U.D.C. 543.422.25 : 547.1

Directly Bonded $^{13}C-^{13}C$ Spin-Spin Coupling Constants in Structural Studies

L.B.Krivdin and G.A.Kalabin

The review presents the present state of research into the directly bonded $^{13}C-^{13}C$ spin-spin coupling constants (SSCC)—the parameters of NMR spectra which are most difficult to measure and which contain unique structural information. The principal factors determining the magnitude of the direct $^{13}C-^{13}C$ SSCC, namely the hybridisation of the interacting atoms, the electronic influence of substituents, steric and solvation effects, and the influence of the unshared electron pairs of the heteroatoms, are analysed. The possibilities of using the directly bonded $^{13}C-^{13}C$ SSCC for the solution of a wide variety of structural problems in chemistry are examined; special attention is devoted to the prospects for the employment of these parameters in stereochemistry and conformational analysis.
The bibliography includes 232 references.

I. INTRODUCTION

The measurements of the constants for the spin–spin coupling between ^{13}C nuclei ($^{13}C-^{13}C$ SSCC or $^{n}J_{SS}$) under the conditions of the natural abundance of this isotope (~1.1%) involves the recording of the ^{13}C NMR spectra of molecules containing simultaneously two ^{13}C nuclei. The fraction of such molecules in the natural mixture of isotopomers is only ~0.01%, i.e. one molecule out of 10 000. This fact and also the low relative sensitivity of the ^{13}C NMR method make the $^{13}C-^{13}C$ SSCC the parameters of the high-resolution NMR spectra of organic compounds which are most difficult to obtain.

The first studies involving the experimental measurement of $^{13}C-^{13}C$ SSCC date back to the beginning of the 1960s [1-3] and were carried out for model compounds enriched in ^{13}C. The complexity of the synthesis of a wide range of such compounds was one of the reasons why such studies have been non-systematic during the last 10–15 years. The situation changed significantly at the end of the 1970s with the appearance of commercial Fourier Transform NMR spectrometers improved by the incorporation of pulse type programmers and highly sensitive devices for the recording of the signal ensuring a real increase of the sensitivity of the method, amounting on average to two orders of magnitude. Together with successes in the synthesis of ^{13}C-labelled compounds, this led to a vigorous growth of studies on the $^{13}C-^{13}C$ SSCC.[4-10] Thus, whereas in 1979 about 700 experimental values of the direct $^{13}C-^{13}C$ SSCC ($^{1}J_{CC}$) were known, in 1981 as many as approximately 1800 were measured.[10]

The method for the observation of ^{13}C satellites in the ^{13}C NMR spectra under the conditions of the "suppression" of the signals of the principal isotopomers, developed by Bax,

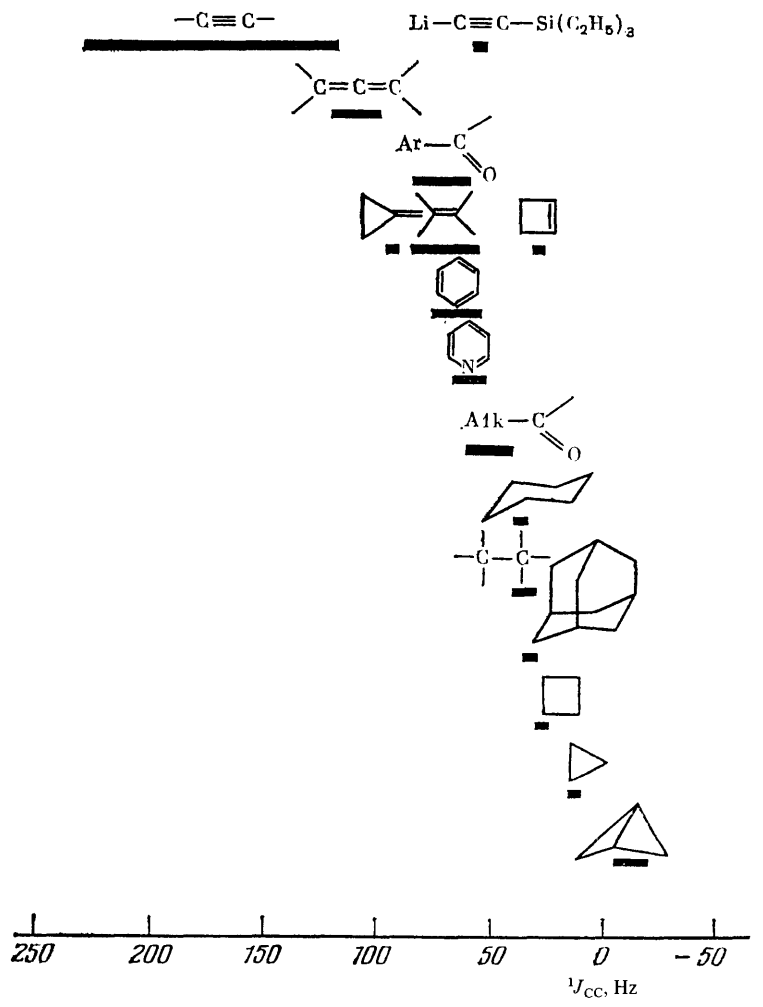

Figure 1. The ranges of variation of the directly bonded $^{13}C-^{13}C$ SSCC for different classes of organic compounds.[8,9]

Freeman, and Kempsell,[11,12] occupies a special place in the development of the research into the $^{13}C-^{13}C$ SSCC. The essential feature of the method, which the authors called INADEQUATE (Incredible Natural Abundance Double Quantum Transfer Experiment), consists in the conversion of the magnetisation of the satellites into the "two-quantum coherence" state $\mathcal{F}_2$ with subsequent separation of the components of $\mathcal{F}_2$ and the component of magnetisation $\mathcal{F}_0$ corresponding to ^{13}C nuclei without $^{13}C-^{13}C$ SSCC. Without increasing the sensitivity compared with the usual procedure for the recording of ^{13}C signals, the method facilitates significantly the measurement of weak signals due to $^{13}C-^{13}C$ SSCC in specimens with a natural isotopic content, because it eliminates the problem of their overlap with the strong signals of the main isotopomers, the signals of impurities, and also the signals modulated by the rotation of the tube. A two-dimensional version of the basic inadequate INADEQUATE method [13–15] and also a version which has been modified and combined with certain other pulse sequences[16–24] were realised subsequently. As a result, the measurement of $^{13}C-^{13}C$ SSCC on modern spectrometers has now become just as easy as the recording of the ^{13}C NMR spectra themselves 15 years ago.

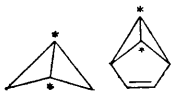
This review surveys the available data solely on the directly bonded $^{13}C-^{13}C$ SSCC, because the geminal, vicinal, and long-range $^{13}C-^{13}C$ constants have already been the subject of a recent careful examination.[8,9] As can be seen from the correlation diagram presented (Fig.1), the range of variation of the directly bonded $^{13}C-^{13}C$ SSCC is exceptionally large: from −20 Hz in bicyclobutanes to +230 Hz in acetylenes.† Their information content is also high, because the accuracy of the measurement of these SSCC is to within 0.1 Hz and less. Attention is concentrated on the principal applications of $^1J_{CC}$ which have arisen in the solution of a wide variety of structural problems of organic chemistry such as the use of $^1J_{CC}$ in stereochemistry and conformational analysis, the study of the effects of substitution and the

† The few experimental measurements of the signs of $^nJ_{CC}$ suggest that all the direct and vicinal $^{13}C-^{13}C$ SSCC are positive (with the exception of sterically strained systems of the bicyclobutane series), while the geminal constants are of variable sign.[5,6]

properties of substituents, the establishment of methods for the biosynthesis and the determination of the structures of complex synthetic and natural products, and the structural studies of the nature of the carbon–carbon bond (estimation of the amounts of *s* character, i.e. of the contributions of the 2*s* orbitals of the carbon atoms to the corresponding hybrid atomic orbitals, of the degree of hybridisation of the interacting atoms, of the bond lengths and bond force constants, and certain other important characteristics). The experimental results of individual studies are resorted to to a minimal extent and are used as specific examples. The consideration of the structural applications of the directly bonded $^{13}C-^{13}C$ SSCC is preceded by sections dealing with the state of the theoretical calculations of these constants and the analysis of the structural factors determining their values.

II. THE NATURE OF THE SPIN–SPIN COUPLING BETWEEN DIRECTLY BONDED CARBON NUCLEI

Calculation of the directly bonded $^{13}C-^{13}C$ SSCC on the basis of the modern theory of spin–spin coupling do not as a rule lead to quantitative agreement with experiment, but make it possible in a number of instances to understand the principal trend in the variation of the experimental values of $^1J_{CC}$. This Section deals briefly with the main results of the theoretical study of $^1J_{CC}$; a more detailed discussion of the theoretical problems and of the problem concerning the calculation of $^1J_{CC}$ may be found elsewhere.[25,26]



1. The Coupling Mechanisms

The magnetic moments of two directly bonded ^{13}C nuclei interact via the spin polarisation mechanism. The directly bonded $^{13}C-^{13}C$ SSCC corresponding to this interaction are determined by three contributions arising via three independent mechanisms of the spin–spin coupling: the Fermi-contact mechanism (contact electron–nucleus interaction), the spin–orbital mechanism (the interaction of the orbital electron currents with the nuclear moments), and the dipole–dipole mechanism (the interaction of electronic and nuclear dipoles).[27]

The Fermi-contact contribution is proportional to the product of the *s* orbital densities at the corresponding nuclei, while the two non-contact contributions are proportional to the products of the one-centre integrals of the valence *p* electrons of the interacting carbon nuclei. The first acceptable algorithm for the calculation of the above contributions was proposed by Blizzard and Santry,[28,29] who established that in many instances the Fermi-contact contribution only is sufficient for the calculation of $^1J_{CC}$; the inclusion in the calculation of the non-contact contributions leads in the general case to an improvement of the agreement between the theoretical and experimental values of $^1J_{CC}$, which is shown particularly for the $^{13}C-^{13}C$ SSCC for the triple bond.

The problem of the ratio of the contributions to the directly bonded $^{13}C-^{13}C$ SSCC has been studied thoroughly using a wide variety of non-empirical and semiempirical methods.[28–43]

In the general case the Fermi-contact contribution ($^1J^{Fc}$) is positive and as a rule predominates, the spin–orbital contribution ($^1J^{SO}$) is negative, and the dipole–dipole contribution ($^1J^{dd}$) has a variable sign and is insignificant. The non-contact interactions become significant for unsaturated and especially sterically strained systems with "unusual" hybridisation. In the latter, the role of the non-contact interactions increases mainly as a result of the decrease of the Fermi-contact contribution, which may be negative in the given instance.[44–48] For example, in the molecules of bicyclobutane (I) and benzvalene (II), a structural isomer of benzene, all three contributions to $^1J_{CC}$ by the bridging carbon atoms# are comparable in magnitude and negative,[44] i.e. the theory predicts in this case the negative sign of the resulting constant, which was subsequently confirmed experimentally.[49,50]

(I) (II)

Another extreme example is provided by acetylene derivatives in which all three contributions are positive.[26,39–41]

Table 1. The relative contributions of $^1J^{Fc}$, $^1J^{SO}$, and $^1J^{dd}$ (Hz) to the directly bonded $^{13}C-^{13}C$ SSCC for ethane, ethylene, and acetylene calculated using various methods.[26]

Method of calculation	H_3C-CH_3		$H_2C=CH_2$		$HC\equiv CH$	
	^1JFC	^1JSO + ^1Jdd	^1JFC	^1JSO + ^1Jdd	^1JFC	^1JSO + ^1Jdd

Non-empirical method involving direct summation with respect to states	17.4	0.6	69.2	—1.2	190.7	2.2
Non-empirical generalised Hartree–Fock method	—	1.2	—	—7.4	—	19.7
Method of finite perturbations in terms of the INDO approximation	41.5	—	82.1	—	163.8	—
Self-consistent theory of finite perturbations in terms of the INDO approximation	35.6	—2.2	70.6	—14.7	140.8	31.9
Method of finite perturbations in terms of the MINDO/3 approximation	29.9	0.2	72.3	2.5	84.0	87.5
Method involving direct summation with respect to states in terms of the INDO approximation with localised molecular orbitals	27.2	—1.1	71.6	—2.7	141.6	3.6
Experiment (Ref.2)	34.6		67.6		171.5	

It is noteworthy that the results of the study of the ratio of the contributions to $^1J_{CC}$ depend greatly on the computational methods employed, and they should therefore be interpreted with a certain amount of caution. Table 1 presents the values of the Fermi-contact contributions and the sums of the non-contact contributions ($^1J^{dd}$ + $^1J^{SO}$), calculated by several methods for ethane, ethylene, and acetylene molecules. Different methods yield a very significant scatter both in the estimates of the relative significance of the individual contributions and in the calculated $^1J_{CC}$, which is manifested particularly strikingly for the acetylene molecule. The method of finite perturbations in terms of the MINDO/3 approximation is apparently least applicable to the calculation of $^1J_{CC}$ for acetylenic compounds in view of the fact that the relative role of non-contact interactions is then found to be clearly too high.

Here and henceforth the asterisk denotes the interacting carbon nuclei.

2. The Types of Coupling

The three mechanisms of the coupling of the ^{13}C nuclear spins enumerated above can involve the participation of orbitals of the σ or π type. In order to separate these two types of coupling, the method of partly restricted and molecular orbitals was used in terms of the INDO approximation and it was shown that the Fermi-contact coupling takes place mainly via the σ system, while both types of non-contact coupling involve almost completely the π-electron system.[51] Using the method of direct summation with respect to states, it was established, in terms of the INDO approximation, that the spin–spin coupling between the ^{13}C nuclei linked directly in the acetylene, ethylene, and benzene molecules takes place via the σ mechanism.[52] A similar conclusion was reached as a result of the calculation of $^1J_{CC}$ for the same molecules by the method of the self-consistent theory of finite perturbations in terms of the INDO approximation with subsequent exclusion of the one-centre exchange integrals between the 2*s* orbital and one or more of selected 2*p* orbitals of one of the interacting carbon atoms.[53]

Thus, in the case where the Fermi-contact contribution predominates (which is the case in almost all compounds), the spin–spin coupling between carbon nuclei linked directly takes place via the σ-electron system.

III. THE PRINCIPAL FACTORS DETERMINING THE VARIATION OF THE DIRECTLY BONDED $^{13}C-^{13}C$ SSCC

1. Hybridisation of the Interacting Atoms

The main factor determining the variation of the directly bonded $^{13}C-^{13}C$ SSCC is the hybridisation of the interacting carbon atoms. In the very first experiment, it was already observed that the $^1J_{CC}$ increase sharply with increase of the amount of *s* character, i.e. the contribution by the 2*s* orbitals of the carbon atoms involved in the formation of the corresponding carbon–carbon bond.[1–3]

The observed variation becomes understandable if account is taken of the fact that the Fermi-contact contribution $^1J^{Fc}$ (which, as mentioned above, predominates in the vast majority of cases) is proportional to the *s* character of the bond in terms of the "average excitation energy" approximation:[27]

$$^1J^{Fc} = \frac{64\pi^2\beta^2}{9(\Delta E)}\langle s_A|\delta(r_A)|s_A\rangle\langle s_B|\delta(r_B)|s_B\rangle P^2_{s_As_B}. \quad (1)$$

where β is the Bohr magneton, ΔE the average excitation energy, $\langle s_A|\delta(r_A)|s_A\rangle$ and $\langle s_B|\delta(r_B)|s_B\rangle$ are the one-centre integrals for the 2*s* orbitals of the carbon atoms A and B, and $P_{s_As_B}$ is the corresponding first order density matrix of the valence *s* electrons.

(a) The Formal Relation with Hybridisation

The first quantitative description of the directly bonded $^{13}C-^{13}C$ SSCC in the context of the hybridisation of the interacting atoms was proposed by Frei and Bernstein, who measured $^1J_{CC}$ for thirteen ^{13}C-labelled compounds corresponding to six formal types of hybridisation of the interacting atom and established that the SSCC $^1J_{CC}$ (Hz) is proportional to the product of the *s* characters of the hybrid orbitals forming the corresponding carbon–carbon bond:[3]

$$^1J_{AB} = 576 s_A s_B - 3.4 \quad (2)$$

Later, an analogous relation was obtained by Günther and Herrig.[54]

A more accurate description of this relation was proposed by Newton et al.,[44] who observed a correlation between the experimental $^1J_{CC}$ (Hz) and the products of the *s* characters of the hybrid orbitals calculated by the method of finite perturbations in terms of the INDO approximation for sixteen hydrocarbons of different structure:

$$^1J_{AB} = 621 s_A s_B - 10.2 \quad (3)$$

The last relation differs from Eqn.(2) by a significant negative constant term, which is important, as will be shown below, for the description of the variation of $^1J_{CC}$ for sterically strained systems.

An attempt has been made[55] to include in the correlation equations of types (2) and (3) the overlap integral of the hybrid orbitals of the interacting atoms, but the relation obtained has not been widely used.

If it is assumed that the one-centre overlap integrals of the 2*s* orbitals of the carbon atoms in Eqn.(1) are constant, then, under conditions where the Fermi-contact interaction predominates, the SSCC $^1J_{CC}$ should be proportional to the square of the corresponding element of the density matrix $P^2_{s_As_B}$. Similar relations have been noted in other studies.[53,56,57] Recalculation of the data of Maciel et al.[53] by the method of least squares using the experimental values of $^1J_{CC}$ known at the present time led us§ to Eqn.(4) describing the variation of 60 values of $^1J_{CC}$ for 47 compounds with different hybridisation of the interacting atoms ($r = 0.956$, $s = 3.5$ Hz):

$$^1J_{AB} = 475.7\,(\pm 19.0)P^2_{s_As_B} + 6.6\,(\pm 1.8) \quad (4)$$

The description of the variation of $^1J_{CC}$ in the context of the hybridisation has been satisfactorily confirmed experimentally for various compounds,[54–56] including charged systems.[61]

(b) The Inadequacy of the Hybridisation Model

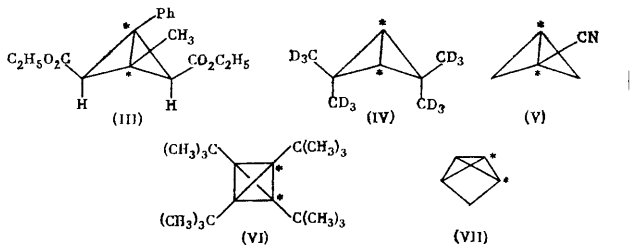
The successful description of the variation of $^1J_{CC}$ within the framework of the concept of hybridisation has become possible only for a set of systems with a wide variation of the *s* character of the bonds being compared and without substituents having markedly different electron-donating (electron-accepting) and steric properties. A number of examples are known where the hybridisation model does not reflect even the principal trend in the variation of $^1J_{CC}$.[62–66] There may be several reasons for the inadequate description in this instance.

The constant term in the correlation equations (2)–(4) corresponds to a constant overall contribution of the non-contact interactions independent of the *s* character of the bond.[30] Therefore the inconstancy of the non-contact interactions may introduce a significant error in the calculation of $^1J_{CC}$ by means of these equations, which applies in the first place to the spin–orbital contribution.

On the other hand, the effect of substituents, which is underestimated or, conversely, overestimated in the formal calculations of the amount of *s* character of the hybrid orbitals or the elements of the density matrix of the valence *s* electrons (different electronic and steric effects, the effect

§ L.B.Krividin, S.V.Zinchenko, V.V.Shcherbakov et al., Zhur.Org.Khim., 1987 (in the Press).

of unshared electron pairs of heteroatoms, etc.) can induce a significant variation of $^1J_{CC}$. For example, the range of variation of $^1J_{CC}$ for a triple bond, caused by the influence of substituents, is ~170 Hz (Fig.1).



The correlation of $^1J_{CC}$ with various characteristics of the *s* character of the bond are based on the fairly rough (average excitation energy) approximation, which has been used to eliminate summation with respect to triplet states in the second-order perturbation theory.[33] The use of various quantum-chemical methods leads to an appreciable scatter of the *s* character of the bond, which also affects the overall quality of correlations of types (2)–(4). For example, the sum of the amounts of *s* character of the four equivalent hybrid orbitals of the central carbon atom of neopentane, calculated using the most accurate Eqn.(2), is 136%, i.e. it exceeds by 36% the maximum permissible value.[67]

The sterically strained mono-, di-, and poly-cycloalkanes—compounds with "unusual" hybridisation—constitute a special case. For example, the bond between the bridging carbon atoms in bicyclobutane is believed to be of the $sp^{2.4}$–$sp^{2.4}$ type (which corresponds to 4% of the *s* character of the hybrid orbitals forming the bridge bond).[68] The interest in the ^{13}C–^{13}C SSCC for these compounds is therefore understandable.[44–50,68–79]

On the basis of the simplest model of the structure of the cyclopropane ring, each carbon atom forms two exocyclic hybrid orbitals with 33% of *s* character of the sp^2 type and two endocyclic orbitals with 17% of *s* character, which corresponds approximation to sp^5 hybridisation. The use of the classical Frei–Bernstein equation [Eqn.(2)] leads to $^1J_{SS} \cong$ 16 Hz as the directly bonded ^{13}C–^{13}C SSCC between two ring carbon atoms of the cyclopropane ring,[70] which is close to the experimental value of 12.4 Hz.[47]

In the case of bicyclobutane, even the Frei–Bernstein equation predicts a negative value of the constant ($^1J_{CC} \cong$ −3 Hz) for the coupling between the bridging carbon atoms, while according to the more accurate Eqn.(5), the value in this case should be above −10 Hz.[44] As mentioned above, the same result follows also from the calculation of the three theoretical contributions to the given constant.[44,75]

The theoretical prediction of the negative sign of the directly bonded ^{13}C–^{13}C SSCC between the bridging carbon atoms in systems of the bicyclobutane type has been confirmed experimentally by Pomerantz and Finkelmeier, who carried out unique experiments involving the measurement of the signs of the ^{13}C–^{13}C SSCC for 1-methyl-[3-^{13}C]phenylbicyclo[1.1.0]butane-1,3-*exo*,*endo*-2,4-dicarboxylate (III) ($^1J_{CC}$ = −5.4 ± 0.5 Hz [49]) and 2,2,4,4-tetra(trideuteriomethyl)bicyclo[1.1.0][1,3-$^{13}C_2$]butane (IV) ($^1J_{CC}$ = −17.49 ± 0.2 Hz [50]). In the light of these data, the corresponding SSCC $^1J_{CC}$ for 1-cyanobicyclobutane (V) ($^1J_{CC}$ = 16.0 Hz [71,72]), tetra-t-butyltetrahedrane (VI) ($^1J_{CC}$ = 9.2 Hz [48]), and tricyclo[2.1.0.$0^{2,5}$]pentane (VII) ($^1J_{CC}$ = 19.0 Hz [76]) should also be regarded as negative.

As already mentioned, the hybridisation $^1J_{CC}$ model suffers from a number of limitations. In sterically strained systems, the limitation associated with failure to take into account the geminal (for three-membered rings) and vicinal (for four-membered rings) ^{13}C–^{13}C interactions, which involves independent pathways and lead to an additive contribution to the direct constant, assumes special importance.[30,47,48] For example, according to Stöcker's data,[47] the geminal interaction in cyclopropane leads to the contribution $^2J'_{CC}$ = −20.08 Hz, while the direct interaction leads to the contribution $^1J'_{CC}$ = 33.45 Hz, which results in the constant $^1J_{CC}$ = $^1J'_{CC}$ + $^2J'_{CC}$ = 12.47 Hz, agreeing exactly with the experimental value $^1J_{CC}$ = 12.4 Hz.[47] In the given interpretation, cyclopropane is a molecule with the "usual" sp^3 hybridisation.

Thus, in describing the variation of $^1J_{CC}$ within the framework of a simple hybridisation model, much care must be exercised in taking into account more secondary factors such as the electronic and steric effects of the substituents, the ratio of the contributions of the non-contact interactions in the series of compounds compared, and certain others.

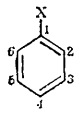
2. Effects of Substitution

A factor of secondary importance, determining the variation of $^1J_{CC}$, is the electronic influence of substituents via the system of bond electrons (the steric effects of substituents will be considered separately). Derivatives of acetylene,[39,80–82] ethylene,[57,83–90] ethane,[56,91,92] benzene,[31,37,93–103] pyridine,[104] adamantane and diamantane,[106–108] and also, to a lesser extent, those of other compounds,[34,47,62,63,70,77,109–122] have been most thoroughly investigated in this sense. This Section deals with the general consideration of the effects of substitution without presenting extensive factual data; these data have been partly included in two compilations.[5,6]

(a) General Characteristics

The linear increase of $^1J_{CC}$ with increasing electronegativity of the first atom of the substituent (E_X)[37,39,88] or other characteristics reflecting its induction properties and acting via the system of σ-bonds of the molecule[81,94,95,123] has been noted in a series of studies of the influence of substituents on directly bonded ^{13}C–^{13}C SSCC. For example, for monosubstituted ethylene and acetylenes, these relations have the following form respectively:[39,88]

$$^1J_{CC} = 14.4E_X + 33.1 \quad (5)$$



$$^1J_{CC} = 43.4E_X + 17.3 \quad (6)$$

According to the results obtained by the method of finite perturbations in terms of the INDO approximation, electronegative substituents X in the C–C–X fragment diminish the *s* character of the hybrid carbon orbital involved in the formation of the C–X σ-bond, which leads in its turn to an increase of the *s* character of the second hybrid orbital of the same carbon atom forming the C–C bond.[92] This increases the contribution of the Fermi contact interaction of the two carbon atoms considered and hence increases the constant $^1J_{CC}$, which is apparently a general principle for any system. These ideas have been confirmed by the results of calculations of ~70 values of $^1J_{CC}$ for more than 40 derivatives of ethane, ethylene, acetylene, and benzene by the self-consistent finite perturbation theory in terms of the INDO approximation.[32] According to the results of the last study quoted, the influence of substituents on $^1J_{CC}$ for a neighbouring carbon–carbon bond is exerted mainly as a result of the alteration of the Fermi-contact contribution to the ^{13}C–^{13}C SSCC.

The only known exceptions are cyclopropane derivatives in which the electronegative substituents CO_2H, CN, and COR (R = H or alkyl) decrease $^1J_{CC}$ compared with the unsubstituted cyclopropane; this may be explained by the interaction of the *p* orbitals of the α-carbon atom of the substituent with the "Walsh orbitals" of the cyclopropane ring, which decreases the *s* character of the endocyclic hybrid carbon orbital forming a carbon–carbon ring bond.[47] Account must also be taken of the fact that the spin–orbital interaction, sensitive to the redistribution of π-electron density,[51] makes a major contribution in the given instance to the ^{13}C–^{13}C constant.[44–48]

The influence of substituents on $^1J_{CC}$ decreases rapidly with increase in the number of intervening bonds separating the interacting atoms from the site of substitution.

For example, the ranges of the variation of $^1J_{CC}$ in the series of monosubstituted benzenes (VIII) are respectively Δ^1J_{CC} = 21.3 Hz, $\Delta^1J_{2,3}$ = 4.7 Hz, and $\Delta^1J_{3,4}$ = 1.9 Hz.[37]

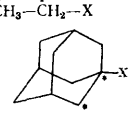
(VIII)

An analogous relation is characteristic also of adamantane,[107] diamantane,[108] and pyridine[104] derivatives. The character of the dependence of $^1J_{CC}$ for the ^{13}C nuclei in the β- and γ-positions relative to the site of substitution on the electronegativity of the substituent may be directly opposite for different compounds.[37,104,107,108] It can be assumed that $^1J_{CC}$ for the even more remote bonds is almost insensitive to the influence of substituents transmitted via the system of σ-bond electrons.

A dependence of $^1J_{CC}$ on the π-electronic properties of substituents has been noted in some cases[31,38,47,93,96,99,100,101] but in most cases these effects are apparently associated with the π-induced redistributions of s-electron density, i.e. ultimately with the change in the *s* character of the bond.

The question of the additivity of the effects of substitution, which has so far been scarcely investigated, is extremely interesting for the practical application of $^1J_{CC}$ in structural studies. The additivity of the effects of substitution in the benzene rings of aromatic ethers and sulphides on $^1J_{CC}$, with the exception of instances of specific interaction of substituents in close proximity, has been noted.[124] The additivity of the influence of the phenyl group on $^1J_{CC}$ for the double bond has also been established.[38] A distinct non-additivity has been observed for the ^{13}C–^{13}C SSCC for the cyclopropane ring[47] and the triple bond.[80,125] For example, the experimental values of $^1J_{CC}$ for compounds (IX), (X) and (XI) exceed the values of this constant calculated using an additive scheme respectively by 10.2, 12.0 and 32.0 Hz:[125]

$(C_2H_5)_3Si{-}C{\equiv}C{-}Si(C_2H_5)_3$ (IX)



$(C_4H_9)_3Sn{-}C{\equiv}C{-}Sn(C_4H_9)_3$ (X)

$(CH_3)_3Sn{-}C{\equiv}C{-}Si(CH_3)_3$ (XI)

(b) Comparative Analysis of the Effects of Substitution

Table 2 gives a compilation of the increments Δ^1J_{CC} for the commonest substituents in certain model systems corresponding to different types of hybridisation of the interacting atoms. The Δ^1J_{CC} increase sharply with the increasing *s* character of the corresponding carbon–carbon bonds, which

Table 2. The substitutional increments in $^1J_{CC}$ (Hz) for the commonest substitutents[a].

also demonstrates the dependence, presented in Fig. 2 of the Δ^1J_{CC} for the substituents $Si(CH_3)_3$, $COCH_3$, CN, and OCH_3 on the product of the *s* characters of the interacting atoms. This is most notable when the values of $^1J_{CC}$ for the "strongest acting" substituents $Si(CH_3)_3$ and OCH_3, amounting to −40 and +60 Hz respectively for acetylene derivatives corresponding to the *sp*–*sp* hybridisation, are compared.

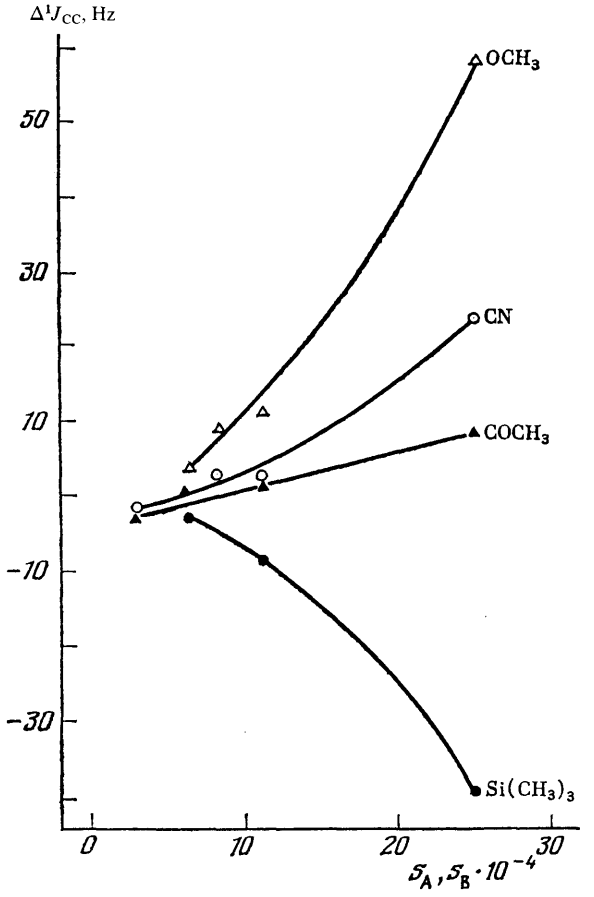

Figure 2. Variation of the increments Δ^1J_{CC} for certain substituents with the product of the amounts of *s* character of the interacting atoms.

3. Steric Effects

The directly bonded $^{13}C-^{13}C$ SSCC are stereospecific with respect to the spatial distribution of individual structural fragments of the molecule, which makes it possible to use these parameters for the solution of a wide variety of stereochemical problems. The principal types of steric effects of substituents reflected in the values of $^1J_{CC}$ are briefly considered below.

(a) Effects Association with Changes in Valence Angles

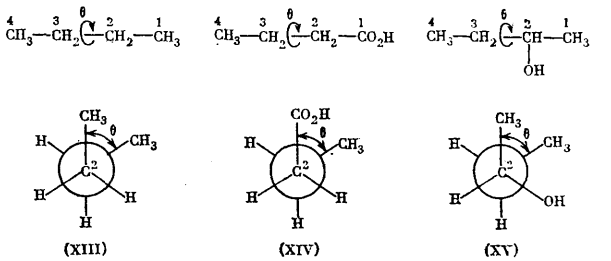
The steric interactions of substituents are capable of inducing changes in molecular geometry leading to changes in the hybridisation of individual orbitals (which is determined in the first place by the bond angles) and hence to changes in the *s* characters of the bond and the corresponding $^{13}C-^{13}C$ SSCC. The first experimental manifestation of such effects has been observed in a study of $^1J_{CC}$ for ethane derivatives.[92] At first sight the unexpected increase in $^1J_{CC}$ on successive increase in the number of methyl groups at one of the interacting carbon atoms becomes understandable if account is taken of the fact that this leads to a gradual increase in the bond angle in the $^{13}C-^{13}C-CH_3$ fragment compared with the tetrahedral bond angle (by 5° [92]) and hence to an increase in the *s* character of its hybrid orbitals and correspondingly in the Fermi-contact contribution to the constant $^1J_{CC}$.

A quantitative description of this relation has been proposed by Pomerantz and Bittner,[126] who established that $^1J_{CC}$ for the fragment (XII) in a series of monohydrocarbons with a known geometry exhibits a quadratic dependence on the bond angle:

(XII)

$$^1J_{CC} = -0.00566\,\varphi^2 + 1.377\,\varphi - 49.04. \quad (7)$$

When ϕ is increased from 60° to 126.5°, $^1J_{CC}$ increases from 13.3 to 35.14 Hz.[126]



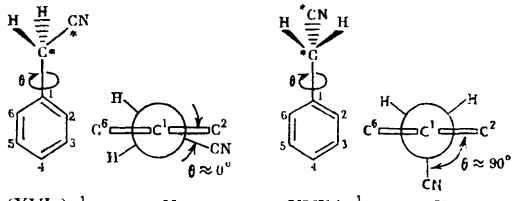
In a later study,[78] it was shown that, when cyclopropane, for which the observed $^1J_{CC}$ is the sum of the SSCC for two independent types of spin–spin coupling, is excluded from consideration, the observed dependence is linear:

$$^1J_{CC} = 0.166\,\varphi + 14.91 \quad (8)$$

Extrapolation of Eqn. (8) to ϕ = 60° leads to the "true" value of the directly bonded carbon–carbon constant for cyclopropane: $^1J_{CC} \cong 25$ Hz.[78]

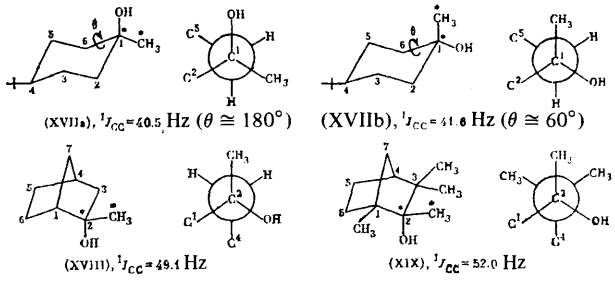
(b) Effects Associated with Changes in the Mutual Orientation of the Bonds

Calculation of $^1J_{CC}$ by the method finite peturbations in terms of the INDO approximation for butane (XIII), butyric acid (XIV), and 2-butanol (XV) revealed a distinct stereospecificity of $^1J_{1,2}$ with respect to the mutual orientation of the C(1)–C(2) and C(3)–C(4) bonds, i.e. the dependence of $^1J_{CC}$ on the dihedral angle θ:[33]



(XIII) (XIV) (XV)

The increase in θ from 0° to 180° reduces $^1J_{CC}$ by 4.5–6 Hz.

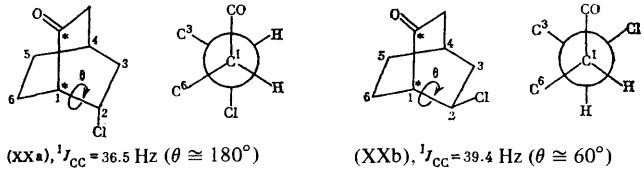


A difference between the theoretical values of $^1J_{CC}$ calculation was performed taking into account only the Fermi-contact contribution) for the planar and orthogonal conformers of benzyl cyanide (XVIa, b) has been noted.[127] This too can be explained by the change in the C(2)–C(1)–CH_2–CN

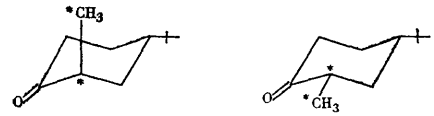
dihedral angle θ.

(XVIa), $^1J_{CC}$ = 76.3 Hz (XVIb), $^1J_{CC}$ = 75.0 Hz

The experimental values of $^1J_{CC}$ for *cis*- and *trans*-4-t-butyl-2-methylcyclohexanols (XVIIa, b), *exo*-2-methyl-2-norborneol (XVIII), and *exo*-2-methyl-2-fenchone (XIX) [33] reflect the same relation.



(XVIIa), $^1J_{CC}$ = 40.5 Hz ($\theta \cong 180°$) (XVIIb), $^1J_{CC}$ = 41.6 Hz ($\theta \cong 60°$)

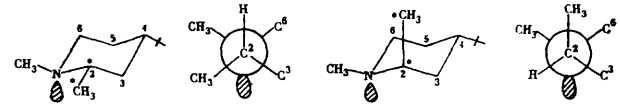


(XVIII), $^1J_{CC}$ = 49.1 Hz (XIX), $^1J_{CC}$ = 52.0 Hz

Analogous effects have also been noted in certain diamantane derivatives. [108]

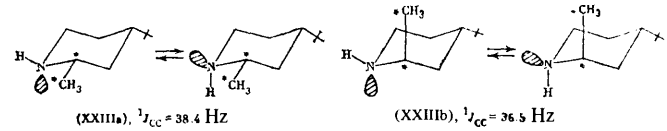
The relation discussed above has also been observed in the $^{13}C-^{13}C-C-X$ fragment, where X is a heteroatom, as happens in the *exo*- and *endo*-derivatives of bicyclo[2.2.2]octanone (XXa, b) [128] and the pairs of 4-t-butyl-2-methyl-cyclohexanone diastereoisomers (XXIa, b). [129]

(XXa), $^1J_{CC}$ = 36.5 Hz ($\theta \cong 180°$) (XXb), $^1J_{CC}$ = 39.4 Hz ($\theta \cong 60°$)



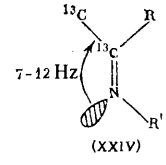
(XXIa), $^1J_{CC}$ = 33.8 Hz (XXIb), $^1J_{CC}$ = 37.6 Hz

The striking stereospecificity of $^1J_{CC}$ with respect to the orientation of neighbouring bonds makes it possible to employ these constants also for the solution of various problems in conformational analysis.



