-compound gave rise to the dicarbamate in 50% yield:

In the absence of the tetra-alkylammonium salt, the main product is aniline. The corresponding iron compounds are inactive. It has been suggested that the reaction proceeds via the formation of a nitrene derivative of ruthenium, i.e. $Ru_3(CO)_{10}NPh$. The same features have been observed when the reaction is carried out in the presence of the platinum complex $PtCl_2(PPh_3)_2$;[184] the reaction is promoted by Lewis acid.

5. Reduction by the CO + H_2O Mixture

The possibility of reducing nitro-compounds to the corresponding amines by the CO + H_2O mixture has been studied vigorously during the last ten years. Rhodium complexes are widely used. Rhodium carbonyl complexes $Rb_6(CO)_{16}$ and $[Rh(CO)_2Cl]_2$ catalyse the reduction of nitrobenzene at 150 °C and CO pressure of 50–120 atm; the yield of aniline reaches 85–95% and the formation of urea or formamide derivatives is not observed:[185]

$$PhNO_2 + 3CO + H_2O \rightarrow PhNH_2 + 3CO_2 .$$

Iron carbonyls are also active. The first stage is probably the formation of a nitrene derivative. If the reaction is carried out in pyridine[185] but in the presence of added *NN*-dimethylbenzylamine,[186] the selectivity is significantly higher. The attempt to heterogenise the catalyst by grafting it to the Amberlist A-2 resin modified with *NN*-dimethylbenzylamine was unsuccessful: the rate of hydrogenation fell and the senstivity of the catalyst to air increased. Aliphatic nitro-compounds are not reduced in this system, which made it possible to carry out a selective reduction:

The study of the role of amines[187] led to the conclusion that the acceleration of the reaction may be a consequence of the formation of a more active species incorporating the amine as a ligand. The $Rh_6(CO)_{16}$–γ-aminopyridine system, which makes it possible to reduce nitrobenzene under mild conditions (80 °C, CO pressure below 1 atm), is optimal. Other rhodium clusters are also active—$Rh_2(CO)_4Cl_2$ and $Rh_4(CO)_{12}$; the iron and ruthenium clusters exhibit a low activity. It has been noted that the rate of reaction can be increased significantly in the presence of the $Rh_3(CO)_{12}$ and $Ru_3(CO)_{12}$ clusters only by introducing chelating nitrogen-containing bases into the reaction mixture.[188] Thus the yield of aniline reaches 100% after the introduction of 3,4,7,8-tetramethylphenanthroline or 3,4,5,6,7,8-hexamethylphenanthroline [189] in the proportions chelating agent : rhodium = 3.

The use of iron carbonyl $Fe(CO)_5$ as the catalyst of the reduction of nitrobenzene leads to the formation of aniline at 25 °C and a CO pressure of 50 atm if the reaction is performed in aqueous glyme with added triethylamine. Part of the catalyst is then irreversibly decomposed with formation of iron oxides.[190] The reaction proceeds rapidly at pH 12. The reducing species is $HFe(CO)_4^-$. $Rh_6(CO)_{16}$, $Os_3(CO)_{12}$, $H_2Os(CO)_{10}$, $H_4Os_4(CO)_{12}$, and $Ir_3(CO)_{12}$ are active under the same conditions. In their study of the reaction mechanism with the aid of CO + D_2O, the authors showed that, at least to the

extent of 88%, the reducing agent is the CO + D_2O mixture and not D_2 (reduction via the reaction CO + $D_2O \rightarrow CO_2 + D_2$), as suggested previously by Iqbal.[191] Furthermore, the rate of generation of deuterium (or hydrogen) is lower by two orders of magnitude than the rate of reduction of nitrobenzene, i.e. the reaction with molecular hydrogen does not play an important role.

At 80 °C and a CO pressure of 60 atm, the platinum complex $PtCl_2(PPh_3)_2$ is active in the presence of the Lewis acids $ZnCl_2$, $SnCl_2$, $SnCl_4$, etc., the highest rate being observed after the introduction of $SnCl_4$.[192] The yield of aniline falls on reducing the temperature or replacing the CO + H_2O mixture by hydrogen. The reaction takes place in stages, the Lewis acid being necessary in the second stage:[193]

$$PhNO_2 + 2CO \rightarrow PhN\langle + 2CO_2 ,$$

$$PhN\langle + CO \rightarrow PhNCO ,$$

$$PhNCO + H_2O \rightarrow [PhNHCOOH] \xrightarrow{-CO_2} PhNH_2 .$$

The dependence of the yield of aniline on the initial CO pressure has been noted for the ionic ruthenium complex $[Ru(COD)Py_4].(BPh_4)_2$. Thus the yield of aniline (in THF) is 36% at 15 atm, 62% at 30 atm, 74% at 45 atm, and 90% at 60 atm.[194] The authors rule out the possibility of the formation of an intermediate phenylnitrene derivative, since *o*-nitrobiphenyl produces only *o*-aminobiphenyl without an admixture of carbazole. The reaction does not occur when water is replaced by methanol or phenol.

The palladium complexes $Pd_3(CO)_3(PPh_3)_4$, $Pd_4(CO)_3(PPh_3)_4$, and $Pd_{10}(CO)_{12}(PPh_3)_6$, which are active and stable in the presence of an excess of triphenylphosphine, have been synthesised.[195]

In conclusion, we shall describe systems in which water may be replaced by unsaturated compounds. In the presence of $Rh_6(CO)_{16}$ the following reactions can be achieved with a high efficiency:[185]

$$2PhNO_2 + H_2 + 5CO \rightarrow PhNH{-}CO{-}NHPh + 4CO_2 \quad (70{-}80\%)$$

$$PhNO_2 + R{-}CH{=}CH_2 + 2CO \rightarrow Ph{-}N\langle_{CH_2{-}CH{-}R}^{CH_2} + 2CO_2 , \quad (60\%)$$

$$PhNO_2 + Ph{-}C{\equiv}C{-}Ph + 4CO \rightarrow Ph{-}N\langle_{C(=O){-}C(=O){-}Ph}^{C(=O){-}C{-}Ph} + 2CO_2 , \quad (85\%)$$

$$PhNO_2 + PhCHO + 3CO \rightarrow PhCH{=}N{-}Ph + 3CO_2 , \quad (60{-}85\%)$$

$$PhNO_2 + C_6H_4(CHO)_2 + 3CO \rightarrow C_6H_4(CH_2)(CO)N{-}Ph + 3CO_2 . \quad (50{-}60\%)$$

6. Reduction by Alcohols

A few studies are known where alcohols were used as reductants for aromatic nitro-compounds. Depending on the alcohol and the catalyst, the reaction products can be aromatic amines, 2,3-dialkylquinolines, hydrazo- and azo-derivatives, and arylhydroxylamines. When an aromatic nitro-compound reacts with an alcohol, hydrogen is transferred catalytically from the alcohol; aniline and an aldehyde (stage I) are then formed and can subsequently give rise to various condensation products (stage II). It has been shown that the ruthenium complex $RuCl_2(PPh_3)_3$ catalyses this reaction and a mixture of products is obtained:[196]

$$PhNO_2 + RCH_2CH_2OH \xrightarrow{180^\circ} PhNH_2 + \text{2-R-quinoline} + + PhNHCH_2CH_2R + PhN(CH_2CH_2R)_2$$

In methanol and isopropyl alcohol, the reaction proceeds selectively (stage I alone); in ethanol, propanol, and butanol, it is possible to obtain 10–40% of quinolines (stage II). A reaction scheme has been proposed to which a ruthenium chelate complex of a Schiff base dimer is an intermediate.[197] A high yield of mono- and di-alkylquinolines is attained in the presence of equimolar mixtures of rhodium and molybdenum complexes;[198] the latter complex, as a Lewis acid, promotes the condensation reaction.

In the absence of molybdenum compounds, rhodium complexes catalyse only the first stage.[199]

Rhodium complexes containing triphenylphosphine are active in solution in a base. Under these conditions, dinitro-compounds are not reduced.[198] The iridium complexes $Ir^I(X)(CH_2{=}CH_2)_2Cl$, where X = 2,2-bipyridyl or 1,10-phenanthroline and some of its derivatives, is the most active.[200] The activity is satisfactorily correlated with the pK_a of the chelate [chelating agent?]. The reduction reaction proceeds in stages and, by altering the alkali : catalyst ratio, it is possible to obtain a high yield of azo- or hydrazo-derivatives. In the presence of the 4,4-diphenylbipyridyl complex, arylhydroxylamine was isolated in a high yield.

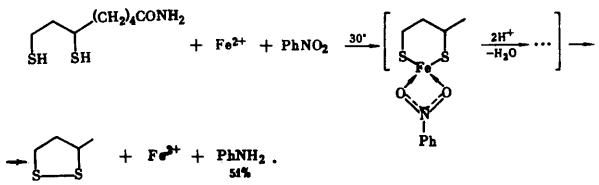
The above procedure is extremely promising, permitting the simultaneous synthesis of products of practical importance (for example, anilines and ketones or aldehydes). Extensive search for more active, stable, and readily available catalysts is essential.

IV. ENZYMIC REACTION OF AROMATIC NITRO-COMPOUNDS

The biological activity of aromatic nitro-compounds, which is manifested by their toxicity[201] (cardiac poisons) and mutagenic,[202] carcinogenic,[203–205] and antibacterial[206–209] activities, is associated with their enzymic reduction. The reduction to aromatic amines or other derivatives is effected by animal tissue homogenates (animals ranging from fish to mammals[210,211]) under aerobic conditions. In animal organisms, aromatic nitro-compounds accumulate mainly in the liver, so that most of the studies have been devoted to the metabolism of aromatic nitro-compounds in mammalian livers.

It has been shown that the reducing activity is localised both in the soluble (cytosol) fraction and in the microsomal fractions, the electron donors being NADP and NADP-H_2 (nicotinamide adenine dinucleotide phosphate and its reduced form). The reduction in cytosol is catalysed by xanthine oxidase[212–214] or DT-diaphorase[215] (enzymes containing an iron–molybdenum cluster linked to sulphur[216,217]). In the microsomal fraction, the reduction of aromatic nitro-compounds is catalysed by other enzymes. *p*-Nitrobenzoic acid can be reduced by purified NADP-H_2-cytochrome *c* reductase, isolated from microsomes, in the presence of flavin adenine dinucleotide.[213,218] Cytochrome P-450 [219–220] or cytochrome b_5 in the presence of NADP-cytochrome b_5 reductase also possess reducing capacity. Later studies established that both microsomal components—NADP-H_2-cytochrome P-450 reductase and cytochrome P-450—are essential for the reduction of nitrobenzene to aniline.[222] The reductase catalyses the first stage in the reduction of the nitro-group, while both components are essential for the reduction of the intermediate arylhydroxylamine. The same features have been observed also in the reduction of *p*-nitrobenzoic acid. The authors note that nitrobenzene-reducing activity is in the main concentrated in the microsomal fraction, while the cytosol fraction exhibits a low activity.

The high activity of an enzyme system comprising three protein components, namely cytochrome b_5, NADP-cytochrome b_5 reductase, and an unknown protein factor, has been noted.[221] The necessity for the presence of several enzymes has also been emphasised in other studies.[223–225] It a study involving microsomal enzymes from



mouse liver homogenate, it has been shown that there are at least two uridine diphosphate transglucuronylases, in the presence of which it is possible to synthesise glucuronide from uridine diphosphate glucuronate and *p*-nitrophenol.[223-225]

The final products of the reduction of aromatic nitro-compounds are usually the corresponding anilines, but it is possible to isolate also intermediate reduction products. It has been shown[203] that the reaction proceeds via the pathway $-NO_2 \rightarrow -NHOH \rightarrow -NH_2$, different enzymes being active in the first and second stages.

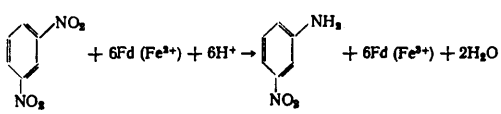
The reduction of 2,4-dinitrotoluene (by cytosol xanthine oxidase) to 2,4-diaminotoluene takes place in stages via 2-amino-4-nitrotoluene and 4-amino-2-nitrotoluene.[226,227] Nitroso-derivatives have not been observed, although their formation is entirely probable, since it has been shown that nitrite reductase in micro-organisms and plants reduces nitrite to hyponitrite and further to hydroxylamine and ammonia:

$$NO_2^- \rightarrow N_2O_4^{2-} \rightarrow NH_2OH \rightarrow NH_3 .$$

The enzymes are known to contain iron thiols;[217] studies[228,229] on the reduction of monosubstituted nitrobenzenes in the presence of the dihydrolipoamide (coenzyme in acyl transfer and redox reactions)—iron(II) system in a weakly basic medium are therefore of interest:

It has been noted that the system is unreactive in relation to the reduction of C=C, C=O, CN, and ester groups. The yields of the products (in %) are as follows:

(a) for *p*-substituted aromatic nitro-compounds:



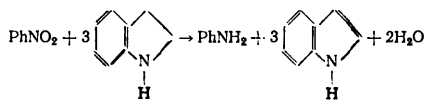
CH_3	OCH_3	NH_2	CN	$COCH_3$	$OCOCH_3$	Cl
35	73	77	94	90	66	58

(b) for *o*-substituted aromatic nitro-compounds:

$COCH_3$	CHO	OCH_3	NH_2	CN
73	67	81	97	84

In the series of thiols, the highest activity is shown by cysteine.

The reduction of 2,4-dinitrophenol, nitrobenzene and *m*-dinitrobenzene by ferredoxin (and iron-containing protein) has been described:[230]



where $Fd(Fe^{2+})$ is the reduced form of ferredoxin, which acts in this reaction as a single electron donor. 2,4-Dinitrophenol is reduced under these conditions to 2-amino-4-nitrophenol.

It is seen from the data presented in this Section that the enzymic reduction of aromatic nitro-compounds takes place in the same way as the reduction by transition metal complexes. An unusual feature is that the enzyme systems are mainly iron and molybdenum clusters linked to sulphur. Comparison of the enzyme systems with coordination compounds shows that the enzyme systems are more selective and that catalytic properties most similar to theirs are shown by platinum group metal complexes with highly conjugated ligands.[4]

V. OTHER REACTIONS

Hydrogen transfer from cyclic amines to aromatic nitro-compounds catalysed by noble metal salts has been described:[231,232]

A high activity has been observed for $RuCl_3.H_2O$ and $RhCl_3.3H_2O$, in the presence of which the yield of aniline is 88 and 82% respectively. Palladium, rhenium, and platinum chlorides are weakly active, while cobalt and nickel compounds and phosphine complexes of rhodium and ruthenium do not catalyst the reaction. Secondary cyclic amines—indoline, tetrahydroquinoline, 3-pyrroline, piperidine, and pyrrolidine—are effective hydrogen donors. The authors explained this by their pronounced coordinating properties. The rate-limiting stage is the activation of the nitro-group, since the intermediate nitrosobenzene and phenylhydroxylamine are reduced under these conditions faster by two orders of magnitude than the nitro-group, while azo- and hydrazo-benzene are reduced an order of magnitude faster. A mechanism involving the coordination of the aromatic nitro-compound to the complex has been suggested:

$$RhCl_3 + Ind \rightarrow Rh^ICl + Inl + 2HCl ,$$
$$Rh^ICl + PhNO_2 \rightarrow Rh^ICl(PhNO_2) ,$$
$$Rh^ICl(PhNO_2) + 3Ind \rightarrow Rh^ICl + PhNH_2 + 3Inl + 2H_2O .$$

where Ind = indoline and Inl = indole.

The direct synthesis of the anilides RCONHPh from an aromatic nitro-compound and organic acids RCOOH can be achieved by employing molybdenum carbonyl.[233] Depending on the substituent, the yield of anilides ranges from 46 to 85%. The reaction is selective with respect to the nitro-group; the C=C bond and the OH, C=O, OCH_3, COOH, NH_2, CN, etc. groups are not reduced. In the presence of another catalyst, namely $RuCl_2(PPh_3)_3$, and added triethylamine, aniline was obtained under the same conditions.[234] The $PtCl_2(PPh_3)_2 + SnCl_2$ system exhibits activity in the reductive acylation of aromatic nitro-compounds in a CO atmosphere:[235]

$$PhNO_2 + RCOOH + 3CO \rightarrow PhNHCOR + 3CO_2 .$$

$SnCl_4$ can be replaced here by other Lewis acids.

- - - o0o - - -

Thus one may conclude that the use of coordination compounds in the chemistry of aromatic nitro-compounds is developing vigorously; this has made it possible to obtain complexes with a fundamentally new structure and complex catalysts effective and selective in reduction reactions can be created on the basis of theoretical ideas. It is likely that coordination compounds based on aromatic nitro-compounds may possess interesting biological properties (see, for example, Nishida et al.[236]).

The Structure and Electron-donor Properties of Organic Compounds of Selenium(II)

E.N.Gur'yanova

The results of studies of the structure and complex-forming power of organic compounds of selenium have been summarised. The principal characteristics of the geometry of the molecules and their orbital state and electron-donor properties have been discussed. Quantitative estimates of the complex-forming power of selenium compounds have been given. The questions of the generation of selenium-centred free radicals and their stabilisation by complex formation have been examined. The bibliography contains 225 references.

I. INTRODUCTION

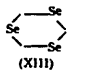
The organic chemistry of selenium has developed intensively in recent years, and is acquiring increasing importance in various branches of science and technology. One factor responsible for this was the discovery of the part played by selenium in living organisms.[1-3] The biochemical role of this element was understood when it was shown that selenium-containing proteins are components of various enzymes.[3] Another important factor in the development of the organic chemistry of selenium was the discovery of "organic metals", that is organic superconductors obtained from charge-transfer complexes and radical-ion salts using selenium compounds.[4,5] Research is being carried out to find new promising selenium-containing compounds for these purposes, and their structures are being studied.[6-9] Organic selenium compounds are used to obtain films of semiconducting materials.[10] In addition, a number of organoselenium compounds are highly reactive towards free radicals, and this opens up the possibility of their use as antioxidants.[3] There are indications that selenium compounds are more effective antioxidants than the corresponding sulphur compounds.

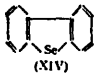
Various aspects of the chemistry of selenium have been dealt with in a monograph,[1] collected papers,[2,3] and reviews,[11-13] but a number of problems which have developed in recent years have not yet been summarised. This applies, in particular, to studies of the electronic structure and orbital state of organoselenium compounds, and their complex-forming power.

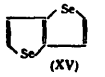
An extremely important aspect of the electronic structure of molecules is the nature of the occupied and unoccupied molecular orbitals: their energy, symmetry, and degree of delocalisation. Of particular interest are the boundary orbitals—the highest occupied (HOMO) and the lowest unoccupied (LUMO) molecular orbitals, since the nature of these orbitals is the main factor determining such important properties of molecules as the ionisation potential, electron affinity, spectral properties, and reactivity, including complex-forming power. Published summaries of the coordination properties of selenium compounds deal chiefly with inorganic compounds[11] and complexes with transition metal ions.[12,13]

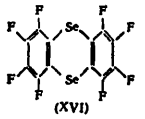
In the present review, an attempt has been made to summarise the results, obtained chiefly in recent years, of studies of the geometry and molecular-orbital state of organic compounds of divalent selenium, and their coordination properties with respect to acceptors of different types (σ, ν, π). Particular attention has been paid to the quantitative estimation of the electron-donor power of organoselenium compounds. The questions of the generation of selenium-containing free radicals and their stabilisation by complex formation have been examined.

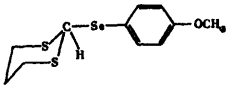
II. SELENIDES

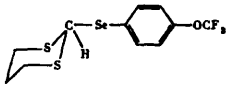












1. The Geometry and Molecular-Orbital State of Selenides

The selenium atom in organic selenides R_2Se, as in compounds of the type RSe−SeR or $R_nE=Se$ (E = C, P) in accordance with the state of the valence electrons $4s^2p_z^2p_xp_y$, has two bonded (p_x, p_y and four non-bonded (s^2, p_z^2) electrons. The extent of the participation of the atomic orbitals of selenium in the formation of the molecular orbitals of a given compound to a large extent determines the geometry of the molecules and their properties.

The structural parameters of a number of selenides, found by X-ray diffraction (XRD) in the crystalline state, by microwave spectroscopy (MWS) and by electron diffraction (ED) in the vapour are given in Table 1. For a complete picture, Table 1, in addition to data obtained in recent years, also includes data given earlier.[2,3] Judging from the values of the valence angle CSeC (92−96°) for the aliphatic selenides (I)−(V), the participation of the valence 4*s* orbital in the formation of the Se−C σ-bond in these compounds is slight. In the aromatic compounds (VI)−(VIII), the CSeC angle is larger, 100−106°. The Se−C bond lengths depend to a marked extent on the state of hybridisation of the carbon atom, and have the following values: for the aliphatic compounds (Se−C_{sp^3}) 1.94−1.98 Å (I)−(V), (XVII), (XVIII), for the aromatic compounds (Se−C_{sp^2}) 1.90−1.92 Å (VI)−(X), (XVII), (XVIII), and for Se−C_{sp} (selenocyanate group) 1.84−1.85 Å (IV), (IX). The differences in the Se−C bond lengths for aliphatic and aromatic compounds can be seen particularly clearly by comparing the data for the cyclic compounds(XII), (XIII), and (XIV)−(XVI). The observed changes in the bond length in the order Se−C_{sp^3} > Se−C_{sp^2} > Se−C_{sp} are fairly large, and apparently cannot be attributed entirely to the differences in the state of hybridisation and hence in the dimensions of the corresponding carbon atoms. Thus the difference in the C−H bond lengths for different valence states of the carbon atom does not exceed 0.03 Å: C_{sp^3}−H (1.09), C_{sp^2}−H (1.07), C_{sp}−H (1.06 Å), whereas in the CC multiple bond series, these differences

are ten times greater: $C_{sp^3}-C_{sp^3}$ (1.54), $C_{sp^2}-C_{sp^2}$ (1.39), $C_{sp}-C_{sp}$ (1.20 Å). Comparison of these data makes it possible to regard the decrease in the length of the Se–C bond in the above series as evidence of additional Se–C bonding as a result of the interaction of the lone pair of electrons (LPE) of the selenium atom with the π-system of the electrons of the aromatic (unsaturated) fragment ($p\pi$-conjugation).

*Se–CN bond length 1.854 Å, **1.837 Å.

A similar sequence is observed in the change in the dipole moments of the Se–C bonds. The dipole moments of the Se–C bonds,[31] calculated from the experimental dipole moments of the corresponding compounds by the vector additivity method, are:

$$\overleftarrow{Se}-C_{sp^3}\ 0.70 > \overleftarrow{Se}-C_{sp^3\,(unsaturated)}$$

$$0.53 > \overleftarrow{Se}-C_{sp^3\,(aromatic)}\ 0.30 > \overleftarrow{Se}-C_{sp}\ -0.75\ (Д).$$

The decrease in the dipole moment of the Se–C bond for different valence states of the carbon atom, and the change in its direction (for $Se-C_{sp}$) may be due to a number of factors. In Ref.31, the observed changes in the dipole moments were attributed to differences in the electronegativity of the carbon atom in different valence states:

$$C_{sp^3}\text{—}2.6,\ C_{sp^3\,(unsaturated)}\ \text{—}2.7,\ C_{sp^2}\ \text{—}2.8,\ C_{sp}\ \text{—}3.2,$$

electronegativity of the selenium atom –2.4.[32] The sequence indicated, however, may be determined not only by this factor but also by the changes in the lengths of the corresponding bonds, and also by the possibility of charge transfer from the selenium atom to the aromatic (unsaturated) p-electron system ($p\pi$-conjugation).

The idea of possible $p\pi$-conjugation in aromatic and unsaturated selenium compounds is often used to explain the properties of the corresponding compounds, as described below. The most reliable information on the orbital state of molecules is given by photoelectron spectroscopy (PES). When combined with quantum-chemical calculations in the approximation of Koopman's theory, according to which the ionisation potential is equal to the energy of the corresponding orbital with the sign reversed ($IP_i = -\varepsilon i$), this method makes possible the quantitative characterisation of the orbital state of molecules.

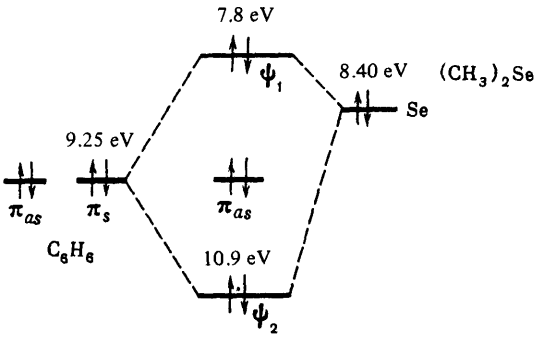

Figure 1. Formation of the HOMO of selenoanisole.[35]

According to quantum-chemical calculations, the first ionisation potential of aliphatic selenides corresponds to an HOMO which is a 4p orbital populated chiefly by an LPE of the selenium atom.[33] An interesting feature is that this orbital is the HOMO not only in dialkyl selenides but also in the series of compounds $(H_3M)_2Se$, where M = Si, Ge.[34] The HOMO of the aromatic selenides includes not only a 4p orbital of the selenium atom but also a contribution from the π_s orbital of the aromatic fragment. The formation of the molecular orbitals of selenoanisole is represented in Fig.1.[35] The mixing of the π_s orbital of the aromatic fragment with the p orbital of the LPE of the heteroatom raises the HOMO relative to the levels of the orbitals of the interacting fragments. Estimation of the contribution of the LPE of the selenium atom to the HOMO of selenoanisole by the HMO method with the parametrisation of the PES calculation[36–38] gave the value 0.834,[39] which is appreciably greater than that for the anisole molecule (0.446) and close to the contribution for the thioanisole molecule (0.738). According to Ref.40, the contribution of the LPE of the heteroatom to the HOMO of the compounds $C_6H_5ECH_3$ of the oxygen sub-group increases in the order: O (0.54) < S (0.77) < Se (0.84) < Te (0.89). The opposite order was obtained in an estimation of the contribution of the π-component of the aromatic fragment.[41] Similar results were obtained by calculating the resonance integrals $\beta(C_{sp^2}-E)$,

where E = O, S, Se, for compounds $C_6H_5ECH_3$. The participation of the LPE of the selenium atom in the general $p\pi$-conjugation system is indicated by the results of the determination of the dipole moments of the interaction ($\Delta\mu_{int}$) for substituted selenoanisoles[42] and phenylselenoacetylenes.[43]

The state of the HOMO is extremely sensitive to the steric and electronic effects of the substituents. For *p*-substituted selenoanisoles, a linear relationship has been established between the first ionisation potential (IP_1), characterising the energy of the HOMO, and the σ^+-constants of the substituents.[39] A similar relationship between IP_1 and σ_m was established for disubstituted selenophenes.[44] For the aromatic compounds C_6H_5SeR, the conformation of the selenide molecules, like that of the corresponding compounds of oxygen and sulphur, is determined to a large extent by the competition between two effects: $p\pi$-conjugation (which is a maximum for a planar molecule, when the angle φ between the plane of the phenyl ring and the CSeC plane is 0°) and steric effects (the tendence for the SeR group to be displaced from the plane of the ring as a result of the mutual repulsion of the substituent R and the *ortho*-hydrogen atoms of the phenyl ring). Depending on the contributions of these effects, which determine the barrier to the rotation of the SeR group relative to the aromatic fragment, an affective conformation of the molecule with a definite angle φ, or an equilibrium between planar (φ = 0°) and orthogonal (φ = 90°) conformers can apparently be produced.

From the doublet character of the first PES band of selenoanisole, it was concluded that the gas phase contains two rotamers;[3] the first component of the band (8.0 eV) was assigned to the HOMO of a planar conformer, and the second (8.3 eV) to a rotamer with minimum overlap of the $4p-\pi$-orbitals. Judging from the intensity of these bands, the ratio of the rotamers is ~1 : 1. At the same time, PES did not detect the presence of rotamers for the corresponding compounds C_6H_5SeR (R = C_2H_5 or iso-C_3H_7) where the 8.3 eV band was assigned to an orthogonal conformer.[45] The differences in the energies of the rotamers are small, even for the corresponding oxygen and sulphur compounds. Thus the difference between the energies of the planar and orthogonal conformers does not exceed 1.3 kcal mole^{-1} for anisole ,[46] and 0.8 kcal mole^{-1} for thioanisole.[47,48] For the selenium compounds, the difference between the energies of the planar and orthogonal conformations should be even smaller. This is apparently one of the reasons why they cannot be distinguished by some methods. Studies of the dipole moments and Kerr constants of selenoanisole and diphenyl selenide in inert solvents indicated that these compounds are conformationally homogeneous, with an angle φ = 32° for the first compound[49] and φ = 48° for the second.[50] According to electron diffraction data, the angle φ in the selenoanisole molecule in the gas phase is 40 ± 13°.[19] The introduction of electron-acceptor substituents in position 4 of the phenyl ring of selenoanisole leads to flattening of the molecules: for the 4-Cl- and 4-Br-derivatives, $\varphi < 20°$, and for the 4-NO_2-derivative, $\varphi \simeq 0°$.[49] At the same time, the ^1H and ^2H NMR spectra of 4-chloroselenoanisole in a liquid-crystal solvent[51] indicated that the angle of rotation of the phenyl ring relative to the CSeC plane is ~40°. The planar *s-trans*-structure with a maximum conjugation is characteristic of aryl vinyl selenides.[52] According to the dipole moments and the Kerr constants, the C_6H_5SeCN molecule, unlike selenoanisole, has a planar conformation.[53] The infrared (IR) spectra of crystalline specimens in polarised light[54] also detected no signs of conformational non-homogeneity in aryl selenocyanates. Electron-donor substituents (OCH_3, $N(CH_3)_2$ in position 4 of the phenyl ring do not break down the planar conformation of phenyl selenocyanates, but electron-acceptor substituents (Cl, Br, NO_2) lead to slight breakdown of the coplanarity of the C_6H_4SeCN fragment.[53] Birefringence established an increase in the non-coplanarity of 1,4-disubstituted compounds of selenium of the type $RSeC_6H_4SeR$ (R = CN or CH_3), compared with the monosubstituted compounds.[55] In a study of the conformation of the molecules of aliphatic selenides R_2Se (R = CH_3, C_2H_5), proton magnetic resonance data, in agreement with IR and Raman spectroscopic data, showed that in these compounds there is free rotation of R about the C–Se bond.[56] The IR and Raman spectra of diethyl selenide in argon and nitrogen matrices, however, indicate the existence of conformational isomerism in the solid state.[57] NMR is extremely promising for the study of the electronic and geometric structure of organic selenides. Various nuclei are studied, including the ^{77}Se isotope, whose natural concentration is 7.6%.

The differences between the chemical shifts δ of ^{77}Se in different compounds are fairly large (in a number of cases reaching 10^2-10^3 p.p.m.[58,59]) and are not sensitive to the solvent,[59,60] and this makes possible a fairly reliable determination of the electronic state of the molecules.

The number of published papers on the study of organic selenides by ^{77}Se NMR has increased considerably in recent years, Since the chemical shift reflects the charge state of an atom, the values of δ for ^{77}Se are sidely used in studies of intramolecular electronic interactions. For a large group of compounds of the type XC_6H_4SeR, a linear relationship has been established between δ for ^{77}Se and the Hammett constant σ (X).[59] A more detailed ^{13}C and ^{77}Se NMR study of compounds of the type XC_6H_4SeR indicated that δ $^{13}C(1)$ are linearly correlated with σ_I and σ_R of the substituents.[61] The values of δ ^1H, δ ^{13}C, and δ ^{77}Se have been used in studies of the conformation and intramolecular electronic interactions in a number of compounds: $PhSeCH=CH_2$,[62] $CH_3SeC\equiv CR$,[63] mono-, di-, and triseleno-substituted ethylenes,[64] and condensed five-membered heterocyclic compounds based on selenophene.[65] Data on the temperature dependence of δ ^{77}Se for phenylselenylcyclohexane derivatives have been used to estimate the barrier to inversion of the cyclohexyl fragment.[66] ^{77}Se NMR has been used to study the structure of molecules containing selenium–sulphur bonds, of the type XC_6H_4Se-SR, which provide models of biological systems.[67] Measurements of the ^{77}Se and ^{125}Te chemical shifts for analogous organic selenides and tellurides indicated that there is a linear relationship between these quantities: δ Te = 1.60 δ Se.[68,69] The relationship between δ ^1H, δ ^{13}C, and δ ^{77}Se for cyclic compounds of selenium has been studied.[70,71] ^{77}Se NMR gives extensive information on the composition of the compounds formed in the binary sulphur–selenium system.[72]

In addition to the chemical shift of the selenium atom, another parameter extremely sensitive to change in the electronic structure of molecules is the spin–spin coupling constant $^1J(^{77}Se-^{13}C)$. In a series of selenides RSeR', this constant increases with increase in the *s*-character of the hybridised orbital or the carbon atom forming the bond with the selenium atom.[73,74] In a series of selenoanisoles, $^1J(^{77}Se-^{13}C)$ increases when acceptor substituents (4-NO_2-) are introduced into the aromatic ring, and decreases when donor substituents (4-NH_2-) are introduced, due to the change in the intensity of the $p\pi$-conjugation and the Se–C bond order.[73] In Ref.75, the stereochemistry of aromatic compounds of selenium was studied using the spin–spin coupling constant of atoms at a greater distance from one another, namely $^2J[^{77}Se-^{13}C(2, 6)]$. The nature of the dependence of $^2J[^{77}Se-^{13}C(1)]$ on the number and nature of the *ortho*-substituents in various aromatic compounds of selenium has been established. The influence of the $^{13}C:^{12}C$ isotope effect on the shielding of ^{77}Se in compounds RSeR' has been determined,[76] and a correlation between Δ ^{77}Se and the length of the Se–C bonds established. The measured spin–spin coupling constants of the selenium nuclei for a number of dialkyl polyselenides $R-(Se)_n-R$ (n = 2–5) indicated that the polyselenide chain has a linear structure.[77]

Valuable information on the electronic and spatial structure of aromatic and unsaturated compounds of selenium is provided by ^{13}C NMR. For selenides C_6H_5SeR, the values of δ for ^{13}C in position 4 of the phenyl ring (relative to TMS) are as follows:[78]

R	CH_3	C_2H_5	C_3H_7	*iso*-C_3H_7	$C(CH_3)_3$
$\delta^{13}C$ (4)	125.55	126.24	126.16	126.84	128.10

The differences in the inductive constants of these R are comparatively small, so that they should have practically no influence on the charge state and hence on the magnitude of δ for the C(4) atom. The observed nature of the change in δ $^{13}C(4)$ with increase in the size of R reflects the influence of steric effects on $p\pi$-conjugation in aromatic selenides; this is indicated by the fairly good correlation between $\delta^{13}C(4)$ and the steric constants E_s^0 of the substituents.[78] ^{13}C NMR has been used to determine the dependence of the degree of $p\pi$-conjugation and the conformational state on the nature of the substituents in substituted selenoanisoles.[79–81] Acceptor substituents lead to an improvement, and donor substituents to a deterioration, in the conditions for $p\pi$-conjugation and hence for coplanarity of the molecules. The relationship between the values of σ for ^{13}C and the constants σ_I and σ_R of the substituents has been established for phenyl vinyl selenides[82] and divinyl selenides.[83] δ ^{13}C data have been used to determine the previously unknown values of σ_R^0 for the selenium-containing substituents C_2H_5Se (–0.12) and $CH_2=CHSe$ (–0.09),[83] and ^{19}F NMR data for the *para*-fluorine atom in the aromatic fragment have been used to determine σ_p for the substituents CF_3Se (0.44) and $(CF_3)_3CSe$ (0.54).[84] The interaction of the LPE of the selenium atom with the π-electron system of the aromatic (unsaturated) fragment has been studied by ultraviolet spectroscopy combined with quantum-chemical calculations. The nature of the electron transitions has been studied in derivatives of selenoanisole and their isologues[85] and in substituted aryl allyl selenides,[86] alkyl vinyl selenides, and divinyl selenide.[87] Quantum-chemical calculations of the electron transitions in the PPP approximation have shown that the resonance integrals and hence the degree of $p\pi$-conjugation in a series of analogous compounds of the group VI elements decrease in the order: $\beta(C-O) \gg \beta(C-S) > \beta(C-Se) > \beta(C-Te)$.[85,87] Possible $p\pi$-bonding in the compounds $CH_2=CH-C\equiv CSeCH_3$ and $C_2H_5C\equiv C-C\equiv CSeCH_3$ is indicated by the results of quantum-chemical calculations (CNDO/2).[88] At the same time, studies of the IR spectra of selenoanisole, phenyl selenocyanate, and their derivatives[89,90] showed that the spectra of these compounds represent the sum of the practically non-perturbed spectra of the phenyl ring and the $SeCH_3$(SeCN) group), from which it was concluded that there is very little intramolecular interaction. As the authors themselves point out, however, this conclusion was reached without carrying out a normal-coordinate analysis, so that it is not sufficiently well-founded.

2. The Electron-Donor Properties of Selenides

The properties of selenides as electron donors is determined to a large extent by the state of the HOMO, and primarily by its energy and symmetry. According to quantum-chemical calculations (CNDO/2) for dimethyl selenide, the contribution of the LPE of the selenium atom to the HOMO is 0.88, so that the charge on the selenium atom is 0.77.[88] Evidence that the HOMO of aliphatic selenides consists chiefly of the $4p^2$-LPE of the selenium atom is provided by the results of structural studies of the complexes formed by selenides. Table 2 gives the published structural parameters of complexes of selenides with σ-acceptors (A = I_2, ICl) and ν-acceptors (A = $PdCl_2$, $PtBr_2$). The angle (<C–Se–A) formed by the coordinate bond Se–A with the Se–C bond is 100–107°, that is the donor–acceptor bond Se–A, in accordance with the orientation of the orbital of the $4p^2$-LPE, is almost perpendicular to the plane of the C–Se–C bonds of the selenide molecule. The lengths of the intermolecular bonds (r_{DA}) of the complexes vary over a fairly wide range; this can be clearly seen by comparing the values of $\Delta r = e_{DA}^{expt} - (r_D + r_A)_{cov}$, where r_{DA}^{expt} is the experimental length of the intermolecular bond, and r_D and r_A the covalent radii of the atoms of the molecules of the donor and the acceptor involved in the formation of the donor–acceptor bond (the covalent radii of the atoms given by Pauling[98] were used in the calculations). For the comparatively weak complexes formed by selenides with halogens, the values of Δr are large, whereas for the complexes with compounds of Pd and Pt, the length of the intermolecular bond is practically equal to the sum of the covalent radii of the corresponding atoms.

Table 2. Structure of selenide complexes.

Complex	D–A bond	r_{DA}, Å	Δr*, Å	C–Se–A angle, °	Refs.
	Se–I	2.762	0.26	100.5	[91]
	Se–I	2.829	0.33	100.5	[92]
	Se–I	2.755	0.25	107.0; 102.0	[93, 94]
	Se–I	2.630	0.13	104.1; 99.0	[93]
$PdCl_2 \cdot 2(C_4H_9)_2Se$	Se–Pd	2.424	0	100.8; 109.5	[95]
$PdCl_2 \cdot [CH_3SeCH(CH_3)_2]_2$	Se–Pd	2.40 2.36	–0.07	105.5; 103.7; 107.4; 104.2	[96]
$PtBr_2 \cdot 2$ 	Se–Pt	2.43	0	110.5; 107.2	[97]

*$\Delta r = r_{DA}^{expt} - (r_D + r_A)_{cov}$.

From the previously established relationship between $-\Delta H$ and Δr,[99] covering a wide range of molecular complexes of the $n\nu$ and $n\sigma$ types, including the complexes of selenides with a number of acceptors, the energy of formation of the Pd–Se and Pt–Se bonds in these complexes should be greater than 15 kcal mole^{-1}.

Complex formation by organic selenides with iodine has been studied in most detail by electronic spectroscopy.[100–134] The spectra of the complexes contain new bands, charge-transfer bands (CTB), not present in the spectra of the starting materials. The positions (ν_{CTB}) and energies ($h\nu_{CTB}$) of the charge-transfer bands in the spectra of the complexes have been established, and the stability constants determined. The temperature dependence of the equilibrium constants has been used to determine the thermodynamic parameters of complex formation by iodine with alicyclic[101] and cyclic selenides,[102,103] and with aromatic selenides of the substituted selenoanisole[104–109] and diphenyl selenide[100,110,111] types. In Ref.112, complex formation by selenides of different kinds with iodine was studied not only by electronic spectroscopy but also by calorimetric titration. The compositions and enthalpies of formation of the complexes were determined, and their electronic spectra studied. The values of $-\Delta H$ for the complexes of a number of selenides with iodine are given in Table 3. For aliphatic selenides, equations were obtained, relating the values of $-\Delta H$ to $h\nu_{CTB}$ and $-\Delta H$ to $\Sigma\sigma^+$ (the sum of the inductive constants of the substituents). Aromatic selenides, like the aliphatic compounds, behave as

n-donors towards I_2, and the coordination centre is the selenium atom. A noteworthy feature is that the absolute values of $-\Delta H$ for the complexes of I_2 with aromatic selenides are smaller than those for aliphatic selenides (Table 3); this is apparently related not only to the differences in the influence of the inductive effects but also to the expenditure of energy to break down the $p\pi$-conjugation in the aromatic selenides. According to Raman spectroscopic data, the wavenumber of the I—I vibrations decreases from 215 cm^{-1} in the original I_2 molecule to 165 cm^{-1} in the complex $(CH_3)_2Se.I_2$ and 160 cm^{-1} in the complex $(C_2H_5)_2Se.I_2$.[113] The stretching wavenumber of the intermolecular Se—I bond in the complex $(C_2H_5)_2Se.I_2$ was found to be 100 cm^{-1}.[114] This value is much lower than the vibrational wavenumber of the intermolecular Se—B bond (256 cm^{-1}) in the complex $(CH_3)_2.Se.BF_3$.[115] These differences are apparently due to the difference in the strengths of the intermolecular bonds in these complexes. Systematic spectral studies of complexes of iodine with substituted selenoanisoles[104–109] revealed a number of general regularities of complex formation. A linear relationship was established between the values of $-\Delta H$ and the constants $\sigma_{m,p}$ of the substituents in the phenyl ring, and also between $-\Delta H$ and the displacement of the iodine band in the electronic spectrum on complex formation $\Delta\nu_{I_2}$, and between the changes in the enthalpy ΔH and the entropy ΔS in complex formation.[104–106] The solvatochromism of the charge transfer bands was used to study the influence of solvents of different character on the thermodynamics of the formation of complexes of selenoanisoles with iodine.[108,109] Analysis of the experimental data showed that the observed differences in the values of $-\Delta H$ for a given complex in different solvents are due chiefly to the contribution of the specific solvation of the iodine molecule. For the molecules of the donor and the complex in the series of solvents studied, specific solvation takes place for the most part.

Table 3. Enthalpies of formation of the complexes (kcal $mole^{-1}$).

Selenide	I_2 (Ref.112) 1:1	$AlBr_3$ (Ref.129) 1:1	$SnCl_4$ (Ref.128) 1:1	$SnCl_4$ (Ref.128) 1:2
$(C_2H_5)_2Se$	9.9	—	—	—
$(C_3H_7)_2Se$	9.7	29.9	14.3	27.7
$(C_4H_9)_2Se$	10.2	—	14.6	28.4
$(C_8H_{17})_2Se$	9.8	30.1	13.9	27.8
$(C_6H_5CH_2)_2Se$	9.2	27.4	—	—
$C_6H_5SeCH_3$	7.6	24.9	—	—
$C_6H_5SeC_3H_7$	8.4	26.2	—	—
$C_6H_5SeCH_2CH{=}CH_2$	8.0	26.1	—	—
$(C_6H_5)_2Se$	3.6	22.6	—	—
$(4\text{-}CH_3C_6H_4)_2Se$	—	23.8	—	—

Organic selenides form complexes with π-acceptors; the complexes of aromatic selenides and derivatives of selenophene with tetracyanoethylene (TCE) have been studied in most detail by electronic spectroscopy. The observed charge-transfer bands in the spectra of these complexes are due to electron transitions from the HOMO of the selenide to the LUMO of the TCE molecule. In most cases, the spectra of the complexes of aromatic selenides, like the spectra of the complexes of other π-donors with TCE, contain not one but two charge-transfer bonds, corresponding to electron transitions from the highest orbitals [π_s $\nu_{max}(CTB_1)$ and π_{as} $\nu_{max}(CTB_2)$, see Fig.1] of the selenide molecule to the LUMO of the acceptor molecule. The position of the maximum of the first CTB [$\nu_{max}(CTB_1)$] and its energy [$h\nu_{max}(CTB_1)$] are directly related to the energy of the HOMO and to the first ionisation potential (IP_1) of the corresponding selenide. A linear correlation between $\nu_{max}(CTB_1)$ and IP_1 was established for the complexes of TCE with selenophene and its substituted derivatives.[116,117] The complexes formed by heterocyclic compounds of selenium with TCE are more stable than those formed by the corresponding heterocyclic compounds containing sulphur.[118] For selenophenes containing different substituents in position 2, a correlation was established between the first ionisation potential and the σ_m-constants of the substituents.[119] Spectral studies of the complexes of TCE with substituted selenoanisoles, together with photoelectron spectroscopic data and quantum-chemical calculations,[39,107,120–123] established the principal regular features of the formation of the intermolecular bonds and the properties of the complexes. The nature of the electron transitions and the two observed CTB in the spectra of the complexes was examined, the regular features of the influence of electronic and steric effects on the position and intensity of the CTB were established, and the relationship between the spectral parameters and the orbital characteristics of the molecules determined. A large amount of experimental material on the complexes of TCE with substituted selenoanisoles and phenyl selenocyanates[124] established a linear relationship between the energy of the first CTB and the electrophilic σ^+-constants of the substituents.

A study of the electrochemical oxidation of substituted selenoanisoles[125] also established a linear relationship between the potential $E_{1/2}$ and the electrophilic constants of the substituents σ^+. The value of the electrochemical reaction constant ($\rho = -0.28$) was found to be practically equal to the constant found from a spectrophotometric study of the complexes of selenoanisoles with TCE ($\rho = -0.25 \pm 0.03$). This appears quite logical, since both of these methods characterise the state of the HOMO of the compounds being studied. The second charge-transfer band of the complexes of TCE with substituted selenoanisoles, unlike the first band, is little influenced by substituents,[123] and its position and energy are close to those of the CTB of the complex of TCE with benzene.

The linear relationship between $\nu_{max}(CTB_1)$ and IP_1 for TCE complexes covers a wide range of varied electron donors containing different heteroatoms, and has the form:[126]

$$IP_1\,(eV) = 5.86(\pm 0.06) + (1.31 \pm 0.03) \times 10^{-4}\,\nu_{max}(CTB_1)\,(cm^{-1}). \quad (1)$$

This equation is widely used to determine the ionisation potentials of complex heteroaromatic compounds, including selenium-containing compounds (such as arylselenoacetylenes,[127] selenides containing a carbonyl group,[107] etc.) from the measured CTB in the spectra of the complexes with TCE. Thus the electron-donor properties of selenides towards iodine (σ-acceptor) and TCE (π-acceptor) have now been fairly fully studied by electronic spectroscopy. There are extremely few published data, however, on the structural and thermodynamic parameters of complexes of selenides with other acceptors, including ν-acceptors. Calorimetric titration has been used to determine the enthalpies of formation of the complexes of a number of selenides with tine tetrachloride (with the 1:1 and 2:1 compositions),[128] aluminium tribromide,[129] and boron tribromide.[130] The enthalpy of formation of the complex $(CH_3)_2Se.Ga(CH_3)_3$ has been determined by the gas dissociation method.[131] The values of $-\Delta H$ (kcal $mole^{-6}$) for a number of complexes of selenides with aluminium tribromide and tin tetrachloride are given in Table 3. The selenides form fairly stable complexes with these acceptors. Studies of the complex-forming power of bis-selenides of the type $RSe(CH_2)_nSeR$ towards PT and Pd salts by ^1H, ^{77}Se, and ^{195}Pt NMR, ultraviolet, and IR spectroscopy made it possible to solve various problems of the stereochemistry of the complexes formed and to determine the relationship between the parameters found.[132] ^1H NMR and IR spectroscopy established the formation of H-complexes of a number of selenides with phenol.[133-135]

Analysis of the results of an IR Fourier spectroscopic study of the complex $H_2Se.HF$ in an argon matrix led to the conclusion that it has a pyramidal structure,[136] which is consistent with the view that the $4p^2$-LPE of the selenium atom takes part in the formation of an intermolecular H-bond. Non-empirical quantum-chemical calculations for the complex $H_2Se.HCN$ [137] also indicate that it has a pyramidal structure.

A detailed study of the IR and Raman spectra of the complex $(C_2H_5)_2Se.HCl$ in argon and nitrogen matrices revealed fine effects due to conformational isomerism. The different rotational isomers of diethyl selenide react with HCl to give complexes with different stability.[57] In addition to the 1 : 1 complexes, 1 : 2 complexes with branched H-bonds were detected. The formation of complexes with the same composition was also established in the reaction of diethyl selenide with HCl in CCl_4.[138] It was concluded that the H-bond in the complex in the argon matrix is stronger than that in an inert solvent.

The high sensitivity of the chemical shift in the ^{77}Se NMR spectra has been used successfully to study complex formation by phenyl selenylacetate with the enzyme α-chymotrypsin. The composition of the complex (1 : 1) was established, and its dissociation constant determined.[139] Thus organic compounds of selenium, like the corresponding compounds of the other elements of the oxygen subgroup of group VI form fairly stable complexes with various acceptors. To estimate the degree of similarity and difference in the electron-donor properties of these compounds, various parameters of the complexes which they form can be compared. The most reliable characteristic of the complex-forming power of a given donor towards a given acceptor is the enthalpy of formation of the complex. The enthalpies of formation $-\Delta H$ (kcal mole^{-1}) of a number of 1 : 1 complexes are given below.[129,130,135,140] There are practically no published quantitative data on the complex-forming power of tellurium(II) compounds.

Donor	Acceptor				
	I_2	BBr_3	$AlBr_3$	$SnCl_4$	C_6H_5OH
$(C_2H_5)_2O$	4.3	18.8	36.5	5.8	5.9
$(C_3H_7)_2S$	8.1	22.8	31.1	12.6	4.2
$(C_3H_7)_2Se$	9.7	22.8	29.9	14.6	3.7

Thus the order of change in the values of $-\Delta H$ in the series ethers – sulphides – selenides is different for the reactions with different acceptors.

As noted above, the electron-donor properties of molecules are determined to a large extent by the energy state of the HOMO, given by the first ionisation potential. For the compounds RER^1 of the elements of the oxygen sub-group, the values of IP_1 (eV) are as follows:

R	R^1	O	S	Se	Te
—	—	13.6	10.4	9.75	9.01
CH_3	CH_3	10.0	8.65	8.40	7.89
C_6H_5	CH_3	9.29	8.07	7.99	7.60
C_6H_5	C_6H_5	8.09	7.80	7.79	—

The values of IP_1 decrease with increase in the principal quantum number of the element, in the order O > S > Se > Te. A large change is observed on going from the oxygen compounds to the sulphur compounds, and the differences in the IP_1 values for the sulphur and selenium compounds are much smaller. Judging from the IP_1 values, the donor properties of the compounds of the elements of group VI should increase in the following order: O < S < Se < Te. This order is not always observed, however, This can be clearly seen by comparing the order of change in the values of $-\Delta H$ for the complexes of ethers, sulphides, and selenides with iodine (Se > S > O) and with phenol (O > S > Se). Of considerable importance in the formation of the intermolecular bond are the conditions of overlap of the interacting orbitals—the HOMO of the donor molecule and the LUMO of the acceptor molecule.

The overlap integrals of the corresponding orbitals (indicated in brackets) for a number of model donor–acceptor bonds are given below:[130,140]

Acceptor	Donor			
	R_2O ($2sp^2$)	R_2S ($3p$)	R_2Se ($4p$)	$R_3P{=}Se$ ($4p$)
I ($5p$)	0.27	0.34	0.41	0.47
B ($2sp^2$)	0.34	0.46	0.41	0.50
Al ($3sp^2$)	0.40	0.38	0.43	—
Sn ($5sp^2d$)	0.76	0.60	0.63	—
OH ($1s$)	0.43	0.36	—	—

The order of change in the overlap integrals for the complexes of the oxygen, sulphur, and selenium compounds with iodine agrees with the order of change in IP_1, so that the enthalpy of formation of the complexes of I_2 with the selenides should be greater than for the sulphides and ethers, as observed experimentally. For the complexes with compounds of boron, aluminium, and tin, the order is slightly different, and this is reflected in their enthalpies of formation. An important part in the formation of intermolecular bonds is played by steric effects. These decrease with increase in the size of the central atom of the donors indicated (O > S > Se), and for the above acceptors they are most clearly revealed in the complexes $D.BBr_3$ and $D.SnCl_4$. Thus the order of change in the electron-donor properties of a given series of compounds is determined by a number of factors, and may be different for the reactions with different acceptors.

III. THE STRUCTURE AND COORDINATION PROPERTIES OF COMPOUNDS OF THE TYPE $R_nE{=}Se$

The intensive development of the chemistry of selenium in recent years has drawn the attention of research workers to the selenium analogues of ketones, phosphine oxides, and carboxylic acid amides, that is compounds containing E = Se bonds. Of these, the compounds containing $\geqslant P{=}Se$ and $\geqslant C{=}Se$ bonds have been most fully studied. Structural studies have shown that the phosphorus atom in selenophosphoryl compounds (Table 4) is at the centre of a slightly distorted tetrahedron; the average values of the SePC and CPC valence angles are 111 – 114° and 103 – 106° respectively. The rings of the aromatic fragments of the compounds studied are rotated relative to one another; the angles made by the plane of the ring with the C – P – Se plane are different compounds, and also vary over a wide range for different rings in the same compound, for example from 13° to 56° in compound (XVII). An exception is the fairly symmetrical (C_3) structure of the molecule of tris(2-furyl)-phosphine selenide (XX); the angles made by all three furyl groups with the C – P – Se plane in this compound are almost identical, and the torsional angles O – C – P – Se are 48.2, 46.3, and 46.7°. A noteworthy feature is the relatively large difference in the lengths of the C – P and P = Se bonds for different phosphine selenides. The observed differences have been attributed to the influence of steric effects [for example for compounds (XVII) and (XVIII)], the inductive effect of the substituents [for compounds (XVIII) and (XIX)], and the ability to form $C_{(2p)\pi}-P_{(3d)\pi}$ bonds. Thus according to Ref.145, the fact that the C – P bond in the molecule of tris-(2-furyl)phosphine selenide (XX) is shorter than that in other triarylphosphine selenides is due to the increase in the extent of the $C_{(2p)\pi}-P_{(3d)\pi}$ interaction resulting from the stronger σ-electron-acceptor properties of the 2-furyl group compared with the phenyl group. The fact that the P = Se bond in compounds (XIX) and (XX) is shorter than in compounds (XVI) – (XVIII) has also been attributed to the σ-electron-acceptor properties of the trifluoromethylphenyl or furyl groups and the consequent increase in the *s*-character of the orbital of the P atom in the bond with Se.[145,149]

The vibrations of the $\geqslant P{=}Se$ bond are not characteristic, and vary over a wide range, depending on the composition and structure of the substituents on the phosphorus atom. Thus for compounds

of the type $R_3P=Se$, the vibrational wavenumbers assigned to the P=Se bond are:[150]

R_3	$(CH_3)_3$	$(C_2H_5)_3$	(cyclo-C_6H_{11})$_3$	$(C_6H_5)_3$
$\nu_{P=Se}$ (cm^{-1})	441	422	543	560

According to Raman spectroscopic data, the values of $\nu_{P=Se}$ for the compounds $(C_6H_5)_2P(Se)CH_2-P(X)(C_6H_5)_2$ vary in the range 525–535 cm^{-1} for X = O, S, Se, or the LPE of the P atom.[151]

Table 4. Structural parameters of compounds containing $\geqslant P=Se$ and $\geqslant C=Se$ bonds.

Compound	Bond length, Å C–P, P = Se, or C = Se	Angle C–P–Se, °	Refs.
$(C_6H_5)_3P=Se$ (XVI)	1.826; 2.106	—	[141]
$(2\text{-}CH_3C_6H_4)_3P=Se$ (XVII)	1.834; 2.116	112.7	[142]
$(3\text{-}CH_3C_6H_4)_3P=Se$ (XVIII)	1.820; 2.109	—	[143]
$(3\text{-}CF_3C_6H_4)_3P=Se$ (XIX)	1.815; 2.094	113	[144]
$(2\text{-}C_4H_3O)_3P=Se$ (XX)	1.778; 2.094	114.9	[145]
$4\text{-}(CH_3)_2NC_6H_4P(=Se)(CH_3)_2$ (XXI)	1.82; 2.105	113.3	[146]
$CH_2=C=Se$ (XXII)	— 1.706	—	[147]
O=C=Se (XXIII)	— 1.7098	—	[147]
S=C=Se (XXIV)	— 1.695	—	[147]
HN=C=Se (XXV)	— 1.717	—	[147]
$CH_3N=C=Se$ (XXVI)	— 1.708	—	[147]
$C_2H_5N=C=Se$ (XXVII)	— 1.709	—	[148]

For compounds with different substituents on the phosphorus atom, such as $(C_2H_5)_2ClP=Se$ [152] or $(RO)_nR_{3-n}P=Se$ (n = 1–3; R = CH_3, C_2H_5),[153,154] the spectra show splitting of the $\nu_{P=Se}$ bands, attributed to the presence of rotational isomers. The ratio of the intensities of the corresponding bands can be used to determine the relative concentration of the isomers in the mixture and the thermodynamic parameters of the equilibrium.[154]

A study of the electronic spectra of compounds R′R″R‴P=Se [155] showed that the selenophosphoryl group, like the thiophosphoryl group, has chromophoric properties. The relationship between the position of the long-wave band (230–280 nm), assigned to a $n-\pi^*$ transition, and the nature of the substituents on the phosphorus atom has been studied.

Extremely important characteristics of a chemical bond are its polarity, polarisability, and the anisotropy of the polarisability. The P=Se bond is fairly polar; the magnitude of its dipole moment depends on the nature of the substituents, and for compounds of the type $R_3P=Se$ has the following values:[156]

R_3	$(C_6H_5)_3$	$[(CH_3)_2N]_3$	CH_3Cl_2
$\mu_{P=Se}$ (D)	3.73	3.88	2.89

A linear correlation is observed between the dipole moments of the P=Se bond and the inductive constants of the substituents.[156] Measurements of the dipole moments and the Kerr effect have been used to determine the polarisability and the anisotropy of the polarisability of the P=Se bond in the cyclic selenophosphate $CH_3-C(CH_2O)_3P=Se$.[157]

Vaulable information on the nature of the P=Se bond has been obtained by ^1H, ^{31}P, and more particularly ^{77}Se NMR.[145,149,151,158,159] The values of the chemical shifts δ ^{77}Se and the spin–spin coupling constants $^1J(^{31}P-^{77}Se)$ depend to a significant extent on the nature and stereochemistry of the substituents on the phosphorus atom. Electron-acceptor substituents in compounds of the type $R_3P=Se$ lead to an increase in $^1J(^{31}P-^{77}Se)$, whereas electron-donor and bulky substituents decrease it.[159] For a number of compounds $(XC_6H_4)_3P=Se$, a linear relationship has been established between $^1J(^{31}P-^{77}Se)$ and the constants of the substituents.[158]

The spin–spin coupling constant between directly bonded atoms is increased chiefly by the Fermi-contact interaction of the moment of the nucleus and the spin of the electron of the *s*-orbital. This made it possible to examine the observed changes in the values of $^1J(^{31}P-^{77}Se)$ in a series of analogous compounds in relation to the influence of the substituents on the population of the 3*s*-orbital of the phosphorus atom.[145,159] The $^1J(^{31}P-^{77}Se)$ values for compounds of the type $Ar_3P=Se$ indicate that the 2-thienyl and 2-furyl groups in the corresponding phosphine selenides are electron-accepting.[145,159]

Stable compounds containing C=Se bonds were obtained comparatively recently,[160–162], and have been less extensively studied. Structural studies have shown that the C=Se bonds, like the P=Se bonds (see Table 4) have similar lengths in different compounds; the differences do not exceed ±0.01 Å.

The NMR spectra of organoselenium compounds containing C=Se bonds have shown that the ^{77}Se chemical shift has an unusually high sensitivity to the electronic state of the selenium atom.[161–163] The values of δ ^{77}Se for a number of compounds of this type are much greater, sometimes by ~2000 p.p.m., than δ ^{77}Se for dimethyl selenide, and are extremely sensitive to the structural and electronic characteristics of the molecules.[161] The ^{13}C and ^{77}Se NMR spectra of a number of heterocyclic compounds containing C=Se bonds show that δ (C=^{77}Se) is much more sensitive (by a factor of more than 70) to the influence of structural and electronic effects than δ (^{13}C=Se).[163] Thus ^{77}Se NMR opens up extensive possibilities for studying the structure of organoselenium compounds of this type. Published data on the coordination properties of compounds of the type $R_nE=Se$ relate chiefly to compounds containing $\geqslant P=Se$ bonds. The $\nu_{P=Se}$ band in the IR spectrum is displaced to lower wavenumbers on complex formation. The magnitude of the displacement depends on the composition and structure of the phosphine selenide molecules, and also on the properties of the acceptor. Thus for the complexes of triphenylphosphine selenide with tantalum pentafluoride[164] and iodophenylacetylene,[165] $\Delta\nu_{P=Se}$ had the values 20 cm^{-1} and 21 cm^{-1} respectively. A displacement of the $\nu_{P=Se}$ band by 13–14 cm^{-1} has been observed in the spectra of the complexes of various bidentate phosphine selenides with mercury thiocyanate.[166] Ultraviolet (UV) spectroscopy and calorimetry have been used to determine the thermodynamic parameters of complex formation by phosphine selenides with I_2 [167,168] and $SnCl_4$.[167,169] The enthalpies of formation ($-\Delta H$, kcal $mole^{-1}$) of the 1:1 complexes studied are given below; the values of $-\Delta H$ for the corresponding complexes with $R_3P=O(S)$ are given for comparison:

Donor	Acceptor I_2	Acceptor $SnCl_4$	Donor	Acceptor I_2
$(C_4H_9)_3P=O$	6.4	25.8	$[(CH_3)_2N]_3P=O$	7.3
$(C_4H_9)_3P=S$	9.0	15.6	$[(CH_3)_2N]_3P=S$	8.1
$(C_4H_9)_3P=Se$	13.0	15.4	$[(CH_3)_2N]_3P=Se$	12.5

Thus phosphine selenides form fairly stable complexes with I_2 and $SnCl_4$. The donor properties of the selenium atom in the compounds $R_3P=Se$ are slightly stronger than in the corresponding compounds R_2Se. The relative complex-forming power of the series of compounds $R_3P=X$, where X = O, S, Se, judging from the $-\Delta H$ values for the complexes with I_2, is given by the sequence Se > S > O. The same order was found by UV spectroscopy for the complexes with I_2, ICl, and IBr.[170] The opposite order is observed for the complexes with tin tetrachloride: O > S ⩾ Se. The values of $\Delta\nu_{OH}$ and $\Delta\nu_{NH}$ in the IR spectra of a number of proton donors (naphthol, phenol, pyrole, halogenated alcohols) in their reaction with the compounds $(C_6H_5)_3P=O(S)(Se)$ showed that

their ability to form H-complexes also decreases in the order O > S > Se.[171] Since the differences in the influence of steric factors in complex formation involving these compounds are apparently small, the reversal of the order of their donor properties in the H-complexes and the complexes with $SnCl_4$, compared with I_2, is apparently related chiefly to the conditions of overlap of the interacting orbitals of the molecules of the donor and acceptor, as noted above. The complexes of phosphine selenides of the series $(C_6H_5)_n.(C_4H_9)_{3-n}P{=}Se$ (n = 1–3) with HgX_2 and CdX_2 (X = Cl, Br) have been studied by ^{31}P NMR.[172] The spin–spin coupling constant $^1J(^{31}P-^{77}Se)$ decreases on complex formation, in agreement with IR spectroscopic data ($\Delta\nu_{P=Se}$).

There are almost no published data on the electron-donor properties of compounds containing P=Se bonds. UV spectroscopy has been used to study complex formation by a number of cyclic selenoamides with iodine.[173] The temperature dependence of the equilibrium constants was used to determine the enthalpies of formation of the complexes, which vary over a fairly wide range (6.0–12.0 kcal mole^{-1}), depending on the substituents.

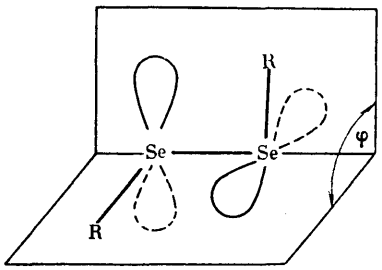

Figure 2. Spatial structure of organic diselenides.[177]

IV. THE STRUCTURE AND ELECTRON-PROPERTIES OF DISELENIDES

Diselenides R–Se–Se–R, like other compounds of the oxygen sub-group with dielement bonds, have a skewed conformation (Fig.2). Structural data (Table 5) show that the interplanar angle C–Se–Se/Se–Se–C (θ) is 75–90°, depending on the composition and structure of R. The Se–C_{sp^3} bond lengths (1.95–2.02 Å) in the molecules of aliphatic diselenides are longer than the Se–C_{sp^2} bond lengths (1.91–1.93 Å) in aromatic diselenides (Table 5). The reason for the observed differences is apparently analogous to that examined above in the analysis of the bond lengths in monoselenides. The Se–Se bond lengths depend on the composition and structure of the groups R, vary over a fairly wide range from 2.28 Å to 2.33 Å for the diselenides indicated in Table 5, and differ from the value 2.34 Å for the length of the ordinary Se–Se bond in elemental selenium.[182]

The main factors responsible for the skewed conformation of diselenides (Fig.2) are: a) the mutual repulsion of the $4p^2$ lone pairs of electrons of the selenium atoms; b) the possibility of additional $p_\pi-d_\pi$ Se–Se bonding; and c) the mutual repulsion of the groups R. Quantum-chemical calculations of the barrier to rotation relative to the diselenide bond in dimethyl diselenide, carried out by the CNDO/2 method with optimisation of the geometry[183] and by the expanded Hückel method,[184] and also non-empirical calculations using different basis sets,[185] showed that they are fairly high. Thus according to these data, the energy of the conversion of the skewed conformation (θ ≃ 90°) into the *cis*-form (θ = 0°) has the values 6,[184] 11.19,[185] or 18.09 [2185] kcal mole^{-1}, and the energy of the conversion into the *trans*-form (θ = 180°) has the values 3,[184] 4.86,[185] or 11.51 [185] kcal mole^{-1}. Analogous calculations of the barrier to rotation relative to the diselenide bond in the $CF_3Se-SeCF_3$ molecule gave the values 45 kcal mole^{-1} for the *cis*-form and 15 kcal mole^{-1} for the *trans*-form.[184] The determination of the barriers to rotation (kcal mole^{-1}) from the temperature dependence of the ^1H NMR spectra of a number of aromatic diselenides gave the following results:

$C_6H_5CH_2Se-SeC_6H_5$	6.3	[186]
$(C_6H_5CH_2)_2Se_2$	<5.6	[186]
$[2,4,6\text{-}(t\text{-}C_4H_9)_3C_6H_2]_2Se_2$	12.5	[187]

The barrier to rotation in the diselenides is ~20% lower than that in the corresponding disulphides.[186] The greater length of the Se–Se bond, compared with that of the S–S bond, apparently decreases the interaction in the diselenide bond, compared with the disulphide. This can explain the lower stability of polyselenides (for example triselenides) compared with polysulphides. It has been suggested[188] that bulky groups such as $[(CH_3)_3Si]_3C$ can stabilise polyselenide bridges. The structure of the triselenide $[(CH_3)_3Si]_3C-Se-Se-Se-C[Si(CH_3)_3]_3$ has been determined.

The measured dipole moments of aromatic diselenides[189–193] indicated that in inert solvents, as in the crystalline state, the diselenides have a coiled conformation; the dihedral angle is 72–85°. The temperature dependence of the dipole moments of diphenyl diselenide and its symmetrically disubstituted derivatives (CH_3, F, Br) confirmed the skewed conformation of the molecules in solution (benzene, 298°) and slight oscillation or rotation of the ArSe groups about the Se–Se bond with increase in temperature.[191] The dipole moments and Kerr constants of disubstituted diphenyl diselenides were used to estimate not only the dihedral angles θ but also the angles of rotation of the phenyl rings (Φ) relative to the C–Se–Se plane in the diselenides studied.[190,192] When electron-donor substituents ($N(CH_3)_2$, OCH_3, CH_3) are introduced into the 4 and 4′ positions of the phenyl rings, the angle Φ increases in proportion to the electron-donor strength of the substituent. On the other hand, strong electron-acceptor substituents (for example NO_2) lead to flattening of the $4\text{-}NO_2C_6H_4Se$ fragment (angle Φ ≃ 0). A linear relationship was established between $\cos^2\Phi$ and σ^+ for the substituent. The dependence of the observed increase in the polarisability of diaryl diselenides on the nature of the substituent has been interpreted in terms of possible conjugation of the two aromatic fragments through the dislenide bridge.[189,192] The possible interaction of the π-electron system of the phenyl rings with the diselenide bridge is indicated by the results of quantum-chemical calculations (Del Re, SSP-PPP), the dipole moments, and the magnitude of the π-charges on the atoms of diphenyl diselenide and a number of

its 4,4′-disubstituted derivatives.[194] Evidence of intramolecular π-electron interaction involving the diselenide bridge of diaryl diselenides is provided by the dependence of the observed changes in the integral intensity of the absorption bands of the Se–Se bond in the Raman spectra on the nature and position (*ortho*, *meta*, *para*) of the substituents.[195] Electron-donor substituents, which increase the electron density of the diselenide bond and hence its polarisability, lead to an increase in the intensity of the corresponding band in the Raman spectrum. For the substituents CH_3, OCH_3, and $N(CH_3)_2$, its value was greatest for 4,4′-dimethylaminodiphenyl diselenide. The decrease in intensity on going from the *para*- to the *ortho*- or *meta*-substituted diphenyl diselenides indicates a decrease in the degree of interaction of the $p\,\pi$-conjugation type between the diselenide bridge and the substituents in the isomer order indicated.[195] Evidence of $p\,\pi$-electron interaction between the diselenide bridge and the aromatic fragments of diaryl diselenides is also provided by the observed linear dependence of the intensity of the Raman bands assigned to the Se–Se bond on the angle of rotation of the phenyl ring. The vibrational wavenumbers of the Se–Se bond for different dislenides lie in the range 270–300 cm^{-1}.[195–200]

The UV spectra of aliphatic diselenides contain one absorption band at about 310 nm.[201] The appearance of this band is usually attributed to an electron transition from the HOMO, formed by a n^--combination of the atomic orbitals of the LPE of the selenium atoms, into the antibonding σ*-orbital of the diselenide bridge. The UV spectra of aromatic diselenides contain three absorption bands at ~250, 270, and 330 nm.[202] The spectral characteristics of the long-wave band are apparently analogous to those of the band observed in the spectra of aliphatic diselenides. The electron transitions at shorter wavelengths are analogous to the absorption bands of selenoanisole, and are probably due to the transfer of electron density from the diselenide bridge to the aromatic fragments.

The formation of the molecular orbitals and the nature of the electron transitions in aromatic diselenides and their isologues were examined in Ref.202.

Valuable information on the nature of the intramoelcular electronic interactions in diselenides has been obtained by ^{77}Se NMR,[203,204] and more particularly by combined ^{13}C and ^{77}Se NMR studies.[205] Comparison of the value of δ $^{13}C(4)$ and δ $^{13}C(3, 5)$ of diphenyl diselenide with δ ^{13}C for benzene showed that the C_6H_5. .SeSe group behaves as both a π-donor and a δ-acceptor towards the phenyl ring, increasing the shielding of C(4) and decreasing the shielding of C(3, 5). The specific features of the influence of substituents in the phenyl rings on the shielding of the selenium atoms of diselenides have been established.[205]

There are extremely few published data on the complex-forming power of diselenides. Spectrophotometry has been used to study complex formation by a number of 4,4′-disubstituted diphenyl diselenides with iodine in heptane.[206,207] Irrespective of the component ratio in the solution, the diaryl diselenides react with I_2 to form 1 : 1 complexes. In contrast to this, in the dimethyl diselenide–I_2 system, 1 : 2 complexes are formed in addition to the 1 : 1 compounds.[206] The difference in the behaviour of the dialkyl and diaryl diselenides in their reactions with I_2 to some extent reflects the difference in their electronic states. Calculations of the electron density distribution by the Del Re and HMO methods showed that the effective (σ + π) electronic charge on each selenium atom of the diphenyl diselenide molecule is much lower than the σ-charge on the selenium atom in the dimethyl diselenide molecule.[206] The results of this calculation indicate that the localisation of electron density on the selenium atoms is greater in dimethyl diselenide than in diphenyl diselenide. This on the one hand confirms the $p\,\pi$-conjugation in aromatic compounds of selenium and on the other hand explains the differences in the donor properties of aromatic and aliphatic diselenides.

Spectrophotometry has been used to study complexes of diphenyl diselenide and its disubstituted derivatives with tetracyanoethylene.[207,208] 1 : 1 complexes are formed in the systems studied. The spectra of the complexes, like the spectra of the complexes of TCE with diaryl monoselenides, contain two CTB. The position of CTB_1 depends on the nature of the substituents in the aromatic fragments. A linear relationship was established between $h\nu_{max}(CTB_1)$ and $\Sigma\sigma^+$. The position of CTB_2 is approximately the same in the spectra of all the complexes (380–390 nm). The spectral characteristics of the complexes of TCE with diaryl diselenides were used, in accordance with Eqn.(1), to estimate the ionisation potentials of the latter. The ionisation potentials were obtained for a large group of *p*-disubstituted diphenyl dislenides. The ionisation potential of diphenyl diselenide, found from the correlation equation (1) (8.2 eV),[208], shows good agreement with the value of IP_1, 8.3 eV, determined by PES.[193] PES has been used to determine the ionisation potentials of a number of compounds with dielement bonds, of the type $(CH_3)_2XYCH_3$, where X = P, As; Y + S, Se. The experimental IP_1 values have been compared with the calculated (CNDO/2) energies of the HOMO. The first two PES bands are due to the removal of electrons from orbitals which are linear combinations of orbitals occupied by the LPE of the corresponding heteroatoms.[209]

The heat of formation of the complex of diphenyl diselenide with phenol has been estimated by IR spectroscopy. The donor properties of the selenium atom in the diselenide are much weaker than in the monoselenide: 1.9 kcal $mole^{-1}$ and 3.3 kcal $mole^{-1}$ respectively.[135]

Table 6. Ionisation potentials of diselenides (eV) and the dipole moments (μ_c, D) and enthalpies of formation ($-\Delta H_c^0$, kJ $mole^{-1}$) of their complexes with $GaCl_3$ (benzene, 298 K).[210]

Complex	IP_1 diselenide (Ref.207)	μ_c	$-\Delta H_c^0$
$(4\text{-}CH_3C_6H_4)_2Se_2\cdot GaCl_3$	8.07	8.6	87
$(C_6H_5)_2Se_2\cdot GaCl_3$	8.21	7.5	82
$(4\text{-}FC_6H_4)_2Se_2\cdot GaCl_3$	8.28	—	80
$(4\text{-}ClC_6H_4)_2Se_2\cdot GaCl_3$	8.28	6.2	79
$(4\text{-}BrC_6H_4)_2Se_2\cdot GaCl_3$	—	6.5	77

Cryometric, calorimetric, and dielectric constant measurements have been used to study complex formation by a number of diaryl diselenides with gallium trichloride. Irrespective of the reagent ratio in these systems, the 1 : 1 complexes are formed. Only one of the selenium atoms of the diselenide bridge forms a donor–acceptor bond with the gallium halide. The high values of the dipole moments and the heats of formation of the complexes (Table 6) indicate that they are *nv*-complexes, like the complexes formed by monselenides with aluminium tribromide.[129] Table 6 shows that the donor properties of the selenium atom in diaryl diselenides, characterised by the $-\Delta H_c^0$ values, depend on the nature of the substituents in the ring. Electron-donor substituents (CH_3) increase the strength of the intermolecular Se → Ga bond, and halogen atoms (F, Cl, Br) decrease it. Although the data are limited, the relationship between the $-\Delta H_c^0$ values and the constants σ of the substituents can be followed.[210] A correlation is also observed between the $-\Delta H_c^0$ values and the ionisation potentials the diselenides, obtained from spectrophotometric data for the charge-transfer complexes (CTC) with TCE.[207] An attempt to determine the thermodynamic parameters of complex formation by diaryl diselenides with the stronger

acceptor aluminium tribromide led to the discovery of a new method for generating and stabilising selenium-containing radicals (see below).

Thus published data on the coordination properties of organic diselenides indicate that only the first steps have been taken in this field.

Table 7. *g*-Values and line widths (G) in the EPR spectra of diaryl diselenide–aluminium tribromide–benzene systems at 298 K.[210]

Diselenide	Signal No. in the EPR spectrum		
	I	II	III
$(C_6H_5)_2Se_2$	2.0761 (23.75)	2.0300 (9.60)	2.0021 (1.67)
$(4\text{-}FC_6H_4)_2Se_2$	2.0694 (17.50)	2.0332 (5.83)	2.0025 (6.25)
$(4\text{-}ClC_6H_4)_2Se_2$	2.0730 (23.30)	2.0380 (11.70)	2.0027 (5.42)
$(4\text{-}BrC_6H_4)_2Se_2$	2.0744 (24.17)	2.0319 (12.50)	2.0026 (4.58)

V. SELENIUM-CONTAINING FREE RADICALS

Free radicals containing an unpaired electron on a selenium atom have been little studied. Until recently, the possible participation of selenium-centred radicals in chemical reactions was doubted. Thus in a published review[2] it was noted that there is very little published information on the preparation and chemistry of organoselenium radicals, and from its analysis it was concluded that there is no convincing proof that organoselenium radicals take part in the processes examined. A similar conclusion that the existence of organoselenium radicals has not been proved was reached in Ref.211. At the same time, photochemical reactions involving organoselenium compounds are acquiring increasing importance in present-day organic synthesis, and the mechanism of these reactions is discussed in terms of the formation of selenium-centred radicals.[212] Selenium-centred radicals have been detected by EPR in the low-temperature photolysis of a number of organic selenides and diselenides;[213–215] determination of the *g*-values showed that they are greater for radicals containing selenium (2.095–2.099) than for sulphur-containing radicals (2.06).[214] The EPR spectrum of the photolysis products of organoselenium compounds in a number of cases are much more complex than the corresponding spectra of the sulphur compounds. It has been shown that, in contrast to sulphur compounds, the photolysis and radiolysis of various selenium compounds, in particular diselenides, are accompanied by the rupture of not only the Se–Se bond but also the C–Se bond, to give the radicals R$^{\cdot}$, RSe$^{\cdot}$, and RSe–Se$^{\cdot}$.[213,215,216] This distinguishes the photochemistry of the diselenides from that of the disulphides, where only the S–S bond is broken, to give RS$^{\cdot}$ radicals. Interesting results were obtained in a study of the photolysis of a number of selenides and diselenides in the presence of nitrosodurene, used to trap radical species.[217] In a number of systems, EPR detected the selenylnitroxide radical. The mechanism of the process was found to depend on the composition and structure of the organoselenium compound. Thus dibenzyl diselenide and diphenyl diselenide react differently on ultraviolet irradiation in the presence of nitrosodurene; the C–Se bond is broken in the first compound, and the Se–Se bond in the second.[217] In addition, studies of the photochemical reactions of a number of diselenides with tertiary phosphines[218,219] showed that, irrespective of the nature of R in the R_2Se_2 molecule (CH_2, C_2H_5, $CH_2C_6H_5$, C_6H_5) and the composition of the phosphine [$CH_3(C_6H_5)_2P$, $(CH_3)_2C_6H_5P$, $(C_6H_5)_3P$], the reaction

$$R_2Se_2 + Ar_3P \xrightarrow{h\nu} R_2Se + Ar_3P{=}Se$$

takes place by a chain mechanism, and the first stage in all cases is the rupture of the diselenide bond. This reaction has been recommended as a method for synthesising the corresponding selenides, and phosphine selenides, since it gives almost quantitative yields of the products under mild conditions.

Thus organoselenium free radicals, like the sulphur-containing radicals, formed by photolysis and radiolysis, are unstable. They are detected only at low temperatures in solid matrices. The stability of free radicals is usually increased by increasing the delocalisation of the electron spin density, and also by steric shielding of the atoms carrying the unpaired electron.[211] Complex formation has been proposed[220–222] as a new effective method for generating and stabilising free radicals containing a heteroatom. Thus stable sulphur-containing radicals of the type $ArS^{\cdot}.MX_3$ were obtained for the first time by the reaction of diaryl disulphides with strong electron acceptors (aluminium and gallium halides). The formation of these radical complexes results from the decrease in the strength of the disulphide bond on complex formation, and the homolytic rupture of the bond when the interactions are sufficiently strong. Quantum chemistry has shown that the free electron of the radical complex is localised chiefly on the sulphur atom. The properties and reactivity of a number of radical complexes $RS^{\cdot}.MX_3$ have been studied.[223,224] Studies of similar reactions of diaryl diselenides with aluminium tribromide and gallium trichloride in benzene or cyclohexane[210,225] have shown that the first stage is the formation of 1:1 donor–acceptor complexes. This stage, like all complex-formation reactions, is very rapid. The second stage, leading to the rupture of the corresponding bonds with the addition of a second molecule of the halide to the 1:1 complex, is slower. Its rate depends on the nature of the acceptor and the aryl fragment of the diselenide. As noted above, the relatively low rate of the second stage of the reaction of diaryl diselenides with gallium trichloride made it possible to measure the heat of formation and dipole moments of the complexes $Ar_2Se_2.GaCl_3$, formed in the first stage.[210] Freshly prepared benzene solutions of the complexes of diaryl diselenides with gallium trichloride do not give signals in the EPR spectra. When solutions containing an excess of gallium trichloride are left to stand, a brightly coloured oil separates, and signals appear in the EPR spectra, indicating the presence of paramagnetic species. In the reaction of diaryl diselenides with a stronger electron acceptor (aluminium tribromide) in benzene or cyclohexane, the separation of paramagnetic products is observed when the components are mixed. The EPR spectra of Ar_2Se_2–$AlBr_3$–benzene systems contain three singlets. The high *g*-values of the singlets I (~2.070) and II (~2.030) differ considerably from the *g*-value of the free electron (2.0023); the large line width makes it possible to assign them to radicals containing a heavy atom, in this case selenium. In view of what has been said on the possible rupture of the C–Se and Se–Se bonds in the diaryl diselenide molecule, the observed singlet I ($g \simeq 2.07$) was assigned to the radical complex $ArSeSe^{\cdot}.AlBr_3$, and the singlet II ($g \simeq 2.03$) to the radical complex $ArSe^{\cdot}.AlBr_3$. This assignment was confirmed by the signal in the EPR spectrum of the $(C_6H_5)_2Se$–$AlBr_3$–benzene system, where only the rupture of the C–Se bond is possible, to give the radical complex $C_6H_5Se^{\cdot}.AlBr_3$. The spectrum of this system contains a singlet with a *g*-value of 2.034, which was assigned to singlet II (the radical complex $C_6H_5Se^{\cdot}.AlBr_3$). The *g*-value and the form of the third singlet in the EPR spectra of Ar_2Se_2–$AlBr_3$–benzene systems differ from those of the singlets assigned to the selenium-centred radicals. The *g*-value, which is close to that of the free electron, indicates that this singlet is due to a stabilised hydrocarbon radical, formed by the homolytic rupture of the C–Se bond.

The proposed mechanism of the reaction of diaryl diselenides with aluminium tribromide was confirmed by gas–liquid chromatography (GLC). The displacement of the radicals from the complexes formed in the $(C_6H_5)_2Se_2-AlBr_3-$benzene system by a stronger donor (D = $(C_2H_5)_2O$, H_2O) gives the complexes D.$AlBr_3$ and the products of the reaction of the displaced free radicals. GLC showed that the reaction mixture contains diphenyl diselenide, diphenyl selenide, and diphenyl. Other products, including C_6H_5SeH and C_6H_5Br, were not detected. Like the thiyl radical complexes Ar$^{\cdot}$.MX_3, the selenium-containing radical complexes are highly stable; the EPR spectra of specimens in sealed ampoules (in the absence of moisture) remain unchanged for a long time (several months). By analogy with the radical complexes ArS$^{\cdot}$.MX_3,[223] the stability of the organoselenium radical complexes is apparently due to the following effects: a) a decrease in the electron density on the selenium atom on formation of a donor–acceptor bond involving a lone pair of electrons of the selenium atom and a vacant orbital of the metal atom, and a consequent lowering of the level of the orbital of the unpaired electron; b) the steric shielding, by the acceptor molecule MX_3, of the selenium atom carrying the free electron.

The formation of radical complexes by the reaction of diaryl diselenides with the halides of group III metals has been observed not only when the reaction is carried out in solution, but also when the components are fused together. The EPR spectra indicate that the nature of the radical complexes formed is the same for the reactions in the melt and in solution.[210]

Thus complex formation by diaryl selenides and diaryl diselenides with strong electron acceptors can provide a source of stable selenium-centred radicals.[210,225]

Organosilathianes

M.D.Mizhiritskii and V.O.Reikhsfel'd

Published data on the synthesis and physical and chemical properties of organosilathianes have been summarised and systematised, and the possibilities for their practical application examined and evaluated.
The bibliography contains 215 references.

I. INTRODUCTION

The methods of synthesis and the physical and chemical properties of organosilathianes, and the possibility of their practical application, have been the subject of a large number of papers, which have not yet been reviewed. The increasing use of organosilathianes in polymer chemistry and in preparative synthesis, and the accumulation of experimental data on their methods of synthesis and properties, make it necessary to systematise the available material. The present review examines published work on the synthesis, properties, and applications of organosilathianes, published up to 1986.

II. METHODS OF PREPARATION

1. The Reaction of Organosilicon Compounds with Sulphur

A simple and convenient method for obtaining organosilathianes is by the insertion of sulphur at an Si–H bond.[1-5] The resulting organosilane thiols, when left to stand,[6] heated,[5] or treated with organochlorosilanes[7,8] or organoaminosilanes,[9] are converted into organosilathianes:

$$2Ar_nR_{3-n}Si{-}H + S \xrightarrow[\text{decalin, } 10\text{-}20\text{ h}]{180\text{-}200^\circ} 2Ar_nR_{3-n}SiSH \xrightarrow{-H_2S} (Ar_nR_{3-n}Si)_2S \quad (1)$$

$Ar = Ph$; $R = Me, Et, Pr, Ph$

$$3Ph_2SiH_2 + 6S \xrightarrow{-3H_2S} (Ph_2SiS)_3$$

$$4PhSiH_3 + 12S \xrightarrow{-6H_2S} PhSi(SSiPh)(SSiPh)(SSiPh)$$

$$R_3SiSH + ClSiR'_3 + R''_3N \xrightarrow[-R''_3N\cdot HCl]{} R_3SiSSiR'_3 \quad (2)$$

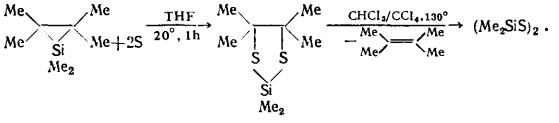
$$(RO)_3SiSH \xrightarrow{(R'O)_3SiNH_2,\ -(RO)_3SiSiNH_4} (RO)_3SiSSi(OR')_3$$

$$(RO)_3SiSH \xrightarrow{Me_3SiNR''_2,\ -(RO)_3SiSH_4NR''_2} (RO)_3SiSSiMe_3$$

$NR''_2 = NEt_2$, $NHSiMe_3$.

In reaction (2), instead of organosilane thiols, it is possible to use alkali and alkaline earth metal triorganosilanethiolates:[2,10]

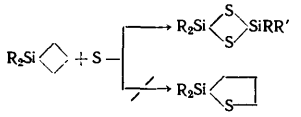
$$(R_3SiS)_nM + nClSiR'_3 \rightarrow nR_3SiSSiR'_3 + MCl_n$$



$M = Li, Na, K$ $(n=1)$ [2]; Ca, Sr, Ba $(n=2)$ [10] .

At a high temperature, sulphur is also inserted into the Si–C bond. For example, tetrabutylsilane at 240° gives hexabutyldisilathiane:[11]

$$Bu_4Si + S \rightarrow [Bu_3SiSBu] \rightarrow (Bu_3Si)_2S + Bu_2S \ .$$



A similar reaction is observed with disilylhydronaphthalenes.[12]

The introduction of sulphur into strained silicon-containing rings takes place under much milder conditions (20°, 1–3 h), for example:[13]

With increase in temperature, the insertion product decomposes to a cyclic silathiane and an unsaturated hydrocarbon.

Cyclosilathianes are also obtained by the reaction of sulphur with dialkylsilacyclobutane[14] and with compounds containing Si–Si bonds:[15]

$$R_2HSiSiHR_2 + S \rightarrow (R_2SiS)_2 + R_2SiH_2 + R_3SiH + R_2Si(SSi(H)R)$$

$$R_3SiSiR_3 + S \rightarrow (R_2SiS)_2$$

$$(Me_2Si)_5 + S \xrightarrow{180^\circ} (Me_2Si)_5S$$

$R = Me$, i-Pr, t-Bu, cyclohexyl .

Sulphur is very easily inserted at an Si–Hg bond; the resulting unstable insertion product decomposes under the influence of ultraviolet radiation[16-18] or when heated:[19]

$$(Et_3Si)_2Hg + S \xrightarrow{20^\circ} Et_3SiSHgSiEt_3 \rightarrow (Et_3Si)_2S + Hg$$

$$(Et_3SiS)_2Hg \xrightarrow{\Delta} (Et_3Si)_2S + HgS \ .$$

Finally, sulphur can be inserted directly at an Si–S bond, forming organosilylsulphanes:[20]

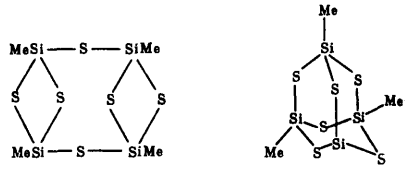
$$R_3SiSSiR_3 + nS \xrightarrow{200^\circ} R_3SiS_{n+1}SiR_3$$

$R = Me, Et$; $n = 1-8$.

2. Reactions with Hydrogen Sulphide

The most widely used method for synthesising organosilathianes is by the thiolysis of organochlorosilanes in a solvent in the presence of tertiary amines. This method was used to obtain the first linear[21–23] and cyclic[24–26] silathianes:

$$2R_3SiCl + H_2S + 2R'_3N \xrightarrow[-2R'_3N\cdot HCl]{} (R_3Si)_2S \ .$$



With triorganohalogenosilanes, this reaction gives hexaorganodisilathianes:[21,22,27–32] when the silicon atom has a substituent with a high electronegativity or a large volume, triorganosilane thiols are obtained in addition to disilathianes. The conversion of silane thiols or their salts to disilathianes is readily carried out by reactions (1)–(3).

The reaction of diorganodihalogenosilanes with hydrogen sulphide gives cyclic silathianes:[33–36]

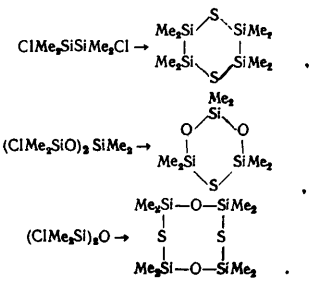
$$nR_2SiCl_2 + nH_2S \xrightarrow[-2nR_3N\cdot HCl]{2nR_3N} (R_2SiS)_n \ . \quad (4)$$
$$n = 2, 3$$

With methyldichlorosilane, the reaction products, in addition to trimethylcyclotrisilathiane, also contain crystalline $[(MeSi)_2S_3]_2$,[33] which is assigned the structure (I)[31] or (II):[34,38]

$$MeHSiCl_2 + H_2S \xrightarrow[-R_3N\ HCl]{R_3N} (MeHSiS)_3 + \left[(MeSi)_2S_3\right]_2$$

(I)

(II)



Products of this type are obtained by the reaction of H_2S with methyl(methoxy)dichlorosilane or organotrichlorosilanes in the presence of a hydrogen chloride acceptor:[24,31,37,39]

$$RSiCl_3 + H_2S \xrightarrow[-R_3N\cdot HCl]{R_3N} [(RSi)_2S_3]_2 \xleftarrow[-MeOH]{R_3N,\ -R_3N\cdot HCl} Me(MeO)SiCl_2 + H_2S \ .$$

With a deficit of the tertiary amine, 1,3-dichloro-1-3-dialkylcyclodisilathianes (III) can be isolated from the reaction mixture;[24] compounds (III) react further with hydrogen sulphide and the amine to give $[(RSi)_2S_3]_2$, confirming structure (I):

$$2PrSiCl_3 + 2H_2S + 4C_5H_5N \rightarrow \underset{\text{(IiI)}}{\text{Pr(Cl)Si(S)(S)Si(Cl)Pr}} \xrightarrow{2H_2S,\ 4C_5H_5N} (I) \ .$$

Various organochlorosilanes and organosiloxanes also undergo thiolysis and cothiolysis. This makes it possible to obtain a wide range of cyclic products,[40–43] for example:

The reaction of triethyl- and tripropylsilylamines and triethyl-N-(2-phenylethyl)silylamine with hydrogen sulphide gives the disilathiane and a small quantity of the silane thiol:[21,44]

$$Et_3SiNH_2 + H_2S \rightarrow (Et_3Si)_2S + Et_3SiSH \ .$$

Tris-silylamine and N-methyldisilylamine absorb H_2S at room temperature and under pressure to give disilathianes and ammonium salts of silane thiols:[45,46]

$$(H_3Si)_3N + 2H_2S \rightarrow H_3SiS^-NH_4^+ + (H_3Si)_2S$$
$$(H_3Si)_3NMe + 3H_2S \rightarrow (H_3Si)_2S + 2H_3SiS^-MeNH_3^+ \ .$$

Treatment of these salts with trimethylchlorosilane gives unsymmetrical trimethyldisilathiane,[45] and the reaction with BCl_3 gives disilyl sulphide:[46]

$$H_3SiSH\cdot NH_3 + Me_3SiCl \xrightarrow{-NH_4Cl} H_3SiSSiMe_3$$
$$H_3SiSH\cdot MeNH_2 + BCl_3 \xrightarrow[-MeNH_3\cdot HCl]{} [(H_3SiS)_3B] \xrightarrow[-B_2S_3]{} (H_3Si)_2S \ .$$

Hexamethyldisilazane and N-trimethylsilylaniline reacts with hydrogen sulphide with difficulty to give trimethylsilanethiol in ~14% yield.[45]

At the boiling point, organocyclosilazanes undergo slow thiolysis with the subsequent transformation of the silazane groups into silathiane groups:[47,48]

$$[R_2SiNH]_n \xrightarrow[-NH_4SH]{2nH_2S} \left[(R_2SiNH)_{n-1}(R_2SiS)\right] \xrightarrow[-NH_4SH]{2nH_2S} \left[(R_2SiNH)_{n-2}(R_2SiS)_2\right] \longrightarrow \cdots \rightarrow$$
$$\xrightarrow[-(n-2)NH_4SH]{2(n-2)H_2S} [R_2SiS]_m \quad (5)$$
$$R = Alk,\ m = 2, 3;\ n = 3, 4 \ .$$

Imidazole is an effective catalyst for the thiolysis of hexamethyldisilazane.[49–51] Its catalytic action involves the ready formation of N-trimethylsilylimidazole, which subsequently silylates hydrogen sulphide:[51]

$$(Me_3Si)_2NH + 2HN\langle\rangle \xrightarrow{-NH_3} 2Me_3SiN\langle\rangle \xrightarrow[-2HN\langle\rangle]{H_2S} (Me_3Si)_2S \ .$$

Another method of improving reaction (5) is by the combined thiolysis of SiN- and SiCl-containing compounds:[52,53]

$$2(Me_3Si)_2NH + 3H_2S + 2Me_3SiCl \rightarrow 3(Me_3Si)_2S + 2NH_4Cl \ , \quad (6)$$

$$(R_2SiNH)_n + R_2SiCl_2 + H_2S \xrightarrow{-NH_4Cl} (R_2SiS)_m \ , \quad (7)$$
$$n = 3, 4;\ m = 2, 3$$

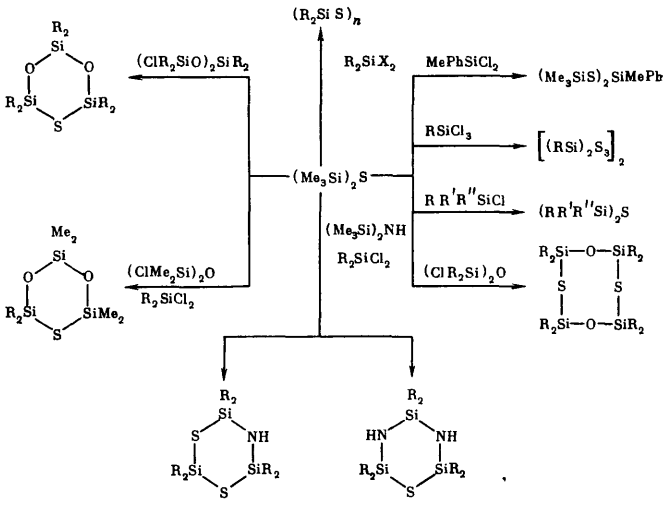
$$Me_3SiNR_2 + H_2S + Me_3SiCl \rightarrow (Me_3Si)_2S + R_2NH\cdot HCl \ . \quad (8)$$

Carboxylic acid silylamides[54] and trimethylcyanosilane[55] react readily with hydrogen sulphide to give hexamethyldisilathiane in high yield (86%):

$$\left.\begin{array}{l} MeC(OSiMe_3)=NSiMe_3 \xrightarrow[-MeCONHSiMe_3]{H_2S} \\ Me_3SiCN \xrightarrow[-HCN]{H_2S} \end{array}\right\} \rightarrow (Me_3Si)_2S \ .$$

To conclude this section, mention must be made of a method for obtaining disilathiane by the action of an electric discharge on an equimolar mixture of SiH_4 and H_2S.[56]

3. Reactions of Hexamethyldisilathiane



Reactions (6) and (8) have proved extremely promising for the synthesis of linear organosilathianes, in particular hexamethyldisilathiane, which has been obtained chromatographically pure in almost quantitative yield. The synthesis of cyclic silathianes by reaction (7), however, in spite of the high activity of the starting materials, has a significant disadvantage, namely the formation in a number of cases of a mixture of cyclosilathianes and cyclosilathiazanes, difficult to separate.

An effective method for the synthesis of linear and cyclic organosilathianes, organosilathiaoxanes, and organosilathiazanes is based on the trans-silylation of hexamethyldisilathiane by organochlorosilanes:[57]

$$n/2\ (Me_3Si)_2S + R_{n-4}SiCl_n \rightleftarrows nMe_3SiCl + R_{4-n}SiS_{n/2} \quad (9)$$
$$R = Alk, Ar;\ n = 1-3$$

This equilibrium reaction takes place with difficulty even on prolonged heating (200–250 °C). In the presence of catalytic quantities of amines or DMF, however, its rate increases markedly, and the reaction is quantitative when the trimethylchlorosilane is continuously removed.

The extensive synthetic possibilities of reaction (9) can be illustrated by the following examples:[57–62]

These examples show that this method can be used to obtain organosilicon compounds containing Si–S–Si bonds with practically any specified structure.

The splitting of cyclosilathianes by bifunctional organosilanes has been proposed as a method of obtaining polymeric organosilathianes.[63] An NMR study of the equilibrium of the reaction between $(Me_2SiS)_3$ and Me_2SiX_2, where X = Cl, Br, OMe, SMe, at 150 °C and 200 °C showed that the reaction is displaced towards the formation of the cyclic dimers and trimers, and also short chain molecules.[64,65]

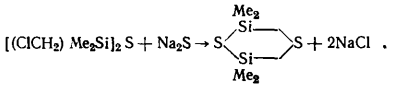
4. Reaction with Inorganic Sulphides

A general method for synthesising organosilathianes is by the reaction of organo-iodosilanes with the sulphides of silver[23,24,66–68] and mercury:[68–77]

$$2nR_3SiI + M_nS \rightarrow (R_3Si)_2S + MI_n$$
$$R = Alk, Ar;\ M = Hg, Ag;\ n = 1, 2$$

The same reaction can be used to obtain Si–H-containing organosilathianes:[76,77]

$$Me_nH_{3-n}SiI + HgS \xrightarrow[-HgI]{35^\circ} (Me_nH_{3-n}Si)_2S$$



The reaction of mercury sulphide with di-iodosilane gives a mixture of oligomers $(H_2SiS)_x$, containing as the principal component $(H_2SiS)_3$, which cannot be isolated from the mixture, because of its low thermal stability. When kept in the light (20°, 8 d), the oligomers are converted into a resinous polymer, which when heated in a vacuum is depolymerised to give trisilathiane. Unlike its alkyl homologues, trisilathiane is unstable, and polymerises at room temperature. In contact with pumice or aluminium sulphide, its stability is increased, and decomposition begins only at 250 °C:[77]

$$HgS + H_2SiI_2 \xrightarrow[benzene]{80^\circ} (H_2SiS)_n \xrightarrow[10^{-3}\ mmHg]{210^\circ} (H_2SiS)_3 \xrightarrow[[Al_2S_3]]{250^\circ} H_3SiSH + (H_3Si)_2S + H_2S$$

The passage of trimethylchlorosilane vapour (400°) through a molten eutectic LiCl/KCl mixture containing 25% potassium sulphide gave hexamethyldisilathiane in 81% yield.[78,79]

Hexamethyldisilathiane is also formed when trimethylchlorosilane is heated with anhydrous sodium sulphide in a sealed tube.[80]

Sodium sulphide can also be used to obtain cyclic silathianes, for example:[81]

Organochlorosilanes react vigorously with ammonium hydrogen sulphide even in the cold, to give organosilathianes in high yield (up to 90%):[82]

$$2R_3SiCl + 2NH_4SH \xrightarrow[-H_2S]{-2NH_4Cl,} (R_3Si)_2S$$

In addition to the desired compounds, the reaction products also include Si–N-containing compounds, formed by an ammonolysis side reaction.

The reaction of disilanes with sulphur tetrafluoride can in principle be used to synthesise various organosilathianes:[83]

Hexamethyldisilathiane has been isolated as one of the products of the reaction of trimethyl(dimethylamino)silane with phosphorus pentasulphide:[84]

$$8Me_3SiNMe_2 + P_4S_{10} \rightarrow 2\ (Me_3Si)_2S + 4\ (Me_2N)_2P(S)SSiMe_3$$

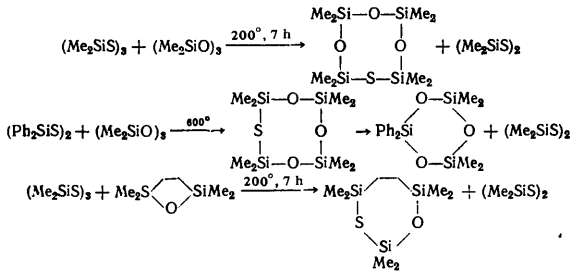
5. Thermal Rearrangements of Sulphur-Containing Organosilicon Compounds

When distilled at atmospheric pressure, hexamethylcyclotrisilathiane undergoes rearrangement to give the cyclic dimer:[36,64,85]

$$2(Me_2SiS)_3 \rightleftarrows 3(Me_2SiS)_2 \quad (10)$$

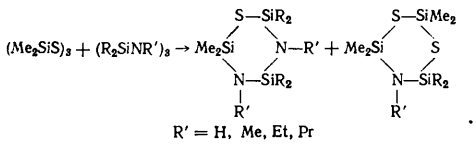
A ^1H NMR study of this equilibrium in solution showed that high temperatures and high dilution facilitate the formation of small rings. The ring strain energy in the cyclic dimer is ~3 kcal per monomer unit.[86]

2,4,6-Trimethyl-2,4,6-triphenylcyclotrisilathiane[36] and hexaphenylcyclotrisilathiane[35] behave similarly.



The existence of equilibrium (10) explains the lack of agreement in the physical constants given by many authors for various cyclosilathianes. For example, for hexaphenylcyclotrisilathiane, melting points 188–198° [35] and 191–193° [4] have been given; two melting points have also been given for trimethyltriphenylcyclotrisilathiane: 109° [59] and 112.5–114°.[87] It has been suggested that reaction (10) may take place with the intermediate formtion of silathiane oligomers[64,65,67] or the unstable species $[R_2Si=S]$:[88]

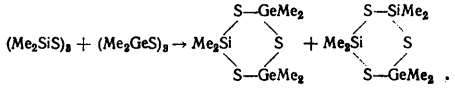
$$(Me_2SiS)_3 \rightleftarrows -(-Me_2SiS-)_n- \rightleftarrows (Me_2SiS)_2 \quad (11)$$



$$(Me_2SiS)_3 \rightleftarrows [Me_2Si=S] + (Me_2SiS)_2$$
$$2[Me_2Si=S] \rightleftarrows (Me_2SiS)_2 \quad (12)$$

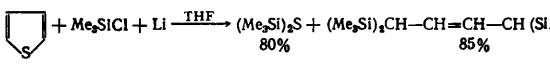
Equilibrium (11) was proved in Refs.63, 65, and 77, and reaction (12) was confirmed by carrying out the reactions of cyclosilathianes with hexamethylcyclotrisiloxane or 1,1,3,3-tetramethyl-2-oxa-1,3-disilacyclopentane, which act as "traps" for $[Me_2Si=S]$. Thus when

these reagents are heated, the products are the cyclosilathiaoxanes and the cyclodisilathiane:[88-90]

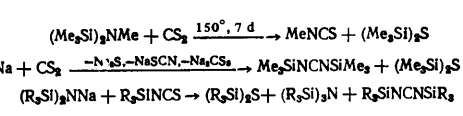


Cyclic organosilathiazanes have been obtained by heating hexamethylcyclotrisilathiane and hexaorganocyclotrisilazanes:[91,92]

Depending on the group, this exchange reaction gives a mixture of the cyclotrisiladithiazane and the cyclotrisilathiadiazane or only the cyclotrisiladithiazane.



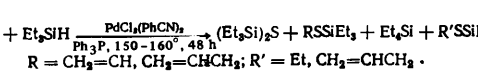
The exchange reaction between hexamethylcyclotrisilathiane and hexamethylcyclotrigermanium sulphide gives mixed heterocyclic compounds containing silicon, germanium, and sulphur atoms:[93]



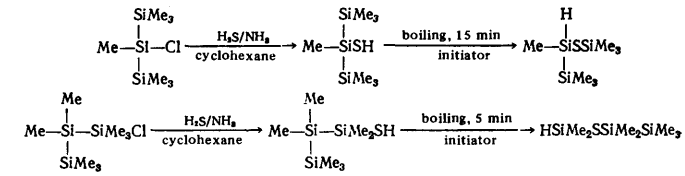
6. Other Methods

This section deals with studies whose aim was not the directed synthesis of organosilathianes.

An exception is the reaction of thiophene with the reagents usually employed for C-silylation:[94]



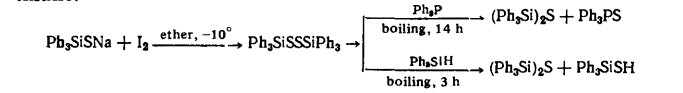
Silazanes and their N-metal derivatives react with CS_2, COS, and RNCS to give mixtures of products including hexamethyldisilathiane:[92-98]



A similar result was obtained in the reaction of carbon disulphide with trimethylsilyl esters of isothiocyanatocarboxylic acids.[99]

The splitting of unsaturated sulphides by triethylsilane, in addition to other products, gives hexaethyldisilathiane:[100]

Under the influence of the radical reaction initiators benzoyl peroxide or azo-bis-isobutyronitrile, trisilanethiols undergo rearrangement to give silathianes:[101]



Trialkylsilanethiols do not undergo this rearrangement, even on prolonged boiling in xylene.

The insertion of dimethylsilylene, obtained by the thermal decomposition of $(Me_2Si)_6$, at an Si–S bond provides an interesting method for obtaining unsymmetrical silathianes:[102]

Hexaphenyldisilyl disulphide is obtained by the action of iodine on sodium triphenylsilanethiolate.[103] Treatment of this compound with triphenylphosphine or triphenylsilane gives hexaphenyldisilathiane:

III. PHYSICAL PROPERTIES

In spite of recent progress in the synthesis of organosilathianes, their physical properties have been comparatively little studied.

Data on the structure of various linear and cyclic organosilathianes have been obtained by electron diffraction and microwave spectroscopy:[104,105]

Compound	Bond length Si–S, Å	Si–S–Si	Angles, degrees S–Si–S	Refs.
$(Me_2SiS)_2$	2.18±0.03	75	105	[104, 105]
$(Me_2SiS)_3$	2.15±0.03	110	115	[104, 105]
$(H_3Si)_2S$	2.136±0.002	97.4±0.7	—	[6]

Comparison with the C–S–C angle in dimethyl sulphide (98°51′)[106] shows that there is no π-bonding in disilyl sulphide.

The Si–S–Si stretching bands in the infrared (IR) spectra of linear and cyclic silathianes lie in the following ranges (cm^{-1}):[107] 396–416 $[(Cl_3Si)_2S]$; 437–493 $[(Me_3Si)_2]$; 480–524 $[(H_3Si)_2S]$; 493–530 $\{[(PhCH_2)_3Si]_2S\}$; 519–556 $\{[(p\text{-}MeC_6H_4)_3Si]_2S\}$; 518–572 $[(Ph_3Si)_2S]$. The displacement of ν_{Si-S} to higher wavenumbers is attributed to the decrease in the polarity of this bond in the last three compounds. It has been suggested[107] that in view of the strong inductive effect of the phenyl group, structures $Ph_3Si^- = S^+$ with a $(p \rightarrow d)_\pi$ double bond plays a significant part in the resonance system.

The Raman and IR spectra of hexamethyldisilathiane have been used to determine the force constant (2.20×10^5 dyne cm^{-1}), The Si–S–Si angle (104°), and the bond dissociation energy (63 kcal $mole^{-1}$).[108]

An overall similarity is observed in the Raman spectra of hexamethyl- and hexachlorodisilathianes, whose molecules have C_{2v} symmetry. The comparatively small splitting of $\nu_{Si-S-Si}$ [47 cm^{-1} in $(Me_3Si)_2$ and 21 cm^{-1} in $(Cl_3Si)_2S$] shows that the Si–S–Si angle is close to 90°. The spectra of $(Me_2SiS)_2$ and $(Cl_2SiS)_2$ indicated that the Si_2S_2 ring is planar. On going from the linear to the cyclic disilathiane, the spectra show an increase in $\nu_{s(Si-S-Si)}$ and an increase in ν_{as} to approximately the same extent as on going from propane to cyclobutane.[109]

In the Raman spectrum of molten tetramethylcyclodisilathiane, the strongest lines of hexamethylcyclotrisilathiane were detected, indicating the existence of the equilibrium $3(Me_2SiS)_2 \leftrightarrows 2(Me_2SiS)_3$.[110]

The vibrational spectra indicate that $(Me_2SiS)_2$ has a planar structure with D_{2h} symmetry, in agreement with electron diffraction data and dipole moment measurements. The choice between models with symmetry C_{3v} (chair form) and C_s (boat form) for $(Me_2SiS)_3$ is not so obvious, although the combined spectroscopic data provide evidence for the latter. Comparison of data on the structure of cyclosilathianes with the magnitude of the Si−S−Si angle in $(H_3Si)_2S$ shows that the tetramethylcyclodisilathiane ring is strained as a result of a deviation from the normal valence angles.[110]

There are no unambiguous published data on the conformational transformations of cyclosilathianes. Thus according to X-ray diffraction data, *trans*-2,4,6-trimethyl-2,4,6-triphenylcyclotrisilathiane is present in the crystals in a boat form,[111] whereas in solution (according to ^1H NMR data) is is present as boat forms undergoing rapid interconversion, although the chair form cannot be completely excluded.[87]

Gas-phase electron diffraction showed that hexamethylcyclotrisilathiane is non-planar.[105] From a comparison of the experimentally determined value of the dipole moment with the values calculated for the chair and boat models, it was suggested[112] that $(Me_2SiS)_3$ exists chiefly in the chair form, although a small concentration of the boat form is possible. From the Raman and IR spectra, it was concluded[110] that hexamethylcyclotrisilathiane in the liquid state is present in the boat form.

The conformational transformations of methylphenyl-,[113] methylethyl-,[111] and methylvinylcyclosilathianes[111] have also been studied.

The dispole moment of hexamethyldisilathiane, measured in benzene at 25 °C, is 1.44 D. The dipole moments of $(Me_3Si)_2S$ and $(Me_3Si)_2O$ have been used to estimate the angles Si−S−Si (~97−98°) and Si−O−Si (~150°). The large difference in the angles is regarded as proof of $(p \rightarrow d)_\pi$ interaction in the Si−O bonds, and its absence in the Si−S bonds.[29]

The dipole moments of $(Me_2SiS)_2$ and $(Me_2SiS)_3$ have been calculated, assuming that the atomic polarisation of the cyclosilathianes is the same as that for the corresponding cyclosiloxanes: $\mu_{(Me_2SiS)_2}$ = 0.00; $\mu_{(Me_2SiS)_3}$ = 1.03 D.[112]

A study of compounds containing Si−S and S−Si−N bonds showed that the replacement of a C−S bond by an Si−S bond has no effect on the magnitude of the diamagnetic susceptibility;[114] similar data were obtained in Ref.115. This indicates that there is no $(p \rightarrow d)_\pi$ interaction in the Si−S bond.

Table 1. Effect of $(p \rightarrow d)_\pi$ conjugation in Si−E bonds.[40]

Physical properties	E = N		E = O		E = S	
	found	calculated	found	calculated	found	calculated
Bond length, Å	1.74±0.02; 1.72±0.03	1.81	1.63±0.04; 1.69±0.03	1.76	2.14±0.02	2.15
Force constant, mdyne Å^{-1}	4.1	3.3	4.7	3.7	2.2	2.2
Angle Si-E-Si, °	119.6±1; 131	109°28′	130±10; 145	109°28′	97.4±0.7; 104; 110	109°28′

The absence of this interaction is also indicated by ultraviolet (UV),[116] ^1H, ^{13}C,[117,118] and ^{29}Si NMR,[77] and Raman[119] spectroscopy.

Thus almost all studies of the physical properties of organosilathianes in one way or another deal with the problem of $(p \rightarrow d)_\pi$ conjugation. This problem is of primary importance for the chemistry of compounds containing Si−O and Si−N bonds, but it is not so important for the chemistry of organosilathianes, since the question of the existence of $(p \rightarrow d)_\pi$ conjugation in the Si−S−Si system has not yet been resolved unambiguously.

Thus from a comparison of the bond lengths, force constants, and Si−E−Si angles, it has been concluded that there is no $(p \rightarrow d)_\pi$ interaction in silathianes[40] (Table 1). This is confirmed by the physical properties of disilathianes.[6,120,121]

Nevertheless, many attempts have been made to estimate the extent of $(p \rightarrow d)_\pi$ conjugation in organosilathianes by UV, IR, and ^1H NMR spectroscopic studies.[122-131] It was assumed that $(p \rightarrow d)_\pi$ conjugation involves partial displacement of the p_π electrons of the S atom to the d_π orbitals of Si. As a result, the negative charge on the sulphur atom and the basic strength of the compound decrease.[129]

From an analysis of the IR spectra of substituted silicon hydrides containing Si−O and Si−S fragments, it was concluded[130] that the extent of $(p \rightarrow d)_\pi$ conjugation changes in the approximate ratio SiO : SiS = 2 : 1.

Thus $(p \rightarrow d)_\pi$ interaction (whether it exists or not) does not have the significant influence on the chemical properties of organosilathianes observed for organosiloxanes or organosilazanes. This is confirmed by a calculation of the overlap integrals of the Si−S bond,[131] where it was shown that the small magnitude of the overlap integral of the unoccupied atomic orbitals at this bond is one of the principal reasons for its high chemical activity.

IV. CHEMICAL PROPERTIES

An analysis of published data has shown that reactions involving the heterolytic splitting of Si−S−Si bonds in organosilathianes can be divided into two groups: exchange reations and insertion reactions.

The first group includes the great majority of known reactions of organisilathianes, taking place according to the general scheme:

$$\equiv Si-S-Si\equiv + X-Y \rightarrow \equiv Si-X + Y-S \ .$$

1) Y = H—"protic silylation" reactions (exchange between a silyl group and a mobile hydrogen atom), for example:

$$\equiv Si-S-Si\equiv + 2REH \rightarrow 2 \equiv SiER + H_2S. \qquad (13)$$

E = O, NH, S; R represents an organic or hetero-organic group.

2) Y = M—"aprotic silylation" reactions (exchange between a silyl group and a metal atom), for example:

$$\equiv Si-S-Si\equiv + HgR_2 \rightarrow 2\equiv SiR + HgS \ .$$

3) Y = Si—trans-silylation reactions (exchange between one silyl group and another), for example:

$$\equiv Si-S-Si\equiv + 2\equiv Si^*-E \rightleftarrows \equiv Si-S-Si^*\equiv + \equiv Si-E + \equiv Si^*-E \rightleftarrows \rightleftarrows \equiv Si^*-S-Si^*\equiv + 2\equiv Si-E \ .$$

4) Y = E—reactions involving the redistribution of functional groups (exchange between a silyl group and functional groups), for example:

$$X = Cl,\ \equiv Si-S-Si\equiv + 2\rangle P-Cl \rightarrow 2\equiv Si-Cl + \rangle P-S-P\langle$$

$$X = O,\ \equiv Si-S-Si\equiv + \equiv Sn-O- \rightarrow 2\equiv Si-O- + \equiv Sn-S- \ .$$

The second group includes reactions taking place according to the

$$\equiv Si-S-Si\equiv + X-Y \rightarrow \equiv Si-S-X-Y-Si\equiv \ . \qquad (14)$$

1) 1,1-insertion, for example:

$$\equiv Si-S-Si\equiv + [:SiR_2] \rightarrow \equiv Si-S-SiR_2-Si\equiv \ .$$

2) 1,2-insertion, for example:

$$\equiv Si-S-Si\equiv + (CF_3)_2CO \rightarrow \equiv SiOC(CF_3)_2S(CF_3)_2COSi\equiv .$$

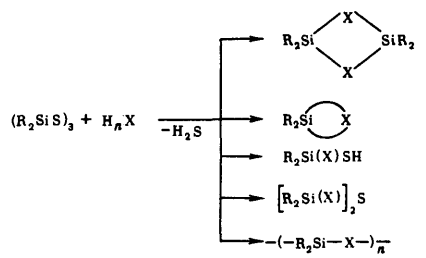
3) 1,3-insertion, for example:

$$\equiv Si-S-Si\equiv + CH_2(O)CH_2 \rightarrow \equiv SiOCH_2CH_2SCH_2CH_2OSi\equiv ,$$

4) 1,4-insertion, for example:

5) 1,*n*-insertion, or example:

$$\equiv Si-S-Si\equiv + S_8 \rightarrow \equiv Si-S_n-Si\equiv .$$



1. Exchange Reactions

a) "Protic silylation"

The reaction of organosilathianes with proton-donor reagents involves exchange between a mobile proton of an inorganic, organic, or hetero-organic compound and a silyl group.[62] Organosilathianes silylate monohydric and polyhydric alcohols and phenols,[30,80,132–144] aminoalcohols and phosphorylated alcohols,[139,145] mineral and carboxylic acids,[70,71,90,146,149] inorganic and organic acids of phosphorus,[61,146,150,151] boron, arsenic, and sulphur,[61,151] enols,[152] aldoximes and ketoximes,[152] aromatic thiols, thioglycols,[61,153] amines and their derivatives,[80,154] and silanols and siloxanediols;[155] the silyl derivatives are formed in high yields.

Depending on the original reagent ratio, products of complete or partial silylation may be formed. In the case of cyclic silathianes, monomeric linear and cyclic compounds, and also polymers, have been obtained:

$$(R_3Si)_2S + 2H^{\pm}_nX \xrightarrow{-H_2S} 2R_3SiXH_{n-1} \rightarrow \cdots \rightarrow \xrightarrow[-H_2S]{(R_3Si)_2S} (R_3Si)_nX$$

The following general regular features of this reaction (13) have been established: the presence of bulky or electron-donor substituents on the silicon atom leads to a decrease in the activity of organosilathianes. The introduction of alkoxy groups into the silathiane molecule leads to the same result, and this has been attributed[135,137] to an increase in the $(p \rightarrow d)_\pi$ interaction in the Si–S bond. Cyclic silathianes are more active than the linear compounds, and cyclodisilathianes have the highest activity.[135,137]

A study of the model reaction of hexamethyldisilathiane with various proton donors (REH) made it possible to arrange them in the following order of decreasing activity: ROH > RR^1NH > RSH. This order corresponds to the decrease in the energy of the ≡Si–E bond formed in reaction (13).[61] The rate of the reaction of organosilathianes with proton donors increases when the molecule of the proton donor contains electron-acceptor substituents, which increase its acidity, and also when the reaction is carried out in polar solvents and in the presence of nucleophilic catalysts (tertiary amines, DMF, acetonitrile).[61]

The synthetic possibilities provided by organosilathianes as silylating reagents have been demonstrated by the reactions of hexamethyldisilathiane and hexamethylcyclotrisilathiane with a wide range of proton donors (Tables 2 and 3).

b) Aprotic silylation

There are only a few published examples of silathiane reactions of this type: the splitting of Si–S–Si bonds by organic compounds of mercury[156–162] and phenyl-lithium.[2]

Depending on the organic group, organomercury compounds react with organosilathianes to give products containing an Si–C or an Si–O bond:

$$(Me_3Si)_2S \xrightarrow{-HgS} \begin{cases} \xrightarrow{Hg(CONEt_2)_2} Me_3SiCONEt_2 \\ \xrightarrow{Hg(COOMe)_2} Me_3SiOMe + Me_3SiCOOMe \\ \xrightarrow{Hg[C(N_2)COOEt]_2} Me_3SiCN_2COOEt \\ \xrightarrow{Hg(CH_2COOR)_2} Me_3SiCH_2COOR , \end{cases} \quad (15)$$

$$R_3SiSSiMe_3 \xrightarrow{-HgS} \begin{cases} \xrightarrow{Hg(CH_2COR')_2} R_3SiOC(R')=CH_2 + Me_3SiCH_2COR' \\ \xrightarrow{HgR''_2} R_3SiR'' + R''SiMe_3 , \end{cases} \quad (16)$$

$$(R_3Si)_2S + Hg(CH_2COR'')_2 \rightarrow 2R_3SiOC(R'')=CH_2 + HgS \quad (17)$$

R_3=MePhC$_{10}$H$_7$-α; R′=H, Me, OMe, Ph; R″=MeCOO, MeO; R‴=OMe, OCH=CH$_2$, OCOPh, OCOMe

Reactions (15)–(17) provide an effective method for synthesising a number of silicon compounds which are difficult to obtain; in particular, a new class of compound, carbamoylsilanes, has been synthesised in this way.[158]

In the reaction of phenyl-lithium with hexaphenyldisiladithiane, the S–S bond, and not the Si–S bond, is split first:[2]

$$Ph_3SiS-SSiPh_3 + PhLi \rightarrow Ph_3SiSLi + PhSSiPh_3 \xrightarrow[-PhSLi]{PhLi} Ph_4Si .$$

c) Trans-silylation reactions

The principal regular features and synthetic possibilities of the trans-silylation of organosilathianes by organohalogeno- and organopseudohalogenosilanes and -siloxanes were discussed in section II.

d) Reactions involving the redistribution of functional groups

Organosilathianes are split by inorganic halides to give the corresponding sulphides and organohalogenosilanes

$$\equiv Si-S-Si\equiv + M-X \rightarrow 2\equiv Si-X + M-S \quad (18)$$

MX=BCl_3 [153], PCl_3, PBr_3, $POCl_3$ [163]; PCl_5 [164]; $AsCl_3$, $SbCl_3$ [165]; $TiCl_4$ [166, 167]; $SnCl_4$, VCl_3, $CrCl_3$ [167]; $PdCl_2$ [166]; $HgCl_2$ [70]; $PbCl_2$, $CdCl_2$, AgCl, AgBr [23]; NH_4Cl, KBr [168]; HgI_2 [169]

The splitting of the Si–S bond by the ammonium, sodium, and potassium salts of inorganic and organic acids[168] and by silver salts (AgCN, AgNCS, AgNCO, AgOCOMe) [23] takes place similarly. Hexa-alkyldisilathianes do not react with silver iodide.[23]

Disilathiane[70] and 1,3-dimethyldisilathiane[71] do not react with methyl iodide, and hexamethyldisilathiane does not react with lower alkyl halides.[61] On prolonged boiling, higher alkyl halides react with organosilathianes according to the scheme:

$$\equiv Si-S-Si\equiv \xrightarrow[-\equiv SiX]{RX} \equiv SiSR \xrightarrow[-\equiv SiX]{RX} R_2S .$$

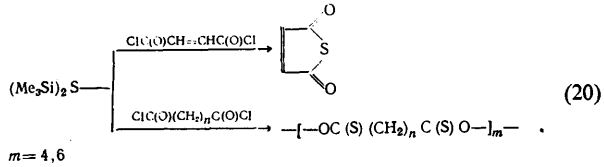
*Boiling until liberation of H_2S stopped.

Increase in the electron-acceptor power of the substituents on the carbon atom of the alkyl halide, the polarity of the medium, and the basic strength of the sulphur atom increases the reactivity of organosilathianes towards alkyl halides.[61]

Acyl halides are much more reactive than alkyl halides towards organosilathianes:[61,170–172]



$$\equiv Si{-}S{-}Si \equiv \xrightarrow[-\equiv SiX]{RC(O)X} \equiv SiOC(S)R \xrightarrow[-\equiv SiX]{RC(O)X} [RC(O)]_2S \quad (19)$$

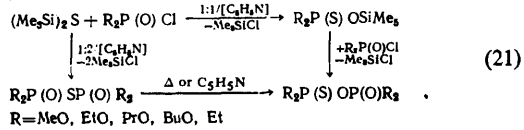
A study of the reaction of hexamethyldisilathiane with dicarboxylic acid halides showed that with fumaryl chloride, the cyclic sulphide is formed, whereas with the chlorides of adipic and sebacic acids, polyacyl sulphides are formed:[171]



(20)

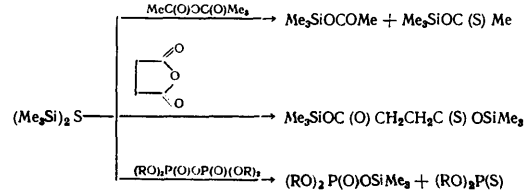
m = 4, 6

The reaction rate is increased in the presence of tertiary amines. Their catalytic action can be attributed to the formation of the N-acylammonium cation, which is more active in the exchange reaction than the original acyl halide.

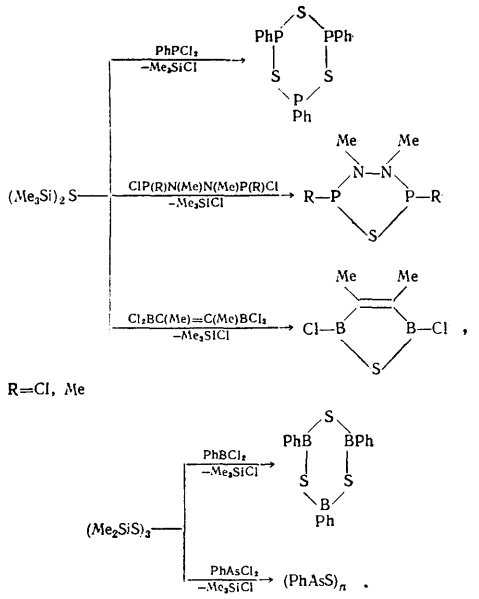
The chlorides of phosphorus(V) acids react similarly with organosilathianes:[61,173]

(21)

R=MeO, EtO, PrO, BuO, Et

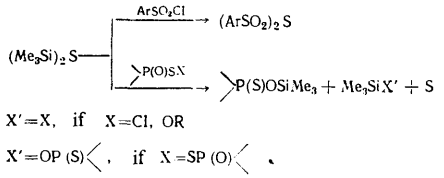


The halides of phosphorus(III) acids are more active than dialkyl phosphorochloridates towards hexamethyldisilathiane. The reaction involves the intermediate formation of silyl esters of phosphorus thio-acids:[174,175]



(22)

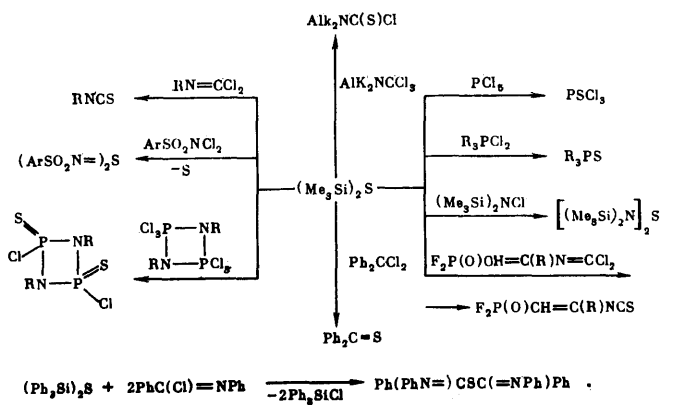
R=Ph [163], CF_3 [175], Me_2N [173]



Dialkyl chlorophosphites [reaction (22)] give a mixture of products difficult to separate, formed by the thermal isomerisation of intermediate compounds and the final tetra-alkyl monothiopyrophosphites.[176,177] Carboxylic acid anhydrides and pyrophosphates undergo exchange reactions analogous to reactions (19)–(21):[61,171]

The reaction of the dichlorides of acids of phosphorus, boron, and arsenic with organosilathianes gives cyclic or polymeric products:[153,163,165]

Organosilathianes react equally readily with the halides of sulphonic acids,[61] phosphorylated sulphenyl chlorides, and their derivatives:[178]



The exchange reaction of halogenogermanes with disilathiane and hexamethyldisilathiane gives mixed silyl germyl sulphides, which disproportionate when heated to give the symmetrical sulphides:[179]

$$(Me_3Si)_2S + H_3GeF \xrightarrow{-Me_3SiF} H_3GeSSiMe_3$$

$$(H_3Si)_2S + H_3GeCl \xrightarrow{-H_3SiCl} H_3GeSSiH_3$$

$$R_3SiSGeR'_3 \overset{\Delta}{\rightleftarrows} (R'_3Ge)_2S + (R_3Si)_2S \ .$$

Reactions of type (18) can be used to synthesise many sulphur compounds which are difficult to obtain:[61,103,164,180]

Thus exchange between organosilathianes and halogen-containing reagents with an E–X bond, where E is an element from groups I–VIII, and X = F, Cl, Br, I, makes reaction (18) a new general method for introducing sulphur into the molecules of inorganic, organic, and hetero-organic compounds.

Hexamethyldisilathiane reactions vigorously and exothermally with metal oxides[181] according to the scheme:

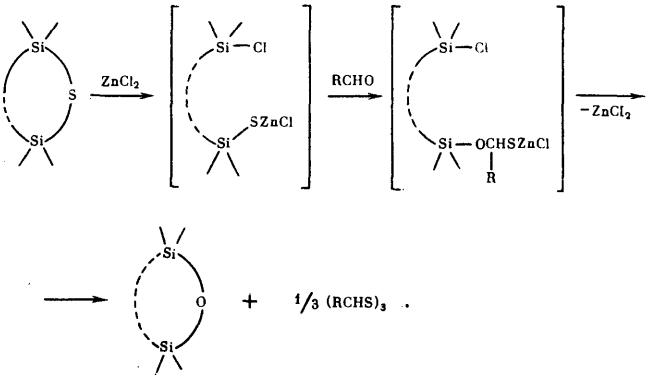
$$n\,(Me_3Si)_2S + MO_n \rightarrow n\,(Me_3Si)_2O + MS_n \qquad (23)$$
$$M=Ba,\ Pb,\ Mn,\ Zn,\ Ca$$

Cyclic silathianes are even more reactive in reactions of type (23). Thus hexamethylcyclotrisilathiane inflames spontaneously in its reaction with manganese dioxide even in a stream of nitrogen.[181]

In contrast to this, the passage of a mixture of oxides of nitrogen through a solution of hexa-alkyldisilathianes in ether does not lead to rupture of the Si–S–Si bonds, and the reaction products are bis-(trialkylsilyl) sulphones.[20]

Hexamethyldisilathiane undergoes an exchange reaction with phosphorus(V) oxide to give phosphorus(V) sulphide, tris(trimethylsilyl) phosphate, and tris(trimethylsilyl) thiophosphate:[61]

$$12(Me_3Si)_2S + 3P_4O_{10} \rightarrow 6(Me_3SiO)_3PO + 2(Me_3SiO)_3PS + P_4S_{10} \ .$$



Phosphorus(V) sulphide in turn can also react with hexamethyldisilathiane to give the tris(trimethylsilyl) ester of trithiophosphoric acid.[84]

$$6(Me_3Si)_2S + P_4S_{10} \rightarrow 4(Me_3SiS)_3PS \ .$$

Organosilathianes react when heated with aldehydes and various perhalogenoketones;[183] the final products in the case of aldehydes are the products of the exchange reaction, siloxanes and thioaldehydes, and in the case of ketones the products of an insertion reaction. These data led to the proposal[182] of a general scheme for the reactions of organosilathianes with carbonyl compounds, including as an intermediate stage the formation of an unstable compound of type (IV), which subsequently decomposes to stable products by a four-centre mechanism. The introduction of halogen atoms, which have a strong electron-acceptor effect, into the molecule of the carbonyl compound stabilises the insertion product to such an extent that it can be isolated and characterised:[183]

$$(Me_3Si)_2S + RCHO \xrightarrow{50-80^\circ} \underset{(IV)}{[Me_3SiOCHRSSiMe_3]} \xrightarrow{-(Me_3Si)_2O}$$
$$\rightarrow [RCHS] \rightarrow {}^1/_3\,(RCHS)_3$$
$$R=Me,\ Et,\ Pr,\ Ph,\ p\text{-}O_2NC_6H_4,\ p\text{-}MeOC_6H_4 \qquad (24)$$
$$(Me_3Si)_2S + RR'CO \xrightarrow{70^\circ,\ 7\ d} (Me_3SiOCRR')_2S$$
$$R=CF_3,\ CF_2Cl;\ R'=CF_3.$$

In contrast to hexamethyldisilathiane, cyclic silathianes react with aldehydes at a higher temperature (140–150 °C) and in the presence of a catalyst ($ZnCl_2$) according to the scheme:[182]

The difference in the reactivities of the linear and cyclic organosilathianes towards aldehydes can be attributed to the difficulty of formation of an insertion product involving cyclosilathianes, a structure with many-membered rings is not characteristic for the insertion product.

Organosilathianes have been proposed as mild reducing agents for sulphoxides[61,184] and selenoxides.[61] The reaction apparently also takes place by the mechanism of reaction (24):

$$(Me_3Si)_2S + RR'E^+-O^- \xrightarrow[-(Me_3Si)_2O]{} RR'E + S$$
$$E = S,\ Se;\ R = Me,\ Et,\ Ph;\ R' = Me,\ Ph$$

In the reactions of hexamethyldisilathiane with various compounds of germanium, tin, and lead, exchange between the sulphur atom of the organosilathiane and an oxygen atom of the heteroorganic reagent is observed:[185]

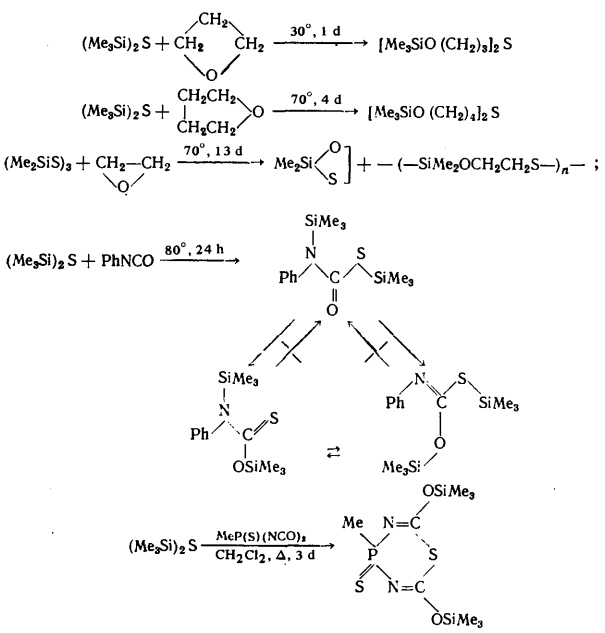
$$(Me_3Si)_2S \xrightarrow[-Me_3SiOMe]{R_3MOMe} (R_3M)_2S$$
$$(Me_3Si)_2S \xrightarrow[-(Me_3Si)_2O]{(R_2M)_2O} (R_3M)_2S$$
$$(Me_3Si)_2S \xrightarrow[-(Me_3Si)_2O]{R_2MO} R_2MS$$

M = Ge, Sn, Pb; R = Et, Bu

Exchange between the sulphur atom of an organosilathiane and a hydrogen atom takes place as a result of reduction by metal hydrides.[23,30] Thus lithium hydride reacts with hexamethyldisilathiane in dioxan to give trimethylsilane.[23]

A study[30] of the stereochemistry of the reduction of 1,3-diphenyl-1,3-dimethyl-1,3-di-α-naphthyldisilathiane by lithium tetrahydroaluminate showed that at 20° the reduction takes place with inversion of the configuration, and at 85° racemisation takes place:

$$(+)\text{-}R_3Si^*SSi^*R_3 \xrightarrow{LiAlH_4} (+)\text{-}R_3Si^*H + [R_3Si^*S^-\ (LiAlH_3)^+] \xrightarrow{HCl}$$
(V)
$$\rightarrow [(+)\text{-}R_3Si^*SH] \xrightarrow{Et_2NH} (+)\text{-}R_3Si^*S^-\ H_2N^+Et_2$$
(VI)



The structures of the complex (V) and the salt (VI) were proved by independent syntheses:

$$(+)\text{-}R_3Si^*SH + LiAlH_4 \xrightarrow[-78°]{-H_2} \ldots \xrightarrow[24\ h]{20\ °C} (V) \xrightarrow[Et_2O,\ -Bu_2O]{85°} (-)\text{-}R_3Si^*H$$
$$(+)\text{-}R_3Si^*SSi^*R_3 \xrightarrow{MeOH/Et_2NH} (VI)$$

2. Insertion Reactions

In hetero-organic chemistry, insertion reactions are usually classified according to the group being introduced, and are subdivided into 1,1-, 1,2-, ..., 1,*n*-additions to the substrate X–Y of the hetero-organic compound Z'_nM-Z, where Z'_n is the sum of the substituents, M a metal or non-metal, and Z the migrating group. In accordance with this generally accepted classification,[186] it is possible to systematise insertion reactions involving organosilathianes according to the type of addition (see start of section IV). In view of the limited number of known reactions of organosilathianes taking place by the insertion scheme (14), however, the reactions will be examined together, without breakdown into different types.

Oxygen-containing heterocyclic compounds,[187,188] organic[188] and organophosphorus[189] isocyanates, and arenesulphonyl isocyanates and arenesulphonyl isothiocyanates[190,191] split the Si–S bond in organosilathianes according to the schemes:

$$(Me_3Si)_2S + p\text{-}XC_6H_4SO_2N{=}C{=}Y \xrightarrow{80°,\ 24\ h} p\text{-}XC_6H_4SO_2N(SiMe_3)\text{–}C(SSiMe_3){=}Y \rightarrow$$
$$\rightarrow p\text{-}XC_6H_4SO_2N(SiMe_3)_2 + CSY$$
X=H, Me, Cl; Y=O, S

Thus exchange and insertion reactions involving organosilathianes are undoubtedly related, since, as can be clearly seen from the reactions of hexamethyldisilathianes with aldehydes, ketones, and arenesulphonyl isocyanates, the exchange reactions take place with the intermediate formation of the insertion product. Depending on the stability of this product, the reaction may either stop at the insertion stage or proceed further to give the exchange products.

An analogous mechanism can be proposed, for example, for the reactions of organosilathianes with oxides:

$$\equiv Si{-}S{-}Si\equiv + M{-}O \rightarrow [\equiv Si{-}O{-}M{-}S{-}Si\equiv] \rightarrow$$
$$\rightarrow \equiv Si{-}O{-}Si\equiv + M{-}S\ .$$

In conclusion, mention may be made of the only reaction involving organosilathianes that does not lead to splitting of the Si–S–bonds: the reaction of hydride-containing alkylcyclosilathianes with unsaturated compounds in the presence of $H_2PtCl_6.6H_2O$:[132,192]

$$[R(H)SiS]_3 + CH_2{=}CR'R'' \longrightarrow [RSi(CH_2CR'R'')S]_3 + [RSi(CR'R'')S]_3$$
(Me)

V. POSSIBILITIES FOR THE PRACTICAL APPLICATION OF ORGANOSILATHIANES

The first mention in the patent literature of the possible use of organosilathianes appeared in 1952, when they were patented as heat-stabilisers and anti-foaming agents for mineral oils[193] and lubricating materials.[194] In 1953, a patent was published on the use of organosilathianes as fungicides, insecticides, and additives to siloxanes.[26] It has been reported[195,196] that compounds containing an Si–S bond promote the droplet condensation of steam. Because of the difficulty of obtaining organosilathianes, however, the question of their practical utilisation remained open for a long time.

The main fields of application of organosilathianes were established only after convenient and effective methods had been developed for synthesising compounds with varied structures containing the Si–S–Si fragment[52,53,57,62,197] and their principal properties had been studied.[22,40,61,197,198]

Organosilathianes are the closest structural analogues of organosiloxanes, but unlike the latter, they are extremely active in reactions involving the heterolytic splitting of the Si–S–Si bonds. Thus the possible application of polymers containing only silathiane bonds is limited. Moreover, unlike siloxanes, organosilathianes do not form homopolymers with a high molecular weight.[63–65] Thus the main efforts of research workers have been directed towards the synthesis of new heteropolymers containing Si–S–Si bonds. A method for obtaining these heteropolymers is based on the reactions of cyclic silathianes and silathiaoxanes with boric, phosphoric, and phosphorous acids and their salts.[197–200]

The synthesised bora- and phosphasilathiaoxanes are liquid products, which have the advantage over their analogues the bora- and phosphasiloxanes that they can be uniformly distributed in rubber in sufficient quantities.[197–200]

The use of borasilathiaoxanes in heat-resistant self-cross-linking resins improves the technology of the resin mixtures and their autohesion properties, and leads to milder vulcanisation conditions (a decrease in the irradiation dose).[198–200]

Siloxane sealants modified by phosphasilathiaoxanes have improved thermal stability and improved adhesion and physicomechanical properties.[198–200] Moreover, organosilathianes can be used to modify the properties of not only organosilicon polymers, but also organic polymers. Thus a study [201] of the possible use of hexa-methylcyclotrisilathiane as a stabiliser in the thermal and radiation ageing of polymethyl methacrylate showed that the stabilising effect of this cyclotrisilathiane is particularly marked at high radiation doses and at the temperature of the start of the decomposition.

The high reactivity of organosilathianes towards proton donors is responsible for their application primarily as reagents for silylating inorganic, organic, and hetero-organic compounds.[30,61,71,79,80,132–165,202–205]

A study of the silylating power of organosilathianes indicated that their efficiency is greater than that of traditional silylating agents based on compounds with a $\equiv$Si–X bond, where X = H, Cl, NR_2.[61]

One of the main advantages of organosilathianes as silylating agents is the simplicity of the silylation process, which is carried out by mixing and heating the starting materials (30–120 °C) for a short time (0.5–3 h) to give a high yield (70–98%) of the silyl derivatives. The course of the reaction is conveniently followed gas-volumetrically from the quantity of hydrogen sulphide formed. The reaction does not require a large excess of the proton donor or the use of catalysts and solvents. Moreover, organosilathianes can be used for the effective selective silylation of proton donors containing two or more active groups in the molecule.