4. Effects of Unshared Electron Pairs of Heteroatoms

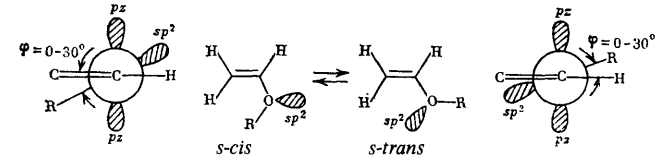
The stereospecificity of the directly bonded $^{13}C-^{13}C$ SSCC with respect to the orientation of the unshared electron pair of the nitrogen atom was first noted by Barna and Robinson for pairs of diastereoisomers of piperidine derivatives. [129] $^1J_{CC}$ for the *cis*-isomer of 4-t-butyl-2-*N*-dimethylpiperidine (XIIa) with the *gauche*-disposition of the C(2)–CH_3 bond and the unshared electron pair of the nitrogen atom is greater by 4 Hz than the corresponding constant for the *trans*-isomer (XXIIb):



(XXIIa), $^1J_{CC}$ = 39.3 Hz (XXIIIb), $^1J_{CC}$ = 35.3 Hz

The difference between the constants for the corresponding NH derivatives is reduced to ~2 Hz as a consequence of the shift of the conformational equilibrium of the *trans*-isomer (XXIIIb) towards the form with the *gauche*-orientation of the unshared electron pair and of the carbon–carbon bond considered:

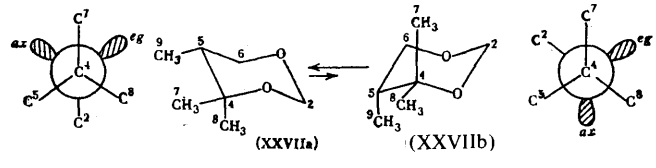
(XXIIIa), $^1J_{CC}$ = 38.4 Hz (XXIIIb), $^1J_{CC}$ = 36.5 Hz



The effect of the unshared pair of the imino-nitrogen, leading to an additional contribution to $^1J_{CC}$ for the neighbouring carbon–carbon bond of the fragment (XXIV), amounting to up to 12 Hz, which permits an unambiguous identification of the configurations of a wide variety of imines, has been noted in a series of studies. [123,130–135]

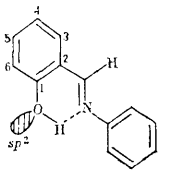
(XXIV)

An analogous influence of unshared electron pairs has also been established for a series of oxygen-containing compounds. [90,124,136,137]



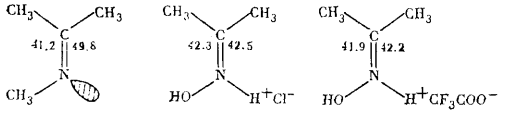
The shift of the conformational equilibrium in a series of alkyl vinyl ethers towards the *s-trans*-conformer with the *cis*-orientation of the sp^2-hybridised unshared electron pair of oxygen with respect to the double bond leads to an additional contribution to the corresponding $^{13}C-^{13}C$ constant up to ~4 Hz: [136]

s-cis *s-trans*



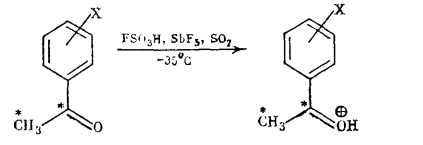
R = CH_3 (XXV), $^1J_{CC}$ = 78.6 Hz; R = $C(CH_3)_3$ (XXVI), $^1J_{CC}$ = 82.2 Hz

The same effect has been observed also for the sp^3-hybridised unshared electron pairs of the oxygen atom of 4,4,5-trimethyl-1,3-dioxan (XXVII). [137] The equilibrium in this compound is displaced towards the conformer (XXVIIa). The constant $^1J_{4,7}$ exceeds $^1J_{4,8}$ by ~3.5 Hz owing to the additional contribution to the former by the axial sp^3-hybridised unshared pair of the neighbouring oxygen atom in the preferred conformer (XXVIIa), while the contributions of the equatorial unshared electron pair to the two constants are the same.



(XXVIIa) (XXVIIb)

According to Krivdin et al.,[124] the contribution of the hybridised unshared pair of the oxygen of the hydroxy-group in compound (XXVIII), rigidly fixed in the *cis*-position with respect to the C(1)–C(6) bond as a consequence of the formation of a strong intramolecular hydrogen bond, is ~7 Hz, which is comparable to the contribution by the unshared electron pair of the imino-nitrogen.



(XXVIII)

In view of the practical importance of the effects considered in stereochemical studies on heteroatomic compounds, the elucidation of the nature of the influence of the unshared electron pairs of the heteroatoms on the $^{13}C-^{13}C$ SSCC is of great interest. In their first study,[129] Barna and Robinson suggested that the observed effect is caused by the steric overlapping of the unshared electron pair of the heteroatom with the antibonding orbitals of the neighbouring C–C bonds, which increases $^1J_{CC}$ for the *cis*- and *gauche*-orientations and decreases this constant for the *trans*-orientation of the unshared pair and of the corresponding bonds.[129] However, the results for the protonation of the acetoxime (XXIX) support the view that the unshared electron pairs of the heteroatoms give rise to an additional contribution to the $^1J_{CC}$ for the neighbouring bond in the *cis*-position and hardly influences the $^1J_{CC}$ for the bond having the *trans*-orientation.[138] The constants $^1J_{CC}$ (Hz) for acetoxime (XXIX) and its protonated forms (XXIXa, b) are presented below.[138] They demonstrate unambiguously that the positive contribution to $^1J_{CC}$ for the neighbouring bond having the *cis*-orientation is in fact "removed" on protonation of the unshared electron pair.

(XXIX) (XXIXa) (XXIXb)

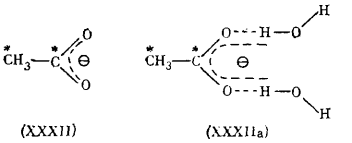
The "unexpected" decrease in $^1J_{CC}$ by ~5 Hz on protonation of the carbonyl oxygen in substituted acetophenones (XXX) with formation of the stable oxonium ions (XXXI)¶ [100] should also be apparently explained by the removal of the additional positive contribution of the unshared electron pair of the carbonyl oxygen to the corresponding constant.

(XXX), $^1J_{CC}$ = 43–44 Hz (XXXI), $^1J_{CC}$ = 38–40 Hz

So far nothing is known about the influence of the unshared electron pairs of other heteroatoms on the directly bonded $^{13}C-^{13}C$ SSCC. According to our own preliminary data,† one can assume that the effect under discussion is insignificant for the halogens, sulphur, and phosphorus.

5. Effects of the Medium

The effects of the medium are manifested in the variation of three main contributions to the direct SSCC caused by the influence of the solvent: the magnetic shielding induced by the magnetic moments of neighbouring molecules, dispersion effects of the exchange type, and intermolecular electrostatic interactions.[139] In the absence of specific solvation effects, the theory predicts the variation of the directly bonded SSCC for the two interacting A and B nuclei as a function of the dielectric constant of the solvent ε in accordance with Eqn.(9), which reflects mainly the variation of the contribution by the intermolecular electrostatic interactions:[140]



$$^1J_{AB} = a\left(\frac{\varepsilon-1}{\varepsilon}\right)^2 + b\left(\frac{\varepsilon-1}{\varepsilon}\right) + c \qquad (9)$$

However, the changes in the experimental values of $^1J_{CC}$ are comparable to the accuracy of the measurement of the constants even for a wide range of variation of the polarity of the medium.[34,80,123,141,142]

The few measurements of the temperature dependence of $^1J_{CC}$ indicate a low sensitivity of the $^{13}C-^{13}C$ SSCC to temperature.[39,123,142] For example, the constants $^1J_{CC}$ for a series of halogeno-derivatives of ethane, acetonitrile, and acetic acid increase by only 0.1–0.3 Hz when the temperature is raised by 100 °C.[142] The constants $^1J_{CC}$ are almost independence of the concentrations of the test compounds.[123]

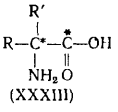
The weak sensitivity of the $^1J_{CC}$ to solvation effects permits a correction comparison of the constants measured under different experimental conditions and, what is particularly important, in different solvents.

Like the conformational changes in the molecules induced by the solvent, in individual instances the specific associative processes may induce very large changes in the $^{13}C-^{13}C$ SSCC. For example, the calculated constants $^1J_{CC}$ for the acetate anion (XXXII) and its solvated form (XXXIIa) differ by ~35 Hz:[53]

(XXXII) (XXXIIa)

IV. STRUCTURAL APPLICATIONS

1. The Nature of the Carbon–Carbon Bonds and the Properties of Substituents



The direct $^{13}C-^{13}C$ SSCC can be used to estimate the hybridisation of individual atoms, and *s* characters of the bonds, and the *s* characters of individual orbitals and also

¶ In superacid media at −35 °C.

† L.B.Krivdin, V.V.Shcerbakov, and G.A.Kalabin, "Konstanty Spin–Spin Vzaimodeistviya $^{13}C-^{13}C$ Geteroatomnykh Soedinenii" (The $^{13}C-^{13}C$ Spin–Spin Coupling Constants for Heteroatomic Compounds) (Edited by V.A.Koptyug et al.), NIOKh Sibir.Otd.Akad.Nauk SSSR, Novosibirsk, 1988 (in the Press).

to refine the distribution of *s* electron density on carbon nuclei. The values of $^1J_{CC}$ are also reflected by the product of "empirical factors",[143] including the elements of the relative *s*-electron density, the C–C bond order, and the singlet–triplet excitation energy. A dependence of $^1J_{CC}$ on the π-bond order calculated by the Hückel method has been noted for a series of condensed aromatic hydrocarbons.[38,105,116,120]

On the other hand, the dependence of $^1J_{CC}$ on the *s* electron density and the weak sensitivity to π-electronic effects permit a wide-scale use of these parameters in the study of the induction properties of substituents in various systems.[37,39,81,88,94,95,123] One of the practical applications of such relations is in the method for the determination of the pK_a for carboxy-groups based on the dependence of $^1J_{CC}$ for the interaction of the carboxy-carbon atom with the neighbouring α-carbon atom in aminoacids (XXIII) on the degree of ionisation of the carboxy-group:[144–148]

(XXXIII)

On passing from an acid to a neutral medium, $^1J_{CC}$ for aminoacids diminishes by ~6 Hz; a further increase in pH, accompanied by a transition of the carboxy-group from the zwitterionic state to the anionic state, leads to a successive decrease in $^1J_{CC}$ by ~1 Hz.[145] The relation under discussion provides a unique possibility for the selective titration of individual amide groups in natural and synthetic peptides labelled with the ^{13}C isotope and for the determination of the degree of their ionisation in the active centres of enzymes.

The relation between $^1J_{CC}$ and the internuclear distances r_{CC} (Å) is of great interest. Eqn.(10) for the hybridisation of the interacting sp^3–sp^3, sp^3–sp^2, and sp^2–sp^2 atoms and Eqn.(11) for sp^3–sp, sp^2–sp, and sp–sp can be fitted to the available data:[54]

$$^1J_{CC} = -167r_{CC} + 294 \quad (10)$$

$$^1J_{CC} = -571r_{CC} + 855 \quad (11)$$

Eqns.(10) and (11) reflect the general trend involving a decrease of $^1J_{CC}$ with increase of the distance between the interacting atoms and can be used solely for rough estimates of r_{CC}.

More accurate equations have been obtained for a narrow range of condensed aromatic hydrocarbons, naphthalene, anthracene, phenanthrene, pyrene, and benzo[a]pyrene:[149]

$$^1J_{CC} = -143r_{CC} + 257 \quad (12)$$

$$^1J_{CC} = -119r_{CC} + 227 \quad (13)$$

Eqn.(12) corresponds to the case of the interaction of the methylidyne and quaternary ^{13}C nuclei, whilst Eqn.(13) corresponds to two methylidyne carbon nuclei.

The directly bonded dipole–dipole ^{13}C–^{13}C SSCC for partly oriented molecules in the nematic phase contain a large contribution due to the anisotropy of indirectly bonded carbon–carbon constants and their use for the determination of the internuclear distances r_{CC} is therefore limited.[150]

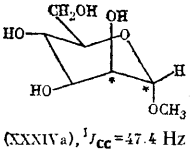
A study of the relaxation of the ^{13}C satellites in the carbon spectrum of phenylacetylene established that the ratio of the relaxation times for the pairs of satellites being compared corresponds exactly to the theoretical ratio of the dipole–dipole contributions to relaxation, which are proportional to r_{CC}^{-6}.[151] Thus the relaxation times of the ^{13}C satellites can also be used to estimate bond lengths.

A correlation between $^1J_{CC}$ and the bond force constants K_{CC}, whose experimental measurement is frequently difficult, has been observed.[152,153] The form of the equations depends on the hybridisation of the interacting atoms:

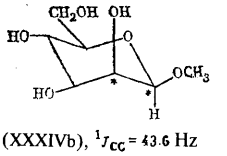
$$sp^3 - sp^3: K_{CC} = 0.0344\,^1J_{CC} + 3.25 \quad (14)$$

$$sp^2 - sp^2: K_{CC} = 0.1800\,^1J_{CC} - 3.25 \quad (15)$$

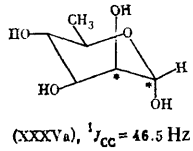
$$sp - sp: K_{CC} = 0.0295\,^1J_{CC} + 11.04 \quad (16)$$



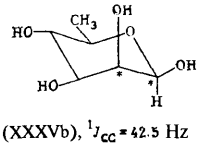
The use of these equations made it possible to define the bond force constants for a series of compounds, including epoxyethane, propene, butadiene, and diacetylene.[152]



The directly bonded ^{13}C–^{13}C SSCC made it possible to expand significantly the ideas about the nature of the carbon–carbon coordinate bonds in transition and non-transition metal complexes.[154–157] In particular, it has been established that, in a series of allyl complexes, there is a strong "reverse donation" from the highest occupied molecular orbits of the ligand to the unoccupied orbitals of the metal, which is manifested by a sharp decrease of the constant $^1J_{CC}$ for the bonds in the ligand.[156]



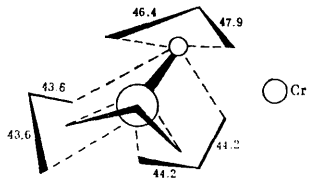
2. Stereochemical Studies



The marked stereospecificity of the directly bonded ^{13}C–^{13}C SSCC gives rise to major prospects for the use of these parameters in stereochemistry and conformational analysis. A series of problems associated with the steric orientation of the unshared electron pairs of heteroatoms have been solved with the aid of the ^{13}C–^{13}C SSCC: a new universal method has been developed for the determination of the configurations of compounds with imino-nitrogen;[123] the conformational analysis of a wide range of unsaturated and aromatic ethers and sulphides has been carried out;[90] a new method has been proposed for the identification of azole isomers;[158] the steric structure of pyrazolines—the products of the incomplete reduction of pyrazoles—has been studied.[159]

The directly bonded ^{13}C–^{13}C SSCC have found extensive applications in the stereochemistry of biologically important carbohydrates.[160,161] The constants $^1J_{CC}$ are presented as an example for methyl α- and methyl β-D-mannopyranosides (XXXIVa, b) and α-L- and β-L-rhamnoses (XXXVa, b). Here the constants are stereospecific with respect to the orientation of the substituent (OH, OCH_3) at C(1) and can thus be used to determine the steric structure of related glycosides and free sugars:[161]

(XXXIVa), $^1J_{CC}$ = 47.4 Hz



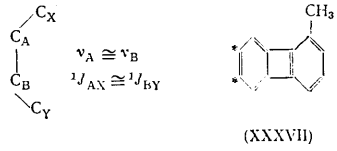
(XXXIVb), $^1J_{CC}$ = 43.6 Hz

(XXXVa), $^1J_{CC}$ = 46.5 Hz

(XXXVb), $^1J_{CC}$ = 42.5 Hz

In the studies of Benn and Rufinska,[155,156] the constants $^1J_{CC}$ were used to investigate the stereochemistry of allyl complexes of metals. For example, the measurement of $^1J_{CC}$ (Hz) for the dinuclear chromium complex (XXXVI) makes it possible to determine unambiguously the bridging η^3-allyl

groups, for which the values of $^1J_{CC}$ are significantly smaller:

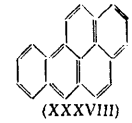


(XXXVI)

Thus the application of the directly bonded $^{13}C-^{13}C$ SSCC to the solution of a wide variety of stereochemical problems has led to the creation of a new promising method for the determination of the conformation and configurational structures of molecules.

3. Tracing Out the Carbon Skeleton of Complex Molecules

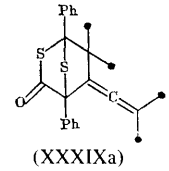
A universal method for the assignment of the ^{13}C NMR signals, which has come to be called "tracing out the carbon skeleton" has been developed using the directly bonded $^{13}C-^{13}C$ SSCC.[162] In the two-dimensional version of INADEQUATE, the carbon skeleton of the molecules is traced out by observing the two-quantum frequencies in the dimension $\mathcal{F}_1$ to which the usual carbon spectrum with ^{13}C satellites corresponds in the dimension $\mathcal{F}_2$; the ^{13}C nuclei linked directly are then readily identified from the identical two-quantum frequencies.[162] The use of this method is especially effective when the chemical shifts of the interacting nuclei are almost identical and the constants for their interaction with the neighbouring carbon nuclei are so close that they cannot be distinguished to within the accuracy of the experimental measurement, as happens, for example, in 1-methylbiphenylene (XXXVII):[163]



(XXXVII)

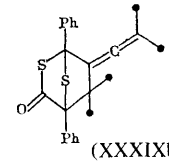
Despite the advantages noted above, when the two-dimensional version of INADEQUATE is used, two difficulties are encountered: the extremely acute problem of sensitivity, which frequently cannot be overcome even in the most sophisticated NMR spectrometers (in order to record a single two-dimensional INADEQUATE spectrum, it is necessary to obtain at least ~1000 ^{13}C satellite carbon spectra) and, on the other hand, the low numerical resolution in the transformed spectra which precludes the measurement of $^1J_{CC}$ with the necessary accuracy.

The alternative one-dimensional version of the INADEQUATE method is free from the above disadvantages. In this method, the carbon skeleton is traced out by identifying the carbon–carbon bonds as a result of the successive comparison of the values of $^1J_{CC}$ measured for each signal in the ^{13}C NMR spectrum. The COSMIC [164] and CABSA [165] programs ensure the complete automation of such an experiment.

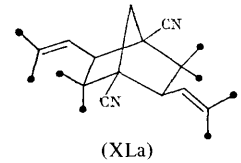


In the case of a high spectral signal density, the use of the DOUBTFUL pulse sequence[166] makes it possible to achieve an unambiguous assignment of the quaternary signals under INADEQUATE conditions with their preliminary filtration.

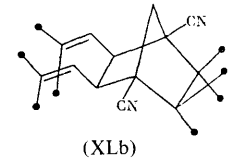
The method discussed is used widely for the assignment of the ^{13}C signals for complex organic compounds containing up to 40 carbon atoms. In a number of instances, the signals have been reassigned.[149,167–177] For example, the application of this method resulted in the reassignment of 11 out of the 20 ^{13}C NMR signals of the benzo[*a*]pyrene (XXXVIII) molecule.[149]



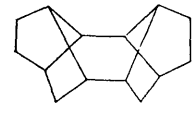
(XXXVIII)



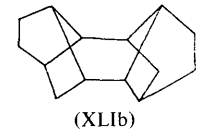
The isomers (XXXIXa, b),[178] (XLa, b),[179] and (XLIa, b),[180] which have very similar structures and cannot be distinguished on the basis of the ^{13}C NMR spectra, have been identified with the aid of this method.



(XXXIXa)

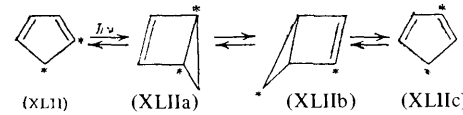


(XXXIXb)

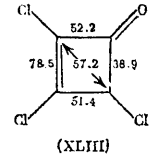


(XLa)

(XLb)

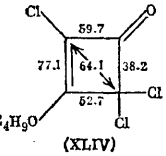


(XLIa)

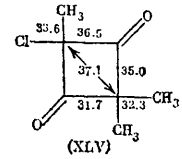


(XLIb)

The method for tracing out the carbon skeleton has already found application in the determination of the reaction mechanisms and for the identification of the intermediates.[76,181,182] An elegant example of studies of this kind is the determination of the pathway followed in the photoisomerisation of [1,2-$^{13}C_2$]cyclopentadiene (XLII):[76]



(XLII) (XLIIa) (XLIIb) (XLIIc)

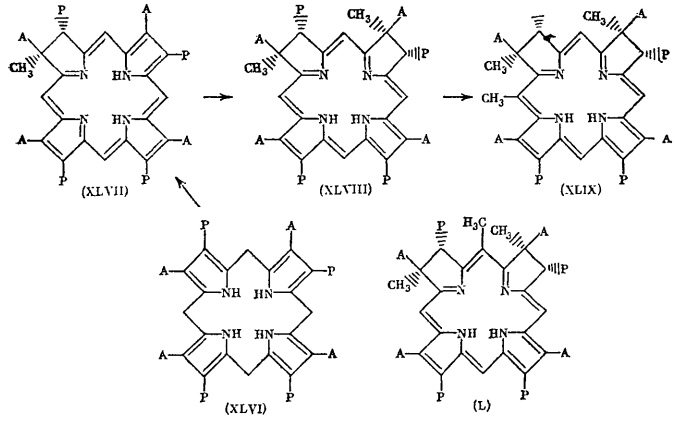


The unusually high values (tentatively positive) of the geminal constants $^2J_{CC}$ for the polychloro-derivatives of cyclobutenone and cyclobutanedione (XLIII)–(XLV), which can reach and actually exceed the values of $^1J_{CC}$, constitute a serious obstacle to the use of the method:[183]

(XLIII)

(XLIV)

(XLV)



The two-dimensional version of the method discussed can be used to assign the repeating structural fragments in polymers without measuring the constants $^1J_{CC}$. The principal structural units (guaiacyl, syringyl, and pinoresinol) of the natural polymer lignin have been unambiguously assigned in this way.[184]

Thus, the method for tracing out the carbon skeleton is one of the most promising and rapidly developing applications of the direct $^{13}C-^{13}C$ SSCC in structural studies.

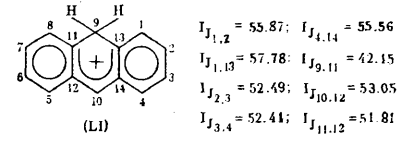
4. Determination of Biosynthetic Pathways

Directly bonded $^{13}C-^{13}C$ SSCC are widely used to determine the biosynthetic pathways for complex natural products.[9,185,186] The selective introduction of the ^{13}C isotope into the precursor molecule not only makes it possible to trace by the NMR method the fate of an individual atom as it passes through a sequence of biochemical reactions *in vivo* but also to determine unambiguously the site where ^{13}C is incorporated and to establish the structure of the compounds formed by the method for tracing out the carbon skeleton.

For example, the use of directly bonded $^{13}C-^{13}C$ SSCC makes it possible to establish, in the biosynthesis of vitamin B_{12}, the chain of successive transformations of intermediate precursors—sirohydrochlorin (XLVIII)—urogen-III (XLVI) derivatives.[187,188] The structure (L) had been attributed earlier erroneously to compound (XLIX).

The majority of studies concerning the use of $^1J_{CC}$ for the determination of biosynthetic pathways were based on the investigation of microbial metabolites enriched in [1,2-$^{13}C_2$]-acetate in the biosynthetic process. The earliest example of such investigations dates back to 1973: the incorporation of [1,2-$^{13}C_2$]acetate in dihydrolatumcidin.[189] The principles underlying the above study are widely used nowadays. In connection with the devlopment of the methods of synthesis of compounds enriched in the ^{13}C isotope, the most varied ^{13}C-labelled precursors, such as, for example, [U-$^{13}C_6$]-D-glucose,[190] [3,5-$^{13}C_2$]-L-tyrosine and [1,2-$^{13}C_2$]glycine,[191] [4,5-$^{13}C_2$]lysine,[192] [3,4-$^{13}C_2$]glutamate,[193] [1,2-$^{13}C_2$]propionate,[194] [2,3-$^{13}C_2$]succinate,[195,196] [5,6-$^{13}C_2$]nicotinic acid,[197,198] and certain others[199,200] have been used with increasing frequency in recent years.

The structures of about 300 most important products of the metabolism of animals and plants—polyketides, mixed metabolites, terpenes and steroids, aminoacids, and amino-acid metabolites—have now been determined with the aid of the $^1J_{CC}$ constants.



---o0o---

During the preparation of the manuscript for printing, a number of studies dealing with the improvement of methodological procedures for the experimental measurement of $^{13}C-^{13}C$ SSCC, relating to problems of increasing the sensitivity of the basic INADEQUATE method in its one-dimensional and two-dimensional versions, the compensation for non-resonance effects, the development of new pulse sequences, and also for the elucidation of the possibility of measuring directly bonded $^{13}C-^{13}C$ dipole–dipole SSCC in the ^{13}C NMR spectra of solids have been published.[201–208]

The studies of the stereospecificity of the $^{13}C-^{13}C$ SSCC with respect to the orientation of the unshared electron pairs of heteroatoms (nitrogen[209,210] and oxygen[211–213]) have continued. The new experimental data confirm the conclusion that the additional contributions of the unshared pairs of these heteroatoms to the $^{13}C-^{13}C$ SSCC for neighbouring bonds are positive.

The structures of α-longipinene (a sesquiterpene),[214] the product of the cyclisation of the sesquiterpene hydrocarbon caryophyllene,[215] 1-methoxy-*endo*-tetracyclo[6.3.0.$0^{2,11}$.$0^{3,7}$]-undec-9-ene—the product of the photochemical cycloaddition of anisole to cyclopentene,[216] and the complex condensed heterocycle benzo[*b*]phenanthro[4,3-*d*]thiophen have been determined using the methods for tracing out the carbon skeleton, and their signals in the ^{13}C NMR spectra have been fully assigned.

There has been significant progress in studies on the $^{13}C-^{13}C$ SSCC for charged systems—carbonium ions of the bis-homotropylium type,[218] α-cyanodiaryl- and 1,1-diaryl-2-butynyl cations,[219] and also six-membered heteroatomic cations—the pyrylium, thiapyrylium, and seleninium ions.[220] In the last study,[220] the fundamental conclusion was reached that the lower values of $^1J_{CC}$ for positively charged systems compared with their neutral analogues can be accounted for by charge polarisation. This conclusion has been confirmed by the results of a unique experiment involving the measurement of $^1J_{CC}$ (Hz) for the anthracenium cation (LI) with the natural isotopic abundance.[221]

Progess has been noted in the theoretical study of $^{13}C-^{13}C$ SSCC. In this connection, special mention should be made of the study of Fronzoni and Galasso concerning the use of the non-empirical *ab initio* method to calculate $^1J_{CC}$ for monoheterocyclopropanes and cyclopropenes.[222] The work on the creation of a set of quantum-chemical programs IPPP RPA INDO (Inner Projections of the Polarisation Propagator at the Random Phase Approximation level using the INDO method), which makes it possible to investigate the mechanisms of the transfer of individual contributions to $^{13}C-^{13}C$ SSCC (fermi-contact, spin–orbital, and dipole–dipole) via bonds, individual molecular orbitals (including antibonding orbitals), and unshared electron pairs of heteroatoms is being completed.[223]

The work on the compilation of extensive experimental data has been completed and a survey of $^{13}C-^{13}C$ SSCC for the triple bond in a series of organoelemental and heteroatomic derivatives of acetylene is being prepared for printing.[224] Directly bonded $^{13}C-^{13}C$ SSCC have been used[225–232] for the solution of specific structural problems in the chemistry of saturated and carbocyclic, unsaturated, and aromatic, as well as heterocyclic compounds having different structures.

Metal Carbonyl Catalysts of the Synthesis of Organic Compounds from Carbon Monoxide and Molecular Hydrogen

A.L.Lapidus and M.M.Savel'ev

Studies on the synthesis of organic compounds from carbon monoxide and hydrogen in the presence of catalysts obtained by the thermal decomposition of metal carbonyls on inorganic carriers are examined. The characteristic features of the interaction of various metal carbonyls with the carriers and the mechanisms of the formation of the metal carbonyl catalysts are discussed. The bibliography includes 165 references.

CONTENTS

I. Introduction 17

IV. Conclusion 25

I. INTRODUCTION

The catalytic syntheses based on carbon monoxide and hydrogen constitute the basis of industrial methods of preparation of hydrocarbons and also of a number of oxygen-containing products. A vigorous search for active and selective catalysts capable of effecting these promising processes, which make it possible to obtain valuable compounds, including the components of motor fuels based on a non-petroleum raw material, is being vigorously prosecuted at the present time in our country and abroad.[1]

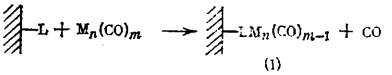
A new trend in this field involves the application of catalysts based on metal carbonyls. These catalysts can be divided into three main groups: the metal carbonyl systems proper, usually employed under the conditions of homogeneous catalysis, heterogenised complexes of transition metals, and catalysts obtained by depositing metal carbonyls on carriers with their subsequent decomposition. The application of catalysts of the first two types in the synthesis of hydrocarbons from CO and H_2 has been described in detail by the present authors[2] and their application in the synthesis of oxygen-containing compounds has been described by Dombek.[3]

The present review deals with catalysts of the synthesis of organic compounds from CO to H_2 obtained by decomposing metal carbonyls deposited on various carriers. The first studies on these lines were carried out 8–10 years ago. The number of publications devoted to this problem has continuously increased in recent years.

II. THE INTERACTION OF METAL CARBONYLS WITH THE SURFACES OF CARRIERS

The decomposition reactions of metal carbonyls on carriers and the catalyst formation reactions have been examined in a review.[4] Certain data concerning the mechanism of the interaction of metal carbonyls with inorganic carriers and also the catalytic properties of systems obtained by decomposing deposited metal carbonyls have been published.[4-6]

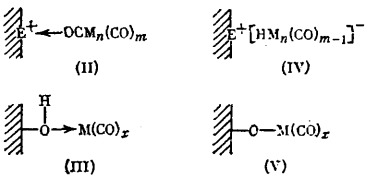
Inorganic carriers such as Al_2O_3, SiO_2, MgO, TiO_2, aluminosilicates, and zeolites are normally used to prepare the metal carbonyl catalysts. In certain cases the surfaces of the carriers are modified by functional groups (NR_2, PR_2, etc.) which are capable of being coordinated to the transition metal.



Two methods of synthesis of metal carbonyl catalysts are most widely used.[4] The first is based on the impregnation of the carrier with a solution of the carbonyl complex, usually in an organic solvent, with subsequent drying of the catalyst. In this case it is possible to obtain catalysts with any metal content, but at a high metal concentration the structures of the surface complexes obtained are as a rule inhomogeneous.

The second method is based on the adsorption of the metal carbonyl on the surface of the carrier from the gas phase or an organic solvent. Here the maximum content of the transition metal in the catalyst is determined by the adsorption capacity of the surface of the carrier used. In this instance the structure of the surface complex formed is more homogeneous.

Both methods of synthesis of the metal carbonyl catalysts are fairly universal and can be employed for virtually any types of carbonyl complexes as well as carriers.



In a general form, the interaction of carbonyl complexes with the carrier surface can be described by the following schemes.[7]

(1) The substitution of CO or another ligand in the coordination sphere of the carbonyl complex by a functional group of the modified carrier:

(I)

(2) The interaction of the carbonyl complex with Lewis (E^+) or Brønsted centres on the surface of the unmodified oxide carrier with formation of various immobilised complexes:

(II) (IV) (III) (V)

Account must be taken of the fact that the interaction of the complexes with the carrier surfaces is described only approximately by the schemes presented above. The carbonyl complexes of transition metals readily react with acid or basic agents and the carrier surfaces as a rule contain a wide range of the corresponding functional groups. There is therefore a possibility of the parallel chemisorption of metal carbonyls on various surface centres with formation of several types of structures.

The interaction with a carrier may be accompanied by the decomposition of the carbonyl cluster or, conversely, by the formation of polynuclear cluster structures from mononuclear complexes. The occurrence of such processes greatly complicates the selective preparation of complexes of a specific type fixed on the carrier surface.

It must be emphasised that the direct interaction of the complexes with the active centres on the surface is of decisive importance only when the number of molecules of the carbonyl complex is comparable to the number of chemisorption centres on the carrier surface, i.e. virtually only for "low percentage" deposited metal catalysts. Otherwise the process is complicated still further as a consequence of the physical absorption of the carbonyl complexes on the outer surface and in particular within the carrier pores.

It is known[6] that the number and ratio of the Lewis and Brønsted centres on the surfaces of inorganic carriers depends greatly on the conditions of their preliminary treatment. Therefore, depending on the methods of preparation from the same initial reagents, it is possible to obtain catalysts having a different structure of the surface carbonyl complexes. IR spectroscopy is usually employed together with other physicochemical methods to investigate the mechanism of the interaction of carbonyl complexes with carriers and also the structures of the surface complexes produced.[4,6]

Account must be taken of the fact that the catalytic properties of the given systems have been studied to the greatest extent in reactions at temperatures below 200 °C (hydrogenation, isomersation, metathesis of olefins, etc.), for which a partial or complete decompostion of the surface carbonyl complexes does not occur. On the other hand, the syntheses of organic compounds from CO and H_2 normally require the application of higher temperatures. Therefore, after the deposition of the metal carbonyl on the carrier, the catalyst is in this case subjected to a preliminary heat treatment (*in vacuo* or in an atmosphere of CO, H_2, He, or a mixture of gases) in order to carry out a complete or partial decomposition of the complex and to form deposited metal particles (in an oxidised or reduced state). However, we may note that the carbonyls decompose also in the initial stages of the synthesis of CO and H_2 directly in the atmosphere of the synthesis gas.

1. Group VI Metal Carbonyls

The thermal decomposition of Group VI metal carbonyls has been investigated[9–31]) on various inorganic carriers by IR,[9–11,14,17,19,25,26,30] EPR,[10–12,19,21,22,27,28] NMR,[18] and XPE† spectroscopy[15] and by the thermoprogrammed decomposition method[13,16,20,21,23,31] (Table 1). The formation on chemisorption of the carbonyls of the surface complexes $M(CO)_5$ (ads), which exist at 20–40 °C [structure (III)][9,10] may be included among the general features of the given process. At temperatures of about 100 °C, the subcarbonyl species $M(CO)_3$(ads) are formed on the Al_2O_3 surface from molybdenum and tungsten carbonyls.[10,18–21] Such complexes have not been observed on the SiO_2 surface.[13] It has been suggested[14] that the stability of the subcarbonyl species increases with decrease in the acidity of the surface OH groups of the carrier. At 200 °C and above the carbonyl complexes decompose irreversibly with formation of oxidised forms of the metal.

In the general case the decomposition of the Group VI metal carbonyls on Al_2O_3 can be represented by the scheme[10,19]

$$M(CO)_6 + Z{-}OH \xrightarrow[-CO]{60^\circ} (Z{-}OH)M(CO)_5 \xrightarrow[-CO]{100^\circ} \rightarrow (Z{-}OH)_x M(CO)_3 \xrightarrow[-CO]{200^\circ} (Z{-}O^-)_x M^{x+} + H_2$$

This scheme includes the chemisorption of the metal carbonyls on the carrier surface, partial decarbonylation with formation of subcarbonyls at higher temperatures, and finally the complete decarbonylation and oxidation of the metal by the protons of the surface OH groups. The carriers (SiO_2, Al_2O_3) employed in the above studies were as a rule subjected to a preliminary vacuum treatment at temperatures of about 400 °C. If Al_2O_3 is subjected to a preliminary heat treatment at 950 °C, the interaction of the carbonyl with the surface proceeds differently: the decomposition of the carbonyl at temperatures above 200 °C leads to the formation of metallic molybdenum[21,23,24] or tungsten.[31] This has been explained by the appreciable decrease in the concentration of the surface OH groups in the course of the preliminary high-temperature treatment of the carrier, which stabilises the metal in the reduced state.

Table 1. The state of the metals in the thermal decomposition of chromium, molybdenum, and tungsten carbonyls on different carriers.

Initial carbonyl	Carrier	*T*, °C	State of the metal
$Cr(CO)_6$	Al_2O_3 [9,10], SiO_2 [9]	20—40	$Cr(CO)_5$ (ads.)
	Al_2O_3 [10,11], SiO_2 [12,13]	200	Cr^{2+}, Cr^{3+}
$Mo(CO)_6$	Al_2O_3 [9,14—19], SiO_2 [9]	20—40	$Mo(CO)_5$ (ads.)
	Al_2O_3 [14—16, 18—21]	100	$Mo(CO)_3$ (ads.)
	Al_2O_3 [11,14, 19—24], SiO_2 [13,14, 22,25], MgO [14], HY zeolite [26-29]	200	Mo^{3+}, Mo^{5+}
	Al_2O_3* [21,23,24], NaY [26,27]	200—500	Mo^0, Mo^{2+}
$W(CO)_6$	Al_2O_3 [9,10], SiO_2 [9,30]	20—40	$W(CO)_5$ (ads.)
	Al_2O_3 [10,31]	100	$W(CO)_3$ (ads.)
	Al_2O_3 [10,11,31], SiO_2 [12,13]	200	W^{4+}, W^{6+}
	Al_2O_3* [31]	>200	W^0

*Al_2O_3 dehyrated at 950 °C.

Analogous results have been obtained in the study of Mo-zeolitic catalysts. The decompostion of $Mo(CO)_6$ adsorbed on a type HY zeolite leads to the formation of oxidised forms of molybdenum.[26–29] On the other hand, an NaY type zeolite, containing a smaller number of OH groups, stabilises molybdenum in the zerovalent state.[26,27]

The degree of dispersion of the active component has a considerable influence on the catalytic properties of the deposited systems. Unfortunately the degree of dispersion of the metal has been determined only in a few studies. The decomposition of $Mo(CO)_6$ deposited on Al_2O_3, subjected to a preliminary heat treatment at 950 °C, leads to the formation of Mo clusters 40 Å in diameter with an overall formal charge on the metal of +0.3.[23] In contrast to metallic molybdenum, these particles do not absorb nitrogen. The authors suggest that, in the course of the decomposition of the molybdenum carbonyl on the carrier surface, Mo^{2+} ions are formed initially and then become centres for the crystallisation of zerovalent molybdenum. Such electron-deficient molybdenum clusters differ in their properties from metallic molybdenum.[23] These differences can be caused also by the different degrees of dispersion of the metal on the catalyst surface.

Thus catalytic systems containing reduced molybdenum and tungsten can be obtained by decomposing molybdenum and tungsten carbonyls on Al_2O_3 or a type NaY zeolite.

†X-Ray photoelectron spectroscopy (Ed. of Translation)].

It must be emphasised that such systems cannot be obtained from inorganic molybdenum and tungsten compounds by their reduction with hydrogen.

2. Iron Carbonyls

Numerous studies have been devoted to the interaction of complexes of iron carbonyls with the carrier surface and also to the decomposition of the surface complexes in order to obtain iron catalysts[32–57] (Table 2). The special interest in systems of this kind is due to the fact that the iron catalysts are used in industrial syntheses of hydrocarbons from CO and H_2, the synthesis of ammonia, the preparation of hydrogen, etc. IR,[32,33,35,36,38,41–43,46,47,52,54] EPR,[33,41] UV,[38,39,52] NMR,[34] and Mössbauer spectroscopy[40,41,43,55,57] and the thermoprogrammed decomposition method[39,41,42,44,50,51] are used to investigate the deposited iron carbonyl system. Since the iron carbonyl complexes are unstable in air, the systems are studied *in vacuo* or in an inert gas atmosphere.

Table 2. The state of the metal in the thermal decomposition of iron carbonyls on different carriers.

Initial carbonyl	Carrier	T, °C	State of the metal
$Fe(CO)_5$	Al_2O_3 (Refs.32, 33), MgO (Ref.32), HY zeolite (Ref.34–36), NaY zeolite (Refs.35–37)	20—40	$[HFe_3(CO)_{11}]^-$ or cluster Fe carbonyls
$Fe_2(CO)_9$	NaY zeolite (Ref.38)	20—40	»
$Fe_3(CO)_{12}$	Al_2O_3 (Refs.32, 33, 39), MgO (Refs.32, 40, 41), HY and NaY zeolites (Ref.42), SiO_2 (Ref.39), aluminosilicate (Refs. 43, 44)	20—40	»
$K_2[Fe_3(CO)_{11}]$	Al_2O_3 (Ref.45)	20—40	»
$Fe(CO)_5$	MgO* (Ref.46)	20—40	$[Fe(CO)_4]^{2-}$
$K_2[Fe(CO)_4]$	Al_2O_3 (Refs.47–49), SiO_2 (Refs.47, 48)	20—40	»
	Al_2O_3 (Refs.50, 51); MgO (Ref.46); HY and NaY zeolites (Refs.35–37, 42, 52), TiO_2 (Refs.4, 53)	40—200	$[Fe(CO)_{1-3}]_x$ (ads.)
$Fe(CO)_5$, $Fe_2(CO)_9$, $Fe_3(CO)_{12}$	Al_2O_3 (Ref.54), HY zeolite (Refs.34–36, 42), TiO_2 (Ref.53), aluminosilicate (Refs.43, 44, 56)	100—300	Fe^{2+}, Fe^{3+}
	Al_2O_3 (Ref.33, 39, 47, 50, 51, 54, 55) MgO (Ref.40)	100—300	Fe^{2+}, Fe^0
	MgO* (Ref.46), NaY zeolite (Refs.35, 36, 42), graphite (Ref.37)	100—300	Fe^0

*MgO dehydrated at 800 °C.

The iron carbonyl complexes are extremely reactive. Their distinctive feature, compared with Group VI metal carbonyls, is their ability to form stable cluster structures on the carrier surface. The mechanism of the interaction of iron carbonyls with the surfaces of inorganic carriers is complex. However, it is possible to note a number of common features characteristic of these systems.

The interaction of $Fe(CO)_5$, $Fe_2(CO)_9$, and $Fe_3(CO)_{12}$ with oxide carriers leads to the formation of carbonyl clusters containing three or four iron atoms on the surface.[32–44] Mononuclear complexes of the type $[Fe(CO)_4]^{2-}$ have been identified only for MgO dehydrated at 800 °C [46] and on Al_2O_3 promoted with potassium.[47–49]

It has been suggested[32,38–42] that iron carbonyls are chemisorbed on the carrier with formation of structures of types (II) and (III). As a result of this interaction, the mononuclear iron carbonyls trimerise with formation of carbonyl clusters. The stabilisation of the mononuclear complexes on MgO and Al_2O_3 is apparently caused by the appreciable decrease in the concentration of the surface OH groups as a result of the preliminary treatment or modification of the carrier.[46–49] Thus, regardless of the type of carriers and also the initial iron carbonyls, complexes having cluster structures are stabilised on the surface in most cases.

The study of the thermal decomposition of the surface carbonyl complexes *in vacuo* or in an inert gas atmosphere showed that, up to 200 °C, stable subcarbonyl species exist on the carrier surface (Table 2). The structure of these surface complexes has been studied inadequately. They are formed on decarbonylation of the initial complexes and in certain cases the process is reversible. Treatment with carbon monoxide regenerates the initial carbonyl complexes on the carrier surface.[34,37,42,43,46] Thus one of the characteristic features of the decomposition of iron carbonyls on carriers is the intermediate formation of relatively stable subcarbonyl species. The main decarbonylation product is carbon monoxide.[33,34,42,43,50,57]

Further decarbonylation at higher temperatures leads to the irreversible decomposition of the subcarbonyl species with formation of oxidised or reduced forms of iron. Together with CO, H_2 and traces of hydrocarbons are evolved under these conditions. The formation of H_2 is explained by the interaction of zerovalent iron with the protons of the surface OH groups:[34,42,50,57]

$$2Z{-}OH + Fe^0 \rightarrow (Z{-}O^-)_2Fe^{2+} + H_2 .$$

From this it follows that the ratio of the oxidised and reduced forms of iron in the deposited iron carbonyl catalyst is determined mainly by the nature of the carrier, i.e. by the properties of the surface OH groups, and also by the ratio of these groups and the active component.

The decomposition of iron carbonyls on the HY zeolite leads to the oxidation of iron to Fe^{2+}, while the NaY zeolite mainly stabilises iron in the zerovalent state.[35,36,42] Graphite has no surface OH groups and the oxidation of iron is therefore not observed on decomposition of $Fe(CO)_5$ on this carrier.[57] It has been shown that, with increase in the MgO dehydration temperature, the fraction of reduced forms of iron increases.[40,41,46] The authors explain this by the decrease in the concentration of surface OH groups during the preliminary heat treatment.

A decrease in the concentration of surface OH groups is also caused by the treatment of Al_2O_3 with potassium hydroxide.[58] It has been shown[54,55] that an increase in the fraction of the reduced forms of iron in the catalyst obtained with increase in the potassium content is observed in the decomposition of iron carbonyls deposited on Al_2O_3 subjected to a preliminary treatment with KOH.

We shall consider the available few data concerning the influence of the nature of the carrier on the degree of dispersion of the catalyst formed. Iron particles 40–50 Å in size have been obtained in the decomposition of the same iron carbonyl complex on Al_2O_3 and particles 140 Å in size have been obtained on SiO_2.[47] Particles of the active component 20–90 Å in size have been detected after the decomposition of iron carbonyls on Al_2O_3 [33] and MgO.[40] It has been established that catalysts containing more highly dispersed particles are formed on decomposition of $Fe(CO)_5$ on Al_2O_3 than in the reaction using $Fe_3(CO)_{12}$.[50,51] An increase

in the decomposition temperature of the carbonyl complexes decreases the degree of dispersion of the iron particles obtained on Al_2O_3 or graphite.[50,51,57] The synthesis of hydrocarbons from CO and H_2 on an iron carbonyl catalyst has a considerable effect on the degree of dispersion of the iron particles. After such synthesis at 270 °C at atmospheric pressure, the size of the iron particles obtained by decomposing $Fe(CO)_5$ on Al_2O_3 increased by a factor of 10–25 (to 200–500 Å).[33]

Thus the degree of dispersion of the active component in the catalyst obtained by decomosing iron carbonyls on carriers depends on a series of parameters (the conditions in the decomposition of the carbonyl complexes, the nature of these complexes, and the properties of the carrier). At the same time we may note that the carbonyl systems are characterised by a higher degree of dispersion, which is a general feature of distinguishing them from the deposited catalysts obtained from inorganic iron compounds.[53]

3. Ruthenium and Osmium Carbonyls

The ruthenium and osmium carbonyl complexes frequently manifest common properties in their interaction with the surfaces of oxide carriers and also on heat treatment[59–87] (Table 3). These systems have been investigated by the IR,[44,59–68,71–85,87] UV,[65,79] and EPR spectroscopy[86] and by the thermoprogrammed decomposition method.[44,59,64,73,77]

Table 3. The state of the metal in the thermal decomposition of ruthenium and osmium carbonyls on different carriers.

Initial carbonyl	Carrier	T, °C	State of the metal
$Ru_3(CO)_{12}$*	Al_2O_3 (Refs.59-65), SiO_2 (Refs.44, 59, 61-63, 65, 66) MgO (Ref.60), TiO_2 (Ref.61), NaY zeolite (Refs.62, 63)	25–100	$[HRu_3(CO)_{10}]$ $(OM\lessdot)$ or cluster Ru carbonyls
	Al_2O_3 (Refs.59, 61, 64, 65, 67), SiO_2 (Ref.61), TiO_2 (Ref.61)	~100	$Ru^{II}(CO)_2(OM\lessdot)_2$
	Al_2O_3 (Refs.59-64, 65, 67-72), SiO_2 (Refs.44, 59, 61-63, 65, 66), TiO_2 (Ref.61), NaY zeolite (Refs.62, 63)	>100	Ru^0, Ru (ox.)
$Os_3(CO)_{12}$**	Al_2O_3 (Refs.73-83), SiO_2 (Refs,71, 73-75, 80), MgO (Refs.84, 85), TiO_2 (Refs.73-75, 80), ZnO (Ref.75)	25–100	$[HOs_3(CO)_{10}]$ $(OM\lessdot)$ or cluster Os carbonyls
	Al_2O_3 (Refs.75-77, 81, 83, 86), SiO_2 (Refs.71, 75), MgO (Ref.85), TiO_2 (Ref.73), ZnO (Ref.75)	200–400	$Os^{II}(CO)_2(OM\lessdot)_2$
	Al_2O_3 SiO_2 (Refs.73, 74, 79, 80), TiO_2 (Refs.73, 74, 80)	200–300	Os_{12} carbonyl clusters
	Al_2O_3 (Refs.81, 87)	300	Os^0, Os (ox.)

*In Refs.59 and 60, the initial carbonyl was $H_4Ru_4(CO)_{12}$.
**In Refs.71, 73, and 74, the initial carbonyl was $Os_6(CO)_{18}$.

At temperatures up to 100 °C, the ruthenium clusters retain their structure on the surfaces of certain inorganic carriers. However, on SiO_2 and Al_2O_3 they acquire a structure of the type $[HRu_3(CO)_{10}](OM\lessdot)$.[59,61,66] A structure of type (IV) is obtained on the more basic MgO carrier.[60]

It has been shown[59] that the amount of $Ru_3(CO)_{12}$ chemisorbed on Al_2O_3 is proportional to the concentration of surface OH groups, which depends in its turn on the temperature of the preliminary treatment of the carrier.

At higher temperatures, partial decarbonylation of the surface complexes with formation of stable subcarbonyl species, apparently of the cluster type, is observed on Al_2O_3. Such species have not been detected[59] on SiO_2 but it has been established[61] that subcarbonyls are formed. The oxidation state of ruthenium in such surface complexes, formed on Al_2O_3 and SiO_2, changes from 0 to +4.[59,61,64–68] The cluster $[Ru_6C(CO)_{16}]^{2-}$ is formed on MgO.[60]

Above 100 °C, the subcarbonyl decomposes with formation of oxidised or reduced forms of ruthenium.[72] It is noteworthy that this process is reversible—treatment of the catalysts with CO at 200 °C regenerates the initial subcarbonyl, which apparently indicates a high degree of dispersion of ruthenium on the carrier surface and possibly the retention of the cluster structure of the "residues" of the complex.[59,61,69] It has been established[64,67,68] that, on decomposition *in vacuo* of the ruthenium carbonyls deposited on Al_2O_3, ruthenium produces less reduced but more highly dispersed particles than on decomposition of the above carbonyls in an H_2 atmosphere.

The degree of dispersion of ruthenium in the catalysts obtained has been determined[63,66,69,70] from the degree of adsorption of H_2 or CO. It has been shown[69,70] that the degree of dispersion of the catalyst obtained by decomposing $Ru_3(CO)_{12}$ on Al_2O_3 is four times higher than for the analogous sytems based on $RuCl_3$. Particles 20–40 Å in size have been detected on the surfaces of the latter. The size of the ruthenium crystallites obtained as a result of the decomposition of $Ru_3(CO)_{12}$ on Al_2O_3,[69] SiO_2,[66] and the NaY zeolite[63] does not exceed 10–14 Å.

The structure of the surface complexes formed as a result of the adsorption of $Os_3(CO)_{12}$ on carriers is the same as for the surface ruthenium carbonyls.[71,75–77] However, the deposited osmium carbonyls are more stable and their decomposition requires higher temperatures. At the present time there is no single view concerning the structure of osmium subcarbonyls on the Al_2O_3, SiO_2, MgO, and TiO_2 surfaces. It has been suggested[71,75–77,81,83,85] that mononuclear species of the type $Os^{II}(CO)_{2-3}$(ads.) are stabilised on the carrier surface. On the other hand, it has been concluded[73,74,79,80,84] that the subcarbonyls formed have a cluster structure and that they incorporate up to 12 osmium atoms. Such differences have been explained[73] by the different preliminary types of treatment of the carrier. It has been suggested that osmium carbonyl clusters are stabilised on carriers dehydrated to a high degree and that a high concentration of surface OH groups leads to the dissociation of the Os–Os bonds and the formation of mononuclear species. Further studies are necessary in order to establish reliably the structure of the subcarbonyl species and also the factors which determine the latter.

Osmium subcarbonyls on the Al_2O_3, SiO_2, TiO_2, and MgO surfaces are distinguished by a high stability and do not decompose *in vacuo*, in an inert gas atmosphere, or in an atmosphere consisting of a mixture of CO and H_2 even at 300–400 °C.[75,76,84–86] However, the formation of metallic osmium has been observed after the treatment of the catalyst in an H_2 atmosphere at 300 °C.[81]

It has been suggested[75,84–87] that the degree of dispersion of osmium in the catalysts investigated is very high and that its distribution is close to being molecular.

Having compared the ways in which iron, ruthenium, and osmium carbonyls interact with the surfaces of inorganic carriers, one may conclude that the formation of surface carbonyl complexes with a cluster structure is characteristic of all these systems. Their thermal stability increases in the sequence Fe < Ru < Os. In certain cases,[75,82,84] surface

osmium carbonyls are detected in the catalyst after the synthesis from CO and H_2 at atmospheric pressure and temperatures in the range 300–400 °C.

4. The Carbonyls of Other Group VIII Metals

The interaction of cobalt, rhodium, and iridium carbonyls with inorganic carriers has been little studied. It has been demonstrated by IR spectroscopy that tetranuclear cluster carbonyls are formed on the Al_2O_3, SiO_2,[88–92] MgO, TiO_2, and ZrO_2 [90] surfaces, The structures of these complexes apparently correspond to structure (III). On the other hand, it has been found that[93] $Co_3(CO)_9CH_3$ disproportionates on the surfaces of Al_2O_3, SiO_2, or the NaY zeolite with formation of Co^{2+} and $[Co(CO)_4]^-$ and that the carriers can be arranged in the following sequence in terms of the rate of this reaction: Al_2O_3 > NaY > SiO_2.

The study of the thermoprogrammed decomposition of cobalt carbonyl complexes on Al_2O_3 and SiO_2 showed[88,89,91] that, up to 100–150 °C, the relatively stable subcarbonyl complexes exist on the surface. At higher temperatures these species decompose irreversibly with formation of metallic cobalt and its oxidised forms.[89–92,94,95]

The degree of dispersion of the active component on the carrier surface depends on the conditions in the preparation of the catalyst and also on the nature of the carrier. An increase in the rates of temperature rise during the decomposition of surface carbonyl complexes leads to the formation of more dispersed catalysts.[92,94] The cobalt particles size on SiO_2 is greater than on Al_2O_3 and TiO_2. In certain cases it is possible to obtain systems containing cobalt crystallites 20–50 Å in size.[92] The lower degree of dispersion of the Co/SiO_2 catalysts has been explained[92] by the weak bond between the carbonyl complexes and the surface. Modification of the SiO_2 surface by titanium hydride complexes promotes the growth of the degree of dispersion of the metal in the cobalt catalysts.[96]

As in the case of cobalt carbonyls, the interaction of rhodium carbonyls with the SiO_2 surface does not alter the structure of the initial complexes.[97–99] On the other hand, the adsorption of $Rh_4(CO)_{12}$, $Rh_6(CO)_{16}$, or $[Rh(CO)_2Cl]_2$ on Al_2O_3 from the gas phase or an organic solvent followed by treatment with CO leads to the formation of only the one complex $Rh_6(CO)_{16}$ on the surface.[97,99,100] In the interaction of $Rh_6(CO)_{16}$ with Al_2O_3 or MgO, the surface mononuclear carbonyl $Rh^I(CO)_2$ (OM–) (here M = Al or Mg) was identified by IR spectroscopy.[101,102]

At 100–200 °C *in vacuo* or in an H_2 atmosphere, the surface rhodium carbonyls decompose with formation of metal crystallites[100,103,104] whose size is close to 10 Å.[103] In the course of the decomposition of rhodium carbonyls on carriers, the intermediate formation of subcarbonyl surface complexes was discovered.[95,98,102,104,105] In contrast to pure H_2, in the presence of a mixture of CO and H_2, the surface carbonyl complexes are present together with metallic rhodium on the ZnO surface even at 400 °C.[104]

The interaction of $Ir_4(CO)_{12}$ with Al_2O_3 and SiO_2 has been investigated[106,107] by IR spectroscopy. At 20–100 °C the carbonyl is physically adsorbed on the carrier surface, to a lesser extent on SiO_2 than on Al_2O_3. Iridium carbonyl decomposes on carriers *in vacuo* at 100–200 °C with the intermediate formation of subcarbonyl mononuclear species of the type of $Ir(CO)_2$(ads.).[107] On raising the temperature to 300 °C, the surface iridium complexes are converted irreversibly into metallic iridium. Oxidised forms of iridium are then also formed on Al_2O_3 under these conditions and are reduced to the metal on treatment with H_2 at 300 °C.[108,109] According to Anderson and Howe,[108] the size of the iridium crystallites is approximately 10 Å, while Tanaka et al.[109] state that species incorporating about 20 iridium atoms are formed.

It has been established by IR spectroscopy that a complex of the type $Ni(CO)_nL_{4-n}$ (n = 2, 3; L = Ph_3P or Al_2O_3) is formed at room temperature as a result of the adsorption of $Ni(CO)_4$ on Al_2O_3 containing Ph_3P.[110] The decomposition of $Ni(CO)_4$ adsorbed on Al_2O_3, HY and NaY zeolites,[111] and NaX and CaX zeolites,[112,113] has been investigated. The size of the metallic nickel crystallites is 500–2000 Å on Al_2O_3 [111] and less than 30 Å on type X zeolites.[113] The decomposition of the carbonyl on zeolites proceeds with the intermediate formation of subcarbonyl complexes with the ratio Ni : CO = 1. It has been suggested[113] that the nickel crystallites are localised within the zeolite cavities and that this prevents the aggregation of the highly dispersed particles.

Highly dispersed platinum catalysts with metallic platinum particle size less than 10 Å have been obtained by decomposing the complexes $[NEt_4][Pt_3(CO)_6]_n$ (n = 1–5) deposited on SiO_2 or Al_2O_3.[114] The carbonyl complexes were decomposed at 160–250 °C *in vacuo* or in an H_2 atmosphere.

The interactions of heterometallic carbonyl clusters with inorganic carriers have been studied in a number of investigations[115–124] in order to obtain highly dispersed bimetallic particles on their surfaces. It has been shown[115] that the interaction of the $H_2RuOs_3(CO)_{13}$ cluster with Al_2O_3 in an atmosphere of CO and H_2 at 100–200 °C results in the formation of the $[H_3RuOs_3(CO)_{12}]^-$ anion on this surface. On the other hand, $H_3FeOs_3(CO)_{13}$ on SiO_2 decomposes at 130 °C in argon, forming metallic iron and $HOs_3(CO)_{10}(O–Si\leq)$.[116] The osmium cluster formed is fully decarbonylated at temperatures above 250 °C with formation of metallic osmium, whose particle size is about 16 Å.[116]

It has been suggested that the decomposition of $Co_2Rh_2(CO)_{12}$ and $Co_3Rh(CO)_{12}$ on ZnO [105,117] and $Co_2Rh_2(CO)_{12}$ on SiO_2 [118] leads to the formation of highly dispersed bimetallic particles. It has been shown[119] that the decomposition of $Co_2Rh_2(CO)_{12}$ or $Co_3Rh(CO)_{12}$ on Al_2O_3 at 400 °C in hydrogen makes it possible to obtain bimetallic clusters in which the ratio of the metals remains approximately the same as in the initial carbonyl complexes. Catalysts of analogous composition, obtained by the deposition of the salts $RhCl_3$ and $CoCl_2$, are much less dispersed.[119]

Bimetallic catalysts containing particles 15–30 Å in size have been obtained from $H_2RhOs(CO)_{10}$(acac) and $H_2FeOs_3(CO)_{12}$ using Al_2O_3 as the carrier.[120]

The decomposition of the carbonyls $Fe_nRu_{3-n}(CO)_{12}$ (n = 1–3) on charcoal leads to the formation of Fe–Ru crystallites whose surface is enriched in iron.[121] The use, instead of the bimetallic cluster, of a mixture of $Fe_3(CO)_{12}$ and $Ru_3(CO)_{12}$ having the same composition altered appreciably the properties of the catalysts.

A similar study of the properties of catalysts obtained by decomposing $Ru_3(CO)_{12}$ on a reduced Pd/SiO_2 catalyst[122–124] showed that at room temperature the carbonyl is adsorbed on the surface and is then partly oxidised. The subsequent reduction of the catalyst with hydrogen leads to the formation of bimetallic Ru–Pd particles whose size is less than 16 Å.

Thus, catalysts containing the reduced metals can be obtained by decomposing transition metal carbonyls on inorganic carriers. It is noteworthy that the decomposition conditions and also the nature of the carbonyl and the carrier influence significantly this process. During the decomposition of almost all metal carbonyls, the formation of intermediates subcarbonyl complexes on the carrier surfaces was observed. At the present time the influence of various factors on the degree of dispersion of the active component in the catalyst obtained has not as yet been adequately elucidated. Nevertheless, there is no doubt that the catalysts

obtained from metal carbonyls are characterised by a higher degree of dispersion than those prepared from inorganic compounds. This is apparently caused by the mild preliminary treatment of the metal carbonyl catalyst. We may note that the metal-deposited systems, prepared by traditional methods, are usually reduced with hydrogen at high temperatures, which leads to the sintering of the metal into large crystallites.

III. SYNTHESIS OF ORGANIC COMPOUNDS FROM CO AND H_2 IN THE PRESENCE OF METAL CARBONYL CATALYSTS

As stated above, deposited metallic catalysts, obtained from metal carbonyls, are distinguished from traditional systems having the same composition by a higher degree of dispersion and a higher degree of reduction of the active component. In particular, metal carbonyl catalysts are therefore characterised by a higher specific activity in the synthesis of hydrocarbons or oxygen-containing compounds from CO and H_2.

The use of polymetallic carbonyl clusters makes it possible to obtain in a number of instances catalysts with unique properties, frequently exhibiting a high selectivity in many chemical reactions.

1. Molybdenum and Tungsten Catalysts

Molybdenum and tungsten carbonyl catalysts, deposited on Al_2O_3 and containing from 1% [20,23,24] to 3–5% [125,126] of molybdenum or tungsten, are used for syntheses from CO and H_2. The activity of the molybdenum catalysts is approximately 5 times greater.[23,24] Comparison of the molybdenum and tungsten carbonyl catalysts with traditional systems of analogous composition has shown that the latter are less active. This has been attributed to the higher degrees of reduction and the greater degree of dispersion of the active component in the carbonyl systems.[23,24,125,126] Preliminary treatment of the carrier before the adsorption of the carbonyl has an appreciable influence on the activity of the molybdenum carbonyl catalyst. In a flow system at atmospheric pressure at 300 °C, the activity of the catalysts based on Al_2O_3 heat-treated at 950 °C is 0.04 mol CH_4 (g-atom Mo)$^{-1}$ s^{-1}, while that for Al_2O_3 heated at 500 °C is 0.001 mol CH_3 (g-atom Mo)$^{-1}$ s^{-1},[23,24] which is apparently due to the lower degree of reduction of molybdenum in the latter case.

The principal products of the synthesis from CO and H_2 in the presence of molybdenum carbonyl complexes at atmospheric pressure are CH_4 and CO_2. Together with the latter, C_2H_6 and C_3H_8 are formed in much smaller amounts.[23,24] A mixture of C_1–C_6 hydrocarbons, with CH_4 and C_2H_6 predominating, has been obtained from CO and H_2 at 25 atm, 350 °C, and a volume flow rate of 1300 h^{-1}.[125] Promotion of the molybdenum carbonyl catalyst with 4% of potassium lowers the activity and increases the fraction of olefins in the synthesis product, whose content does not, however, exceed several per cent.[125] The activity and selectivity of the catalyst remained unchanged during 5–20 h of their use.[23,24,125] A mixture of C_1–C_4 hydrocarbons, with the contents of CH_4 (60%) and C_2H_6 (25%) predominating, has been obtained from CO and H_2 at 350 °C and 25 atm in the presence of a tungsten carbonyl complex based on Al_2O_3.[126]

2. Iron Catalysts

The considerable interest shown by investigators in iron carbonyl catalysts is due to the high selectivity of these systems in the synthesis of light olefins from CO and H_2 and also by the ready availability and low cost of $Fe(CO)_5$. Unfortunately, comparison of the results obtained by different authors is not always possible because different methods are used even for synthesis of catalysts having the same composition. This also applies to the methods of synthesis from CO and H_2.

Iron carbonyl catalysts based on Al_2O_3, SiO_2, MgO, La_2O_3, and MnO exhibit a high selectivity in the synthesis of light olefins from CO and H_2, whose yield can exceed 50% at 170 to 300 °C and 1–10 atm.[33,40,127–129] The greatest fraction is that of C_3H_6, which falls somewhat under the conditions where the catalyst has been used for a long time.[33] At the same time a decrease of the degree of dispersion of the catalyst is observed. On these grounds, the authors[33] concluded that light olefins are synthesised from CO and H_2 on highly dispersed particles of the active component of the catalyst.

At 250 °C, the highest activity is shown by catalysts based on MgO, while those incorporating Al_2O_3, SiO_2, TiO_2, and ZrO_2 are less effective.[130] The composition of the synthesis products in the presence of all these systems is approximately the same. Thus the CH_4 content is 27–37%, while the proportion of olefins in the C_2–C_3 fraction is 72–96%.[130]

The physicochemical and catalytic properties of systems obtained by decomposing potassium carbonyl ferrates on Al_2O_3 and SiO_2 have been studied in detail.[47] A mixture of C_1 and C_6 hydrocarbons, whose olefin content exceeds 50%, is formed in the presence of these systems from CO and H_2 at 270 °C and atmospheric pressure. The degree of conversion of CO was 2–7% on the Al_2O_3-based catalyst and 0.2% on the SiO_2-based catalyst. Catalysts of analogous composition, prepared using inorganic compounds (salts) of iron and potassium, show an activity smaller by a factor of 40–50.[47] The change in the atomic ratio K : Fe in the carbonyl catalysts from 2 to 1 for an overall iron content of 3% tends to increase the activity by a factor greater than 3 with the simultaneous diminution of the yield of olefins and C_5–C_6 hydrocarbons and an appreciable decrease in the activation energies for the methane formation and conversion reactions of CO.[47]

The influence of the conditions of the synthesis from CO and H_2 and also of the composition of the Fe/Al_2O_3 carbonyl catalysts promoted with potassium on its activity and selectivity has been investigated.[45,49,55,131,132] Comparison of the catalysts obtained from $Fe(CO)_5$ [49,132] and $Fe_3(CO)_{12}$ [45,131] showed that, for the same iron and promoting agent contents, they exhibit identical properties in synthesis from CO and H_2. The main products of the synthesis in the presence of these systems at 350–450 °C were CH_4, C_2H_4, C_3H_6, and CO_2. The increase in the iron content in the catalyst from 0.15 to 1.8% for a constant content of the promoting agent (potassium) lowered the fraction of ethylene and propene in the products of the synthesis from 70 to 40% and increased the degree of conversion of CO from 4 to 20%.[132] The Fe–K–Al_2O_3 catalysts containing 7–8% of potassium exhibit the highest activity.[131,132] The increase in the activity of the Fe–K–carbonyl catalyst with increasing content of potassium in the latter has been attributed[55] to the decrease in the fraction of the oxidised form of iron formed on decomposition of the initial carbonyl complexes. The increase in the selectivity of the Fe–K–Al_2O_3 catalyst in the formation of ethylene and propene is favoured by a decrease in the temperature of the synthesis (from 450° to 350 °C), by a decrease in the H_2 : CO ratio (from 4 : 1 to 1 : 3), and also by an increase in the volume flow rate of CO and H_2 (from 15 to 100 h^{-1}).[131]

Type Y zeolites can be used as carriers for iron carbonyl catalysts,[37,42,133] The main products of the synthesis from CO and H_2 under static conditions in the presence of iron catalysts containing the HY, NaY, and CaY zeolites at 1–20 atm and 250–400 °C were C_1–C_4 alkanes and also CO_2.[37,42]

The increase in the iron content from 3 to 8% led to an appreciable growth of the activity of these systems.[37] Mixtures of C_1–C_4 hydrocarbons containing up to 30% of ethylene and propene have been obtained in a flow system in the presence of iron carbonyl catalysts containing the BeY, MgY, CaY, SrY, and BaY zeolites at 1 atm and temperatures in the range 300–400 °C.[133] In terms of their activity in the synthesis of hydrocarbons from CO and H_2, the above catalyst can be arranged in the sequence BaY > SrY > CaY > MgY > BeY. It is the same as the sequence based on the increase in the acid properties of the carriers—type Y zeolites.[133]

Iron carbonyl catalysts of the synthesis of hydrocarbons from CO and H_2 can undoubtedly be of practical value. Analysis of patent literature[48,134–137] shows that effective catalytic systems, based on deposited iron carbonyls and permitting the synthesis of lower olefins from CO and H_2 with a high selectivity, have now been created.

3. Ruthenium and Osmium Catalysts

The properties of ruthenium and osmium carbonyl catalysts in syntheses from CO and H_2 depend greatly on the experimental conditions. As stated above, at temperatures up to 200 °C, these systems are reversibly decarbonylated. Thus, when the synthesis is carried out in the above temperature range, the catalyst surface contains, together with the oxidised and reduced forms of the active component, also cluster carbonyl complexes, which has a definite influence on the activity and selectivity of the above systems.

It has been shown[33,47,48,60] that at 200 °C and 1–20 atm the activity of the ruthenium carbonyl catalyst containing Al_2O_3 is higher than that of traditional systems. At the same time the composition of the hydrocarbons obtained (C_1–C_5) differs insignificantly from that of the product of synthesis in the presence of catalysts prepared from inorganic ruthenium compounds. When ruthenium carbonyls are deposited on MgO, the ruthenium carbonyl cluster persists on the catalyst surface during the synthesis from CO and H_2 and it has been possible to isolate it after the synthesis and to identify as $[Ru_6C(CO)_{16}]^{2-}$.[60] A distinctive feature of such systems is their lower activity and also the high content of olefins in the hydrocarbon mixtures formed (23–28%). At the same time up to 21–27% of C_1–C_2 alcohols are formed.[60] A mixture of C_1–C_6 hydrocarbons containing up to 80% of olefins has been obtained from CO and H_2 at 200 °C and 500 mmHg in the presence of the $Ru_3(CO)_{12}/Al_2O_3$ catalyst.[70] Promotion of the ruthenium carbonyl catalyst with potassium lowers its activity and increases its selectivity in relation to the formation of olefins. The introduction of boron or phosphorus into the catalyst produces the opposite results.[138] The $Ru_3(CO)_{12}/CeO_2$ catalyst, in the presence of which a mixture of hydrocarbons containing 35% of C_2–C_4 olefins was obtained from CO and H_2, has been proposed.[139]

Catalysts active in the synthesis of C_1–C_5 hydrocarbons at 270 °C have been obtained using $Na[HRu_3(CO)_{11}]$. In terms of their activity, these catalysts on different carriers can be arranged in the following sequence of the latter Al_2O_3 > SiO_2 > MgO > TiO_2. Catalysts containing TiO_2 and MgO are the most selective in the formation of ethylene and propene.[140]

At temperatures of about 300 °C and above, methane is formed as the main product from CO and H_2 in the pesence of ruthenium carbonyl catalysts containing SiO_2,[128,141] Al_2O_3, or the NaY zeolite.[141] Methane is also produced selectively from mixtures of CO_2 and H_2 in the presence of the above ruthenium carbonyl systems.

Catalysts obtained by adsorbing $Ru_3(CO)_{12}$ on type NaX, NaY, KL, and NaM zeolites and also SiO_2 have been investigated.[142,143] The metal content in the catalyst was from 0.4 to 1.4%. In terms of their specific activity, the catalysts on different carriers can be arranged in the sequence NaY > NaX > NaM > KL, SiO_2.[142] The activation energy for the conversion of CO in the presence of these catalysts is about 23 kcal mol^{-1}. At 250 °C and 1 atm, the main products of the synthesis were C_1–C_5 hydrocarbons. The $Ru_3(CO)_{12}$/NaY catalysts proved to be the most selective as regards the formation of olefins and made it possible to obtain up to 45% of C_2–C_4 olefins under the conditions indicated. The increase in the temperature of the synthesis from 200° to 340 °C increases the fraction of methane and reduces the olefin/paraffin ratio in the synthesis products.[142] A ruthenium carbonyl catalyst on the HM zeolite has been proposed for the synthesis of C_1–C_7 hydrocarbons, including up to 69% of C_4–C_5 hydrocarbons, from CO and H_2.[144]

There have been only a few studies of the catalytic properties of osmium carbonyl catalysts.[33,80–82,84,87] In particular, the kinetics of the conversion of CO and CO_2 into methane at 180–400 °C has been studied.[80] In terms of their activity these catalysts can be arranged in the sequence SiO_2 > TiO_2 > Al_2O_3 as a function of the carriers used.[80] A mixture of C_1–C_4 hydrocarbons has been obtained in the presence of osmium catalysts based on SiO_2 at 200 °C [33] or on MgO at 300 °C.[84] As for the ruthenium systems, the osmium carbonyl catalysts containing the active component in the metallic state are more active than the catalysts on the surfaces of which the carbonyl complexes are present.[81,82] The introduction of potassium into the osmium carbonyl catalysts[82] increases their selectivity in relation to the formation of olefins.

It has been shown[87] that osmium catalysts based on Al_2O_3 are active in the synthesis of C_1–C_7 alkanes at 250–300 °C and 10 atm. Their activity increases with decrease in the degree of dispersion of the metallic osmium. It has been suggested[87] that the active centres for the synthesis of alkanes are metallic osmium clusters and those for the synthesis of oxygen-containing compounds are carbonyl complexes on the catalyst surface.

4. Cobalt Catalysts

In the presence of cobalt carbonyl catalysts, the main products of the synthesis from CO and H_2 are saturated hydrocarbons with a normal structure. It has been shown[145–147] that the pore diameter in the carrier (Al_2O_3, aluminosilicate) influences decisively the process selectivity: a decreases in the pore diameter shifts the selectivity maximum towards the formation of lighter hydrocarbons without altering the catalyst activity. For example, the main products of the synthesis in the presence of the 2% CO/Al_2O_3 catalyst at 200 °C and with an average carrier pore diameter of 300 nm are C_{14}–C_{20} alkanes, while for an average pore diameter of 6.5 nm the main products are C_4–C_9 alkanes.[147] The authors[147] explain this phenomenon by selective condensation (as a function of the molecular weight) within the catalyst pores of the hydrocarbons formed during the synthesis with their subsequent hydrogenolysis to lighter hydrocarbons. However, these features are valid only for systems in which almost the entire cobalt is present in the catalyst pores, i.e. for catalysts containing small amounts of cobalt (several per cent).

The influence of the nature of the carrier and also of the conditions in the preparation of the cobalt carbonyl catalyst (1–4% CO) on its properties in the synthesis of hydrocarbons for CO and H_2 has been studied in detail.[90–92,94,148–152] It has been shown that,[92,94] when the temperature is raised rapidly in the decomposition of carbonyl complexes, the latter break down with formation of highly dispersed metallic particles on the SiO_2, Al_2O_3, and TiO_2 surfaces. These

catalysts exhibit an activity exceeding by a factor of 2–10 the activity of systems based on inorganic cobalt compounds. If the decomposition is carried out with a slow temperature rise (~1 K min^{-1}), less dispersed catalysts are formed and exhibit a low activity in the synthesis of organic compounds from CO and H_2. The main products of the synthesis using cobalt catalysts on Al_2O_3, MgO, SiO_2, TiO_2, and ZrO_2 containing 1–24% CO are, at 160–180 °C, C_4–C_{22} hydrocarbons with the normal structure.[148] It has been suggested that[148] in this instance α-olefins are intermediates in the synthesis of the alkanes. In terms of their activity the above catalysts can be arranged in the following sequence based on the nature of the carrier: $SiO_2 > TiO_2 > ZrO_2 \geq Al_2O_3 > MgO$.[92]

Cobalt catalysts on TiO_2 and ZrO_2 manifest a high selectivity in relation to the formation of higher molecular weight hydrocarbon fractions.[92,149] An increase in the surface concentration of cobalt and also preliminary partial oxidation of the catalyst with air shift the selectivity maximum towards the formation of heavier hydrocarbons.[149] It is noteworthy that, in the presence of the Co/MgO and Co/Al_2O_3 catalysts, up to 25% of alcohols is formed together with hydrocarbons.[148] It has been concluded[96] that an increase in the degree of dispersion of cobalt lowers the specific activity of the catalyst and increases the fraction of light hydrocarbons as well as oxygen-containing compounds in the synthesis products.

The synthesis of hydrocarbons from CO and H_2 in the presence of cobalt carbonyl catalysts (5–15% Co) has been investigated.[91,150,152] The main products of the synthesis at 180–200 °C and atmospheric pressure were C_5–C_{22} hydrocarbons. The properties of the catalyst were estimated from the yields of the liquid hydrocarbons (B_L) per nm^3 of the mixture with the volume ratio $CO:H_2 = 1:2$ at a volume flow rate of 100 h^{-1}. In the absence of promoting agents, $B_L = 42$ nm^{-3} for the catalyst with 5–7% Co on Al_2O_3 and 28–34 g nm^{-3} for the catalyst with the same metal content on SiO_2.[150–152] Promotion of Co/SiO_2 by metal oxides (MgO, NiO, ZrO_2, and CoO) increases B_L.[151] Thus the introduction of up to 30% of CoO into the 7% Co/SiO_2 catalyst induces a sharp increase in B_L to 83 g nm^{-3}.[151,152] When a high-silica zeolite of the pentasil type is used as the carrier ($SiO_2:Al_2O_3 = 42$), the yields of liquid hydrocarbons are low, but the composition of the synthesis product differs appreciably from that obtained in the presence of the Co/Al_2O_3 or Co/SiO_2 catalysts.[152] The paraffins formed in the presence of the Co-zeolitic catalyst consisted mainly of C_5–C_{14} hydrocarbons and their content of isoalkanes reached 44%. A characteristic feature of these catalysts is also the presence in the synthesis products of small amounts of aromatic hydrocarbons.[152] The properties of cobalt carbonyl catalysts on SiO_2 and Al_2O_3 are appreciably influenced by the conditions in their preliminary treatment and by the gas employed in this process (CO, CO + H_2, Ar). Preliminary treatment of the catalyst with a mixture of CO and H_2 at 150 °C proved to be optimal.[91]

The kinetics of the synthesis of C_1–C_5 hydrocarbons from CO and H_2 in the presence of cobalt carbonyl catalysts (1.2–1.9% Co) has been investigated.[153] At 220 °C and for the ratio $CO:H_2 = 1:3$, the rates of reaction were 2.5×10^{-4} mol CO (g-atom Co)$^{-1}$ s^{-1} in the presence of Co/Al_2O_3 and Co/ZrO_2 and 4.4×10^{-4} mol CO (g-atom Co)$^{-1}$ s^{-1} in the presence of Co/SiO_2.

The activity of the cobalt carbonyl catalyst depends on the structure of the initial cobalt cluster. The catalyst obtained by depositing $Ph_2C_2Co_4(CO)_{12}$ on Al_2O_3 is the most active.[154] It has been established that the catalyst obtained by decomposing $Co_2(CO)_8$ or $Co_4(CO)_{12}$ on SiO_2 fully converts the $CO:H_2 = 1:2$ mixture into methane and CO_2 at 300–450 °C and a volume flow rate of 500 h^{-1}. A highly active cobalt catalyst promoted with palladium or platinum has been proposed for the synthsis of hydrocarbons.[155]

5. Rhodium, Iridium, and Platinum Catalysts

A distinctive feature of deposited rhodium, iridium, and platinum carbonyl catalyst is their high selectivity in relation to the formation of methanol and ethanol from CO and H_2. The catalyst obtained from $Rh_4(CO)_{12}$ and ZnO, CaO, or MgO showed the greatest selectivity in relation to the formation of methanol (91–99%) at 200–220 °C and 1 atm.[156–158] Using TiO_2, ZrO_2, ThO_2, amd CeO_2 as carriers for the rhodium carbonyl catalyst, it is possible to direct the process selectivity towards the predominant formation of ethanol from CO and H_2. Rhodium systems on SiO_2 and Al_2O_3 catalyse the formation of C_1–C_4 hydrocarbons.[33,156–158] It has been suggested[156] that, with decrease in the basicity of the carrier and with increase in its acidity, the selectivity of the catalyst in relation to the formation of oxygen-containing compounds diminishes and that in relation to the formation of hydrocarbons increases. The kinetics of the synthesis of CH_4 and ethanol in the presence of rhodium catalysts has been studied.[153] At 220 °C and for the ratio $CO:H_2 = 1:3$, the rates of reaction were 1.2×10^{-4} (Rh/Al_2O_3), 2.2×10^{-3} (Rh/ZrO_2), and 4×10^{-5} mol CO (g-atom Rh)$^{-1}$ s^{-1} (Rh/SiO_2). For the catalyst on ZrO_2, the rate of formation of methane under these conditions is 10 times greater than the rate of synthesis of ethanol. In the presence of catalytic systems on Al_2O_3 or SiO_2, mainly only hydrocarbons were formed from CO and H_2.[153]

The structure of the initial rhodium carbonyl cluster exerts a significant influence on the course of the synthesis in the presence of rhodium catalysts on La_2O_3.[156,158] Catalysts synthesised from $Rh_4(CO)_{12}$ and $Rh_6(CO)_{12}$ are the most active and selective in relation to the formation of alcohols. A method of synthesis of ethanol from CO and H_2 at 250 °C and 25 atm in the presence of the $Rh_6(CO)_{16}/ThO_2$ catalyst promoted with 1% Eu has been proposed.[159]

Iridium carbonyl catalysts on Al_2O_3 catalyse the formation of C_1–C_4 alkanes at 180–285 °C and 1 atm, the main product being CH_4 (72–78%).[33,47] On the other hand, the formation of methanol as well as methane was observed in the presence of the $Ir_4(CO)_{12}/ZnO$ catalyst.[157]

Catalysts based on cluster platinum carbonyls and ZnO or MgO are characterised by a high selectivity in relation to the formation of methanol (94–99%) at 170–260 °C and atmospheric pressure.[157]

6. Catalysts Based on Bimetallic Carbonyl Clusters

A promising trend in the synthesis of heterogeneous catalysts involves the use of bimetallic transition metal carbonyl clusters in the preparation of new catalytic systems. Polymetallic carbonyl clusters of almost all the Group VIII elements have now been synthesised.[160] The study of catalysts obtained by the thermal decomposition of bimetallic carbonyl clusters on the surfaces of inorganic carriers was initiated several years ago, but results demonstrating the promising nature of this procedure have already been obtained.