Organosilathianes may prove to be equally useful for introducing a sulphur atom into the molecules of organic and hetero-organic reagents,[57–62,103,153,170–175,180,204] and also as mild reducing agents for a number of oxygen-containing compounds.[61,184]

Thus the progress made in the application of organosilathianes in polymer chemistry and in preparative organic synthesis show the undoubted promising possibilities provided by further studies of the practical application of organosilathianes.

While the present manuscript was being prepared for printing, the following papers were published, and reference to these provides a valuable supplement to the material examined above: the reduction of oxides of sulphur, selenium, and tellurium by hexamethyldisilathiane, obtained *in situ*;[203] the use of the boron trichloride–hexamethyldisilathiane system for the conversion of carbonyl compounds into thiocarbonyl compounds;[204] the synthesis of cyclosilaselenosilathianes by the insertion of sulphur and selenium into octamethyltetracyclosilane;[205] the synthesis of diacetoxydisilathiane by the photochemical thiolysis of methyl(vinyl)diacetoxysilanes—the first example of the conversion of a silicon–oxygen bond into a silicon–sulphur bond;[206] the reactions of hexamethyldisilathiane with compounds containing an element–chlorine bond;[207] the synthesis of functionally substituted organosilathianes;[208] organosilathianes in organic synthesis;[209] the reaction of hexamethyldisilathiane with phosphorus(V) oxide;[210] organosilathianes as silylating agents;[211] the mass spectrometry of organocyclosilathianes;[212] the synthesis of low-coordination compounds of silicon by the thermal decomposition of cyclosilathianes;[212–214] and the molecular and crystal structure of tetramethylcyclodisilathiane.[215]

The Structure and Properties of Highly Conducting Polyacetylene Complexes

V.M.Skorobogatov and I.V.Krivoshei

The physicochemical characteristics of polyacetylene and its charge-transfer complexes have been examined. Data on the structural, electrical, magnetic, and optical properties have been discussed from a single viewpoint. Particular attention has been paid to a critical analysis of the soliton concept in relation to the structural and electrophysical properties. The probable mechanisms of the conductivity of polyacetylene have been examined.
The bibliography contains 118 references.

I. INTRODUCTION

The first accurately solvable theoretical models used to study the electrical and magnetic properties of a solid were one-dimensional chains (for example the familiar models of Peierls, Ising, and Heisenberg). These one-dimensional models remained mathematical abstractions until the nineteen-seventies, when Shchegolev[1] drew attention to the possibility of obtaining real quasi-one-dimensional systems by chemical methods. This was soon followed by the description of the quasi-one-dimensional charge-transfer complex (CTC) TTF–TCNQ,† in which were detected not only metallic conductivity but also superconducting fluctuations close to 60 K. Although the latter were not confirmed, the sensational character of the report led to a rapid increase in the number of published papers on systems of small dimensions with unusual electrophysical properties.[2]

Polyconjugated organic polymers were the subject of detailed studies even in the nineteen-sixties, and important contributions to their study were made by Berlin, Cherkashin, Davydov, Liogon'kii, and others.[3,4] Almost all polyconjugated systems were found to be paramagnetics and semiconductors with interesting optical properties. Because of the low quality of the specimens, the impossibility of obtaining single crystals, and the uniformity of the principal characteristics, however, interest in the electrophysical properties of conjugated organic polymers decreased sharply in recent years. The renewal of interest in these materials is probably due to the discovery of the interesting properties of the inorganic polymer polythiazyl $(SN)_x$, whose single crystals show metallic conductivity under ordinary conditions, and become superconducting at T_c = 0.3 K.‡ Thus it has been shown that among polyconjugated compounds there are systems which do not contain a metal and which at the same time show metallic and even superconducting properties over a wide temperature range.

This striking result led to the discovery[5] of the unusual properties of the simplest polyconjugated organic polymer, polyacetylene $(CH)_n$, doped with electron donors or acceptors. As a result of doping, the specific conductance σ changes by many orders of magnitude, and, depending on the doping level, may take different values, typical of dielectrics, semiconductors, and even metals[6] (Fig.1).

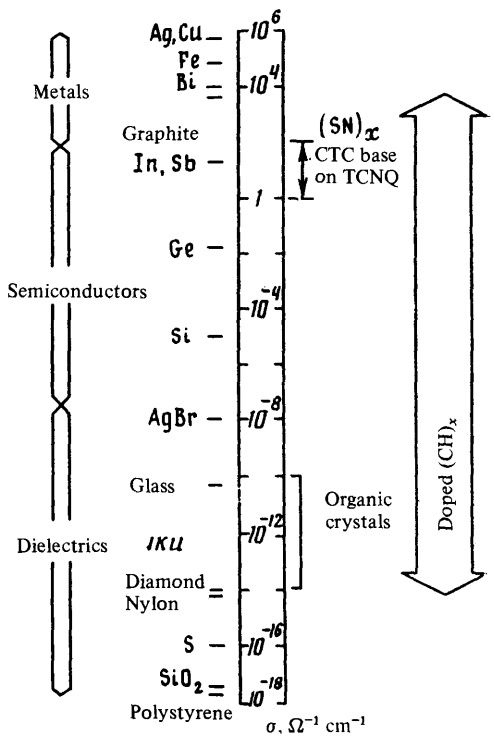

Figure 1. The specific conductance of doped PA and typical solids.[6]

† Here and subsequently, TTF = tetrathiafulvalene, and TCNQ = tetracyanoquinodimethane.

‡ See M.M.Labes, P.Love, and L.F.Nichols, Chem.Rev., 1979, 79, 1.

The simplicity of the molecular structure of polyacetylene (PA), the ease of obtaining high-quality films, and the possibility of varying their properties in planned fashion drew particular attention to PA. PA apparently provides an unprecedented example of a chemical compound whose properties have been studied using almost the entire range of physical methods. In theoretical chemistry and physics, PA provides a unique testing ground for that most modern (an popular) concept, the theory of solitons.

The main aim of the present review is to analyse the soliton concept, which is exotic in chemistry, but extremely popular in present-day physics. Since the soliton models of PA and analogous systems claim to provide a unique and systematic description and explanation of the principal physical properties, their examination is of considerable interest for the experimental and theoretial chemistry of conjugated polymers. The total number of published papers on PA is very large; it reached a maximum in 1983–1984, but had decreased considerably by 1987, while remaining high compared with other conducting polymers. Since PA is the prototype of all poly-conjugated organic systems, it is hoped that the present review will lead to a better understanding of other polymers such as poly-*p*-phenylene, polypyrrole, polythiophen, etc.

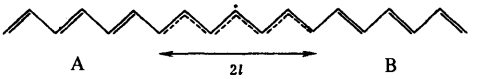
II. ELECTRONIC STRUCTURE

For many years the efforts of chemists have been concentrated on the synthesis of polyconjugated compounds with the longest possible chain. These studies have been based on both simple quantum-chemical calculations by the Hückel method and experimental data on the optical and electrical properties of model low-molecular-weight systems, according to which the width of the energy gap E_g (that is the energy of the transfer of a π-electron from the ground state to the lowest excited singlet state) and hence σ increase with increase in the number of conjugated units $N_{C=C}$. In the limiting case as $N_{C=C} \to \infty$, the electrons should be completely delocalised, the bonds beween the C atoms should be completely equivalent, and the ground state of the polymer should become metallic. Among the vast number of compounds synthesised, however, it has not been possible to discover one whose electrophysical properties are not semiconducting. This has led to a number of phenomenological explanations, details of which can be found in familiar monogaphs.[3,4] A significant feature is that all the explanations have taken into account not the intrinsic electronic properties of the polyene chain but numerous secondary factors, chiefly conjugation defects and disorder in the supermolecular structure.

This situation apparently arose because of the sharp separation between the chemistry of macromolecular compounds and solid-state physics. At the same time, for physicists, this problem had been settled long before: the impossibility of the metallic state in one-dimensional systems follows from Peierls' theorem, according to which a regular one-dimensional chain of atoms is unstable with respect to deformation leading to doubling of the lattice period *a*:

The change from a structure with equalised bonds to a structure with alternation of the bonds is called a Peierls transformation. In the band theory of solids, in the Peierls phase, the conductivity band is split exactly in the middle, as a result of which this phase is dielectric. The Peierls transformation is energetically favourable as a result of the lowering of the total energy of the lattice. This instability is characteristic of any one-dimensional metal, and the nature of the distortions is determined by the degree of filling of the conductivity band: if $1/n$ is the degree of filling of the band, then the change to the dielectric state is associated with *n*-merisation of the lattice. Since for PA, $n = 2$, there should be alternation of the double and single bonds in the chain. The alternation of the bonds in PA can now be regarded as a factor established experimentally from X-ray[7] and electron[8] diffraction data and from solid-state NMR spectra;[9,10] the difference between the lengths of the double and single bonds is 0.06–0.08 Å.

Thus an ideal crystal of PA should be a dielectric. At the same time, the experimental values of σ show a wide scatter, $10^{-5}-10^{-12}$ Ω^{-1} cm^{-1}.[11,12] The comparatively high values of σ are due to defects of different kinds in the molecular and crystal structure of real specimens; the paramagnetic defects are of particular interest. Polyacetylene exists as *cis*- and *trans*-isomers; the former is thermodynamically stable only at low temperatures, and is the main product of the catalytic polymerisation of acetylene by the most widely used method of Shirakawa.[13] The paramagnetism of PA is due entirely to the presence of the *trans*-isomer, and on thermal isomerisation (which is irreversible, because of side reactions leading to cross-linking of the chain and partial degradation of the polymer), the increase in the proportion of the *trans*-segments is accompanied by an increase in the concentration of spins and an increase in σ.[12]



For the subsequent discussion it is important to note that the ground state of *trans*-PA is doubly degenerate: change in the alternation sequence does not alter the energy. Thus the existence of two resonance phases A and B of equal energy is possible:

There is no degeneracy in *cis*-PA: change in the alternation sequence converts the *cis*-transoid phase C into the less stable *trans*-cisoid phase D:

It was the energetic equivalence of the phases A and B that provided the basis of the solution model of *trans*-PA, better known as the Su–Schrieffer–Heeger (SSH) model.[14] Strictly speaking, a soliton is an isolated wave, which retains its structure after collision with any other isolated wave of the same type. In solid-state physics, the term solitons is usually employed to describe non-linear excitations leading from one potential energy minimum to another with the same energy, and they are regarded as quasi-particles. In the case of *trans*-PA, a soliton is a topological defect in the alternation, extending over several bonds, so that the phase A is gradually converted into the phase B:

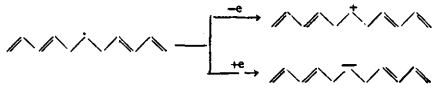
In the SSH model, the *trans*-PA chain is represented by a one-dimensional lattice with an elastic constant *K*, at each site of which there is one π-electron and phonon interactions are taken into account by a Hamiltonian of the form:[14]

$$H = \sum_{n,S}^{N} \beta_{n,n+1} (a^{+}_{n,S} a_{n+1,S} + a^{+}_{n+1,S} a_{n,S}) + \frac{1}{2} K \sum_{n} (u_n - u_{n+1})^2$$

The first summation is the Hückel Hamiltonian for N electrons, written in the representations of secondary quantisation, where $\beta_{n,n+1}$ is the resonance integral of the bond between the atoms with numbers n and $n + 1$, and $a^{+}_{n,S}$ *and* $a_{n,S}$ the operators of the generation and annihilation of π-electrons in the states with number n and spin S. The second summation represents the energy of the elastic lattice with displacements u_n of the lattice sites from their equilibrium positions. Thus $\beta_{n,n+1} = \beta_0 - \alpha(u_{n+1} - u_n)$, where α is the electron–phonon interaction constant. If only the electronic energy is taken into account, the one-dimensional lattice will be unstable with respect to Peierls doubling of the lattice period, and will be

transformed into the state with alternation of the bonds. Doubling corresponds to the condition $u_n = (-1)^n u_0$, where u_0 is the displacement of the lattice sites in the defect-free chain of *trans*-PA. Thus a gap $E_g = 2\Delta = 8\alpha u_0$ is produced between the valence band and the conductivity band. The soliton excitations are introduced by means of the function

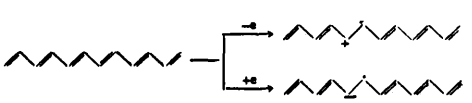
$$\Delta_n = \Delta \text{th}(na/l) \quad (1)$$



where l is the half-width of the soliton, whose wavefunction has the form

$$\Phi_n = l^{-1/2} \cos(\pi n/2) \text{ sech } (na/l) \quad (2)$$

Thus in the SSH model, solitons appear not from the internal structure of the solution, but as localised electronic states in the centre of the gap with the given topology of the defect. In view of the considerable computational difficulties, the SSH Hamiltonian allows only a numerical solution. When the parameters E_g + 1.4 eV, band width $4\beta_0$ = 10 eV, and K = 21 eV Å^{-2} are used, the SSH model gives the energy of the soliton $E_s = 2\Delta/\pi \simeq 0.42$ eV and $l = 2\beta_0 a/\Delta = 7a$. The relatively large size of the soliton compared with the lattice period shows that the discrete character of the lattice plays practically no part, and that the energy of the capture of a soliton by a lattice site does not exceed several meV. The effective mass of the soliton is only a few times greater than the mass of the electron, so that the soliton has a very high mobility.



In the continuum model[15] [$na = x$; $\Delta_n \rightarrow \Delta(x)$], the function (1) strictly describes the configuration of the ground state with the boundary conditions $\Delta(x) \rightarrow \pm\Delta$ as $x \rightarrow \pm\infty$. Unlike the discrete SSH model, the continuum model makes it possible to obtain analytical solutions. In most cases the results of calculations using the two models agree qualitatively, although the concrete definition of the structure of the soliton in the discrete model makes it possible to take account of various fine effects.

The solitons just examined have spin, but not charge, so that they are responsible for the paramagnetism of PA, but are not current carriers. The role of carriers is played by spin-free charged solitons, which should be produced by the reaction of a donor or acceptor of electrons with defect chains of *trans*- PA:

From a chemical viewpoint, neutral solitons S$^{\cdot}$ are radicals, positive solitons S$^+$ are carbocations, and negative solitons S$^-$ are carbanions, and in all cases the electron density is delocalised over a certain section of the chain with length $2l$. Fig.2 illustrates the situation in the representations of the band structure of solids.

Thus PA becomes a conductor as a result of doping and the associated rearrangement of the electronic structure, and not as a result of a phase transformation of the chain into a metastable state, which is not produced in compounds of this class. In other words, the electron or hole formed as a result of doping and charge transfer, after a certain characteristic time, are converted into a localised state with the formation of a soliton. If the doping reaction involves not only defect chains having spin but also defect-free chains, then solitons should be generated in pairs.[14] Numerical calculation[16] shows that with slight doping, the energetically preferred formation is not a non-bonded soliton–soliton pair S$^{\pm}$–S$^{\cdot}$ but a polaron P$^{+\cdot}$ (in other words a radical-ion), representing a bound state:

The phases of the alternation on the two sides of the soliton are opposed, whereas the formation of a polaron does not lead to changes in the phases. Two symmetry levels now appear in the energy gap (Fig.2), one of which is situated ~0.3 eV above the top of the valence band, while the other is situated at the same distance below the bottom of the conductivity band. On further doping, two processes compete with one another; the polaron states begin to form a band, and neighbouring polarons may recombine to give spin-free bipolarons (carbodications):

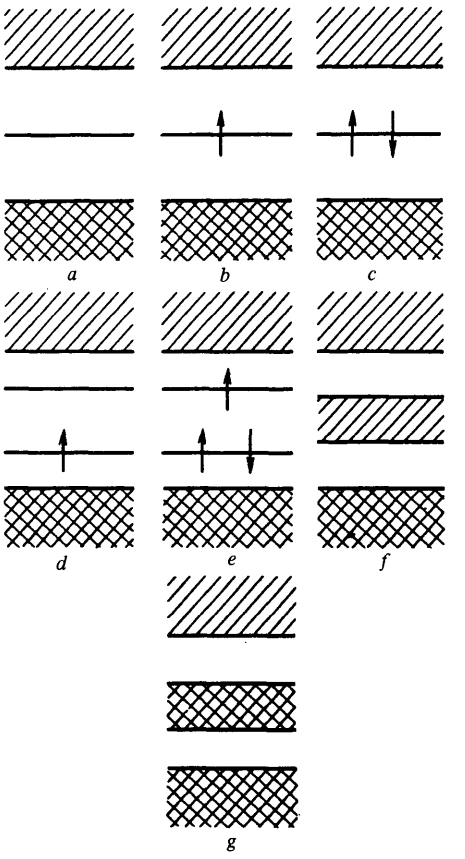


Figure 2. The band structure of states of the soliton type with charge q and spin S: *a*) positive soliton S$^+$ ($q = +e$, $S = 0$); *b*) neutral soliton S$^{\cdot}$ ($q = 0$, $S = 1/2$; *c*) negative soliton S$^-$ ($q = -e$ $S = 0$); *d*) positive polaron P$^+$ ($q = +e$, $S = 1/2$); *e*) negative polaron P$^-$ ($q = -e$, $S = 1/2$); *f*) soliton lattice S$^+$ ($q = Nye$, $S = 0$); *g*) soliton lattice S$^-$ ($q + -Nye$, $S = 0$).

Because of the degeneracy of the ground state of *trans*-PA, the bipolarons are unstable, and dissociate to give charged solitons forming a conductivity band within the gap (Fig.2). The conductivity is now due not to jumps between localised soliton states but to the soliton band. This band subsequently becomes broader, and finally joins up with the top of the conductivity band and the bottom of the valence band, the gap collapses, and the highly doped PA becomes a quasi-metal with ordinary electronic conductivity.

Thus for highly conducting complexes of PA, two fundamentally different conductivity mechanisms are postulated. The first is due to the movement of quasi-particles—spin-free charged solitons (or bipolarons)—which are combined with distortions of the lattice and which form a band (either completely filled or unpopulated) within the gap. The novel and unique character is revealed in highly doped specimens and is associated with the ordinary movement of electrons as a result of the overlap of the conductivity, valence, and soliton bands.

The polaron model is more general than the soliton model, since it does not require degeneracy of the ground state. This requirement, generally speaking, is extremely strict, and is not satisfied even for *cis*-PA. Nevertheless, the electrophysical properties of the two isomers are completely analogous; moreover, analogous properties are shown by poly-*p*-phenylene, polypyrrole, and other polymers, for which there is no degeneracy. Between the soliton and polaron models of PA, however, there is a deep internal relationship, which follows from relativistic φ^4 field theory;[17] a universal method for obtaining soliton, polaron, and other quasi-particle solutions has been proposed, for example, in Ref.18. The large number of modifications of the SSH model will not be discussed (the interested reader can find details in a published review[19] and the references therein), and attention will be concentrated on the cardinal question of whether the soliton theory is in fact necessary and sufficient to explain the properties of PA and, in the wider sense, all conducting polymers.

III. ELECTRICAL PROPERTIES

The general character of the changes in the static electrical conductivity σ when PA is doped with various typical acceptors to the maximum levels attainable experimentally is shown in Fig.3,[20] where y denotes the number of moles of dopant per mole of CH units. Thorough studies[21] showed that the detailed form of the $\sigma(y)$ relationship is determined by the previous history of the specimens: the method used to synthesise the PA, the isomeric composition, the type of dopant, and, to the greatest extent, by the method of doping. In general, it is assumed[21] that the slower the introduction of the dopant, the narrower the range of values of y within which the main increase in the electrical conductivity takes place. For example, when *trans*-PA is doped with iodine vapour at $p \leqslant 0.1$ mmHg, σ increases by a factor of 10^4 in the range $10^{-3} \leqslant y \leqslant 10^{-2}$.[21] On the other hand, the $\lg\sigma - \lg y$ graphs obtained by doping *cis*- and *trans*-PA with AsF_5 vapour at different pressures[21] were practically linear throughout the range of values of y, and the same results were obtained when PA was doped rapidly (p = 0.3 mmHg) with iodine vapour.[22] The dependence of the thermo-EMF on the doping level is also determined by the rate of doping;[21,23] the lower the rate of doping of PA, the narrower the range of values of y within which the thermo-EMF decreases from the values typical of semiconductors ($\sim 10^3$ μV K^{-1}) to the values typical of metals (~ 10 μV K^{-1}).

The observed effects are usually attributed to the more or less uniform distribution of the dopant throughout the volume of the PA specimens. It is assumed that the most uniform distribution is achieved with so-called cyclic doping. In this method, the exposure of the film of PA to the vapour of the dopant, for example AsF_5 (at T = 143 K, $p < 0.1$ mmHg), is alternated either with evacuation or with freezing-out the non-absorbed AsF_5 at 7 K,[21,23,24] and this procedure is repeated until the required doping level is achieved. Thus the experimental justification for the theory of uniform doping is the exceptional sensitivity of various electrophysical characteristics to the doping method: the more uniform the distribution of the dopant, the sharper the semiconductor–metal transition.

At the same time, it follows from even simple estimates of the entropy effects and the energy of lattice deformation on doping[25] that aggregation of the dopant in stacks or layers is energetically preferable to its random distribution (with the possible exception of the small Li^+ ions). Direct measurements of the distribution profiles by electron-probe X-ray microanalysis[26] in all cases showed an extremely non-uniform distribution of the dopants at low values of y even in thin PA films (~ 10 μm), and relatively uniform distribution was achieved only by doping to y_{max}. The effect achieved by cyclic doping is not clear; it is not fully understood how repeating the low-temperature cycles is able to achieve the required uniformity.

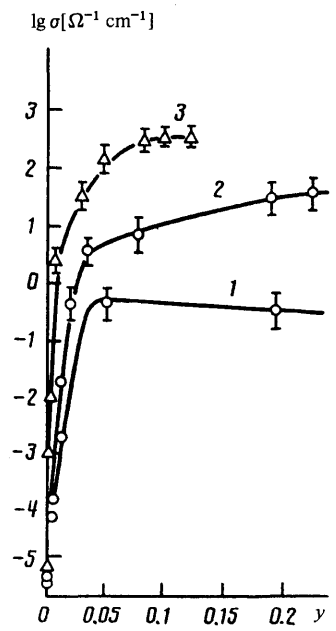

Figure 3. Dependence of the electrical conductivity of PA on the doping level;[20] *1*) $(CHBr_y)_x$, *2*) $(CHI_y)_x$, *3*) $[CH(AsF_5)_y]_x$.

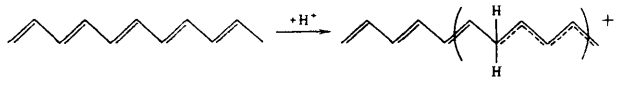

Thus diffusion is an activated process, and its rate decreases exponentially with temperature. It is significant that the characteristic distribution profiles of the dopant into the bulk of the specimens remain completely unchanged even when the films are kept for one week in a dynamic vacuum.[27] This phenomenon is probably due to fixation of the dopant as a result of chemical reactions, so that free diffusion stops. For the same reason, deviation from Fick's law is observed, as shown in experiments[28] on the kinetics of diffusion.

Unfortunately, there are extremely few published data on the chemistry of the reactions of PA with dopants. Extensive photoelectron, Mössbauer, and Raman spectroscopic data make it possible to formulate the most extensively studied reactions as follows:

$$2(CH)_x + 3y\,AsF_5 \rightarrow 2[(CH)_x^{y+}(AsF_6^-)_y] + y\,AsF_3$$
$$(CH)_x + 2y\,FeCl_3 \rightarrow [(CH)_x^{y+}(FeCl_4^-)_y] + y\,FeCl_2$$
$$2(CH)_x + 3y\,I_2 \rightarrow 2[(CH)_x^{y+}(I_3^-)_y]$$

The actual situation, however, is much more complex than indicated by these simple equations. After doping with AsF_5, the composition of the specimens usually corresponds to the formula

$[CH(AsF_n)_y]_x$, where $5 \leqslant n \leqslant 6$,[29] depending on the doping conditions. In addition to I_2 molecules, $(CHI_y)_x$ contains the ions I_5^-, I_3^-, and I^-,[30] and when bromine is used as dopant, most of it adds on across the double bonds of PA, forming saturated segments $-CHBr-CHBr-$.[31] Some dopants undoubtedly form covalent bonds with PA, as shown for bis(fluorosulphuryl)peroxyl [32] and trimethyloxonium salts, which are effective CH_3^+ cation donors.[33] Doping by protic acids which are not oxidising agents, for example, HF, apparently takes place by the same mechanism:[34]

In published discussions of the $\sigma(y)$ relationships, however, the independent variable y taken is always the total analytical concentration of the dopant, which is found either gravimetrically or (for the smallest values of y) using tracer atoms. It is assumed *a priori* that all the absorbed dopant forms a highly conducting complex with PA. This assumption is in general incorrect; spectrophotometric analysis of the equilibria by the Benesi–Hildebrand method in PA–I_2 [35] and PA–Br_2 [36] systems showed that the composition of the conducting complexes corresponds to the formula $[(CN)_n(X_2)]$, where X = I or Br, and $(CH)_n$ is a segment of the continuous conjugation ($n < x$). Thus S_3^- ions may also be produced by side reactions which are not related to the formation of conducting complexes. Additional evidence in support of this conclusion is apparently provided by data on the thermal desorption of iodine from $(CHI_7)_x$:[37] treatment of the specimens at 383 K for 105 min lowered the conductivity by a factor of 10^4 with a decrease in y by a factor of 5, but at the same time the intensity of the band at 107 cm^{-1} in the Raman spectrum due to I_3^- ions increased by a factor of 14.

The formation constants of $[(CH)_n(I_2)]$ and $[(CH)_n(Br_2)]$ are 64 $mole^{-1}$ and 8 $mole^{-1}$ respectively, and the concentrations of the active states in PA accessible for complex formation at 0.4 mole dm^{-3} for I_2 and 0.9 mole dm^{-3} for Br_2.[35,36] Thus many of the properties of doped PA are determined by the chemical character of the dopant. Thus it has been shown[35] that for the overall formula $(CHI_{0.25})_x$, the equilibrium composition which is entirely responsible for the electrical conductivity corresponds to the formula $(CHI_{0.008})_x$.

Thus for the vast majority of dopants, the true concentration dependence $\sigma(y)$ must be regarded as unknown. The same is true of the concentration dependence of the thermo-EMF. For its determination, it is necessary to take as independent variables not the total but the equilibrium concentrations of the dopants. Thus use of the equilibrium concentrations may lead to radical changes in the established relationships between the composition and properties of PA. From the classical relationship for semiconductors

$$\sigma = c\mu e \qquad (3)$$

where c is the concentration of the carriers, μ their mobility, and e the charge of the electron, it follows that σ is linearly dependent on the equilibrium concentration of the conducting complex. In fact, the dependence is exponential,[35,36] as is characteristic of the Mott mechanism of conductivity in disordered solids, which involves jumps of variable length between localised states.[38] Data obtained at room temperature[35,36] show very good agreement (correlation coefficient 0.995) with the Mott law $\sigma \sim \exp(-T^{-1/4})$ throughout the range studied, $0.007 \leqslant y \leqslant 0.25$. Thus the use of the equilibrium concentrations shows that there are no signs of a semiconductor– metal transformation and hence of a change in the mechanism of the conductivity, at least in this range of nominal values of y.

Representation of the data[35,36] in the form of the usual $\sigma(y)$ relationships gives typical *S*-shaped curves. On these graphs it is possible to distinguish three regions. In the first ($y \lesssim 10^{-4}-10^{-3}$), the $\sigma(y)$ dependence is weak; in the second ($10^{-3} \lesssim y \lesssim 10^{-2}$), the $\sigma(y)$ dependence is very strong, and this is interpreted as a semiconductor–metal transformation;[21,39] in the third, quasi-metallic, region, the conductivity is saturated (the values of y_{max} depend on the nature of the dopant). According to the soliton model, the change from one region to another should be accompanied by a change in the conductivity mechanism. The chief test for identifying the mechanisms is the temperature dependence of σ. Considerable efforts have been made to establish the $\sigma(T)$ relationships as accurately as possible, but in spite of the large amount of experimental data, no clear and systematic picture has yet been revealed. Typical graphs[39,40] are shown in Fig.4, and lead to two conclusions. Firstly, in all cases the temperature dependence is activational, but with increase in y the $\sigma(T)$ dependence becomes weaker (for dopants such as AsF_5,[39] $FeCl_3$,[41] and $(FSO_2O)_2$ [32] in the range 300–250 K, even a slight increase in σ, corresponding to the behaviour of metals, is observed). Secondly, there is no clearly defined phase transformation, which would have been revealed by an abrupt change in the $\sigma(T)$ relationship at a certain critical concentration of the dopant.

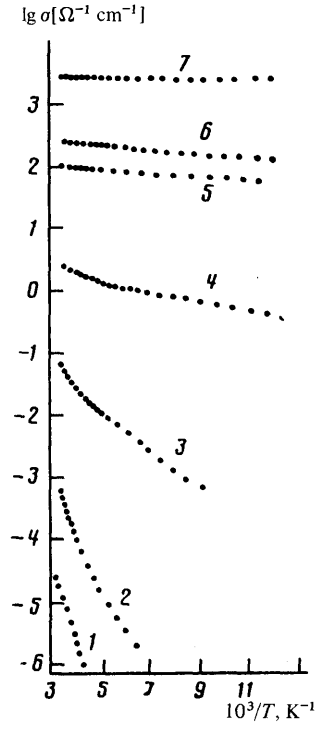

Figure 4. Temperature dependence of the electrical conductivity of $[CH(AsF_5)_y]_x$ [39] for y = 0 (*1*), 0.0028 (*2*), 0.0059 (*3*), 0.010 (*4*), 0.050 (*5*), 0.10 (*6*), and 0.14 (*7*).

For the analytical description of the $\sigma(T)$ dependence, different authors have used relationships of the form $\exp(-T^{-1})$, $\exp(-T^{-1/4})$, $\exp(-T^{-1/2})$, or T^x, where $x > 10$ (see the literature cited in Ref.11). This variety suggests that in fact, none of the proposed relationships is satisfied over a sufficiently wide range of temperatures. The same conclusion was reached after detailed $\sigma(T)$ measurements for $(CHI_y)_x$ specimens with different previous histories;[11] any functional relationship provided a satisfactory description of the experimental

data only in a more or less limited temperature range. It should be emphasised that, unlike the $\sigma(y)$ relationships, the $\sigma(T)$ relationships were found to be independent of the method used to dope PA.[42] If however the published conclusions[21,23] regarding the fundamental influence of non-uniform distribution of the dopant on the electrical properties of PA are accepted, then it is impossible to explain why these non-uniformities (or their absence) have no influence on the nature of the fundamentally more important $\sigma(T)$ relationships.

Generally speaking, the lack of agreement and often the direct contradiction between different experimental data on the electrical properties of PA are to a large extent due to the extremely complex morphology of the specimens, which makes correct measurements extremely difficult. In most photomicrographs obtained using the scanning electron microscope, PA films and powders appear as accumulations of disordered intertwined fibrils with a thickness of 10–80 nm and a length of tens of nm.[13,20] In films obtained by the standard method of Shirakawa, the volume fraction of the fibrils is ~40%. These fibrils in turn are made up of disordered, twisted, and intertwined micro-fibrils with a thickness of 3–5 nm.[43] On the other hand, transmission photographs show the presence of lamellae with a diameter of several tens of nm and a thickness of several nm; these lamellae combine in irregular stacks to form pseudo-fibrils.[6] High-resolution electron microscope data[44] show, however, that the morphological sub-units of both the original and the doped PA are globules with a diameter of 20–50 nm. These globules combine to form clusters, monolayers, or fibril-like formations, that is secondary structural elements. These elements then form tertiary structures: lamellae (monolayers lying on top of one another), loose networks, and their combinations with relative contributions determined entirely by the synthesis conditions. In freshly prepared PA, the globules are apparently joined to one another only by cohesive forces. Thus the polymerisation of acetylene in the presence of surface-active substances gives emulsions with spherical PA particles;[45] ultrasonic dispersal of the PA suspensions gives colloidal solutions.[46]

In one way or another, the basic structure of PA may become similar to a highly porous sponge with a specific surface of 35–60 $m^2\ g^{-1}$.[20,47] The electrical resistance of these specimens is made up of many terms which depend on temperature in different ways: the resistance of the inter-crystallite contacts within each fibril or globule, the resistance of the inter-fibril or inter-globule contacts, the resistance of the amorphous phase, and also terms determined by the high anisotropy of the three principal components of the specific conductance tensor. The macroscopic conductivity should naturally be determined by the largest of these resistance terms, but the real picture is complicated considerably when account is taken of geometric factors (the maximum specific resistance does not always correspond to the maximum resistance) and the fact that the ratio of the different components of the resistance may change with change in temperature. As a result, the $\sigma(T)$ relationship for non-crystalline specimens generally does not reflect the properties of the conducting complexes, and the data leave wide scope for speculation.

At the same time, unambiguous information on the intrinsic $\sigma(T)$ relationship can be obtained by the simple and elegant method of short-circuited potential electrodes (SPE), which eliminates the influence of the resistance of the inter-crystallite contacts and the small components of the specific conductance tensor.[48] The SPE method is qualitative, but it makes it possible to deduce the true temperature dependence of the largest of the components of the specific conductance tensor, by predicting the general course of the relationship for single crystals. The data obtained[49] by the SPE method at $T \geqslant 77$ K for highly conducting PA specimens (Fig.5) show that the true $\sigma(T)$ relationship has the form typical of metals, and is independent of the morphology of the PA. For $[CH(FeCl_3)_{0.06}]_x$, the SPE method established metallic behaviour as far as $T = 1.9$ K.[50]

IV. MAGNETIC PROPERTIES

The magnetic properties of PA have attracted particular attention from the very beginning. The experiments have been designed to answer the questions, of fundamental importance for the soliton concept, of whether the unpaired electrons are in fact highly mobile, whether their diffusion is chiefly one-dimensional, and whether at medium doping levels the paramagnetism disappears and the charge is carried by spin-free solitons.

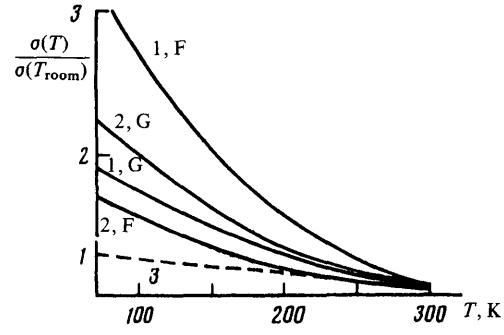

Figure 5. Temperature dependence of the reduced electrical conductivity, obtained by the SPE method;[49] *1*) $[CH(ClSO_3H)_y]_x$, *2*) $[CH(NOClO_4)_y]_x$ (*G* = globular PA, F = fibrillar PA); *3*) current-carrying silver paste.

An important factor for a theoretical description is how the spin density is distributed along the PA chain. The first source from which attempts were made to extract this information was EPR data.[51,52] The spectrum of PA contains an intense singlet with a width of several G, whose characteristics depend markedly on the previous history of the specimen.[12] The paramagnetic of PA is not associated with the charge carriers; treatment with ammonia lowers the conductivity by several orders of magnitude, but does not alter the EPR spectrum.[52] The experimental form of the EPR line is effectively reproduced[51] if the SSH spin wavefunction in form (2) is adopted. These and other similar calculations (see for example Refs. 53 and 54), however, do not take account of all the parameters determining the EPR spectra of π-electron radicals: the anisotropy of the *g*-value and the hyperfine interactions (HFI), the relative orientation of the tensor elements, and relaxation processes. Definite conclusions about the HFI and the number of nuclei involved in the interaction with the soliton can hardly be reached by modelling a singlet EPR line with an unresolved hyperfine structure (HFS). It has been correctly pointed out[55] that from the mathematical viewpoint, this is equivalent to solving one equation with many unknowns. As a result, a large number of wavefunctions, completely dissimilar to the function (2), are capable of reproducing the experimental EPR spectra equally successfully.

More reliable information on the distribution of spin density can be obtained by double electron–nuclear and triple electron–electron–nuclear resonance (ENDOR and EENTOR respectively): the ENDOR spectra are characterised by two and only two individual sets of HFI tensors for the C and H nuclei, and in the EENTOR spectra the relative intensities of the signals reflect directly the proportions of the nuclei involved in a given HFI.[56] It follows from ENDOR that in *trans*-PA, neighbouring C atoms are magnetically non-equivalent, and the spin densities on them are $\rho_1 = |0.06|$ and

$\rho_2 = |0.02|$, and from EENTOR it follows that they have opposite signs: $\rho_1 = +0.06$, $\rho_2 = -0.02$. Thus the unpaired electron must be delocalised over approximately 50 C atoms. This estimate seems too high. The accuracy of the determination of the absolute values of ρ, which depends on the choice of model used to calculate the components of the tensors, should not be overestimated; other data[57] indicate the value $\rho \geqslant 0.01$. The ratio $\rho_2/\rho_1 = -0.33$, found directly from the ENDOR line, is more correct.[58] Since negative values of ρ can appear only as a result of Coulombic interactions (the potential of the single-site electron–electron repulsion, estimated by the Hartree–Fock method, is ~ 3 eV [58]), it is clearly necessary to take account of electron correlations. The neglect of these correlations is probably the most significant unsatisfactory feature of the SSH model.

The main evidence of the unique character of the spins in *trans*-PA is the difference in the behaviour of the PA isomers, established in experiments[53] on the dynamic polarisation of the nuclei (DPN). These experiments involve the measurement of the dependence of the amplitude of the ^{1}H NMR signal at the nuclear Larmor frequency ω_n on the frequency of the microwave pumping, close to the electronic Larmor frequency ω_e. For mobile spins, the signal is amplified on pumping at a frequency ω_e (the so-called Overhauser effect). If however the spins are fixed (the frequency of their jumps is lower than ω_n), then the signal is amplified on pumping at a frequency $\omega_e + \omega_n$ and is weakened in the case of the frequency $\omega_e - \omega_n$ (the so-called solid-state effect). In fact, at room temperature, the Overhauser effect was observed in *trans*-PA, and the solid-state effect in *cis*-PA. Quantitative estimates of the dynamics of the spins and the dimensions of their diffusion[53] were obtained from the frequency dependence of the proton spin–lattice relaxation time T_{1H}. If the diffusion is one-dimensional, and the protons relax on the diffusing spins, then the relationship $f(\omega) = (2D_{||}\omega)^{-1/2}$ is fulfilled, where $f(\omega)$ is function of the spectral density, and $D_{||}$ the diffusion coefficient of the spins, related to the coefficient of translational diffusion by the relationship $D'_{||} = a^2 D_{||}$. From the experiments[53] it follows that $D_{||} = (3-6) \times 10^{13}$ s^{-1}, and the anisotropy of the spin diffusion is $D_{||}/D_{\perp} \simeq 10^6$.

The $T_{1H}^{-1} \sim \omega^{-1/2}$ relationship is not specific for one-dimensional diffusion, however, and may also be determined by nuclear spin diffusion (NSD) to fixed electronic spins, taking place by a reorientation of the nuclear spins with their subsequent relaxation on paramagnetic centres. Measurements of T_{1e} by the spin-echo method[59] show that the NSD model describes the experimental data no less satisfactorily than the one-dimensional model,[53] although the anisotropy and delocalisation of the solitons are completely neglected. The adequacy of the NSD model is confirmed by a large amount of ^{1}H, ^{2}H, and ^{12}C NMR data (see for examples Refs.60–62), and from spin-echo measurements[63,64] it follows that there are several types of paramagnetic defect. The high-resolution DPN spectra[10] reveal a solid-state defect in *trans*-PA even at room temperature. The great majority of continuous conjugation segments in *trans*-PA obviously do not contain highly mobile spins; otherwise, the movement of the solitons along the chains would have led to dynamic averaging of the bond lengths, that is to the suppression of alternation, and this does not agree with experiment. Although the discussion of the paramagnetic defects in PA is not complete, it may be concluded that the various magnetic resonance methods up to the present have provided information on those properties of the topological defects which are determined by their local structure, and not on their kinematic properties.

In non-doped PA, the paramagnetism obeys the Curie law. It would seem that proof of the inverse relationship between the charge and spin of the current carriers, predicted by the soliton model, should be easily obtained by measuring the dependence of the magnetic susceptibility on the doping level. Up to the present, however, irrefutable data have not been obtained. Measurements made by the Faraday method[65] and the Schumacher–Slichter method, based on a combination of NMR and EPR,[24] show a regular decrease in the temperature-independent Curie susceptibility χ_C and the absence of temperature-independent Pauli susceptibility χ_P when *trans*-PA is doped with moderate amounts of AsF_5. On the other hand, according to EPR data,[66] doping *cis*-PA leads to the rapid appearance of χ_P and its regular increase in proportion to y. A comparative EPR study[67] of the doping of *cis*- and *trans*-PA with AsF_5 only partly resolved the contradictions, by confirming that doping *cis*-PA is accompanied by an increase in χ_P, whereas in cyclically doped *trans*-PA, χ_P is negligibly small. These phenomena were again attributed to the non-uniform doping of *cis*-PA.

The quantitative determination of the concentration of spins [S$^\cdot$] in highly conducting materials encounters fundamental difficulties; increase in σ is accompanied by a greater skin-effect, produced when the thickness of the skin-layer and the characteristic dimensions of the specimen are comparable. The EPR line becomes asymmetrical, and no longer gives quantitative information on [S$^\cdot$]. Faraday's method,[65] which does not have this disadvantage, measures the total static magnetic susceptibility $\chi = \chi_D + \chi_C + \chi_P$, where χ_D is the diamagnetic component, which must be calculated from the Pascal constants. The accuracy of these calculations is undoubtedly low, because of the lack of accurate information on the state of the dopant in PA and the uncontrolled defects in the molecular structure of PA. Moreover, it is necessary to calculate the difference $\chi - \chi_D$; these quantities are of the same order of magnitude, and are greater than χ_C and χ_P by 1–2 orders of magnitude, so that the subtraction unavoidably leads to a high loss of accuracy.

The adequacy of the Schumacher–Slichter method[24] has not been established. For example, measurements of χ for $(CHBr_y)_x$ specimens by the Faraday method give $\chi_P \simeq 0$ for $0 < y < 0.02$, and $\chi_P \geqslant 4 \times 10^{-6}$ CGS units per mole of C for $y > 0.02$, whereas according to the Schumacher–Slichter method, $\chi_P \lesssim 10^{-8}$ CGS units per mole of C, irrespective of y.[68] The most convincing data are apparently EPR data[69] obtained for $[CH(AsF_5)_y]_x$ specimens prepared as extremely thin needles, which prevented complications resulting from the skin-effect. Irrespective of the isomeric composition of PA, at $T \lesssim 50$ K, superposition of two EPR lines with the same g-value, one narrow and one broad, was observed. The characteristics of the narrow line make it possible to assign it to conductivity electrons, responsible for χ_P. A remarkable feature is that χ_P increases regularly with increase in y in the same sense as the elecrical conductivity, from which it clearly follows that the current carriers in $[CH(AsF_5)_y]_x$ are classical in character. At the same time, the broad line is associated with localised electrons, responsible for χ_C; after the specimens have been treated with ammonia, only the broad line remains in the spectra. The same behaviour is characteristic of $[CH(SbF_5)_y]_x$.[69]

When PA is doped with iodine, the picture changes. EPR data[21,7] show a gradual decrease in the intensity of the signal and its complete disappearance in highly doped specimens, but the Faraday method[71] detects quite significant Pauli paramagnetism ($\chi_P \leqslant 2 \times 10^-$ CGS units per mole C). Other Faraday measurements,[72] however, do not show any significant χ_P, and the same result was obtained b EPR.[73] In Ref.73, however, in contrast to Refs.21 and 70, it was noted that with increase in the doping level, after the initial sharp decrease, the value of χ_C at $y \geqslant 0.1$ becomes constant. A more systematic picture was obtained when the EPR measurements were extended into the range of helium temperatures.[74] It was found tha not only the spin susceptibility, but also [S$^\cdot$], depend on temperatur and at $T \leqslant 10$ K, the values of [S$^\cdot$] are almost the same for the doped and non-doped specimens. Thus the absence of the EPR signal at high temperatures is directly related to the high conductivity; at y_{max}, the signal is not detected even at $T = 4.2$ K.

The characteristic features of the EPR in $(CHI_y)_x$, and also in $(CHBr_y)_x$, can be explained using the ideas developed for disordered semiconductors,[38,75] in which the EPR signal is usually due to defects in the crystal structure. This signal often disappears when the semiconductor is doped. On the other hand, an EPR signal due to lattice defects is not observed in any metal. This may be due either to the shielding by the conductivity electrons of the Coulombic repulsion between defect states having spins or to the hybridisation of the wavefunctions of localised electrons and conductivity electrons. Similarly, the magnetic properties of $(CHI_y)_x$ may be due to the interactions of localised and band states. Doping generates Pauli spins, which do not give an EPR signal, because of strong spin–orbit scattering on iodine, but which interact with Curie spins. As a result, the paramagnetism is determined both by Coulombic interactions between the localised states and by hybridisation of localised and band states; the increase in the hybridisation with increase in y may lead to the apparent disappearance of the local magnetic moment. In highly doped $(CHI_y)_x$, even at helium temperatures the conductivity is high, and no EPR signal is observed. This mechanism should be ineffective in $[CH(AsF_5)_y]_x$, because of the much weaker spin–orbit interactions at the As atoms, which are highly shielded by the F atoms coordinated to them. Thus published data[74] demonstrate directly the importance of the effects of localisation in in $(CHI_y)_x$ and $(CHBr_y)_x$.

There are much fewer experimental data on the magnetic properties of PA doped with donors. The most important results are those obtained[76] by EPR *in situ* in the liquid-phase doping of thin films of *trans*-PA using a solution of sodium-benzophenone in THF. At low doping levels, the paramagnetic susceptibility of *trans*-$(N_yCH)_x$ remained practically constant, and differed little from that of non-doped *trans*-PA, but close to $y \simeq 0.05$ it increased sharply, accompanied by marked broadening of the EPR line and the appearance of temperature-independent χ_P. These data were interpreted[76] as proof of a first-order phase transformation at $y = y_c$ from a soliton lattice with zero density of states at the Fermi level $N(E_F)$ to a new quasi-metallic lattice, a "polaron metal", with a finite density $N(E_F)$. Such far-reaching conclusions appear doubtful, however, since there is insufficient information on the chemistry of the reactions in the PA–reducing agent system. Thus it has been established[77] that the solvation of Na^+ ions by THF has a marked influence on the width of the EPR line and the conductivity of specimens whose composition in the general case corresponds to the formula $[Na_y(THF)_z(CH)]_x$. At low values of y, solvation has a marked influence of σ, so that $\sigma_{z>0}/\sigma_{z=0} \simeq 10^4$, and with increase in y to 0.2, this ratio tends to 1; at low values of y for solvated Na^+ cations, $\Delta H < 1$ G, whereas for the non-solvated cations, $\Delta H \simeq 6$ G; at $y \simeq 0.01$, these ΔH values becomes equal.

Comparison of published conductivity and EPR data[77] also shows that there are strong interactions between the charge carriers and the local magnetic moments, that is the situation is analogous to that examined above for $(CHI_y)_x$; fairly strong spin–orbit scattering on the Na^+ ions should be expected. As a result, the paramagnetism of $(Na_yCH)_x$ should be determined by the simultaneous influence of several physical and chemical factors, among which the non-uniformity of the doping is of considerable importance. In Ref.76, the distribution of Na^+ was *a priori* regarded as uniform, but NMR data[78] show that even at y_{max}, the spectrum still contains a signal characteristic of non-doped PA.

In conclusion it may be noted that the absence of an EPR signal in the case of doped PA cannot be taken as evidence for the existence of spin-free solitons; for example, the same property is shown by chalcogenide and many other electrically conducting glasses.[38,75] In fact, the density $N(E_F)$ is most probably finite, but the electrons form pairs with antiparallel spins, so that the one-electron density of states $N(E_F)$ is equal to zero.

The reader interested in the detailed characteristics of non-crystalline solids is referred to published monographs.[38,75] It should be noted that the automatic transfer to disordered systems of ideas borrowed from classical band theory is not possible, and easily leads to artefacts.

V. OPTICAL PROPERTIES

The electronic absorption spectra of PA are completely typical of polyconjugated systems. The absorption bands of *cis*-PA has a clearly defined vibrational structure with maxima at 2.1, 2.3, and 2.4 eV, whose positions and intensities depend slightly on the previous history of the specimen. *cis–trans*-Isomerisation displaces the main maximum to 1.9 eV, and, as is often observed, to the disappearance of the vibrational structure.[79] By analogy with short polyenes, the absorption maximum can be assigned to a $\pi-\pi^*$ transition; the absorptivities, $\alpha \simeq 1.5 \times 10^5$ cm^{-1},[79] are characteristic of inter-band transitions in typical semiconductors.

After doping, the absorption band characteristic of the original PA becomes weaker, and is replaced by a new very broad structureless band at 0.5–0.9 eV. Typical results obtained by electrochemical doping[80] are shown in Fig.6. The absorption close to 0.7 eV is characteristic of all doped forms of PA, and is therefore associated with the electronic structure of the PA framework. Since the position of the new band corresponds approximately to the half-width of the band gap in the spectrum of the original PA, in the SSH model this band is called the "absorption in the middle of the gap". In addition, doping leads to the appearance in the infrared range of three strong bands at 0.17, 0.16, and 0.11 eV, whose positions are practically independent of the type of dopant, but are sensitive to the isotopic composition of the PA.[81]

The optical characteristics of PA have been discussed in detail.[19] It may be noted that in the SSH theory and its modifications, the spectrum of doped PA is determined by the characteristic vibrations of the charged solitons; the interaction of the solitons with π-electrons is accompanied by the appearance of new vibrational modes, three of which should be active in the infrared (IR) range. The IR absorption is described equally well by introducing topological defects of not the soliton type (C_{2v} symmetry) but the polaron type (C_{2h} symmetry). Particular attention has been paid to the absorption at about 0.7 eV, associated with the appearance of localised soliton levels exactly in the middle of the gap. Calculations[19] show that the appearance of a soliton in the PA chain should lead to the suppression of direct inter-band transitions, and the intensity of the transitions between the soliton levels should increase with increase in y as far as y_c, after which saturation should take place as a result of the overlap of these levels and the formation of a soliton band. The last conclusion, however, does not agree with experimental data,[33,36] according to which the optical density at 0.7 eV is proportional to the equilibrium concentration of the PA–dopant complex. The IR absorption data[82] also show a regular decrease in the transmission with increase in y as far as y_{max}.

The view that doping produces conjugation defects of different types is entirely reasonable. It is obvious, however, that the optical absorption can hardly be determined by the mobility of these defects; the broken bonds in three-dimensional inorganic amorphous semiconductors also give states situated "within the gap", but these states are not soliton states.[38] Thus the absorption spectra cannot serve as a test for solitons. A clear example is provided by a paper[83] whose authors reject completely the concept of conjugation defects, and attribute the "absorption within the gap" to charge transfer; a donor dopant adds an electron to the conductivity band, and an acceptor dopant generates a hole in the valence band. The conclusion that

there is alternation of the bonds in the PA chain is preserved completely, and the absorption is attributed to electromagnetic interactions between neighbouring chains. If however account is taken of the non-uniform distribution of the dopant, then the "absorption within the gap" can be directly related to an optical dielectric anomaly, characteristic of granulated metals. In this connection it may be noted that the maximum close to 0.7 eV, which is clearly defined in the reflectance spectra of $(CHI_y)_x$ films, disappears after the films have been compressed (unlike the other maxima in the IR range), and are replaced by a reflectance edge.[84] This phenomenon is readily explained in terms of the composite structure of doped PA using the familiar Maxwell–Harnett theory,§ but cannot be understood in terms of soliton models.

The charge-transfer model also provides an extremely effective interpretation of the three IR bands of doped PA; they are attributed to the interaction of the stretching vibrations of the framework with charge oscillations in a partly oxidised or reduced segment of the polymer; this is analogous to the situation for charge-transfer complexes based on TCNQ.[85] On the other hand, the IR spectra of β-carotene, which is an appropriate model compound with eleven conjugated bonds, are completely analogous to the spectrum of PA.[81,86] Thus published data[81,84–86] indicate that the optical absorption in PA is molecular in character. Quantum-chemical calculations of the electronic and vibrational structure[87,88] of model oligomeric radical-cations $C_{2n}H_{2n+2}^{+}$, cations $C_{2n+1}H_{2n+3}^{+}$, and dications $C_{2n}H_{1n+2}^{2+}$ [87,88] show that species of all three types are capable of contributing to the observed absorption. Moreover, the calculation[88] predicts intensive absorption close to 0.7 eV for β-carotene or PA doped with donors, with the formation of radical-anions $C_{2n}H_{2n+2}^{\cdot-}$; subsequent measurements[89] showed complete agreement with these predictions.

VI. PROBABLE MECHANISMS OF CONDUCTIVITY

An understanding of the mechanisms of charge transfer is hardly possible without taking account of the real structure of PA. The very complex morphology of PA was discussed above. Although the degree of crystallinity of the specimens reaches 80%, the average size of the crystallites is small, and does not exceed several nm.[90] The disorientation of the crystallites and the scatter in their sizes and shapes makes the direct determination of the crystal structure impossible; the diffraction patterns of PA seldom contain more than ten reflections, so that the crystallographic parameters have to be selected by a combined analysis of the diffraction patterns and calculations of the crystal packing.[25] The crystalline phase coexists with an amorphous phase; measurements of the thermo-stimulated creep[91] show that PA contains both amorphous volumes and thin inter-phase layers, separating the crystallites. It cannot be assumed that the general nature of the packing of the macromolecules in the amorphous phase differs significantly from that in the crystalline phase; the maxima of the diffuse scattering on the diffraction patterns coincide with the position of the principal reflection, but in the amorphous phase the concentration of packing defects (folds and twists in the chains, vacancies, etc.) is increased.

The diffraction patterns, however, are insensitive to local molecular defects, which to a large extent determine the charge transfer. The defects due to the presence in PA of sp^3-hybridised C atoms are particularly important. Acording to NMR and DPN data,[92,93] their concentration amounts to several percent. The presence of C(sp^3) atoms naturally breaks the conjugation chains. The Raman spectra, which provide a unique source of information on the magnitude of $N_{C=C}$,[94] show that, usually, not more than 20% of the chains have $N_{C=C} \geqslant 20$.

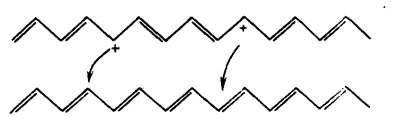
§ See, for example, L.Genzel and U.Kreiberg, Z.Phys., 1980, **37**, 93.



The macroscopic resistance of PA is apparently determined by a large number of factors (see section III). The indeterminacy associated with the disordered nature of the PA structure is so great that it is possible to construct only phenomenological models of charge transfer. When the real structure of PA is taken into account, it immediately becomes obvious that charged solitons or polarons cannot be responsible for the macroscopic conductivity; since they are topological conjugation defects, they can move only within the continuous conjugation segments. These segments are comparatively small, however, and the value of σ for doped PA is not related to the value of N_{C-C}; the electrical and magnetic properties of doped and non-doped PA are practically independent of the molecular mass in the range $400 \leqslant M_n \leqslant 920\,000$.[11] The results of studies of copolymers of acetylene with carbon monoxide,[95] where the mole fraction of CO was varied in the range 5–13%, are even more convincing. In these copolymers, the conjugation chain is frequently interrupted by $-C(=O)-$ units, so that $6 < N_{C-C} < 20$, yet the electrical properties of the doped and non-doped copolymers are the same as the corresponding properties of PA. The expected results were obtained from numerical calculations using the SSH model,[96] according to which the $-C(=O)-$ group in the *trans*-PA chain acts as a trap for neutral or negative solitons, and as a repulsion barrier for positive solitons.

For weakly doped ($y \lesssim 0.005$) *trans*-PA, Kivelson[97] proposed a mechanism of charge transfer by inter-soliton jumps. Every time a mobile soliton $S^{\cdot}$ passes close to a charged soliton $S^{\pm}$ which is bound by Coulombic attraction to an ion of the dopant and is therefore immobile, isoelectronic hopping of an electron to a neighbouring chain becomes possible:

Measurements of macroscopic characteristics, namely the frequency–temperature dependence of σ [98] and the $\sigma(T)$ relationships at different pressures,[99] agree well with the predictions,[97] but more detailed experiments on the influence of magnetic fields on the mobility of the carriers[100] gave results which contradicted the Kivelson model. In fact, the Kivelson mechanism is realistic only when the following requirements are satisfied simultaneously: 1) N_{C-C} should be very large, so that the solitons $S^{\cdot}$ can move along the chain without hindrance; 2) most of the chains should contain $S^{\cdot}$; and 3) the dopant should be distributed uniformly. From the previous sections it is clear that none of these requirements is in fact satisfied.

The corner-stone of the soliton concept is the assumption that the ground state of the chain is degenerate. The model of Ref.97 is obviously inapplicable in principle to either *cis*-PA or other conducting polymers. A different model[101] claiming to explain the mechanisms of conductivity in all doped polymers assumes interchain charge transfer by the correlated jumps of bipolarons:

The model of Ref.101 is designed primarily to explain spin-free charge transfer, and its experimental basis is the apparent absence of paramagnetism in doped PA. A semiquantitative calculation using this model reproduces only the general course of the $\sigma(y)$ relationship; so many assumptions, simplifications, and fitting parameters are used, however, that the agreement with experiment appears artificial. The greatest objections can be made to the actual idea of high-temperature jumps of bipolarons between the chains; by definition, the bipolarons in PA are not simply charged quasi-particles but topological defects in intramolecular chemical bonds. For this reason, the bipolaron model of Ref.101 can be regarded as an artefact, and its indvidual aspects will not be examined in detail.

It has been pointed out many times that the general character of the $\sigma(T)$ relationships for PA is similar to that of the typical relationships for doped inorganic amorphous semiconductors. This is why efforts are made to explain the electrical properties of PA using ideas based on jump mechanisms. For disordered systems, a unique role is played by $\sigma(T)$ measurements using alternating current. To ensure macroscopic conductivity using direct current or at low frequencies, the carriers must pass through the entire specimen; in a disordered system, this is possible only when there is a percolation network. At sufficiently high frequencies, percolation considerations are directly inapplicable, and the movement of the carriers reduces to jumps back and forward between two neighbouring localised states. This situation can be described by the so-called pair approximation.[75] A corresponding model for PA was proposed by Summerfield,[102], whose calculations adequately reproduce the static and frequency $\sigma(T)$ relationships, including the imaginary part of the complex conductivity, which is not consistent with the Kivelson model, and provide a qualitative description of the evolution of the density of states close to the Fermi level during doping. It should be emphasised that the Summerfield model does not contain assumptions about the nature of the states between which the jumps take place, in particular about their mobility, and at the same time reproduces the experimental data[98] more effectively than the Kivelson model.[97]

The electrical properties of moderately and highly doped PA are best described by the model of Sheng,[103] which was initially developed for granulated metals and which assumes the formation in PA of quasi-metallic clusters separated by narrow potential barriers—the non-doped PA regions. The movement of the carriers between the clusters takes place by tunnelling at low temperatures, and by thermally activated jumps at high temperatures. Thus detailed measurements[104] show a gradual decrease in the strength of the characteristic Mott relationship $\sigma \sim \exp(-T^{-1/4})$ when PA, moderately doped with AsF_5, is cooled to a temperature below 16 K; in the range $0.03\ K < T < 1\ K$, the conductivity of highly doped $[Ch(AsF_5)_{0.1}]_x$ becomes independent of temperature.[105] This behaviour cannot be explained without using tunnelling concepts.

Measurements of the temperature, field, and frequency dependence of the conductivity, and thermo-EMF measurements,[106] also show excellent agreement with Sheng's theory. The most convincing proof is apparently provided by the experiments of Refs.49 and 50 (see Fig.5); highly doped PA is in fact a system of non-combined quasi-metallic clusters. In this cluster model, the superposition of two main transfer mechanisms can be proposed. In one limiting case, the movement of the carriers is similar to the movement of the electrons in a metal, that is the interaction with the lattice is relatively weak, and the carriers have a high mobility and a comparatively long mean free path. In the other limiting case, the interaction with the lattice is strong, and the carriers have a very short mean free path and a low mobility. Within the clusters, the carriers probably move as a wave packet. Thus at a temperature below the Debye temperature, they may move as non-localised polarons of small radius in a narrow energy band, and at a temperature above the Debye temperature, the carriers move by jumps. This model is attractive, particularly since in polymers the Debye temperature is not strictly defined, and in fact there may be a distribution of Debye temperatures. Estimation of the drift mobility of the carriers μ, which is defined as the average rate of movement of the current carrier in the direction of the field and which is therefore a macroscopic characteristic, using the simple equation (3), gives for weakly doped PA the value $\mu = 5 \times 10^{-5}\ cm^2\ V^{-1}\ s^{-1}$.[39] As shown by Ioffe,[107] the average mean free path L of a carrier with an

effective mass m^* at ordinary temperatures is given by the expression $L \simeq 10^{-8}\ \mu(m^*/m_0)^{1/2}$, where m_0 is the mass of the free carrier. Assuming that the order of magnitude of the ratio m^*/m_0 is close to 1 gives for weakly doped PA the value $L \simeq 10^{-5}$ Å. This is many orders of magnitude smaller than the lattice constant a, so that the concepts of mean free path or mobility lose their significance. For highly doped PA, Eqn.(3) gives $\mu = 1\ cm^2\ V^{-1}\ s^{-1}$;[39] Ioffe's equation gives $L \simeq 1$ Å, which is also unlikely.

Dielectric measurements at high frequencies of $1.5-5\ cm^{-1}$ [108] revealed a high microscopic mobility (see Table), however, and it was concluded that the frequency dependence of the conductivity can be described by the superposition of two mechanisms. The first is due to free carriers, the absorption on which is described by the Drude relationship, and the second is associated with carrier jumps with the participation of phonons between microscopic states. At the microscopic level, these states are localised, so that the conductivity for direct and alternating current can be examined successfully using jump models.

Electrophysical characteristics of doped PA (accuracy of the determination ±25%).[108]

Specimen	n, cm^{-3}	τ, ps	μ, $cm^2\ V^{-1}\ s^{-1}$	σ, $\Omega^{-1}\ cm^{-1}$
trans-$(CHI_{0.011})_x$	$1.1\cdot10^{15}$	2.7	$3.7\cdot10^3$	0.5
trans-$[CH(AsF_5)_{0.011}]_x$	$5.0\cdot10^{15}$	10.0	$15.0\cdot10^3$	9.5

Notation: n and τ are the concentration and the mean free path of the current carriers μ the mobility of the carriers, and σ the specific conductance.

VII. THE STRUCTURE OF THE CONDUCTING PHASE

In a first approximation, doped PA can apparently be regarded as a composite containing two phases: non-doped and doped to saturation. In principle, depending on the previous history of the specimens, the volume fraction of the conducting phase can vary in the range $0 \leqslant f \leqslant 1$. The limiting cases correspond to the hypothetical single crystals, and in real specimens, some intermediate situation is established. This interpretation can be justified by the following experimental data.

1. In the absorption spectra there is an isosbestic point,[35,36,80] indicating the existence of only two states in PA–dopant systems, irrespective of the doping level (Fig.6).

2. Periodic recording of the diffraction patterns during doping always show a gradual decrease in the intensities of the reflections from the original PA, and the appearance of a new set of reflections. No signs of intermediate structures are detected.[109-111]

3. The reduced volume of the PA specimens is linearly dependent on the concentration of the dopant.[112]

Analysis of the experimental data indicates that the electron-conducting structures are formed first in the amorphous phase of PA. In fact, the first signs of the doped phase on the diffraction patterns appear only at $y \geqslant 0.02$; at $0 < y < 0.02$, only an increase in the intensity of the background scattering due to the adsorption of iodine on the PA surface was observed.[110] The swelling of the specimens during doping becomes appreciable only at $y \geqslant 0.05$.[112] The main increase in σ, however, takes place at $y \lesssim 10^{-2}$ (Fig.3). On doping with iodine from the gas phase, σ increases by five orders of magnitude in a time $t = 10^3$ s, and is saturated after $t = 10^4$ s, and both σ_{max} and the value of t at which it is reached are completely independent of the thickness of the PA films, which in the experiments of Ref.47 was varied from 5×10^{-6} cm to 10^{-2} cm.

At the same time it follows from kinetic data[47] that the diffusion of iodine in PA is very slow, with a coefficient $10^{-14}-10^{-13}\ cm^2\ s^{-1}$. Even for the small non-solvated Li^+ ion, the diffusion coefficient in PA is $\sim10^{-13}\ cm^2\ s^{-1}$ at 356 K.[113] These values are typical of solid-state diffusion. Thus the depth of the diffusion according to Fick's law $l_D = (2Dt)^{1/2}$ is ~0.1 μm at $t = 10^3$ s, which appears unlikely. It is known, however, that the diffusion coefficient along the grain boundaries in polycrystalline specimens is many times greater, and the activation energy of diffusion significantly lower, than in the volume of the granule. Moreover, it has been found[35,37] that the mass of the specimens in I_2 vapour increases rapidly at $t \leqslant 10$ s, and only at $10\ s < t < 10^4$ s, increases according to a t^n law, where $1/3 < n < 1/2$, indicating solid-state diffusion.

The combined data on the distribution profiles of the dopants and the kinetics of doping lead to the following picture. In the rapid first stage, the entire external surface of PA is covered with a monolayer of the dopant. In the slower second stage, the dopant diffuses into the amorphous phase, occupying the spaces between the crystallites. In the third stage, the dopant diffuses into the crystallites, and a new crystalline phase is formed. This picture is consistent with the morphology of PA and with the established $\sigma(y)$ relationships, without introducing doubtful assumptions about the uniform distribution of the dopant. The sharp increase in σ close to y_c (Fig.4) is naturally attributed to percolation, which takes place when the electrically conducting structures are formed in the space between the crystallites; the subsequent increase in f does not make a significant contribution to the macroscopic conductivity. In fact, the high conductivity is not determined by high crystallinity, since doping amorphous PA with iodine gives the same value of σ_{max} as doping highly crystalline specimens.[114]

The question of how the conducting phase of PA is "constructed" can be examined. The conductivity mechanisms which were examined above and which provide an adequate description of the electrical properties of PA are completely indifferent to the specific structure of the localised states or quasi-metallic clusters. There is apparently no particular need to assume that doped conjugated polymers differ fundamentally from the familiar low-molecular-weight charge-transfer complexes (CTC) of the TTF–TCNQ type.[2] In the last case, before the formation of the CTC, the electron clouds of the donor and the acceptor are closed, and when the molecular crystal is formed, extensive charge transfer takes place, converting the crystal to the quasi-metallic state; the initially completely full band becomes half-filled. It may be said that in this case, TCNQ is "doped" by TTF or vice versa, so that the concepts of "dopant" and "matrix" can be interchanged.

From this viewpoint, doped PA represents a particular case of systems of the TTF–TCNQ type with a low and varying concentration of donor or acceptor molecules. The optimum magnitude of the charge transfer is 0.5–0.8 e.[115] This is possible either with partial charge transfer or when a CTC with stoichiometry different from 1:1 is formed. In PA, both situations are probably realised; the first may be characteristic of chemical doping, and the second of electrochemical doping, when the dopant is only a source of counterions preserving the electrical neutrality of PA. The role of donors or acceptors in PA is played by conjugated segments of varying length, bounded by defects in the molecular structure.

The basic principle of supermolecular organisation, ensuring high conductivity, is well known; it is necessary to have a non-stratified bifilar type of packing, where the donors and acceptors crystallise in regular isolated stacks, within which mixed valence states are produced, and the movement of the carriers takes place by a so-called

relay mechanism.[2] The individual details of this mechanism as applied to conducting polymers have been discussed by Wegner.[116] Two models of the packing in doped PA have now been developed on the basis of the diffraction patterns and calculations. The first model [25] assumes structural analogies with intercalated graphite; the acceptor molecules are introduced between the close-packed planes of PA. In the resulting layer structures, the transfer of the carriers should take place chiefly within the partly oxidised planes of PA, and should be quasi-two-dimensional in character. It is noteworthy that this model is unsuitable for interpreting the diffraction patterns of PA doped with alkali metals. For these complexes, a quasi-one-dimensional structure is assumed, in which the metal ions occupy channels in the tetragonal lattice formed by four parallel PA chains.[25] If the analogy with graphite is retained, however, there are no grounds for expecting such significant differences between the structures of the various complexes.

On the other hand, it follows even from a previous analysis[110] that the diffraction patterns for $(CHI_y)_x$ are consistent not only with the intercalation model. In an alternative model, the dopant is introduced between PA layers in which the planes of the macromolecules are arranged normal or almost normal to the plane of the layer. The relationship between the two models is illustrated schematically in Fig.7. The analogy between the second model[110,116] and the packing of low-molecular-weight CTC and radical-ion salts of TCNQ is obvious. The most convincing evidence in support of this type of packing was recently obtained in a diffraction analysis of highly oriented films of *trans*-$[CH(SbF_6)_y]_x$.[116] The crystal structure can be represented as the superposition of two incommensurable sub-lattices: the first is formed by the PA chains, and the second by the SbF_6^- ions. The second lattice is hexagonal and disordered along the crystallographic direction coinciding with the axes of the PA macromolecules. The distance between neighbouring PA segments forming the stacks is 3.44 Å, which ensures effective interaction between the π-electrons. In this model, the PA segments reduced or oxidised to radical-ions are stabilised by complex formation with neighbouring neutral segments according to the scheme

$$(CH)_n^{\pm\cdot} + (CH)_n \rightleftarrows [(CH)_n(CH)_n]^{\pm\cdot}$$

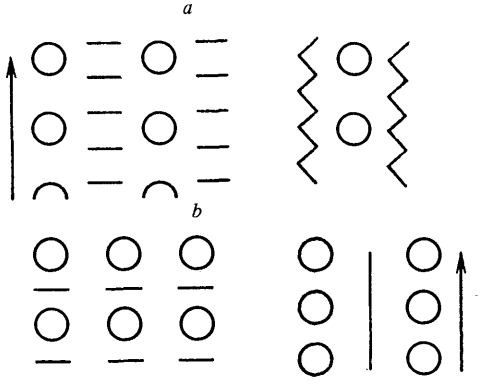


Figure 7. Probable crystal packing in doped PA (on the left—projection along the PA chain direction, on the right—projection at right angles to the PA chain direction): *a*) quasi-one-dimensional model,[116] *b*) quasi-two-dimensional model;[25] the arrows show the preferred direction of charge transfer; the circles represent the dopant, and the dashes the end faces of the planar PA chains.

It follows directly from this scheme that the complex formation is possible not only in the crystalline phase but in all cases where a minimum of two PA segments are arranged relative to one another in such a way that charge transfer is possible between them. These complexes are apparently acceptable as the prototype of the localised states; their concentration increases with increases in y, and they merge at any $y = y_c$. It is appropriate to recall that the packing of the macromolecules in the amorphous phase differs little from that in the crystallites. According to the appropriate comparison made in Ref.117, the local structure of the rigid-chain polymers is more like the packing of raw spaghetti in a partly filled box than the packing of cooked spaghetti in a pan. This makes clear the importance in amorphous polymers of the intermolecular interactions which stabilise the quasi-metallic state and which make possible the existence of conducting clusters of appreciable dimensions.

The "metallic character" of the clusters, revealed by the different slopes of the curves in Fig.5, is variable, and depends on the dopant. In "physical" soliton models, dopants of the same type (for example acceptors) are not distinguished. For chemists, the different electrophysical properties of PA—dopant complexes can be attributed to the difference in the degree of charge transfer and the difference in the stability constants of the CTC (see section III). The most stable complexes are probably formed in the reaction of PA with AsF_5, which is a very strong Lewis acid. The correctness of these arguments is apparently confirmed by the data of Ref.108, given in the Table.

- - - o0o- - -

From the extensive range of fundamental problems relating to PA, as before, the question of the nature of the conductivity is attracting the greatest attention. There arises the question of whether solitons (or polarons) are physically real, or merely an elegant but artificial method of description. The answer to this question is important not only for theoreticians. The development of new materials of practical importance can hardly be achieved without a detailed understanding of the electronic processes responsible for their properties. A complete understanding has obviously not yet been reached. The chemistry and physics of macromolecular "synthetic metals", of which PA is the prototype, still appear as a mosaic, and considerable efforts are required to establish a clear and consistent picture.

Nevertheless, the information which has already accumulated up to the present provides some possibilities for generalisation. According to the familiar Occam's principle, entities are not to be multiplied beyond necessity. In accordance with this principle, the present authors consider that the principal properties of PA and its analogues can be examined using more traditional non-soliton approaches. The soliton concept, however, has provided an exceptionally effective stimulus for theoretical and experimental studies which might not have been carried out in a different situation. This has led to a better understanding of the entire set of relationships between the structure and properties of matter—one of the cardinal problems of present-day chemistry.[118]

The Glass Points and Dielectric Relaxation of Carboxyl-containing Copolymers and Ionomers Based on Them

I.A.Ionova, Yu.B.Monakov, and S.R.Rafikov

The influence of the content and distribution of carboxy-groups along the polymer chain, the amount and nature of the cations introduced, and the dielectric constant of the polymer matrix on the dielectric relaxation and the glass points of carboxyl-containing copolymers (CCC) and their ionomers is considered. It is shown that the specific features of the properties of the ionomers are determined by the formation of ionic aggregates: multiplets in the presence of a low content of ion clusters at a fairly high concentration of ions which depends on the structure of the initial copolymer. It is concluded that the type of distribution of the carboxy-groups and the dielectric constant of the polymer matrix have a decisive influence on the ion aggregation process.
The bibliography includes 85 references.

I. INTRODUCTION

The partial or complete neutralisation of the COOH groups in carboxyl-containing copolymers leads to the occurrence of ionic interactions, which imparts to the copolymers unique properties capable of being varied within wide limits.[1-4] In the majority of ionic copolymers, this interaction of the ions entails microphase separation caused by the incompatibility of the salt groups and the hydrocarbon units of the chain.[5] At a certain concentration of the ions, the phase separation leads to the coexistence of two types of ionic aggregates, namely multiplets and clusters.

The introduction of ions into polymers is reflected most notably in the rheological behaviour of the melts, the relaxation of stresses, the dynamic, mechanical, and dielectric properties, and the glass point.[6-12] The present reivew deals with questions concerning the dielectric relaxation and glass points of ionomers based on carboxyl-containing copolymers of different composition and structure. Thermomechanical and dielectric studies make it possible to obtain information about the molecular mobility and the character of the aggregation of the salt groups and about the influence of this aggregation on important technological characteristics of the ionomers.

II. CONTRIBUTION OF HYDROGEN BONDS TO THE INTERMOLECULAR INTERACTION IN CARBOXYL-CONTAINING COPOLYMERS

The properties of polymers containing carboxy-groups are determined to a large extent by their ability to form hydrogen bonds between the C-OH groups. In contrast to chemical cross-links, hydrogen bonds are unstable, dissociating and reforming anew under the influence of thermal motion. However, it is in fact the hydrogen bonds that have a decisive influence on the mechanism of the vitrification of polymers[13] and on their mechanical properties in the highly elastic and viscofluid states.[14]

The majority of the carboxy-groups in carboxyl-containing copolymers are linked by hydrogen bonds into dimeric complexes[15-17] whose heat of dissociation varies from 7 to 15 kcal mol^{-1},[18-21] which agrees well with data for low-molecular-weight carboxylic acids.

Spectroscopic studies make it possible to characterise quantitatively the formation of hydrogen bonds from the temperature variation of the absorption band maxima corresponding to the $\nu(C=O)$ vibrations of the free COOH groups and dimeric associated species (1740-1750 and 1695-1705 cm^{-1} respectively).[22-26] On heating to the glass point T_g, the relative intensities of these bands hardly change, while at higher temperatures the low-frequency band weakens and the intensity of the 1740 cm^{-1} band increases.[18,22] For the styrene-methacrylic acid (MAA) (85:15) copolymers, an inflection associated with the dissociation of the intermolecular hydrogen bonds appears on the curves for the temperature variation of the 1700 and 1745 cm^{-1} absorption band intensities at 120 °C, which corresponds to the glass point, also found to be 120 °C by other methods.[18,27]

Detailed study of the temperature variation of the intermolecular interaction energy in polystyrene (PS) and in the styrene-MAA copolymer (16 mole %) by differential IR spectroscopy[28,29] showed that appreciable disruption of the hydrogen bonds and weakening of the van der Waals intermolecular interaction (interaction mainly between benzene rings) begin already in the region of the temperature of the β-transition;† the first stage of this process occurs in the range of the glass points. The character of the temperature variation of the energy for intermolecular bonds of different types is different. Relatively weak van der Waals interaction changes stepwise, falling especially sharply after the attainment of the fluidity temperature. In the case of hydrogen bonds, the temperature variation of the energy shows breaks at characteristic temperatures.[28]

The main effect occurring when carboxy-groups are introduced into the copolymer—the formation of hydrogen bonds—intensifies the intermolecular interaction. However, the copolymerisation of styrene with MAA entails also a series of other effects: a weakening of the van der Waals interaction, an increase in mechanical losses in the region of the β-transition compared with PS; an increase in the

†The β-transition, which corresponds to the onset of the movement of short sequences of styrene units, is a precursor of the movement which occurs at T_g.[30,31]

degree of coiling of the chains.[29] It follows from the study of the conformational changes in the styrene–MAA copolymer that these effects are especially pronounced, starting from an MAA concentration of 10–15 mole %, in the copolymers, and the average distances between the hydrogen bond bridges become comparable to the increase in the size of Kuhn's kinetic segment in PS.[29]

In view of the small decrease in the intermolecular interaction energy on transition through the glass point,[28] the appreciable change in the mechanical properties of polymers in the region of T_g cannot be explained solely by the decrease in intermolecular interaction energy and is apparently induced by the appearance of cooperative segmental motion. This is confirmed by the shift of T_g towards higher temperatures with increase in the content of COOH groups in the copolymer. Thus the increase in the MAA content in the copolymer with methyl methacrylate (MMA) from zero to 15 and 28% is accompanied by an increase in the glass point from 103 °C to 109° and 137 °C respectively.[17] The shift of T_g towards higher temperatures with increase in the number of carboxy-groups is caused by the increased hydrogen bond network. In the butadiene–MAA copolymer, the increase in the number of hydrogen bonds with increase in the content of the acid also increases the dynamic modulus of elasticity and T_g.[32] The dependence of T_g on the content of the acid component is described most satisfactorily by the equation for cross-links.[20,32]

The majority of the experimental data lead to the conclusion that interchain cross-links are formed preferentially via hydrogen bonding.[15,18,23] The change in the thermodynamic parameters in the ethyl methacrylate–MAA copolymers with increase in the MAA content is also explained by the intensification of the interchain interaction as a consequence of the formation of hydrogen bonds:[33] a decrease in their heat capacity, entropy, and free energy and an increase in the equilibrium constant and the limiting copolymerisation temperature, which corresponds to an increase in the thermodynamic stability of the copolymers. The above changes in the thermodynamic parameters of the copolymers are much greater than might have been expected from the additivity of the properties of the copolymers relative to the corresponding homopolymers.

The intramolecular bonds probably begin to appear in the presence of a fairly high content of carboxy-groups. In a study[34] of the physicomechanical properties of MAA and butyl acrylate copolymers, a maximum was observed on the curves for the dependence of the stability on composition. The presence of the maximum has been explained by the fact that initially an increase in the MAA content entails an increase in the number of intermolecular hydrogen bonds and hence the stability of the copolymer increases. On further increase in the MAA fraction in the copolymer, intramolecular bonds begin to appear, which leads to the coiling of the macromolecules into globules; as a result, the stability of the copolymer diminishes owing to the decrease in the energy of cohesion. In polyacrylic acid, dimerisation takes place mainly via the carboxy-groups belonging to the same hydrocarbon chain.[35]

III. DIELECTRIC RELAXATION PROPERTIES OF CERTAIN CARBOXYL-CONTAINING COPOLYMERS

The study of the dielectric properties of CCC provides important information about the role of hydrogen bonds in molecular relaxation proceses. The results of the investigation of the dielectric relaxation processes in copolymers of ethylene with methacrylic and acrylic acids have shown that α- and β-relaxation processes predominate in these copolymers.[36,40] The relaxation α-transition is associated with vitrification processes in the copolymer. The number of dipoles participating in the α-process can be calculated from the experimental data by the Onsager equation

$$N = \frac{9kT}{4\pi\mu^2} \frac{(2\varepsilon_0 + \varepsilon_\infty)(\varepsilon_0 - \varepsilon_\infty)}{\varepsilon_0 (\varepsilon_\infty + 2)^2}$$

where N is the number of dipoles, T the absolute temperature, μ the electric dipole moment of the COOH groups amounting to 1.75 D,[37] and ε_0 and ε_∞ are the relaxation and non-relaxation dielectric constants respectively. The number of free COOH groups determines the intensity of the observed α-relaxation. The α-process is in fact associated with their mobility and reorientation in the external electric field.[38,39] The low-temperature β-process is determined in both copolymers by the low mobility of the main chains of the copolymer.[36]

The β-relaxation observed in the copolymers of MAA and the polar methyl methacrylate at temperatures below T_g is essentially due to the movement of the ester side groups.[41] This is confirmed by the finding that any change in the MAA content does not shift the β-relaxation peak along the temperature axis (Fig.1), while the intensity of the dielectric relaxation $\Delta\varepsilon_\beta$ diminishes linearly with increase in the MAA fraction in the copolymer. The activation energy for the β-process has been estimated as 19 kcal mol^{-1}.[41] The sharp peak in the region of high temperatures (Fig.1) corresponds to the α-process, which is determined by the segmental thermal motion of the chain. With increase in the MAA content in the specimen, the temperature at which α-relaxation is observed shifts towards higher values and at the same time the activation energy for the α-process increases, which means that the segmental motion of the main chain of the copolymer is limited by the MAA units.

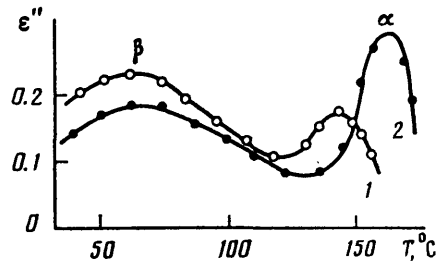

Figure 1. Temperature variation of the dielectric losses coefficient ε'' for the MMA–MAA copolymers at 30 Hz; MAA content (mole %): 1) 15; 2) 28.[41]

For the α-process, the increase in the relaxation intensity with temperature is caused by the increase in the number of mobile units as a result of the dissociation of the hydrogen bonds and the number of mobile units is assumed to be proportional to the dissociation constant. The dissociation energy of the hydrogen-bonded MAA dimer in the highly elastic state has been determined from the temperature variation of the relaxation intensity for α-processes ($\Delta\varepsilon_\alpha$). It proved to be 13 kcal mol^{-1}, which agrees with the dissociation energy determined from IR studies[17] for the MAA dimer in the MMA–MAA copolymer and with data for the dimers of other acids. However, the dissociation energy of the dimeric complex in the vitreous state is much lower than in the highly elastic state (0.7 kcal mol^{-1}). This has been attributed to differences between the supermolecular structures of the vitreous and highly elastic states. Although it follows from IR studies that the most intense

dissociation of hydrogen bonds occurs in the highly elastic state, a large number of the hydrogen-bonded dimeric complexes remain stable even at temperatures above T_g, as shown by the low value of the dissociation constant (4.27×10^{-5} mol cm^{-3}) and by the character of the dependence of the dielectric relaxation intensity on the number of cross-links.[17] Hence it follows that, even in the highly elastic state of the CCC, the hydrogen bonds act as fluctuating intermolecular bonds, although their energy is lower by a factor of 10 than the energy of covalent cross-links.

The replacement of methacrylic acid by acrylic acid (AA), i.e. the absence of α-methyl groups, influences the molecular mobility of the MMA–AA copolymer. In the study of the dielectric properties of these copolymers, two relaxation transitions were also observed: the high-temperature α-transition associated with segmental mobility and the low-temperature β-transition due to the mobility of the side groups.[42] In the case of the α-process, the relaxation intensity $\Delta\varepsilon$, calculated from the area under the curve describing the variation of the dielectric losses coefficient ε'' with $1/T$ in accordance with the Williams equation, increases with increase in temperature (in contrast to the methacrylate homopolymer for which $\Delta\varepsilon$ is almost independent of temperature). The dissociation energy of the AA dimers, determined from the temperature variation of $\Delta\varepsilon$, agrees well with the calculation based on the IR spectra. The activation energy ΔH^* and the temperature of the maximum T_{max} for the α-process decrease with increase in the content of the AA dimer in contrast to the MMA–MAA copolymer, for which both ΔH^* and T_{max} increase with increase in the MAA fraction.[41] On the other hand, the dissociation constants of the dimers of both copolymers, found from the IR spectra, are the same. Evidently, in the absence of the α-methyl group, the acrylic fragments play an important role in the increased segmental mobility in the copolymer at temperatures exceeding the glass point when the AA dimers decompose. The characteristics of the β-process depend little on the AA content, as in the case of the MMA–MAA copolymer.

In the case of the styrene–MAA copolymer,[43] a single peak, whose position and height increase with increase in the MAA content, is observed in the temperature variation of the dielectric losses coefficient ε'' in the region of the glass point. This is associated with the fact that an increase in the MAA fraction in the copolymer increases the number of cross-links formed by the acid dimers, which increase T_g and hence shift the α-relaxation to the region of higher temperatures. Calculations based on the monomer–dimer equilibrium have shown that 20% of the COOH groups are in a free state at T_g; they in fact contribute to ε''. With increase in temperature, the dimers $\rightleftarrows$ free COOH groups equilibrium is displaced to the right. Therefore, the higher the temperature corresponding to the ε'' peak, the greater its intensity. The initial sharp rise on the curve describing the variation of the temperature of the α-relaxation maximum ε'' with the content of carboxy-groups[43] is explained by the fact that, at low concentrations of the dimeric complexes, cross-links can suppress molecular motion more effectively that at high concentrations. This is also indicated by the minimal electrical conductivity σ (COOH groups make the main contribution to σ) at a concentration of 5 mole %, which is associated with the influence on σ not only by the properties of the charge carriers but also by the molecular mobility of the polymer matrix.

In the styrene–MAA block copolymers (with an MAA content of 5–30 mole %), two clear-cut α-processes are observed: at ~130 °C (α_1) and at 180 °C (α_2). The presence of two maxima, corresponding to the α-processes, not only confirms the block structure of the copolymers synthesised in emulsion but also indicates their microheterogeneity, i.e. the existence of two phases in the specimen.[44] One phase contains predominanatly polystyrene (PS) blocks and the other is enriched in poly-MAA blocks. The α_1-process at 130 °C is associated with the manifestation of segmental mobility of the PS blocks and its position depends only slightly on the ratio of the monomer units in the copolymer. The α_2-process at 180 °C is due to the molecular mobility in the region of the phase containing the poly-MAA blocks. With increase in the MAA content in the copolymer, the α_2-process shifts somewhat towards high temperatures and its intensity increases.

Thus the properties of CCC are mainly determined by their ability to form hydrogen bonds. Additional contacts at the intramolecular and intermolecular levels arise as a result of the hydrogen bonds, which increases the glass points and fluidity of the CCC. At low temperatures, the carboxy-groups exhibit a tendency to dimerise via hydrogen bonding, which renders them dielectrically inactive. With increase in temperature, the hydrogen-bonded carboxy-groups dissociate and exert the corresponding influence on the dielectric relaxation, for the behaviour of which free COOH groups are responsible.

IV. TRANSITION TO THE VITREOUS STATE IN IONOMERS

A partial or complete neutralisation of the carboxy-groups in the CCC leads to the appearance of a series of their specific properties, which are similar for different classes of ionomers. Thus the ability to adsorb water, the character of the variation of T_g with the concentration of ions, and the mechanical and dielectric properties of ethylenic and stryrene ionomers are very similar, while polystyrene and polyethylene differ markedly,[45] which is due to the characteristic features of the structures of the ionomers determined by the manifestation of ionic interactions.[46–53]

Neutralisation of carboxy-groups in CCC influences especially the glass point, which increases after the introduction of ionised groups into the polymer.[54–65] This increase in T_g is associated mainly with the decrease in segmental mobility as a consequence of ionic interactions and therefore depends on the nature of the cation.[5] Analysis of T_g data from the standpoint of the anion–cation interaction as a factor limiting segmental mobility led to the following general T_g relation[57] for fully neutralised silicates, phosphates, and acrylates:

$$T_g = Aq/a + B$$

where q is the charge on the cation, a the distance between the centres of the charges on the anion and the cation, and A and B are constants. Graphically the dependence of T_g on q/a for both polyphosphates and other fully ionised homopolymers is represented by straight lines having the same slope.[66] In partially neutralised polyphosphates T_g also varies linearly with q/a, but partly neutralised acrylate systems do not exhibit such a dependence. This may be caused by the presence of highly structured rigid associated species, which appreciably diminish the segmental mobility of the polymer.

In organic ionomers, a linear dependence of T_g on q/a is in general not observed, because the morphology of these materials is fairly complex and may vary with the concentration of ions. When the content of ions in the ionomers is low, the initial increase in T_g with the concentration of ions is in most cases linear (from 2 to 10 K per mole % of the ion-containing comonomer).[5,67,68] The glass points of sodium ionomers based on ethylene[69] obey satisfactorily the equation

$$T_g = n_1 T_{g1} + n_2 T_{g2},$$

where n_1 and n_2 are the mole fractions and T_{g1} and T_{g2} are the glass points of the two homopolymers. The study of different mechanisms of the increase in T_g for styrene ionomers[19] leads to the conclusion that the main mechanism of the rise of T_g in these ionomers involves the formation of cross-links between ionic domains and not a copolymerisation effect, as in ethylenic ionomers.[69] It is most likely that the regular increase in T_g with the concentration of ions

in both ionomers is caused by a superposition of two effects: the cross-linking and copolymerisation mechanisms with the influence of one of these mechanisms predominating in each type of ionomer.

The monotonic variation of T_g with the ion content of ethylenic ionomers and also the results obtained in the study of the relaxation of stresses, the absorption of water, and the dynamic, mechanical, and dielectric properties show that ionic aggregates are present in these ionomers even at very low concentrations of the ionic comonomer.[70] On the other hand, the study of the character of the variation of the glass points and of the fluidity of the ionomers based on styrene (20 mole % MAA) over a wide ion concentration range[65] reveals the breakdown of the linear dependence of the transition temperatures on the ion concentration for 30% neutralisation (~6 mole %).

Such breakdown of the monotonic variation with increase in the content of sodium methacrylate above 6 mole % has been observed for all the parameters of the styrene-based ionomers;[71] this is a result of the change in the morphology of the ionic aggregates, namely the transition from small multiplet formations to higher-order ionic accumulations—clusters. The existence of clusters is due to the equilibrium between the electrostatic forces arising between individual multiplets‡ and the elastic forces of the macromolecular chains, which resist the attraction of the multiplets.[72] One of the necessary conditions for the formation of clusters is that the interactions of the hydrocarbon chains with one another and with ions should be different,[73] which ensures an effective attraction between the ions and tends to stabilise the clusters. High ion concentrations and low dielectric constants of the polymer matrix are also necessary for the formation of clusters; on heating above a critical temperature, the clusters decompose.[73]

The unusual dependence of T_g on the content of the acrylic acid salt in ethyl acrylate copolymers is also associated with the formation of ionic clusters.[5,56] A single general curve is obtained for all the ions investigated (Na^+, Cs^+, Li^+, K^+, Ca^{2+}, Ba^{2+}) when the function $T_g = f(Cq/a)$ is plotted. Here C is the content of salt groups, q the charge on the cation, and a the distance between the centres of the charges on the anion and cation (Fig.2). The non-linear section corresponds to the deviation from the principle of the temperature–time superposition in the relaxation of stress for the ethyle acrylate–sodium acrylate copolymer (12 mole % of the ion-containing comonomer) and reflects the formation of clusters. Evidently in the region of low values of Cq/a, to which corresponds the linear section of the curve, the multiplets exert the dominant influence, while the clusters determine the behaviour of the ethyl acrylate ionomers for higher values of Cq/a. It follows from the data of Matsuura and Eisenberg[56] that the "cluster formation" principle, determining the rheological behaviour of ionomers, depends both on the ion concentration and on q/a; the character of the dependence of T_g on q/a, illustrated in Fig.2, is encountered only in materials in which fairly intense cluster formation takes place.[5] The effect involving the increase in T_g almost by a factor of two when the ion content in ethyl acrylate ionomers varies from 10 to 25% can be understood if it is supposed that the clusters ensure a more effective cross-linking than simple multiplets.

An important factor influencing T_g for ionomers is the amount of water which they have absorbed; water, whose content increases with ion concentration, lowers T_g. It has been shown that T_g for the sodium salt of polyacrylic acid decreases by ~8 K each time the water content is raised by 10%.[66] In ethyl acrylate-based ionomers in the presence of a definite amount of water (≥20 wt.%), T_g varies linearly with the water content regardless of the ion concentration (in the region of 20–50 mole % of sodium acrylate).

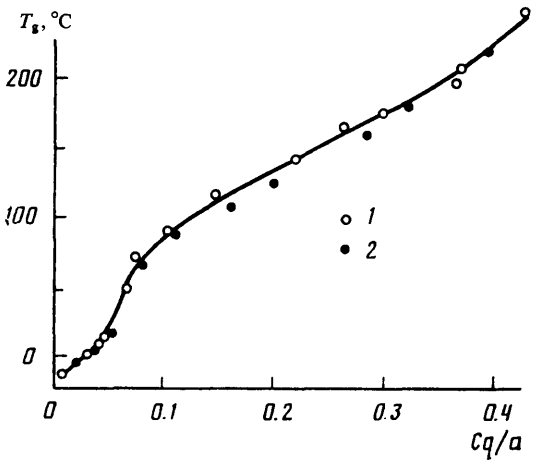

Figure 2. Dependence of T_g for ionomers based on the ethyl acrylate–acrylic acid copolymer on Cq/a for different ions: 1) Na^+, Li^+, Ca^{2+}, and Ba^{2+}; 2) K^+ and Cs^+.[56]

These data are qualitatively similar to the attainment of a plateau on the plot of T_g against ion concentration, which is observed for ionomers based on styrene–n-butyl methacrylate copolymers.[74] The glass points of these ionomers increase with increase in the ion content to 1.5 mole %. The limiting value of T_g is higher by 5–20 K that the T_g for the initial copolymer and depends on the molecular weight of the copolymer. The plateau on the relation between T_g and ion concentration can be accounted for by the balance between the influence of the ions, which increases the rigidity of the chain, and the plasticising action of water. In ionomers based on copolymers of acrylic acid and methyl methacrylate, T_g increases with increase in ion concentration in the range $0-1.5 \times 10^{-3}$ equiv. cm^{-3}.[75] Above the critical concentration (1.5×10^{-3} equiv. cm^{-3}), which is independent of the content of acrylic acid in the initial copolymer, T_g does not change. This can be explained by the for-mation of clusters of ionised groups which do not influence T_g. It has been suggested by Matsuura and Eisenberg[56] that the contradictions between the results of their studies of T_g for ethyl acrylate-based ionomers and the data of Tsutsui et al.[75] may be due to a number of causes. It may be that the character of the dependence of T_g on the ion content in these ionomers reflects the differences between the structures of the copolymers or clusters. Furthermore, the high degree of conversion of ionomers based on MMA–AA copolymers (36.5–48.7%), which is much higher than the degree of conversion of ethyl acrylate ionomers (7.2–14.5%), may lead to a high compositional inhomogeneity in the polymer and as a consequence to the separation of the specimen into different phases. Another possible cause of the disagreements is the presence of water, remaining in the specimens investigated by Tsutsui et al. after drying under mild conditions, which decreases T_g.

The nature of the cation should evidently exert an appreciable influence on the T_g of the ionomers via the parameter q/a. It follows from the study of a series of ionic copolymers based on butadiene that the univalent cations Na^+ and Li^+ have a greater influence on T_g than the univalent anion I^-.[76,77] There are indications

‡Multiplets are small compact ionic aggregates.

that Mg^{2+} ions in the ionised ethylene–acrylic acid copolymers are more effective from the standpoint of the increase in T_g than Na^+ ions. The dependence of the glass point and fluidity of the ionomers on the nature of the cation introduced can be traced satisfactorily in ionomers based on statistical styrene–methacrylic acid (20 mole %) copolymers.[64]

Under identical neutralisation conditions, the glass points and fluidities of the ionomers containing Na^+ ions exceed the corresponding values for the copolymers neutralised by Rb^+ ions.[64]. The reason is apparently that, as a result of the aggregtion of the salt groups of the ionomers in the hydrocarbon matrix, there is a possibility of a distribution of the ionised carboxy-groups in which they find themselves opposite one another, so that an electrostatic interaction takes place between them. If account is taken of the fact that the strength of interaction between ions is inversely proportional to the distance between them, which is determined by the radii of the ions, then "ionic cross-linking" with the Na^+ cation, which has a greater radius than the Rb^+ cation, is more stable. For this reason, specimens of ionomers containing Na^+ have higher transition temperatures than the corresponding Rb^+.

Another picture is observed if bivalent metal acetates have been used for the neutralisation of the carboxy-groups of the styrene–MAA statistical copolymer. Neutralisation by Zn^{2+} and Ca^{2+} ions alters very slightly the glass points and fluidities of the ionomers. This phenomenon can be explained by the fact that the neutralising agents in this case are not the doubly charged metal ions M^{2+} but singly charged ions of the type $M(CH_3COO)^+$ formed via the reaction[78]

$$M(CH_3COO)_2 \rightleftarrows M(CH_3COO)^+ + CH_3COO^-$$

The acetate groups in such singly charged ions shield the ionic charges by virtue of their large size, diminishing thereby the stability of the ionic cross-linking, i.e. they manifest a kind of plasticising effect. This is confirmed by the finding that the thermomechanical curves for ionomers with different contents of both Zn^{2+} and Ca^{2+} are identical and exhibit all the temperature-dependent transitions characteristic of thermoplastics. Furthermore, ionomers with 30% substitution by Ca^{2+} and Zn^{2+} ions are readily soluble in dioxan and dimethylformamide, which also confirms the absence of "cross-links".[64]

For the same content of salt groups, the mode of their distribution along the copolymer chain has a great influence on the glass points of ionomers.[64,65] Thus, whereas in statistical styrene–methacrylic acid copolymers a complex type of dependence of T_g on the ion concentration is observed, the introduction of MAA into the polystyrene chain in the form of a block leads to the absence of such dependence of T_g on the degree of neutralisation. This is caused by the characteristic features of the structure of these polymers: the ionomers formed are block copolymers having the composition (MA-Na–MAA)–(styrene–MAA–MA-Na)$_m$. Statistical copolymers are formed within the limits of the blocks and the distribution of the monomers in them is as follows: in the first block, there is more sodium methacrylate (MA-Na) than methacrylic acid, while in the second block the styrene–MAA content greatly exceeds the content of sodium methacrylate. Since the size of the styrene–MAA–MA-Na blocks is comparable to the size of the kinetic segment, ionic cross-links have little influence on T_g,[65] which is confirmed by the insignificant displacement of the maximum of the tangent of the dielectric losses angle for the α_1-process towards higher temperatures with increase in the degree of neutralisation.

The properties of ionomers based on graft copolymers are determined by the length of the blocks containing the ionogenic groups. They are similar to those of the ionomers of block-copolymers provided that the chain length of the grafted polyacid is sufficiently large. Thus the thermomechanical curves for ionomers based on graft ethylene–maleic anhydride copolymers,[64] in which the length of the side sections containing carboxy-groups is fairly considerable, showed the appearance of additional transition temperatures due to the manifestiation of the presence of ionic cross-links; these temperatures depend on the content of the acid and the degree of its neutralisation. The T_g for the monomers investigated are independent of the degree of neutralisation and are close to the melting point of polyethylene (100 °C). However, if the sections of the grafted polyacids are short (several monomer units), then the variation of the glass point with ion concentration in the ionomers of graft copolymers will resemble that for the ionomers of statistical copolymers. Such behaviour has been observed for ionomers based on graft styrene–MAA copolymers in which the short chains of the grafted poly-MAA are distributed statistically along the polystyrene chain.[44]

Thus the mode of distribution of the carboxy-groups (statistical block and graft copolymers) leads to different types of aggregation of the salt groups in the corresponding ionomers, which is distinctly manifested by the behaviour of the T_g of the ionomers. However, ion aggregation is difficult in a medium with a high dielectric constant,[5,73] which is reflected by the absence of a dependence of T_g for such ionomers (ionomers based on MAA–MAA copolymers) on the nature and amount of the cations and by the weak dependence of the maximum in the tangent of the dielectric losses angle for α-relaxation on the degree of neutralisation.

V. DIELECTRIC RELAXATION OF IONOMERS

The neutralisation of the carboxy-groups in the CCC alters the dielectric relaxation of the copolymers, owing to its sensitivity to the presence of the polar groups of acids and salts directly involved in the formation of clusters. Dielectric studies can yield valuable information about the structure and character of the molecular motion of ionomers.[40,43,55,79–84]

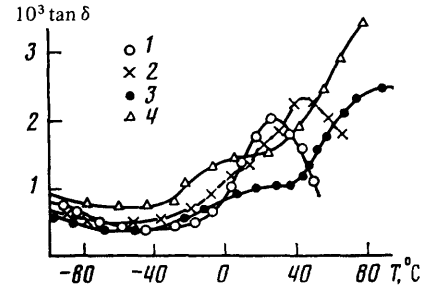

Figure 3. Temperature variation of tan δ for the sodium salts of the ethylene–MAA copolymer (4.1 mole %) at 1 kHz; degree of neutralisation (%): 1) 0; 2) 19; 3) 41; 4) 72.[79]

The intensity of α-relaxation in ethylene–MAA copolymers diminishes with increase in the extent of neutralisation and α_1- and α_2-relaxations appear (Fig.3).[79] The α_1-relaxation is associated with the T_g of the ionic phase of the ionomer; this is confirmed by the absence of α_1-relaxation in the copolymer and by the increase in its intensity and its shift towards higher temperatures with increase in the degree of neutralisation and by the bend in the curve describing the frequency and temperature variation for the α_1-process. The bend in the frequency-temperature variation for the α_2-process shows that this relaxation characterises the T_g of the hydrocarbon phase,

which becomes dielectrically active by virtue of the presence of free carboxy- or salt groups linked to the segments of this phase. The water absorbed by the ionomers shifts the α_1-peak towards lower temperatures, which is associated with the plasticising effect of water on the ionic phase. At a temperature of about –43 °C, an additional peak appears, whose height is approximately proportional to the water content and whose position depends slightly on its amount.[79] Modern calculations of the relaxation intensity have shown that the mobility of the water molecules themselves is responsible for this peak.

In the sodium salts of the ethylene–acrylic acid copolymer (9.3 mole %), the temperature of the α-relaxation maximum does not change and the height of the peak increases with increase in the degree of neutralisation W to 20%; for $W > 30\%$, the temperature of the α-maximum rises and the height of the peak diminishes following the appearance of α_1-relaxation.[40] Simultaneously with the change in the character of the temperature variation of the maximum and height of the relaxation peak as a function of the degree of neutralisation, the character of the temperature variation of the relaxation time also changes: for low extents of neutralisation, it is described by the Williams–Lundell–Ferry equation, whilst for high extents of neutralisation it is described by the Arrhenius equation. The dielectric increment $\Delta\varepsilon = \varepsilon_0 - \varepsilon_\infty$, calculated from the Cole–Cole diagram for the α-relaxation, increases in proportion to the degree of neutralisation up to 20% ($\Delta\varepsilon = 0.119$ for $W = 0$ and 0.826 for $W = 20\%$), diminishing rapidly with increase in the degree of neutralisation above 30%. The influence of the degree of neutralisation on all the relaxation properties of the ethylene–AA copolymer indicated can be explained by the formation of ionic clusters for $W > 30\%$.[40] Since Δε at 30% neutralisation is higher than for the copolymer, it is concluded that not all the COONa groups are combined into clusters and it is suggested that these groups are dielectrically active in the α-relaxation process.

Detailed study of β-relaxation has thrown defnite light on the investigation of the structure and molecular motion in ionomers, because its extent is associated with the polar COONa groups which have not entered the clusters. Indeed, for the sodium salts of the copolymer, the position of the β-peak along the temperature scale is independent of the degree of neutralisation W, but the peak height increases with increase in W.[40,57] The dielectric increment for β-relaxation increases in proportion to the degree of neutralisation up to 20% and diminishes for $W > 30\%$. Since at low ion concentrations aggregation is not observed, the number of polar COONa groups responsible for β-relaxation increases with increase in the ion content. As a result of the formation of ionic clusters at a higher ion concentration, the number of polar groups involved in β-relaxation diminishes. Consequently the dielectric β-relaxation provides new evidence for the existence of clusters in ionomers.

The formation of ionic aggregates in copper(II) salts of the ethylene–acrylic acid copolymer proceeds with more difficulty than in the sodium salts owing to the complex structure of the copper(II) salts.[84] The temperature dependence of the dielectric losses coefficient ε″ for the copper salt of the ethylene–AA copolymer, which has in the main the dimeric structure of hydrated copper acetate,[85] is characterised by two maxima located at 50 °C (α-relaxation) and –100 °C (β-relaxation) for 20% neutralisation. The first maximum is due to the molecular Brownian movement at temperatures above T_g and the second is associated with the local molecular mobility below T_g, as in the sodium salts of these copolymers. In the region of α-relaxation the temperature T_{max}, corresponding to the maximum value of ε″, increases with increased extent of neutralisation and a diminution of ε″ is observed simultaneously up to $W = 34\%$. The α-relaxation process at $W = 71\%$ has a complex character and consists of α_2-relaxation at 0°C and α_1-relaxation at 60 °C. The dependence of the logarithm of the frequency of the ε″ maximum on $1/T_{max}$ satisfies the Williams–Lundell–Ferry equation for $W < 5\%$ and the Arrhenius equation for $W > 20\%$,[84] which indicates the retardation of the Brownian movement as a consequence of the interaction of the ionic groups with increase in the extent of neutralisation from 5 to 20%. The dependence of the dilelectric increment Δε on the extent of neutralisation passes through a maximum at $W = 5\%$, but at $W > 20\%$ the quantity Δε gradually diminishes, while T_{max} increases, owing to the onset of ionic aggregation at $W > 20\%$ (Fig.4). The increase in Δε and the decrease in T_{max} in the specimen neutralised to the extent of 71% indicate that, in the highly neutralised polymer, many Cu^{2+} ions can remain outside the ionic aggregates. This has also been observed for β-relaxation. The α_2-relaxation, appearing in the 71% neutralised specimen, refers, according to the authors,[84] to the molecular motion of short segments, incorporating copper(II) salts, between ionic aggregates. This is confirmed by the low activation energy for α_2-relaxation (~ 18 kcal mol^{-1}).[84]

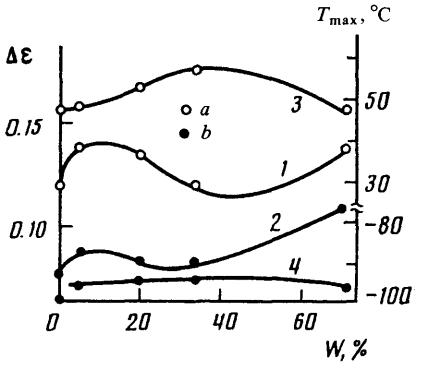

Figure 4. Dependence of the dielectric increment Δε (curves *1* and *2*) and of the position of the relaxation maximum T_{max} (curves *3* and *4*) on the degree of neutralisation W for the α- and β-relaxation in the copper(II) salts of the ethylene–AA copolymer (9 mole %): *a*) α-relaxation; *b*) β-relaxation.[84]

α_2-Relaxation has also been observed in the copper(II) salts of the styrene–methacrylic acid copolymer.[84,85] These salts have three types of structure: I—monomeric, II—monohydrated copper acetate, and III—pseudo-anhydrous copper formate, the fraction of each depending on the method used to prepare the copper carboxylate. These structures influence the molecular motion of the polymer; however, ionic aggregation in all the copper(II) salts of the styrene–MAA copolymer could not be observed either by the low-angle X-ray diffraction method or by electron microscopy.

Ionic aggregation with formation of clusters occurs in ionomers based on styrene with MA-Na (fully neutralised specimens containing between 2 and 9 mole % of sodium methacrylate).[80] The temperature variation of the tangent of the dielectric losses angle (tan δ) shows, after the subtraction of the losses due to conduction, two readily distinguishable overlapping maxima for all the ion concentrations except 2 mole %. Both peaks shift towards high temperatures with increase in the ion content. The low-temperature peak is due to regions with a low ion concentration, while the high-temperature peak is associated with large aggregates which have a higher T_g. The overall area under the peaks for the variation of tan δ with the reciprocal of temperature is correlated very satisfactorily with the overall ion concentration in the ionomers (correlation coefficient

0.975). The area under the low-temperature peak (α_2-relaxation) increases with increase in the salt content up to 5 mole % and then remains constant at higher concentrations.[5,57] This is evidence for the saturation of the hydrocarbon matrix by ionic groups at this ion concentration; at the higher ion concentration, all the additional ions are combined into clusters. On the other hand, the area under the high-temperature peak (α_1-relaxation) increases continuously with increasing concentration of the salt groups; at an ion concentration >5 mole %, the increase accelerates.

With increase in temperature, the concentration of ionic groups in the hydrocarbon phase grows at the expense of the ion-rich region, i.e. the clusters decompose at high temperatures. This is indicated by the change in the relative sizes of the two relaxation peaks with increase in frequency. When the frequency is raised, which shifts both relaxation peaks towards higher temperatures, the height of the α_2-peak increases compared with the high-temperature α_1-peak.[57,80]

Thus it follows from the dielectric studies of the fully neutralised sodium ionomers based on the styrene–MAA copolymer[80] that clusters and multiplets coexist starting with an ion concentration of 2 mole %; the hydrocarbon matrix is saturated by ionic groups at 5–6 mole % of sodium methacrylate; the clusters dissociate at elevated temperatures. In the partly neutralised styrene–MAA polymers (9 mole %) two dielectric relaxation peaks appear at relatively low degrees of neutralisation (starting with 25%) in the region of the transition to the vitreous state, indicating the simultaneous presence of both multiplets and clusters in the ionomers.[43]

The temperature of the maximum T_{max} and the intensity ($T\Delta\varepsilon$) of the peak depend on the degree of neutralisation (Fig.5). Both peaks shift towards higher temperatures with increase in the extent of neutralisation W. However, at $W > 65\%$ (which corresponds to 5.85 mole % of the salt in the ionomer)[43] the increase in the extent of neutralisation leads to a faster shift of T_{max} for the high-temperature peak; on the other hand, T_{max} for the low-temperature peak increases very slowly, which is due to the saturation effect. Thus, as in fully neutralised styrene–MAA copolymers, in the partly neutralised copolymers containing ~6 mole % of ions the matrix is saturated by multiplets, while on further increase in the ion concentration the ionic groups begin to combine into clusters.

In the fully neutralised polymers, only 2% of the COO^-Na^+ groups are in a "free" state (are present as simple ion pairs), while in the remaining polymers they are combined into multiplets or clusters.[43] The presence of COO groups in partly neutralised copolymers increases the degree of dissolution of salt groups in the polymer matrix, such groups becoming dielectrically active.

While T_{max} for the low-temperature α_2-peak of the partly neutralised polymer is appreciably higher than for the pure salt containing the same number of ionic groups, in the case of the high-temperature peak the opposite situation obtains. Furthermore, the intensity of the α_2-peak of the partly neutralised polymer is much greater than that of the peak of the pure salt. The higher intensity of the low-temperature peak of the partly neutralised polymer is associated with the fact that the COONa groups combine with the COOH groups. Apart from giving rise to a considerable number of small clusters in the partly neutralised specimens (the clusters in the pure salt are more stable and larger), these additional interactions suppress the molecular motion in the matrix and shift the α_2-peak relative to the pure salt.

The different modes of distribution of the MAA units in the statistical block and graft copolymers lead to different characters of the aggregation of the salt groups in the corresponding monomers, which is clearly manifested in dielectric relaxation.[44] For the statistical styrene–MAA copolymers, the qualitative changes in the temperature variation of $\tan\delta$ for the sodium, rubidium, zinc, and cadmium ionomers with increase in the degree of neutralisation take place in the same manner. For all the ionomers, the intensity of the α-process increases with increase in the degree of neutralisation, which can be explained by the increase in dipole moment as the carboxy-groups are neutralised. The shift of the α-process to the high-temperature region is associated with the restriction of the segmental mobility with increase in the degree of neutralisation owing to ionic interactions. The high-temperature $\tan\delta$ maximum (above 200 °C) corresponding to molecular mobility in ionic clusters, whose presence might have been expected on the basis of earlier data,[43,80] could not be observed either because of the low fluidity temperatures of the ionomers investigated (below 200 °C) or as a consequence of the large dielectric losses associated with the increase in the electrical conductivity of the material in the region of the transition to the viscofluid state.

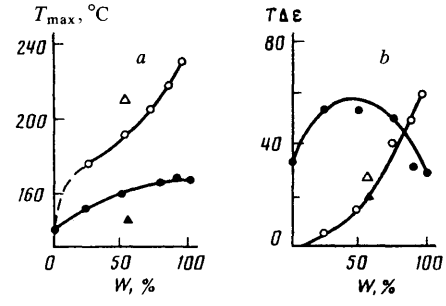

Figure 5. Dependence of T_{max} (*a*) and $\Delta\varepsilon$ (*b*) on the degree of neutralisation W for the high-temperature (1) and low-temperature (2) relaxation in the partly neutralised styrene–MAA copolymer (9 mole %); 3) and 4) the values of T_{max} and $T\Delta\varepsilon$ for the high- and low-temperature dielectric relaxation maxima respectively for the fully neutralised copolymer containing 5.06 mole % of the salt.[43] [The numbering of the symbols was omitted from the figure in the Russian text (Ed. of Translation).]

For the ionomers based on the styrene–MAA block copolymers, two distinct α-relaxation processes are observed, which makes it possible to infer their microheterogeneity.[44] The α_1-process is associated with the segmental mobility of the styrene–MAA–MA–Na blocks, while the α_2-process is determined by the segmental mobility of the phase enriched in MA–Na. With increase in the degree of neutralisation, the maxima in the tangent of the dielectric loss angle for the α_1- and α_2-processes become more intense, the α_2-process shifting markedly towards high temperatures (Fig.6). The small displacement of the process agrees with the small increase in the softening temperatures of the ionomers. The increasing intensity of the α_1-process shows that the PS blocks in these block copolymers do indeed contain statistically distributed MA–Na units which have a high dipole moment. The blocks enriched in MA–Na are segregated into a separate phase. The shift of the α_2-process to the temperature range above 250–300 °C (with a corresponding shift of the fluidity temperature) indicates intense ionic interactions within sections of this phase. Evidently the sizes of these sections are such that they incorporate blocks ranging from several macromolecules.

Therefore the viscous flow of the ionomer can begin only at a temperature where the energy of thermal motion is sufficient to dissociate the intermolecular ionic bonds to "deinhibit" the molecular mobility in these sections.

For the ionomers based on graft styrene–MAA copolymers, a single peak corresponding to the α-process is observed in the temperature variation of tan δ; its position and intensity vary with increasing degree of neutralisation similarly to the peak for the α-process involving ionomers based on statistical copolymers. Such similarity of the properties of the ionomers of graft and statistical copolymers shows that the short chains of graft poly-MAA [44] are distributed statistically along the chain of the PS macromolecule.

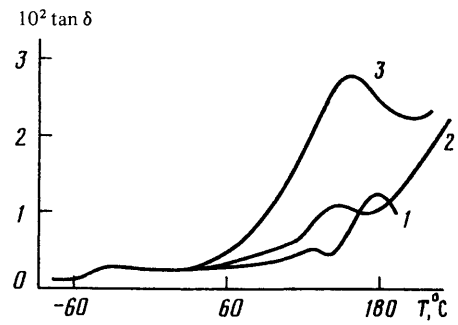

Figure 6. Temperature variation of tan δ for the styrene–MAA block copolymers (12 mole %) (curve *1*) and of its sodium ionomers (curves *2* and *3*); degree of neutralisation (mole %): 2) 10; 3) 40.[44]

Thus the dielectric behaviour of the ionomers can be most convincingly interpreted from the standpoint of microphase separation: whereas there is only one peak of the dielectric losses angle tangent for the initial copolymer, after neutralisation two such peaks with a fairly high intensity appear. This phenomenon reflects the existence of two glass points. The first of these is the T_g of the matrix, which contains a small amount of ionic groups, while the second is the T_g of the phase-separated ion-rich region. In other words, below a certain ion concentration the dielectric behaviour of the polymers is determined by small compact ionic aggregates (multiplets), which behave like cross-links, while above this critical concentration the larger ionic aggregates (clusters) influence the properties of the ionomers.

The dielectric relaxation and the character of the variation of T_g with ion concentrations for monomers based on vitreous and partly crystalline CCC are qualitatively similar despite the differences between the stabilities of the main chains and the dielectric constants of the hydrocarbon matrices. The nature of the neutralised groups determines the capacity of the salt groups for aggregation and therefore influences the physical properties of the ionomers. The mode of distribution of the salt groups along the polymer chain and the dielectric constant of the polymer matrix have a decisive influence on the aggregation of ions. The nature of the cation and its content influence the properties of the ionomers at specific concentrations of the carboxy-groups, which depend on the structure (type) of the initial copolymer.

Problems in the Physical Chemistry of Membrane Processes

Ya.M.Kolotyrkin

The new problems of modern industry can be solved only on the basis of fundamentally new technologies, materials, and energy sources. Among the new chemical technologies, a unique position is occupied by membrane technology. Membrane processes may find extensive application in practically all spheres of human activity. Membrane technology is already demonstrating its technical and economic advantages in a number of large-scale production processes. Approximately one quarter of the world production of desalinated water, reaching about 10 million cubic metres per day, is now obtained by membrane technology. The use of electrodialysis with ion-selective membranes for water treatment in modern thermal power engineering enables the country to save annually more than 300 thousand tons of sulphuric acid, 250 thousand tons of alkali, and 5 thousand tons of ion-exchange resins, and to reduce by more than 600 thousand tons the annual discharge of mineral salts into water systems.

The change to membrane electrolysis in the production of caustic soda and chlorine makes it possible not only to intensify considerably the large-scale production of these materials and to reduce the energy required, but also to ensure the production of highly pure alkali, and hence to avoid the use of mercury electrolysis, which at present is one of the principal sources of mercury contamination of the environment. The introduction of a membrane separation unit in the production of a number of chemical products using hydrogen (the synthesis of ammonia and methanol, the oxo-synthesis, hydrocracking, and hydro-desulphurisation) gives a significant increase in productivity and decrease in energy consumption. The use of membranes to control the composition of the gaseous medium in fruit- and vegetable-storage chambers makes it possible to increase the storage times of agricultural products by 2–8 months with no loss of quality.

The possibilities provided by membrane technology have not been fully explored. The operational parameters of membranes depend on many factors, including the thermal and chemical stability of the starting materials, and the conditions of their transformation and modification. The membranes acquire a definite structure, whose characteristics determine the specific nature of the transfer of ions and molecules through the membranes. Thus the production of highly effective membranes for a definite purpose is associated with a range of varied problems in physical chemistry and materials science, the solution of which requires fundamental studies of the structure and functional properties of the membranes. It is necessary to introduce into research practice modern methods which make it possible to control the structure and other characteristics of the materials at all stages of the preparation and modification of the membranes. At present, unfortunately, these studies are hindered by the lack of the appropriate equipment in research centres.

The advantages of membrane technology can be fully realised only with the optimum organisation of the membrane processes, requiring the selection of sound separation schemes, membrane apparatus parameters, and working conditions. The problems associated with the optimisation of membrane processes must be

solved using appropriate mathematical models containing phenomenological parameters characterising the properties of the membrane system. The selection of these parameters should also be based on the results of physicochemical studies of membrane separation processes with allowance for the change in the functional properties of the membranes during use.

The solution of this entire range of physicochemical and materials-science problems is necessary for the formulation of the integral concept of the development of membrane technology and the choice of its most effective applications. The complex character of the problems arising requires the coordination of effort in the organisation of planned scientific research and the establishment of a membrane technology, including the development of monomers, fibres, films, and fabrics for reinforcing membranes, and of thermally and chemically stable adhesives for membrane elements used for different purposes. In the Soviet Union at present this coordination is carried out by the MNTK (Inter-branch Scientific and Technical Complex) "Membrany" (Membranes), which combines the forces of more than thirty plants, institutes, and laboratories of the Ministry of the Chemical Industry, the Academy of Sciences of the USSR, the Ministry of Higher Education, and other departments.

The programmes of fundamental research work which have now been developed have been designed primarily to solve general theoretical problems associated with the determination of the nature of the selectivity of the transfer of components in membranes of different type, the development of the scientific principles of the synthesis of new polymeric materials, and the production of membranes based on them. Promising possibilities are provided by the synthesis of inorganic materials of new types for membranes, characterised by higher ionic conductivity values and a high thermal stability, which is extremely important for the production of membrane systems combining separating properties with other functional properties (for example catalytic). As yet, insufficient attention is being paid to these questions. At the same time, recent achievements, particularly in the production of ceramics with several functions (including special electrical properties), indicate the promising possibilities provided by this search.

Of the specific new types of membrane whose development it is extremely important to complete, mention may be made of the following: ion-exchange membranes (cation-exchange, anion-exchange, bipolar), stable to reactive media and high temperatures (up to 80 °C); perfluorinated membranes with different functional groups for membrane electrolysis and various special purposes; thermally and chemically stable membranes for reverse osmosis; highly selective membranes for separating carbon dioxide, ammonia, sulphur-containing gases, helium, oxygen, and other components from gas mixtures; composite membranes with high permeability for haemofiltration; microfiltration membranes for purifying highly reactive liquids in the chemical, biological, and other industries, capable of being used at temperatures up to 150 °C; and highly effective liquid and quasi-liquid (impregnated liquid) membranes for extracting required components from natural and industrial solutions.

In view of the promising possibilities provided by their development, it is necessary to search for biofunctional membranes with catalytic, energy-transforming, and information-transforming properties by immobilising fragments of biological systems on synthetic supports.

The papers in the present collection reflect some of these directions in the development of fundamental studies of the physical chemistry of the processes involved in the membrane separation of liquid and gas mixtures. In addition to the examination of the general regular features of the transport of ions and molecules through membranes with different functions, the characteristics of the membrane processes of gas separation, reverse osmosis, ultrafiltration, and electrodialysis have been analysed. The problems associated with the development of new membrane materials and the production of membranes, and problems of membrane biocatalysis, have also been discussed.

The development of the scientific principles of the technology of membranes of different types and the physicochemical principles of the processes involved in membrane separation is making it possible to develop and introduce into practice various membrane processes for separating liquid and gas mixtures and obtaining new substances, and also membrane catalytic processes.

In the technical and economic validation of new technologies, including membrane technology, it is necessary to adopt a comprehensive approach involving without fail an adequate analysis of all the advantages of the new technologies, including allowance for the effects of the technological processes on the environment, estimation of the effect of the loss of various substances discharged in industrial effluents, and allowance for the cost of water. Ecological factors may be very important, since new technologies should produce little or no waste products, practically eliminating the loss of valuable components and reducing considerably the harmful influence of industrial products on the enviroment.

All this means that new economic thinking is required to raise technology to a new level. Scientist-economists, when carrying out a comprehensive technical and economic analysis of the change to new technological processes, must not simply fix the existing state of affairs, but must look ahead and see the future. Only comprehensive technical and economic validation with calculation of the economic effect can open the road to the new technologies and enable them to be introduced.

From Biological to Synthetic Membranes

S.F.Timashev

The main principles of the functioning of transport systems in biological membranes and especially of processes involving the selective transport of ions and molecules in synthetic membranes (ion-exchange, gas separating, reverse osmosis, ultrafiltration, membranes, etc.) are examined. It is shown that, under the conditions of intense mass and electromass transfer, the transport of ions and molecules in synthetic membranes acquires features characteristic of transport processes in biological membranes both as regards the organisation of the transport (transport via channels) and in terms of the principal kinetic features. The prospects for further research into the physical chemistry of membrane separation processes and processes leading to the formation of new substances, including membrane catalysis, are discussed.

I. INTRODUCTION

Membrane technology is faced by major and large-scale problems whose solution requires the creation of new membrane materials and membranes of different types with effective functional characteristics (permeability, selectivity with respect to the target component, combination of catalytic and separating properties) and also a change-over to intensive mass and electromass transfer conditions in membrane systems (increase in current density, high effective pressure, the use of external influences). This necessitates not only a profound knowledge of the physical chemistry of the membrane separation, the characteristic features of ion and molecule transport processes in synthetic (organic, inorganic) membranes, but also the understanding of the main principles of the functioning of the most effective membrane systems in living nature. The heuristic value of the latter knowledge can be hardly overestimated. In the first place, this is a source of new ideas and concepts concerning the ways of increasing the selectivity of the transport of charged and neutral species, the most effective methods for the intensification of transport processes, the detailed mechanisms of the recording and transfer of information, and the methods for the transformation and utilisation of energy of external sources in a wide variety of processes.

However, in order that these ideas should acquire a pragmatic shape, it is essential to make them available to a wide range of specialists engaged in problems of the physical chemistry of membrane separation and problems concerning the creation of new materials and membranes based on them. This is particularly necessary, since studies on transport processes in native systems and synthetic membranes are prosecuted by different scientific groups almost independently. This article is one of the first attempts at the realisation of this important programme (see also the authors previous communications[1,2]).

II. CHARACTERISTIC FEATURES OF ION AND MOLECULE TRANSPORT PROCESSES IN BIOLOGICAL MEMBRANES

The cells of a living organism include a wide variety of types of membranes and membrane structures[3]—surface membranes (cell or plasmatic membranes) and a multiplicity of intracellular membranes. The surface membranes fulfill important barrier functions maintaining the internal autonomy of the cells and protecting them from the entry of foreign substances. Enzyme transport systems, using the energy stored in the organism and ensuring the supply to the cell and the removal from the latter of different components which makes it possible to maintain the required concentrations of the necessary substances within the cells and in their organelles, function simultaneously in the surface membranes.

Biological membranes consist of lipids and proteins. It has been established that there exist several hundreds of types of membrane lipids. More than half of them (up to 90%) are double layer forming phospho- and glyco-lipids, which manifest pronounced diphilic properties, i.e. they can be divided in space into polar and non-polar parts (the latter consist of hydrocarbon chains).

Under physiological conditions, the double layers are in a liquid crystal state and the description of their molecular organisation must therefore include the dynamic aspect apart from the structural (geometrical) aspect. The lipid double layer is illustrated schematically in Fig.1.[4] An important element of this model comprises the regions in the sublayer *a* in which short-range order ("cluster") is retained, their characteristic transverse dimension amounting to 0.8 nm. They incorporate up to 40–60 hydrocarbon chains (20–30 phospholipid molecules). The molecular packing in the clusters is fairly close to the crystal packing and is "more compact" than in the isotropic region *i* of the double layer.

The clusters are dynamic formations with a lifetime of $\sim 10^{-7}$ s. They are continuously decomposed and reformed, migrating along the double layer. The movement of the lipid fragments in the cluster should then occur simultaneously, i.e. it should represent a cooperative process. The boundary regions between such migrating clusters can be regarded as dynamic defects in the double layer.

In biological membranes, the complex dynamic system of the lipid double layer described includes a large number of protein molecules having different dimensions and shapes. In particular, proteins occupy 35% of the surface of the membrane in erythrocytes. The structural organisation of the phospholipids in the regions corresponding to binding to the protein can then change significantly, so that one may speak of the existence of protein–lipid complexes. The hydrocarbon chains of the phospholipids exist under native

conditions in a quasi-liquid state, the effective viscosity of the double layer amounting to ~5 P at 20 °C and this is why the protein molecules are capable of migrating along the membrane. The "liquid-mosaic" model of the structure of the membranes proposed by Singler and Nicholson has played a major role in the abandonment of the view that lipids constitute a simple structural partition.[3] If one imagines a section through the membrane in the plane perpendicular to its surface, then the proteins incorporated in the membrane double layer must produce a mosaic pattern. Such mosaic model of the membrane, presupposing the existence under native conditions of both double layer sections and regions constituting protein–lipid complexes, is the most attractive.

The distribution of various components (both proteins and lipids) in the membrane is asymmetric for functional reasons. The lateral mobility of the protein fragment in the double layer permits the formation of the most varied structures with a non-uniform (highly non-equilibrium) redistribution of components in the membrane. These can be lipid–lipid and protein–lipid clusters, protein–lipid domains differing in the composition of the proteins and lipids from other regions of the membrane, and domains comprising components within the membrane formed as a result of the binding of the latter to physiologically active compounds distributed on the surface of the membrane. The appearance of such complex metastable formations in biological membranes, which are thermodynamically open systems and exchange matter and energy with the environment, greatly expands the functional possibilities of cell structures.

In order to understand the principal characteristic features of the complex transformations occurring in the transport systems of biological membranes during their functioning, we shall consider the principles of the action of bacterial rhodopsin or bacteriorhodopsin (BR)—the simplest of the transport systems in which photodependent proton transport takes place and a proton electrochemical potential gradient $\Delta\mu_{H^+}$—the macroergy of biological systems according to Metchell's chemo-osmotic hypothesis[5]— is established on the cell membrane. Bacteriorhodopsin is the sole protein component of the purple membranes (PM) ("end-plate") of halobacteria, containing retinal as the chromophoric group, which forms a Schiff base with the protein component of the molecule—opsin BR consists of 248 aminoacid residues.

The attempts to establish the disposition of the protein in the lipid layer were based on the hypothesis that the hydrophobic sections of the polypeptide chain of the molecule should be disposed in the inner hydrocarbon region of the membrane, while the hydrophilic sections should be exposed to the aqueous phase. A scheme for the disposition of BR within the PM in the form of a sequence of seven α-helical blocks passing through the lipid double layer follows from these ideas.[6] The use of computers in order to select the α-helical structures having the lowest energies led to the conclusion[7] that each of the seven α-helical segments contains between 28 and 32 aminoacid residues and that pairs of charged groups form salt bridges within the membrane or are distributed on its surface.

Apart from the absorption in the region of 280 nm, typical for proteins, the BR spectrum is characterised by a broad absorption maximum at a wavelength $\lambda_{max} \simeq 560-570$ nm and a minor band near 400 nm. Continuous illumination of BR with white light shifts λ_{max} in the "light–dark" difference spectrum to the region of 412 nm. The state corresponding to $\lambda_{max} \simeq 412$ nm is stabilised in salt solutions or on lowering the temperature; in the dark, this state relaxes thermally to the initial state. The study of the kinetics of the formation and decomposition of the product absorbing at $\lambda_{max} \simeq 412$ nm by flash photolysis demonstrated the presence of intermediates, which precedes the formation of the product absorbing in the short-wavelength region, and also of a series of subsequent adducts. It has been suggested that the intermediate states be specified in the alphabetical order using the letter subscripts to λ_{max} in the differential optical spectrum.

The schematic photocycle obtained by Lozier et al.[8] is illustrated in Fig.2, which indicates the half-lives of the intermediates at room temperature under physiological conditions. The photochemical process is only the first stage–the formation of the intermediate K which takes place over a period of ~10 ps. This is followed by spontaneous thermally induced transitions between the states, such transitions being increasingly retarded in each succeeding stage. In particular, the activation energy for the K → L transition proved to be 0.5 eV and that for the L → M and M → BR transitions was found to be 0.7 eV. Later measurements[9] in the temperature range from 160 to 300 K yielded 0.68 eV for the activation energy for the

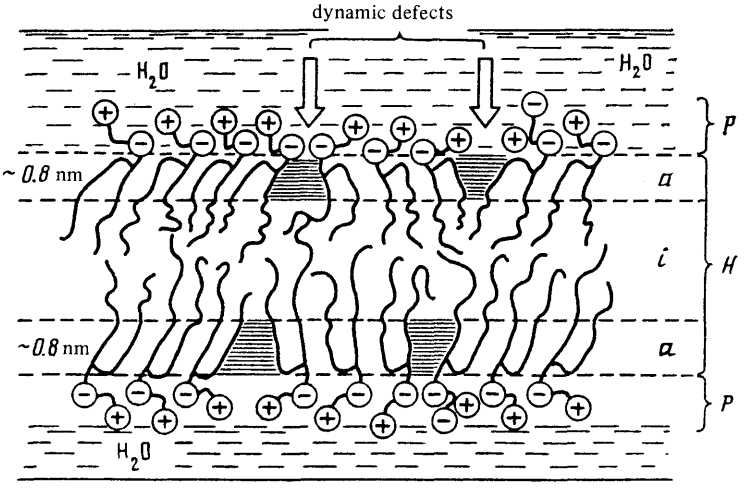

Figure 1. Schematic illustration of the structural organisation of the lipid double layer: *P*–the region of polar groups; *H*–the region of hydrocarbon chains; *a*–"anisotropic" region; *i*–"isotropic" region.[4]

K → L and L → M transitions. The lower rate of the L → M process is caused by the reduced entropy of activation in this stage.

The time of the total turnover of the BR photocycle is 0.01 s under physiological conditions and can increase by several orders of magnitude when the conditions are changed (the temperature and humidity are reduced and certain chemical compounds are present). The O_{640} and N_{530} intermediates cannot always be detected reliably, because the O state is very sensitive to external conditions, for example, to the pH of the medium. The existence of the N intermediate is indicated merely by the presence of the corresponding shoulder on the differential optical spectra. The primary process in the photocycle—the formation of the K_{630} state—takes place under the influence of light even at helium temperatures (2–9 K). A decrease in temperature shifts λ_{max} towards longer wavelengths.

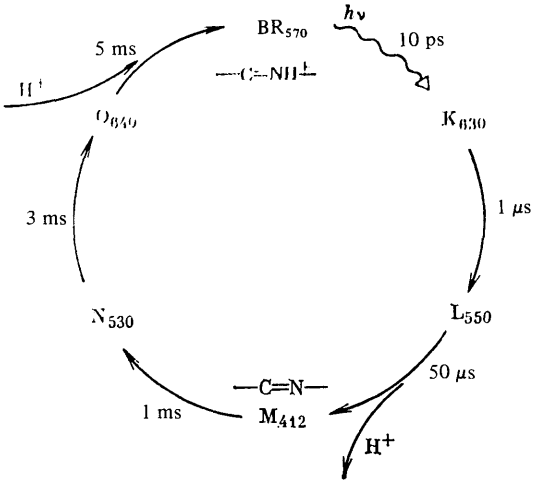

Figure 2. Schematic representation of the photocycle of bacteriorhodopsin[7] (the approximate time of formation of the first intermediate—the batho-intermediate K—and the half-lives of the subsequent intermediates L, M, N, and O are indicated; the subscripts denote the absorption band maxima of the corresponding intermediates in nanometers).

The discussion of the complex processes occurring in this surprising photodependent system and in other transport enzymes is outside the framework of this review (for further details about them, see, for example, Stoeckenius et al.[9]). The corresponding analysis made it possible to formulate appropriately the main principles of the functioning of transport systems in biological membranes.[1,2,10,11]

1. The transport of ions and molecules is determined by the submicrostrucure of the membrane and takes place via submicrochannels—specialised (ionic channels in excited membranes and transport ATPases) or arising in fluctuations of the structure of the lipid double layer. Ion transport with participation of complex forming agents (ionophores) takes place to a limited extent under native conditions.

2. The conductivity of a single ionic channel has multilevel character owing to the possibility of the formation of metastable conformations of the protein subunits of the ionic channels.

3. The selectivity of the ionic channels is determined by the different capacity for hydration of the transported ions and by the presence of regulatory ("gate") polar fragments in the vicinity of the entrances to the channels.

4. The state of the surfaces of the biological membranes (surface enzymes, receptor sections) can determine to a large extent the selectivity of the transmembrane ion transport, the transfer of information within the cell by changing either the charge state or the chemical activity of the surface enzymes as a result of a change in external factors.

5. The transport of ions and water molecules across biological membranes can be achieved under highly non-equilibrium conditions.

6. The transport processes in membranes are highly non-stationary; individual stages of the transport are coupled with conformational transformations in membrane fragments.

7. The ion transport in membranes is influenced decisively by the local electric field within biological membranes. By means of a redistribution of the charge density and by the creation of additional and local electric fields (relative to those already existing), the "mild" utilisation of the energy evolved in the organism in a wide variety of energy dependent processes occurring *in vivo* is achieved, especially in the active ion transport in ATPase (Na^+, K^+-ATPase, Ca^{2+}-dependent ATPase, the H^+-ATPase of the internal membranes of mitochondria) and photodependent (BR) transport enzymes.

8. Ultrahigh temperature thermal fluctuations, occurring in biological systems which are thermodynamically open, have a decisive influence on the characteristics of the activated (including transport) processes in biological membranes and are responsible for the non-Arrhenius character of the activated process.[11,12]

The native systems are immeasurably more complex than the synthetic systems and one can therefore speak merely of a comparison of the most general principles of the functioning of transport systems *in vivo* and of the processes involving the separation of liquid and gaseous mixtures using synthetic membranes in intense mass and electromass transfer. Under intense conditions of membrane separation, the permeability of artificial membranes and the selectivity of the transport through them of different components (ions, molecules) actually depend greatly on the characteristic of the structure, in particular the submicrostructure, of the membrane, of the kind which obtains in biological membranes. The possibility of increasing the efficiency of membrane separation methods actually consists in the specific formation of the structure and state of the surfaces of the membranes in order to impart to them the required properties.

III. THE NATURE OF THE SELECTIVE TRANSPORT OF COMPONENTS IN SYNTHETIC MEMBRANES

The mechanisms of the transport of ions and molecules in synthetic membranes of different types are extremely varied, although they are evidently not as complex as in native membranes. In the analysis of the principal features of ion and molecule transport through synthetic membranes given below we shall concentrate attention on the elucidation of the causes of the selective transport of the components of liquid and gaseous mixtures in polymer membranes which are most widely and effectively employed in membrane technology.

1. Separation of Components in Baromembrane Processes

Reverse osmotic, ultrafiltration, and microfiltration processes are classified as baromembrane processes. The last two processes are evidently determined by the dimensions of the membrane pores or, more precisely, by the pore size distribution function (the characteristic ranges of pore sizes in ultrafiltration and microfiltration membranes are respectively $R_{uf} \simeq 5-50$ nm and $R_{mf} \simeq 0.1-10$ μm). The principal requirements which must be met by such membranes are high thermal and chemical stability (in the first place because of the necessity for periodic regeneration of the membranes by washing in special solutions) and relative uniformity of the pores as regards size when the porosity of the membrane is high.

The characteristic pore sizes in reverse osmosis membranes, $R_{os} \lesssim 1-5$ nm, make it possible to retain the hydrated ions present in solution and at the same time to let through, with a definite degree of selectivity, molecules of different nature (for example, in the separation of mixtures of water with alcohol). A decisive role can then be played not by sieve effects, as in ultrafiltration and microfiltration, but by the influence of the field of surface forces[13,14] (dispersion, Coulombic, and structural forces[15]) on the species (ions and molecules) passing through. The efficiency of the operation of reverse osmosis membranes is therefore determined not only by the pore size distribution but also by the chemical structure of the polymer—the type of functional groups and their mutual disposition in space.

In asymmetric, first-generation, reverse osmosis membranes based on cellulose acetates, the structure of the selective layer (its thickness is usually ~0.2 μm) was not sufficiently rigid. In the course of the functioning of such membranes, some rearrangement of the structure apparently takes place and submicrochannels, which pass through the selective layers and through which a stream of solvent molecules moves (for example, in the demineralisation of salt solutions),[16] are formed.

New generation reverse osmosis membranes permitting the large-scale desalination of natural waters (brackish water, sea water) have been created recently. Composite membranes obtained on microporous polysulphone supports by the interfacial polycondensation of aromatic diamines (for example, *m*-phenylenediamine) with tricarboxylic acid chlorides (for example, trimesic or cyclohexane-1,3,5-tricarboxylic chlorides[17,18]) have the most effective functional parameters. Such aromatic polyamide coatings are characterised by high chemical, mechanical, and thermal stabilities owing to the rigid three-dimensional structure of the polymer molecules resembling the structure of a non-ordered zeolite. High permeability to water (~ 1 m^3 m^{-2} day^{-1}) with a salt retention up to 99.5% at working pressures in the range 20–30 MPa, which are anomalously low for reverse osmosis (on membranes of previous generations such efficiency was achieved at pressures in the range 5.0–6.0 MPa), is then ensured. However, an inadequate stability in relation to sterilising agents, including chlorine, is characteristic of such membranes, which limits the scope of their use for water treatment and for the processing of industrial waste. Increased resistance to oxidants is attained for polymeric materials not containing NH groups, in particular, polypiperazinamides. The corresponding reverse osmosis membranes (developed by the Separam Company) with a selectivity with respect to NaCl of about 95% and an efficiency of ~ 1.0 m^3 m^{-2} day^{-1} (at a working pressure of ~4MPa) are stable in salt solutions at a chlorine concentration of 50 p.p.m.

When water flows during the desalination process through the rigid system of submicropores (cavities) and channels of the selective layer of reverse osmosis membranes, the salt retention is determined both by the size of the channel, connecting the hydrated cavities, and by the random force field generated by all the fragments of the polymer in the region of the channel.

For the calculation of the hydrodynamic resistance of the selective layer, one can use the approaches based on theories of the flow of liquid in a random labyrinth[19,20] which were developed earlier for problems concerning the transport of a non-wetting liquid (for example, mercury) in porous materials.[21,22] According to Neimark,[22] it is useful to represent the pore distribution in space in the form of a three-dimensional lattice whose linkages (edges) correspond to the pore channels and the nodes correspond to the sites of their intersection, i.e. the cavities. In this approach, the problem of the relative distribution of the liquid and gaseous phases (the cavities and channels which are respectively filled and unfilled by water molecules) reduces to the classical problem of the theory of flow—the problem of percolation via connections.[19]

We shall consider the process involving the "forcing" of a non-wetting liquid into a pore system.[22] At an excess pressure P, the non-wetting liquid can be forced through pore channels whose effective size exceeds a certain quantity R_+, which depends on P and the field of surface forces in the channel. Such pore channels with $R > R_+$ will be called supercritical. The fraction p of supercritical pore channels is determined by the channel size distribution function $\varphi(R)$:

$$p = \int_{R_+}^{R_{max}} \varphi(R)\, dR.$$

Considering the liquid phase in terms of the macroscopic approximation, it is convenient to introduce the concept of the surface tension (coefficient) σ_s at the liquid–vapour interface and of the wetting angle θ. For a cylindrical pore, $R = 2\sigma_s \cos\theta/P$.

At an excess pressure P, the non-wetting liquid penetrates only into the pores which are linked to the outer surface of the specimen by a sequence of supercritical pore channels. It is known that for $p < p_c$, where p_c is the lattice percolation threshold, the probability of the existence of a continous sequence of supercritical channels decreases exponentially with increase in the length of such sequence. Under these conditions, the non-wetting liquid penetrates only into supercritical pores in the immediate vicinity of the outer surface. Only when the excess pressure increases so much that the fraction p of the supercritical pore channels exceeds the percolation threshold p_c does the non-wetting liquid penetrate into the bulk of the specimen. The corresponding pressure is referred to as the break-through pressure. Its value p_c is determined from the relation

$$p_c = \int_{R_+(P_c)}^{R_{max}} \varphi(R)\, dR. \qquad (1)$$

The phenomenon of break-through (the penetration of a non-wetting liquid into the bulk of the specimen) at $p > p_c$ is due to the formation of an infinite connected system of supercritical pores or of an infinite cluster (IC). The IC incorporates cavities (nodes) and supercritical channels (edges or connections) and the cavities are connected to the outer surface by a continuous sequence of supercritical channels. For large specimens containing a macroscopically large number of elementary pores, one can neglect the edge effects and assume that the IC is distributed uniformly in the bulk of the specimen and that the degree of saturation (it characterises the relative volume of the liquid phase in the overall volume of the system of pores and channels) of a specimen having finite dimensions is equal to the corresponding quantity for a semi-infinite medium.