Catalysts obtained by decomposing the $H_2FeRu_3(CO)_{13}$ and $Fe_2Ru(CO)_{12}$ clusters and a mixture of $Fe_3(CO)_{12}$ and $Ru_3(CO)_{12}$ on SiO_2 have been tested in synthesis from CO and and H_2 at 250–280 °C and 1–19 atm.[128,161] The catalyst based on $H_2FeRu_3(CO)$, in the presence of which methane is mainly formed from CO and H_2, showed the highest activity. The catalyst based on $Fe_2Ru(CO)_{12}$ was less active but more

selective in relation to the formation of olefins. It is noteworthy that, when the Ru–Fe cluster was replaced by the equivalent mixture of $Fe_3(CO)_{12}$ and $Ru_3(CO)_{12}$, the activity and selectivity of the specimen did not change. On the other hand, the opposite result has been described:[121] the replacement of catalysts obtained by decomposing $Fe_nRu_{3-n}.(CO)_{12}$ ($n = 0-2$) on charcoal by catalyst prepared from the mixture of $Fe_3(CO)_{12}$ and $Ru_3(CO)_{12}$ altered the catalytic properties of the system. The main products of the synthesis in the presence of these systems at 275 °C were C_1-C_4 alkanes.

Effective catalysts for the conversion of CO into methane have been obtained by decomposing the complex $H_2FeRu_3.(CO)_{13}$ on Al_2O_3, SiO_2, or the NaY zeolite.[141]

It has been shown[116] that, in terms of its activity and selectivity in the synthesis of C_1-C_4 hydrocarbons at 250 °C and 1 atm, the $H_2FeOs_3(CO)_{13}/SiO_2$ catalyst occupies an intermediate place between the $Fe_3(CO)_{12}/SiO_2$ and $Os_3(CO)_{12}/SiO_2$ catalysts.

The synthesis from CO and H_2 in the presence of the $H_2FeOs_3(CO)_{13}/Al_2O_3$ catalyst at 270 °C and 10 atm yielded CH_4 (49%), C_2H_6(11%), and $(CH_3)_2O$ (36%).[120] The $H_3CpNi.Os_3(CO)_9/Al_2O_3$ catalyst, active in the synthesis of CH_4 and C_2H_6 from CO and H_2 at 250–350 °C, has been described.[162]

The properties of the catalysts obtained by decomposing the cluster anion $[FeCO_3(CO)_{12}]^-$ depend greatly on the nature of the carrier. When aminated silica gel was used as the carrier,[163] a catalyst for the selective synthesis of light olefins from CO and H_2 at 240 °C and 1–40 atm was obtained. A characteristic feature of this catalytic system is the reduced content of olefins and the shift of the selectivity maximum towards light hydrocarbons with increase in pressure. On the other hand, the decomposition of $[FeCo_3(CO)_{12}]^-$ on SiO_2 promoted with titanium hydride complexes makes it possible to obtain a system which catalyses the formation of methanol (10%) and ethanol (30%) together with hydrocarbons at 180 °C and 1 atm.[164]

The introduction of platinum into the iron carbonyl catalyst greatly increases the activity with retention of a high selectivity in relation to the formation of light olefins.[165] The authors[165] suggest that, under the conditions of the preparation of the catalyst and the synthesis from CO and H_2, the platinum surface is partly coated by iron, which is responsible for the increase in activity.

The properties of catalysts based on $Co_2Rh_2(CO)_{12}$, $Co_3Rh(CO)_{12}$, $Co_4(CO)_{12}$, and $Rh_4(CO)_{12}$ on Al_2O_3, SiO_2, and ZrO_2 have been investigated.[153] At 200–220 °C and for the ratio $CO:H_2 = 1:3$, the main products of the synthesis were methane and ethanol. The bimetallic Co–Rh catalyst occupies an intermediate position between the cobalt and rhodium catalysts as regards activity. An increase in the Co:Rh ratio lowers the rate of conversion into methane and to a lesser extent, the rate of synthesis of ethanol. The maximum selectivity in relation to the formation of ethanol is reached for the ratio $Co:Rh = 1:1$.[153]

A comparative study of catalysts based on $Fe_3(CO)_{12}$ and $[NEt_4]_2[Fe_2Mn(CO)_{12}]$ on various carriers (Al_2O_3, SiO_2, MgO, TiO_2, and ZrO_2) has been carried out.[130] With the exception of the catalyst incorporating MgO, they all yield comparatively little methane and a large amount of heavy hydrocarbons in the synthesis. It is noteworthy that in this respect they differ from the catalysts of analogous composition obtained from iron and manganese nitrates. The authors[130] suggest that the Fe–Mn interaction takes place on the carrier surface also after the decomposition of the metallic cluster, in contrast to systems obtained by the decomposition of nitrates.

The Pd–Ru crystallites have been obtained[124] on the SiO_2 surface by adsorbing $Ru_3(CO)_{12}$ on the Pd/SiO_2 catalysts and by subsequent treatment with hydrogen. An increase in the Pd/Ru ratio drives the synthesis from CO and H_2 towards the preferential formation of methanol and the activity of the catalyst then passes through a minimum.

Thus the use of polymetallic carbonyl clusters for the preparation of catalysts constitutes a promising method of synthesis of highly dispersed catalysts. The fact that the additivity of the properties of the catalysts obtained by the separate deposition of the complexes is not observed in many instances, which indicates the possibility of the interaction of transition metals also after the decomposition of the carbonyl clusters, merits special attention.

IV. CONCLUSION

The synthesis of organic compounds from CO and H_2 is a complex and in most cases a multistage process incorporating consecutive and parallel reactions, the key stages of which are those involving the growth and termination of the hydrocarbon chain and also hydrogenation. The composition of the products of synthesis is influenced very strongly, together with the type of the catalyst employed, by the reaction conditions (temperature, pressure, volume flow rate, the ratio of CO and H_2, etc.). Therefore, as a consequence of the difference between the conditions and methods of synthesis, comparison of the results obtained in different studies in the presence of carbonyl catalytic systems having identical or similar compositions is not always possible.

This comparison is also hindered by two other factors. Different workers have used different carriers for the deposition of metal carbonyls and also different methods of deposition of the carbonyls and of the preliminary treatment of the catalyst. Furthermore, the methods employed to test the catalysts also differed: the contact time was varied from 1–2 h at a constant temperature to 5–20 days with a temperature rise. By analysing the above data, one can therefore achieve only the most general conclusions and comparisions.

Mainly metal carbonyl catalysts based on Group VI and VIII metals are active in the synthesis of light hydrocarbons and, in particular, of methane. In this case, the chain termination stage apparently predominates over the propagation stage. For example, the preferential formation of methane from CO and H_2 has been described for deposited molybdenum and tungsten,[20,23,24,125,126] iron,[37] ruthenium,[128,141] osmium,[33,80] cobalt,[141] rhodium,[153] and iridium catalysts.[33,47,157] The synthesis of C_1-C_4 hydrocarbons in the presence of iron,[37,42] ruthenium,[33,47,48,60,136,143,144] osmium,[81,82,84,87] cobalt,[153,154] and rhodium catalysts[33,156–158] has been described.

The ruthenium[60,70,136,138–140] and especially iron catalysts[33,40,45,47–49,55,127–137] are characterised by high selectivity in relation to the formation of lower olefins. These systems apparently possess a lower hydrogenating capacity, so that under the conditions of the synthesis the olefins formed initially are not hydrogenated to the corresponding alkanes. In the presence of these systems, there is no significant chain growth either.

Methanol and ethanol has been obtained only in the presence of rhodium[153,156–159] and iridium catalysts.[157]

High-molecular-weight hydrocarbons are formed from CO and H_2 only in the presence of cobalt systems,[90–92,94,96,145–152] which indicates the predominance of the hydrocarbon chain propagation stage over the termination stage in this instance.

Thus metal carbonyl catalytic systems for the specific synthesis of lower olefins, alcohols, or high-molecular-weight hydrocarbon from CO and H_2 have been most thoroughly developed and investigated. These catalysts can also be treated from a practical standpoint. The manufacture of iron and cobalt carbonyls has been achieved on an industrial

scale, which leads to prospects for the use of metal carbonyl systems based on them (with a low metal content) for the creation of stable and effective catalysts of synthesis from CO and H_2.

The fact that the systems are convenient for the investigation of the mechanisms of the syntheses of organic compounds from CO and H_2 and also of the influence of the composition and structure of the catalyst on its catalytic properties and for the elucidation of the nature and structure of the active centre for the synthesis is also fairly important.

Thus one may expect that in the future studies on the metal carbonyl catalysts of the synthesis of chemical products from CO and H_2 will continue.

Reactions of Free Radicals with Organic Cations

V.I.Bogillo and I.P.Gragerov

The kinetics and mechanisms of the reactions of organic cations of different types with neutral radicals, radical-anions, and radical-cations are considered and the dependences of the rates of these reactions on the nature of the substituents in the reactants, the charges on the radicals, the nature of the solvents and counterions, and the presence of crown ethers are analysed. The applications of the reactions of cations with radicals in the alkylation and arylation of organic compounds, in diazotypes, and in cationic and radical polymerisation are briefly surveyed.
The bibliography includes 128 references.

I. INTRODUCTION

As early as the beginning of the 1940's, the interaction of free radicals with diazonium cations was postulated[1,2] to account for the formation of azobenzenes in the reduction of diazonium salts. It was later established that the dediazotisation processes in methanol,[3-10] hypophosphorous acid,[11,12] and cyclic ethers[13,14] proceed via a radical-chain mechanism and that diazonium cations interact with radicals in the chain propagation and termination stages. Subsequent studies showed that the reactions of radicals with organic cations are very common in organic chemistry and are important in organic synthesis, in the electrochemistry of organic compounds, in polymer chemistry, and in diazotypes. Their kinetics and mechanisms have a number of characteristic features of general interest for the chemistry of organic cations and free radicals. The present review is devoted to the analysis and survey of the available literature data on the kinetics and mechanisms of the reactions of organic cations with neutral radicals, radical-anions, and radical-cations and their practical applications.

II. REACTIONS WITH DIAZONIUM CATIONS

Reactions of radicals with diazonium cations have been most thoroughly investigated. Various processes involving the thermal, photochemical, and radiation-chemical reduction of these cations result in the formation of aryl radicals, which can interact with the initial cations or can abstract hydrogen atoms from solvent molecules, forming radicals which also react with the cations. It has been suggested that the attack by radicals can be directed to the aromatic nucleus of the cation or to the diazo-group. The reactions of the first type account for the formation of arylazobenzenes, for example, in the reduction of diazonium salts by potassium hexacyanoferrate(II) in water.[2] The following reaction mechanism has been proposed:[2]

$$RC_6H_4^{\cdot} + RC_6H_4N_2^{+} \rightarrow RC_6H_4C_6H_4(R)N_2^{+} \quad (1)$$

$$RC_6H_4C_6H_4(R)N_2^{+} + RC_6H_4^{\cdot} \xrightarrow{-H^{+}} RC_6H_4C_6H_3(R)N{=}N{-}C_6H_4R \quad (2)$$

Among the products of the chain reaction of methanol with p-$ClC_6H_4N_2^{+}BF_4^{-}$, initiated by γ-radiation in water, the isomers of dichlorobiphenyl were isolated.[15] The authors suggest that these are formed as a result of reactions of type (I) and subsequent reduction of the radical-cation and the elimination of nitrogen. The isotopic composition of the biphenyl, formed on treatment of $PhN_2^{+}Cl^{-}$ with an aqueous solution of alkali in deuteriated benzene, has been explained[16] on the basis of a reaction mechanism involving the addition of the phenyl radical to the aromatic nucleus of the diazonium ion as one of the stages. However, we may note that the attack by radicals on the aromatic nucleus of the diazonium cation has not been unambiguously demonstrated, as the products of the above reactions can also be obtained in a different way.

The attack by the radicals on the diazo-group, i.e.

$$Ar^{\cdot} + ArN_2^{+} \rightarrow ArN{=}NAr^{+} \xrightarrow{e^{-}} ArN{=}NAr \quad (3)$$

has been proposed by Waters[1] to account for the formation of symmetrical azobenzenes in the Sandmeyer reaction. However, these azo-compounds can be obtained as a result of the recombination of aryl and diazenyl radicals and direct evidence for the formation of the radical-cations derived from azo-compounds was not obtained in Waters' studies.

Such evidence was obtained appreciably later in the study of the EPR spectra of the products of the benzenediazonium cation with sodium dithionate.[17,18] The authors observed in the EPR spectrum a quintet corresponding to the interaction of the unpaired electron with two equivalent nitrogen nuclei ($a_{N(1)} = a_{N(2)} = 9.2$ G). The g-factor for the radical was 2.0035. The observed spectrum was initially erroneously attributed to the diazenyl radical $C_6H_5N_2$. However, quantum-chemical calculation for the latter demonstrated[19] that it is a σ-radical in the ground state and that its nitrogen atoms are non-equivalent: $a_{N(1)} = 5.8$ G and $a_{N(2)} = 14.6$ G. This result agrees well with the hyperfine interaction (HFI) constants for diazenyl radicals obtained on decomposition of benzeneazoalkanes. It has been concluded[19] that the EPR spectrum obtained in the earlier studies[17,18] corresponds to the azobenzene radical-cation, since the calculated[19] and experimental[17,19] HFI constants for the nitrogen atoms in this radical-cation were found to agree.

On the basis of the dependence of the radiation-chemical yield in the consumption of the salt p-$CH_3C_6H_4N_2^{+}BF_4^{-}$ on its concentration in the chain decomposition process initiated by γ-radiation in aqueous methanol solution, it has been suggested[15] that chain termination proceeds via reaction (3) and the rate constant for this reaction was calculated ($k = 4.2 \times 10^6$ litre mol^{-1} s^{-1}).

It has been suggested[19] that not only aryl but also many other radicals can react via mechanism (3). The first evidence for this was obtained in relation to the radicals generated by the abstraction of hydrogen atoms from β-carbon atoms in alcohols or aldehydes by aryl radicals in the chain decomposition reaction of p-$CH_3C_6H_4N_2^+BF_4^-$ initiated by γ-radiation in aqueous solutions of ethanol, isopropyl alcohol, or aldehydes (RH_2). The reaction rate constants were determined from kinetic data:

$$\beta\text{-}RH^{\cdot} + p\text{-}CH_3C_6H_4N_2^+ \rightarrow p\text{-}CH_3C_6H_4N{=}N{-}\beta\text{-}RH^+ \qquad (4)$$

They proved to be 1.1×10^4 and 3.8×10^4 litre mol^{-1} s^{-1} for the radicals $HOCH_2CH_2^{\cdot}$ and $HOCH(CH_3)CH_2^{\cdot}$ respectively.[20]

The influence of substituents in the nucleus of the diazonium cation on the rate of reaction (4) with β-radicals of isopropyl alcohol has been investigated.[15] It was found that the values of $\lg k_4$ are correlated with the σ^+ constants of the substituents in the cation: $\rho_+ = -0.5$ for the substituents p-CH_3O, p-CH_3, and p-Cl, while the inclusion of p-CN and p-NO_2 in this series lowers ρ_+ to −1.0. The acceleration of the reaction following an increase in the electron-donating capacity of the substituent has been explained[15] by the stabilisation of the electron-deficient radical-cation when substituents are introduced into the nucleus.

By analogy with the azo-coupling reaction, the addition of radicals to the diazo-group and subsequent reduction of the radical-cations to neutral azo-compounds were called the free-radical azo-coupling reaction.[21-23] This reaction became a convenient method of synthesis of alkylaryldiazenes, especially those with tertiary alkyl residues:

$$R^{\cdot} + ArN_2^+ \rightarrow R{-}N{=}N{-}Ar^+ \xrightarrow{M^{n+}} R{-}N{=}N{-}Ar + M^{(n+1)+}$$
$$M^{n+} = Ti^{3+},\ Fe^{2+} \qquad (5)$$

The radicals $R^{\cdot}$ are generated either in the reactions of aryl radicals with alkyl iodides or in the reactions of ketones or dialkyl sulphoxides with hydrogen peroxide in the presence of iron(II) salts. The yield of azo-compounds is 30–80% of theoretical depending on the nature of $R^{\cdot}$.

The rate constants for the addition of radicals to diazonium cations have been estimated[22] at 0 °C in methanol: $k_5 \cong 10^6$ litre mol^{-1} s^{-1} for $CH_3^{\cdot}$ and $C_2H_5^{\cdot}$ and $k \geqslant 10^8$ litre mol^{-1} s^{-1} for $(CH_3)_3C^{\cdot}$. This addition is reversible, since high yields of azo-compounds are obtained solely in the presence of relatively high concentrations of metal salts, which reduce the intermediate radical-cation and therby shift the equilibrium towards the final product. According to the authors of two investigations,[21,22] the addition of alkyl radicals to the diazonium cations is significantly accelerated if the degree of charge transfer from the radical to the cation in the transition state of reaction (5) increases. However, this hypothesis conflicts with the acceleration mentioned above, of the addition of isopropyl alcohol β-radicals under the influence of electron-donating substituents in the nucleus of the cation, since evidently the degree of charge transfer from the radical to the cation should fall with increase in the electron-donating capacity of the substituents.

Yet another common and thoroughly investigated type of reactions of radicals with diazonium cations involves electron transfer from the radicals to the cations:

$$R^{\cdot} + ArN_2^+ \rightarrow R^+ + ArN_2^{\cdot} \qquad (6)$$

It has sometimes been suggested (see, for example, Bargon and Seifert[19]) that these reactions proceed in two stages—with the intermediate formation and subsequent decomposition of the radical-cations $Ar{-}N{=}N{-}R^+$.

Evidence for the single-stage course of the reduction of diazonium cations with α-radicals derived from benzyl alcohol has been obtained[15,24] from data on the kinetics of the chain decomposition of diazonium salts initiated by γ-radiation in aqueous solution of the alcohol. Electron transfer from these radicals to the diazonium cations is the rate-limiting chain propagation step in the chain process. It has been found that the $\lg k$ for these reactions are correlated with the σ^+ constants of the substituents in the diazonium cations and that $\rho^+ = 0.55$ (the reaction is accelerated by electron-accepting substituents). We may note that a positive value of ρ has been obtained also for the correlation of the half-wave potentials in the polarographic one-electron reduction of substituted diazonium salts in sulpholan with the σ constants of the substituents in these salts.[25] The above data agree with a single-stage mechanism of electron transfer from the benzyl alcohol α-radicals to the diazonium cations.

The acceleration of the reactions with increase in the electron-accepting capacity of the substituents in diazonium cations has been observed also for the interaction of these cations with the radicals $^{\cdot}CH_2OH$ and $(CH_3)_2^{\cdot}COH$ investigated by pulse radiolysis.[26] The rates of the reactions increase on passing from the primary to the tertiary radical, which agrees with the decrease in the oxidation potential of the radicals[27] and hence corresponds to the mechanism involving electron transfer from the radicals to the cations in the slow stage.

The kinetics and mechanisms of the reduction of diazonium salts by stable triarylverdazyl radicals have been studied.[28] The products of the one-electron oxidation of the radicals, namely the verdazylium cations, were obtained in 90–95% yield. The products of the reduction of the cations ArN_2^+, i.e. the diazenyl radicals $ArN_2^{\cdot}$, were identified with the aid of chemically induced dynamic nuclear polymerisation (CIDNP) of the benzene formed from $PhN_2^{\cdot}$. The choice between the mechanism involving direct electron transfer in the slow stage of the process and the mechanism involving the formation and subsequent homologous decomposition of the radical-cation derived from the azo-compound was made on the basis of kinetic data. The reactions investigated are of first order with respect to each reactant and their rate constants k, calculated from the kinetic curves for the destruction of the radicals and the curves for the accumulation of verdazylium cations, agree over a wide range of variation of k (from 10 to 10^5 mol^{-1} s^{-1}). These data show that, even if the radical-cation is formed in the intermediate stage of the reaction, its stationary concentration is low. The values of $\lg k$ for the reactions considered increase linearly with increase in the reduction potentials of the diazonium cations and with decrease in the oxidation potentials of the verdazyl radicals, which agrees with the mechanism involving direct electron transfer from the radical to the cation in the slow stage. It has also been found that the $\lg k$ for the reactions of the triphenylverdazyl radical with the p-t-butylbenzenediazonium cation in various aprotic solvents decrease with increase in the donor number of the solvent. This is probably associated with the decrease in the equilibrium constant for the formation of the complex, preceding the electron transfer between the reactants, with increase in the strength of the donor–acceptor bonds between the diazonium cation and solvent molecules.

Electron transfer from radicals to diazonium cations has been postulated in the chain propagation stages of many chain processes involving the decomposition of diazonium salts in solutions containing substrates such as alcohols,[3-10,15,20,24,29] ethers [dioxan and tetrahydrofuran (THF)],[13,14,30,31] hypophosphorous acid,[11,12,32-34] cysteine,[34] and 2,4,6-triphenyl-4H-pyran,[35] but the kinetics has been studied in only some of the investigations,[14,15,20,24,30-35] where it was postulated

that the chain propagation process consists in the abstraction of hydrogen atoms from the substrate molecules by aryl radicals or the β-radicals of the substrates and in electron transfer from the substrate radicals formed to the diazonium cations. If the rate of the first of these stages is higher than that of the second, then the rate of the process is limited by electron transfer from the radicals to the cations and chain termination takes place mainly on recombination of the substrate radicals. The increase in the electron-donating capacity of the radicals derived from substrates or in the electron-accepting capacity of diazonium cations can make the first stage rate-limiting and chain termination then occurs on interaction of the aryl radicals or the substrate β-radicals with the diazonium cation.

Since the rate constants for the abstraction of hydrogen atoms from the CH bonds by phenyl radicals are known[36,37] and the rate-limiting chain propagation stage can be found from the type of the overall kinetic equation for the chain process, the above considerations make it possible to estimate the upper or lower limit to the rate constants for reactions (6). Thus, in the hydroquinone-initiated decomposition of diazonium salts in aqueous dioxan, the rate-limiting chain propagation stage involves electron transfer from the dioxan radical to the diazonium cation and the rate constant for this process must be lower than that for the abstraction of the H$^{\cdot}$ atom from the dioxan molecule by the phenyl radical, i.e. lower than the value 4.8×10^6 litre mol^{-1} s^{-1} known from the literature.

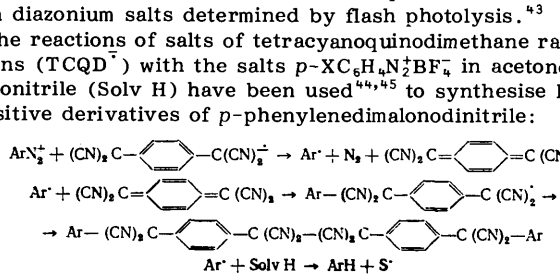
We may note that in those cases where the rate-limiting chain propagation stage consists in electron transfer from the substrate radicals to the diazonium cations, a correlation is usually observed between the overall rate of the chain process and the σ constants of the substituents in the nucleus of the diazonium cation with a positive value of the constant ρ (see, for example, Rykova et al.[31]). In doubtful cases, this feature can serve for the confirmation of the nature of the rate-limiting chain propagation stage and for the estimation of the limits of the rate constants for reactions (6).

It has been established[38,39] that the interaction of stable nitroxy-radicals with diazonium salts leads to electron transfer from the radicals to the cations. When crystalline diazonium tetrafluoroborates or chlorides are added to liquid di-t-butyl nitroxide, nitrogen is evolved and immonium salts are formed.[38] The phenyl or *p*-nitrophenyl radicals formed in this reaction recombine with the initial nitroxy-radicals, affording *NN*-di-t-butyl-*O*-phenylhydroxylamine or *NN*-di-t-butyl-*O*-(4-nitrophenyl)hydroxylamine in yields up to 75%, while the 2,4-dinitrophenyl and 2,4,6-tribromophenyl radicals abstract hydrogen atoms from the t-butyl group of the nitroxy-radical, forming *m*-dinitrobenzene or 1,3,5-tribromobenzene in yields of 22 and 13% respectively. The appearance of aryl radicals in the reaction has been confirmed by the formation of substituted bromobenzenes in the presence of CBr_4.

Intramolecular cyclisation leading to fluorescence (the Pschorr reaction) is not observed in the interaction of nitroxy-radicals with diazotised 2-aminobenzophenone, hydrogen atoms being abstracted by the benzophenone radicals from the nitroxy-radicals.[38] However, it was shown later that the interaction of nitroxy-radicals with *o*-substituted diazonium salts in acetone leads to the expected products of the intramolecular cyclisation. These data confirm the radical mechanism of the version of the Pschorr reaction considered.

Electron transfer from radical-anions to diazonium cations is also very common, but its systematic study has begun relatively recently. Reactions of this type have been postulated in chain propagation stages of the decomposition of diazonium salts in alkaline media[7,34] and in aqueous solutions of hypophosphorous acid.[34] It has been assumed[11,12,32,33] that diazonium cations interact with the $H_2PO_4^{\cdot}$ radical in the chain propagation stages of the last reaction; however, it is more likely that the conjugate base of the neutral radical, namely the radical-anion $HPO_2^{\cdot-}$, actually reacts with the cations. This is indicated by the detection of the $HPO_2^{\cdot-}$ species from the characteristic EPR spectrum comprising a doublet (a = 484 G) of doublets (a = 90 G) with a g-factor of 2.0028 in the oxidation of hypophosphorous acid with hydrogen peroxide in the presence of Tl^{3+} ions at pH between 2 and 8, i.e. under conditions where the acid reacts with diazonium salts; under these conditions, the signal of the $H_2PO_2^{\cdot}$ radicals is absent.[40] When a mixture of the salt $PhN_2^+BF_4^-$ and a phenyl radical trapping agent (maleic acid) was added to the given mixture, EPR signals corresponding to $HPO_2^{\cdot-}$ and the adduct of Ph$^{\cdot}$ with maleic acid were identified. It has been suggested[40] that the reaction

$$PhN_2^+BF_4^- + HPO_3^{\cdot2-} + H_2O \rightarrow Ph^{\cdot} + N_2 + H_2PO_3^- + HBF_4$$



proceeds under these conditions.

The lower limit for the rate constant of the reaction of the diazonium cation with $HPO_2^{\cdot-}$ was found from chain kinetic data for the decomposition of p-$CH_3C_6H_4N_2^+BF_4^-$ initiated by γ-radiation in aqueous H_3PO_2 solution:[34] $k = 2.5 \times 10^6$ litre mol^{-1} s^{-1}. It was also shown in this study that the rate constant for the reaction of the diazonium cation with $HPO_2^{\cdot-}$ is lower than that for the reaction with the radical $^{\cdot}CH_2OH$, i.e. is smaller than 1.8×10^9 litre mol^{-1} s^{-1}.[25]

The rate constants for the interaction of substituted semiquinone radical-cations with substituted diazonium salts in water have been determined[26] by pulse radiolysis. It was found that the introduction of electron-accepting substituents into the aromatic nucleus of the diazonium cations and of electron-donating substituents into the semiquinone radical-anion accelerates the reaction, which agrees with the mechanism involving electron transfer from the radical-anions to the diazonium cations in the slow stage of the process. Comparison of the rate constants for the reactions of diazonium cations with the neutral radicals and radical-anions having identical oxidation potentials showed that the rate depends not only on the redox potential of the radical but also on its charge, since the interaction between ions of opposite charge lowers the activation energy and accelerates the reaction of radical-anions compared with neutral radicals.

The chain propagation stages of the synthetically important radical-chain arylation of quinones by a diazonium salt in aqueous solutions apparently involve the interaction of the diazonium cations with semiquinone radical-anions.[41,42] It has been suggested that complexes of the radical-anions with diazonium cations, having an absorption maximum at 380 nm, are formed in the slow stages of these reactions and then decompose rapidly with evolution of nitrogen. It has been found from overall kinetic data for the arylation process that the rate constant for the formation of the complex is 500 litre mol^{-1} s^{-1}. We may note that the value obtained is doubtful, since it is almost five orders of magnitude lower than the rate constants for the reactions of semiquinone radical-anions with diazonium salts determined by flash photolysis.[43]

The reactions of salts of tetracyanoquinodimethane radical-anions ($TCQD^{\cdot-}$) with the salts p-$XC_6H_4N_2^+BF_4^-$ in acetone or acetonitrile (Solv H) have been used[44,45] to synthesise light-sensitive derivatives of *p*-phenylenedimalonodinitrile:

A detailed study of the influence of the nature of the reactants and of the medium on the rate of reactions of this type has been undertaken.[46] Their kinetics are described by second-order equations—first order with respect to each reactant. The rate of reaction diminishes with decrease in the reduction potentials of the diazonium salts. It increases on passing from $TCQD^{\cdot}$ to the *p*-choranil radical-cation which has a higher oxidation potential than $TCQD^{\cdot}$. The dependence of lg *k* for the reactions of $PhN_2^+BF_4^-$ with $TCQD^{\cdot}$, with the *p*-chloronil radical-anion, and with a series of neutral verdazyl radicals in dimethyl sulphoxide on the oxidation potentials of the radicals is described by a single straight line. This indicates a small difference between the contributions of the electrostatic interaction to the free energy of activation by electron transfer from the radical-anions and neutral radicals to the diazonium cation. It has also been established that, in reactions involving electron transfer from radical-anions and neutral radicals to diazonium cations, the selectivity of the reactions diminishes with increase in the reactivity of the radicals. As in the reaction of the diazonium cation with the triphenyl-verdazyl radical, the rate of reaction of the diazonium cation with $TCQD^{\cdot}$ diminishes with increase in the donor number of the aprotic solvent.

The rates of reaction of diazonium salts with the radical-anion salts may be influenced also by the nature of the cation in the latter.[47] Thus in acetonitrile the rate of reaction of $p\text{-}(CH_3)_2NC_6H_4N_2^+BF_4^-$ with the $TCQD^{\cdot}$ radical-anion salts is independent of the nature of the cation M^+ in these salts, while the rates of the reactions in methanol decrease with increase in the ionic radius of M^+. These data have been explained by the fact that in acetonitrile the radical-anion salts exist in the form of solvate-separated ion pairs or free ions, while in methanol the equilibrium between the solvate-separated ion pairs and the less reactive close ion pairs is displaced appreciably towards the latter with increase in the radius of M^+.

The photodecomposition of diazonium salts served as the basis for diazoprinting processes (the production of diazotypes). It has been suggested that in the presence of quinones these reactions involve the interaction of diazonium cations with semiquinone radicals or radical-anions. The kinetics of these processes in aqueous acetonitrile solutions has been investigated.[48] The semiquinone radicals were generated by the interaction of triplet-excited 1,4-benzoquinone with 2,6-di-t-butyl-4-methylphenol. It has been shown that the rates of reaction increase with increase in the electron-accepting capacity of substituents in the aromatic nucleus of the cation and that the pH of the solution, on which depends the ratio of the concentrations of the neutral semiquinone radicals $QH^{\cdot}$ and the radical-anions $Q^{\cdot-}$, formed on acid dissociation of $QH^{\cdot}$, has an appreciable influence on the rate. Thus the rate constants for the reaction of $p\text{-}NO_2.C_6H_4N_2^+BF_4^-$ falls from 2.8×10^8 litre mol^{-1} s^{-1} to 2.9×10^5 litre mol^{-1} s^{-1} as the pH falls from 2.8 to −0.7.

The photochemical reactions of semiquinone radicals of different nature with diazonium salts in heptane, acetonitrile, and a mixture of acetonitrile and water have been investigated.[43] The radical species $QH^{\cdot}$ and $Q^{\cdot-}$ participants in two main processes: disproportionation into Q and QH_2 (or Q and Q^{2-}) and electron transfer to the diazonium ions. The rate constants for electron transfer from the radicals $QH^{\cdot}$ (k_e) and the radical-anions $Q^{\cdot-}$ ($k_{\bar{e}}$) to the salt $p\text{-}ClC_6H_4N_2^+.BF_4^-$ have been determined by flash photolysis. The constants k_e and $k_{\bar{e}}$ increase with decrease in the reduction potentials of the initial quinones Q, which agrees with the mechanism involving electron transfer from the radical to the cation. The values of $k_{\bar{e}}$ are higher than those of k_e by 2–3 orders of magnitude, which indicates a higher reactivity of the radical-anions compared with the neutral radicals. The rate constants for the disproportionation of $QH^{\cdot}$ and $Q^{\cdot-}$ in the media investigated have also been determined. It follows from the data obtained that the electron transfer to diazonium cations with weak electron-accepting substituents can compete in terms of rate with the disproportionation of only the $Q^{\cdot-}$ species present in appreciable concentrations only at high pH of the solution. However, as noted by Becker et al.,[43] in diazoprinting practice the pH of the medium does not exceed 3 and $QH^{\cdot}$ are the main species present in the system. Electron transfer to the diazonium salts containing only highly electron-accepting substituents in the nucleus can compete with the disproportionation of $QH^{\cdot}$.

The photochemical reduction of diazonium salts can proceed via the mechanism involving direct electron transfer to the cation from the sensitiser in an excited state or from the photochemically generated radical in the ground state. In the reactions of diazonium salts with the radicals derived from semiquinones corresponding to thionine or Methylene Blue, it was possible to distinguish these mechanisms. It was found that the direct electron transfer from the sensitiser in the excited triplet state to the cation proceeds with a low efficiency.[49]

The kinetics of the radical-chain photodecomposition of diazonium salts, sensitised by derivatives of anthraquinone or benzoquinone, in aqueous solutions of alcohols, sodium formate, sodium oxalate, and ethylenediaminetetraacetate (EDTA) and in poly(vinyl alcohol) matrices has been investigated.[50–53] The reaction mechanism proposed by the authors had been known previously for the decomposition of salts in alcohols and ethers.[14,15] When an aqueous ethanol is replaced by 0.1 M aqueous solutions of sodium formate, sodium oxalate, and EDTA, the chain length changes and amounts to 500, 4 and 15 respectively instead of 50 in ethanol. When the reaction is carried out in the polymer matrix in the presence of sodium formate, the chain length diminishes to 4. In order to diminish the rigidity of the polymer matrix and to facilitate the development of the dye-sensitised chain photodecomposition reactions of diazonium salts, plasticisers are introduced into the matrix.[54] It has been established that oxygen serves as a trapping agent for radicals and diminishes the chain length.

It has been shown[55] that diazonium cations quench the fluorescence of the triplet-excited anthracene and certain other hydrocarbons via the electron transfer mechanism with formation of hydrocarbon radical-cations in yields close to 100%. A number of other sensitisers in the triplet state transmit energy to the diazonium cations and the excited cations then decompose via a heterolytic mechanism with formation of aryl cations. The homolytic reaction pathway is characteristic only of triplets with a relatively low excitation energy and a high electron-donating capacity.

It has been shown[56] that the biradicals formed on photodissociation of γ-methylvalerophenone can also serve as the initiator of the chain decomposition of diazonium cations in methanol. The chain length in this process is 25. It has been established[57] by EPR that neutral radicals are formed in the photochemical reduction of riboflavin or protonated riboflavin cations in poly(ethylene glycol) films and interact with diazonium cations, initiating the chain process. In aqueous poly(ethylene glycol) solution, the chain length is close to 400, whilst in films it falls to 40. The application of the above initiators makes it possible to shift the region of the spectral sensitivity of diazo-materials to 500 nm.

The photosensitised deocomposition of diazonium salts in micellar solutions has been studied.[58–60] In the case of a surfactant forming negatively charged micelles (sodium dodecasulphonate), dynamic (with $k_d = 8.6 \times 10^{10}$ litre

mol^{-1} s^{-1}) and static (with K_{ass} = 210 mol $litre^{-1}$) quenching of the fluorescence of anthracene by added p-$CH_3C_6H_4N_2^+BF_4^-$ is observed. In the case of a compound giving rise to positively charged micelles (dodecyltrimethylammonium chloride), the efficiency of the dynamic quenching fell ($k_d = 1.9 \times 10^9$ litre mol^{-1} s^{-1}) and static quenching was not observed at all. It was concluded[60] that the efficiency of the quenching is determined mainly by the Coulombic interaction of the charges of the micelle and the quenching agent.

It has been shown[61,62] that the rates of the reactions of ketyl radicals, generated on photoirradiation of α-phenylbenzoin, with p-$ClC_6H_4N_2^+BF_4^-$ increase with increasing fraction of the excited radicals, which is associated with the decrease in the free energy of the electron transfer reactions on excitation.

A study has been devoted to the solution of the problem whether or not the photosensitised decomposition of diazonium salts in the presence of aromatic ketones proceeds via the electron transfer or the energy transfer mechanism.[63] It was demonstrated by the CIDNP method that diazonium salts decompose via the mechanism involving electron transfer from the excited ketones in the T_1 state to the diazonium cations with rate constants of (1.0–9.8) × 10^9 litre mol^{-1} s^{-1}. In the reactions of fluorenone and pyrene with the cations, the electron is transferred from these compounds in the S_1 state, which is most stable.

The data described facilitate the search for diazoprinting compositions incorporating diazonium salts and initiators, which decompose under the influence of light to radicals which interact with the cation initiating their chain decomposition.[64]

Aryl radicals and cations derived from the initial radicals are formed in the reactions involving the reduction of diazonium cations by radicals. These active species can initiate the radical and cationic polymerisation. The use of such systems for photopolymerisation is particularly promising. A system consisting of a photoinitiator (a benzoin ether or potassium oxalatoferrate) and a coinitiator (bisdiazonium salts) has been proposed[65] for the initiation of radical photopolymerisation. It was shown that the bisdiazonium salts induce the photopolymerisation of acrylamide at the same rate as diazonium salts but afford polymers with twice as high a molecular weight. The increase in the molecular weight of polyacrylamide was explained by the fact that in the case of bisdiazonium salts the products of the polymer chain termination contain diazonium groups capable of initiating further polymerisation.

The chain decomposition of diazonium salts can occur on transfer to the latter of an electron from the radical-anions $CO_2^{\cdot-}$ formed on photoirradiation of the complex oxalates $K_3[Fe(Ox)_3]$ and $K_3[Co(Ox)_3]$ at the wavelength of the charge transfer band.[66] The quantum yields in the evolution of nitrogen increase with increasing electron-accepting capacity of the substituents in the diazonium cations. Such systems are effective initiators of the photopolymerisation of acrylamide in the spectral range 400–500 nm.[67] The quantum yield of the photopolymerisation reaches 805 in the case of potassium trisoxalatocobaltate and the p-methoxybenzenediazonium salt.[68]

Systems comprising derivatives of benzoin and diazonium salts have been used to initiate the photopolymerisation of glycidyl isobutyl ether. It was established that the rate of polymerisation increases with increase in the electron-accepting capacity of the substituents in the cation and also in the following series of counterions associated with the p-$ClC_6H_4N_2^+$ cation: $BF_4^- < SbF_6^- < BF_6^-$.[69] Photopolymerising layers for the preparation of relief images in the manufacture of printing plates or recording materials have been proposed on the basis of systems consisting of diazonium salts, oligomers, and photoinitiators (benzoic acid esters[70] or aromatic carbonyl compounds[71]).

It has been established[72] that the reduction of substituted diazonium salts by tetra-t-butylbispyrylium, tetramethyl-p-phenylenediamine ($TMPA^{+\cdot}$), tetraphenylbenzidine, and *N*-methylphenothiazine radical-cations obeys a second-order equation and proceeds via the electron transfer mechanism. The logarithms of the rate constants for these reactions decrease linearly with increase in the standard free energy of electron transfer. The rate of reaction of $PhN_2^+BF_4^-$ with $TMPA^+$ and the selectivity in the reduction of substituted diazonium salts by $TMPA^{+\cdot}$ increase with increase in the electron-donating capacity of the solvent. The addition of crown ethers to the solution accelerates the reaction. The rate increases also with increase in the ionic strength of the solution, Cl^- ions exhibiting a specific accelerating effect. These features of the influence of the medium are the opposite of those in the reactions of organic cations with neutral radicals[28] and with radical-anions.[46] They have been explained[72] by the fact that electron transfer takes place in "bridged" complexes incorporating solvent with crown ether molecules or the Cl^- anion, distributed between the organic cation and the radical-cation. The formation of a "bridge" lowers the electrostatic repulsion between the cation and the radical-cation, brings them closer together, and accelerates the reactions. The magnitude of the effect is determined by the electron-donating capacity and polarisability of the "bridged" molecules. In contrast to this, the reduction of organic cations by neutral radicals or radical-anions requires the desolvation of the reactants and the formation of an ion–dipole complex or a close ion pair in which electron transfer actually takes place.[47]

III. REACTIONS WITH THE ONIUM CATIONS OF GROUP V–VII ELEMENTS

Various thermal and photochemical reduction reactions of iodonium and sulphonium salts as well as the reduction reactions of diazonium salts proceed via a radical-chain pathway. Electron transfer from the chain propagating radical to the onium cations has been postulated in the chain propagation stages of these reactions. It has been shown[73–75] on the basis of kinetic data and observations of CIDNP effects of the products that the reactions of diphenyliodonium chloride with dibutylamine, monoethanolamine, and triethylamine proceed via this mechanism. In the reaction with dibutylamine, the rate-limiting chain propagation stage is electron transfer from the dibutylaminyl radical to the cation. In contrast to this, the rate-limiting chain propagation stage in the interaction of iodonium cations with monoethanolamine and triethylamine is abstraction of hydrogen atoms from the amine by phenyl radicals. The differences between the nature of the rate-limiting stages have been attributed[75] to the fact that the radicals $(C_2H_5)_2N\dot{C}HCH_3$ or $\dot{N}HCH_2CH_2OH$ are less stable than $(C_4H_9)_2N^{\cdot}$; the rate of formation of the first two radicals is therefore reduced, which makes the process rate-limiting.

The interaction of alcohol α-radicals with onium cations has been postulated during the chain propagation stages of the reactions of diaryliodonium cations with 2-nitropropane anions in methanol[76] and also in the reactions involving the decomposition of iodonium[77,78] and sulphonium[79] salts by sodium alkoxides in alcohols. It has been suggested[79] that the reaction with sulphonium cations leads to the formation of radical-cations of the type $R_3S^{+\cdot}$–$C(OH)(CH_3)_2$, but the nature of the

products formed can also be accounted for by electron transfer from the alcohol α-radical to the sulphonium cation.

The kinetics of the reduction of iodonium salts and onium salts of Group VI elements by stable verdazyl radicals and tetracyanoquinodimethane and *p*-chloranil radical-anions has been investigated.[80] It follows from the kinetic data obtained that the diphenyliodonium cation is a much weaker electron acceptor than diazonium ions. However, when the phenyl residue in the iodonium cation is replaced by the perfluoroalkyl residue, the rates of reactions with radicals increase sharply. For iodonium and sulphonium salts, they depend on the inductive effects of the substituents at the central atom and decrease in the following sequence: $n\text{-}C_6F_{13} > n\text{-}C_3F_7 \gg Ph > CH_3$.

The rates of the reactions of the onium cations of Group VI elements with the verdazyl radical in acetonitrile increase with increase in the principal quantum number of the central atom—in the sequence S < Se < Te. The half-wave potentials for the irreversible one-electron polarographic reduction of the cations in acetonitrile increase in the same direction. This finding has been explained by the fact that, in the transition states of the reaction considered, the bond between the central atom and the carbon atom of the substituent is appreciably weakened. The strength of this bond falls with increase in the principal quantum number of the central atom. This lowers the standard free energy and the energy of the reorganisation reactions in the above series and increases the rate.[81] An analogous behaviour has been observed in the series of isotypical onium cations of Group V and VII elements with alkyl and aryl substituents at the central atom. The ease of their irreversible polarographic reduction increases in the following series of cations: ammonium < phosphonium < arsonium,[82] chloronium < bromonium < iodonium.[83] The explanation of this feature is analogous to that quoted above.[81]

Processes in which onium salts undergo one-electron reduction have been used to generate alkyl or aryl radicals. The study of the products of the reduction of sulphonium salts of different structure by graphite or naphthalene radical-anions in tetrahydrofuran led Beak and Sullivan[84] to the following reaction mechanism:

$$RR'R''S^+ \xrightarrow{e^-} RR'R''S^\cdot \rightarrow R^\cdot + R'SR'' .$$

The selectivity of the bond dissociation in the radical $RR'R''S^\cdot$ depends on the nature of the residues R and in the reduction of monophenylsulphonium salts diminishes in the following sequence of R: benzyl > s-alkyl > n-alkyl > methyl > phenyl. It has been suggested that an electron is transferred in the first stage of the reaction from the radical-anion to the phenyl residue of the sulphonium cation and a π-ligand radical-anion associated with the sulphonium cation is formed. This species then decomposes into a sulphide and a hydrocarbon radical, it being assumed that the transition state of the decomposition process involves the overlap of a singly occupied molecular orbital of the aromatic nucleus with the σ* orbital of the homolytically dissociating bond. The selectivity of the decomposition is determined mainly by the relative energies of the radicals formed, although it is also influenced by steric factors. Alkylsulphonium cations are not reduced by the radical-anions employed, since the energy of their highest occupied molecular orbital is much higher than for the phenyl-substituted salts.

Another mechanism of the reduction of sulphonium salts, involving a synchronous electron transfer and the dissociation of the S–R bond, has been proposed.[85] It is based on the observed high sensitivity of the peak potentials on the voltage–current curves for the electrochemical reduction of phenyl- and naphthyl-dialkylsulphonium salts to the electron-accepting capacity of the leading group, which determines the relative energy of the σ* molecular orbital of the bond ruptured on reduction.

The nature of the radicals formed in the electrochemical reduction of sulphonium cations in the presence of radical trapping agents (nitrosodurene, t-butyl phenyl nitrone) has been investigated by the cyclic voltamperometric and coulometric methods at a constant potential with recording of the intermediate products by EPR.[86] In certain cases difficulties arose, associated with the greater ease of the reduction of the trapping agents than of the cations. They were overcome by using the indirect homogeneous reduction of the cations by redox catalysts (anthracene, 1,8-dinitronaphthalene), whose electrochemical reduction occurs at more positive potentials than the reduction of the trapping agents. Under these conditions, the radical-anions formed from the catalysts do not reduce the trapping agent but do reduce the sulphonium cations, being themselves oxidised to the initial hydrocarbons.

A preparative study of the products of the electrochemical reduction of sulphonium and butyltrimethylammonium salts, carried out using electron transferring agents such as fluorene and *p*-cyanoaniline, showed that alkylated derivatives of the transferring agents are formed with a high current yield.[87] In this connection, we may point out that the reactions of onium salts with electrochemically generated radical-anions[88,89] or radical-dianions[90] can serve as a convenient method for the alkylation or arylation of organic compounds formed on oxidation of these radical-anions. The reactions of tetraalkylammonium salts with the electrochemically generated triphenylphosphine or triphenylphosphine oxide radical-anions lead to the exchange of the organic residues linked to the phosphorus:[89]

$$Ph_3P \xrightarrow{e^-} Ph_3P^{\cdot-}$$
$$Ph_3P^{\cdot-} + (C_4H_9)_4N^+ \rightarrow [Ph_3PN(C_4H_9)_4]^\cdot$$
$$[Ph_3PN(C_4H_9)_4] \rightarrow C_4H_9\dot{P}Ph_3 + (C_4H_9)_3N$$
$$C_4H_9\dot{P}Ph_3 \rightarrow Ph^\cdot + C_4H_9PPh_2$$
$$C_4H_9PPh_3 \rightarrow C_4H_9^\cdot + Ph_3P .$$

The possibility of the reactions of electrochemically generated neutral radicals and radical-anions with onium cations, usually employed as supporting electrolytes in electrochemical synthesis in aprotic solvents of low polarity, must be taken into account in the reduction of organic compounds at high cathodic potentials. Thus, in the electrochemical reduction of benzonitrile in a solution of a tetraethylammonium salt, a reaction of the type of Hofmann degradation of the tetraalkylammonium cation by the benzonitrile radical-anion takes place.[91] It has been found that the rate of disappearance of the radical-anion increases linearly with increasing concentration of the ammonium salt.

In reactions with onium cations, the radical-anions can serve either as donors of one electron or as nucleophiles. In order to elucidate the relative contributions of these types of reaction of the benzophenone radical-anion, use was made of the aryltrimethylammonium salts, which give rise to N–Ar bond dissociation products in one-electron reduction and to products of the rupture of the $N-CH_3$ bonds following the attack by nucleophiles.[92,93] It was found that the above ratio is 2:3 for the reaction of $(C_6H_5)_2CO^-K^+$ with $C_6H_5N^+(CH_3)_3ClO_4^-$ in THF.[93] It increases with increase in the electron-accepting capacity of the substituents in the aromatic nucleus of the ammonium cation. When the nature of the counterion in the radical-anion salt is varied, the contribution of the nucleophilic substitution diminishes in the sequence $K^+ > Na^+ > Li^+$. These data[93] led to the conclusion

that the nucleophilic substitution process is more sensitive to the nature of the counterion M^+ in the radical-anion salt than the electron transfer process and that the latter is more sensitive to the structure of the electrophile than nucleophilic substitution.[92]

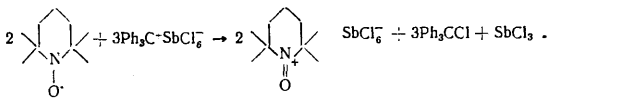
Yet another type of reaction with ammonium cations is characteristic of radicals having pronounced electrophilic properties ($Cl_2^{\cdot-}$, $HPO_4^{\cdot-}$, $SO_4^{\cdot-}$, $OH^{\cdot}$), which abstract hydrogen atoms from the alkyl substituents of the cation. The rates of reaction increase with increase in the number of C–H bonds in the alkyl residues and the relative reactivity of the radicals increases in the sequence $Cl_2^{\cdot-} < HPO_4^{\cdot-} < SO_4^{\cdot-} < OH^{\cdot}$, which is identical with the series based on the relative reactivities of the radicals in processes involving the abstraction of a hydrogen atom from other aliphatic compounds. The data described show that the reactions of radicals with ammonium cations involve the abstraction of $H^{\cdot}$ atoms in the rate-limiting stage. The influence of the positively charged nitrogen atom is manifested by a decrease in the rate constant for the abstraction of $H^{\cdot}$ from the α-carbon atom by two orders of magnitude and from the β-carbon atom by a factor of five compared with the rate constant for the abstraction of $H^{\cdot}$ from aliphatic hydrocarbons.[94]

A series of studies[95–98] have dealt with the influence of added diazonium, iodonium, and sulphonium salts on the yields and molecular weights of the polymers formed in the thermal or photochemical cationic polymerisation of alkyl vinyl ethers or THF. It was found that in the presence of sources of radicals (azobisisobutyronitrile, benzoyl peroxide) but in the absence of onium salts, the thermal polymerisation of these monomers does not occur, as happens also in solutions of the onium salts in the monomers. However, polymerisation does take place when both a radical initiator and an onium salt are added simultaneously to the solution. The following mechanisms of the formation of cations (polymerisation initiators) have been proposed:

$$X^{\cdot} + CH_2{=}CHOR \rightarrow X{-}CH_2\dot{C}HOR\,,$$
$$\sim\!-CH_2\dot{C}HOR + Ar_2I^+ \rightarrow \sim\!-CH_2CH{=}\overset{+}{O}{-}R + ArI + Ar^{\cdot},$$
$$Ar^{\cdot} + CH_2{=}CHOR \rightarrow ArCH_2\dot{C}HOR\,,$$
$$ArCH_2\dot{C}HOR + Ar_2I^+ \rightarrow ArCH_2,\ CH{=}\overset{+}{O}{-}R + ArI + Ar^{\cdot},$$
$$X^{\cdot} + \langle\!\rangle\!\!\rangle \rightarrow XH + \langle\!\rangle\!\!\rangle^{\cdot} \xrightarrow{Ar_2I^+} \langle\!\rangle\!\!\rangle^{+} + ArI + Ar^{\cdot}\,.$$

Here $X^{\cdot}$ is a radical derived from the initiator and $\sim\!-CH_2\dot{C}HOR$ is the macroradical. Evidently the role of the onium cations consists in the one-electron oxidation to carbonium ions of the radicals, formed with participation of the initiators or macroradicals. If these carbonium ions are unstable and decompose with elimination of protons, then the latter can also initiate polymerisation.

The method considered is especially effective in cationic photopolymerisation. Irradiation with hard ultraviolet light is necessary for the initiation in the absence of onium salts and the quantum yields are low, whereas in the presence of onium salts, the radical photoinitiators may be benzoin and its ethers or alkoxyacetophenones, which absorb light at wavelengths greater than 380 nm and decompose with high quantum yields. Detailed reviews[99,100] have been devoted to the development of initiating systems for photopolymerisation processes involving electron transfer to onium cations of different types from sensitisers in the excited state or from nucleophilic radicals formed on photolysis of benzoin derivatives and ketals and also on photoabstraction of hydrogen from aromatic ketones.



IV. REACTIONS WITH CARBONIUM IONS

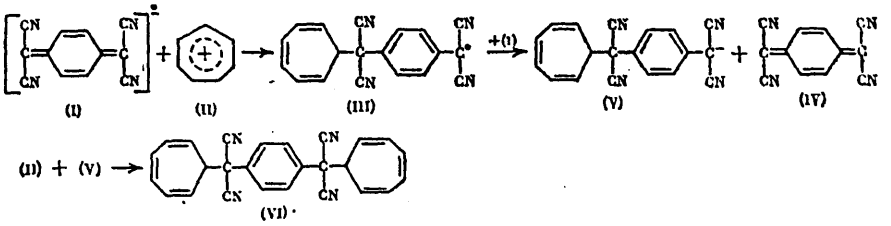
The reactions of neutral radicals and radical-ions with carbonium ions have been postulated in the stages of certain radical processes involving carbonium ions, but there have been scarcely any quantitative studies of such processes. Two mechanisms of these reactions have been proposed—the one-electron reduction of the carbonium ion by the radical to the corresponding hydrocarbon radical or the recombination of the reactants.

The reactions in which triphenylcarbenium ions are reduced by a nitroxy-radical give rise to the stable triphenylmethyl radical; in the absence of atmospheric oxygen and water, an equilibrium displaced towards the initial reactants is established in organic solvents:

$$\rangle N{-}O^{\cdot} + Ph_3C^+ClO_4^- \rightleftarrows \rangle\overset{+}{N}{=}OClO_4^- + Ph_3C^{\cdot}\,.$$

In the presence of oxygen, which binds triphenylmethyl radicals, this equilibrium is wholly displaced to the right and triphenylmethyl peroxide, triphenylmethanol, and an immonium salt are formed. If $SbCl_6^-$ is the anion in the salt, then the anion and not the carbonium ion is reduced:[101]

In the reaction of $Ph_3C^+ClO_4^-$ with di-t-butyl nitroxide in the presence of oxygen, the peroxy-radical $Ph_3CO_2^{\cdot}$ has been shown[102] to abstract a hydrogen atom from the alkyl group of the nitroxide with formation of the hydroperoxide Ph_3CO_2H, the olefin $H_2C{=}C(CH_3)_2$, and the nitroso-compound $(CH_3)_3.CN{=}O$.



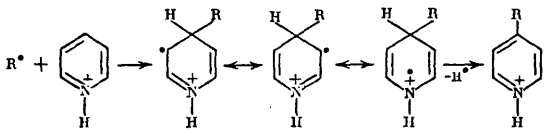
The formation of bitropyl in the reduction reactions of the tropylium cation may be the result of the recombination of tropyl radicals or of the attack by the tropyl radical on the tropylium cation and the subsequent reduction of the bitropyl radical-cation to a neutral compound. The latter mechanism has been proposed for the electrochemical reduction of tropylium (Tp^+) fluoroborate in acetonitrile, which leads to bitropyl:[103]

$$Tp^+ + e^- \rightarrow Tp^{\cdot},$$
$$Tp^+ + Tp^{\cdot} \rightarrow Tp_2^{\cdot+},$$
$$Tp_2^{\cdot+} + Tp^{\cdot} \rightarrow Tp_2 + Tp^+.$$

This mechanism is based on the agreement between the observed experimental slope of the polarographic reduction wave and the calculated slope for the mechanism quoted.

The reaction of tropylium fluoroborate with the oxygen radical-anion leads to benzene, benzaldehyde, cycloheptatriene, CO, and O_2.[104] It has been suggested that $O_2^{\cdot-}$ recombines with the cation in the first reaction stage. This is based on the ratio of the products of the reaction of the tropylium salt with a typical nucleophile—the O_2^{2-} anion, which does not differ from the ratio of the products of the reactions of the salts with $O_2^{\cdot-}$.

The interaction of the lithium salt of the tetracyanoquinodimethane radical-anion (I) with tropylium iodide (II) in acetonitrile affords tetracyanoquinodimethane (IV) and αα′α′-tetracyano-αα-ditropyl-p-xylene (VI). The following reaction mechanism has been proposed on the basis of the high yields of these products and the absence of bitropyl among them:[105]



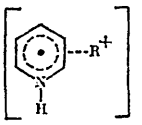
Here the radical-anion plays the role of the nucleophile. However, the product (IV) can also be formed as a result of the one-electron reduction of the cation (II) by the radical-anion (I). The reaction of compound (IV) with the tropyl radical (VII) formed simultaneously gives rise to the product (VI) if the rate of reaction of the species (IV) with (VII) is higher than the rate of dimerisation of the radicals (VII).

A mechanism of the last type, involving electron transfer from the radicals to the tropylium cation, has been proposed on the basis of kinetic data and the analysis of the products of the reactions of tropylium fluoroborate with substituted verdazyl radicals and tetracyanoquinodimethane or *p*-chloranil radical-anions.[106] It has been confirmed by the finding that the rates of these reactions increase with decrease in the oxidation potentials of the radicals and by the fact that the linear relation between the logarithms of the rate constants and the half-wave potentials for the polarographic reduction of the cations, which is characteristic of electron transfer reactions, has been observed for the reactions of the verdazyl radical with substituted diazonium, tropylium, and 2,4,6-triphenylpyrylium salts in acetonitrile.

In contrast to the reactions of diazonium cations with the triphenylverdazyl radical and with the tetracyanoquinodimethane radical-anion, whose rate diminishes with increase in the donor number of aprotic solvents,[28,46] the rate of reduction of the tropylium cation by the triphenylverdazyl radical depends only slightly on this parameter of the medium. This difference has been explained[106] by the fact that the increase in the degree of delocalisation of the charge on passing from the diazonium to the tropylium cation entails a decrease in the energy of the specific solvation of the tropylium cation by electron-donating solvents. As a consequence of the low specific solvation energy, the rates of the reactions of the tropylium cation with the radicals depend significantly on the non-specific solvation of the cation and the radical, so that $\lg k$ increases with increase in $1/\varepsilon$ (where ε is the dielectric constant of the medium). The rate of reaction of the tropylium cation with the tetracyanoquinodimethane radical-anion diminishes with increase in the polarisability of the solvent P, since an increase in P promotes the solvation of the readily polarisable radical-anion.

V. REACTIONS WITH THE CATIONS OF HETEROAROMATIC COMPOUNDS

The interaction of nucleophilic radicals with protonated heteroaromatic bases leads to homolytic substitution products, for example:



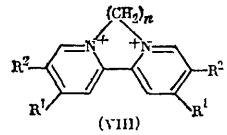
In recent years, reactions of this type have acquired synthetic importance.[107-111] Their rates are high and they exhibit a high positional selectivity and selectivity with respect to the substrate, in contrast to radical substitution reactions involving the molecules of neutral aromatic compounds, which are characterised by relatively low rates and positional selectivity and also by a weak sensitivity of the rate to the nature of the substituents in the aromatic nucleus. It has been suggested[112,113] that the principal cause of the above differences is appreciable polar effects in the reactions of the radicals with the cations. The transition state in these reactions is a charge-transfer complex and the degree of charge transfer is determined by the electron-donating capacity of the radical (the energy level of its singly occupied molecular orbital) and by the electron-accepting properties of the cations (the level of their lowest unoccupied molecular orbital).

The view described above has been confirmed by a number of observations. Thus the rates of the reactions of the heptyl radical with substituted pyridinium cations increase with increase in the electron-accepting capacity of the ring substituents, which is associated with a decrease in the activation energy for a constant pre-exponential factor. The activation energy falls and the rate and selectivity increase, because electron-accepting substituents stabilise the transition state corresponding to the electron transfer.[112]

It has been found[113] that the relative rates of homolytic substitution in the α-position in the rings of γ-substituted pyridines in an acid medium diminish with increase in the ionisation potential of the radicals (on passing from the benzyl to the phenyl radical) and also with increase in the σ constants of the substituents in the rings of the benzyl radicals.

We may note that the rule governing the correlation between the reactivity and selectivity, according to which an increase in the rates of reactions entails a decrease in their selectivity, breaks down in the cases considered. It has been suggested[112] that this rule does not hold at all in radical reactions with a highly polar transition state. However, it follows from certain data[26,46] that this rule does hold in reactions involving total electron transfer from radicals to diazonium cations.

The influence of the nature of the solvent on the kinetics of the reactions considered has been studied in relation to the bioxanyl, benzoyl, carbamoyl, α-aminomethyl, and undecyl radicals with protonated 4-cyano- and 4-methyl-quinolines.[114] An increase in the content of water in dioxan and also in the concentration of acetic acid in dioxan or in dimethylformamide increase the reaction selectivity. This has been explained by the interaction of water or acid molecules with the unshared electron pairs of the radicals, which increases the ionisation potential of the latter and diminishes the contribution by the form



to the transition state. The reaction is thereby slowed down and its selectivity increases. We may note that this explanation does not take into account the change in the solvation of the cations and furthermore contradicts the increase in selectivity with increasing rates of the reactions considered discovered by Citterio et al.[112]

The limiting case of a polar transition state is observed in processes involving total electron transfer from the radical to the cation of the heteroaromatic compound. In such cases, electron transfer products are formed instead of the products of the addition of the radicals to the cations. Total electron transfer may be expected in the reactions of cations with nucleophilic radicals such as $(CH_3)_2\dot{C}OH$, $(C_6H_5)_2\dot{C}OH$, and $C_{10}H_8^{\cdot-}$. The study of the kinetics of the interaction of the radicals $(CH_3)_2\dot{C}OH$ with substituted pyridinium cations in water revealed a correlation between $\lg k$ and the σ constants of the substituents in the cation with the very high positive value $\rho = +8.5$.[115] This observation is a serious argument in support of a transition state close to a charge-transfer complex.

The formation of radicals from the cations of heteroaromatic compounds on their reduction by the photochemically generated radicals $(C_6H_5)_2\dot{C}OH$ or $C_{10}H_8^{\cdot-}$ has been demonstrated unambiguously by EPR.[116] The interaction of cations with classical ionic nucleophiles (OH^-, tertiary amines) leads to the same heteroaromatic radicals. It has been suggested[16] that in all the cases quoted an electron is transferred from the nuclophile to the electron-accepting cation.

The kinetics and the equilibrium in the reduction of dications having the general formula

(VIII)

where $n = 2-4$, $R^1 = H$ or CH_3, and $R^2 = H$ or CH_3, in their interaction with e_{aq}, $CO_2^{\cdot-}$, and $(CH_3)_2\dot{C}OH$ in water have been investigated by pulse radiolysis[117] and it has been found that the rates of the reactions with equated electrons are independent of the reduction potentials of the dications, while the rate of electron transfer from the radicals falls with decrease in these potentials. The rate constants for electron exchange between the radical $(CH_3)_2\dot{C}OH$ and protonated acetone and between the substituted pyrazinium bromide radical-cation and its unreduced form have been estimated from data derived from the equations of the theory of outer-sphere electron transfer reactions developed by Marcus. They proved to be $(2-6) \times 10^6$ litre mol^{-1} s^{-1} and 5×10^7 litre mol^{-1} s^{-1} respectively.

Irradiation of solutions of benzophenone or xanthone and *NN'*-dimethyldipyridinium dichloride (MB^{2+}) in aqueous isopropyl alcohol solution by light at a wavelength greater than 366 nm leads to the generation of the radical-cations $MB^{\cdot+}$ as a result of electron transfer to MB^{2+} from the photochemically generated ketyl radicals or from the alcohol α-radicals. The radical-cations reduce water with evolution of hydrogen, being reoxidised at the same time to the initial dications.[118,119] A significant increase in the quantum yield in the decomposition of water has been achieved by irradiating solutions of γ-ketoalcohols and MB^{2+} in aqueous acetonitrile solution by near ultraviolet light.[120] Thus the radicals $Ph\dot{C}(OH)CH_2.CH_2\dot{C}(OH)Ph$, which reduce MB^{2+} to $MB^{\cdot+}$ with a high rate constant [$(1-3) \times 10^8$ litre mol^{-1} s^{-1}] and a quantum yield of 0.7, have been generated in the system with $PhCH(OH)CH_2.CH_2COPh$.

The formation of the radical dimers in the electrochemical reduction of 3-ethyl-2-methylbenzothiazolium (BT^+) as well as the formation of bitropyl in the reduction of tropylium cations are treated as a result of the attack by the electrochemically generated radical on the initial cation:[121]

$$BT^+ \xrightarrow{e^-} BT^{\cdot},$$
$$BT^+ + BT^{\cdot} \rightarrow BT\text{-}BT^{\cdot+},$$
$$BT\text{-}BT^{\cdot+} \xrightarrow{e} BT\text{-}BT,$$
$$BT\text{-}BT^{\cdot+} + BT^{\cdot} \rightarrow BT\text{-}BT + BT^+.$$

The voltamperogram of the cation has two peaks. The first corresponds to a reversible process at a high rate of scanning of the potential, while the second peak corresponds to an irreversible process at all the rates of scanning of the potential investigated. The mechanism presented above was proposed on the basis of the dependence of the heights and potentials of both reduction waves for the cation on its concentration.

VI. CONCLUSION

In this Section we shall deal with certain general questions of the kinetics and mechanisms of the reactions considered. The data examined in the review show that the main types of reactions of organic cations with radicals involve the addition of the latter to the cations and electron transfer between these reactants. The reactions in which a hydrogen atom is abstracted from the C–H bonds of the hydrocarbon substituent of the cations are encountered much more rarely. They are characteristic of electrophilic radicals, for example, of $OH^{\cdot}$ and $SO_4^{\cdot-}$.

The presence of a charge on organic cations and the low energy of their lowest unoccupied molecular orbitals may be noted as characteristic features of the electronic structure of such species. The high electron affinities[122] and half-wave potentials for polarographic reduction[123] are related to these features. Since the majority of the radicals considered in this review are nucleophilic in character, one can assume that the main factors determining the direction and energetics of both addition and electron transfer reactions between radicals and cations are the Coulombic interaction between these species and the interaction of the singly occupied molecular orbital of the radicals, which have a high energy, with the lowest unoccupied orbital of the organic cations. The attack by the radicals should therefore be directed to the atoms of the cation having the minimum electron density. These conclusions are confirmed by data obtained for the recombination of cations of the type $H-C{=}O$ and $HO-\overset{+}{C}{=}O$, etc. with hydrogen atoms in the gas phase:[124] the activation energy for the addition of the $H^{\cdot}$ atom to the heteroatom is considerable, while the activation energy for the addition to carbon is low or zero.

The polar character of the transition state in the addition of electron transfer reactions considered is usually reflected by high positive values of the constants ρ in correlation equations linking the logarithms of the rate constants with the σ constants of the substituents in the aromatic nuclei of the cations[15,24,31,35,69,112,115] and the α constants in the equations relating the free energies of activation for the reactions to the free energies of electron transfer between the reactants.[125] The polar character of the transition state is also manifested by the acceleration of the reactions with increase in the electron-accepting capacity of the substituents in the cation[15,24,26,28,43,46,69,72,80,112,115] and in the electron-donating capacity of the radicals.[22,26,28,46,48,72,80,106,113,117] However, we may note that a negative value of ρ has been

obtained for the addition of isopropyl alcohol β-radicals to diazonium cations according to kinetic data for the chain radiolysis of diazonium salts in aqueous isopropyl alcohol.[15] This observation needs to be checked by a direct kinetic method.

A distinctive feature of the reactions involving the addition of radicals to cations investigated hitherto is the increase in selectivity with increase in the reactivity of the radicals or the cations,[112] while in the reactions involving electron transfer from the radicals to the cations the usual rule operates—the selectivity diminishes with increase in reactivity. The reactions involving the reduction of onium cations of Group VI elements by radicals are now known to be an exception to this rule.[81]

The rates of the reactions considered depend not only on the electron-donating capacity of the radicals and the electron-accepting capacity of the cations but also on the sign and magnitude of the charges on the radicals. For the reactions of neutral radicals with cations, the contribution of the ion–dipole interaction to the free energy of activation may be neglected, while for the interaction of radical-ions with cations this contribution is significant; for example, in acetic acid, for a distance between the reactants in the collision complex of 5 Å, this contribution is more than 40 kJ litre mol^{-1}.[126] In the reactions between radical-ions and large cations in media with a high dielectric constant, this contribution is reduced and in slow reactions is insignificant.[46] It increases, for example, with increase in the electron-donating capacity of radicals, leading to a sharp acceleration of the reactions.[26]

In contrast to the reactions involving electron transfer from the radicals to neutral organic compounds, in which the effects of the medium are determined by the solvation of the polar transition state,[127] in reactions involving electron transfer from the radical to the cations these effects are associated mainly with the solvation of the initial reactants. It has been shown for the reactions with electron transfer from neutral radicals, radical-anions, and radical-cations to the diazonium and tropylium cations[72,103] that the character of the influence of the nature of the solvents, of the added crown ethers, and of the nature of the counterions depends on the characteristic features of the structure of the organic cations and the charge on the radicals.

The kinetics of the reduction of organic cations by radicals can be described in terms of the theory of the outer-sphere electron transfer reactions developed by Marcus.[128] The rate constants k for more than 90 reduction reactions of diazonium, tropylium, verdazylium, and pyrylium cations with neutral radicals, radical-anions, and radical-cations as well as with diamagnetic organic molecules have been found[125] from the redox potentials of the reactants with the aid of the equations of this theory. It has been shown that, when account is taken of the energy of the reorganisation of only the outer coordination sphere, the calculated constants k exceed the experimental values by 1–7 orders of magnitude. Quantum-chemical calculations have shown that the reduction of the diazonium and tropylium cations to the corresponding radicals is accompanied by a significant change in structure, which leads to high energies of reorganisation of the inner coordination sphere of the cations in the reduction process. Calculation of the constants k taking this factor into account yielded a satisfactory agreement between the experimental and calculated values within the limits of 1–2 orders of magnitude.

It has been shown[125] that processes involving direct electron transfer to organic cations can be distinguished from processes in which electron transfer is preceded by the formation of an intermediate product of the recombination of the reactants with the aid of calculations based on the equations of the Marcus theory. Only for reactions of the first type is it possible to obtain a satisfactory agreement between the experimental constants k and the values calculated from the redox potentials of the reactants and the energies of the reorganisation reactions. For reactions of the second type, the experimental recombination rate constants exceed by many orders of magnitude the values calculated from the Marcus theory. This difference is greater the stronger the bond in the intermediate compound ruptured on dissociation into the electron transfer products.

Nucleophilic Substitution in Hexachlorocyclopentadiene

S.A.Ismailov

Nucleophilic substitution reactions occurring when hexachlorocyclopentadiene is acted upon by various bases are surveyed and discussed critically. Certain characteristic features of reactions of this type are demonstrated.
The bibliography includes 133 references.

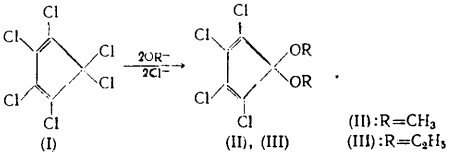
CONTENTS

I. Introduction 41
II. Substitution on treatment with saturated and unsaturated alcohols (monohydric and dihydric), monothiols and dithiols, and monoamines and diamines 41
III. Substitution on treatment with tervalent phosphorus and organometallic compounds 47

I. INTRODUCTION

The "chlorine accumulator",[1] namely hexachlorocyclopentadiene (HCCPD), which is widely used in organic syntheses, has been frequently the subject of review articles[2-5] and a monograph, the first in the periodical literature, devoted to the chemistry of this and related compounds, has been published recently.[6] HCCPD is a unique synthon for perchlorinated skeletal compounds. It was also the first representative of dienes with "reversed electronic character" in relation to the dienophile in the diene synthesis[8,9] and hence permitted the treatment of the mechanism of the Diels–Alder reaction at a still deeper level. By virtue of the ready formation of the aromatic pentachlorocyclopentadienyl anion, HCCPD has become an irreplaceable object for the development of the concept of "X-philic reactions" in organic chemistry.[10]

The diene adducts obtained on its basis are used as fireproofing agents, which make polymers incombustible[11-20] and most of them exhibit pronounced insecticidal,[21-26] fungicidal[27-30] and herbicidal properties.[31-41] Some of these pesticides, such as aldrin, dildrin, etc., are used in the national economy.[42] However, in recent years the range of applications of these compounds has been sharply curtailed and in some countries their use has been prohibited,[43] since they suffer from a significant disadvantage—their natural degradation in nature is slow and it involves the formation of toxic perchlorinated compounds.[44]



It is believed that one of the possible solutions of this problem is the modification of HCCPD [45] and its diene adducts[46] by substituting some of the chlorine atoms by functional groups. Despite the existing exceptions,[46,48] the substitution of chlorine atoms by alkoxy-groups by the S_N1 mechanism in the HCCPD adducts is usually difficult owing to the high energy of the sp^2-hybridised carbonium anion at the bridgehead of the norbornene skeleton;[49-51] direct substitution also cannot be achieved because of steric hindrance in the attack by the nucleophile from the rear of the bridging carbon atom. Since HCCPD contains two allylic chlorine atoms and four vinyl chlorine atoms and these can be readily exchanged for different anions, the most acceptable and the simplest method of modification involves nucleophilic substitution in the HCCPD itself and not in its adduct. The present review is devoted to such reactions.

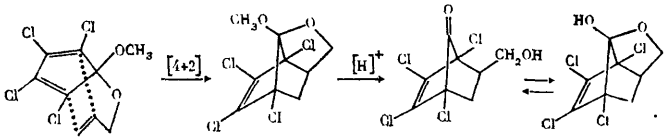
Analysis of the literature data demonstrates certain characteristic features of these reactions compared with nucleophilic substitution in other halogenocarbons.

On the other hand, the diene adducts obtained from substituted perchlorocyclopentadienes are of interest, because, by virtue of the presence of the readily hydrolysable ketal group, they are key compounds for the synthesis of useful substances with specified steric structures, which are otherwise difficult to obtain.[52-54]

II. SUBSTITUTION ON TREATMENT WITH SATURATED AND UNSATURATED ALCOHOLS (MONOHYDRIC AND DIHYDRIC), MONOTHIOLS AND DITHIOLS, AND MONOAMINES AND DIAMINES

A number of studies have been devoted to the nucleophilic substitution of chlorine atoms in HCCPD by saturated monoalkoxide anions.[55-59] It was first shown in 1947 [60] that the interaction of HCCPD (I) with KOH in ethanol at room temperature leads to 1,2,3,4-tetrachloro-5,5-diethoxycyclopentadiene (III) in a high yield. Other 5,5-dialkoxy-1,2,3,4-tetrachlorocyclopentadines can be obtained analogously:[55]

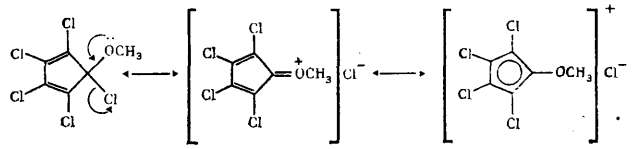
(I) (II), (III) (II): R=CH_3 (III): R=C_2H_5



The dienes (II) and (III) are stable compounds which readily enter into the Diels–Alder reaction with various dienophiles, like HCCPD. The stability of these dienes is determined by the presence of the ketal group,[61,62] which ensures the partial shielding of the tetrachlorocyclopentadiene ring and hence hinders the dimerisation process. This is confirmed by the striking tendency of 1,2,3,4-tetrachlorocyclopentadienone,[55] 1,2,3,4-tetrachlorocyclopentadiene,[63] and 1,2,3,4,5-pentachlorocyclopentadiene[64,65] to dimerise via the Diels–Alder reaction.

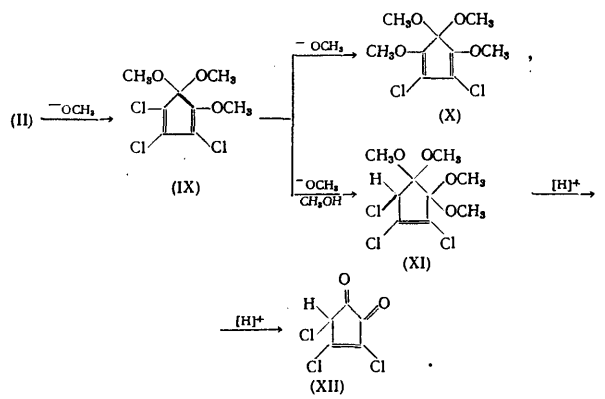
The high reactivity of HCCPD in nucleophilic substitution has aroused special interest. This compound should apparently be inert with respect to the action of a nucleophile, since direct substitution of the allylic chlorine atoms is difficult owing to steric hindrance to the attack by the nucleophile. Substitution via the ionisation mechanism is impossible, since it requires the formation of the antiaromatic pentadienyl cation, which is destabilised by the overall inductive effect of the five chlorine atoms; this carbonium ion is stable only at low temperature.[66]

Kinetic studies of the interaction between HCCPD and a methanol solution of KOH showed[67] that the reaction is of second order (of first order with respect to HCCPD and the base). Consequently, the rate of reaction is determined by the first bimolecular stage, while a second chlorine atom is substituted in the rapid stage. The authors emphasise that the reaction of HCCPD with an equimolar amount of KOH in



methanol gives rise exclusively to compound (II) both with refluxing and in the cold, approximately 50% of the HCCPD being recovered. It was not possible to detect the intermediate—the monomethoxy-derivative (IV).