We shall assume that the pore channels of different sizes are distributed at random. Then the distribution of the supercritical channels in the lattice will also be random: the probability that an arbitrarily selected connection is supercritical is equal to the fraction p of the supercritical pore channels. The following characteristics of the IC are considered in the percolation theory: the connectivity function $Q_c(p)$—the fraction of connections included in the infinite cluster among all the lattice connections; the percolation probability $Q_p(p)$—the fraction of nodes included in the IC relative to all the lattice nodes; the relative conductivity $\sigma(p)$—the ratio of the lattice conductivity, in which conductors constitute a fraction p and the fraction of insulators is $1 - p$, to the conductivity of the lattice in which all the connections are conductors. The characteristics of the relative phase distribution are expressed in terms of these functions. In the example considered, the non-wetting liquid occupies the pores incorporated in the IC formed by supercritical connections and the degree of saturation λ is expressed in terms of the connectivity function and the percolation probability:

$$\lambda = v_p Q_p(p) + (1 - v_p) Q_c(p), \tag{2}$$

where v_p is the fraction of the volume of the cavities in the overall pore volume and $1 - v_p$ the fraction of the volume of the pore channels.

The effective transport coefficients of the liquid in the system of channels are porportional to the conductivity of the IC:

$$D(\lambda) = D(1)\sigma(p), \tag{3}$$

where $D(\lambda)$ and $D(1)$ are the effective transport coefficients for a degree of saturation λ and for the complete filling of the pore space respectively.

The connectivity function, the percolation probability, and the relative conductivity for a simple cubic lattice have a non-linear threshold character and are identically equal to zero for $p < p_c$. Such behaviour is typical for any lattices regardless of their topology. The percolation threshold is mainly determined by the lattice coordination number z. The approximate equality $p_c \simeq 1.5/z$ is known to hold. In the vicinity of the percolation threshold, the asymptotic scaling relations are valid:

$$Q_p \propto Q_c \propto (p - p_c)^{\beta}, \tag{4}$$

$$\sigma \propto (p - p_c)^{t}. \tag{5}$$

The critical indices of the percolation probability (β) and conductivity (t) are[22] in the ranges $0.35 < \beta < 0.47$ and $1.5 < t < 2.0$. Under conditions remote from the percolation threshold, the linear equation of the self-consistent field theory is valid for conductivity $\sigma(p)$:

$$\sigma(p) = \left(p - \frac{2}{z}\right)\left(1 - \frac{2}{z}\right)^{-1}. \tag{6}$$

The percolation probability $Q_p(p)$ and the connectivity function $Q_c(p)$ can be fitted[23] by a power relation; at $p \gtrsim 2p_c$, they differ little from the asymptotic relations:

$$Q_p(p) \to 1, \quad Q_c(p) \to p. \tag{7}$$

According to the scaling hypothesis, the geometry of the percolation system, including the structure of the IC, is determined by a single characteristic dimension—the correlation length L. Under conditions remote from the percolation threshold at $(p - p_c)/p_c \simeq 1$, the correlation length can be of the same order of magnitude as the size $\overline{R}_1$ of a single structural element. At $p \to p_c$, the correlation length increases without liimit in accordance with the power law

$$L \propto (p - p_c)^{-1+\delta}. \tag{8}$$

The critical index of the correlation length for three-dimensional lattices is $1 - \delta \simeq 0.9$.[22] For distances $r \gg L$, the IC is homogeneous and for $r \ll L$ a correlation in the distribution of elements belonging to the IC is manifested. In the vicinity of the percolation threshold, where $L \gg \overline{R}_1$, there is a region where $\overline{R}_1 \ll r \ll L$, in which the IC possesses the so called fractal properties, i.e. it is characterised by a non-traditional dependence of its volume (or surface) on the geometrical scale. For example, the number of elements in the IC at a distance $r' < r$ from a selected element increases in proportion to r^{d_f}, where the so-called fractal dimensionality d_f is not equal to the dimensionality of the space d:

$$d_f = d - \beta/(1 - \delta) \tag{9}$$

(in the three-dimensional case, $d_f = 2.5$). Ideas concerning fractal properties of the IC proved fruitful in the study of the geometrical features of the relative distribution of phases in the pore space.

The dependence of the relative conductivity σ on the fraction of the elements incorporated in the IC is of interest for the calculation of the effective transport coefficients in partly saturated porous media. It follows from the scaling relations (4) and (5) that

$$\sigma \propto Q_p^{t/\beta} \propto Q_c^{t/\beta}. \tag{10}$$

From Eqn.(2), it follows that in the scaling region the effective transport coefficients with respect to the non-wetting phase are linked by a power relation to the degree of saturation and that the power exponent is equal to the ratio of the critical indices of the relative conductivity and the percolation probability:

$$D(\lambda) \propto \lambda^{t/\beta}. \tag{11}$$

An interpolation expression for $D(\lambda)$ has also been obtained:[22]

$$D(\lambda) = D(1)\frac{2.88}{(1 + 1.31v_p)^{3.48}}\lambda^{3.48} \quad \text{for } \lambda < 0.433(1 + 1.31v_p). \tag{12}$$

The characteristic features of the penetration of a non-wetting liquid into porous systems can be analysed on the basis of Eqns.(11) and (12) as a function of the applied pressure. However, for the corresponding analysis of the permeability to water of reverse osmosis membranes it is essential to possess independent data on the structural parameters of the selective layer, including the pore size distribution function and the surface force field parameters. Unfortunately, there are virtually no such data at the present time. When the appropriate investigations are carried out, it will become possible to assess more effectively the potential possibilities of the method of reverse osmosis for the separation of various, including aqueous organic and organic, liquid mixtures. At the present time relations of type (11) and (12) have been established for gas and electrolyte transport processes in porous nickel electrodes.[24]

Ultrathin surface layers of submicroscopic thickness (~10 nm), made of organic and inorganic (for example, polyphosphazenes) materials and produced on ultrafiltration or microfiltration supports, can serve as carrier structures with fractal properties in the separation of mixtures of electrolytes, in the separation of gaseous mixturres under intense separation conditions, and in electrocatalytic processes. Not only the corresponding permeability constants but also the parameters of the selectivity of the separation can then depend on the thickness of the ultrathin layer. The ways of creating such structures can be related to the use of the Langmuir–Blodgett method for the formation of monomolecular films and mixed structures with a high degree of molecular order and of the electrochemical, plasmachemical, and photochemical methods for the deposition of ultrathin layers. In fact one is dealing with a qualitatively new level of membrane technology, because the permeability

of the membranes to the target components increases by more than an order of magnitude and hence there is a significant decrease in the materials consumption in the membrane process. The technical sophistication involved in the creation of such barrier structures and ultrathin layers must be the highest possible and must involve an ultrapure technology (as regards materials and the concentration of aerosols in the surrounding space) employing the experience and methods of electronic industry.

2. The Diffusion-Migration Transport of Species in Membranes

In many synthetic membranes, molecules and ions are transported via a mechanism involving the dissolution of the components in the membrane matrix and the subsequent diffusional or diffusional-drift transport through the bulk of the membrane. In membranes of this type (ion-exchange and gas separation membranes) there are no rigidly fixed pores, although they do possess a definite free volume. In the case of flexible chain polymers, the effects associated with the redistribution of the free volume due to the mobility of fragments of the matrix play a decisive role in transport processes.[25] In rigid chain polymers (below the glass point T_g), the efficiency of the transmembrane transport of species is usually correlated with the structural non-equilibrium nature of the polymer matrix, characterised by the presence of definite submicrocavities in the vicinity of bulky substituents in the side chains.[26–28]

The traditional method of describing mass and electromass transfer processes in non-porous membranes involves the use of quasi-equilibrium ideas and the neglect of the "surface resistance", it being supposed that the transport of ions and molecules through the boundary regions takes place at a high rate (at the membrane–medium interfaces, there is equilibrium with respect to the species which have crossed the membrane). Therefore, if the membrane separates two volumes of gas with different concentrations of species of one kind, then, together with the consideration of local values of the diffusional flux of species in the membrane

$$J = -D\frac{\partial c}{\partial x} \quad , \tag{13}$$

where $c(x, t)$ is the local concentration of species in the membrane, D the diffusion coefficient, x the coordinate normal to the surface of the membrane, and t the time, it is necessary to introduce the sorption isotherm of the component in order to determine the concentrations of species near the surface. On the simplest assumptions concerning the form of the isotherm (the Henry isotherm), an expression follows from Eqn.(13) for a stationary flux of species passing through the membrane:

$$J = \Pi\Delta P/d;\ \Pi = D\gamma \quad , \tag{14}$$

where Π is the permeability constant of the material, γ the thermodynamic parameter of the solubility of the component in the given material (the Henry constant), ΔP the drop of the pressure of the component across the membrane, and d the thickness of the membrane. If the species migrating in the bulk of the membrane is acted upon by lateral forces—in the presence of an electrical potential gradient $\partial\varphi/\partial x$ (transport of particles with an electrical charge q) and also in the presence of a convective flux (for example in the case of transport in liquid and quasi-liquid membranes)—then the expression for the local flux of species J assumes the form

$$J = -D\frac{\partial c}{\partial x} - c(x)\cdot\left[\mu\frac{\partial\varphi}{\partial x} - u\right] \quad , \tag{15}$$

where μ is the electrical mobility of the species linked to the coefficient D by the Einstein relation $\mu = \xi qD/k_BT$ (T is the absolute temperature, k_B the Boltzmann constant, and $\xi \simeq 1$ a phenomenological numerical parameter) and u is the rate of drift of the species under the influence of the convective movement of the medium. The use of Eqn.(15) together with the sorption isotherm of the component transported in the membrane makes it possible to generalise Eqn.(14) and to take into account simultaneously the diffusion, electrodiffusion, and convective diffusion processes.

In considering the diffusional transport processes in real solid-phase membranes, inorganic and polymeric organic, complications arise due to the presence in them of different kinds of inhomogeneities: structural defects and inclusions of another phase. These defects and inhomogeneities can serve as capture sites for the given species, can give rise to local mechanical stresses influencing the transport processes, can effectively sort the diffusing components, etc. The description of mass transfer in such inhomogeneous media is complex even under the conditions of small fluxes of the transported species. The situation becomes immeasurably more complex if it is necessary to take into account non-linear effects associated, for example, with the characteristics of the sorption of the diffusing components in an inhomogeneous matrix.[29] Intuitively it is clear that the description of the transport of species must be based on the use (appropriately justified) of effective diffusion coefficients D_{eff}, which depend on the characteristic features of the transport of the species in those regions of the membrane which are characterised by different equilibrium solubilities of individual components and also on the spatial distribution of such regions in the matrix.[30]

3. Non-Equilibrium Transport Conditions

The traditional quasi-equilibrium approach to the description of processes involving the membrane separation of the components of gaseous and liquid mixtures is justified only for a low density of the fluxes J_i of the components i crossing the membrane, when $J_i \ll J_{io}$, J_{io} being the "exchange flux" density of the component i in the regions of the membrane–external medium interfaces and also at the boundaries between the micro- and submicro-regions in the bulk of the membrane differing in structure. In such cases there is equilibrium with respect to the species i in different regions of the system and the fraction of the species passing to each of the structurally different regions within the membrane is determined by the thermodynamic parameters of these regions.

On passing to extremely highly non-equilibrium regimes in membrane separation under the conditions of electrodialysis, electrolysis, and elevated pressures in gas separation, when $J_i \lesssim J_{io}$, the quasi-equilibrium models of the "dissolution and diffusional-migration transport" become inadequate. Under these conditions, the state of the membrane–medium interface determines the character of the distribtuion of the transported species between the external medium and the membrane. The state of the boundary separating regions with different physicochemical characteristics in the bulk of the membrane determines the distribution of the pathways (fluxes) of the species in the membrane matrix and, with increase in J_i, the condition $J_i \simeq J_{io}$ begins to hold at a greater number of interfaces. It therefore becomes necessary to consider in previously structurally indistinguishable regions increasingly finer details (with dimensions down to several nm), which influence the redistribution of the species in the matrix under the conditions of intense mass transfer. The transport of molecules and ions through synthetic membranes

acquire certain features characteristic of the most effective membranes—namely biological membranes, both as regards the type of organisation of the transport (transport via "channels") and as regards the principal kinetic relations.

We shall consider below a series of problems in the model description of transport processes in membrane systems under extreme regimes and shall demonstrate what new possibilities can arise in the membrane separation of liquid and gaseous mixtures under these conditions.

The transition from quasi-equilibrium mass transfer regimes to extreme (non-equilibrium) regimes can be conveniently illustrated in relation to the transport of the molecules of simple gases through membranes based on siloxane–containing block copolymers. A relation between Π and ΔP has been observed[32,33] in a study of the permeability of such membranes to the molecules of simple gases (CO_2, O_2, and N_2), which consists in a considerable (severalfold) increase in Π when P changes from 1 to 5 kPa. According to quasi-equilibrium ideas, Π = const if D and γ are independent of pressure. In an analysis[34] of the sorption isotherms of the molecules of simple gases (CO_2 and O_2) in siloxane-containing Silar block copolymers, no anomalies were noted: the adsorption isotherms were linear throughout the experimental pressure range (up to 75 kPa). It is therefore most natural to assume that, under conditions[32,33] where $P > 5$ kPa, the filling of both phases of the block copolymer, rigid and flexible, is non-equilibrium and transport takes place mainly in the flexible phase. The latter conclusion is also confirmed by the results of a study[35] in which correlations were observed between the mobility of the fragments of the siloxane phase of the block copolymer and the effective diffusion coefficients.

On passing to non-equilibrium mass transfer regimes, the effective solubility parameter σ differs from the equilibrium value γ ($\sigma < \gamma$), which leads to the possibility, in principle, of influencing the permeability constants of membranes by modifying the membrane–medium interface. This possibility has been realised in a study[36] where it was shown that the chemical modification of the gas–polymer interface by the polymerisable fluorine-containing allyloxysilane, which exhibits surface-active properties, can increase almost by a factor of two the permeability constants Π of the modified membranes relative to the corresponding values for the initial (unmodified) membranes. Under the conditions of such modification, the diffusion coefficients D of gases in the membranes remain almost unchanged and DSC [differential scanning calorimetry?] data also indicate the unchanged state in the bulk of the membrane after its modification: the thermograms of the initial and modified membrane are completely identical. The equilibrium value γ should not therefore change as a result of the above modification and the observed effect must be attributed to a change in the effective solubility: $\sigma_{mod}/\sigma_{init} \simeq 2$.

In order to solve the problems of membrane separation in non-equilbrium transport regimes, another procedure is needed, in particular the use of the method of the theory of flow (of a liquid in a random labyrinth).[19–20] Here the effective pathways in the transmembrane transport of species ("infinite clusters"—IC, in terms of the terminology of the theory of flow) are produced by a system of localisation centres separated from one another by an optimum average distance. This situation obtains in the transport of ions through perfluorinated sulphonic acid cation-exchange membranes characterised by a specific submicrostructure characteristic of comb polymers: the hydrophobic matrix at the hydrated ionogenic group in the amorphous regions of the perfluorinated polymer forms associated species—"clusters" with characteristic dimensions of ~ 5 nm.

A fragment of the amorphous part of the perfluorinated sulphonic acid cation-exchange material is illustrated in Fig.3. According to this structural model, the pathways followed in the flow of ions and water molecules are within ion-exchange clusters ("ionic channels" in a hydrophobic matrix). The transport of ions over macroscopic distances (the formation of IC) becomes possible for a sufficiently high degree of hydration of the ionogenic groups (centres between which ion jumps are effected), whereupon an effective linkage is established between adjacent ionogenic groups.

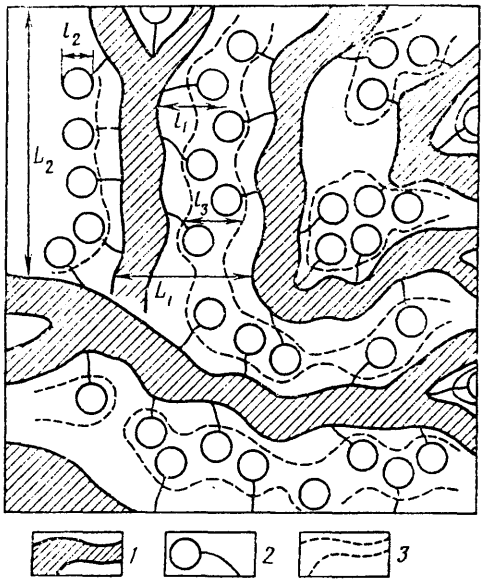

Figure 3. Schematic illustration of a fragment of the amorphous part of a sulphonic acid cation-exchange membrane:[37] 1) main polymer chain; 2) hydrated counterions and ionogenic groups under the conditions of a low moisture content (the "chlorine electrolysis" conditions); 3) "channels" for the transport of ions and water molecules in the presence of a high moisture content; the distance $L_1 \simeq$ 4 nm is estimated from low-angle X-ray scattering data, $L_2 \simeq$ 10 nm from Mössbauer spectroscopic data, l_1 and l_2 from DENR and NMR data, and l_3 from data obtained by reference porometry and DENR.

Under the conditions of a high moisture content when the average number of water molecules n per ionogenic group exceeds 15, virtually all the functional groups of the membrane are "bound" and the polymer matrix is on average uniformly threaded by a random network of channels hydrated to the maximum extent, through which the diffusional transport of ions takes place. The specificity of such ionic transport is low.

With decrease in the moisture content, some of the "bonds" between adjacent centres are broken so that "dead ends" appear in the random network of channels.[20] In the flow model, the dependence of the specific resistance of the membrane ρ on the moisture

content for low values of n ($n < 10$, "chlorine electrolysis" conditions) is of the form[37]

$$\rho \simeq \frac{R_0 r_c}{[\nu(n) - \nu_c]^{2-\delta}} \cdot \exp\left[p\,(\bar{n}^{1/s} - n^{1/s})^{\mu_s} + \frac{\varepsilon(n)}{k_B T}\right], \qquad (16)$$

$$p = \left[2\alpha_s \left(\frac{3}{4\pi\rho_0}\right)^{1/s}\right]^{\mu_s}, \quad \bar{n} = \frac{1}{6}\pi\rho_0 r_c^3,$$

where R_0, α_s, and μ_s are parameters determining the probability of the jump by ions between adjacent ionogenic groups, $\varepsilon(n)$ is the activation energy for such a jump, $\nu(n)$ the average number of bonds between a specified ionogenic group and adjacent groups whose centres are separated from the centre of the specified group by distances not exceeding the characteristic average value r_c, ν_c is the threshold value of $\nu(n_c)$ for which IC arise, and ρ_0 is the effective density (packing density) of water molecules in the hydrated ionogenic group–counterion complex.

Attention should be drawn to the decisive role of the entropy factor in Eqn.(16) which depends exponentially on n and is determined by the parameters α_s, μ_s, and r_c in establishing the specificity of the ionic transport. A similar situation apparently arises also in the ionic transport in biological membranes. In the region of low values of n, the following relations between the quantities ρ for ions of different types (for a fixed n) are valid in the case of sulphonic acid cation-exchange membranes:

$$\rho_{H^+} < \rho_{Li^+} < \rho_{Na^+} < \rho_{K^+} < \rho_{Cs^+}.$$

Analysis of the relation obtained permits the conclusion that there is contact interaction of the hydrated cation with the ionogenic centre (the sulpho-group), which is consistent with Eisenman's series XI in the binding of ions within the channels of membranes capable of being excited.[38] This means that the ionic channels of sulphonic acid cation-exchange membranes are systems with a high "field strength" (such as, for example, the Na^+-channels in the squid axon). The creation of membranes with other types of ionogenic groups ensures new possibilities for the selective transport of ions and leads to the realisation of other Eisenman selectivity series (for example, among the eleven which exist for cations).

Spectroscopic studies using ^1H and ^7Li NMR[19] have shown that the character of the relation defined by Eqn.(16) is determined by the characteristics of the elementary ion transport between the functional groups. This means that the specificity of ion jumps under the conditions of limited capacity for hydration of the functional groups (this situation actually obtains also in the ionic channels of biological membranes) is associated with the entropic multipliers of the rate constants for the corresponding jumps. For ions of different types, one may point to certain critical values of n_i such that, for $n < n_i$, the transport of ions of type i is significantly retarded as a consequence of the formation of cation–functional group contact ion pairs. When sulphonic acid cation-exchange membranes are used, these values for the H^+, Li^+, and Na^+ ions are respectively ~ 2, ~ 4, and ~ 6. In particular, this is indicated by the dependence of the chemical shift of the water protons in the membrane on the moisture content of the latter:[39] for $n > n_i$, the ions indicated retain their individuality in the membrane—they exist in the form of the complexes $[H_5O_2]^+$, $Li^+.4H_2O$, and $Na^+.6H_2O$.

One of the main consequences of Eqn.(16) is large local heat evolution in perfluorinated membranes when a high-density electric current j passes through them (under the conditions of "chlorine electrolysis" and $j \simeq 0.3$ A cm^{-2} and when the overall moisture content in the membranes is low, we have $\nu \gtrsim \nu_c$ because of the high concentration of the resulting alkali, reaching 20–40%). It has been shown [20] that, in the vicinity of the flow threshold, the bulk of the Joule heat is evolved within a small volume on a limited number of "bonds" (at the "heating points")[40] and in the limit $\nu \to \nu_c$ the fraction of the volume carrying almost the entire Joule heat tends to zero.

Before discussing certain consequences arising from the above, we may note that perfluorinated ion-exchange membranes are "non-cross-linked". Therefore, under the influence of local heat evolutions, the conformation of the polymer chains in the membranes may change, giving rise to the formation of metastable structurally-conformational states of the amorphous fragments with an arrangement of the side chains characteristic of each such state.

For sufficiently extreme electromass-transfer regimes under the conditions of a low moisture content in the region of the "heating point", there is a possibility of a virtually complete dehydration of the functional groups, so that the probability of ion jumps in this region falls sharply and the corresponding transport section is eliminated from the IC. However, the "evaporated" water molecules formed on dehydration can hydrate functional groups which had not been previously included in the IC and a new percolation pathway arises. The above mechanism of the "flickering of transport pathways" ensures high thermal stability of the non-cross-linked perfluorinated ion-exchange materials.[37]

One may note that the effective mechanical properties of the non-cross-linked copolymers, necessary for the functioning of the membrane in such extreme regimes, are determined by the PTFE crystallites ensuring the "physical" reinforcement of the perfluorinated matrix. Such crystallites (their characteristic size is ~ 10 nm) are formed by fragments of different copolymer molecules without functional groups. The intermolecular distances realised in PTFE crystallites at room temperature are attained in PTFE crystals at elevated temperatures (470–490 K). Closer packing of the above fragments is prevented by the presence of functional groups in the macromolecules. In order to diminish the "wedging" influence of the ionogenic groups on the PTFE crystallites, perfluorinated membranes are obtained from ternary copolymers [in particular, in polymerisation one introduces, apart from tetrafluoroethylene and the perfluorinated ester with sulphonyl fluoride or carbonyl fluoride groups, a third monomer of the type $CF_2 = CFO(CF_2)_3CF_2$, which is responsible for the formation of buffer zones between the PTFE crystallites and the amorphous section containing ionogenic groups; this improves the mechanical properties of the membranes].

4. Characteristics of the Transport of Species in Liquid and Quasi-liquid Membranes

A promising development is the use of liquid and quasi-liquid† membranes for the selective extraction of target components. It has been suggested that they be used[41,42] especially for the extraction of metals in hydrometallurgical industries, for the concentration of valuable components in waste and natural waters (including sea water). In this connection, a series of problems arise: (1) the development of a scientific basis for the search for complex-forming

†Quasi-liquid membranes or impregnated liquid membranes are understood to constitute liquid systems (the solvent with the complex-forming agent, catalyst, etc. contained in it) immobilised in an inert porous base; in the foreign literature the term "supported liquid membranes" is usually employed for such membranes.

agents ensuring a high extraction selectivity; (2) stabilisation of complex emulsions ("Li membranes"[43]) and film systems (in Boyadzhiev's columns) for the solution of technological problems in liquid membrane extraction; (3) enhancement of mass exchange processes in the region of the liquid membrane–liquid medium interfaces.

We shall confine ourselves to considering only mass exchange processes without dwelling on problems of the description of transport in the region of membrane–medium interfaces in view of the necessity to use boundary conditions of a fairly general type.[16]

As shown previously by Lev and Buzhinskii,[45] the formation of complexes in the interfacial region by the transported species with complex-forming agents present in the liquid membrane may retard the process and lead to the appearance of "surface" resistance. However, the situation can become still more complex when such complex formation occurs in macroscopic (~ 1 μm) regions of liquid membranes, for example, as a consequence of the formation in such layers of submicrodispersions of the external (in relation to the membrane) solution. In this field, there are still many fundamental difficulties to be overcome.

We shall consider the problems of mass transfer associated with its enhancement by spontaneous convection, which may develop in the boundary regions of the liquid membrane (and the electrolyte if it constitutes a medium external in relation to the membrane).[46] We shall confine ourselves to considering the classical problem of the transport of CO_2 molecules through liquid and quasi-liquid membranes formed on the basis of aquous alkali metal carbonate solutions, in connection with the results obtained recently,[47] which demonstrated the fundamental role of the effects of the spontaneous convection of the solution in this process.

The mechanism of the transport of CO_2 through liquid alkali metal carbonate layers can be represented in a simplified way by the following two stages:[48]

(1) dissolution of carbon dioxide accompanied by a heat change of ~ 26.2 kJ mol^{-1}:

$$CO_2 + CO_3^{2-} + H_2O \rightarrow 2HCO_3^- ;$$

(2) the transport of HCO_3^- ions through the membrane and the evolution of carbon dioxide on the other side of the membrane where the CO_2 partial pressure is reduced and the reverse reaction

$$2HCO_3^- \rightarrow H_2O + CO_3^{2-} + CO_2$$

takes place. The process is accelerated when catalysts are introduced into the system, such catalysts frequently consisting of the anions of weak acids, for example, arsenic acid.

The kinetics of the transport of CO_2 through a liquid membrane consisting of a layer of liquid (3.2 *N* Cs_2CO_3 + 0.25 N Na_3AsO_3 solution; pH 13.6) enclosed between two hydrophobic asymmetric polyvinyltrimethylsilane films have been investigated.[47] These films exhibit a high gas permeability (the permeability to CO_2 is 3×10^{-8} mol m^{-1} s^{-1} Pa^{-1}), so that they do not introduce any distortions into the measurements (error $\leqslant 0.5\%$). The kinetics of the transport of carbon dioxide were investigated for the horizontal and vertical positions of the cell. For the horizontal position of the membrane, CO_2 was supplied to the cell in two ways: in one case carbon dioxide was injected into the upper cavity and a carrier gas (helium) into the lower cavity, while in the second case the opposite arrangement was used. As a result, the coefficients of the gas permeability Π of membranes of different thickness d were found at +20 °C.

It was noted[47] that, for the horizontal position of the cell, a steady increase in Π with increasing d was observed. The permeability coefficients depended on the way in which gas was supplied into the cell, the difference between the values of Π increasing with decrease in the thickness of the membrane. For the vertical position of the cell, Π initially increased with increase in d and then fell sharply. The values of Π for different orientations of the membrane differ by more than an order of magnitude (for $d = 3600$ μm).[47] Such behaviour of Π can be explained only by convective movements in the solution.

The appearance of convective movements within the liquid membrane can be caused by different factors. In particular, the heat evolution of dissolution of CO_2 induces local heating in the membrane and hence changes in the surface tension at the gas–liquid interface leading to Marangoni effects. It is therefore of interest to calculate formally the diffusion coefficient D and the solubility σ_{eff} of CO_2 molecules in the carbonate solutions on the basis of the model of the transmembrane gas transport, which includes the instantaneous dissolution and diffusional transport as the limiting stage. According to this model, $\Pi = D\sigma_{eff}$. The results of such calculation, based on the solution of the diffusion equations with boundary conditions of the first kind, have shown[47] that the values of D and σ_{ef} vary non-monotonically as the thickness of the membrane is altered. Starting with $d = 2600$ μm, the diffusion coefficient increases sharply while the solubility coefficient diminishes. Such behaviour of D and σ_{eff} may be caused by the initial stages in the development of the convective movement indicated. By reducing diffusional restrictions, these movements diminish the solubility coefficients. The induced transport of CO_2 molecules through the membrane takes place with participation of the "carriers" of these molecules—HCO_3^- ions. The low rate constant for the dehydration reaction $HCO_3^- \rightarrow CO_2 + OH^-$ (10^{-4} s^{-1} [49] at pH > 8) can mean that the process has two rate-limiting stages—transport and chemical stages, whose characteristic times are comparable. Therefore the lifetime of these carriers may prove to be of the same order of magnitude as their residence time in the region of the liquid–gas interface, which ultimately diminishes σ_{eff}.

The liquid and also quasi-liquid membrane described are characterised by a unique selective permeability to CO_2. Thus the ratio α of the permeability constants of such membranes for CO_2 and O_2 is $\sim 10^2 - 10^3$. Despite the fairly large number of studies devoted to gas transport processes through quasi-liquid membranes, the question of the contribution of the individual stages of these processes (diffusion, solubility) to the establishment of the high selective permeability of the membrane to CO_2 nevertheless remains obscure. Furthermore, the influence of the inert base on the kinetic characteristics of quasi-liquid membranes and on the methods of stabilisation of these characteristics has not been elucidated.

An attempt to find an answer to these questions has been made in a study[47] of inert, alkali-resistant polymeric matrices into which solutions of 3.2 *N* Cs_2CO_3 and a catalyst (0.25 *N* Na_3AsO_3) had been introduced. The choice of these particular substances (whose concentrations correspond to the saturation of the solution by caesium bicarbonate when CO_2 is passed through) is determined by the high gas permeability coefficients of such membranes. Hydrophilic porous filters based on UEM-270 ethylcellulose with an average pore diameter $I = 27$ nm and a thickness $d = 72$ μm, and also the polysulphone UPM ($R = 50$ nm, $d = 100$ μm) and poly(vinyl chloride) ($R = 170$ nm, $d = 100$μm) have been used as polymeric matrices.

The relative pore volume was estimated from the difference between the weights in the moist and dry states and was found to be 73% for UEM-270, 58% for UPM, and 76% for PVC.

The corresponding $\sigma_{eff}(P)$ relations were calculated from the experimental[47] permeability coefficients Π and the effective diffusion coefficients D of carbon dioxide in quasi-liquid membranes and a number of conclusions were reached.

1. The carbon dioxide sorption isotherms (the dependence of the amount of CO_2 absorbed by the carbonate solution on its partial pressure in the gaseous mixture) is significantly non-linear and is almost independent of the nature of the polymeric matrix of the membrane.

2. The diffusion coefficient D increases with increase in the CO concentration in solution and depends greatly on the average pore size in the initial matrix. For relatively small average pore dimensions (27 and 50 nm), D is almost constant. However, the increase of R from 50 to 170 nm alters D almost by a factor of 5. Such behaviour of the diffusion coefficients can be explained by the appearance in the large pores of a kind of convective displacements of the structural units of the solution (associated ions and water molecules) as a consequence of the local heating of the solution during the course of the binding of CO_2 molecules.

3. The character of the variation of the permeability coefficient Π as the carbon dioxide pressure in the initial mixture is varied is associated with the antiparallel dependences of D and σ on P.

In conclusion of the Section, we shall discuss factors determining the high selectivity of the quasi-liquid membrane. The permeability, diffusion, and solubility coefficients of carbon dioxide and oxygen in the UEM-270 porous filters saturated with distilled water or the 3.2 N Cs_2CO_3 + 0.25 N Na_3AsO_3 solution are presented below (for $P_{CO_2} = P_{O_2} = 100$ kPa[47]):

		$10^{13}\Pi$, mol s^{-1} m^{-1} Pa^{-1}	$10^{10}D$, m^2 s^{-1}	$10^{4}\sigma$, mol m^{-3} Pa^{-1}
CO_2	H_2O	1.48	4.05	3.65
CO_2	3.2N Cs_2CO_3+0.25N Na_3AsO_3	2.74	$2.4\cdot10^{-2}$	$1.14\cdot10^{3}$
O_2	H_2O	$5.51\cdot10^{-3}$	4.0	$1.38\cdot10^{-1}$
O_2	3.2N Cs_2CO_3+0.25N Na_3AsO_3	$1.7\cdot10^{-3}$	$2.7\cdot10^{-1}$	$6.3\cdot10^{-3}$

For a membrane containing distilled water, $\alpha \simeq 27$. The selectivity of a quasi-liquid membrane increases to 160.

The example considered makes it possible to understand how high selectivity coefficients of liquid and quasi-liquid membranes can be attained and what are the possible ways of increasing the permeability to the target components. Here it is naturally necessary to achieve the stability of such systems, which may become a complex problem in their practical employment (for example owing to ageing or the elution of the reagents from the quasi-liquid membrane, as a consequence of the poisoning of the complex-forming carrier, owing to difficulties in its regeneration, etc.).

Microporous polypropylene,[50] polytetrafluoroethylene, poly(vinyl chloride), and polysulphone,[51] used in ultrafiltration and microfiltration processes, serve nowadays as bases for quasi-liquid membranes. Impregnation of such filters with liquid reactive carriers makes it possible to obtain membranes for the effective separation of liquids and gaseous mixtures combining the high efficiency of the porous membranes with the high selectivity of the carrier.[52–54] We may point to advances in the creation of highly selective membranes for the isolation of oxygen from air (the ratio of the corresponding permeability constants is $\sim 26-50$) which permitted the attainment of a nitrogen content in oxygen of only 9–15% after a single-stage separation.[55]

Liquid membranes of the emulsion type, stabilised by surfactants, have already found application in industry. In particular, the effectiveness of the use of such systems for the isolation of zinc[56] and sodium[57] ions, enzymes,[58] copper,[59] phenol,[60] and other organic and inorganic substances has been demonstrated (see also Van et al.[61]).

5. Membrane Processes Involving the Isolation of Vapour Mixture Components

New possibilities of the isolation of vapour components from liquids and vapour–gas mixtures have usually been attributed to the development of a new membrane process – membrane distillation.[62,63] We shall consider initially the simplest model ideas about the character of the movement of the gaseous mixture in porous systems in relation to transport in a straight cylindrical capillary.[64]

The movement of gases in such a capillary is determined by the Knudsen parameter Kn – the ratio of the number of collisions of the molecules with the walls to the number of intermolecular collisions. To within a constant multiplier of the order of magnitude of unity, the parameter Kn is equal to the ratio of the average length of the free path of the molecule l to the capillary diameter:

$$\mathrm{Kn} \simeq l/2r_c \qquad (17)$$

Since the lengths of the free path l_i of molecules in different gases in a gaseous mixture are of the same order of magnitude, the parameter Kn for a mixture of gases is approximately constant. Depending on the value of Kn, three characteristic gas flow regions are distinguished: the Knudsen region (Kn $\gg$ 1), the transitional region (Kn $\simeq$ 1), and the molecular region (Kn $\ll$ 1).

For Kn $\gg$ 1, the components of the gaseous mixture move through the capillary almost independently of one another. The total molar flux of the ith component under the conditions of Knudsen flow is therefore proportional to the gradient dc_i/dx of the molar concentration c_i of the component (the x axis is directed along the capillary axis):

$$J_i = c_i v_i = -D_i^K \frac{dc_i}{dx} = -D_i^K \left[c \frac{dy_i}{dx} + y_i \frac{dc}{dx} \right], \quad y_i = c_i/c, \; c = \sum_i c_i \qquad (18)$$

where D_i^K is the Knudsen diffusion coefficiient, c the total molar concentration, and v_i the velocity of the ith species along the capillary. For a cylindrical capillary under the conditions of diffuse reflection of the species from the walls (accommodation coefficient $\gamma_{a,i} = 1$), we have

$$D_i^K = \frac{2}{3} r_c \bar{w}_i \qquad (19)$$

where $\bar{w}_i = (8k_BT/\Pi m_i)^{1/2}$ is the average thermal velocity of type i molecules. If there are N such cylindrical pores per unit surface of the membrane, then the permeability constant Π_i of this membrane for type i molecules can be represented in the following form taking into account Eqn.(19) and the equation of state of an ideal gas:

$$\Pi_i = \frac{8R^3N}{3N_A} \left(\frac{\pi}{2m_i k_B T} \right)^{1/2} \qquad (20)$$

where N_A is the Avogadro number.

The relationship (Kn $\ll$ 1) obtains in fairly broad capillaries. The average linear velocities of the components are then constant along the section of the capillary, while the molar fluxes are related to the gradient of the driving forces by the Stefan–Maxwell system of equations. For constant P and T and also in the absence of external

forces, the Stefan–Maxwell system of equations can be conveniently put in the form

$$\frac{\mathrm{d}c_i}{\mathrm{d}x}=\sum_{i\neq j}(c_iJ_j^{T,P}-c_jJ_i^{T,P})/D_{ij}c \quad . \tag{21}$$

Here $J_i^{T,P}$ is the molar flux of the ith component for constant P and T and D_{ij} is the mutual diffusion coefficient of components i and j. Here we may note one non-trivial factor. Under the conditions of isobaric-isothermal molecular flow (Kn $\ll$ 1) of a mixture of gases in a long capillary, the interaction of the gas with the walls also proves very significant, since it determines the inter-relation between the partial fluxes. In order to obtain the corresponding conditions, we shall take into account the fact that, for a zero pressure drop across the capillary, the overall momentum $M_{\parallel}$, transmitted to the walls of the capillary when all the molecules of the mixture interact with them is zero:

$$M_{\parallel}=\sum_i M_{\parallel,i}=0 \quad , \tag{22}$$

$$M_{\parallel,i}=\frac{1}{4}c_i\bar{w}_im_iv_i(r_c)\gamma_{a,i} \quad .$$

Taking into account the relation $w_i \propto m_i^{-1/2}$, we find from Eqn.(22) the expression

$$\sum_i m_i^{1/2}\gamma_{a,i}J_i^{T,P}=0,$$

which yields the required relation for the case of the diffuse reflection of the component or for the independence of the coefficient $\gamma_{a,i}$ of the type of species:

$$\sum_i m_i^{1/2}J_i^{T,P}=0 \tag{23}$$

This is the so called Graham condition.[65]

In the case of a binary gaseous mixture with P = const. and T = const., we obtain from Eqns.(21) and (23)

$$J_i^{T,P}=D_{ij}(1-\alpha_{ij}c_i/c)^{-1}\frac{\mathrm{d}c_i}{\mathrm{d}x}=-D_{ij}c(1-\alpha_{ij}y_i)\frac{\mathrm{d}y_i}{\mathrm{d}x} \quad , \tag{24}$$

where $\alpha_{ij}=1-(m_j/m_i)^{1/2}$. Eqn.(24) has the form of Fick's law only for a small mole fraction ($y_i \ll 1$) of the diffusing component (diffusion of an impurity) or for the diffusion of components with the same molecular weights ($m_1 = m_2$); in the latter case $J^{P,T} = J_1^{P,T} + J_2^{P,T} = 0$.

The transitional regime (Kn $\simeq$ 1) in the flow of a gaseous mixture in capillaries is significantly more difficult to investigate. In the corresponding analysis, one usually employs interpolation formulae. The expression for the partial flux in the case of isobaric-isothermal flow of the binary mixture is usually represented in the form

$$J_i^{T,P}=-D_{b,ij}c\frac{\mathrm{d}y_i}{\mathrm{d}x} \tag{25}$$

and the Bosanquet expression [64] is used for $D_{b,ij}$—the binary diffusion coefficient in the transitional regime:

$$D_{b,ij}^{-1}=\frac{1}{D_i^K}+\frac{1-\alpha_{ij}y_i}{D_{ij}} \tag{26}$$

When transport in a porous medium is considered, the coefficients D_i^K and D_{ij} are usually renormalised by introducing into them the multiplier ε/ζ, where ε is the velocity of the material and ζ the tortuosity of the pores.

The above expressions for the fluxes of the components of gaseous mixtures in capillaries in different flow regimes can be used for the analysis of the problems of the membrane separation of gaseous and vapour–gas mixtures. In the first place, we have in mind here the Knudsen flow regime in which the mixture of gases passing through a porous membrane is enriched, in accordance with Eqn.(20), in the lighter components. However, such processes are not sufficiently effective owing to the relatively small mixture separation factors in cases of greatest practical interest. Admittedly, in the membranes with a continuous diffusion layer employed for technological purposes, the possibility of the existence of "through" submicrodefects and transport via such defects must be taken into account in accordance with the formulae quoted above.

The calculation of gas fluxes in capillaries is of greater current interest in connection with the development of the physicochemical principles of membrane distillation. This process consists in the selective mass transfer of water vapour through a finely porous hydrophobic membrane separating two aqueous solutions whose temperatures are different. The vapour molecules are transferred from the heated surface of the aqueous solution through the membrane pores and are concentrated on the cooled side. Evidently, the above process can find practical application (purification of sewage, desalination, concentration of solutions) in those cases where the cost of setting up a temperature gradient on the membrane is low (for example, when waste heat from industrial manufacturing processes is used). In the desalination of an NaCl solution, the flux $J = 3 \times 10^{-2}$ m^3 m^{-2} day^{-1} when the temperature difference between the two sides of a porous polypropylene membrane $\Delta T = 10$ K.[63] One of the advantages of the above process over distillation is the possibility of carrying it out for small temperature differences.

At the present time the membrane distillation method is used successfully not only for the purification of aqueous solutions with involatile solutes (salts, glucose) but also for the separation[69] and concentration[70] of mixtures (water–alcohol mixtures, for example) when all the components are volatile. Under these conditions, together with the traditional versions of the method, new ones are investigated:[69,71,72] membrane distillation with evaporation into a vacuum and membrane distillation with an air gap or "thermal evaporation" through a membrane (a distillate from a 3.4% aqueous NaCl solution has been obtained by this method[71]). In the application of the latest versions, the efficiency of the process increases significantly as a result of the possibility of maintaining a larger temperature difference.

Evidently, the methods indicated make it possible to achieve effective evaporation through porous membranes in contrast to the traditional processes involving evaporation through non-porous polymeric membranes.[35,36,73] However, the traditional method has not lost its importance, especially in connection with the development of the new membrane materials,[74] which retain their separating characteristics in the course of prolonged use. In evaporation through a non-porous membrane, the driving force of the process is the difference between the chemical potentials of the substance on the two sides of the membrane. The permeating substance is removed in the vapour phase by creating a vacuum or together with a stream of inert gas.

Like the membrane gas separation process, this process ensures a high degree of separation in a single stage at a relatively high flow rate through the membrane. It can be used for the separation of mixtures of hydrocarbons and aqueous organic mixtures and also for the dehydration of solutions. The possibility of separating with its aid azeotropic mixtures and mixtures with similar boiling points and solubilities is of greatest value. Since the efficiency of the separation in evaporation through a membrane is determined by the permeability constants, i.e. the products of the diffusion coefficients of the components and their thermodynamic solubilities, it follows that, in order to increase the selectivity of the transport, it is desirable to

introduce into the polymer matrix functional groups capable of interacting strongly with individual components of the mixture to be separated (for example, the introduction of electron-donating groups in the presence of electron-accepting molecules in the mixture[75]). This makes it possible to attain a high process selectivity (including the possibility of separating isomers[75]) by varying the chemical composition and structure of the polymeric selective layer in the composite membranes usually employed for such purposes (together with asymmetric polysulphone membranes). The idea of imprinting[76] (preliminary "tuning") of the polymer matrix with respect to species of a specific type, which increases the degree of selective sorption of the given component, is especially promising in this instance (as in reverse osmosis and gas separation processes).

We may also point to studies of the removal of traces of organic substances (chloroform, trichloroethylene, etc.) from water[77] and of the separation of water–alcohol[78,79] and other aqueous organic mixtures.[80,81] Composite membranes with a selective layer based on polyamidoimides and polyamides are effective for the separation of mixtures of water with acetic acid.[82]

In conclusion of this Section, we shall deal with the interesting phenomenon of the oscillation of the permeability and selectivity with respect to components migrating through a membrane, which has been observed in the evaporation of an aqueous solution containing 10 vol.% of isopropyl alcohol through an asymmetric polyvinyltrimethylsilane (PVTMS) membrane with a thickness of the active diffusion layer of 0.2 μm.[83] The experimental apparatus consisted of a thermostatted cell with a membrane fixed with a vacuum tight joint. On the side of the diffusion layer, the membrane was in contact with the liquid and on the opposite side there was a chamber, evacuated to a residual pressure of 0.1–1.0 Pa, containing a trap cooled with liquid nitrogen. In order to avoid concentration polarisation, the liquid was thoroughly stirred. The flux density was calculated from the mass of the condensed vapour which had passed through the membrane and its composition characterised the selectivity of the membrane. The amount of evaporated liquid constituted only a very small fraction of the initial amount, so that its concentration remained almost constant throughout the experiment. The auto-oscillatory regime was established after an induction period. Alcohol and water evaporated preferentially for the minimum and maximum flux density through the membrane respectively.

According to Ageev and Sekacheva,[83] the mechanism of the observed process is as follows. According to the conditions governing the formation of asymmetric membranes, internal stresses arise in the active PVTMS layer. When the polymer comes into contact with the solution of the alcohol, whose molecules in this case play the role of a surfactant, the strength of the membrane diminishes and the stretching forces due to the internal stresses become capable of causing local disruption of the material with formation of microcracks directed into the interior of the membrane. The surfactant migrates preferentially from the solution into the zone of the microcrack, since it is sorbed by the hydrophobic polymer significantly more effectively than water; this promotes the growth of the microcrack to a micropore characteristic of the porous layer of an asymmetric membrane. The stretching and compressing internal stresses diminish under these conditions. The walls of the micropore formed are "lined" with the surfactant, whose molecules are linked to the non-polar polymer via their hydrophobic component, while the hydrophilic component is oriented towards the body of the pore. The imparting of hydrophilic properties to the surface of the micropore promotes preferential transport of water molecules and an increase in the overall flux as a consequence of the decrease in the activation energy for the transmembrane transport. The increased water concentration in the pores induces the desorption of the surfactant, an increase in surface tension, and hence an increase in cohesive forces. The latter tend to decrease the surface area and the structure becomes continuous again. The collapse of micropores increases the stretching snd hence the compressing internal stresses. The mechanism of mass transfer changes to an activated one, which leads to the preferential migration of the surfactant and the process is repeated. Thus the oscillations in the flux and concentration are accompanied by oscillations in the internal stresses. As the internal stresses relax, the oscillations should decay. The oscillation period is related to the time of structural transitions which is controlled by the kinetics of the sorption and desorption of the surfactant.

The mechanism described can be regarded as the manifestation of the Rebinder effect in polymeric systems. Reversible structural transitions play in this instance the role of a kind of feedback relay issuing commands to include and exclude non-activated flow stages, which in fact leads to the oscillatory regime in the operation of the membrane. The corresponding mathematical procedures, adequately representing the phenomenon described, have been developed.[84]

IV. MEMBRANE CATALYSIS

New possibilities in the application of membrane technology are associated with the development of membrane catalysis – the creation of chemical reactors in which catalytic reactions on the surface or in the bulk of the membrane are combined with the simultaneous controllable supply of the initial reactant (frequently in a specified "activated" form) through the membrane to the reaction zone or the removal of the products from the reaction zone (situation characteristic of native system "bioreactors"). The possibilities of the selective transfer of the reactants or products through the membrane are naturally related to the difference between the permeability constants $\Pi_i = D_i\sigma_i$ for individual components.

Membrane catalysis was first applied in the hydrogenation reactions of hydrocarbons and the reaction of carbon monoxide with hydrogen using membrane catalysts made of palladium and its alloys.[85] The efficiency of such processes is determined by the high permeability of palladium membranes to hydrogen and the formation on their surface of catalytically active adsorbed atomic hydrogen.[86] Not only the catalytic activity of the catalyst but also the flux of hydrogen atoms arising from the bulk of the membrane to the surface (the atoms can carry a small effective charge[87]) depends on the state of the catalyst surface.

The use of membrane catalysts based on palladium and its alloys and also silver and nickel makes it possible to carry out various processes of practical importance with a high degree of efficiency: hydrogenation of acetylene to ethylene, of diene hydrocarbons to olefinic hydrocarbons, and of naphthalene to tetralin, dehydrogenation of alkenes and alkanes, etc. (see the articles contained in the compendium edited by Gryaznov and Klabunovskii[85]).

Membrane catalysts based on transition metal and rare metal oxides exhibiting a higher ionic conductivity at elevated temperatures have begun to be developed in recent years.[85–94] A wide-scale search is being prosecuted at the present time for systems of this kind, used in the first place for the oxidation of organic compounds. Processes involving the oxidation of ethylene[89] and propene[90] to the corresponding epoxides with separation of oxygen and the initial

hydrocarbon on the membrane, which was based on yttrium-stabilised zirconium oxides deposited on a porous silver catalyst, have been carried out. The O^{2-} ions are electrochemically "pumped up" through the solid electrolyte to the catalyst. The selectivity of this process is appreciably higher than in the case where molecular oxygen is supplied to the system (without "pumping" O^{2-}). When scandium- or yttrium-stabilised zirconium oxides were used as the solid electrolyte (membrane), it was possible to achieve also the oxidative dehydrogenation of ethylbenzene.[91] The removal of oxygen from platinum and gold catalysts significantly increased the rate of decomposition of NO.[92] Analogous studies have been carried out on the oxidation of SO_2,[93] the electrochemical oxidation of H_2, CO, and CH_4,[94] etc.

In a number of studies bismuth oxide stabilised by the addition of other oxides was used as the solid electrolyte. Such systems are stable up to 800 °C and exhibit a high conductivity with respect to oxygen ions.[88] In particular, the $(Bi_2O_3)_{0.85}(La_2O_3)_{0.15}$ system has been used not only as a membrane separating atmospheric oxygen from the given reagent (propene in helium) but also as the catalyst of the oxidative dehydrodimerisation of propene.[88] Dissociative adsorption and reduction of molecular oxygen take place on the catalyst surface on the air side; the oxygen ions then migrate to the opposite side of the catalyst membrane where they substitute the ions of the lattice oxygen functioning as the oxidant. The selectivity in the formation of C_3 dimers was greater than in the case where oxygen and propene were supplied from one side; there is no loss of catalytic activity if the rate of the process is limited by the supply of oxygen ions to the reaction surface.

There is no doubt about the likely usefulness of such research, because an increase in the process selectivity frequently plays a decisive role in the assessment of the economic value of a particular method of synthesis of the required product. Further progress will also be associated with the determination of the nature of the catalytic effect in the reactions investigated, the establishment of the role of promoting additives, and the search for methods for additional activation of the catalyst surface.

The nature of the catalytic activiy of solid-phase systems is associated primarily with the specific features of the submicrostructure in the catalyst regions near the surface (characteristic size $\sim$1–10 nm) and with the distortion of the equilibrium configuration of the ligands and hence with the decrease in the symmetry of the local environment of the "active centre", which may be a transition metal ion or group of ions. The symmetry of the crystal field acting on such a centre is then reduced compared with the symmetry typical for an equilibium matrix. As a consequence of this, the parameter Δ of the splitting of the d levels of the transition metal ion in the active centre diminishes, which leads to a rearrangement of the electron sybsystem of the centre and an increase in the fraction of the high-spin state of the ion with an increased catalytic activity.[95]

Apart from structural factors, the chemical activity of the surface layers of the solid-phase matrix can depend significantly on its dynamic properties. In the region of structurally non-equilibrium fragments, the vibrational relaxation time of the local thermal excitations,[96] whose energy exceeds the strain energy of the structurally non-equilibrium matrix, can be significantly retarded. For this reason, catalytic reactions in the course of which thermal energy is locally evolved and there is a possibility of a rearrangement of the matrix, can exert an additional influence on the activated processes occurring in the matrix, including their influence on the kinetics of the catalytic processes proper, and can lead to a non-Arrhenius character of the temperature variation of the rate constants.[11,12,96]

We may also note the role of the conformational mobility of the structural fragments in the region of the active centre, which is responsible for the increase in the entropic factor governing the rate constant for the elementary reaction and increases the probability of the realisation of the "lock and key" relationship in the substrate–active centre system.[97]

All the factors indicated can influence the kinetics of the catalytic reaction on the surface of an inorganic membrane and further experimental studies promoting the elucidation of the role of each of them are therefore essential (the application of Mössbauer spectroscopy for this purpose is extremely effective[95,97]).

One may note yet another factor which is important in the analysis of the catalytic process with participation of oxygen – the presence of different, in the simplest case two, forms of adsorbed oxygen: the weakly chemisorbed (non-reconstructive) form, exhibiting as a rule an increased reactivity,[98,99] and the "deep (reconstructive) form of adsorption" involving stronger binding to the surface.[99] These forms obtain in the adsorption of oxygen both on oxide and metallic catalysts.[100–102] It has been suggested that the formation of these forms is due to adsorption on different active centres of the surface. One cannot rule out also another possibility – the formation of metastable adsorbed forms in adsorption on a single centre (for further details, see Savchenko[99]).

The quantum-chemical nature of the dual character of the adsorption of certain molecules on the same centres can be understood if account is taken, following Balabanov et al.,[103] of the exponential decrease in the intensity of exchange adsorbent–adsorbate interaction (the resonance integral) with increase in the distance of the adsorbate molecule from the catalyst surface. Here the energy of the ground state of the system is characterised by two minima located at different distances from the geometrical surface of the adsorbent and to which correspond bonds with different amounts of ionic character (a more covalent bond corresponds to a minimum at a greater relative distance). The above states of the molecule in adsorption can correspond to these minima: "closely bound" molecules and molecules adsorbed on the "outer surface" of the adsorbent (the weakly chemisorbed form). One of these states should be regarded as metastable. The appearance of a particular form of adsorption depends not only on the thermodynamic characteristics of the system but also on the adsorption conditions.

The formation of two forms of oxygen chemisorbed on metals has been considered.[101,104] As an example, we shall consider the possible reorganisation of the initial electronic structure of the real surface of silicon (an adequate set of experimental data exist for the system) in its electrochemical formation (as a consequence of the adsorption of the oxygen of water[105]). The SiO^- bond formed at the SiO_2–electrolyte interface is shorter (its length is 1.55 Å) than the Si–O–Si bridge bonds, because the extra electron pair at the anionic oxygen atom promotes the overlap of the p_π orbits of oxygen and the unoccupied d_π orbit of silicon, i.e. an increase in the $Si-O^-$ bond order (which is close to two).[106] If the initial dipole moment of the surface is such that the negative pole is directed to the outside (of Mikhailovskii et al.[101]), then such "contact" dipoles (the "strong form of chemisorption") can lead to a decrease in the initial dipolar jump in the vicinity of the $Si-O^-$ dipoles, i.e. the deformation of "holes" in the initial dipolar layer; the electrostatic field of the $Si-O^-$ dipoles can suppress[107] the anodic process, namely it can release positively charged ions into the electrolyte from the surface layers of SiO_2. The possibility of "controlling" the kinetics of chemical reactions on the SiO_2 surface thereby arises, provided that they are associated with the transport of positively charged ions through the

SiO_2–electrolyte interface. Evidently, when the SiO_2 surface is formed in another way (in the absence of anodic polarisation), the $Si–O^-$ dipoles are not formed and a weak chemisorption form of the silicon–oxygen bond, activating the anodic process, arises.

Such opposite (or sharply different) influences of various forms of adsorption of molecules on the kinetics of interphase physicochemical processes occurring with their participation can apparently be regarded as a fairly general phenomenon. In particular, on the basis of the model proposed, ideas can be developed[108] concerning the dependence of the atomic catalytic activity on the amount of ionic character of the metal–oxygen bond and ways of increasing the catalytic activity of the catalysts, including membrane catalysts, can be sought by means of a specific treatment of their surfaces. Here one must bear in mind that additional heating with subsequent quenching can accelerate the activated transitions of molecules between different adsorption states[98] and, in particular, can activate the reactive forms.

Membranes obtained by immobilising fragments of biological systems (enzymes or whole bacterial cells) on inorganic and organic supports or on polymers of different nature have the most unique catalytic properties. The high efficiency of such systems is manifested in organic synthesis[109] and in biotechnology (the preparation of aliphatic acids and glycerol from vegetable oils,[110] the conversion of lactose into glucose and galactose,[110] the manufacture of caffeine,[111] antibiotics,[112] etc.).

Further progress in this direction will undoubtedly be associated with the discovery of methods for the stabilisation of the funcional characteristics of such membrane reactors and with the search for methods of intensifying the processes including the procedure involving a change in the conditions of such processes and in the external influences. The creation of jumps in the electrochemical potentials of different ions on either side of the basic synthetic membrane (of the type of the liposomal membrane), on which enzymes are immobilised, may prove effective. The opposed or unidirectional ionic fluxes ("antiport" or "symport") through the basic membrane arising in this instance alter the local composition of the electrolyte in the vicinity of the immobilised enzymes and thereby influence the rate of formation and the yield of the reaction products. The use of photodependent systems, in particular of bacteriorhodopsin in order to couple processes involving the utilisation of light energy and the enzymic reaction proper, appears promising.[113]

V. CONCLUSION

Evidently the advances in the construction and creation of membrane reactors for the solution of biotechnological problems will be determined by the advances in the study of not only the general principles but also of the details of the functioning of the native systems.

The investigation of ion and molecule transport processes in synthetic membranes can in its turn contribute new ideas to the understanding of the characteristics of the functioning of the native systems. As mentioned above, ionic transport in the channels of perfluorinated sulphonic acid cation-exchange membranes under the conditions of limited ion hydration can model the transport in the channels of biological membranes – the elementary jumps of the ions between adjacent functional groups. Studies on the transport processes in vitreous polymers make it possible to put forward hypotheses concerning the nature of the multilevel character of the conductivity of the native ionic channels. The study of the characteristics of ionic transport in synthetic membranes and of the effects of concentration polarisation in the regions of the electrolytes adjoining the membranes has created a basis for a number of hypotheses[1] about hitherto puzzling effects of the action of electromagnetic radiation on biological systems.[114]

In the analysis of the most complex and artificially nonreproducible biological phenomena, one must bear in mind the idea expressed by Frenkel':[115] "the more complex the system considered, the simpler should be, through necessity, its theoretical description ... a good theory of complex systems should constitute merely a good "caricature" of the systems, exaggerating their most typical properties and deliberately ignoring all other, insignificant properties". However, even in the creation of such "caricatures" a wide variety of models appear, which indicates the impossibility at the present time of identifying any unique fundamental schemes for the realisation of native processes. The clear inadequacy of the experimental data, especially under conditions *in situ*, must then be partly made good by intuitive ideas based on the knowledge of the physical chemistry of a wide variety of non-biological processes (catalytic, electrochemical, and mechanochemical). In the solution of the problems of the construction of bioreactors, the situation is somewhat simplified: there is no need to consider new concepts (apart from the known physicochemical ideas), because one is dealing with the characteristics of the functioning of only the individual units of complex biological systems and the most general problems of living organisms as essentially self-organising and self-developing systems are not involved.

The physical chemistry of the elementary processes in native and synthetic membranes is the same despite the immeasurably greater complexity of biological systems. Future advances in the sciences concerned with the study of transport processes *in vivo* and in artificial membranes, namely the understanding of the principles of the functioning of living systems and new practical achievements in mem-brane technology, can be seen to be engendered by the close inter-relation between such sciences.

Modern Ideas About Diffusion in Polymer Systems

A.E.Chalykh and V.B.Zlobin

The experimental data and theoretical approaches concerning processes involving the diffusion of low-molecular-weight substances in polymer systems are examined. Information is presented about the influence on diffusion of the degree of crystallinity and filling, of the physical state of the diffusion media and the size of spherulites, of the composition and structure of the copolymer macromolecular chains, and of the size of the diffusing molecules. The possibility of using diffusion measurements to investigate the phase and supermolecular structures of polymers, the construction of phase diagrams, and to determine the thermodynamic parameters of the interaction of the components of polymer solutions is demonstrated. The bibliography includes 101 references.

I. INTRODUCTION

Considerable interest has been shown in recent years in the study of diffusion phenomena in polymers. In our country alone, a whole series of monographs[1-10] devoted to the consideration of various aspects of this problem were published between 1980 and 1987. There are several causes of such interest. Firstly, the vigorous development of membrane technology, the need to create effective anticorrosion polymer coatings, and the description of the kinetics of phase decompositions, structure formation, as well as polymerisation at high conversions require detailed information about the mutual diffusion and self-diffusion coefficients and their dependence on concentration, temperature, pressure, and phase and supermolecular structures of polymeric media. Secondly, the development of theoretical concepts, mainly reptation ideas concerning the translational mobility of macromolecules in solutions and melts,[10,11] has stimulated experimental studies on the molecular dynamics of chains[1,10] and the development of new methods for the investigation of the local mobility of end groups, monomeric units, and macromolecules as a whole.[8,9] The development of the theory of free volume and activation zones[7,10] plays an analogous role in the study of the diffusion of low-molecular-weight substances. Thirdly, the creation of effective methods for the investigation of mutual diffusion and self-diffusion, on the one hand, and the development of phenomenological and thermodynamic approaches,[12] on the other, promoted in their turn not only the solution of a whole series of practical problems but also the development of a new trend—the use of diffusion measurements for the study of molecular, phase, thermodynamic, and defect characteristics of polymer materials.[3,6,7,10,13]

Evidently, in a single review it is impossible to consider even in a concise form the present state of research into various aspects of the problem of diffusion phenomena in polymers. We shall therefore confine ourselves to a small group of questions which are fundamentally important both for the prediction of the separating properties of membranes and for the analysis of the characteristics of their formation and the determination of their structural-morphological and phase inhomogeneities.

The review does not discuss the question of the mechanism of the diffusion of low-molecular substances in polymeric media. However, one should bear in mind that, in considering research results, we were guided by the following postulates. The translational thermal movement of small molecules in polymers takes place, regardless of their physical state, as a result of consecutive elementary jumps over distances of the order of the molecular diameter of the diffusing species. The occurrence of an elementary jump requires the presence near the molecule of a microcavity—vacancy, whose volume v^* is greater than the volume of the diffusing molecule V or is comparable to it. A vacancy is formed via a thermofluctuation mechanism as a result of a set of small-scale segmental movements manifested in a β-relaxation process.[1,8,14] The rotation of low-molecular-weight species in polymer media is a faster process than translation and during the period of its "settled life" the molecule has sufficient time to undergo repeated changes in its orientation.[1]

Within the framework of a qualitative picture of the mechanism of diffusion in polymers, two virtually equivalent expressions are used for the diffusion coefficient:

$$D = D_0 \cdot \exp(-E/RT) \quad (1)$$

(the so called activated diffusion model) and

$$D = A_1 \cdot \exp\left(-\gamma \frac{v^*}{v}\right) \text{ or } D = A_2 \cdot \exp\left(-\frac{B}{f}\right) \quad (2)$$

(the free volume model). Here D_0, A_1, and A_2 are the pre-exponential factors, E is the apparent activation energy for diffusion, R is the gas constant, γ and B are constants, and v and f are the free volume and the fraction of the free volume in the diffusion medium. Different expressions for D_0, E, and f can be found in a number of publications.[1,7,10]

II. THE INFLUENCE OF THE NATURE OF LOW-MOLECULAR-WEIGHT SUBSTANCES ON THEIR DIFFUSION IN POLYMERS

It has been shown[1-10] that the rate of mutual diffusion and self-diffusion in polymer systems is determined not only by external factors (temperature, composition, and pressure) but by a whole series of internal parameters, which depend both on the individual characteristics of the system components and on the properties of the system as a whole. We shall enumerate some of them: molecular weight (M_1) and molecular weight distribution (MWD) of the polymer, the monomeric coefficient of friction, the microviscosity, and the thermodynamic non-ideality of the solution. The influence of molecular-chemical parameters of the low-molecular-weight component (diffusant, penetrant, sorbate, and solvent) and, in particular, its M_1 and the dimensions, shape, and structure of its molecules on its diffusion in polymeric media is considered in this Section. We may note that the determination of a quantitative relationship between the molecular characteristics of the diffusant and its diffusion parameters in polymers is one of the main problems of diffusion kinetics, because it opens up extensive possibilities for predicting the selective and protective properties of membranes, coatings, and shells.

1. The Influence of the Molecular Weight of the Diffusant

In considering the influence of the molecular weight of the molecules diffusing in polymers on D, one usually employs the empirical Auerbach equation

$$D = KM_1^{-b} , \qquad (3)$$

where K nd b are constants. This type of relation is common to all cases of translational migration of molecules in viscous media and, from a formal point of view, it follows from hydrodynamic ideas concerning diffusion.[15] Eqn.(3) holds both in low-molecular-weight media, for example in the diffusion of saturated hydrocarbons, alcohols, diols, and triols in benzene, methanol, and water,[2,16] and in the diffusion of macromolecules in infinitely dilute solutions; in the former case, $b = 1$, while in the latter b varies from 1/2 to 1.[15,17]

The diffusion of low-molecular-weight substances in polymeric media of different nature is in most cases described satisfactorily by Eqn.(3). Comparative analysis of the numerical values of the constants of Eqn.(3) for different homologous series, carried out by a number of investigators,[2,7,9] permits the following conclusions. Firstly, Eqn.(3) holds as a rule within the limits of a single homologous series of diffusants, for example, $Y-(CH_2)_n-CH_3$, i.e. when the functional group P is constant and only the number of repeating units n changes. When Y is altered, i.e. on passing from one homologous series to another, the $\lg D - \lg M_1$ plot shifts along the ordinate axis, but b remains almost unchanged. This effect is observed, for example, for polybutadiene, polyethylene, polyisoprene, and polyvinyltrimethylsilane on passing from saturated hydrocarbons to their isomers, alkylbenzenes, and dibasic saturated and aromatic acid esters.[7,9]

Secondly, for polymeric media, we have $b > 0.5$ and its value increases on passing from one polymer to another in proportion to the increase in their molar cohesion energy δ_2 (δ_2 is the solubility parameter[18,19]). The quantity K varies in inverse proportion to the monomeric coefficient of friction of the macromolecules ξ and the molar volume of the diffusing molecule or functional group V_x. The following expressions have been proposed:[7]

$$b = 1.4(\delta_2 - \delta_0) \text{ and } K = kT/V_x\xi,$$

where k is an empirical constant and δ_0 the minimum value of δ_2 for polymers.[18] This makes is possible to estimate the diffusional component of the separation coefficient for the polymer membrane:

$$\alpha = \frac{D_i}{D_j} = \frac{V_{xj}}{V_{xi}}\left(\frac{M_i}{M_j}\right)^{-1.4(\delta_i-\delta_0)} , \qquad (4)$$

where the indices i and j denote diffusants of different nature.

Thirdly, cyclic, halogen-containing, and aromatic compounds with condensed benzene rings constitute a special group among hydrocarbons. For these classes of diffusants, as for azo-dyes and antioxidants,[20,22] the slope of the $\lg D - \lg M_1$ straight line is fairly large ($b \geqslant 4$). Two factors should be noted: (1) the $\lg D - \lg M_1$ straight lines for the above systems intersect on extrapolation with the corresponding straight line for saturated hydrocarbons at the point which corresponds to the molecular weight of methane; (2) when a new repeating group, for example CH_2, is introduced into the molecules of these compounds, they initiate new $\lg D - \lg M_1$ straight lines. The unusual behaviour of diffusants of these classes compared with open-chain hydrocarbons is due to the fact that the introduction of a certain repeating group alters not only M_1 each time but also the cross-section of the diffusing species.

Finally, the displacement of the functional group along the skeleton of the diffusant molecule and the change in its nature for V_x = const. as a rule do not affect D even if one is dealing with the translational diffusion of polar substances in polar polymers.[23,24]

Together with the molecular weight, in the analysis of diffusion processes involving low-molecular-weight substances in polymeric media the geometrical parameters of the diffusing molecules are widely used: the molar volume V, the length l, and the cross-section σ. The above data permit the claim, in our view, that the molecular weight as well as other indirect characteristics (the critical volume V_{cr}, the constant b_W in the van der Waals' equation, and the viscosities of liquids) play the role of independent arguments in the equation for the rate of transport only because they characterise the geometry and structure of the diffusing molecules. For example, the relation between D and M_1 for the homologous series of alkanes is determined by the fact that M_1 is directly related to the length of the molecules; in the case of cyclic hydrocarbons, the variation of M_1 characterises to a first approximation the variation of the cross-section of the diffusing molecules. The role of the geometrical constants of molecules diffusing in polymeric media has been examined in a number of studies.[24-30]

The free volume model is the most convenient for the analysis of the influence of molecular volume on the diffusion of molecules in polymers. It is natural to suppose that the critical volume of the vacancies is proportional to the molar volume of the diffusing molecule: $v^* \cong aV$, where a is a constant. Evidently a similar relation can be formulated also for V_{cr} and b_W. On substituting these relations in Eqn.(2), we obtain the expression[7]

$$\ln D = \ln A - \gamma \frac{a}{v} V \qquad (5)$$

The activated diffusion model, where it is assumed that $E = E_0 + bV$, leads to an analogous result.[6,10,31]

Analysis of the experimental data within the framework of this approach showed[3,7,9,20,31] that, for the majority of systems where the shape of the diffusant molecules is close to spherical, a satisfactory agreement with theoretical predictions is observed. The experimental points corresponding to different representatives of homologous,

genetic, and, what is especially important, isolytic series are disposed in the vicinity of $\ln D - V$ straight lines whose slope is determined by the average free volume of the polymeric diffusion medium.

However, in the case of significantly asymmetric diffusant molecules, even for members of a single homologous series, Eqn.(5) is valid only to a first approximation. This is associated with the fact that, in the derivation of Eqn.(5), no account was taken of the specific features of the structure of both the diffusant molecules and the vacancies in the polymeric medium: they were all represented approximately by effective spheres, in conformity with the solid sphere model. On the other hand, it has been noted[7] that a is a function of the ratio σ/l; the smaller a is, the smaller is the ratio σ/l. Analysis of these data permitted[7] a number of conclusions concerning the character of the orientation of molecules in polymeric media relative to the direction of the diffusion flux. It was established that the transverse dimensions of the vacancies for linear and bulky molecules are significantly smaller than their length and effective cross-section (solid sphere) and are identical—for members of the given homologous series—with the dimensions of the largest functional group. For all the members of a single homologous series, the cross-sections of the vacancies remain unchanged. Under these conditions, they depend only slightly on the nature of the polymeric medium in which the diffusion process takes place.

From this it follows that molecules with a complex structure are oriented in the diffusion flux relative to the concentration gradient in such a way that they suffer the least resistance from the polymer matrix.

2. Activation Energy for Diffusion and Molecular Size

Depending on the structure and shape of the diffusant molecules, they can be divided into four groups: spherical, non-spherical, bulky, and linear.

Spherical molecules. This group includes, for example, the inert gas molecules. Analysis of experimental data has shown that the number of studies of diffusion in the same polymers of four and more types of spherical molecules is small.[31,32] For these diffusants, E increases with increase in the diameter d of the molecules (Fig.1). On passing from one polymer to another, the character of the dependence of E and d remains the same and only its steepness changes. Thus the dependence of E and d for polydimethylsiloxane can be fitted by the power equation $E \propto d^n$, where $n = 1$; for *cis*-polyisoprene and polyethylene $n = 2$ and for poly(vinyl acetate), poly(vinyl chloride), and poly(ethyl methacrylate) $n = 3$. Thus the power exponent increases with increase in the molar energy of cohesion of the polymeric medium. The unusual behaviour of E for diffusion in polar and non-polar polymers at temperatures above the glass point is striking. For the diffusion of He and Me in polyisoprene and polyethylene, E was found to be greater than for the diffusion in poly(vinyl acetate) and poly(ethyl methacrylate), while the opposite effect was observed for Ar, Kr, and Xe.

The experimental relations between E and d for the simplest diffusants cannot be fully accounted for within the framework of the Meers, Brandt, Pola–Di Binedetto, and Pace–Datyner models,[10,33,34] although they all correctly predict the qualitative picture of the changes in the activation energy for diffusion as a function of the molecular diameter, the size of the macromolecular segment, and the molar energy of cohesion of the polymeric medium. It has been shown[7,35] that a balanced approach requires not only the introduction of two different expressions for the energy formation of vacancies in the diffusion medium ($E_g \propto X^2$ and $E_g \propto X^3$, where X is the diameter of the vacancies) but also the allowance for the character of the distribution of vacancies with respect to size. Only then is it possible to explain also the anomalies in the variation of E for $d \leqslant 2.8$ Å and the dependence of E on the previous thermal history of polymer membranes.[36]

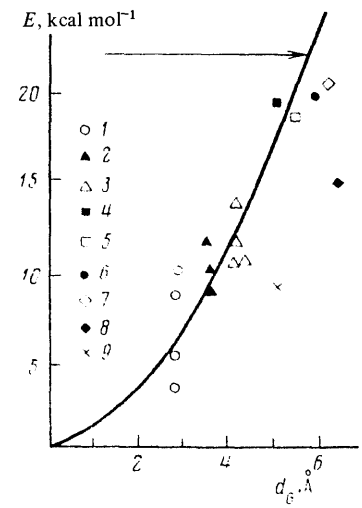

Figure 1. Dependence of the activation energy for the diffusion of gases in polyethylene on their gas-kinetic diameter:[7] 1) He; 2) Ne; 3) Ar; 4) Kr; 5) Rn; 6) CCl_4; 7) $C(CH_3)_4$; 8) SF_6; 9) CH_4. The continuous curve was calculated by the equation $E \propto d^n$, where $n = 2$; the arrow denotes the activation energy for the viscous flow of the polyethylene melt.

Non-spherical molecules. The molecules of simple gases can be included in this classes of diffusants: H_2, N_2, O_2, CO, CO_2 etc. By analogy with the inert gases, the gas-kinetic diameter d_G is usually employed as the main parameter characterising their dimensions. However, the behaviour of these molecules in diffusion processes in gaseous and condensed media is fundamentally different. Non-spherical molecules in the gas phase exist most of the time in a state of "free motion" and they interact with one another during a relatively short fraction of the time. During their movement, the molecules rotate freely, which leads to the absence of a correlation and the mutual orientation of the molecules during subsequent collisions.

In a polymeric phase the position is different. The dissolved gas molecule vibrates most of the time in a cell[1] until a vacancy of specific size appears next to it. For a spherical molecule, it is immaterial on which side a vacancy appears provided only that the relation $X > d$ holds. The situation is different for non-spherical molecules. Their shape can be represented approximately by an ellipsoid of rotation[37] with longitudinal ($d_{\|}$) and transverse ($d_{\perp}$) dimensions. Evidently, since $d_{\|} > d_{\perp}$, the probability of the appearance of

a vacancy with $X \geqslant d_{\perp}$ is greater than that of the appearance of a vacancy with $X \geqslant d_{||}$. Therefore the gas-kinetic diameters of these molecules are always greater than the diameters of the vacancies.[35,37]

The following mechanism has been proposed[32,37] for the determination of the effective sizes of non-spherical molecules diffusing in polymers. It is based on the experimental graphical dependence of E on d for the diffusion of inert gases in the given polymer. The effective diameter d_{eff} of any molecule, including a non-spherical molecule, can be determined from this relation and the activation energy for the diffusion of the diffusant investigated, which is also found experimentally. It has been shown[7] that d_{eff} for diffusing molecules changes somewhat (up to 8%) both on passing from one polymer to another and when the conditions in the preparation of the same polymer are altered. Thus, for this group of diffusants one can use in the calculation of E the power relations $E \propto d^n$, which have been obtained for spherical test molecules, but for d one must use not the gas-kinetic but an effective molecular diameter.

Bulky molecules. The CH_4, CCl_4, $C(CH_3)_4$, C_6Cl_6, SF_6, etc. molecules belong to this class of diffusants. If their size is estimated from d_6 or from the structural diameter, than the values of E for such substances should not fit on the relation between E and d obtained for the inert gases (Fig.1). The values of d_{eff} found by the above method for these molecules are always smaller than d_G and for bulky molecules the discrepancies are greater than in the case of non-spherical molecules. Graphical analysis[37] has shown that the minimum dimensions of the molecules which determine their motion in the polymer matrix are similar for all the substances enumerated.

A characteristic feature of bulky molecules is their variable diameter along the threefold symmetry axis in the tetrahedron [CH_4, CCl_4, $C(CH_3)_4$] and along the fourfold axis in the octahedron (SF_6). Thus in methane the apical atom has a diameter of 2.34 Å, while the diameter of the plane of the base of the pyramid is 4.4 Å. For sulphur hexafluoride, these values are 1.86 and 6.4 Å. Comparison of these quantities shows that the diameters of the apical atoms are always smaller than the values of d_G, which are in their turn smaller than the molecular sizes in other cross-sections. It follows from the foregoing that vacancies whose critical diameters are smaller than d_G are responsible for the migration of bulky molecules in polymeric media.

Linear and chain molecules. For diffusants of this class, the parameter characterising the molecular size used traditionally has been either their molecular weight, or the number of repeating groups, or the number of carbon atoms in the chains n_C. For these systems, the dependence of E on M_1 can be fitted by the semi-empirical expression

$$E = A + B \lg M_1 , \qquad (6)$$

where A and B are empirical constants. The method described above has been used[7,37] to estimate the sizes of vacancies through which the elementary step in the translational movement of oligomeric and polymeric molecules takes place. Comparison of the relations between E and n_C for different members of the homologous series of olefins, including polyethylene melts,[2,10] with the corresponding relation between E and d for the molecules of ideal gases shows that the size of the vacancy changes from 3.4 to 5.6 Å on passing from methane to a polyethylene macromolecule with $M \cong 10^5$. Assuming that the movement of linear molecules takes place via the reptation mechanism, it is easy to demonstrate that 4–5 monomeric units participate in the formation of the reptation loop of the polyolefin.

Theoretical studies on the activated model of diffusion in polymers have been directed mainly towards the development of the ideas of Brandt and Meers. At the present time the most effective molecular theory of diffusion is the Pace–Datyner theory,[33,34] which made it possible to obtain analytical expressions for D_0 and E in the Arrhenius equation on the basis of information about the macromolecular structure, crystallographic data, intermolecular interaction parameters, and the molecular diameter. One should also note a theoretical study[35,37] in which an attempt was made to take into account the contribution to E by the size distribution of the free volume vacancies of the polymeric medium. In these investigations, expressions were obtained for the average size of the free volume vacancy and the average size of the vacancy participating in the elementary diffusion step; the form of the relation between E and d was discovered and a formula was proposed for the determination of the volume of activation. Presumably these investigations permit the solution also of the converse problem—the determination of the size distribution of the free volume vacancies in the polymer membrane from data for the diffusion of the inert gases.

III. THE INFLUENCE OF THE NATURE OF THE HIGH-MOLECULAR-WEIGHT COMPONENT

1. The Influence of the Molecular Weight, the Molecular Weight Distribution, and the Three-dimensional Cross-linking

The influence of the molecular weight (MW) of the polymers on their permeability to gases and vapour has been most fully studied.[20] It has been found that a change in the MW of the macromolecules in the diffusion medium from 1×10^4 to 1×10^6 does not affect the rate of transport of gases and vapours. A small change in the permeability of polyisobutylene to moisture (from 10.7×10^{-13} to 3.3×10^{-13} mol cm^{-2} cm^{-1} h^{-1}) has been noted after an increase in its MW from 4.5×10^3 to 25×10^3.[38] The influence of the MW of polymers on the diffusion of monomers, solvents, and oligomers has been studied in less detail.

Most of the experimental data obtained for such systems refer to infinitely dilute solutions of polymers.[10,15] For this range of concentrations in binary systems, the mutual diffusion coefficient D_{21}, characterising the translational mobility of macromolecules in solvents, varies with the MW of the polymer (M_2) in accordance with the equation

$$D_{21} = K M_2^{-b} , \qquad (7)$$

where K and b are constants. Individual investigations have been carried out in the field of concentrated solutions.[2,7] With increase in the MW of the polymer, the diffusion coefficients in these solutions either remain unchanged, as, for example, in the benzene–polycarbonate, benzene–polystyrene, and octadecane–*cis*-polyisoprene systems or decrease, tending asymptotically to their limiting values for a certain M_2', as has been observed, for example, in the dioctyl phthalate–poly(vinyl chloride) ($M_2' = 4 \times 10^4$), cyclohexanone–polyhydroxyesters ($M_2' = 1.5 \times 10^4$), and hexadecane–polyethylene ($M_2' = 5 \times 10^3$) systems. The polystyrene–cyclohexanol, polybutadiene–diheptyl phthalate, and polyhydroxyesters–dibutyl

phthalate systems, for which the mutual diffusion coefficient in the middle range of solution compositions increases with increase in the MW of the polymer, are exceptions.

In the middle 1970s, the interest in this problem grew again in connection with the creation of telomers and oligomers with a narrow MWD and the development of methods permitting the measurement of the partial mobilities of solution components.[10,11] Interesting results were obtained for the influence of the MW of the polymeric component on the self-diffusion (D_1^*) and mutual diffusion (D_V) of the solvents and empirical relations linking D_V and D_1^* to the MW of the polymers were proposed;

$$\lg D_V = \lg D_{V,\infty} + A/M_2 \text{ and } \lg D_1^* = \lg D_{1,\infty}^* + B/M_2 , \quad (8)$$

where A and B are empirical constants and $D_{i,\infty}$ are the diffusion coefficients at $M_2 \to \infty$. It was shown that the anomalies described above in the variation of the diffusion coefficients are associated with the thermodynamic non-ideality of the systems and the remoteness of their state from the critical state.[2-10]

It has been shown[2,7] that the problem of the influence of the MW of the macromolecules on the diffusion properties of polymer matrices and membranes can be approached from the standpoints of the free volume theory, because the fraction of the free volume of the diffusion medium f depends on M_2 as a consequence of the variation in the number of end groups per unit volume. It follows from the statistical theory of polymers and the results of numerical modelling that the Brownian movement of the end groups of linear macromolecules is more intense than the thermal movement of the units of the main chain. This effect has been called the "hot ends" effect.[11,39] Semiquantitative estimates have shown that the end groups of macromolecules possess kinetic energy which is greater by 20–25% than that of the internal groups.[40] Frenkel' suggested that the mobility of the end groups be characterised by the diffusion coefficient of the monomer.[41] Direct estimates of the rotational and translational mobilities of the chain units and end groups of macromolecules in the condensed phase and in solution have been made.[1,42]

All these factors make it possible to attribute to the end groups of the macromolecules a local free volume different from the local free volume of the main chain units and the monomer. The average free volume of the diffusion medium made up of such molecules can then be represented by the sum of the local free volumes. In accordance with this hypothesis, the following relations have been obtained for polymer melts:

$$\ln \frac{D}{D_\infty} = \frac{B}{f_\infty} \cdot \frac{aM_2^{-1}}{f_\infty + aM_2^{-1}} , \quad (9)$$

$$\lg D \simeq \lg D_\infty + A/M_2 . \quad (10)$$

The last equation holds for $M_2 > 10^3$. Here a and A are constants and f_∞ is the fraction of the free volume of the polymer membrane at $M_2 \to \infty$. It can be seen that Eqn.(10) agrees fully with the empirical expressions (8). These equations have been used in calculations from experimental data of the numerical values of the free volumes corresponding to the end groups (f_e) and the monomeric units (f_{un}). It has been shown that $f_{un} < f_e < f_1$, where f_1 is the free volume per unit of monomer. Under these conditions, f_e is greater by 15–30% than f_{un}. The quantity f_e can be regulated by varying the chemical nature of the functional end group.[43]

In conclusion of this Section we may note that, firstly, the diffusion coefficients of low-molecular-weight substances in polymer glasses also decrease with increase in the MW of the macromolecules. However, this dependence is less pronounced, is observed in the region of low molecular weights, and is manifested against the background of a considerable scatter of experimental points.[44] Subsequently, direct experiment demonstrated[10,44] that the rates of diffusion of gases and solvents in polymers are determined by their number-average MW in conformity with the conclusions which follow from the free volume theory.

The question of the influence of the MW of macromolecules on the diffusion properties of polymeric media is in its theoretical aspect part of the more general problem of the contribution of the end units of macromolecules to the kinetic properties of polymeric bodies. One must distinguish two extreme cases: in the first, the free or "hot" ends of the chains are of decisive importance, while in the second fixed or "cold" ends are important. The first case obtains in systems with linear macromolecules and the second in systems incorporating three-dimensionally cross-linked structures. Whereas the free ends of the chains exert a perturbing influence on the conformational state of the segments of macromolecules, increasing their mobility and free volume, the fixed chain ends have the opposite effect.

Experimental studies on the molecular movements and the rates of diffusion of low-molecular-weight substances in cross-linked polymers have demonstrated unambiguously the retarding effect of the modes of the three-dimensional network on the mobility of the structural elements of polymer chains.[8,11,31,45] Evidently, for a quantitative description of the effect of cross-links on the parameters of polymer matrices and membranes, one can use the ideas concerning the local free volumes of the units and modes. Within the framework of this approach, the following expressions have been obtained:

$$\ln D = \ln D_\infty - \frac{B}{f_\infty} \cdot \frac{a' M_n^{-1}}{f_\infty - a' M_n^{-1}} , \quad (11)$$

$$\ln D = \ln D_\infty - \frac{B a'}{f_\infty^2} \cdot M_n^{-1} . \quad (12)$$

Eqn.(12) holds for $M_n \geqslant 8 \times 10^2$. Here B and a' are constants and M_n is the molecular weight between the nodes of the three-dimensional network. Eqn.(12) agrees with the empirical relation between D and M_n.[20,31] One should bear in mind that Eqn.(12) is valid only for sufficiently high M_n, typical for vulcanised elastomers, whereas Eqn.(11) is valid over the entire range of densities of three-dimensional networks, up to the values of M_n characteristic of resites, epoxides, and polyesters. Eqn.(11) can be extended also to the vitreous and crystalline states of three-dimensionally cross-linked polymers. The rate of diffusion can be related with the aid of Eqn.(11) also to the number of nodes in the three-dimensional network, the molecular parameters of the cross-linking agent, the content of the hardening agent, the radiation dose, and the kinetics of the process leading to the formation of networks.[7,20,46,47]

2. Diffusion in Static Copolymers and Polymer–Solvent 1–Solvent 2 Systems

The introduction into the polymer chain of units differing from the elements of the main chain in chemical composition, structure, and stereochemical parameters imposes a definite imprint on the molecular movement within the polymer systems, altering the rate of diffusion in them. In terms of the character of their behaviour, any polymer chains whose monomeric units differ in some way from one another can be included in the class of copolymers. However, the diffusion properties of copolymers cannot be described in a unique

fashion. This is because the properties of copolymers are determined not only by the concentration of units of different types but also by the character of their distribution along the chain, the stereochemical interaction, the phase structure of the system, and the nature of the solvent. It is therefore always essential to take into account the specific features of the real system investigated.

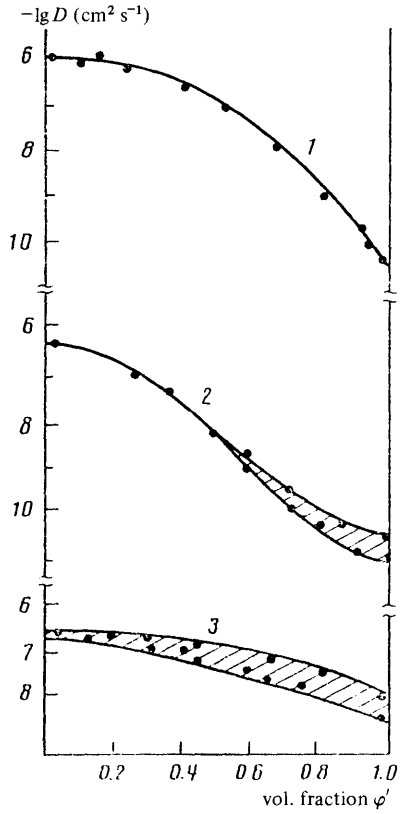

Figure 2. Dependence of the diffusion coefficients of low-molecular-weight substances on the composition of statistical copolymers: 1) styrene–butadiene copolymer in dibutyl sebacate (70 °C); 2) styrene–butadiene copolymer in benzene (25 °C); 3) vinyl chloride–vinyl acetate copolymer in water (20 °C).[9,31,92]

In this Section we shall consider the diffusion properties of single-phase amorphous statistical copolymers. Fig.2 presents typical dependences of the diffusion coefficients of low-molecular-weight substances on the composition of the copolymers. It can be seen that, for different states of the statistical copolymer, three types of dependence of D on φ' obtain (φ' is the volume fraction of the homopolymer units in the chain). If $T_{exp} > T_g$ (T_{exp} is the experimental temperature) for any composition of the copolymer, including homopolymers, then the decrease of D with increased presence in the chain of units which increase its kinetic rigidity is as a rule described by a smooth convex curve (curve *1* in Fig.2). The diffusion coefficients are in this case extrapolated from the average range of compositions of the copolymers to values corresponding to D in the homopolymers. If the diffusion medium is in the vitreous state ($T_{exp} < T_g$) for any composition of the copolymer, including homopolymers, then the overall tendency in the variation of D, mentioned above, persists but the dependence becomes less pronounced (curve *3* in Fig.2). This is caused by the insignificant change in D on passing from one homopolymer to another combined with the significant dependence of the absolute values of D on the previous thermal history of the specimens.[20,31]

The third type of dependence (curve *2* in Fig.2) is characteristic of systems in which the transition from the highly elastic to the vitreous state occurs for a definite composition of the copolymer ($T_g' < T_{exp} < T_g''$, where T_g' and T_g'' are the glass points of the homopolymers). In these systems, the dependence of D on φ' acquires an S-shaped character and the diffusion coefficients obtained by extrapolation from the range of compositions corresponding to the highly elastic state to the region of the vitreous state (D_{exp}) do not as a rule agree with the experimental values of D for the homopolymers. It has been suggested[46–48] that the ratio D_{exp}/D_{ext} be used as the coefficient of the structural non-equilibrium of the given copolymer or homopolymer.

According to Reitlinger's classification,[20] the polymer–solvent 1–solvent 2 systems belong to the class of polymer–liquid–gas systems. The inclusion of these systems in the group of statistical polymers may give rise to surprise. There are two reasons for such inclusion: firstly, the identity of the phase states of diffusion media of this type; secondly, the qualitatively identical effects of the copolymer units and the molecules of the dissolved liquids on the segmental mobility of the macromolecules and hence on the diffusion properties of the membranes.

The polymer–solvent 1–solvent 2 systems include two groups of three-component systems differing solely in the character of the distribution of one of the components in the polymer matrix. The first (and main) group comprises systems in which the polymer membrane is in contact with a mixture of two or more solvents which penetrate it simultaneously. In systems of the second group (plasticised and modified polymers, moistened polymers, and polymers saturated with the vapours of monomers, solvents, etc.[31,49]), one of the components was distributed in the membrane beforehand while the other participates in the transport process. Here it is significant that the concentration of the first component is kept constant throughout the process. Despite the different form of treatment of the mass transfer process kinetics in these systems, the self-diffusion coefficients of the low-molecular-weight substances in these media can be analysed within the framework of a single approach.[7,53]

Although there have been numerous experimental or, more precisely, technological studies of the permeability of polymer membranes to various mixtures of low-molecular-weight substances,[49,50] few investigations have been devoted to the kinetics of the transport and diffusion of individual components. Nevertheless, one can already claim unambiguously that the variation of the ratio of the components in the media in contact with the polymer membrane has little effect in the course of the process: the same sequence of partial fluxes is retained as for the individual components, but their absolute magnitudes and the diffusion coefficients found from the delay time for each partial flux (D_θ) change somewhat.[51] Under these conditions, a feature common to all mixtures is observed: the greater the content in the solution of the solvent diffusing at the lowest rate, the smaller the difference between the partial fluxes D_θ of the mixture components; the overall flux of the mixture as a whole has as a rule a value intermediate between the partial fluxes

of the individual components; the overall flux usually attains a stationary value when stationary transport of the component diffusion at the lowest rate is established.

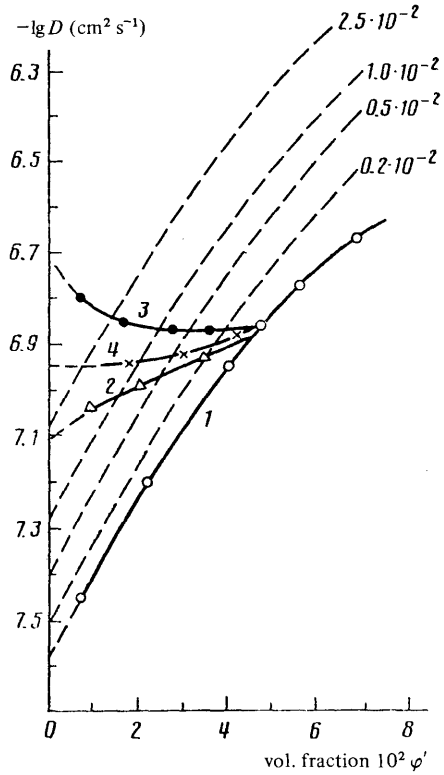

Figure 3. Dependence of the individual (curve *1*) and partial (curves *2*–*4*) diffusion coefficients of hexane in polyethylene on its content in various systems: 1) polyethylene–hexane; 2) polyethylene–hexane–pentachloroethane; 3) polyethylene–hexane–ethyl acetate; 4) polyethylene–hexane–cyclohexane. Dashed curves—theoretical relations calculated by Eqn.(14) for different contents of pentachloroethane in polyethylene (the numerals opposite the curves denote the concentrations φ'' in volume fractions).

The sequence of the permeation of the solvents through membranes affects the diffusion coefficients found along different sections of the non-stationary stage of the process. The variation of D_θ with the time of observation, described by Ferry,[51] is related to the mutual influence of the solvents in the course of their joint permeation. Special attention should be paid to the values of D_θ calculated in the initial stages of the permeation of the diffusants. Comparison of the partial flux D_θ of the solvent which diffuses first with its coefficient D_s calculated from the results of sorption measurements demonstrates their satisfactory agreement, while D_θ for the solvent diffusing after the first is higher, i.e. the effect involving the mutual plasticisation of the polymer membrane in the transport process takes place. Such effects are naturally not observed in the study of the kinetics of permeation and sorption (swelling) in systems of the second group.[48]

In the study of the characteristics of the diffusion and permeability of polymer membranes with respect to mixtures of low-molecular-weight substances, the composition of the solutions of the low-molecular-weight substances is usually employed as an independent argument. In our view, the use of the solubilities of the components in the polymeric medium as the independent variables is more promising for the analysis of the transport processes of multicomponent systems through polymer membranes. In this case, the experimental diffusion coefficients can be related to the concentration dependence of D in the polymer–diffusant binary system. Indeed, the partial diffusion coefficients of hexane diffusing from mixtures with different solvents have as a rule larger absolute values than in the polyethylene–hexane binary system (curve *1* in Fig.3). With increase in the concentration of hexane in the polymer (this corresponds to the increase in its content in the solution in contact), its partial diffusion coefficient can both gradually increase (curve *2* in Fig.3) and decrease (curve *3*) or can remain unchanged (curve *4* in Fig.3. However, and this is the most important factor, in all cases the partial concentration variations of D for this solvent approach the corresponding variations for the same component in the binary system. Extrapolation of the variation of the partial values of D to $\varphi_1 = 0$ makes it possible to find the diffusion coefficients of the given component in the matrix containing the maximum possible amount of the sorbed solvent 2. These values of D are specific to each polymer–solvent 2 system. As a rule, $D'' > D'$, where D' is the diffusion coefficient of solvent 1 in the polymer for $\varphi_1 = 0$ and D'' is the partial diffusion coefficient of the same solvent in the polymer saturated with solvent 2. The ratio of these diffusion coefficients can be used to estimate the plasticising effect undergone by the polymer matrix under the conditions of the simultaneous diffusion in the latter of the two solvents.

For three-component systems of the second group, analogous relations have been found experimentally. In this case, when a plasticising component is introduced into the polymer, the value of D for low-molecular-weight substances increases with increasing plasticiser concentration, as happens when copolymer units are introduced into the macromolecular chain. Only in isolated instances where the plasticiser reduces the segmental mobility, i.e. behaves as an antiplasticiser, do the diffusion coefficients of gases, water, and solvents diminish somewhat under these conditions.[52]

In order to interpret the results and to predict the diffusion properties of copolymers plasticised in three-component systems, one may use the expression

$$\ln\frac{D}{D'} = \frac{B}{f'}\left(\frac{\beta\varphi''}{f'+\beta\varphi''}\right) , \qquad (13)$$

$$\ln\frac{D}{D'} = \frac{B}{f'}\left(\frac{\beta_1\varphi_1''+\beta_2\varphi_2''}{f'+\beta_1\varphi_1''+\beta_2\varphi_2''}\right) , \qquad (14)$$

which follow from the classical free volume theory.[7] In Eqn.(13), D' is the diffusion coefficient of the test component in the homopolymer, f' its free volume fraction, φ'' the volume fraction of either the copolymer units or the plasticiser, $\beta = f' - f''$, and f'' is the free volume fraction either in the second homopolymer or in the plasticiser. In Eqn.(14), D' is the partial diffusion coefficient of the test component in the polymer, f' its free volume fraction, $\beta_1 = f_1'' - f'$, and $\beta_2 = f_2'' - f'$, where f_i'' is the free volume fraction in each solvent, φ_i'' the volume fraction of the corresponding solvent, and B are constants. The results of the calculation by Eqn.(14) for the polyethylene–hexane–pentachloroethane system are presented in Fig.3 in the form of dashed lines (each dashed line corresponds to a specific value of D for pentachloroethane). It can be seen that the

experimental curve for the partial diffusion coefficients (curve *2*) intersects the theoretical relation at certain points corresponding to the average values of D for the given composition of the polymer–solvent 1–solvent 2 system. In recent years, this method has been developed further.[53]

3. Diffusion in Polymeric Glasses

It has been shown in a whole series of experimental studies[3,5,6,9] that, when $T < T_g$, the mass transfer of low-molecular-weight substances in polymeric diffusion media cannot be described using solely the molecular characteristics of the macromolecules. The activation energy for the diffusion of low-molecular-weight substances in polymeric glasses is as a rule lower than in the highly elastic state of the same medium. Admittedly, for certain diffusants, usually helium and hydrogen, these differences do not exist. For the same diffusant, the quantity E in the polymeric glass is a function of the excess free volume: the greater the latter, the smaller the value of E. A linear realation is observed between the diffusion coefficients of the low-molecular-weight substances and the densities of the glasses ρ and the latter vary comparatively little; for example, $\lg D = 8.2 - 14.5\rho$ ($1.19 \leqslant \rho \leqslant 1.23$ g cm^{-3}) for the diffusion coefficients of water in hardened epoxide resins.[46]

All these facts led many investigators[55–58] to turn to a more detailed consideration of the structure of the polymeric glass and to the study of the characteristics of mass transfer at $T < T_g$.

In our view, there are no fundamental differences between the mechanisms of the diffusion of fairly large molecules of low-molecular-weight substances in polymeric media at temperatures below and above T_g: in both cases the vibration of the diffusing molecule takes place as a result of the appearance near it of a microcavity vacancy of the appropriate size. The number of vacancies per unit volume depends in the general case on temperature, the packing density of the macromolecules, pressure, the content of modifying agents, etc. Thus one can assume that the principal relation (2) of the free volume theory is valid also for polymeric glasses.

According to this approach, the difference between the states of the polymer matrix above and below T_g is associated with the fact that the thermal movement of the structural elements of the macromolecule, responsible for the diffusional migration of the low-molecular-weight substances, takes place under these conditions for different supermolecular organisations of the medium. At $T > T_g$, the diffusion process takes place in a medium with an equilibrium or nearly equilibrium packing of the chains ($f = f_t$, where f_t is the free volume fraction associated with the thermal expansion of the matrix), whereas at $T < T_g$ the process takes place under the conditions of a non-equilibrium albeit quasi-stationary structural organisation of the matrix, for which $f > f_t$. It is natural to assume that in the latter case $f = f_t + f_v$, where f_v is the free volume fraction association with the non-equilibrium nature of the matrix, the so called excess free volume. Evidently, f_v is the "frozen" free volume determined by the non-equilibrium nature of the structure and the relaxation nature of the vitrification process. It is determined by the previous history of the specimen, whereas f_t is determined by its chemical nature, composition, and external conditions. One may say that f_t is the level of defectiveness of the structure against the background of which the effect of f_v is manifested. The fact that f_t plays a definite role also at $T < T_g$ is indicated by relaxation spectrometric data.[54,60,61] Since the diffusion coefficients of low-molecular-weight substances in polymers are an integral characteristic of the mobility of the macromolecular fragments, the nature of these elements and their concentration must inevitably influence the mass transfer process also at $T < T_g$. At any rate, a whole series of properties of polymeric glasses exhibit a dependence on the molecular characteristics of the system, which although weak is nevertheless explicit.[61]

Unfortunately, neither the vacancy solution model, nor the Simha–Boyer model, nor the results of experiments on the annihilation of positrons[62,63] permit an unambiguous differentiation of the contributions to f by f_t and f_v. Attention is therefore concentrated nowadays on the search for direct correlations between the diffusion permeability constants, on the one hand, and the results of structural studies on the other. The equation

$$\ln \frac{D}{D_s} = \frac{B}{f_s}\left[\frac{(1-f_s)(1-\rho/\rho_s)}{(1-f_s)\rho/\rho_s - 1}\right] \qquad (15)$$

has been obtained[7,46] within the framework of the free volume theory. For a narrow range of variation of the density of the polymer matrix, it can be put into the simple form

$$\ln D = \alpha - \gamma\rho \qquad (16)$$

It relates the diffusion parameters to an integral structural characteristic of the polymer ρ, namely its density, and agrees well with experimental data. In Eqns.(15) and (16), α and γ are constants and ρ_s, f_s, and D_s are respectively the density, the free volume, and the diffusion coefficient of the polymer in a selected standard state (for example, at T_g).

The experimental data accumulated to date on the diffusion absorption of gases and solvents in polymeric glasses and the permeability to these substances are consistent with the qualitative structure of the model. The vacancies constituting the free volume are combined into vacancy capillaries with a variable radius and a thermally fluctuating wall, i.e. one which constantly alters the "frozen" average size of the vacancy capillary. The size of the vacancy capillary (its average radius and the radii at the narrowest and widest points) is determined by the parameters of the vacancies at $T > T_g$.[33,34] The thermal mobility of the macromolecular fragments at $T < T_g$ (i.e. f_t) is localised in the outer layers of the capillary and is independent of its size. Hence it follows, for example, that E and the character of the mass transfer process depend on the ratio of the average vacancy diameter $\bar{X}$ and the diffusant diameter d. Evidently, the greater the value of $\bar{X}$, the smaller that of E. For certain values of $\bar{X}$, the quantity E, measured at a temperature above T_g, is equal to the activation energy for diffusion in the vitreous state. For $\bar{X} \gg d$, there is a possibility of a non-activated mechanism of gas permeability.[20,31] If this model is adopted, then, in order to create highly productive and selective membranes, one must use polymers whose macromolecules are separated from one another by a fairly large distance and which have large groups characterised by a high effective modulus of the bending of the chain and which also contain mobile fragments. An indirect confirmation of this model is probably provided by data for gas separation on polytrimethylsilyl-propyne.[64]

IV. DIFFUSION IN HETEROGENEOUS SYSTEMS

A fairly large group of polymer systems belongs to the class of heterogeneous diffusion media: crystalline homopolymers and copolymers, polymer blends and block copolymers, filled and gas-filled polymers, multilayer and combined film materials, protective

coatings, and membranes, i.e. one-component or multicomponent systems which exist under the experimental conditions in two-phase or multiphase states. The study of diffusion processes in these systems is prosecuted nowadays in three directions. In the first place, a detailed study is made of translational diffusion processes involving the components or macromolecular fragments responsible for the formation of the phase structure of these media. This aspect of the problem has been analysed in detail in relation to a whole series of binary polymer systems: reactive oligomer–elastomer systems,[65,66] gas-filled elastomers and plastics,[7,67] the formation of a porous structure,[68] and the growth of the particles of the disperse phase in the metastable and labile regions of the phase diagram.[69,70] The second direction is associated with the study of the role of diffusion processes in the formation of transitional zones in multilayer systems.[71] The third direction combines studies on the diffusion properties of heterogeneous polymeric media, mainly in relation to gases, water, organic solvents, electrolytes, monomers, etc.

Despite the fact that the first two directions are closely related to mass-exchange processes between individual phases in heterogeneous systems, this relation is mainly terminological. To a large extent, they are associated with mutual diffusion and self-diffusion processes in various zones of the phase diagram, on the one hand, and with the phase decomposition kinetics, on the other. We shall therefore deal here only with the studies of the diffusion of low-molecular-weight substances in heterogeneous polymeric materials.

Following Chalykh,[7] we shall divide all heterogeneous polymer systems into two large groups. In the first group, we shall place systems whose disperse phase does not participate in the sorption and diffusion processes involving low-molecular-weight substances and influences them only indirectly by acting on the density and segmental mobility of the chains in the dispersion medium. This group includes crystalline polymers, melts comprising crystalline polmers with elastomers and thermoplastics, and polymers filled with mineral powders or fibres. The second group is made up of systems whose disperse phase and dispersion medium participate simultaneously in the sorption, diffusion, and permeation processes. Mixtures of amorphous polymers, block copolymers, and gas-filled systems belong to this group.

1. Diffusion in Systems with Impermeable Particles of the Disperse Phase

It has been demonstrated convincingly by X-ray diffraction that the crystalline phase of the majority of synthetic and natural polymers is impermeable to the molecules of various diffusants. Systems in which the diffusants form solvates with the macromolecules, clathrate complexes, or molecular complexes should probably be exceptions.[72] However, there is so far no information about the translational diffusion coefficients in such phase formations.

The diffusion low-molecular-weight substances in partly crystalline polymers has now been studied in greatest detail.[1,6,7,20,31] Nevertheless, the following main problem still remains open: what is the relation between the supermolecular and phase organisations of these polymers, on the one hand, and the translational mobility of the low-molecular weight substances dissolved in it, on the other. The crystallite is usually employed as the structural element constituting the diffusion medium and the diffusion and permeability coefficients are related to the degree of crystallinity φ_c, using for this purpose empirical or semiempirical relations:

$$D = D_a(1-\varphi_i)^n; \quad P = P_a(1-\rho)^m \quad , \tag{17}$$

$$D = D_a \exp\left(-\frac{B}{f_a}\cdot\frac{\varphi_c}{1-\varphi_c}\right) \quad , \tag{18}$$

$$D = D_a(\tau\beta)^{-1} \quad . \tag{19}$$

where D_a is the diffusion coefficient of low-molecular-weight substances in the amorphous phase or in the amorphous analogue of the crystalline polymer, P_a the permeability coefficient of the same media, τ the tortuosity factor of the pathway, β the immobilisation factor of the crossing chains, f_a the fraction of free volume in the amorphous phase of the polymer, and n, m, and B are empirical constants. It has been shown in a number of studies that n varies in the range from 1.3 to 2.[7,20,31] According to self-diffusion data, $n = 8$.[73]

Another view has been expressed in a number of studies[74–76] whose authors suggest that the diffusion properties of crystalline polymers are determined by their spherulitic level and that the variation of D and P should be attributed not to the variation of φ_c but to the variation of the "degree of spherulitic character". This approach is based on two groups of experimental results; firstly, there are autoradiographic data, according to which the transport of the diffusant in coarsely spherulitic specimens takes place along the boundaries of the spherulites and, secondly, the results of numerical calculations of the permeability coefficients, according to which the peripheral regions of the spherulites are more permeable than their middle section. However, it has been shown for the majority of crystalline polymers that the variation of the size of the spherulites Φ from 2 to 40 μm for film thicknesses in the range 150–300 μm does not affect D and P. An increase in D and P has been observed only for values of Φ comparable to the thickness of the membranes, whereupon breaks in continuity within the spherulites and along their periphery go right through these formations. Therefore one should probably not use the spherulitic level as the cornerstone it being more useful to treat the problem in terms of the spectrum of translation pathways localised both in the intercrystallite and interspherulite spaces, differing from one another in tortuosity, in the packing density of the crossing chains, and in the number of defects.

This problem has been solved[77] within the framework of the permeation theory. It was assumed that the problem of mass transfer in partly crystalline polymers can be formalised as the problem of nodes whose size is much smaller than the thickness of the membrane. A node is permeable when it contains the amorphous phase and is impermeable when it contains a crystallite. Diffusion in such a system occurs only when the fragments of the permeable phase form an infinite cluster, i.e. when the content of the amorphous phase exceeds the permeation threshold φ_a^c, which is 0.16 for the model considered. Using the relation between the tortuosity of the infinite cluster and the fraction of the permeable nodes[78] $\tau \propto (\varphi_a - \varphi_a^c)^t$, where t is the critical index which varies from 1.6 to 2 (the space is three-dimensional) and Eqn.(15), one can obtain the expression

$$D = D_a(\varphi_a - \varphi_a^c)^t \quad , \tag{20}$$

which describes satisfactorily the experimental data over a fairly wide range of variation of the degree of crystallinity of the polymers. It is noteworthy that the critical index is extremely sensitive to the molecular weight, the MWD, the composition of the macromolecules, and the degree of branching of the latter.

However, there exists a fairly large group of experimental data which indicates an anomalous variation of the diffusion properties of crystalline polymers: an increase in D and φ_a with increase in φ_c, the variation of the critical index for φ_c = const., and the decrease in the activation energy for diffusion with increase in φ_c. These results (Fig.4) have been obtained as a rule for high degrees of crystallinity in the vicinity of φ_a^c. The rate of increase in D with increase in φ_c can vary. For some specimens, an almost abrupt increase in D is observed, for others, a more common case, there is a gradual increase, and for the third group, D = const. This character of the variation of D with φ_c has been attributed[58,79,80] to the decrease in the immobilisation factor of the crossing chains. This effect has been explained[7] by the variation of the chain packing density ρ_a in the amorphous phase.

The anomalous variation of D can be explained analogously also within the framework of the percolation approach. Indeed, we shall begin with the hypothesis that the tortuosity of the transport channel increases with increase in φ_c in accordance with Eqn.(20). Then all the structural changes occurring within the channel must be reflected in D_a. Fig.4 shows that most of the experimental data for this range of values of φ_c occupy an intermediate position between two curves calculated by Eqn.(20) for $D_a = 10^{-7}$ cm^2 s^{-1} and for $D_a = 10^{-3}$ cm^2 s^{-1}. The first value corresponds to the diffusion coefficient of the low-molecular-weight substance in the amorphous analogue of the polymer, for example, polyethylene, while the second corresponds to the diffusion coefficient of the same diffusant but in the gas phase, where the transport channel is identified with a crossing pore having Knudsen dimensions.[81]

Evidently, there may be several versions of structural organisation for the transport channel in real materials: the appearance within the channel of local breaks in continuity—closed pore and microcracks; an inhomogeneous distribution of density along the channel cross-section; a general decrease in the density of the amorphous phase. Calculations have shown that, when the first version of the channel structure obtains, a deviation from the theoretical relation (20) is observed only for $\varphi_c \geqslant 0.7$ (curve *9* in Fig.4), i.e. virtually near the permeation threshold. The appearance in the channel of defects of the second type leads to an abrupt alteration of D and its subsequent decrease with increase in φ_c (curve *7* in Fig.4). Finally in the third case D = const., or a weak increase in D, or sharp increase with increase in φ_c can be attained depending on the character of the variation of φ_c (curve *8* in Fig.4). Comparison of these results with experimental data shows that the formation of the transport channel with the first and third versions of the defective structure is more realistic under normal crystallisation conditions.

In the case of crystallisable copolymers and comb polymers, their diffusion properties in each specific case are determined by the coefficient D of the low-molecular-weight substances in the homopolymers, the composition of the crossing chain, the kinetic mobility of the segments, and the degree of crystallinity. An attempt to predict the diffusion properties of crystalline variable-composition copolymers has been undertaken[7,84] within the framework of the free volume theory and the statistical theory of the crystallisation of copolymers.[85] It has been shown that account must be taken of at least three variable parameters for the description and prediction of their properties: φ_c, the composition of the crossing chains, and the

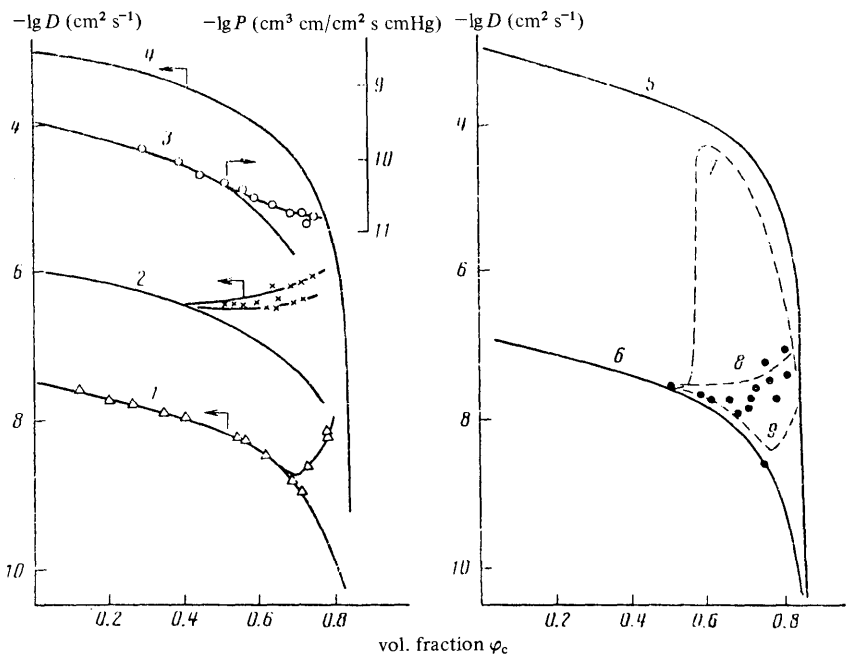

Figure 4. Dependence of the diffusion and permeability coefficients of low-molecular-weight substances on the degree of crystallinity of the polymers: 1) polypropylene–hexane; 2) polyethylene–methane; 3) polyethylene–nitrogen; 4) and 5) calculation by Eqn.(20) for $D_a = 10^{-3}$ cm^2 s^{-1}; 6) calculation by Eqn.(20) for $D_a = 10^{-7}$ cm^2 s^{-1}; 7)–9) calculation by Eqn.(20) for different models of the structure of the amorphous phase (for explanation, see text).

distance of the system from the permeation threshold. Analogous calculations can probably be performed also with the aid of Eqn.(20).

For amorphous polymers filled with the impermeable particles of a disperse phase with a different chemical nature, it is also possible to differentiate three regions of the degree of filling (φ_f) in which the diffusion parameters depend on φ_f in different ways: the region $\varphi_f \leqslant 0.10$ where the introduction of the filler decreases D and P; the region $\varphi_f > 0.20$ where as a rule D and P increase with increase in φ_f; the region of middle compositions of disperse systems where both the constancy of D and P and their extreme changes can be observed as a function of the nature of the polymer and the filler. Thus the general tendency in the variation of the diffusion properties of filled polymers is analogous to that described above for crystalline polymers. The specific features of filled systems are manifested by the fact that all the phenomena described occur in a comparatively narrow range of the bulk phase content of the disperse phase particles. The few structural-morphological studies on these systems have shown that the deviations from Eqn.(20) are associated, on the one hand, with the flocculation of the particles of the disperse phase to give chain cluster formations, and, on the other hand, with the formation of defects—local breaks in continuity concentrated either at the interface or within the cluster structures. Direct evidence for the formation of such structures has been obtained in a study of the gas permeability of porous membranes formed by filling elastomers with powdered salts and their subsequent elution.[86] The formation of crossing porosity has been noted[87] already at $\varphi_f \cong 0.05$.

In conclusion of this Section, we may note that, despite the large amount of experimental data on diffusion in filled polymers and on their permeability, they still remain the least investigated. This is due to the virtual lack of combined studies in which diffusion data would have been supplemented by structural-morphological information, the determination of local diffusion coefficients, and the estimation of the degree of defectivness of the medium. The study[88] in which the percolation approach was used to analyse mass exchange processes in multicomponent polymer coatings is not an exception in this sense.

2. Diffusion in Block Copolymers, Polymer Blends, and Gas-filled Polymers

Assessment of the set of experimental data obtained for the diffusion behaviour of media containing a permeable disperse phase permits the conclusion that the behaviour of these systems shows no fundamental qualitative and quantitative differences despite the significant difference in the chemical and phase states of the particles of the disperse phase, their disperse characteristics, structural organisation, and local diffusion coefficients. When the disperse phase is impermeable to low-molecular-weight components for thermodynamic reasons, the diffusion properties of all these media are characterised by a single transport or macroscopic diffusion coefficient, while the sorption and permeation kinetics are of the normal, Fick type. On the other hand, if both the disperse phase and the dispersion medium are involved simultaneously in the diffusional transport of low-molecular-weight substances, then distinct pseudo-normal sorption and permeation kinetics are observed,[7] while the diffusion properties of the system are characterised by local and effective diffusion coefficients. The reproducible anomaly in the kinetics of the attainment of sorption equilibrium observed in these polymers after repeated sorption–desorption cycles yields direct information about the disperse structural organisation of the medium. The diffusion properties of such media are influenced by the differences between the diffusion coefficients of low-molecular-weight substances in the disperse phase and the dispersion medium. Since D for organic solvents is a function of concentration,[91] it is frequently found that in one region of sorption isotherms the medium is "heterogeneous" according to diffusion data while in another it is "diffusionally homogeneous".

The dual character of the behaviour of polymer media containing permeable particles of the disperse phase is also manifested when diffusion coefficients measured by different methods are compared. Thus the rotational and translational diffusion coefficients of iminoxy-radicals, found by microwave spectroscopic methods (D_R), exceed the corresponding coefficients of translational mobility obtained by sorption–permeability methods (D_S).[42] Whereas D_S diminishes with increasing content of the disperse phase, D_R = const.

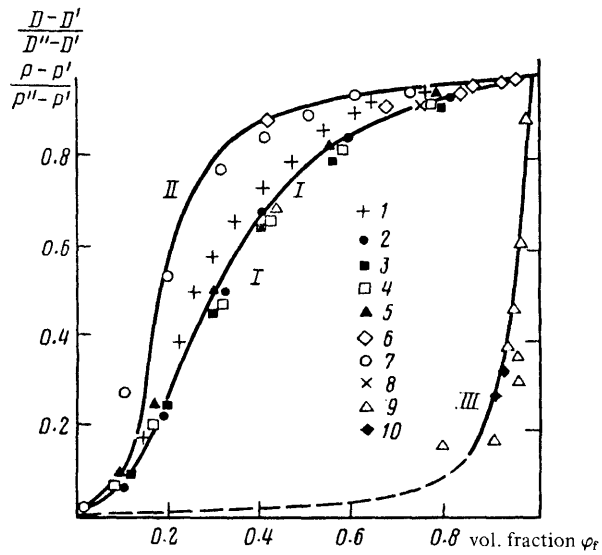

Figure 5. Dependence of the reduced diffusion coefficients of low-molecular-weight substances (I) and of the reduced permeability coefficients of heterogeneous polmeric materials (II) as well as gas-filled polymeric systems obtained by sintering (II) and foam formation (III) on the porosity and content of the permeable phase: 1) "Silar" poly(block copolymer); 2) polystyrene–polybutadiene blend; 3) styrene–butadiene block copolymer; 4) sulphone–butadiene block copolymer; 5) blend of poly(vinyl chloride) and nitrile rubber; gas-filled polymers; 6) SKN-30 nitrile rubber (elution of KCl); 7) polyurethane (sintering of particles); 8) polyamide fibres (unwoven material); 9) polyester-urethane foam; 10) polystyrene foam; D, D', and D'' are the diffusion coefficients and P, P, and P'' are the permeability coefficients of the mixture and of each pure components respectively; φ_f is the content of the permeable phase (in the case of gas-filled polymers, it is their porosity).

Fig.5 presents experimental reduced diffusion and permeability coefficients for many polymeric media with a permeable disperse phase. Curves illustrating the variation of the permeability of gas-filled polymer systems obtained by sintering powders and by foam formation are presented for comparison.[89,90] For all the systems, the

character of the variation of the effective coefficients D and P is the same. In the region of phase reversal (which occurs in the vicinity of the permeation threshold when the problem of nodes in a lattice-free model is considered), D and P undergo the greatest changes. The critical index t is close to 1.7 even for gas-filled systems. The dependence of the permeability coefficients on the porosity—the volume fraction of the permeable phase for polymeric foam materials—is of special interest. Despite the fact that the content of gas inclusions reaches up to 93 vol.%, the permeation threshold in this system has not been attained. These results can be explained within the framework of the problem of connections.[90] The accumulation in the specimen of pore walls disrupted by influences of one kind or another leads to the formation of passable connections between the lattice nodes and to the appearance of an infinite cluster, which is manifested by a sharp and abrupt increase in gas permeability.

Several approaches have been proposed for the theoretical study of the diffusion of low-molecular-weight substances in heterogeneous polymer systems with a permeable disperse phase: the Maxwell, Nielson, and Robinson equations, the Zolotarev–Dubinin bidisperse model, and the percolation model. It is necessary to compare the proposed equations, to determine their scope in predicting the behaviour of heterogeneous diffusion systems, and to estimate the structural-morphological features of the test objects. First attempts of this kind have already been undertaken.[7,88,91–93]

V. DIFFUSION METHODS FOR THE STUDY OF POLYMER SYSTEMS

1. Construction of Phase Diagrams

The diffusion methods for the study of polymer systems are based on the investigation of the concentration distribution of the components in the mutual diffusion zone, i.e. in the zone corresponding to the spontaneous mixing of the components. At the present time, it has been demonstrated for various systems that the characters of the concentration profile and of the phase diagram for the system are closely interrelated (Fig.6). Thus, if the polymer system is characterised by amorphous layer formation and exists during the experiment above the upper consolute temperature (UCT) or below the lower consolute temperature (LCT), then the distribution curves indicate a continuous variation of concentration on passing from one component to another. At T < UCT (or T > LCT), a concentration jump is observed on the diffusion profiles, whose position corresponds to the two-phase region on the concentration scale of the phase diagram. The composition of the solutions on either side of the phase boundary then coincides with the composition of the

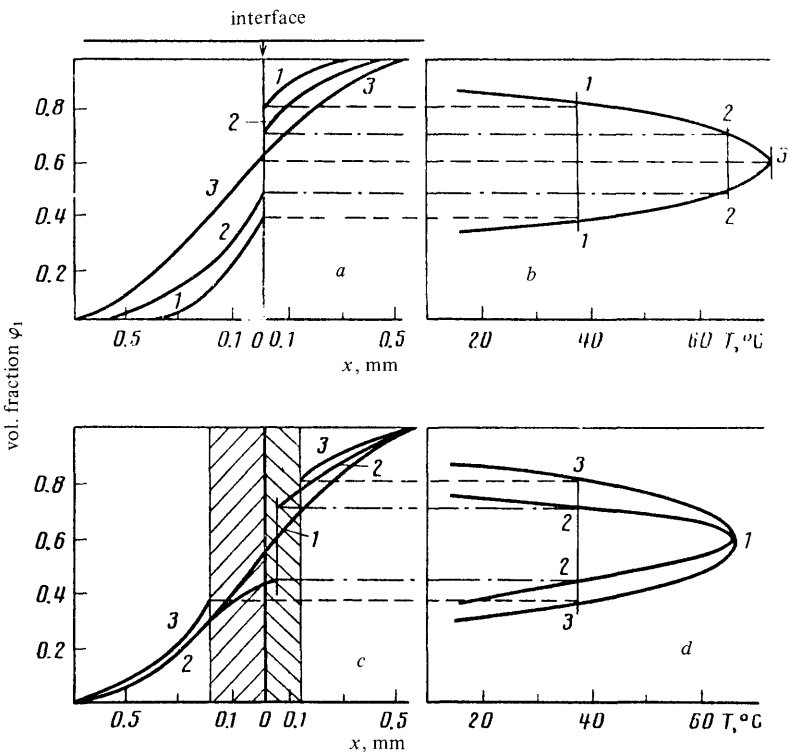

Figure 6. Concentration distribution curves in the mutual diffusion zone (*a*, *c*) and the phase diagrams (*b*, *d*) constructed on their basis. Curves *1*–*3* corresponding to increasing (*a*) and decreasing (*c*) temperatures; the boundary concentrations on curves *2* and *3* (*c*) correspond to the spinodal and binodal curves. The phase decomposition regions are shown cross-hatched; x is the diffusion coordinate.

coexisting phases. Thus, by determining the variation of the boundary concentrations at different temperatures and the instant of disappearance of the interface, one can plot, as shown in Fig.6, the binodal curve of the phase diagram.

If the binary system is characterised by a crystalline equilibrium (in the general case by a combination of crystalline and amorphous equilibria), then the distribution of concentration in the mutual diffusion zone includes additional regions corresponding to the dissolution of the diffusant in the crystalline polymer and its fusion if the dissolution takes place at $T < T_m$ [T_m is the melting point]. In order to characterise this region, it is necessary to identify experimentally the amorphous and crystalline states of the solutions. For example, when measurements are performed by the interference or polarisation-interference methods, the concentration profiles must be recorded in both ordinary and polarised light.[94]

An inherent feature of the diffusion method for the construction of phase diagrams is the possibility of determining the spinodal curve and also of the kinetics of phase decomposition in the region of metastable and labile solutions.[95] For this purpose, the diffusion process is carried out initially under conditions such that a concentration field arises in the miscibility zone and the range of variation of the composition of the solutions must be fairly broad. By driving the system as a result of a sharp change in temperature to the region of phase separation, it is possible to observe and record different stages in the decomposition of labile and metastable solutions. By determining under these conditions the boundary concentrations, established at different times near the phase boundary, one can plot (Fig.6) the spinodal curve, test the position of the binodal curve, and determine the concentration-temperature range corresponding to phase reversal. These methods are of great practical interest, because it is precisely under these conditions (i.e. in the presence of the concentration or diffusion coefficient gradient) that the stuctures of coatings, membranes, and adhesion junctions are established.

2. Phase and Structural Analysis of Polymer Blends and Block Copolymers

The phase and structural analysis of heterogeneous polymer systems presupposes the determination of quantitative information about the phase composition of the specimen, the size and shape of the particles of the disperse phases, the compositions of the coexisting phases, and the size and structure of the interfaces. Detailed investigations of various aspects of mass transfer process involving low-molecular-weight substances in such systems have shown that the characteristic features of their phase state and supermolecular organisation are most strikingly manifested in the kinetics of the attainment of sorption equilibrium.[13,91,98]

The kinetics of the sorption (desorption) of solvents by block copolymers and polymer blends are characterised by a series of specific features, which make it possible to differentiate them as a special class of heterogeneous sorbents. In the first place, the type of kinetic curve depends on the nature of the sorbate and its thermodynamic affinity for the blocks forming the disperse phase and the dispersion medium. Thus, when a selective solvent (SS) which is not sorbed by the disperse phase is used as the sorbate and the dispersion medium is in the highly elastic state, then the sorption kinetics are as a rule of the normal, Fick type. The situation is different if the sorbate is a common solvent (CS) for both phases. In this case, the type of the kinetic curve depends on how much the diffusion coefficients of the sorbate in the disperse phase (D') and in the dispersion medium (D'') differ.

The diffusion in such systems can be naturally characterised with the aid of models taking into account the phase structure of the sorbent, for example, with the aid of the bidisperse Zolotarev–Dubinin model. Two diffusional relaxation times have been introduced in this model: $T = \Gamma L^2/D''$ for the dispersion medium and $\tau = R^2/D$ for the disperse phase. Here L and R are the sizes of the specimen and the phase inclusion respectively and Γ is the Henry coefficient. Depending on the ratio of T and τ, the following cases can obtain: for $T \gg \tau$, the rate of sorption and the type of kinetics are determined by the transport in the dispersion medium; for $T \ll \tau$, the sorption kinetics are determined by the diffusion initially into the dispersion medium and then into the disperse phase and there is a possibility of both two-stage and pseudo-normal kinetics; for $T \cong \tau$, an intermediate case arises; when $\tau \to \infty$, normal sorption, involving the transport of the test substance in the dispersion medium, takes place. Thus, having determined from the experimental data for the sorption kinetics the values of T and τ and having assumed that the diffusion phase coefficients in the disperse phase and in the dispersion medium are close to the diffusion coefficients of the corresponding homopolymers, it is possible to estimate the average sizes of the particles of the disperse phases.

Several methods have been proposed for carrying out calculations of this kind.[13] The most rational procedure for the treatment of kinetic sorption curves has been described in a study[99] whose authors derived simple relations between the principal process characteristics by the numerical calculation of various linear and concave sorption isotherms for sorbents with a bidisperse structure:

$$\gamma(t) = 1 - \exp\left\{A(\varepsilon)\left(\frac{t}{\tau+T}\right)^{B(\varepsilon)}\right\} \qquad (21)$$

where γ is the relative degree of filling of the sorbent by the sorbate, t the time, $\varepsilon = \tau/(\tau + T)$, and $A(\varepsilon)$ and $B(\varepsilon)$ are empirical coefficients which depend on the form of the disperse phase. Their numerical values have been published.[99] These analytical formulae can be used to find from the experimental curves both D' and D'' and the corresponding diffusion relaxation times and hence also certain structural parameters of the medium. It is significant that this method does not require the knowledge of the entire sorption curve.

3. Determination of the Thermodynamic Parameters of the Mixing of the Components

New possibilities for the determination of the chemical potentials of the components in solutions of polymers (μ_i) are provided by the method of non-equilibrium thermodynamics, which makes it possible to relate in a fairly general and clear form the mutual diffusion and partial self-diffusion ($D^*_{i,\varphi}$) coefficients of the components to the thermodynamic characteristics of the solutions:

$$D_V = D^*_{i\varphi}\frac{\partial \ln a_i}{\partial \ln \varphi_i} = D^*_{i,\varphi}\frac{\varphi_i}{RT}\frac{\partial \Delta\mu_i}{\partial \varphi_i} \quad , \qquad (22)$$

where a_i is the activity of the ith component and φ_i its volume fraction. It follows from Eqn.(23) that

$$\Delta\mu_i = RT\int_1^{\varphi_i}\left(\frac{D_V}{D_{i,\varphi}}\right)\varphi_i^{-1}\,d\varphi_i \qquad (23)$$

Eqn.(23) makes it possible to determine the change in the chemical

potential of any component of the diffusion system.[7,100] The calculations can be performed in accordance with the following scheme: initially, one determines experimentally the concentration dependence of D_V and then also experimentally or by calculation, using the Fujita equation, one finds the concentration variation of the partial self-diffusion coefficient of the ith component. Next $D_V/D^*_{i,\varphi}$ is plotted against $\ln \varphi_i$, graphical integration is carried out, and finally $\Delta\mu_i$ is determined by Eqn.(23). The subsequent treatment of the $\Delta\mu_i - \varphi_i$ relation in order to obtain the Gibbs free energy is traditional.[101]

It has been suggested[7] that the concentration variations of D_V and D^*_i be used to determine the interaction parameters χ characterising the thermodynamic affinity of the components in the Flory–Huggins theory. For this purpose, one can use the equation

$$D_V = D^*_{i,\varphi}\left[1 - \left(1 - \frac{V_1}{V_2}\right)\varphi_1 - \chi 2\varphi_1\varphi_2\right] , \qquad (24)$$

where V_1 and V_2 are the molar volumes of the components and φ_1 and φ_2 are their volume fractions. For polymer–low-molecular-weight substance systems with $V_1 \ll V_2$, this relation assumes the form

$$D_V = D^*_{i,\varphi}(1 - \varphi_1 - 2\chi\varphi_1\varphi_2) . \qquad (25)$$

If one uses the relative diffusion coefficient D_1, then, instead of Eqn.(25), one can obtain the simplest expression for the calculation of χ in a binary polymer system:

$$D_1 = D^*_1(1 - 2\chi\varphi_1) . \qquad (26)$$

Thus, both in the determination of $\Delta\mu_1$ and $\Delta\mu_2$ and in calculations of χ, it is essential to have information about the concentration variations of D_v and D^*_i. The integral values of χ can be estimated by means of extrapolated values of $D_{11}(\varphi_1 \to 1)$ and D^*_{11}, because $D_{11}/D^*_{11} = 1 - 2\chi$. The errors in the determination of $\Delta\mu_i$ and χ are related mainly to the error in the measurement of the mutual diffusion and self-diffusion coefficients and amount to ~15%.

4. Structural Studies on Crystalline and Filled Polymers

It is possible to differentiate several structural-morphological levels in these systems. The first is associated with the organisation of the crossing chains in the amorphous phase and determines its density, the distribution of density on passing from one crystallite to another, and the positions of the end groups and folds. The second has a bearing on the relative positions of the crystallites in space, their size, character, aggregation, internal structure, and degree of defectiveness. The third, superspherulitic level determines the character of the packing of the spherulites and their interrelation and internal structure. This structural hierarchy can be extended also to filled polymers after the introduction of the corresponding terminological refinements. Thus the amorphous phase of crystalline polymers is identical with the polymeric dispersion medium, the second level determines the distribution of the particles of the disperse phase, and the third determines the distribution of aggregates of the filler particles.

Analysis of experimental data has shown that the results of diffusion measurements make it possible to characterise to some extent each of the above structural-morphological levels. However, we believe that it is most useful to employ diffusion measurements for the study of the structure of the amorphous phase of crystalline polymers.

It has been suggested[58,80] that diffusion methods be used for the structural analysis of crystalline polymers. However, the authors confine themselves to the establishment of qualitative relations between the diffusion coefficients and the structural parameters of the media determined by other methods. This approach cannot be regarded as a method of structural analysis, because it reduces essentially to the solution of the converse problem—the use of information about the structure of the specimens for the interpretation of the results of diffusion measurements.

As already mentioned above, the application of diffusion methods in structural analysis presupposes something different: the determination of quantitative analytical relations between the diffusion constants and the structural characteristics of crystalline and filled polymer matrices. If Eqn.(18) is used for this purpose, then, when information is available about D and D_a, it is possible to estimate φ_c, and, when D and φ_c data are used, one can calculate the density of the amorphous phase in real polymeric materials. These estimates can be performed with the aid of the equation

$$\frac{\rho}{\rho_a} = \frac{\rho_c}{\rho_a}\left(1 - A + \frac{\rho_a}{\rho_c}A\right) , \qquad (27)$$

where ρ_c, ρ_a, and ρ are respectively the densities of the crystallites, the amorphous analogue, and the amorphous phase of the real polymer, $A = \ln(D/D_a)/\ln(D_{calc}/D_a)$, D_a and D are respectively the diffusion coefficients of the low-molecular-weight substances in the amorphous analogue and in the real polymer, and D_{calc} is the diffusion coefficient calculated by Eqn.(18) from D_a, f_a, and φ_c. On passing to filled polymers, the approach remains the same and only the physical significance of the symbols in Eqn.(27) changes.[7]

In this Section, we have considered certain possibilities in the application of diffusion methods to the physicochemical analysis of polymer systems. It is to be expected, that, as the methodological, molecular-kinetic, and phenomenological approaches are perfected, these possibilities will expand and will find an honourable place among other integral methods for the analysis of real polymeric materials.

Molecular-kinetic Models of the Transfer of Substances in Inorganic Membranes

Yu.K.Tovbin

Molecular-kinetic models of the transfer of susbstances through crystalline inorganic membranes have been examined, taking account of the influence of the principal real properties of the system: the interaction between the particles adsorbed on the surface and between the particles dissolved in the volume of the membrane; the non-uniformity of the region of the solid next to the surface; the restricted mobility of the particles; and the change in the state of the volume phase during the transfer of the diffusing substance. The possibility of applying these models to the problems of transfer through vitreous inorganic and polymeric membranes has been discussed.
The bibliography contains 110 references.

I. INTRODUCTION

Inorganic membranes represent a wide range of inorganic compounds which can be used to separate mixtures of substances. The materials used for inorganic membranes include metals, alloys, metal oxides, silicate glasses, ionic crystals, and zeolites.

The problem of the transfer of hydrogen in metals and alloys is of the greatest scientific and technical importance. It is related to the solution of a large number of problems: the purification and enrichment of gas mixtures;[1-3] membrane catalysis, used in hydrogenation and dehydrogenation processes to obtain highly pure substances, monomers for synthetic materials, intermediates for the production of vitamins, drugs, and dyes;[4,5] hydrogen power engineering,[3,6] etc. The higher permeability of silver catalysts[4,5] and catalysts based on simple and complex oxides[7-10] towards oxygen is also used in membrane catalysis to increase the selectivity of redox processes. Silicate glasses and ionic crystals are widely used to obtain membranes for ion-selective electrodes, used in analysis.[11] The high permeability of glasses towards inert gases, particularly helium,[1,2] is a prerequisite for the technical application of the glasses in gas-separation processes. Molecular sieves based on natural and synthetic zeolites[12,13] have widely different permeabilities for different substances, so that they can be used in gas separation and membrane catalysis.

Inorganic membranes have a high selectivity and increased mechanical strength and thermal stability compared with membranes based on organic polymers, and this makes them irreplaceable at high temperatures.

A basis for the description of the processes of mass transfer through membranes[14-40] is provided by the following scheme (Fig.1). The stream of the substance is supplied to the membrane surface *a*, where it is adsorbed and dissolves in the region next to the surface. The substance diffusing then passes through the volume phase of the membrane and leaves it through the surface *b*. In Fig.1, *k* denotes the number of the crystallographic layers perpendicular to the direction of the flow of the substance; the thickness of these layers is approximately equal to the diameter of the particles of the substance diffusing. κ_a and κ_b denote the thickness of the membrane surface regions, whose properties may differ considerably from one another and from those of the bulk phase. In the general case, $\kappa_a \neq \kappa_b$; in most of the works cited, it is assumed that $\kappa_a = \kappa_b = 1$.

Models of the processes involved in the solution and transfer of substances in solids are based on diffusion equations, supplemented by appropriate boundary conditions. Various questions related to the derivation of expressions for the diffusion coefficient and the search for boundary conditions based on a discrete scheme of randomly moving particles,[22,36] the role of saturation of the volume and the surface by the particles of the substance diffusing,[14-17,19,21,23,24,26,29] allowance for the non-equilibrium character of the processes in the surface regions and in the bulk of the membrane,[18,20,25,27,28,30,32,34,35,37,38,40] and the influence of the asymmetry of the membrane and the contribution of surface and volume defects[31,33,35,39] have been examined in detail.

In the one-dimensional model, the values of the local concentrations of the particles are related to a particular layer *k*; these values are the average values in the volume of the given layer. In macro-non-uniform systems, this scheme may be over-simplified. In layer and composite membranes, it is necessary to take more detailed account of the distribution of the non-uniform regions of the membrane within each layer,[41,42] and this makes it necessary to use two-dimensional instead of one-dimensional models of the transfer process.

All the models used at present are based on the description of the rates of the elementary processes of adsorption–desorption and migration of the particles from the law of mass action,[43] which assumes that all the particles are distributed randomly and that each behaves independently of the others. This assumption is justified only when the concentration of the particles is low. Another important assumption made in most models of mass transfer is the assumption (explicit or implicit) that the membrane is inert and that its role reduces to the determination of the sequence and inter-relationship of the absorption centres (these are usually interstices) involved in the transfer of the particles.

In many situations, these assumptions do not reflect the real properties of the systems and the conditions under which the transfer processes take place, since they are made without allowance for complex cooperative effects. Two groups of cooperative effects can be distinguished. The first is associated with a high density of sorbed particles. Most of the sorbed particles form a relatively strong bond with the solid, leading to their adsorption on the surface and absorption in the volume. The total quantity of sorbed molecules may be comparable with the number of adsorption and absorption centres. In this situation, the average distance between the sorbed particles is comparable with their dimensions, and at these inter-particle distances, appreciable interactions are possible (the nature of these interactions will not be made more specific here[44–47]). This leads to the appearance of different phase states of the sorbed particles, in particular their separation into layers and (or) ordering.[47–50] The phase state of the sorbed particles depends on their local concentration and on the temperature of the system.

The second group of cooperative phenomena is associated with the interaction of the sorbed particle with the atoms of the solid, leading to a change in the distribution of the components of the membrane in the bulk and in the surface regions, compared with their distribution in the absence of the molecules of the gas phase. In many cases, hydrogen and oxygen form chemical compounds with metal atoms, leading to a change in the properties of the membranes (a whole series of solid solutions with variable composition may be formed). This is reflected in the appearance of hysteresis on the sorption–desorption graph, an increase in the volume of the metal when the stream of gas passes through it, cracking of the metal, etc.[51,52] The energy stresses arising when hydrogen is dissolved have been estimated.[53] Similar cation redistribution phenomena are observed in solid electrolytes[54,55] and zeolites.[12] The nature of the change in the state of the solid depends on the intensity of the flux of the diffusing substance.

II. THE INFLUENCE OF INTERACTIONS BETWEEN THE PARTICLES ON THE RATES OF THE ELEMENTARY PROCESSES

The cooperative character of the transfer processes influences primarily the rates of the elementary processes. The transfer of a substance through a membrane consists of at least two stages: adsorption–desorption and migration. If the membrane is a catalyst, stages involving the adsorption and desorption of another reagent and the stage of chemical transformation also take place on one of its sides. The interactions between the particles influence the rates of each stage, and hence the rate of the overall process.

The description of the rates of the elementary processes will be based on the fundamental postulates of the theory of absolute reaction rates,[56] the initial version of which is applicable to ideal systems, that is to systems of non-interacting particles.

It is not possible to take formal account of the non-ideal nature of the system[56–58] using the activity coefficients of the reagents and the activated complexes, since the calculation of the activities in turn requires model representations of the interactions between the particles and of the structure of the condensed phase. When allowance is made for the interaction of neighbouring particles,[59] the generalisation of the expression derived from the theory of absolute reaction rates leads to a change in the concentration dependence of the rates of the elementary processes. The reason for this can be illustrated for the bimolecular reaction $iZ + jZ$, where i, j = A or v, AZ is an adsorption centre occupied by a particle A, and vZ is an unoccupied centre. With this notation, the stage involving the adsorption of an A_2 molecule is written as $A_2 + 2vZ \rightleftarrows 2AZ$, and the stage involving the migration of the particles is written as $AZ_k + vZ_q \rightleftarrows vZ_k + AZ_q$, where the indices k and q correspond to the numbering of neighbouring centres in the volume or on the surface. A uniform lattice in which each site has z neighbours can be

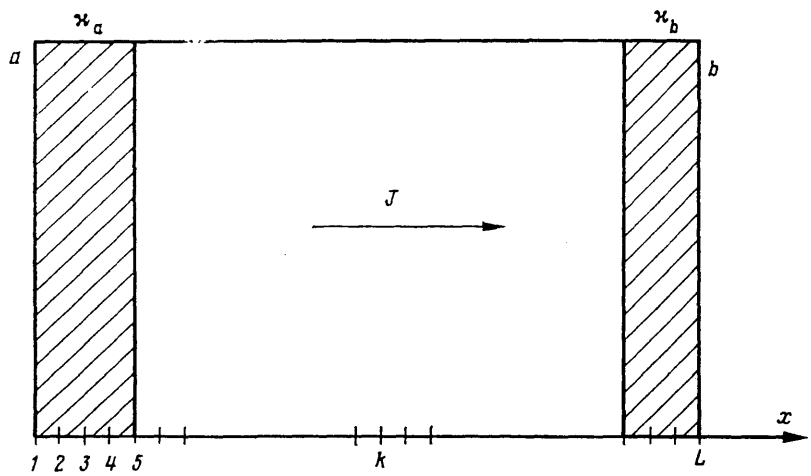

Figure 1. Diagram of a membrane; k is the layer number, κ_l is the thickness of the surface region l, $l = a, b$.

considered. For planar lattices, the sites correspond to adsorption centres, and for these, $z = 3$, 4, or 6; in volume lattices, the sites correspond to absorption centres, and for these, $z = 4$, 6, 8, or 12.

When there is no interaction between the particles, the rate of the reaction $iZ + jZ$ is expressed as $V_{ij} = k_{ij}\theta_i\theta_j$, where k_{ij} is the reaction rate constant, and $\theta_i(\theta_j)$ the concentration of the component $i(j)$ (its mole fraction), which characterises the probability that any site of the lattice is occupied by a particle of type $i(j)$. (Subsequently, quantities relating to different regions of the lattice: on the surface, in the bulk, or in a specific layer of the membrane, will be distinguished.) The normalisation condition is

$$\sum_{i=1}^{s} \theta_i = 1,$$

where s is the number of components of the system, including the unoccupied sites v. Usually,

$$k_{ij} = \hat{k}_{ij}\exp(-\beta E_{ij}),$$

where E_{ij} is the activation energy of the reaction, $\beta = (kT)^{-1}$, and k_{ij} the pre-exponential factor in the expression for the rate constant. If $i = j = A$, then k_{AA} is the rate constant of the desorption; if $i = A, j = v$ (or vice versa), then k_{Av} is the rate constant of the migration; if $i = j = v$, then $k_{vv} = k_{vv}p_{A_2}\exp(-\beta E_{vv})$ is the effective rate constant of the adsorption, where the partial pressure of the molecules of the gas phase p_{A_2} has been included to ensure uniform-ity of the form of the expression for the rate V_{ij}.

The influence of the interaction of neighbouring particles is revealed primarily by the fact that the height of the activation barrier of the elementary reaction changes with change in the local composition. $E_{ij}(n\sigma)$ denotes the energy of the interaction of the reagents ij with their neighbours in the ground state, and $E^*_{ij}(n\sigma)$ the energy of the interaction of the activated complex with its neighbours in the transition state. The configuration of neighbouring particles is given by the indices n and $\sigma(n)$, where n defines the number of neighbouring particles A in the sites of the first coordination sphere around the pair of reagents ij, and $\sigma(n)$ defines the way in which they are arranged for a fixed value of n (Fig.2). The difference $E^*_{ij}(n\sigma) - E_{ij}(n\sigma)$ gives the change in the height of the activation barrier for a given local configuration $n\sigma$. For a fixed position of all neighbouring particles, the rate of the elementary process at the two central sites is written as follows:

$$V_{ij}(n\sigma) = k_{ij}\theta_{ij}(n\sigma)F_{ij}(n\sigma),\quad F_{ij}(n\sigma) = \exp\beta[E^*_{ij}(n\sigma) - E_{ij}(n\sigma)]. \qquad (1)$$

where $\theta_{ij}(n\sigma)$ is the probability of existence of the configuration $n\sigma$ round the central particles ij. This quantity is the probability of a complex event, and to determine the reaction rate it must be expressed in terms of θ_i.

The expression for the rate V_{ij} of the reaction being considered, related to the entire surface, is obtained by averaging the expression (1). If $\alpha_{ij}(n\sigma)$ denotes the statistical weight of the configuration $n\sigma$, then

$$V_{ij} = k_{ij}\sum_{n}\sum_{\sigma(n)}\alpha_{ij}(n\sigma)\theta_{ij}(n\sigma)F_{ij}(n\sigma) \qquad (2)$$

where the first summation is carried out over the number of particles n, and the second is carried out over the different configurations $\sigma(n)$ for a fixed value of n. The set of configurations of particles A for a planar lattice with $z = 4$ is shown in Fig.2.

The paired interactions between nearest neighbours can be taken into account.[59] ε_{ij} denotes the magnitude of the interaction of particles i and j occupying neighbouring sites and present in the free state. Naturally, $\varepsilon_{ij} = \varepsilon_{ji}$. If one of the particles is an unoccupied

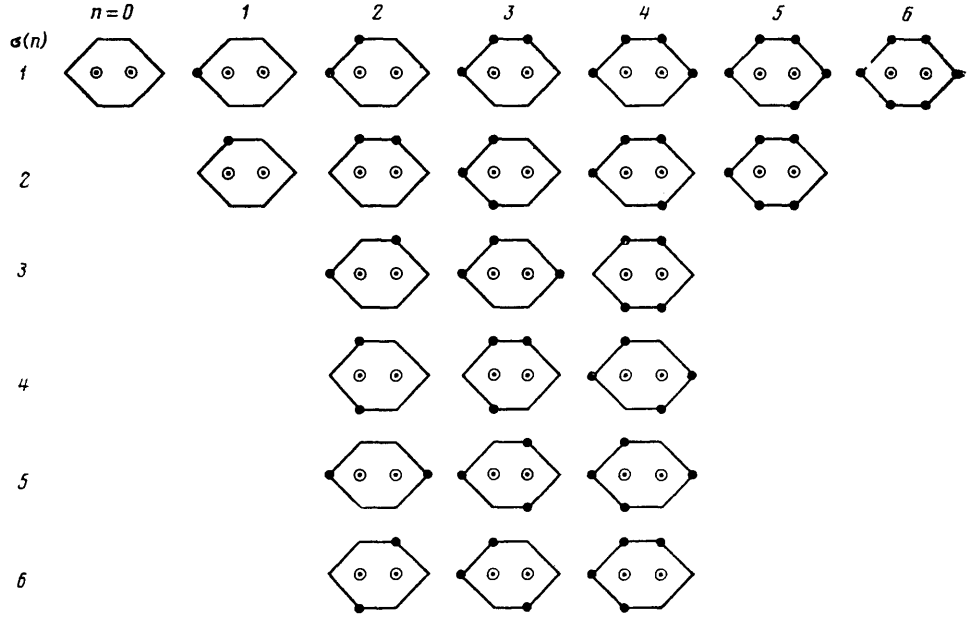

Figure 2. Configurations of particles A in the first coordination sphere round the central particles in a square lattice; the light circles represent the central particles, and the black circles the adsorbed particles A.

site, then $\varepsilon_{iv} = 0$. The formation of the activated complex involves the transfer of particles from the ground state to the activated state, corresponding to a change in the positions of the reagents relative to their neighbours. The energy of the interaction of the reagent i with a neighbouring particle j in this transition state is denoted as ε^*_{ij}. Although $\varepsilon^*_{iv} = 0$, nevertheless $\varepsilon^*_{vA} = \varepsilon^*_{AA}$, since the interaction of the activated complex with its neighbours is independent of the direction of the reaction. For paired interaction of the particles, the magnitude of $E_{ij}(n\sigma)$ is independent of the way in which the particles are arranged:

$$E_{ij}(n\sigma) = \varepsilon_{ij} + \varepsilon_{iA}n_1 + \varepsilon_{iv}(z-1-n_1) + \varepsilon_{jA}n_2 + \varepsilon_{jv}(z-1-n_2) \quad (3)$$

where n_1 and n_2 are the numbers of particles A around the particles $i(n_1)$ and $j(n_2)$, so that $n_1 + n_2 = n$. This expression has the following structure: the term ε_{ij} corresponds to the interaction of the original reagents, the next two terms correspond to the interaction of the particle i with its neighbours, and the last two terms to the interaction of the particle j with its neighbours. One of the sites closest to each central site is occupied by the other reagent, and the remaining $z - 1$ sites are occupied by neighbouring particles. For the activated complex, the interaction of its fragments "i and j" relates to the internal energy, so that in the expression for $E^*_{ij}(n\sigma)$, the first term ε_{ij} is not present, and the other terms contain ε^*_{ij} instead of ε_{ij}. This leads to the expression

$$F_{ij}(n\sigma) = \exp\beta[-\varepsilon_{ij} + n_1\delta\varepsilon_{iA} + (z-1-n_1)\delta\varepsilon_{iv} + n_2\delta\varepsilon_{jA} + (z-1-n_2)\delta\varepsilon_{jv}] \quad (4)$$

where $\delta\varepsilon_{ij} = \varepsilon^*_{ij} - \varepsilon_{ij}$.

Only one of the simplest methods of calculating the functions $\theta_{ij}(n\sigma)$ will be considered. It will be assumed that all the configurations with different $\sigma(n)$ are equally probable [for example, $\theta_{ij}(31) = \theta_{ij}(34)$]. Taking account of the distribution of the particles A in neighbouring sites round different central particles, it is then possible to write:

$$\sum_{\sigma(n)} \alpha_{ij}(n\sigma) = C^{n_1}_{z-1}C^{n_2}_{z-1},$$

where $C^{n_1}_{z-1}$ is the number of combinations of n_1 from $z - 1$. The function $\theta_{ij}(n\sigma)$ can be written as

$$\theta_{ij}(n\sigma) = \theta_{ij}t_{iA}^{n_1}t_{jA}^{n_2}t_{iv}^{z-1-n_1}t_{jv}^{z-1-n_2}$$

This form of expression indicates that the probability of a given many-particle configuration is approximated by the probabilities of simpler events, namely the probability of finding the particle i (θ_i) and the probability of finding the particles i and j in a pair of neighbouring sites (θ_{ij}): $t_{ij} = \theta_{ij}/\theta_i$, where t_{ij} is the conditional probability of finding a particle j next to a particle i; $\theta_{iA} + \theta_{iv} = \theta_i$. This is the so-called quasi-chemical approximation.[60,61] With allowance for the foregoing, including Eqn.(4), the expression (2) can be rewritten as follows:[59,64,67]

$$V_{ij} = k_{ij}\exp(-\beta\varepsilon_{ij})\sum_{n_1=0}^{z-1} C^{n_1}_{z-1}\Phi_{iA}^{n_1}\Phi_{iv}^{z-1-n_1} \times \times \sum_{n_2=0}^{z-1} C^{n_2}_{z-1}\Phi_{jA}^{n_2}\Phi_{jv}^{z-1-n_2} = k_{ij}\exp(-\beta\varepsilon_{ij})(S_iS_j)^{z-1} \quad (5)$$

where

$$S_i = \Phi_{iA} + \Phi_{iv}, \quad \Phi_{ij} = t_{ij}\exp(\beta\delta\varepsilon_{ij})$$

In the general case of an arbitrary number of components s, the functions θ_{ij} can be determined in terms of the concentrations of the particles by solving the system of equations (equilibrium distribution of the particles):[61]

$$\theta_{ii}\theta_{jj} = \theta_{ij}^2\exp[\beta(\varepsilon_{ii} + \varepsilon_{jj} - 2\varepsilon_{ij})], \quad \sum_{j=1}^{s}\theta_{ij} = \theta_i, \quad \sum_{i=1}^{s}\theta_i = 1 \quad (6)$$

The expressions for the rates of the elementary processes taking place on one and on two sites can be written in the form:[59]

$$V_i = k_i\theta_i(S_i)^z, \quad V_{ij} = k_{ij}\exp(-\beta\varepsilon_{ij})\theta_{ij}(S_iS_j)^{z-1}, \quad S_i = \sum_{j=1}^{s} t_{ij}\exp(\beta\delta\varepsilon_{ij}) \quad (7)$$

When the particles interact, the form of the expressions for the reaction rates changes as a result of the appearance of the functions S_i and as a result of the change in the probability that the reagents meet ($\theta_{ij} \neq \theta_i\theta_j$). When the reaction rates of each stage in the forward and back directions are equal, the equilibrium relationships between the concentrations of the particles are obtained with allowance for the interaction between nearest neighbours.[59] The interactions between the particles alter considerably the kinetic characteristics of the adsorption–desorption processes[62–64] They justify the empirical equations of Becker and Langmuir for the rate of desorption and of Zel'dovich and Roginskii for the rate of adsorption in chemisorption on uniform surfaces (the linear dependence of the logarithms of the rates of the processes on the degree of coverage) and the power dependence of the rate of desorption on the degree of coverage (Benham–Bart–Kwan kinetics),[65] and explain the existence of ranges corresponding to rapid and slow chemisorption.[66] The effects of correlation between particles being repelled leads to the splitting of the thermodesorption spectra on a uniform surface.[63]

Eqns.(7) can be used to estimate the self-diffusion coefficient D^*_i, characterising the transfer of a labelled component i under equilibrium conditions.[59,67,68] θ^*_{ik} denotes the fraction of the labelled component i in the layer k. The flux of the labelled particles J in the direction of the x axis is represented as the difference between the numbers of labelled particles A transferred in unit time into neighbouring vacancies from the layer k into the layer $k + 1$ and vice versa:

$$J = k_{iv}(\theta^*_{ik} - \theta^*_{i,k+1})t_{iv}(S_tS_v)^{z-1} \quad (8)$$

Comparison of this equation with the expression for Fick's first law ($J = -D^*_i d\theta^*_i/dx$) with the condition that the change in the concentration of labelled particles between neighbouring layers is small ($\theta^*_{i,k+1} = \theta^*_{ik} + ad\theta_i/dx$, where a is the lattice parameter) gives:

$$D^*_i = a^2k_{iv}t_{iv}(S_tS_v)^{z-1} \quad (9)$$

Expressions for the self-diffusion coefficient taking account of the interaction between the particles using other approximations, and for other mechanisms of migration, are obtained analogously.[69] In multi-component systems, the concept of self-diffusion coefficient is defined in different ways.[69] Nevertheless, in each specific case, it can be expressed in terms of the rates of jumping of the particles. In general, the situation is more complex than described here in terms of the traditional approach.[56,69] The complication is due to the fact that, for a number of mechanisms, there is a correlation between successive jumps of the particles, leading to the appearance of a correlation factor in Eqn.(9).[69] According to available estimates, for a binary system in the absence of interaction it varies from 1 to 0.65 for $0 \leqslant \theta \leqslant 1$.[70] This model has been used[71] to explain the anomalously low values of the activation energies of self-diffusion in the metals γ-U, β-Ti, and β-Zr.[72]

The expressions obtained for the elementary processes make it possible to construct kinetic equations describing the change in the surface concentrations of adsorbed species during surface reactions. These reactions, on the one hand, are of fundamental interest for membrane catalysis, and on the other hand define the boundary conditions for the processes of mass transfer through a membrane. The form of these equations can be examined for a model example. It will be assumed that the following three-stage process takes place: 1) $A_2 + 2Z \leftrightarrows 2AZ$, 2) $B + Z \leftrightarrows BZ$, 3) $AZ + BZ \rightarrow 2Z + C$. The first stage may represent, for example, the dissociative adsorption of hydrogen molecules in hydrogenation or dehydrogenation, or the adsorption of oxygen molecules in redox reactions. The second stage corresponds to the adsorption of the other reagent, and the third to the formation of the product C. If the given process takes place on one side of a membrane with a uniform surface, the kinetic equations have the form (in the adsorption system, three components are considered: A, B, and v):

$$\begin{gathered}\dot{\theta}_A = z[V_{vv}(1) - V_{AA}(1) - V_{AB}(3)] \\ \dot{\theta}_B = V_v(2) - V_B(2) - zV_{AB}(3) \\ \theta_A + \theta_B + \theta_v = 1\end{gathered} \tag{10}$$

The significance of the terms on the right-hand sides of Eqns.(10) can be seen from Eqns.(7); they contain the additional indices of the stage numbers ($\alpha = 1, 2, 3$), since the parameters of the interaction $\varepsilon_{ij}^{*}(\alpha)$ are different for different stages. If the reaction involves the molecules of the gas phase, the effective reaction rate constant contains as a factor the partial pressure of the substance involved in the given stage α.

If the process takes place on a catalytic membrane and the component A is transferred through it to the surface b on which the component B is adsorbed, the kinetic equations for the component A on the different surfaces have the form:

surface a:

$$\dot{\theta}_A = z[V_{vv}(1) - V_{AA}(1)] - I_A(a)$$

surface b:

$$\dot{\theta}_A = I_A(b) - zV_{AB}(3) \tag{11}$$

where the term $I_A(l)$, $l = a, b$ denotes the flux of the particles A from the surface l into the bulk of the membrane (the expression for I_A is given in the next section). The process of transfer of the component A corresponds to the stage $\alpha = 4$. The kinetic equation for the component B relates to the surface b, and its form coincides with that of expression (10).

The kinetic equations (10) and (11) are based on Eqns.(6) and (7), which are applicable when the surface mobility of the particles is high, ensuring their equilibrium distribution. This situation is apparently always realised for hydrogen atoms. For the atoms of oxygen and other moleecules, denoted B, it is possible to have situations in which the rate of their migration is comparable with the rate of the elementary reactions. The system of kinetic equations (10) and (11) must then be altered,[73,74] since Eqns.(6) are replaced by the kinetic equations for the functions θ_{ij}.

III. EQUATIONS FOR THE TRANSFER PROCESS

It is simplest to examine the characteristic features of models with restricted mobility of the particles for the case of the migration process. It will be assumed that the component A is transferred in the volume of the membrane through the interstices (vacancy mechanism). The concentration of particles in the layer k, denoted by θ_k, changes as a result of the exchange of the particles with the vacancies of neighbouring layers:[75]

$$\dot{\theta}_k = -z_{k,k-1}(V_{k,k-1}^{Av} - V_{k,k-1}^{vA}) - z_{k,k+1}(V_{k,k+1}^{Av} - V_{k,k+1}^{vA}) \tag{12}$$

where z_{kq} is the number of sites in the layer q, adjacent to a site in the layer k;

$$q = k,\ k \pm 1,\ \sum_q z_{kq} = z_k,$$

and z_k is the number of neighbouring sites for a site in the layer k. For uniform lattices, the numbers z_k and z_{kq} are constant for all the layers, whereas for non-uniform lattices these numbers are different. The quantity V_{kq}^{Av} is the rate of migration of a particle A from a site of the layer k into a vacancy of the layer q.

$$V_{kq}^{Av} = k_{Av}\theta_{kq}^{Av} \prod_{p=k+1}^{k-1} [S_{kp}^{A}(4)]^{z_{kp}-\Delta_{qp}} \prod_{p=q+1}^{q-1} [S_{qp}^{v}(4)]^{z_{qp}-\Delta_{kp}} \tag{13}$$

where Δ_{kq} is the Kronecker symbol, and the functions S_{kq}^{i} represent the generalisations of Eqns.(7) for the case of a non-uniform distribution of the particles in the lattice sites:

$$S_{kq}^{i}(\alpha) = \sum_{l=1}^{s} \theta_{kq}^{il} \exp[\beta\delta\varepsilon_{il}(\alpha)]/\theta_k^i \tag{14}$$

Eqns.(13) and (14), obtained in the quasi-chemical approximation, show that the right-hand sides of Eqns.(12) contain the unknown functions θ_{kq}^{ij}, that is the system of equations (12)–(14) is not closed. In Eqns.(12) the same migration process leads to a change in the concentration of the particles in each layer and a change in the concentration of pairs of neighbouring particles, influencing through the inter-particle interaction the height of the activation barrier of the elementary process. Thus for the system of kinetic equations (12) to be closed, it is necessary to add to it the kinetic equations for the functions θ_{kq}^{ij}. With allowance for the normalisation relationships

$$\sum_{j=1}^{s} \theta_{kq}^{il} = \theta_k^i; \quad \sum_{i=1}^{s} \theta_{kq}^{il} = \theta_q^l; \quad \sum_{i=1}^{s} \theta_i = 1 \tag{15}$$

For the binary system A–v, it is sufficient to introduce one equation for the function θ_{kq}^{AA}:

$$\dot{\theta}_{kq}^{AA} = -\sum_{h=k+1}^{k-1} (z_{kh} - \Delta_{qh})[V_{hkq}^{\overline{vA}A} - V_{hkq}^{\overline{Av}A}] - \sum_{h=q+1}^{q-1} (z_{qh} - \Delta_{kh})[V_{kqh}^{A\overline{Av}} - V_{kqh}^{A\overline{vA}}]$$

$$V_{hkq}^{\overline{vl}l} = V_{hk}^{vl}\psi_{kq}^{il}, \quad \psi_{kq}^{il} = \theta_{kq}^{il}\exp[\beta\delta\varepsilon_{il}]/(\theta_k^i S_{kq}^i) \tag{16}$$

where the first summation corresponds to the migration of a particle A from the layer k into a neighbouring site of the layer h and back again, and the second summation corresponds to the migration of another particle A from the layer q into a neighbouring site of the layer h. The terms of Eqns.(16) are expressed in terms of the rates of the elementary processes (13); the "reacting" species are indicated by a bar above the symbol. The functions ψ_{kq}^{ij} take account of the influence on the rate of change in θ_{kq}^{AA} of a neighbouring particle not taking part in the elementary process at the given moment of time.

The equations for the functions θ_{kq}^{ij} are constructed assuming that after a characteristic short time interval, only one elementary process takes place.[73–76] Finally, the system of equations (12)–(16) is closed and is solved with the specified initial conditions $\theta_k(\tau = 0)$ and $\theta_{kq}^{AA}(\tau = 0)$, $q = k, k + 1$. Equations for the θ_{11}^{ij} for restricted mobility of the reagents on the membrane surface, supplementing Eqns.(10) or (11) for the model process being considered, are given in Ref.76.

Thus restricted mobility of the particles must lead to the appearance of equations for the paired distribution functions θ_{kq}^{ij} (or for t_{kq}^{ij}). This applies to diffusion-controlled reactions,[36] ideal models of systems with a high concentration of particles[70,77] and single-layer transfer,[78] and ideal models of transfer processes with an arbitrary concentration of particles.[73-76,79]

The phase interface produces a change in the properties of the surface regions of solids. This is revealed in a change in the distance between the surface crystallographic layers and the lattice parameter in the layers, and also in structural transitions and a change in the concentration profile of the surface region.[80-83] As a result, there is a change in the properties of the absorption centres in the surface region. Study of the surface properties shows that outside the critical range, the thickness of the surface region does not exceed 5–10 layers,[82-85] but its non-uniformity may have a considerable influence on the characteristics of the membrane permeability. In the surface region, the structure of Eqns.(12)–(16) remains unchanged (the layer $k = 1$ corresponds to the surface layer of adsorbed particles), but in the terms it is necessary to replace the parameters ε_{ij}, ε_{ij}^{*}, and k_{Av} by the analogous parameters ε_{kq}^{ij}, ε_{kq}^{ij*}, and k_{kq}^{Av}, depending on the layer number. Thus $I_A(a) = V_{12}^{Av} - V_{12}^{vA}$, and analogous expressions are applicable for $I_A(b)$.

For long times ($k_{Av}\tau \gg 1$), instead of the discrete system of equations, it is possible to use the diffusion equation

$$\frac{\partial\theta}{\partial\tau} = \frac{\partial}{\partial x}\left(D(\theta)\,\frac{\partial\theta}{\partial x}\right);\quad x = (k-\varkappa)\,a \tag{17}$$

for which the system of equations for $0 \leqslant k \leqslant \kappa$ represents the boundary condition relating the bulk value of the concentration θ to the concentration of particles in the gas phase. In the diffusion approximation, $\dot{\theta}_{\kappa-1}^{A} = 0$,[29,75] so that the equation for the layer $\kappa - 1$ can be written in the form

$$D(\theta)\,\frac{d\theta}{dx} + z_{\varkappa-1,\varkappa-2}\,(V_{\varkappa-1,\varkappa-2}^{vA} - V_{\varkappa-1,\varkappa-2}^{Av}) = 0 \tag{18}$$

The form of the other equations in the surface region depends on the relationship between k_{Av} and k_{kq}^{Av}. If $k_{kq}^{Av}\tau \ll 1$, it is necessary to use the original system of differential equations; otherwise, for all intermediate layers $\dot{\theta}_k^{A} = 0$, leading to the appearance of an algebraic relationship between $\theta_A(x = 0)$ and the pressure of the molecules in the gas phase. For $k_{kq}^{Av} \leqslant k_{Av}$, this relationship is determined by the steady-state relationships $\dot{\theta}_k^{A} = 0$, and for $k_{kq}^{Av} \gg k_{Av}$ it is determined by equilibrium relationships of type (6).[86] The change to the diffusion approximation also corresponds to the steady-state condition for the kinetic equations for the functions θ_{Av} in the volume of the solid. For a qualitative estimate of the diffusion coefficient (mass transfer) it is possible to use the condition of local equilibrium distribution of the particles.[71] In Ref.71 it was found that in the range of separation into layers, the diffusion coefficient may take negative values (condensation of the substance diffusing). A mathematical description was also obtained for experimental data[87] on the diffusion of oxygen atoms on the (110) face of tungsten. In the surface layers, the equations for θ_{kq}^{Av} either remain differential, if $k_{kq}^{Av}\tau \ll 1$, or become steady-state algebraic relationships of the form $\dot{\theta}_{kq}^{Av} = 0$, if $k_{kq}^{Av} \lesssim k_{Av}$, or into equilibrium algebraic relationships,[86] if $k_{kq}^{Av} \gg k_{Av}$.

IV. EQUATIONS FOR THE CHANGE IN THE STATE OF THE MEMBRANE

If the interaction between the atoms of the solid and the particles being transferred is sufficiently strong, it may lead to a change in the state of the membrane in the bulk. The non-equilibrium distribution of the substance diffusing along the thickness of the membrane leads to a redistribution of the atoms of the solid both along the thickness of the membrane and within each layer. If it is assumed that the particles of the substance diffusing migrate through the interstices of an alloy, and that the atoms of the alloy migrate, in accordance with the vacancy mechanism, through substitution lattice sites, then there arises the problem of describing the processes involved in the migration of particles of different kinds in different sub-lattices (immiscibility of the particles of different sub-lattices). For clarity, the treatment will be restricted to the case of a disordered alloy with a face-centred cubic (FCC) lattice, in which the dissolved particles occupy only octahedral interstices. The distances between the atoms of the alloy and between the particles of the substance diffusing in neighbouring interstices are greater than the distance between a particle and a neighbouring atom; in the general case, therefore, it is necessary to examine the problem in which account is taken of the interactions of not only nearest neighbours, but also more distant neighbours.[88-90]

The symbol γ will be used to denote the sites of the substitution sub-lattice of the alloy, and the symbol δ to denote the sites of the interstice sub-lattice. The equations for the evolution of the components of the alloy in the direction of the flux of diffusing substance will then have the form:

$$\dot{\theta}_k^{i}(\gamma) = -z_{k,k-1}\,[V_{k,k-1}^{i\nu}(\gamma\gamma) - V_{k,k-1}^{\nu i}(\gamma\gamma)] - z_{k,k+1}\,[V_{k,k+1}^{i\nu}(\gamma\gamma) - V_{k,k+1}^{\nu i}(\gamma\gamma)] \tag{19}$$

where $\theta_k^{i}(\gamma)$ is the mole fraction of the atoms i in the sites of the sub-lattice γ of the layer k. The structure of Eqns.(19) coincides with that of the equation for the transfer of the substance diffusing (12), which also remains applicable in the present case if its left-hand side contains $\theta_k^{A}(\delta)$, and its right-hand side the terms $V_{kq}^{A\nu}(\delta\delta)$. The indices in brackets indicate the sites of the sub-lattices containing the migrating atoms and particles, and also the vacancies. The terms of Eqns.(19), according to Ref.90, have the form ($\lambda = \gamma, \delta$):

$$V_{kq}^{i\nu}(\gamma\lambda) = \hat{k}_{i\nu}\theta_{kq}^{i\nu}(\lambda\lambda)\prod_{h=k+k_R}^{k-k_R}\prod_{r_h}\prod_{\sigma}[S_{kh}^{i}(\lambda\sigma\,|\,r)]^{\varkappa_{qh}(\lambda\sigma|r)} \times \prod_{h=q+k_R}^{q-k_R}\prod_{r_h}\prod_{\sigma}[S_{qh}^{\nu}(\lambda\sigma\,|\,r)]^{\varkappa_{qkh}(\lambda\sigma|r)}$$

$$\delta\varepsilon_{kh}^{ij}(\lambda\sigma\,|\,r) = \varepsilon_{kh}^{ij*}(\lambda\sigma\,|\,r) - \varepsilon_{kh}^{ij}(\lambda\sigma\,|\,r);$$

$$\varkappa_{kqh}(\lambda\sigma\,|\,r) = z_{kh}(\lambda\sigma\,|\,r) - \Delta_{qh}(\lambda\sigma) \tag{20}$$

where $z_{kq}(\lambda\sigma\,|r)$ is the number of sites of the sub-lattice in the layer q at a distance r from a site in the sub-lattice λ in the layer k; $\Delta_{qh}(\lambda\sigma)$ is the Kronecker symbol, equal to 1 for $q = h$ and $\lambda = \sigma$, and equal to 0 in other cases; $\theta_{kq}^{ij}(\sigma\lambda)$ is the probability of finding the particles i and j in the layers k and q in the sub-lattices λ and σ; the parameter of the interaction between i and j is denoted by $\varepsilon_{kq}^{ij}(\lambda\sigma\,|\,r)$. If the layers being considered correspond to a uniform volume, then the indices k and q can be omitted, but in the surface regions the layer number is important. In Eqn.(20), account is taken of the paired interactions with all neighbours situated within R coordination spheres, whose centres are the particles i and v (if the neighbours are situated in the layers $k \pm k_R$ and $q \pm k_R$ respectively). The quantity k_R differs from R, since the distance between neighbouring coordination spheres r and $r + 1$ does not exceed the

distance between neighbouring layers. For example, for a volume lattice with $z = 6$ with $R = 2$, the quantity $k_2 = 1$, as with $R = 1$ and $R = 3$; the distances between the particles, corresponding to $R = 1$, 2, and 3, are a, $a\sqrt{2}$, and $a\sqrt{3}$ respectively. The quantity $k_R = 2$ only for $R = 4$, when the distance between the particles is $2a$. An analogous situation is observed for any other structure.

Thus for a fixed layer number h, the product is taken over all the sites in the layer at different distances from the central particle. In the general case, these sites may belong to different sub-lattices. They must be distinguished in explicit form, since this determines the type of particles s_σ over which the summation in the functions $S^i_{kh}(\lambda\sigma \mid r)$ is carried out. The structure of the solid determines unambiguously the type σ of the sub-lattice in the layer h at a distance r from a site of type λ in the layer k. The parameter of the interaction of the activated complex, formed from a particle i in a site of the sub-lattice δ of the layer k and a neighbouring particle j situated at a distance r in a site of the sub-lattice σ in the layer h, is denoted by $\varepsilon^{ij*}_{kh}(\lambda\sigma \mid r)$; k_{iv} is the pre-exponential factor of the migration rate constant. Eqn.(20) differs from the analogous expression given in Ref.90 in that it takes account of the independent influence of each neighbouring particle j on the central particles i and v.

Eqns.(19) must be supplemented by equations for the functions $\theta^{ij}_{kh}(\lambda\sigma \mid r)$. In the general case it is necessary to examine all pairs of particles in different sub-lattices (in the interstice sub-lattices, the substitution sub-lattices, and pairs of a mixed type containing a particle in the interstice sub-lattice and an atom in the substitution sub-lattice), since they are all taken into account in the functions $S^i_{kh}(\lambda\sigma \mid r)$. These equations have the following general structure:[90]

$$\dot{\theta}^{ij}_{kq}(\lambda\sigma \mid r) = -\sum_h \varkappa_{kqh}(\lambda\sigma \mid r)\,[\overline{V^{vij}_{hkq}}(\lambda\lambda\sigma \mid r) - \overline{V^{ivj}_{hkq}}(\lambda\lambda\sigma \mid r)] - \\ -\sum_h \varkappa_{qkh}(\sigma\lambda \mid r)\,[\overline{V^{ijv}_{kqh}}(\lambda\sigma\sigma \mid r) - \overline{V^{vj}_{kqh}}(\lambda\sigma\sigma \mid r)] \qquad (21)$$

In the first summation, the sites h denote adjacent sites of the sub-lattice λ, corresponding to the first index λ in the argument of the term, $\lambda = \gamma$, δ; in the second summation, h denotes adjacent sites of the sub-lattice δ, corresponding to the last index in the argument of the term. The particles taking part in the elementary process are indicated by a bar above the symbol. The terms of Eqns.(21) are defined by the equations:

$$\overline{V^{vij}_{hkq}}(\lambda\lambda\sigma \mid r) = V^{vi}_{ik}(\lambda\lambda)\,\psi^{ij}_{kq}(\lambda\sigma \mid r)\,\psi^{ij}_{kq}(\lambda\sigma \mid r)\,\psi^{vj}_{hq}(\lambda\sigma \mid r), \\ \psi^{ij}_{kq}(\lambda\sigma \mid r) = \theta^{ij}_{kq}(\lambda\sigma \mid r)\exp[\beta\delta\varepsilon^{ij}_{kq}(\lambda\sigma \mid r)]/[\theta^i_k S^i_{kq}(\lambda\sigma \mid r)] \qquad (22)$$

The normalisation relationships have the form:

$$\sum_{j=1}^{s_\sigma} \theta^{ij}_{kq}(\lambda\sigma \mid r) = \theta^i_k(\lambda);\quad \sum_{l=1}^{s_\lambda} \theta^{ij}_{kq}(\lambda\sigma \mid r) = \theta^j_q(\sigma);\quad \sum_{i=1}^{s_\lambda} \theta^i_\alpha(\lambda) = 1 \qquad (23)$$

With allowance for these relationships, the system of equations (19)–(23) is closed, and it can be solved by specifying the initial and boundary conditions.

The above equations are readily generalised by taking account of the real characteristics of different systems in the following cases: 1) when the number of interstices does not coincide with the number of sites in the substitution lattice (for example for tetrahedral interstices in a FCC lattice); 2) when the migration of the particles of the substance diffusing takes place through interstices of different types and (or) the alloy is in an ordered state; and 3) when there is an additional displacement of the particles of different sub-lattices; in this case the atoms of the alloy move into the interstices and migrate in them, and the particles of the substance diffusing occupy vacancies in the substitution lattice.

From these equations under quasi-equilibrium conditions for individual sub-systems (sub-lattices) it is possible to obtain equations describing the distribution of the particles of the substance diffusing in different phase states (phase transformations involving ordering and separation into layers or any one of these may take place), as in Ref.55, where the analysis was carried out in the molecular field approximation. In this approximation, there are no effects of correlation of interacting particles. The question of taking account of correlation effects is central in kinetic studies. They may lead to qualitative changes in the description of the kinetic characteristics of a system.[63]

V. VITREOUS INORGANIC AND POLYMERIC MEMBRANES

The molecular models of the transfer of substances in crystalline membranes, described above, are capable of reflecting many important aspects of transfer processes in vitreous membranes. This also applies to silicate glasses[91,92] and to vitreous polymeric membranes. Since the latter are of practical importance, they will be considered in more detail. The available experimental material and an analysis of the trends in the development of transfer models indicate an analogy between the processes taking place in crystalline and vitreous solids. Thus the use of high pressures in a number of gas-separation systems[1,2,93–95] leads to a relatively extensive saturation of the membranes by the diffusing substance. In this case, the appearance of effects of mutual influence is possible. These effects may be due to either the direct interaction of the molecules or an indirect interaction through the polymeric matrix. The substance diffusing may alter the internal state of the polymeric matrix. Relaxation processes also influence the nature of the transfer.[96,97] The elementary processes in glasses, in particular the migration jumps of molecules, and the state of the glasses are inter-related.[98] This makes necessary a combined description of the evolution of the gas–matrix system.

An important role in the transfer of substances in vitreous and crystalline membranes is played by surface processes. A change in the properties of the surface alters its adsorption properties and the solubility of gases in the bulk of the membrane. The latter has a marked influence on the degree of non-equilibrium character of the mass-transfer conditions.[99–101] Thus the surface modification of polymeric membranes based on block copolymers of an arylene sulphoxide with dimethylsiloxane produces a marked change in their gas-permeability with respect to O_2, CO_2, and N_2.[102] The role of the surface in the processes involved in the transfer of ions through polymeric membranes was examined in Refs.103 and 104.

The state of a surface can be described using the multi-layer surface region scheme examined above. The main problem is the relationship between the migration processes and the evolution of the states of the glass. In Ref.98 this problem was solved by changing to the problem of the evolution of the Ising systems: the state of a given elementary volume is characterised by its "internal" energy and the energy of its interaction with a neighbouring elementary volume (the elementary volumes form a lattice in the bulk of the glass). In each elementary volume there is a set of discrete energy minima. The transitions between different energy states of the elementary volume are described by the equations of Glauber.[105,106] They are closed using the molecular field approximation.

The equations given in the previous section are also Glauber equations, but they were closed using a more accurate approximation taking account of short-range correlation effects. They can be used to obtain a description of vitreous systems if each discrete state of the elementary volume [98] is related to atoms of a definite type in the alloy. A more detailed description of the states of glasses is also possible, however, if a particular direction is distinguished in the volume and the group of possible states of the fragments of the polymer (or silicate) chain is examined relative to this direction. A change in the relative orientation of neighbouring fragments of the chains takes place either as a result of internal rotation within a given fragment or cooperatively as a result of conformational rearrangements of several fragments.[107-110] The transitions between different states are associated with the overcoming of corresponding activation barriers.

This formulation of the problem makes it possible to solve a wide range of problems associated with the transfer of substances through vitreous membranes.

- - -o0o- - -

Problems related to the present state of the molecular-kinetic theory of transfer processes in solid crystalline and vitreous membranes, based on the use of information on the interactions between the particles, have been examined. The energy parameters are divided into two groups, characterising the interaction of the particles in the ground and transition states. The expressions proposed for the rates of the reactions in the forward and back directions for each stage of the process are consistent with the description of the equilibrium distribution of the particles.[59,88] This makes it possible to determine the parameters of the interaction of the particles in the ground state on the basis of independent measurements of the thermodynamic characteristics (for example the heats of adsorption and absorption, the isotherms of these processes, equilibrium diagrams, etc.).

A characteristic feature of the models taking account of the restricted mobility of the components of a solid is the existence of kinetic equations which describe the changes in the concentrations of different pairs of particles, and this makes it possible not only to characterise the evolution of local compositions but also to estimate the relative arrangement of the components, that is it makes it possible to obtain the details of the membrane structure and to describe its rearrangement. This in turn makes it possible to raise the question of the influence of the method of preparation of the membranes on their permeability.

A Phenomenological Theory of Diffusion in Heterogeneous Media and Its Use in Describing Membrane Separation Processes

I.N.Bekman and I.P.Romanovskii

Within the framework of a unified methodical treatment a critical analysis is given of different methods for the phenomenological description of the processes of the gas permeability of heterogeneous media: lamellar, dispersion type, containing individual inclusions, etc. The introduction of a continuous geometrical factor allows generalised expressions for the effective transport parameters to be obtained. Mathematical modelling methods are used to check the adequacy of the mathematical apparatus considered. The prospects for a directed choice of the structure of the material for controlling the efficiency and selectivity of a gas-separating membrane are investigated.
The bibliography includes 50 references.

I. INTRODUCTION

Composite materials are today being more widely used in membrane technology. A targetted search for such materials requires the development of a systematic approach to the construction of membranes which possess a given efficiency and selectivity using substances with known diffusion properties.

The aim of this review is to consider the prospects for using the steric and chemical organisation of a heterogeneous material to control the parameters of a gas-separating membrane. Consideration is given primarily to an analysis of the current phenomenological theories of diffusion in heterogeneous media and to mathematical modelling of the permeability of various types of such media. Recommendations are given for selecting the topology of the composite material which will provide the required transport properties for the membrane.

II. TYPES OF HETEROGENEOUS STRUCTURES AND THE MAIN APPROACHES TO THE DESCRIPTION OF DIFFUSION IN HETEROGENEOUS MEDIA

The methods for setting up the mathematical apparatus for diffusion in heterogeneous media are determined by the types of structure of the heterogeneous materials.[1-3]

In a "macroheterogeneous" medium which includes non-uniformities of structure comparable with the length of the diffusion wave, there is a distinction between the mechanisms of sequential diffusion (diffusion in a lamellar membrane, in which planar non-uniformities of structure are orientated perpendicular to the direction of flow[4]), parallel diffusion (diffusion along channels isolated from each other and orientated along the direction of flow[5]), dissociative diffusion (diffusion along interpenetrating networks of defects; this can be regarded as parallel diffusion along interconnected channels between which there is reversible exchange of the atoms of the diffusant[6-8]), and the mechanism by which the diffusive flow passes round individual large obstacles of a specific shape and dimensions.[2,9-12] The phenomenological theory of mass transport in media of this type is fairly well developed (see, for example, Refs.1, 15). One exception is the problem of transport in materials containing individual large inclusions, a general solution of which is at present unknown. For such systems there are also no methods for calculating the effective coefficients of permeability and diffusion.

The main class of "microheterogeneous" structures is made up of dispersion media, i.e. solids containing a dispersion of inclusions of a specific shape and size which have different thermodynamic and kinetic properties from the base material. A phenomenological theory of transport in dispersion media was proposed by Maxwell (see Ref.14) to describe the electrical conductivity of dispersions[15-18] and then adapted to the problems of thermal conductivity[19] and diffusion.[20,21] In this model a calculation is first made of the perturbations of the lines of diffusion flow caused by an individual obstacle of a given shape (its dimensions are postulated to be much smaller than the thickness of the specimen) situated in an inifinite homogeneous medium and then the sum is taken of all the perturbations caused by an ensemble of inclusions of the same shape arranged in a specimen of infinite size. In early work this treatment was used to describe diffusion in dilute dispersions but subsquently it was developed as applied to concentrated dispersions and the orderly packing of inclusions of phases of a different nature.[5,22-27] This theory was used to describe diffusion in media containing inclusions with a simple geometrical form: a sphere, plate, cylinder, ellipsoids of rotation, etc. Unfortunately it does not take into account the possibility of a discontinuity in the concentration profile at the boundary between the inclusion and the enclosing medium. The model has a great number of variants and, depending on the method used to sum the perturbations, it leads to different expressions for the effective permeability constant. Up to the present there has been no success in using this theory to describe non-steady-state diffusion.

A model for diffusion in dispersion media which was developed independently[28,29] was first proposed to describe the kinetics of adsorption by biporous sorbents and later to describe the process of sorption of vapours by filled polymers.[30] Within the scope of this theory the kinetics of non-steady-state diffusion from the surrounding medium into a specimen of a specific shape containing identical

inclusions (the shape of the specimen and the inclusions is made arbitrary but simple: a sphere, cylinder, or plate), the dimensions of which are considerably smaller than the length of the diffusion wave, are discussed. Linear and non-linear situations were analysed and expressions given for the initial statistical moments from the kinetic curve, so permitting estimates of the effective diffusion coefficients to be obtained.[31] A significant limitation of this treatment, severely restricting its range of application, is the requirement that the diffusion coefficient in the inclusion be much smaller than the diffusion coefficient in the base material of the specimen.

It would appear that a description of diffusion in a dispersion of point defects can be obtained from the models discussed above by simply reducing the size of the inclusions. However, in practice the theory of diffusion in defect media was developed quite independently by adapting the mathematical machinery which describes diffusion accompanied by a chemical reaction between the diffusant and the solid. Thus, diffusion with temporary retention of the diffusant in the defects (reversible capture in the traps) is interpreted as a reversible first-order chemical reaction,[32,33] diffusion with permanent capture as an irreversible first-order chemical reaction,[34] and diffusion with capture in defects of limited capacity (i.e. diffusion with adsorption at the defects which formally obey the Langmuir isotherm) as a second-order chemical reaction.[35,37] In earlier work dilute dispersions of defects were considered and then a conversion made to essentially heterogeneous media.[38,39] This approach has been fairly well developed so far: the appropriate equations for Fick's first and second laws have been rigorously set down, the formulae for describing non-steady-state mass transport obtained, and the expressions for the effective diffusion coefficients given. For example, the expression for the effective diffusion coefficient in a concentrated dispersion of point defects takes into account the diffusion coefficients both in the enclosing medium and at the defects and also the occurrence of different types of sorption isotherm in the inclusions and in the main component of the medium.[39]

A special class is formed by structures generated from dilute dispersions of point inclusions when the volume fraction of the latter is increased (for brevity in the present work we shall call such heterogeneous substances percolation-type structures[40,41]). The importance of such structures is due to their flexibility which allows conversion from one of the types of structure discussed above to another.

In fact, dispersion of point defects occurs at low concentrations of the inclusions. As their concentration increases the point inclusions are joined together in extended formations (clusters) and the dispersion is characterised by functions for the size and shape distribution of the clusters. In spite of the random nature of the cluster formation this type of dispersion medium obeys strictly defined statistical rules and the evolution of the system can be quantitatively described in terms of percolation theory using such concepts as the percolation threshold and the critical index.[42] At a certain value of the volume fraction a continuous cluster is generated (there is "puncturing" of the membrane accompanied by a sharp change in the transport properties of the membrane). In this case, direct transfer is impossible along any of the components of the heterogeneous structure (an analogue of a lamellar medium). When the volume fraction of the new phase is increased further reversal of the phases takes place, i.e. the old phase now forms inclusions in the new.

It is clear that, depending on the volume fraction of the inclusions, diffusion in a percolation-type medium can be described as "chemical" diffusion, diffusion with reversible capture, diffusion in a dispersion medium, dissociative diffusion, or dispersion in a lamellar medium. A unified description of the evolution of the system from a diffusion point of view requires the percolation theory to be amalgamated with the equations for non-steady-state transfer. However, this course involves serious difficulties. In its current form the percolation theory requires the complete absence of transport along one of the components of the medium and is used only to describe steady-state conditions of permeability.

To sum up this short analysis of known models for diffusion in heterogeneous media the following comments can be made.

(1) There are two main approaches to setting up the mathematical machinery. The first is based on replacing the heterogeneous medium by a homogeneous medium with the same effective diffusion properties. This replacement can be made if the characteristic size of the non-uniformities in the structure is smaller than the length of the diffusion wave. The second approach is used to describe diffusion in media containing individual large inclusions whose size clearly exceeds the length of the diffusion wave. In this case account is taken of the spatial arrangement of the components of the medium, the local values of the coefficients of solubility and diffusion in each component, the shape and size of the inclusions, and also the diffusion resistance of the phase boundary.

Unfortunately up to now these two methods of describing diffusion in heterogeneous media have been developed quite independently of each other. Moreover, even within the framework of a single approach there have arisen different variants which start from almost the same physical principles but lead to different final expressions. For example, depending on the method chosen for averaging the concentration field, the permeability constant P of a dispersion of inclusions is given by the formulae:[1,27]

$$\frac{P}{P_1}=\frac{P_2+2P_1-2\Phi_2(P_1-P_2)}{P_2+2P_1+\Phi_2(P_1-P_2)}$$

where Φ_1 and Φ_2 are the volume fractions and P_1 and P_2 the permeability constants of components 1 and 2 respectively;

$$\frac{P}{P_1}=\frac{P_2+2P_2-W-\Phi_2(2P_1-2P_2-W)}{P_2+2P_2-W+\Phi_2(P_1-P_2+W)}$$

where $W = 0.78(P_2 - P_1)^2/(2P_1 + P_2)$; or

$$P_1P^3-3P_1P_2P^2+(3P_1P_2^2+(P_2-P_1)^3\Phi_1^3)P-P_1P_2^3=0$$

$$2P^2+[P_2-2P_1-3\Phi_2(P_2-P_1)]P-P_1P_2=0$$

$$\left(\frac{P}{P_1}-1\right)=3\Phi_2\left[\frac{P_2+2P_1}{P_2-P_1}-\Phi_2+\frac{\beta(P_2-P_1)\Phi_2^{10/3}}{P_2+(4P_1/3)}+\ldots\right]^{-1}$$

where for simple cubic packing of spheres $\beta = 0.523$ [15] (in Ref.23 $\beta = 1.31$), for body-centred cubic packing of spheres $\beta = 0.129$,[23] and for face-centred cubic packing $\beta = 0.0752$.[23]

An analysis of these expressions shows that they give approximately the same results if $P_2 < P_1$ but considerably different results if $P_2 > P_1$.

With such a diversity of expressions a natural question arises: which of these formulae is most valid physically and universal? Below, by analysing the known models within the framework of a single methodological approach, we shall discuss diffusion in various types of heterogeneous media (dispersion, lamellar, containing individual inclusions, etc.) and shall show that the modified Maxwell equation generated as a result of this analysis allows almost all the known methods of describing diffusion in heterogeneous media to be unified. The adequacy of the treatment will be checked by comparison with the results of mathematical modelling of diffusion in heterogeneous media.[43]

(2) Almost all the structure types described above are represented among specific polymer systems.[44,45] For example, parallel diffusion is observed in polymers with a spherulitic structure when the membrane thickness is comparable with the diameter of the spherulites.[46] Sequential diffusion takes place in lamellar membranes obtained by compressing several films with different diffusion properties, in polymers whose surface has been modified chemically or by radiation, etc. In investigating composites based on polymers and porous specimens the distortions of the diffusion flow lines must be taken into account. The geometrical form of the non-uniformities in the structure must be allowed for in work with crystalline polymers or filled materials.[47]

Diffusion with temporary retention of the diffusant in traps occurs in glassy polymers, block-copolymers, etc. A model for dissociative diffusion will, generally speaking, always be used in describing the processes of mass transport in polymers: the presence of macro-chains necessitates taking into account diffusion along two interconnected channels (along and across the chains) which involve different values of the diffusion coefficient.

The application of the theory of diffusion in heterogeneous media to real polymeric solids often leads to inadequate results: the parameters of the shape of the inclusions calculated from diffusion data do not correspond to those measured on an electron microscope.[21] This is because definite geometrical shapes for the defects in the structure are rarely met in actual systems. Furthermore, a whole spectrum of inhomogeneities in structure is usually present in the materials. Such a situation occurs, in particular, on reversal of the phases.

These difficulties can be overcome by introducing into the modified Maxwell equation a continuous geometrical factor, the values of which are either determined experimentally or calculated by mathematical modelling methods.

(3) In membrane technology a very important aim is to develop methods for a directed choice of the spatial and chemical organisation of the membrane structure, which will ensure that the efficiency and selectivity of the membrane are high. Below we shall set out a theory of diffusion in heterogeneous media for describing the permeability to mixtures of gases and demonstrate a method for choosing a spatial structure of the membrane that is optimal from the point of view of solving problems in membrane-separation of gaseous mixtures.

III. ANALYTICAL TREATMENT OF THE PERMEABILITY OF TWO-COMPONENT HETEROGENEOUS MATERIALS

The following concepts are used in setting up a phenomenological theory of mass-transport in heterogeneous media:

the topology of the medium, i.e. the spatial arrangement of the discontinuities (layers, inclusions, dispersions of inclusions, etc.);

the diffusion properties of the initial components of the medium (the coefficients of diffusion and solubility in these components of the substances being separated);

the type of sorption isotherm of the diffusant in each of the components of the medium; and

the type of diffusion experiment, i.e. a certain set of initial and boundary conditions (in the present work we were restricted to the permeability method).

The output parameters are:

the permeability constant of the heterogeneous medium P which determines the magnitude of the steady-state flow through the membrane;

the mean concentration of the diffusant in the specimen;

the effective non-steady-state diffusion coefficient being used to estimate the time taken to reach a steady state;

the form of the concentration and kinetic dependences;

the dependence of the diffusion parameters on the density of the inclusions and their shape, the structure of the heterogeneous material (thickness and form of the membrane, size of the inclusions, etc.), the partial pressure at the entrance of the membrane, the drop in pressure at the specimen, etc.

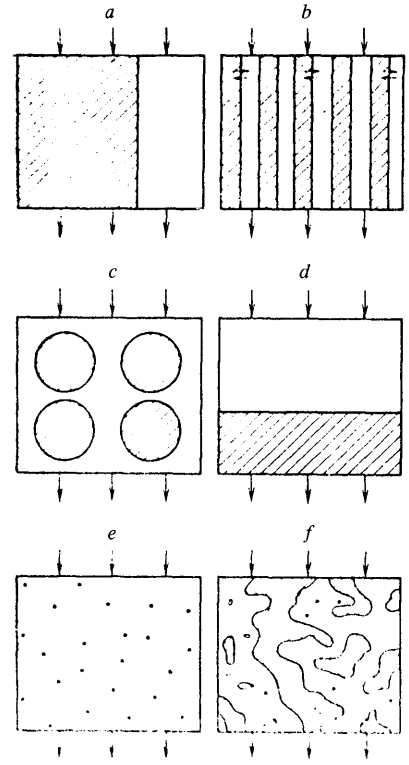

Figure 1. Main types of heterogeneous system.[2]

We are restricted to consideration of five main topological types of two-component material. In the first type of material, mass transport takes place along two channels isolated from each other, i.e. there is parallel diffusion (Fig.1*a*). In the second type of membrane there can be reversible exchange of the diffusant atoms, i.e. dissociative diffusion (Fig.1*b*). In the next type of structure the diffusion medium contains inclusions of a specific shape and size (as an example cubic packing of spheres is shown in Fig.1*c*). A lamellar medium (Fig.1*d*) gives sequential diffusion through layers of different components. The fifth type is a percolation-type structure (a dilute dispersion of point defects is shown in Fig.1*e* and a dispersion of clusters of defects in Fig.1*f*).

The process of diffusion in a heterogeneous medium is usually considered as a random walk of the diffusant particles in the energy field created by the material of the medium (the field does not

change when the diffusant particles pass through it). For a homogeneous isotropic medium the diffusion coefficient D can be represented in the form:

$$D=kd^2$$

with

$$k=k_0\cdot\exp(-\Delta G/k_BT)=\gamma f\nu_0\cdot\exp(-\Delta G/k_BT)$$

where k is the rate constant for the passage of a diffusant atom from one energy state to another, d is the length of a diffusion jump, i.e. the distance between two nearest states, γ is the number of routes by which a transition from one state to another is possible, f is a correlation factor (the fraction of successful jumps, which we shall asume to be 1), ν_0 is the number of jumps in unit time, ΔG is the energy of the transition from one diffusion state to another, k_B is the Boltzmann constant, and T the temperature.

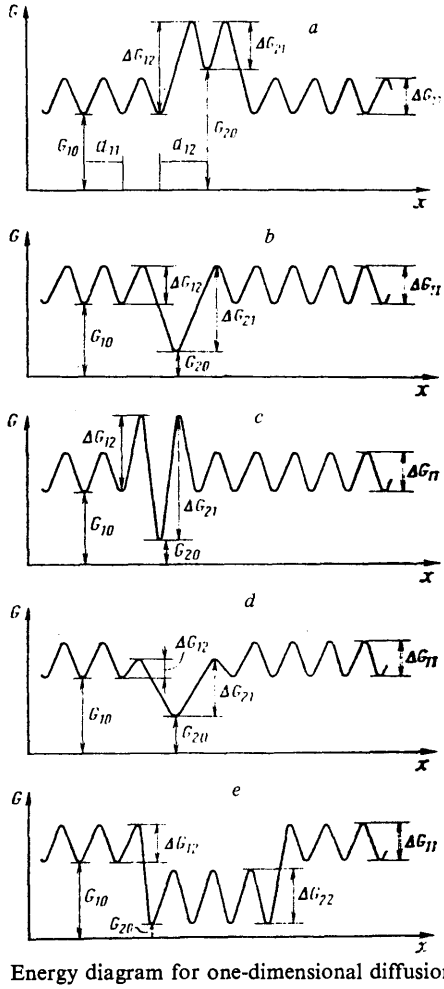

Figure 2. Energy diagram for one-dimensional diffusion (x is distance).[2]

In a two-component medium there are two types of energy state. A site in the base material of the solid will be designated by a subscript 1 and a site in a non-uniformity in the structure by a subscript 2. To describe diffusion in such a system we shall use four transition rate constants k_{11}, k_{12}, k_{21}, and k_{22} and the corresponding lengths of the diffusion jumps d_{11}, d_{12}, d_{21}, and d_{22}. All these parameters are independent of the diffusant concentration but dependent on the temperature:

$$k_{ij}=k_{ij,0}\cdot\exp(-\Delta G_{ij}/k_BT)$$

The pre-exponential factor is determined only by the nature of the diffusant.

Certain types of energy diagram for diffusion in a two-component medium are shown in Fig.2. The migration of the diffusant is determined by the positions of the two potential wells of types 1 and 2 relative to the zero level (i.e. by the energies G_{10} and G_{20}) and also by the magnitude of the energy barriers on entrance to and exit from the potential well (ΔG_{11} for a transition in the base matrix, ΔG_{12} for a transition from the base matrix to an inclusion, ΔG_{22} for diffusion in an inclusion, and ΔG_{21} for exit from an inclusion to the base material of the specimen). If the free energy is higher in state 2 than in state 1 (Fig.2*a*) it is unfavourable for the diffusant to remain in state 2 (an "anti-trap") and it tries to leave. On the other hand, a state with a lower free energy (Fig.2*b*) fills up with diffusant spontaneously (a "trap"). The transition to another phase may be hindered ($\Delta G_{12} > \Delta G_{11}$, Fig.2*c*), remain the same as on transition to an adjacent base state (Fig.2*b*), or may be facilitated (Fig.2*d*), depending on the properties of the boundary between states 1 and 2. If component 2 is an extended inclusion, transitions of type 2−2 appear on the energy diagram (Fig.2*e*).

By the local diffusion coefficient is understood the value $D_{ij} = k_{ij}d_{ij}^2$. Note that $D_{11}\equiv D_1$ and $D_{22}\equiv D_2$ (where D_1 and D_2 are the diffusion coefficients in phases 1 and 2), and that in general D_{12} is not equal to either D_{21} or D_{11}. Thus the presence of additional energy barriers at the entrance to a defect leads to a three-phase diffusion problem for a two-component heterogeneous medium.[48]

By analogy with the concepts used in describing the kinetics of chemical reactions, the value of the ratio of the rate constant for a 1−2 transition to the rate constant for a 2−1 transition is called the equilibrium constant:

$$K=k_{12}/k_{21}=D_{12}/D_{21}=\exp\{-(\Delta G_{12}-\Delta G_{21})/k_BT\}=\exp\{(G_{10}-G_{20})/k_BT\}$$

We shall now turn to a consideration of the population of the energy states of the system by the diffusant atoms. The following symbols will be introduced:

$$\Phi_1=N_1/N=V_1/V,\ \Phi_2=N_2/N=V_2/V\ (\Phi_1+\Phi_2=1)$$

are the volume fractions of components 1 and 2 respectively, where N_1 and N_2 are the numbers of states of types 1 and 2 ($N_1 + N_2 = N$), V_1 and V_2 the volumes of components 1 and 2 ($V_1 + V_2 = V$) in the composite material; the relative populations are $\theta_1 = n_1/N_1$ and $\theta_2 = n_2/N_2$, where n_1 and n_2 are the numbers of diffusant atoms occurring in states 1 and 2; the total population (solubility) of the two-component system is $\theta = n/N = (n_1 + n_2)/(N_1 + N_2)$ and the mean population is $\theta = \Phi_1\theta_1 + \Phi_2\theta_2$.

The linear sorption isotherm is described by the expression:

$$\theta(x=0)=K_\gamma p_0$$

where K_γ is the solubility constant and p_0 the partial pressure of the diffusant on entry to the membrane.

The exchange of the diffusant atoms between the two types of potential well is usually represented in the form:

$$V_1(A)+V_2(0)\underset{k_{21}}{\overset{k_{12}}{\rightleftarrows}}V_1(0)+V_2(A)$$

where $V_1(a)$ and $V_2(A)$ are the diffusant atoms in potential wells of types 1 and 2 respectively and $V_1(0)$ and $V_2(0)$ are vacant sites. If each of the components of the medium is characterised by a linear sorption isotherm then the equilibrium solubility of the diffusant in the first component will be θ_{10} and in the second θ_{20}. Linearity of the sorption isotherm implies that the concentration of free sites in the matrix of the heterogeneous material is sufficiently large, i.e. the relative population is less than 1. At equilibrium:

$$n_2N_1/n_1N_2=k_{12}/k_{21}=K;\ \theta_2=K\theta_1$$

i.e. the equilibrium constant is the ratio of the local solubilities, $K = \theta_2/\theta_1$. Taking into account that the relative population of the first (main) component is not altered by the presence in the material of the second component, the total population is given by the expression

$$\bar{\theta}=\theta_{10}(\Phi_1+K\Phi_2)$$

where θ_{10} is the population of an "ideal" material containing no non-uniformities.

There are various methods for determining experimentally the solubility of the diffusant in the solid: measurement of the mass of the specimen in a steady state of permeability, determination of the amount of diffusant in the specimen after a steady state has been reached, or by dividing the steady-state flow of the diffusant through the membrane by the diffusion coefficient determined from the time lag. In a homogeneous material all these methods give the same result and the solubility measured by the permeability method is equal to half the value determined from the equilibrium sorption. For a heterogeneous medium, on the other hand, such conformity is not observed although the relationship $\theta_2 = K\theta_1$ is always valid.

Let us turn to a consideration of the value of the permeability, i.e. the constant of proportionality between the steady-state flow of the diffusant through the membrane and the difference in the partial pressures on entry to and exit from the membrane. The symbols $\chi_2 = P_2/P_1$ and $\chi = P/P_1$ are used. The known expressions for diffusion in heterogeneous media can now be reduced to a common form of notation.

For dissociative diffusion and its special case of parallel diffusion:

$$\chi=\Phi_1+\chi_2\Phi_2;\ \ \bar{\theta}=\theta_{10}(\Phi_1+K\Phi_2) \qquad (1)$$

For a dispersion of inclusions of identical shape and size (modified Maxwell formula):

$$\chi=(\Phi_1+a\chi_2\Phi_2)/(\Phi_1+a\Phi_2);\ \ \bar{\theta}=\theta_{10}(\Phi_1+K\Phi_2) \qquad (2)$$

where

$$a=a_0/(a_0-1+\chi_2),$$

a_0 being a geometrical factor depending only on the shape of the inclusion. For some simple forms of inclusion this can be calculated analytically: e.g. $a_0 = 3$ for inclusions with a spherical shape and 2 for inclusions in the form of a cylinder with its axis perpendicular to the diffusion flow, etc. Eqn.(2) is valid for dilute suspensions ($\Phi_2 < 0.3$); on changing to closest packing of the inclusions additional terms must be introduced into formula (2).[1] On the whole, Eqn.(2) is satisfied as long as the inclusions retain a definite shape and continuous diffusion flows along one of the components of the heterogeneous medium are possible. It is important to stress that when there is reversal of the phases (i.e. when the matrix and the inclusion change roles) "hysteresis" of the permeability may occur.

For a lamellar material the mean concentration of the diffusant (solubility) in the membrane for a steady state of permeability is given by the expression:[4]

$$\bar{\theta}=\theta_{10}(\chi_2\Phi_1^2+2\Phi_1\Phi_2+K\Phi_2^2)/(\chi_2\Phi_1+\Phi_2)$$

and the permeability is equal to:

$$\chi=(\Phi_1+\Phi_2/\chi_2)^{-1} \qquad (3)$$

The common form of notation for the permeability of the main types of structure which is used in the present work shows clearly the general character of the modified Maxwell formula (2), from which the other diffusion models arise as special cases when an appropriate choice of the geometrical form parameter a_0 ($a_0 \geqslant 1$) is made. The limiting cases are parallel diffusion ($a_0 = \infty$) and sequential diffusion ($a_0 = 1$). This approach allows us to extend the application of the Maxwell formula derived for the case of inclusions of a simple form (discrete integral values of a_0) to cases where the inclusions have an arbitrary structure (continuous fractional values of a_0). Numerical modelling methods can be used to find the values of a_0 for inclusions with the "exotic" shape of rectangular blocks, crosses, etc., for a lamellar medium with a variable boundary, and also to study the evolution of a_0 during reversal of the phases, which results from formation of the nuclei, growth of the nuclei of a new phase, nucleation and growth of the nuclei, etc. The value of a_0 is a measure of the distortions of the flow lines, i.e. the lines along which the product of the diffusion coefficient and the gradient of the diffusant concentration remains constant: for a given χ_2 the smaller is a_0 the greater is the distortion.

In the analysis of the permeability of a dilute dispersion of point inclusions there are considerable difficulties due to the disappearance of diffusion along the second component of the medium at small values of Φ_2. In such structures the transport properties of the material are determined mainly by the characteristics of the intercomponent boundaries. In accordance with a statistical treatment,[38] we may write, using our symbols:

$$\chi=\Phi_1^2+\frac{D_{12}+KD_{21}}{D_{11}}\Phi_1\Phi_2+\chi_2\Phi_2^2$$

Using the relation $D_{12} = KD_{21}$, we obtain:

$$\chi=\Phi_1^2+2\frac{D_{12}}{D_{11}}\Phi_1\Phi_2+\chi_2\Phi_2^2 \qquad (4)$$

$$\bar{\theta}=\theta_{10}(\Phi_1+K\Phi_2)$$

The expressions obtained are valid for any values of Φ_2, i.e. they are suitable for describing the permeability of a dispersion of point inclusions during the complete reversal of the phases taking place by a "percolation" process.

IV. MATHEMATICAL MODELLING OF THE PERMEABILITY OF HETEROGENEOUS MEDIA

The analytical approaches to the description of diffusion in heterogeneous media which were discussed previously are valid only with various kinds of assumptions and have a limited use. Numerical methods of mathematical modelling[43] must therefore be used to solve such problems of the permeability of heterogeneous media as transport in a composite containing a concentrated dispersion of inclusions or in a medium containing irregularly shaped inclusions, when there is a complex distribution of non-uniformities through the thickness of the specimen, when there are specific energy barriers at the entry to the inclusion, etc.

In that work[43] modelling was carried out for diffusion in systems with linear sorption isotherms on the basis of the statistical treatment described above. The whole of the heterogeneous material was divided by a rectangular grid into separate cells corresponding to different diffusion states; a matrix of the energy transitions ΔG_{ij} was then set up and from it the rate constants for exchange between diffusion states of different types (k_{ij}) were calculated. After the initial and boundary conditions had been assigned the resultant system of linear differential equations was solved by a Monte Carlo method with a constant time interval.

The program[43] was intended for modelling of mass transport in a two-dimensional heterogeneous medium with an arbitrary topology of inclusions in various diffusion experiments using permeability, sorption, and desorption methods, the method of concentration waves, local diffusion probing, etc. In the course of the calculation the distribution of the concentration of the diffusant in the heterogeneous medium and the total and local flows across the outer boundaries of the specimen are indicated and the total population of the specimen by the diffusant (the solubility) is found. The program also enables a treatment of the kinetic functions to be carried out with the aim of determining the non-steady-state effective diffusion coefficient. For a "percolation" type of medium the program enables a cluster analysis of the inclusions to be carried out, the open, continuous, and closed porosities to be determined, and the mean size of the inclusions to be found.[43] A test of the program, performed for a homogeneous medium, showed a high accuracy ($\sim$0.1%) for the calculation of all the output parameters and also that the postulated functions $k_{ij} = f(\Delta G_{ij})$ are satisfied.

Modelling of diffusion in heterogeneous media was carried out for an extensive set of K, χ_2, and Φ_2 parameters for all the structures discussed above. In the first stage, situations for which analytical formulae are known were investigated and in the second, situations for which there is no phenomenological theory of diffusion.

A test of known published models showed that there is a rigorous mathematical description only for cases of parallel and dissociative diffusion and also for diffusion in a lamellar medium. When extended inclusions of a specific shape and size are present an analytical description is possible for certain simple forms (sphere, cylinder, spheroid), for which the "experimental" values of a_0 agree with the theoretical values and for $\Phi_2 \leqslant 0.3$. As Φ_2 increases the description of the process by the analytical formula becomes worse, with χ approaching χ_2 more rapidly than the theory predicts. We have obtained confirmation [34] of the occurrence of diffusion hysteresis, whereby the permeability of heterogeneous materials of identical composition depends on their method of preparation and in particular on whether a dispersion of component 2 in component 1 was prepared or vice versa. Confirmation was also obtained of the assumption that the geometrical parameter a_0 depends not only on the ratio of the width of the inclusion to its length but also on the "distorting power" of the particular form of inclusion as regards the diffusion flow lines. In particular, the modelling method gave the value $a_0 = 1.55 \pm 0.15$ for an infinite block with a square cross-section placed perpendicular to the direction of flow (the a_0 value for such a geometry cannot be calculated analytically). This value is smaller than the value $a_0 = 2$ for a cylinder because a block with a square cross-section distorts the diffusion flow lines considerably more severely.

It is important to stress that the effect of the geometry of the inclusions on the permeability depends considerably on the energy parameters of the components of the heterogeneous structure. A typical dependence of χ on K and D_2/D_1 is shown in Fig.3; the example shown is of the permeability of a dispersion medium with inclusions in the form of a cylinder, for which $a_0 = 2$ and $\Phi_2 = 0.1$. Thus, when $\chi_2 = 1$ (which does not imply at all that the diffusion properties of the components are identical, since for linear isotherms $\chi_2 = KD_2/D_1$) the permeability is independent of K and D_2/D_1. When $\chi_2 = 0$ (the case of impermeable obstacles) the permeability of the heterogeneous medium depends on both its composition and the geometry:

$$\chi = \Phi_1 \frac{a_0 - 1}{a_0 - \Phi_1} \qquad (5)$$

If, however, the inclusion is highly permeable (a pore, $\chi \to \infty$), the permeability of the heterogeneous medium increases more slowly in the general case, reaching the limiting value $\chi = 1 + a_0\Phi_2/\Phi_1$.

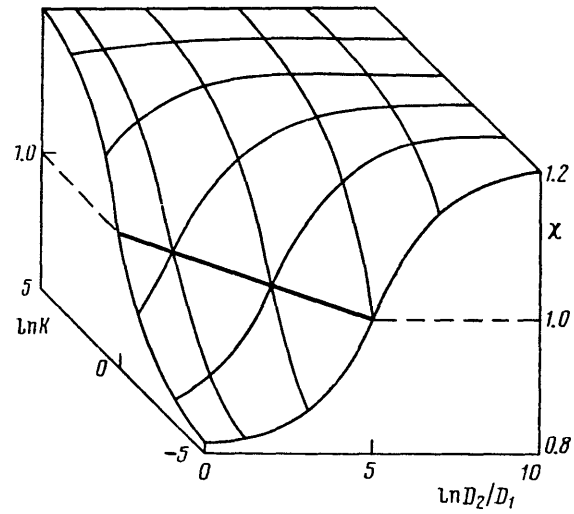

Figure 3. Dependence of the permeability on the transport parameters of a composite[2] (a lattice of cylinders, $a_0 = 2$, $\Phi_2 = 0.1$).

In the modelling of the permeability of a dispersion of point inclusions, the phenomenological model gives only a semiquantitative description. The divergence from theory reaches 20–30% but the theoretical and "experimental" functions $\chi(\Phi_2)$ change in a similar way. The theory is qualitatively correct in prediciting the occurrence of extrema in the function $P(\Phi_2)$ and also their positions, to within $\sim$10%. An attempt was made to improve the accuracy of the numerical calculation by changing the coordination number of the diffusion state from 4 to 8. The discrepancy between the theoretical and "experimental" results was then reached. We assume, although it was not stated when the phenomenological model was set up,[38] that in the statistical summation of the four types of flow it is tacitly understood that the coordination number is equal to infinity. A detailed analysis of this matter showed that, even with high values of the coordination number, complete agreement between the theoretical conclusions and the results of the mathematical experiment cannot be obtained. Thus mathematical modelling of the permeability of heterogeneous media of the "percolation" type by numerical

methods gives more reliable results because in the anlaytical treatments no account is taken of the distortion of the lines of diffusion flow around the point inclusions and their clusters.

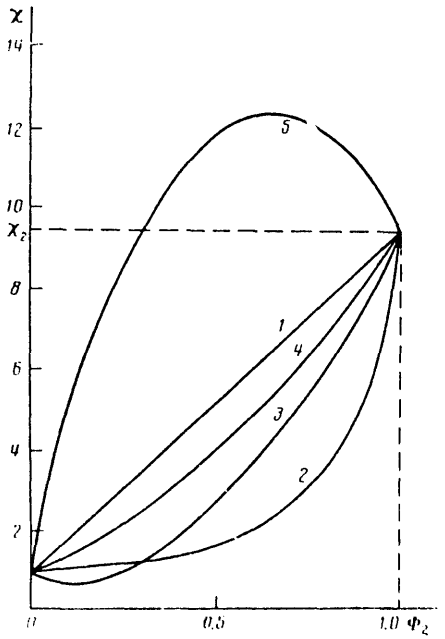

Figure 4. The permeability of percolation-type structures: *1*) parallel diffusion; *2*) a lamellar medium; *3*–*5*) percolation structures for which $D_{12} \to 0$ (*3*), $D_{11} < D_{12} < D_{22}$ (*4*), or $D_{12} \gg D_{11}$ and $D_{12} \gg D_{22}$ (*5*) (from data in Ref.43).

The dependence of the permeability on the volume fraction of the second component is shown for various types of structure in Fig.4. For almost all the structures the $\chi(\Phi_2)$ curves lie between the two limiting cases: dissociative or parallel diffusion (the straight line *1*) and diffusion in a lamellar medium (curve *2*). Exceptions are provided by dispersion structures of the "percolation" type (Fig.1*f*). As follows from Eqn.(4), the dependence of χ on the local transport parameters envisages an effect of the intercomponent layers on the transport (it has already been mentioned that in this case a situation arises which requires the solution of a "three-phase" diffusion problem for a two-component medium). Depending on the conditions at the boundary between the components, the $\chi(\Phi_2)$ curve may pass below the straight line for the limiting case $a_0 = 1$, corresponding to a low permeability of the intercomponent layer ($D_{12} \to 0$, curve *3*), with a possible minimum on the curve; or it may be completely within the permissible region (the permeability of the intercomponent layer lies between the corresponding values for the components of the medium, curve *4*) or it may be situated above the limiting straight line for $a_0 = \infty$. The last situation arises when the permeability is high at the boundary (i.e. when $D_{12} \gg D_{11}$ and $D_{12} \gg D_{22}$, curve *5*), a maximum on the $\chi(\Phi_2)$ curve being possible.

In addition to the steady-state values of the flows, permeability kinetic curves have been obtained by numerical methods[43] and the effective diffusion coefficients calculated.[49] Without discussing these results in detail we note that in a number of cases the theory predicts the possibility that substantial errors will arise in the experimental determination of the steady-state flow of the diffusant through the membrane and hence of the permeability constant. This is because a "pseudo-steady-state" of permeability may be reached for certain values of the local transport parameters; at diffusion times 2–3 times greater than the delay time an almost constant flow through the membrane (significantly smaller than the steady-state flow) is established and this may be erroneously regarded as a true steady state, although times 20–30 times longer are required to achieve the latter.

The total population (solubility) in all the types of structure considered agrees with the values predicted theoretically.

V. SELECTION OF THE STRUCTURE OF THE MATERIAL AS A MEANS OF CONTROLLING THE EFFICIENCY AND SELECTIVITY OF A GAS-SEPARATING MEMBRANE

We have so far discussed the permeability of membranes with respect to any one gas. We shall now turn to the problem of the membrane separation of a mixture of gases and assess the prospects for a directed choice of the structure of the heterogeneous medium in order to achieve the optimum efficiency and selectivity for the membrane.

Suppose that a mixture of two gases is supplied to the input side of a membrane and the process of transport of each of them through the membrane is characterised by its own set of parameters D, K, χ, and θ. These parameters are dependent on the composition and topology of the membrane but independent of the composition of the gaseous mixture. We shall take as the selectivity factor the relationship:

$$\alpha = \alpha_i \chi'/\chi'' \qquad (6)$$

where χ' and χ'' are the permeabilities of the first (object) and second gases respectively and α_i are the selectivity factors of the initial components, $\alpha = P_i'/P_i''$.

The effectiveness of operation of a gas-separating system is characterised by two parameters: the efficiency (i.e. the permeability for the object component, χ'), which determines the amount of product obtained, and the selectivity, which determines its purity. Optimisation of membrane separation is a complex problem because it is far from always possible to obtain high efficiency and a high product purity simultaneously. As is known, membrane separation can be used either to purify the flow passing through the membrane or to concentrate the object product over the membrane. The requirements for selecting χ'' and α are of course different in these cases. If the object product is the gas passing through the membrane, high values of χ' and α are chosen but in the reverse case low values of χ' and α are required.

The effects of the local transport parameters of the heterogeneous medium on the flow of the object component χ' and on the selectivity factor α are different: a decrease in D_2'/D_1' and K' leads to a reduction in χ' and α, but a decrease in D_2''/D_1'' and K'' increases α while leaving χ' unchanged. Since the change in χ' and α in heterogeneous structures of different types takes place differently, then, depending on whether the membrane works by purification or concentration, these parameters will have the optimum values for quite different spatial organisations of the material. It follows from Eqn.(6) that α is a function of six parameters (if the topological factor a_0 is taken as one of them). We shall therefore restrict ourselves to a few examples.

The first two examples are taken from Ref.50 in which measurements were made of the gas permeability of PVTMS (component 1) – PDMS (component 2) block copolymers of various compositions (PVTMS represents polyvinyltrimethylsilane and PDMS polydimethylsilane). We shall discuss Kr–Xe and H_2–Xe gas mixtures, the transport parameters of which are given in the Table (the problem of separating such gas mixtures arises in the AES gas purification system). The Table also shows the experimental values[50] of the steady-state flows and the selectivity factors together with those calculated by us for different structures. For a Kr–Xe mixture the experimental selectivity factor (α = 0.56) is close to the value calculated (0.61) for the parallel (or dissociative) diffusion mechanism (see Table, gas mixture No.1). However, there is a considerable discrepancy between the experimental and calculated values of χ' (2.04 and 10.4 respectively). This may be explained by extra resistance to transport at the boundaries between the components of the block copolymer. In this case the membrane used in the experiment is close to the optimum from the point of view of concentrating the Kr. In using a membrane for Xe purification its efficiency can be increased (by a factor of 5) if a structure which ensures a dissociative or parallel diffusion mechanism is created.

For an H_2–Xe mixture (Table, mixture No.2) the theoretical value of the efficiency with respect to the object material (H_2) is slightly dependent on the structure of the membrane and is close to the experimental value (evidently for hydrogen, resistance to diffusion at the boundary between the components does not play a significant role). However, the theoretical analysis shows that the membrane structure used in the experiment was not the optimum as regards selectivity; in this case a lamellar membrane should be used.

The possible occurrence of extremal relationships between α and the structure are demonstrated on the model example (Table, mixture No.3). Here, to obtain the optimum ratio between the flow and the selectivity a structure having a dispersion of cylinders (filaments elongated perpendicular to the flow) must be created. If, however, it is required to concentrate gas 1 over the membrane and to pass gas 2 through it, then it is better to arrange for sequential diffusion (i.e. to prepare a membrane in the form of layers orientated perpendicular to the flow).

The effect of the structure on the gas-separation parameters χ' and α is conveniently studied using the topology–property diagrams which we have proposed. To construct such diagrams (Fig.5) the reciprocal of the geometrical factor a_0 is plotted along the abscissa (the value of $1/a_0$ varies from 0, corresponding to no perturbation of the flow lines, to 1, corresponding to a severe perturbation) and χ' and α as the ordinate.

Effect of topology and local transport parameters on the permeability (χ') and selectivity (α) of a heterogeneous membrane.*

Mixture no.	Gas	D_2/D_1	K	α_1	Parameter	Calculated for different types of structures**				Experimental (Ref.50)
						I	II	III	IV	
1	Kr	47.9	0.67	1.5	χ'	10.4	1.79	1.41	3.81	2.04
	Xe	160.4	0.52		χ''	25.6	1.82	1.41	8.37	—
					α	0.61	1.46	1.49	0.68	0.56
2	H_2	2.10	1.19	11.0	χ'	1.45	1.30	1.22	1.13	1.4
	Xe	160.4	0.52		χ''	25.62	1.82	1.41	8.37	—
					α	0.62	7.8	9.4	1.5	2.7
3	1	0.1	1.0	7.0	χ'	0.73	0.61	0.27	0.54	—
	2	10.0	5.0		χ''	15.71	1.81	1.42	5.40	—
					α	0.32	2.34	1.33	0.70	—

*The parameters χ', χ'', and α for the gas mixtures nos.1 and 2 were calculated using published experimental data;[50] gas mixture no.3 is a model.

**Φ_2 = 0.3; I) parallel diffusion; II) a dispersion of cylinders; III) a lamellar medium; IV) a dispersion of point inclusions.

These diagrams first of all enable the geometrical factor a_0 to be estimated from gas permeability data. a_0 can be determined experimentally by measuring either the efficiency of the membrane or the selectivity factor. Agreement between the values of a_0 found by different methods indicates the absence of resistance at the boundary between the components. The discrepancy between the values of a_0 obtained from χ' and α (in Fig.5 the range of uncertainty for a_0 is shaded) is large for the Kr–Xe mixture (Fig.5*a*), far larger than the corresponding range for the H_2–Xe mixture (Fig.5*b*).

Such diagrams can thus be used for diffusion-structure analysis, i.e. to determine the topological characteristics of a membrane used in a separation process. On the other hand, they can be used to

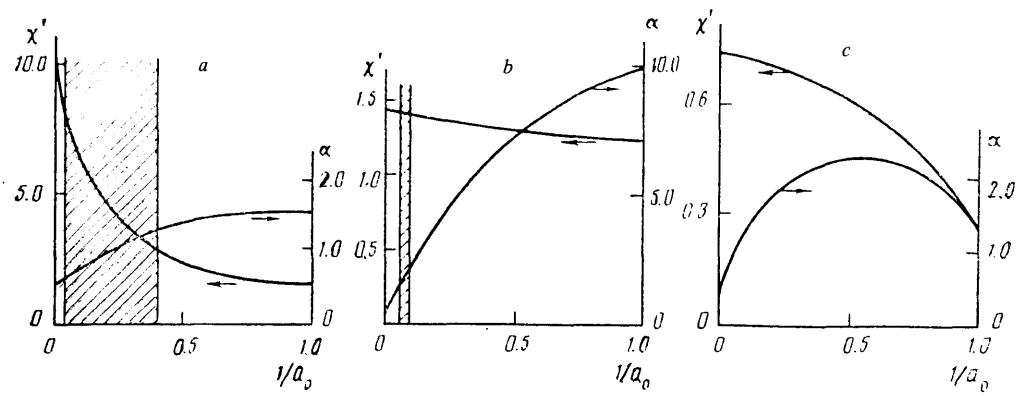

Figure 5. Permeability (or selectivity)–topology diagrams: *a*) separation of a Kr–Xe mixture on a PVTMS–PDMS block copolymer;[50] *b*) separation of an H_2–Xe mixture on a PVTMS–PDMS block copolymer;[50] *c*) a model example (gas mixture no.3 in the Table).[43]

select the optimum structure for gas-separating membranes because, for known transport properties of the initial components, they display clearly the properties of any heterogeneous structures. In the case shown in Fig.5*a* selection of the structure enables primarily the efficiency of the membrane to be controlled, altering it by an order of magnitude; the selectivity, however, is only altered by a factor of 1.5. Fig.5*b* illustrates the reverse case: the structure of the membrane controls mainly the selectivity while the efficiency remains almost constant. A more complex version is shown in Fig.5*c*. Here, as was indicated above, a change in the topology leads to extremal values of α. The region where the extremum occurs is shown clearly in the diagram. Analysis of the component functions χ' and α allows a quick estimate of, for exmaple, the loss in efficiency of the membrane as the selectivity is increased; there is also the possibility of introducing a single component function, the plotting of which requires additional information on a specific chemical-technological process.

Methods for Obtaining Polymeric Membranes

L.P.Perepechkin

Methods for obtaining semipermeable polymeric membranes have been described. Various aspects of the physicochemical processes taking place during the production of membranes from polymer solutions and melts have been examined. Methods for obtaining membranes by sintering polymers, and methods for transforming continuous films and the walls of hollow fibres with continuous walls into porous membranes, have been described. Data on the preparation of composite membranes have been given. Particular attention has been paid to methods which have found practical application in technical processes for obtaining membranes as films and hollow fibres.
The bibliography contains 117 references.

I. INTRODUCTION

In the present work, an attempt has been made to review the most important information on the preparation of non-ionogenic polymeric membranes. For lack of space, the review does not deal with methods for obtaining ion-exchange and liquid membranes, membranes with a relay transfer mechanism, or dynamic membranes and polymeric membranes with metallic coatings.

Membranes can be classified in different ways.[1,2] For the present purpose, it is most appropriate to classify them according to their structural characteristics. It is usual to distinguish continuous and porous membranes. Because of their technical importance, the independent types examined include asymmetric and composite membranes, in which the thin active (towards the system being separated) layers have a higher density than the remaining part, which acts as a supporting carrier. The two layers have the same chemical composition in the asymmetric membranes, and different chemical compositions in the composite membranes.

The production of membranes with a given structure is determined by the specific features of the system being separated and the mechanism of its separation. Thus continuous membranes are used to separate mixtures by the diffusion penetration of the components, and porous membranes are used to separate mixtures by the phase penetration of the components. The separating power, permeability, and stability of the operational characteristics of membranes depend on the chemical character of the polymer and on its structure, which in turn is determined by the method and conditions of preparation of the membranes, and in a number of cases by the properties of the original polymer solution or melt.

The correct choice of polymer is of considerable importance for the production of membranes for a particular purpose. An important role is played by the affinity of the polymer for the penetrating component of the mixture being separated. In particular, for the diffusion penetration of substances through a membrane, the efficiency of their sorption by the polymer acquires considerable importance. The use of block copolymers is of interest for the directed control of the sorption of gases and their diffusion coefficients. The properties of the membranes differ considerably, depending on the type of block copolymer (for a given mass ratio of the blocks). In the case of silane–siloxane block copolymers it has been shown[3] that the composition dependence of the permeability is described satisfactorily by a "disperse phase–dispersion medium" model for block copolymers of the type AB, and by an inter-penetrating polymeric network model for block copolymers of the type BAB.[4]

The treatment of amorphous–crystalline membranes with reagents bringing about their additional crystallisation with the simultaneous formation of sub-micro-pores with dimensions of ~ 1 nm also makes it possible to increase the gas permeability. As shown[5] for polyethylene–terephthalate films, the increase in permeability is brought about by an increase in the sorption of gases by the polymeric material, and this increase is different for different gases.

A sharp increase in the permeability of polymers with respect to various gases is observed when there is a specific interaction. Thus membranes of a copolymer of ethylene difluoride and ethylene tetrafluoride show an increase in their permeability with respect to ammonia during use as a result of chemical changes taking place in the polymer.[6] The permeability reaches $(0.6-1.5) \times 10^{-10}$ cm^3.cm/cm^2.s.Pa, and the separation factor reaches 5000 for the ammonia–hydrogen system, and 37000 for the ammonia–nitrogen system.

For the effective separation of liquid systems, the wettability of the membrane material by the penetrating component of the mixture being separated is of considerable importance. If the wetting angle of the membrane is greater than 90°, part of the energy is used up in overcoming the forces of surface tension at the phase boundary. kat the same time, the polymeric material of the membrane should not undergo marked swelling in the system being separated, to avoid a change in the pore dimensions and compaction of the membrane under the influence of the pressure applied to it. The last requirement applies to a lesser extent to polymers designed for the production of dialysis membranes than to polymers used in membrane processes involving the application of pressure.

In a number of cases, particularly in the separation of liquid systems by ultrafiltration, an important role is played by the redistribution of the electron density in the macromolecules, since this factor may influence the preferential sorption by the membrane of individual components of the system being separated. Since in most

cases the membranes are produced from polymer melts or solutions, it is desirable that the polymer melt without decomposing or dissolve in available solvents.

II. THE PRODUCTION OF CONTINUOUS MEMBRANES

Continuous membranes are most frequently obtained by casting from melts or by dry forming from polymer solutions.† The production of selectively permeable membranes from polymer melts does not differ fundamentally from the production of films and fibres designed for other purposes.

Fusion and crystallisation are first-order phase transformations, that is these processes are accompanied by a discrete change in the internal energy and specific volume. When a polymer melt is cooled, long-range order may appear in it, that is ordered formations, comparable in magnitude with the segments of the macromolecules and with the length of the polymer chains, may be produced. Compact formations preserved in the melts (not broken down on fusion) often act as growth centres for the crystallites in the polymer.[7]

The diffusion permeability of polymeric membranes depends on the diffusion coefficient of the penetrating substance in the polymer and on its sorption by the polymer. The maximum values of the penetration coefficients are characteristic of highly elastic flexible-chain polymers. The permeability of the polymer generally decreases with increase in the rigidity of the chains and increase in the number of polar groups.[8] A decrease in permeability is also observed when the polymers are cross-linked, although the sorption of gases changes little.[9] The permeability of membranes is influenced by the ratio of the amorphous and crystalline phases in the polymer, where the dependence is often non-linear, and also by the structure of the amorphous regions and the morphological characteristics of the crystalline formations.

A decrease in the crystallinity of the polymer usually leads to an increase in the permeability of the membranes.[10,11] An exception is provided by membranes of poly-4-methylpent-1-ene, whose density is lower in the crystalline state than in the amorphous state.[12] Up to a definite limit, the dimensions of the spherulitic formations have no significant influence on the gas permeability, which increases significantly only with further increase in the size of the spherulites, as a result of the development of micro-cracks.[13]

To decrease the crystallinity of membranes, branched polymers are used. Thus the crystallinity of branched polyethylene is 50 to 60%, whereas that of the non-branched analogue reaches 70 to 80%.[14] A decrease in the crystallinity of the polymer can apparently be brought about by marked superheating of the melt (50 to 55 K above the melting point), which leads to the formation of a completely isotropic system and to the disappearance of the crystallisation nuclei.[15]

An important role in the control of the crystallinity of the material is played by the rate of cooling of the melt.[16] If the melt is cooled rapidly to the vitrification temperaturre of the polymer, the rate of crystallisation approaches zero, and its duration tends to infinity. According to Avrami's equation:[17]

$$a = 1 - \exp(-k' t^{n_A})$$

†The terms "dry" and "wet" forming are taken from chemical fibre technology. In dry forming, the solvent is removed by evaporation, and in wet forming it is removed by mixing with a precipitant.

where a is the degree of crystallinity; k' the crystallisation rate constant; t the time; and n_A the Avrami coefficient, which varies from 1 to 4 and characterises the morphological features of the crystal formed, and also the mode of production of the crystallisation centres (thermal or athermal). For the slow formation of structures with three-dimensional order, $n_A = 4$, and for the instantaneous formation of one-dimensional structures, $n_A = 1$. Intermediate values correspond to the instantaneous formation of structures with three-dimensional order, the slow formation of structures ordered in two dimensions, and other cases.[18]

Homogeneous (continuous) membranes can be obtained by dry forming from polymer solutions by analogy with the processes involved in the production of cinematographic films and acetate textile fibre. In this case the original system (solution) does not separate into phases, but remains single-phase until the solvent is completely removed; as the solvent is removed, the viscosity of the system increaes by several orders of magnitude, and the system loses its fluidity. The increase in the viscosity as a result of the increase in the concentration of the polymer in the system can be described by the equation[19]

$$\lg \eta = \nu c^{\alpha}$$

where η is the viscosity; c the polymer concentration; and ν and α are constants which depend on the nature of the polymer and the solvent.

The rate of evaporation of the solvent influences the properties of the membranes formed. Thus when crystallising polymers are used, slow evaporation of the solvent facilitates crystallisation, often leading to a decrease in the permeability of the membranes. The rate of evaporation of the solvent depends on its vapour pressure above the solution p_1 decreases. This is observed in the first stage of the evaporation of the solvent from a liquid film or a stream of solution (in the production of membranes in the form of a hollow fibre). The difference in the chemical potentials in different layers of the solution leads to diffusion of the solvent from the inner layers, and the rate of diffusion gradually decreases, accompanied by an increase in the concentration of the polymer in the solution and an increase in the solution viscosity. For solutions with medium concentration, this process is described approximately by the equation[20]

$$Q/t = bc^{r/s}$$

where Q/t is the rate of diffusion of the solvent in the solution, and b a constant which depends on the nature of the polymer and the solvent, temperature, and other factors.

The difference in the rates of removal of the solvent from different layers of the liquid film or fibre leads to non-uniformity of the structure along the thickness of the membrane.[21] For example, in films produced on rigid supports it is possible to distinguish three layers: a compact upper layer, a loose intermediate layer, and a plane-orientated lower layer. In the production of membranes in the form of hollow fibres, the polymer molecules are oriented in the channels of the holes in the die. After the jets leave the holes, the induced orientation of the polymer is partly reduced as a result of relaxation processes, but usually it cannot be eliminated completely. The influence of orientation on the gas permeability of the polymer is indeterminate. The permeability depends on the relative quantity of cavities in the material. For example, the cold stretching of polyethylene by 297% leads to a decrease in the number of cavities.[8] There is a simultaneous decrease in the sorption, diffusion

coefficient, and permeability. On the other hand, when nylon-66 is stretched, the number of cavities increases, leading to an increase in the permeability, and this effect overlaps the influence of the increase in crystallinity. A five-fold increase in the orientation of polypropylene, although leading to loosening of the structure, a decrease in the crystallinity, and a decrease in the diffusion rate, does not bring about a significant change in the sorption and permeability.[8] A decrease in permeability was observed[22] as a result of the uniaxial stretching of polyethylene, and is attributed to the rearrangement of the spherulitic and micro-spherulitic structures in the highly oriented material and to the significant deviation from thermodynamic eqiuilibrium in the amorphous regions in the layers between the crystallites.

The dependence of the permeability of polymeric materials on the degree of biaxial stretching is complex, and in a number of cases extremal. Polyethylene–terephthalate films are more sensitive to biaxial than to uniaxial stretching. Polypropylene and polyethylene show a slight decrease in permeability at low deformations, and an increase at deformations exceeding a certain critical value. This can be attributed to the appearance of sub-micro-cracks or to recrystallisation. Polyethylene tetrafluoride, whose macromolecules are highly rigid, shows an increase in permeability on even slight biaxial orientation.[8]

All these relationships must be taken into account in the production and application of membranes. Dry forming can be used to obtain ultra-thin membranes (thickness 300–500 nm) from polymer solutions with low concentrations (0.5–2%) on a liquid surface (mercury, water). The volatile solvent should not be miscible with the liquid support.[23] The membrane formed is practically isotropic, and has a high permeability. Considerable difficulties arise, however, when these membranes are used. To avoid these difficulties, asymmetric and composite membranes have been developed, and have found extensive application.

III. THE PRODUCTION OF POROUS MEMBRANES

Porous membranes are obtained by different methods. In particular, continuous membranes can be made porous by "bombarding" them with the ions of heavy elements, for example ^{136}Xe, ^{84}Kr, and ^{40}Ar,[24] or with radioactive decay products.[25] The starting materials are continuous films of polyethylene–terephthalate, polyamide, polycarbonate, etc. When they strike the polymer film, the ions bring about cracking degradation of the polymer. The density of the breakdown brought about by the particle is proportional to the square of its electrical charge and approximately inversely proportional to the square of its velocity. Since the maximum possible critical rate of loss of energy by the particle in the polymer dt/dx increases with increase in the atomic mass of the particle, there exists a lower limit of the mass of the ions capable of forming "traces". The beam of ions is collimated to ensure that the direction of the "traces" is perpendicular to the membrane surface. The film treated with the ions is subjected to strong ultraviolet irradiation to intensify the subsequent etching, which is carried out using solutions of alkalis or acids, depending on the nature of the polymer. During etching, pores are formed in the film; the form of the pores depends on the ratio of the rate of extraction of the material along the axis of the "trace" v_t to the rate of extraction of the material from the undamaged surface v_s. The form of the pores is close to cylindrical when $v_t > v_s$; when $v_t \simeq v_s$, a conical depression is formed in the film. These membranes, which are usually called nuclear filters, are most widely used in microfiltration processes.

Another method for converting continuous into porous membranes involves swelling the original membrane, with a cryptoheterogeneous structure, and then fixing the resulting pores.[26]

Methods for obtaining porous membranes by stretching continuous membranes under strictly controlled conditions have been used increasingly in recent years. These processes can be carried out in two ways. One involves the use of the familiar Rebinder effect. Stretching continuous films in adsorption-active media makes it possible to produce membranes with a developed system of continuous connecting pores.[27] This principle has been used, for example, to obtain a porous hollow polyethylene fibre.[28] For this purpose, the fibre was subjected to thermal treatment for 30 min at 90–120°, after which it was kept in trichloroethylene or perchloroethylene at a temperature above the vitrification temperature of the polymer. The fibre was then stretched by 200–300%, and then subjected to thermal fixation at 85–120°, when it was allowed to shrink by 5%. A similar process has been carrried out for films of polytetrafluoroethylene[29,30] and polyethylene–terephthalate.[31] In particular, when films of vitreous polyethylene–terephthalate were stretched by 200% in n-propanol, the quantity of pores was brought to 3.2×10^{12} cm^{-2}, with average dimensions of $\sim$4.6 nm.

Continuous membranes of crystallising polymers can also be made porous without using adsorption-active media.[32–37] The process usually involves the stages of preliminary heating of the material, stretching to produce a system of pores in the material, and thermal fixation of the porous structure. The formation of pores when the membrane is stretched can be represented as an increase in the distance between the lamellae; when an external force field is applied to the system, the "through" chains are partly "drawn out" from the lamellae into amorphous region.

The degree of stretching influences the pore dimensions.[32] The stretched membrane is subjected to thermal fixation at the temperature of the preliminary heating or a slightly higher temperature. The thermal fixation is carried out under slight tension, which controls the partial shrinkage of the material. Since this is accompanied by the relaxation of a considerable proportion of the internal stresses, the membrane subsequently does not undergo appreciable shrinkage deformation, and its porosity is preserved.

This method of producing porosity has been most widely used in the preparation of hollow fibres of polyalkenes,[33–36] poly-*p*-phenylene sulphide,[37] etc. Porous polyalkene membranes can be used to separate gas mixtures as a result of the difference in the rates of penetration of the individual components through the pores by a Knudsen flow mechanism. These materials appear promising for removing contaminants from liquid fuel and oils by ultrafiltration, and also for carrying out membrane distillation, a process in which increased interest has recently been shown.[38,39]

When porous polyalkene membranes are used in the separation of aqueous systems, the polymer is often made hydrophilic, for example by treating it with sulphuric acid or by grafting hydrophilic monomers.[40] Membranes can be made hydrophilic by treating them with a gas mixture containing SO_2 and F_2.[41]

One method of producing porous membranes is by sintering powders or by calendering finely dispersed polymers. A detailed analysis and description of the processes involved in the production of micro-filtration membranes by this method have been given.[42] It is particularly appropriate to use this method with polymers which cannot be brought into the viscous-flow state by fusion or solution.

The primary example of polymers of this kind is polytetrafluoroethylene, which has a high chemical stability and can withstand temperatures above 200°, Polytetrafluoroethylene membranes are obtained by sintering its powder in pure form[43–45] or in mixtures with binding agents, including other fluorine-containing polymers. A number of petroleum products have been used as binding agents.[46,47] The mechanical strength of polytetrafluoroethylene membranes not containing a binding agent is usually insufficient. To eliminate these disadvantages, membranes with a fibrous filler are prepared.[2] These membranes, with a thickness of 0.12–0.15 mm, have pores with dimensions up to 500 Å. They are hydrophobic, and therefore impermeable to water at low pressures (up to 1.2 MPa).

Examples of the production of membranes by sintering are also known for other polymers, in particular polyalkenes, with the introduction into the mixture of materials which can be removed by water, for example starch.[48] The sintering is carried out at a temperature above the vitrification temperature of the polymer. Interdiffusion of the macromolecules of the particles in contact with one another takes place. The adhesion of the particles leads to a decrease in the specific surface of the system, and hence to the liberation of free energy:[42]

$$\Delta E = \sigma_{pa}(1/r - 1/R) \qquad (1)$$

where σ_{pa} is the surface tension of the polymer at the boundary with air, r the radius of the contact surface, and R the radius of the particle.

During the technical process, it is extremely important not to allow complete merging of the particles, since this naturally leads to closure of the pores. It is important to stop the process at the first stage of the sintering. The duration of this stage (τ) for a number of systems can be determined if the familiar Frenkel' equation[49] is written in the form: $\tau = 2\pi r^2\eta/3R\sigma_{pa}$, where η is the viscosity of the melt.

The method of obtaining porous membranes by separating polymer solutions into phases has been most widely used. This method opens up extensive possibilities for the directed control of the structure and operational properties of membranes.

Solutions of macromolecular compounds are not ideal. For these solutions, the following relationship applies: $\Delta G_{rs} = \Delta G_i + \Delta G^E$, where ΔG_{rs} is the free energy of the real solution, ΔG_i the free energy of the ideal solution, and ΔG^E the excess free energy. Positive values of the deviation ΔG_{rs} correspond to poor miscibility of the components.[50] When ΔG^E reaches $\sim 0.5\ RT$,[51] the solution separates into phases.

The decomposition of polymer solutions into phases can take place by two mechanisms—nucleation and spinodal. Analysis of the equilibrium diagram of a polymer–solvent system (Fig.1) leads to the following basic postulates.[52] The region lying above the binodal corresponds to a thermodynamically stable single-phase solution. This region is characterised by the inequality $(\partial^2 g/\partial x^2)_{pT} > 0$, where g is the average free energy of the system, and x the molar concentration of one of the components. The region lying between the binodal and the spinodal corresponds to a metastable state of the system. For the range of metastable states, the inequality $(\partial^2 g/\partial x^2)_{pT} > 0$ is again applicable. In this region, the diffusion fluxes of the components are directed in such a way that they decrease the fluctuations. The formation of a new interface is energetically unfavourable, and the work of formation of the nuclei of the new phase provides a measure of the metastability of the solution.[52] Thus the system is unstable only with respect to heterophase fluctuations exceeding a certain critical value.[53] If this critical value is exceeded, a spontaneous increase in the fluctuations takes place.

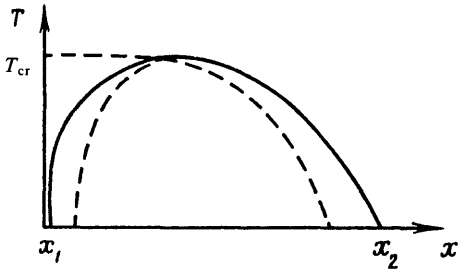

Figure 1. Equilibrium diagram of a polymer–solvent system (continuous line–binodal, broken line–spinodal): T–temperature, x_1–concentration of the solvent, x_2–concentration of the polymer.[52]

As the nuclei of the new phase are formed, the concentration of the polymer in the solution decreases. At the same time there is an increase in the coefficient of self-diffusion of the macromolecules,[54] and it follows from scaling theory that this increase for concentrated solutions shows a cubic dependence on the mass fraction of the polymer in the solution. The increase in the coefficient of self-diffusion of the macromolecules leads to the growth of the nuclei of the new phase. The rate of the formation and growth of the nuclei depends on the degree of supersaturation of the solution. The degree of supersaturation in turn can be controlled by changing the temperature, using precipitants with different compositions, and changing the concentration of the polymer in the original solution. The development of the growth of the nuclei of the new phase when there is a sufficient quantity of polymeric material in the system leads to the nucleation breakdown of the polymer solution into phases, that is to the formation of a polymeric framework including regions of a phase with a low polymer concentration (this is usually a mixture of the solvent and the precipitant in which a small quantity of the polymer, mainly its low-molecular-weight fractions, is dissolved).[55] The polymeric framework formed as a result of the breakdown of the solution into phases is subjected to syneretic contraction, as a result of which it becomes more compact, with the simultaneous partial separation of a liquid phase. The polymer is converted from a highly fluid into a highly elastic (and sometimes vitreous) state.

On the spinodal, the work of formation of the nuclei of the new phase is equal to zero; the equation of the spinodal is $(\partial^2 g/\partial x^2)_{pT} = 0$.[52] Under the spinodal lies a region corresponding to a thermodynamically unstable state of the system. This state corresponds to the inequality $(\partial^2 g/\partial x^2)_{pT} < 0$. In the initial stage of the spinodal decomposition of the system into phases in the homogeneous solution a set of concentration fluctuations is produced, and these can be regarded as a set of sinusoidal waves with a fixed length λ equal to the dimensions of the structures formed. The fluctuations may not reach the critical value, as in the nucleation process of breakdown into phases. Subsequently, at the points where the fluctuations are

produced, as a result of the existence of a component flux directed against the concentration gradient, micro-regions of the heterogeneous structure are enriched in these components, and begin to coalesce.[56] The temperature at which the rate of formation of the interconnected micro-regions of phase separation is a maximum corresponds to a definite composition. If the volume fraction of one of the components is greater than 15%, then in the final stage of the process, the coalescence initiated by hydrodynamic factors ensures that each phase is connected.[51] At this stage, the dimensions and composition of the structures may be the same as in the nucleation mechanism of the breakdown, that is two phases with concentrations of a given component x_1 and x_2 may coexist in equilibrium. When the change in temperature is rapid, however, a non-equilibrium system with a matrix (continuous) phase may be preserved.[57] The structures formed in this case differ from those produced in nucleation breakdown. In the coalescence process, the initially spherical particles form either cellular or network structures,[58,59] which form the basis of the highly porous membranes.

The theory of spinodal decomposition applied to polymeric systems was developed by De Gennes.[60] Spinodal breakdown has been studied experimentally by a number of workers.[56–59,61,62]

In practice, semipermeable membranes are produced mainly by the breakdown of solutions into phases by the nucleation mechanism. The original (forming) solution is converted to the metastable state by changing either its temperature or its composition. The latter is achieved either by evaporating the solvent from the three-component solution containing the polymer, the solvent, and the precipitant (spontaneous gel formation method) or by using the method of wet forming to obtain the membranes.

The method of spontaneous gel formation is widely used to obtain film membranes for ultra-filtration and micro-filtration. Its essential features are as follows. A solution of the polymer is prepared in a mixture of a solvent with a non-solvent, which should be less volatile than the solvent. The solvent is then evaporated from a film of the liquid deposited on a stationary or moving support. As a result of the change in the composition of the system, it breaks down into phases with the production of a gel which forms the basis of the highly porous membrane.

To analyse the processes taking place, it is appropriate to examine the equilibrium diagram of a three-component polymer–solvent–non-solvent (precipitant) system, represented in general form in Fig.2.[63] The solid phase (polymer) can be isolated from the solution with the composition A by different methods. For systems with an upper critical temperature of mixing, $T_1 > T_2$, and for systems with a lower critical temperature of mixing, $T_1 < T_2$. If the solution A contains a solvent whose vapour pressurre is higher than that of the precipitant, the decomposition of the solution into phases takes place as a result of the evaporation of the solvent. At the point B_2, the system loses its homogeneity, and decomposes into phases with compositions x_1 and x_2, after which, as a result of the evaporation of the solvent and the precipitant, it acquires the composition P. If however the precipitant is more volatile than the solvent, the composition of the system changes along the path AGP, and the system remains homogeneous throughout.

To obtain membranes by the wet forming method, the original system is enriched in the precipitant by diffusion processes, with a simultaneous decrease in the concentration of the solvent. At the point B_1 below the temperature T_2 (or at the point B_1' below the temperature T_1), the solution breaks down into phases with compositions x_1 and x_2 (below the temperature T_2) or x_1' and x_1' (below the temperature T_1). On subsequent "elution" of the solvent by the precipitant, the system arrives at the composition C_1 or C_2, and then, as a result of drying along the paths C_1P or $C_1'P$, at the composition P.

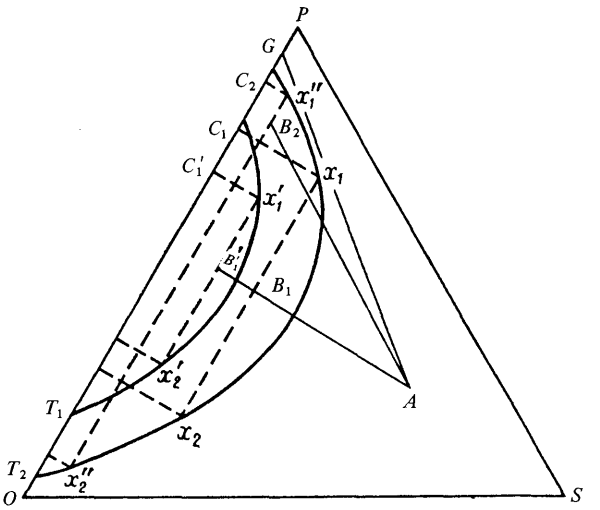

Figure 2. Equilibrium diagram of a three-component system (for explanation see text).[63]

Analysis of the diagram shows that for systems with an upper critical temperature of mixing, the concentration of the polymer in the framework phase increases with decrease in the temperature of the phase separation. This is important for controlling the parameters of the porous structure of the membranes.

In addition to thermodynamic factors, it is also necessary to take account of kinetic factors, which have a considerable effect on the structure and properties of the membranes. For example, the change in composition along the path AB_2C_2P may take place so rapidly that the breakdown of the system into phases cannot take place.[64] Because of the very high viscosity of the gel, the conversion of the system from the heterogeneous to the homogeneous state on the section C_1P (paths $C_1'P$; C_2P) is extremely difficult, so that after the removal of the precipitant from the gel, the system may remain heterogeneous for an unlimited time.

One of the most widely used technical methods for controlling the degree of supersaturation of the forming solutions is by using precipitant baths with different composition, in particular with different ratios of the precipitant and the solvent. In practice, baths containing a small quantity of solvent are called "hard", and baths containing a large quantity of solvent are called "soft". The use of hard precipitant baths, which bring about extensive supersaturation of the solution, leads to the production of a large quantity of nuclei of the new phase in the system and to their rapid growth. Steric hindrance, however, restricts the growth of the particles of the new phase. As a result, a membrane with fine pores is formed. A similar effect can be achieved by increasing the polymer concentration in the solution and by changing the temperature of the system.

The influence of these factors on the structure and properties of membranes obtained from cellulose esters has been studied by many workers.[65–74]

In the study of the wet forming of membranes from aromatic polyamides, polyacrylonitrile, and other polymers it has been shown[75,76] that the morphological characteristics of the membranes vary considerably, depending on the polymer precipitation conditions. Soft precipitation of the polymer from highly concentrated solutions gives a regular spongy material. Hard precipitation of the polymer from solutions with a low concentration gives a membrane permeated by large rod-shaped pores. In the formation of these pores, a decisive influence is assigned[77–80] to local convection currents in the liquid, arising as a result of the exothermic character of the interaction of the solvent with the precipitant.

Breakdown of solutions into phases by the spinodal mechanism is as yet very rarely carried out in technical practice. In this connection, mention may be made of the process carried out by the West German firm "ENKA Membrana" for obtaining tubular and capillary membranes, known by the trade name "Accurel", from solutions of polypropylene in an organic oil (other solvents may also be used). The heated solution is extruded through a specially designed die, after which it is rapidly cooled. This gives a highly porous isotropic membrane, which can be used successfully as a micro-filter.[81]

IV. THE PRODUCTION OF ASYMMETRIC MEMBRANES

The different conditions of formation of the structure of the films and fibres in different layers leads to the formation of asymmetric membranes. Since the preparation of the first asymmetric membranes,[82,83] the most widely used but not the only method for obtaining them has been by dry–wet forming. In this process, the solvent is partly evaporated from the surface layer of the solution, after which the solution (in the form of a liquid film or filament) is placed in a precipitating bath, where it breaks down into phases. As a consequence of the higher concentration of the polymer in the surface layer, a compact polymeric sheath is formed on the surface of the membrane, giving it its high separating power. At the same time, the loose polymeric matrix formed from the layer with the lower concentration ensures that the membranes are highly permeable to the penetrating components of the system being separated. The active (selective) layer usually corresponds to a small fraction of the thickness of the asymmetric membrane. The absolute thickness of the active layer varies from 0.1 μm^2 to 0.25 μm,[84,85] although thicker layers up to 4 μm are also encountered.[10]

The parameters of the process of the partial evaporation of the solvent from the surface of the liquid film or filament (chiefly the rate of evaporation) play an important role in the production of the structure of the asymmetric membrane.[86,87] The lower the rate constant of the evaporation of the solvent, the higher the permeability of the membranes for a given selectivity. Since the rate constant of the evaporation of the solvent depends on several factors (the concentration of the solvent vapour in the evaporation zone, temperature, etc), it is possible to obtain membranes with identical properties for different parameters of the technical process. A necessary condition, however, is a constant value of the solvent evaporation rate constant, which has an optimum value for each composition of the forming solution.

An important role in the formation of asymmetric membranes is played by surface phenomena.[88] If the surface tension σ_1 at the boundary between the solvent and air containing the solvent vapour is lower than the surface tension σ_2 at the boundary between the solution and air containing the solvent vapour, then the surface of the forming solution in contact with air is enriched in the solvent, and the polymer is sorbed on the support, forming an asymmetric membrane with the compact layer in contact with the support. If however $\sigma_1 > \sigma_2$, then the surface in contact with air is enriched in the polymer, and after the breakdown of the solution into phases, the compact selective layer is formed on this surface.

Since the structure and properties of the membranes depend on the structure of the forming solutions, the rates of their breakdown into phases, and the surface properties of the system, the importance of the correct choice of solvent is obvious. Frequently, the solvent used is a two-component mixture, one of whose components is an effective solvent, while the other is a swelling agent.

A noteworthy procedure developed by a number of workers[89–93] involves the selection of the solvent from the magnitude of the Hildebrand solubility parameter δ. It is known[94,95] that $\delta = (\Delta E/v)^{1/2}$, where v is the molar volume, ΔE the energy of cohesion, $\Delta E = \Delta E_d + \Delta E_p + \Delta E_h$, and ΔE_d, ΔE_p, and ΔE_h the components of the energy of cohesion due to the action of dispersion forces, polar forces, and hydrogen bonds respectively.

From the equations given it follows that $\delta^2 = \delta_d^2 + \delta_p^2 + \delta_h^2$.

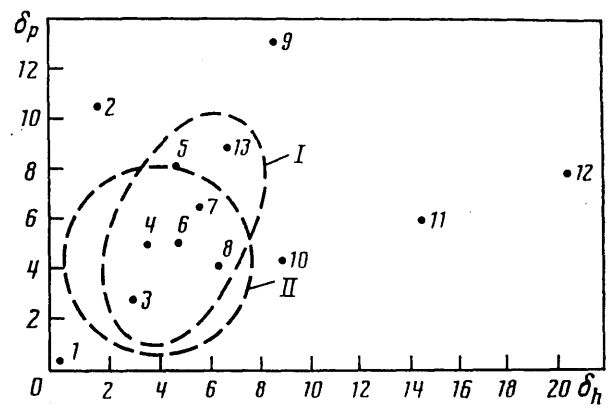

Figure 3. Solubility diagrams of cellulose acetate (*I*) and polysulphone (*II*):[89] *1*) carbon tetrachloride, *2*) ethylene carbonate, *3*) methylene chloride, *4*) acetone, *5*) dimethyl sulphoxide, *6*) dimethylacetamide, *7*) dimethylformamide, *8*) acetic acid, *9*) formamide, *10*) ethanol, *11*) glycerol, *12*) water, *13*) mixture of acetone and formamide (6:4).

The range of solubility of substances can be represented in the form of a sphere on coordinates $\delta_d - \delta_p - \delta_h$.[96,97] Since for most substances the values of δ_d are similar,[96] it has been proposed that the mutual solubility of substances be characterised using two-dimensional diagrams on coordinates $\delta_p - \delta_h$ (Fig.3). The action of weak forces can be taken into account by a generalised parameter $\delta_v = (\delta_d + \delta_p)^{1/2}$.[98] The range of solubility can then be represented on coordinates $\delta_v - \delta_h$. The fraction of each component of δ can be

represented as follows:

$$f_d = \frac{\delta_d}{\delta_d + \delta_p + \delta_h}; \; f_p = \frac{\delta_p}{\delta_d + \delta_p + \delta_h}; \; f_h = \frac{\delta_h}{\delta_d + \delta_p + \delta_h}$$

The range of solubility can then be represented on a triangular Hashimoto diagram[93] (Fig.4).

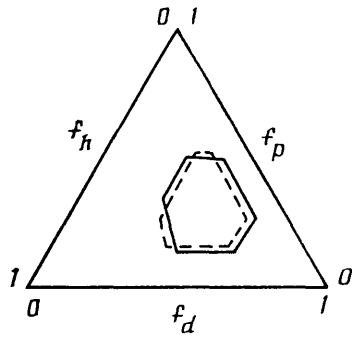

Figure 4. Diagram of secondary cellulose acetate (continuous line) and cellulose triacetate (broken line) on Hashimoto coordinates. For explanation see text.[93]

To obtain a highly permeable asymmetric membrane, the orioginal solution should satisfy the following requirements:[89] all the components of the dissolving mixture should be compatible with the precipitant; the composition of the solution before the breakdown into phases should correspond to the range lying at the solubility boundary; the concentration of the structure-formation centres in the solution before the breakdown into phases should be high, to ensure the rapid precipitation of the polymer; when the volatile component of the dissolving mixture is removed, the solubility of the polymer should decrease.

The breakdown of the forming solution gives the so-called "primary gel". To give the membrane a compact structure, it is subjected to annealing involving thermal treatment in a liquid medium, which produces shrinkage deformations in the polymeric material. A necessary condition for effective shrinkage is the devitrification of the polymer.[63] For cellulose acetate in an aqueous medium, the devitrification temperature is 90–95°.[99] Thus the annealing temperatures of 75–85° given by Brock[100] for cellulose acetate membranes are too low.

The shrinkage of the polymer takes place to a greater extent in the surface layer than in the loose matrix. This is due to the higher concentration of stresses in the surface layer of the membrane as a result of the more rapid precipitation of the polymer on the surface of the liquid film, compared with the volume. Annealing leads to an increase in the salt-retention power of membranes designed for reverse osmosis, and increases their water permeability.

The membranes obtained in this way have an ultraporous structure, and are extensively impregnated by liquid. When the liquid evaporates, the forces of capillary contraction bring about closure of the pores, as a result of which the membrane may lose phase permeability. To avoid this, the membrane is usually impregnated with glycerol, a liquid with a low volatility. This membrane retains its operational properties for a time interval sufficient for the preparation of the separating module.

Asymmetric membranes are used for the separation of both gas mixtures and mixtures of solutions by reverse osmosis and ultrafiltration. An example is a gas-separating membrane of polyvinyltrimethylsilane, which has permeability coefficients with respect to O_2 and N_2 of 15.0 x 10^{-15} mole.m/m^2.s.Pa and 3.5 x 10^{-15} mole.m/m^2.s.Pa respectively.[1] Asymmetric membranes are widely used as ultra-filters with molecular-mass retention limits from 1000 to 300 000, and also to separate solutions by reverse osmosis.[77–87]

V. THE PRODUCTION OF COMPOSITE MEMBRANES

In recent years there has been an increase in interest in the production of composite membranes. This development is regarded as particularly promising.[101] Composite membranes are obtained by depositing a layer of another polymer on a porous base. The first successful attempts were made in the early nineteen-seventies,[102] and in recent years the method has been developed on the industrial scale. Membranes with unique properties have been obtained. It is suggested that composite membranes undergo less deformation on the application of pressure, compared with asymmetric membranes. Polymers with unique properties can be used to obtain the selective layer of composite membranes. Since the coating is thin, the quantity of polymer used for the production of the membrane is small, so that the cost of the polymer is not usually a limiting factor.

Several methods can be used to obtain composite membranes. A popular method involves the deposition of the active layer by plasma polymerisation in a glow discharge.[103–108] Various organic compounds can be subjected to plasma polymerisation, including compounds which cannot be polymerised by ordinary methods, for example benzene. In the glow discharge, benzene is apparently converted into acetylene, which then polymerises.[109] The monomers used include acetylene, allylamine, 4-vinylpyridine, N-vinylpyrrolidone, 4-picoline, 4-ethylpyridine, 4-methylbenzylamine, 3,5-dimethylpyridine, and other compounds.[109]

Plasma polymerisation can be carried out by electrodeless and electrode methods. To establish the electrodeless discharge, the discharge tube is placed inside a solenoid, through which the electric current passes. The discharge takes place when definite values of the current strength and frequency have been reached. The polymer formed is deposited on a porous support in the zone of the glow discharge. The supports used include ultra-filters with pore dimensions of ~25 nm,[109] hollow fibres, porous glass, and other porous materials.

When the electrode method is used, the polymer is deposited on the electrodes, which may be porous plates; the distance between the plates is 5–40 mm.[109] Before the stream of monomer is supplied, the air is evacuated from the plasma polymerisation chamber to a residual pressure of ~10^{-1} Pa. The monomer vapour is then introduced into the chamber to a pressure of 10 Pa, after which an inert gas is added to increase the pressure to 25 ± 5 Pa. A high-frequency generator is then used to create a glow discharge, which brings about the polymerisation of the monomer.

The water permeability of the membrane obtained naturally depends on the hydrophilic character of the polymer formed. Thus if methacrylic acid is used as the original monomer, the water permeability of the membrane is 5.85 x 10^{-6} m^3/m^2.s, and when vinyl

acetate is used, the water permeability is 2.02 x 10^{-6} $m^3/m^2.s$, and the selectivity towards sodium chloride is almost the same in both cases. A highly selective and highly permeable membrane for reverse osmosis can be obtained by treating a porous polyacrylonitrile membrane with a plasma with the introduction of He, H_2, and O_2 into the discharge zone.[110] This gives a cross-linked surface layer containing $-OH$, $>C=O$, and $>NH$ groups.

Composite membranes are also obtained by the vacuum deposition of a thin (0.05 μm) active polymer layer on a porous support,[111] and also by depositing polymer solutions with a low concentration on a porous base and then evaporating the solvent.[112,113] In the last case, the adhesion interaction between the polymer and the material of the support is of considerable importance. The thermo-dynamic characteristic of the adhesion is the loss of free energy per unit surface area of contact between the solids in contact. The work of adhesion is given by

$$W_a = \sigma_{sa} + \sigma_{la} - \sigma_{sl}$$

where σ_{sa}, σ_{la}, and σ_{sl} represent the surface tension at the solid base–air, solution–air, and solution–solid base boundaries respectively. This equation shows that to improve the adhesion of the solution to the porous base, it is necessary to select systems for which the surface tension at the boundary with one another is a minimum. Composite membranes obtained by depositing polyelectrolyte complexes on a porous base have found practical application.[114]

Methods for obtaining composite membranes by depositing on a porous base a thin film formed as a result of interphase polycondensation are of considerable interest.[115–117] This method has been used to obtain membranes for reverse osmosis with a selectivity (with respect to sodium chloride) of up to 99% with a specific permeability of 0.40–0.55 $m^3/m^2.d$.[117]

In the near future, technical development will be directed towards the search for new polymers for the production of highly effective gas-separating membranes and membranes with functions analogous to those of biological membranes.

Selectively Permeable Polymers and Gas-separation Membranes: Structure and Transport Properties

S.G.Durgar'yan (deceased), Yu.P.Yampol'skii, and N.A.Plate

The relationship between the permeability coefficients and the sorption and diffusion properties of highly elastic and vitreous polymers has been examined. The concept of free volume can be used to interpret the characteristics of transport not only in highly elastic but also in vitreous polymers. The properties are discussed of the basic polymeric materials of gas-separation membranes; heterophase polymeric systems such as block copolymers and polymers with liquid-crystalline additives and additives undergoing specific interaction, and also quasi-liquid membranes with components facilitating the transport of gases. The bibliography contains 84 references.

I. INTRODUCTION

The considerable progress made in the last ten years in the field of membrane gas-separation has been the result of the development of a number of membranes characterised by high efficiency and selectivity combined with stability of their properties in the media being separated. A high efficiency can be achieved by producing a definite "architecture" of the membrane as a polymeric solid or by selecting for the membrane a polymeric material characterised by high diffusion and sorption parameters. Most frequently, these two approaches are combined.

The gas-permeability coefficients of polymers may differ by 5–6 orders of magnitude, depending on their structure, whereas for comparison, in liquids, the values vary by only 1–2 orders of magnitude. This is due to the varied structural characteristics of the polymeric materials and the marked influence of the structure of the polymer on the rate of gas transfer. It is thus possible to ensure that the polymeric membranes have the required permeability and selectivity by influencing the structure of the polymer. At the same time, a characteristic compensation effect has been shown to exist: the most selective polymers have a low permeability, and highly permeable polymers are insufficiently selective or have poor mechanical and film-forming properties.[1-3]

The traditional approach to the analysis of the permeability and selectivity of non-porous gas-separation membranes involves the resolution of the diffusion and thermodynamic components of the permeability coefficients P_i and the separation factors $\alpha_{ij} = P_i/P_j$:

$$\alpha_{ij} = P_i/P_j = \sigma_i D_i/\sigma_j D_j = \alpha_{ij}^{\sigma}\alpha_{ij}^{D} \qquad (1)$$

The wide range of variation in the gas-permeability coefficients of polymers, noted above, is determined chiefly by the range of their diffusion properties. The sorption parameters, characterising the thermodynamic component of the permeability coefficient, differ to a much smaller extent for different polymers. It is traditionally assumed that the driving force of the mass transfer of simple gaseous molecules, and the concentration or activity gradient, is due to van der Waals intermolecular interaction. At the same time, a marked and selective increase in the permeability may be expected if any components of the mixture being separated undergo stronger specific interactions with the membrane material (electron donor–acceptor interactions, reversible coordinate bonding in a complex, and hydrogen bond formation).

With allowance for these characteristics of mass transfer in membranes and the requirements which they must satisfy, attention will subsequently be concentrated on the progress made in the development and application of polymeric materials in gas-separation membranes, and an attempt will be made to indicate the most promising apparent routes for the development of membrane science.

II. DIFFUSION AND FREE VOLUME IN POLYMERS

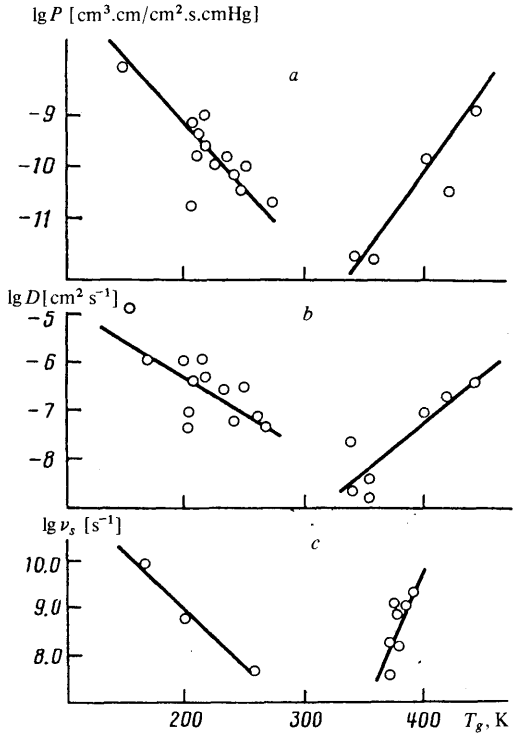
1. Highly Elastic Polymers

Polymers with high diffusion coefficients are attracting attention as materials for selectively permeable gas-separation membranes. The diffusion coefficients of gases depend on various properties of the polymer—density, presence and frequency of cross-linkages, degree of crystallinity, nature of the substituents, nature of the interchain interactions, and many others, but a direct correlation between these characteristics and the diffusion coefficients of gases can be observed only for a limited number of structurally similar series of polymers. With wide variation in the chemical character of the polymers, the diffusion coefficients show a statistically significant correlation only with the vitrification (glass) temperature T_g or the difference between the temperature of the measurement of the diffusion coefficient T_m and the glass temperature, $T_m - T_g$. This difference is sometimes regarded as a measure of the kinetic rigidity of the macro-chain. The relationship between the diffusion coefficients D at a given T_m and the glass temperatures

$$\lg D = A + BT_g, \quad (B<0)$$

was first noted in Ref.4. In Ref.4, however, this relationship was established only for a limited number of combinations of the diffusing substances and polymers with $T_g < 298$ K (rubbers and

partly crystalline polyalkenes). The universal character of Eqn.(2) for the highly elastic range was subsequently confirmed[5] by an analysis of published data[6,7] for a large number of polymers and gases. Fig.1 shows that with increase in temperature in the highly elastic range (left-hand branches of the curves), both the diffusion coefficients and the permeability coefficients decrease.



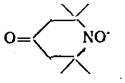


Figure 1. Correlation of the permeability coefficients of nitrogen (*a*), the diffusion coefficients of nitrogen (*b*), and the frequencies of rotation of the spin probe

ν_s (*c*) with polymer glass temperatures (from published data[6,7]).

The coefficient of translational diffusion of a gas in a polymer is an integral quantity, which may depend both on the local properties of the polymer and on its morphology (the sinuosity of the diffusion paths in the membrane, the presence of supermolecular structures, etc.). It is therefore extremely interesting to note the analogous decrease, with increasing T_g in the highly elastic range, in the coefficients of rotational diffusion of spin probes in polymers[5] (Fig.1). This shows that the observed decrease in D is related chiefly to the local mobility of the polymer chains. The fact that the diffusion coefficients of gases in rubbers, like the parameter of the Williams–Landel–Ferry equation a_T,[8] can be expressed as a single-valued function of T_g or the difference $T_m - T_g$ agrees with the view that the diffusion of gases in polymers at $T_m > T_g$ is determined chiefly by the segmental mobility

Since the free volume in rubbers is predominantly fluctuational in character, it is not surprising that different versions of the theory of free volume have been used successfully to describe the diffusion of gases in polymers at temperatures above T_g. The theory of free volume is based on the view that in a polymer, as in a liquid, there exists a free volume, whose elements, as a result of the random movement of the kinetic units making up the polymer, are displaced in space, and this makes possible the diffusion of small dissolved molecules or the viscous flow of the macromolecules in the polymer. According to the Cohen–Turnbull model of the free volume,[9] the diffusion coefficient can be represented as

$$D = A\mathscr{P}(v^*, v_f) = A \exp(-\gamma v^*/v_f) \qquad (3)$$

where $\mathscr{P}(v^*, v_f)$ is the probability that a molecule with a volume v^* enters a cavity with a volume $v > v_f$; γ is the overlap coefficient of the elements of the free volume, $0.5 < \gamma < 1$ (for simplicity, it can be taken as equal to 1); and A a constant.

In this simple form, however, the model cannot easily be used for the numerical estimation of diffusion coefficients in polymers. Various modifications of the model,[10–12] differing in the ways in which the dependence of v_f on temperature and the concentration of the diffusing substance is given, make it possible to use the thoery to describe the diffusion of organic solvents in rubbers. Subsequent refinement of the model of free volume led to the equation:[10,13,14]

$$D = RTA_d \exp(-B_d/v_f) \qquad (4)$$

where B_d characterises the volume of the substance diffusing, and A_d is a constant.

In this equation, the free volume v_f is given as a function of the temperature and pressure, that is it depends on the coefficient of thermal expansion of the polymer α and its compressibility β, and on a coefficient δ which allows for the influence of the diffusing substance on v_f (that is plasticising effects). Since the values of α and β for many polymers are known, for a complete description of the diffusion of gases it is sufficient to know the parameters A_d, B_d, and δ. This has been demonstrated for the transfer of CO_2, CH_4, C_2H_4, and C_3H_8 through polyethylene membranes at high pressures. The dependence of the permeability coefficient on the pressure (p_m) can be described by the equation:[14]

$$\ln \bar{P}(p_m) = \ln[\sigma_0 RTA_d \exp(-B_d/v_f)] + (B_d/v_f^2)(\delta\sigma_0 - 2\beta)p_m \qquad (5)$$

where $p_m = 1/2(p_1 + p_2)$, p_1 and p_2 are the pressures below and above the membrane respectively, and σ_0 the solubility coefficient of the gas in the polymer.

The traditional approach in the determination of the parameters of the free volume model requires a study of the diffusion in the polymer of gaseous probe molecules with different dimensions, that is the solution of the inverse diffusion problem. It should be noted that the integral free volume $V_f = v_f N$ can also be determined independently from data on the viscosity and the thermal expansion, crystallographic data, etc. At the same time, in the case of the diffusion of gases in polymers, the size distribution of the elements of the free volume is more important. This can be estimated using probe methods, which make it possible to study the behaviour in the polymer of probes of different character and dimensions, sensitive to those characteristics of the free volume which influence the diffusion of gas molecules.

Fig.2 shows the correlation between T_g and the free volume determined by the positron annihilation method[15] in the disordered regions of polymers $(v_f)_i$. Comparison of Figs.1 and 2 shows that the diffusion and permeability coefficients on the one hand, and the

free volume $(v_f)_i$ on the other, decrease in the same way with increase in the glass temperature in the highly elastic range of the polymer. This shows that the values of $(v_f)_i$ determine the diffusion coefficients of gases in rubbers in accordance with the equations of the theory of free volume. In particular, assuming that the process of gas diffusion involves chiefly the free volume in the disordered regions, and substituting $(v_f)_i$ in Eqn.(3), it is possible, from a comparison of the parameters of this equation with the dimensions of the molecules of the diffusing gases, to conclude that the geometry of the elements of the free volume in rubbers is cylindrical, in agreement with the assumed geometry of the segment of the polymer chain. It should also be noted that as T_g approaches T_m, the free volume $(v_f)_i$ decreases to a low value. This shows that the measured free volume in rubbers is sensitive to the segmental mobility.

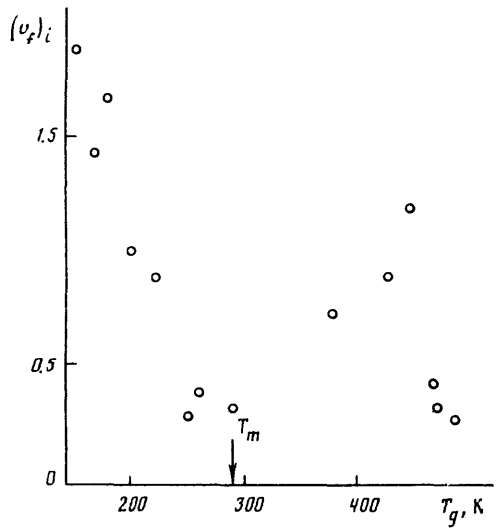

Figure 2. Correlation between the free volume $(v_f)_i$ and vitrification temperatures of polymers.[15]

At temperatures appreciably lower than T_g, the translational mobility of particles with low molecular weight is determined by the α-relaxation processes in the polymers. The small-scale† mobility in a polymer, which is often interpreted as β-transitions, is apparently appreciable close to T_g; in the highly elastic range, its contribution is small compared with that of the segmental mobility. The experimental data making it possible to estimate the role of small-scale mobility in the vitreous range will be examined below.

†The term small-scale mobility is usually employed to denote the vibrations and rotations of small groups in a polymer, which are preserved at temperatures both above and below T_g. Information on these motions in a polymer (for example the rotations of the phenyl group in polystyrene or of the methylene group of the main chain of polyvinyl chloride) can be obtained by NMR.

Among highly elastic polymers, the highest diffusion and permeability coefficients are observed for polydimethylsiloxane (PDMS) and other siloxanes differing from PDMS in the substituents on the silicon atom of the main chain (alkyl, phenyl, etc.). Polydimethylsiloxane has a lower glass temperature (150 K) than other polymers. The diffusion coefficients in it (at a temperature of 300 K) are high, and their order of magnitude is close to that of the diffusion coefficients in liquids. This is a consequence of the high flexibility of the main chain and the weak inter-chain interaction. Thus an increase in the size of the substituent (the replacement of a methyl by a phenyl group) or the introduction of a polar substituent (the nitrile group) leads to a decrease in the diffusion and permeability coefficients. It has been suggested that the elementary act in the diffusion of the molecule of a gas in a siloxane is controlled by the cooperative movement of a section of the chain containing three monomeric silicon-containing units.[16]

In spite of the high diffusion parameters of PDMS, a serious obstacle to the use of this polymer as a material for gas-separation membranes is its low selectivity with respect to many gases, and also its poor mechanical and film-forming properties. Various methods are used to overcome these disadvantages: the introduction of fillers, cross-linking, block copolymerisation, and the deposition of thin layers of PDMS on polymer supports. For example, the first gas-separation membranes were prepared from filled PDMS on a fabric support.[17] Cross-linked siloxanes are used to obtain composite membranes with a polysulphone support.[18] Non-cross-linked PDMS can be deposited on polymer supports to suppress defects or to produce thin layers with high gas-transport parameters.[19] Copolymers containing siloxane blocks will be examined in detail in section IV.

2. Vitreous Polymers

At temperatures below the vitrification temperature, the segmental mobility in a polymer disappears. From this it might have been expected that vitreous polymers would have a small free volume, and hence lower diffusion and permeability coefficients than rubbers. Since the temperature dependence of the diffusion and permeability coefficients is described by Arrhenius equations with $E_D > 0$ and $E_p > 0$, decrease in temperature leads to a decrease in P and D. In most cases, a break is observed on the Arrhenius relationships, that is the values of E_D and E_p change on passing through T_g.[6,7] At the same time, the view, which has been accepted for many years, that polymeric glasses always have lower diffusion and permeability coefficients than highly elastic polymers is not correct. In recent year, many vitreous polymers with higher diffusion and permeability coefficients than most rubbers and amorphous–crystalline polymers with low vitrification temperatures have been studied. This and other characteristics of mass transfer and sorption in vitreous polymers can be explained using the model of double sorption.[20]

Studies of the thermodynamics of sorption in a large number of vitreous polymers (see for example the paper by Paul[20] and the references therein) indicate that the sorption isotherms have the form shown in Fig.3, and are described by the equation:

$$C = k_D p + C'_H bp/(1 + bp) \qquad (6)$$

where C is the solubility, expressed in cm^3 gas (at normal temperature and pressure) per cm^3 polymer, and p the pressure, atm. The first term corresponds to the Henry isotherm (k_D is the solubility

coefficient), and the second to the Langmuir isotherm; b is the adsorption equilibrium constant, and C'_H is the adsorption capacity for the "Langmuir" fraction of the sorbed molecules. It should be borne in mind that the adsorption being considered takes place not at the gas–polymer interface but in the regions of lower density in the bulk of the vitreous polymer, that is in the elements of the non-equilibrium free volume.

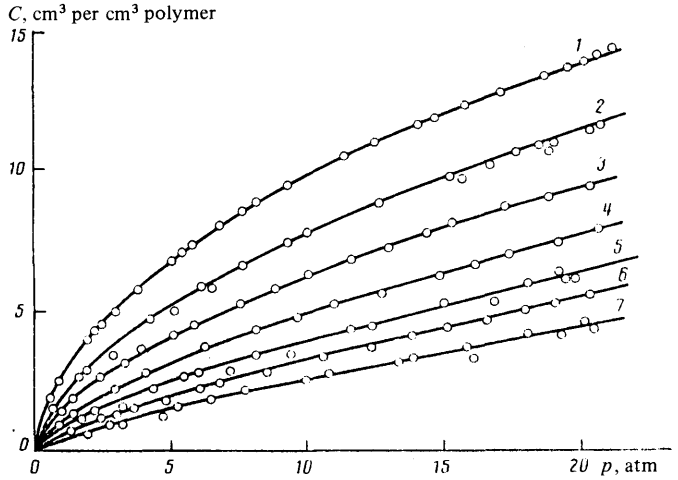

Figure 3. Sorption isotherms for carbon dioxide in polyethylene–terephthalate[21] at different temperatures K: *1*) 298, *2*) 308, *3*) 318, *4*) 328, *5*) 338, *6*) 348, *7*) 358.

The lower the temperature (in the vitreous range), the more convex the sorption isotherm towards the ordinate (see Fig.3). Since the quantity C'_H is determined as the intercept cut off on the ordinate by the asymptote approached by the sorption isotherm at high pressures (its equation is $C = C'_H + k_D p$), it follows that as T_m decreases or as the vitreous polymer moves away from its T_g, the values of C'_H increase. With increase in temperature, the curves become less convex, and at $T_m \geqslant T_g$ the isotherms become linear.

Thus the Henry isotherm describes physical solution in the polymer at temperatures both higher and lower than T_g; the second term is characteristic only of the vitreous state. At low pressures, the effective solubility coefficient is $\sigma = k_D + C'_H b$, and for highly elastic polymers, $\sigma = k_D$. This explains why the solubility coefficients are higher in polymeric glasses than in rubbers.[22] With increase in temperature, the value of σ decreases, not only because $\partial k_D/\partial T < 0$ and $\partial b/\partial T < 0$; there is a simultaneous decrease in the adsorption capacity C'_H, which reaches zero at T_g (Fig.4).

It is considered[20] that the quantity C'_H is a measure of the integral non-equilibrium free volume, which increases as the temperature $T_m < T_g$ moves into the low-temperature range. A number of data support this view. The value of C'_H at different temperatures can be determined not only from sorption data, but also from dilatometric curves.[23] This independent estimate, assuming that the density of the adsorbed gas is close to the density of its liquid phase, leads to very good agreement with the values of C'_H calculated from the sorption isotherms[21] (Fig.4).

Solution of the diffusion equation, including the two diffusion coefficients D_D and D_H for the physically dissolved and "Langmuir" fractions of the sorbate molecules respectively,[24] leads to the following expression for the observed diffusion coefficient of the gas D:

$$D = D_D \frac{1 + C'_H b/k_D}{1 + D_H C_H b/D_D k_D} \qquad (7)$$

It can readily be seen that with increase in C'_H or as the vitreous polymer moves away from its T_g, the diffusion coefficients of the gases should increase. With increase in T_g, as noted above, the diffusion coefficients of gases in polymers do in fact increase[5] (see Fig.1). This effect is evidently related to the characteristics of the thermodynamic state of polymers having high glass temperatures, since increase in T_g is accompanied by an increase in the rotational mobility of substances with low molecular weights (spin and electrochromic probes).[5] The increase in the non-equilibrium free volume in vitreous polymers whose glass temperatures are sufficiently high is also indicated by data obtained by positron annihilation[15] (Fig.2). The correlation between the activation energy of diffusion and T_g also indicates that the fraction of the free volume in polymers increases with increase in T_g.[25]

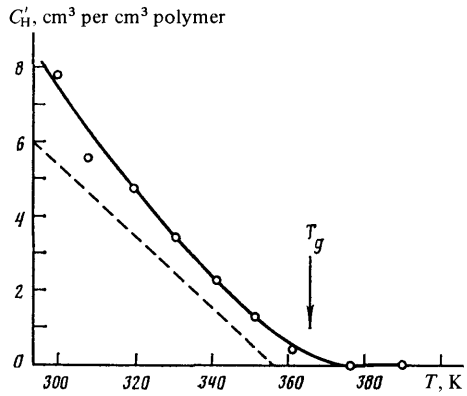

Figure 4. Temperature dependence of C'_H (for CO_2) in polyethylene–terephthalate.[21]

There arises the question of how universal are the thermodynamic relationships obtained from the model of double sorption for vitreous polymers. What is the range of change in the non-equilibrium free volume or the values of C'_H equivalent to it for different polymers? Answers to the last question are provided by the published[26] dependence of C'_H on T_g (at constant temperature) for different polymers (Fig.5). In spite of the marked differences in the chemical character of the polymers examined and the wide range of glass tem peratures, the value of C'_H is determined only by the extent to which the polymer has moved from its glass temperature. The relationshi shown in Fig.5 also applies for other sorbates (for example SO_2 [27]).

Thus the high diffusion and permeability coefficients of polymers with high glass temperatures are due to the appreciable magnitude o the non-equilibrium free volume. Physically, this means that a vitreous polymer at room temperature has the same free volume as some highly elastic polymer at a much higher temperature. The increase in the non-equilibrium free volume with decrease in the

temperature T_m in the range below T_g, that is with increase in the difference $\Delta T = T_g - T_m$, is apparently related to the fact that the decrease in the amplitude of the small-scale movements at lower values of T_m and large differences ΔT leads to the appearance in the vitreous matrix of an additional free volume, which is greater, the larger ΔT.[21,28]

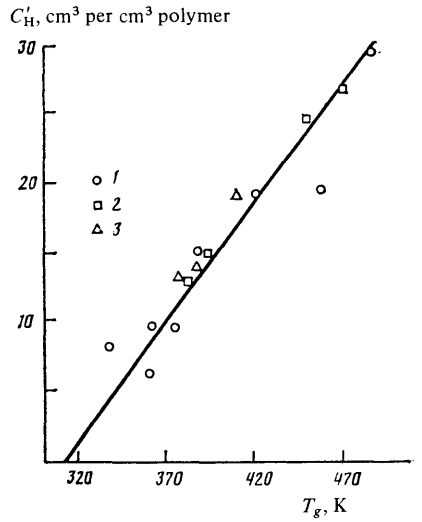

Figure 5. Correlation between the parameter C'_H for the sorption of CO_2 at 308 K and the glass temperature of polymer:[26] *1*) homopolymers, *2*) copolymers of polyphenylene oxide and polystyrene, *3*) copolymers of a polycarbonate and a polyester.