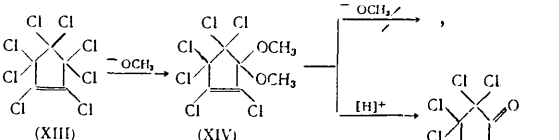
However, a study has been recently published[68] in which it was possible to demonstrate indirectly the formation of 1,2,3,4,5-pentachloro-5-monomethoxycyclopentadiene (IV). Treatment of the unpurified diene (II), obtained by the method of McBee et al.,[7] with potassium allylate in allyl alcohol at 50 °C in the course of 4 h led to the isolation of the pure colourless diene (II) and ~3% of compound (VI):



(V) (VI) (VII) (VIII)

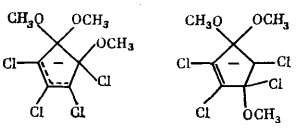
The structures of compounds (VI), (VII), and (VIII) obtained were established by spectroscopic methods and by chemical reactions. The intermediate triene (V) can be formed only from the monomethoxy-derivative (IV) when the latter is treated with potassium allylate. The yellow colour of the diene (II) obtained by the method of McBee et al.[67] has been explained by the presence of a small amount of the monomethoxy-derivative (IV) as an admixture, to which the following resonance structures were ascribed:[67]

(IV)



The subsequent reaction of the diene (II) with the methoxide anion is claimed[67] to afford the trimethoxy-compound (IX), which undergoes two simultaneous reactions after brief treatment with the methoxide anion:

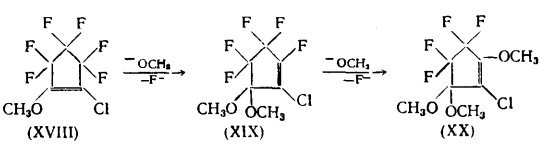
(IX) (X) (XI) (XII)



Trichlorotetramethoxycyclopentene (XI), whose structures was inferred from hydrolysis with formation of a compound allegedly identical with the known 3,4,5-trichlorocyclopent-3-ene-1,2-dione (XII),[69] was believed to be the main reaction product under these conditions. However, the position of the OCH_3 group in compounds (IX), (X), (XI), and (XII) was established incorrectly (see below). The tentative diene structure (IX) and (X) of the compound were proved by involving them in the diene condensation with maleic anhydride and also by the IR and UV spectroscopy.

Bimolecular nucleophilic substitution of chlorine in HCCPD could be achieved, in principle, in three positions—at the 1-, 2-, and 5-carbon atoms. Direct substitution of the allylic chlorine atom in the 5-position via the S_N2 mechanism is impossible. The inability of compound (XIV) to react further with the methoxide anion is consistent with this hypothesis:[67]

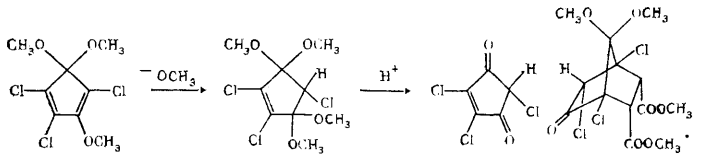
(XIII) (XIV) (XV)



If substitution takes place at one of the two allylic centres in compound (XIII), then the second centre should also react on the reasonable assumption that the dimethoxymethylene group in the product (XIV) does not deactivate the remaining allylic dichloromethylene group. This fact shows that the vinyl position is the centre of attack. The possibility of vinyl attack in these systems follows from the reactivity of the dienes (II) and (IX). The preferred direction of the attack on one of the two centres of the vinyl component of the cyclopentadiene ring has been explained as follows:[67] in reactions of this type, the affinity for nucleophiles characteristic of the substrate undergoing substituion is more important than the polarisability of the nucleofuge. The rate of formation of new bonds depends on the relative stability of the charged intermediate, which is the driving force of the reaction. The increase in the stability of the intermediate anion can be achieved by the charge distribution among several bonds. Hence, in the case of compound (II) there should be two types of vinyl chlorine atoms undergoing substitution and one of two charged intermediates, (XVI) and (XVII), should be formed:

(XVI) (XVII)

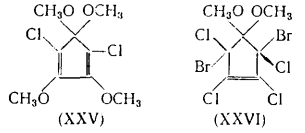
The above considerations give preference to the formation of the structure (XVI), but, contrary to expectation, the structure (XVII) is produced, as we shall see below.



Information about the allylic shift of the double bond and the vinyl attack in these reactions has been obtained[67] with the aid of the reactions of the model compound (XVIII):

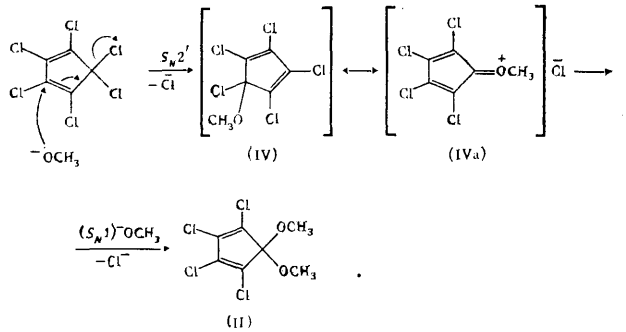
(XVIII) (XIX) (XX)

By adding slowly a methanolic solution of alkali to the product (XVIII), compound (XIX) was obtained, whose structure indicates the allylic migration of the double bond on substitution. The subsequent addition of the methoxide ion leads to the product (XX). The formation of compound (XX) indicates vinyl substitution in the 1-position in the cyclopentene ring without involving the chlorine atom, which has



been explained[67] by the relatively high reactivity of the vinyl fluorine atom compared with the vinyl chlorine atom. However, in order to make sure of the reliability of the results, it would be useful to employ the chlorinated analogue of compound (XVIII). This type of substitution in compound (II) should lead to the formation of the structure (XXI) and not (IX). Indeed, when the above reaction was carried out, the authors[70,71] showed that the methoxide anion attacks the carbon atom in the 2-position in the cyclopentadiene ring and compound (XXI) was isolated under these conditions, its structure being established by its conversion into compound (XXII) by treatment with the methoxide anion and acid hydrolysis of this product the corresponding diketone (XXIII):

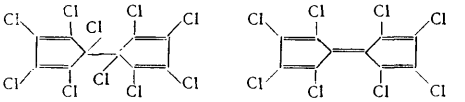
(XXI) (XXII) (XXIII) (XXIV)



The mistake by McBee et al.[67] was that they attributed the structure of compound (XII) to the ketone (XXIII) obtained. The physicochemical constants of these isomeric ketones are fortuitously identical. The structure of compound (XXI) was demonstrated by diene condensation with dimethyl maleate and the hydrolysis of the product to the corresponding ketone (XXIV). From these data, the structure (XXV) and not (X) can be attributed to the second diene obtained by McBee et al.[67] The structure (XXI) had been attributed to the product as early as 1965 [70] and was then confirmed in 1973;[71] this phenomenon was called the "anomalous effect".

It is noteworthy that the direction of attack by the nucleophile on the vinyl component of the cyclopentadiene ring probably depends on the relative electron density at the carbon atom, i.e. the anion should attack the carbon atom at which the electron density is lowest. Unfortunately, there are no quantitative data concerning this hypothesis for such a system. The vigorous interaction of the diene (II) with electrophilic bromine, leading to the 1,4-adduct (XXVI), may indicate the validity of the above hypothesis.[55]

(XXV) (XXVI)

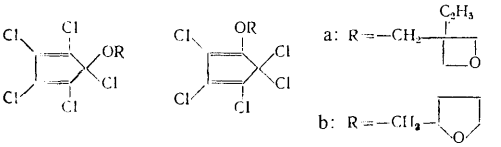


Thus the following mechanism has been put forward[71] based on the kinetic data for the reaction of HCCPD with the methoxide anion[67] and the stereochemical reactions of the products:[70,71]

(IV) (IVa) (II)

As can be seen from this scheme, regardless of the way in which the first chlorine atom in HCPPD undergoes bimolecular substitution, the rate of the second stage of the reaction will be appreciably higher, since the intermediate—pentachloro-5-methoxycyclopentadiene (IV)—undergoes unimolecular exchange of the allylic chlorine via the carbonium ion (IVa), in which the methoxy-group ensures additional resonance stabilisation. On the other hand, the exceptional sensitivity of α-chloro-ethers to bases is well known.[67,69]

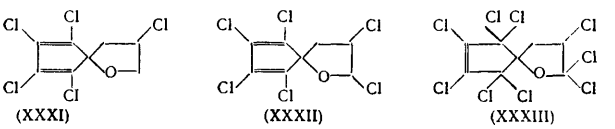
It is of interest that compounds (XXVII) and (XXVIII), obtained by the reaction of HCCPD and Cu_2Cl_2, are exceptionally inert with respect to the action of alkoxides,[72,73] which has been explained by steric and resonance effects. These compounds also fail to undergo the diene condensation with dienophiles of different types.



(XXVII) (XXVIII)

The reaction of HCCPD even with more bulky nucleophiles, such as isopropyl, t-butyl,[57] and benzyl alcohols,[74] etc. affords 5,5-disubstituted products. The reactions with phenol[75] and thiophenol[76] give rise to the monosubstituted as well as the disubstituted products.

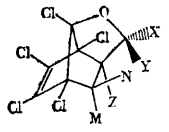
A study[77] in which the reaction involving the substitution of chlorine in HCCPD by 2-ethylhexoxide was considered and it was shown that it proceeds exclusively with formation of a monosubstituted product—pentachlorocyclopentadienyl 2-ethylhexyl ether—is of considerable interest.



It has also been established[78] that the nucleophilic substitution reaction of HCCPD with two bulky nucleophiles—3-ethyl-3-hydroxymethyloxetan and tetrahydrofurfuryl alcohol—leads simultaneously to two isomeric monosubstituted compounds (XXI) and (XXX) without the formation of disubstituted products:

(XXIX a, b) (XXX a, b)

The authors emphasise that both products interact vigorously with methanol in the presence of acid catalysts and that R is then substituted by CH_3. However, the reaction mechanism is not described. The absence of *gem*-disubstituted products in this reaction has been explained by steric factors generated by the nucleophiles themselves. The structures of the compounds obtained were established by the analysis of their IR spectra and of the Diels–Alder adducts obtained with various dienophiles. The formation of the isomer (XXX) is probably associated with the 1,5-migration of the chlorine atom in the cyclopentadiene ring.

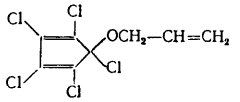


The nucleophilic substitution of a chlorine atom in HCCPD by unsaturated anions has its characteristic features. It has been claimed[79] that, when the allylate anion reacts with HCCPD, the monosubstituted adduct (XXXI) is formed.

(XXXI) (XXXII) (XXXIII)

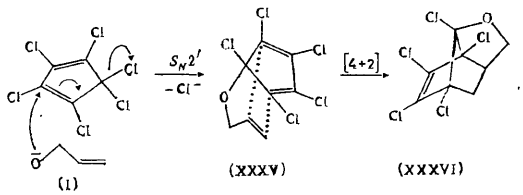
A patent[80] describes a study of the chlorination reaction of this compound, which allegedly yielded compounds (XXXII) and (XXXIII), but the structure (XXXI) attributed to the initial compound is incorrect.

Sometime later, an analogous reaction was carried out with monomethyl-substituted allyl alcohols and it was discovered that it takes place readily at 25–30 °C in aprotic solvents with formation of the oxatricyclononene skeleton: [81]



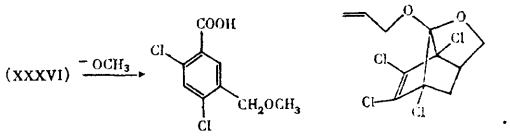
(XXXIV)

where X, Y, Z, M, and N are various alkyl and aromatic groups.



It is noteworthy that the author[81] does not reject the formation of compound (XXXI) in the case of allyl alcohols; an attempt was made to account for the cyclisation reaction in the formation of compound (XXXIV) by the electronic and structural effects generated by the alkyl or aryl substituents.

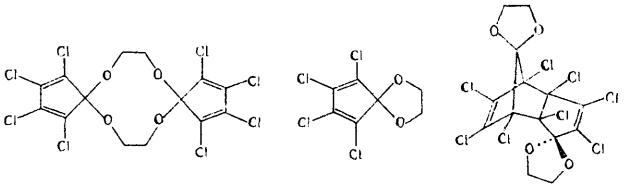
In 1969 the reaction with allyl alcohol was repeated[82] under fairly severe conditions (100–150 °C) and the structure (XXXV) was attributed to the product thus obtained:



(XXXV)

However, spectroscopic data and data based on chemical reactions are not quoted to prove the structure of the final products. It was shown later[83] that the compound obtained under these conditions does not react with maleic anhydride and that there are no absorption bands of the diene chromophore in its UV spectrum (in methanol). It was found that the position of the absorption maximum and its intensity (λ_{max} = 238 nm, ε = 2800) are identical with those calculated for the pentachlorocyclopentene structure. On the other hand, the IR spectrum of this compound contains one narrow absorption band at 1620 cm^{-1}, which is characteristic of the ClC=CCl fragment instead of the two bands which are usual for structures of type (XXXV). The structure of the compound obtained was finally established by analysing its ^1H NMR spectrum using nuclear double resonance. The ^1H NMR spectrum reveals the absence of allylic protons and is fully consistent with the structure (XXXVI). Compound (XXXV) is evidently a precursor in the formation of the final product (XXXVI) via the mechanism

(I) (XXXV) (XXXVI)

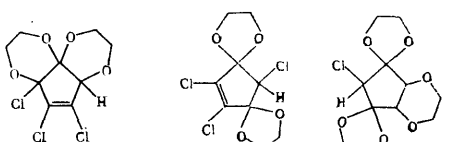


Compound (XXXVI) is formed as a result of the intramolecular [4 + 2]cycloaddition of the intermediate unstable triene (XXXV). The subsequent reaction involving substitution by anions via the S_N1 mechanism in the adduct (XXXV) was not observed under these conditions. However, on refluxing in a methanolic solution of alkali, the product (XXXVI) undergoes a skeletal rearrangement with formation of 4,6-dichloro-3-methoxymethylbenzoic acid (XXXVII), whose structure was determined by spectroscopic and chemical methods: [84]

(XXXVII) (XXXVIII)

The corresponding data confirming the structure (XXXVI) were also obtained almost simultaneously by Jung and Light; [85] in addition, they obtained 15% of the disubstituted product (XXXVIII).

Nucleophilic substitution in HCCPD by various diols has been investigated comprehensively. [86–93] Using ethylene glycolate as the nucleophile, the crystalline compound (m.p. 279 °C), to which the structure (XXXIX) was attributed, had been obtained even earlier: [55]

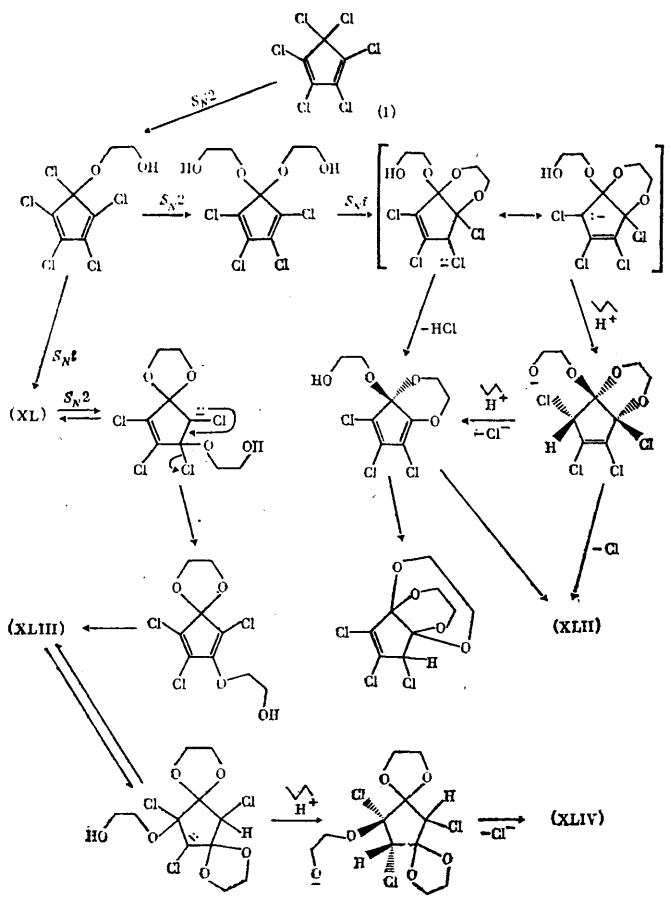


(XXXIX) (XL) (XLI)

It was latter established[87] that, when this reaction is carried out under fairly mild conditions (15 °C) and in the presence of a sixfold excess of ethylene glycol, the formation of low-melting crystals (m.p. 65–66 °C) is observed; the structure of the compound (XL) obtained was determined mainly chemically—by involving it in the diene condensation with various dienophiles. Thus the product was a monomer—a spirodiene.

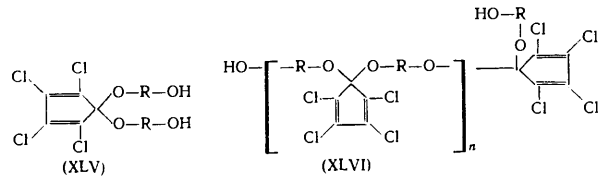
This reaction was investigated in even greater detail by Chang; [86] three crystalline compounds were then isolated (m.p. 107–108.5°, 79.5–80°, and 64.5–65.5 °C). The substance with m.p. 64.5–65.5 °C, which is 1,2,3,4-tetrachloro-6,9-dioxaspiro[4,4]-nona-1,3-diene (XL), can be obtained in 90% yield from one mole of HCCPD, 2.1 moles of KOH, and 8 moles of ethylene glycol. On heating (2 h, ~100 °C) or on storage in solutions for a fairly long time, compound (XL) dimerises to the product (XLI) (m.p. 279 °C) and not the product (XXXIX). The structure (XLI) was established chemically (this compound is inert to the action of dienophiles) and spectroscopically. The high tendency of the diene (XL) to dimerise, in contrast to the diene (II), has been explained by the steric influence of the ketal group. However, the author did not establish the structures of the other two compounds which he obtained (with m.p. 107–108.5° and 79.5 to 80 °C).

Subsequently, this reaction was investigated[70] at relatively high temperatures (55–60 °C) and mainly five compounds were then obtained: (XL), (XLI), (XLII), (XLIII), and (XLIV).



(XLII) (XLIII) (XLIV)

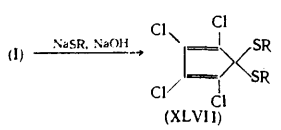
In the presence of an excess of the glycol and alkali and under more severe conditions (50–120 °C) the product (XLII) is formed. (On raising the reaction temperature to



140 °C, the formation of compound (XLIV) is observed.[92] The proposed reaction mechanism[70] is indicated in Scheme 1.

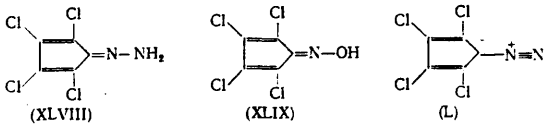
Scheme 1

As can be seen from this scheme, the author attempts to explain the initial attack by the nucleophile from the standpoint of the S_N2 mechanism, but this is impossible, as noted above. On the other hand, the monoalkoxy-intermediate formed should also be converted into the dialkoxy-compound via the S_N1 mechanism and not the S_N2 mechanism.[67,71]



The interaction of HCCPD with polyhydric alcohols containing ≥2 hydroxy-groups, compounds with non-neighbouring carbon atoms, leads to the formation of 1,2,3,4-tetrachloro-5,5-di(hydroxyalkoxy)cyclopentadienes (XLV) and the polyketals (XLVI):[90]

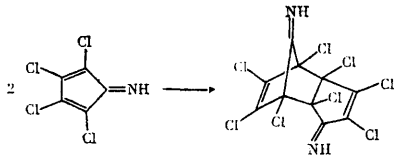
(XLV) (XLVI)



The ratio of the products obtained depends on the stoichiometry of the initial components taken for the reaction.

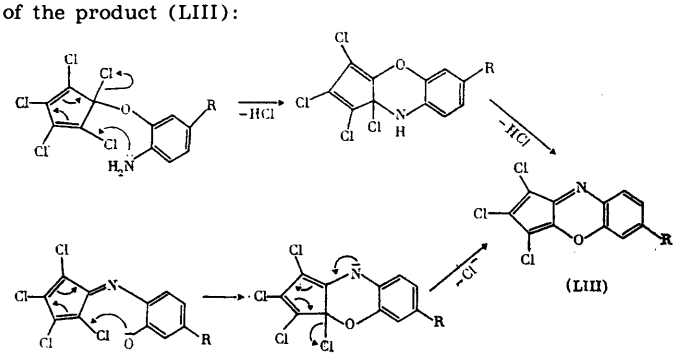
The reactions between HCCPD and various thiols in alcohol solution, leading to 5,5-thioketals (XLVII), proceed analogously to the reactions of HCCPD with alcohols:[57,94]

(XLVII)



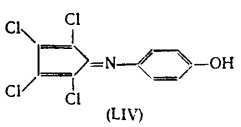
HCCPD reacts actively with hydrazine and hydroxylamine, which results in the formation of tetrachlorocyclopentadienone hydrazone (XLVIII) and oxime (XLIX):[95-98]

(XLVIII) (XLIX) (L)



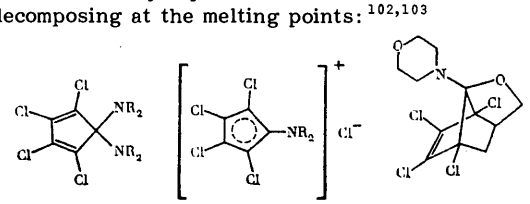
Dehydrogenation of the product (XLVIII) leads to the formation of tetrachlorodiazocyclopentadiene (L) in a high yield. In contrast to 1,2,3,4-tetrachlorocyclopentadienone, the above compounds are stable at room temperature.

It is of interest that the substitution product (LI), obtained by the reaction of HCCPD with ammonia at low temperatures (~−70 °C), is unstable and dimerises at the instant of formation to form the bisimine (LII):[99-100]



(LI) (LII)

The interaction of HCCPD with *o*-aminphenols in the presence of C_2H_5ONa yields[101] cyclopentabenzoxazines (LIII). The authors quote two alternative mechanisms of formation of the product (LIII):

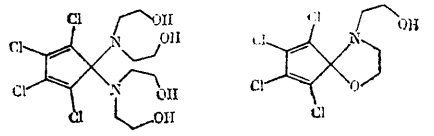


(LIII)

Which of the two nucleophilic centres (NH_2 or OH) is the first to be attacked has been demonstrated by using *p*-aminophenol as the nucleophile, which affords a single product—*p*-hydroxyazafulvene (LIV), which indicates the dominant role of the NH_2 group compared with the hydroxyl in this reaction:

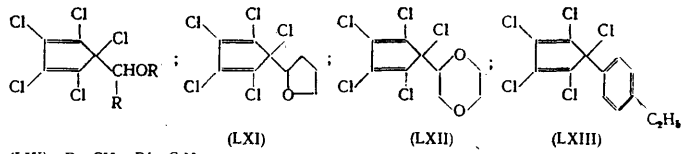
(LIV)

When secondary amines such as morpholine, piperidine, and dimethylamine are used as the nucleophiles, 5,5-disubstituted tetrachlorocyclopentadienes (LV) are formed as a rule, decomposing at the melting points:[102,103]



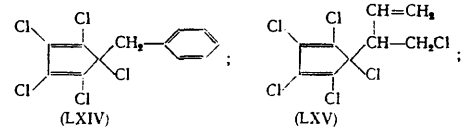
(LV) (LVa) (LVI)

The monosubstituted product (LVa) was not isolated, which the authors explain by its instability when acted upon by bases.



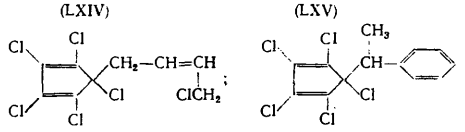
It is curious that treatment of compound (LV) with allyl alcohol for 4 weeks (25 °C) entails the replacement of one morpholino-group by the allylate anion with formation of the oxatricyclononene structure (LVI).

The interaction of diethanolamine with HCCPD led to the spiro-compound (LVIII) and not to the usual substitution product (LVII):[104,105]

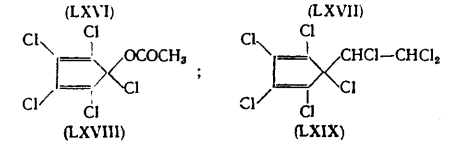


(LVII) (LVIII)

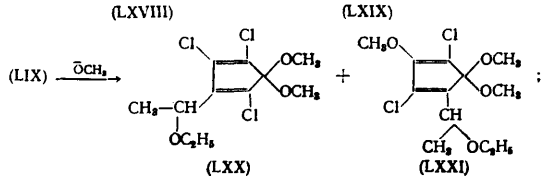
The HCCPD derivatives (LIX)–(LXIX) monosubstituted by functional-groups in the 5-position, synthesised by photo-initiated radical reactions,[106,107] undergo nucleophilic substitution on reaction with two typical nucleophiles: the methoxide anion and morpholine;[45] it was shown that the reaction proceeds in two stages with formation of 5,5-disubstituted products:



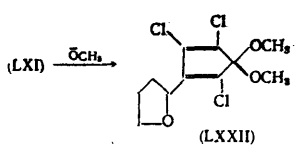
(LXI) (LXII) (LXIII)



(LIX): R=CH_3, R'=C_2H_5
(LX): R=CH_2Cl, R'=C_4H_9

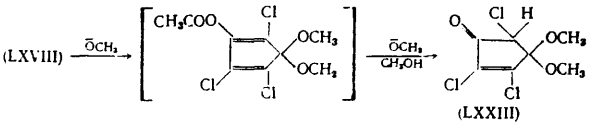


(LXIV) (LXV)



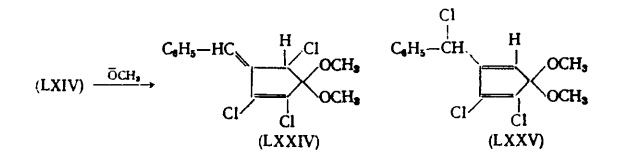
(LXVI) (LXVII)

(LXVIII) (LXIX)



(LXX) (LXXI)

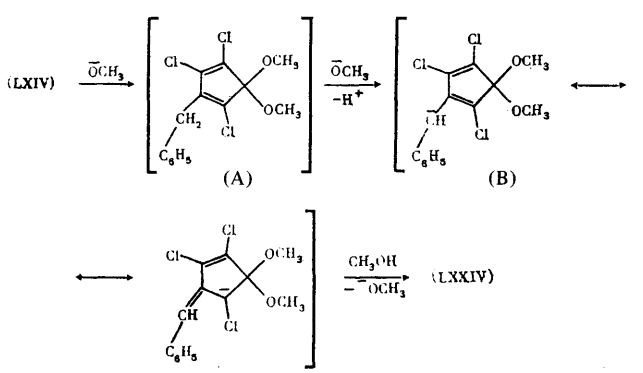
(LXXII)



After prolonged heating, the authors were able to isolate the trimethoxy-derivative (LXXI).

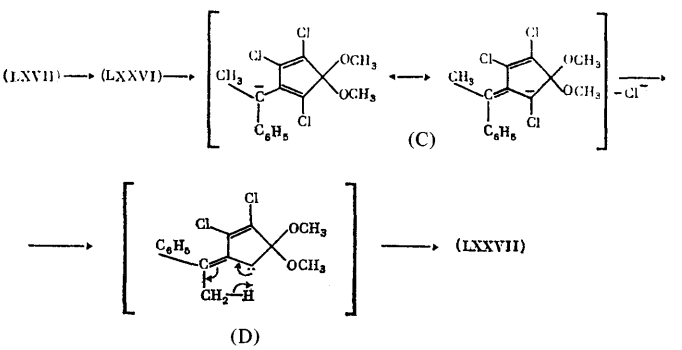
The 5-acetoxy-derivative (LXVIII) readily reacts with the methoxide anion, which affords a high yield of the ketone (LXXIII):[45]

(LXXIII)



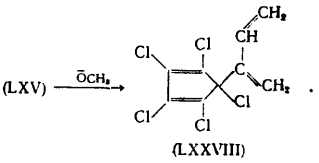
The authors emphasise that the interaction of compounds (LXIV) and (LXVII) with the alkoxide proceeds in a more complex manner and that the rearranged products (LXXIV) and (LXXVII) are then formed in satisfactory yields:

(LXXIV) (LXXV) (LXXVI) (LXXVII)



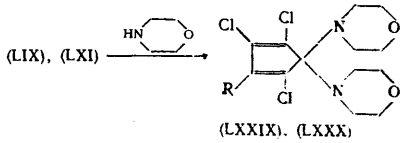
Compound (LXXVI) is fully converted during the reaction into the product (LXXVII). It has been established on the basis of spectroscopic data that the structure (LXXIV) is more probable than the structure (LXXV).

Consequently, the reactions of the benzyl compounds proceed in an unusual manner and involve three stages—methoxylation, dehydrochlorination, and hydrogen transfer from the substituent to the cyclopentadiene ring:



(A) (B) (LXXIV)

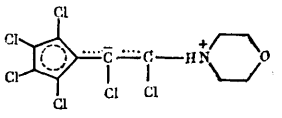
Compound (LXXVII) can also be obtained via the above pathway, but the subsequent conversion of the anion (C) into the carbene (D) and the 1,4-sigmatropic shift in the latter lead to the product (LXXVII):



(C) (D)

Treatment of compound (LXV) with an equivalent amount of the alkoxide results in an almost quantitative formation of the bisdiene (LXXVIII):[45]

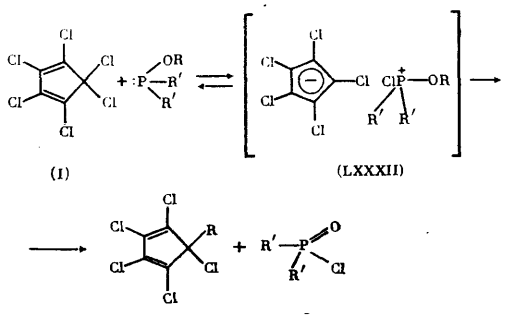
(LXXVIII)



Compounds (LIX) and (LXI) react readily with morpholine, forming the 5,5-disubstituted products (LXXIX) and (LXXX):

(LXXIX), (LXXX)

(LXXIX): R=CH(CH$_3$)OC$_2$H$_5$; (LXXX): R=

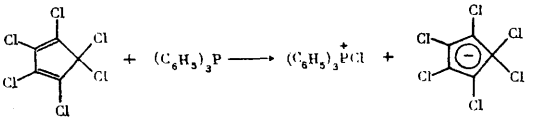


The reaction between the diene (LXIX) and morpholine proceeds differently and results in the formation of a dark-red product having the overall formula $C_{11}H_9Cl_6NO$. The structural formula (LXXXI) was attributed to it from spectroscopic data and physical properties:

(LXXXI)

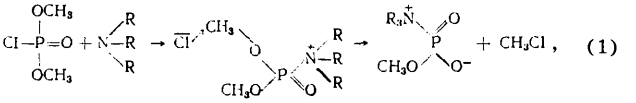
III. SUBSTITUTION ON TREATMENT WITH TERVALENT PHOSPHORUS AND ORGANOMETALLIC COMPOUNDS

The high tendency of HCCPD to form the stable aromatic pentachlorocyclopentadienyl anion on interaction with tervalent phosphorus and organometallic compounds has led to a new effective way of obtaining halogenocyclopentadienes with functional-group substituents[108–110] and has stimulated the development of the field of halogenophilic reactions.[10] According to the mechanism proposed by Mark,[111] the above reaction is a two-stage process; the allylic chlorine is abstracted by the nucleophile in the first stage with formation of the pentachlorocyclopentadienyl anion (LXXXII), while in the second stage the latter is alkylated with formation of 5-alkylpentachlorocyclopentadiene (LXXXIII):



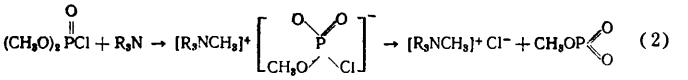
(I) (LXXXII)

(LXXXIII)



Repeated alkylation of compound (LXXXIII) gives rise to a mixture of three isomers: 5,5-, 1,5-, and 2,5-dialkyltetrachlorocyclopentadienes. Alkylation of HCCPD via the above scheme does not proceed in accordance with the S_N2 mechanism, in contrast to the Arbuzov rearrangement, which has been confirmed by the reactions of sterically hindered phosphites (t-butyl dimethyl phosphite, t-butyl diethyl phosphite) with HCCPD, which lead to the formation of 5-monosubstituted pentachlorocyclopentadienes.

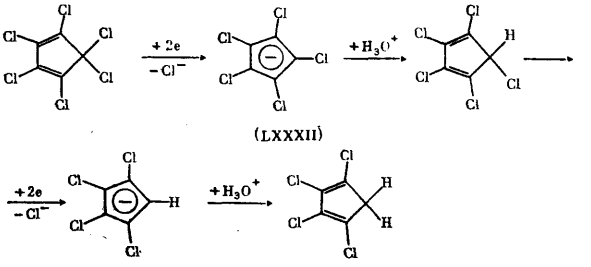
The ^{31}P NMR signal of the chlorotriphenylphosphonium cation (LXXXIV) has been detected on interaction of HCCPD with triphenylphosphine (at −80 °C), which indicates the simultaneous formation of the anion (LXXXII):[112]



(LXXXIV) (LXXXII)

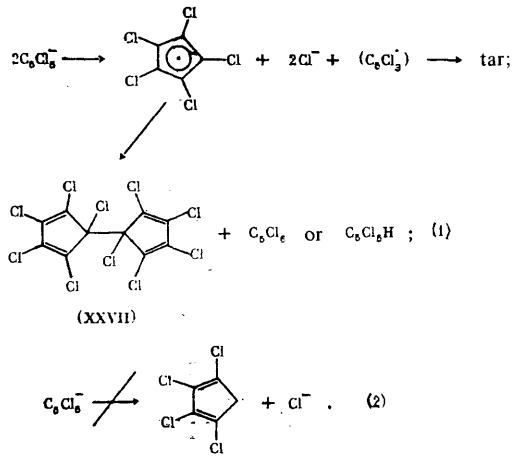
The use of trimethyl phosphite as the nucleophile led to charring of the reaction mixture as a consequence of the formation of the very reactive intermediate $(CH_3O)_2POCl$ during the reaction. In order to eliminate this difficulty, the equivalent amount of a tertiary amine, which decomposes the undesired product $(CH_3O)_2POCl$ via the mechanisms (1) or (2),[113] was added to the reaction mixture:

(1)



(2)

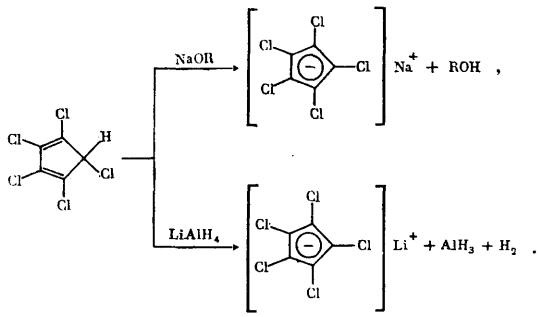
If the phosphorus atom is the centre of nucleophilic attack, then the reaction proceeds via the mechanism (1).



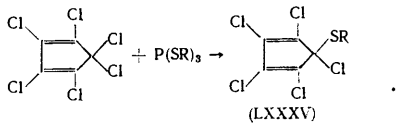
Tri-t-butyl phosphite exhibits a high reactivity in its reaction with HCCPD.[110] The high reactivity of this nucleophile can be accounted for by the high inductive effect of the t-butyl group compared with the normal alkyl groups and also by its large bulk, which increases the O–P–O angle and results in the approach of the hybridisation of the valence electrons of phosphorus to the sp^3 type. This facilitates the transition to the tetracoordinate state.

The formation of the anion (LXXXII) has also been demonstrated by the electrochemical reduction of HCCPD at a dropping mercury electrode in unbuffered and acid aqueous ethanol solutions:[114,115]

(LXXXII)



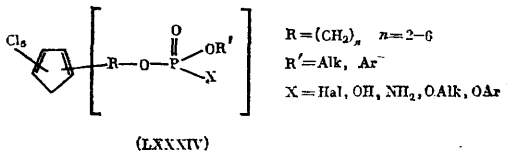
It is noteworthy that the basicity[114] and nucleophilicity[116–118] of the anion (LXXXII) are low, but the anion is rapidly oxidised with formation of the pentachlorocyclopentadienyl radical, owing to the overlap of the occupied π orbitals of the cyclopentadiene ring with the $3p_y$ orbitals of chlorine and this destabilises the π orbitals:



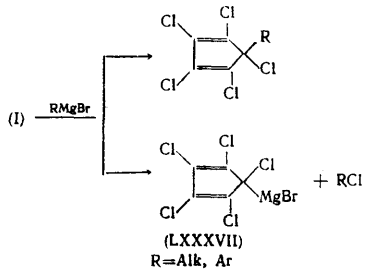
(XXVII)

The isolation of bispentachlorocyclopentadienyl (XXVII) serves as confirmation of the proposed mechanism (1).[116]

The anion (LXXXII) is also readily generated from pentachlorocyclopentadiene by reaction with strong bases:[65,116,118]



In contrast to the reaction of trialkyl phosphites with HCCPD, the interaction of the latter with trialkyl phosphorothioites leads to the formation of 1,2,3,4,5-pentachlorocyclopentadienyl sulphide (LXXXV), which exhibits a high biological activity:[119,120]

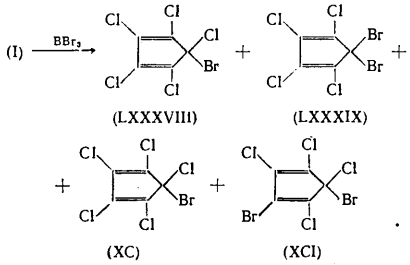


(LXXXV)

In contrast to acyclic phosphites, cyclic phosphites having the general formula OROPOR′, give rise on reaction with HCCPD, to pentachlorocyclopentadienyl phosphates (LXXXVI)[121,122] possessing insecticidal and herbicidal activities:

(LXXXIV)

HCCPD interacts vigorously with Grignard reagents, which results in the formation of monosubstituted products and other secondary compounds:[123,124]

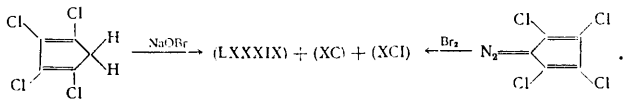


(LXXXVII)
R=Alk, Ar

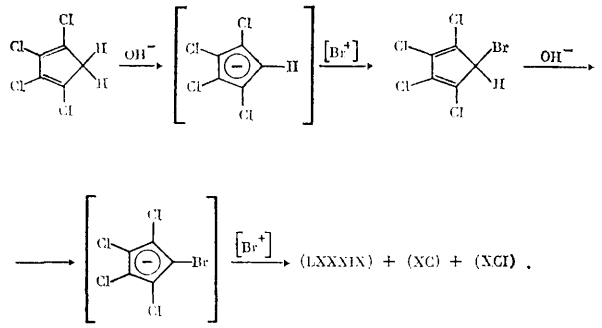
The authors were unable to obtain a Grignard reagent from HCCPD by the direct interaction of the latter with magnesium owing to the marked charring of the reaction mixture. It was therefore necessary to obtain initially the Grignard reagent of a halogenohydrocarbon and, by the reaction of the latter with HCCPD, to synthesise the desired product (LXXXVII). It was established that one chlorine atom is substituted by MgBr in this reaction, since only 1,2,3,4,5-pentachlorocyclopentadiene and a small amount of its dimer are formed on dilution of the reaction mixture with water. In addition two further compounds were isolated from the reaction mixture—bispentachlorocyclopentadienyl and a hydrocarbon. The interaction of HCCPD with RMgBr and subsequent mixing with solutions of halogenohydrocarbons in ether lead to 5,5-disubstituted derivatives of HCCPD.[123]

The chlorophilic reaction strikingly manifests the extensive synthetic possibilities for the preparation of new HCCPD derivatives with functional-group substituents in the synthesis of mixed polyhalogenocyclopentadienes.[125–132]

During recent years, much attention has been devoted to the synthesis of polyhalogenocyclopentadienes in connection with the vigorous development of ecological chemistry and the chemistry of skeletal compounds with functional-group substituents.[7,125]

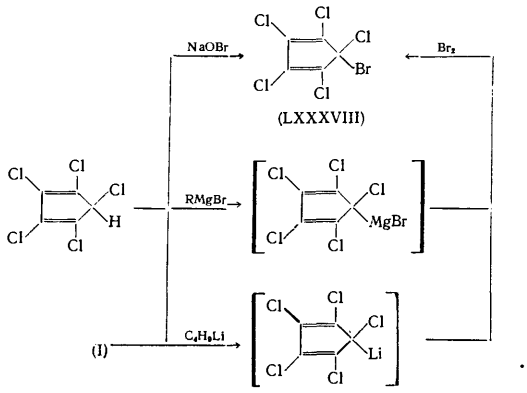


In the temperature range 160–170 °C, HCCPD reacts with PBr_3 to form 5-bromo-1,2,3,4,5-pentachlorocyclopentadiene.[127] In the presence of a catalytic amount of $AlBr_3$, the above reaction with PBr_3 leads to the successive substitution of chlorine atoms by bromine.[128,129] However, the question of the isomerism of the mixed polyhalogenocyclopentadienes obtained was not considered in these investigations and the authors unambiguously attributed structures with bromine atoms at C(5) to the compounds synthesised. ^{13}C NMR has been used to demonstrate the structures.[125] It was established reliably on the basis of the spectroscopic data that the reaction products are 5-bromo-1,2,3,4,5-pentachlorocyclopentadiene (LXXXVIII), 5,5-dibromotetrachlorocyclopentadiene (LXXXIX), 1,5-dibromotetrachlorocyclopentadiene (XC), 2,5-dibromotetrachlorocyclopentadiene (XCI), and a small amount of an extensive bromination product.