It has been suggested[29] that in the free volume, the fractions f_T and f_v corresponding to the thermal motion and the non-equilibrium character of the polymer respectively should be distinguished. Since f_T and f_v should be expected to change in opposite ways on moving away from T_g, it follows from the equation

$$D = \alpha \exp\left[-\beta(f_T + f_v)\right] \qquad (8)$$

which comes from the theory of free volume, that extremal relationships may appear, for example with change in T_g by plasticising the glassy polymer. Relationships of this type have in fact been obtained for the translational and rotational mobility of substances with low molecular weight.[29–33]

Additional confirmation of the role of small-scale mobility in diffusion phenomena observed in vitreous polymers is provided by the correlation between the frequency of rotation of the small groups of the macro-chains (from NMR data with rotation of the specimen at the "magic" angle) and the diffusion coefficients of gases (H_2, CO).[32] The extremal character of the relationships for v_f is also indicated by data obtained by using electrochromic probes to study the free volume in glassy polymers.[34] These relationships are observed when T_m does not differ greatly from T_g, that is when the contribution (f_T) of the small-scale mobility to v_f becomes appreciable against the background of f_v.

Although the model of double sorption can be used to describe the mass transfer and sorption of both individual gases and their mixtures,[35] in the great majority of glassy polymers which have been studied, the phenomenological character restricts its predictive power. It is intuitively clear that the coefficients of diffusion, permeability, and gas-separation selectivity should be determined not so much by the integral free volume (C'_H) as by the size distribution of the elements of the free volume and their distribution in space, the interaction between the substance diffusing and the polymer, and the equilibrium between the two groups of sorbate molecules (physically dissolved and adsorbed).

The model cannot give this information, so that it is desirable to study diffusion and sorption in vitreous polymers by independent methods. Thus the existence of a rapidly established equilibrium between the two groups of sorbed molecules, corresponding to the Henry and Langmuir isotherms, has been demonstrated by NMR.[36] It was recently shown that by studying the thermodynamics of sorption by reverse gas chromatography it is possible to estimate the characteristic dimensions of the elements of the non-equilibrium free volume in a polymer.[37] It was found that the more closely the geometric dimensions of the sorbate molecule correspond to the dimensions of the element of the non-equilibrium free volume, the more exothermic the mixing process and the more hindered the state of the sorbed molecules. This is revealed in large negative entropy effects.

On the other hand, attempts are being made to construct a diffusion model which takes account of the energy of the inter-chain interaction and the geometric dimensions of the molecules of the diffusing substance and the substituents of the macro-chains.[38,39] It will be shown below that the available data on the diffusion and sorption properties of vitreous polymers make it possible in some cases to relate their large free volume to definite characteristics of the structure.

III. VITREOUS POLYMERS—MATERIALS FOR GAS-SEPARATION MEMBRANES

The recent increase in interest in energy-saving and ecologically clean technologies, and progress in the chemistry and technology of the treatment of polymers, led in the nineteen-seventies and eighties to the development of several types of industrial gas-separation membranes, used in various technological processes. All gas-separation membranes used in present-day practice are based on glasssy polymers.

Just as among highly elastic polymers the greatest free volume is shown by the silicon-containing polymer PDMS, among vitreous polymers the maximum values of D and P are characteristic of polymers containing Si in side groups; polyvinyltrimethylsilane (PVTMS)[40] and polytrimethylsilylpropyne (PTMSP).[41] Both PVTMS and PTMSP are amorphous high-molecular-weight polymers with high glass temperatures (170° and >200° respectively). Both polymers are readily soluble in various organic solvents, and form strong thin films. PVTMS is used to prepare a highly efficient asymmetric membrane with a diffusion layer thickness of 0.2 to 0.3 μm,[42] widely used to separate gases. The diffusion and permeability coefficients of these polymers with respect to various gases and, for comparison, the corresponding data for PDMS are given in Table 1.

It is considered that polymers in the highly elastic state are characterised by higher values of P and D than polymeric glasses. The data given in Table 2 refute these ideas. The diffusion and permeability coefficients in PVTMS are fairly high, although they are lower than the values of P and D in highly elastic PDMS. At the same time, the values of P and D for vitreous PTMSP are greater by an order of magnitude than those for PDMS.

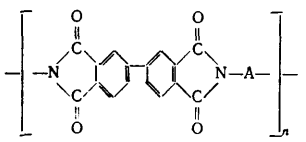
Table 1. Permeability coefficients of organosilicon polymers and the diffusion coefficients of various gases in them.

Polymer	$10^9 P$, $cm^3.cm/cm^2.s.cmHg$				$10^7 D$, $cm^2 s^{-1}$			
	H_2	CH_4	O_2	N_2	H_2	CH_4	O_2	N_2
PDMS	65	95	60	28	430	130	160	150
PVTMS	20	1.3	4.3	1.1	180	1.8	7.6	3.6
PTMSP	700	400	400	200	—	227*	358*	255*

*Data given by Y.Ichiraku, S.A.Stern, and T.Nakagawa, J.Membrane Sci., 1987, **34**, 5.

Table 2. Permeability of the products of the polycondensation of 4,4'-hexafluoroisopropylidenediphthalic anhydride with various diamines.[44]

Diamine	$10^9 P$, $cm^3.cm/cm^2.s.cmHg$		α_{H_2/CH_4}
	H_2	CH_4	
3,5-Diaminobenzoic acid	3.4	0.012	275
1,5-Naphthylenediamine	7.8	0.072	109
1,3-Phenylenediamine	3.6	0.013	270



In glassy silicon-containing polymers with trimethylsilyl substituents, the appreciable free volume is probably due to the non-equilibrium state of the polymer, the large inter-chain distances, and the existence of local cavities close to the bulky substituent. This is confirmed by the relatively low density of these glassy polymers, by the results obtained by the spin probe method,[43] and by data on the thermodynamics of sorption.[37] An interesting feature is that the replacement of one methyl group by a linear alkyl group in the $Si(CH_3)_3$ groups of both glassy polymers leads to an appreciable decrease in the permeability coefficients. The long-chain alkyl group apparently fills the cavities present in the polymer, decreasing the free volume.

High diffusion coefficients are also characteristic of other polymers with bulky (non-planar) substituents: poly-4-methylpent-1-ene (PMP), poly-N-isopropylacrylamide, etc. The presence of these groups leads to relatively loose packing of the chains and to the presence of regularly arranged elements of the free volume. In particular, PMP shows an interesting characteristic: in contrast to other partly crystalline polyalkenes, its crystalline phase is characterised by an anomalously low density, lower than that of the amorphous phase. As a result, mass transfer in this polymer takes place not only through the amorphous phase but also through the crystalline phase.

Another group of vitreous polymers with high diffusion coefficients is formed by rigid-chain glassy polymers with rings in the main chain: polysulphone, polyphenylene oxide, polyimides, and cellulose acetate. The high diffusion parameters of these polymers are apparently due to weak inter-chain interactions and to steric hindrance, which prevents close packing.

The use of an aromatic polysulphone has made it possible to achieve the most impressive success in the field of industrial membrane gas-separation: the production of an asymmetric composite hollow fibre,[19] which is now used by the firm of Monsanto (USA) in apparatus for separating the gas mixtures H_2/N_2, H_2/CH_4, etc. The total number of assemblies of this kind throughout the world is much greater than 100. The coefficients of permeability and diffusion of gases in the polysulphone are lower by at least 1–2 orders of magnitude than those in the most permeable vitreous polymers, but with the thickness of the diffusion layer in the hollow fibre of ~ 0.1 μm this ensures a sufficiently high permeability with respect to hydrogen (30 litre $m^{-2} h^{-1} atm^{-1}$) with sufficiently high separation factors, for example $\alpha_{H_2/CH_4} = 37$ and $\alpha_{H_2/CO} = 23$.[19] The selectivity of the asymmetric hollow fibres, however, is only slightly lower than that of continuous films of the polysulphone, because of the thin protective covering, which "heals" defects.

Polyimides, that is the products of the polycondensation of aromatic diamines and dianhydrides, give a very high selectivity of separation of many gas mixtures. A simple and important example is provided by the polyimides obtained from the anhydride of biphenyltetracarboxylic acid:

where A is an aromatic residue. The chemical structure of polymers of this class can be varied considerably by introducing different units joining the aromatic rings, but most polymers retain high gas-transport parameters (Table 2).

The firm of Ube Industries (Japan) uses polyimides with the above structure to produce gas-separation membranes in the form of an asymmetric hollow fibre (trade mark Upilex).[45] These membranes can be used at temperatures up to 150° and pressure drops up to 140 atm, and give a separation factor of 200–250 for H_2/CH_4 mixtures.

Not only synthetic but also natural polymers can be used as material for membranes. The best examples are the cellulose esters (acetate, nitrate, ethylcellulose). The influence of hydrogen bonding decreases with increase in the degree of esterification of the cellulose. Cellulose acetate is used to produce asymmetric membranes with thin working layers with a thickness of ~ 0.1 μm,[46] used in the gas-separation equipment of the reel type which the firm of Separex (USA) offers for separating CO_2/CH_4 mixtures in the production of natural gas and in the tertiary production of petroleum. The data given below show that the gas-transport parameters of this polymer are comparable with those of polysulphone:

Gas	H_2	O_2	N_2	CH_4	CO_2	C_2H_6
$10^9 P$, $cm^3.cm/cm^2.s.cmHg$	0.35	0.068	0.023	0.014	2.0	0.0068

The H_2/CH_4 separation factor is equal to several tens of units.

IV. HETEROPHASE POLYMER MEMBRANES

The difficulty of producing polymer membranes having the required permeability, selectivity, and stability was noted above. Attempts are increasingly being made to solve this problem by using composite materials containing phases in the highly elastic and glassy states, and also the phases of low-molecular-weight solid and liquid additives.

A trend which is developing particularly actively is that associated with the production of various block copolymers, used as materials for separation membranes, into which a rigid vitreous block is introduced in addition to flexible siloxane components. This family of materials includes siloxane–carbonate,[47,48] siloxane–sulphone,[49] siloxane–arylate, siloxane–urethane, and other types of block copolymer.

In the selection of the components for the synthesis of block copolymers, particular attention is paid to the improvement of the mechanical properties, the chemical stability in the media being separated, or, finally, the selectivity of separation of the various components. In particular, the good mechanical properties of siloxane–carbonate block copolymers have made it possible to use them to produce ultrathin composite membranes with a diffusion layer thickness of 0.1–0.2 μm. The permeability coefficients of one of these membranes (MEM-079) are given below:[50]

Gas	N_2	CH_4	CO_2	H_2	H_2O
$10^9 P$, $cm^3.cm/cm^2.s.cmHg$	0.35	0.44	8.4	4.5	100

Improved mechanical and film-forming properties are also shown by siloxane–arylate block copolymers.[51] Their selectivity is determined by the selectivity of the siloxane component.

In siloxane–sulphone block copolymers,[49] since there are no easily hydrolysed Si–O–C bonds in the main chain, there is a sharp increase in the hydrolytic stability. In this respect, these block copolymers are much superior to siloxane–carbonate and siloxane–arylate block copolymers (Carbosil, Silar) and cross-linked siloxane polymers (Lestosil). The high chemical stability of polysulphones is also used in the production of other block copolymers (Seragel) which show a high selectivity in the separation of the mixtures SO_2/N_2, H_2S/CH_4, CO_2/CH_4, etc.[49]

Block copolymers in which not only the highly elastic but also the rigid (glassy) block has high gas-transport parameters might be of particular interest as selectively permeable polymers. This combination of properties has been realised in block copolymers containing PVTMS as the rigid block, and PDMS or polydienes (for example polybutadiene) as the soft (highly elastic) block.[52]

In polymers of this type, the permeability and diffusion coefficients of gases are highly sensitive to the composition and morphology of the copolymer. If the concentration of one of the components of the block copolymer is less than 20%, electron microscopy and analysis of the dependence of P and D on the copolymer composition show that it generally has a morphology of the "disperse phase–dispersion medium" (DPDM) type. At a concentration of one of the blocks equal to 50 ± 15%, phase inversion takes place, and the morphology is best described by a model of two interpenetrating networks. Since the siloxane phase has much higher values of P and D, a sharp increase in the integral diffusion and permeability coefficients is observed, and the overall composition dependence of these quantities is S-shaped. The proposed models of mass transfer in these systems (examined, in particular, in Ref.53) provide an insufficiently accurate description of the diffusion process over a wide range of compositions.

Attempts to refine the diffusion models encounter two fundamental difficulties. One difficulty is that the morphology of real heterophase block copolymers and polymer mixtures cannot always be reduced to simple structures of the DPDM type. Sometimes one of the components may form both a continuous and a disperse phase, and the latter is present in larger dispersion elements of the second component (an analogue of multiple emulsions).[54] Partial mixing of the chains at the phase interfaces and spatial non-uniformity of the membrane, for example enrichment of its surface in one of the components, are possible. As a result, different diffusion paths may be realised when different gases and vapours are transferred through these heterophase membranes.[53,55] This indicates the importance of the selection of the nature of the "diffusion probe" in the diffusion-structural analysis[56,57] of relatively complex systems of this type. In the analysis of uniform structures, the variable parameters may be the geometric dimensions of the different probes (cross-section, molar volume, etc.), whereas in the case of heterophase systems it is also necessary to vary the solubility parameter of the diffusing substance or its components, which influence the affinity of the diffusing substance and the separate phases of the polymer. At the same time, a new possibility is opened up for increasing the selectivity of gas separation using composite non-uniform membranes.

The second difficulty is that in the description of mass transfer in these membranes it is necessary to specify the local properties (coefficients of diffusion, solubility, etc.) of the individual phases. Since these are not known, it is assumed that these phases have the properties of the homopolymers. To verify the justification for this approach, it is appropriate to use probe methods. In particular, the spin probe method has shown that the diffusion coefficients of gases in the silane phase of silane–siloxane block copolymers coincide with the diffusion coefficnets in PVTMS.[53] At the same time, as shown by reverse gas chromatography[58] and spin probe[53] methods, the thermodynamic properties of the siloxane phase in copolymers differ considerably from those of PDMS.

The search for materials for separation membranes reduces to the search for polymers in which high values of P_i (and hence D_i or σ_i) for some gases are combined with low values of these parameters for other gases. In a large number of cases (He/N_2,[1] H_2/CH_4,[59] O_2/N_2 [3]) it has been shown that for most polymers, a single correlation applies: higher values of P_i correspond to a lower selectivity α_{ij}. An attractive method of overcoming this difficulty is by producing membranes in which transfer takes place through a phase in a different state of aggregation, for example in the liquid phase. The diffusion coefficients are usually greater by 2–3 orders of magnitude in liquids than in polymers. If the liquid phase filling the pores of the membrane shows selective solvent power for one of the components of the medium being separated, a highly permeable and selective membrane should be obtained. Quasi-liquid membranes of this type have been proposed for separating various gas mixtures. Some examples are given in Table 3. Attempts to use quasi-liquid membranes to separate CO, H_2S, and SO_2 from mixtures with other gases have been reported.[3]

In spite of the obvious advantages of membranes of this type, their use involves considerable technical difficulties: removal of solution from the pores of the membrane is possible; with increase in the gas pressure, the rate of transfer often does not increase, as in ordinary polymer membranes, but decreases; the effective thickness of the membranes is generally not less than 100–200 μm, whereas in polymer membranes it may be three orders of magnitude smaller; also the complex-forming reagents added to the solutions are often insufficiently stable.

Attempts are therefore still being made to give the membrane an increased selectivity with respect to the passage of certain gases without a significant lowering of the diffusion coefficients on transfer through the polymer phase.

Table 3. Characteristics of various quasi-liquid membranes.

Mixture	Diffusion medium	α_{ij}	$10^9 P_i$, $cm^3.cm/cm^2.s.cmHg$	Refs.
CO_2/CH_4	aqueous solutions of K_2CO_3 and Cs_2CO_3	—	—	[59]
CO_2/O_2	ditto	160	10	[60]
O_2/N_2	Co complexes in aqueous solutions	20—30	10^2	[3]
C_2H_4/C_2H_6	aqueous $AgNO_3$ solution	70—1000	10—10^2	[61]
Alkanes $(C_2—C_4)/CH_4$	n-decane, n-hexadecane	4—60	10^2—10^3	[62]

Specifically interacting additives may be present in the membrane as a solid solution. Thus the introduction of a number of inorganic salts (KF, KNO_3, etc.) into membranes based on mixtures of cellulose and polyethylene glycol leads to a selective increase in the permeability and solubility of CO_2, and also to selectivity of the separation of a CO_2/N_2 mixture with very little decrease in the effective diffusion coefficients of CO_2.[63] The porphyrin complex of cobalt(II), added to a polybutyl methacrylate matrix, increases both the permeability towards oxygen and α_{O_2/N_2}:[64,65]

Concentration of the complex, %	$10^9 P$, $cm^3.cm/cm^2.s.cmHg$	α_{O_2/N_2}
0	0,64	3,2
2,5	0,98	4,8
4,5	2,3	12,0

Many other types of complex interacting specifically with oxygen are known (Schiff bases, chelate complexes, haems with different structures, etc.), and their methods of synthesis and sorptive properties have been studied.[66]

If a complex-forming additive with an affinity for one of the components of the mixture being separated is not covalently bonded to the polymer, it may show a tendency to undergo phase segregation, as a result of which its efficiency decreases. Preference must be given to immobilisation of the additive on the macro-chain. There are at present few examples of studies in which an increase in selectivity and permeability has been observed as a result of the ionic, covalent, or other bonding of the complexes to the polymer matrix.[67—69] The search for membranes of this type for the concentration of oxygen from air and water is particularly intensive.

Extremely interesting possibilities for membrane gas separation are opened up by the use of polymer membranes containing low-molecular-weight liquid crystals, and membranes based on liquid-crystal polymers. Mixtures of polymers and liquid crystals with different structure and morphology show a higher permeability than the vitreous polymer matrix into which they are introduced.[70,71] These systems are characterised by a sharp inflection on the temperature dependence of the permeability coefficient with a few degrees of the temperature (T_m) of the crystal→liquid crystal transition. The values of P, for example for the $C_1—C_4$ hydrocarbons, increase by a factor of 100—200.[70,72,73] This increase is a consequence of the fact that at the temperature of the phase transition there is a sharp change in the solubility coefficients, but a particularly marked change in the diffusion coefficients.[74] Similar relationships were previously observed for the polyethylene—paraffin wax system;[75] an abrupt increase in the diffusion coefficients was observed in the region of the melting point of the paraffin wax.

The dependence of the permeability coefficients of C_n n-alkanes on the carbon number n is determined by the physical state of the poly-mer matrix;[22] for rubbers and partly crystalline polymers, P increases with increase in n, whereas for polymer glasses it decreases. The conversion of a system from the crystalline to the liquid-crystalline state leads to a qualitative change in the relationships, and hence in the mechanism of transfer, at temperatures below T_m, the highest permeability coefficients among $C_1—C_4$ n-alkanes are observed for methane, whereas above T_m they are observed for butane.[72—74] Thus the use of polymers containing added liquid crystals opens up the possibility of controlling not only the permeability but also the selectivity of membranes.

It is interesting, in particular, that in systems containing liquid crystals in the mesomorphic state, the separation factor α_{O_2/N_2} increases with increase in temperature.[76] This is an example, as yet rarely encountered, of a simultaneous increase in both the permeability and the selectivity.

Another possibility for improving the characteristics of a membrane separation process is by the effect of electrical and magnetic fields on the rate of mass transfer in the membranes. Thus the permeability coefficient with respect to n-butane increases by a factor of ~5 when an electric potential of ~700 V is applied to a membrane containing a liquid crystal, to bring about orientation of its molecules.[71]

The permeability and selectivity also depend significantly on the characteristics of the actual liquid-crystal state. Poly-γ-benzyl glutamate can form a smectic phase when obtained from a solution in benzene, and a cholesteric phase when obtained from a solution in methylene chloride. As a consequence of the lower density of packing in the cholesteric phase, the permeability coefficient with respect to benzene is six times greater.[77]

Liquid-crystal polymers should apparently have a number of advantages over mechanical mixtures of polymers and low-molecular weight liquid crystals. Studies in this direction have only just begun however. It has been established, in particular, that if the mesogenic groups (that is the groups giving the polymer its liquid-crystal properties) are in the main chain, the changes observed on passing through the temperature of the phase transition are more marked than when these groups are present in the side chains and lead to the formation of smectic liquid crystals.[76] The nature of the temperature dependence of the permeability of comb-shaped liquid-crystal polymers can be altered considerably by recrystallisation of the side chains.[78]

Almost all present-day membranes are obtained from familiar polymer materials, sometimes with slight modification. The directed synthesis of polymers for gas-separation membranes is as yet a rare exception. At the same time, accumulated knowledge of the chemical character and structure of polymers and their physical and phase states, and the understanding of the regularities and physicochemical principles of mass transfer in these materials are on the one hand providing a basis for the directed synthesis of polymers specially designed for separation membranes. On the other hand, these developments are opening up the possibility of producing membranes in the form of complex multifunctional structures.

The membranes which will be produced in the next ten years should reach a qualitatively new level: the range of gases being separated will increase, the permeability will increase by at least 1—2

orders of magnitude, and the quantitative single-stage extraction of the components of mixtures and operation under severe conditions will become possible.

While the present review was being prepared for publication, a number of papers confirming the role of the free volume in the sorption and transfer of gases in vitreous polymers were published. Maeda and Paul[79–81] have studied the influence of added plasticisers on the sorption, diffusion, and permeability of gases in polysulphone and polyphenylene oxide, and also the specific volumes of mixtures containing these polymers. It was shown that the free volume, determined as the difference $v_f = v - v_0$, where v is the specific volume, and v_0 the occupied or van der Waals volume, that is the specific volume at 0 K, provides and excellent description of the diffusion and permeability coefficients of gases in a wide range of plasticised and non-plasticised polymers. In some cases an appreciable increase in the selectivity of separation of gases α_{ij} can be achieved by changing the free volume.[82] Estimates of the characteristic dimensions of the elements of the non-equilibrium free volume in vitreous polymers by the spin probe method[43] and by reverse gas chromatography[37,83] have been confirmed by an independent determination using photochromic and fluorescent probes.[84] It was established that in polystyrene, the average volume of the elements is 260–280 Å^3, and that elements with dimensions greater than 400 Å^3 are not present, that is the size distribution is fairly narrow.

The Role of Interphase Phenomena in the Processes of Ion Transport Through Liquid Membranes

V.V.Tarasov and A.A.Pichugin

The principal interphase phenomena accompanying the transfer of a substance through liquid membranes (chemical reactions, the formation of supersaturation and microheterogeneity zones, spontaneous interphase convection), which are related to many important characteristics of the kinetics of ion transport, have been examined. By influencing these processes it is possible to control the rate of trans-boundary transfer.
The bibliography contains 61 references.

I. INTRODUCTION

Liquid membranes are finding increasing application for the extraction, concentration, and separation of substances of different kinds,[1,2] and also for modelling individual functions of biological cell membranes.[3-5]

A liquid membrane is a layer of an organic phase separating two aqueous solutions. This layer may be thick or extremely thin, and may be free or deposited on a solid porous material which gives the resulting system mechanical stability. A large number of emulsions of the water–oil–water type are also used. Processes using these emulsions are called membrane or emulsion extraction.[2]

Irrespective of how the membrane process is organised, a common feature is the presence of "accepting" and "delivering" phase interfaces; extraction takes place at the first of these, and re-extraction at the second. Another common feature is that the physicochemical phenomena at the boundaries of the immiscible liquids and in the extremely thin layers adjoining them, and also at the boundaries with the solid, play an extremely important and sometimes a decisive role in ion transport.

These interphase phenomena include chemical reactions, adsorption, surface association, the formation of supersaturation and microheterogeneity zones (SMZ), the formation of condensed interphase films (CIF), and spontaneous interphase convection (SIC). In thin membranes or when organic phases fixed to solid carriers are used, the formation of inverse micelles and aqueous channels becomes important. These phenomena are closely related to one another and to the processes of ion transport. A good example is provided by spontaneous interphase convection, a phenomenon whose study may give results of considerable scientific and practical importance, in particular the development of the cheapest methods of intensifying ion transport in heterogeneous systems.

The aim of the present review was to examine the principal interphase processes accompanying the transfer of substances through liquid membranes and their inter-relationships and interdependence.

II. CHEMICAL REACTIONS

The liquid phase of a membrane usually contains a carrier, that is an active component which interacts with ions to give lyophilic compounds soluble in the organic phase. The carriers may be neutralic, acidic, or basic substances, which react with the ions being extracted by ion exchange, the formation of coordination compounds, or both mechanisms simultaneously (chelate formation). In a number of cases, for example when salts of amines and quaternary ammonium bases are used as carriers, an important role is played by the formation of ion pairs (contact pairs and pairs separated by water molecules) and hydrogen bond formation. The transfer of metal ions by macrocyclic crown ethers and cryptands takes place as a result of the inclusion of the metal cation in the cavity of the macro-ring, in which it is retained, usually, by ion–dipole interaction forces. Donor–acceptor interactions and the formation of coordinate bonds may also play an important role in this case (for example in the transfer of actinide and lanthanide ions).

Thus as in the "classical" method of extraction,[6,7] in membrane methods using carriers, mass transfer is accompanied by chemical reactions, whose rate may have a significant influence on the intensity of the entire process of mass exchange. As in extraction, it is possible to distinguish processes involving the previous formation of the compound being extracted (that is a compound of the component being extracted and the carrier), the actual formation of the extractable compound, chemical transformations of the latter during its transport through the membrane, decomposition of the extractable compound at the other side of the membrane, and subsequent reactions involving its decomposition products.

Experience accumulated in the study of the kinetics of chemical reactions in extraction[7] indicates that the formation and rupture of hydrogen bonds, proton transfer, and ionic and molecular association or dissocation do not limit the rate of trans-membrane transfer, but may influence it concentration dependence by changing the individual resistances to the diffusion of each of the components in the membrane phase and in the aqueous solutions surrounding it.

The formation (and decomposition) of coordination compounds of the carriers and the components being extracted are slower, and therefore create an additional (chemical) resistance, taken into account by appropriate equations for the additivity of the phase resistances.[7] In this case, within homologous series of organic carrier reagents, as in extraction,[7] correlations may be observed between the stabilities of the compounds and the rates of trans-membrane transfer. The formation (and decomposition) of intra-complex kinetically inert compounds is even slower.[7] These reactions, which often determine the rates of extraction and re-extraction, may also limit the rate of trans-membrane transfer,[2,8] It must be borne in mind, however, that the role of the diffusion resistance of the organic phase is greater in a membrane process than in extraction, particularly in those cases where this phase is fixed on a solid support, which prevents the development of natural or forced convection.

Thus in many cases of practical importance it is necessary to take account of the rates of chemical reactions and the resistance to transfer which they create. The method used to take account of ion transport processes (the form of the equation for the additivity of the phase resistances) and, which is more important, the method used to identify these processes, depend to a significant extent on the mechanism and topology of the chemical reactions.

Chemical reactions are most frequently localised not in the entire volume or a multiphase system but only in an extremely small part of it, called the reaction zone. Exceptions are encountered only in very slow homogeneous chemical reactions, which generally are not of interest for processes of practical importance. The reaction zone coincides with the region where the main diffusion resistances are concentrated, that is with the interphase region, so that all the phenomena which alter the hydrodynamic conditions or the composition of the liquids in the interphase region should also influence the kinetics of the chemical reactions and the intensity of the mass-exchange process as a whole.[7]

One of the most obvious methods of intensifying ion transport is by increasing the rates of the chemical reactions using added catalysts. In the discussion of the mechanism of their action, two different types of interphase reactions are considered: surface and bulk (next to the surface).[7] In the transport of ions through membranes, reactions of the first type create the so-called "small merry-go-round", and those of the second type create the "large merry-go-round".[3,9] The role of the "small merry-go-round" in ion transport through a phase interface is still disputed, although the question has been widely discussed in the study of the kinetics of extraction[7] and membrane processes,[3-5,9] and has also been examined by specialists in the synthesis of organic substances in two-phase systems.[10]

The most definite conclusions reached in the study of the mechanism of formation of extractable compounds reduce to the following:[7] a surface reaction, that is a reaction involving adsorbed substances, is always accompanied by a corresponding reaction next to the surface, the contribution of the first of these being greatest at low concentrations of reagents having surface-active properties. In non-steady-state processes, the surface reaction predominates at low exposures of the phases, but subsequently the second reaction channel (the "large merry-go-round") develops, and its contribution increases.

A method has been developed for calculating the contributions of the two reaction channels,[11] and the conditions controlling each of them have been found. In particular, it has been shown for the reactions between copper ions and hydroxyoximes that extremely small quantities of added ionic surface-active substances (SAS) have a greater influence on the rates of surface reactions than on the rates of reactions localised in layers of the aqueous phase next to the surface. Anionic SAS increase the rate of both the formation and the decomposition of the copper hydroxyoximate, whereas cationic SAS decrease the rates of these reactions (see Table and Refs. 12 to 14). The acceleration factor reached 8, and the retardation factor 25, so that by using SAS it is possible to change the rate of the process by a factor of 200.[11,12]

The influence of SAS on the parameters of the extraction and re-extraction of copper in systems containing 2-hydroxy-5-octylbenzophenone oxime.[11]

Notation: F is the acceleration factor; P_s and P_v the contributions of the surface and volume reactions respectively; and c_{SAS} the SAS concentration.

* Conditions: pH 3.0, copper concentration in the aqueous phase 0.11 M.

** Conditions: pH 2.4, copper concentration in the organic phase 0.031 M.

Two explanations of the influence of these modifying agents are of interest. The first is based on the assumption that the stages determining the rates of the chemical reactions involved in the formation or decomposition of the extractable complexes take place within the electrical double layer, in which the nature of the distribution of the potential is influenced by ionic SAS. If these stages involve intermediate positively charged complexes, it follows that anionic SAS, as a consequence of electrostatic interaction, will increase the surface concentration of these complexes, leading to an increase in the reaction rates. The opposite picture for the adsorption of cationic SAS.

The second explanation, which reduces to so-called micellar catalysis, assumes the existence of supersaturation and micro-heterogeneity zones under non-equilibrium conditions in the interphase region. Adsorption on microheterogeneous particles, and a specific distribution of the substances between the bulk and micellar phases, may lead to an appreciable change in the overall reaction rate.[15,16]

It is important to note that "catalytic" effects of identical sign (but not absolute magnitude) have been observed not only in the transport of ions through "free" interfaces but also when an organic medium fixed on a porous hydrophobic material (polyethylene, Teflon) is used.[17]

Finally, it is necessary to discuss the mechanism of action of modifying agents which do not have strong surface-active properties but which themselves are capable of extracting ions weakly but rapidly. These substances include, for example, 2-(α,α-dimethylbenzyl)-4-methyl-6-nitrosophenol (ONP). The Table shows that increase in the ONP concentration leads to an increase in the contribution of the reaction next to the surface, which becomes the predominant reaction at high ONP concentrations. The acceleration is most probably due to the appearance of an additional reaction channel in the layers next to the surface in the organic phase; when ONP is present, an exchange reaction between the *o*-nitrosophenol residue (R′) and the hydroxyoxime residue (R) begins:

$$CuR_2' + H_2R \rightleftarrows CuR_2 + H_2R'$$

The production of additional reaction channels in the aqueous and organic phases is the main reason for the increase in the rate of the transfer of cations by alkyl hydrogen phosphates[18] and tri-n-octylphosphine oxide.[19]

In organic syntheses in two-phase systems, this mechanism of the acceleration of ion transport is known as "transport catalysis".[10]

III. SUPERSATURATION AND MICROHETEROGENEITY ZONES AND CONDENSED INTERPHASE FILMS

The transport of ions through a phase interface is accompanied by the transfer of the solvent, in particular water, since dehydration is not instantaneous. It penetrates to a definite depth, depending on the ratio between the diffusion coefficients and the rate constants of dehydration.

The existence in the interphase region of hydrodynamic fluctuations which are due to the statistical nature of the turbulent pulsations produced under the influence of the mixing assemblies or as a result of the existence of Marangoni–Gibbs effects, leads to corresponding fluctuations in the depth of penetration of the reaction and the concentration fields. The local values of these concentrations may exceed the solubility limit, leading to supersaturation and the formation of microheterogeneous regions of the "water in oil" and "oil in water" type. This is associated with the phenomenon, frequently observed in extraction, of the production of a "fog", extending from the phase interface into the volume of the phases. The formation of SMZ provided a basis for the development of the concept of the "sandwich" structure of the interphase region in the transport of ions through a liquid–liquid phase interface.[7,17]

According to these ideas, the interphase region includes the adsorption layer and the adjoining supersaturated and microheterogeneous layers layers of the organic and aqueous phases, whose properties and extent depend significantly on the direction and intensity of the ion transport. The assumption that there is a dynamic interphase structure, in contrast to the static structure usually considered, has made it possible to explain successfully the electrical properties of the interfaces in various liquid–liquid systems, and also a whole series of unusual kinetic relationships (saturation of the mass fluxes through the "delivering" phase interface,[7,17,20] the extremal dependence of the rate of ion transport on the concentration of the complexes being transferred in the organic phase,[17] the loss of the sensitivity of the mass fluxes to change in the intensity of mixing,[17,20,21] etc.).

The production of SMZ next to the boundaries of liquid–liquid systems has a marked influence on the intensity of mass exchange. On the one hand, it decreases the trans-boundary mass flux as a result of the shielding of the surface and the decrease in the concentration gradients at right angles to the boundary, and on the other hand it increases the rate of extraction as a result of the production of tangential gradients in the interphase tension and the development of spontaneous interphase convection under the influence of Marangoni–Gibbs effects. It is true that this mechanism appears distinctly only at free boundaries, so long as the microheterogeneity zones do not undergo phase transformations. The latter are sometimes observed at strictly definite (critical) concentrations of the substance being extracted in the aqueous solutions[7,17,20] and are accompanied by an abrupt change in the rate of ion transport as a result of sharp changes in the rheological properties of the interphase boundaries. Thus SMZ have a definite aggregation (or kinetic) stability. When they lose this stability, they are converted into viscous CIF under some conditions, and into solid CIF under other conditions.[7,22]

An important consequence of the formation of SMZ in ion transport through liquid membranes is a change in the equilibrium conditions at the interphase boundaries and hence in the overall diffusion resistance calculated from the equation for the additivity of the phase resistances. For steady-state transport processes, these local boundary conditions remain unchanged with time, but they do not coincide with the conditions found on the basis of known distribution coefficients. For non-steady-state processes, the equilibrium boundary conditions change with time, since the composition and width of the SMZ do not remain constant, but depend on the magnitude of the trans-boundary fluxes.

If the thickness of the membrane is smaller than the width of the SMZ (the latter may reach $10^{-4}-10^{-3}$ cm),[17,22] the liquid is microheterogeneous throughout the entire thickness of the membrane. The quantity of the substance being transferred in it may then differ considerably from that calculated from data on the equilibrium for macroscopic phase volumes.

The production of SMZ is apparently the initial stage in the formation of aqueous "channels" in impregnated membranes, and is the reason for electrical breakdown in electrodialysis through extraction membranes.[23] If these conclusions are correct, one method of combatting breakdown may be by introducing into the system substances which increase the rate of dehydration of the ions.

The formation of CIF influences the rate of ion transport to an even greater extent than the formation of SMZ. This phenomenon is characteristic of ions which tend to undergo hydrolysis and hydrolytic association, so that their extraction is accompanied by the formation of "medusae" ("beards", "caps"), which bring about a marked deterioration in the separation of the emulsions into layers and decrease the efficiency of mass-exchange equipment.[7,17] The formation of CIF (gels) is the main reason for the decrease in the efficiency of ultra- and micro-filtration equipment and the non-rationality of the use of large pressure drops.[24,25] The mechanism of the production of gels in ultra- and micro-filters is of course different from that in extraction. The result is the same in both cases, however, namely a sharp increase in the diffusion resistance, and sometimes a decrease in the selectivity, so that it is necessary to find methods of combatting concentration polarisation of this type.

The regular features of the formation of CIF at the boundaries of liquid–liquid systems have been studied in detail for the ions of metals in the central part of the periodic system of the elements (Zr, Hf, Nb, Ta, Ti, Si, etc.).[22] There is no doubt that the conclusions reached can be extended to processes involving liquid membranes. The methods used to prevent the formation of CIF are more varied in this case than in filtration. A decisive role is played by the state of the ions in the aqueous solution and by the nature of the carrier,

the modifying reagents, and the organic solvents, whose selection can reduce film formation to a minimum.[22] It is also possible to control the processes of CIF formation by adding surface-active substances to the aqueous solutions, and also by applying a potential difference between the phases.[22]

IV. SPONTANEOUS INTERPHASE CONVECTION

Because of its considerable scientific and practical importance, the phenomenon of spontaneous interphase convection has recently been attracting increased interest.[26,27,32,33] The phenomenon is of fundamental importance, since it provides a source of information on the regular features of the production and development of the self-organising dissipative structures in non-equilibrium open systems[28,29] and on the mechanisms of the processes of the change from "order" to "chaos".[30] The practical importance of this phenomenon is due to the promising possibilities provided by the development of highly effective low-energy methods for intensifying mass-exchange processes. Published experimental data indicate that the breakdown of hydrodynamic stability, leading to the appearance of conductive movements in the interphase region, can increase the rate of ion transport by several orders of magnitude as a result of the breakdown of the diffusion boundary layer and the decrease in concentration polarisation.

Spontaneous interphase convection may be due both to local changes in the bulk properties of the phases in the region next to the surface and to the loss of mechanical stability by the interphase boundary as a result of local breakdown of the balance of the tangential forces acting on it. A decisive influence on the local changes in the bulk and surface properties is exerted by chemical reactions, processes of adsorption and surface association, the formation of zones of extended non-uniformity, such as SMZ and CIF, and the action of an electromagnetic field.[7,27]

Allowance for the role of each of these factors, not to mention their combinations, often encounters fundamental difficulties, since at present there are no adequate models for many processes of this type. For an adequate treatment of the phenomenon of SIC it is possible to use the methods of the thermodynamics of irreversible processes. A thermodynamic analysis makes it possible to obtain in the most general form expressions for the criteria of hydrodynamic instability and to reveal the importance of various perturbing parameters.[28,31] At the same time, the use of these criteria for a quantitative interpretation encounters serious difficulties, since it requires the experimental determination of phenomenological coefficients, and this is an incorrect aim at the existing level of knowledge of SIC.

From the viewpoint of the quantitative interpretation of the regular features of SIC and the study of its mechanisms, it is apparently preferable to use the classical hydrodynamic approach, based on the solution of the differential equations of the momentum balance together with the equations of state relating the pressure, density, and temperature, and the equations of convective heat transfer and diffusion. The role of the various interphase processes responsible for the breakdown of hydrodynamic stability is taken into account by introducing perturbations not only into the main equations but also, when necessary into the corresponding boundary conditions. The analysis of the stability involves the determination of the conditions which lead to an unlimited increase in the perturbations in relation to the coordinates and time.[31,32]

To develop methods for controlling the hydrodynamic instability, it is necessary to know the properties (bulk or surface) whose local changes lead to its appearance. An analysis of published data shows, however, that it is not always possible to distinguish clearly the contribution of these factors. At the same time there is no doubt that local breakdown of the balance of the tangential forces acting on the interphase surface has a decisive influence on the production of the SEC for processes of ion transport through liquid membranes with free boundaries. For these processes, the study of the role of capillary and surface electrical forces is of the greatest interest from the practical viewpoint.[34–38]

Capillary instability (Marangoni–Gibbs instability) is due to local fluctuations in the magnitude of the interphase tension. The physical significance of the mechanism of the production of instability in this case has been clearly demonstrated in Refs.31, 33–38, where it was shown that for a non-equilibrium distribution of the interphase tension in at least one of the phases there should be a movement leading to the appearance at the interphase surface of a friction force tending to balance the interphase tension gradient. The changes with time in the interphase tension gradients unavoidably lead to perturbations with time in the velocity field, which may either be quenched or increased with the passage of time. The last case corresponds to hydrodynamic instability.

The production of stable or unstable hydrodynamic conditions depends on the existence of a critical value of the interphase tension gradient, and when this is exceeded, the perturbations of the velocity field produced by the fluctuations in the interphase tension begin to increase with time. The critical value of the interphase tension gradient can be characterised by the so-called Marangoni critical number (Ma_{cr}). It has been shown that if $Ma < Ma_{cr}$ the perturbations of the velocity field are quenched with time, and when $Ma \geqslant Ma_{cr}$ the movement becomes unstable.[33,36]

An attempt has been made[39] to establish a quantitative correlation between the rate of interphase transfer and the Marangoni number under conditions of non-equilibrium distribution of the interphase tension. Subsequently, a rigorous theoretical foundation for the correlation obtained[40] was derived from an analysis of the kinetics of mass transfer in a thin film with a specified interphase tension drop at the mobile interphase boundary. The acceleration factor has been determined[41–43] for interphase transfer in a two-phase system formed by two plane-parallel layers of the immiscible liquids, where the fluxes of each of them had an ordered circulation structure. The circulation structures were described by solving the Navier–Stokes equations for a given tangential force at the interphase boundary. This analysis gave the dependence of the acceleration factor η on the Peclet number Pe. For small Peclet numbers, the relationship $\eta \sim Pe^2$ is fulfilled, whereas as $Pe \to \infty$, $\eta \sim Pe^{0.5}$. Since the rate of convective movement and hence the magnitude of Pe are proportional to the interphase tension gradient, the interphase transfer can be intensified by altering the interphase tension.

The existence of a tangential component of the intensity of the electric field acting on the interphase boundary leads to the product of so-called electrocapillary instability, whose regular features cannot be described without taking account of the ionic nature of the reagents being transferred through the phase interphase or adsorbed on it. A large amount of experimental data indicating the existence of an instability of this kind has been published. An example is given in Ref.44, where is was shown that the oscillator movements of an oil–water phase interface are produced only if the organic phase contains a dissolved electrolyte. This system can serve as a simple and clear example of the existence of positive and negative feedback controlling the hydrodynamic instability. The existence of this feedback is a necessary condition for the production of SIC.[28] The positive feedback is provided by the adsorption of SAS

(cetyltrimethylammonium chloride) and the negative feedback by the interphase transfer of ions.

The basic principles of the instability of this system were described in Ref.37, which examined a simple model in which the appearance of SIC was due to the action of electrostatic forces. The main result obtained in the work cited is that for ionic mass transfer between two immiscible electrolyte solutions, the hydrodynamic stability of the interphase boundary is controlled not only by the Ma number but also by an electrical factor.[37] This factor may either stabilise or destabilise the phase interface.

The search for correlations between the electrochemical and hydrodynamic parameters under conditions of hydrodynamic instability was dealt with in Ref.45. A one-to-one correspondence was established between the appearance of ordered flow, induced by ion transfer, and oscillations in the electrical voltage. In this connection, mention may be made of an extremely interesting method for visualising dissipative structures[46] in the chemisorption of carbon dioxide by aqueous solutions of amines. By using a polarisation-optical method it has been possible to record the formation of convective cells in the form of spindles with cylindrical symmetry.

The Marangoni instability produced by the adsorption of substances forming condensed interphase films at a phase interface has been studied.[47-54] The conditions were found for the production of SIC in the form of both ordered and random flow, and their characteristic parameters were determined. The experiments were carried out in a system formed by mercury and an electrolyte solution containing an added SAS, which formed a condensed interphase film.[47] In this system, third-order polarographic maxima are observed, due to the tangential movement of the interphase boundary as a result of the formation of regions with an increased interphase tension. Breakdown of the hydrodynamic stability took place only on the adsorption of substances with a high attraction constant.

A study of adsorption at a toluene–water boundary during the extraction of tetrachloropalladate anions by trioctylamine[48] made it possible to record the formation of a non-uniform CIF with the simultaneous appearance of spontaneous surface convection, produced by local changes in the interphase tension as a result of the non-uniform supply of the substance to individual regions of the interphase surface.

An extremely marked increase in the rate of mass exchange under conditions of hydrodynamic instability was recorded[49-54] in a study of SIC during the extraction of metals in systems of practical importance. An increase in the rate of ion transport by more than two orders of magnitude was observed. A large amount of experimental materials showed that the breakdown of the hydrodynamic stability of the interphase boundary and the appearance of spontaneous movements in the liquid in the interphase region always take place when the extraction process is accompanied by the formation of CIF.

A typical example is provided by the extraction of the lanthanides and various actinides from nitric acid solutions by solutions of di-2-ethylhexyl hydrogen phosphate in non-polar diluents such as octane, decane, and toluene.[7] A study of the kinetics of mass transfer in a system consisting of two layers of phases in contact in tubes with a diameter of 1–3 mm without deliberate mixing showed that extremely intensive SIC takes place for several tens of seconds after the phases are brought into contact. The coefficients of mass transfer reach values of $(5-8) \times 12^{-2}$ cm s^{-1}. The breakdown of hydrodynamic stability was due to the non-uniform formation of CIF at the interphase surface. The interphase tension gradients produced lead to an oscillator movement of the interphase boundary and to intensive movement of the liquids in the interphase region, which is gradually quenched and stops completely when the film produced forms a continuous layer covering the entire interphase surface and reaches a certain strength level. If part of the interphase film is subsequently removed, mass transfer through the renewed sections of the surface again leads to destabilisation of the interphase boundary and the appearance of intensive movements in the phases.

Spontaneous rupture of the continuous interphase film and the production of movement of the interphase boundary and the adjoining layers of liquid are frequently observed. Sometimes this process is periodic in character.[53] The production of hydrodynamic instability is influenced significantly by the concentrations of the reacting components. Critical values have been detected for the metal and extracting agent concentrations, above which mass transfer unavoidably leads to breakdown of the hydrodynamic stability of the interphase boundary and the appearance of spontaneous surface convection. The concentration ranges of the existence of SIC are fairly wide, from 10^{-1} g litre^{-1} to several tens and even hundreds of g litre^{-1} with respect to the metal concentration and from 10^{-3} M to 1–1.5 M with respect to the concentration of the extracting agent.

In these extraction systems it was experimentally established for the first time that the rate of ion transport under SIC conditions depends on the ratio of the thicknesses of the layers of the phases in contact. There exists a critical value of the ratio of the thicknesses, at which extremely high rates of mass transfer are observed.[52-54] Thus breakdown of the ratio of the thicknesses of the phases acts as another destabilising factor. This conclusion is consistent with the results of theoretical studies[35] which show that the ratio of the thicknesses of the layers of the phases in contact influences the dimensions of the range of stable states. Cine- and photo-recording in cells with a width of 1 cm has revealed the structure of the hydrodynamic fluxes in the interphase region.[53] At all ratios of the thicknesses of the layers of the phases in contact different from the critical ratio, SIC appears in the form of circlation cells. The calculated values of the Reynolds number for currents of this kind did not exceed 150. At a ratio of the layer thicknesses equal to the critical ratio, the nature of the movement of the liquid changes sharply. Intensive eruptions, penetrating to a depth of 2–3 cm into the aqueous phase, are produced. The maximum rate of movement of the liquid reaches several tens of cm s^{-1}, and the value of the Reynolds number lies in the range 200–2000. Forced mixing of the phases did not have a negative influence of the parameters of mass transfer under SIC conditions, and merely decreased slightly the time interval before it began in those cases where these conditions were not established immediately after the phases were brought into contact. Other conditions being equal, the surface of even relatively large drops with a diameter of 3–5 mm was found to have a higher hydrodynamic stability than a planar phase interface. For this reason, ion transport through a planar interphase surface was more intensive. The addition of small quantities of various SAS, for example dodecanol, initiated the production of SIC.

The above material represents the main ideas regarding the role of SIC in the transfer of substances through free interphase boundaries. The question of the role of SIC in the constrained movement of liquids and contrained diffusion in systems with non-free interphase boundaries remains open. For its solution, it is necessary to take account of the existence of long-range surface forces[55] in the analysis of the role of hydrodynamic instability in the processes of transport through impregnated liquid membranes and multiple emulsion membranes.

Published experimental data indicate that hydrodynamic instability can also lead to an appreciable intensification of ion transport in systems with non-free interphase boundaries.[56-60] Thus the passage of an alternating electric current through impregnated membranes increases the rate of ion transfer,[58,59] probably due to the appearance of convective movements in the membrane phase. The dependence of the rate of ion transport on the frequency of the alternating current is described by a curve with a maximum.[59] The authors of Ref.60 consider it more promising to use an alternating current with a frequency of 1 Hz, and they assume that a current with this frequency acts directly on the liquid–liquid interphase surface, leading to the production of tangential movement on it.

An attempt to establish the relationship between the characteristic dimensions of the pores in an impregnated membrane and the rate of transfer[61] showed that increase in the pore diameter leads to a significant increase in the effective values of the diffusion coefficients in the membrane, apparently as a result of the production of convective movements in the pores.

- - - o0o - - -

Thus many characteristic features of the kinetics of ion transport through liquid membranes are related to interphase processes of different kinds. The existing views on these processes do not yet give a completely consistent picture. At the same time there is no doubt that systematic studies in this field can give results of scientific and practical importance which should lead to a deeper understanding of the regular features of ion transport and to the solution of the problems of intensifying and controlling the rates of membrane processes.

New Trends in the Development of Polymeric Materials for Reverse Osmosis Membranes

Yu.E.Kirsh and Yu.M.Popkov

Synthetic polymeric materials used for the preparation of asymmetric and composite membranes are examined. The reactions leading to the synthesis of these polymers and ways of obtaining a thin barrier layer which determines the principal quality parameters of the membranes are described. Attention is specially concentrated on the interfacial polycondensation reaction between acid chlorides and amines in order to create a barrier layer with a high selectivity and permeability.
The bibliography includes 32 references.

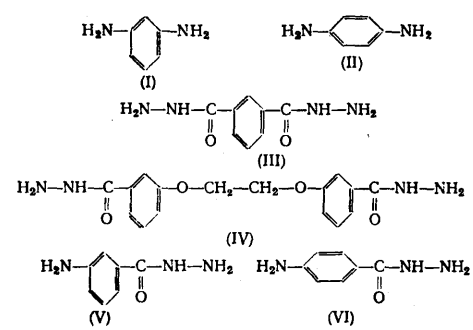
I. Introduction 566
II. Polymeric materials for asymmetric membranes 566
III. Polymeric materials for composite membranes 567

I. INTRODUCTION

Membranes for reverse osmosis have found most extensive application in devices and apparatus designed for the desalination of brackish waters and sea water, for the conversion of industrial waste water into high-quality fresh water, for the separation of valuable side products in the petroleum, petrochemical, chemical, electrochemical, and cellulose-paper industries, for the concentration of food products in the food industry, etc.[1-3]

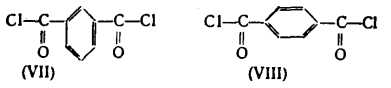
Numerous papers and patents concerning the preparation of reverse osmosis membranes incorporating synthetic polymers have been published during the last 10–15 years. Despite the considerable advances made, the interest in the search for new approaches in this field has not waned. A series of unsolved problems remain in the science of membranes of the type considered. Certain difficulties still exist in the interpretation of the mechanism of the segregation of water from aqueous salt solutions. Ideas concerning the influence of the chemical structure of the polymer and the processes occurring during its synthesis, its conformational and configurational states under the conditions of the formation of the membrane, and the arrangement of the macromolecules and their associated species on the surface as well as other macromolecular characteristics on the separation of substances under the conditions of reverse osmosis have been inadequately developed.



A survey of the available information about the polymeric materials used in the manufacture of the membranes can promote the development of these ideas and can stimulate the development of membranes for reverse osmosis with a high selectivity and permeability and capable of working at low pressures.

II. POLYMERIC MATERIALS FOR ASYMMETRIC MEMBRANES

Qualitatively new acetylcellulose membranes were first prepared in 1959,[2,4] which promoted a vigorous development of the application of reverse osmosis in the desalination of water. Such membranes are prepared by pouring a solution containing a water-soluble pore-forming additive over a solid surface with subsequent evaporation of the solvent at low temperature, coagulation in ice water, and annealing in hot water. Cellulose acetate containing 39.8% of acetyl groups is normally employed.[4] In this case, the membrane has an asymmetric structure, because it consists of a very thin dense surface layer, called the barrier layer, and a more porous lower layer. The molecules of the permeating solution encounters most resistance in a thin barrier layer, where they are in fact separated. However, such membranes also suffer from a series of disadvantages. The susceptibility of the acetate groups of acetylcellulose to hydrolysis in acid and alkaline solutions limits the employment of the membranes in practice and their sensitivity to microbial infection dimishes their useful life in the purification of water.



For this reason, membranes for reverse osmosis, which have a higher chemical stability than traditional acetylcellulose membranes, began to be developed since 1969. New polymeric materials distinguished by a high chemical and thermal stability have been found and new approaches have been devised to the creation of a thin barrier layer[5,6] in asymmetric and composite membranes. The latter differ from the former by the fact that their barrier layer consists of a polymeric material differing from the material of the coarsely porous base.

The first asymmetric membranes made from a non-cellulose material[5] found extensive application in the desalination of brackish waters and sea water. The modular devices for this purpose consists of hollow fibres made from aromatic polyamines or polyhydrazides. These polymers are synthesised by condensing aromatic diamines, aromatic dihydrazides, or aromatic aminohydrazides with aromatic acid chlorides in a solvent—*N*-methylpyrrolidinone (or dimethylacetamide).[5-8] *m*-Phenylenediamine (I), *p*-phenylenediamine (II), the dihydrazides (III) and (IV), for example, the dihydrazide of isophthalic acid (III), and aminohydrazides, for example, the hydrazides of *m*-aminobenzoic acid (V) and *p*-aminobenzoic acid (VI), are used as the first component:

The second component is a mixture of isophthaloyl chloride (VII)

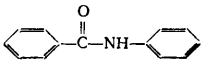
and terephthaloyl chloride (VIII) in proportions of 7 : 3.

(VII) (VIII)

The polymers obtained are readily soluble in organic solvents. When only the acid chloride is used instead of the mixture, the resulting polymer can undergo rapid crystallisation, which hinders the preparation of the casting solution.

The casting solution for the preparation of asymmetric planar membranes can contain, for example, 15 wt.% of the polymer in dimethylacetamide with added $LiNO_3$ (35% of the weight of the polymer[5]). The film obtained on a glass plate after casting is kept in air and then placed in ice water for 1 h, after which it is washed with distilled water. The influence of the concentration and nature of the solvent and also of the nature of the salts on the formation of an asymmetric membrane has been considered.[8] The data presented in Table 1 show that the structure of the polymer influences the permeability of the membrane to water, while the selectivity remains equally high. The flux of liquid through a homogeneous film prepared from one of the aromatic polyamides [the diamine (I) and (VII/VIII) in proportions of 7 : 3] is smaller by a factor of almost 180 than that through an asymmetric membrane of the same thickness made from the same material and having the identical selectivity.[5]

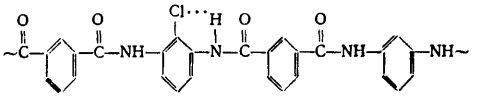
Table 1. The flux of water (P) and the selectivity (S) of certain polyamide membranes.*[6]



Composition of initial monomer mixture		P, litre m^{-2} h^{-1}	S, %
component 1	component 2		
(I)	(VII)/(VIII) (7:3)	8.5	99.8
(IV)/(III) (5:8)	(VII)/(VIII) (7:3)	22	99.3
(V)/(VI) (8.3:1.7)	(VII)/(VIII) (7:3)	28	99.5

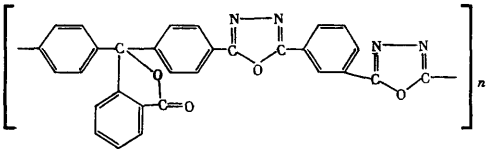
*Conditions of the test: 30 °C; 3.5% NaCl solution; pressure over the membrane 10.3 MPa.

Electron microscopy of the thin barrier layer in the asymmetric polyamide-hydrazide membrane showed a closer-packed layer comprising "micelles" having a diameter of 40–60 nm. This layer consists of spherical aggregates or globular domains between which there are 7.5–10 nm cavities.[8]



Membranes based on aromatic polyamides are manufactured in the form of hollow fibres with an external diameter of 85 μm, an internal diameter of 42 μm, and a barrier layer whose thickness ranges from 0.1 to 1 μm.[5] These membranes have a high mechanical strength, which eliminates the need for the employment of a support capable of withstanding a high pressure, and their chemical stability is also high at neutral pH.

After prolonged use of such membranes, their sensitivity to the chlorine dissolved in water was observed.[5] In order to elucidate the mechanism of the decrease in the selectivity of the membrane prepared from compounds (I), (VII), and (VIII) [for (VII)/(VIII) = 7 : 3], a study was made of the interaction of a compound modelling the material of this membrane with bromine dissolved in water.[9] Benzanilide (IX), which contains all the principal groups present in the polymer, was chosen as the model compound:



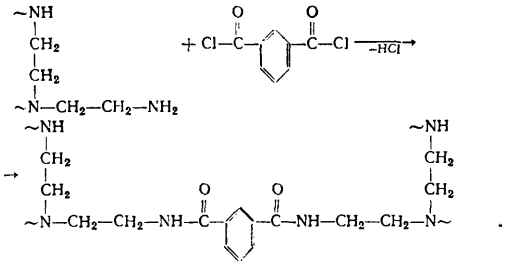
(IX)

As bromine acted on compound (IX), it gradually replaced the hydrogen in the benzene ring of the amino-component. The results obtained permitted the conclusion that, when the polymer was treated with chlorine, substitution took place in the ortho-position of the benzene ring of the diamine, i.e.

and that intramolecular hydrogen bonds between the halogen atom and the H–N group in the compound formed arose instead of the intermolecular hydrogen bonds –C=O...N–N–. Naturally such chemical changes disturb the structure of the polyamide chains and alter the submicrostructure of the polymer and hence increase the flux of liquid and reduce the selectivity of the membrane with respect to the salt. This confirms the existence of a close relation between the initial structure of the polymer, the conformation and state of the macromolecules in the aggregates, and the arrangement of the macromolecules in the barrier layer, on the one hand, and the permeability of the membrane to water and its selectivity in the reverse osmotic process, on the other.

Poly-1,3,4-oxadiazole is also used as the polymeric material for an asymmetric membrane:[10]

The membranes are obtained by casting a 20–40% solution of the polymer in methylpyrrolidinone onto a glass or metallic surface polished to a mirror finish with subsequent maintenance of the film in an atmosphere with a humidity of 80–100% for 1 h and the coagulation of the film in a precipitation bath containing water. As a result, the barrier layer is generated at the support–film boundary and not at the film–air boundary, as happens, for example, in the preparation of polyamide membranes with rock-forming additives. The membrane obtained is capable of retaining 98.5–99.2% of the salt from a 1% NaCl solution and its permeability to water is 20–25 litre m^{-2} h^{-1}.



III. POLYMERIC MATERIALS FOR COMPOSITE MEMBRANES

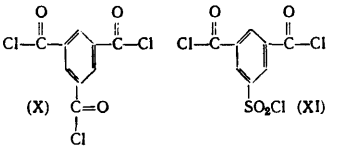
A composite membrane for reverse osmosis consists of a thin barrier layer, a microfilter, and a base, usually a polyester base, which serves to increase the mechanical strength. Microfilters made of a polysulphone, which possesses high chemical and mechanical stability, are usually employed. Numerous investigations have been devoted to the preparation of a barrier layer,[11] from which it can be seen that the creation of this layer requires a high degree of technological sophistication and constitutes to some extent an art, scientifically well-founded criteria for the selection of the type of polymer (structure and type of functional groups) being so far lacking.

One can distinguish several principal approaches to the creation of the barrier layer. They are based on the possibility of the occurrence of the following chemical reactions on the surface of the support: (1) interfacial polycondensation between the amine and the acid chloride; (2) acid polycondensation; (3) radiation-induced cross-linking and plasma polymerisation.

1. Interfacial Polycondensation

Polyethyleneimine + aromatic acid dichlorides. In 1970 a new method was developed for the creation of the barrier layer by the interfacial polycondensation of the low-molecular-weight isophthalic acid chloride (VII) with high-molecular-weight polyethyleneimine (PEI).[11] The polysulphone support is saturated with an aqueous solution of PEI (0.5–1% solution) and is transferred to hexane containing compound (VII) (0.1–1% solution). The chemical polycondensation reaction with evolution of HCl takes place rapidly at the water–hexane interface. Since the PEI used contains primary and secondary amino-groups (the ratios of the primary, secondary, and tertiary groups are 3 : 4 : 3) and has a high molecular weight (from 10^4 to 6×10^4), interchain cross-linking of the PEI molecules takes place via the mechanism

The presence of cross-linked or branched polymer molecules at the interface between two liquids leads to the arrest of the reaction owing to the restriction of the diffusion of the amine from the aqueous phase and of the acid chloride from the organic phase. PEI which failed to react therefore remains under this layer. In order to obtain a high quality membrane, heat treatment at 110 °C, which promotes the cross-linking of the pure PEI with evolution of ammonia, is necessary.



A membrane of the NS-100 type[12] consists of three layers of different porosity: the barrier layer made up of the cross-linked polyamide, the transversely cross-linked PEI layer which enters into the pores of the support, and the polysulphone microfilter. The role of the first and second layers in the creation of a high-quality membrane has been demonstrated by the following two experiments. When PEI is simply cross-linked without polycondensation, the resulting membrane has a low selectivity (70% with respect to NaCl) combined with a high water flux (92 litre m^{-2} h^{-1}).[11] If the NS-100 membrane is subjected to heat treatment at 75 °C and not at 110 °C, its selectivity falls from 99 to 96%.

Although the NS-100 membrane has a high salt-retaining capacity, it also suffers from a number of disadvantages: an insufficiently large water flux at a pressure of 10.3 MPa (~30 litre m^{-2} h^{-1}), a high sensitivity to chlorine, and a low mechanical strength of the upper layer.

In order to overcome these disadvantages, attempts have been made to replace PEI by other polymeric amines.

Polymeric aliphatic amines + dichlorides and trichlorides of aromatic acids. It has been suggested that compounds obtained from polyepichlorohydrin and ethylenediamine [13] and from polyepiiodohydrin and 4-(aminomethyl)piperazine [14] be used as the polymeric amines. A barrier layer more resistant to oxidation by chlorine can be obtained by condensation with compound (VII).[15]

Polymeric amines of other structures have been obtained by the reaction of amines with a polymeric anhydride, for example, by the reaction of triethyleneamine with the copolymer of maleic anhydride and methyl acrylate.[16] It has been suggested that a mixture of compound (VII) with the chloride of benzene-1,3,5-tricarboxylic acid (X) be used as the second reaction component:

After the interfacial polycondensation between the above polymeric amine and the mixture of acid chlorides, the membrane was dried at 115–120 °C. The flux at a pressure of 4.1 MPa and 25 °C was 98 litre m^{-2} h^{-1} for a 0.5% NaCl solution with a selectivity of 96.8%.

In order to alter the permeability and selectivity of the barrier layer, methods have been developed for its preparation from polyamides containing different numbers of free amino- and carboxy-groups.[17] Partly protonated or partly alkylated PEI and the chloride of benzene-1,3,5-tricarboxylic acid (X) and 3-chlorosulphonylisophthaloyl chloride (XI) were used. However, the barrier layer obtained was extremely hydrophilic and possessed a low selectivity.

Low-molecular-weight amines + dichlorides and trichlorides of aromatic acids. In order to obtain a barrier layer resistant to the prolonged action of chlorine, low-molecular-weight diamines (in particular, piperazine[18,19]) have also been used. The interaction of piperazine with compound (VII) makes it possible to produce a layer fairly resistant to chlorine and having a selectivity of 90–96% with respect to sea water. However the NS-300 membranes obtained in this way have not come to be widely used because they are inferior to the NS-100 membrane in their selectivity and permeability.

There exist interesting data concerning the influence of the composition of the mixture of compound (VII) with compound (X), interacting with piperazine, on the characteristics of the membranes for reverse osmosis.[6] The change in composition influences significantly the selectivity and permeability of the membrane relative to NaCl solution and solutions of bivalent metal salts ($MgCl_2$) (Table 2).

The conditions governing the formation of the barrier layer are as follows: the aqueous phase containing 1% of piperazine, 1% of Na_3PO_4, and 0.5% of dodecyl sulphate and the hexane phase containing 1% of the acid chlorides. The membrane obtained from a mixture of 33% of compound (X) with 67% of compound (VII) and piperazine is most effective for the separation of $MgCl_2$. It is characterised by a very high permeability combined with an extremely high degree of salt retention. The membrane obtained from 10% of compound (X) and 90% of compound (VII) possesses a high capacity for the retention of the salt from NaCl solution. The presence of free carboxy-groups in the barrier layer, formed as a result of the

hydrolysis of the residual acid chloride groups, promotes the retention of salts with bivalent ions:

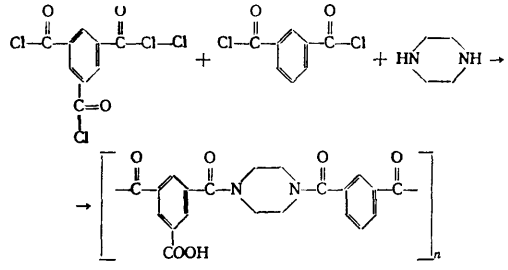


Table 2. The influence of the composition of the mixture of isophthaloyl chloride and the chloride of benzene-1,3,5-tricarboxylic acid on the properties of the membrane with respect to $MgCl_2$ and NaCl solutions.[11]

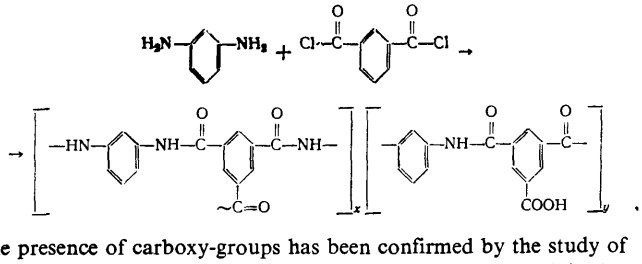
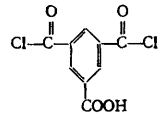


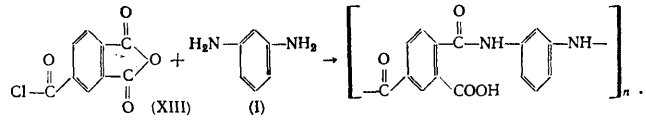
Composition, %		0.5% $MgCl_2$ solution (1.4 MPa)		3.5% NaCl solution (10.3 MPa)	
(X)	(VII)	P, litre m^{-2} h^{-1}	S, %	P, litre m^{-2} h^{-1}	S, %
100	0	43	99.3	133	68
75	25	52	99.3	160	64
33	67	128	99.9	157	65
25	75	97	99.6	121	78
10	90	30	99.9	55	96
0	100	6.7	99.0	33	98

Notation: P is the water flux and S the selectivity.



The NS-300 membranes are not manufactured on an industrial scale because of the considerable non-reproducibility of their properties.[11] The reaction of piperazine with the acid chloride is itself probably difficult to control. When piperazine is replaced by aromatic diamines, it is possible to obtain high-quality membranes for reverse osmosis.

Aromatic diamines + aromatic tricarboxylic acid chlorides. The creation in 1978 of the FT-30 membrane was a major step foward in the development of the technology for the preparation of highly efficient membranes for reverse osmosis.[20,21] The barrier layer on a polysulphone support is created in this case by the interfacial polycondensation of aromatic diamines, for example, compound (VII), with aromatic acid trichlorides, for example, compound (X). Linear chain sections, sections with branched macromolecules, and regions of cross-linked macromolecules arise during the reaction.



It has been demonstrated by the ESCA method that the polymer in the barrier layer contains 72% of cross-linked and branched forms (x) and 28% of linear sections with a carboxy-group (y):[22]

The presence of carboxy-groups has been confirmed by the study of the adsorption of cationic dyes. The lack of solubility in sulphuric acid indicates a cross-linked structure of the polyamide barrier layer. The presence of the cross-linked structure influences significantly the characteristics of the membranes for reverse osmosis.[11] Thus, if the barrier layer is obtained from the bifunctional acid chloride (XII)

mixed with compound (I), whereupon a cross-linked structure does not arise, then the membrane exhibits a low selectivity with respect to NaCl (from 60 to 80%). The layer obtained from the acid chloride of trimellitic anhydride (XIII) and the diamine (I) has the same characteristics:

These data indicate the existence of a definite relation between the degree of cross-linking and the morphology of the formations (aggregates) generating the barrier layer.

It has been observed by electron microscopy that the barrier layer in the FT-30 membrane consists of several layers of different density with an overall thickness of ~0.25 μm.[11] It possesses a high chemical stability and resistance to wear. The membrane can be sterilised in boiling water without change in its properties. The recommended pH range in the solutions where the membrane is sufficiently stable is between 3 and 11. The membrane can be regenerated by treatment with phosphoric and nitric acids. It is more resistant to chlorine than the NS-100 membrane, the greatest stability being observed at pH 5–6. With increase in pH, the properties of the membrane subjected to the action of dissolved chlorine are impaired. This membrane has found extensive practical application in roll-type elements and is characterised by 99.0–99.2% salt retention and a flux of 40 litre m^2 h^{-1} when a 3.5% solution is used under pressure of 5.5 MPa.

A new composite membrane for reverse osmosis, obtained by employing interfacial polycondensation, has been developed recently.[23] The barrier layer consists of a cross-linked aromatic polyamide, whose structure is close to that of the series FT-30 membrane. The membrane is characterised by an extremely high (99.5%) salt retention with respect to NaCl (0.15% solution), a high water flux (40–50 litre m^{-2} h^{-1} at 1.5 MPa), and resistance to chlorine and hydrogen peroxide.

Thus the interfacial polycondensation method gives rise to considerable possibilities for the preparation of highly efficient membranes for reverse osmosis. Presumably more efficient membranes with a high selectivity and permeability at a reduced working pressure (1–2 MPa) can be developed in this way. A low working pressure is extremely significant from the standpoint of reducing the energy consumption in the desalination process.

2. Acid Polycondensation

In order to obtain a barrier layer on the surface of the polysulphone microfilter, the acid polycondensation reaction of low-molecular-weight hydroxyl-containing compounds is used.[24,25] For

this purpose, one prepares a mixture of furyl alcohol, sulphuric acid, and a solution of polyoxyethylene (molecular weight 10^4) in proportions of 2:2:1. Polyoxyethylene is introduced in the form of a solution of 80:20 mixture of water and isopropyl alcohol. The reaction mixture is deposited on the surface of the support and dried at 125–140 °C. This results in acid polycondensation of furfuryl alcohol with formation of a polymeric barrier layer. However, after prolonged tests the membrane selectivity with respect to NaCl falls, which is associated with the irreversible swelling of the layer in the salt solution, the hydrolysis of the sulphate linkages, and oxidation (by the oxygen and chlorine dissolved in water).

When 1,3,5-tri(hydroxymethyl)isocyanuric acid (XIII) is used together with furyl alcohol for the condensation reaction, it is possible to obtain a membrane with better parameters.[25] The surface of the support is treated with a mixture of one part of compound (XIII) and two parts of furyl alcohol. The polymerisation on the surface is carried out at 150 °C. The membrane obtained is characterised by the following parameters: 99.5% salt retention with respect to NaCl (0.25% solution) and a flux of 20.5 litre m^{-2} h^{-1}. The Toray Industries (Japan) Company developed an extremely effective membrane (PEC-1000) for reverse osmosis apparently using the above condensation reaction between furyl alcohol and compound (XIII) in the presence of an acid.[26]

The cross-linking of sulphonated polysulphone on the surface of the support can also be included among the acid polycondensation reactions.[6] For this purpose, the initial polysulphone is sulphonated with chlorosulphonic acid in order to obtain a water-soluble polymer. The surface of the microfilter is coated with an aqueous solution of the polymer and is subjected to heat treatment at 100° to 140 °C, which results in the formation of a barrier layer comprising the cross-linked sulphonated polysulphone. Together with a high selectivity with respect to NaCl (98%), this membrane has a small water flux (2.5 litre m^{-2} h^{-1}). A major advantage of the membrane is its high resistance to chlorine after very prolonged action of the latter (5000) h).[27]

3. Radiation-induced Cross-linking and Plasma Polymerisation

The method consisting in the cross-linking of a surface film made up of sulphonated poly(phenylene oxide) (SPPO) by ^{60}Co γ-radiation has been applied to produce chlorine-resistant membranes with a high permeability.[8] The SPPO film is deposited on a porous polysulphone support, dried, and exposed to radiation. Best results have been obtained for doses of 2–5 Mrad; the salt retention increased from 88 to 98% and the water flux rose from 20 to 40 litre m^{-2} h^{-1}.

It has also been suggested that plasma polymerisation of vinyl and other organic compounds be used to create a barrier layer on a dry macroporous support.[29–32] However, these studies have not so far gone beyond laboratory research.

The data presented indicate the existence of a wide variety of approaches to the creation of membranes for reverse osmosis. The use of the interfacial polycondensation reaction between amines and an acid chloride is most promising. The possibility of extensive variation of the structure of both the low-molecular-weight components and of the polymers has been demonstrated in this instance. This helps in its turn to establish a relation between the structure of the polymer and the properties of the barrier layer under the conditions of reverse osmosis and hence to elucidate the mechanism of the segregation of water from aqueous salt solutions under pressure.

Modelling Reverse Osmosis

S.S.Dukhin, N.V.Churaev, V.N.Shilov, and V.M.Starov

After a brief presentation of the principal kinetic and thermodynamic aspects of the theory of reverse osmosis, the present review examines various physicochemical mechanisms of the selectivity of membranes with respect to electrolyte solutions: the electrochemical mechanism, related to the charge of the pore surface; the dielectric exclusion of ions, due to image forces; and the structural mechanism, due to the change in the properties of water in fine hydrophilic pores. Methods for calculating the changes in the standard chemical potentials of ions on entering the membrane phase, and the effects of the Donnan exclusion of ions with allowance for the different charge of the membrane have been described. It has been concluded that it is appropriate to use charged membranes to separate electrolyte solutions at low concentrations. The problem of the transport of solutions through the fine pores of membranes has been formulated, taking account of the equilibrium distribution coefficients of the ions, their mobility, the charge of the membrane, and the phenomenon of concentration polarisation. Routes to the further development of the theory as applied to membranes of different types, different compositions, and solution concentrations have been discussed.

I. INTRODUCTION

The desalination of aqueous solutions by reverse osmosis is finding increasing practical application because of the much smaller quantity of energy required for membrane separation. This raises the question of the development of a theory of reverse-osmosis separation, which can be constructed using different mathematical and physical models of membranes and different physicochemical theories of the mechanism of their selectivity. The present review examines the effect on the selectivity of membranes of the charge on the pore surface, the dielectric and Donnan exclusion of ions from the membrane phase, and the structural changes in water in fine pores.

A distinguishing feature of the approach developed here is that it takes account of the influence of the fields of long-range surface forces on the equilibrium and on the transport of the solutions in membranes. As shown below, the main predictions which follow from the theoretical examination of the reverse osmosis of electrolyte solutions are confirmed experimentally.

II. KINETIC AND THERMODYNAMIC ASPECTS OF THE THEORY OF REVERSE OSMOSIS

In the reverse-osmosis desalination of solutions, the liquid which has passed through the membrane contains less dissolved substance than the liquid entering the membrane. The ability of a membrane to separate a substance is characterised quantitatively by its selectivity

$$\varphi = 1 - (c_2/c_0) \qquad (1)$$

where c_0 and c_2 are the concentrations of the salt in the original solution and beyond the membrane respectively. In the present review, for simplicity, only a binary uni–univalent electrolyte will be examined.

The excess of the salt in front of the membrane is removed continuously by the tangential flow of liquid, which ensures a steady-state process. Since the solvent passes through the membrane, whereas the salt is retained to some extent, its concentration directly at the front surface of the membrane, that is on the high-pressure side, is higher than its concentration in the incoming stream. The diffusion boundary layer produced in this way in front of the membrane is usually called the concentration polarisation layer.

The quantity of salt retained by the membrane in unit time is given by the difference $vc_0 - vc_2$, where v is the linear velocity of the liquid. This excess of salt is removed from the membrane surface by the diffusion flux, which is directed in the opposite direction to the convective flow and which can be expressed in terms of the thickness of the diffusion layer:

$$vc_0 - vc_2 = -D_e \operatorname{grad} c|_{x=0} \sim D_e \frac{c_0 - c_1}{\delta} \qquad (2)$$

where $D_e = (D^+ + D^-)/2$ is the effective diffusion coefficient of the ions in the free solution, and c_1 is the concentration of the salt at the front surface of the membrane. The description of the external-diffusion kinetics in reverse osmosis has been the subject of a large number of studies (see Ref.1); it reduces to the solution of the equation for convective diffusion with the boundary condition (2), which can be expressed in terms of the membrane selectivity, usually

assumed to be given. The concentration polarisation is also usually assumed to be known in the examination of internal-diffusion kinetics.

In the description of the steady-state process of reverse osmosis, it will be assumed that the applied pressure difference and the flux of the liquid Q are given, that there is no transfer of charge through the membrane ($I = 0$), and that the quantities Q,I, and the salt flux J_s are the same in all sections of the membrane. Since the transport of the salt is purely convective in the free solution beyond the membrane,[2-4] this leads to the important boundary condition:

$$c_2 = c|_{x=h} = J_s/2Q \qquad (3)$$

where h is the thickness of the dividing layer of the membrane. This condition makes it possible to express the unknown quantity c_2, which cannot be calculated directly, in terms of the other quantity J_s, which is also unknown but which can be calculated. For this purpose, the membrane model must be specified.

Reverse osmosis results from the difference between the kinetic and equilibrium properties of the solution in the pores of membrane and in the bulk. Different workers have related the decrease in the salt flux through the membrane to the decrease within the membrane in either the velocity or the concentration of the ions. This distinction, which is sometimes encountered in the literature, is unjustified, since the principal role may be played by either factor, depending on the properties of the membrane.

Ion transport in biological membranes[5] and concentrated dispersions (pastes)[6] has been more extensively studied than reverse osmosis. Reverse-osmosis membranes occupy an intermediate position between biological membranes and the systems which are the traditional objects of study in colloid science. Reverse-osmosis membranes with very fine pores are closer to biological membranes, and those with relatively large pores are closer to traditional colloid-chemical systems.

One of the difficulties of modelling reverse-osmosis processes is due to the wide variety of processes influencing demineralisation. Frequently, however, it is possible to distinguish the process predominating for given pore dimensions.

When reverse-osmosis membranes with very fine pores are used, a factor which also appears in biological membranes becomes important, namely the commensurability of the dimensions of the hydrated ion and the pore (the ion channel in biological membranes). A hydrated ion cannot penetrate into a pore with sufficiently small dimensions,[7] and this predetermines the ideal semi-permeability of the membrane. The difference between the observed selectivity and the maximum possible selectivity is probably due to the presence in the membrane of pores with different dimensions. If the dimensions of the hydrated ion are smaller than but close to those of the pore, the rate of flow of the liquid in the pore containing the ion is lowered. Since for a moderate salt concentration a large fraction of the pores do not contain ions, the average rate of ordered movement of the ions of the salt may be appreciably lower than the average rate of flow of the liquid.

In real membranes, the pores have a variable cross-section. As a result, both the pore dimensions and the molecular forces of the interaction of the ion with the pore walls change along its path. These changes can be described by regarding them as a series of energy barriers and potential wells. Here, the Eyring method for describing ion transport, widely used in the examination of biological membranes,[5] may prove useful. For membranes whose pore dimensions are commensurate with those of the hydrated ions, kinetic factors also become important; in this case there may be considerable deviations from equilibrium.[8,9]

Decrease in the pore dimensions leads to an increase in the selectivity of the membranes, but at the same time their efficiency decreases. It is therefore appropriate to decrease the thickness of the dividing layer of the membrane while at the same time increasing its porosity. This trend in the technology of reverse osmosis in the last ten years has led to considerable progress, associated with the production of so-called composite membranes, which show simultaneously high selectivity and efficiency.[10-12] Composite membranes also have certain disadvantages, however. The technology of their production is still complex and expensive, and the actual membranes are inconvenient in use, in particular because of their high sensitivity to mechanical damage. Progress in the use of composite membranes probably depends primarily on progress in the technology of their production.

One widely used model is the homogeneous model of a membrane.[13,14] Its characteristic feature is the possibility of any ion path, whereas in the heterogeneous model it is assumed that ion transport takes place only through the pores. In the homogeneous model it is assumed that the ions can be regarded as dissolved in the membrane. Research workers have encountered considerable difficulties in validating this model.[15] The reason is that real membranes are not perfect or free from defects, and in transport processes the defects behave like pores. In this connection, some authors[16,17] have considered two possible ion transport paths in a membrane: through the pores and through homogeneous regions.

It is appropriate to divide membranes into porous and diffusion membranes.[18] The latter are quasi-homogeneous gels, through which the solvent and the dissolved substance penetrate under the influence of a concentration gradient. These membranes have a high hydrodynamic resistance, so that they must be used in the form of ultra-thin films with a thickness of 0.02—0.04 μm, fixed to porous supports.

The representation of a membrane as a heterogeneous system is much more widely encountered. Dytnerskii's capillary-filtration model of selective permeability[7] is applicable only in this representation. The familiar model of Sourirajan[19] combines the representations of flow through pores and of preferential adsorption of the dissolved substance or the solvent on the "walls" of the pore.

The increased interest in the heterogeneous model and the importance of taking account of surface forces in this model have been noted.[20-24] Sourirajan's model has also undergone changes in this direction. Previously, in this model, the lowered concentration of the ions in the pores of the membrane was explained using the Gibbs adsorption equation.[19] The limited nature of this approach is indicated by the fact that it does not take account of the pore radius, which is an extremely important parameter in reverse osmosis. In the new improved model,[24] the concentration of ions in the pore is described with allowance for surface forces, which decrease with increasing distance from the pore wall, so that the increase in its radius becomes a factor which lowers the selectivity of the membrane.

The interest in the heterogeneous model of the membrane is not accidental, since it makes it possible to explain a number of features. Firstly, the wider the pore, the more justified becomes the use of the theory of surface forces.[25] On the other hand, the narrower the pore, the lower the accuracy of this theory, and the more difficult the quantitative description of the lowered velocity of the ions. Secondly, the sharp decrease in selectivity with increase in the pore

dimensions makes the wider pores responsible for the "ion leakage" in reverse osmosis. This means that even when the average pore dimensions are commensurate with the dimensions of the hydrated ion, the selectivity due to the presence of a certain proportion of wider pores is still important.

This justifies the particular attention paid in the present work to selectivity mechanisms which operate at pore dimensions appreciably greater than the dimensions of the hydrated ion.

Different levels of the theoretical description of reverse osmosis exist, corresponding to different degrees of detail in the model. At the most descriptive level, the given quantities are the kinetic coefficients characterising the membrane as a whole. In this case, the parameters of reverse-osmosis desalination are found as functions of these coefficients.[25-28] The kinetic coefficients characterising the membrane as a whole are in turn determined by the geometric structure of the membrane, the local values of the concentrations, and the local kinetic characteristics of the solution (such as the viscosity and diffusion coefficients of the components). The specification of these last quantities as parameters of the model and the formulation of the problem of reverse osmosis on this basis move the theoretical description to the next level. The problem of calculating the equilibrium local concentrations in the capillaries of the membrane at the molecular level is now being solved[29] on the basis of the method developed by Yukhnovskii.[30] As far as the more complex problem of calculating the local values of the kinetic coefficients in the membrane at the molecular level is concerned, only the first steps are being taken in this direction, and these coefficients still have to be specified as parameters of the model.

The above two approaches to the theory of reverse osmosis were first combined in Refs.2 and 23. The results obtained are of only limited value, however, since account was taken of only one selectivity mechanism influencing the concentration of ions in the membrane, namely the charge mechanism. Soviet scientists have recently developed a complex approach in the theory of reverse osmosis, with allowance for a variety of mechanisms. This has been the result of systematic studies of surface forces[25] and non-equilibrium electrical surface phenomana[31-33]—a new direction in colloid science.

III. NON-EQUILIBRIUM ELECTRICAL SURFACE PHENOMENA AND REVERSE OSMOSIS

As early as 1947, Deryagin[34] pointed out that the involvement of the electrical double layer in convective ion fluxes should lead (by analogy with the flow potential) to a decrease in the concentration of the dissolved substance between the ends of the capillary. The effect described was detected much later, and was subsequently called reverse osmosis. If this effect is analogous to the flow potential, there should also exist a phenomenon analogous to electro-osmosis, namely slippage in the diffuse atmosphere of the ions or molecules under the influence of the concentration gradient. In Ref.34 the existence of this effect, called capillary osmosis, was justified rigorously on the basis of thermodynamic considerations, but the conclusions applied to the case of a non-electrolyte, that is a diffuse structure of the adsorption layer of the molecules was assumed. The theory of capillary osmosis in electrolytes was developed later using the methods of the thermodynamics of irreversible processes.[35,36]

Osmosis, however, that is the flow of a substance through an ideal selective membrane under the influence of a concentration gradient, can be completely balanced by applying a pressure equal in magnitude to the osmotic pressure. As a result, the flow stops, and the system moves into a state of thermodynamic equilibrium. This constitutes a qualitative difference between osmosis and flow through an ideal membrane, that is capillary osmosis, and this is emphasised by the difference in the names. Thus osmosis is simply a limiting case of capillary osmosis, when the selectivity of the membrane tends to unity. Strictly speaking, non-ideal selective membranes are used for desalination, and it is more correct to call the corresponding process reverse capillary osmosis, and not reverse osmosis.

IV. PRINCIPLES OF THE THEORY OF NEW ELECTROKINETIC PHENOMENA AND REVERSE OSMOSIS

In the examination of reverse osmosis in membranes with relatively wide pores, it is possible to introduce the concept of the convective flow of ions, that is the entrainment of the ions by the flow of liquid. In addition, it is also necessary to take into account the diffusion of the ions relative to the liquid, brought about by the difference between the concentrations of the ions in front of and behind the membrane. This effect, which lowers the selectivity of the membrane, cannot be eliminated completely, but its negative influence can be lowered considerably by increasing the rate of flow to such an extent that the following condition is satisfied:

$$\mathrm{Pe}=vh/D_{\bullet}\gg 1 \tag{4}$$

The Peclet number Pe can be used to estimate the ratio of the intensities of the convective and diffusion fluxes. When $\mathrm{Pe}\ll 1$, diffusion makes it possible to practically equalise the difference in concentrations at the capillary inlet and outlet. When $\mathrm{Pe}\gg 1$, on the other hand, diffusion is suppressed by the strong convective flux, and the selectivity of the membrane approaches its limiting value. The basic law of conservation of the number of ions under steady-state conditions is given by

$$\operatorname{div} j^{\pm}=0 \tag{5}$$

applied to the one-dimensional problem of flow through a membrane in the form

$$\partial j^{\pm}/\partial x=0 \tag{6}$$

where $j^{\pm}$ represents the densities of the fluxes of the cations and the anions. The main difference between the diffusion-electrical theory of electrokinetic phenomena[31,32] and the classical theory of Smolukhovskii lies in the fact that it shows that it is necessary to use not a single overall law of charge conservation but the laws of conservation for the cations and anions separately. In the diffusion-electrical theory, the expression for the density of the ion fluxes is written taking account of three transport mechanisms: convection, diffusion, and electromigration:

$$j^{\pm}=c^{\pm}(x)\,v-D^{\pm}\frac{\mathrm{d}\,c^{\pm}}{\mathrm{d}\,x}\mp D^{\pm}\frac{F}{RT}c^{\pm}(x)\frac{\partial\psi}{\partial x} \tag{7}$$

where c represents the concentrations, and $D^{\pm}$ the diffusion coefficients, of the cations and the anions, ψ is the electric potential, F the Faraday number, R the universal gas constant, T the absolute temperature, and the distance x is measured in the direction of the flow of the liquid through the membrane. The expression for the ion fluxes in the macrokinetic theory of reverse osmosis is also written in this form.[2-4] Finally, for the production of a steady-state flow potential $\Delta\psi$, the condition $I = 0$ must be satisfied.

Later[3,4] and earlier[2] studies show almost no differences from the macrokinetic viewpoint. The examination of the action of surface forces in Refs.3, 4, and 32, however, raises the theory of reverse osmosis to a qualitatively new level. The authors of Ref.2 took account of a single mechanism for the decrease in the concentration of the ions close to the surface, namely the charge mechanism, due to the presence of the electrical double layer. In Refs.3, 4, 37, and 38, the macrokinetic theory was given a much more general character as a result of the inclusion of the energy of the effective interaction of the ion (or molecule) U with the pore surface. This energy is obviously a function of the distance from the ion to the surface, that is a function of r in the model of a cylindrical capillary (r is the distance to the axis of the capillary). In particular, the dependence of U on r can characterise the energy of electrostatic interaction, so that the theoretical considerations put forward in the pioneering work[2] can be regarded as a particular case of the general theory developed in Refs.3, 4, 37, and 38.

The considerable mathematical difficulties associated with the theory of the non-equilibrium electrical double layer and hence non-equilibrium electrical surface phenomena have been overcome[31,32] by using the principle of local equilibrium and by examining the conditions under which it is possible to neglect the deviations from local equilibrium. The theory of reverse osmosis was developed similarly in Refs.2 and 37–39 for the model of a cylindrical pore. The same approximation has also been extended to surface forces of any character acting on the ions in the pore.[3]

For each transverse cross-section at a sufficient distance from the ends of the capillary, it can be assumed approximately that the distributions of the concentration $C_i(x,r)$ and the energy $U_i(x,r)$ for an ion of the ith kind will be the same as if each section of the capillary were in equilibrium with an electrolyte volume characterised by definite parameters of the thermodynamic equilibrium, different for different sections of the capillary, namely the values of the concentrations of its components $c_i(x)$, the electrostatic potential $\psi(x)$, and the pressure $p(x)$. These parameters should naturally have values intermediate between the corresponding values for the solution on the two sides of the capillary.

Eqns.(7) and (5) for the ion fluxes can be supplemented by the Stokes equation

$$-\operatorname{grad} p-\sum_i C_i \operatorname{grad} U_i+\eta\Delta v=0 \tag{8}$$

where p is the hydrostatic pressure in the capillary, η the viscosity of the liquid, and Δ the Laplace operator.

Inside the capillary, where the force field of its walls is effective, the potential of the average force $f_i(r)$ is variable. As a result, its changes also alter the concentrations of the components of the solution $C_i(r)$ and the pressure $P(r)$. The corresponding distributions can be represented as the sums of their values in the uniform solution c_i and p and the changes Δc_i and π due to the influence of the walls:[3]

$$U_i=\psi+f_i;\quad C_i=c_i+\Delta c_i;\quad P=p+\pi \tag{9}$$

It can be assumed that in a cross-section at a sufficient distance from the ends of the capillary, f_i, Δc_i, and π depend only on r, and not on x. In each cross-section, local equilibrium is preserved, that is the radial fluxes are equal to zero:

$$j_r=0;\quad v_r=0 \tag{10}$$

Integrating Eqns.(7) and (8) with allowance for Eqns.(9) and (10) and using the boundary conditions for $x = 0$, which corresponds to the free electrolyte solution, where

$$f_i=0;\quad c_i=c_0;\quad \pi=0 \tag{11}$$

gives

$$C_i(x,r)=c_i(x)\exp\left(-\frac{f_i}{kT}\right);$$
$$\pi=kT\Sigma\,\Delta c_i=kTc_i(x)\sum_i\left[\exp\left(-\frac{f_i(x,r)}{kT}\right)-1\right] \tag{12}$$

where k is the Boltzmann constant.

After substituting Eqns.(12) in Eqns.(7) and (8), the latter can be represented as linear combinations of the gradients of the parameters of the thermodynamic equilibrium along the direction x:

$$Q=k_{11}\left(-\frac{\mathrm{d}p_0}{\mathrm{d}x}\right)+k_{12}\left(-kT\frac{\mathrm{d}\ln c}{\mathrm{d}x}\right)+k_{13}\left(-\frac{\mathrm{d}\psi}{\mathrm{d}x}\right) \tag{13}$$

$$J_S=k_{21}\left(-\frac{\mathrm{d}p_0}{\mathrm{d}x}\right)+k_{22}\left(-kT\frac{\mathrm{d}\ln c}{\mathrm{d}x}\right)+k_{23}\left(-\frac{\mathrm{d}\psi}{\mathrm{d}x}\right) \tag{14}$$

$$I=k_{31}\left(-\frac{\mathrm{d}p_0}{\mathrm{d}x}\right)+k_{32}\left(-kT\frac{\mathrm{d}\ln c}{\mathrm{d}x}\right)+k_{33}\left(-\frac{\mathrm{d}\psi}{\mathrm{d}x}\right) \tag{15}$$

The coefficients k_{ik} represent integrals whose calculation in accordance with Eqns.(12) requires a knowledge of the concentrations $C_i(x,r)$ in the capillary for equilibrium with a volume solution with concentration $c(x)$. Using the Onsager principle, $k_{21} = k_{12}$, $k_{32} = k_{23}$, and $k_{31} = k_{13}$.

V. THE CHARGE MECHANISM OF REVERSE OSMOSIS

1. Donnan Exclusion of the Ions

The system of equations (13)–(15) was first proposed in Ref.39 for the particular model in which the concentration of the ions in the capillary differs from the bulk concentration only as a consequence of the charged state of the capillary walls, and the potential of the average force is equal to the product of the charge of the ion z_i and the electrostatic potential: $U_i = z_i\psi$. This corresponds to the assumption that the solution in the capillary forms a diffuse electrical double layer, described in the Gouy–Chapman theory by the equation

$$\Delta\Psi=\varkappa^2\operatorname{sh}\Psi, \tag{16}$$

where $\Psi = e\psi/kT$, and the Debye length is given by the expression:

$$\varkappa^{-1}=\left(\frac{\varepsilon kT}{4\pi e^2 c}\right)^{1/2} \tag{17}$$

where e is the charge of the electron, and ε the dielectric constant.

The system of equations (13)–(15) together with the boundary conditions (3) and (11) was solved in Ref.2 using a number of simplifications, which are discussed in Ref.3. In particular, the distribution $\Psi(r)$ for each cross-section of the capillary of radius a was selected to satisfy the boundary condition:

$$\Psi|_{r=a}=\Psi(c_0) \tag{18}$$

This assumption is justified in two limiting cases, when

$$\varkappa a\gg 1 \tag{19}$$

$$\varkappa a\ll 1 \tag{20}$$

When Eqn.(19) applies, the solution of the electrolyte with a composition different from the bulk composition occupies only a small

region of the capillary next to the wall. Thus $c(x)$ differs little from c_0, and the selectivity of the membrane is correspondingly low. When Eqn.(20) applies, the potential $\psi(r)$ and hence f_i change little in the transverse cross-section of the capillary. In this case, however, ψ is almost the same for all cross-sections of the capillary, so that the simplification (18) is justified.

In Ref.3, the system of equations (13)–(15) was solved over a wide range of values of κa both with the boundary condition (18) and assuming that the charge density on the capillary surface is constant:

$$\sigma_0 = -\varepsilon \frac{d\Psi}{dr}\Big|_{r=a} = \text{const} \qquad (21)$$

It was found that the selection of the conditions for a constant charge or a constant potential has little influence on the selectivity, that is the indeterminancy associated with the usually insufficient knowledge of the mechanism of production of the double layer has no significant influence on the predictive power of the theory. In Ref.2, good agreement was obtained between theoretical and experimental data on the dependence of the selectivity on various parameters (the Debye radius, the Peclet number, and the surface potential).

Similar results were obtained for colloidal membranes.[40] A large amount of evidence for the decisive role of the surface charge has been obtained in the study of the selectivity of dynamic membranes formed from colloidal particles[41] and polyelectrolytes.[42] Although the desalinating action of cellulose acetate membranes is not determined by the charge mechanism, in the range of low concentrations this mechanism also makes a definite contribution to the selectivity in this case.[43] This was reflected in Ref.44, where the dependence of the selectivity of these membranes on the pH of the solution was described by an extremal curve with a minimum lying at the pH which ensured that the charge of the membrane was equal to zero. Since the contribution of the charge mechanism for symmetrical electrolytes is independent of the sign of the charge of the membrane, the selectivity when the charge is equal to zero should pass through a minimum. Thus the results obtained in Ref.44 shows fairly convincingly that the charge mechanism also operates in cellulose acetate membranes.

The possibility of using charged membranes with wide pores in reverse osmosis is indicated by the results obtained in Ref.45, where it was found that even the cellulose acetate ultra-filtration membranes UAM-100, in spite of the extremely low density of the surface charge of the cellulose acetate and the large pore dimensions, retain some selectivity up to an electrolyte concentration of 10^{-2} M, reaching a maximum selectivity $\varphi = 0.6-0.65$ at the minimum concentration studied, 10^{-4} M.

For high Peclet numbers, the electrolyte concentration remains practically constant and equal to c_0 along practically the entire thickness of the dividing layer (a rapid decrease in concentration takes place close to the boundary of the dividing layer and the wide-pore layer of the membrane), and the charge mechanism of reverse osmosis is revealed extremely clearly. In the case of high selectivity, which is of the greatest practical importance, the corresponding expression for the selectivity of the membrane acquires a simple form when condition (20) is satisfied.

There is a definite similarity between the charged dividing layer of an asymmetric reverse-osmosis membrane and the ion-exchange membrane used in electrodialysis. This membrane is not directly applicable for reverse osmosis, because of its large thickness and corresponding high hydrodynamic resistance. The main electrochemical regular features in the ion-exchange membrane–electrolyte system also apply, however, to the charged dividing layer of an asymmetric membrane.[46]

These regular features are: a) the shielding of the electric field of the ion by the charge of opposite sign at distances greater than the Debye length; b) the local electrical neutrality of the homogeneous phases at distances from the phase interface greater than the shielding length, and the integral electrical neutrality of the heterogeneous system as a whole; and c) the constant electrochemical potential within the heterogeneous system, that is the equality of the electrochemical potentials in the resin and electrolyte phases. Local electrical neutrality is understood to indicate that the algebraic sum of the charges of the ions is equal to zero within each physically infinitely small volume.[46] This definition will be used in the examination of the ratio of the concentrations of the mobile cations and anions in the ion-exchange membrane.

The matrix of ion-exchange membranes contains ionogenic groups, which on contact with the solvent dissociate to give a charge fixed by the surface.[50] The ions of an electrolyte whose sign is the opposite of the sign of the surface charge of the membrane are usually called counter-ions, and the ions with the same charge are called co-ions. The membrane phase must contain sufficient counter-ions to compensate the surface charge. These counter-ions are described as being exchange sorbed. Moreover, in accordance with the third of the above conditions (constant electrochemical potential), the membrane phase must also contain some co-ions. In other words, since the co-ions are in the electrolyte, they must also be present in the membrane, but at a different concentration. Since the membrane and the co-ions have charges of the same sign, the concentration of the latter in the membrane phase is lowered. It is also clear that the membrane should also contain counter-ions which in turn compensate the charge of the co-ions present. These co-ions and counter-ions are usually described as the non-exchange sorbed electrolyte. It follows that the concentration of non-exchange sorbed electrolyte in the membrane phase is lower than the concentration of the equilibrium solution. This phenomenon is called Donnan exclusion of the electrolyte from the ion-exchange membrane phase.[46–48]

In accordance with the electrical neutrality condition, the exchange sorbed counter-ions cannot leave the membrane phase, since they compensate the surface charge. Only the non-exchange sorbed electrolyte can leave the membrane; the filtrate is therefore desalinated relative to the solution being separated.

The concentration of co-ions in the membrane is lower, the larger the Donnan electric potential jump Ψ_D.[46,48] This equilibrium potential jump is produced as a consequence of the removal of some of the counter-ions from the membrane layer next to the surface into the electrolyte, as a result of which a volume charge is produced in the electrolyte layer next to the surface due to the excess of counter-ions; a volume charge of opposite sign is produced simultaneously in the membrane layer next to the surface Some of the counter-ions leave the membrane, since their concentration in the highly charged membrane is higher than that in the surrounding electrolyte. The lowered concentration of co-ions in the membrane is described in terms of the Donnan potential using the familiar Boltzmann equation.

The Donnan potential is greater, the greater the exchange capacity or the corresponding concentration of surface charges in the volume of the membrane c_f and the lower the electrolyte concentration. These qualitative relationships are confirmed by a quantitative

analysis, which leads, on the basis of a quantitative examination of the third and fourth conditions, to an expression which describes the Donnan potential and hence, using the Boltzmann equation, the concentration of co-ions in the membrane:[46–48]

$$c^{co} = \frac{1}{2}[(c_f^3 + 4c_0^3)^{1/3} - c_f] \quad (22)$$

In the case of low electrolyte concentrations, which is of the greatest interest, when

$$c_0 \ll c_f \quad (23)$$

this equation is simplified to:

$$c^{co} \simeq c_0^3/c_f \quad (24)$$

This leads to the following expression for the selectivity:

$$\varphi = \left(1 - \frac{c^{co}}{c_0}\right) = \left(1 - \frac{c_0}{c_f}\right) \quad (25)$$

from which it follows that the selectivity may approach 1 with decrease in the electrolyte concentration, when condition (23) begins to be satisfied.

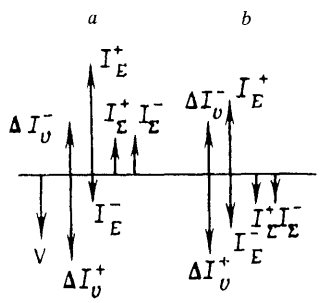

Figure 1. Influence of the transport numbers of the ions on the selectivity of the membrane.

Eqn.(25) can give a value of the selectivity which is too high, since it does not take account of the fact that the polarisation field, at the same time as retarding the counter-ions, increases the transport of co-ions through the membrane. If it is assumed that the membrane is negatively charged, the convective flux of counter-ions I_v^+ will be greater, and that of the negative ions I_v^- will be less, than if the liquid passed through a capillary, preserving the original concentration, when $I_{v0}^+ = I_{v0}^-$. In Fig.1, the corresponding arrows show the magnitude and direction of the excess convective fluxes $\Delta I_v^\pm = I_v^\pm - I_{v0}^\pm$. The distance between the ends of the arrows for ΔI_v^+ and ΔI_v^- gives the magnitude of the electric current due to the convective flux of the ions (the so-called flow current). The arrows $I_E^\pm$ characterise the ion fluxes produced under the influence of the polarisation electric field. The condition that the electric current through the membrane be equal to zero is satisfied if the distance between the ends of the arrows ΔI_v^+ and ΔI_v^- is equal to the distance between the ends of the arrows I_E^+ and I_E^-. The resulting excess fluxes of the cations I_Σ^+ and anions I_Σ^- are the same, and equal to the excess flux of the salt.

Desalination takes place when the excess flux of the salt and the flow of liquid take place in opposite directions. Fig.1*a* shows that this situation obtains if

$$I_E^+/I_E^- = a_E^+/a_E^- > \Delta I_v^+/\Delta I_v^- \quad (26)$$

where $a_E^\pm$ represents the so-called transport numbers, defining the fraction of the total current carried by the cations and the anions respectively when a potential difference is applied to the membrane in the absence of other thermodynamic forces. If the opposite inequality is satisfied (Fig.1*b*), filtration through the membrane leads to concentration of the salt. The passage of the counter-ions close to the fixed charges of the membrane may be retarded by electrostatic forces of attraction, so that $a_E^- > a_E^+$. If the fixed charges are hydrated, the distance of closest approach increases, and the electro-static attraction becomes weaker, so that the hydrophilic character of the membrane helps to satisfy condition (26).

Information on other studies of the charge mechanism is given in a detailed review.[44] The data given more or less agree with the above conclusions.

2. Asymmetric Charged Membranes as a Basis for the Creation of a Technology for the Desalination of Slightly Mineralised Water Using Low-Pressure Reverse Osmosis

The extensive introduction of reverse osmosis is being retarded, firstly, by the complexity of the equipment, and, secondly, by the low intensity of the mass exchange processes.[1,7] The first difficulty is to a large extent due to the need to use high pressures, which is unavoidable in the demineralisation of salt water, since in this case it is necessary to overcome a high difference in osmotic pressure.

In the demineralisation of brackish water, however, and in particular in desalination technology, the osmotic pressure drop is much smaller. For the requirements of power engineering and the electronics industry and for the demineralisation of brackish water, it is possible in principle to create a technology of reverse osmosis using moderate pressures. The equipment for reverse osmosis at pressures of ~10 atm is much simpler. When the membranes of the MGA series used at present are employed, however, an appreciable decrease in pressure would lead to an unacceptably large decrease in efficiency. It is appropriate to use these and similar membranes, which retain the required selectivity at high salt concentrations (as a result of the very small pore dimensions), for the demineralisation of salt water. Their use to treat weakly mineralised water is not the optimum technological solution, however. Up to the present, the synthesis of membranes has been aimed at ensuring the optimum geometric characteristics (pore dimensions, porosity, thickness of the active layer), and insufficient attention has been paid to colloid–electrochemical methods for intensifying selective membrane transport. Neglect of the role of the membrane charge is probably justified in the technology of the demineralisation of salt water. With decrease in the salt concentration, however, the conditions for demineralisation by reverse osmosis change radically.

The technology of the low-pressure reverse osmosis of slightly mineralised water should be based on asymmetric relatively wide-pore membranes with the optimum charge.

The reverse-osmosis membranes used at present are very weakly charged.[49–53] The idea that the introduction into the membrane matrix of a fixed surface charge might make the active layer looser

(as a result of the electrostatic repulsion of the charges on the surface of the pores) and hence make the membrane more efficient while preserving its high selectivity as a result of the long-range action of the electrostatic forces was first put forward in Ref.54. Since then, about a dozen papers have described attempts to synthesise and study the properties of charged reverse-osmosis membranes. The most interesting studies are those described in Refs.55 and 56. The first describes a method for obtaining membranes by sulphonating or aminating a polystyrene–butadiene resin. These membranes had a fairly high selectivity (95–98%) at low concentrations, but their efficiency was low (0.1–5 litre m^{-2} d^{-1} $atom^{-1}$) due to the large thickness of the membrane (500 μm) and its symmetrical structure. It might be possible to use this method to synthesise much thinner membranes with a high efficiency.

Another method for obtaining highly efficient membranes[56] involves the deposition and subsequent grafting of a thin layer of a polyelectrolyte on the surface of an ultra-filtration membrane. This method has been used to obtain thin-layer composite membranes with a very high efficiency (30–150 litre m^{-2} d^{-1} atm^{-1}). The selectivity was low, however (60% with respect to singly-charged anions). The authors of Refs.55 and 56 (and of other similar studies, for example Refs.57 and 58) apparently did not conclude that the most appropriate field of application of charged membranes is with fairly dilute solutions. The lack of understanding of the fact that the average concentration of co-ions along the cross-section of the pores in charged membranes can be lowered considerably has prevented a full evaluation of the advantages of charged reverse-osmosis membranes, so that work devoted to their development and study is still fairly fragmentary. Systematic work on the synthesis, study, and use in desalination of asymmetric charged membranes is therefore necessary.

VI. THE SELECTIVITY OF NON-CHARGED MEMBRANES AND THE STANDARD CHEMICAL POTENTIALS OF IONS

The lowered concentration of a salt in non-charged membranes leads to a decrease in the value of the standard chemical potential (SCP) of the ion in the pores of the membrane, due to the interaction of the ion with the polymeric dielectric matrix of the membrane or to the change in the structure of water in it.[59] A quantitative characteristic of this effect is provided by the distribution coefficient, that is the ratio of the average concentrations of the ions in the membrane phase c_m and in the bulk of the electrolyte:

$$\gamma = \bar{c}_m / c_0 \tag{27}$$

This characteristic, which is extremely important for reverse osmosis, is readily expressed in terms of the SCP, taking into account the condition for electrochemical equilibrium in the membrane–electrolyte system for both the cations and the anions, $\mu_e^{\pm} = \mu_m^{\pm}$, where $\mu_e^{\pm}$ and $\mu_m^{\pm}$ are the electrochemical potentials of the ions in the electrolyte and membrane phases respectively.

When the familiar expression for the electrochemical potential of an ion in a dilute electrolyte is used, these equations acquire the form:

$$\mu_{m0}^{\pm} \pm e\psi_m + kT \ln c_m^{\pm} = \mu_{e0}^{\pm} \pm e\psi_e + kT \ln c_0^{\pm} \tag{28}$$

where $\mu_{m0}^{\pm}$ and $\mu_{e0}^{\pm}$ are the standard chemical potentials of the ions in the membrane and electrolyte phases respectively. Eliminating the interphase potential jump from these equations and making use of the condition for local electrical neutrality in the membrane and electrolyte phases gives:

$$c_m = c_0 \exp\left[\frac{\mu_{e0}^{+} - \mu_{m0}^{+} + \mu_{e0}^{-} - \mu_{m0}^{-}}{2kT}\right] \tag{29}$$

Since in the non-charged membrane the concentrations of the cations and the anions are equal, a flow potential and hence electromigration fluxes of the ions are not produced. At high Peclet numbers, the diffusion fluxes are also unimportant. This means, however, that the salt concentration in the filtrate c_2 coincides with the salt concentration in the membrane c_m. This makes it possible to make the equation for the selectivity more specific:

$$\varphi = 1 - \gamma = 1 - \exp\left[\frac{\mu_{e0}^{+} - \mu_{m0}^{+} + \mu_{e0}^{-} - \mu_{m0}^{-}}{2kT}\right] \tag{30}$$

where γ is defined by Eqn.(27).

VII. THE DIELECTRIC EXCLUSION OF IONS FROM MEMBRANE PORES

1. Image Forces

A decisive role in the mechanism of the dielectric exclusion of ions from the pores of a membrane is played by the interaction of the ion with the polarisation charges,[60–64] which are produced at the interface between media characterised by different dielectric constants (DC). Since for a single planar interface the interaction of an ion with this interface can be described formally as an interaction with a fictitious charge or image, the phenomenon being considered is usually described as the production of "image forces". These forces play an important role in many electrochemical systems.[65]

It is possible to consider first the limiting case of an isolated ion, that is to assume that the shielding length is so much greater than the characteristic pore dimensions that the shielding can be neglected. Since the DC of the membrane matrix ε_m is lower than the DC of the solvent ε, the sign of the polarisation charges on the surface of the pores coincides with the sign of the charge on the ion. The repulsion between like charges leads to an increase in the SCP of the ion, which in accordance with the condition of constant electrochemical potentials leads to a decrease in the electrolyte concentration in the pores.

In the case of a charged membrane, only the concentration of the co-ions is lowered, and the concentration of the counter-ions is increased, whereas in the pores of a non-charged dielectric membrane the concentrations of both the cations and the anions are lowered (the concept of co-ion and counter-ion in this case is obviously meaningless); in the case of a binary symmetrical electrolyte, their excess SCP are approximately equal.

From the obvious fact that the rate of flow of the liquid and the concentration of the electrolyte have maximum values in the central part of the pore, it follows that the main contribution to the salt flux is made in this region. The results of calculations for the case of a flat capillary[66] confirm this qualitative conclusion and show that the salt flux can be estimated with a relative uncertainty of not more than 20–30%, from a knowledge of only the concentration in the central part of the pore.

The dependence of the intensity of dielectric exclusion on the geometry of the pore space is of considerable interest. When there is no shielding in the system, there is only one characteristic length, namely the pore dimensions. By changing to dimensionless

coordinates in the equations, it can be shown that in all cases the excess SCP due to the image forces W is inversely proportional to the pore dimensions. Moreover, it is always directly proportional to the square of the charge of the ion $q = ez$ and inversely proportional to the DC of the solvent. Thus irrespective of the shape of the pore, it is possible in the expression for the excess SCP of the ion to distinguish the factor $2W\varepsilon R/q^2$, and the remaining factor depends on the ratio of the DC of the matrix to that of the solvent, $\beta = \varepsilon_m/\varepsilon$.

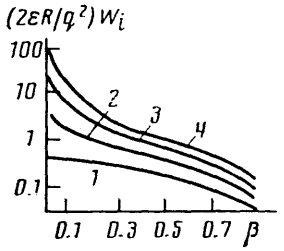

Figure 2. Dependence of the intensity of the dielectric exclusion on the geometry of the pore space:[64] *1*) ion close to a plane, *2*) planar gap, *3*) cylinder, *4*) sphere.

Fig.2 gives the dependence of $2W\varepsilon R/q^2$ on the parameter β for four cases, where the ion is situated: 1) at a distance R from a planar interface, 2) in the middle of a planar gap with a width of $2R$, 3) on the axis of a cylindrical capillary with a radius R, and 4) at the centre of a spherical cavity with a radius R.[64] A noteworthy feature is the very strong dependence of the intensity of dielectric exclusion on the geometry of the system, particularly at low values of β.

The physical significance of this dependence is that, as is well known, the density of the energy of the electric field is inversely proportional to the DC of the medium. It is for this reason that the standard chemical potential of an ion increases close to bodies with a lower DC. When a medium shows dielectric non-uniformity, the lines of force of the electric field are deformed. In this connection, the extent to which the geometry of the pore space is closed is very important; this determines the possibility that the lines of force of the field "by-pass" the regions with lower DC. For example, in the case of a single planar interface there is an entire half-space with an increased DC. In this case the energy of the "image forces" is low. At the same time, for the limiting closed geometry of a sphere, all the lines of force penetrate the medium with the low DC, so that the magnitude of W is a maximum in this case.

A spherical pore is of interest only as an example of limiting closed geometry, since flow of a liquid is impossible in it. It may be noted that the curves corresponding to the geometries of a sphere and a cylinder lie not far from one another (Fig.2), and the intensity of dielectric exclusion is also fairly high in the latter case. For example, the selectivity of a cylindrical capillary with a diameter of 3 nm ($\varepsilon_m = 3$, $\varepsilon = 80$) is ~ 0.9. Decrease in the pore dimensions evidently leads to a sharp increase in the selectivity. Thus in the case of the dielectric exclusion mechanism, membranes with cylindrical pores should "function" most effectively.

The dielectric exclusion of ions in real membranes can be reduced approximately to the solution of the electrostatic problem of an ion in a right cylindrical capillary. The membrane selectivity due to this mechanism is high, even if the pore size is much greater than the size of the ion.

The interaction of the separated ion with the polarisation charges is complicated by the presence of other ions in the pore. In the pore, each ion is surrounded by an atmosphere of counter-ions, as in the free solution. If the Debye radius is smaller than the pore radius, then the electric field of an ion situated at the centre of the pore does not in practice reach the pore surface and does not polarise it, so that the image forces are weak. A quantitative theory of this effect of shielding of the image forces has been developed using the model of a flat capillary. In this case it is possible to obtain a very simple approximate equation for the excess SCP of an ion situated on the axis of the capillary:[67,68]

$$W = \frac{-q^2}{2\varepsilon R} \ln [1 - \alpha \exp(-2\varkappa_i R)] \qquad (31)$$

where

$$\alpha = (\varepsilon - \varepsilon_m)/(\varepsilon + \varepsilon_m);$$

and $\varkappa_i^{-1}$ is the shielding length inside the pores.

Since as already noted in the case of dielectric exclusion the concentration of the ions of both signs in the pores is lowered, the "internal" shielding length is greater than the "external" length (that is the shielding length in the bulk of the equilibrium solution). Thus an increase in the selectivity of the membrane in this case leads to a decrease in the shielding effect, whereas an increase in the density of the fixed charge of ion-exchange membranes, which is accompanied by an increase in their selectivity, leads to the opposite effect.

Another interesting characteristic of Eqn.(31) is that when $\alpha < 1$, the decrease in the magnitude of W begins not at $\varkappa_i R \simeq 1$ but at $\varkappa_i R \simeq 0.2$. This is due to the fact that in the absence of shielding a large contribution to the SCP of the ion is made by so-called "multiple images". In other words, this phenomenon can be described as mutual polarisation of the surfaces; as a result, the polarisation charge as it were extends along the surface to distances which are much greater than the width of the capillary. The shielding of the interactions with it therefore naturally begins at $\varkappa_i R < 1$.

Fig.3 shows the theoretically calculated concentration dependence of the excess SCP of ions situated in flat capillaries with different widths.[68] It can be seen that the smaller the width of the pores of the membrane, the higher the concentration at which the decrease in selectivity begins. This corresponds completely with what has been said above. It should be noted, however, that even in the case of highly selective membranes, the decrease in selectivity takes place at concentrations which are not very high. This conclusion does not fully agree with experiment. Here, it is helpful to introduce the concept of non-local dielectric shielding in polar media,[69-71] which takes account of the fact that dipole shielding, like ion shielding, is fully developed only at distances greater than the correlation length (for ion shielding this is the Debye length). For water, these distances have been estimated[69] as 0.5–0.7 nm, that is they are commensurate with the dimensions of fine pores.

Strictly speaking, the interaction of an ion with polarisation charges is influenced not only by ionic shielding but also by dielectric shielding. In the local approach used up to the present, this feature is taken into account by dividing the quantity W by the static DC of the solvent. If account is taken of the non-local character of the dielectric response, it may be concluded that the DC

close to the ion is effectively lowered (since at small distances the bound charge cannot be completely formed); the interaction with the polarisation charges separated on the surface therefore increases. This leads, firstly, to a considerable intensification of the dielectric exclusion, and, secondly, to a change in the ratio of the relative contributions of single and multiple images in the excess SCP of the ions in favour of the former. The explanation for this is that the correlation length cannot be much larger than the pore dimensions; thus only the interaction with the first images experiences weak dielectric shielding, and the interaction with the other images takes place in practically the same way as in a medium with a static DC. In this situation, ionic shielding as far as $\kappa_i R \simeq 1$ should lead to a decrease in the already small contribution of the multiple images, and a significant decrease in the intensity of dielectric exclusion begins at $\kappa_i R \gtrsim 1$.

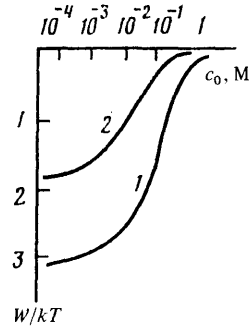

Figure 3. Concentration dependence of the SCP of ions for a model of membranes with a pore half-width of 0.3 nm (*1*) and 0.5 nm (*2*).[68]

2. The Combined Effect of the Dielectric and Charge Mechanisms

In moderately wide charged pores, the simultaneous operation of the charge and dielectric mechanisms leads to a decrease in the concentration of co-ions. If it is assumed that these effects are additive, the distribution coefficient of the co-ions is given by the equation:

$$\gamma = \frac{c^+}{c_0} = \exp\left[\frac{-e\psi + W}{kT}\right] \qquad (32)$$

The equation used to find the Donnan potential now contains the SCP, which depends on the image forces:

$$\operatorname{sh}\frac{e\psi}{kT} = \frac{c_f}{2c_0}\exp(W/kT) \qquad (33)$$

Simplifying this equation for the case of greatest interest, that of high values of the Donnan potential and substituting the result in Eqn.(32) gives

$$\gamma = \frac{c_0}{c_f}\cdot\exp(-2W/kT) \qquad (34)$$

and it can be seen that in this case there is not simple multiplication of the Donnan and dielectric factors but a quadratic increase in the intensity of dielectric exclusion.

Increase in the fixed charge, however, leads to an increase in the concentration of counter-ions, so that the shielding influence is increased. As a result, the effects of dielectric exclusion in the case of highly charged ion-exchange membranes apparently are not very significant. Membranes having a moderate charge are more promising for the combination of the effects of these two mechanisms. This leads to the practical conclusion that it is appropriate to give membranes a surface charge not only for desalination but also for the demineralisation of so-called brackish water with a higher concentration.

VIII. THE HYDROPHILIC CHARACTER OF MEMBRANES AND REVERSE OSMOSIS

In addition to the electrochemical mechanisms examined above (the Donnan and dielectric exclusion of ions), another factor leading to a decrease in the concentration of the dissolved substance in sufficiently fine pores of membranes is the change in the structure of water.[72,73] This is confirmed by the fact that hydrophilic reverse osmosis membranes effectively retard not only an electrolyte but also the neutral molecules of substances such as sugar, alcohol, and acetone.

The change in the solvent power of the pore water of hydrophilic membranes with respect to ions is due to a number of factors.[59,74] One of the results of the change in the structure of water is a lowering of its dielectric constant. The intrinsic energy of an ion in the membrane pores, calculated, for example, by the Born method, is then found to be higher than that in the free solution,[75] leading to a decrease in the concentration of the ions in the membrane pores. The Born approximation may be inadequate, however, since the mechanism of the phenomenon being considered may in fact be much more complex.[76,77]

Since there is no theoretical justification for the influence of the hydrophilic character of membranes on their selectivity, the results of some recent experiments are of particular interest. The experiments were carried out using three membranes of different hydrophilic character.[78] The most hydrophilic was a composite polyamide membrane (*A*), obtained by interphase polycondensation.[79] The other two reverse-osmosis membranes were prepared from homopolymers based on polyhydroxydiazole (*B*) and the even more hydrophobic polycarbonate (*C*). For this series of membranes, the selectivity coefficients were measured for alkali metal chloride solutions with different concentrations c_0. The highest selectivity was observed for the most hydrophilic membrane *A* (Fig.4).

The preservation of a high selectivity over a wide range of electrolyte solution concentrations (as far as 0.5–1 M) is a distinguishing feature of hydrophilic membranes. Nevertheless, their selectivity decreases with increase in the concentration of the solutions. This is due to the breakdown of the characteristic structure of water in the fine pores and the gradual approach of the structure of the solution to that in the bulk. The breakdown takes place as a result of the influence of the ions on the structure of water, which increases with increasing concentration of the solution; this increasing influence suppresses and then exceeds the influence of the hydrophilic surface of the pores.

It is natural to expect that ions which have a stronger influence on the structure of water should bring about a greater decrease in the selectivity with change in concentration. Thus Li^+ ions, which have the smallest radius and the highest hydration numbers, in all cases (Fig.4) bring about a sharper decrease in the selectivity

coefficient. On the other hand, Cs^+ ions, which have the largest radius and small hydration numbers, have less influence on the structure of water in the pores, leading to preservation of the high selectivity of the membrane and its weaker dependence on the concentration of the solution.

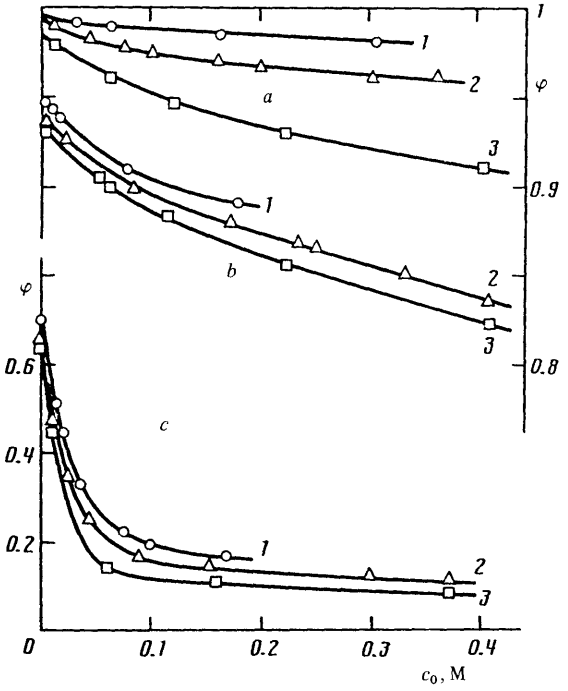

Figure 4. Dependence of the selectivity coefficient φ on the concentration of solutions of the electrolytes CsCl (*1*), KCl and NaCl (*2*), and LiCl (*3*) for membranes with different hydrophilic character.[78]

IX. THE MACROKINETIC THEORY OF REVERSE OSMOSIS AND THE PHYSICAL MODELLING OF MEMBRANES

It can be seen from the foregoing that calculations at the molecular level at present make it possible to determine only the equilibrium distributions of the components in the pores of a membrane. Even in this case, however, a purely theoretical approach to specific membranes is impossible, since, firstly, the size distribution of the pores is unknown, and, secondly, it is impossible to take account of the change in the structure of water, a factor which cannot yet be calculated quantitatively.

This makes it necessary to carry out a range of experimental measurements and compare the results with the results of a calculation of the kinetic coefficients using the system of equations of macrokinetic theory. A system of equations of this kind[80] has been used to develop a set of required measurements. The general formulation of the problem, given in section IV, was simplied in Ref.80 by introducing the boundary condition (20). This made it possible to calculate the kinetic coefficients and to obtain equations for the selectivity φ and the flow potential $\Delta\psi$:

$$\varphi = 1 - \frac{\exp(\mathrm{Pe}/k_1)}{1 - k_2 + k_2 \cdot \exp(\mathrm{Pe}/k_1)} \tag{35}$$

$$\Delta\psi = FR_m\bar{c}_0 Q - \frac{RT}{F}(a_E^+ - a_E^-)\frac{\bar{c}_s}{2c_0} \tag{36}$$

where

$$\frac{\mathrm{Pe}}{k_1} = \frac{1}{4}\frac{F^2}{RT}\cdot\frac{[\bar{c}_s - (a_E^+ - a_E^-)\bar{c}_0]QR_m}{a_E^+ a_E^-};\quad k_2 = \left[\frac{\bar{c}_s}{2c_0} - (a_E^+ - a_E^-)\frac{\bar{c}_0}{2c_0}\right]$$

$\bar{c}_s = \bar{c}^+ + \bar{c}^-$, $\bar{c}_0 = \bar{c}^+ - \bar{c}^-$ are the average concentrations of the cations and the anions in the hydrodynamically mobile part of the pore space (with a statistical weight corresponding to the distribution of the rates in viscous flow); and R_m is the electrical resistance per unit surface area of the membrane.

To determine c_0 and c_s it is sufficient to measure the following parameters by the usual methods: 1) the selectivity coefficient φ, 2) the membrane potential difference $\Delta\psi$, 3) the resistance of the membranes R_m, and 4) the transport numbers $a_E^{\pm}$. This set of measurements can give information on two of the most important characteristics of the mechanism of reverse osmosis, namely the Donnan potential (see part 1 of section IV) and the differences in the standard chemical potentials of the ions (section V). The introduction of this set of measurements in laboratories working on the theory and technology of reverse osmosis will make it possible to check different versions of the theory of reverse osmosis. A physical model of the membrane should be constructed in each specific case; this will lead to optimisation of the conditions for reverse osmosis and indicate methods for improving the quality of membranes.

X. A GENERALISED MATHEMATICAL MODEL OF THE REVERSE OSMOSIS OF ELECTROLYTES

The most general mathematical model of the processes of reverse osmosis,[4,81] which can be regarded as a further generalisation of the conclusions in Refs.3 and 37, has recently been developed. The generalisation was achieved by taking simultaneous account of membrane transport and external-diffusion kinetics, the charge and non-charge mechanisms of the exclusion of ions from the membrane pores, and the extension of the theory to unsymmetrical electrolytes and electrolyte mixtures. This has made it possible to obtain a number of results of practical importance.

The combined description of convective diffusion within a membrane and in the concentration polarisation layer involves two dimensionless Peclet numbers, one internal [Eqn.(4)], and one external, Pe_0. When

$$\mathrm{Pe}_0 = mv\delta/D \ll 1 \tag{37}$$

(where m is the porosity of the membrane, and D the diffusion coefficient in the bulk solution), concentration polarisation does not lower the selectivity of the membrane. At low flow rates v, this condition is fulfilled, but condition (4) is not. With increase in the rate, however, condition (4) begins to be satisfied, but condition (37) is no longer satisfied. Thus the theory[4,81] predicts a maximum on the curve giving the dependence of the selectivity of the membrane on the flow rate, corresponding to optimum separation conditions (curve *1* in Fig.5). The calculations were carried out for the following conditions: $\gamma_- = 10^{-2}$, $\gamma_+ = 0.1$ (which corresponds to the preferential introduction of cations into the pores), and $2h/m\delta = 1.5$. The value of the last parameter was selected for those

conditions of mixing of the solution being separated for which, for a membrane with a porosity $m = 0.2$, the thickness of the non-mixed layer δ is approximately seven times the thickness of the dividing layer of the membrane h.

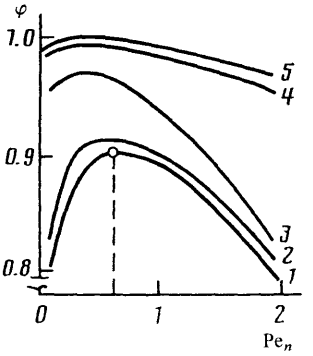

Figure 5. Dependence of the selectivity coefficient φ on the external Peclet number for different surface charges of the membrane σ: *1*) 0; *2*) 0.01; *3*) 0.1; *4*) 1; *5*) 5.[80]

From the general solutions obtained[37,38] it follows that the maximum value of the selectivity $\varphi_{max} = 1-\gamma$ is achieved for $Pe/Pe_0 \geqslant 5$. For a binary electrolyte solution

$$\gamma = \gamma_+^{z_-/z} \cdot \gamma_-^{z_+/z} \qquad (38)$$

where $z = z_+ + z_-$; z_- and z_+ are the valences of the anions and the cations.[81]

The surface charge of a membrane $\sigma = c_f/c_0$ increases its selectivity (curves *2*–*5*). For cellulose acetate membranes, the magnitude of the dimensionless charge at $c_0 = 10^{-2}$ M is $\sigma = 0.1$ (curve *3*), increasing to 1 at $c_0 = 10^{-3}$ M (curve *4*). Thus the influence of the surface charge is greater, the lower the concentration of the electrolyte solution being separated. Thus at $c_0 \geqslant 0.1$ M, the influence of the charge ($\sigma \leqslant 0.01$) is vanishingly small (curve *2*).

For an unsymmetrical electrolyte, a solution can be obtained without taking account of the influence of concentration polarisation, that is by assuming that $Pe_0 \ll 1$. Fig.6 shows the dependence of the selectivity of the membrane on the dimensionless surface charge $\Delta = \sigma/z_+z_-$ (for a 1–1 electrolyte, $\Delta = \sigma$). For $\Delta = 0$, the selectivity of the membrane was taken as equal to $\varphi_{max} = 0.9$. For the unsymmetrical electrolytes $BaCl_2$ (curves *1* and *2*) and $LaCl_3$ (curves *3* and *4*), the selectivity depends on the sign of the charge of the membrane pore surface Δ. Here, curves *1* and *3* correspond to $\Delta > 0$, and curves *2* and *4* to $\Delta < 0$. The efficiency of the retardation of the solution is much greater when the sign of the charge of the multiply-charged ion is the same as the sign of the charge of the membrane. This is because the surface charge has a stronger influence on the more highly charged ion. Thus for $BaCl_2$ and $LaCl_3$, a higher selectivity is achieved when the membrane has a positive charge. On the other hand, for the effective separation of, for example, Na_2SO_4 solutions, it is appropriate to use negatively charged membranes, in agreement with experiment.

Since the values of Δ depend on c_0, the graphs in Fig.6 also reflect the influence of the electrolyte concentration for a fixed membrane charge ($c_f = 5 \times 10^{-3}$ M). The corresponding values of $c_0 = c_f/z_+z_-\Delta$ are given on the upper scale of the abscissa. Fig.6 shows that decrease in the electrolyte concentration leads to an increase in the selectivity of the membrane, due to its surface charge. The same situation is observed for the symmetrical binary electrolyte KCl (curve *5*), but since the charges of the ions have the same value, the sign of the surface charge in this case does not influence the selectivity.

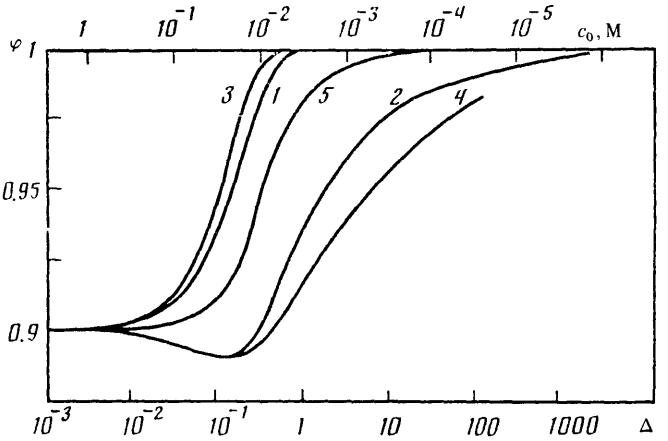

Figure 6. Dependence of the selectivity of a reverse-osmosis membrane on the dimensionless surface charge Δ and on the concentration c_0 of the solutions being separated: *1,2*) $BaCl_2$, *3,4*) $LaCl_3$, *5*) KCl.

The macrokinetic theory examined above for binary solutions[81] has been generalised[82–84] for the case of multicomponent electrolyte solutions. In contrast to the case of binary solutions, in this case the separation involves a change in not only the concentration but also the composition of the solutions. In contrast to the case of binary solutions, in this case the separation involves a change in not only the concentration but also the composition of the solution. The components of the mixture have a mutual influence on one another, whose mechanism is determined by the dependence of the membrane potential $\Delta\psi$ on the composition of the electrolyte solution and the distribution coefficient γ_i for each ion.

This brief review of the present state of the theory of the reverse-osmosis separation of electrolyte solutions shows the great variety of physicochemical factors responsible for the selective action of membranes. Corresponding methods for calculating the selectivity can be developed for each of the retention mechanisms. In real membranes, however, the surface charge, the dielectric exclusion of ions, and the change in the properties of water in the fine pores may exert their influence simultaneously. It is difficult to determine *a priori* the extent of their influence, particularly since there are insufficient data on the structure of the pore space in membranes and on the localisation of the charges and active centres on the surface of the pores and in the bulk of the membrane, which influence both the properties of water and the distribution of ions in

the pore solution. Information on the contribution of a particular mechanism of selectivity can now be obtained by carrying out comprehensive studies of membranes using the procedure developed.[80]

The main qualitative conclusions from the above examination are that for the separation of electrolyte solutions with a low concentration it is necessary to use membranes with a high surface charge, and for the separation of solutions with a higher concentration it is necessary to use membranes whose pore surface is highly hydrophilic. By giving membranes these new properties, it is possible, while retaining fairly high selectivity values, to increase slightly the pore dimensions, and this makes it possible to increase the efficiency or to decrease the expenditure of energy used to pump the solution through the membrane, by using smaller pressure differences.

This also leads to the conclusion that for the separation of solutions with different compositions and concentrations it is necessary to prepare membranes of different types, differing not only in the pore dimensions, as is the case at present, but also in their surface electrical properties and hydrophilic properties.

The main task, whose solution requires the use of the methods of the statistical mechanics of molecular systems and numerical and physicochemical experimental methods, is the refinement of the calculation of the changes in the intrinsic energy of ions in fine pores and the characteristics of the structural state of water. This will make it possible to refine and predict quantitatively the values of the equilibrium distribution coefficients which at present appear as a parameter in the equations of the theory of reverse osmosis.

Concentration Polarisation in the Electrodialysis Process and the Polarisation Characteristics of Ion-selective Membranes

E.M.Balavadze, O.V.Bobreshova, and P.I.Kulintsov

Complications in the electrodialysis process, due to the occurrence of concentration polarisation, are analysed. It is shown that most present-day methods for measuring the electrochemical characteristics of ion-selective membranes are not suitable for monitoring the behaviour of these membranes over a wide range of polarising current densities. An analysis of the polarisation characteristics of electromembrane systems shows the advantages of a system with a rotating membrane disc. It is shown that in the polarisation process there is a significant deterioration of the electrochemical properties of heterogeneous membranes whereas the properties of homogeneous perfluorinated sulpho-cation-exchange membranes remain almost unchanged.

I. INTRODUCTION

The intensive growth of industry and power engineering, the utilisation of natural resources and the development of agriculture in new areas with limited supplies of fresh water, and the growth of population are creating a shortage of fresh water all over the world. At the same time the increasing volume of sewage is having a deleterious effect on the environment and the condition of the water basins. One of the key questions in the solution of problems of environmental conservation is the development of efficient methods for separating mixtures into their components.

Membrane methods of purifying and concentrating solutions are favoured because of their low energy consumption and material content, simplicity of maintenance, and economy. Of the various membrane technologies electrodialysis has a special place in that it provides unique possibilities for carrying out deionisation and concentration of electrolyte solutions and also synthesis and chemical reactions of various substances. A very widespread application of electrodialysis, both in the USSR and abroad, is the desalination of water. Questions of the theory and practice of electrodialysis are discussed most fully in Wilson's monograph,[1] which retains its value to the present day, and also elsewhere.[2-5] Electrodialysis (ED) is the process of directional transport of ions through an electromembrane system (EMS), which consists of one or several membranes, particularly ion-selective membranes, placed in the electrolyte solution. The driving force of the ED process is the electric potential gradient. In Fig.1 is shown a typical ED scheme employing ion-selective membranes which is used to deionise and concentrate electrolyte solutions. If (as in Fig.1) a stack of alternating cation-selective and anion-selective membranes is placed between a pair of electrodes, then the ions will migrate in equivalent quantities from the solution in the deionisation chambers (*I*), which have anion-selective membranes on the anode side and cation-selective membranes on the cathode side, to the adjacent concentrating chambers (*II*), which have cation-selective membranes on the anode side and anion-selective membranes on the cathode side, and will be removed from the concentrating chambers with the enriched solution (the concentrate).

The rate of transport of the ions through the EMS is determined by the current density and is directly dependent on it. However, the current density is restricted to a limiting value corresponding to the reduction of the ion concentration at the surface of the membrane on the desalination chamber side to zero. The limiting current density depends on the physicochemical properties of the solution undergoing treatment and the membranes and also on the hydrodynamic conditions in the chambers of the electrodialysis equipment, which are dependent on the constructional performance of the chambers and the rate of flow of the solution.

The concentration polarisation of the EMS which occurs as a result of the diffusion constraints leads to high energy consumption and also favours the deposition of precipitates of sparingly soluble salts and hydroxides on the membrane surfaces, so reducing the efficiency of the ED process.

II. BASIC PRINCIPLES OF THE ELECTRODIALYSIS PROCESS

The requirements imposed on electrodialysis apparatuses and on the organisation of the electrolyte deionisation process in them are determined by the interrelation between technological parameters that are governed by the state of the EMS.

The concentrations of the solutions remain constant in the central part of the flow and vary only within the so-called diffusion layers, which are adjacent to the surfaces of the ion-selective membranes. The thickness of a diffusion layer is an arbitrary concept and is defined by the coordinate (on an axis perpendicular to the membrane surface) at which the concentration of the solution differs from the concentration in the central part of the flow by 1%. The variation in the concentration in the diffusion layer is caused by the difference in the transport numbers of the ions in the solution and membrane phases. When the density of the current passing through the electromembrane system is increased the concentration of the diluate at the surface of the membrane falls. The limiting current density is the density at which this concentration approaches zero.

The state of the EMS can be regarded as defined if we know how the electric potential is distributed in it and also the concentrations and rates of flow of the working solutions. A theoretical analysis of the mass exchange in the ED process reduces to the solution of

equations for electrodiffusion and convective diffusion. These equations, together with the equation of motion, the conditions of continuity and electroneutrality of the solution, and also the equation for the current density at the solution–membrane interfaces, form a closed system of equations.

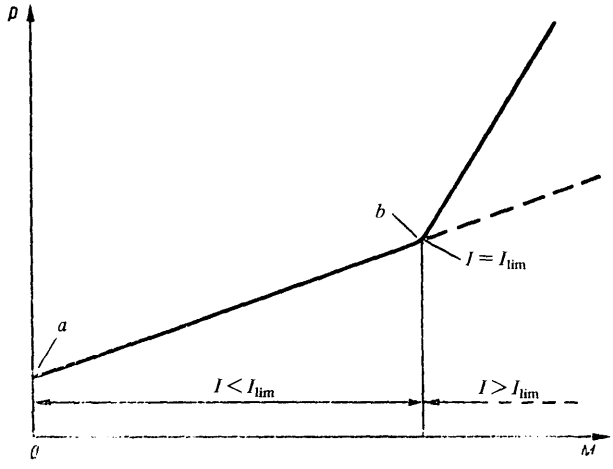

Figure 2. Relationship between the energy consumption P (calculated per unit mass) and the specific mass-transport M in the electrodialysis process.[4]

The relationship between the energy consumed in the electrodialysis and the amount of material transported across the effective area of the membrane in unit time is shown in Fig.2. Point *a* corresponds to the minimum energy consumption (P_{min}) required to achieve a given degree of deionisation in the absence of concentration polarisation and ohmic resistance of the solution and the membranes, and with a number of ther assumptions:[1]

$$P_{min} = 2RT\left(\frac{\ln(c_i/c_0)}{1-c_i/c_0} - \frac{\ln(c_i/c_c)}{1-c_i/c_c}\right)$$

where P_{min} is the minimum specific (i.e. per unit mass transferred) energy consumption, c_i and c_0 are the initial and final concentrations of the diluate, and c_c is the concentration of the mother liquor.

Point *b* corresponds to the limiting current density; on the section *ab* there is a proportionate increase in the specific energy consumption as the mass transport through the EMS increases. However, at current densities above the limiting value (the section to the right of point *b*) the slope of the curve changes, indicating unproductive energy consumption. To achieve a given degree of deionisation of the solution being treated it is possible, having increased the specific mass transport, to reduce the effective area of the ion-selective membranes correspondingly, e.g. by reducing the number of working chambers in the electrodialysis apparatus.

To intensify the ED process the working current density in the electrodialysis apparatus should be increased to its limiting value. To increase the limiting current density, i.e. to remove the diffusion constraints, the construction of the electrodialysis apparatus must be further perfected and the electrochemical properties of the ion-selective membranes improved.

III. POLARISATION CHARACTERISTICS OF ION-SELECTIVE MEMBRANES

In spite of the progress achieved in investigating the mechanism of electro-mass-transport in an EMS (which is substantially different at current densities below and above the limiting diffusion value[6-11]), most current methods of measuring the electrochemical properties of membranes (see, for example, a previous review[12]) do not make it possible to assess the behaviour of the membrane under investigation over a wide range of variation of the polarising current. This relates primarily to the monitoring of the selectivity of membranes through the transport numbers of the ions,[1,3,12] which remain constant only for small variations in the concentrations of the ions in the membrane phase.[13] The most promising methods for estimating the electrical conductivity of membranes are, in our opinion, those which enable the resistance of the EMS to be measured during the process of their polarisation.[14,15]

A study of the volt-ampere curves of the EMS enables the mechanism of electro-mass-transport in these systems under different polarisation conditions to be judged.[16-23] In most of this work the EMS's are investigated with a flowing solution although, owing to the difference in accessibility of the membrane surfaces as regards diffusion, a detailed study of the ion-transport mechanism in this type of system is difficult in principle. In other work[24-28] EMS's with free convection are examined because in the systems, in contrast to the flow type, identical thicknesses of the diffusion layers can be obtained.

In classical electrochemistry there is a system with forced convection, which is unique in its way and which ensures equal accessibility of the electrode surface as regards diffusion; this is the rotating disc electrode (RDE).[29,30] The theory of such a system has also been developed.[31] The first attempts to apply the RDE method to electro-membrane systems were reported in Ref.32 and later in Ref.33. They have, however, remained virtually undeveloped owing to the technical complexity of the experiment. The main defect in the apparatus that was proposed[32] is caused by mounting the membrane under investigation on a spindle with the aid of a nut; this disturbs the equal accessibility of the surface and the hydrodynamics of the system. A common defect of the apparatuses developed in Refs.32 and 33 is that the desalination and concentrating chambers adjacent to the membrane are not equivalent and this fundamentally limits the range of possible investigations.

An apparatus with a vertically aligned rotating membrane, which separates symmetrical immovable half-cells with polarising and measuring electrodes filled with solution, has been described.[34] We presume that precisely this type of EMS is suitable for use in studying the polarisation characteristics of membranes because, under conditions of equal accessibility of the membrane surfaces in respect of diffusion and with the possibility of accurate calculation of the thickness of the diffusion layer, the polarisation characteristics of the system can be analysed and the extra-diffusion stage of the electro-mass-transport isolated.

A disadvantage of voltammetry with linear scanning of the flow, as applied to an EMS, especially when dilute solutions are used, is the large drop in voltage in the regions between the membrane and the measuring electrodes, as a result of which there is a reduction in the accuracy of recording the overvoltages associated with the limiting stages of the electro-mass-transport. To eliminate the ohmic drop in voltage in the solution, which is not connected with the concentration polarisation processes, compensating measuring circuits are devised. A circuit similar to that proposed in Refs.35 and 36 is shown in Fig.3. The membrane being examined (*1*) is in a cell which contains, in addition to the polarising (*2*, *3*) and measuring (*4*, *5*) electrodes, a further electrode (*6*). First, in the absence of concentration polarisation on input of an alternating current pulse to the polarising electrodes, the amplification factor of the second differential amplifier DU2 is chosen so that the difference in the voltage drops between the probes *4* and *5* on the one hand, and *5* and *6* on the other, which is registered by the recording graph plotter, is equal to zero. Then, on input of a linearly increasing current from the

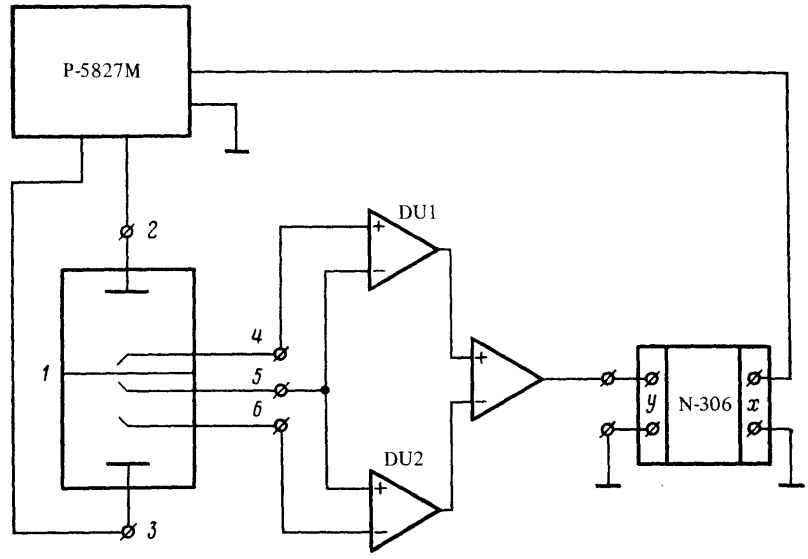

Figure 3. Block diagram of the apparatus for obtaining the volt-ampere characteristics of an EMS: P-5827M) potentiostat; N-306) graph plotter; DU1, DU2) differential amplifiers.

potentiostat, the volt-ampere curves registered by the recorder reflect the change in the voltage drop in the EMS due to concentration polarisation.

Specimens of well known commercial brands of membrane have been examined. The heterogeneous membranes MK-40, MA-40, and MA-41,[37] used in electrodialysis processes, are hydrophilic and possess a "porous" structure containing unexchangeable absorbed solution. The homogeneous perfluorinated sulpho-cation-exchange membranes (PSM), which have their main use in chlorine electrolysis processes,[38] are hydrophobic and in dilute solutions have properties close to the ideal selective membrane.

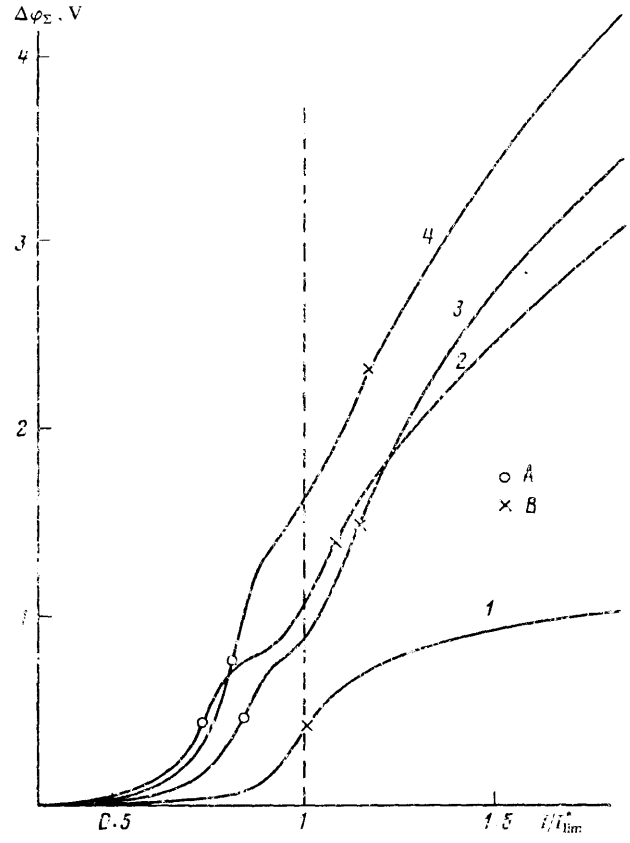

Figure 4. Volt-ampere curves for EMS's with the membranes: *1*) PSM; *2*) MA-41; *3*) MK-40; *4*) MA-40.

The volt-ampere curves shown in Fig.4 were obtained for the commercial grade membranes in 0.01 M sodium chloride solution with the membrane disc rotated at 100 rev min^{-1}, corresponding to a diffusion layer thickness $\delta = 5.8 \times 10^{-3}$ cm.[31] The possibility that the theory developed in Ref.16 is applicable to the system being used is confirmed by the occurrence of a characteristic linear dependence of the limiting current density on the square root of the angular velocity of rotation of the disc; this dependence is satisfied in the range of speeds 100–600 rev min^{-1}. In Fig.4 the dimensionless current density quantity I/I^*_{lim} (where I^*_{lim} is the limiting electrodiffusion current density for an ideally selective membrane) is plotted along the abscissa axis. In a solution of a binary electrolyte the following relationships are satisfied:[29,39]

$$I^*_{lim} = \frac{z_1 F D^* c_0}{(1 - t_1)\,\delta} \tag{1}$$

and

$$\delta = 1.61\,(D^*)^{1/3} \nu^{1/6} \omega^{-1/2}$$

where c_0 is the initial concentration of the solution, δ is the thickness of the diffusion layer, F the faraday, D^* the diffusion coefficient of the electrolyte solution, z_1 the charge number of the counter ion, ν the kinematic viscosity, and ω the angular velocity of rotation of the disc.

The volt-ampere curve for a homogeneous PSM is characterised by a relatively small voltage drop in the polarisation process: at the inflection point corresponding to the limiting current density I_{lim} the drop is 440 ± 30 mV. This is close to the value (450 mV) calculated using an equation obtained from Ref.40 and subtracting the ohmic voltage drop in the solution, which is not connected with concentration polarisation processes:

$$\Delta\varphi_\Sigma = 2\Delta\varphi_M + \frac{RT}{z_1 F} \ln\left\{\frac{[1 + \exp(\Delta\psi_M)]^2}{4\exp(\Delta\psi_M)}\right\}$$
$$\Delta\psi_M = \Delta\varphi_M \frac{z_1 F}{RT} \tag{2}$$

The membrane potential $\Delta\phi_M$ is determined by the diffusion relaxation method developed in Refs.26 and 28. The value $\Delta\phi_\Sigma$ can be used to estimate the polarisability of the membrane and the quantity $I_{lim} \cdot \Delta\phi_\Sigma$ characterises the energy consumption on polarisation of the system in the limiting state.

If the surface of the homogeneous PSM on the desalination chamber side is rubbed with emery paper the limiting current density decreases and the voltage drop increases, indicating a partial extension of the diffusion constraints on the transport of ions into the membrane phase because of the increased roughness of its surface.

The inflection point on the volt-ampere curve for the PSM (Fig.4) is displaced slightly to the right with respect to the limiting current density for an ideally selective membrane, I^*_{lim}. This indicates that the selectivity of the membrane is non-ideal. To estimate the reduction in selectivity we introduce a dimensionless quantity representing the displacement of the limiting current density for this membrane relative to the ideally selective membrane:

$$s = \frac{I_{lim} - I^*_{lim}}{I^*_{lim}} \tag{3}$$

The relative displacement for the PSM is 0.02, showing that it has a high selectivity.

On the volt-ampere curves for the heterogeneous membranes (Fig.4) two inflection points, to the left and right of I^*_{lim}, can be found using the three tangent method. If the displacement of the first point (point *A* in Fig.4) is evaluated using expression (3) it will be negative and that of the second point (point *B* in Fig.4) will be positive. The heterogeneous membranes investigated contained from 11 to 20 vol.% of equilibrium solution.[41] It is therefore likely that concentration polarisation in EMS's containing heterogeneous membranes involves both a near-membrane region in the solution, defined by the size of the δ-layer, and a near-surface region in the membrane pores occupied by the unexchangeably absorbed electrolyte, which can be defined by an effective thickness $\bar{\delta}$. The current density values corresponding to the *A* points in Fig.4 are probably

the limiting current densities in the $(\delta + \bar{\delta})$-layers whereas the *B* points represent the onset of the limiting state in the δ-layers of the "free" solution.

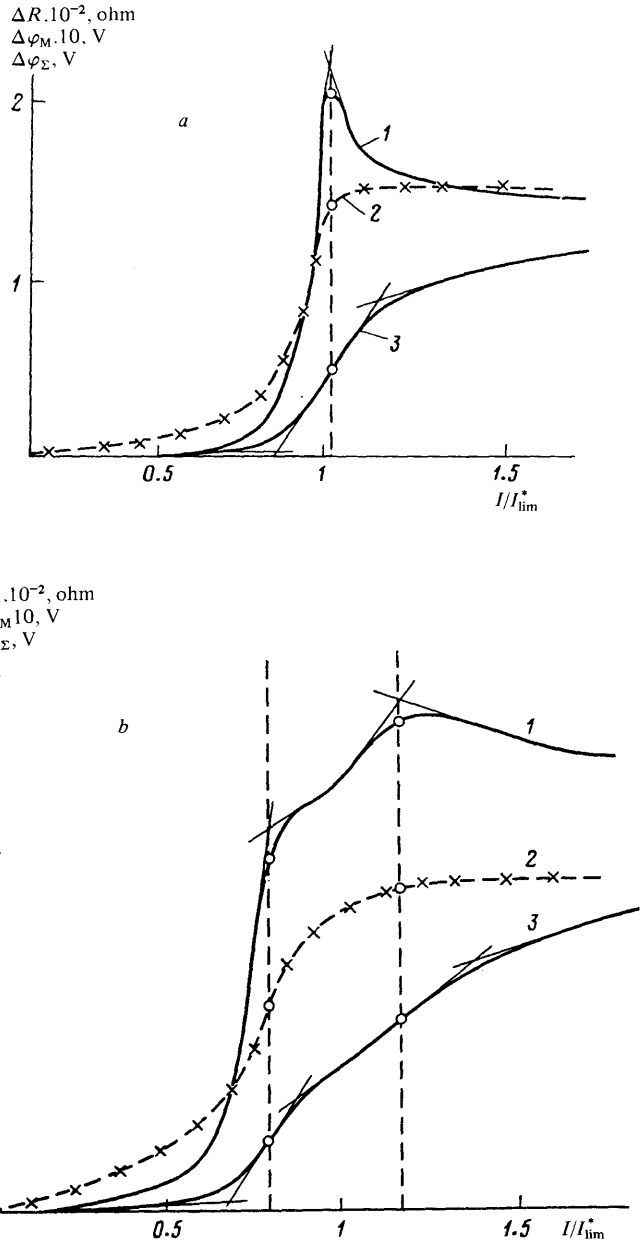

Figure 5. Plots of the change in resistance (*1*), membrane potential (*2*), and total voltage drop (*3*) against the dimensionless current density for EMS's with the membranes: *a*) PSM; *b*) MK-40. 0.01 M NaCl solution, rate of rotation of the membrane disc = 100 rev min^{-1}.

Thus the first inflection point on the volt-ampere curve is probably associated with the concentration polarisation which is due to the diffusion constraints on the transport of ions in the solution contained in the heterogeneous membrane phase. The value of the current density $\bar{I}_{lim}$ corresponding to this sudden change in the difference between the potentials can be termed the limiting current density for the equilibrium solution of the membrane. This is confirmed by the weak dependence of $\bar{I}_{lim}$ on the rate of rotation of the membrane.

To test the stated assumptions and to locate the inflection points on the volt-ampere curves more accurately by using the method described in detail in Refs.42 and 43, the ohmic resistance of the EMS in the polarisation process was determined. In Fig.5 the volt-ampere curves are compared with the variation of the resistance with current density for EMS's with PSM (Fig.5*a*) and MK-40 (Fig.5*b*) membranes, identical conditions being used. In the first case the inflection point on the volt-ampere curve coincides with the maximum on the curve for ΔR as a function of I/I^*_{lim} and corresponds to the limiting electrodiffusion current density in the solution. For the MK-40 membrane the $\Delta R(I)$ curve shows two local maxima which coincide with the inflection points on the volt-ampere curve corresponding to the negative and positive relative displacement of the limiting current density.

Fig.5 also shows the dependence of the membrane potential $\Delta\phi_M$ on the dimensionless current density, as obtained by the diffusion relaxation method.[28] For the homogeneous PSM $\Delta\phi_M$ reaches a maximum at I_{lim} and then shows hardly any change. For the MK-40 membrane the sharp jump in $\Delta\phi_M$ begins at the limiting current density in the equilibrium solution of the membrane $\bar{I}_{lim}$ but the membrane potential reaches saturation only at a current density equal to the limiting electrodiffusion current density in the free solution I_{lim}, which is determined from the second inflection point on the volt-ampere curve.

This is confirmed by an analysis of curves, obtained under similar conditions,[28,29] showing the decrease in the membrane potential with time for PSM and MK-40 membranes at different current densities (Fig.6). Fig.6 also shows curves calculated assuming purely extra-diffusion kinetics for the process. For the PSM the observed and calculated curves agree. The reason for the slightly larger experimental values of $\Delta\phi_M$ is probably that the value of the liquid diffusion potential was not taken into account in the calculation. In the case of the MK-40 membrane the drop in the membrane potential in the first 0.1 s is considerably more rapid than would be expected if purely extra-diffusion processes took place; the experimental curves lie considerably above the calculated curves. Similar results were obtained for the heterogeneous membranes MA-40, MA-41I, and also MK-44 and MK-41, indicating that they are strongly polarisable compared to homogeneous membranes.

Analysis of results obtained by independent methods suggests that concentration polarisation of an EMS is due to both intra- and extra-diffusion constraints on electro-mass-transport. With the heterogeneous membranes MK-40, MK-44, MK-41, MA-40, and MA-41 the diffusion constraints on the transport of ions in the membrane phase permit a limiting state to be reached at current densities I_{lim} smaller than the limiting current density for an ideally selective membrane I^*_{lim}. A further increase in the current leads to the establishment of a limiting state in the free solution at current densities $I_{lim} > I^*_{lim}$, indicating non-ideal selectivity of the heterogeneous membranes. The relative displacement of the limiting current density *s* gives a quantitative description of the selectivity of the membranes in the limiting state and the product $I_{lim}.\Delta\phi_\Sigma$ gives the energy consumption on polarisation of the membrane.

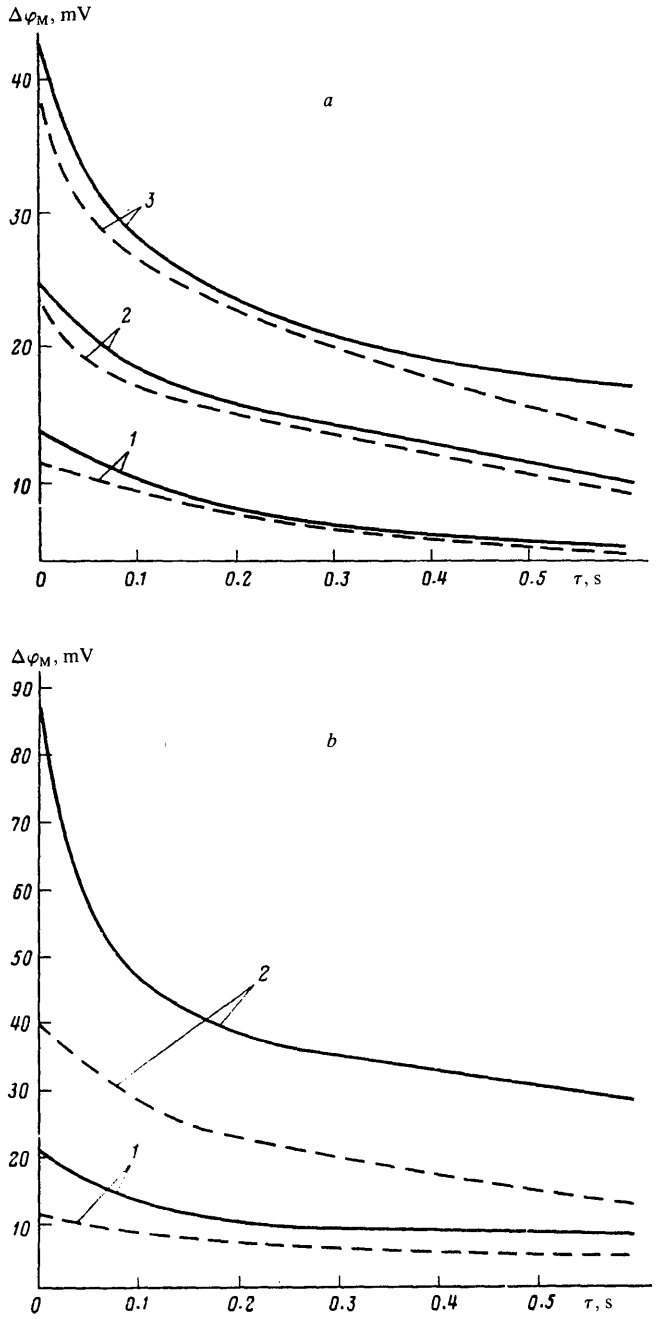

Figure 6. Experimental (full lines) and calculated (broken lines) curves showing the decrease in the membrane potential for a PSM (*a*) and an MK-40 membrane (*b*) with time after switching-off the polarising current. Polarising current density (mA cm^{-2}): *1*) 1; *2*) 2; *3*) 3; rate of rotatation of the membrane disc 100 rev min^{-1}, 0.01 M NaCl solution.

The values of the limiting electrodiffusion current densities, their displacements, and the voltage drops corresponding to $\bar{I}_{lim}$ and I_{lim} (see Table) can be used to judge the energy consumption on polarisation of the membranes and their selectivity; in our opinion this provides fairly full information on the electrochemical behaviour of membranes in the polarisation process.

Polarisation characteristics of EMS's containing different membranes.*

Membrane	10^3c, M	I^*_{lim}, mA cm^{-2}	$\bar{I}_{lim}$, mA cm^{-2}	$\bar{s}$	$\Delta\bar{\varphi}_\Sigma$, mV	I_{lim}, mA cm^{-2}	s	$\Delta\varphi_\Sigma$, mV
PSM	11.5	5.0	—	—	440	5.1	+0.02	440
MK-40	10.0	4.2	3.5	−0.17	450	5.1	+0.21	1750
MA-41I	10.0	6.75	4.6	−0.32	280	8.2	+0.21	1680
MA-40	10.0	6.75	5.2	−0.23	680	7.6	+0.13	2200

* The parameters $\bar{I}_{lim}$, $\bar{s}$, and $\Delta\bar{\phi}_\Sigma$ describe the membrane phase.

The data in the Table indicate that the heterogeneous membranes MK-40, MA-40, and MA-41 have a negative value of s as well as a positive value and this is explained by their polarisability owing to the presence of unexchangeably absorbed electrolyte in the membrane phase. The homogeneous PSM has only a positive displacement which is much smaller than the corresponding values for the heterogeneous membranes; this indicates that it has a high selectivity whereas the selectivities of the heterogeneous membranes in the polarisation process are reduced. The values of $\Delta\phi_\Sigma$ for the heterogeneous membranes, which are much larger (by a factor of 4—5) than the corresponding value for the PSM, typify a higher energy capacity of processes with heterogeneous membranes.

- - - o0o - - -

Analysis of the polarisation characteristics of an EMS in a system with a rotating membrane disc thus indicates that the limiting stage of the mass transport through heterogeneous membranes is internal diffusion when the current density is below the limiting value for an ideally selective membrane but external diffusion at current densities above I^*_{lim}. Polarisation of the membrane entails a reduction in its selectivity and an increase in the electrical resistance of the system. When homogeneous PSM's are polarised the mass-transport process takes place under extra-diffusion control.

In other words, in the polarisation process heterogeneous membranes which contain a sufficient amount of the equilibrium solution display a considerable deterioration in their electrochemical properties. In this case increasing the intensity of the electrodialysis process only by removing the extra-diffusion constraints will be not be sufficiently effective. Consequently, in our opinion, special attention must be given to the production of new, desirably homogeneous types of membrane.

Bacteriorhodopsin as a Possible Element of Membrane Bioreactors

A.V.Maksimychev and S.K.Chamorovskii

Certain approaches to the creation of membrane bioreactors, representing an example of integrated membrane systems, are examined. The characteristic features of the use of organised molecular assemblies in such systems as sensor and regulatory elements are discussed. The properties of the retinal-protein complex of bacteriorhodopsin as a promising component of integrated membrane systems, capable of carrying out regulatory functions, are examined.
The bibliography includes 139 references.

I. INTRODUCTION

The application of membrane technology in modern industry makes it possible to economise on resources and energy and to reduce greatly the influence of unfavourable factors on the environment. In recent years a tendency has arisen in membrane research to combine various processes, since "integration" of technological stages makes it possible to make the best use of the potential advantages of membrane systems. This procedure represents the embodying of the principles constituting the basis of the functioning of biological systems, which are distinguished by the specificity and interdependence of processes, the combination of a number of functions in a single element, and the existence of regulatory mechanisms at various stages of the process.[1] An excellent example of integrated photochemical processes is natural photosynthesis. It includes the collection of solar energy by the chlorophyll of the antenna and by other pigments, the transfer of the excitation energy to the reaction centre, the separation of charges in the photosystems I and II, electron transfer, and other processes.[2] The concept of "integrated membrane systems" presupposes not only the application of various membranes in successive separation stages, but also the combination of functions, for example, the coupling of chemical reactions with membrane separation, the incorporation in the system of membrane sensors for the control of the dynamics and optimisation of the processes, etc.[3] It may be expected that the combined application of membrane systems will prove most effective in fields such as agroindustry, petrochemistry, biotechnology, and the processing of sewage.

II. MEMBRANE BIOREACTORS

1. Membranes in Chemical Reactions

One of the vigorously developing branches of membrane technology involves the creation of membrane reactors (MR) in which the reaction products (or one of the products) are separated from the reaction mixture. The advantages of MR are manifested particularly in carrying out reversible reactions: the continuous removal of the products shifts the reaction in the forward direction and makes it possible to achieve a high degree of conversion of the starting materials. One of the possible ways of carrying out such a process is associated with the use of selective gas separation membranes.[4,5] A schematic illustration of a MR of this type is presented in Fig.1. (Since questions concerning membrane catalysis are considered in detail in another review in the present issue of the journal,[1] we shall confine ourselves to only certain examples). The non-equilibrium nature of the process in this type of flow MR with a microporous glass membrane made it possible to increase the degree of conversion of cyclohexane into benzene by a factor of ~2.5 compared with the equilibrium value. The advantages of the MR are manifested particularly clearly when a palladium membrane, permeable exclusively to H_2, is used.[4] In this case the degree of conversion of cyclohexane reaches 99.5% and, when the flow rates of the starting material and inert carrier gas are suitably selected, it can be increased still further. Thus benzene becomes virtually the only component at the outlet from the MR, which eliminates the necessity for the separation of benzene and cyclohexane, reducing considerably thereby the cost of the industrial manufacturing process.

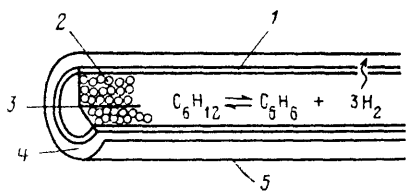

Figure 1. Schematic illustration of a membrane reactor with a palladium membrane for the dehydrogenation of cyclohexane:[4] 1) palladium membrane; 2) catalyst; 3) cyclohexane; 4) inert carrier gas; 5) shell.

Another most imporatant trend in the development of the MR is the study of the properties of catalysts stabilised on polymer membranes. In this case the membrane plays the role of a medium in which a high local concentration of the reactants and the necessary

environment can be created. A large number of studies have been devoted to the photocatalytic decomposition of hydrogen sulphide in the presence of colloidal CdS immobilised on a fluorine-containing cation-exchange membrane of the Nafion type.[6-8] The internal structure of membranes of this type simulates the structure of the inverted micelles, because it includes ionic structures connected by channels and incorporated in the hydrophobic fluorocarbon phase.[9,10] Cationic substrates sorbed in the membrane channels from the aqueous phase are acted upon by a powerful electric field,[11] which apparently must be taken into account in considering the catalytic properties of the complexes. The high chemical stability of the perfluorinated polymer membranes makes it possible to employ them in corrosive media over a wide temperature range. The photodecomposition of H_2S has aroused interest in connection with the search for non-traditional energy carriers, to which the molecular hydrogen obtained as a result of the reaction belongs. Furthermore, it is possible to reduce in this way the effect of the environment by toxic sulphur compounds, many tonnes of which are evolved as waste in chemical, metallurgical, and petrochemical industries.[6] Finally, elemental sulphur, the secondary reaction product, is a valuable raw material and natural gas deposits with a high hydrogen sulphide content may serve as its source.

Another possible application of membrane photocatalysts for the solution of ecological problems is associated with the purification of sewage. The photodegradation of chlorophenols in aqueous solutions, activated by doping with polyphenylacetylene immobilised on a poly(vinyl chloride) membrane, has been investigated.[12] The immobilisation of polyphenylacetylene makes it possible to stabilise it, preventing, in particular, the liberation of the doping agent. The rate of photodecomposition of organic impurities increases significantly with increase in the electrical conductivity of the membrane. It has been suggested that the mechanism of the photodegradation includes the formation of intermediate radical states, while the presence in the membrane of an organic conductor with electronic conductivity permits photoinitiation and accelerates oxidation-reduction processes.

2. Membrane Bioreactors

The development of MR in which chemical reactions take place under the influence of catalysts of biological origin has expanded greatly in recent years. Apparatus of this kind is referred to as membrane bioreactors (MBR). The solution of a set of problems associated with the application of MBR, including the manufacture, isolation, and purification of enzymes and their use as immobilised biocatalysts, is nowadays a leading branch of biotechnology. Membranes serve as a cheap and reliable base for the immobilisation of enzymes and for the creation of compact and flexible devices in which the separation process is coupled with a chemical reaction. Biocatalysts are placed on one side of a suitable membrane, the substrate is brought into contact with the biocatalyst, and the resulting product, whose molecules must be fairly small, permeates through the membrane. This general principle of the design of MBR has been applied in the following main types of MBR used, differing in configuration and the reaction conditions:[13] (1) membrane modules combined with a reaction compartment which contains the biocatalyst in a dissolved form; (2) reactors with membranes in the form of hollow fibres in which the enzyme is usually located on the outer side of the membrane, while the substrate circulates through the inner space within the fibres; (3) reactors with a membrane made of a mouldable solution containing the biocatalyst; (4) reactors with the enzyme fixed by cross-links on a microporous film or grafted covalently to the latter.

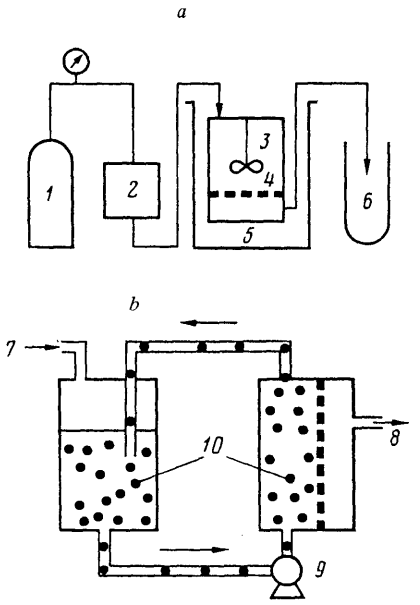

Figure 2. Membrane bioreactors with continuous mixing:[18] *a*) direct filtration reactor: 1) gas cylinder for the establishment of the transmembrane pressure; 2) compartment with the substrate; 3) reaction vessel with stirrer; 4) membrane; 5) thermostatted compartment; 6) vessel for the product; *b*) membrane flow bioreactor: 7) initial mixture; 8) product; 9) pump; 10) biocatalyst.

The appearance of MBR of the first type became possible after the creation in 1965 of the ultrafiltration membrane,[14] which was used to concentrate enzymes.[15,16] In 1970 the first membrane bioreactor was constructed in which a solution of α-amylase from *B.subtilis* was used to hydrolyse starch.[17] A considerable proportion of the enzymes used as biocatalysts have molecular weights ranging from 10 to 100 kDa and are retained by membranes designed for ultrafiltration. Reactors of the first type operate under ideal mixing conditions and are most suitable for reactions inhibited by the product, since the latter is continuously removed as it is formed, which increases the yield. Two varieties of ideal mixing MBR, differing in the organisation of the substrate and product streams are known (Fig.2).[18] Fig.2*a* presents a scheme for a MBR operating under direct filtration conditions. A significant disadvantage of such MBR is the contamination of the membrane and also concentration polarisation, the elimination of which requires vigorous stirring of the contents of the reaction compartment. Reactors constructed in accordance with the above scheme are used mainly for laboratory research. A flow MBR free from the above disadvantages was first proposed by Porter and Michaels[19] (Fig.2*b*). In contrast to the scheme in Fig.2, the separating membrane module is in this case physically separated from the reaction vessel containing enzymes or whole cells as the catalyst. The flow MBR makes it possible to use

the biocatalyst repeatedly and to organise the operation of the system under stationary conditions. Reactors of this type are suitable for industrial use, for example, in apparatus for the treatment of sewage.[20,21] For the normal functioning of MBR of the type considered, it is essential that the product molecules should be significantly smaller than the substrate and biocatalyst molecules. By virtue of this limitation, MBR of the given type have found applications mainly in the hydrolysis of proteins, starch, and cellulose.[18] Low concentrations of the components and relatively low rates of conversion are characteristic of the MBR operating under ideal mixing conditions.

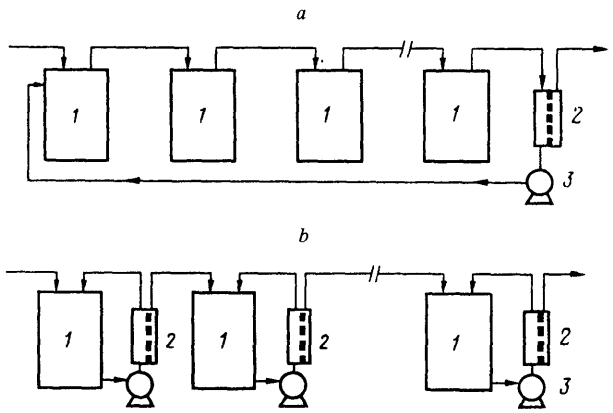

Figure 3. Cascade membrane bioreactors with modules for membrane separation in the concluding stage (*a*) and in each stage (*b*): 1) reactor; 2) membrane separation unit; 3) pump.[18]

The search for highly productive systems, in which a high degree of conversion of the starting material is attained, led to the creation of cascade MBR (Fig.3).[18] Two types of cascades are used: with the membrane separation unit in the concluding stage (Fig.3*a*) and with recirculation of the unreacted component at each stage (Fig.3*b*). Cascade systems of the later type are fairly expensive but ensure a high flexibility of the system, since they create the possibility of carrying out each stage under optimum conditions, which is especially convenient for multienzyme processes.

A higher degree of integration of the chemical reaction and the membranes separator is achieved in MBR based on hollow fibres, since in such devices the membrane separation cell also functions as the reactor. The principal advantage of devices based on hollow fibres is a high ratio of the membrane's surface area to the volume which it occupies. Furthermore, the operating conditions for such MBR approach the ideal displacement regime, which permits the attainment of a high degree of conversion of the substrate. A MBR based on commercial hollow fibres in which an enzyme is enclosed was first described by Rony.[22] Subsequently different versions of hollow fibre MBR, representing two main configurations (Figs.4*a* and 4*b*), were proposed. In the scheme illustrated in Fig.4*a*, the enzyme is deposited on the outer surface of a hollow fibre and the substrate flows through its interior. The products can be removed either from the outer side or from the inner volume within the fibre. Preliminary ultrafiltration of an enzyme solution or a cell suspension through the membrane is widely used for the deposition of the biocatalyst on the surface of the hollow fibre. For example, yeast cells have been deposited in this way on the outer surfaces of ultrafiltration hollow fibres.[23] The cells are then fixed quite firmly in order to ensure the operation of the MBR in the course of ~12 days. The yield of the reaction product is directly proportional to the amount of cells charged into the reactor, but, for a high charge density, there is a sharp increase in the pressure necessary to maintain an acceptable rate of passage of the substrate. An appreciable increase in the transmembrane pressure is undesirable, since under these conditions the biocatalyst is washed off the fibres at a much higher rate. The method of fixation of enzymes by means of physical adsorption has many advantages: a simple and universal deposition procedure, the reduction to a minimum of the steric hindrance in the microenvironment of the enzyme, which is accompanied by an insignificant loss of its activity, and also the absence of the necessity for the introduction of any additives to the biocatalyst, which facilitates the formation of sterile preparations.

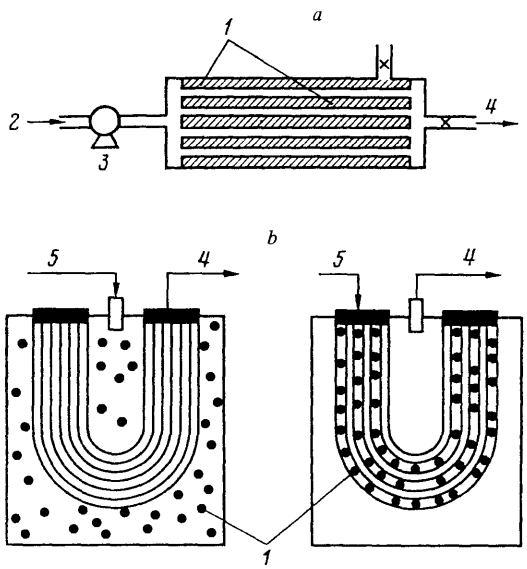

Figure 4. Principal configurations of bioreactors with membranes in the form of hollow fibres: *a*) bunch of fibres in a shell; *b*) bunch of fibres in a compartment containing the biocatalyst or serving for the removal of product; 1) biocatalyst; 2) initial mixture; 3) pump; 4) product; 5) substrate.[18]

The hydrolysis of triglycerides with formation of aliphatic acids and glycerol belongs to the class of technically important reactions. This reaction has been achieved[24,25] in MBR constructed in the form of a module with hollow aromatic polyamide fibres. The hydrolysis of triglycerides from vegetable oils occurred in the presence of lipase from *Candida cylindracea* immobilised on the inner surfaces of the hollow fibres. The enzyme was immobilised by the preliminar ultrafiltration of an aqueous solution of the lipase through the hollow fibres. The substrate—a vegetable oil emulsion—was supplied continuously into the interior of the hollow fibres. The polyamide

membrane is permeable to only one of the reaction products – glycerol, which diffused into the aqueous phase on the outer side of the fibre. Aliphatic acids were removed from the MBR as part of the composition of the lipid phase. The polyamide fibre ensures an effective separation of the phases without their dispersion in any way. Hollow fibre MBR permit the attainment of ~90% conversion of the substrate in 2–3 h,[25] and the time of the stable operation of the system is more than three weeks. A MBR of analogous design has been used for the large scale preparation of 6-aminopenicillanic acid.[26]

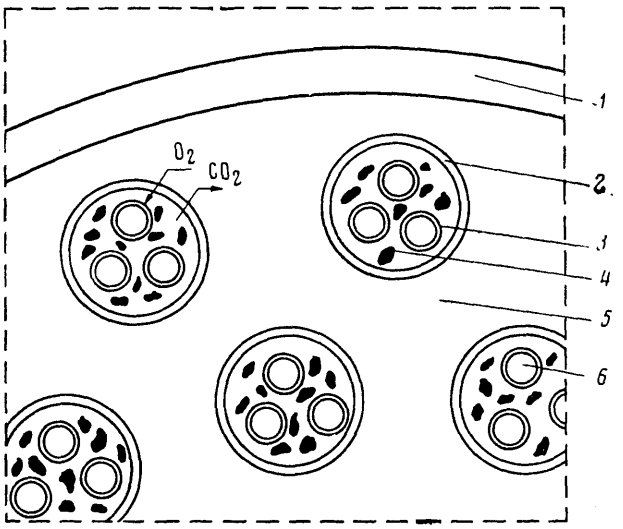

Figure 5. Cross-section through a bioreactor with a double hollow fibre:[28] 1) glass tube; 2) silicone tube; 3) polypropylene hollow fibre; 4) immobilised cells; 5) gas phase; 6) liquid phase.

One of the limitations imposed on the employment of hollow fibre MBR is that the substrate and product must have a low molecular weight, permitting their diffusion through the membrane. This is why such reactors are frequently used for the hydrolysis of oligomers.[18] Another main disadvantage of apparatus based on hollow fibres, already noted in the first relevent investigation,[22] is the limitation of the rate of the chemical reaction by diffusion processes. For example, when MBR with hollow fibres made of polypropylene were used for the production of phenylalanine by mutant strains of *E.coli*,[27] it was observed that the rate of the chemical reaction is limited by the diffusion of oxygen, necessary for the metabolism of the above cells. It has been suggested that reactors of this type are more suitable for systems with a low consumption of oxygen or when anaerobic organisms are employed. Analogous difficulties arise also when gases are evolved in the course of the enzymic reaction. The attempts to overcome these limitations led to the creation of MBR based on double hollow fibres.[28] Fig.5 illustrates schematically the design of a double hollow fibre bioreactor suitable for the cultivation of aerobic cells. The micro-organisms are located in the space between silicone tubes through the walls of which oxygen permeates and hollow polypropylene fibres through which the liquid phase passes. The productivity of the MBR based on double hollow fibres can exceed by a factor of 20–30 that of the traditional enzyme reactors.

MBR are known in which the biocatalyst is enclosed in a porous polymer matrix.[13] The biocatalysts may consist of enzymes or whole cells resistant to the action of the organic solvents used in the formation of the membrane. Many bioreactors of this type have been developed for the processes used in the food industry. In order to combine in a single cell ultrafiltration and the hydrolysis of lcatose in milk and whey, a planar version of the MBR has been proposed.[13] Lactose is immobilised in a microporous poly(vinyl chloride) film placed directly behind the ultrafiltration membrane (Fig.6). The coupling of the processes makes it possible to avoid the undesirable contact between the enzyme and particles of milk fat. An analogous process has been achieved in the presence of the bacteria *Sulfolobus solfataricus* in a MBR of a different geometry.[29] The biocatalyst was incorporated in a membrane matrix made in the form of a hollow fibre consisting of a mixture of polysulphone, polyvinylpyrrolidinone, and *NN*-dimethylacetamide. An increase in the content of lyophilised cells in the mixture impaired the mechanical properties of the fibres and reduced the regularity of the membrane structure. However, these negative effects can be compensated for by varying the molecular weight of polyvinylpyrrolidinone. The study of the relation between the functional characteristics of the given MBR and their kinetic and hydrodynamic parameters showed that they can operate under both diffusional and kinetic conditions depending on the conditions specified at the inlet.

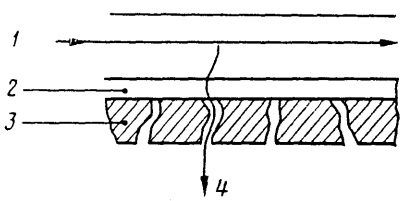

Figure 6. Schematic illustration of a flat membrane reactor with immobilised enzyme:[13] 1) substrate; 2) ultrafiltration membrane; 3) film with immobilised enzyme; 4) hydrolysate.

The microenvironment influences significantly the activity of the biocatalyst incorporated in the polymer matrix. The mechanical properties of the polymer, its biocompatibility, and its resistance to decomposition by bacteria play an important role.[30]

Membrane bioreactors in which the enzyme is immobilised as a result of the formation of cross-links or as a result of covalent attachment to the carrier surface have many advantages: they are stable, make it possible to organise the process under continuous and controlable conditions, and it is possible to obtain a uniform and relatively cheap product.[18] However, depending on the method of immobilisation, different enzymes can lose between 10 and 90% of their activity in a free state as a consequence of steric hindrance and diffusional limitations. One of the ways of overcoming the diffusional control of the chemical process in the MBR is based on the application of an asymmetric ceramic membrane.[31] Invertase is immobilised in such a membrane by filtration through a porous support and subsequent treatment with glutaraldehyde. The high

mechanical strength of the membrane makes it possible to carry out the chemical reaction under filtration conditions at pressures in the range 50–450 kPa. The contact time between the enzyme and the substrate depends on the pressure, whose variation makes it possible to regulate the rate of the reaction. The elimination of diffusional limitations ensures a significant increase in the flow of substance through the membrane.

The investigations carried out assisted in the development of a large number of a wide variety of MBR designs and demonstrated the wide scope of their uses. Among the fields in which the application of MBR may prove very effective, we may specify the preparation of ecologically pure and renewable energy carriers. The last 15 years have been characterised by a sharp increase in the employment of alcohol-containing automobile fuels which in certain countries have already acquired practical importance.[32,33] Analysis shows[32] that the coupling of fermentation with processes involving reverse osmosis, ultrafiltration, and evaporation through a membrane makes it possible to improve the economic parameters of the manufacturing process and to justify the wide-scale employment of butanol, ethanol, and acetone as fuels. The designs of various membrane fermenters,[34,35] including those for the synthesis of ethanol,[18] are being vigorously developed.

Methane and molecular hydrogen are believed to be a promising basis for future power engineering. One of the possible ways of obtaining H_2 – via the photodecomposition of hydrogen sulphide – was mentioned previously. An alternative approach is based on the fact that hydrogen and methane are the products of a large number of micro-organisms,[33,36,37] including phototropic micro-organisms for which light serves as the energy source. Hydrogen can be evolved both by whole cells and by isolated polyenzyme systems containing hydrogenases,[38] the activity of the hydrogenases exceeding appreciably the activity of the catalysts based on platinum group metals and persisting for a long time at a high level (the half-inactivaion period is about 60 days[39]). Thus the creation of fermenters for the manufacture of hydrogen and methane in which the principles of MBR would be realised (see, for example, Fig.5) is of undoubted interest for the solution of energy problems. The survey of modern concepts in the design of MBR for plant cells has been published.[40] A favourable factor for the development of hydrogenase-containing MBR is also the fact that, when hydrogenases are incorporated in lipid liposomes (a procedure used for the immobiliisation of biocatalysts on synthetic membranes[41]), an increase not only in the stability but also in the activity of the enzyme is observed in a number of instances.[42]

3. Organised Molecular Assemblies

Organised molecular assemblies – structures formed spontaneously by amphiphilic molecules in aqueous solutions – are of considerable interest for the development of integrated membrane systems. The simplest organised molecular assemblies are monolayers on interfaces, and micelles, microemulsions, double layers, and vesicles.[43] The tendency towards self-organisation by lipid molecules in the form of a double layer determines the principal structural features of biological membranes. Liposomes, closed double layer lipid membranes containing an internal aqueous phase with dimensions in the range 20–500 nm, as well as molecular monolayers have attracted most attention. The use of liposomes to carry out chemical reactions is determined by the following main factors.[41,43] Firstly, in the inner volume and in the walls of the liposome, the test substances are present at relatively high concentrations. Secondly, the formation of liposomes is accompanied by the creation of a surface with an extremely large area. For example, at a lipid concentration of 4 mg ml^{-1}, the area of liposomal membranes is ~ 1 m^2 ml^{-1}. Thirdly, liposomal membranes are characterised by a high permeability to non-electrolytes (10^{-4}–10^{-6} cm^3 cm^{-1} s^{-1}) and a low permeability to hydrophilic molecules (10^{-9}–10^{-10} cm^3 cm^{-1} s^{-1}). A liposome containing in the inner aqueous phase some kind of enzyme is in essence a membrane microreactor constructed at the molecular level.[44] Liposomes can be used in MBR for the soft immobilsation of enzymes:[41] initially the enzyme is built into the liposomal membrane, where it is incorporated in the inner aqueous phase, and the liposomes are then immobilised on a porous membrane. The stability of the immobilised liposomes is higher compared with the free liposomes. Another way of increasing stability consists in creating around the vesicle a polymer shell chemically bound to the outer surface of the membrane.[45] The vesicles, which are stable in the course of several months, can be prepared from molecules with double bonds which undergo polymerisation after the formation of the vesicles.[43]

Microcapsules, which are analogous to polymeric vesicles but are larger, have been investigated as "containers" for biocatalysts in pioneering investigations.[46,47] Microcapsules having diameters ranging from 1 to 100 μm have been obtained by interfacial polycondensation, aqueous solutions of the enzymes being emulsified in an organic phase. A solution of the enzyme, whole cells, or their fragments were enclosed in nylon or collodion capsules, no appreciable leakage of the protein from the capsules being observed in the course of approximately a week. The membranes of the capsules are permeable to low-molecular-weight substrates and products, their transport taking place by means of diffusion via water pores ~ 1.6 nm in diameter, and in the most successful specimens the activity of the enzyme, measured as the rate of accumulation of the product, approaches the activity in the native state.[46] The possibility of using microcapsules in biochemical studies *in vitro* and also for therapeutic purposes *in vivo* has been studied. One of the significant limitations in the use of systems of this kind consists in the risk of the denaturation of the protein in interfacial polymerisation in the course of the formation of the microcapsule. Earlier studies on the encapsulation of enzymes served as a basis for the development of the first MBR containing the biocatalyst within hollow fibres.[22]

The development of studies on microencapsulation led to the creation of systems in which interfacial catalytic reactions can be carried out at a liquid/liquid interface. The enzyme is immobilised on the outer surface of a porous nylon capsule filled with an aqueous buffer solution,[48] which is placed in the organic phase (Fig.7). The synthesis of peptides takes place at the interface between the aqueous phase and chloroform, the enzyme being protected from the inactivating effect of the organic solvent by a surface layer of buffer solution seeping through. In contrast to the traditional capsule MBR, in this bioreactor, the molecular weights of the starting materials and products need not necessarily be low. Other advantages of the system are the simplicity of the separation of the biocatalyst from the substrate and product and also the absence of an induction period in the catalytic reaction associated with swelling processes.[48]

The use of an organised assembly of molecules in the form of a monolayer at the interface ensures major technological possibilities. The method of depositing monomolecular layers on the surface of a solid support proposed by Langmuir constitutes nowadays the basis of numerous developments in the field of microelectronics, optics, and electro-optics and for the creation of photoelectric converters and information processing systems.[49] The introduction of methods

for the preparation of ultrathin layers into membrane technology makes it possible to outline new approaches to the creation of integrated systems.[50] In the first place, one should note the possibility of obtaining infinitesimally thin composite membranes which could be used to devise highly productive MBR. The high degree of order in the molecular arrangement in the monolayer makes it possible to carry out chemical reactions under unusual conditions where highly specific effects can be manifested. The successive deposition of different monolayers permits the creation of mixed structures whose properties can be controlled at the molecular level with attainment of maximum integration. The introduction of suitable functional components into a thin layer system renders them sensitive to chemical, electrical, or optical signals, which can be used to control properties of the deposited film. In such systems, one can achieve not only material transfer but also transfer of information. Thus the study of integrated membrane systems requires the expansion of traditional ideas about the membrane as a passive selectively permeable partition, because in systems of this kind it can play the role of an active element acting on the chemical state of the given substance (membrane reactors) or participating in the generation and transformation of signals (membrane sensors).

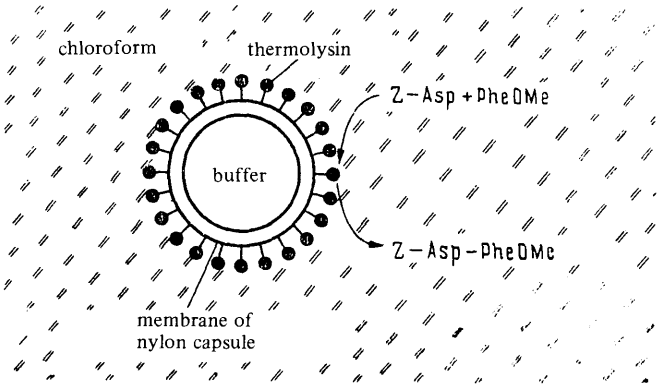

Figure 7. Design for a capsule membrane bioreactor for the synthesis of peptides.[48]

We shall deal briefly with certain examples of the use of thin-layer membrane systems. A method has been proposed for the formation of a thin-layer membrane from fragments of cell walls of certain bacteria.[51] The immobilisation of glycoprotein fragments having pores of uniform size 2–6 nm in diameter on the surface of a porous synthetic support makes it possible to use the resulting membrane for ultrafiltration in the pH range from 1 to 13.

Studies on processes involving the photoinitiated intramolecular electron transport in ordered donor–sensitiser–acceptor systems, formed by the Langmuir–Blodgett method, showed that it is possible to achieve states with separated charges on a nanosecond time scale.[50] A system functioning as a photodiode has been obtained by depositing on a gold electrode monomolecular films containing bound residues of viologen, pyrene, and ferrocene.[52]

Thin-layer membranes have found extensive applications as sensitive elements in chemical sensors for biomedical research and for the control of processes in bioreactors *in situ*.[53] One of the ways of creating sensor devices consists in the use of the structure of a semiconducting field transistor as the base for the deposition of a membrane exhibiting a specific chemical sensitivity.[53–55] Planar silicon transistors with an oxide or nitride dielectric film are usually employed, the immobilised enzyme being deposited on the region of the transistor gate. The change in the electrical potential at the gate as consequence of the chemical interaction with the substrate modulates the state of the conducting channel, which is recorded by electrical methods. This principle has been used to create biosensors sensitive to glucose, ATP, glutamic acid, urea, and other organic compounds.[53–55] Biosensors of this type have many undoubted advantages: they can be miniaturised, are readily "integrated" in technological schemes, make it possible to combine various sensors in a single semiconductor crystal, have good metrological characteristics, and there exists a sophisticated technology for their preparation. The use of enzymes in biosensors ensures the possibility of recording a broad spectrum of substances with an enormous sensitivity (the concentration of the substances detected can be as low as 10^{-19} M).[56] The use of thin-layer membranes in sensor devices is justified by the fact that the response time of the sensor is inversely proportional to the square of the thickness of the sensing membrane and can amount to several seconds.[54]

Membranes based on double-layer and multilayer molecular structures have been used successfully for the highly selective determination of anions and cations by electrochemical[57,58] and spectroscopic[59] methods. A monomolecular lipid layer at the water/air interface has been investigated as a model of the olfactory membrane.[60] The absorption of a gaseous component (diethyl ether) or its incorporation in the lipid monolayer increases sharply the permeability of the film to water vapour.

Photo- or chemo-sensitivity of the membranes can be used not only for the creation of recording systems but also for the active regulation of the functional properties of membranes in integrated systems. The possibility of a controlling effect on the components of complex membrane systems greatly extends the number of independent operational variables and permits the realisation of new operating conditions and an increase in the flexibility of such systems, for example, membrane bioreactors.

One of the biological objects having a wide set of functional properties which can find technical applications is the membrane protein complex bacteriorhodopsin. The principal properties of bacteriorhodopsin and the possibilities for its employment in membrane systems are considered below.

III. FUNCTIONAL PROPERTIES OF BACTERIORHODOPSIN IN ARTIFICIAL SYSTEMS

1. Purple Membranes Containing Bateriorhodopsin

It is well known that lipid membranes play a key role in the processes involving the transformation of energy by living cells. In the highly specialised biological membranes effecting fundamental processes such as respiration or photosynthesis, the multienzyme complexes bound to the membrane catalyse a whole chain of coupled electron- and proton-transfer reactions in the course of which chemical energy is stored.[61]

Recently the so called purple membranes (PM), synthesised by the bacteria *Halobacterium halobium*, have attracted the attention of investigators. In these comparatively simple but highly specialised

membranes, a vector transmembrane transfer of H^+ takes place under the influence of light.[62]

The purple membranes from *H. halobium* consist to the extent of ~75% of a single protein—bacteriorhodopsin (Br),[62] while the remaining 25% comprises acid lipids.[63] Bacteriorhodopsin is a single chain protein consisting of 248 aminoacid residues[64,65] and having a molecular weight of ~26.5 kDa. The chromophoric group of the protein is the aldimine of retinal, which is bound covalently to the ε-amino-group of lysine, forming a Schiff base.[62]

The X-ray low-angle and diffraction methods[66] as well as limited proteolysis and immunochemical binding to monoclonal antibody experiments[67] have shown that the polypeptide chain of the Br molecule has seven α-helical transmembrane strands connected by protein sections exposed to the aqueous phase on the surface of the membrane. According to electron microscope data, the Br molecules in the plane of the membrane form a dense hexagonal quasi-crystalline lattice,[68] whose main structural element is Br trimers (Fig.8).

The Br in the membrane can exist in two stable forms—the dark-adapted and light-adapted forms between which transitions are possible. In the light-adapted Br, the retinal is in the fully *trans*-conformation, while the dark-adapted Br is an equimolar mixture of 13-*cis*- and fully *trans*-isomers.[69] Both 13-*cis*-Br and the fully *trans*-Br are photochemically active and are characterised by cycles of photochemical transformations.

The photochemical cycle of the light-adapted fully *trans*-Br has been studied in fair detail from the primary sub-picosecond stages. During the cycle, deprotonation and subsequent reprotonation of the Schiff base and the isomerisation of retinal with respect to the C(13)=C(14) double bond take place. During the photocycle, the fully *trans*-Br passes through at least six metastable states—the intermediates J, K, L, M, N, and O, whose lifetimes are in the range 0.4 ps–(5–10) ms (see the relevant reviews[70,71]).

Very much less is known about the photocycle of 13-*cis*-Br, for which three intermediates have been postulated: ^{x}C, ^{y}C, and ^{610}C (610 nm is the maximum of the optical absorption of the intermediate). In the ^{y}C state the photocycle branches and there is a probability of the transition of Br to the fully *trans*-form.[72]

The nature of the primary intermediate in the photocycle has continuously attracted the attention of investigators, because this is in fact the site where energy is stored and is subsequently used for the transmembrane transfer of H^+.

It has been established with the aid of pulse laser absorption and fluorescence spectroscopy with sub-picosecond time resolution that, after the absorption of a light quantum, the light-adapted Br passes to a singlet excited state, whose lifetime is τ = 0.4–0.7 ps.[73] The rate of relaxation of the excited state is the same as the rate of formation of the intermediate J, the absorption spectrum of which has undergone a bathochromic shift of ~30 nm relative to the Br spectrum. The intermediate J is converted in its turn over a period = 5 ps into the intermediate K whose absorption spectrum has undergone a bathochromic shift of 20 nm relative to the Br spectrum.[73,74] The lifetime of the intermediate K is 1–2 μs and is the same as the time required for the formation of the photocycle intermediate having an absorption maximum near 550 nm (L_{550}). In this and preceding stages, the albumin of the retinal in Br is in the protonated state.

The next stage in the cycle of photochemical transformations of Br is the transition from the intermediate L_{550} to one of the functionally most important forms, namely M_{412}, which corresponds to the deprotonated state of the Schiff base of retinal. The intermediate M_{412} is formed ~40 μs after the absorption of a photon. The formation of the M_{412} photoproduct can be recorded by low-temperature or pulse absorption spectroscopy at the absorption band near 410 nm and also from the appearance of the 1570 cm^{-1} band due to the C=C stretching vibrations in the kinetic resonance Raman spectra.

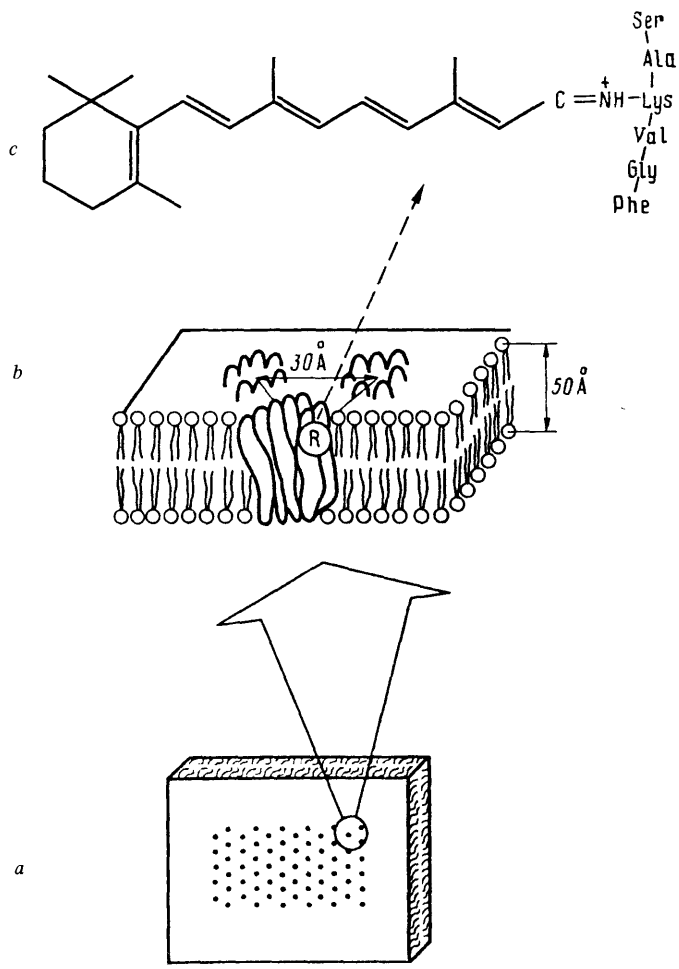

Figure 8. The structure of purple membranes containing bacteriorhodopsin:[68] *a*) fragment of the purple membrane, the dots denoting the molecules of bacteriorhodopsin forming a quasi-crystalline structure; *b*) bacteriorhodopsin trimer; *c*) chromophoric group of bacteriorhodopsin—retinal, bound as a Schiff base with Lys-216 of the polypeptide chain of bacteriorhodopsin.

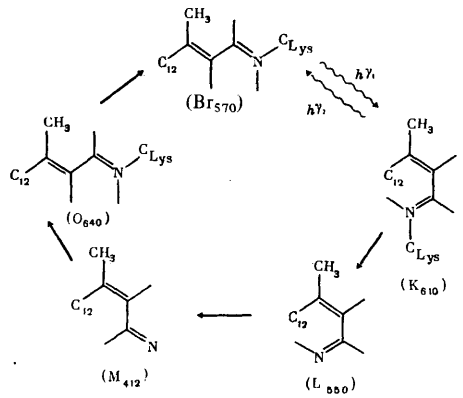

The process leading to the formation of the M_{412} form is one of the key stages in the functioning of Br as a light-dependent proton pump. The most significant changes in the ionic state of a number of aromatic aminoacid residues and carboxy-groups of the protein

have been recorded in the stages involving the formation and decomposition of the M_{412} intermediate. It has been established that a proton is split-off from the Schiff base and H+ is transferred through the membrane at this stage.

Approximately 10 ns after the formation of the M_{412} intermediate, the regeneration of the initial form Br_{570} is observed. As a rule, this transition is described by the following sequence of photoreactions: $M_{412} \rightarrow (N_{520}) \rightarrow O_{640} \rightarrow Br_{570}$ (the N_{520} intermediate is enclosed in brackets because many workers have failed to confirm its existence). The application of pulse Raman spectroscopy with picosecond time resolution made it possible to investigate the dynamics of the conformational changes in retinal. In the range 1100–1400 cm^{-1}, the Raman spectra of 13-*cis*-Br and fully *trans*-Br differ significantly. The Raman spectrum recorded several picoseconds after the application of the laser flash to the light-adapted (fully *trans*-Br) specimen resembles very closely the spectrum of 13-*cis*-Br. When the medium with H_2O is replaced by one with D_2O, an analogous spectral correspondence is observed between the "picosecond intermediate" and 13-*cis*-Br but in a somewhat different wavelength range (950–1050 cm^{-1}). The band corresponding to the -C=NH bond of the Schiff base (1646 cm^{-1}) in the picosecond time range is broadened and undergoes a shift, which may indicate a change in the electronic structure and in the direct environment of the -C=NH groups.[75,76]

Quantum-chemical analysis of the vibrational spectra with retinal-deuteriated or ^{13}C-modified in the C(15)-position, recorded by Fourier-transformation IR spectroscopy, as well as the resonance Raman spectra of the analogous Br preparations with biosynthetically ^{13}C-modified retinal have shown that the following changes in the chromophore structure take place: Br_{570} (fully *trans*) → K(13, 14-*s*-*cis*) → L(13, 14-*s*-*cis*) → M(13-*cis*) → O(fully *trans*).[77,78]

The cycle of photochemical transformations of the light-adapted Br and the structural rearrangments of retinal near the Schiff base are illustrated in the scheme below:

2. Photoelectric Processes

In the course of the photochemical reactions of Br, protons are transferred from the intracellular volume through the membrane to the outer medium, which creates a gradient of the electrochemical potential of hydrogen ions on the cell membrane. The energy stored in the form of the difference between the electrochemical potentials is used for the synthesis of ATP, membrane transport, the motion of the bacterial cell, metabolic processes, etc. The exact mechanism of the active proton transport in Br has not been established. The energetic, structural, and kinetic aspects of the functioning of the proton channel have been discussed in the literature.[79,80]

The direct experimental measurement of the photoelectric activity of Br[81,82] is based on the retention of its functional properties when it is incorporated in artificial phospholipid membranes, liposomes, or phospholipid-impregnated membrane filters separating electrolyte solutions. The action of light induces the transfer of H^+ between the membrane-separated sections and creates an electrical potential difference, which can be measured with the aid of reversible electrodes or potential-sensitive probes.

The use of a low-inertia recording system as well as pulse laser excitation permits an increase in the time resolution of the method of measurement of the photopotential down to microseconds[83] and picoseconds.[84,85] The processes involving an increase and fall in the photopotential generated by Br have several phases correlated to a first approximation with the formation and decomposition of the intermediates K, L, and M in the Br photocycle.[83] It has been suggested that the generation of photopotential in such systems is associated with the intramembrane displacement of charged groups (displacement currents) and the transmembrane H^+ transport.

Model systems containing Br as part of the composition of artificial lipid membranes can consist of liposomes or planar macroscopic membranes. It has been shown with the aid of potential-sensitive dyes that a photopotential up to 200 mV arises on the membrane in artificial lipid vesicles under stationary conditions.[86] In the liposomes, the direction of proton transport can be the same as the direction of transport in cells or can be opposed to it[87] depending on the method of preparation of the liposomes, the type of lipids used, and the pH of the medium.[88,89]

The Br in liposomes can be incorported as a single protein component or in combination with other membrane proteins, such as ATPase, cytochrome oxidase, and other enzymes of the respiratory chain.[87,90–93] In the last case, the membrane electrochemical potential, generated by Br on illuminaion, can provide the energy for phosphorylation processes and can exert a regulatory effect on the activity of enzymes. The organised molecular assemblies obtained when Br and other enzymes are incorporated in double layer lipid membranes make it possible to achieve functional coupling between proteins, the monomeric Br serving as a more effective source of energy than the native purple membranes by virtue of the closer packing of the monomer in the liposome.[94]

Br is capable of being sorbed at the octane/water interface and, under illumination in the presence of an electron acceptor in the octane phase, a potential difference up to 0.5 V is generated between the phases.[95] When ATPase is introduced into such a system, photophosphorylation can take place in the latter.

The photoelectric activity of Br in planar double-layer ("black") lipid membranes was first demonstrated in two studies.[96,97] It was established that the photopotential of 100–180 mV, arising when the system is illuminated with light at a wavelength of ~560 nm (the Br absorption maximum), diminishes to zero under the influence of blue light absorbed by the intermediate M driving the photocycle. An analogous regulation of the photoelectric properties of Br by light having different spectral composition occurs also in other model systems.

The principal disadvantage of planar double layer lipid membranes is their low stability. The addition of fillers to solutions from which the membranes are formed makes it possible to increase severalfold the lifetime of the membrane and the breakdown potential.[98] Even more stable systems are obtained when Br is sorbed on lipid-impregnated porous filters or collodion membranes.[99]

The photoelectric activity of Br immobilised in polyacrylamide gel has been recorded in a number of studies.[100,101] The kinetic characteristics of the photoelectric signals indicate that Br remains intact on polymerisation of the gel.

Br or purple membranes can be immobilised in other polymer matrices [poly(vinyl alcohol), gelatin]. Such dry membranes with additives modifying the spectroscopic and kinetic properties of Br have come to be called "Biokhrom" films. They constitute a promising photochromic material for the reverse optical recording of information.[102]

The immobilisation of Br increases the stability of this protein, which is high even in the absence of this step and is unique for biological systems. Thus Br retains its photochemical activity over a wide temperature range (from helium temperatures to ~370 K), a wide pH range (3–10), and a wide range of ionic strengths of the solution (from distilled water to saturated NaCl solution) and exhibits a high resistance to the action of proteolytic enzymes[67,103] and certain organic solvents and detergents.[104] The "Biokhrom" films or dry films prepared from purple membranes retain their funcional activity for many months and even years and withstand without loss of activity up to 10^7 "light–dark" switching cycles. For certain applications, such "solid state" systems, obtained by immobilising and drying Br on solid supports, are in fact most promising. The functioning of Br in dry membranes has a number of characteristic features compared with its functioning in the whole cell or in an aqueous suspension of purple membranes.

3. Characteristics of the Photochemical Reactions of Bacteriorhodopsin in Dry Membranes.

Br retains its capacity for reversible photochemical reacions under the conditions of partial dehydration, the reaction cycle in fairly moist films ($\gtrsim$60%) being virtually the same as in an aqueous suspension.[105,106] The formation and decomposition of the intermediate M, i.e. deprotonation and protonation of the chromophoric group of Br in the absence of water as the liquid phase, show that these processes apparently proceed in the cell with participation of endogenic proton donors and acceptors, which are probably the aminoacids tyrosine and aspartic acid localised in the vicinity of the Schiff base.[80,105]

Together with the similarity of the photochemical processes occurring in suspension and in dry purple membrane preparations, certain significant differences are observed between them: (1) for a low humidity, the position of the maximum in the absorption spectrum of multilayer purple membrane films undergoes a hypsochromic shift of 5–10 nm compared with the maximum in the spectrum of the suspension.[107] (2) The dark and light adaptation in multilayer purple membrane films of a relative humidity < 100% differs from the adaptation in the purple membrane suspension.[107,108] In the films which are in the light-adapted state, the ratio between the Br isomers with 13-*cis*-retinal and the fully *trans*-retinal depends on the wavelength of the exciting light and on the humidity. (3) Together with the photochemical reactions of fully *trans*-Pr in dry purple membrane preparations, photoreactions of 13-*cis*-Pr, from the photocycle of which the deprotonated intermediate M is absent, are observed. (4) The photochemical cycle of the fully *trans*-Br in dry membranes is reduced compared with the photocycle in an aqueous suspension – the intermediates L and O are absent[106,109,110] while in moist membranes the characteristics of the Br cycle approach those of the photocycle in cells.[111]

After extensive dehydration of the purple membrane, the absorption maximum of Br shifts from 570 to 530 nm.[112] According to Raman spectroscopic data, in the new state aldimine is in the deprotonated form, while retinal is predominantly in the 13-*cis*-configuration. Under illumination, the dehydrated Br_{530} undergoes a photochemical reaction cycle with the following stages: the formation of a batho-intermediate with a spectral maximum at 630 nm, the formation of an intermediate with a maximum at 412 nm (formation time τ = 2.5 ms), and relaxation of the latter over a period τ = 2 s to the initial form Br_{530}.

Apart from the features of the photocycle indicated above, in dry films one can also note an increase in the lifetime of the intermediate M, which amounts to several seconds and even several tens of seconds at room temperature[109,110,113] compared with several milliseconds in an aqueous suspension. The lifetime of the state M increases also after the addition of glycerol to aqueous solutions of purple membranes.[114,115]

Methods for the preparation of oriented films or membranes containing purple membranes as the working element have been developed for a more far-reaching study and more complete utilisation of the molecular photochromic and photoelectric properties of Br.

4. Methods for the Preparation of Oriented Films of Purple Membranes and the Photoelectric Properties of Such Films

Various procedures for orienting purple membranes have been described: by the centrifugation method,[116] at the air/water interface as a result of hydrophobic interactions,[117] in a magnetic field as a consequence of the anisotropy of the diamagnetic susceptibility of the protein segments,[118] on charged surfaces modified with polylysine,[119] in the electric field of an air condenser,[105] and in an electric field applied directly to the suspension.[120] Chemical cross-linking has also been used to orient the purple membranes and to stabilise the resulting structure.[121]

The orienting of purple membranes in a magnetic field[118] is based on the diamagnetic properties of the α-helical structure of the protein, which is the preferred form of organisation of the Br molecules. Exposure of a purple membrane suspension to the action of a magnetic field results in the appearance in the former of a certain degree of order which can be fixed by drying.

Oriented purple membrane films have been obtained by the deposition onto a support of monolayers formed by the Langmuir–Blodgett method.[117,122] The study of the state of the purple membrane monolayers in a mixture of purple membranes with aliphatic acids at the air/water interface made it possible to determine their dynamic characteristics and to confirm the possibility of the formation of multilayers by the Langmuir–Blodgett method.[123] Membrane systems consisting of oriented molecular purple layers, obtained by the Langmuir–Blodgett method and deposited on a thin Teflon support or another neutral carrier, have been regarded by some workers as prototypes for molecular computing elements.[124,125] This system is fairly readily available and sufficiently stable to be able to carry out rigorous quantitative measurments and at the same time the molecular organisation of the purple membrane is fairly complex, which creates a basis for the modification of its structure bv controlling the photosignal.

Multilayer films, within which the purple membranes are arranged rigorously parallel to the plane of the support, can be obtained by centrifugation and sedimentation methods.[116] However, in this procedure for the formation of the film, the purple membranes can be oriented with equal probability with both its cytoplasmic and

periplasmic surface directed towards the support. The preparations obtained are distinguished by a high degree of purple membrane packing order, but the direction of the photoinduced H^+ transport in each membrane is selected at random out of the two possible directions.

A similar ordering of the film can be achieved by drying a purple membrane suspension on a glass, mylar, or mica plate. In this case, the purple membranes are spontaneously "arranged" in the plane of the suport by virtue of the much greater diameter of the purple membrane compared with its thickness (about 300 and 5 nm respectively). However, in such spontaneous sedimentation, bending of the purple membrane discs and other distortions in their structure may be observed.

The methods for orienting purple membranes based on the different properties of the cyto- and peri-plasmatic surfaces are of considerable interest. Purple membranes have a large permanent dipole moment due to the different surface charge densities on the opposite sides of the membrane. The dipole moment is ~ 140 D at pH 7.[126] The freezing of the purple membrane suspension in an external electric field makes it possible to create and fix a preferred orientation of the purple membrane relative to the applied electric field vector.[127]

In order to obtain preparations of oriented purple membranes, drops of a suspension deposited on an electrically conducting support and dried in a permanent electric field have also been used.[105] However, since the drying was carried out in the field of an air condenser, the appreciable difference between the dielectric constants of air and the purple membrane suspension precluded the attainment of an appreciable electric field strength within the suspension and, furthermore, the field inside the drop was significantly inhomogeneous. A high degree of order was not therefore attained in the purple membranes in preparations obtained by the above method.

An appreciably greater order was achieved using the electrophoretic method for the deposition of purple membranes on a flat electrode.[120] In this case, the electric field is applied directly to a deionised purple membrane suspension. It is known that purple membranes contain acid lipids,[63] which are negatively charged in a neutral medium. For this reason, purple platelets exhibit an electrophoretic mobility and at a pH of about 7 the purple membranes move towards the anode.

Analysis of the methods enumerated shows that the electrophoretic deposition and subsequent drying of purple membranes on an electrically conducting support make it possible to obtain preparations in which the Br platelets are ordered to the maximum extent. Under the influence of light, such highly oriented membrane structures generate an electric potential up to 10–11 V (for a thickness of the specimen of about 10 μm [128]). The photoelectric signal generated by Br consists of two components: the displacement current associated with the redistribution of charges within the membrane and the constant photocurrent induced by the transmembrane proton transport and coupled with electrochemical reactions on the surfaces of the electrodes.[129]

The appreciable value of the photosignal and the compactness of the system, tending to decrease parasitic electrical capacitances, made it possible to record by means of the picosecond laser technique the increase in the photoelectric signal, whose front proved to be shorter than 5 ps,[84] and also to create on the basis of purple membranes the first biological photodiode having the picosecond time resolution.[85]

An important property of the Br-containing membranes is the dependence of the spectroscopic and photoelectric characteristics on the applied external electric field, which creates a basis for controlling membrane systems.[71,130]

5. The Use of Bacteriorhodopsin in Membrane Reactors

The use of external influences for regulating the conditions in the operation of MBR reflects the tendency towards the organisation of processes in accordance with the principles applied in biological systems. Flexible rearrangeable systems apparently exhibit greater potential possibilities for their optimisation. The study of photochemical reactions in polymer films as a possible way of regulating the properties of membranes is of undoubted interest. Photosensitive polypeptide membranes can be prepared from poly-L-glutamic acid containing chromophoric *para*-rosaniline groups.[131] On irradiation with UV light, photodissociation, accompanied by the conformational transition of the polypeptide to the α-helical structure, takes place. In the dark, the structure relaxes to the initial structure and the process is thermally activated. Since the transport properties of the membrane depend on the conformational state of the polypeptide,[132] illumination can be used as a way of altering the permeability of the membrane. Apart from photodissociation, a further two photochemical processes, leading to a significant alteration of the properties of the molecules forming thin membranes, are known: *cis–trans* isomerisation and reactions involving a change in the hydrophilic properties of the head groups of amphiphiles. Photoreactions of the latter type have been investigated in multilayers of photosensitive amphiphilic molecules formed by the Langmuir–Blodgett method.[133] When the films are illuminated with near UV light, their permeability to ions diminishes, which has been attributed to the formation of a more compact film structure. The transition of the membrane to a non-conducting state is photoreversible, relaxation ocurring under the influence of visible light. Thus the system behaves as an ionic phototrigger: the absorption of small radiation doses induces a fairly appreciable change in the electric current. An interesting feature of the compounds examined is that, in relation to Br, they can play the role of a photoinhibitor, because the region corresponding to absorption by the induced UV-irradiated form of the substance overlaps the absorption band of Br.[133]

The permeability of synthetic polyvinyl polypeptide copolymer membranes, which form polypeptide microdomains, depends significantly on the pH of the medium,[134] which determines the conformational state of the polypeptide sections. For an appropriate choice of geometry and also of the method of immobilisation of the pigment, one can apparently make use of the proton transport function of Br to influence processes involving the transport of organic substrates through the membranes considered. Probably other enzymes catalysing reactions with participation of H^+ can also be regarded as possible regulators of the pH-dependent properties of synthetic membranes. Oxidation-reduction processes also influence the properties of certain membranes, for example, poly-L-cysteine membranes.[135]

The permeability of multilamellar membranes formed from amphiphiles of the liquid crystal type is a function of the electric field applied to the membrane.[136] Depending on the chemical composition of the membrane, its permeability depends either on the lateral or the transmembrane electric field. In the latter case, the photoelectric activity of Br can apparently be used to regulate the permeability of liquid crystal films.

The electric potential influences not only the passive processes involving the permeation of substances through the membrane but in certain cases determines also the activity of the biocatalyst. Thus an appreciable increase in the activity of alcohol dehydrogenase, immobilised on an electrically conducting polypyrrole membrane, with increase in the potential applied to the support has been observed.[137] The increase in enzyme activity has been attributed to

the overcoming of the diffusional restrictions for products and substrates as a consequence of the change in the overall charge on the membrane matrix. Presumably the use of Br, which possesses electrogenic properties, in systems of this type is extremely effective, because the application to the membrane of a potential of 0.7 V increased by a factor greater than 10 the activity of the enzyme.[137] Photopotentials of this magnitude can be comparatively readily obtained using oriented Br preparations. In order to regulate the photoactivity of KBr itself, it has been suggested that cationic amphiphiles, capable of forming double layers in the aqueous phase, be used.[138] These substances form bonds with the negatively charged groups on the purple membrane surface, which blocks the processes involving proton capture from the medium by Br. Another approach to the regulation of the properties of Br is associated with the development of gene engineering. The methods of gene engineering made it possible to obtain Br analogues in the molecules of which individual aminoacid residues have been replaced by others.[139] Hitherto 14 such mutants, whose proton transport activity and spectroscopic activities are different to those of native Br, have been obtained.

Thus a wide variety of types of membrane bioreactors, which are capable of being constructed and are suitable for carrying out a large number of industrially important processes with effective economical parameters, have been developed. Presumably a more far reaching recourse to the principles of the organisation of processes in biological systems will prove extremely useful for further development of MBr. The creation of more flexible and effective integrated membrane systems may be promoted by the employment of regulatable elements whose properties change under the influence of chemical substances, light, electric or magnetic fields, and also other types of influence. It appears of interest to investigate highly non-equilibrium MBR operating conditions under which spatial-time oscillations arise in the concentrations and fluxes of the components. A far-reaching modulation of properties can be obtained in hybrid systems incorporating particular biological complexes and funcional polymer membranes. In such systems, it is possible to control the mineralistaion of the working volumes and to normalise the supply of substrates as a result of the symport or antiport of the components transferred by the transport proteins. Br, which has extensive functional possibilities and an exceptionally high stability, is a convenient object for use in control elements. In ordered molecular assemblies, Br can play the role of a rapidly acting photoelectric and photoelectrochemical converter. The simplicity and susceptibility to technological formulation of the preparation of Br-containing membrane systems creates preconditions for their practical use. The study of the possible application in hybrid systems, apart from Br, of other energy-dependent biological complexes—the reaction centres of photosynthesising systems, transport ATPases, etc.—is also of undoubted interest.

Relaxation and Two-dimensional Phase Transitions in the Electrical Double Layer

V.A.Benderskii and G.I.Velichko

The excess entropy of formation and the characteristic relaxation times of the electrical double layer at the interface between the metal and electrolyte solution have been determined by the laser temperature jump method, consisting in the measurements of the electrical signal of an electrochemical cell on heating a metallic electrode by nanosecond laser pulses. The combination of the laser temperature jump data and data obtained by electrochemical methods shows that the orientational rearrangement of the solvent monolayer and the adsorption of surfactants occurring when the electrode potential and the solution composition are altered have the character of two-dimensional first- and second-order phase transitions.
The bibliography includes 73 references.

I. INTRODUCTION

Data obtained by classical electrochemical surface tension and differential capacitance methods serve as the experimental basis for the electrochemical double layer (EDL) theory. Their measurement at the interfaces beween electrolyte solutions and ideally polarisable metallic electrodes with atomically smooth surfaces, in particular, the mercury electrode, has ensured a quantitative descriptiion of the principal phenomena: the formation of surface excess amounts of ions in the dense and diffuse parts of the EDL and the adsorption in its inner part of dipolar solvent molecules, ions, and surfactants (see, for example, Frumkin[1] and Delahay[2]). However, in connection with the development of theoretical models of the EDL, for the testing of which it is necessary to have data on its structure and dynamic properties, it was discovered that these traditional methods have limitations. The study of the packing and orientation of the molecules and of the interactions between them, of the molecular mobility in the interface, of the change in the degree of hydration of the ions on passing from the bulk of the solution to the EDL, and of a multiplicity of similar questions stimulated the creation of new

methods. One of these is the method of the laser temperature jump (LTJ) in which the temperature coefficients of the decrease in the potential and the characteristic relaxation times of the EDL are measured. The first of these quantities is thermodynamic and in this respect the LTJ method supplements the traditional electrochemical methods. The dependences of the relaxation times on the electrode potential and the solution composition, first measured with the aid of the LTJ method, revealed a relation between the dynamics of the EDL and its structure.

The first studies of the EDL by this method were closely related to the investigation of photoemission from metals into electrolyte solutions.[3] In one of the first studies of the characteristics of the photoemission,[4] it was observed that the change in the potential of the electrode following its pulse illumination is caused not only by the emission of electrons from the metal into the solution but also by the heating of the electrode by the light absorbed in it. The pulse heating signal γ_h was separated from the photoemission signal using light at a sufficiently long wavelength for which there is no photoemission. According to Korshunov et al.,[4] γ_h exhibits a characteristic dependence on the electrode potential E and, in particular, it changes sign near the zero-change potential (ZCP). Barker and Cloke,[5] who studied the $\gamma_h(E)$ relation in greater detail, observed a shift of the zero response potential (ZRP), at which $\gamma_h = 0$, relative to the ZCP, amounting to between −0.10 to −0.15 V and being caused by the dipole potential jump. At the ZRP, the water dipoles in the inner part of the EDL undergo reorientation. Barker and Cloke[5] studied the $\gamma_h(E)$ relations in acid solutions and showed that γ_h has a constant component due to thermal diffusion.

In the first investigations,[4,5] the electrode was heated by light pulses with a duration $t_0 \gtrsim 10^6$ s, whereupon the kinetics of the heating signal are determined by the form of the pulse and the time constant of the electrochemical cell. Measurements have been made[6] of $\gamma_h(E, t)$ on laser heating ($t_0 \cong 10^{-8}$ s), which showed that in dilute electrolyte solutions in the vicinity of the ZCP, the relaxation time of the diffuse part of the EDL corresponds to the time of the diffusional displacement of ions by the Debye length, while the relaxation time of the dense part of the EDL increases sharply over a wide range of potentials close to ZRP.

It has been shown[7] that the heating signal is proportional to the derivative of the excess entropy of the EDL S^σ with respect to the charge of the electrode, i.e. S^σ has an extremum at the ZRP. In the range of potentials corresponding to the ideal polarisability of the mercury electrode, three ZRP, corresponding to two maxima and a minimum in S^σ maxima, the sharp increase in the relaxation times in their vicinity, and also the anomalies in the excess heat capacity calculated from the temperature variations of S^σ justify the hypothesis that the orientational rearrangement of the monolayer of water dipoles in the inner part of the EDL, occurring under the influence of its electric field, is a two-dimensional second-order phase transitions.[8,9]

Further investigations by the LTJ method demonstrated that the $\gamma_h(E)$ and $\tau(E)$ relations are extremely sensitive to the change in the structure of the EDL associated with the adsorption of inorganic anions and surface-active organic substances.

The question of two-dimensional phase transitions was raised in one of the first communications by Frumkin,[10] who stated that, in the presence of a strong intermolecular attraction of the adsorbed organic molecules, the adsorption layer becomes a two-phase formation in a certain range of coverages. This interaction is taken into account phenomenologically in the Frumkin adsorption isotherm by the introduction of the attraction constant, at the critical value of which a first-order phase transition occurs.[11] Application of the LTJ method established that the cooperative rearrangement of the EDL takes place as a result of transitions of different orders.

In the present review the principles of the new method and the results of its application are consistently examined for the first time.

II. PULSE HEATING OF THE METALLIC ELECTRODE

The change in the temperature of the surface of a metal in contact with a solution under the influence of a light pulse absorbed by the metal is described by the relation (see, for example, Benderskii and co-workers):[3,7]

$$\Delta T(t) = \frac{L(1-R)}{\sqrt{\pi\varkappa c\rho}}\left(1+\sqrt{\frac{\varkappa_1 c_1\rho_1}{\varkappa c\rho}}\right)^{-1}\int_0^t \frac{f(t')}{\sqrt{t-t'}}\,dt' \quad , \tag{1}$$

where κ, c, ρ, κ_1, c_1, and ρ_1 are the thermal conductivities, heat capacities, and densities of the metal and solution respectively, L is the light intensity, R the coefficient of the reflection of light by the metal, and the normalised function $f(t)$ describes the form of the laser pulse. The maximum temperature jump generated by a pulse with a duration t_0 is

$$\Delta T_m = \frac{L(1-R)}{\sqrt{\pi\varkappa c\rho}}\left(1+\sqrt{\frac{\varkappa_1 c_1\rho_1}{\varkappa c\rho}}\right)^{-1}\sqrt{t_0} \quad . \tag{2}$$

The time variation of the surface temperature at $t \gg t_0$ is independent of the characteristics of the metal and is described by the relation

$$\Delta T(t) = \Delta T_m\sqrt{\frac{t_0}{t}} \quad . \tag{3}$$

Relations (1)−(3) are valid when the thickness of the electrode d and the size of the laser spot, i.e. the diameter of the heating zone r, satisfy the condition implying that the heat is removed solely along the normal to the interface and that there is no increase in the heated area:

$$d, r \gg 2\sqrt{\frac{\varkappa}{c\rho}t} \quad . \tag{4}$$

For a liquid mercury electrode placed in an aqueous solution ($\kappa = 7.9 \times 10^{-2}$ J cm^{-1} K^{-1} s^{-1}, $c = 0.14$ J g^{-1} K^{-1}, $\rho = 13.6$ g cm^{-3}, $\kappa_1 = 5.9 \times 10^{-3}$ J cm^{-1} K^{-1} s^{-1}, $c_1 = 4.2$ J g^{-1} K^{-1}, and $\rho_1 = 1.0$ g cm^{-3}) and illuminated with light at a wavelength 500−700 nm ($R \cong 0.70$ for normal incidence), the quantity $\Delta T_m/L = 2.2 \times 10^{-5}$ K kW^{-1} cm^2 when $t_0 = 4$ ns. This estimate shows that heating of the electrode by 1−2 K is effected by a light pulse with a peak power of 50−100 kW cm^{-2}. For the working electrodes with an area of approximately 10^{-3} cm^2 usually employed in measurements, this heating can be readily achieved with the aid of the usual nanosecond lasers having a peak power of 1−10 kW.

For observation times ranging from 10^{-8} to 10^{-6} s, the thicknesses of the heated layers of the metal and solution are $10^{-5}-10^{-4}$ cm and $10^{-6}-10^{-5}$ cm respectively, which means that the temperature jumps are localised outside the EDL in the bulk of the metal solution, i.e. the LTJ signal arises in the following galvanic cell:

metallic electrode	heated zone in the metal	heated zone in the solution	solution

and has three components:

$$\gamma_h = \gamma_{h1} + \gamma_{h2} + \gamma_{h3} \tag{5}$$

determined by the thermo-e.m.f. of the metal ($\mathscr{V}_{h3}$), the thermal diffusion potential of the solution ($\mathscr{V}_{h2}$), and the temperature coefficient of the decrease in the potential of the EDL $\mathscr{V}_{h1}$. The temperature jump induces a change in the potential of the EDL due to the temperature variation of its capacitance and composition. When the time constant of the electrochemical cell is large compared with the observation time, the outer source of polarisation does not have sufficient time to alter the initial charge of the electrode q, so that $\mathscr{V}_{h1}$ is recorded under coulombostatic conditions. The following relations are valid for low values of ΔT:

$$\mathscr{V}_{h1}=\left(\frac{\partial\varphi}{\partial T}\right)_q\Delta T,\ \mathscr{V}_{h2}=\alpha\Delta T,\ \mathscr{V}_{h3}=\alpha_s\Delta T \tag{6}$$

where $(\partial\phi/\partial T)_q$ is the temperature coefficient of the decrease in the potential in the EDL. When $q = 0$, this quantity is known for a series of electrochemical systems[12,13] and is of the order of magnitude of 10^{-3} VK^{-1}, which exceeds by two orders of magnitude the coefficients of the thermo-e.m.f. α of metals, i.e. $\mathscr{V}_{h1}\gg\mathscr{V}_{h2}$. The coefficient α_s is given by [14]

$$\alpha_s=\sum_i\frac{t_i}{z_i}S_i \tag{7}$$

where S_i is the transport entropy of ions of the ith kind having a charge z_i and a transport number t_i. The values of α_s for ions without anomalous mobility are of the order of 10^{-5} VBK^{-1}, so that the contribution of thermal diffusion to the LTJ signal can also be neglected. For solutions containing the anomalously mobile hydrogen and hydroxide ions, this contribution is significant and adds to $\mathscr{V}_h$ a component which is independent of the electrode potential.[7] With this exception, the LTJ signal is determined with adequate accuracy by the characteristics of the EDL and not the bulk phases:

$$\mathscr{V}_h\simeq\left(\frac{\partial\varphi}{\partial T}\right)_q\Delta T\ . \tag{8}$$

III. TEMPERATURE COEFFICIENTS OF THE POTENTIAL DROP IN THE ELECTRICAL DOUBLE LAYER

For a constant potential and phase composition, the equation of the electrocapillary curve is

$$-\mathrm{d}\gamma=\Gamma_s\mathrm{d}T+q\mathrm{d}E_\pm+\Gamma_\mp\mathrm{d}\mu\ , \tag{9}$$

where γ is the surface tension, $\Gamma_\pm$ the relative excess surface amounts of cations and anions respectively, $E_\pm$ the potential of the electrode, measured relative to the reference electrode, reversible with respect to the cations or anions, and Γ_S the excess surface entropy defined by the relation

$$\Gamma_S=S_{int}-m_M^\sigma S_M^0-m_W^\sigma\left(S_W^0-\frac{n_S}{n_W}S_S^0\right) \tag{10}$$

where S_{int} is the specific surface entropy, m_M^σ and m_W^σ are the numbers of moles of the metal and water per unit surface area, n_W and n_S the volume fractions of water and the salt, and S_M^0, S_W^0, and S_S^0 the standard entropies of the metal, water and the salt. Instead of Γ_S, we shall introduce the excess entropy of formation of the EDL, which is equal to the difference between the entropies of the components at the interface and in the bulk phases:

$$S^\sigma=S_{int}-m_M^\sigma S_M^0-m_W^\sigma S_W^0-m_+^\sigma S_+-m_-^\sigma S_-\ , \tag{11}$$

where S_+ and S_- are the entropies of the ions at the given activity of the salt. Bearing in mind that the electrode charage is equal to the difference between the excess surface amounts of the ions, we find from Eqns.(10) and (11)

$$q=\Gamma_--\Gamma_+ \tag{12}$$

$$\Gamma_s=S^\sigma+\Gamma_\pm S_s\mp qS_\mp \tag{13}$$

For a 1:1 electrolyte, the relation between the potential measured relative to the reference electrode and the potential drop in the EDL is described by the expression

$$F\mathrm{d}E_\pm=F\mathrm{d}\varphi\mp S_-\mathrm{d}T\pm\frac{1}{2}RT\mathrm{d}\ln a\ , \tag{14}$$

where F is the Faraday. In Eqn.(14), account was taken of the fact that

$$\mathrm{d}\mu=-S_s\mathrm{d}T+RT\mathrm{d}\ln a;\ S_s=S_s^0-R\ln a,\ \frac{\mathrm{d}\mu_\pm}{\mathrm{d}\ln a}=\frac{1}{2}RT,$$

where a is the activity of the salt. On substituting Eqns.(12)–(14) in Eqn.(9), we find

$$-\mathrm{d}\gamma=q\mathrm{d}\varphi+RT\left(\Gamma_\pm\pm\frac{q}{2F}\right)\mathrm{d}\ln a+S^\sigma\mathrm{d}T \tag{15}$$

Under coulombostatic conditions, used in the LTJ measurements, the thermodynamic potential is represented by the function

$$\xi=\gamma+q\varphi\ , \tag{16}$$

and, on going over to the latter, we obtain the main relation

$$-\mathrm{d}\xi=-\varphi\mathrm{d}q+RT\left(\Gamma_\pm\pm\frac{q}{2F}\right)\mathrm{d}\ln a+S^\sigma\mathrm{d}T. \tag{17}$$

The cross differentiation of Eqn.(17) leads to the relations

$$-\left(\frac{\partial\varphi}{\partial T}\right)_{a,q}=\left(\frac{\partial S^\sigma}{\partial q}\right)_{a,T}\ , \tag{18}$$

$$\left(\frac{\partial S^\sigma}{\partial\ln a}\right)_{q,T}=R\left(\Gamma_\pm\pm\frac{q}{2F}\right)+RT\left(\frac{\partial\Gamma_\pm}{\partial T}\right)_{a,q}\ . \tag{19}$$

The first of these relations constitutes the basis of the LTJ method and follows directly from the expression for the free energy of the charged interface:

$$\Delta G^\sigma=\Delta Q_0^\sigma+\int_0^q\varphi(q)\mathrm{d}q\ , \tag{20}$$

where ΔG_0^σ describes the non-electrical component of the free energy related, in particular, to the chemisorption and interaction of the adsorbed species with one another. Eqn.(19) relates the derivative of S^σ with respect to the activity of the salt to the temperature coefficient of the surface excess amounts. Under coulombostatic conditions, the first part of Eqn.(19) is the same for the anions and cations by virtue of relation (12). Differentiation of Eqn.(19) with respect to q yields the dependence of $V_h=(\mathscr{V}_h/\Delta T)=(\partial\varphi/\partial T)_{a,q}$ on the salt concentration:

$$\left(\frac{\partial V_h}{\partial\ln a}\right)_q=-R\left[\left(\frac{\partial\Gamma_\pm}{\partial q}\right)_{a,T}\pm\frac{1}{2F}\right]-RT\left(\frac{\partial^2\Gamma_\pm}{\partial q\,\partial T}\right)_a. \tag{21}$$

It follows from Eqn.(18) that, by measuring the dependence of V_h on q by the LTJ method, it is possible to find $S^\sigma(q)$ to within a constant, which is independent of q:

$$S^\sigma(q)=S^\sigma(0)+\int_0^q V_h(q)\mathrm{d}q\ . \tag{22}$$

Eqn.(21) relates the concentration variation of V_h to the surface excess amounts of the ions and their temperature coefficients.

IV. METHODS OF MEASUREMENT

The LTJ method has been described in detail.[7] The circuit of the laser electrochemical relaxometer, designed for LTJ measurements, is illustrated in Fig.1. Heating is achieved by means of pulses from a laser based on rhodamine 6G (λ = 595 nm). At the selected light wavelength, the influence of photoemission can be neglected at electrode potentials more positive than −1.5 V.† The duration of the laser pulse is 4 ns for a peak power of 3 kW. The form of the pulse is recorded by a high-speed photocell. The laser light is focussed onto the cathode of the electrochemical cell. The LTJ signal is amplified by a broad band amplifier with a transmission band of approximately 200 mHz and is recorded by means of a stroboscopic oscillograph. When the frequency of the repetition of the laser pulses is 25 Hz, the stroboscopic conditions in the recording of the LTJ signal ensure its averaging over approximately 10^3 pulses, which makes it possible to achieve a sensitivity of the apparatus of 4×10^{-5} V, corresponding to minimum measurable values of V_h of 2×10^{-5} V K^{-1}. Further increase of sensitivity has been achieved[15] by employing a multichannel analyser in which the LTJ signal is divided by the amplitude of the laser pulse, which diminishes the error associated with the scatter of its values. Since the values of $(\partial\varphi/\partial T)_{q=0}$ for a series of solutions are known from independent electrochemical measurements,[10,11] the apparatus is calibrated directly in units of V_h and not γ_h, which eliminates the error associated with the determination of ΔT.

The working mercury electrode of the electrochemical cell (Fig.1) is made in the form of a smooth surface produced at the top of a glass capillary into which a thin platinum ring 0.35 mm in diameter has been sealed. As a result of the wetting of the ring with mercury, it is possible to avoid the appearance of capillary waves,[16] which interfere with the measurements, up to values of L = 1 MW cm^{-2}.

The $V_h(E)$ dependences are measured at a fixed instant. The delay of the instant of measurement relative to the maximum in the laser pulse is set at between 10 and 250 ns. The automatic scanning of the potential is performed after 30 − 100 s and the electrode surface is renewed after recording each $V_h(E)$ curve. The time variations of V_h are measured at constant electrode potentials. The relaxation time τ is determined by comparing the $V_h(t)$ kinetic curves with the curves calculated by Eqn.(1) for the measured form of the laser pulses. The relative values of τ for different E can be found to within 2 − 3 ns. The absolute values of τ contain a constant component which is determined by the transient characteristics of the cell and the amplifier. According to Benderskii and Velichko,[7] this component can be reduced to 5 − 10 ns. Konovalov and Raitsimring[15] succeeded in reducing its contribution to 1 − 2 ns.

In principle, the values τ may be found from the measured frequency dispersion of the differential capacitance. However, the scope of the high-frequency measurements is restricted by the time constant of the electrochemical cell, determined by the finite resistance of the volume of the electrolyte.[13,17] The maximum frequency of the measurements, attained at the present time, is 2 MHz and does not permit the observation of the relaxation of the EDL in the absence of the specific adsorption of organic substances.[17] The LTJ method is the only one which permits measurements of τ shorter than 10^{-6} S.

Eqn.(8) established a relation between V_h and the temperature coefficients of the differential capacitance of the EDL:

$$V_h = \left(\frac{\partial\varphi}{\partial T}\right)_{q=0} + \int_0^q \frac{\partial}{\partial T}\left(\frac{1}{C}\right) \mathrm{d}q \ . \qquad (23)$$

$$\frac{\partial V_h}{\partial q} = \frac{\partial}{\partial T}\left(\frac{1}{C}\right) \ . \qquad (24)$$

The validity of these relations in aqueous 0.5 M NaF solutions, for which the values of $\partial/\partial T(1/C)$ are known,[18,19] has been confirmed.[7] The $V_h(E)$ relations, measured by the LTJ method in aqueous 0.5 M NaF solution, agree with the relations calculated from the electrochemical data available for this solution,[18,19] which constitutes a test of the method. It must be emphasised that the accuracy of the determination of $V_h(E)$ from the temperature coefficients of the differential capacitance of the EDL is much lower than in the LTJ method. Despite the high accuracy of the measurement of C, reaching values to within 0.1 and 0.2% (see, for example, Charles et al.[20]),

† The potentials are read relative to the potential of the saturated calomel electrode.

the error in the measurements of $\partial C/\partial T$ is 5–10% owing to the smallness of the changes in C with temperature (0.01–0.10 F K^{-1}); integration with respect to E of the variable-sign function $\partial C/\partial T$, which enters into Eqn.(23), leads to errors in V_h up to 10–20%, increasing in the region of positive potentials under absorption conditions as a consequence of the increase in C. For this reason, there have been few calculations of the $S^\sigma(q)$ relations from electrochemical data.[20-23] Such measurements have been confined to the region of comparatively low positive charges ($q \leqslant 10$ μC cm^{-2}) and did not permit the discovery of a number of features of the EDL observed by the LTJ method.

V. THE LASER TEMPERATURE JUMP IN DILUTE ELECTROLYTE SOLUTIONS

According to the Gouy–Chapman theory, V_h is the sum of the temperature coefficients of the potential drop in the dense (φ^{M-2}) and diffuse (φ_2) parts of the EDL:

$$\left(\frac{\partial\varphi}{\partial T}\right)_q = \left(\frac{\partial\varphi^{M-2}}{\partial T}\right)_q + \left(\frac{\partial\varphi_2}{\partial T}\right)_q \qquad (25)$$

and the latter is given by

$$\left(\frac{\partial\varphi_2}{\partial T}\right)_q = \frac{\varphi_2}{T}\left(1 - \frac{kT}{e\varphi_2}\tanh\frac{e\varphi_2}{2kT}\right) . \qquad (26)$$

By measuring the dependence of V_h on q at different activities of the electrolyte and using Eqns.(25) and (26), two main postulates of the EDL theory have been tested:[7,24,25] the independence of the structure of the dense part of a, i.e. the constancy of $(\partial\varphi^{M-2}/\partial T)_q$ when a varies, and the validity of Eqn.(26), according to which the dependences of V_h on $(\partial\varphi_2/\partial T)_q$, calculated from Eqn.(26) for a different q should be represented by straight lines with identical slopes of unity. A similar method of testing the EDL theory has been used in the analysis of the differential capacitance curves.[2] The excess entropy of formation of the diffuse part of the EDL is

$$\Delta S_2 = -q\frac{\varphi_2}{T}\left(1 - \frac{3kT}{e\varphi_2}\tanh\frac{e\varphi_2}{4kT}\right) . \qquad (27)$$

If the theory is valid and ΔS^{M-2} is constant at different electrolyte activities, the relations between S^σ and ΔS_2 should be represented, as in the case of V_h, by straight lines with a slope of unity.

The $V_h(E)$ relations for the mercury electrode in aqueous NaF solutions with different electrolyte concentrations intersect at one point corresponding to the ZCP. As shown in Fig.2, the relations between V_h and $(\partial\varphi_2/\partial T)$ agree well with Eqns.(25) and (26) for $E \lesssim -0.1$ V. In the region of more positive potentials, the deviations exceed somewhat the insignificant adsorption of the fluoride ions. The excess entropy of formation of the EDL diminishes as the solution is diluted. The experimental relation between S^σ and ΔS_2 corresponds to the Eqn.(27).

Thus the results of the measurements agree well with the classical theory of the diffuse double layer in dilute electrolyte solutions (at concentrations below 0.1 M) in the absence of specific adsorption. Previously this theory was repeatedly confirmed by differential capacitance measurements (see, for example, Delahay[2]) and the LTJ method has made it possible to demonstrate that the thermal characteristics of the EDL are also described satisfactorily by it. It is noteworthy that the LTJ method not only yields an independent test of the theory of the concentration-dependent diffuse double layer but also makes it possible to find the values of φ_2 under conditions remote from the ZCP, where the influence the electrtolyte concentration on the CE curves is weakest and the accuracy of the determination of φ_2 by the differential capacitance method is reduced.

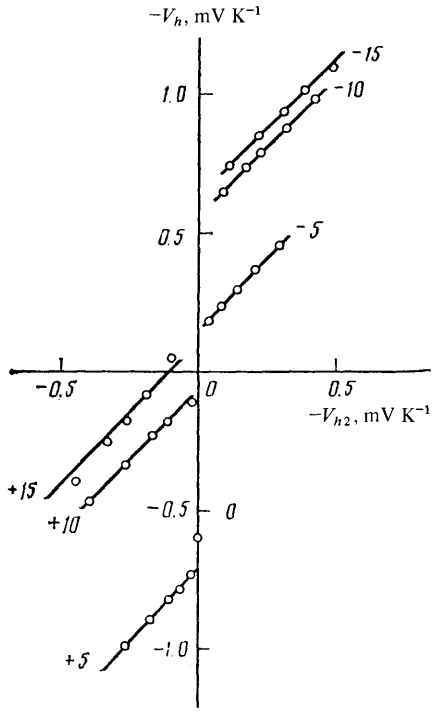

Figure 2. Dependence of V_h on $(\delta\Phi_2/\delta T)_q$ for different electrode charges (indicated in the figure in μC cm^{-2}); the continuous lines correspond to Eqns.(25) and (26).[25]

The kinetics of the LTJ signal in dilute solutions have been investigated in a study[6] where it has been shown that a slow increase in $V_h(t)$ takes place in the vicinity of the ZCP and that the characteristic time of the increase rises in inverse proportion to the electrolyte concentration. The theoretical description of the relaxation of the diffuse part of the EDL, based on the simultaneous solution of the continuity equations for the currents due to ions of both signs and the Poisson equation, shows that the spatial-time variation of the charge density is described by the same equation as the relaxation of the Debye atmosphere.[26] For a low initial change in the potential, its decrease takes place with a characteristic time given by

$$\tau_d = \varkappa^2 D,\ \varkappa^2 = \frac{8\pi e^2 a}{\varepsilon kT} , \qquad (28)$$

where $\varkappa^{-1}$ is the Debye length and D the coefficient of the dipolar diffusion of ions. The characteristic EDL relaxation times in the vicinity of the ZCP, measured by Benderskii et al.,[6] increase from 10 to 50 ns if the electrolyte concentration is reduced from 0.01 to 0.002 M, i.e. the $\tau_d(a)$ relation agrees with Eqn.(28).

As stated above, in the classical EDL theory it is assumed that the properties of its dense part in the absence of specific adsorption are independent of the electrolyte concentration. To test this principal hypothesis of the theory, measurements have been made[27] by

the LTJ method of the $V_h(E)$ relation in KF solutions at concentrations ranging from 1 to 12 M. A characteristic feature of this electrolyte[28] is the independence of the ZCP of the salt concentration and the insignificant increase in the differential capacitance for high negative charges ($q < -15$ μC cm^{-2}). Its more appreciable increase at $q \geqslant 0$ is attributed to the partial dehydration of the fluoride ions in such concentrated solutions, which dimishes the effective thickness of the EDL. According to Benderskii et al.,[27] the $V_h(E)$ and $S^\sigma(q)$ relations are also relatively insensitive to the KF concentration. Furthermore, the relaxation characteristics of the EDL hardly change, which means that the aqueous layer in the inner part of the EDL remains unaltered even at such high concentrations of the specifically non-adsorbable ions where the number of molecules in the bulk of the solution is no longer sufficient for the formation of the hydration shells, which are produced in dilute solutions.

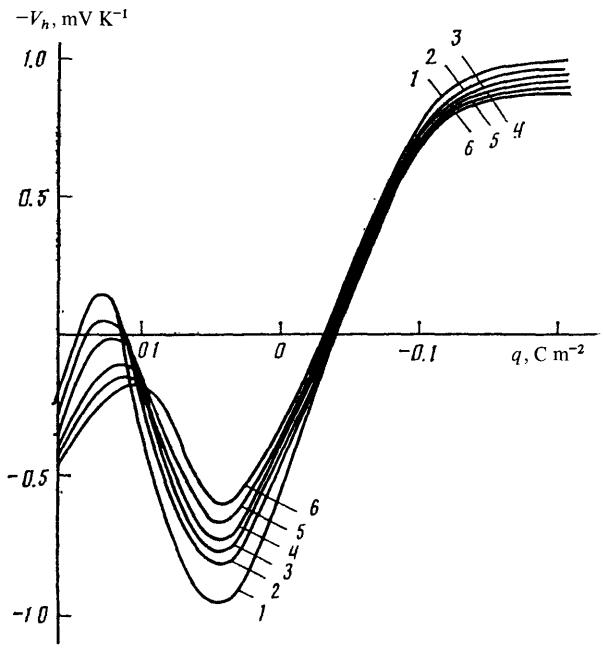

Figure 3. The $V_q(q)$ relations at different temperatures (°C): 1) 10; 2) 20; 3) 30; 4) 40; 5) 50; 6) 60; mercury electrode in aqueous 0.9 M NaF solution.[9]

At first sight, the agreement with experiment of the simple EDL theory over such a wide range of electrolyte concentrations is surprising bearing in mind that concentrated solutions are not described by the Debye–Hückel theory, which constitutes the basis of the simple EDL theory. The main reason for the observed agreement is apparently the independence of the structure of the dense part of the EDL of the electrolyte concentrations, by virtue of which a sharp dependence of the dielectric characteristics on the concentration and size of the ions, predicted by modern electrolyte models (see Carnic and Torrie's review[29]), is not manifested in the observed integral characteristics of the EDL.

VI. THE EXCESS ENTROPY AND HEAT CAPACITY OF THE DENSE PART OF THE ELECTRICAL DOUBLE LAYER

As can be seen from Figs.3 and 4, in the absence of specific adsorption, the $V_h^{M-2}(E)$ curves for the mercury electrode have three ZRP, implying that the dependence of the excess entropy of formation of the dense part of the EDL on the electrode charge is characterised by a minimum and two maxima in the vicinity of which there is a sharp increase in the relaxation time. With increase in temperature, the $S^\sigma(q)$ curves becomes gradually symmetrical relative to the $q = 0$ axis: the maximum and minimum in S^σ in the vicinity of $q > 0$ disappear above 40 °C, while the maximum at $q < 0$ shifts from -4.2 to -3.6 μC cm^{-2} in the range 0–65 °C.[8,9]

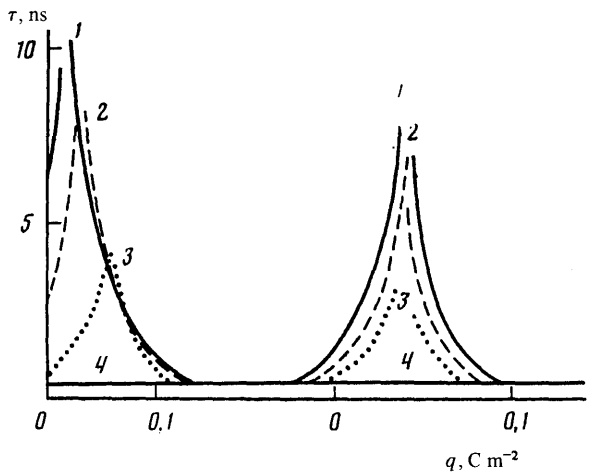

Figure 4. $\tau(q)$ relations at different temperatures °C: 1) 10; 2) 20; 3) 40; 4) 60; mercury electrode in aqueous 0.96 M NaF solution; accuracy of the measurement of τ to within 2 ns.[9]

The excess heat capacity of formation of the dense part of the EDL, given by

$$c^\sigma = T\left(\frac{\partial S^\sigma}{\partial T}\right)_{q,a} . \qquad (29)$$

has been found[9] from the temperature variation of $S^\sigma(q)$. The $S^\sigma(q)$ and $c^\sigma(q)$ relations at different temperatures are presented in Fig.5.

The properties of the dense part of the EDL are determined by the monolayer of the dipolar solvent molecules adsorbed on the metal.[1] By virtue of the interaction of the dipoles with the EDL field and with one another and also by virtue of specific adsorption forces, this two-dimensional layer undergoes orientational ordering. The orientation of the dipole depends on the field strength in the inner part of the EDL, i.e. on the charge of the electrode, which leads to a non-linear $q(E)$ relation. The decrease in the potential within the dense part of the EDL can be represented in the form

$$\varphi = \frac{\delta}{\varepsilon} q + \frac{Np}{\varepsilon} f(q) , \qquad (30)$$

where δ is the effective thickness of the dense part of the EDL, ε is its dielectric constant in the absence of orientational polarisation, determined by the molecular polarisability of the solvent molecules, and N and p are the surface density and the dipole moment of the

solvent molecules. The function $f(q)$ characterises the degree of orientation of the dipoles. In strong electric fields (for $q \to \pm\infty$), the dipoles are fully oriented and $f = \pm 1$, so that, for constant δ/ε and Np/ε, f becomes a linear function of q. According to Trasatti,[30,31] the $\varphi(q)$ curves for aqueous electrolyte solutions are not only linear but also have the same slope for different *sp* metals in the region of high negative potential ($q \leqslant -10$ μC cm^{-2}), which indicates the universality of Eqn.(30).

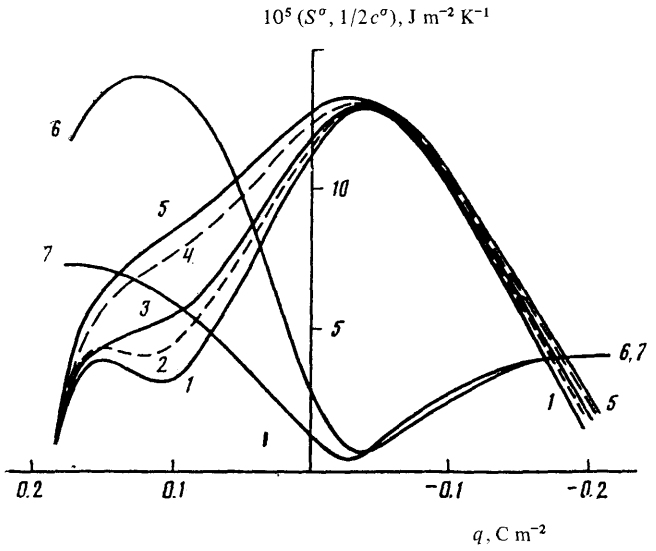

Figure 5. $S^\sigma(q)$ (curves *1*–*5*) and $c^\sigma(q)$ (curves *6* and *7*) relations at different temperatures (°C): 1) 10; 2) 20; 3) 40; 4) 60; 5) 70; 6) 15; 7) 65; mercury electrode in aqueous 0.96 M NaF solution.[8]

In the initial model of the two-dimensional,[32] two possible dipole orientations were considered. In this case f is determined by the numbers of dipoles oriented along the electric field and in opposition to it and in the case of isolated dipoles is described by the relation

$$f = \frac{N_+ - N_-}{N} = \tanh u, \quad u = \frac{p}{\varepsilon kT}(q - q^*) \ . \tag{31}$$

For $q = q^*$, both orientations are equally probable and $f = 0$. The characteristic charge q^* is non-zero as a consequence of the difference between the free energies of adsorption for the two orientations. The potential at which $q = q^*$ is identical with the ZRP, because the orientational entropy is a maximum for $N_+ = N_-$. The $\tau(q)$ relation is described by the expression

$$\tau = \frac{\tau_0}{\cosh u} \tag{32}$$

and also has a maximum equal to τ_0 at $q = q^*$. Thus in the two states model the ZRP is universal for all metals for which Eqn.(30) holds and corresponds to the absence of a dipole potential jump, i.e. to $f = 0$.

Since the two states model does not lead to a quantitative description of the differential capacitance curve (*CE* curves) at different temperatures, models have been developed with a larger number of states (see, for example, Refs.33–38) taking into account the possibility of the formation of dipolar associated species in the two-dimensional layer.‡ In the presence of n states of the $2d$ layer, the number of ZRP is at least $n - 1$ regardless of the characteristics of these states.[39] Each of them corresponds to a local entropy maximum determined by the equality of the probabilities of two definite states. For example, in the three states model[37] (two opposite orientations of the dipoles and their aggregates which have no moment), the $S^\sigma(q)$ relation should have two maxima corresponding to the conversion of the dipoles into aggregates. Curves *1* and *2* shown in Fig.5 can be regarded as experimental proof of the existence of at least three states of the water dipoles in the two-dimensional layer. However, the $\tau(q)$ relations do not agree with the hypothesis of the existence in the two-dimensional layer of isolated water molecules and their low-molecular-weight associated species, because in this case, as in the two level model, the decrease in $\tau(q)$, like that in $S^\sigma(q)$, is determined by u and may occur over a wide range of q values. The pronounced $\tau(q)$ relation is clearly not described by Eqn.(32) and indicates a cooperative character of the rearrangement of the $2d$ layer at the ZRP, which is not described by the models put forward in the literature.[32–39] It has been suggested[8,9] that, in the region located between the ZRP ($q_1 < q < q_2$, q_1 and q_2 correspond to the ZRP), there exists below 40 °C an ordered state of the water molecules of the type of two-dimensional ice, which is decomposed by the electric field at the ZRP as a result of the reorientation of the dipoles. The disruption of the antiferromagnetic ordering in strong magnetic fields is an analogue of this process.[40] The free energy of an ordered state of the antiferroelectric type increases with increase in $|q - q_0|$ (q_0 corresponds to the minimum in S^σ) and a structural phase transition to a paraelectric state, whose energy diminishes with increase in $|q - q_{1,2}|$, occurs at the points q_1 and q_2. Above 60 °C, the paraelectric state exists at all values of q, which is indicated by the disappearance of the ZRP, corresponding to q_1 and q_0, and of the $\tau(q)$ peaks. The $S^\sigma(q)$ and $c^\sigma(q)$ relations in this state agree with relations calculated in terms of the molecular field approximation[41] for reasonable values of the parameters: $p = 1.3$ D and $N = 2 \times 10^{15}$ cm^{-2}.[9] The fluctuation theory of phase transitions has been used for the description of the $2d$ layer at lower temperatures.[8,9] The singular part of the free energy in the critical region Φ_S is a function of the parameter $A(T - T_c)$,[43] in which A and the critical temperature T_c depend on $(q - q_0)^2$, provided that the order parameter $l \propto (q - q_0)^2$. The equation for the critical values, $A(T - T_c) = 0$, has two roots:

$$q_{1,2} = q_0 \pm \Delta(T) \ . \tag{33}$$

The $\Phi_S(q)$, $l(q)$, and $\tau(q)$ relations are determined by the values of the universal critical indices:

$$\Phi_S \propto U^{2-\alpha}, \ l \propto U^{\beta}, \ \tau^{-1} \propto \frac{\partial^2 \Phi_S}{\partial l^2} \propto U^{2-\alpha-2\beta}, \qquad U = B(T)\,|\,(q - q_0)^2 - \Delta^2(T)\,| \ , \tag{34}$$

where $B(T)$ is a non-singular function of temperature. It follows from Eqn.(34) that the increase in the relaxation time should occur at the points q_1 and q_2, where the order parameter l becomes zero,

‡ Despite the difference between the numbers of states and the values of the parameters (the adsorption energies, the dipole moments, N and ε), all these models make it possible to describe satisfactorily the *CE* curve at different temperatures, which, rather than indicating the reliability of these models, is more likely to be evidence for the insensitivity of the experimental data to their choice, associated with the large number (5–7) of parameters, which are in essence adjustable.

and $S^{\sigma}(q)$ is a maximum. In agreement with the hypothesis of the universality of the critical indices, the values of $\gamma = 2 - \alpha - \beta$ are identical at the points q_1 and q_2 and amount to approximately 0.7.

It is noteworthy that at the critical points the maxima in the second derivatives of Φ_S with respect to q and T (the differential capacitance, V_h, and c^{σ}), which are the usual signs of second-order phase transitions, are not observed. The absence of singularities on the curves indicated can apparently be accounted for by the fact that they are determined by the low critical index α, which may be close to zero for two-dimensional systems.[42] On the other hand, the $\tau(q)$ singularities are determined by the larger critical index γ and for this reason are easier to observe experimentally. Furthermore, the ordered state of the non-commensurate lattice on the surface of the liquid metal is most likely to be appreciably converted into an amorphous form, which widens the region of the transition. This is indicated, in particular, by the higher heat capacity of the antiferroelectric state compared with the paraelectric state (Fig.5).

The phase transitions in the two-dimensional layers have been the subject of vigorous research (see Vilches' review[44]) and in this connection one may point to a series of systems whose behaviour is close to that of the new EDL model proposed by Benderskii and co-workers.[8,9] For example, the transition from the planar to the perpendicular oreintation of nitrogen[45] and ethane[46] molecules as well as the dimerisation of nitric oxide[47] have the character of phase transitions. In most cases the lattice parameteers of two-dimensional crystals close to the three-dimensional parameters are incommensurate with the lattice of the support. On the basis of these data, one can hardly be surprised that water molecules on the surface of metals are capable of forming an ordered structure.

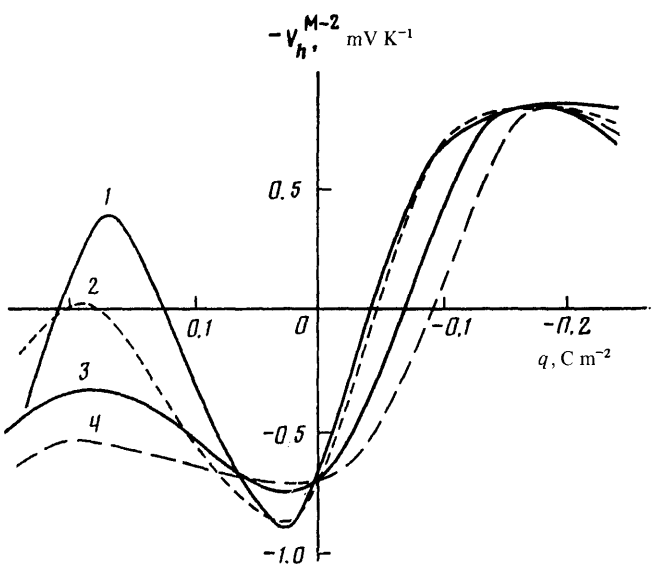

Figure 6. $V_h^{M-2}(q)$ relations at the interface between the mercury electrode and 1 M aqueous solutions of different salts: 1) KF; 2) KCl; 3) KBr; 4) KI.[50]

The values of τ in the vicinity of the ZRP, measured[7] for different *sp* metals, amount to $10^{-7}-10^{-8}$ s, while in the ordering region they do not exceed 3×10^{-8} s. Comparison of these values with the dipolar relaxation times in liquid water ($\sim 10^{-11}$ s) and in ice crystals ($\sim 10^{-5}$ s at 0 °C) makes it possible to infer the mobility of water molecules at the interface. The rotation of dipoles in ice crystals is due to the translational movement of Bjeruum defects.[48] In the cavities within vitreous ice, the rotational relaxation time at -10 °C is approximately 10^{-10} s.[49] Presumably at $q \leqslant 0$, where water molecules form M–O bonds with the surface, the rotation of the dipoles does not entail the rupture of these bonds and takes place similarly to relaxation in liquid water and not in the crystal.

In conclusion of this Section, we shall deal with the question of the correspondence of the ZRP and the potential at which there is no dipole jump. As stated above, these potentials agree only in the two state model. For $n > 2$, in the general case none of the ZRP correspond to $f = 0$ and the identification of the ZRP for $q < 0$ with the potential at which $f = 0$, postulated in a number of investigations,[22,30,31,35] requires a more careful study, like the determination of the dipole jumps at the ZCP based on it. The latter jumps are regarded as a measure of the hydrophilicity of metals.[1,30] The difference between ZCP and ZRP (for $q < 0$) diminishes with increase in hydrophilicity in the sequence Hg, Pb, Bi, Cd, Ga. The values of $-q_2$, corresponding to the ZRP, decrease in the same sequence as a result of the increase in the slope of the qE curves in the region of low values of q.[7]

VII. ADSORPTION OF ANIONS

The $V_h(E)$ curves for aqueous KCl, KBr, and KI solutions (Fig.6) differ in the region of the adsorption of halide ions.[50] In analysing these curves, it is necessary to take into account the contribution to $(\partial\varphi_2/\partial T)$ by the temperature coefficients of the excess adsorbed surface anions:

$$\left(\frac{\partial q_1}{\partial T}\right)_q = q_1 \frac{\Delta G_a}{RT}(1 + B_2\Gamma_i)^{-1}, \qquad (35)$$

where $q_1 = F\Gamma_i$, Γ_i is the surface excess, ΔG_a the free energy of adsorption, and B_2 the second virial coefficient, which is known from electrochemical data.[51]

The $S^{\sigma}(q)$ relations, found taking into account the correction defined by Eqn.(35), are illustrated in Fig.7. The adsorption of anions leads not only to a decrease in S^{σ} but also to the disappearance of the ZRP in the region $q > 0$, which is accompanied by the simultaneous disappearance of the relaxation time peak. The $\tau(q)$ peak is retained in 1 M KCl solution at $q < 0$ but its width becomes smaller than in the fluoride solution. In the region of the adsorption of BR^- and I^-, an increase in τ to 5–6 and 8–10 ns respectively is observed. The disappearance of the $S^{\sigma}(q)$ minimum shows that the specific adsorption of ions disrupts the ordered state of the two-dimensional layer, in particular as a consequence of the change in the orientation of the dipoles participating in the formation of the hydration shells of the adsorbed ions.§ Within the framework of the theory,[42] the introduction of impurities into the 2*d* layer decreases the critical transition temperature, which is taken into account in Eqn.(33) by the function ΔT, which depends on the degree of coverage θ:[54]

$$\frac{\Delta(T,\theta)}{\Delta(T,0)} = \begin{cases} 1-\theta, & \theta \ll \theta_c, \\ |\theta - \theta_c|^{f_c}, & \theta \propto \theta_c, \end{cases} \qquad (36)$$

§ It has been suggested[52,53] that the hydration shells of ions do not undergo major distortion on adsorption. Quantum-chemical calculation[53] has shown that the disposition of the ion and free water molecules in a single plane corresponds to the minimum energy of the hydrated Cl^- anion.

where θ_c is the permeation threshold at which the transition disappears and t_c is the critical index of the breakdown of the transition. In this model the disordering of the two-dimensional layer takes place, judging from the disappearance of its cooperative rearrangement at the ZRP already at comparatively low degrees of coverage ($-q_1 = 3-5$ μC cm^{-2}) corresponding to average distances of 2–3 nm between the adsorbed ions. The EDL relaxation time in the adsorption region is apparently determined by the movement of the adsorbed ion and its higher value compared with the Debye relaxation time characterising the relaxation of ions in the diffuse part of the EDL (see above) reflects the decrease in the mobility of ions and their hydration shells on adsorption.

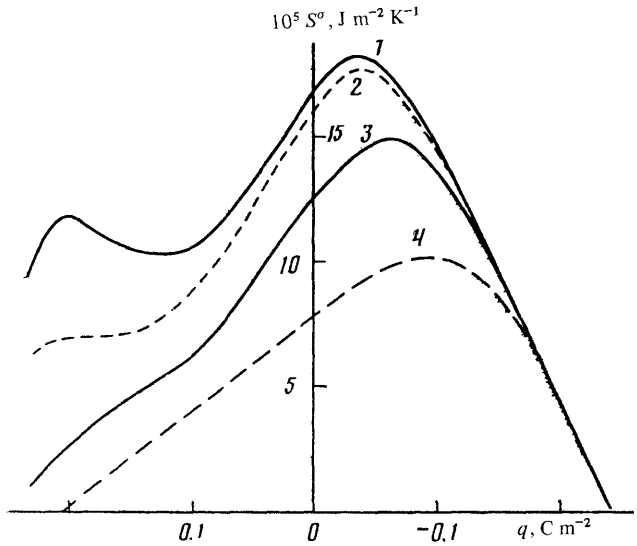

Figure 7. $S^\sigma(q)$ relations at the interface between the mercury electrode and 1 M aqueous solutions of different salts: 1) KF; 2) KCl; 3) KBr; 4) KI.[50]

The values of B_2 can be found by comparing the $S^\sigma(q)$ curves in solutions of specific adsorbable ions and in the solution where there is no adsorption. The values of B_2 have been obtained[50] for Br^- and I^- (2.2×10^{-14} and 3.3×10^{-14} cm^2 respectively), which agree with other data,[20,55] and the relation between B_2 and q for Cl^-, noted by Charles et al.,[20] has been confirmed. Because of the repulsion of the adsorbed ions, their distribution on the surface with increasing Γ_i ceases to be random, which entails a decrease in S^σ. The increase in the electric field strength of the EDL, i.e. in q, causes disordering in the distribution of the adsorbed ions in the two-dimensional layer, i.e. a decrease in B_2.

The negative Gibbs adsorption of chloride ions at the interface between the mercury electrode and concentrated LiCl solutions, in which the activity of the salt changes almost by three orders of magnitude when its concentration c_S is raised from 1 to 12 M, ensuring a broad region in which the thermodynamic relations (19) and (21) can be tested, has been investigated[56] by the LTJ method. With increasing c_S, the $V_h(E)$ curves shift to the region of more negative potentials (Fig.8), the ZRP being located in the region more negative by 0.15–0.30 B than the ZCP, the difference between these potentials increasing, i.e. the maximum entropy occurs for more negative charges.

The shift of the ZRP is accompanied by a shift of the EDL relaxation region, the width of the $\tau(E)$ peak decreasing and the values of τ increasing. The $(\partial S^\sigma/\partial \ln c)_{q,T}$ for a concentrated LiCl solution do not agree with Grahame's theory not only in magnitude but also in sign. The temperature coefficients of the surface excess amounts found from Eqn.(19) for $q < -5$ μC cm^{-2} are $(\partial\Gamma_\pm/\partial T)_q > 0$ [according to Grahame's theory $(\partial\Gamma_\pm/\partial T)_q < 0$] and their absolute values are more than an order of magnitude greater than expected. Negative values of the theoretical coefficients are associated with the fact that an increase in temperature tends to equalise the ion concentrations in the solution and in the double layer. The observed positive values of $(\partial\Gamma_\pm/\partial T)_q$ imply that the excess surface amounts of ions of both signs are negative. Thus the sign of $(\partial\Gamma_\pm/\partial T)_q$ is a direct consequence of the negative adsorption of the salt for $q < 0$ noted in the literature.[28,57] In Grahame's theory the presence of non-adsorbable ions at the interface and in the bulk of the solution for $q = 0$ is assumed to be equally probable. Evidently this approximation breaks down if the hydration conditions in the bulk phase and at the interface are different. Such difference arises in concentrated electrolyte solutions where the number of water molecules is insufficient for the construction of the hydration shells of the ions.

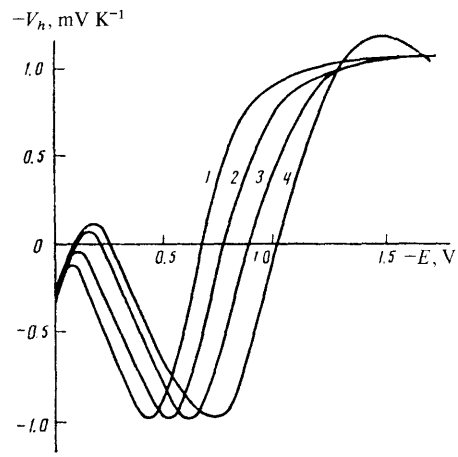

Figure 8. $V_h(E)$ relations at the mercury–concentrated aqueous LiCl solutions interface; LiCl concentration (M): 1) 1; 2) 4; 3) 8; 4) 13.7.[56]

In contrast to Grahame's theory, there is a broad range of values of q where the increase in c_S diminishes S^σ as a consequence of the ordering of the ionic component [of the EDL?], possibly on formation of a layered structure.[58] The retention of the form of the $V_h(q)$ curves and the EDL relaxation in the region of the ZRP for high values of c_S implies that water molecules remain in the inner part of the EDL even in very concentrated solutions which is also due to the negative adsorption of the salt.

If the water layer were located between the outer and inner Helmholtz planes, the shift of the ZRP should have corresponded to the constancy of $q + q_1$ and the charge at the ZRP should have increased with increase in $-q_1$, whereas in fact q diminishes. This means that the layer of water molecules is located between the metal and the inner Helmholtz plane (the plane corresponding to the maximum approach by the adsorbed ions). This hypothesis agrees with the data indicated above demonstrating a comparatively small deformation of the hydration shells of ions on adsorption.

VIII. ADSORPTION OF ORGANIC SUBSTANCES

The principal difference in the LTJ in the case of the adsorption of organic surfactants (OS) consists in the constancy of their surface excess Γ under the conditions of the pulse heating of the electrode, which is responsible for the short duration of the heat pulse compared with the time of attainment of the adsorption-desorption equilibrium and follows directly from the frequency dependence of the initial capacitance $C_1 = (\partial\Gamma/\partial E)(\partial\Gamma/\partial q)^{-1}_{T,c}$. This capacitance is observed at frequencies below 10^4 Hz,[59] while the times of the LTJ measurements do not exceed 10^{-6} s. For this reason, LTJ refers to non-equilibrium conditions relative to the bulk of the solution. On the other hand, in the heated layer near the electrode, there is sufficient time for diffusion to establish equilibrium between the surface excess and the OS concentration, i.e. the LTJ is measured under conditions described by the thermodynamic potential corresponding to the q, T, and Γ variables. For this potential, we have

$$V_h = \left(\frac{\partial\varphi}{\partial T}\right)_{q,\Gamma} = -\left(\frac{\partial S^\sigma}{\partial q}\right)_{T,\Gamma} . \quad (37)$$

In Eqn.(7), the component of V_h due to the thermal diffusion of the OS is neglected. In order to determine S^σ, it is necessary to convert the values of V_h into the derivative $(\partial S^\sigma/\partial q)_{T,c}$ measured at a constant OS volume concentration and not at a constant Γ. This change in the variables q, T, and μ leads to the relation

$$\left(\frac{\partial\varphi}{\partial T}\right)_{q,\Gamma} = \left(\frac{\partial\varphi}{\partial T}\right)_{q,c} + \left(\frac{\partial\varphi}{\partial \ln c}\right)_{q,T}\left(\frac{\partial \ln c}{\partial T}\right)_{q,\Gamma} , \quad (38)$$

which has been obtained[60] by the standard method involving the transformation of the variables of the thermodynamic functions[43] (p.83). On the assumption that the adsorption isotherm is congruent relative to the electric variable,[59] it can be expressed in the form

$$c\cdot\exp(-G_a/RT) = f(\Gamma) , \quad (39)$$

where ΔG_a is the free energy of adsorption, which depends on q but is independent of Γ. It follows from Eqns.(38) and (39) that

$$\left(\frac{\partial S^\sigma}{\partial q}\right)_{T,c} = -V_h + \frac{\Delta G_a}{T}\left(\frac{\partial\Gamma}{\partial q}\right)_{T,c} . \quad (40)$$

The surface pressure[2]

$$\Pi = RT\Gamma_m f(\Gamma) , \quad (41)$$

where Γ_m is the maximum coverage, corresponds to the isotherm (39). According to Everett,[61] we have

$$\left(\frac{\partial\Pi}{\partial T}\right)_\Gamma = -\Gamma_m\theta^2\left(\frac{\partial S^\sigma}{\partial\theta}\right)_{T,c} , \quad (42)$$

where $\theta = \Gamma/\Gamma_m$ is the degree of coverage. A relation between ΔG_a and the molar entropy of adsorption S_a follows from Eqns.(39) and (42):

$$S_a = \left(\frac{\partial S^\sigma}{\partial\Gamma}\right)_{T,c} = S_a^0 + \frac{\Delta G_a}{T} - R\ln c , \quad (43)$$

where S_a^0 is the part of the molar entropy of adsorption determined by the change in the internal degrees of freedom of the adsorbate. If structural changes in the adsorbate molecules, caused by their interaction, take place in the course of surface coverage, S_a^0 is a function of Γ. On substituting Eqn.(43) in Eqn.(40) and integrating with respect to q taking into account the fact that desorption takes place at high negative electrode potentials ($\Gamma = 0$ at $q \to -\infty$), we find

$$S^\sigma = S_1^\sigma + \Delta + S_\infty - R\Gamma\ln c , \quad (44)$$

where

$$S_1^\sigma = \int_0^\Gamma S_a^0\,d\Gamma, \quad \Delta = \int_{-\infty}^{q}\frac{\Delta G_a}{T}\left(\frac{\partial\Gamma}{\partial q}\right)_{T,c} dq . \quad (45)$$

S_∞ is the integration constant. Integration of Eqn.(40) under the same conditions yields

$$S^\sigma = S_h + \Delta + S_\infty , \quad (46)$$

where

$$S_h = -\int_{-\infty}^{q} V_h(q)\,dq . \quad (47)$$

Eqns.(44) and (46) establish a relation between S_h (the integral of V_h) and S^σ and its structural components S_1^σ:

$$S_h = S_1^\sigma - R\Gamma\ln c . \quad (48)$$

It follows from Eqn.(48) that the $S_h(q)$ relation describes the change in the EDL structure and is independent of the configurational component S^σ, which is given by $S_2^\sigma = \Delta - R\Gamma\ln c$. Since S_2^σ usually exceeds S_1^σ severalfold,[60] the $S_h(q)$ curves, i.e. the LTJ data, contain more information permitting the discovery of the structural changes in the EDL than the $S^\sigma(q)$ curves. The logarithmic dependence of S_h on the OS concentration is due to the definition of S^σ as the difference between the entropies of the components on the surface and in the bulk phases in the standard state, the transition to which corresponds to a change in $S = S^0 - R\ln c$. The above thermodynamic analysis is valid when the function $S^0(q)$ is continuous, which can be tested experimentally. If there are no jumps in S^σ in the region of adsorbability, the relation

$$\int_{-\infty}^{+\infty}[V_h(q, 0) - V_h(q, \Gamma)]\,dq = 0, \quad (49)$$

which follows from the condition that the values of S^σ are identical regardless of adsorbability of all OS concentrations, is valid.

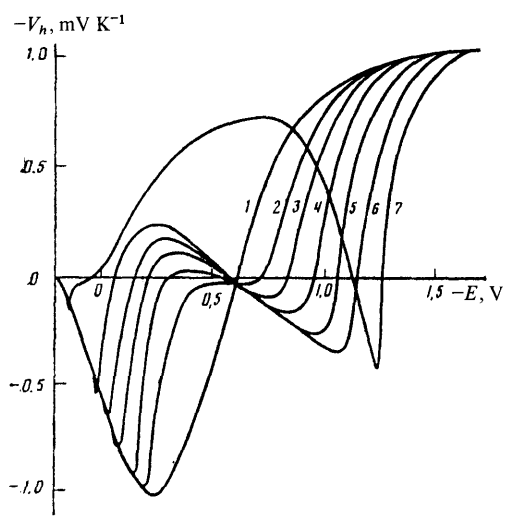

Figure 9. $V_h(E)$ relations at the interface between the mercury electrode and 1 N aqueous Na_2SO_4 solution with added n-pentyl alcohol at concentrations of 0, 5×10^{-3}, 1×10^{-2}, 1.5×10^{-2}, 3×10^{-2}, 5×10^{-2}, and 0.15 M (curves *1*–*7* respectively).[62]

The adsorption of aliphatic n-alcohols ranging from C_3 to C_6 on the mercury electrode has been investigated by the LTJ method.[60,62] Typical $V_h(E)$ relations are presented in Fig.9. With increase in the OS concentration, the deviations from the background V_h^0 curve

increase. For $\Gamma \cong \Gamma_m$, a second $V_h(E)$ section, with a constant positive slope corresponding to a quadratic $\Delta G_a(q)$ relation, appears. In the region of adsorbability, there are three ZRP.

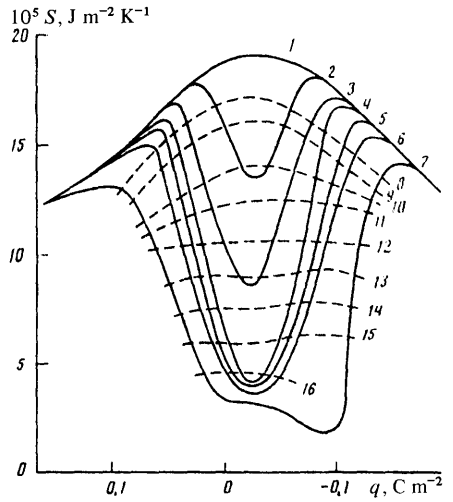

Figure 10. $S_h(q)$ relations in the adsorption of n-pentyl alcohol on the mercury electrode from aqueous 1 N Na_2SO_4 solution with the same OS concentrations as in Fig.9; the dashed curves *8—16* represent the $S^{\sigma}_{\Gamma}(q)$ relations for constant degrees of coverage ranging from 0.1 to 0.9 in 0.1 steps respectively.[60]

The extreme two of these potentials coincide with the potentials of the maxima on the $C(E)$ differential capacitance curves and correspond to degrees of coverage $\theta_c \cong 0.5$. The $V_h(E)$ curves for different c intersect at approximately one point corresponding to the maximum adsorption potential. A typical $S_h(q)$ relation is illustrated in Fig.10 and demonstratres the presence of two maxima and a minimum in the structural entropy of the EDL. The validity of Eqn.(48) has been verified.[60] The values of Γ_m found from the linear sections of the $S_h(\ln c)$ curves agree with the results of electrochemical measurements.[59] Fig.10 also presents the $S^{\sigma}_h(q)$ relations for constant Γ, calculated from the $S_h(q, c)$ curves by Eqns.(45) and (46) using the parameters of the adsorption isotherms taken from Damaskin et al.[59] The change in the form of the curves with increasing Γ shows that, for $\theta \gtrsim 0.4$, the adsorption of aliphatic alcohols cannot be regarded as the substitution of isolated water molecules by isolated OS molecules. The cooperative character of the rearrangement of the EDL is manifested by the sharp increase in relaxation time near the ZRP corresponding to the S_h maxima.¶ Theoretical analysis of the $V_h(E)$, $C(E)$, and $\tau(E)$ relations for the adsorption of OS has been carried out[63] on the basis of the ideas concerning the two-dimensional second-order phase transitions examined in Section V of this review. According to the present authors,[60,62] Eqn.(49) holds only at low concentrations of n-pentyl ($< 5 \times 10^{-2}$ M) and n-hexyl ($< 3 \times 10^{-2}$ M) alcohols. For higher values of c, a sharp decrease in V_h (down to $V_h < 0$) is observed and, after the break at the minimum, there is just as sharp an increase (to $V_h > 0$). The appearance of V_h peaks (Fig.9), corresponding to jumps in S_h (Fig.10), indicates the occurrence of first-order phase transitions.

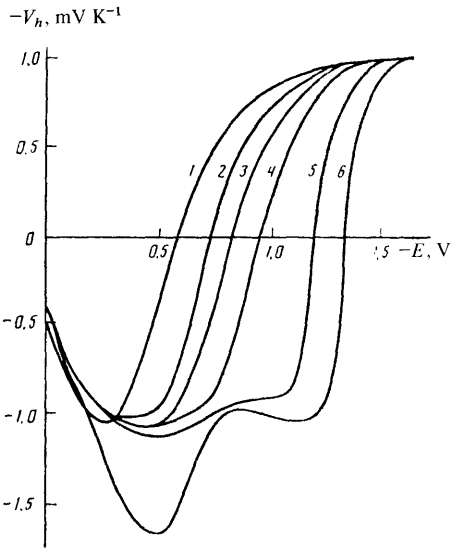

Figure 11. $V_h(E)$ relations for the adsorption of phenol on the mercury electrode from aqueous 0.5 M Na_2SO_4 solution; the phenol concentrations are 0, 4×10^{-3}, 2×10^{-2}, 4×10^{-2}, 0.1 and 0.4 M for curves *1—6* respectively.[64]

The LTJ method has been used[64] to investigate the adsorption of phenol and 1,3,5-trihydroxybenzene (THB). The choice of phenol was dictated by the fact that, according to Damaskin et al.[65] and Sarangapani and Venkatesan,[66] its adsorption, like that of the majority of aromatic OS, is possible in two orientations—planar and perpendicular, the second of which occurs at fairly high concentrations ($> 4 \times 10^{-5}$ M) in the vicinity of the ZCP, while the first obtains at high positive potentials.[67] Apart from the adsorption-desorption maxima, jumps in differential capacitance have been observed[66,68] in the adsorption of THB on mercury and were attributed to the formation of two-dimensional crystals of the THB dihydrate. The $V_h(E)$ curves for the above compounds are presented in Figs.11 and 12. The potentials for the $C(E)$ maxima coincide with the ZRP at different OS concentrations and are also characterised by EDL relaxation time peaks (Fig.13). In contrast to the systems examined previously (Fig.4), the $\tau(E)$ peaks are highly asymmetric. In the region of abrupt changes in capacitance in the course of the adsorption of THB, V_h peaks arise. The values of τ in the range of E between the ZRP and the V_h peak is much greater than in the supporting electrolyte and amounts to approximately 30 ns. In the vicinity of the V_h peak, i.e. in a first-order phase transition, there is

¶ The S^{σ}_{Γ} relations were known previously only for low degrees of coverage ($\theta < 0.4$) of the mercury electrode by thiourea.[23] It has been concluded[23] that S^{σ}_{Γ} is an additive function of the degree of coverage, consisting of two contributions, associated with the adsorbed water and OS molecules. LTJ data have shown that this conclusion cannot be extended to the range of higher coverages.

a sharp decrease in τ down to values less than 10 ns. It has been suggested[64] that the order of the phase transitions in the EDL can be determined from the following features of the $C(E)$, $V_h(E)$, and $\tau(E)$ curves (see Table). The simultaneous appearance of $C(E)$ peaks and $V_h(E)$ zero values at the second-order phase transition points follows directly from the form of the singular component of the thermodynamic potential (34) when Δ is independent of T. The constancy of the degree of coverage at which the transition takes place ($\theta_c \cong 0.5$) indicates its similarity to transitions of the order–disorder type; when $\theta < \theta_c$, random coverage of the nodes (adsorption sites) takes place and, when $\theta \cong \theta_c$, a state with a short-range order in their distribution arises. Such transitions in planar lattices have been investigated in fair detail.[44–47,69,70] The critical values of θ_c, corresponding to the formation of "an infinite cluster" of occupied nodes (the permeation threshold), depends on the lattice geometry, the configuration of the molecules, and their orientation in adsorption.[71,72]

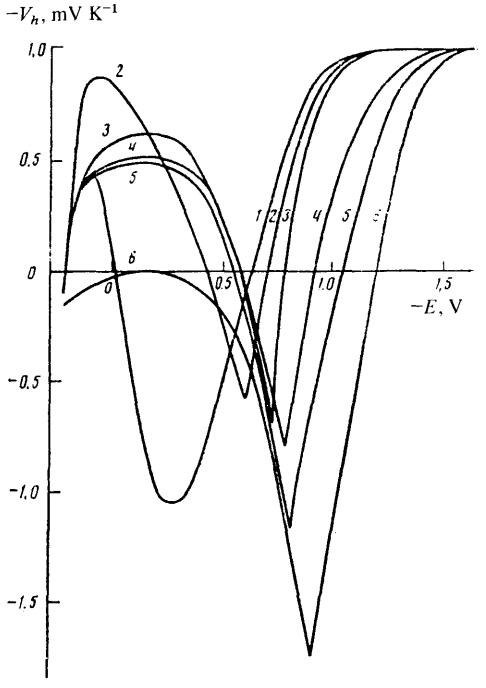

Figure 12. $V_h(E)$ relations for the adsorption of 1,3,5-trihydroxybenzene on the mercury electrode from aqueous 0.5 M $LiClO_4$ solution with OS concentrations of 0, 4×10^{-5}, 10^{-3}, 5×10^{-3}, 2×10^{-2}, and 0.1 M for curves *1*–*6* respectively.[64]

Although some of the features enumerated in the Table can be poorly expressed (for example, in the adsorption of aliphatic alcohols jumps in τ are not observed in first-order transitions, while in the adsorption of phenol one observes minima at low values of c instead of negative v_h peaks), nevertheless the combination of LTJ data and electrochemical measurements makes it possible to establish the occurrence and order of the phase transitions in the EDL when the potential is varied.