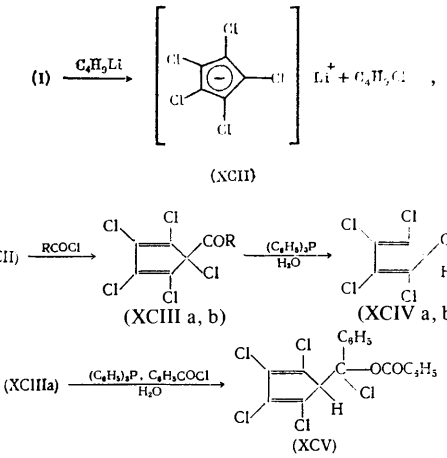
(LXXXVIII) (LXXXIX)

(XC) (XCI)



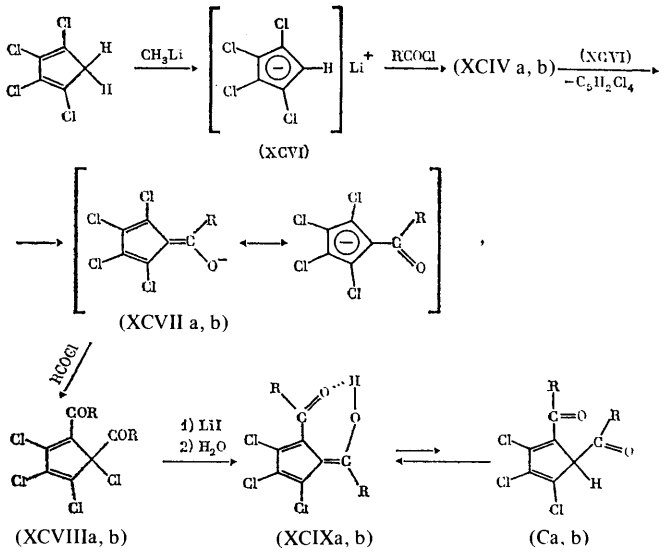
Compounds (LXXXIX), (XC), and (XCI) have been obtained by brominating tetrachlorocyclopentadiene with sodium hypobromite or by the interaction of tetrachlorodiazocyclopentadiene with bromine:[125]

This yields a mixture of three isomers in approximately equal proportions. The simultaneous formation of three dibromide isomers on bromination of tetrachlorocyclopentadiene was explained by the authors[125] with the aid of the following scheme:



The absence of monobromides with vinyl hydrogen atom from the reaction products indicates the regioselective attack by the electrophilic bromine on the 5-position in the anion (E). However, attack on the anion (F) by the electrophile can also take place non-regioselectively, which in fact results in the formation of three isomers. The monobromide (LXXXVIII) has been obtained by the reaction of pentachlorocyclopentadiene with NaOBr and also by the reaction of pentachlorocyclopentadienylmagnesium bromide or pentachlorocyclopentadienyl-lithium with bromine:[125]

Contrary to the data of Williamson et al.,[130] Zaichikova et al.[125] established, on the basis of chemical reactions and with the aid of ^{13}C NMR, that the bromine atom does not migrate in the cyclopentadiene ring in the monobromide (LXXXVIII) on heating and under the conditions of this diene synthesis.



Pentachloro- and tetrachloro-cyclopentadienyl-lithium are widely used in the synthesis of HCCPD derivatives monosubstituted by functional groups.[65,126,133] A new method of synthesis of compound (XLII) has been developed and a number of syntheses based on it have been carried out.[126] In contrast to the known procedures for synthesising compound (XCII) with the aid of lithium amalgam and $LiAlH_4$,[118] it was synthesised from HCCPD and butyl-lithium in pentane at −70 °C and was immediately made to react with strong electrophiles—carboxylic acid chlorides,[126] which results in the formation of unstable 5-acylpentachlorocyclopentadienes (XCIIIa, b):

These ketones (XCIIIa, b) are used in synthesis without additional purification at the instant of their formation, as shown in the scheme.

An unexpected result has been obtained[126] in the reduction of the ketone (XCIIIa) by triphenylphosphine in the presence of an excess of benzoyl chloride. It was established from spectroscopic data that, together with the formation of compound (XCIVa), its enolic form is acylated with the intermediate formation of tetrachlorophenylbenzoyloxyfuvene and the addition to the latter of hydrogen chloride. The structure of compound (XCV) was confirmed by its specific synthesis.

The acetylation of tetrachlorocyclopentadienyl-lithium (XCVI) with acetyl chloride at −50 °C led to the stable crystalline product (XCIXb) whose structure was determined by spectroscopic methods; for example, the signal due to the chelate proton in the ^1H NMR spectrum is in the region of $\delta = 16.10$ p.p.m.

Thus the existing experimental data on nucleophilic substitution in HCCPD demonstrate that this structurally simple compound has interesting chemical properties and reveal the following features of reactions of this type.

Nucleophilic substitution of the chlorine atoms in HCCPD by alkoxides, thiolates, and amines proceeds in two stages: initially the anion attacks the 2-position in HCCPD via the S_N2' mechanism and then the allylic chlorine atom (in the 5-position) is abstracted via the S_N1 mechanism and the final reaction products are 5,5-disubstituted 1,2,3,4-tetrachlorocyclopentadienes.

Substitution by treatment with alkoxides obtained from allyl alcohol and its derivatives proceeds anomalously with formation of 5-monosubstituted products.

Substitution by treatment with tervalent phosphorus and organometallic compounds takes place with formation of the aromatic pentachlorocyclopentadienyl anion, whose alkylation affords 5-alkyl-1,2,3,4,5-pentachlorocyclopentadiene.

However, together with the above findings, there exist also unsolved problems in this field, in particular there are no data concerning the carbanionic (Ad_N type) addition—elimination mechanism, which may compete with the mechanism of the S_N2' type in the reactions of HCCPD with alkoxides (the formation of 1,3,4-trichloro-5,5-difluoro-2-methoxycyclopentadiene on interaction of 1,2,3,4-tetrachloro-5,5,difluorocyclopentadiene, a derivative of a HCCPD homologue, with the methoxide anion can be readily explained with the aid of the Ad_N mechanism[65,71]); the formation of only monosubstituted products in the reaction of HCCPD with certain saturated alcohols is unexpected;[77,78] there have been no quantum-chemical calculations for HCCPD and 1,2,3,4-tetrachloro-5,5-dimethoxycyclopentadiene, with the aid of which it might be possible to predict the regioselectivity of the reactions, etc.

Reactions Involving the Addition of Dithio-acids to Unsaturated Compounds

V.N.Drozd, M.L.Petrov, N.Ya.Kuz'mina, and A.S.Vyazgin

Data on the reactions involving the addition of dithiocarboxylic, dithiocarbamic, and other heterosubstituted dithio-acids to compounds with a multiple bond are surveyed. It is shown that the character of the addition depends on the nature of the dithio-acid: dithiocarbamic and xanthic acids add via an ionic mechanism, while for dithiocarboxylic acids there is a possibility also of radical addition as well as cycloaddition together with the ionic addition.
The bibliography includes 126 references.

III. Dithiocarboxylic acids 56

I. INTRODUCTION

In contrast to the reactions involving the addition of carboxylic acids to multiple bonds, which have been investigated in detail, those of the sulphur analogues (dithio-acids) have attracted the attention of investigators relatively recently. The interest in these reactions is associated both with the active development of the chemistry of organosulphur compounds and with the practical application of dithio-acid esters—the products of the interaction of unsaturated compounds and dithio-acids.

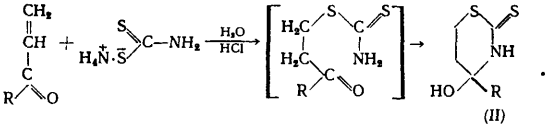
Divinyl sulphide and its derivatives have been obtained by reactions of dithio-acid salts.[1-4] The vinyl esters of various dithio-acids have found applications in the synthesis of polymeric materials.[5-9] The products of the interaction of dithio-acids with unsaturated compounds have a fairly broad spectrum of biological activity. Thus dithiocarbamic acid esters exhibit insecticidal, acaricidal, nematocidal, and fungicidal activities.[10-13] A wide variety of heterocyclic sulphur derivatives have been obtained from the products of the interaction of dithio-acids with unsaturated compounds. For example, one may note the synthesis of sulphur analogues of pyrimidine derivatives which form part of the composition of nucleic acids—uracil and thymine,[14] as well as the synthesis of derivatives of tetrathiafulvalene, which are used to obtain "organic metals"—radical-ion salts with conducting properties.[15]

In connection with the undoubted practical value of dithio-acid esters, their properties and the methods of their synthesis have been considered in fair detail in a series of books, monographs, and reviews.[1-4,16-19] However, the reactions involving the addition of dithio-acid to unsaturated compounds have not been described in these publications.

The present review is devoted to the consideration of the characteristic features of reactions involving the addition of dithio-acids to the multiple bonds of a wide variety of unsaturated compounds.

II. DITHIOCARBAMIC AND XANTHIC ACIDS

1. The Addition of Dithiocarbamic and Xanthic Acids to Double Bonds



The first reactions of dithio-acids with unsaturated compounds were carried out in relation to the interaction of unsubstituted and *N*-monosubstituted dithiocarbamic acid with alkenes activated by electron-accepting substituents. The regioselectivity of the reaction and the fact that the reactions are carried out in polar solvents (water, alcohol) permit the claim that all cases involve the ionic addition of dithiocarbamic acid with formation of dithio-esters (I) in high yields (60–90%):[20-26]

$$R^1NHCS_2H + R^2R^3C{=}R^4Z \rightarrow R^1NHC(S)SCR^2R^3CHR^4Z \quad (I)$$

$R^1 = H, Alk; R^2, R^4 = H, Alk; R^3 = H, Alk, Ar, CCl_3;$
$Z = CHO, CONAlk_2, COAlk, CO_2Alk, CN.$

The exclusively ionic character of the addition can probably be accounted for by the fact that the unsubstituted and *N*-monosubstituted dithiocarbamic acids, generated by treating ammonium salts with HCl, can behave as the inner salts $R\overset{+}{N}H_2C(S)S^-$ under the reaction conditions.

The dithio-esters (I), obtained by condensing dithiocarbamic or *N*-alkyldithiocarbamic acids with αβ-ethylenic carbonyl compounds, have been converted by intramolecular cyclisation into the corresponding 1,3-thiazines (II),[21,23,24] sometimes without isolating compounds (I):[22]

(II)

In the reactions of dithiocarbamic acids with substituted divinyl ketones, the attack is directed to the less substituted double bond:[26]

$$Me_2C{=}CHCOCH{=}CH_2 \xrightarrow[-5^\circ C, HCl]{RR^1NCS_2^-N^+H_4(Na^+)} Me_2C{=}CHCOCH_2CH_2SC(S)NR^1R;$$
$R = H, Alk, R^1 = Alk, Ar, PhCH_2.$

The reactions of salts of dithiocarbamic acids with alkenes, activated by electron-accepting substituents, also lead to the dithio-esters (I):[13,27-35]

$$R^1R^2NCS_2^-Kat^+ + R^3R^4C{=}CR^5Z \xrightarrow{H_2O} R^1R^2NC(S)SCR^3R^4CHR^5Z \quad (I)$$

$R^1, R^2 = H, Alk, (CH_2)_n; R^3, R^4, R^5 = H, Me, Ph; Z = COAlk,$
$CO_2Alk, CONH_2, CN, NO_2, SO_2Alk; Kat = K, Na, NH_4, AlkNH_3, Alk_2NH_2, Alk_3NH.$

It has been noted in a number of studies[29,30] that, together with the dithio-esters (I), the reaction mixture contains considerable amounts of the sulphides $(ZCHRCHR)_2S$ (III), the sulphide becoming the main product in the presence of an

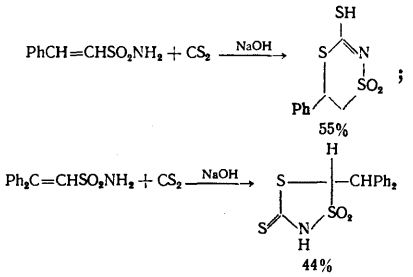
excess of the base. A possible mechanism of the formation of these compounds has been put forward:

$$RNHCS_2^-Na^+ + H_2C=CHCN \xrightarrow{H_2O} (I) + NaOH,$$
$$(I) \xrightarrow{OH^-} RN=C=S + HSCH_2CH_2CN;$$
$$HSCH_2CH_2CN + H_2C=CHCN \rightarrow (NCCH_2CH)_2S.$$

However, the possibility that the sulphide ion is generated in the rearrangement of the dithiocarbamate anion to isothiocyanate under the influence of the base is not ruled out:

$$RNHCS_2^- \rightleftarrows RN=C(S^-)SH \xrightarrow{OH^-} RN=C=S + S^{2-} + H_2O;$$
$$S^{2-} + 2H_2C=CHCN \xrightarrow{H_2O} (NCCH_2CH_2)_2S.$$

In order to increase the yield of compound (I), it has been suggested that the reaction be carried out in the presence of acetic acid and with cooling (at 0 °C).[30]



Reactions of dithiocarbamic salts with activated alkenes are reversible and are accompanied by the isomerisation of the alkenes:[10,31,34,36-38] in the reaction of triethylammonium *NN*-diethyldithiocarbamate with dimethyl fumarate, the equilibrium is attained when 82% of the reaction product (I) has accumulated in the mixture.[39]

The reaction of perfluoropropene with sodium *NN*-dialkyldithiocarbamate in an effectively solvating solvent [dimethylformamide (DMF)] affords, together with the expected product (I) of the addition of the dithiocarbamate anion to the double bond, also the product (IV) of the substitution of the fluorine atom at the double bond by the dithiocarbamate group:[40]

$$CF_3CF=CF_2 + R_2NCS_2^-Na^+ \rightarrow \underset{(I)}{CF_3CFHCF_2SC(S)NR_2} + \underset{(IV)}{CF_3CF=CFSC(S)NR_2}.$$

However, it has been shown[40] that a mixture of the (*Z*)- and (*E*)-isomers of compound (IV) is formed when hydrogen fluoride is eliminated from the dithio-ester (I) under the reaction conditions.

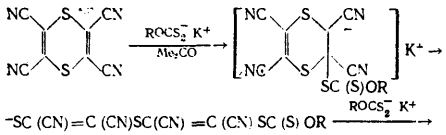
The reaction, described by Hasegawa et al.,[41,42] can be classified as an example of intramolecular nucleophilic addition of the dithiocarbamate anion to the double bond:

In the presence of electron-donating substituents in the *para*-position in the benzene ring, the yields increase to 95%.

The reactions of organyldithiocarbamic acids, formed from carbon disulphide and a secondary amine, with alkyl vinyl ethers and sulphides has been investigated recently; in the general case, the reaction proceeds as electrophilic addition, leading to 1-alkoxy- and 1-alkylthio-1-(organyldithiocarbamoyl)ethanes in yields ranging from 77% to quantitative:[43,44]

$$2R^1_2NH + CS_2 \rightarrow R^1_2NCS_2^-\overset{+}{N}H_2R^1_2 \overset{CS_2}{\rightleftarrows} 2R^1_2NCS_2H \xrightarrow{R^2XCH=CH_2} R^1_2NCS\underset{\underset{S}{\|}}{C}HCH_2\underset{\underset{XR^2}{|}}{}$$

X = O, S.



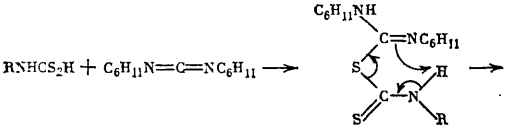
As expected, alkyl vinyl ethers proved to be more reactive in the reaction investigated than alkyl vinyl sulphides: the former react at 45–55 °C and the latter at 100 °C.

Numerous examples of the ionic addition of *O*-alkylxanthic acids to activated alkenes are known:[45-47]

$$R^1OCS_2H + R^2R^3=CHZ \rightarrow R^1OC(S)SCR^2R^3CH_2Z;$$
R^1 = Me, Et, n-Pr, iso-Pr, iso-Bu; R^2 = H, Me, Ph; R^3 = H, Me;
Z = COAlk, COAr, CO_2H, $CONH_2$, Ac.

Free xanthic acids are generated by treating the potassium salts with H_2SO_4.[45]

The reaction of potassium *O*-alkylxanthate with tetracyano-1,4-dithiine and tetracyanothiophen has been investigated.[48] Nucleophilic attack on the double bond is in this case always accompanied by ring opening with formation of compounds (V) and (VI):



$$\rightarrow K^+ -SC(CN)=C(CN)SC(CN)=C(CN)SC(S)OR \xrightarrow{ROCS_2^-K^+} \rightarrow \underset{(V)}{(Z,E)\text{-}[K^+ -SC(CN)=C(CN)]_2S} + \underset{(VI)}{(ROCS)_2S}.$$

Like the reaction of dithiocarbamates, that of triethylammonium xanthate with dimethyl fumarate is reversible;[39] equilibrium is attained when 67% of the adducts (VII) has accumulated in the reaction mixture:

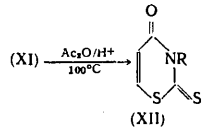
$$EtOCS_2^-\overset{+}{H}NEt_3 + (E)\text{-}MeO_2CCH=CHCO_2Me \rightleftarrows \underset{(VII)}{\rightleftarrows EtOC(S)SCH(CO_2Me)CH_2CO_2Me} + Et_3N.$$

In the case of a heterodouble bond (C=N), the reactions with dithiocarbamic acid proceed in a more complex manner, although here too the initial formation of the product of nucleophilic addition has been postulated.[49] Thus dithiocarbamic acid reacts with dicyclohexylcarbodiimide to form the isothiocyanate (VIII) and *NN'*-dicyclohexylthiourea (IX):

$$RNH_2 + CS_2 \rightarrow RNHCS_2H$$

$$\rightarrow \underset{(VIII)}{RN=C=S} + \underset{(IX)}{C_6H_{11}NHC(S)NHC_6H_{11}}.$$

When dimethyl azodicarboxylate was allowed to react with *O*-alkylxanthic acids, the product (X) of nucleophilic addition to the N=N bond was isolated:[45]



$$ROCS_2H + MeO_2CN=NCO_2Me \rightarrow \underset{(X)}{ROC(S)SN(CO_2Me)NHCO_2Me}.$$

2. The Addition of Dithiocarbamic and Xanthic Acids to Alkynes and Nitriles

Only alkynes activated by electron-accepting substituents react with dithiocarbamic acids. The reaction is exclusively ionic. Thus free dithiocarbamic acid and its *N*-monoalkyl derivatives, obtained from the ammonium salts *in situ*, add to the triple bond of propiolic acid and its esters at a low temperature with formation of *S*-vinyl esters of dithiocarbamic acid (XI):[14,50,51]

$$RNHCS_2^-\overset{+}{N}H_4 + HC\equiv C-CO_2R^1 \rightarrow \underset{(XI)}{(Z)\text{-}RNHC(S)SCH=CHCO_2R^1};$$
R, R^1 = H, Alk.

All the adducts of type (XI) obtained have the (*Z*)-configuration, cyclising to the corresponding 1,3-thiazines (XII) on heating in acetic anhydride in the presence of H_2SO_4:[14]

(XII)

The reactions of dithiocarbamic acid salts with non-activated alkynes have been widely investigated in recent years. The synthesis of *NN*-dialkyl-*S*-vinyl dithiocarbamates (XII) from acetylene, carbon disulphide, and secondary aliphatic amines in the presence of traces of KOH should probably be regarded as the first example of such reactions: [52,53]

$$HC{\equiv}CH + CS_2 + Alk_2NH \rightarrow \underset{(XIII)}{Alk_2NC(S)SCH{=}CH_2} .$$

It has been noted that the best yields of compound (XIII) (52–60%) are obtained at a pressure of 13–18 atm and 130 °C in DMF or water. [53]

A series of studies by Trofimov and co-workers on the interaction of dithiocarbamate anions with non-activated acetylenes have been a logical continuation of these investigations. [1–4,54] The reaction is carried out in polar aprotic solvents: dimethyl sulphoxide (DMSO), tetrahydrofuran (THF), hexamethylphosphoramide (HMP), and dioxan containing 1–6% of water. The reaction products are the corresponding *S*-vinyl esters of dithiocarbamic acids (XIII) and divinyl sulphides (XIV):

$$R^1_2NCS_2^-M^+ + R^2C{\equiv}CH \xrightarrow{H_2O} \underset{(XIII)}{(Z)\text{-}R^1_2NC(S)SCH{=}CHR^2} + \underset{(XIV)}{+ (Z,Z)\text{-}(R^2CH{=}CH)_2S} ;$$

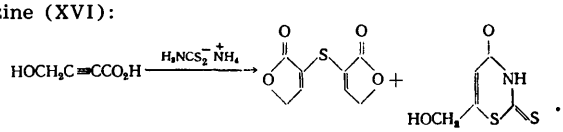
$$R^1 = Alk;\ R^2 = H, Ph;\ M = Na, K .$$

The divinyl sulphides (XIV) are the products of secondary reactions of the *S*-vinyl esters (XIII): [1–4]

$$(XIII) + OH^- \rightarrow \begin{matrix} H \\ R^2 \end{matrix}\!\!>\!\!=\!\!<\!\!\begin{matrix} H \\ S^- \end{matrix} + [R^1_2NC(O)SH] \xrightarrow{R^2C{\equiv}CH}$$

$$\rightarrow \underset{(XIV)}{(Z,Z)\text{-}(R^2CH{=}CH)_2S} + R^1_2NC(O)S^- .$$

The divindyl sulphides (XIV) are formed especially readily in "superbasic media" (DMSO, H_2O, KOH solutions), where they become the main products. The best yields of the dithio-esters (XIII) have been obtained in THF in the presence of an excess of dithiocarbamate anions, at a moderate temperature, and for a long reaction time and also when buffer systems, preventing the accumulation of the base in the reaction mixture, were used. [54]



The reaction of the ammonium salts of dialkyldithiocarbamic acids with diacetylene leads to butenyne esters having exlusively the (*Z*)-configuration. [55] The reaction does not stop after the addition of one dithiocarbamate molecule:

$$R^2NCS_2^-\overset{+}{N}H_4 + HC{\equiv}C{-}C{\equiv}CH \xrightarrow{H^+} (Z)\text{-}HC{\equiv}C{-}CH{=}CH{-}SC(S)NR_2$$

$$\xrightarrow{R_2NCS_2^-\overset{+}{N}H_4} (Z,Z)\text{-}(Z,E)\text{-}R_2NC(S)SCH{=}CH{-}CH{=}CHSC(S)NR_2 .$$

Activated aceylenes also interact with dithiocarbamic acid salts. Thus the interaction of propiolic acid with dithiocarbamate anions at room temperature leads to low yields of the dithio-esters (XI), [56] which are also formed from *N*-alkyldithiocarbamic acids *in situ*. [14] All the adducts of type (XI) obtained have the (*Z*)-configuration. On heating in water in the presence of hydrobromic acid, the dithio-esters (XI) are converted into the (*E*)-isomers, while in the case of *N*-monosubstituted dithiocarbamic acids the dithio-esters (XI) cyclise to the 1,3-thiazines (XII). [56]

The main product of the interaction of ammonium dithiocarbamate with 4-hydroxy-2-butynoic acid is the divinyl sulphide (XV) together with a small amount of the 1,3-thiazine (XVI):

(XV), 30% (XVI), 6%

The reaction with the ethyl ester of this acid results in a significant increase in the yield of compound (XVI) (to 64%), but linear adducts have not been isolated in either the former or the latter case. [51]

According to Kishida and Terada, [57] the only products of the reaction of ammonium dithiocarbamate with functional derivatives of substituted and unsubstituted propiolic acid are the divinyl sulphides (XVII):

$$RC{\equiv}CX + H_2NCS_2^-\overset{+}{N}H_4 \rightarrow \underset{(XVII)}{(Z,Z)\text{-}(XCH{=}CR)_2S} ;$$

$$R = H, Me, Ph,\ X = CN, CO_2Et .$$

^1H NMR data demonstrate convincingly that the adducts (XVII) obtained have the (*Z*,*Z*)-configuration. On irradiation with UV light or on heating, the (*Z*,*Z*)-isomers are converted into the (*Z*,*E*)-form. The authors [57] explain the formation of (*Z*,*Z*)-divinyl sulphide (XVII) by the *trans*-nucleophilic addition to the triple bond. This view is shared by almost all investigators. [54–56] However, Cain and Warrener, [14] who carried out similar studies, believe that the configuration of the adducts does not indicate in this instance the preferential *trans*-addition of the sulphur-containing nucleophiles to the triple bond but reflect in reality merely the fact that the (*Z*)-isomer is more stable in the crystalline state.

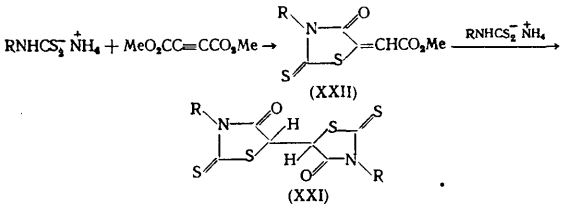
In the reaction with tertiary propargyl chlorides, the dithiocarbamate anion initially substitutes the chlorine atom and only then adds to the triple bond. [58]

$$R^1_2NCS_2^-Na^+ + ClCR^2R^3C{\equiv}CH \xrightarrow[20°C]{H^+} \underset{(XVIII)}{(Z)\text{-}R^1_2NC(S)SCR^2R^3CH{=}CHSC(S)NR^1_2} ;$$

$$R^1 = Alk,\ R^2 = R^3 = Me;\ R^2 = H,\ R^3 = Me .$$

The product (XVIII) has the (*Z*)-configuration but isomerises on heating to 50 °C.

α-Acetylenic ketones react with *NN*-dialkyldithiocarbamic salts to form the corresponding *S*-vinyl dithio-esters (XIX), which are readily converted on heating into divinyl sulphides (XX): [59,60]



$$R^1_2NCS_2^-Cat^+ + R^2C{\equiv}CCOR^3 \rightarrow \underset{(XIX)}{R^1_2NC(S)SCR^2{=}CHCOR^3} \rightarrow \underset{(XX)}{(R^3COCH{=}CR^2)_2S} ;$$

$$R^1 = Alk;\ R^2, R^3 = H, Me, Ph;\ Cat = Na, K, NH_4 .$$

By carrying out the reaction in a two-phase system (water–diethyl ether), it is possible to avoid the charring of the products (XIX) and the formation of divinyl sulphide (XX). [59] The dithio-esters (XIX) are formed as a mixture of the (*Z*)- and (*E*)-isomers with the (*Z*)-isomer predominating. The appearance of the (*E*)-isomer, formally corresponding to the breakdown of the *trans*-addition rule, is due to the ease of the transition (*Z*) → (*E*). The decrease in the activation barrier to the isomerisation has been explained by the strong through-conjugation of the S–C=C–C=O system, which loosens the C=C bond. [1] When ammonium dithiocarbamate ($R^1 = H$) is introduced into the above reaction, the only product is the divinyl sulphide (XX). [60]

The nature of the products of the reactions of ammonium dithiocarbamates with dimethyl acetylenedicarboxylate (DMAD) depends significantly on the reaction conditions. In the

reaction of DMAD with an excess of ammonium *N*-alkyldithiocarbamate, the bisthiazolidinones (XXI) are formed. On the other hand, when the ammonium salt is added to an excess of DMAD, the reaction products are the thiazolidinones (XXII):[61]

(XXII)

(XXI)

The salts of *NN*-disubstituted dithiocarbamic acids react with acetylenecarboxylic acid esters regiospecifically and stereospecifically with formation of only the linear products (XXIII) (*trans*-nucleophilic addition) regardless of the electronic properties of the substituents at the nitrogen atoms and also of the nature of the cation and the solvent:[39,62,63]

$$R^1_2NCS_2^-Kat^+ + R^2C{\equiv}CCO_2Me \xrightarrow{H^+} (Z)\text{-}R^1_2NC(S)SCR^2{=}CHCO_2Me\ ;$$
(XXIII)

R^1 = Alk, $PhCH_2$; R^2 = H, CO_2Me, Ph; Kat = Na, $HNEt_3$.

In the presence of an excess of the dithiocarbamic salt, the adduct (XXIII) combines with a second dithiocarbamic acid molecule, forming a mixture of the *dl*- and *meso*-forms of the dimethyl esters of 2,3-bis(*NN*-dialkylthiocarbamoylthio)-succinic acid (XXIV):[39]

$$(Z)\text{-}R^1_2NC(S)SCR^2{=}CHCO_2Me + R^1_2NCS_2^-H\overset{+}{N}Et_3 \rightarrow$$
$$\rightarrow R^1_2NC(S)SCHR^2CH(CO_2Me)SC(S)NR^1_2\ ;$$
(XXIV)

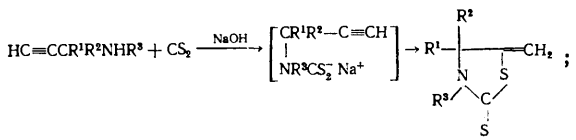
R^1 = Et, R^2 = CO_2Me .

The non-stereospecificity of the addition of the second dithiocarbamic acid molecule is probably caused by the partial isomerisation of the adduct (XXIV) to the thermodynamically more stable diastereoisomer in the presence of the base. This hypothesis is confirmed by the results of a study of Angadiyavar et al.:[64] when DMAD was allowed to react with salts of secondary amines and *NN*-dialkyldithiocarbamic acids, only the thermodynamically more stable *erythro*-isomers of α-amino-β-dithiocarbamoylsuccinates (XXV) were found. In the first stage, the triple bond of DMAD is subjected to nucleophilic attack by the dithiocarbamate anion with formation of the monoadduct (XXVI). The formation of the diadduct (XXV) is a consequence of the addition of the secondary amine to compound (XXVI):

$$Alk_2NCS_2^-H_2\overset{+}{N}Alk_2 + MeO_2CC{\equiv}CCO_2Me \rightarrow Alk_2NC(S)SC(CO_2Me){=}$$
(XXVI)

$$={=}CHCO_2Me + HNAlk_2 \rightarrow Alk_2NC(S)SCH(CO_2Me)CH(CO_2Me)NAlk_2\ .$$
(XXV)

Acetylenic and diacetylenic compounds activated by the trifluoromethyl group (a σ-acceptor substituent) also interact with the triethylammonium salts of *NN*-dialkyldithiocarbamic acids regiospecifically and stereospecifically, forming only linear adducts of type (XXVII):[63,65]



$$Alk_2NCS_2^-H\overset{+}{N}Et_3 + CF_3C{\equiv}CR \rightarrow (Z)\text{-}Alk_2NC(S)SC(R){=}CHCF_3 + NEt_3\ ;$$
(XXVII)

R = H, CF_3 .

The dithiocarbamate anion adds to trifluoromethyldiacetylenes contrary to the Markovnikov rule:[63]

$$Alk_2NCS_2^-H\overset{+}{N}Et_3 + CF_3C{\equiv}CC{\equiv}CR \rightarrow (Z)\text{-}Alk_2NC(S)SC(CF_3){=}$$
$$={=}CHC{\equiv}CR + NEt_3\ .$$

Apart from the intermolecular interaction of dithiocarbamates and acetylenes, there exist examples of the intramolecular nucleophilic addition of these salts to the triple bond:[66–69]

R^1, R^2, R^3 = H, Me, iso-Pr.

The yield is a maximum for R^3 = H.[67]

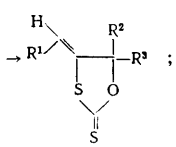
The addition of xanthic acid salts has been studied in less detail than for dithiocarbamates. Thus it has been noted that, like dithiocarbamates, the ethylxanthate anion interacts with non-activated acetylenes.[70] The main reaction product is the divinyl sulphide (XXIV), although under certain conditions it is possible to isolate the intermediate vinyl ester (XXVIII):

$$EtOCS_2^-\overset{+}{N}a + RC{\equiv}CH \rightarrow \underset{\text{(XXVIII)}}{EtOC(S)SCH{=}CHR} + \underset{\text{(XIV)}}{(Z,Z)\text{-}(RCH{=}CH)_2S}\ .$$

The addition of the xanthate anion to diacetylene in alcoholic solutions leads to the formation of the corrsponding vinyl acetylenic dithio-esters with the (*Z*)-configuration:[71]

$$ROH + CS_2 + HC{\equiv}C{-}C{\equiv}CH \xrightarrow[70^\circ C]{KOH} (Z)\text{-}ROC(S)SCH{=}CHC{\equiv}CH\ ;$$
R = Me, Et, Bu .

Activated acetylenes such as derivatives of acetylenecarboxylic acids also combine with alkylxanthates regiospecifically and stereospecifically to form the corresponding vinyl dithioesters (XXIX):

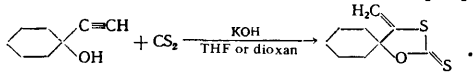


$$R^1OCS_2^-Kat^+ + R^2C{\equiv}CCO_2R^3 \rightarrow \underset{\text{(XXIX)}}{(Z)\text{-}R^1OC(S)SCR^2{=}CHCO_2R^3} \rightarrow$$
$$\xrightarrow{R^1OCS_2^-Cat^+} \underset{\text{(XXX)}}{R^1OC(S)SCHR^2CH(CO_2R^3)SC(S)OR^1}\ ;$$

R^1, R^3 = Alk; R^2 = H, CO_2Alk; Cat = NH_4, $HNEt_3$.

The adduct (XXIX, R^1 = Et, R^2 = CO_2Me) can react with a second xanthate molecule to form a 2 : 1 adduct of type (XXX).[39]

The reactions of carbon disulphide with substituted propargyl alcohols take place via a mechanism involving the intramolecular addition of xanthates to the triple bond:[72,73]

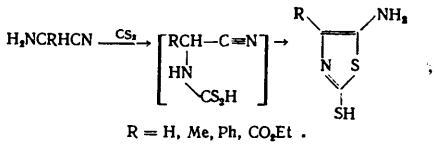


$$R^1C{\equiv}CCR^2R^3OH \xrightarrow{NaH} R^1C{\equiv}CCR^2R^3ONa \xrightarrow{CS_2} \underset{\text{(XXXI)}}{R^1C{\equiv}CCR^2R^3OCS_2Na} \rightarrow$$

(XXXII)

R^1 = H, Me, Ph, R^2, R^3 = H, Me, Et, n-Pr.

The intermediates (XXXI) can be isolated as the methyl esters after alkylation with methyl iodide.[74,75] Other experimental conditions for this reaction have also been proposed:[76]



A single example of the interaction of potassium ethyl trithiocarbamate with phenylacetylene has been described in the literature.[77] This results in the formation of a mixture of the "usual" product (XXXIII) and the "anomalous" product (XXXIV) of the addition of the anion:

$$EtSCS_2^-K^+ + HC{\equiv}CPh \xrightarrow[THF/H_2O]{130^\circ C} \underset{\text{(XXXIV)}}{H_2C{\equiv}CPhSEt} + \underset{\text{(XXXIII)}}{(Z)\text{-}PhCH{=}CHSEt}\ .$$

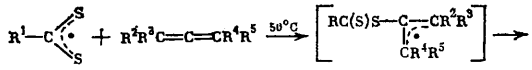
There is also a possibility of intramolecular nucleophilic cyclisation with participation of the carbon–nitrogen triple bond. Thus it has been demonstrated[78–80] that the reaction

of carbon disulphide with α-aminonitriles leads to 5-amino-2-mercaptothiazoles:

R = H, Me, Ph, CO_2Et .

III. DITHIOCARBOXYLIC ACIDS

Derivatives of dithiocarbamic and xanthic acids have found extensive applications in industry. On the other hand, the chemistry of dithiocarboxylic acids RCS_2H, where R = aryl or alkyl, has been studied to a much lesser extent, for a number of reasons, than the chemistry of derivatives of dithiocarbamic and xanthic acids.[16–18] The compounds indicated differ significantly both from the related carboxylic and monothiocarboxylic acids. In the first place, the RCS_2H are stronger acids than the RCOSH and RCO_2H (the pK_a are 2.55, 3.33, and 4.75 respectively for R = Me [81]) and the character of their interaction with saturated compounds may be different.



1. The Addition of Dithiocarboxylic Acids to Unsaturated Compounds

Examples of radical addition to unsaturated compounds do not exist for dithiocarbamic and other heterosubstituted dithio-acids. On the other hand, reactions involving radical addition to alkenes, dienes, allenes, and compounds with a strained double bond (norbornadiene) have been investigated in detail for aliphatic dithiocarboxylic acids.[9,82–85] The distinctive features of these reactions are as follows: dithiocarboxylic acids add to the double bonds of alkenes which have not been activated by electron-accepting substituents; the reaction is initiated in the presence of a source of free radicals and leads to the formation of not only the adducts (the corresponding dithio-esters) but also to cycloaddition products (see the next Section).

However, under certain conditions cyclisation may not in fact be observed. Thus the interaction of dithiobenzoic acid with styrene in the presence of azobisisobutyronitrile results in the exclusive formation of α-phenylethyl dithiobenzoate.[84] The introduction of a source of free radicals into the isoprene–dithioisobutyric acid system results in the formation of only a mixture of the dithio-esters (XXXV) and (XXXVI) [83]— the products of the 1,4-addition of the dithiocarboxylic acid to the olefin:

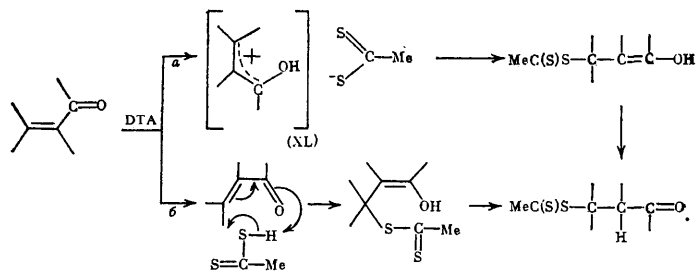
$$CH_2{=}CMeCH{=}CH_2 + \text{iso-Pr}CS_2H \xrightarrow{R^{\cdot}} \underset{\text{(XXXV)}}{\text{iso-Pr}C\,(S)\,SCH_2CMe{=}CHMe} + \underset{\text{(XXXVI)}}{Me_2C{=}CHCH_2SC\,(S)\,Pr\text{-iso}}.$$

The addition of dithio-acids to allenes under mild conditions (40–50 °C) leads to the vinyl dithio-esters (XXVII): [85]

$$\longrightarrow \underset{\text{(XXXVII)}}{R^1C(S)SC(CHR^4R^5){=}CR^2R^3}\ ;$$

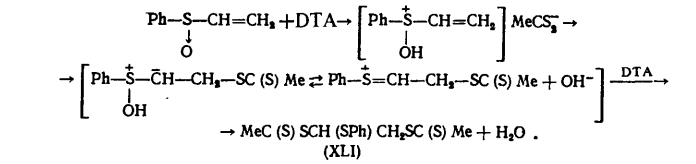
R^1 = Me, Et; R^2=R^4=H, R^3R^5=$(CH_2)_6$; R^2=R^3=Me, R^4=R^5=H; R^2=R^3=R^4=H; R^5=Me .