A characteristic feature of mixtures of water and aliphatic compounds with a terminal polar group (amphiphiles) is the formation of liquid crystal phases due to the fact that the equilibrium packing of the amphiphile molecules should ensure the shielding of the hydrophobic hydrocarbon chain from water. According to the cT diagram for amphiphile–water mixtures,[70] an increase in the amphiphile concentration entails a transition from a solution of isolated molecules to a micellar phase. On further increase in c, the micellar phase is converted into liquid crystal mesophases—hexagonal and lamellar, which are then converted into an amphiphile crystal. The micellar phase–mesophase transitions and the transitions between the mesophases can be both of the first and second order, while the mesophase–crystal transition is usually a first order transition of the type of fusion. Presumably structures with different disposition of the adsorption sites and different packing of the hydrocarbon chains are formed at the interface between the metal and the aqueous solution of amphiphiles. Second-order phase transitions are apparently associated with the formation of two-dimensional mesophases containing the oriented OS and water molecules. The first-order phase transition can be attributed to the formation of OS crystals or mixed OS–water crystals at the interface. In the adsorption of aromatic alcohols, a mesophase is formed in second-order phase transitions, is less ordered (has a higher entropy) for a higher density of the OS, and, judging from the relaxation times of approximately 10^{-8} s, contains water molecules capable of changing their orientation as the temperature is varied. In the first-order phase transition, this mesophase is converted into two-dimensional crystals in which the OS and water molecules are linked by hydrogen bonds. According to X-ray diffraction data,[73] similar planar packing is characteristic of phenol and THB hydrates.

Manifestation of phase transitions in different relations.

Relation	Order of phase transition	
$C(E)$	jump	maximum*
$V_h(E)$	peak	zero
$\tau(E)$	jump	peak

*It may be that the finite $C(E)$ values at the maxima on the CE curve are due to the fairly large amplitudes and high modulation frequencies of the electrode potential in the measurements, while the values corresponding to thermodynamic equlibrium are singular at the transition points.

The determination by the LTJ method of the transition potentials in solutions with different OS concentrations leads to the possibility of constructing cE phase diagrams for the adsorption layers. Fig.14 presents as examples diagrams of this kind for solutions of n-pentyl alcohol and THB. For low values of c, a second-order transition from a two-dimensional solution to a water crystal (line II) occurs in the region of adsorbability. With increase in c, two second-order transitions occur in the first case, bounding the region of existence of the mesophase ($\theta \geqslant \theta_c$). On further increase in the OS concentration, first-order transitions (line I) from the mesophase to the crystal are observed. In the case of THB, the latter exists up to the maximum attainable values of c.

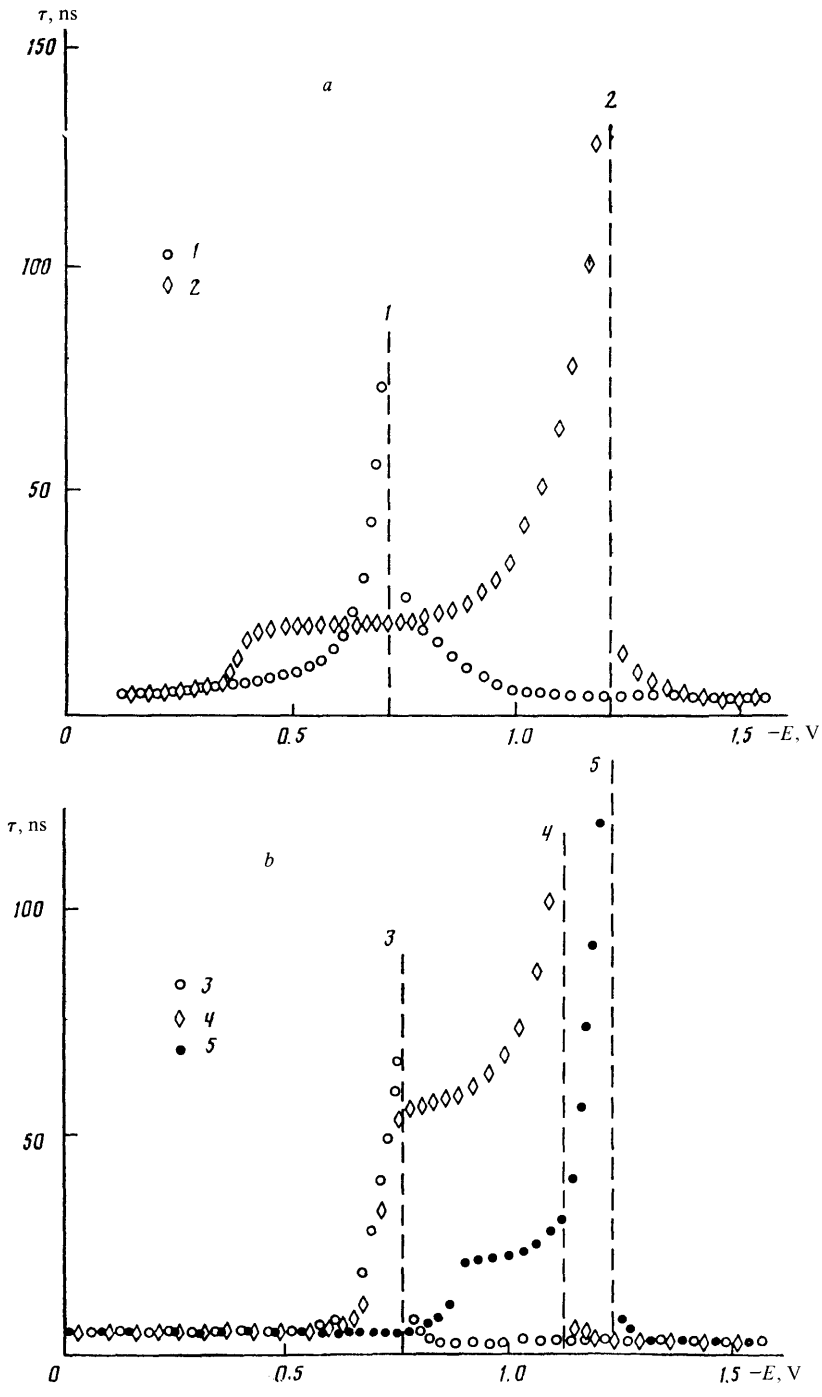

Figure 13. Characteristics EDL relaxation time for the adsorption of phenol (*a*) and 1,3,5-trihydroxybenzene (*b*) on mercury; the OS concentrations are 4×10^{-3}, 0.2, 10^{-3}, 4×10^{-2}, and 0.1 M for curves *1*—*5* respectively.[64]

Despite the limited number of examples of the application of the LTJ method, the data obtained show that the combination of the new method with the traditional procedures ensures a fairly complete thermodynamic description of the EDL both in terms of derivatives of the thermodynamic potential with respect to electrical variables and activities and in terms of temperature. The sharp changes in the relaxation times observed by the LTJ method in the regions of singularities in these derivatives display a set of different phase states of the EDL and the transitions between them of both first and second orders. Further development of this field will be associated

with the testing of structural models of two-dimensional phases and phase transitions, which can be achieved, in particular, with the aid of electroreflection spectra and IR and Raman spectroscopy. The version of LTJ developed is designed for the measurement of relaxation times within a comparatively narrow range $10^{-8}-10^{-6}$, which is known *a priori* not to include the entire relaxation spectrum of the EDL. The high thermal conductivities of metals and the possibility of changes in the duration of the laser pulses make it possible to extend the dynamic range of the LTJ (approximately to $10^{-10}-10^{-4}$ s), creating thereby the relaxation spectroscopy of the EDL.

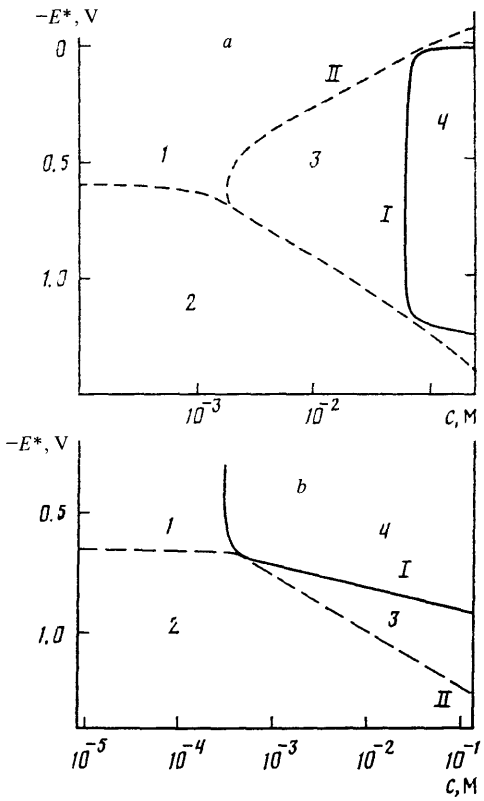

Figure 14. EDL phase diagrams for the adsorption of n-pentyl alcohol (*a*) and 1,3,5-trihydroxybenzene (*b*) on mercury; the continuous and dashed lines indicate the first- and second-order transitions respectively: 1) ice crystal; 2) OS solution in water; 3) mesophase; 4) mixed crystal of water and OS.[60,64]

Photonics of the Triplet States of Molecular Complexes

E.I.Kapinus and I.I.Dilung

The review surveys the results of studies on the photophysical and photochemical reactions of triplet exciplexes and triplet-excited molecular complexes which are stable in the ground state. These two groups of excited molecular compounds are compared and the influence of the electronic structure on the kinetics and mechanisms of the elementary photoprocesses is analysed. The formation reactions and properties of the triplet exciplexes of various classes of organic substances are examined in detail.
The bibliography includes 110 references.

IV. Formation of the triplet states of molecular complexes as a result of intersystem crossing 629

I. INTRODUCTION

Many photochemical reactions—oxidation-reduction, isomerisation, addition, etc. reactions—proceed with participation of excited organic donor—acceptor molecular compounds. Complex formation keeps the reactant molecules near one another and orients them appropriately in space, thereby promoting the occurrence of the process.

Electron donor—electron acceptor (EDA) complexes or, in other words, charge-transfer complexes (CTC) are formed on charge transfer from an occupied donor orbital to an unoccupied electron acceptor orbital, which results in a decrease in the energy of the molecular system and a chemical bond is formed. According to Mulliken,[1] the molecular complex is a resonance hybrid of the so called non-bonded (AD) and ionic (A^-D^+) structures†:

$$AD \leftrightarrow A^-D^+ , \qquad (1)$$

In the hypothetical non-bonded state AD, there is no interaction between the molecules forming part of the complex. A dissociative potential surface corresponds to the complex (Fig.1). A potential surface of the bonding type corresponds to the "pure" ionic state A^-D^+. In this state, the components are held together by Coulombic attraction forces. If the structures A and D and A^-D^+ are capable of interconversion (1), then a mixed state arises and is described by the wave function

$$\psi_N = a_1\psi(AD) + a_2\psi(A^-D^+) , \qquad (2)$$

and has less energy than AD or A^-D^+. The new state has a potential surface with a minimum corresponding to the equilibrium configuration of the real complex.

In describing the excited states of molecular compounds, one must also take into account the locally excited structures—hypothetical structures without interaction between the components with the excitation localised on A or D (A^*D or AD^*):[2]

$$^1\psi_E = b_1^1\psi(AD) + b_2^1\psi(A^-D^+) + b_3^1\psi(A^*D) + b_4^1\psi(AD^*) . \qquad (3)$$

† The letter A denotes an electron acceptor molecule, D denotes an electron donor molecule, and an asterisk denotes an electronically excited species.

The contribution of each term in Eqns.(2) and (3) is determined by the energy of the corresponding state. The energies of the structures A^*D and AD^* are close to those of the corresponding excited molecules A^* and D^*. For the majority of organic CTC, the energies of the "pure" singlet and triplet charge-transfer states do not differ greatly. For gas-phase systems, they are estimated with the aid of the equation[1]

$$E(A^-D^+) = IP - EA - W$$

where IP is the ionisation potential of the electron donor, EA the energy of the electron affinity of the acceptor, and W the energy of the Coulombic interaction of the ions in the charge-transfer state. In the calculation of the energies of the structures A^-D^+ of the complexes in solutions, it is essential to take into account the solvation energy ΔH_s:

$$E(A^-D^+) = IP - EA - W - \Delta H, \qquad (5)$$

The difficulty of calculating the latter can be obviated by using the corresponding electrochemical potentials:

$$E(A^-D^+) = E_{1/2}^{ox} - E_{1/2}^{red} - W . \qquad (6)$$

Naturally, in this case $E(A^-D)$ refers to the solvent in which $E_{1/2}^{ox}$ and $E_{1/2}^{red}$ were determined. In order to convert it into the expressions for other media, it is necessary to introduce correction terms into Eqn.(6). The Coulombic interaction energy of two molecular ions in Eqns.(4)—(6) is usually substituted by the electrostatic interaction energy of two unlike points charges (e) separated by a distance equal to the sum of the molecular radii r (usually ~0.5 nm) in a medium with a dielectric constant ε:

$$W = \frac{e^2}{\varepsilon \cdot r} . \qquad (7)$$

In more accurate calculations of the attraction energy of the ions, account is taken of the distribution of charges in space.[3]

In those cases where $E(AD) \ll E(A^-D^+) \ll E(A^*D), E(AD^*)$, the charge-transfer state is the lowest excited state of the complex. For the opposite relations $E(A^-D^+) \gg E(A^*D), E(AD^*) \gg E(AD)$, the

locally excited state is the lowest. If the energies of the locally excited and charge-transfer state are similar, their effective mixing takes place.

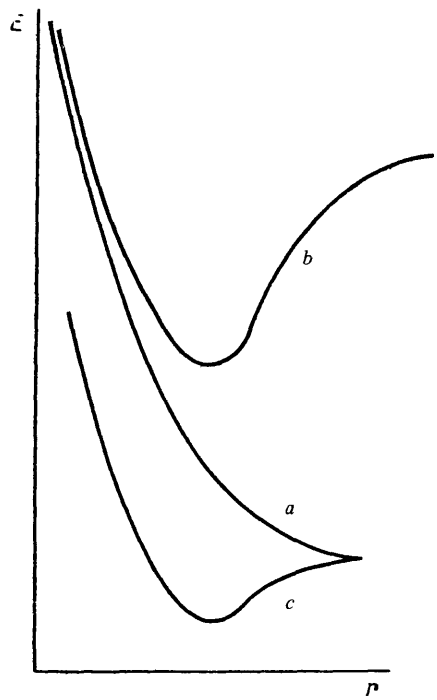

Figure 1. The potential energy (E) curves for the non-bonded state (a), the charge-transfer state (b), and the molecular complex (c); r is the distance between the species.[1]

Depending on the fraction of the charge-transfer state in the ground state, which to a large extent determines the stability of the donor–acceptor complex, it is possible to distinguish two limiting types: highly stable complexes with virtually complete charge transfer and complexes in which there is no charge transfer and no interaction of the components associated with it. Compounds of the latter group exist only at the instant of the collision of their reactant molecules (contact CTC). They are formed from the molecules of weak donors and weak acceptors.[4] Very powerful electron donors and electron acceptors give rise to complexes of the other extreme type mentioned above–radical-ion salts in which the energies of charge-tgransfer states are similar to or even lower than the energies of the non-bonding structures.[5]

The ground state of contact complexes involves repulsion for intermolecular distances corresponding to the equilibrium configurations of the molecular compounds. When the components are moved apart to a distance of approximately 0.3 nm, a small minimum appears on the potential surface for the system, which is due to relatively long-range but weak universal intermolecular forces.[6] Such van der Waals complexes have been detected and investigated with the aid of the special technique of cooled molecular beams.[7] However, in liquid solutions at room temperature, van der Waals forces are not able to ensure any appreciable stability of the molecular compounds formed on collision of the molecules of weak electron donors and weak electron acceptors.

The conversion of the contact complexes into a polar excited state greatly strengthens the bond between the components. Such donor–acceptor compounds, which exist virtually only in the excited state, have been called exciplexes or heteroexcimers.[8] Following the loss of the electronic excitation energy, the exciplexes pass to a state with a dissociative potential surface and decompose. As a consequence of the large difference between the energies $E(A^-D^+)$ and $E(AD)$, in exciplexes, in contrast to the excited CTC, there is no interaction between the structures AD and A^-D and the stabilisation of the ground state induced by such interaction is lacking (Fig.2).

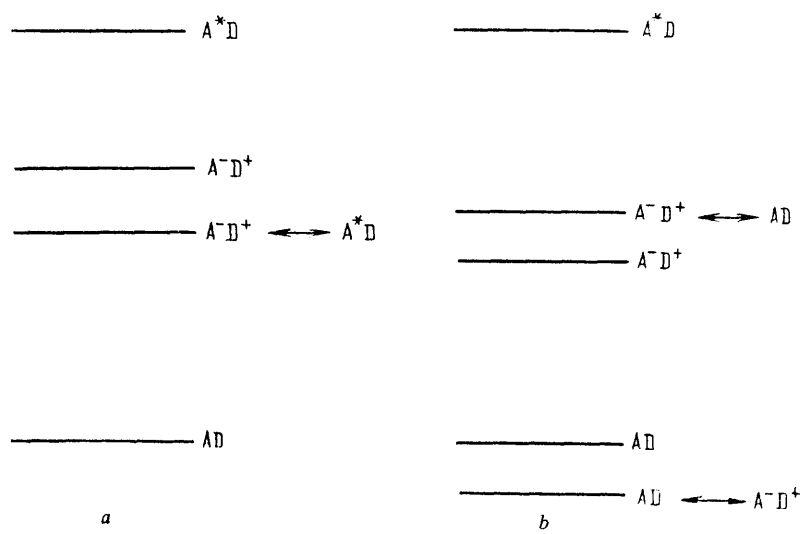

Figure 2. The energy level scheme for exciplexes (a) and CTC (b).

The rule of overall spin conservation of the system holds in electron exchange. Charge-transfer triplet states do not therefore interact with the AD state and the term containing AD does not enter into the expression for the wave function for the triplet-excited molecular state $^3\psi_E$:

$$^3\psi_E = c_1^3\psi(A^*D) + c_2^3\psi(A^-D^+) + c_3^3\psi(AD^*) \quad . \qquad (8)$$

Thus the triplet states of both exciplexes and CTC are not perturbed by the interaction with the non-bonded state AD. From this point of view, there are no differences between the triplet-excited EDA compounds, which are stable in the electronic ground state, and the triplet exciplexes. The study of both groups of molecular complexes yields mutually complementary information.

The excited CTC can be obtained on direct photoexcitation of molecular compounds:

$$AD \xrightarrow{h\nu} {}^1(A^{\delta-}D^{\delta+})^* \rightsquigarrow {}^3(A^{\delta-}D^{\delta+})^* \quad .$$

In liquid solutions, complex formation reactions also take place between excited and unexcited molecules

$$^1A^* + D \rightleftarrows {}^1(A^{\delta-}D^{\delta+})^* \quad ,$$
$$^3A^* + D \rightleftarrows {}^3(A^{\delta-}D^{\delta+})^* \quad .$$

Both complexes with a dissociative ground state and molecular compounds, which are fairly stable in the unexcited form, are formed via a dynamic pathway.

Systematic studies on the photonics of molecular compounds have been carried out since the beginning of the 1950's. Initially organic CTC having a stable ground state were investigated.[8-11] The study of Leonhard and Weller[12] initiated an avalanche of publications devoted to singlet exciplexes. The triplet exciplexes, discovered at the beginning of the 1970's,[13,14] have been studied much less than the singlet exciplexes. This is due to the complexity of their experimental detection and investigation: in liquid solutions, the triplet exciplexes do not as a rule luminesce. These excited compounds evidently play an important role in many photochemical processes. Their photophysical properties differ significantly from those of the singlet exciplexes. The insufficiency of experimental data is fully compensated by data obtained in studies on CTC. As already stated, the electronic structures of the triplet exciplexes and triplet-excited EDA complexes are identical, which makes it possible to construct an integral picture of this important group of excited species on the basis of seemingly unrelated facts.

II. PHOTONICS OF TRIPLET-EXCITED ELECTRON DONOR–ELECTRON ACCEPTOR COMPLEXES

1. Luminescence-spectroscopic Properties

The phosphorescence spectra of molecular complexes, whose triplet state is locally excited, are very similar to the corresponding spectra of the "free" electron acceptors or donors. An example of such molecular compounds is provided by the complexes of trinitrobenzene, tetracyanobenzene, and tetrachlorophthalic anhydride with aromatic hydrocarbons – benzene, toluene, and naphthalene.[16-19]

Detailed analysis of the phosphorescence spectra[16-19] nevertheless reveals distinctive features of the complex formation. For example, the vibrational structure of the phosphorescence spectra of the CTC is more closed compared with the phosphorescence spectra of the corresponding components and furthermore vibrations with lower frequencies are manifested in them.[18] In many cases a small but nevertheless appreciable bathochromic shift of the phosphorescence spectra of the electron donor, depending on the donor–acceptor parameters of the components of the EDA complexes, is observed.[18] For example, the 0–0 transition in the phosphorescence of naphthalene occurs in the region of 21.3×10^{-3} cm^{-1}, while for the complex of naphthalene with dichloro-*o*-phthalic anhydride it occurs in the region of 21.37×10^3 cm^{-1} (Table 1).

Table 1. The positions of the bands ($\tilde{\nu}_{phosph}$) and the phosphorescence quenching times (τ_{phosph}) for the EDA complexes of naphthalene in frozen solutions.

Electron acceptor	Solvent	$\tilde{\nu}_{phosph}$, 10^{-3} cm^{-1}	τ_{phosph}, s	Refs.
Dichloro-*o*-phthalic anhydride	PEI	21.37	2.1	[26]
Tetrachloro-*o*-phthalic anhydride	PEI	21.3	1.65	[26]
Tetrabromo-*o*-phthalic anhydride	PEI	21.2	0.29	[26]
Pyromellitic anhydride	n-propyl ether	21.3	1.8	[23]

Note: PEI is a 3 : 1 mixture of isopropyl ether and isopentane.

The lifetimes of the phosphorescent locally excited states of molecular complexes are usually shorter than the lifetimes of the corresponding states of the "free" components of the CTC,[16-18] which may serve, together with spectroscopic data, as evidence for complex formation. However, if the acceptor contains no heavy atoms, then complex formation does not affect greatly the phosphorescence lifetimes. As for the usual organic molecules, the introduction of heavy atoms into the complex shortens appreciably the duration of the phosphorescence.[20]

Thus the electronic transitions in the locally excited triplet states of molecular compounds can be regarded as electronic transitions perturbed by complex formation and occurring in the photoexcited component. Complex formation intensifies the spin–orbit coupling, which fixes in its turn the single S_1 and the triplet T_0 states, and the radiative transitions to the ground state $S_1 \rightarrow S_0$ and $T_0 \rightarrow S_0$.[21] This results in the acceleration of intersystem processes, which is manifested by a shortening of the lifetimes of the phosphorescent states of the photoexcited components.

The triplet–triplet absorption spectra of the CTC of this group resemble the triplet–triplet absorption spectra of the corresponding "free" CTC components. However, in these spectra too one can observe distinct features of complex formation—the broadening of the absorption bands and the appearance in the long-wavelength part of the spectrum of bands due to charge transfer from the excited triplet state localised on one of the components to the unoccupied level of the electron acceptor.[22]

Complexes with the lowest triplet charge transfer states have completely different phosphorescence spectra. These spectra consist of structureless bands due to reverse charge transfer, whose maxima undergo a hypsochromic shift with increase in the electron affinity of the acceptor.[16-19] The duration of the phosphorescence of the EDA complexes of this group is shorter, as for the previous

group, then the duration of the phosphorescence of the "free" component with the lowest triplet state energy when this is closest to the energy of the triplet state of the complex.[23] The shortening of the phosphorescence lifetime as a result of complex formation is caused, according to Hayashi et al.,[23] by a change in the rates of both radiative and non-radiative transitions.

The triplet–triplet absorption spectra of complexes of this group have been studied in detail in relation to the CTC of tetracyanobenzene with durene and hexamethylbenzene.[25] The absorption spectra of molecules in the charge transfer state do not resemble the triplet–triplet absorption spectra of the "free" components. They manifest electronic transitions involving reverse charge transfer and transitions leading to locally excited states of the ion:[25]

$$A^-D^+ \begin{cases} \longrightarrow AD^* \\ \longrightarrow A^{-*}D^+ \\ \longrightarrow A^-D^{+*} \end{cases}$$

The triplet locally excited complexes and the triplet complexes in the state involving virtually complete charge transfer between the components can be regarded as corresponding to extreme points in the series of excited complexes in which the degree of charge transfer can vary from 0 to 100% depending on the nature of the reactants. The change in the degree of polarity of the excited CTC influences strongly the luminescence-spectroscopic properties. As the degree of charge transfer is altered, the lifetimes and the positions of the phosphorescence bands change, and the absorption bands of the triplet-excited complexes are displaced.[2,23–25] These effects are strongest when the degree of charge transfer exceeds 50%.[24]

2. Dissociation of Triplet-Excited CTC into Ions

The products of the total electron transfer can be formed on dissociation of both singlet- and triplet-excited EDA complexes. Each of these mechanisms has its specific features.

The degree of involvement of states of different multiplicity in ionic dissociation processes of the CTC is determined in the first place by the thermodynamic conditions. In solvents with a high dielectric constant ε, the energy of the charge-transfer state is close to the energy of the state with dissociated ions. The EDA complexes in the charge-transfer state can therefore dissociate into free ions in highly polar solvents. On the other hand, locally excited complexes are unable to decompose spontaneously into ions.

The numbers of the free radical-ion species formed on dissociation of singlet- and triplet-excited states are determined by the rates of internal conversion, ionic dissociation, and intersystem processes involving the formation and deactivation of triplet states. However, the kinetics of these reactions have been scarcely investigated.

It is usually regarded as fully demonstrated that radical-ions are formed as a result of the dissociation of the triplet-excited CTC if the test system satisfies the following features.

1. The increase in the concentration of the radical-ion products occurs in the microsecond range parallel to the decrease in the intensity of the phosphorescence or the triplet–triplet absorption. For example, the photoexcitation in the charge transfer band of the complex of tetracyanobenzene with tetrahydrofuran in dichloroethane is accompanied by the formation of the radical-ion of the electron acceptor in the course of 300 μs. The time during which the concentration of the products of the ionic dissociation of the CTC increases then corresponds to the quenching time of the phosphorescence of the complex.[27]

2. Oxygen is an effective quenching agent for triplet states[21] and the yield of the products of the ionic dissociation of the triplet-excited CTC therefore diminishes as the solutions are saturated with oxygen. However, in the analysis of the influence of oxygen on the formation of radical-ion species it is essential to take into account the fact that this criterion is less rigorous, because oxygen can also quench a singlet-excited state and can accelerate intersystem crossing. For this reason, the data concerning the influence of oxygen on the yields of the radical-ions formed on photoexcitation of CTC require in general a careful kinetic analysis.[28]

3. If the radical-ion species arise as a result of the dissociation of the CTC in the triplet state, then the introduction into the solution of sensitisers, which are capable, after the transition to the triplet state, of transferring their energy to the complexes and of exciting their triplet states, increases the yield of the products of the total electron transfer.[29,30]

The triplet mechanism of the formation of radical-ion species operates only in the case of complexes whose lowest triplet states are charge-transfer states. The complexes of tetracyanoethylene, tetracyanobenzene, and pyromellitic dianhydride with π- and *n*-type electron donors, such as mesitylene, α-methylstyrene, dioxan, tetrahydrofuran, etc. serve as examples.[29,30]

If the lowest triplet states of the CTC belong to the class of locally excited states, then the ionic dissociation of the triplet-excited complexes does not take place. However, even in this case radical-ions may be formed following the absorption by the triplet-excited complexes of a second light quantum,[34–36] which converts the complex into a high-lying charge-transfer state:

$$AD \xrightarrow{h\nu} {}^1(AD)^* \rightarrow {}^3(A^*D) \xrightarrow{h\nu} {}^3(A^-D^+)^* \rightarrow A^- + D^+ .$$

Two-quantum CTC photodissociation processes have been observed experimentally from the quadratic dependence of the yield of radical-ions on the intensity of the exciting light. Analysis of such relations shows that the photoreaction of the complexes of tetracyanobenzene, pyromellitic and tetrachlorophthalic anhydrides with ether proceeds via a two-quantum mechanism, while the reaction of the complexes of the same acceptors with methyltetrahydrofuran, which is a stronger electron donor, involves a one-quantum mechanism.[35] In both the former and the latter group of complexes, the lowest triplet states belong to the locally excited type. The characteristics of the photochemical behaviour of molecular compounds of the first group are determined by the fact that in their molecules the first singlet excited states belong to the class of locally excited states. The dissociation of such molecular compounds is possible only after excitation to high-lying charge-transfer states.

Cases where both singlet- and triplet-excited states of EDA complexes are charge-transfer states are of considerable interest. As already stated, the energies of these compounds are similar and radical-ions can therefore form on dissociation of the CTC in either state. However, this most complex case has been scarcely investigated. It is only known that the relative efficiencies of the singlet and triplet channels leading to the formation of the products of the total electron transfer depend on the polarity of the medium. For example, in moderately polar solvents, the ionic dissociation of excited CTC of tetracyanobenzene and pyromellitic-dianhydride with ether, dioxan, and tetrahydrofuran takes place after the conversion of the complex to the triplet state, while in highly polar solvents—acetonitrile and butyronitrile—it occurs as a result of the decomposition of the singlet-excited CTC.[33]

III. TRIPLET EXCIPLEXES

The interaction of the triplet molecules of porphyrins, carbonyl compounds, dyes, and compounds of other classes with electron donor or electron acceptor molecules results in the formation of excited intermediates, which are frequently referred to in the literature as triplet exciplexes. Nevertheless, these excited molecular compounds are in essence triplet-excited CTC, which have a bonding ground state. This is manifested by the fact that the components of the majority of the so-called triplet exciplexes in the electronic ground state are capable of reacting with one another to form relatively stable molecular compounds. Specific examples will be given below. The application of the term exciplex to triplet-excited CTC is justified, because these excited species are formed via a dynamic mechanism, like the "true" exciplexes. Furthermore, the triplet states of both groups of molecular compounds are not perturbed as a result of the interaction with the non-bonded state.

1. Triplet Exciplexes of Porphyrin Compounds

The tetrapyrrole pigments undergoing reversible oxidation-reduction reactions in the cells of living organisms fulfil a series of key functions in photobiological processes. Studies under model conditions, including solutions and photochemical oxidation-reduction reactions with participation of tetrapyrrole pigments of all types—porphyrins, phthalocyanines, chlorines, etc.—have therefore developed widely.[38] The triplet states of the pigments play the main role in these photoreactions,[39] which is due to the long lifetime of the triplet states of many porphyrin compounds, the high quantum yields of the intersystem crossing, the pronounced electron-donating properties of the triplet-excited molecules, and the spin rules prohibiting the recombination of the primary radical-ion pairs formed. The interaction of the triplet molecules of the tetrapyrrole pigments with electron donors or acceptors shortens the lifetime of the triplet molecules and leads to the formation of "free" products of the total electron transfer in polar media.[38,39] In non-polar solvents, quenching may be accompanied by the appearance of triplet exciplexes.

The formation of a triplet exciplex was first observed in a study[13] in which the products of the pulse excitation of the solution of Zn-tetraphenylporphin in benzene containing *p*-benzoquinone were investigated. As a result of the action of the light pulse in this system, a variable absorption appeared, the kinetics of the disappearance of which were described by a complex two-component curve. It was suggested[13] that one of the components describes the destruction of a triplet exciplex. Subsequently analogous data were obtained in the study of the interaction of the triplet molecules of certain other porphyrins,[14,40-42] phthalocyanines,[42] and chlorophyll[43,44] with electron acceptors.

The hypothesis of the formation of triplet exciplexes on quenching of the triplet states of porphyrin molecules by electron acceptors has been confirmed by the study of the absorption spectra of the intermediates and of their deactivation by energy acceptors, in the study of the slow fluoroescence and pulse photoconductivity of the solutions, and by careful analysis of the kinetic curves.

It has been established[40] that the absorption spectrum of the "long-lived" component of the kinetic curve differs appreciably although not very greatly from the absorption spectra of triplet molecules. The spectra of these intermediates differ also from the absorption spectra of the corresponding radical-ions. The lifetime of the intermediate species shortens after the introduction into the solution of oxygen, azulene, tetracene, and perylene—substances whose molecules have low energies of the triplet states and which can therefore serve as energy acceptors in relation to the triplet porphyrin exciplexes. The rate constants for the quenching of the triplet exciplexes via these substances are close to the diffusion rate constants. The formation of the triplet chlorophyll exciplexes by reaction with organic electron acceptors is accompanied by the appearance of a slow fluorescence, whose spectrum agrees with the well known fast fluorescence spectrum of chlorophyll.[43,44] The appearance of the slow fluorescence in solutions where there are virtually no free triplet chlorophyll molecules can be caused only by processes involving triplet exciplexes. When electron acceptors are added to weakly polar chlorophyll solutions at concentrations sufficient for the complete quenching of the triplet states, an increase in photoconductivity is not observed.[40]

The triplet exciplexes of porphyrin compounds can be regarded as locally excited complexes with a relatively small contribution by the state involving charge transfer from the porphyrin to the oxidant. This is indicated by the absorption spectra of the complexes, which resemble the absorption spectra of the corresponding porphyrins in the triplet state.[40,42-44] This fact may at first sight appear to be unexpected because porphyrins are powerful electron donors.[45] However, together with very pronounced electron-donating properties, porphyrins are characterised by low energies of the triplet states (~ 150 kJ mol^{-1}),[38] so that the lowest triplet state of the EDA complexes of porphyrins with many electron acceptors is a locally excited state.

The contribution of the wave functions of the polar states to the wave function of the excited complex depends on the nature of the reactants, as stated above. With increase in the electron-accepting capacity of the oxidant forming part of the exciplex, the absorption spectrum of the latter becomes increasingly different from the absorption spectrum of the triplet molecules and begins to resemble increasingly the absorption spectrum of the corresponding radical-cation.[46] Even in the case of powerful electron acceptors such as dinitrobenzenes and dinitronaphthalenes, the absorption spectrum of the exciplex nevertheless differs from that of the corresponding radical-cation. Naturally, bands resembling the absorption bands of the radical-anions should also be present in the absorption spectra of the exciplexes. Owing to their low intensity, they are masked by the bands of the radical-cation.

The conclusion that the lowest triplet states of the exciplexes of many tetrapyrrole pigments formed by reaction with electron acceptors have a predominantly locally excited character has been confirmed by thermodynamic calculations.[47] Thus in non-polar media the energy of the triplet state of chlorophyll is lower than the energy of the triplet charge-transfer states of its complexes with nitrobenzene, dinitrobenzene, and *p*-benzoquinone. The triplet chlorophyll exciplexes are therefore locally excited complexes with a small admixture of the charge-transfer state.

With increase in solvent polarity, the energy of the charge-transfer state diminishes owing to its stabilisation by the dipoles of the medium. As a result of this, the formation of radical-ions becomes easier in highly polar solvents than that of exciplexes, which has been confirmed by flash photolysis data: the photoexcitation of solutions of chlorophyll and organic oxidants in highly polar media leads to the formation of a high yield of chlorophyll radical-cations with a characteristic absorption spectrum.[38,39,47]

The inversion of the levels of the locally excited state and the charge-transfer state can occur also without a significant change in solvent polarity after the introduction into non-polar solutions of

polar additives, which are capable of solvating selectively the exciplexes, inducing a decrease in the energy of the charge-transfer states. As an example, one may quote the results of a study[48] in which the influence of added ethanol, acetonitrile, and *N*-methylformamide on the lifetimes and spectroscopic properties of the triplet exciplexes of Zn-aetioporphyrin I with *p*-nitrotoluene was investigated. It was found that the presence of *N*-methylformamide in the solution at a concentration of 0.01 M shortens greatly the lifetime of the triplet exciplex. The increase in the concentration of the additive to 0.02 M is accompanied by the appearance in the spectrum of the variable-absorption bands of the radical-cations. Since such low concentrations of polar substances hardly increase the dielectric constant of the medium, the formation of free radical-ions in these solutions is therefore unlikely. The spectral changes can be explained by the inversion of the energy levels of the locally excited state and the charge-transfer state.

It has also been observed[49] that the quenching of the photo-induced absorption of chlorophyll solutions containing an electron acceptor has two-component kinetics. However, the authors of the above publication were not able to detect any intermediate products with a lifetime greater than 20 ns on interaction of the triplet molecules of the zinc complexes of porphyrins with *p*-benzoquinone and *p*-dinitrobenzene.[49,50] This served as a basis for the conclusion that the kinetic and spectral changes, explained by the formation of triplet exciplexes, are in fact due to the presence of impurities in the specimens consisting most probably of the metal-free pigments. It has to be said that, with the aid of the traditional methods of purification, it is easy to obtain spectroscopically pure preparations of tetrapyrrole pigments in which the content of the main substance is greater than 99.5%. Since metalloporphyrins have characteristic absorption spectra, it follows that extraneous coloured substances can be readily detected spectroscopically. The problem of the genesis of the two-component curves described can be solved by careful analysis of the kinetic curves. This problem will be considered in the next Section. It is possible to identify tentatively the causes of the failure of Renge and co-workers[49,50] to detect the triplet exciplexes of zinc-porphyrins with oxidants. It may be that the solvents or the metalloporphyrins themselves contained polar impurities capable of quenching the exciplexes via the mechanism considered by Roy and Whitten.[48] This may be promoted by the tendency of metalloporphyrins to form complexes.

2. Kinetics of the Quenching Processes with Participation of the Triplet Exciplexes of Porphyrin Compounds

The interaction of triplet-excited porphyrin molecules with electron acceptors is described, like the reactions of the singlet-excited molecules of aromatic substances, by a kinetic scheme which takes into account the possible occurrence of induced quenching—a process first proposed by Nakashima et al.[51] and Kuz'min and Sadovskii[52]—in parallel with the formation of exciplexes:

$$D^* + A \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} (AD)^* \xrightarrow{k_2} D + A \ , \qquad (9)$$

$$D^* + A \xrightarrow{k_4} D + A \ , \qquad (10)$$

$$D^* \xrightarrow{k_3'} D \ . \qquad (11)$$

The standard formal kinetic treatment of this scheme shows[41,42,46] that, subject to the condition $[A] \gg [D^*]$, the time variations of D^* and $(AD)^*$ are described by

$$[D^*] = a_1 \exp(-\lambda_1 t) + a_2 \exp(-\lambda_2 t) \ , \qquad (12)$$

$$[(AD)^*] = b[\exp(-\lambda_1 t) - \exp(-\lambda_2 t)] \ . \qquad (13)$$

Since the absorption spectra of both components of the kinetic curve usually overlap, the overall absorption is recorded under the conditions of flash photolysis:

$$D = D_t + D_e = \epsilon_t l[D^*] + \epsilon_e l[(AD)^*] = F_1 \exp(-\lambda_1 t) + F_2 \exp(-\lambda_2 t) \ . \qquad (14)$$

In Eqns.(12)–(14), we have

$$\lambda_{1,2} = B/2 \pm (B^2/4 - C)^{1/2} \ ,$$

$$B = k_2 + k_{-1} + (k_1 + k_4)[A] = \alpha + \beta[A] \ ,$$

$$C = k_3(k_2 + k_{-1}) + (k_1 k_4 + k_2 k_4 + k_{-1} k_4)[A] = \gamma + \delta[A] \ ,$$

where ϵ_t and ϵ_e are the molar extinction coefficients of the triplet molecules and exciplexes respectively and l is the length of the cuvette. The pre-exponential factors a_1, a_2, b, F_1 and F_2 can be found by the usual procedures from the initial conditions.[46] In Eqn.(14), D_e and D_t are the optical densities due to the absorption of the triplet-excited molecules and the triplet exciplexes.

The lifetimes of the triplet exciplexes τ_e can be found from the dependence of λ_2 on the concentration of the quenching agent A:[42]

$$1/\tau_e = \lambda_{lim} = \lim_{[A]\to\infty} \lambda_2 = k_2 + k_{-1}k_4/(k_1 + k_4) \qquad (15)$$

Eqn.(15) shows that the deactivation of the triplet exciplex can take place in two ways: via the direct intersystem degradation of the electronic excitation energy and as a result of the dissociation of the exciplex with subsequent deactivation of the triplet molecules induced by the quenching agent. The efficiency of each of these channels is characterised by the corresponding terms of Eqn.(15).

If the quenching process proceeds via a state involving the formation of an intermediate excited complex, then it follows from Eqns.(12)–(14) and (1), over a wide range of quenching agent concentrations, the dependences of λ_1 and λ_2 on [A] do not obey the Stern–Volmer equation,[42] which can be written in the form

$$\lambda_{1,2} = \frac{1}{\tau_0} + k_q[A] \ ,$$

where k_q is the quenching rate constant, and (2), as the quenching agent concentration is varied, the intensities of the first and second components of the kinetic curve vary in such a way that $A_1 + A_2 = \text{const}$.[46]

For systems where $k_4 \ll k_1$, the lifetimes of the triplet exciplexes of porphyrins with electron acceptors hardly differ from the lifetimes of the triplet molecules of the corresponding porphyrins in liquid degassed solutions.[42,53] The latter is entirely understandable, because the processes leading to the deactivation of the localy excited complexes can be regarded, as stated above, as weakly perturbed electronic transitions in the photoexcited component of the exciplex. If the rate of deactivation of the locally excited component is high, for example, as a consequence of the spin–orbit coupling, then the lifetime of the corresponding locally excited exciplex is short. Exciplexes of the ruthenium complexes of phthalocyanine with certain organic electron acceptors can serve as confirmation of this.[54] Depending on the axial ligand, the lifetimes of the triplet molecules of the "free" metallophthalocyanine range from 0.43 to 0.32 μs, while the lifetimes of the exciplexes range from 0.77 to 0.18 μs. Like the majority of the exciplexes examined above, these exciplexes are characterised by a low contribution of the charge transfer states. It is of interest that in certain cases the lifetime of the exciplex of the ruthenium complex of phthalocyanine was several times longer than the lifetime of the triplet molecules under the same conditions, which can be explained by the change in the rates of the non-radiative transitions as a result of complex formation.

If the second term in Eqn.(15) is sufficiently large compared with the first, then the lifetimes of even locally excited exciplexes can depend on the nature of the oxidant involved in the complex formation. The data in Table 2, which presents the values of λ_{lim} found from the dependences of λ_2 and τ_e on the oxidant concentration, serve as an illustration of this finding. In the table, the quenching agents are arranged in order of weakening electron accepting properties, while the porphyrins are arranged in order of weakening electron-donating properties. It can be seen that, for each metalloporphyrin, exciplexes with both strong and weak electron acceptors can have high values of λ_{lim}. The values of λ_{lim} which do not differ greatly from the rate constants for the pseudounimolcular deactivation of triplet porphyrin molecules ($\sim 10^3$ s^{-1}) lie in an intermediate region. The lifetimes of such triplet exciplexes, like those of the majority of triplet molecules,[9,21] are determined by the rates of quenching by residual oxygen, impurities, and the solvent. The region of long-lived exciplexes is differentiated in Table 2, an arbitrary boundary being designated by a dashed line.

Table 2. The rate constants for the deactivation of the triplet exciplexes (10^{-3} λ_{lim}, s^{-1}) of metalloporphyrins with electron acceptors in toluene solutions.[53,56]

Quenching agent	TPPMg	TPPAlOH	TPP GaOH	PhcMg	PhcAlCl	TPPInOH

Note: TPP = mesotetraphenylporphin and Phc = tetra-t-butylphthalocyanine.

The size of the region of reduction potentials of the quenching agent $E_{1/2}^{red}$ for which low values of λ_{lim} are observed ($\sim 10^3$ s^{-1}) is determined by the electron-donating properties of the porphyrin. The tabulated data show a tendency towards a narrowing of the region of long-lived exciplexes as the electron-donating capacity of the excited molecules diminishes. The greatest number of long-lived exciplexes are therefore formed by the magnesium complex of mesotetraphenylporphin—one of the metalloporphyrins with the most pronounced electron-donating properties.

The complex dependence of the rate of deactivation of triplet exciplexes on the reduction potential of the quenching agent described above can be explained by the fact that the triplet exciplex can be deactivated not only by direct intersystem degradation but also as a consequence of dissociation with subsequent quenching agent-induced deactivation of the triplet-excited molecules formed. The relative efficiencies of these channels are determined by the ratios of the constants for the formation of the triplet exciplex, the induced quenching, and dissociation. This problem has been analysed in detail.[53,55]

In systems which exist in regions along the boundary of the "peninsula" (Table 2) of the long-lived exciplexes, we have $k_4 \gtrsim k_1$ [53] and therefore the two terms of Eqn.(15) are comparable and both mechanisms of the deactivation of triplet molecules described are important in the description of the process.

The size of the quenching agent concentration range in which distinct two-component quenching curves are observed depends on λ_{lim}. For systems with high λ_{lim}, the quenching times for the first and second components of the kinetic curve can remain close to one another even if the concentration of the quenching agent changes appreciably (by several orders of magnitude). Bearing in mind also that the intensity of the first component diminishes with increase in the concentration of the quenching agent, the kinetics of the disappearance of the induced absorption in such systems remain virtually monoexponential over the entire accessible range of variation of the quenching agent concentration. In this case, the process proceeds in a quasi-stationary manner. The characteristic time of such a curve varies with increasing quenching agent concentration in accordance with a hyperbolic law:[53]

$$1/\tau = \frac{\alpha + \beta [A]}{\gamma + \delta [A]} , \qquad (16)$$

tending to the limiting value defined by Eqn.(15).

In a study of systems which are remote from the peninsula of the long-lived exciplexes, the formation of triplet-excited complexes cannot be observed by kinetic methods. Evidently the exciplexes in such systems have such short lifetimes that the dependence of $1/\tau$ on [A] becomes linear over the entire accessible range of quenching agent concentrations. Such short lifetimes of the triplet exciplexes can be caused solely by high dissociation and deactivation rate constants, because even for systems in the boundary regions the ratio $k_4/(k_1 + k_4)$ does not differ greatly from unity—its maximum value.

The hyperbolic form of the relation between $1/\tau$ and [A] [Eqn.(16)] can be explained by the fact that, with increase in the quenching agent concentration, the equilibrium in the exciplex formation reaction (9) shifts towards the excited complex. Such relations can be regarded as evidence for the reversible formation of the excited complexes when triplet molecules are quenched.[56,57] The equilibrium character of the formation by triplet-excited molecules of complexes with the quenching agent was observed in a study of the quenching of the triplet-excited states of the palladium complex of mesotetraphenylporphin by *NN*-dimethylaniline in liquid degassed solutions.[58] It has to be said that Pd-porphyrins have the fairly rarely encountered property of an intense phosphorescence in liquid deaerated solutions.[38] In a study of the quenching of the above system, characteristic negative deviations from the linear Stern–Volmer relation, associated with the formation of triplet exciplexes, were observed. Calculations showed that the equilibrium stability constant of the triplet exciplex of the above porphyrin with *NN*-dimethylaniline is approximately 10 litre mol^{-1}.[58] It is of interest that Mercer-Smith et al.[58] failed to observe a change in the phosphorescence spectra of the porphyrin after the introduction of an amine into the solution, which can be due to the fact that the triplet exciplex does not phosphoresce or, if it does phosphoresce, then it is locally excited. As already stated, the spectra of such complexes are virtually identical with the spectra of the corresponding components.

Being in the ground state, the molecules of the porphyrins and the electron acceptors can form relatively stable molecular complexes with one another.[58] Taking this factor into account, the majority of

the triplet exciplexes considered in the present Section should be included among excited EDA complexes, using the terminology proposed in the introductory Section. In the triplet-excited state, organic CTC are much more stable than in the ground state: the corresponding equilibrium constants for the excited states are 3 – 5 orders of magnitude greater than for the ground state.[42,46,60] The above triplet exciplexes are much more stable than the stable highly polar singlet exciplexes of aromatic compounds with oxidants or reductants.[61,62]

The high stability of the triplet exciplexes of porphyrins is somewhat unexpected, because, like other locally excited complexes, they cannot have high enthalpies of formation. Charge transfer stabilises them only slightly. The exciton interaction is also negligibly weak, because the energy of the triplet state of porphyrin is smaller by at least 100 kJ mol^{-1} than the energies of the lowest triplet states of the electron acceptors listed in Table 2.

The high stability of the triplet exciplexes is due to their high positive entropies of formation,[60,63] whose origin can be accounted for by a change in the structure of the solvation shells of the reactant molecules. The thermodynamic parameters of the exciplexes satisfy the following general compensation relations regardless of their multiplicity[60,63] (Fig.3):

$$\Delta H = \Delta H_0 + \beta_K \Delta S \ , \qquad (17)$$

where ΔH and ΔS are the enthalpy and entropy of the complex formation reaction, ΔH_0 = –17.7 kJ mol^{-1}, and β_K = 244 K. In plotting Fig.3 and in the calculation of the parameters of Eqn.(7), use was made of virtually all the literature values of ΔH and ΔS for excited complexes known to us. For exciplexes, the isoequilibrium temperature β_K is much lower than the isoequilibrium temperature for donor-acceptor complexes in the electronic ground state, which has been stated[64] to be 337 K. This may indicate that the excited complexes differ from the unexcited ones by a greater sensitivity of the structure to changes in the interaction energy. According to Lefler,[65] where there is a linear relation between ΔH and ΔS, the Gibbs free energy of the chemical reaction ΔG is expressed by the equation

$$\Delta G = \Delta H_0 - (T - \beta_K)\Delta S \ .$$

Since the isoequilibrium temperature for exciplexes lies below room temperature at which the stability constants are usually measured, the transition to more positive ΔS is accompanied in changes in ΔH, which increase the stability of the complex.

The rate constants for the formation of triplet exciplexes of porphyrin compounds with electron acceptors increase with increase in the reduction potential of the quenching agent and reach the diffusion region, where k_1 is almost independent of the nature of the oxidant.[53,66] The slope of the "vertical" branch of the relation between k_1 and the reduction potential of the oxidant is close to $-1/RT$, which is a characteristic feature of electron transfer processes, although the reaction leads to the formation of a locally excited complex with a small admixture of the charge-transfer state. In order to account for this contradiction, it has been suggested[53,66] that the formation of the exciplex involves an electron transfer stage. the entire process can be described by the scheme

$$\underset{\text{collision complex}}{D^* + A \rightleftarrows D^* \cdots A} \rightleftarrows \underset{\text{radical-ion pair}}{D^{\dot{+}} \cdots A^{\dot{-}}} \rightleftarrows \underset{\text{exciplex}}{(AD)^*} \rightarrow D + A \ .$$

After the mutual approach of the reactant molecules through diffusion, an electron is transferred with formation of the primary radical-ion pair. The species then continue to approach one another under the influence of Coulombic forces. This is accompanied by the partial neutralisation of the charges and the solvation environment and the mutual orientations of the molecules in the solvent cage are rearranged. This in fact results in the appearance of structures responsible for the high stability of the triplet exciplexes.

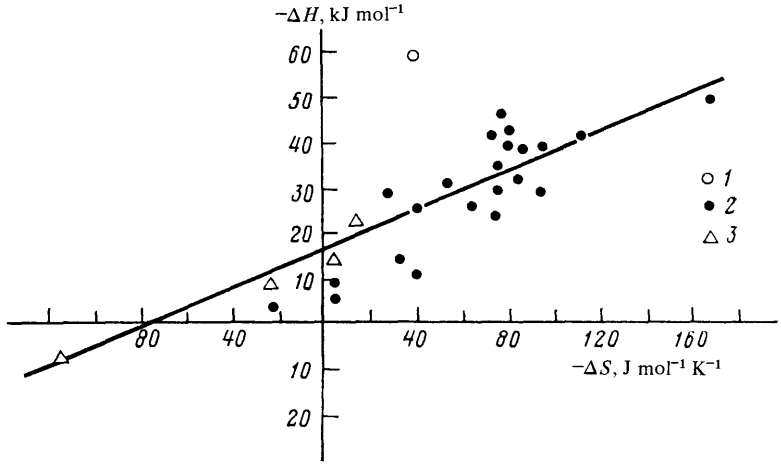

Figure 3. The isoequilibrium relation for exciplexes: *1*) singlet exciplexes in the vapour phase; *2*) singlet exciplexes in liquid solutions; *3*) triplet exciplexes; all the available thermodynamic literature data were used to plot the figure; the ΔH and ΔS for the triplet exciplexes were taken from Refs.60, 63, and 81.

3. Triplet Exciplexes of Carbonyl Compounds

The molecules of carbonyl compounds (quinones, ketones, aldehydes, and others) as a rule undergo photochemical reactions after transition to the triplet state.[67] Depending on the characteristics of their chemical structure, the lowest triplet state of carbonyl compounds can be $\pi\pi^*$, $n\pi^*$ or one of a mixed type. The most important photochemical reactions of organic compounds of this class are in one way or another related[68] to electron transfer, i.e.

$$\left(\rangle C{=}O\right)^* + D \rightarrow \left(\rangle C{=}O\right)^{\cdot-} + D^{\cdot+}$$

or the transfer of a hydrogen atom, i.e.

$$\left(\rangle C{=}O\right)^* + RH \rightarrow \rangle C^{\cdot}{-}OH + R^{\cdot}.$$

In those cases where the reactant RH molecule can serve as both an electron and hydrogen donor, the mechanism of the chemical reactions of the carbonyl compounds occurring under the influence of light is determined by the electronic structure of the excited state.[69]

In the early studies devoted to the photochemical reactions of carbonyl compounds, it was already suggested that these reactions proceed with participation of intermediate excited complexes.[70] However, until the end of the 1970's there were no experimental data of any kind confirming this view. It was first justified experimentally in a study[71] of the quenching of the phosphorescence of benzil PhCOCOPh by anisole and benzonitrile in liquid solutions. In these systems, the quenching of the phosphorescence was exponential, but the dependence of the quenching rate constants on the quenching agent concentration was non-linear. As in the quenching of the triplet molecules of porphyrins, these kinetics are determined by the formation of triplet exciplexes with a lifetime shorter than that of the triplet benzil molecules. The stability constants of these complexes are low (0.12–0.13 litre mol^{-1}).

The quenching of the triplet benzil molecules by triethylamine in moist acetonitrile has been investigated[72] using the method of laser photolysis. The bands of the benzil radical-anions were observed in the variable absorption spectrum. The rate of accumulation of this product proved lower than the rate of deactivation of the triplet molecules of the carbonyl compound, which provided the authors with justification to claim[72] that the electron phototransfer products are formed as a result of the dissociation of a highly polar relatively long-lived triplet exciplex.

The spectrum of the triplet exciplex of the carbonyl compound was first described in communications[74,75] reporting the results of the investigation of the quenching of triplet 2,6-diphenyl-1,4-benzoquinone molecules by tertiary amines. Excited molecular complexes of this type were examined in detail in a recently published review[73] and for this reason they will be only briefly characterised in the present communication.

The excited EDA compounds of ketones and quines can be both highly polar[74–78] and local excited.[78,79] the contribution of the wave function of the ionic state to the molecular wave function of the triplet exciplex is determined by the donor–acceptor properties of the reactant molecules. This question has been investigated in detail in relation to the triplet exciplexes of various quinones and aromatic electron donors.[73] In conformity with the treatment in the introductory Section, in those cases where the energy of the charge-transfer state is greater than or close to the energy of the triplet state of the quinone, locally excited complexes are formed. Their absorption spectra, like those of other locally excited molecular compounds, are close to the absorption spectra of the corresponding locally excited components—in the given instance quinones. The decrease in the energy of the charge-transfer state gradually increases its contribution to the excited complex state. The absorption spectra of such exciplexes, in which the charge transfer state has a lower energy than the energy of the locally excited state, consist of a superposition of the spectra of the corresponding radical-anion and radical-cation. The charge transfer energy is determined also by the solvating properties of the medium and for this reason the addition of even relatively small amounts of methanol (approximately 5%) leads to spectral changes indicating a marked increase in the polarity of the intermediate species.[78] An analogous phenomenon occurs also for triplet exciplexes of porphyrins with electron acceptors.[48]

The nature of the quenching agent determines the lifetimes of the triplet exciplexes. For complexes with the lowest locally excited state, the deactivation rate constants are close to those for the corresponding quinone molecules.[78] This feature is evidently a manifestation of the general feature, already examined, of locally excited molecular compounds. The lifetimes of highly polar triplet exciplexes of carbonyl compounds depend on the energy of the charge-transfer state: the smaller this energy, the higher the rate of deactivation.[77,78] This is apparently a manifestation of the energy gap law,[80] according to which the rate of the non-radiative transition increases with decrease in the difference between the energies of the corresponding energy levels.

A detailed kinetic analysis of the quenching of the triplet states of acetone by durene, which takes place with formation of a weakly polar triplet exciplex as an intermediate, has been carried out.[81] The rate constant for its formation is approximately two orders of magnitude smaller than the rate constant for the diffusion-controlled process. Like the locally excited complexes of porphyrin compounds, the triplet exciplex of acetone with durene has a low enthalpy of formation ($\sim$23 kJ mol^{-1}) and a less negative entropy of formation (–14 J mol^{-1} K^{-1}) than the typical singlet exciplexes. It is important that thermodynamic parameters of this triplet exciplex satisfy the thermodynamic compensation relation examined above.

4. Triplet Exciplexes of Dyes and Related Compounds

The triplet exciplexes formed by representatives of other classes of organic compounds have been much less investigated. In the literature, it is possible to find only individual scattered data concerning the triplet exciplexes of aromatic hydrocarbons, dyes, and heterocyclic compounds.

It has been reported[82] that the pulse photoexcitation of degassed toluene solutions containing *NN*-dimethylaniline apart from a phenazine compound leads to the apperance of a relatively long-lived variable absorption signal, whose spectrum differs from that of the triplet–triplet absorption spectrum of the initial phenazine compound. The authors[82] suggested that the observed intermediate species are triplet exciplexes. Data indicating complex quenching kinetics have been confirmed in a communication[83] where it was reported that the quenching of the long-lived component of the kinetic curve is non-exponential and, furthermore, that these signals are observed in oxygen-saturated solutions. However, later careful studies demonstrated[84] that the intermediates produced on quenching the triplet molecules of phenazine compounds by amines are nevertheless deactivated by oxygen with rate constants which do not differ greatly from the rate constants for diffusion-controlled processes. These intermediates are most probably triplet exciplexes.

Triplet exciplexes are evidently formed also on pulse photoexcitation of the 9-phenylacridinium cation in the presence of organic electron donors in liquid solutions.[85] These exciplexes have an unusual electronic structure: they represent, as it were, the complexes of the uncharged 9-phenylacridine radical and the radical-cation of the corresponding electron donor. Such triplet exciplexes are extremely stable even in polar media. The corresponding equilibrium complex formation constants are approximately 10^5 litre mol^{-1}. Such high stability of the triplet 9-phenylacridinium exciplexes also apparently cannot be accounted for by energy factors, because there is virtually no Coulombic interaction between the components in these excited molecular compounds. Their characteristic feature is that they are formed as a result of the intersystem crossing in the corresponding singlet exciplex, since the quantum yield of the triplet state of the 9-phenyl-acridinium cation is extremely low. This mechanism of the formation of the triplet states of molecular complexes will be examined in the next Section.

Usacheva et al.[96] investigated the intermediates formed on quenching the triplet state of eosin by an electron acceptor (methylviologen) in water. It was found that the quenching is accompanied by the formation of a short-lived intermediate whose absorption spectrum differs appreciably from that of the triplet eosin molecules. At the same time, it was shown that "free" radical species are not formed in the given system. On this basis, one can conclude that the observed intermediate is a triplet exciplex with a significant contribution by the charge-transfer state.

The question of the formation of triplet exciplexes on quenching of the triplet states of aromatic hydrocarbons by electron acceptors is controversial. The formation of triplet exciplexes of anthracene with organic nitro- and halogeno-compounds in benzene has been reported,[40] but this result could not be reproduced by other workers.[87] The latter were unable to detect the formation of triplet exciplexes even on quenching of the triplet 1,2-benzopyrene and 1,2-benzanthracene molecules by electron acceptors. Apparently, if the triplet exciplexes are in fact formed in these systems, they have extremely short lifetimes. The difficulty of studying the products of the pulse photoexcitation of aromatic hydrocarbons is due to the factor that electron acceptors also quench effectively the singlet-excited states, reducing the quantum yield of the triplet molecules and lowering thereby the intensity of the variable absorption signals.

IV. FORMATION OF THE TRIPLET STATES OF MOLECULAR COMPLEXES AS A RESULT OF INTERSYSTEM CROSSING

The triplet states of both EDA complexes and exciplexes can be formed as a result of the intersystem reactions of singlet-excited states on radical-ion pairs. The mechanisms of these processes will be considered in the present Section.

1. Intersystem Crossing in Excited EDA Complexes

On the basis of the study of molecular complexes by nanosecond laser photolysis, it has been concluded[88,89] that in frozen solutions an appreciable if not the main fraction of the triplet states of molecular complexes are produced during the laser flash as a result of intersystem transitions from the unrelaxed Franck–Condon singlet-excited state. Almost simultaneously, an analogous mechanism was put forward also for the intersystem crossing in exciplexes.[90] However, subsequent studies carried out using picosecond laser spectroscopy[91] disproved this mechanism. Although CTC have not been investigated by this method, nevertheless one can postulate that, in donor–acceptor compounds which are stable in the electronic ground state, the intersystem period in liquid solutions should involve mainly the classical mechanism i.e. the relevant transition should be from the thermalised fluorescent state. In frozen solutions the intersystem crossing can take place from the Franck–Condon state, because the structural rearrangements of the complexes in frozen solutions are greatly hindered and the Franck–Condon state is fluorescent.[92,93]

The rates and hence the yields of the intersystem crossing depend on the degree of charge transfer between the components of the complex in the triplet state. The following selection rules have been formulated[94] for the intersystem crossing in EDA complexes: the non-radiative transition between the singlet and triplet charge-transfer states must take place at low rates in contrast to the intersystem transitions from singlet charge-transfer states to the triplet states with a locally excited nature. These postulates were based on the fact that the matrix elements of the spin–orbit coupling of the singlet and triplet charge-transfer states are zero,

$$\langle {}^1\psi(A^-D^+)\,|H_{co}|\,{}^3\psi(A^-D^+)\rangle = 0\ , \qquad (18)$$

in contrast to the matrix elements of the spin–orbital coupling of the singlet-excited charge-transfer states and triplet locally excited states:

$$\langle {}^1\psi(A^-D^+)\,|H_{co}|\,{}^3\psi(D^*A)\rangle = -\langle \pi_a|H_{co}|\pi_d\rangle\ . \qquad (19)$$

In Eqns.(18) and (19), π_a is the highest unoccupied orbital of the acceptor, π_d the highest occupied orbital of the donor, and H_{SO} the Hamiltonian of the spin–orbital coupling. The selection rules formulated by Lim et al.[94] agree with the qualitative estimation of the role of the non-radiative transitions

$$S_1 \rightsquigarrow T \text{ and } S_1 \rightsquigarrow S_0$$

in the deactivation of singlet-excited states of various molecular complexes.[94] The main pathway to the deactivation of singlet-excited states of the CTC of tetracyanoethylene with benzene and its alkyl derivatives, whose triplet states are charge-transfer states, is internal conversion. The lowest triplet states of the complexes of the same donors with tetracyanobenzene are of the locally excited type. In conformity with the selection rules formulated, the rate of interconversion for such molecular compounds exceeds the rate of the internal degradation of the electronic excitation energy of the EDA complex. We may note that the conclusions by Lim et al.[94] concerning the pathways followed in the transformation of the electronic excitation energy were made on the basis of indirect data concerning the influence of the deuteriation of the electron donor molecules on the fluorescence quantum yields of the molecular complexes. The introduction of deuterium into the methyl group induces the strongest effects, because their C–H vibrations have the role of promoting modes in internal conversion proceses. For intersystem transitions between close-lying states, the high-frequency C–H vibrations do not fulfil this role. The influence of their isotope substitution on the rates of the transitions

$$S_1 \rightsquigarrow T$$

should therefore be small. the study of the usual and deuteriated complexes makes it possible to determine which of the non-radiative processes—non-radiative degradation or intersystem crossing—deactivates the singlet-excited CTC states. The conclusions reached

from the analysis of the isotope effects are confirmed by phosphorescence measurements, as shown by the analysis of Nagakura's data.[2]

2. Intersystem Crossing Processes Involving Exciplexes

The photoexcitation of solutions of fluorophors containing quenching agent concentrations for which only the bands of exciplexes are observed in the fluorescence spectrum is accompanied by the appearance of relatively intense absorption bands of the triplet molecules of one of the components of the exciplex. In many cases, the calculated interconversion yields proved to be the same or even higher than in the solutions of the same fluorophors without specially introduced quenching agents.[95] It is important that these effects were observed in systems where there were no heavy atoms intensifying the spin–orbit coupling and accelerating the intersystem transitions.

The triplet–triplet absorption bands under discussion are apparently due to the "free" triplet molecules or locally excited triplet exciplexes. It is usually assumed that the primary products of the intersystem transformations of singlet exciplexes are triplet-excited complexes, but the latter are unstable owing to the low enthalpies of formation and decompose immediately (see, for example, Goldschmidt et al.[95]). This postulate, which has become generally accepted, requires an experimental test in each individual case. This is indicated by the data, discussed above, demonstrating the high stability of the locally excited triplet exciplexes of porphyrin compounds, acetone, quinones, and the 9-phenylacridinium cation, which cannot have high enthalpies of formation. Furthermore, relatively stable triplet exciplexes are formed by phenazine compounds with tertiary amines.[82,84] Singlet fluorescent exciplexes, which may undergo intersystem crossing, are also observed in these systems.[96]

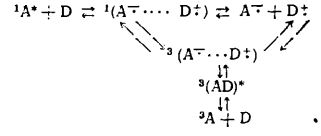
However, despite some uncertainty in the question of the form—"free" or as part of a complex—in which the excited triplet molecule exists, the triplet–triplet absorption recorded in exciplex systems indicates relatively high intersystem crossing yields of the singlet-excited exciplexes.

Studies carried out by the laser photolysis methods have shown that the intersystem crossing in exciplexes takes place after the formation of thermalised fluorescent states. For example, it has been established[97–99] that, as the variable absorption of the exciplex of *NNNN*-tetramethyl-*p*-phenylene-diamine with naphthalene and biphenyl and of anthracene with *NN*-dimethylaniline is quenched, an increase in the intensity of the triplet–triplet absorption band is observed. The kinetics of the accumulation of the triplet molecules then also correspond to the kinetics of the relaxation of the optical density of the absorption band of the singlet-excited complexes. Agreement between the rates of these processes has also been noted in a study[100] of exciplexes of anthracene and pyrene with *NN*-diethylaniline in hexane using the picosecond technique. During the first 200 ps after the laser flash, there were no bands due to triplet molecules in the variable absorption spectrum. This period was sufficient for virtually all the excited species to enter into complex formation and for the excited complexes to pass to the thermalised state. After long periods, an increase in the triplet–triplet absorption, accompanying the destruction of the exciplexes, was observed. These results demonstrated that in non-polar media the intersystem crossing and the fluorescence of the exciplexes are consecutive and not parallel processes.

The formation of triplet states from relaxed exciplexes takes place also in complexes formed as a result of the conformational changes in photoexcited bichromophoric $A-(CH_2)_n-D$ molecules, in which the donor and acceptor groups are linked by a flexible aliphatic chain.[101]

Thus it can now be regarded as established that in non-polar solvents the triplet states are formed as a result of intersystem transitions from relaxed charge-transfer states of the molecular complexes. On this basis, the rate of the intersystem crossing in the exciplex k_T' can be calculated from the formula[102]

$$\frac{k_T'}{k_T} = \frac{(\varphi_T/\varphi_T^0)(\varphi^0/\varphi) - 1}{(\varphi^0/\varphi) - 1} \cdot \frac{\tau_0}{\tau_0'},$$



where τ_0 is the lifetime of the excited fluorophor in the absence of quenching agents, τ_0' the lifetime of the exciplex, φ^0 and φ are the fluorescence quantum yields, and φ_T^0 and φ_T are the quantum yields of the triplet molecules in the absence and presence of the quenching agent respectively.

The rate constants and quantum yields of the intersystem crossing in exciplexes are determined by the nature of the reactants. For example, quenching of the fluorescence of pyrene and anthracene by amines increases the yield of the triplet state of the hydrocarbons.[95] The formation of exciplexes of *NN*-dimethyl-β-naphthylamine with dimethyl isophthalate lowers the yields of the triplet molecules compared with the yield of the triplet molecules of the above amine in the absence of a quenching agent.[103] We may quote yet another example. The rate constants for the intersystem crossing in the exciplexes of 9,10-dicyanoanthracene with aromatic hydrocarbons are approximately 10^7 s^{-1} and those for the exciplexes with tertiary amines are approximately 10^9 s^{-1}.[102] Many of the features of the intersystem crossing in exciplexes can apparently be explained using the selection rules formulated in the previous Section, according to which the intersystem transitions in molecular complexes take place between charge-transfer and locally excited triplet states. The quantum yields in the formation of the triplet molecules diminish as a result of complex formation if the triplet locally excited states have a higher energy than the fluorescent state of the exciplexes. Another factor influencing the yield of the triplet molecules can be a change in the structure of the exciplex. This postulate has been confirmed by the results of a study on the intersystem transitions in intramolecular exciplexes.

The structures of the intramolecular exciplexes are known to be determined by the length of the chain linking the electron donor and electron acceptor groups.[104] For $n = 3$, there is a possibility of the formation of sandwich structures with a parallel arrangement of the planes of the donor and acceptor components. In such exciplexes, the intersystem transitions take place at relatively low rates close to the rates of the intersystem transitions in the majority of aromatic molecules (approximately 10^7 s^{-1}).[101] For $n = 1$ or 2 in singlet exciplexes, the molecules are arranged in planes which are almost perpendicular with respect to one another.[105] The transition from the sandwich to the "perpendicular" structure induces a marked increase in the rate of intersystem crossing.[101] These changes are explained by an increase in the matrix elements of the spin–orbit coupling of the corresponding states, whose values determine the rates of the intersystem transition. The rate of intersystem crossing can evidently be influenced, apart from the factors indicated, also by the charge distribution in the complexes and by the distance between the donor and acceptor groups. As a consequence of this, the rates of the intersystem transitions in exciplexes are extremely sensitive to

various structural factors. It is therefore not surprising that solvents capable of influencing appreciably the structures of excited molecular complexes alter the rates of the transitions from the single-excited to the triplet-excited states. As an example, one may quote again intramolecular exciplexes. An increase in solvent polarity weakens the Coulombic attraction of the charged parts of the exciplex. This alters the structure of the excited complex, which is reflected in the absorption spectra of the exciplexes.[106] Pronounced solvation induces conformational transitions and alters thereby the spin–orbital coupling and the rate of intersystem processes.[101] However, in the study of the influence of the solvent on the spin evolution of the intermolecular exciplex systems, it is essential to take into account the fact that in highly polar media there is a possibility of the operation of completely different mechanisms of intersystem crossing. In this connection, we shall characterise briefly the mechanisms of the formation of triplet-excited molecules in polar media.

In polar solvents, the quenching agent interacting with a singlet-excited molecule can also induce its transition to the triplet state. For example, the flash photoexcitation of acetonitrile solutions of aromatic hydrocarbons and electron donors (or acceptors) induces the appearance of triplet hydrocarbon molecules apart from the radical-ion products.[95] The mechanism of these photoprocesses has been established with the aid of nanosecond and picosecond laser photolysis.[107,108] In highly polar solvents, triplet states are formed as a result of at least two main types of reactions—the relatively slow recombination of the free radical-ions and the rapid intersystem crossing in the geminal radical-ion pairs. It is quite possible that the primary products of the geminal recombination of the radical-ion pairs are triplet exciplexes:[109,110]

It has been suggested that the intersystem transition from a singlet radical-ion pair to a triplet pair takes place via the so called hyperfine interaction mechanism, which is indicated by data concerning the influence of weak magnetic fields on the yields of triplet states.[101]

The Study of the Boundary Viscosity of Organic Liquids by the Blow-off Method

B.V.Deryagin and V.V.Karasev (deceased)

A method is described for the investigation of the boundary viscosity of liquids based on the fact that, when a layer of liquid flows on a flat wall under the influence of a stream of gas flowing above it, the film assumes a wedge-shaped form (the blow-off method). It is shown that the profile of the resulting wedge resembles that of the velocity profile, which makes it possible to determine from this profile the viscosity as a function of the distance to the support. Another method for the layer-by-layer determination of the viscosity is based on the measurement of the thickness of the film as a function of the duration of the blow-off process at a specific distance from the wetting boundary. In order to determine the film profile, optical and especially ellipsometric methods have been used.
In order to extend the range of objects of study, a method has been developed for the investigation of the boundary viscosity of volatile liquids and its theory has been specified. It has been applied to hexadecane and it has been observed that the viscosity decreases at short distances from the wall.
The bibliography includes 67 references.

I. INTRODUCTION

The theory of the stability of colloids[1] is based on the idea of the wedging pressure of thin liquid layers and its components. In devising a theory of lyophobic disperse systems, only two components of the wedging pressure were initially taken into account – the ionic-electrostatic and molecular components.[1] Subsequently, the concept of the structural component of the wedging pressure, for brevity referred to as the structural forces, was introduced to account for the stability of lyophilic disperse systems. The idea of the existence of this component was first put forward by one of the authors of this review on the basis of experiments with wetting and absorption layers on hydrophilic surfaces.[2-5] These forces arise as a result of the overlap of the boundary layers, whose structure has been made anisotropic in contrast to the isotropic structure of the same phase in bulk. On this basis, attempts have been made to create a quantitative theory of structural forces.[6,7]

In order to strengthen the very basis of this approach, it is important to establish by independent, direct methods the existence and to elucidate the character of the structural features of the boundary layers on lyophilic supports. The difficulty of this problem is due to the small thickness and the possible inhomogeneity of boundary layers with an unusual structure. Dielectric structural methods therefore usually yield only an average characteristic. An exception is the method based on the determination of the weakening of the plane-polarised light transmitted through a thin layer of liquid as a function of the thickness of the latter, which has been proposed and developed by Popovskii, Altoiz, and other workers.[8-18] However, this method is applicable only to a specific class of liquids, for example, to substituted benzenes or benzoic acids, which exhibit a specific strong absorption in a definite part of the spectrum.

This review describes the outcome of experiments on the "layer-by-layer" measurement of viscosity by the method involving the blowing off of wetting films of various organic liquids. These measurements made it possible to establish the changes in viscosity occurring as the solid support is approached, as a function of the distance from it. The change in the structure of the liquids in layers near the support under the influence of the latter has been demonstrated thereby, since viscosity is a property sensitive to structural characteristics.

The determination of the viscosity of thin liquid layers is of direct interest for the study of the mass-transfer processes in narrow capillaries, slits, and disperse systems, in particular for the treatment of the boundary lubrication and filtration phenomena and membrane processes.

The flow of liquid through narrow capillaries was used in early investigations, for example in those of Traube and Siar-Hong-Wang[19] and Deryagin and Krylov,[20] who observed anomalous phenomena in the flow of water in porous bodies with a pore diameter of 0.15 μm. It was also found that, as a result of the coating of the pore walls by oleic acid monolayers, the flow rate increased by a factor of 7 (see also the studies of Somov and Churaev[21] and Peschel and Adlfinger[22]).

Deryagin and Samygin developed a centrifugation method.[23,24] It is based on the observation of the movement of a cylindrical air bubble in a sealed tube filled with the test liquid. The movement of the bubble in the direction of the centrifuge axis takes place as a result of the flow of liquid, forming a film between the air bubble and the walls of the tube, in the opposite direction. The viscosity η was calculated from the formula

$$\eta = \frac{2}{3}\frac{h^3}{rv} j \quad ,$$

where r is the radius of the tube, v the velocity of the bubble, j the centripetal acceleration, and h the thickness of the film.

In order to determine the film thickness h, the ends of the tube were narrowed. We shall denote by V_1 and V_2 the volumes of the liquid in these capillary ends by S the area of the film. By vigorous centrifugation with simultaneous heating, the liquid and the wetting film were driven to one end of the tube in which they occupied a volume V_0. The film thickness was determined from the formula

$$h=\frac{V_0-V_1-V_2}{S} .$$

An increase in viscosity at a distance of 0.1 μm from the wall was observed for certain liquids by this method. In one case it was possible to estimate the increase in viscosity at a distance of 0.02 μm. Hence it is clear that the centrifugation method is more sensitive than all previous procedures. However, in this method too the flow of liquid takes place under the influence of volume forces, which precludes the determination of the viscosity as a function of the distance from the wall.

II. THE BLOW-OFF METHOD

The layer-by-layer method for the measurement of the boundary viscosity—the blow-off method—proposed by one of the authors of the present review,[25,27] is a unique procedure which makes it possible to determine the distribution of the viscosity along the thickness of the boundary layer by the most direct and clearest procedure. Its essential feature is as follows. Imagine a channel bounded by two parallel planes which are separated from one another by a small distance $H = 0.2-1.0$ mm; a layer of the test liquid is deposited on one of the walls (Fig.1). When air or nitrogen is blown through, a flow arises in the film. The drop in air pressure arising between the ends of the channel is measured with a differential manometer.

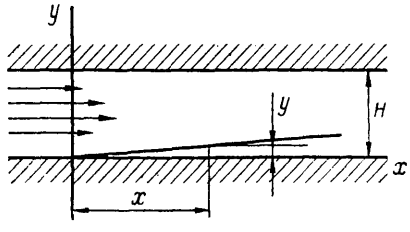

Figure 1. Schematic illustration of the blow-off method.

Tangential and normal forces act on the film. It has been shown that, when a number of conditions are satisfied, the gradient of normal forces may be neglected; in other words, the inequality

$$\delta=\frac{Q_2}{Q_1}\ll 1 ,$$

where Q_1 is the flux under the influence of tangential forces and Q_2 the flux under the influence of the gradient of normal forces, is valid.

If the law of conservation of momentum is applied to the mass of air moving in a slit, we have

$$H\Delta p-2\bar{F}\Delta l=\Delta\int_0^H \rho v^2\,dy ,$$

where $\bar{F}$ is the average tangential frictional force, Δl the length of the slit, ρ the density of air, v the velocity of air molecules, H the slit width, and Δp the pressure difference between the two ends of the slit. Taking into account the continuity equation and applying the parabolic law of the distribution of velocity in a slit, we obtain after appropriate transformations

$$H\Delta p=2\bar{F}\Delta l+\frac{8}{15}H\rho v\Delta v . \qquad (1)$$

Using the relations

$$F=\left(\frac{\partial v}{\partial y}\right)_{y=0}=4\eta\frac{v}{H} ,$$

$$\mathrm{Re}=H\rho v_{max}/\eta ,$$

where η is the viscosity, Re the Reynolds number, and v_{max} the maximum velocity at the centre of the slit, we finally obtain after substitution in Eqn.(1)

$$\frac{\Delta p}{\Delta l}\cong\frac{dp}{dl}=\frac{2\bar{F}}{H}+\frac{2}{15}\mathrm{Re}\frac{\Delta F}{\Delta l} . \qquad (2)$$

On substituting the resulting expression in the formula for the flux ratio, we have

$$\frac{Q_2}{Q_1}=\frac{4}{3}\frac{h}{H}+\frac{4}{15}\mathrm{Re}\frac{h}{\Delta l}\frac{\Delta F}{\bar{F}} . \qquad (3)$$

In order that δ should be small, the ratios h/H, $h/\Delta l$, and $\Delta F/\bar{F}$ should be small. As regards the first condition, it is permissible that $h/H \leqslant 0.01$. The inadmissability of the variation of $\bar{F}$ along the air stream requires that the inequality $\Delta F/\bar{F} < 0.05$ should hold, which was always the case in our measurements. Applying the continuity equation and the Boyle–Marriotte law, we replace $\Delta F/\bar{F}$ by $\Delta p/p$ and obtain the condition $\Delta p/p < 0.05$, which can be readily achieved at $p = 760$ mmHg; $h/\Delta l$ was always less than 10^{-4} in our experiments.

It it is assumed that $\mathrm{Re} < 10^3$, which corresponds to the condition for a laminar blowing off stream, then we obtain $\delta < 1.4\times 10^{-2}$ from Eqn.(1). Assuming simultaneously that $\Delta F/F < 0.05$ and $H/\Delta l < 0.005$, we find from Eqn.(2) that the following relation is valid with a relative error of approximately 2%:

$$\bar{F}=\frac{H}{2}\frac{\Delta p}{\Delta l} .$$

For sufficiently small values of δ, the flow of the film solely under the influence of tangential forces is ensured. By virtue of this condition, the velocity of the molecules is a function solely of the distance from the wall y and is independent of the distance x from the wetting boundary—a situation resembling the collapse of a pack of cards. In particular, the points located on the outer surface of the wetting film also have the same velocity $u(y)$. The velocity of the latter can be found from the change in the film profile obtained as a result of the blow-off process. If the initial profile is described by the expression $x = x_0(y)$ and the final profile, after a time τ has elapsed, is described by the expression $x = x(y)$, then $x = x_0 + u(y)\tau$. One can then write $u(y) = [x(y) - x_0]/\tau$. The viscosity can be inferred from the profile:

$$\eta(y)=\frac{F}{du/dy} .$$

When η is constant, the quantity du/dy must also be constant, which corresponds to the equation $x(y) = \text{const.} \times y$, i.e. the film assumes the form of a wedge with a flat surface. The increase in η for low volumes of y leads to the "blunting" and its decrease to the "sharpening" of the wedge.

III. APPARATUS FOR THE STUDY OF THE BOUNDARY VISCOSITY BY THE BLOW-OFF METHOD

The apparatus for the study of the boundary viscosity by the blow-off method,[28,29] illustrated in Fig.2, consists of a metallic block *1* with a groove, open on top, having a semicircular cross-section, to which two smaller blocks *2* with tubes *7* and channels for the admission and release of gas are attached. Flexible tubing, connecting the

apparatus to the source of gas (nitrogen cylinder, air blower, etc.), is attached to one of the tubes *7*. In block *1*, there is a groove in which a steel insert *3* is placed. A steel or glass plate *4* with an optically polished lower surface is put on top of the apparatus. A gap is formed between the plate *4* and the insert *3* through which air or nitrogen is blown. By selecting the size of the inserts, it was found that the most suitable gap is 0.2 mm. In order to determine the pressure drop in the block *1*, two channels *5* were drilled and connected to the tubes *6*, to which a differential manometer was also connected. The film of the test liquid is deposited on part of the upper plate *4* or on part of the insert *3*. The wetting boundary must be located at right angles to the direction of the stream of gas (Fig.2, line *aa*). A steel plate from the "Kalibr" factory with additional optical polishing was used as the support.

The surface was cleaned with ether. In those cases where special cleanliness was required, the cleaning was carried out with the aid of a gas discharge in argon.[30] The film was deposited by the draining method developed by one of the authors of the present review.[31-33] Several drops of the test liquid were placed on the surface of the plate and the wetting boundary was smoothed out with a thin glass rod. In this deposition method, the film has an inhomogeneous thickness in the initial instant. However, special experiments showed that, in conformity with the theory, this is in no way reflected in the pattern obtained in the blow-off process even after a short time. An apparatus for the study of the boundary viscosity with a variable gap has also been used.[34]

In those cases where special cleanliness is required (for example, in the study of solutions of organic compounds at a low concentration in liquid paraffin) a glass device capable of being disassembled was used,[29] its components being washed with chromic acid mixture, which was followed by treatment in the gas discharge.

Turbine oil and solutions of "metallic soaps" in turbine oil, which are used to improve the lubricating properties of liquids, were investigated for the first time by the blow-off method.[25,26]

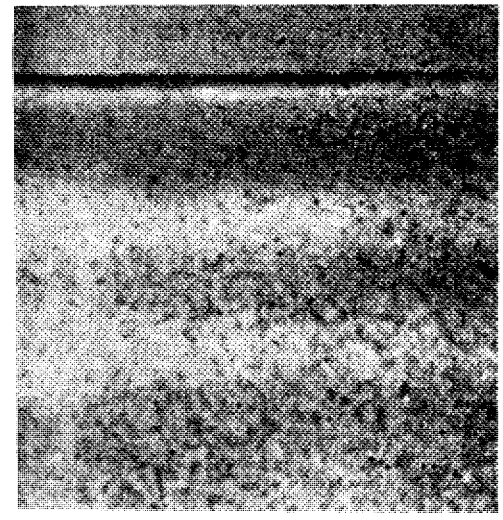

Figure 3. Interference pattern obtained in an experiment involving the blowing off of a 2% solution of aluminium naphthenate in turbine oil; blow-off time 8 min.

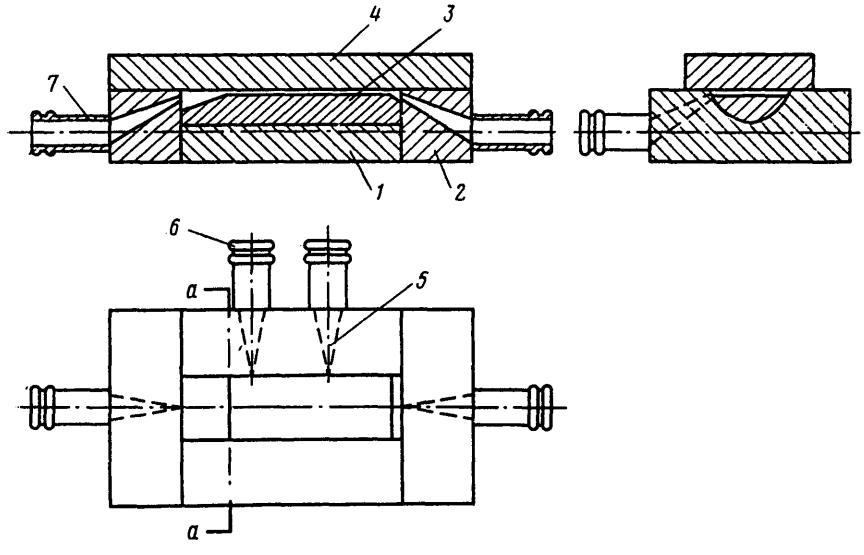

Figure 2. Apparatus for the investigation of the boundary viscosity by the blow-off method.

IV. THE STUDY OF THE BOUNDARY VISCOSITY OF LIQUIDS BY OPTICAL METHODS

1. Determination of the Thickness of Layers by the Interference Methods

Fig.3 presents the interference pattern obtained for a 2.5% solution of aluminium naphthenate in turbine oil The photograph shows the narrow first band, which indicates an increase in the viscosity of the liquid near the wall. The interpretation of this interference pattern leads to the velocity profile illustrated in Fig.4. A similar velocity profile is also observed when aluminium naphthenate is added to other oils.

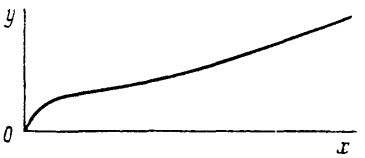

Figure 4. Velocity profile of a 1−2% solution of aluminium naphthenate.

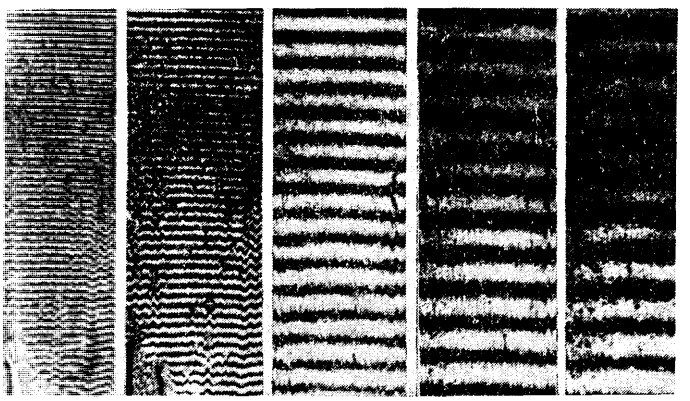

Figure 5. Inteference pattern obtained during the blowing off of turbine oil.

A series of studies have been carried out [35,36] on the properties of various high-molecular-weight organic liquids and solutions of certain polymers in turbine oil and liquid paraffin. For convenience, the authors recorded the blow-off process by filming it. The thickness of the wedge-shaped film was determined from the formula $h = (2n + 1)\lambda/4$, where n is the number of the interference band and λ the wavelength of the monochromatic light. Turbine oil was tested initially. It is seen from the film frames shown in Fig.5 that the distances between the bands are identical. Consequently the viscosity is independent of the distance from the supports, which agrees with the results of earlier studies.[25,26] The pattern is quite striking. The movement of the bands apart as a function of time is observed with a gradual retardation. The thin bands located approximately at right angles to the interference bands represent a parasitic phenomenon due to the interference in the blow-off channel by virtue of the very highly monochromatic nature of the light source.

Fig.6 presents film frames which illustrate the flow of hexamethoxydecane, having an increased viscosity at the boundary with the metal. In this case a small increase in viscosity within the limits of two to three bands is observed. Fig.7 illustrates the flow of a layer of tetraethoxyhexane; in this case the viscosity decreases within the limits of the first two bands. In order to investigate the behaviour of polymers at different temperatures, the apparatus was thermostatted.[37]

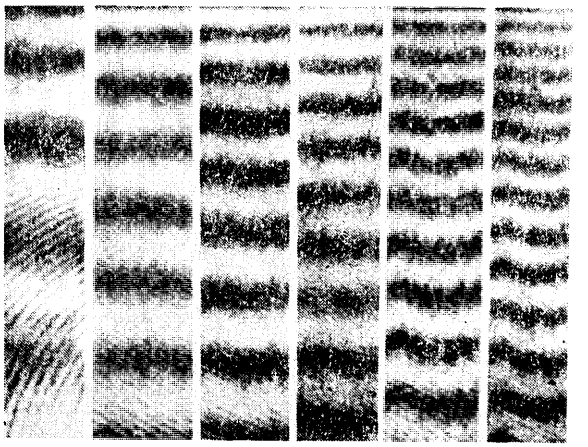

Figure 6. Interference pattern in the course of the blowing off of hexaethoxydecane.

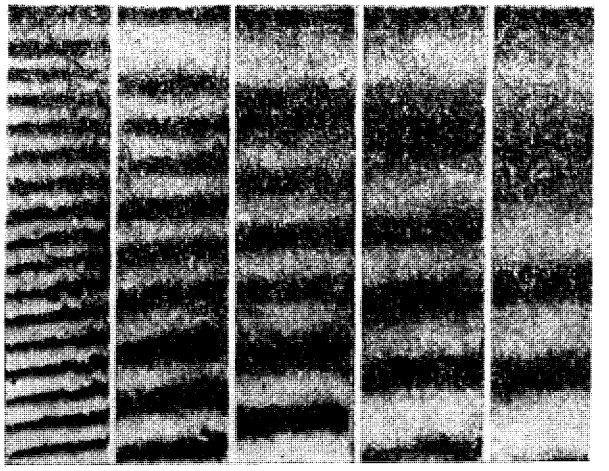

Figure 7. Interference pattern in the course of the blowing off of tetraethoxyhexane.

In the study of polymers of butyl vinyl ether (vinipol) and their solutions in turbine oil and certain other liquids, a change in viscosity was observed as a function of the distance from the solid wall within the limits of $\pm(5-6)$ μm. It was noted that, after the attainment of a definite film thickness, the interference bands disappear and a "ripple" appears on the surface of the film.[35-37] This instability extends over a distance up to 10 μm (Figs.8 and 9). The maximum instability is observed at certain added concentrations of vinipol in turbine oil, which are lower the higher the molecular weight of the vinipol.

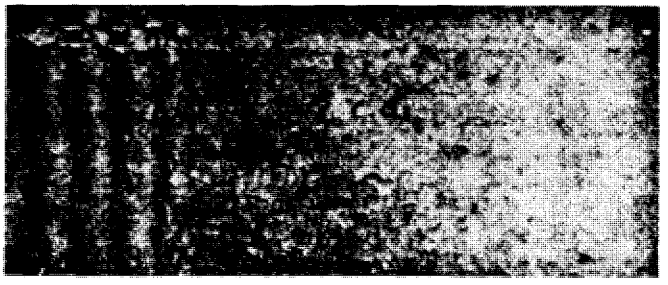

Figure 8. Interference after blowing off a 0.5% solution of vinipol with a molecular weight M = 3850 in turbine oil (Δp = 15 mmHg, τ = 5 min); the break up of the film can be seen (instability zone).

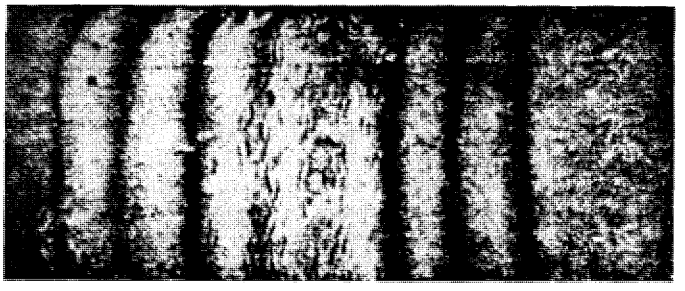

Figure 9. Interference pattern after blowing off a 0.04% solution of vinipol with M = 2100 in turbine oil (Δp = 25 mmHg, τ = 22 min).

In certain cases instability is observed also for "pure" polymers with a narrow molecular weight distribution (MWD). With increase in the molecular weight of vinipol, the thickness of the film, outside the limits of which the region of instability of the interference pattern begins, increases. The instability is manifested to a greater extent if the blowing off is preceded by prolonged contact between the film of the polymer solution and the metal. With increase in temperature, the instability of films of vinipol solutions grows very little, in contrast to the pure vinipol. It follows from thermodynamic considerations that the instability of the wetting film indicates that, in the corresponding range of thicknesses, the derivative of the wedging pressure with respect to the film thickness is positive. Since films whose thickness amounts to several micrometers are unstable, it follows that for such thicknesses the wedging pressure and its derivative have values sufficiently high for the breakdown of liquid films even when their viscosity is high. Evidently the structural component of the wedging pressure is manifested here.[38]

In order to investigate films with a smaller thickness, more accurate optical methods were employed. The photometric method was used first.[39,40] For this purpose, the outlet slit of the monochromator was projected onto the wedge shaped film obtained in the blow-off process. The film thickness was calculated from the intensity of the reflected light. A linear velocity profile was obtained by this method for carefully purified liquid paraffin, which indicates the absence of a specific boundary viscosity.

Polarimetric methods were used to increase the sensitivity still further.[28]

2. Measurement of the Film Thickness by Polarimetric Methods

The scheme illustrated in Fig.10 was used when polarimetric methods were applied to the measurement of the film thickness. When plane-polarised light is reflected from the plate with the film deposited on it, the components of the electric vector of the light wave, lying in the incidence plane and in the plane perpendicular to it, have different reflection coefficients, whose ratio depends on the film thickness. Knowing the ratio of the reflection coefficients, it is possible to determine the film thickness.

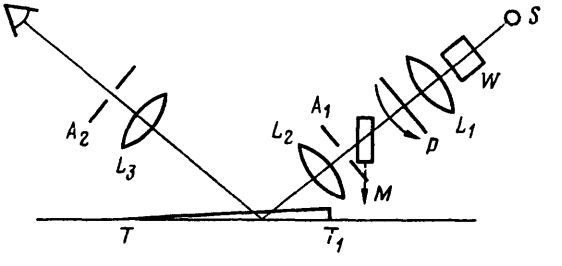

Figure 10. Schematic illustration of the apparatus for the determination of the film profile by the polarimetric method.

An apparatus with a stack of plates (Fig.10) was used to determine the ratio of the reflection coefficients. Here S is the source of monochromatic light (PRK-2 quartz lamp), W a liquid light filter (solution of neodymium nitrate with an admixture of chrysoidine and eosine), L_1 the condenser lens, P a rotating polariser (polaroid), M a stack of 9 x 12 glass plates (12 plates), A_1 an adjustable slit, L_2 a lens focussing the image of the slit onto the object, $T-T_1$ the object of study—a transparent film on a metal or dielectric, A_2 the aperture (slit) diaphragm, and L_3 an image diffusing lens.

The principle of the operation of the apparatus is as follows. If a beam of plane-polarised light is directed onto the surface of the metal with the film deposited on it, then the horizontal and vertical components of the electric vector of the light wave are in general reflected unequally, as a result of which the light flux is modulated on rotation of the polariser. The maximum intensity of the reflected light is attained when the plane of the vibrations in the rotating

polariser coincides with the direction of the most intense component of the above vector and the minimum intensity occurs correspondingly after coincidence with the least intense component (i.e. on rotation by 90°). The degree of polarisation of light transmitted through the stack of plates is known to depend on the angle between the normal to the stack and the beam incident on it. With increase in this angle as a consequence of the rotation of the stack about the axis perpendicular to the direction of the beam and parallel to the direction of the vibrations with the least amplitude, the degree of polarisation increases. Thus, we can always "attenuate" the more intense component of the electric field vector by rotating the stack, making it comparable to the least intense component. In this case modulation ceases, which is observed from the absence of periodic variations in the brightness of the reflected light. The corresponding angle of rotation of the stack depends on the ratio of the reflection coefficients of the horizontal and vertical components of the electric field vector of the light wave.

In order to increase further the accuracy of the reading and to expand the range of the measurable thicknesses towards lower values, a scheme resembling that of the Drude scheme with a photoelectric indicator was used; the scheme was applied in different versions, the locations of the light source and the indicator being interchanged.[41–46] At the present time the film thickness is calculated on a computer by means of appropriate programs.

Polished metallic surfaces are known to possess a microhardness, i.e. there are grooves approximately 40–80 Å deep and 80–160 Å wide in the direction along the plane.† At the end of the experiment, they are filled with the test liquid. However, the optical constants of the plate, measured before and after the experiment, proved to be very similar, which suggests that the liquid in the groove does not exert any special influence on the optical constants of the support. Although a random mosaic structure, consisting of islands and hollows with "diffuse" edges, filled with liquid, is observed on the surface of the metallic plate, the effective refractive index of this system remains close to the refractive index obtained for the specimen of the pure metal with a thin oxide film. Consequently, the film thicknesses are read from a certain arbitrary boundary passing near the tops of the peaks of the surface relief.

3. The Study of Certain Organic Substances by the Blow-off Method Using Polarimetric Procedures

The objects of the study of the boundary viscosity by polarimetric methods were turbine oil and liquid paraffins of different brands: paraffin purified by the acid–alkaline method, paraffin treated over a platinum catalyst by the Elovich method, D-1 oil, and pharmaceutical liquid paraffin purified chromatographically. Rigorously linear velocity profiles were obtained in all cases. After this, a 2.5% solution of vinipol ($M \simeq 4000$) in turbine oil was tested.[48] A decrease in viscosity near the wall over distances up to 1000 Å was observed in this case (Fig.11). In the study of the 0.5% solution of synthetic sodium-butadiene rubber in turbine oil,[48] some increase in viscosity in a layer 100–200 Å thick was observed (Fig.12).

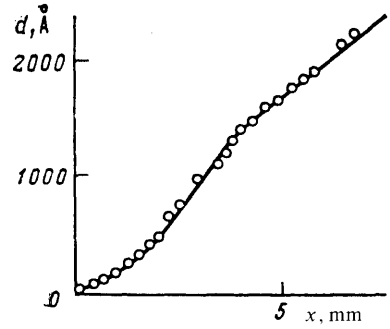

Figure 11. Film profile for a 2.5% solution of vinipol with $M \simeq 4000$ in turbine oil, obtained on the apparatus with a stack of plates.

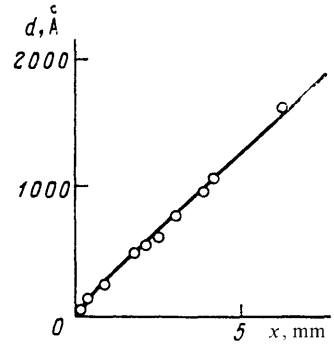

Figure 12. Film profile for a 0.5% solution of sodium-butadiene rubber in turbine oil, obtained on the apparatus with a coherence eliminating device.

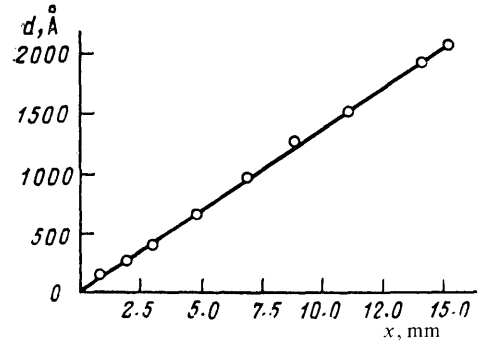

Figure 13. Film profile for purified liquid paraffin.

Further measurements were performed on ellipsometers. In the first place, the velocity profile was obtained for liquid paraffin specially purified on a platinum catalyst. The linear velocity profile was retained down to the thickness of 10 Å (Fig.13). Finally, a large number of organosilicon compounds were investigated.[49,56]

†According to electron microscope data obtained by A.E.Chalykh and Z.E.Sheshenina.

The study of the viscosity of boundary layers of polymers is of special interest from the standpoint of the elucidation of the influence of their molecular characteristics—the molecular weight, the rigidity of the molecular chain, the chemical composiiton, and the level of intermolecular interaction—on the properties of the boundary layers of polymers. We may note that organosilicon polymers and oligomers are very interesting objects for the study of the boundary viscosity. Firstly, polyorganosiloxanes retain their liquid state over a very wide range of molecular weights. Secondly, the replacement of methyl groups in polydimethylsiloxanes by other groups makes it possible to vary within fairly wide limits both the flexibility of the polymer chains of the molecule and the character and level of the intermolecular interaction in polyorganosiloxanes.[57,58]

We investigated polydimethylsiloxane liquids (PMS) with molecular weights ranging from 1000 to 40 000 and viscosities from 0.05 to 20 St[52] (at 20 °C) and a series of substituted oligo-organosiloxanes containing ethyl, phenyl, chlorophenyl, γ-trifluoropropyl, and other groups.[54] The influence of the molecular weight and of the molecular weight distribution of the polymer on its behaviour in boundary layers as well as of temperature and factors such as photo- and thermo-oxidation has been studied in relation to polydimethylsiloxanes. Their boundary viscosity was investigated on glass and metallic surfaces.

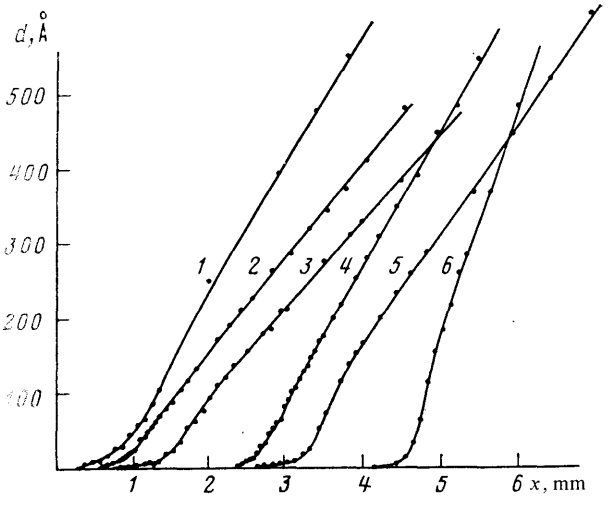

Figure 14. Film profiles for PMS having different molecular weights with a narrow MWD = 1.2–1.5 on steel: 1) PMS-5; 2) PMS-10; 3) PMS-25; 4) PMS-70; 5) PMS-400; 6) PMS-2000.

The velocity profiles for the flow of PMS films having different molecular weights and with a narrow MWD on steel are presented in Fig.14. Their common feature is the presence of three sections in the curve with different slopes and hence with different viscosities of the corresponding liquid layers. A sharp decrease in the viscosity of the liquid is observed for a layer thickness of 20–30 Å, the viscosity is 30–40% higher in the range of thicknesses from 20–30 to 150–200 Å than in the bulk phase, while the viscosity of a layer 150–200 Å thick does not differ from that in the bulk phase determined with the aid of a capillary viscometer. For example, these quantities are respectively 4.92 and 4.70 cP and 69.68 and 68.25 cP respectively for the PMS-5 and PMS-70 polydimethylsiloxanes.

Bearing in mind the extreme flexibility of the main molecular chain and the weak intermolecular interaction, the molecular structure of the PMS in the bulk phase can be represented as an assembly of species whose conformational spectrum is extremely broad—from coiled to uncoiled molecules with the former predominating. The flow velocity profile observed for PMS films can be accounted for by the variation of the conformational equilibrium of the PMS molecules in the force field of the surface of the solid phase.

The anomalously low viscosity of PMS in layers adjoining the surface of the solid phase is apparently due to the uncoiling of the molecular coils and the subsequent orientation of the uncoiled chains parallel to the plane of the support. Such orientation should be promoted by the high polarisability of the $Si^{\tau+}-O^{\tau-}$ bond, each atom of which can become a centre of attraction to the surface of the solid phase and can promote the horizontal orientation of the PMS molecules on absorption. A monomolecular PMS layer with a horizontal orientation of the molecules is known to have a thickness of 5–6 Å. Taking this into account, one can postulate that the "lower" boundary layer is made up of several horizontallly oriented layers of PMS molecules. The anomalously low viscosity can be explained in this instance by the ready slip of these layers relative to one another over planes bounded by methyl groups. The fact that the thickness of the boundary layer is independent of the molecular weight of the PMS confirms the hypothesis of the horizontal orientation of the uncoiled molecular chains. In liquid layers more remote from the support, the influence of this force field on the solid phase is weakened and the polymolecular boundary layer breaks down. The orientation of the molecules, which still have an uncoiled conformation, then becomes random; this should increase the viscosity, which has in fact been observed for liquid layers with a thickness from 20–30 to 150–200 Å. Above this level, the viscosity falls, evidently as a consequence of the coiling of the molecules, and subsequently remains constant and equal to the viscosity of the liquid in the bulk phase. In this range of thicknesses, the surface of the solid phase apparently does not influence the molecular structure of the liquid. According to the results of Fox et al.,[59,60] in the course of time the "lower" layers in the boundary phase should be gradually enriched in the high-molecular-weight component. This should lead to an increase in the viscosity of the PMS in layers fairly close to the support.

Thus the viscosity of layers in the boundary phase is determined by the occurrence of two competing processes: ordered horizontal orientation of the linear molecules, which decreases the viscosity, and the increase in the concentration of the high-molecular component which increases it. In the series of PMS, the viscosity of the "lower" boundary phase of the PMS proved to be reduced in all the cases examined compared with the bulk phase. This means that the process involving the orientation of the molecules predominates and surface fractionation is hardly manifested owing to the narrow MWD of the PMS investigated.

The phenomenon of the fractionation of polymers with respect to molecular weights in the force field of the solid phase has been confirmed in a study of the boundary viscosity of binary mixtures of PMS having different molecular weights with the polydimethylsiloxane liquid PMS-10. The flow velocity profiles of films of these mixtures (Fig.15) differ significantly from the profiles of the films examined previously. They are characterised by the presence of steps in

the range of thicknesses 10–30 Å. The overall form and height of the steps are readily reproducible in replicate experiments and are independent of the molecular weight of the dissolved PMS. It is essential to note that the stepwise profile is obtained when the blowing off is carried out after the film of the test liquid has been maintained for 30 min on the suport. The stepwise profile of the film is not a consequence of its instability, since its form is retained after the blown off film has been kept for 1.5 h with certain intermediate measurements. Steps on the flow velocity profiles of films of binary PMS mixtures (Fig.15) show that in the region adjoining the support there are layers of liquids with an enhanced viscosity which are formed as a result of the enrichment of the boundary layer in the high-molecular-weight components of the mixture,[59,60] i.e. as a result of the surface fractionation of the polymer.

The increase in the viscosity of the boundary layer may indicate the occurrence in the polymer of processes associated with the change (expansion) of the MWD by external influences such as thermo- and photo-oxidation. It is known[61–63] that these processes lead to the cross-linking of the PMS macromolecules resulting in the formation of a gel. The accumulation of the oxidation products at an early stage of the process should alter the MWD and correspondingly the shape of the flow velocity profile of the film. As can be seen from Fig.16, the profiles of the PMS-200 films after thermo-oxidation differ from the initial films by the presence of steps or slip planes in the range of thicknesses up to 20 Å. The height of the steps remains stable throughout the series of experiments regardless of the degree of oxidation. With increse in the degree of oxidation, layers with enhanced viscosity become more distinct in the film profile. On the other hand, judging from the slope of the curves, the bulk viscosity does not change significantly.

In the photo-oxidation of PMS-200, a pattern analogous to that described above is observed (Fig.17): steps and slip planes appear on the film profiles of the liquid subjected to photo-oxidation for 12 and 48 h (curve *3*), such steps and planes being absent from the initial specimen. The bulk viscosity then increases appreciably with increase in the oxidation time and, in contrast to the previous case, is more sensitive to irradiation than the viscosity of the boundary layer.

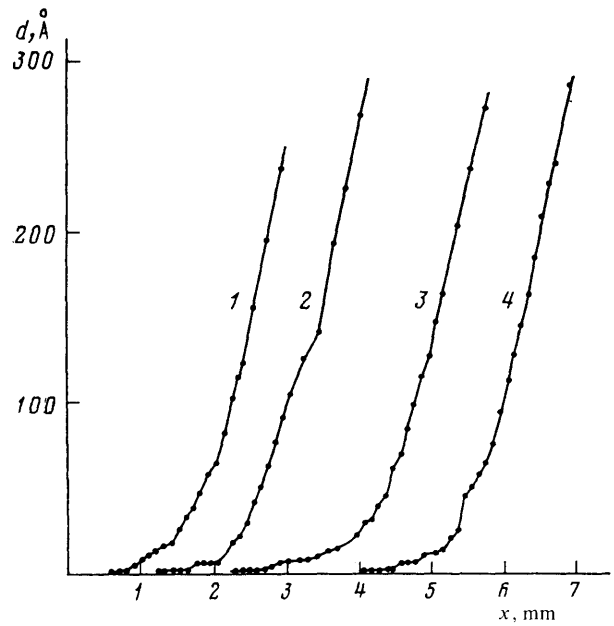

Figure 16. Profiles of PMS-200 films subjected to thermo-oxidation: 1) initial PMS-200; 2) PMS-200 oxidised for 15 h; 3) PMS-200 oxidised for 30 h; 4) PMS-200 oxidised for 45 h.

In both cases (in the thermo- and photo-oxidation of films), together with the stable elements of the profile (steps and slip planes), random bends appear on the velocity profiles which apparently reflect the random structural fluctuations in the polymer manifested in the blow-off process and caused by the presence of polar oxidation products. The formation of an adsorbed layer approximately 6 Å thick, firmly bound to the support, may be noted as a distinctive feature in the case of photo-oxidation.[55,57,58] Presumably this layer is made up of molecules of the test liquid chemisorbed on

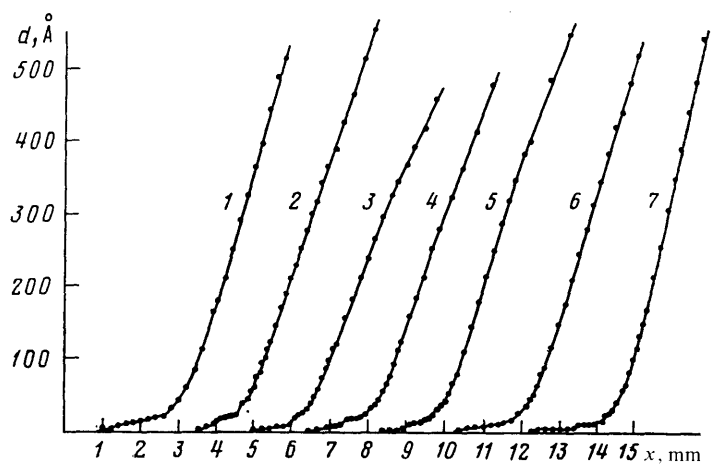

Figure 15. Film profiles for binary PMS mixtures: 1) PMS-10; 2) PMS-10 + PMS-70; 3) PMS-10 + PMS-400; 4) PMS-10 + PMS-2000; 5) PMS-10 + PMS-20 000; 6) PMS-10 + PMS-50 000; 7) PMS-10 + PMS-1 000 000.

the surface of the support by virtue of the presence in them of peroxy-radicals (CH_2OO or other reactive groups), formed as a result of oxidation processes initiated by UV radiation. This layer can be removed from the support only by repolishing its surface.

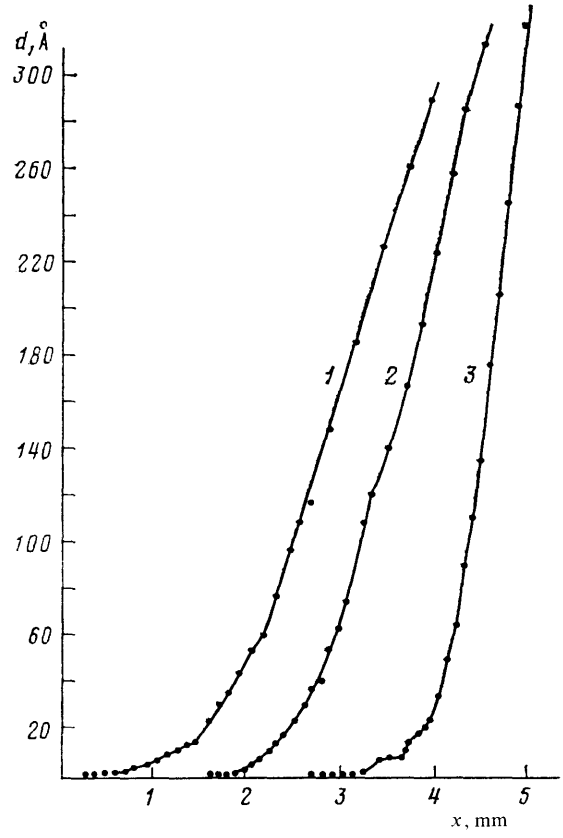

Figure 17. Profiles of PMS-200 films subjected to photodegradation: 1) initial PMS-200; 2) PMS-200 oxidised for 12 h; 3) PMS-200 oxidised for 48 h.

The substitution of methyl groups at the silicon atoms by groups of other chemical nature alters both the level and character of the intermolecular interaction and the degree of flexibility of the molecular chain.[57,58] It was shown earlier[50] that the introduction of polar β-cyanoethyl subsituents into the PMS molecule is accompanied by an appreciable increase in the level of intermolecular interaction as a result of the formation of a fluctuating network of bonds between the polar groups of neighbouring molecules. The flexibility of the molecular chains does not change significantly, which indicates an influence on the behaviour of such polymers in the vicinity of the surface of the solid. Indeed, in the presence of methyl-β-cyanoethylsiloxane units (Fig.18), an increase in the thickness of the boundary layer with an enhanced viscosity on average up to 60 Å is observed. Above 60 Å, the viscosity corresponds to the bulk phase value. It was found that the character of the flow velocity profiles of the film depends on the number of β-cyanoethyl groups. A smooth decrease in viscosity in the boundary layer is characteristic of liquids containing 6 and 100 mole% of methyl-β-cyanoethylsiloxane units (Fig.18, curves *1* and *6*). In the presence of 12.5 and 50 mole % of polar substituents (curves *2*–*5*), the appearance of slip planes at distances of 20 and 40 Å from the support is observed.

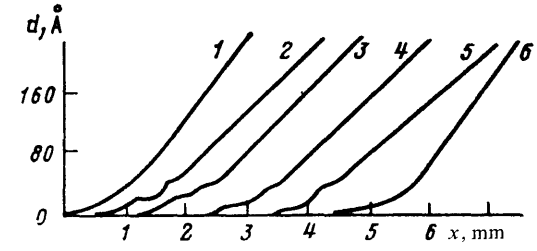

Figure 18. Profiles of films of dimethyl-β-cyanoethylsiloxanes with different contents of β-cyanoethylsiloxy-units: 1) PMS-6.25; 2) and 3) PMS-12.5; 4) and 5) PMS-50; 6) PMS-100.

In contrast to PMS, in dimethyl-β-cyanoethylsiloxanes the polar β-cyanoethyl groups are the centres of attraction to the surface of the support. One can therefore assume that in the given case the molecules are fixed on the surface of the solid phase via these groups. Depending on the number of polar groups, the conformation of the adsorbed molecule can be either extended parallel to the plane of the support or the molecule can have the form of a loop. When their content is low, these groups do not entail a significant change in the conformation of the adsorbed molecule compared with PMS. An analogous pattern has been observed also for a 100% content of methyl-β-cyanoethylsiloxane units (Fig.18, curve *6*). In these two cases, the molecules are adsorbed in a planar fashion, forming several layers, which are bounded by methyl groups and slip relative to one another. The film profiles of dimethyl-β-cyanoethylsiloxanes are therefore identical with the PMS film profiles both for slight and complete substitution of the dimethylsiloxane units.

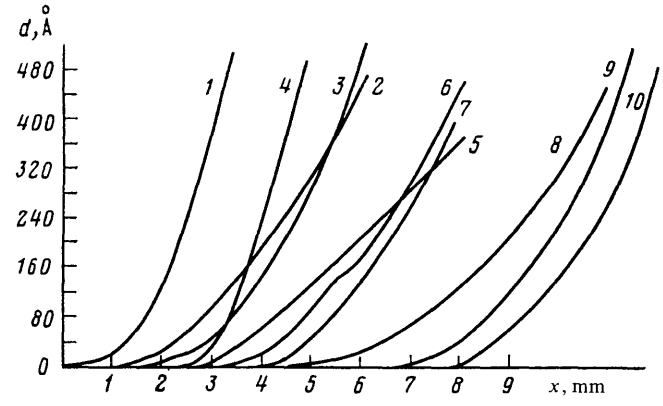

Figure 19. Profiles of films of oligo-organosiloxanes containing units of different types: 1) ethylsiloxy; 2) methylchlorophenylsiloxy; 3)–5) trifluoropropylsiloxy; 6)–9) thienylsiloxy; 10) chlorothienylsiloxy.

When the contents of the methyl-β-cyanoethylsiloxane units are 12 and 50 mole%, the molecules are adsorbed in such a way that the sections of the chains between the polar groups, linked to the surface, form loops which extend into the bulk of the liquid. The presence of slip planes at distances of 20 and 40 Å can apparently be explained by the formation of such structures.

The velocity profiles of films of oligo-organosiloxanes containing methylchlorophenylmethyl-, γ-trifluoropropyl-, thienyl-, and chlorothienyl-siloxane units (Fig.19) are outwardly identical with the film profits of dimethyl-β-cyanoethylsiloxanes, but the region of reduced viscosity extends in these substances to a greater depth (as far as 370 Å).[57,58]

The study of the surface and volume properties of a number of oligoorganosiloxanes[50,57,58] showed that the introduction of polar or bulky substituents reduces the intramolecular mobility. By virtue of this, the complete set of conformational transformations characteristic of polydimethylsiloxanes cannot be realised in the oligomers considered. The absence of an intermediate layer with enhanced viscosity, of the kind observed in PMS, is explained by this factor.

The distribution of polar groups along the molecular chain of oligo-organosiloxanes favours their horizontal orientation and adsorption on the surface. As in the case of the PMS, this reduces the viscosity in the boundary layer. On the other hand, the higher level of intermolecular interaction in oligo-organosiloxanes promotes the transmission of the influence of the force field of the solid phase into the bulk of the liquid to an appreciably greater distance than in the case of PMS. The region of reduced viscosity therefore reaches 350–370 Å in certain cases. The formation of slip planes in layers 20–30 Å thick in the oligomers considered (Fig.19, curves *2*, *3*, *6*, and *9*) can be attributed to their surface fractionation, intensified in the given instance by the presence of polar substituents at the silicon atoms and by the increased adsorption capacity of the molecules of these oligomers.[55,58]

Polydiethylsiloxane liquids in which the level of intermolecular interaction is enhanced compared with PMS occupy an intermediate position between oligo-organosiloxanes with polar groups and PMS as regards behaviour in boundary layers (Fig.19, curve *1*).[58]

It follows from the entire foregoing considerations that our flow velocity profiles of films indicate structural changes in the boundary layers. The observed anomalies in the profiles cannot be attributed to either the action of the capillary forces arising as a result of the microroughness of the support, or to the spontaneous migration of the wetting boundary, or to the surface tension gradients, because experiments with different liquids were not performed on the same support. Despite this, depending on the presence of polar groups, the degree of rigidity of the chain, and other factors, the flow velocity profiles of the films have their specific features, including the presence and absence of curvature in the range of thicknesses from zero to 50 Å. If the microroughness of the support had been the source of the anomalies in the profiles, then the latter would have appeared in all cases. Furthermore, the rate of spreading of the liquid under the influence of the microroughness is extremely low and the degree of spreading is 0.04 cm after 1300 s for the PMS with a viscosity of 0.07 St [64]# on a vertical plate, whilst according to our data a spreading of 0.06 cm was obtained for a PMS with a viscosity of 0.1 St on a horizontal plate after 5100 s. On the other hand, the blow-off experiments were performed over a short period and with viscous liquids. For example, the blowing off of PMS with a viscosity of 0.7 St was performed immediately after depositing the liquid on the support over 420–800 s.[65] The curving of the flow velocity profile of the liquid film was then observed at a distance of 0.3–0.4 cm from the wetting boundary. Judging from the data presented, this fact cannot be explained by the influence of the roughness of the support. Furthermore, the movement of the wetting boundary during the blow-off process was not observed in the experiments.

#Having observed conditions under which the blow-off method involves appreciable errors, Bascom and Singleterry[64] decided to abandon this method. Despite the subsequent explanation,[68] many investigators followed their example having decided to ignore a wide variety of results which we obtained. This is an example of how it is often difficult for a significantly new and novel development to achieve recognition.

V. THE STUDY OF THE BOUNDARY VISCOSITY OF ORGANIC LIQUIDS IN THE BLOW-OFF PROCESS

All the versions of the blow-off method described hitherto are suitable solely for liquids producing films which are stable in time. The blow-off method has been modified for the investigation of unstable films. For this purpose, a procedure has been developed for the observation of films in the course of the blow-off process.[29] The essential feature of the method is that the measurement of the film thickness is always performed at the same site and the dependence of the thickness on the blow-off time is obtained. The dependence of the boundary viscosity on the distance from the support is determined from the formula

$$\eta = \frac{H}{2}\frac{\Delta p}{\Delta l}\frac{dh}{du(h)} ,$$

where $\Delta p/\Delta l$ is the pressure gradient along the blowing off stream and $u = x/t$, x being the distance from the wetting boundary to the point of observation and t the time from the start of the blowing off to the measurement of the thickness h.

A glass apparatus was used for these experiments;[66] the slit was covered by a prism from which the beam emerged at a definite angle and fell on the insert with the film. In the study of boundary viscosity on glass, a total internal reflection prism was used and the film was deposited on the base of the prism.

A series of organic liquids, effectively wetting metals and glass, were investigated by this method. In the first place, the flow velocity profiles were obtained for liquid paraffin of different grades on a metal and glass. Metallic plates of ShKh-15 steel, polished to class 14 quality, were subjected to additional optical polishing. In all cases rigorously linear velocity profiles were obtained, indicating the absence of an unusual boundary viscosity. Velocity profiles were then recorded for solutions of stearic acid in liquid paraffin.[29,65–67] In order to obtain reproducible results on glass, the latter was cleansed in a gas discharge.[30] Appreciable distortions in the profile were observed at a stearic acid concentration of 0.000021 %. A linear profile with slight steps, whose number and height were not reproducible in different experiments, was obtained. At a concentration of 0.00054 %, an increase in the number of steps is observed (Fig.20) and they are appreciably more pronounced. Their height and number are likewise not reproducible. At a concentration of 0.001 %, inadequate wetting is observed, so that on being blown off the film breaks up into fine drops. This can be explained by the formation of an adsorption layer made up of molecules with vertically disposed methyl groups. At a concentration of 0.01 %, the wetting disappears completely and the solution drains off like water from a greasy surface. This occurs as a result of the completion of an adsorption monolayer of stearic acid, which is not wetted by virtually anything.

Solutions of hydrocarbons, consisting mainly of tetracosane ($C_{24}H_{50}$) with chlorinated methylene groups in the middle section of the chain (mono-, tri-, hexa-, and dodeca-chloroparaffins), in liquid paraffin were tested next.[28,65-67] Steel plates additionally polished and cleaned in a gas discharge in argon served as the supports. In the first place, the velocity profiles were obtained for a solution of monochloroparaffin in D-1 liquid paraffin, after its purification in a chromatographic column, and in liuquid paraffin subjected to acid-alkaline purification. It is seen from the plots (Fig.21*a*) that in the given instance a boundary layer with a modified viscosity, having a thickness of approximately 200 Å, is produced. Trichloroparaffin dissolved in liquid paraffin (Fig.21*b*) yields a result similar to the previous one: a boundary layer approximately 300 Å thick is observed near the wall. The results of the study of the solution of hexachloroparaffin are presented in Fig.21*c*. In this case a velocity profile resembling the previous ones was obtained. A change in viscosity is likewise observed in a boundary layer approximately 250 Å thick. Measurements with dodecachloroparaffin could not be performed because of the absence of wetting.

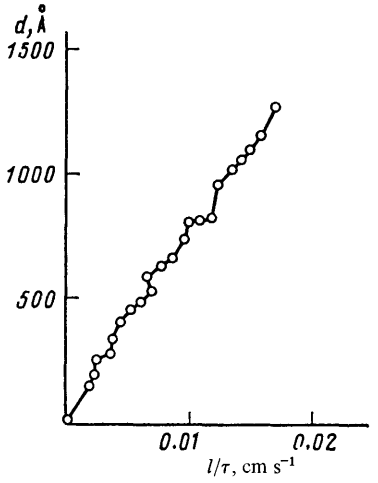

Figure 20. Prifile of a film of 0.00054 % solution of stearic acid obtained on a glass surface during the blow-off process.

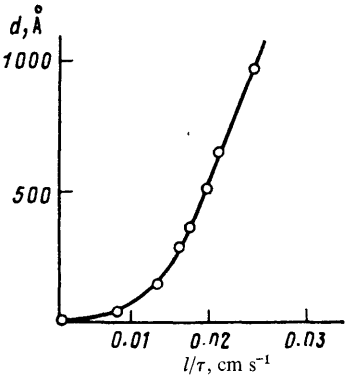

Figure 22. Flow velocity profile of a film of incompletely hydrogenated benzanthrone obtained on a glass surface during the blow-off process.

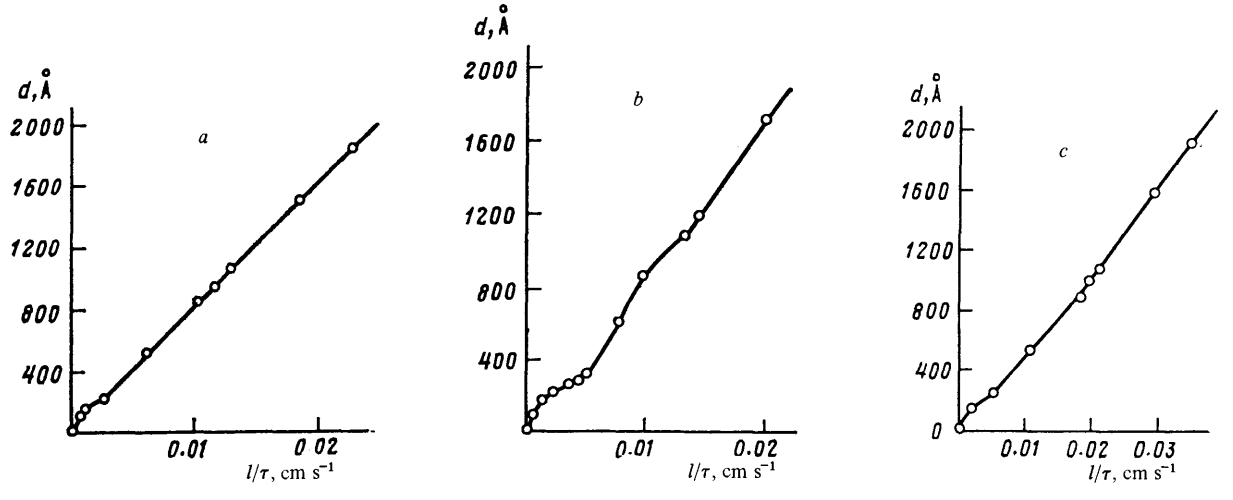

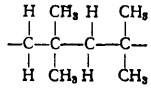

Figure 21. *a*) Profile of a film of 0.01% solution of monochlorotetracosane in liquid paraffin obtained on a steel surface during the blow-off process; *b*) profile of a film of 0.01% solution of trichlorotetracosane in liquid paraffin obtained on a metallic surface during the blow-off process; *c*) profile of a film of 0.01% solution of hexachlorotetracosane obtained on a glass surface during the blow-off process.

Finally, certain individual liquids were blown off. The flow velocity profile was obtained initially (on glass) for the incompletely hydrogenated benzanthrone.[48]§ As the name shows, this substance is not strictly individual. At the start of the experiment, the film was allowed to stand in order that equilibrium should be established in thin layers. Fig.22 illustrates the velocity profile, from which it is seen that, in the immediate vicinity of the wall, the viscosity is appreciably reduced. Above 200–300 Å (naturally this is a very arbitrary figure, since the viscosity varies very smoothly), the viscosity is almost equal to the bulk phase value.

The latest object was polyisobutene, which can be represented by the following formula, for example:

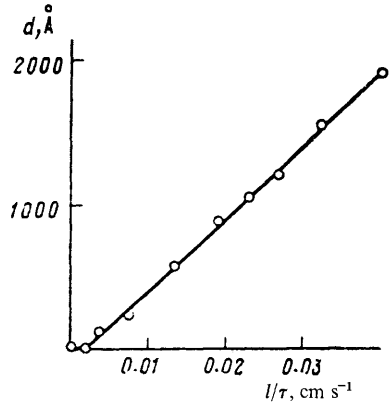

Figure 23. Flow velocity profile of a film of polyisobutene obtained on a metallic surface during the blow-off process.

It is seen from Fig.23 that the velocity profile is close to a linear one; a slip can be seen near the wall. The thickness of the residual film could not be measured. The measurements were performed on a steel plate.[28]

VI. THE STUDY OF THE BOUNDARY VISCOSITY OF VOLATILE LIQUIDS

A limitation of the blow-off method has been hitherto the impossibility of applying it to the study of the boundary viscosity of volatile substances. A modified blow-off method is applicable also to such liquids. In the course of the blowing off of volatile liquids, the film is attenuated also as a result of evaporation. The corresponding theory and method of calculation of the viscosity have been developed by Deryagin and Starov.[34] The viscosity calculations were performed on a computer from the ellipsometrically measured thicknesses of the blown off film at a distance of 2 cm from the initial wetting boundary as a function of time.

The apparatus with a rectangular insert on which the experiment was performed did not differ from the previous ones used to investigate the boundary viscosity by the blow-off method. Hexadecane ($C_{16}H_{34}$), an industrial product of chemically pure grade, was chosen as the test liquid. Specimens subjected to different degrees of chromatographic purification were also tested.

The experiment was performed as follows: a layer of liquid was deposited on the insert as before. Theinset was placed in the apparatus, having determined exactly the position of the wetting boundary, and a stream of air was passed through. The film thickness was determined as a function of time at a fixed site, at a distance l = 20 mm from the wetting boundary; the pressure drop was Δp = 0.0184 mmHg. The corresponding shear stress was 0.4 dyn cm^{-2}. The film thickness was measured as a function of time on an elipsometer using an LG-56 gas laser. Fig.24 presents plots of the dependence of the viscosity on the distance from the support obtained, from which it is seen that the viscosity is reduced in the range of thicknesses from 50 to 200 Å. The reproducibility of the curves in the range of thicknesses as far as 250 Å is complete in different experiments.[34]

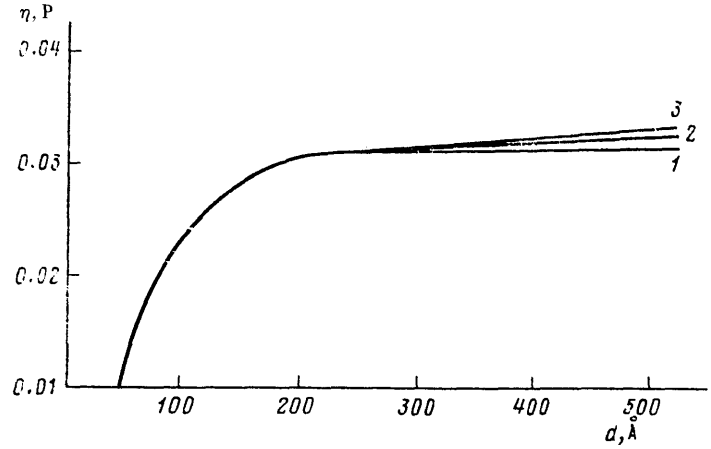

Figure 24. Dependence of the viscosity of hexadecane on the distance from the support.

§This substance was synthesised in A.D.Petrov's laboratory.

The decrease in viscosity which we observed can probably be accounted for by the usual slip of the horizontally oriented molecules. The hexadecane molecule consists of 14 methylene and 2 terminal methyl groups. In the immediate vicinity of the wall, one may expect only a horizontal orientation of the molecules because of their rigidity and fairly considerable length. The horizontal orientation is gradually enhanced as the support is approached owing to the increase in the influence of the force field of the latter.

The results of the application of the blow-off method described show that it provides a unique possibility for discovering the characteristic features of the structure of liquid layers modified under the influence of the adjoining surface of a solid phase, which is reflected by changes in viscosity. Specially rich information is provided by the application of the method to polymers and their solutions. The influence of the support on the structure of the boundary layers of the polymers and also on the stability of the wetting films is observed in this case to a strikingly greater depth, amounting to several micrometers.

Further expansion of the region where the method is applicable will become possible if the procedure can be improved in such a way that evaporation of even a highly volatile liquid can be eliminated during the blowing off of the layer.

Reactions of Saturated Cyclic Sulphides

E.N.Karaulova

The latest advances in the chemistry of saturated cyclic sulphides, mainly with 3-10-membered rings and their derivatives are examined. The results of studies concerning the introduction of functional groups into the sulphides and the conversion of the sulphides into acyclic compounds are surveyed.
The bibliography includes 198 references.

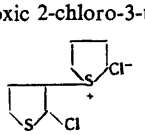
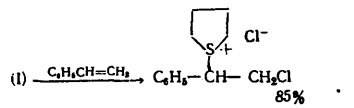
I. INTRODUCTION

During the last 10–15 years the reactions of cyclic sulphides such as sigmatropic rearrangements and reactions with ring opening have found extensive applications in synthetic organic chemistry. New data have been obtained on "traditional" reactions—complex formation and oxidation. The synthesis and the reactions of sulphonium salts have developed vigorously. They are promising for use in the chemistry of dyes and as fungicides and flocculants. Zwitter-ions based on arylthioniacycloalkane salts have found applications as monomers for the preparation of polymers stable in water and acids. The review covers the literature up to 1986, mainly during the last 10 years. Earlier data are described in monographs[1,2] and other reviews.[3-5]



II. COMPLEXES INVOLVING CYCLIC SULPHIDES

Thiolan reacts with chlorine to form the 1:1 complex (I), which is stable in methanol only at a low temperature.[6] On raising the temperature of the complex (I), Pummerer's reaction takes place with the tentative formation of the carbosulphonium ion (II), which undergoes further reactions:[7]



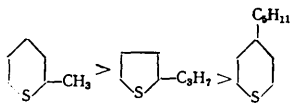
(I) (II) (III)

The dihydrothiophen (III) formed under these conditions adds to the complex (I), affording the toxic 2-chloro-3-thiolanylthiolanium chloride (IV):

(IV)

Hydrogen chloride retards the decomposition of the complex (I), possibly inhibiting the formation of compound (II). The complex (I) reacts with unsaturated compounds giving rise to sulphonium salts; the reaction proceeds effectively with styrene:[7]

The charge-transfer complexes formed by thiolan, thiane, and 1,4-dithiane with iodine absorb in the far IR at the following frequencies respectively: 158, 200 cm^{-1}; 157, 214 cm^{-1}; 165 cm^{-1}, while the complexes of the same sulphides with iodine bromide absorb at 186–188 and 222–228 cm^{-1}.[8]

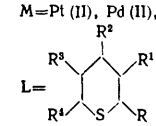


Saturated cyclic sulphides form donor–acceptor complexes with participation of a hydrogen bond with hydroxyl-containing compounds. When they are absorbed on silica and alumina, thiolan and thiane form hydrogen bonds with the hydroxy-groups of the sorbents and there is also an interaction with the electron-accepting centres on the alumina surface.[9] The thermodynamic characteristics of the complexes of thiolan with phenols have been determined: $\Delta H = -3 \pm 0.2$ kcal mol^{-1} and $\Delta S = -9.4$ kcal mol^{-1} K^{-1} for the hydrogen bond in the thiolan–phenol complex, while for the complex of thiolan with resorcinol we have $\Delta H_1 = -4.6 \pm 0.8$ kcal mol^{-1} and $\Delta S_1 = -13$ kcal mol^{-1} K^{-1}.[10]

The ability of sulphides, including cyclic sulphides, to form complexes with mercury(II) acetate has served as the basis of the acidimetric method for the quantitative potentiometric determination of sulphides.[11]

The stability of thiolan complexes (and also *d*-biotin complexes) with biologically important metal ions (Mg^{2+}, Ca^{2+}, Mn^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}) and also with Ag^+ in 50% alcohol, 96% dimethylformamide (DMF), and 98% dimethyl sulphoxide (DMSO) or D_2O) is extremely low; with increase in the concentration of water, the interaction of the sulphides with all the ions except Ag^+ increases.[12]

In order to model the capacity of petroleum sulphides for extraction from K_2ReOCl_5 solution, 13 complexes of 2-propylthiolan, 2-methylthiane, and 4-pentylthiane having the composition $L_2Re(=O)Cl_3$, where L = thiacycloalkane, have been obtained.[13] They have the structure of a flattened octahedron, where the chlorine atoms and one of the ligands are located in the equatorial



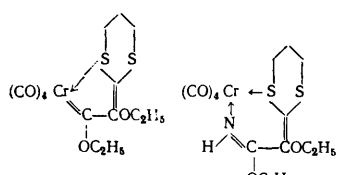
plane, while the oxygen and the second sulphide molecule occupy the vertices of the octahedron. The energy of formation of the complexes and their thermal stability diminish in the sequence of ligands

Acido-complexes with bivalent platinum and palladium salts have been obtained from aryl- and alkyl-substituted thianes, thiadecalins, and perhydrothioxanthenes:[14,15]

$$2L + K_2MCl_4 \xrightarrow{\text{alcohol}} ML_2Cl_2$$

M=Pt (II), Pd (II),

$R=R^4=C_6H_5$, $R=R^4=C_4H_5$, $R^2=CH_3$; $R=R^3=R^4=C_6H_5$; $R=C_6H_5$, $R^3R^4=(CH_2)_4$; $R=R^3=C_6H_5$, $R^3R^4=(CH_2)_4$; $RR^1=R^3R^4=(CH_2)_4$; $R^1=R^3R^4=(CH_2)_4$, $R^2=CH_3$; $RR^1=R^3R^4=(CH_2)_4$, $R^3=C_6H_5$.



On crystallisation from benzene, the last two compounds give rise to $PtL_2Cl_2.C_6H_6$ and $PtL_2Cl_2.2C_6H_6$ respectively. The complexes exhibit a moderate antimicrobial activity; the complexes of bicyclic and tricyclic sulphides show a more appreciable antiphage activity.[14] The complexes of PdL_2Br_2 having the *trans*-configuration have been obtained in 83–94% yields from PdL_2Cl_2 and KBr in aqueous acetone;[15] the complexes PtL_2X_2 have been obtained in aqueous dioxan:

$$L + K_2PtCl_4 + KX \xrightarrow{\text{aqueous dioxan}} PtL_2X_2 ;$$

X = Br, I; L = 2,6-diphenyl, 4-methyl-2,6-diphenyl-, or 2,4,6-diphenylthiane.

The complex of palladium chrloide with 4-methyl-2,5-diphenylthiane has been used[16] as the catalyst in the dehydrohalogenation of 3,4-dichlorobut-1-ene.

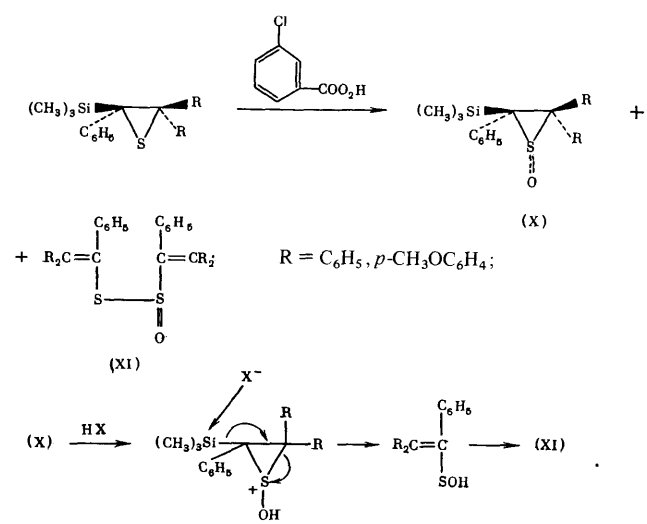
The chelates (V) and (VI) have been obtained from 1,3-dithiane:[17]

(V) (VI)

The formation of complexes by macrocyclic sulphides, especially thiacrown-ethers, has been investigated in recent years (for a review of the complexes between sulphides and transition metals, see Murray and Hartly[18]). Complexes of 1,4,7-trithiacyclononane with univalent copper, nickel, and cobalt tetrafluoroborates have been obtained; the metal atom in these complexes is at the centre of a slightly deformed octahedron. The complexes of 1,4,8,11,tetrathiacyclotetradecane (VII) with rhodium and cobalt salts, i.e. $[Rh(VII)X_2]^+$ and $[Co(VII)X_2]^+$, where X = Cl, Br, NCS, NO, or $1/2Cr_2O_4$, have been investigated. The cobalt complexes are obtained in three ways: from a bivalent cobalt salt with a non-coordinating anion and the sulphide, this step being followed by the reaction of the resulting complex with a coordinating anion and oxidation with air; from a cobalt salt, the sulphide, and an anion accompanied by oxidation in a single stage; in a complex with tervalent cobalt by exchange with a more strongly coordinating anion.[20]

The rhodium complexes have the *cis*-structure. The magnetic moments, molecular conductivities, and absorption IR and visible spectra have been measured for the complexes enumerated above.[20]

The cation $[Rh(VII)]^+$ has been obtained[21] by reducing the rhodium complexes and its capacity for coordination to various anions and electrophiles has been investigated. The cation $[Rh(VII)]^+$ enters into oxidative addition reactions, for example, with acetyl chloride, which involves an increase in the coordination number of rhodium and in its oxidation state (up to Rh^{2+}).



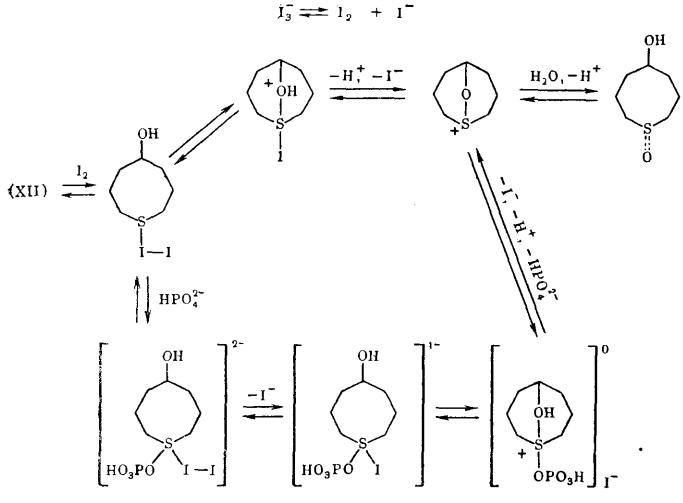
The extracting capacity of the thiacrown-ether (VII) in relation to the cations Na^+, Mg^{2+}, Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, Te^+, Ag^+, Pd^{2+}, Cd^{2+}, and Hg^{2+} (anions—perchlorate, picrate, and tetraphenylborate) has been investigated.[22] Only copper is extracted quantitatively. The complexes of pentathia-15-crown-5-(1,4,7,10,13-pentathiacyclopentadecane) (VIII) with univalent and bivalent copper have been obtained.[23] The electrolytic reduction of the $[Cu(VIII)]^{2+}$ complex in a nitrogen atmosphere leads to $Cu[(VIII)]^+$. Both complexes are monomeric in the crystalline state.

The complex with Cu^{2+} has a square-pyramidal geometry with the copper atom located 0.41 Å above the basal plane, which is made up of four electron-donating sulphur atoms, the fifth sulphur atom being coordinated at the vertex but deviating by 12.8° from the perpendicular. The Cu^+ complex has the structure of a distorted tetrahedron, close to the geometry of the complex with Cu^{2+} but with the exception that one of the C–S bonds in the basal plane is impaired. In both complexes, the perchlorate anions are not coordinated.

The complex of 1,4,7,10,13,16-hexathiacyclo-octadecane (hexathia-8-crown-6) (IX) with nickel picrate (1 : 1) is obtained[24] by refluxing in acetone. The octahedral complex $[Ni(IX)]^{2+}$ has a star structure: the nickel ion is at the centre of symmetry and the thiacrown ether surrounds it.

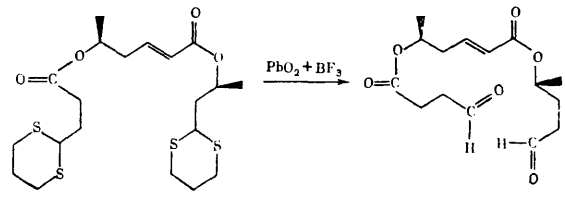
III. OXIDATION OF THE SULPHIDES

The oxidation of thiirans and substituted phenylthiiran oxides by peroxide compounds has been discussed in a monograph.[2] When *cis*-2,3-diphenylthiiran is oxidised with perbenzoic acid, the *anti*-sulphoxide is formed exclusively.[25] When silylated thirrans are subjected to similar oxidation, they give rise to ring opening products together with the sulphoxide (with the *anti*-disposition of the S=O group relative to the silyl group), possibly as a result of the acid-catalysed conversion of the sulphoxide (X) into an unstable sulphenic acid, which dimerises with simultaneous dehydration:[26]



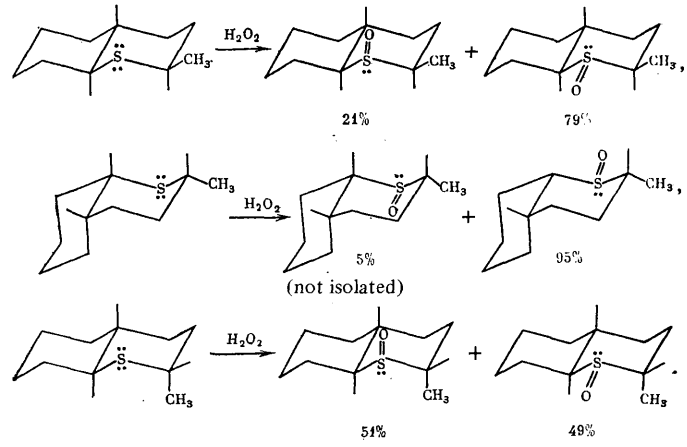
(X) (XI)

The alternative homolytic opening of the ring in compound (X) is not, however, ruled out.



Tetrafluoromethyl-1,3-dithietan is oxidised by chromium trioxide or nitric acid to the monosulphone.[2]

Thiolan is converted into cyclobutane when it is ozonised in oxygen.[27] The oxidation of thiolan to the sulphoxide by gaseous oxygen is catalysed by petroleum metalloporphyrins, most effectively by vanadyl-porphyrins.[28] When thiolan and thiane are oxidised with atmospheric oxygen in the presence of copper(II) dichloride (in isopropyl alcohol at 130 °C and 50 atm),[29] sulphoxides are formed in 50–70% yields and a selectivity of 70–80%; 2-hexytlthiolan is not oxidised under these conditions. Thiolan and thiane are oxidised to the sulphones by refluxing with a solution of copper(II) permanganate or a mixture of potassium permanganate and copper(II) sulphate pentahydrate.[30] 2,5-Dichloromethylthiolan and 2-chloromethyl-5-chlorothiane were oxidised to the sulphoxides with t-butyl hydroperoxide in the presence of $MoCl_5$;[31] 1,3,5,7-tetramethyl-2,4,6,8-tetrathia-adamantane was oxidised in the same way (in benzene) to the 2-oxide in 55% yield.[32] The oxidation of 4-hydroxythiane, 4-hydroxy-4-methylthiane, and 5-hydroxythiacyclo-octane (XII) with iodine in aqueous methanol in the presence of phosphate buffer takes place with participation of the *trans*-annular interaction of the hydroxyl with sulphur;[33] in the case of the sulphide (XII), the bridged intermediate 9-oxa-1-thioniabicyclo[3.3.1]nonane tri-iodide was isolated (not shown in the scheme below) whose oxidation leads to hydroxysulphoxides with a great preponderance of the stereoisomers having the OH and S=O groups in the *trans*-positions (in excess of 92%). Under these conditions, the sulphide–iodine complex is initially formed from the tri-iodide and then decomposes via two pathways, the main pathway depending on the buffer and its reverse process being of second order with respect to the iodide:



The electrochemical oxidation of 4-(*p*-chlorophenyl)thiane in aqueous acetone or acetonitrile in the presence of bromides, for example, $(C_4H_9)_4NBr$, affords[34] isomeric sulphoxides in 80% yield (under the conditions of kinetic control, about 90% of the *trans*-isomer is formed and at equilibrium there is 80% of the *cis*-isomer). One of the sulphur atoms in 2-(α-tetrahydrofuryl)-1,3-dithiane is oxidised by sodium periodate,[34] the yield of the sulphoxide being 70%.

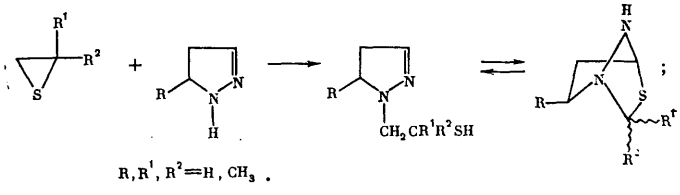
Treatment of 5-(*o*-carboxyphenylamino)-2-phenyl- and 5-(*o*-carboxyphenylthio)-2-phenyl-1,3-dithianes with hydrogen peroxide in acetic acid[36] gave rise to the corresponding bis-sulphones. Extensive oxidation hydrolysis of 1,3-dithianes has been used[37] in one of the stages of the synthesis of gramicidin:

The oxidation of the stereoisomers of 3-methyl-2-thiabicyclo[4.4.0]-decane with hydrogen peroxide in acetic acid[38] led to the isolation of the stereoisomeric sulphoxides:

The oxidation of thiadecalins and thiabicyclo[4.3.0]nonanes has also been discussed in the review.[5]

4-Thiahomoadamantane was oxidised[39] with *m*-chloroperbenzoic acid to the sulphone in 54% yield. 2-*exo*-Hydroxy-4-thiahomo-adamantane (XIII) was oxidised[39] with pyridinium chlorochromate to the corresponding ketone in 48% yield; together with the ketone, 3-thiatricyclo[5.3.1.$0^{4,9}$]undec-5-ene is formed as a result of skeletal rearrangement (with participation of the episulphonium ion).

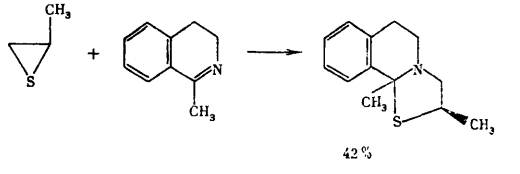
It is appropriate to consider also the oxidation of petroleum sulphides, since saturated cyclic sulphides predominate among them.[1] The oxidation of the petroleum sulphides to sulphoxides is the principal method of converting them into derivatives with functional groups. In the liquid-phase oxidation with atmospheric oxygen in the presence of copper chloride in isopropyl alcohol (heating under pressure),[40] the degree of conversion of the petroleum sulphides does not exceed 90% and the maximum selectivity is then 80% (for a yield of about 70 mole %). When the concentrate of petroleum sulphide is oxidised with oxygen in the presence of copper phenoxide, the formation of sulphoxides is inhibited by the competing reaction involving the oxidation of the hydrocarbons present in the concentrate.[41] The oxidation of petroleum sulphides to the sulphoxides directly in petroleum distillates can be usefully performed with t-pentyl. t-butyl, and cumenyl hydroxperoxides;[42,43] the highest conversions are obtained in oxidation catalysed by molybdenum compounds in the presence of carboxylic acids.[43] Molybdenum naphthenate has been recommended[44] as the catalyst for the oxidation of petroleum sulphides to the sulphoxides with hydrogen peroxide.



The concentrates of petroleum sulphides have been oxidised to the sulphoxides with a mixture of air and nitrogen dioxide.[45] The method can be regarded as successful, since a complex mixture of

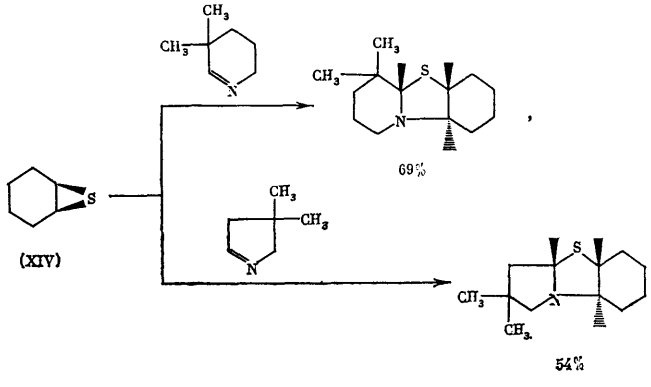
nitrogen-containing products is formed together with the sulphoxides.

IV. REACTIONS WITH OPENING OF THE HETEROCYCLE



1. The Effect of Nucleophiles

When thiiran and its methyl-substituted derivatives react with unsaturated cyclic nitrogen-containing bases, the thiiran ring is opened in accordance with Krasuskii's rule.[46,47] The reaction with 2-pyrazolines results in the formation of 1-(2-mercaptoalkyl)-2-pyrazolines, which are capable of isomerising reversibly to 4-thia-1,8-diazabicyclo[3.2.1]octanes.[46] A mixture of diastereoisomeric mercaptoalkylation products in comparable amounts is formed from 5-methyl-2-pyrazoline:

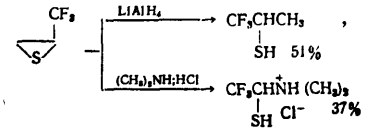


R, R', R²=H, CH_3 .

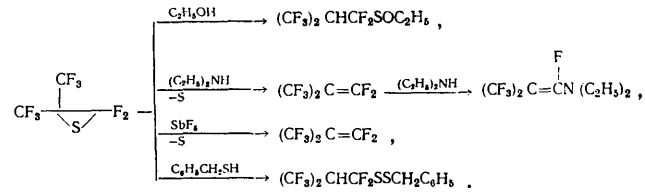
The reaction with 2,3,4,5-tetrahydropyridines and 1-pyrrolines affords the corresponding perhydrothiazolo[2,3-*a*]pyridines and perhydropyrrolo-[2,1-*b*]thiazoles.[47] In the case of methylthiiran, compounds with the *cis*-disposition of the angular substituent and the methyl group are formed:

42%

In the reaction involving epithiocyclohexane (XIV), the opening of the thiiran ring is accompanied by the inversion of the configuration:[47]

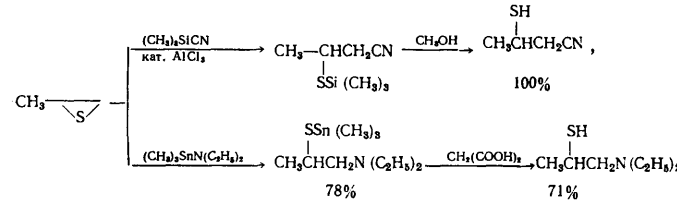


69%



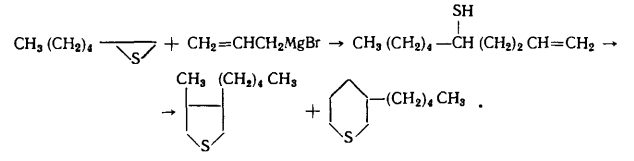
54%

(XIV)

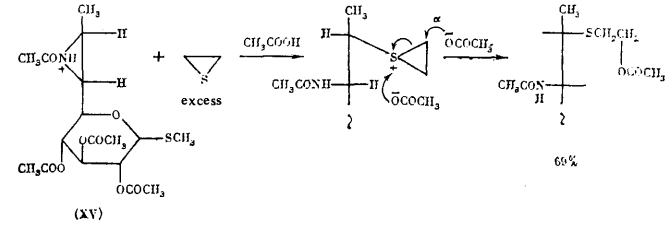


The aminomercaptans $C_4H_9OCH_2CH(SH)CH_2NRR^1$ (R = R^1 = C_4H_9; R = C_6H_5, R' = CH_3) have been synthesised[48] by treating butoxymethylthiiran with amines. Nucleophiles act analogously on trifluoromethylthiiran:[49]

In contrast to this, in the case of perfluorothiiran the attack by the nucleophile is directed to the sulphur atom:[50]



Regioselective opening of the thiiran ring occurs on treatment of organic derivatives of Group IVB elements,[51] such as $(CH_3)_3SnNR_2$ and $(CH_3)_3SiCN$. The subsequent alcoholysis or acidolysis of the reaction products leads to β-amino- or β-cyano-thiols:



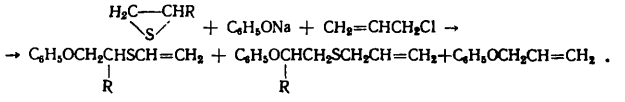
78% 71%

The reaction of thiirans [including epithiocyclohexane (XIV)] with alkenylmagnesium bromides is of great synthetic importance. It yields alkenethiols, whose subsequent cyclisation leads to five-membered and six-membered thiacycloalkanes,[52–54]† for example:[52]

Treatment of tetra-acetylepimine (XV), a derivative of the antibiotic linocomycin, with thiiran in acetic acid affords the 7-(2-acetoxyethyl)thio-derivative:[55]

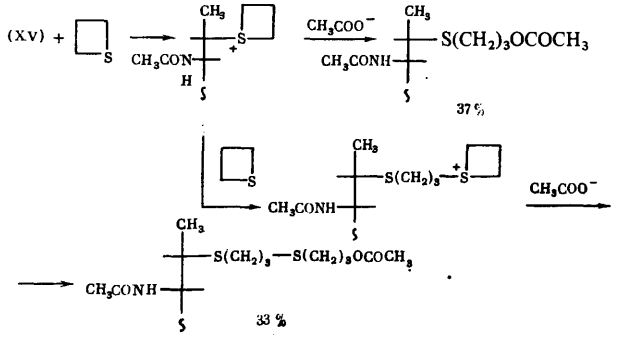
(XV)

The opening of the thiiran ring by phenols under the conditions of base catalysis leads to the polymerisation of the thiiran; in order to suppress it, a powerful electrophile (allyl chloride) is introduced:[2,56–59]

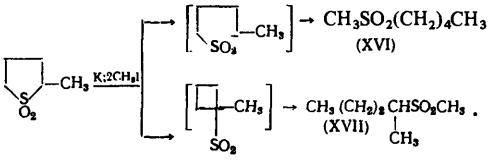


† For a detailed description see Karaulova's review.[4]

The study of the kinetics of the reaction led to the conclusion[56] that its mechanism involves the formation of complexes of sodium phenoxide with thiirans. In the case of substituted phenoxides RC_6H_4ONa (R = *p*-CH_3, *p*-OCH_3, *m*-CH_3, *p*-F, *p*-Cl, *p*-I, or *m*-Cl), the rate of ring opening diminishes as the electron-accepting properties of the substituent are enhanced, but the rate increases as the acidity of the phenol is reduced (by introducing electron-donating substituents).[57] The ring opening is achieved as a result of the joint action of the nucleophile and the proton donor:

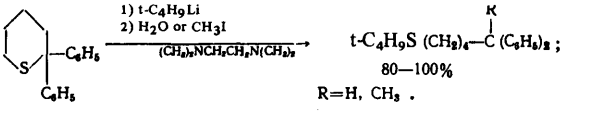


In the reaction of substituted thiirans, the mode of opening of the thiiran ring varies as a function of the electronic character of the substituent:[58]



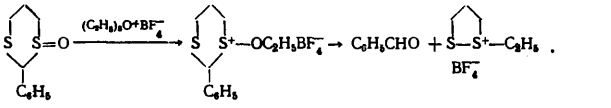
For substituents whose electronic effect is transmitted via the inductive mechanism, products corresponding to the opening of the ring in accordance with Krasuskii's rule predominate (R = CH_3, 75%; R = CH_2OCH_3, 96%; R = C_4H_9, 75%). For substituents containing a π-electron system, anomalous reaction products predominate (R = C_6H_5, 80%; R = $CH{=}CH_2$, 90%). The reaction with disubstituted thiirans proceeds analogously;[59] in highly polar aprotic solvents, the rate and regioselectivity of the reaction increase sharply.[59]

Thietan in acetic acid reacts with the tetra-acetylepimine (XV) via two pathways:[55] the formation of the 7-(3-acetoxypropyl)thio-derivative is accompanied by the interaction with a second thietan molecule:

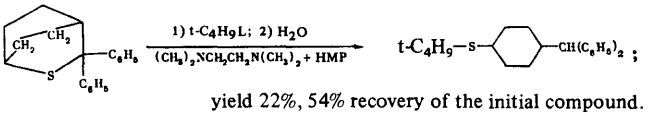


Thiolan and thiane react with compound (XV) only via the first pathway[55]—the 7-(4-acetoxybutyl)thio-derivative (yield 71%) and the 7-(5-acetoxypentyl)thio-derivative (yield 11%) are formed respectively.

Colloidal potassium (obtained by dispersing potassium in toluene by exposure to ultrasound) is an effective reagent for the clevage of the C–S bond.[60] Its effect on sulphone derivative from thietan, thiolan, 2-alkylthiolans, and thiane has been investigated. The yields of alkyl methyl sulphones are 84–94%. It has been shown for 2-methylthiodioxide that the reaction is regioselective—cleavage of the C–S bond takes place mainly at the substituted carbon atom [we have the ratio (XVI):(XVII) = 10:1]:

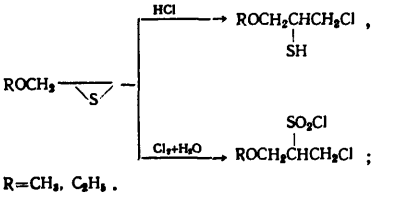


The ring of 2,2-diphenylthiane is ruptured analogously on treatment with t-butyl-lithium:[61]

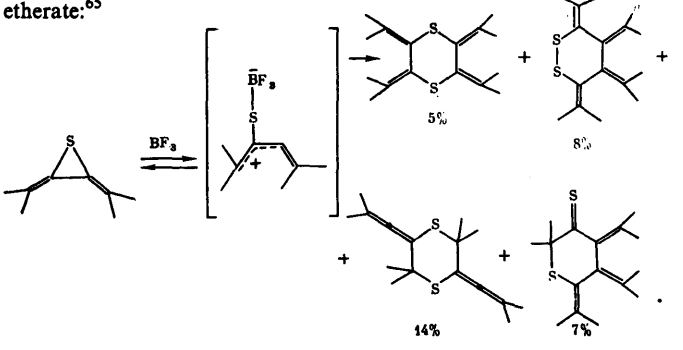


The reductive cleavage of the C–S bond at C(2) in 2,2-diphenyl-1,3-dithiolan takes place on treatment with lithium tetrahydroaluminate in combination with copper and zinc chlorides:[62]

Intramolecular decomposition has been observed[63] on treatment of 2-phenyl-1,3-dithiane-1-oxide with triethyloxonium tetrafluoroborate:[63]

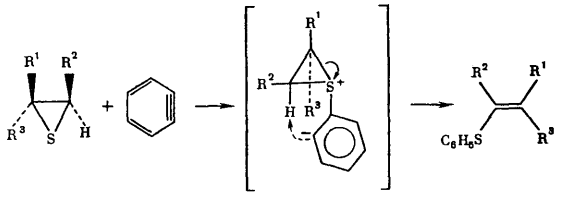


The rupture of the C–S bond in the 3,3-diphenyl-2-thiabicyclo-[2.2.2]octane on treatment with t-butyl-lithium proceeds with difficulty:[61]



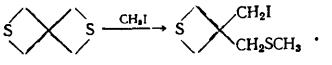
yield 22%, 54% recovery of the initial compound.

2. The Effect of Electrophiles



2-Alkoxymethylthiirans react with hydrochloric acid at low temperatures or with chlorine in accordance with Krasuskii's rule:[64]

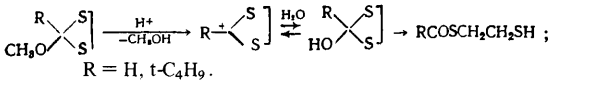
Diallene episulphide ("thiiranoradialene") produces (together with polymers) dithia[6]radialenes on treatment with boron trifluoride etherate:[65]



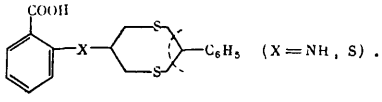
Thiiran as well as methyl 2,2-dimethyl-, hexyl-, phenyl-, and 2,3-diphenyl-thiirans, epithiocyclohexane, and epithiocyclo-octane react with 1,2-dehydrobenzene, which is a powerful electrophile, to form phenyl vinyl sulphides in 71–90% yields:[66]

The anionic component of the intermediate betaine acts as a base and abstracts the acid hydrogen from the three-membered ring with the simultaneous formation of a C–C bond and the dissociation of the C–S bond. The reaction is stereospecific: *cis*- and *trans*-phenylthiostilbenes are formed from *cis- and trans*-2,3-diphenylthiirans respectively.

Trifluoromethylthiiran is attacked by electrophiles (Cl_2, HCL, CH_3COCl) at the sulphur atom. The products are respectively 3-chloro-1,1,1-trifluoropropane-2-sulphonyl chloride (yield 72%), 3-chloro-1,1,1-trifluoropropane-2-thiol (yield 69%), and its acetate (yield 38%).[49]



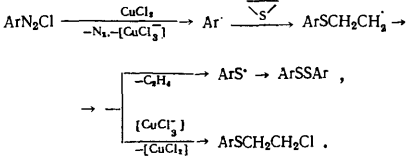
The dithiaspiroheptane ring is opened by methyl iodide:[67]



Thiolan is cleaved reversibly by acetyl bromide on refluxing:[68]

The kinetics and mechanism of the hydrolysis of 2-methoxy-1,3-dithiolans in acid media have been investigated.[69] The reaction proceeds in three stages and leads to 2-mercaptoethyl thiocarboxylates:

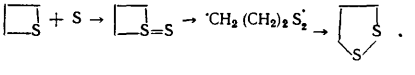
On treatment with mercury(II) chloride, derivatives, of 2-phenyl-1,3-dithiane split off the C_6H_5CH fragment and are converted into the mercaptides of 2-substituted propane-1,3-dithiols:[36]



On treatment with chlorine, 2,4,6-trichloro-1,3,5-trithiane is cleaved, affording $CHCl_2-S-CHCl_2$ and $CHCl_2SCl$.[70]

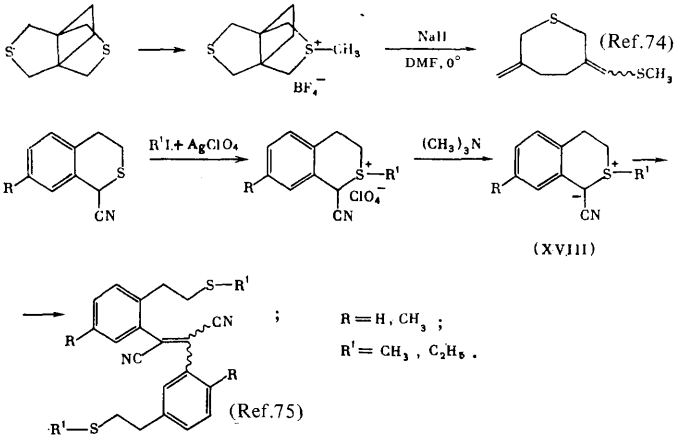
3. Radical Reactions

Episulphides are rapidly desulphurised on heating with *NN*-bis-(trimethylsilyl)aminodimethylphosphine and are converted in a quantitative yield into the corresponding alkenes and the phosphine sulphide.[71] Here there is a possibility of the homolytic cleavage of the heterobond:[2]



The homolytic cleavage of thiiran takes place on treatment with arenediazonium chlorides in the presence of $CuCl_2$:[72]

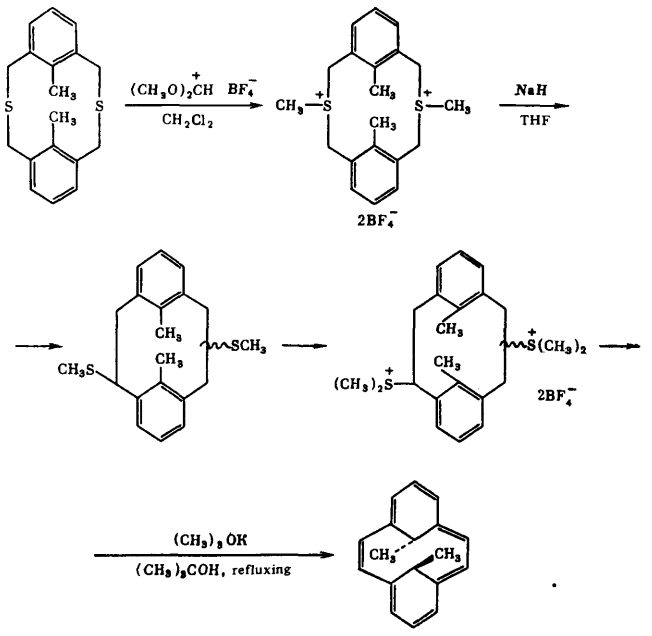
The reaction of thiiran with toluene-*p*-diazonium chloride afforded[72] β-chloroethyl *p*-tolyl sulphide in 50% yield relative to the *p*-toluidine employed.



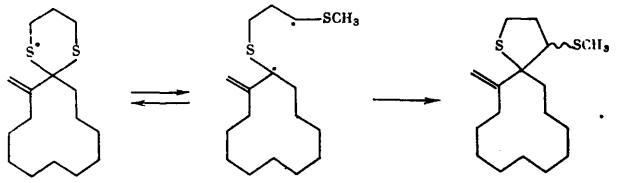
Metastable sulphur is obtained by the photolysis of gaseous COS. Under these conditions, the reaction involving thietan yields 1,2-dithiolan and ethylene in comparable amounmts as the main products.[73] The proposed mechanism of the formation of 1,2-dithiolan is as follows:

V. REARRANGEMENTS WITH CHANGE IN THE NUMBER OF MEMBERS IN THE RING

In recent years, studies on the sigmatropic rearrangements of sulphides, especially semiaromatic sulphides,‡ have been carried out widely. Such rearrangements frequently lead to a change in the number of members in the ring or to the opening of the latter[74,75] (see, for example, Scheme 1).

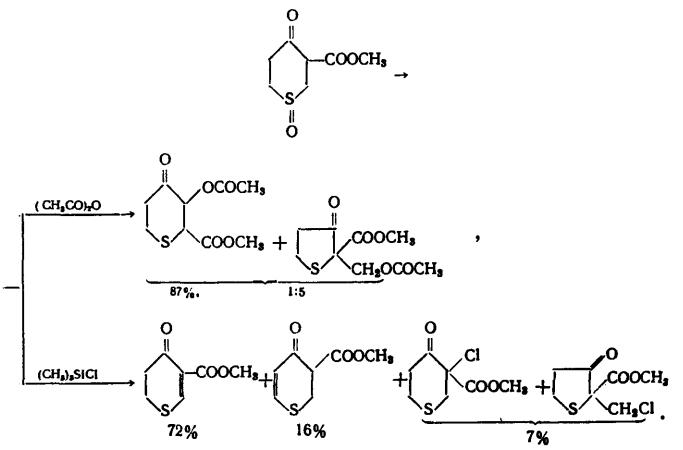


Scheme 1



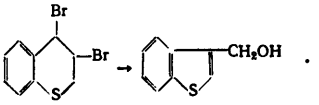
The Stevens rearrangement involves reactions of sulphonium ylides—the cyclic sulphide is initially converted into the sulphonium salt and is then acted upon by a strong base, whereupon an acyclic sulphide linkage is produced. The Stevens rearrangement is frequently used in the synthesis of cyclophanes; with its aid, a cyclic

‡ "Semiaromatic sulphides" are polycyclic sulphides where at least one carbon atom involved solely in a σ-bond, is linked to the sulphur atom.

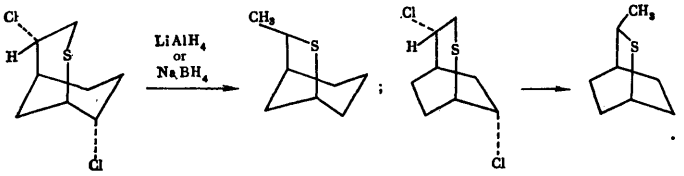


sulphide linkage is replaced (in several steps) by the C=C double bond.[76-78] A convenient methylating agent for the synthesis of the sulphonium salts is dimethoxycarbonium fluoroborate:[76]

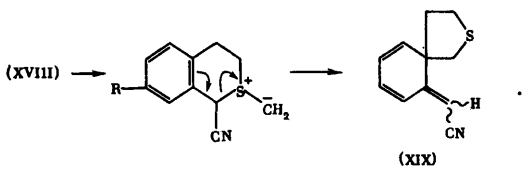
The Stevens rearrangement can also lead to the contraction of the heterocycle:[79]



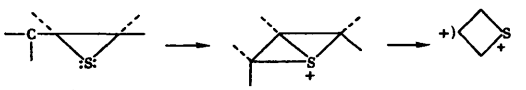
The ring contraction in cyclic sulphides can occur under the conditions of various reactions. Thus the contraction of the six-membered ring is observed on electron impact mass-spectrometry[80] and in the Pummerer rearrangement—both under standard conditions (when the sulphoxide is treated with acetic anhydride) and on reaction with chlorotrimethylsilane:[81]



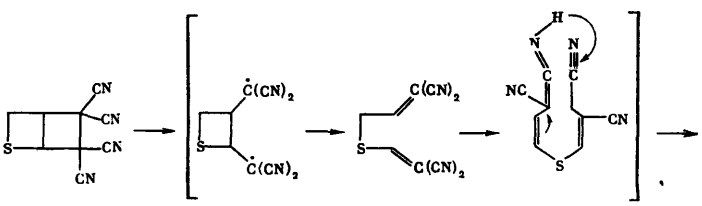
Thiane isomerises to 2-methylthiolan in the temperature range 250–350 °C in the presence of acid catalysts, among which Al_2O_3 is the most selective.[82] Thiane and thiacycloheptane initially isomerise over charcoal treated with nitric acid at 400–500 °C, producing respectively 2-methyl- and 2-ethyl-thiolans, which are then dehydrogenated (via an ionic mechanism) with the preferential formation of thiophens.[83]



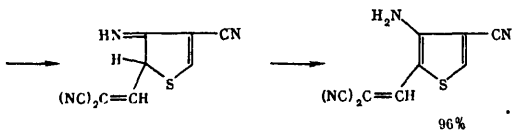
The hydrolysis of bromothiachromans and bromodihydronaphthothiopyrans in aqueous acetone with added potassium hydroxide gives rise to benzo- and naphtho-thiophens respectively,[84] for example:



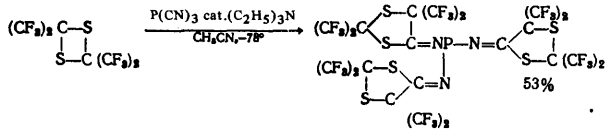
The reductive dechlorination of the adducts of 4-vinylcyclohexene with sulphur dichloride (dichlorothiabicycloalkanes) is accompanied by skeletal rearrangements—redistribution of the carbon bonds between the rings or the contraction of the heterocycle:[85]



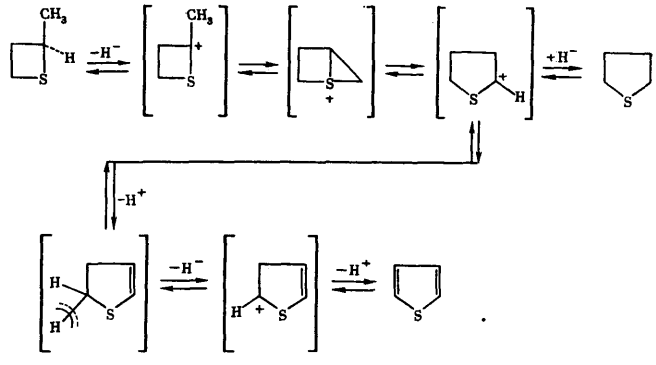
The ylides (XVIII), R′ = CH_3 isomerise in protic solvents (ethanol, methanol) with ring contraction and the formation of the spiro-compound (XIX)[75]—there is initial isomerisation to a methylide, which then undergoes a [2,3]sigmatropic rearrangement (despite the breakdown of aromaticity):



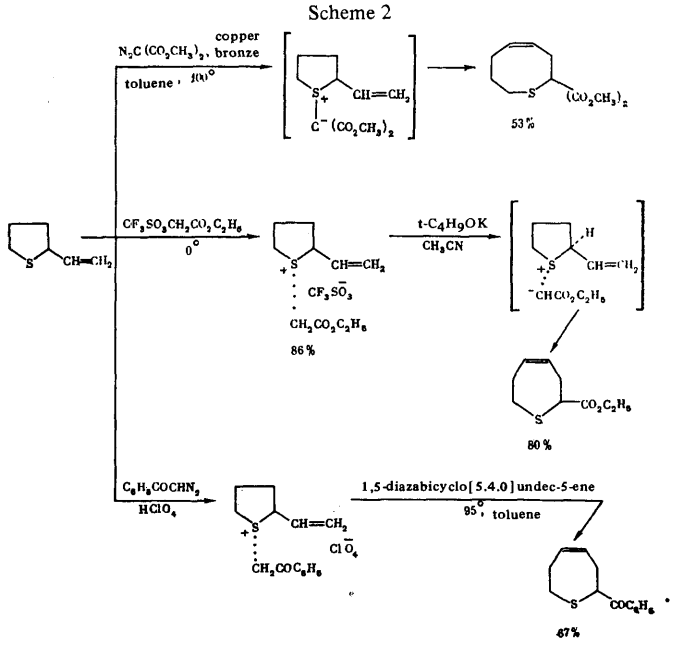
The expansion of the thiiran ring is observed in reactions of epithiohalogenohydrins with nucleophiles.[2] This involves a thiiran–thietan rearrangement. The mechanism includes a cationotropic transformation:



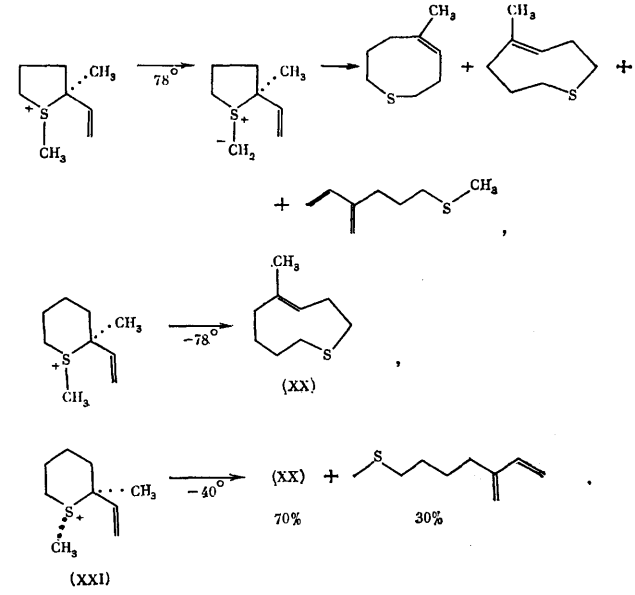
When a solution of 5,5,6,6-tetracyano-2-thiabicyclo[2.2.0]hexane in benzene is refluxed, an arrangement takes place with expansion of the thietan ring and the formation of 3-amino-4-cytano-2-(2,2-dicyanovinyl)thiophen.[86] A radical mechanism involving the opening of both rings with subsequent ring expansion in the acyclic intermediate to form iminodihydrothiophen and tautomerisation of the latter has been proposed:[86]



In the interaction of 2,2,4,4-tetrakis(trifluoromethyl)-1,3-dithietan with $P(CN)_3$ or $As(CN)_3$, the latter react in the isonitrile form, a carbon atom is "inserted" in the dithiethan rings, and 1,3-dithiolan derivatives are formed:[87]

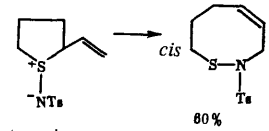


2-Methylthietan isomerises to thiolane on treatment with hydride ion acceptors—triphenylmethyl fluoroborate, chloranil, chlorotriphenylmethane—in the presence of $SnCl_4$,[88] whereupon a thiophen is also formed:



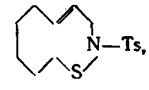
Thiacyclo-octane derivatives are obtained from vinylthiolan. The reaction is of the type of a [2,3]sigmatropic shift and proceeds via an ylide formation stage[89] (see Scheme 2).

Scheme 2

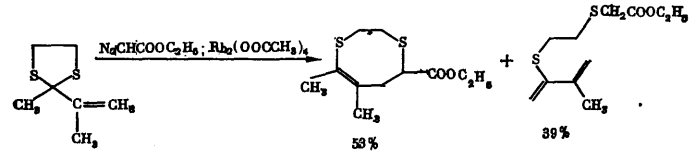


An analogous [2,3]sigmatropic ring expansion has been investigated for the salts of various 2-vinylthiacycloalkanes.[79,90-93] It has been noted that reactions involving 1,2-dimethyl-2-vinyl-substituted thiolanium and thianium hexafluorophosphates (on treatment with potassium t-butoxide) are stereoselective but not stereospecific[90] (see Scheme 3).

Scheme 3

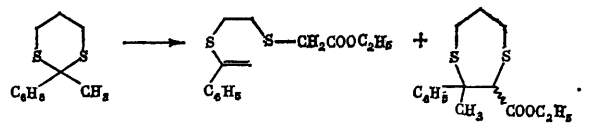


The reaction involving the stereoisomer (XXI) does not take place at −78 °C. The stereochemistry of the ring expansion in the [3,2]sigmatropic rearrangements of sulphonium ylides can depend on the way in which the ylides are formed and on the initial sulphonium salt.[91] On heating *N*-(toluene-*p*-sulphonylimino)-derivatives of 2-vinylthiolan and 2-vinylthiane in xylene, the ring expansion also takes place as a result of the insertion of the nitrogen atom:[92]

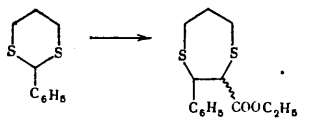


diostereoisomers

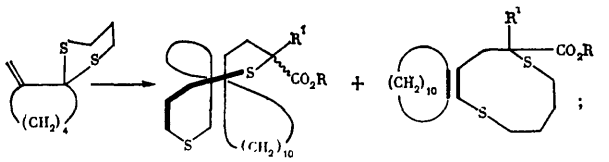
It has been suggested[91] that initially there is pyramidal inversion to the *cis*-diastereoisomer, which then rearranges. On treatment with chloramine-T in methanol at room temperature, 2-vinylthiacycloheptane immediately affords the product of the rearrangement



which has the *trans*-configuration.[92]

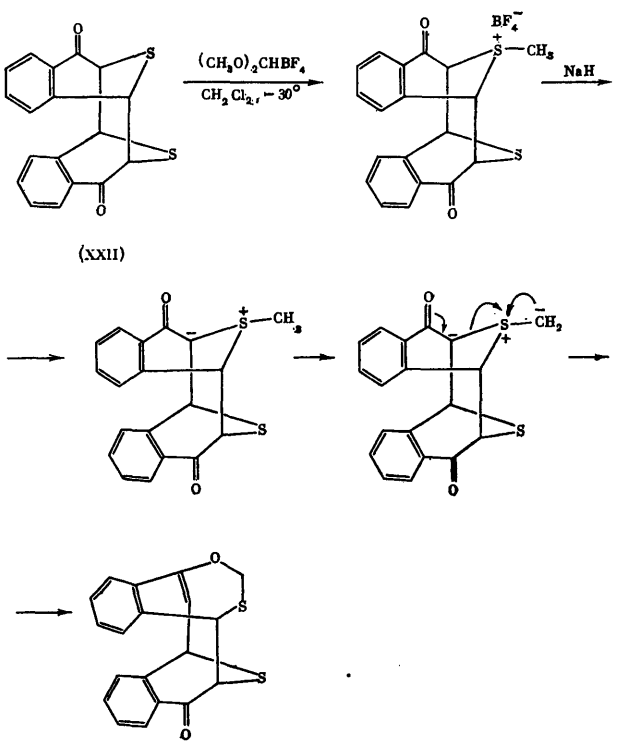


The rearrangement of 2-vinyl-1,3-dithiolans and 2-vinyl-1,3-dithianes was carried out by treatment with diazoacetic ester and rhodium tetra-acetate (the catalyst of the formation of ylides[93]) or copper sulphate,[79] for example:



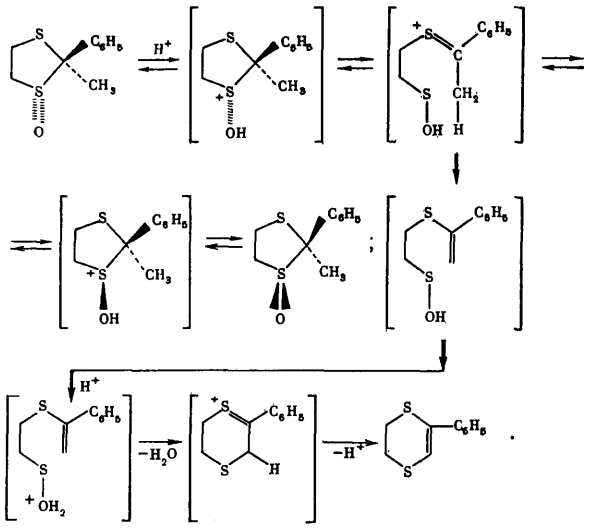
In the reaction involving 2-phenyl-1,3-dithianes under the same conditions, a [1,2]sigmatropic rearrangement takes place:[93]

The diastereoisomer ratio for the insertion product is 15, the isomer where the phenyl and ethoxycarbonyl groups are in the *trans*-positions predominating:

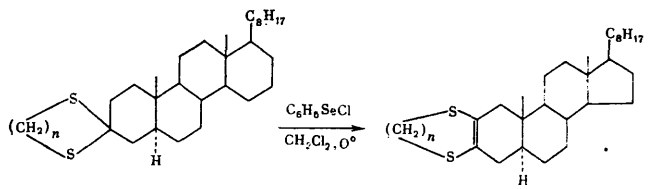


"Betweenanes" have been synthesised using ethyl diazoacetate or diazomalonate via a [2,3]sigmatropic rearrangement:[79]

$R=C_2H_5$, $R^1=H$; $R=CH_3$, $R^1=CO_2CH_3$.

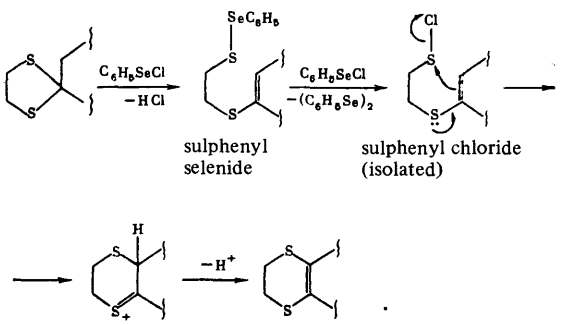


In the [2,3]sigmatropic rearrangement of the "semiaromatic" bis-sulphide (XXII), ring expansion occurred as a result of the incorporation of an oxygen atom:[94]



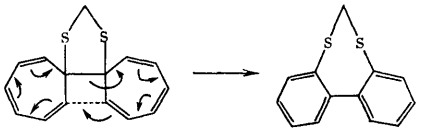
(XXII)

On heating, 2,5-di(chloromethyl)thiolan isomerises irreversibly to 2-chloromethyl-5-chlorothiane and an analogous isomerisation has been observed on heating an aqueous acetone solution of 2,5-di-(hydroxymethyl)thiolan and also on oxidation of 2,5-di(chloro-methyl)thiolan with t-butyl hydroperoxide in the presence of $MoCl_5$.[31]



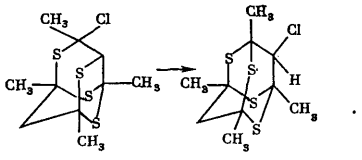
Both *cis*- and *trans*-2-methyl-2-phenyl-1,3-dithiolan monoxides are converted in a quantitative yield into 2-phenyl-1,4-dithiacyclohexene on treatment with acetic anhydride of toluene-*p*-sulphonic acid.[95] The ring expansion reaction is non-stereospecific. On initial protonation with toluene-*p*-sulphonic acid or on acylation with acetic anhydride, intermediate sulphonium ions are formed and then the C–S bond in the sulphoxide is broken and a carbosulphonium intermediate is produced, which then loses a proton; the subsequent ring closure is acid catalysed:

The expansion of the rings of 1,3-dithiolans and 1,3-dithianes takes place on treatment with benzeneselenyl chloride.[96] This reaction has been used to synthesise steroid dihydro-1,4-dithiines and dihydro-1,4-dithiepins:



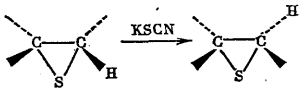
The reaction proceeds with participation of a cationic intermediate:

sulphenyl selenide



sulphenyl chloride (isolated)

The dispirodithiolan (XXIII) slowly rearranges at room temperature;[97] under these conditions, 14 electrons participate in the orbital symmetry-allowed [7,7]sigmatropic shift:



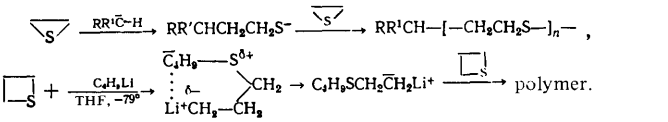
(XXIII)

On treatment with HCl in ether and on storage, the tetrathiahomoadamantane derivative (XXIV) undergoes skeletal isomerisation with expansion of one of the rings, the contraction of the other, and the formation of a tetrathia-adamantane derivative:[32]

Isomerisation without change in the skeleton, namely the epimerisation of episulphides, occurs on treatment with potassium thiocyanate in aqueous solution on heating:[98,99]

The yields in such stereoisomerisation are 10–30% for 5α,6α-epithiopregnanolone.[98] The interconversions of the *cis*- and *trans*-isomers of 3-hydroxy-1,2-epithiocyclohexanol are observed under these conditions; 3-acetoxy-1,2-epithiocyclohexanol isomerises analogously.[99]

The five- and six-membered cyclic sulphonium salts with a methyl substituent in the ring racemise on heating or, in a special case, undergo epimerisation, which apparently proceeds via the pyramidal inversion at the sulphur atom.[100] On treatment with butyl-lithium in tetrahydrofuran, 2α-phenyl-*cis*-1-thiadecalin 1,1-dioxide isomerises to 2β-phenyl-*trans*-1-thiadecalin 1,1-dioxide.[101] The inversion of the configuration on metallation involves the C(2) and C(9) atoms. During deuterium exchange, the configuration at C(2) in the initial 2α-phenyl-*cis*-sulphone is inverted and [2-D]-2β-phenyl-*cis*-1-thiadecalin 1,1-dioxide is formed.[101]

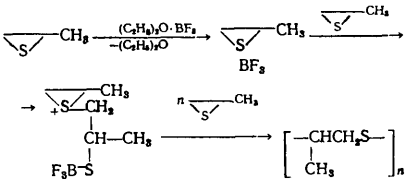


2-Methylthiaindan isomerises over $ZnCl_2/Al_2O_3$ to 3-methylthiaindan to the extent of 20%; the process may proceed with participation of a carbonium ion.[102]

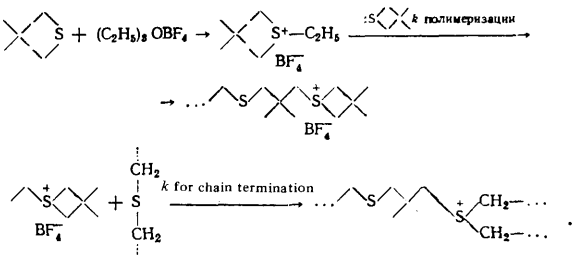
VI. POLYMERISATION OF CYCLIC SULPHIDES

During the 1960's and especially 1970's, the polymerisation of thiirans and thietans became the subject of numerous investigations (see the relevant reviews[2,103,104]). Practical applications were proposed for a number of thiiran and thietan polymers and copolymers (see, for example, the patent literature in the book of Fokin and Kolomiets[2]).

In order to polymerise thiolans and thianes, the latter are initially converted into sulphonium salts (see below).



In the anionic polymerisation of cyclic sulphides, the primary condensation product has more pronounced nucleophilic properties than the initial nucleophile,[2,104] for example:



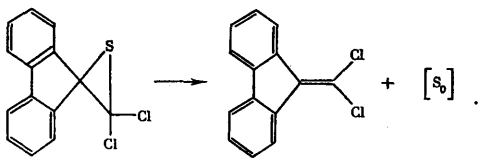
A wide variety of initiators, for example ethyl-lithium, lithium ethanethiolate, 1,4-dilithio-1,1,4,4-tetraphenylbutane,[105] and the potassium salts of aromatic nitriles and ketones[106] are used in the anionic polymerisation of thiirans and thietans. The same initiators are used in the synthesis of block copolymers of dienes with thiirans and thietans.[107,108]

4-Amino-1,2-dithiolane polymerises on heating in chloroform solution.[109]

The cationic polymerisation of thiirans and thietans is usually initiated by onium compounds and proceeds via the formation of a zwitter-ion:[104]

Triethyloxonium fluoroborate[110–114] as well as 1-ethyl-3,3-dimethylthietanium fluoroborate,[110] triethyloxonium hexachloroantimonate,[115] triethyloxonium hexafluorophosphate, perchloric acid, and methyl fluorosulphonate[116] are used as catalysts of the polymerisation of thiirans and thietans. The kinetics and mechanism of the cationic polymerisation of thietans are similar to those described above[114]— chain propagation takes place as a consequence of the nucleophilic attack by the monomer directed to the α-carbon atom of the cyclic sulphonium ion. Polymerisation stops as a consequence of the reaction between the reactive chain end and the sulphur atom in the chain already formed, whereupon an unstrained sulphonium ion incapable of reinitiating the polymerisation is produced:

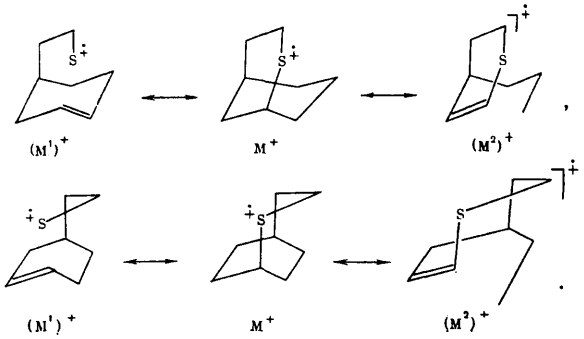
On initiation with the aid of $(C_2H_5)_3OSbCl_6$, chain termination is facilitated by the fact that the growing chain interacts with the counterion, forming an alkyl chloride:[115]



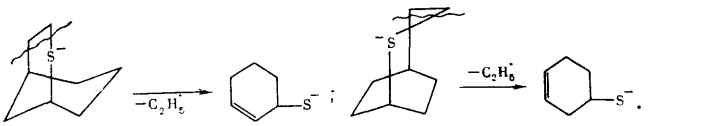
On treatment with hydrochloride, sulphuric, and phosphoric acids, 2-(*N*-carbazolyl)thiiran is converted into oligomers; the interaction with adipic, sebacic, or phthalic acid results in the formation of oligoesters, which are promising as film forming materials for the non-silver recording of information.[117]

VII. THERMOLYSIS AND FRAGMENTATION OF CYCLIC SULPHIDES

A profound change in the carbon skeleton of thiacycloalkanes can occur during their thermolysis and also under the conditions of mass spectrometry (fragmentation under electron impact; the influence of the heating of the specimen cannot be ruled out either).



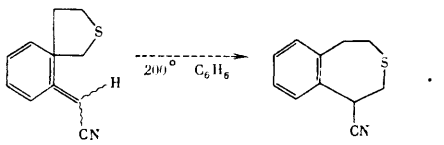
On pyrolysis, thiiran is converted into ethylenethiol and thiophen.[118] The thermolysis of the spirothiiran (XXV) leads to the formation of an olefin as a result of a complex (hitherto not ultimately elucidated) chain of reactions—the reaction order is other than first:[119]



(XXV)

Mass-spectrometric study of alkyl-substituted thiolans and thianes showed[120] that the stability of the molecular ions of β-alkylthiolans is greater than for their α-isomers and that the main process in the decomposition of α-alkylthiolans is the ejection of alkyl radicals as a whole from the molecular ions. In the case of β-alkylthiolans, the main decomposition pathway involves the elimination of only part of the alkyl substituent with retention of one CH_2 group in the charged thiolanium fragment. In α- and β-thianes, the alkyl substituent is eliminated predominantly as a whole, while γ-alkylthianes behave similarly to β-alkylthiolans. The same has been observed for 4-alkyl-2-methylthianes,[121] for which, in addition, the CH_3 group is more readily split-off from the *trans*-isomers, i.e. the latter are less stable in relation to electron impact than the *cis*-isomers. In the *cis*- and *trans*-isomers of 2(4′-alkoxycarbonylbutyl-3-hydroxy-4-ureidothiolans, the splitting-off of the substituents in 3- and 4-positions under electron impact also takes place with different degrees of ease, which makes it possible to identify the geometrical structure.[122]

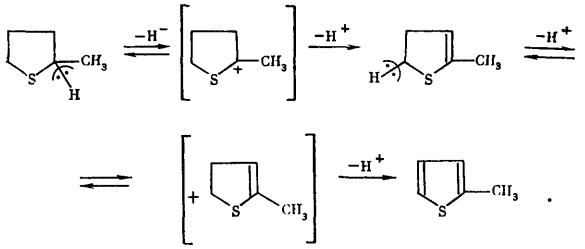
A combination of positive and negative ion mass spectrometry has been used to establish the structures of bridged thiabicyclooctanes and thiabicyclononanes, including methyl-substituted compounds.[12] The characteristic features of the fragmentation of the positive ions M^+ exist in the transition state $(M^1)^+$,$(M^2)^+$:



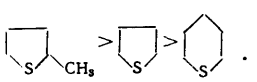
The decomposition of molecular negative ions involves the rupture of the C—C bonds (at the junction) and C—S bonds with localisation of the negative charge on the sulphur atom:

The characteristic feature of the decomposition of negative ions made it possible to infer unambiguously the presence of substituents at the α-carbon atom (relative to the sulphur atom).

The fragmentation of 1,3-dithiolan under electron impact has been examined[124] and the heat of formation of the free radical CHS˙, amounting to 63 kcal mol^{-1}, has been obtained from the appearance potentials of the $[C_2H_5S]^+$ ion.



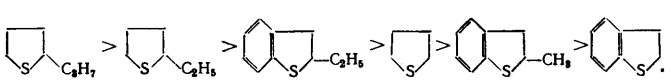
When the spiran (XIX) is heated in benzene (in a sealed tube), thermal isomerisation takes place with formation of a seven-membered ring:[75]



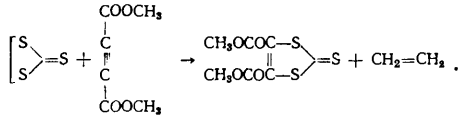
(XIX) 82%

VIII. DEHYDROGENATION AND DESULPHURISATION OF CYCLIC SULPHIDES

Thiolan, 2-methylthiolan, and 2-methylthiaindan are dehydrogenated to the corresponding thiophene derivatives in the presence of acid catalysts—$ZnCl_2/Al_2O_3$ and aluminosilicate;[82,125] the process takes place on aprotic catalyst centres and includes stages in which hydride ions are abstracted and cationic intermediates are formed:



2-Methylthiolan is dehydrogenated more readily than the unsubstituted compound, owing to the greater hydride mobility of the hydrogen atom. It decreases in the sequence[126]

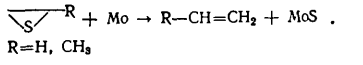


Using cyclic sulphides as hydride ion donors in the ionic reduction of carbonium ions, it is possible to obtain their dehydrogenation products: 2-methylthiophen from thiane (the reaction is accompanied by isomerisation)[127] and 2-methylthiaindene from 2-methylthiaindan in 87% yield (according to gas—liquid chromatographic data).[128]

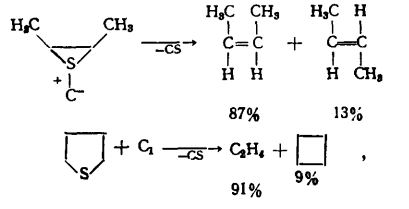
The rate constants for the dehydrogenation of cyclic sulphides in the presence of activated charcoals at 400 °C decrease in the sequence[129]

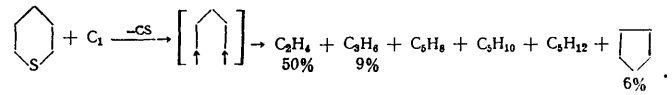
It is appropriate to mention that, according to the EPR spectra of the free radicals formed as a result of the abstraction of hydrogen, the protons in the α-position relative to the sulphur atom in thiolan, thiane, and 4-t-butylthiane are not equivalent.[130]

An unsaturated heterocycle can be obtained from a saturated hetearocycle not only on dehydrogenation but also in an exchange reaction:[131]



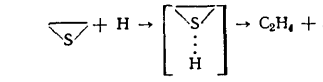
The hydrodesulphurisation of thiirans leads to alkanes; sometimes the reaction stops at the formation of olefins:



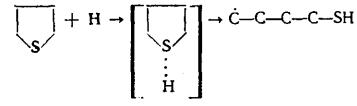


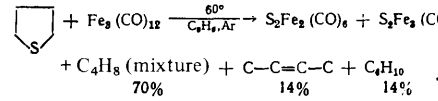
Various hydrodesulphurisation methods have been investigated[132] for the alkylthiirans: dodecylthiiran, 2-methyl-2-nonylthiiran, 2,3-dioctylthiiran, and 3-decyl-2,2-dimethylthiiran. In the presence of Raney nickel of lithium, monosubstituted 2,3-disubstituted thiirans react with ethylamine at a low temperature, giving rise to alkanes. The desulphurisation of tri- and tetra-substituted thiirans stops at the formation of alkenes. On treatment with zinc in acetic acid or with tributyltin tetrahydroborate, only olefins are formed, the reaction being regioselective but not fully stereoselective. The reduction with P_2I_4 in dimethylformamide (DMF) is highly stereoselective and leads to olefins having the same configuration as the initial thiiran. However, the first two methods can also be used to synthesise olefins if the reaction is carried out with heating. The yields are high in all the methods.

When cyclic sulphides are treated with metallic molybdenum, the degree of desulphurisation diminishes with decrease in ring strain.[133] The reaction of thiiran and 2-methylthiiran afforded the corresponding alkenes in 132 and 119% yields relative to the evaporated molybdenum:

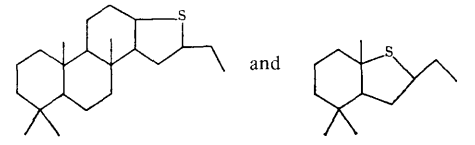


Propene and a small amount of cyclopropane are formed from thietan. It has been suggested that either a biradical is formed as a result of the simultaneous rupture of both C–S bonds or the reaction proceeds with participation of a π-allyl intermediate. The addition of tetraethylthiiran disulphide increases the yield of propene to 77%. The reaction of thiolan results in the formation mainly of hydrogen and a complex mixture of C_1-C_4 products, including 15% of butanethiol. When a cyclic sulphide interacts with carbon vapour (produced from carbon electrodes in a voltaic arc), desulphurisation takes place.[134] The process proceeds via an intermediate ylide, formed when the electrophilic carbon atom and the free electron pair of the suphur atom interact. A CS polymer is formed as a result of the decomposition of the ylide:



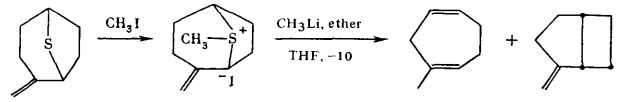


When thiiran is reduced with hydrogen under pressure,[135] ethylene is formed, the sulphur atom being eliminated in the form of a univalent radical:



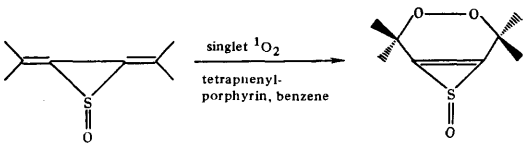
In the reaction involving thiolan, the formation of a mercaptobutyl radical is most probable and in this case the C–S bond is broken:[135]

In the desulphurisation of thiolan by treatment with triiron dodecacarbonyl, the reaction proceeds via a stage involving metal carbonyl sulphide clusters:[136]



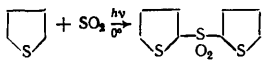
The hydrodesulphurisation of polymethylthiolans and polymethylthianes on the AP-56 industrial platinum catalyst at 350 °C takes place without the decomposition of the carbon skeleton and can be used to investigate petroleum sulphides present in the petrol fractions.[137] Despite the fact that the hydrodesulphurisation over Raney nickel can induce rearrangements and condensation reactions,[1] this reaction has been used to establish the structure in the synthesis of thiabicycloalkanes.[138] The structure of the bicyclic and tetracyclic terpenoid sulphides[139] of the type

found in Athabasca bitumen (a petroleum deposit in Virginia, USA) has also been established with its aid.



In the synthesis of gramicidin, the desulphurisation of 1,3-dithianes takes place on treatment with lead dioxide and boron trifluoride in methanol[37] (see above).

Sulphur is split-off on treatment of methylsulphonium salts [or their precursors?], for example, 2-methylene-8-thiabicyclo[3.2.1]-octane, with methyl-lithium;[140] for the removal of the sulphur atom, it is essential that at least one of the carbon atoms at the junction should be of the benzyl or allyl type:

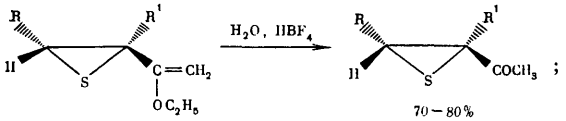


IX. PHOTOCHEMICAL REACTIONS OF THE SULPHIDES

There have been few studies on the photochemical reactions of saturated cyclic sulphurides. The photochemical oxidation of thiiranoradialene sulphoxide (XXVI) leads to thiirene sulphoxide (XXVII) joined to an *endo*-peroxide ring:[141]

(XXVI) (XXVII), 72%

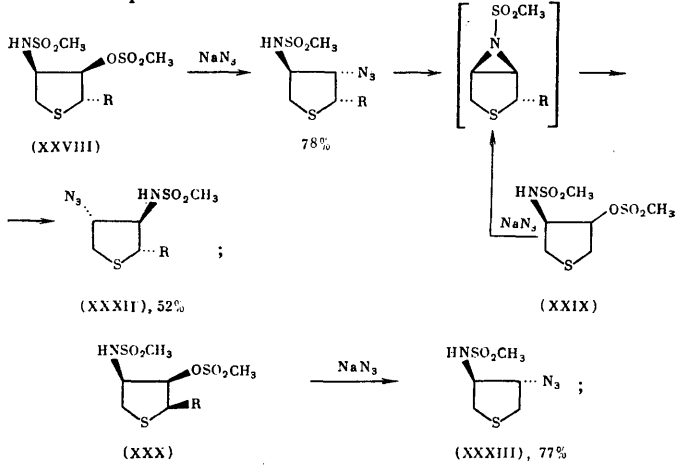
Thiolan combines with sulphur dioxide on irradiation with UV light:[142]



The methylenation of thietans, thiolans, and thianes with the aid of diazomethane on irradiation with UV light leads to alkylthiacycloalkanes;[143] the reaction has been used to identify cyclic sulphides by gas–liquid chromatography.

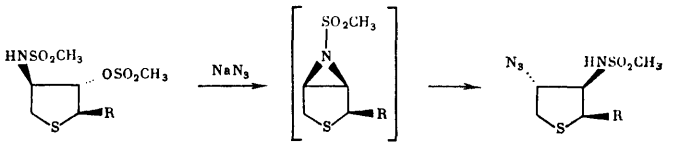
The decomposition of polycyclic "semi-aromatic" sulphides by light results in the formation of cyclophanes.[144]

X. INTRODUCTION OF FUNCTIONAL GROUPS WITHOUT CHANGE IN THE CARBON SKELETON



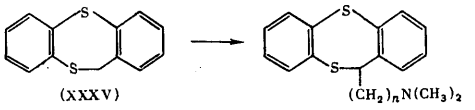
The stereochemical aspect of the study is of special interest in reactions involving the introduction of a functional group.

When ethoxyvinylthiirans undergo acid hydrolysis to acetylthiirans, the configuration is retained:[145]



R, R¹ = H, CH_3.

The reaction of four stereoisomers of 2,3,4-trisubstituted thiolans (XXVIII)–(XXXI) with sodium azide[146] leads to the formation of only the *trans*-3,4-disubstituted compounds (XXXII)–(XXXIV). Consequently, the reaction of the *cis*-3,4-disubstituted thiirans takes place with inversion of the configuration at C(3), while the reaction of the *trans*-3,4-disubstituted compounds proceeds in an unusual manner—without change in configuration. The intermediate formation of the aziridine ring has been suggested[146] and in the case of compounds (XXVIII), (XXIX), and (XXXI) the reaction is accompanied by the migration of the substituents from the 3-position to the 4-position:

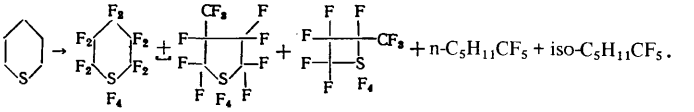


(XXVIII) (XXXII), 52% (XXIX)

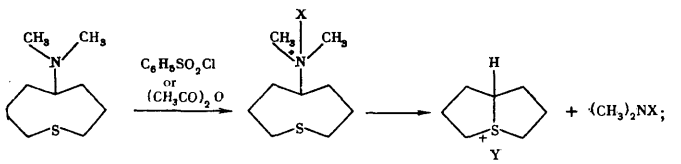
(XXX) (XXXIII), 77%

(XXXI) R = $(CH_2)_4COOCH_3$ (XXXIV), 77%

The reaction of 11*H*-dibenzo[*b*,*e*]-1,4-dithiepin (XXXV) with fairly strong bases leads to the abstraction of the proton in the 11-position and the formation of the corresponding carbanion or an organometallic compound.[147] The reaction of the organolithium compound obtained in this way with 2-dimethylaminoethyl chloride or with 2-dimethylaminopropyl chloride affords compounds (XXXVI) or (XXXVII) (isolated in the form of acid oxalates), which exhibit an antireserpine activity:



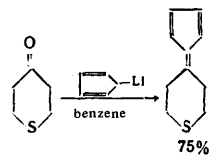
(XXXV) (XXXVI) n = 2 (XXXVII) n = 3



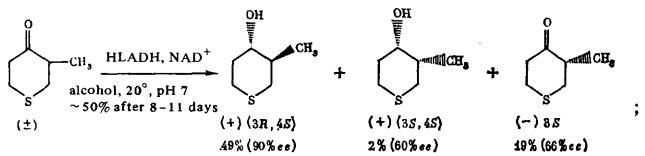
The cyanoethylation of methyl-4-thianones proceeds in different ways depending on the position of the substituent.[148] 2-Methyl-4-thianone gives rise to only 5-(2-cyanoethyl)-2-methyl-4-thianone, 2,2-dimethyl-4-thianone affords only 5,5-di(2-cyanoethyl-2,2-dimethyl-4-thianone, while 3-methyl-4-thianone gives rise to both 3-(2-cyanoethyl)-3-methyl-4-thianone and 3,5-di(2-cyanoethyl)-3-methyl-4-thianone. The authors[148] explain this by the different influences of the substituent on the conformation of the intermediate carbanions.

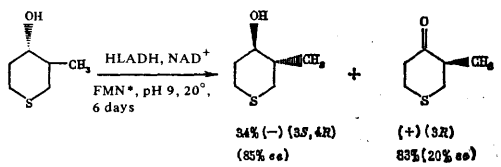
On treatment with *N*-chlorosuccinimide in benzene (at 20–25 °C), thiolan, thiane, and thiepan produce the corresponding α-chlorothiacycloalkanes.[149]

The electrochemical fluorination of thiolan, 2-methylthiolan, and thiane in anhydrous HF at 5–6 °C [150] involves complete fluorination, for example:



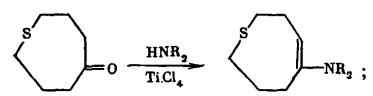
The unusual "functional group elimination" reaction occurring in the interaction of 5-(dimethylamino)-1-thiacyclo-octane with benzenesulphonyl chloride[151] leads to 1-thioniabicyclo[3.3.0]octane benzenesulphonate (compounds of this type are called Eastman's salts) and *NN*-dimethylbenzenesulphonamide in nearly quantitative yields. Acetic anhydride behaves analogously:



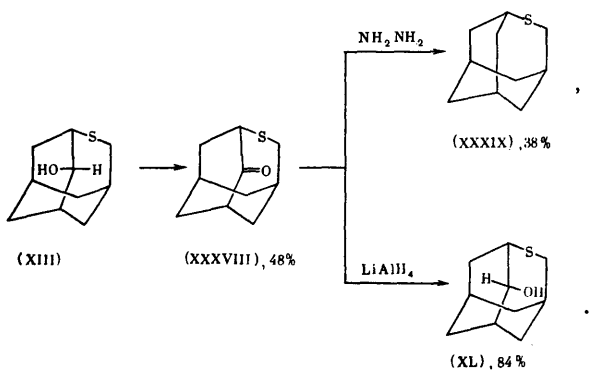


X = $C_6H_5SO_2$ or CH_3CO;
Y = $C_6H_5SO_2O^-$ or CH_3COO^-.

The reactions of the keto-group in thiacycloalkanes are used for synthetic purposes; for example, lithiocyclopentadiene reacts with 4-thianone:[152]

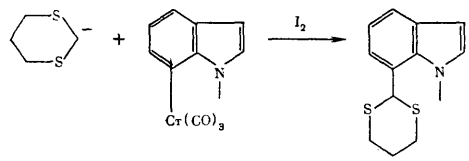


The enzymatic reduction of the keto-group in 4-thianones by horse liver alcohol dehydrogenase (HLADH) in the presence of a co-enzyme—a nicotinamide derivative (NAD^+)—proceeds with high stereoselectivity and enantiomeric selectivity.[153] The oxidation of *trans*-4-thianols with participation of HLADH is also promising for the synthesis of enantiomers which have not reacted (the *cis*-isomers are oxidised very slowly):[143]



*FMN = flavin mononucleotide (recyclising agent).

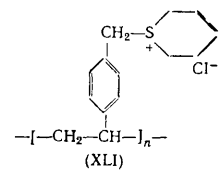
5-Thiocanone reacts with secondary amines to produce enamines—derivatives of tetrahydrothiocin:[154]



$R_2 = (CH_3)_2, -(CH_2)_4-, -(CH_2)_2-O-(CH_2)_2-$.

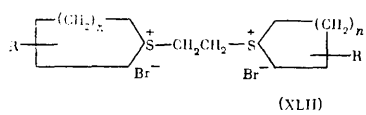
The reduction of 2-methyl-1-thiadecalones and 2-methyl-1-thiahydrindanones with hydrazine hydrate leads to a mixture of stereoisomeric 2-methyl-1-thiadecalins or 2-methyl-1-thiahydrindans; the stereoisomers are separated chromatographically.[155] 4-Thiahomoadamantan-2-one (XXXVIII) [obtained by oxidising compound (XIII)] is reduced[39] to 4-thiahomoadamantane (XXXIX) in the same way; the reduction of compound (XXXVIII) with lithium tetrahydroaluminate leads to a stereoisomer of 2-hydroxy-4-thiahomoadamantane (XL):

Treatment of compound (XIII) with thionyl chloride produces[39] the corresponding chloride in 98% yield; it is reduced with lithium tetrahydroaluminate to compound (XXXIX) in 82% yield.



The nucleophilic attack by 2-lithio-1,3-dithiane is directed to the 7-position in π-indolechromium tricarbonyl and a 7-substituted indole is formed in a high yield;[156] the chromium π-complexes are decomposed with iodine:

XI. THE SYNTHESIS AND REACTIONS OF CYCLIC SULPHONIUM SALTS



The introduction of functional groups into cyclic sulphides by converting them into sulphonium compounds is important. They are extremely promising for practical use and also open up pathways to the synthesis of a wide variety of polyfunctional compounds, especially compounds based on thioniacycloalkanes.

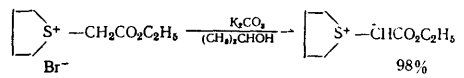
Chlorobenzylthiolanium and chlorobenzylthianium halides are formed when cyclic sulphides interact with chlorobenzyl halides in nitromethane (the yields of the sulphonium salts are 43–72%).[157] The vinylbenzylthianium and vinylbenzyl(3-pentyl)thiolanium halides are obtained analogously to serve as monomers for the preparation of polymers of type (XLI) by radical polymerisation; aqueous solutions of the polymers are used as flocculants:[158]

(XLI)

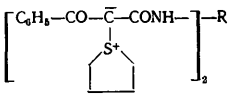
Ethylenebis-sulphonium salts of type (XLII) have been patented[159] as fungicides and agents active against phytopathogenic microbes; the salts are obtained from ethylene dihalide and a cyclic sulphide in DMF at 75 °C:

$n = 0.1$; R = Cl, Br, alkyl, alkoxyl, carboxyl

(XLII)



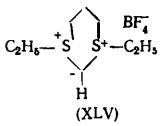
The bis-sulphonium salt (XLIII)



(XLIII)

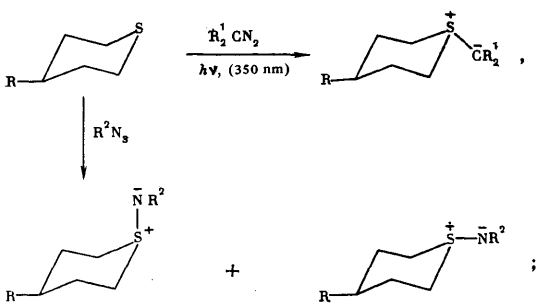
was obtained[160] by heating thiolan and 4,4′-di(chloromethyl)biphenyl in concentrated hydrochloric acid at 65 °C (yield 98%). Salts of this type, including those obtained from thiane and thiepan,[160] serve as intermediates in the synthesis of dyes.

Stable ylides, for example:[161]



can be obtained by treating with bases thiolanium[161] or dithiolanium[162] salts having electron-accepting substituents. Ylides of types (XLIV) are used as cross-linking agents for carboxyl-containing polymers:[163]

(XLIV)



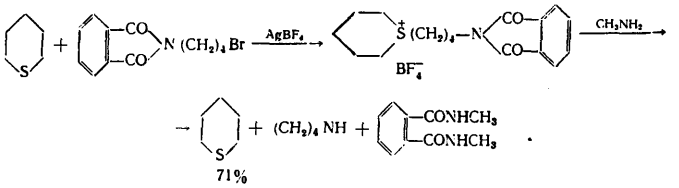
R=$C_6H_4OC_6H_4$, from C_2 to C_{20}.

Bis-sulphonium salts—alkyl-substituted 1,3-dithiolanium and 1,3-dithianium picrates and fluoroborates—are powerful CH acids:[164] 1,3-diethyl-1,3-dithianium bis(tetrafluoroborate) is deprotonated and gives rise to the stable ylide salt (XLV):

(XLV)

Only one sulphonium ylide is formed on interaction of 4-t-butylthiane with carbenes as a result of equatorial addition; on interaction with nitrenes, a 1 : 1 mixture of diastereoisomeric iminosulphuranes is formed in each case:[165]

R = t-C_4H_9, R^1 = $COCH_3$, $COOCH_3$, R^2 = *p*-CH_3-$C_6H_4SO_2$, COO_2H_5.



Eastman's salts—fluorides of 1-thioniabicyclo[4.4.0]decane and 6-methoxycarbonyl-1-thioniabicyclo[4.4.0]decane—have been obtained as *cis*- and *trans*-stereoisomers (isolated in the purest form) and from them ylides were synthesised:[166] the ylide from the *cis*-isomer is more stable.

Conformational analysis of the salts of methyl-substituted *cis*-1-thioniabicyclo[4.3.0]nonane derivatives has been carried out.[167]

The conformational energy of the equilibrium transition between the axial and equatorial forms of 1-methylthianium hexafluorophosphates and perchlorates, obtained by methylating thiane, 2-, 3-, and 4-methylthianes, and the *cis*- and *trans*-stereoisomers of 2,6-, 3,5-, 2,5-, and 2,4-dimethylthianes, 3,4-, 3,3-, and 4,4-dimethylthianes, 3,3,5- and 2,2,4-trimethylthianes, and 4-t-butylthiane, has been measured.[168] Its value is low for these salts (0.0 – 0.3 kcal mol^{-1}). 1-Phenyl- and benzyl-thianium and the diastereoisomeric 4-t-butyl- and 1-benzyl-2,6-dimethyl-thianium fluoroborates, 4-t-butyl-1-ethylthianium perchlorates, and 1-methyl-*cis*- and 1-methyl-*trans*-thiadecalinium hexafluorophosphates and perchlorates have been obtained by alkylating the corresponding sulphides.[168]

Thianes are deuteriated using sulphonium salts;[169] the methiodides are obtained and the acid α-hydrogen atoms are subjected to deuterium exchange (base catalysis in solution in D_2O), the sulphonium salt is reisolated, and dry-distilled to give the deuteriated thiane.

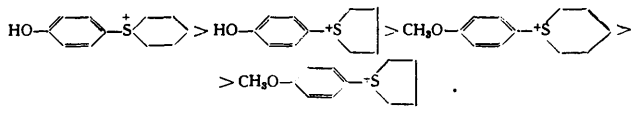
A method for protecting the sulphide sulphur against the action of metal catalysts, electrophiles, and oxidants by converting the sulphides into the 4-aminobutyl- or *p*-methoxybenzyl-sulphonium salts, which are cleaved with regeneration of the sulphides, has been proposed recently:[170]

71%

A method for the preparation of the perchlorates of 4-hydroxyarylthioniacycloalkanes by condensing thiacycloalkanes with phenols in the presence of perchloric acid, phosphoryl chloride, and hydrogen peroxide or by condensing thiacycloalkane oxides under the same conditions but without hydrogen peroxide has been put forward.[171] In the 4-hydroxy-phenylthiolanium and 4-hydroxy-1-naphthylthiolnium perchlorates obtained in this way, there is a hydrogen bond between the hydroxyls of the cation and the oxygen of the anion.[172,173] Furthermore, in 4-hydroxyphenylthianium perchlorate there is a bifurcated hydrogen bond formed by the hydroxyl of another cation and two oxygen atoms of two other anions.[174]

The perchlorates of *p*-hydroxy- and *p*-methoxy-phenylthioniacycloalkanes have been obtained from the petroleum sulphoxides and phenol and anisole.[175] The condensation of the petroleum sulphoxides with phenol then proceeds selectively—only thiamonocycloalkane oxides interact under these conditions.

4-Hydroxy-2(3)-methyl-, 2,4-dihydroxy-, 2,3,4-trihydroxy-, and 2,5-dihydroxy-phenylthiolanium chlorides have been obtained by the reaction of substituted phenols with thiolan and chlorine;[6] the yields (57 – 75%) vary in parallel with the activity of the phenols.

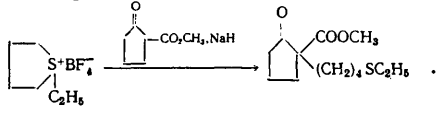


Sulphonium salts have been obtained by the interaction of thiolan with alkenes or quinones in a strong acid.[176,177] The latter method has been modified[178] and has led to a single-stage procedure for the synthesis of a wide variety of salts of 2,5-dihydroxyphenylthioniacycloalkanes in good yields (as a rule 60 – 100%). The OH group in 2,5-dihydroxyphenylthianium perchlorate, located in the 5-position in the cation, is hydrogen-bonded to the oxygen atom of the anion.[179] In the hydrate of 2,5-dihydroxyphenylthianium chloride,[178] there are three types of hydrogen bonds: between the OH group in the 2-position in the cation and the chloride anion, between the OH group in the 5-position in the cation and the oxygen atom of water, and also between a water molecule and two chloride anions.[180]

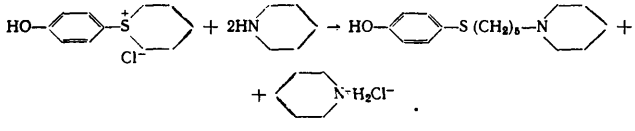
The petroleum sulphides obtained from the middle fractions of petroleum have been converted by condensation with *p*-benzoquinone and hydrochloric acid into the chlorides of 2,5-dihydroxyphenylthioniacycloalkanes (yield up to 75%).[181] Sulphonium salts—water-soluble dyes for polyester fibres—have been obtained[182] by condensing thiacycloalkanes with anthraquinones by Bosshard's method.[177]

The C – S bond dissociation reactions on treatment of arylthiolanium and arylthianium salts with nucleophiles have been investigated.[183-185] The ease of dissociation of the C – S bond varies in parallel with the degree of nucleophilicity of the reagent:[185]

$$CH_3O^- \geqslant Cl^- > Br^- > I^- \geqslant (NO_2)_2C_6H_2O^- .$$

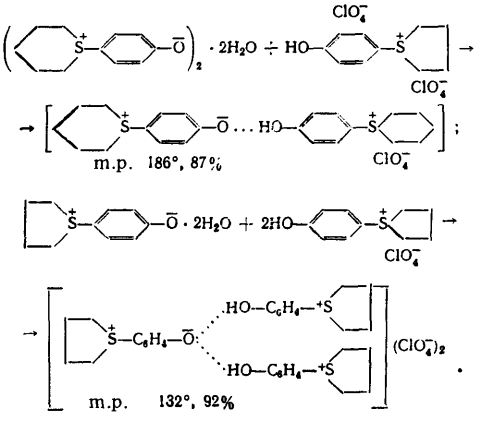


The relative stabilities of the heterocycle in the cations of sulphonium perchlorates decrease in the sequence[185]



The interaction of salts of *p*-methoxyphenylthioniacycloalkanes with an aqueous or methanol solution of potassium hydroxide gives rise to ω-hydroxy-, ω-methoxy-, or ω-chloro-substituted butyl or pentyl *p*-methoxyphenyl sulphides in preparative yields (60–86%).[185]

On treatment with potassium t-butoxide in DMSO, phenylthiolanium perchlorate decomposes into phenyl vinyl sulphide and ethylene, while phenylthianium perchlorate affords 100% of the β-elimination product $C_6H_5S(CH_2)_3CH=CH_2$.[183] When these salts are treated with sodium ethoxide in alcohol, mixtures of β-elimination and α-substitution products are formed; in the case of the thianium salt, the latter predominates.[183]



Cyclic sulphonium salts have been used for the *C*-alkylation of β-ketoesters,[186] for example:

When salts of arylthioniacycloalkanes interact with amines, the C–S bond is broken and the main amine adds on; this reaction constitutes a simple single-stage method of synthesis of ω-aminoalkyl aryl sulphides and their salts, for example:[187,188]

On treatment with bases, *p*-hydroxyphenyl-1-thiolanium and *p*-hydroxyphenyl-1-thianium salts form hydrated zwitter-ions, which readily lose water on heating and polymerise.[171,185,189–193] The zwitter-ions are also stabilised by the perchlorates of *p*-hydroxyphenylthioniacycloalkanes; stable crystalline polysulphonium salts with complex cations, formed with participation of hydrogen bonds, are then obtained:[189,190]

The oligomers produces from *p*-(1-thiolania)phenoxide with the $-[S(CH_2)_4OC_6H_6]-$ fragment have an end group with an unopened thiolanium ring; on treatment with amines, the end group is opened, affording an aminosulphide residue.[190]

Hydroxyarylthioniacycloalkane zwitter-ions are apparently polymerised via a cationic mechanism. The polymers can be used to obtain water-resistant thermoplastic resins, coatings, films, and impregnating agents.[192–195] The hydrated *p*-(1-thiolania)phenoxide and *p*-(1-thiolania)-*o*-cresolate zwitter-ions are used[196,197] as catalysts of the polycyclotrimerisation of aryl isocyanates.

The addition of *p*-t-butylthiolanium bicarbonate or bisulphate to carboxylated polymers increases the water resistance of the films obtained from them.[198]

Transition Metal Percarboxylates, Alkylperoxides, and Hydroperoxides

V.M.Fomin, V.N.Glushakova, and Yu.A.Aleksandrov

Data on methods for preparing transition metal percarboxylates, alkylperoxides, and hydroperoxides are systematically reviewed. The factors determining their stability and the most typical routes for their reactions are discussed. The ability of these compounds to act as efficient carriers of oxygen atoms to substrates of various kinds is emphasised using numerous examples.
The bibliography includes 179 references.

I. INTRODUCTION

The development of the chemistry of peroxide complexes of transition metals (TMPC's), such as complexes of the types $L_nM\langle^{O}_{O}|$, L_nMOOML_n, L_nMOOR (where M is a transition metal, L an organic or other ligand, and R = H, alkyl or a substituted alkyl, or R'CO), is of great importance for solving theoretical and practical problems in the catalytic oxidation of substrates of various kinds. The large amount of data so far accumulated give good reason to suppose that peroxide complexes with this structure, which are intermediates in biological oxygenation processes[1,2] and the catalytic oxidation of alkenes, alkanes, alcohols, amines, phosphines, sulphides, etc. by molecular oxygen and hydroperoxides,[3-11] are responsible for the transfer of oxygen to the oxidisable substrate, which may take place stereospecifically or stereoselectively.

The natural interest of research workers in reactions involving peroxide complexes leads to the publication in the domestic and foreign literature of an ever increasing amount of pertinent data which needs classifying. Progress in the chemistry of transition metal mono- [metal] and di-[metal]-peroxo-complexes $L_nM\langle^{O}_{O}|$ and L_nMOOML_n is comparatively fully reported in a number of reviews.[12-16] The role of the peroxides L_nMOOR (TMPC) in the mechanism of catalytic epoxidation and ketonisation of alkenes is discussed in detail in other reviews.[3-10]

There is an absence of articles of a general nature in which various aspects of the chemistry of TMPC's, such as methods of preparation, physicochemical properties, and stoichiometric and catalytic oxidation involving them, might be discussed.

The aim of the present review is to fill an existing gap in the classification of data on the chemistry of transition metal percarboxylates and alkyl- and hydro-peroxides.

II. METHODS OF PREPARATION

1. Transition Metal Alkylperoxides

Transition metal alkylperoxides are the most widespread of the TMPC's presently known.

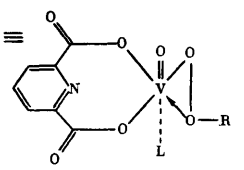
The first peroxides of this type to be prepared were titanium compounds with the general composition $R_{4-n}Ti(OOR)_n$, which are formed by the reaction of titanium halides or alkoxides with t-butyl hydroperoxide:[17]

$$TiCl_4 + n\,Bu^tOOH \xrightarrow[NH_3\cdot py]{0\div 20^\circ C} (Bu^tOO)_nTiCl_{4-n} + n\,HCl, \quad (1)$$

$$Ti(OPr^i)_4 + n\,Bu^tOOH \xrightarrow[py]{0\div 20^\circ C} (Bu^tOO)_nTi(OPr^i)_{4-n} + n\,Pr^iOH. \quad (2)$$

This method[17] for preparing TMPC's, the basis of which is substitution of one of the ligands attached to the metal (usually a halide, hydroxide, or alkoxide):

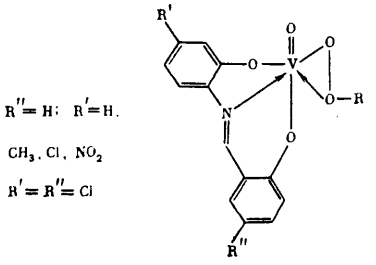
$$L_nMX + ROOH \rightarrow L_nMOOR + HX \quad (3)$$



has also been used to prepare alkylperoxides of titanium (X = acac, OEt; $R = Bu^t$),[7,18-20] vanadium ($X = OEt, OPr^i, OBu^t$, $R = Bu^t$),[21-26] and palladium and platinum (X = an anion of a carboxylic or sulphonic acid; R = alkyl, aryl, or arylalkyl;[27-30] or X = OH; $R = Bu^t$ [31,32]).

If X in the complex L_nMX in Eqn.(3) is a halogen or a carboxylate anion, in place of ROOH the alkali metal salts can be used. The alkylperoxides of palladium, platinum,zirconium, and rhodium have been obtained in this way.[30,33-35]

The preparations[3] of the alkylperoxides of the vanadium dipicolinates (dipic)V(O)(OOR)L [L = H_2O or HMPT (hexametapol); R = Bu^t, cumyl],[36,37] which are described by Eqns.(4) and (5):



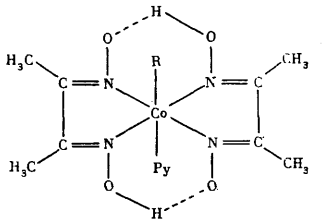
$$V_2O_5 + \text{dipic}\,H_2 + ROOH \xrightarrow{H_2O} \text{(dipic)}\,V(O)(OOR)\cdot H_2O \quad (4)$$

$$V(O)(OPr^i)_3 + HMPT + \text{dipic}\,H_2 + ROOH \rightarrow \text{(dipic)}V(O)(OOR).HMPT + 3Pr^iOH \quad (5)$$

(dipic)V(O)(OOR)·L ≡ 

are variations on Eqn.(3).

Alkylperoxides of oxo-[*N*-(2-oxidophenyl)salicylideneiminato]-vanadium have been obtained in a similar way:[38]



Reactions (4) and (5) have been shown to proceed via the complexes (dipic)V(O)OH.H_2O and (dipic)V(O)(OPr^i).HMPT respectively, which react with ROOH to form the desired products.

The replacement of the ligands attached to the metal by the alkylperoxide moiety can be initiated by ultraviolet light, as in the reaction of alkylpyridinecobaltoximes R[Co]py with R'OOH:[39]

$$R\text{-}[Co]\text{-}py + 2R'OOH \xrightarrow[C_6H_6/N_2]{h\nu} py[Co]OOR' + R'OOR, \quad (6)$$

where R = cumyl or t-butyl, and R' = $C(CH_3)_3$, $C(CH_3)_2C_6H_5$, $CH(CH_3)C_6H_5$, C_6H_{11}, or $CH(CH_3)C_6H_4CH_3$, and [Co] represents a Co^{II} oxime or $(Dmg)_2Co$.

This last process[39] takes place via a stage in which there is photodissociation of the metal–carbon bond and the (py)Co^{II} complex formed then reacts with ROOH.

Another general method for the preparation of transition metal alkylperoxides is based on the attachment of ROOH or the peroxide moiety OOR to transition metal complexes (TMC's), which may take place with or without a change in the oxidation state of the metal:

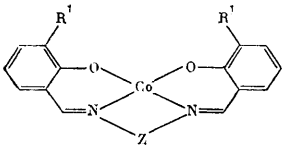
$$L_nM + ROOH \longrightarrow L_nM^{+}\bar{O}OR \quad (7a)$$

$$L_nM + ROOH \longrightarrow L_nM^{2+}(\bar{O}OR)(H^-) \quad (7b)$$

$$L_nM + RO_2^{\cdot} \rightarrow L_nM^{+}\bar{O}OR \quad (8)$$

$$L_nM{=}O + ROOH \rightarrow L_nM\begin{matrix}OOR\\OH\end{matrix} \quad (9)$$

Reaction(7)† has been carried out in the following cases:



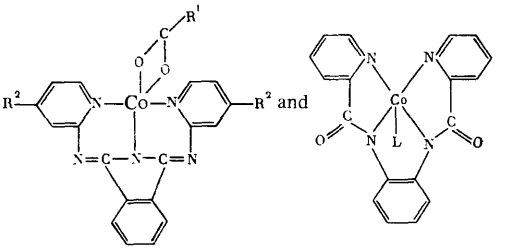
(1) For $(Arene)_2Cr$ complexes and molybdenum and tungsten cyclopentadienyl complexes Cp_2MX_2 (X = Cl, Br, I), giving the peroxides $Ar_2Cr^{+}(OOR.ROOH)^{-}$ (R = Bu^t, cumyl)[40] and $Cp_2MX_2^{+}(OOR.ROOH)^{-}$ (R = t-butyl, cumyl, t-pentyl, or α-phenylethyl)[41–43] respectively:

$$L_nM + 3ROOH \underset{-S}{\overset{SH}{\rightleftarrows}} L_nM^{+}(OOR{\cdot}ROOH)^{-} + ROH + H_2O \quad (10)$$

(2) For cobalt pyridine-acetylacetonates[44] and cobalt(II) complexes with Schiff bases, in reactions with t-butyl and cumyl hydroperoxides, to form cobalt(III) peroxides:[44–47]

$$2[Co^{II}] + 3ROOH \xrightarrow[CH_2Cl_2]{20^\circ C} 2ROO\text{–}[Co^{III}] + ROH + H_2O \quad (11)$$

where [Co^{II}] are the complexes



R^1=H; Z=MeN$\langle^{(CH_2)_3}_{(CH_2)_3}$ (Co (NMe salpr)), $(CH_2)_2$ (Co (salen)), OC_6H_4 (Co (salphen)),

HN$\langle^{(CH_2)_3}_{(CH_2)_3}$ (Co (salpr));

R^1=OMe, Z=$(CH_2)_2$ (Co (MeO salen))

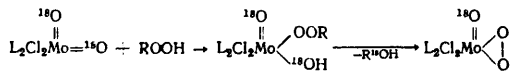
and also other Co^{II} complexes: the 1,3-bis-(2-pyridylimino)isoindole and *N,N'*-bis-(2'-pyridinecarboxamido)-1,2-benzene complexes

Co(R^2BPI^{1-}·OCOR^1) Co(BPB)(4-Mepy)

(3) For the iridium complexes IrX(CO)L_2 (L = PPh_3, PPh_2Me, or $AsPh_3$), which react with t-butyl and cumyl hydroperoxides to give either mono- (X = I) or bis-alkylperoxides (X = Cl, Br):[48–50]

$$IrI(CO)L_2 + ROOH \rightarrow Ir(H)I(OOR)(CO)L_2 \quad (12)$$

$$IrX(CO)L_2 + 2ROOH \rightarrow \begin{matrix}L\\OC\end{matrix}\!\!\begin{matrix}OOR\\|\\Ir\\|\\X\end{matrix}\!\!\begin{matrix}OOR\\|\\L\end{matrix} \quad (13)$$



The complex Ir(H)I(OOR)(CO)L_2 is unstable and is converted to the more stable peroxide Ir(CO)(OOR)I_2L_2 by successive elimination of HI and addition of I_2.

Reaction (8) has been studied in detail as one of the effective methods of inhibiting radical-chain processes involving ROOH or O_2.[51–67] The reaction occurs for TMC's in various groups of the Periodic Table.

---

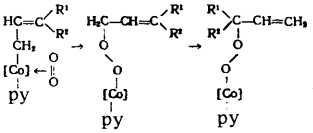
† Reaction (7a) includes oxidation of the initial metal complex to the hydroxide $L_nM^{+}OH^{-}$, the reaction of which with ROOH [Eqn.(3)] also gives the desired product.

An example of Eqn.(9) is the formation of alkylperoxide complexes from the labelled oxo-complex of molybdenum $L_2Cl_2Mo(^{18}O)_2$:[9]

(14)

The possible preparation of alkylperoxide complexes by the reaction of TMC's with ROOH is also discussed in a number of papers on the specific synthesis of these compounds—derivatives of titanium,[68] zirconium,[69] vanadium,[21-26] chromium,[40], and molybdenum,[41] in numerous papers on the hydroperoxide catalytic oxidation of substrates of various kinds (alkenes, alkanes, alcohols, ethers, amines, etc.) on vanadium,[70-76] chromium,[77,78] molybdenum and tungsten,[9,10,70-75] manganese,[79] rhodium,[3-10,80-86] iridium, palladium, and platinum,[3-10] and titanium[20,87] compounds, and in studies of the mechanism of the catalysed decomposition of alkyl hydroperoxides.[88,89]

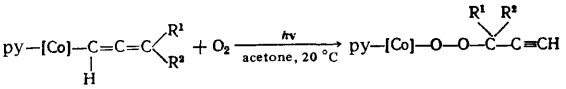
Methods for preparing alkylperoxide complexes are not restricted to reactions of TMC's with ROOH. A considerable number of these compounds are obtained by auto-oxidation of TMC's. If the latter contain a metal–alkyl bond or one emerges during their oxidation, alkylperoxide complexes are usually formed by the insertion of an oxygen molecule into this bond:



$$L_nM-R+O_2\rightarrow L_nMOOR \qquad (15)$$

Reaction (15) has been studied in greatest detail for the alkylcobaloximes R–[Co]–L.[90-103] Depending on the energy of the Co–R bond, which is determined by the nature of R and the ligand in the axial position, the insertion of oxygen may occur under ambient conditions, on photochemical irradiation, or at high temperatures in a chloroform, acetone, or methanol solution:

$$py-[Co]-R+O_2\xrightarrow{h\nu}py-[Co]-OOR \qquad (16)$$



where [Co] represents the cobaloxime.

When R is a substituted allyl group, isomerisation of this group can occur simultaneously with the insertion of oxygen by a concerted mechanism:[97]

(17)

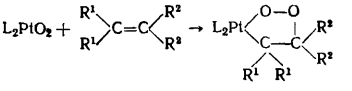
When R is a substituted allenyl or prop-2-ynyl group, in both cases the product contains a prop-2-ynyl radical:

(18)

The mechanism of the insertion of oxygen into the Co–R bond has not been unambiguously established. For the thermal insertion [py(Dmg)$_2$Co–R complexes] three possible mechanisms are proposed: a radical,[96] cryptoradical,[97] and molecular[97] mechanism. Data on the thermal stability of alkylcobaloximes and the kinetics of their oxidation[94,97] agree to a large extent with the cryptoradical mechanism:

$$RCoL\overset{\Delta}{\rightleftharpoons}\{R^{\cdot}\cdots\dot{C}oL\} \qquad (19)$$

$$\{R^{\cdot}\cdots{}^{\cdot}CoL\}+O_2\rightarrow ROOCoL \qquad (20)$$



According to data in Ref.102 the mechanism of the photochemical insertion of oxygen into the Co–C bond can be described by reactions (19) and (20), the only difference being that the formation of the radical pair is initiated by light, although the role of light in the mechanism of photochemical oxidation of alkylcobaloximes has not been unambigously established.[97,101,104]

The production of tungsten benzylperoxide R_3WOOR from hexabenzylditungsten (–74 °C) not only touches on the metal–carbon bond but also on the metal–metal bond.[69,105]

The formation of platinum peroxides by Eqns.(21) and (22) [106-108] provides an illustration of a method for producing alkylperoxide complexes by the oxidation of an M–R bond formed *in situ*.

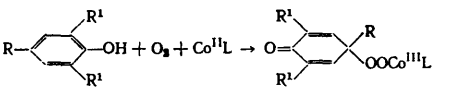
$$LPtMe_2+RI+O_2\rightarrow LPtMe_2(I)OOR \qquad (21)$$

(L = 1,10-phenanthroline or bipyridyl: R = Pr^i or But^t);

(22)

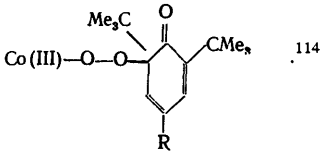
[R^1 = Me, R^2 = CN; R^1 = R^2 = CN; L = PPh_3, P(cyclo-C_6H_{11})$_3$].

Reaction (21) may also have a radical non-chain mechanism, including a reaction of the platinum complex with RO_2 radicals.[107]



The formation of a C–Pt bond in the reaction of the oxygen complex $(PPh_3)_2Pt.O_2$ with $XCPh_3$ (X = Cl, Br) according to Eqn.(23) is unlikely on steric grounds:[108]

(23)



Indirect evidence for the formation of alkylperoxide complexes in accordance with Eqn.(15) has been obtained in studies of the processes of auto-oxidation of other TMC's with σ-bonded organic ligands, viz. $Cp_2Zr(R)Cl$,[34] tetrabenzylzirconium and tetrabenzylhafnium, dialkylzirconocene and dialkylhafnocene,[69,105] the zirconium complex $(tritox)_2ZrMe(OCMe_2CH=CH_2)$ (tritox = Bu^t_3CO),[109] and hexakis(trimethylsilylmethyl)dimolybdenum.[69]

The formation of peroxide compounds of the LCoOOR type on auto-oxidation of cobalt salfuryl [sic?; Schiff base ligands based on salicylaldehyde and amines (Ed.of Translation)] complexes, and also pyridinecobaloxime, which do not contain a direct cobalt–carbon bond and do not form one in the intermediate stages of the reaction, is described by Eqn.(24).[45,110,118]

(24)

where L = $(DmgH)_2$py, salpr, NMe(salpr), and other substituted salfuryl ligands and R^1 = CMe_3. Where R is an aryl group the cobalt-peroxide bond is formed in position 2 of the phenyl ring:

[114]

A distinctive feature of this process [Eqn.(24)] is that the formation of the peroxide CoOOR takes place at the stage where there is a reaction of the phenoxyl radical and the complex $Co^{II}L$, which are formed as intermediates, with the oxygen molecule.[115,118]

2. Transition Metal Hydroperoxides

Transition metal hydroperoxides L_nMOOH are not so numerous as alkylperoxide complexes. Their methods of preparation are in general similar to those described above for L_nMOOR, i.e. based on the reaction of a TMC with either H_2O_2 or molecular oxygen.

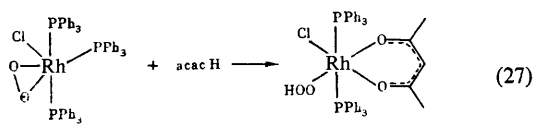
The preparation of permolybdic and pertungstic acids by the addition of H_2O_2 to the metal oxides is well known:[119]

(25)

A similar reaction occurs in the preparation of vanadium hydroperoxides from the complexes $L_nV=O$, where L is picoline.[120] The fact that the vanadyl group is able to react with H_2O_2 but is unaffected by ROOH [see Eqns.(4) and (5) and also Refs.21–26] can be attributed to the higher acidity of hydrogen peroxide compared to an alkylhydroperoxide, which is necessary for the protonation of the vanadyl group and subsequent formation of vanadium hydroxide.

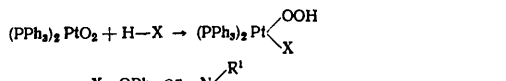
The reaction of H_2O_2 with π-complexes of chromium $(Arene)_2Cr$ and of molybdenum and tungsten Cp_2MX_2 leads to the formation of the hydroperoxides $(Arene)_2Cr^+(OOH.H_2O_2)^-$ [43] and $Cp_2MX_2^+.(OOH.H_2O_2)^-$ [42] respectively. The stoichiometry of the reaction corresponds to Eqn.(10).

The possible reaction of Fe^{II} with H_2O_2 to form the peroxide $Fe^{II}OOH$ has been discussed:[121]



(26)

The substitution of hydroxide, alkoxide, or carboxyl groups attached to the metal by the OOH moiety of hydrogen peroxide in accordance with Eqn.(3) is proposed for the preparation of the vanadium peroxides $V(O)(OR)_2OOH$ and $V(O)(OR)(OOH)_2$ from $VO(acac)_2$,[120] the iron peroxides $[FeL(OH)OOH]^{3-}$ from $[FeL(OH)]^{2-}$ and $[FeL(OH)_2]^{3-}$ (L = ethylenediaminetetra-acetate),[122] and the platinum peroxides $L_2Pt(R)OOH$ from the complexes $L_2Pt(R)OH$, where L = PPh_3, PPh_2Me, $PPhMe_2$, or $P(PhCH_2)_3$ and R = Me, Ph, $PhCH_2$, or CF_3.[32]



Labile hydroperoxide complexes of platinum $[L_2Pt(OOH)(solv)]^+$ and iridium $Ir(OOH)(Cl_2)(C_8H_{12})$ can be obtained by inserting an oxygen molecule into the M–H bond in the corresponding hydrides $[L_2Pt(H)(solv)]^+$ (L = PPh_3, $PPhMe_2$, or PEt_3; solv = an alkene)[33] or $Ir(H)(Cl)_2(C_8H_{12})$.[123]

Reactions of stable oxygen complexes with compounds that are hydrogen-atom donors are also used to obtain the hydroperoxides L_nMOOH. A rhodium hydroperoxide is produced by the reaction of the dioxygen complex $(PPh_3)_3Rh(Cl)O_2$ with acetylacetone in benzene or dimethoxyethane:[124,125]

(27)

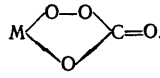
The reaction of this same dioxygen complex with cyclopentadiene in dimethoxyethane gives the hydroperoxide $(PPh_3)(\eta^5\text{-}C_5H_5)(Cl).RhOOh$. Platinum hydroperoxides are formed by the reaction of $(PPh_3)_2PtO_2$ with imides and phenols:[126]

(28)

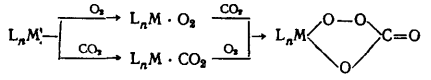
Pt, Pd, and Rh hydroperoxides can also be obtained by the reaction of the oxygen complexes $(PPh_3)_2MO_2$ with proton donors:[51,127,131]

(29)

Consideration has also been given to the possible production of transition metal hydroperoxides as intermediates in the oxidation of the CH bond by a chromium peroxo-complex CrO_5L [L = py, bipy, or phen (1,10-phenanthroline)],[132] the oxidation of water in the presence of manganese complexes,[133] the oxidation with oxygen of a mixture of *p*-nitrophenylhydrazone with the complex Co^{II}(MeO.salen)(py),[116] and also in the oxidation of organic and inorganic substrates by oxygen and H_2O_2 catalysed by Rh, Pd, and Ir complexes.[3–10]



3. Percarboxylate Complexes

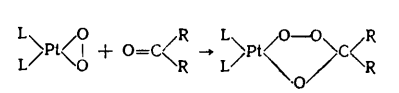


Percarboxylate complexes have been reported for Group VIII metals only.

The oxidation of complexes of these metals with molecular oxygen in a CO_2 medium gives percarboxylate complexes in accordance with overall equation:[128,134–136]

(30)

I.r. and ^1H n.m.r. spectroscopic results[135] and X-ray structure analysis[79] show that the peroxocarbonate ligand is bidentate, forming a five-membered  ring with the metal. Reaction (30) may occur by the insertion of either CO_2 into an  three-membered ring, as is known for compounds of Rh, Ir,[79,135] and Pt,[108,128,134] or an oxygen molecule into a metal–carbon dioxide bond, as is typical of nickel complexes:[137]



(31)

The reaction of the oxygen complexes $(PPh_3)_2PtO_2$ [138] or $Mn(II)O_2$, where Mn(II) represents a porphyrin complex of manganese,[139] with ClCOPh leads to formation of the perbenzoates $(PPh_3)_2PtCl(OOCOPh)$ or Mn(III)OOCOPh respectively. All the indications are that the process takes place via a stage in which an M–COPh metal–carbon bond is formed.

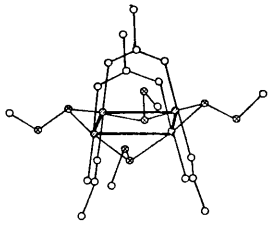
Perbenzoate complexes of rhodium and iridium can be obtained by the reaction of the complexes $M(CO)(MeCN)(PPh_3)_2ClO_4$ with an excess of the sodium salt of *m*-chloroperbenzoic acid in dichloromethane at 0 °C.[140]

There is a certain similarity between the perbenzoates and the perketyl complexes of platinum which are obtained by the addition of aldehydes and ketones to L_2PtO_2, using a excess of the aldehyde or ketone with respect to the oxygen complex:[106,108,127,128,137]

L=PPh_3, P(C_6H_{11})$_3$; R=CH_3, Ph

(33)

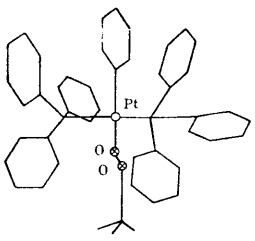
To conclude our report on methods for preparing transition metal peroxide complexes a mention must be made of the similarity in structure between the TMPC's discussed above and the oxygenated



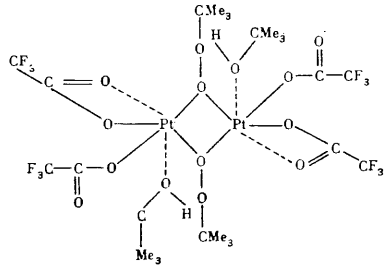
forms of metalloenzymes, e.g. Fe_fOOR, where Fe_f is an iron-containing fragment and R = H, alkyl, or R'CO.

These peroxides are regarded as important intermediates in the oxidation, by molecular oxygen, of myoglobin and haemoglobin in solutions of phenols, amines, and hydrazines[140–142] and of cytochrome P-450 in carboxylic acid solutions,[136,137] the oxidation of horse-radish peroxidase by hydroperoxides ROOH,[146,147] and the catalytic oxidation of substrates of various kinds on metalloenzymes and model systems.[11,148–152]

III. PROPERTIES



Most of the TMPC's that have been isolated, which number almost 200, are crystalline solids but a few are liquids.



They have a considerably higher solubility in polar solvents than in non-polar solvents owing to a significant amount of ionic character in the bond between the metal and the peroxide moiety. When isolated from solutions TMPC's occur as monomers, dimers, tetramers, and also as associates with hydroperoxides and the corresponding alcohols. The structures of some TMPC's are given below:

$[(CCl_3CO_2)Pd(OOBu^t)]_4$

o – Pd, ⊗ – O in a peroxide group (Ref.28)

trans-$(PPh_3)_2Pt(Ph)(OOBu^t)$ (Ref.32) $(CF_3CO_2)_2Pt(OOBu^t)(Bu^t\text{-}BuOH)]_2$ (Ref.30)

The u.v. spectra of TMPC's, like those of organic peroxides, are not very characteristic and so are comparatively rarely used to study their properties.

Alkylperoxides and hydroperoxides of metals have a medium or strong band due to stretches of the O–O bond in the 815–890 cm^{-1} region. In the percarbonate complexes this band is shifted to lower wavenumbers by 30–60 cm^{-1}. For the hydroperoxide complexes there is also absorption at 3400–3500 cm^{-1} (due to O–H stretches). Bands due to peroxide or OH groups of coordinated ROOH or ROH molecules may be mixed in with these bands.

N.m.r. spectroscopy has been widely used to determine the composition and structure of TMPC's.[22,29,31,32,36,37,48,49,93,124,125] Many of the studies were made using ^1H nuclei. The signal due to the R protons in metal alkylperoxides L_nMOOR may be shifted to either high or low field with respect to the protons in organic peroxides depending on the nature of the metal, the ligands attached to it, and the mutual disposition of the latter in the complex. Valuable information on the structure of TMPC's is obtained from n.m.r. data for ^{13}C, ^{19}F, and ^{31}P nuclei present in the ligands attached to the metal.

The stability of TMPC's varies over a wide range: some TMPC's can exist only at low or moderate temperatures while other withstand heating to 200–220 °C without qualitative or quantitative changes in their composition.

An important physical characteristic of TMPC's is the length of the oxygen–oxygen bond l_{O-O} in them. However these values have a unique character and do not enable any correlations to be made between the l_{O-O} lengths in TMPC's and their structure and thermal stability. One can say only that l_{O-O} can vary over a wide range, 1.22–1.50 Å, in different peroxides.[32,36,37,39,102,106,107,115,117,136]

Notwithstanding the small amount of data on the stability of TMPC's there is quite a definite tendency for it to depend on the nature of the metal, the ligands attached to it, and the nature of R. The stability of peroxides of chromium, molybdenum, and tungsten,[40–42,77,153,154] cobalt,[39,90–94,96–98] iridium and rhodium,[48–50,140] and palladium and platinum[31,127] decreases in line with a decrease in the electronegativity of the metal and the electron-acceptor properties of the ligands attached to it. A tendency for the stability of the TMPC to decrease is also observed on increasing the electron-accepting function of the radical R attached to the peroxide group.[83,148–150,155] The influence of the nature of R is clearly shown by comparing the stability of metal hydroperoxides and alkylperoxides: as a rule the latter are considerably more stable than the former.[39,40,77,154]

It is readily observed that the stability of TMPC's decreases as the degree of charge transfer from the metal to the peroxide moiety increases. This is confirmed, for example, by the displacement of the O–O stretching band in the i.r. spectra to lower wavenumbers[31,48–50,127] and the shifts of the resonance lines of the protons in the radical in the ^1H n.m.r. spectra of TMPC's to lower fields when the electron-donor properties of the ligands attached to the metal are increased.[31] The occurrence of this interrelationship between the stability of a TMPC and the degree of charge transfer to the O–O bond is quite reasonable because an increase in the population of the antibonding orbital of this bond leads to a reduction in its energy and bond order and hence to a decrease in the overall stability of the peroxide complexes. From this viewpoint the formation of the associates $(MOOR)_n$[28–30,156] or MOOR.ROH[29] and MOOR.ROOH[41–43,154] can be regarded as a stabilising factor for the TMPC[116,154] resulting from partial delocalisation of the excess of electron density from the O–O bond to the coordinated molecules. The trends in the variation in stability of TMPC's discussed above are characteristic of both the crystalline state of these compounds and their solutions. However, the stabilities of TMPC's are usually appreciably lower in the presence of solvents, especially strongly basic solvents, than in their absence.[36,45,50,112,140,154,157] The effect of the solvents may be that they facilitate either disruption of the associates $MOOR.X_n$ (X = MOOR, ROH, ROOH), which are more stable than the monomeric form MOOR, or an increase in the degree of charge transfer from the metal to the O–O bond, forming donor-acceptor type complexes with the MOOR:

$$M^{\delta+}OOR^{\delta-} + L \rightleftharpoons L \rightarrow M^{\delta+}OOR^{\delta-} \quad (|\delta_1| > |\delta|)$$

Furthermore, the solvents may react chemically with the TMPC's by various routes which arise from both the polar covalent or ionic character of the M—OOR bond and the labile nature of the O—O bond.

In view of what has been discussed above we shall consider the reactions of TMPC's in solution, which can be provisionally divided into three types: (1) reactions with preservation of the MOOR moiety; (2) protolysis or hydrolysis of the peroxide group; and (3) cleavage of the peroxide group.

Reactions of the first type include protolysis of the ligands attached to the metal[158] or their replacement,[94,158] both of which occur with cobalt alkyl peroxides:

$$\underset{(R = CHMe_2,\ L = H_2O)}{ROOCo(DmgH)_2L} + H^+ \rightleftharpoons [ROOCo(Dmg_2H_2)L]^+ \quad (34)$$

$$LCoOOR + H_2O \rightleftharpoons H_2O \cdot CoOOR, \quad (35)$$

(L = pyridine, piperidine, or 2-methylpyrazine; R = Me, Et, Pr^i, Ph).

Reactions analogous to (34) and (35) can be regarded as intermediate stages in the protolysis and hydrolysis of peroxide groups, which occur for peroxide complexes of various metals:[45,50,94,158]

$$L_nMOOR \xrightarrow[(a)]{H^+X^-} L_nMX + ROOH \quad (36)$$

$$L_nMOOR \xrightarrow[(b)]{H_2O} L_nMOH + ROOH, \quad (37)$$

where H^+X^- is a carboxylic or mineral acid.

Reaction (36) [108,154] usually proceeds at a rapid rate, indicating that the M—OOR bond is appreciably ionic. If HX is a mineral acid the process can be explosive and accompanied by decomposition of the ROOH product.[154] The polar character of the M—OOR bond accounts for the instability of cobalt alkylperoxide complexes in chlorine-containing solvents such as chloroform and dichloromethane[45] and of platinum TMPC's in alkyl bromides;[108] this may be due to a reaction of these TMPC's with the C—halogen bond in the solvent:

$$(salen)CoOOBu^t + R\text{-}Cl \rightarrow (salen)CoCl + ROOBu^t \quad (38)$$

If the M—OOR bond is weakly polar, as in peroxide complexes of Pd,[28] the OOR group can be exchanged with an alkene (all the better if the double bond is internal rather than terminal):

$$CF_3C(O)OPdOOBu^t + \text{alkene} \rightarrow CF_3C(O)OPd\text{-alkyl} + Bu^t\text{-}BuOOH \quad (39)$$

An oxidation-reduction process can occur in a TMPC:

$$L_nM^+OOR^- \rightarrow L_nM^0 + RO_2^{\cdot} \quad (40)$$

This reaction is known as one of the methods for generating $RO_2^{\cdot}$ radicals[139,159] in a transition metal complex—hydroperoxide system.

Reactions of TMPC's which are accompanied by decomposition of the peroxide group are the most numerous. In accordance with the effect of M, L, and R on the stability of the peroxide complexes L_nMOOR, as discussed above, the most probable route for the decomposition of these compounds is rupture of the O—O bond[9,26,104,157] which may occur by either a homolytic or a heterolytic mechanism, and may be unimolecular or bimolecular.

The spontaneous homolysis of the O—O bond leads to formation of a radical pair [Eqn.(41)], the fate of which depends on the nature of the metal-complex radical (i.e. the oxidation state of the metal and its ligand environment), the nature of the solvent, etc.:[17,19,26,49,118,160]

$$L_nMOOR \rightarrow L_nMO^{\cdot} + {}^{\cdot}OR \quad (41)$$

The kinetic and activation parameters of reaction (41) have been determined for $(EtO)_3TiOOCMe_3$.[160] The activation energy of the process is low, 50.2 and 79.5 kJ mol^{-1} in CCl_4 and ethylbenzene respectively. A similar value for the activation energy (54.4 kJ mol^{-1}) was found for the homolysis of the peroxide bond in the cobalt complex $Co^{III}(BPI)(OAc)(OOBu^t)$.[118]

Heterolytic rupture of the O—O bond was proposed in Refs.2 and 9 and confirmed for percarboxylate complexes of iron:[145]

$$L_nM^{+n}OOR^- \rightarrow (L_nMO)^{+n} + RO^- \quad (42)$$

Rupture of the O—O bond can occur by the reaction of the peroxide moiety of a TMPC with a C—H bond in the solvent, especially if the latter has a mobile hydrogen atom:

$$L_nMOOR \xrightarrow[-R^{\cdot}]{R'\text{-}H} L_nMOH + RO^{\cdot} \quad (43)$$

It has been shown, in the case of the cobalt peroxides LCoOOR (L = salpr, R = *p*-quinol), that TMPC's can be reduced by alcohols (other than tertiary) to the corresponding hydroxides (at 10° to 20 °C).[112] The alcohols are converted to the corresponding aldehydes. The rate of the reaction increases with increasing acidity of the hydroxy groups and mobility of the α-hydrogen atoms in the ROH. Two possible mechanisms are proposed for this reaction [Eqns.(44) and (45)], both of which involve rupture of the O—O bond:

$$LCoOOR + R''CHOH \rightarrow \text{cage} \rightarrow ROH + R''CHO$$
$$LCoOH \leftarrow R''CH_2OH \quad LCoO^{\cdot} \quad (44)$$

$$LCoOOR + R'OH \rightleftharpoons \text{cage} \rightarrow LCoOH + ROH + R''CHO \quad (45)$$

The concerted mechanism for the transfer of hydrogen atoms to the peroxide bonds seems more preferable, since it corresponds more to the effect of the nature of the R'OH on the rate of the reaction and to the polar character of the Co—OOR bond, which favours the formation of hydrogen bonds.

Under mild conditions (0 °C, methanol or diglyme as solvent) pyCoOOR (R = benzyl, propyl, or cyclohexyl) are reduced by the $NaBH_4$/NaOH system again with cleavage of the O—O bond:[92,97,99]

$$PyCoOOR \xrightarrow[NaOH]{NaBH_4} ROH + PyCoOH \quad (46)$$

Reductive rupture of the O—O bond in the platinum phenylethylperoxide $(Ph_3P)Pt(Br)OOCH(Me)Ph$ under the action of lithium hydroaluminate also takes place under very mild conditions (-78 °C, THF solvent).[108]

If the decomposition of the TMPC involves more than one molecule there may be not only destruction of the peroxide group but also a redistribution of the non-peroxide ligands between the metal atoms of the TMPC molecules taking part in the reaction; this occurs in reactions of the complex $IrCl(OOBu^t)(OCOCF_3)(CO).(PPh_3)_2$.[50]

Changes in a TMPC, which are accompanied by the loss of the peroxide oxygen, may also occur by intramolecular oxidation of a metal–carbon bond or a ligand attached to the metal of a donor-acceptor type, and also as the result of a bimolecular reaction with substrates of various kinds (S).

Reactions of the first type are known for peroxides of zirconium,[69] cobalt,[104] and palladium and rhodium:[33,35,125,155]

$$Cp_2Zr(R')OOR \rightarrow Cp_2Zr(OR')OR \quad (47)$$

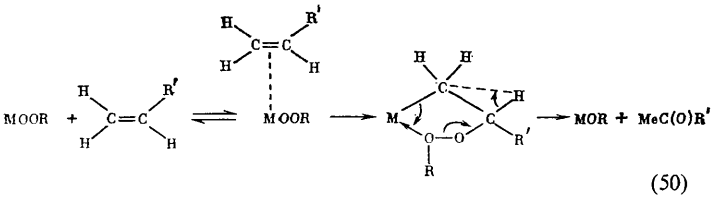
$$(acac)Cl(PPh_3)_2RhOOH \rightarrow (acac)Cl(PPh_3)RhOH + Ph_3P{=}O \quad (48)$$

Reactions of the second type are more numerous and take place according to the following general scheme:

$$L_nMOOR + S \rightarrow L_nMOR + SO \quad (49)$$

These can be regarded as stages in the transfer of oxygen from ROOH to a substrate in the catalytic oxidation cycle of the latter and are therefore of particular interest in a practical, as well as a theoretical, respect. For this reason it is appropriate to consider TMPC reactions that are described by Eqn.(49) in more detail.

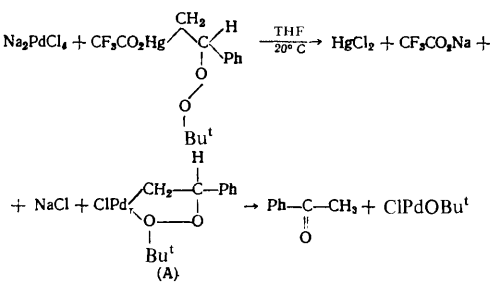
IV. PARTICIPATION IN REACTIONS WHERE THERE IS STOICHIOMETRIC OXIDATION OF ORGANIC AND INORGANIC SUBSTRATES



The ability of TMPC's to act as oxygen atom donors in their reactions with organic substrates (alkenes, aromatic hydrocarbons, cycloalkanols, and alkanes) and hetero-organic or inorganic substrates (PPh_3, CO, NO) has been conclusively demonstrated in numerous instances.[28–32,126,156] The ketonisation of alkenes has been investigated in greatest detail. In the temperature range 0° to 100 °C peroxide complexes of Pd and Pt oxidise terminal linear alkanes to ketones with high selectivity.[28–32,157] Iridium (III) alkylperoxides[110] and hydroperoxides[32] are also able to oxidise terminal alkenes. Since many peroxides have the composition $[L_nMOOR]_m$ it is suggested that the active form is the monomeric form produced by decomposition of the associates in solution.[29]

Cyclic and internal linear alkenes are not usually oxidised. Reactions of the latter with t-butylperoxides of Pd are accompanied by displacement of the corresponding hydroperoxide [Eqn.(38)]. At high concentrations of the terminal alkenes the ketone yield decreases owing to competitive exchange of the t-butylperoxy group by the alkene. In the opinion of the authors of Ref.9 the high sensitivity of the ketonisation reaction of alkenes to their structure is due to the predominant influence of steric factors on this reaction. However, the role of electronic factors is no less significant. This is confirmed, for example, by the considerable increase in the reactivity of the peroxide compounds $RCO_2PdOOBu^t$ and $(PPh_3)_2(R')Pt.(OOBu^t)$ towards alkenes when the electron-accepting properties of R [28] and R' [32] respectively are increased:

R	CH_3	CCl_3	C_6H_4	CF_3
Relative rate of ketonisation reaction	1	60	80	130
R'	Ph	<o-NCC_6H_4	<CF_3	—

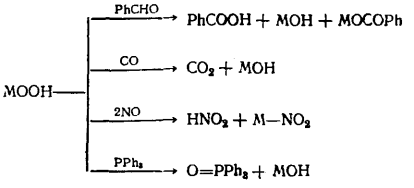


In general, the activity of Pd and Pt peroxides of the composition $L_2(R')MOOR$ as carriers of oxygen to the alkene depends on many factors including the size of the L groups (increasing the volume of L leads to a decrease in the activity of the TMPC) and their mutual orientation (*trans*-forms of alkylperoxides are more active than *cis*-forms), the electronic effects of R' and the nature of R (the hydroperoxides of Pd and Ir are considerably more active than the alkylperoxides of these metals but the reverse is true for Pt peroxides).[32] It is characteristic that, given a similarity in the rules governing the variation of the reactivity of the peroxides as a function of the nature of the ligands attached to the metal, Pd alkylperoxides and hydroperoxides are significantly more active as oxygen carriers than their Pt analogues.[28–32,156]

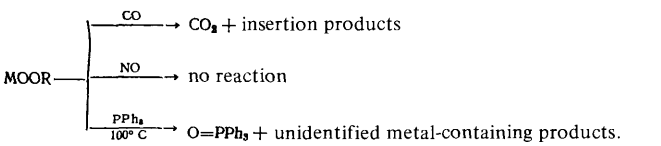
It is generally accepted[3–10] that the transfer of oxygen from the TMPC to the alkene during its ketonisation takes place by a peroxometallation mechanism, the main stages of which are coordination of the alkene by the metal, formation of a five-membered pseudocyclic intermediate, and its subsequent decomposition to the ketone and an alkoxo- or hydroxo-complex:

(50)

The coordination of the alkene stage is confirmed by the inhibiting effect on the rate of oxygen transfer caused by adding alcohols, strongly complexing solvents (dimethylformamide, hexamethylphosphoryl triamide), and alkenes (1,5-cyclo-octadiene),[28] and also the reduction in the ketone yield in the presence of these substances.[48] The formation of the five-membered pseudocyclic complex was demonstrated by using the reaction of a stable peroxide compound of mercury with palladium salts.[28] The resultant unstable intermediate (A) decomposes to form a ketone:



(51)

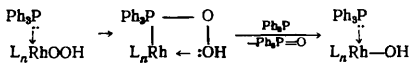


Proof of the formation of a peroxometal ring is also obtained by other preparations of such compounds, which in many cases are fairly stable[108,127,128,134,135,161] [see Eqns.(30), (31), and (33)].

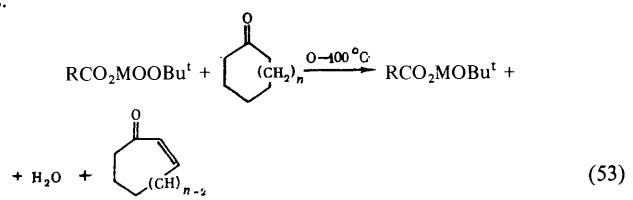
Mechanisms for the decomposition of the ring containing the metal other than that considered in Eqn.(50) are also possible.[9]

Pd and Pt alkylperoxides and hydroperoxides are highly active in oxidising benzaldehyde and a number of inorganic compounds—CO, NO, and PPh_3 (Scheme 1).[31,126]

Scheme 1



All the reactions except the last take place at 20 °C (THF solvent, nitrogen atmosphere). In these reactions, in contrast to the ketonisation of alkenes, the hydroperoxides of both platinum and palladium are more active than their alkylperoxides; this is indicated by the milder conditions under which the various compounds are oxidised by MOOH and also by the higher reaction rates.



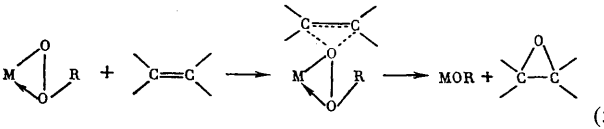
Triphenylphosphine is oxidised in accordance with reaction (49) by treatment with the cobalt alkylperoxide (Bu^tOO)Co(salen) (T = 20 °C),[45] the platinum percarboxylates $(PPh_3)_2PtX(OOCOPh)$, where X = Cl (T = −78 °C) [48] or Br,[103] the rhodium alkylperoxide (1,5-cyclo-octadiene)Rh($OOBu^t$) KBF_4,[33] and the rhodium hydroperoxide $(PPh_3)_2$(acac)(Cl)RhOOH (T = 20 °C).[125,155] The yield of triphenylphosphine oxide is almost quantitative.

The mechanism of the oxidation of triphenylphosphine by the rhodium hydroperoxide[155] (which can be extended to the other reactions in scheme 1 above) involves the formation of a four-membered pseudocyclic complex which undergoes a further reaction with liberation of the products mentioned:

(52)

As oxygen-atom donors the Pd and Pt peroxides $RCOOMOOBu^t$ (R = Me, CCl_3, CF_3) are capable of oxidative dehydrogenation of cycloalkanones (C_5-C_{12}) to the corresponding cycloalkyl-1-en-3-ones.[156]

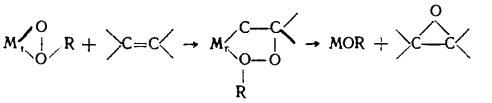
(53)



The ability of cobalt alkylperoxides to oxidise alkanes and cycloalkanes, cyclic and acyclic alkenes, and alkylbenzenes to the corresponding ketones, aldehydes, alcohols, epoxides, and peroxides has been noted.[118] In the opinion of the authors the ability of alkylperoxide complexes to oxidise the hydrocarbons listed above depends on their thermal stability. An increase in thermal stability reduces the oxidative properties of the complexes.

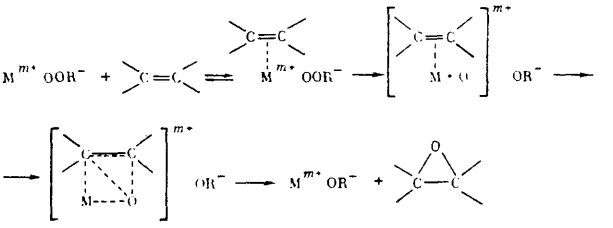
Alkylperoxides and hydroperoxides of transition metals (primarily molybdenum, vanadium, and tungsten) are highly selective oxidising agents for converting alkenes to the corresponding oxides. Evidence has been obtained for the participation of MOOR in the alkyl hydroperoxide epoxidation reactions of alkenes—both indirect evidence[70,162] and direct evidence in the case of $(PPh_3)_2ClPt$.$(OOCOPh)$ [48,49] and $Cp_2MX_2^+(OOR.ROOH)^-$ (X = Cl, Br; R = H, t-butyl, cumyl).[163,164] The ability of $Cp_2MX_2^+(OOR.ROOH)^-$ to cause epoxidation depends on the metal (W < Mo), the halide ligand (Cl < Br), R (cumyl < t-butyl), and on the alkene (oct-1-ene < cyclohexene). It is suggested that the active form of the metal alkylperoxide or hydroperoxide is the monomeric form Cp_2MX.$(OOR)^+X^-$, in which the alkylperoxide moiety is attached to the metal by a polar covalent bond:

$$[Cp_2MX_2]^+ OOR^- \rightleftarrows [Cp_2MX(OOR)]^+ X^- \qquad (54)$$



Metal alkylperoxides with a purely or nearly ionic bond between the metal and the peroxide moiety either have no ability to transfer an oxygen atom to alkenes (e.g. the alkali metal salts of organic hydroperoxides[165]) or have a very small ability to do so (e.g. platinum alkylperoxides in strongly electron-donating media[32]). These results indicate that the effectiveness of transition metal alkylperoxides as oxygen carriers depends on the degree of covalency of the M−OOR bond.[164] A similar conclusion was drawn in Ref.10.

The epoxidation of alkenes by the action of Mo, V, and W TMPC's may proceed by the following mechanisms: (1) by a direct reaction of the alkene molecule with the peroxide moiety:[7]

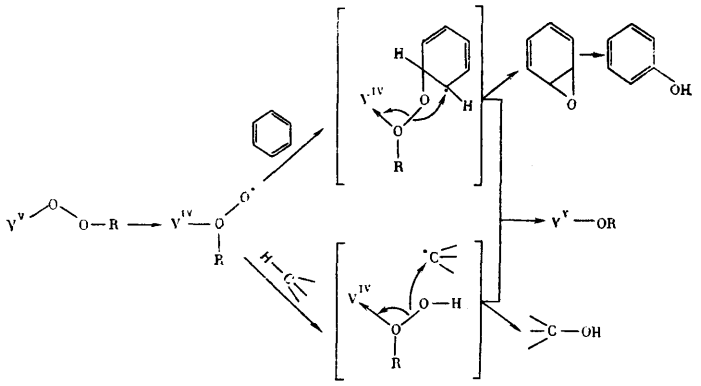


(55)

(2) by a peroxometallation mechanism[3-9,14,15] similar to that discussed above for the ketonisation of alkenes by Pd, Pt, and Ir TMPC's:

(56)

and (3) with the involvement of $(MO)^{m+}$ intermediates (m = 5 for V and 6 for Mo and W),[163] which can be formed from MOOR by heterolytic fission of the peroxide bond[29,145] and can be oxygen-atom donors in the triplet state:



(57)

The vanadium alkylperoxides (dipic)V(O)(OOR)L (R = t-butyl, cumyl; L = H_2O, HMPT) oxidise not only alkenes but also aromatic and saturated hydrocarbons.[36] The selectivity of the processes is usually low. The reactions with alkenes (methylstyrene, butene, cyclohexene, 2-methylpentene) give epoxides (not more than 8% yield) and also the products of oxidative fission and allylic oxidation—aldehydes (10−22%), ketones (4−10%), and alcohols (8−30%).

In contrast to the dipicolinate complexes the compounds (R−OPhsal−R″)V(O)OOR form epoxides with alkenes with a high selectivity,[38] which, in the opinion of those authors, is due to weak coordination of the peroxide oxygen with vanadium; in the dipicolinate complexes the strong coordinate bond between the peroxide oxygen and the hetero-atom hinders coordination of the alkene and consequently inhibits the reaction. A more probable reason for the observed differences in the oxidising properties of the vanadium peroxides is the ability of the dipicolinate alkylperoxide complexes to change into oxygen carriers of a different kind, as is evident from the fact that they oxidise not only alkenes but also aromatic (benzene, toluene, ethylbenzene) and saturated (cyclohexane) hydrocarbons. The latter are oxidised to form hydroxylation products (9−40%), aldehydes (13−27%), and ketones (3−14%).

For the hydroxylation of hydrocarbons by this vanadium alkylperoxide the following mechanism, which is also possible for the oxidation of alkanes, is proposed:

The possible production of octanones by the oxidation of octane with $(Bu^tOO)V(O)(OBu^t)_2$ at room temperature has also been reported.[23,24]

V. PARTICIPATION IN THE CATALYTIC OXIDATION OF ORGANIC AND INORGANIC SUBSTRATES

The formation of TMPC's as intermediates in the catalytic oxidation of organic compounds has been suggested in work on the oxidation of pyrocatechol by oxygen on enzymes containing Fe^{2+}, of the dioxygenase type, and on their model systems,[1,148] and in the oxidation of aromatic compounds and aliphatic alcohols by hydrogen peroxides on an Fe^{III}–pyrocatechol complex.[1,150–152] Similar proposals were subsequently made in a number of papers concerned with the catalytic oxidation of organic[8,10,11,27,31,70–74,110,166–176] and inorganic substrates.[29,31]

Now that a large number of TMPC's have been prepared and their ability to transfer oxygen to organic and inorganic compounds demonstrated (see Section IV), there is no doubt as to the decisive role of these peroxides in the hydroperoxide oxidation of alkenes to the corresponding epoxides on Ti^N, V^V, Cr, and Mo^{VI} complexes[3–10, 69,162,173–178] and to ketones on Pd^{II}, Pt^{II}, Ir^{II}, and Rh^I complexes, [3–10,28,85,116] in the hydroxylation and ketonisation of alkanes on V^V,[23,24] Pd^{II},[1,25] and Co^{III} [46,118] complexes, and also in the oxidation by molecular oxygen of olefins to ketones on Rh^{III} [28] and Pd^{II} [178,179] complexes and phenols to quinones and quinols on Co^{II} complexes.[103,110] The same is true regarding the role of TMPC's in the hydroperoxide oxidation of compounds of phosphorus, sulphur, nitrogen, etc.[31] Generalised schemes have been published for some of the best studied of these catalytic processes.[3–5,10,28,110]

The formation of transition metal alkylperoxides and hydroperoxides as intermediates is energetically very advantageous in catalytic reactions involving molecular oxygen because breaking the O–O single bond in the peroxides requires an energy of 190–250 kJ mol^{-1} [172] whereas dissociation of the oxygen molecule requires 490, 397, or 368 kJ mol^{-1} respectively for the different states $O_2 \rightarrow 2O$ $O_2^* \rightarrow 2O$, and $O_2^- \rightarrow O + O^-$.[1]

---o0o---

The formation of peroxide compounds with the composition L_nMOOR, where R = H, alkyl, or PhCO, is thus characteristic of the transition metals in almost all Groups of the Periodic Table and can therefore be regarded as one of their inherent fundamental properties; the stability of TMPC's which varies over a wide range, depends on the nature of the metal, the ligands attached to it, the nature of R, and, in solution, on the nature of the solvent, all of which together affect the degree of charge transfer from the metal to the peroxide moiety and hence the energy of the peroxide bond. The most typical routes for reactions of TMPC's are: (a) fission of the peroxide bond, which may be spontaneous (homolytic or heterolytic) or due to an interaction with substrates of various kinds, or (b) intra- or inter-molecular transfer of an oxygen atom to an oxidisable substrate; there are good reasons for supposing that the TMPC's which are intermediates in numerous catalytic processes for the oxidation of organic and inorganic compounds by peroxides are responsible for the transfer of oxygen to the oxidisable substrate.

Further study of methods of preparing TMPC's and their properties will make it possible to determine the nature of the actual carriers of oxygen to substrates of various kinds in the homogeneous, heterogeneous, and enzyme catalysis of the processes for oxidation of these substrates by molecular oxygen and by hydroperoxides and to develop methods for obtaining valuable oxygen-containing products and effective initiating systems for the polymerisation of unsaturated compounds.

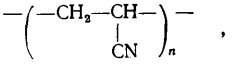
Polymeric Chemical Fibre-reinforced Composite Materials with Reduced Combustibility

L.G.Panova, S.E.Artemenko, N.A.Khalturinskii, and Al.Al.Berlin

The present state of research in the field of the thermal degradation and combustion of fibre-reinforced polymeric composite materials is examined. Special attention has been devoted to questions of the inter-relation between the chemical compositions of the reinforcing fibres and the polymeric binders as well as their thermophysical and thermochemical properties, on the one hand, and the processes occurring on pyrolysis and combustion of the materials, on the other.
The bibliography includes 99 references.

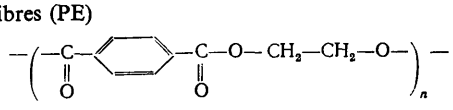
CONTENTS

I. Introduction 680
II. Methods of reducing the combustibility of polymeric composite materials 680
III. Inter-relation between the chemical composition of the reinforcing fibres and polymeric binders and the thermal stability and combustibility of the polymeric composite materials 681
IV. Reduction of the HCN toxicity of the pyrolysis gases from polymeric composite materials reinforced with polyacrylonitrile-containing fibres 683
V. The mechanism of the action of antipyrenes in polymeric composite materials 684



I. INTRODUCTION

Polymeric composition materials (PCM) are at the present time to a large extent responsible for the acceleration of the scientific and technical progress in many branches of the National Economy. The PCM with reduced combustibility, used, for example, in the construction of blocks of flats and public buildings, in transport, etc., are of special interest.

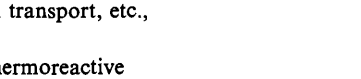


In world practice, polymeric thermoplastic or thermoreactive binders for the synthesis of PCM are reinforced with glass, asbestos, boron, and carbon fibres, aromatic polyamide fibres, and filamental metal oxide, carbide and nitride crystals.[1]

The possibility of reinforcing synthetic resins with chemical fibres manufactured on an industrial scale has attracted the attention of investigators in recent years.[2-22] This is associated with the fact that chemical fibres possess a whole series of specific features which make it possible to extend greatly the range of properties of materials for constructional building purposes: the mass of the articles and components can be greatly reduced, their resistance to vibrations can be increased, they can be stabilised in relation to corrosive media, their antifriction properties can be improved, etc.

The problem of improving PCM possessing a set of specific physicomechanical properties and reduced combustibility and which are at the same time light, strong, and relatively cheap, can be solved by reinforcing resins with modified chemical fibres produced by the chemical industry on a wide scale, such as polyacrylonitrile fibres (PAN)

polyester fibres (PE)



viscose fibres (VF)

poly(vinyl chloride) fibres (PVC)

and copolymeric fibres based on copolymers of acrylontrile and vinyl chloride (AN/VC)

Non-conditioned fibres,[22] which are available both in the chemical fibres industry and in the processing branches of industry (textile, light, etc.),[23] can also be used for this purpose.

II. METHODS OF REDUCING THE COMBUSTIBILITY OF POLYMERIC COMPOSITE MATERIALS

The majority of fibre-filled PCM are combustible materials, which holds back the growth of their manufacture and narrows the region of their applicability and effectiveness. The reduction of the combustibility of PCM is achieved mainly in two ways. The combustibility can be reduced by employing resins containing phosphorus, halogen, nitrogen, etc., compounds which retard or fully suppress combustion and are usually referred to as antipyrenes. Antipyrenes are introduced into the binder at the stage involving the synthesis of oligomers or directly in the formation of the material.[22-34] The second way involves the application of reinforcing systems resistant to combustion: inorganic fibrous fillers (glass, boron, and asbestos fillers); carbon fibre fillers; incombustible thermally stable fibres comprising aromatic polyamides, polyimides, and polyimidoamides; chemical fibres fire-proofed by various antipyrenes.

However, the application of incombustible reinforcing systems without antipyrenes does not solve the problem, because almost the entire polymer matrix burns up in the combustion of the material.[35,36] For example, epoxide PCM containing 60 wt.% of glass fibre

lose up to 40% of their weight when subjected to a test by the "fire tube" method in accordance with GOST 17088-71 [a USSR government standard (Ed.of Translation)].[35]