The interaction of dithiocarboxylic acids with alkylacetylenes has been scarcely investigated, but there are data showing that the free-radical addition of dithioacetic acid (DTA) to 3-hexyne leads to a mixture of the (*Z*)- and (*E*)-vinyl dithio-esters (XXXVIII): [83]



$$EtC{\equiv}CEt \xrightarrow[CCl_4(\text{boil})]{DTA} \underset{\text{(XXXVIII)}}{MeC\,(S)\,SCEt{=}CHEt}.$$

The familiar method of synthesis of dithiocarboxylic acid esters can be regarded as the first example of the thermal interaction of free dithiocarboxylic acids with alkenes activated by electron-accepting substituents: [17,87]



$$R^1CS_2H + R^2R^3C{=}R^4Z \rightarrow \underset{\text{(XXXIX)}}{R^1C\,(S)\,SCR^2R^3CR^4Z}\ ;$$

R^1 = Me, Et; R^2,R^3 = H, Alk, Ar, heteroaryl; R^4 = H, Me; Z = HCO, COR, CO_2H, CO_2Alk, CN, SOAlk, SO_2Alk, NO_2 .

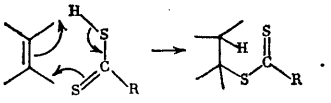
In a study of the mechanism of this reaction, Oae et al.[88] proposed in 1972 two alternative versions, one of which (pathway *a*) presupposes the initial protonation of the electronegative group with formation of the intermediate (XLI) and the subsequent nucleophilic attack by the dithioacetate anion, while the other (pathway *b*) involves concerted addition:

It was found in the same study [88] that DTA can act as a reagent which reduces sulphoxides, sulphonium ylides, and sulphimides to the corresponding sulphides. Thus the reaction of DTA with phenyl vinyl sulphoxide leads to the product (XLI) of addition to the multiple bond with the simultaneous Pummerer rearrangement:

$$\rightarrow \underset{\text{(XLI)}}{MeC\,(S)\,SCH\,(SPh)\,CH_2SC\,(S)\,Me} + H_2O\ .$$

For alkenes with substituents incapable of being protonated with formation of intermediates of type (XL), the interaction with dithiocarboxylic acids leads to adducts in accordance with the Markovnikov rule:

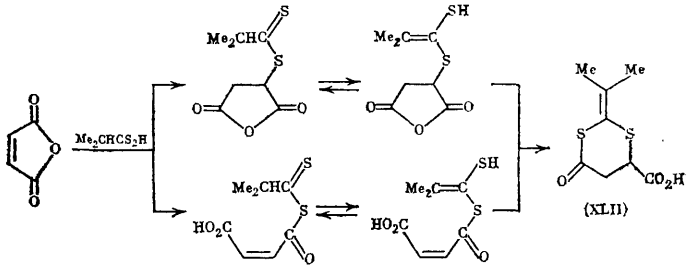
$$CH_2{=}CR^1R^2 \xrightarrow{DTA} MeCR^1R^2SC\,(S)\,Me\ ;$$



R^1 = H, Me; R^2 = Ph, OAlk, SAlk, OAc .

Vinyl esters and sulphides react much more readily than styrene.

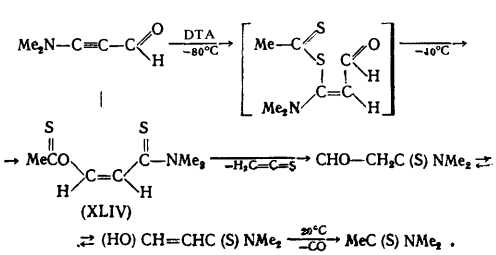
Further studies [9,82–85] showed that the thermal (40–80 °C) addition of dithiocarboxylic acids to alkenes takes place fairly rapidly only when the double bond is activated by a neighbouring aromatic ring, carbonyl group, or heteroatom. In the case of simple alkenes, this is a very slow process even at about 120 °C. The presence of Lewis acids ($BF_3.Et_2O$) induces a faster, compared with a concerted process, ionic addition accompanied by rearrangements usual for reactions of this type, for example: [83]



$$Me_2CH{-}CH{=}CH_2 \xrightarrow{A} MeC\,(S)\,SCH\,(Me)\,CHMe_2\ ,$$
$$\xrightarrow{BF_3Et_2O} MeC\,(S)\,SCMe_2CH_2Me\ .$$

The study of the thermal reaction in relation to deuterio-DTA showed[83] that (*Z*)-addition takes place. According to the authors,[83] the most probable mechanism of the thermal addition of dithiocarboxylic acids to alkenes involves a bimolecular reaction without an ionic or radical intermediate. Such addition may be most conveniently represented as a process occurring as a result of a concerted pericyclic shift (by analogy with "ene syntheses"):

Conjugation in the system increases its reactivity.

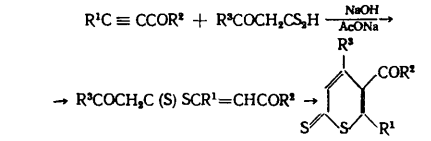


Maleic anhydride reacts with dithioisobutyric acid quantitatively, in the absence of catalysts, affording 1,3-dithiane (XLII). Presumably the addition begins in this case at the C=C bond and is followed by cyclisation via the enethiol form of the diothio-ester; however, Gressier and Levesque[9] do not rule out the possibility of the initial opening of the anhydride ring:

The reaction of DTA with propiolic acid at room temperature leads to a quantitative yield of the product (XLIII) of the Michael addition [a mixture the (*Z*)- and (*E*)-isomers in proportions of 6 : 4]. Methyl propiolate reacts with DTA in boiling CCl_4 and affords a mixture of the (*Z*)- and (*E*)-isomers of compound (XLIII) in proportions of 5 : 95; in the presence of Lewis acids, the isomer ratio is 25 : 75:[86]

$$HC{\equiv}CCO_2R \xrightarrow{DTA} MeC(S)S{-}CH{=}CHCO_2R\ ;\quad (XLIII)$$
$$R = H, Me\ .$$

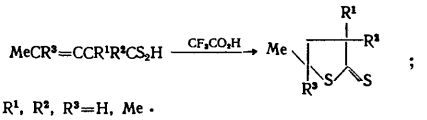
The reaction of DTA with "push-pull" acetylene—a substituted ynamide—leads to an extremely unstable adduct, which rearranges to compound (XLIV) already at −40 °C. However, in contrast to the products of the addition of thiocarboxylic acids, the reaction does not stop at this point: on heating to room temperature, initially thioketen and then carbon monoxide are split off; the reaction product is thioacetamide:[89]



Several examples of the interaction of salts of dithiobenzoic acid with αβ-unsaturated ketones, which proceed with formation of adducts, have been described:[90]

$$PhCS_2MgBr + R^1R^2C{=}CHCOR^3 \rightarrow PhC(S)SCR^1R^2CH_2{-}COR^3\ ;$$
$$R^1, R^2 = H, Me, Ph;\ R^3 = Me, Ph$$

It has been noted that sodium dithiobenzoate is more reactive than the magnesium salt; it also reacts with benzoquinone and 1,2-dihydro-1-methylenenaphthalin-2-one.[90]



The interaction of triethylammonium dithiobenzoate with methyl propiolate in acetonitrile at −70 °C in the presence of an equimolar amount of acetic acid takes place stereoselectively as *trans*-addition with the preferential (>95%) formation of (*Z*)-PhC(S)−CH=CH.CO_2Me (overall yield 88%).[39]

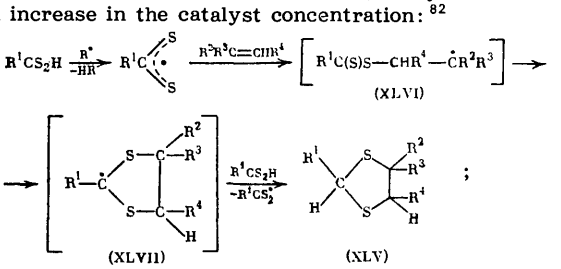
The condensation of salts of β-ketodithiocarboxylic acids with DMAD[91] and α-acetylenic ketones[92] passes through a stage in which dithiocarboxylic acids add to the triple bond and leads to substituted thiopyrans; in a number of instances, the products of the Michael addition were isolated and characterised:[91]

R^1=CO_2Me, Ph; R^2=Me, OMe, Ph; R^3=Ar .

The reaction of αβ-unsaturated β-chloro-substituted aldehydes and ketones with aliphatic dithiocarboxylic acid apparently proceeds analogously.[92,93] The conversion of unsaturated tithiocarboxylic acids into γ-dithiolactones, described by Schonufts et al.,[94] can be regarded as an example of the intramolecular addition of dithiocarboxylic acids to the double bond:

R^1, R^2, R^3=H, Me .

There exist several examples of the interaction of dithiocarboxylic acids with heterounsaturated compounds. Thus the reactions of aromatic dithiocarboxylic acids with aryl isocyanates lead to the corresponding products of addition to the C=N bond:[95]

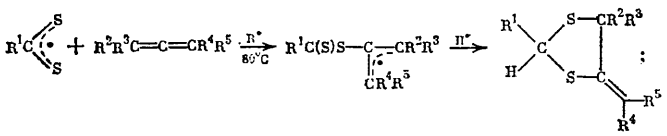


$$R^1CS_2H + R^2N{=}C{=}O \xrightarrow{EtONa} R^1C(S)SC(O)NHR^2\ .$$

Treatment of dicyclohexylcarbodiimide with DTA results in the formation of dicyclohexylthiourea and the unstable DTA anhydride:[49]

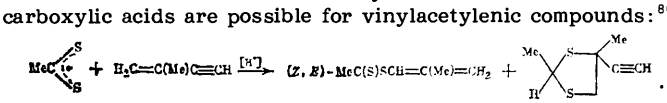
$$C_6H_{11}N{=}C{=}NC_6H_{11} \xrightarrow{2DTA} [MeC(S)]_2S + C_6H_{11}NHC(S)NHC_6H_{11}\ .$$

2. Cycloaddition of Dithiocarboxylic Acids to Unsaturated Compounds



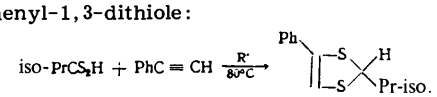
(a). Radical [3 + 2]cycloaddition. As was shown above, many adducts of dithiocarboxylic acids with unsaturated compounds can subsequently give rise to cyclic derivatives. However, in the presence of sources of free radicals, dithiocarboxylic acids can also enter directly into cyclisation reactions involving double bonds. Thus the interaction of DTA with styrene in the presence of azobisisobutyronitrile affords 1,3-dithiolans (XLV) and not dithioesters, the yield increasing with increase in the catalyst concentration:[82]

R^1=Alk; R^2=Ar; R^3=H, Me, Ph; R^4=H, Me .



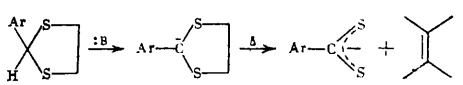
The use of deuterio-DTA in the reaction showed that deuteriation takes place exclusively at the C(2) atom of the dithiolan ring. A more detailed study showed[84] that the dithiolans (XLV) are formed preferentially in the reactions of alkenes having a phenyl substituent with aliphatic dithiocarboxylic acids. The cyclisation reaction (XLVI) → (XLVII) represents a non-trivial instance of thiophilic radical addition to the C=S bond.

The formation of 1,3-dithiolans is observed in the reactions of dithiocarboxylic acids with allenes in the presence of a source of free radicals and on refluxing in benzene:[85]

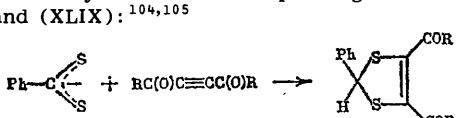


R^1=Me, Et; R^2=R^5=H, R^3R^4=$(CH_2)_6$; R^2=R^3=Me; R^4=R^5=H; R^2=R^3=R^4=H, R=Me.

Both free-radical addition and cycloaddition of dithiocarboxylic acids are possible for vinylacetylenic compounds:[86]



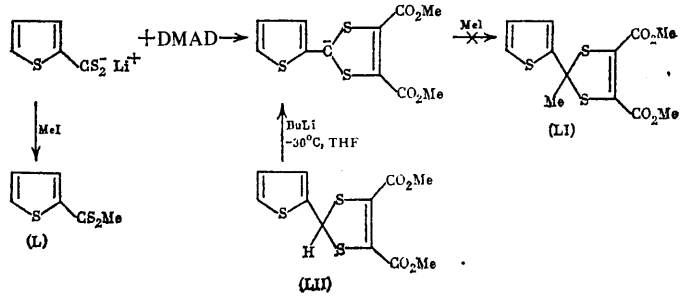
It was found in the same study[86] that the reaction of dithioisobutyric acid with phenylacetylene in the presence of azobisisobutyronitrile (on refluxing in benzene) affords 2-isopropyl-4-phenyl-1,3-dithiole:



(b) Anionic [3 + 2]cycloaddition of dithioate anions. The anions of dithiocarboxylic acids are isoelectronic analogues of allyl anions. The cycloaddition of allyl anions to unsaturated compounds is known to be symmetry-allowed.[96] Although this reaction could not be achieved for the allyl anion itself, such cycloaddition is known for aza- and diaza-allyl anions[97] and a large group of αβ-unsaturated thioate anions and their selenium and tellurium analogues.[98]

A method of synthesis of aromatic dithiocarboxylic acids from 1,3-dithiolans was proposed in 1979:[99]

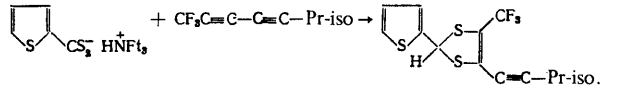
During recent years, this method has been used fairly widely to synthesise derivatives of trithiocarbonic acids[100–102] and also for the preparation of aliphatic dithiocarboxylic acids from 2-substituted 1,3-dithiolans.[103] The above syntheses are examples of anionic [3 + 2]cycloelimination. It was logical to suppose that, when the reactants and conditions have been chosen appropriately, it would be possible to achieve also the reverse reaction involving the anionic [3 + 2]cycloaddition of 1,3-dithia-allyl systems to multiple bonds.



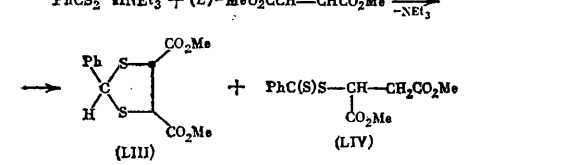
Indeed the reaction of triethylammonium dithiobenzoate with DMAD or dibenzoylacetylene in acetonitrile or methanol at room temperature yielded the corresponding 1,3-dithioles (XLVIII) and (XLIX):[104,105]

R=OMe (XLVIII), Ph (XLIX).

It has been suggested[106,107] that the 1,3-dipole reactivity is a common property of 1,3-dithia-allyl anionic systems. However, it was found unexpectedly that the nature of the group at the central carbon atom of the dithioate group has a decisive influence on the character of the adduct formed:



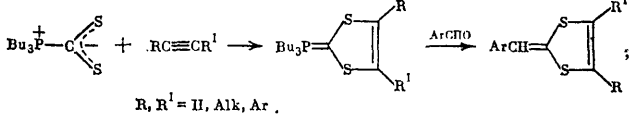
anions of aromatic or heteroaromatic systems (Ar = phenyl, 1-naphthyl, 2-thienyl, 2-furyl, or *N*-pyrrolyl) enter into the cycloaddition reaction.[39,62,105,106] On the other hand, the salts of dithiocarbamic and xanthic acids react with DMAD to form only the alternative adduct resulting from nucleophilic addition to the triple bond and the reaction proceeds exclusively stereospecifically as *trans*-addition.[39] The reaction depends little on the nature of the solvent, while the nature of the salt cation influences significantly its course. Thus the introduction into the reaction of the magnesium salt of naphthalene-1-dithiocarboxylic acid reduced the yield of the cycloadduct to 3–4% and the lithium salt of thiophen-2-dithiocarboxylic acid does not react at all with DMAD: alkylation with methyl iodide for 1 h leads to the formation of only the methyl ester of thiophen-2-dithiocarboxylic acid (L) and not to the expected 2-methyl derivative of 1,3-dithiole (LI):[63]



It has been demonstrated convincingly that the intermediate cyclic carbanion in the form of its lithium salt readily undergoes the reverse anionic [3 + 2]cycloelimination reaction; metallation of the 1,3-dithiole (LII) (obtained by the reaction of the triethylammonium salt of thiophen-2-dithiocarboxylic acid with DMAD) by butyl-lithium in THF at −30 °C and subsequent methylation with methyl iodide led to the subsequent detection in the reaction products, as in the previous case, of only the methyl ester of thiophen-2-dithiocarboxylic acid (L).[63]

Acetylenes whose triple bond has been activated on either side by electron-accepting (π or σ) substituents enter into the cycloaddition reaction: these are acetylenedicarboxylic acid esters, dibenzoylacetylene,[105] the methyl ester and nitrile of phenylpropiolic acid,[63] and hexafluorobutyne.[65]

Acetylenes whose triple bond has been activated by only one electron-accepting substituent react with the anions of dithiocarboxylic acids via the mechanism involving the ionic stereoselective *trans*-addition;[39] however, in the reaction of triethylammonium thiophen-2-dithiocarboxylate with trifluoromethylacetylene, the less stable cycloadduct was detected in the reaction medium together with the stable acyclic adduct. Only the cycloadduct was isolated in the reaction of the same salt with isopropyltrifluoromethyldiacetylene:[63]

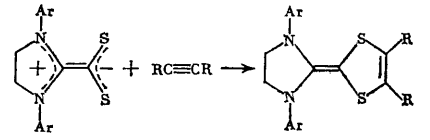


The reaction of triethylammonium dithiobenzoate with dimethyl fumarate takes place via two pathways with formation of both the product (LIII) of anionic [3 + 2]cycloaddition and the product (LIV) of nucleophilic Michael addition to the double bond in proportions of 2 : 1:[105]

Detailed study of the reaction mechanism showed that, under the reaction conditions, the adduct (LIV) cannot be converted into the cycloadduct (LIII) on treatment with a base, by-passing the stage involving decomposition into the initial components; this supports indirectly the concerted mechanism of the cycloaddition reaction.

The betaines formed by the reaction of phosphines with carbon disulphide and also the formamidinium and imidazolidinium dithiocarboxylates, obtained from the corresponding tetra-aminoethylenes and carbon disulphide, constitute unusual 1,3-dithia-allyl systems capable of anionic [3 + 2]-cycloaddition.

The adduct of carbon disulphide and tributylphosphine reacts with acetylene having electron-accepting substituents at temperatures as low as -30–0 °C; arylacetylenes react slowly at room temperature and acetylene itself reacts at temperatures above 100 °C with formation of the corresponding phosphorus ylides:[108,109]

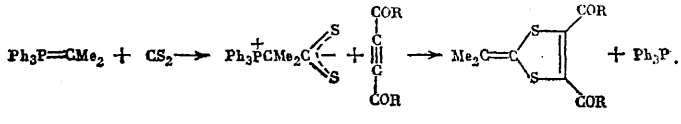


R, R^1 = H, Alk, Ar.

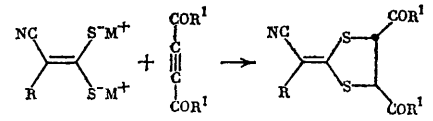
When aromatic aldehydes are introduced into the reaction mixture, the process terminates with the Wittig reaction. It is essential to note that ketones do not enter into this reaction.[109]

The reaction has since been widely used in the synthesis of varied 1,3-dithiole structures—2-substituted 1,3-dithioles [110] and tetrathiafulvalenes.[111,112] A fairly complete survey of the reactions of trialkyl (1,3-dithiolyl)phosponium tetrafluoroborates has been published in two reviews.[113,116]

Formamidinium and imidazolidinium dithiocarboxylates react analogously with doubly activated acetylenes,[117] for example



R = CO_2Alk, P(O)Ph_2, COPh; CF_3.



It is of interest that dipolarophile compounds having activated double bonds (tetracyanoethylene, dimethyl dicyanofumarate, dibenzyl azodicarboxylate) do not enter into the reaction.[118]

Betaines in which the 1,3-dithia-allyl system of the anion is separated from the positively charged centre by carbon atoms have been obtained by the reaction of triphenylphosphonium ylides with carbon disulphide.[119–121]

The 1,3-dithia-allyl system in the α-(triphenylphosphonia)-alkanedithiocarboxylates reacts with the triple bond activated on either side by electron-accepting substituents via the anionic [3 + 2]cycloaddition mechanism with formation of 2-alkylidene-1,3-dithioles; the fact which determines this course of the reaction is the subsequent stabilisation of the intermediate cyclic zwitter-ion as a result of the elimination of triphenylphosphine and the formation of an exocyclic double bond:[112,113]

The salts of 1,1-vinylidenedithioles are formed readily in the reactions of carbon disulphide and compounds having an active methylene group in the presence of bases. These salts, which can be regarded as salts of the dianions of the corresponding dithiocarboxylic acids, also react readily with doubly activated acetylenes, affording *trans*-4,5-disubstituted 2-alkylidene-1,3-dithiolans as the reaction products:[124–126]

R = CN, $CONH_2$, CO_2Et; R^1 = Alk, Ph.

The reactions involving the addition of dithio-acids to unsaturated compounds, examined above, are of undoubted interest also from the theoretical point of view apart from their practical and synthetic importance. Frequently a seemingly not very significant change in the details of the structures of the reactants and the reaction conditions leads to striking qualitative transitions from one mechanism to another, which are sometimes not easy to explain from modern theoretical standpoints.

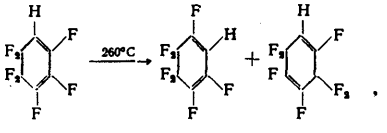
Rearrangements with Migration of a Fluorine Atom

L.S.Kobrina and V.N.Kovtonyuk

The review is devoted to the rearrangement of organic compounds and intermediate species involving the migration of a fluorine atom. The sigmatropic migrations of a fluorine atom are examined from the standpoint of modern theoretical ideas. Special attention has been given in this review to reactions proceeding with migration of a fluorine atom in intermediate species.
The bibliography includes 87 references.

CONTENTS



I. Introduction 62

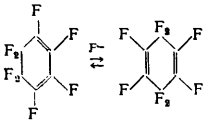
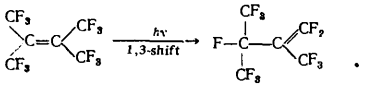
IV. The migrations of fluorine atoms in radicals 65

I. INTRODUCTION

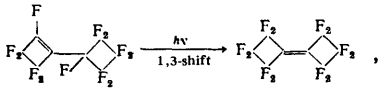


The rearrangements of organic compounds occupy an important place in organic chemistry, serving as a basis of many synthetic methods. In the vast stream of review publications devoted to a wide variety of aspects of rearrangements, much attention has been devoted to rearrangements with migration of halogen atoms in free radicals but there are virtually no reviews on the migration of a fluorine atom.[1] The latter factor is an obstacle to the development of a rigorous theory of reactions of this type, resulting in the propagation of the incorrect view that rearrangements with migration of a fluorine atom are impossible. The work by French investigators devoted to the theoretical study of free-radical rearrangements in which the authors explain the lack of experimental data concerning the 1,2-migration of a fluorine atom by the high barrier of such migration, may serve as an example of this situation.[2] On the other hand, numerous studies indicating the migration of a fluorine atom have been published in the last decade. The aim of the present review is to survey the available literature data on rearrangements with migration of a fluorine atom in a wide variety of situations and to make certain comparisons with the migrations of other halogen atoms, eliminating thereby the contradictions which have arisen between theoretical and experimental studies. The rearrangements in which the fluoride anion participates are not considered in detail in the present review.

II. SIGMATROPIC SHIFTS OF A FLUORINE ATOM IN POLYFLUORINATED OLEFINS AND CYCLO-OLEFINS

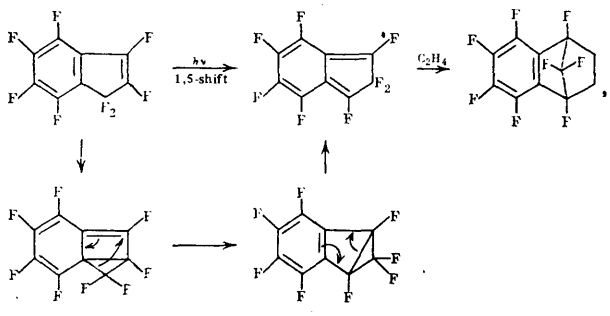


The isomerisation of polyflorinated olefins was first observed by Tatlow[3] in the pyrolysis of octafluorocyclohexa-1,4-diene and 1*H*-heptafluorocyclohexa-1,3-diene in a nickel flow-apparatus:

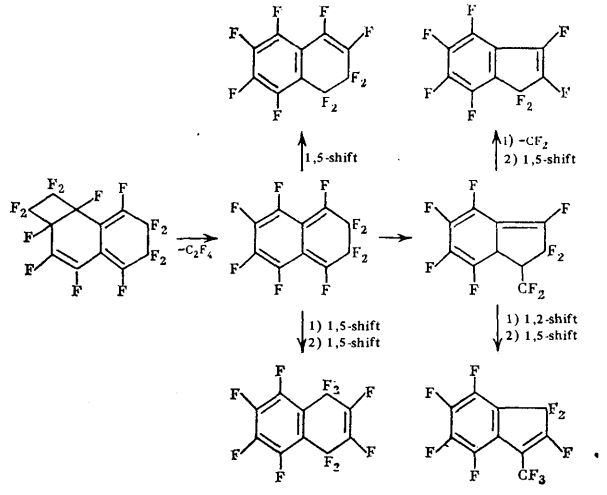


Later, in a study of the isomerisation of two octafluorocyclohexadienes,[4,5] it was shown that the establishment of equilibrium between the two dienes is accelerated by the fluoride anion and it was suggested that isomerisation thermolysis in nickel apparatus[3] also takes place with participation of the fluoride anion:

The photochemical migration of a fluorine atom has been noted in a series of polyflorinated olefins. Thus the photochemical 1,3-shift of a fluorine atom has been resorted to to account for the isomerisation of perfluoro-2,3-dimethylbut-2-ene:[6]

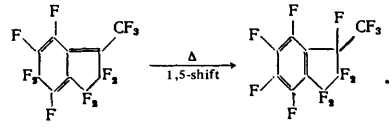


The 1,3-sigmatropic shift of a fluorine atom has been observed in the photolysis of perfluorinated cyclobutene derivatives:[7]

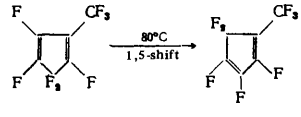


In a series of polycycloalkenes with dienes, the sigmatropic shift of a fluorine atom has been used to explain the isomerisation occurring both in photolysis and in thermolysis:[8-10]

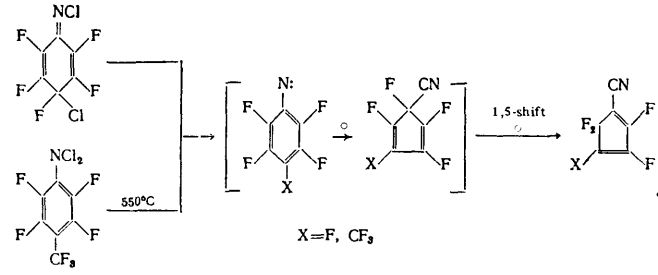
Experimental confirmation of the sigmatropic migration of a fluorine atom in the photolysis of perfluoroindene has been explained—perfluoroisoindene is trapped in the form of an adduct with ethylene.[10] However, there is a possible alternative route to the formation of perfluoroisoindene which does



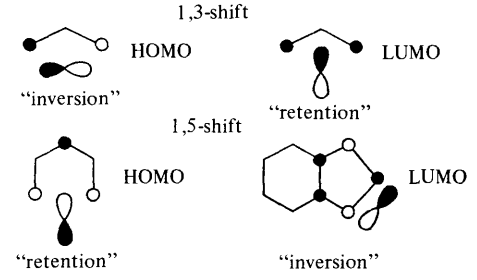
not require the invocation of a sigmatropic shift of a fluorine atom:[11]



The formation of perfluorinated derivatives of 1,2- and 1,4-dihydronaphthalenes and perfluoroindenes in the thermolysis of perfluorinated bicyclictrienes has been explained by sigmatropic shifts of a fluorine atom:[12]

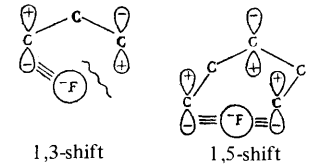


In the literature there are several further examples of thermal isomerisations involving a 1,5-sigmatropic shift of a fluorine atom. Thus, in the thermolysis of perfluoro-7-methylbicyclo[4.3.0]nona-1,4,6-triene, the migration of a fluorine atom leads to perfluoromethylindan:[13]

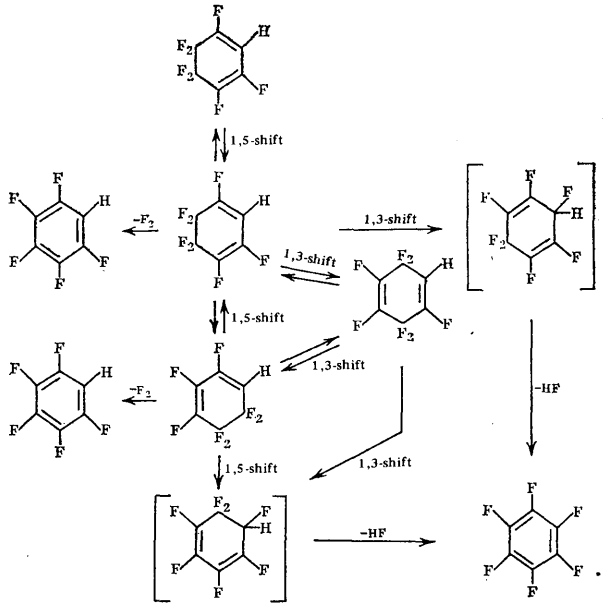


The sigmatropic migration of a fluorine atom has been observed in the thermolysis of perfluoro-2-methylcyclopentadiene:[14]

The 1,5-sigmatropic shift of a fluorine atom has also been invoked to account for the formation of polyfluorinated derivatives of cyclopentadiene in the thermolysis of the epoxy-derivatives of Dewar hexafluorobenzenes[15] and in the thermal isomerisation of perfluorinated arylnitrenes:[16,17]

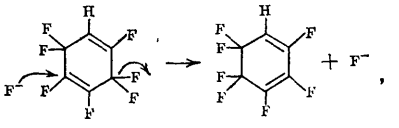


The great practical importance of isomerisations involving a sigmatropic shift of a fluorine atom in the chemistry of polyfluorinated olefins and cyclo-olefins led to attempts at a systematic and theoretical treatment of these processes. The sigmatropic shift of a fluorine atom has been discussed[5] from the standpoint of the theory of frontier orbitals. The frontier orbital approximation shows that, as for the migration of alkyl groups, the 1,3- and 1,5-shifts are allowed for a fluorine atom. The migration can be represented as the displacement of a fluorine atom in allyl or pentadienyl radicals:

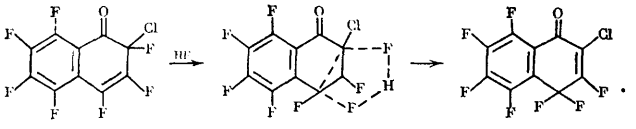


Two lobes of the atomic *p* orbital of the fluorine atom participate in the thermal 1,3-shift and the orbitals of the fluorine atom undergo "inversion" in the migration process. In the photochemical 1,3-rearrangement, occurring in the excited state, the configuration of the orbitals is retained. The rules are reversed for the 1,5-shift: for thermal reactions, the configuration of the orbitals is retained while for photochemical processes "inversion" should be observed.

It is believed[18] that the description of the migration of a fluorine atom within the framework of the sigmatropic shift can be complicated by the involvement of the unshared electron pairs of the fluorine atom. An approximate picture of this effect is secured by considering the migration of fluorine in the form of an anion, having spherical symmetry, in the allyl or pentadienyl cation. In this treatment, only the 1,5-shift is allowed from the standpoint of orbital interaction.



Indeed the pyrolysis of polyfluorocyclohexadienes shows that the 1,5-shift of a fluorine atom is preferred to the 1,3-shift.[18] However, these data cannot indicate the "prohibition" of the 1,3-shift of a fluorine atom. Analysis of the results presented at the beginning of this Section also demonstrates that the thermal 1,5-shifts[12-17] and the photochemical 1,3-shifts of a fluorine atom proceed more readily,[6,7] i.e. those processes in which the configuration of the orbitals of the fluorine atom should be "retained". A



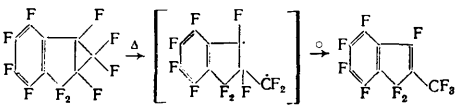
study of the interconversion of heptafluorocyclohexadienes led to the conclusion[5] that the fluorine atom migration processes occurring with "retention" of the configuration of the orbitals of the fluorine atom are preferable to those requiring the "inversion" of such configurations, although the extent of such preference is not high.

The results of the study by Burdon et al.[18] also show that the interpretation of the observed isomerisation invoking sigmatropic shifts of a fluorine atom should be approached with caution, since the 1,3- and also probably the 1,5-migration of a fluorine atom is catalysed by the fluoride anion:

Thus the results of the thermolysis of hepta- and octafluorocyclohexadienes in new Pyrex and quartz tubes differ appreciably from the results obtained in old tubes where more than 20 pyrolyses have been carried out. In pyrolyses in old tubes and also in pyrolyses in the presence of sodium fluoride, the 1,3-migration of a fluorine atom and the aromatisation of the initial dienes begin to proceed to an appreciable extent. Furthermore, fairly numerous examples of the HF-catalysed 1,3-migration of a fluorine atom are known in the literature.[19,20] Such an example is provided by the isomerisation of polyfluorinated cyclic dienones:

III. THE MIGRATION OF A FLUORINE ATOM IN CARBENES, 1,3-BIRADICALS, AND RADICAL-IONS

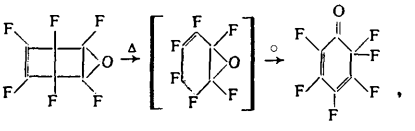
Numerous instances of the 1,2-shift of a fluorine atom in carbenes are known.[21,22] The observed series based on the capacity for migration[23] shows that hydrogen, chlorine, and the perfluoroalkyl group migrate more readily than the fluorine atom:[21,24] $Cl > H > C_2F_5 > F$.



$$CF_3CH: \rightarrow CF_2{=}CHF ,$$
$$C_2F_5{-}CF_2CH: \rightarrow CF_2{=}CH{-}C_2F_5 .$$

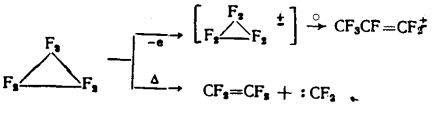
In connection with the study of the vinylidene–acetylene rearrangement, much attention has been devoted recently to the possibility of the formation of difluoroacetylene in the isomerisation of difluorovinylidene:

$$CF_2{=}C: \rightarrow CF{\equiv}CF ,$$



The corresponding calculations by various quantum-chemical methods have been described in a number of publications[25–26] and demonstrated the presence of a fairly high energy barrier (~36 kcal mol^{-1}) to the migration of a fluorine atom in this process, while a hydrogen atom migrates almost without a barrier in an analogous reaction.[26] The presence of a high barrier to the 1,2-migration of a fluorine atom has been attributed by Pople[26] to the antiaromatic character of the cyclic 4π-electron transition state. The high energy barrier to the 1,2-shift of a fluorine atom in this reaction is probably the reason why it has not so far been possible to effect experimentally the rearrangement of difluorovinylidene to difluoroacetylene.[28]

The 1,2-migration of a fluorine atom has been observed in the thermal isomerisation of perfluorocyclopropane derivatives with ring opening:[12,29]

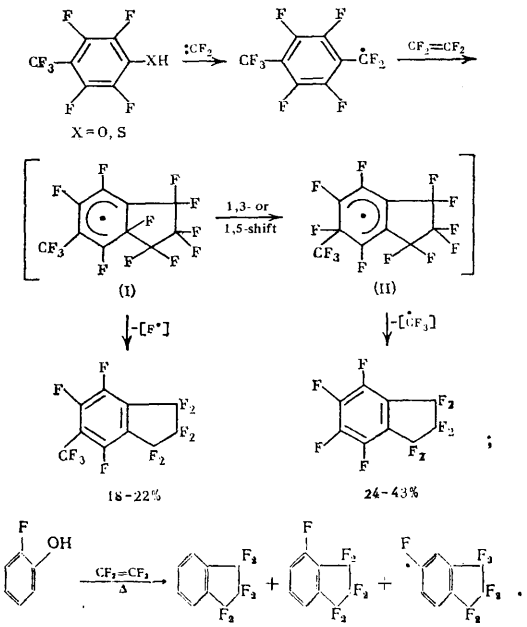


Perfluoromethylindene may be formed in the thermolysis of perfluorinated tricyclic cyclopropane derivatives both as a result of isomerisation wth the opening of the cyclopropane ring and subsequent 1,2-migration of a fluorine atom in the intermediate 1,3-biradical and synchronously.[29]

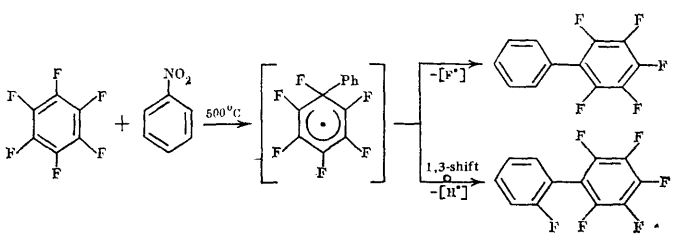
Perfluorocyclohexa-2,4-dien-1-one is formed similarly in the thermolysis of the epoxy-derivative of Dewar hexafluorobenzene,[15] which probably proceeds via the formation of the epoxy-derivative of hexafluorobenzene:

In contrast to the thermal reactions of perfluorocyclopropane derivatives quoted above, it has been suggested that cyclohexadienone is formed from the epoxy-derivative of Dewar hexafluorobenzene as a result of the migration of a fluorine atom in the zwitter-ion.[15]

A rearrangement with migration of a fluorine atom has been observed in the photoionisation of perfluorocyclopropane:[30]



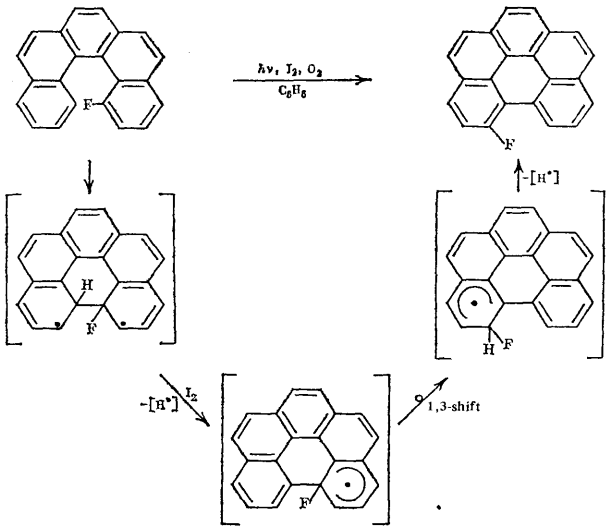
It is noteworthy that the thermolysis of perfluorocyclopropane does not lead to the formation of perfluoropropene but is accompanied by decomposition to tetrafluoroethylene with elimination of difluorocarbene.[31]



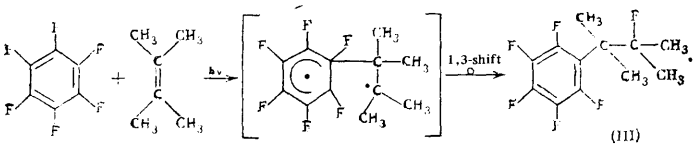
IV. THE MIGRATIONS OF FLUORINE ATOMS IN RADICALS

1. The 1,3- and 1,5-Shifts in Cyclohexadienyl Radicals

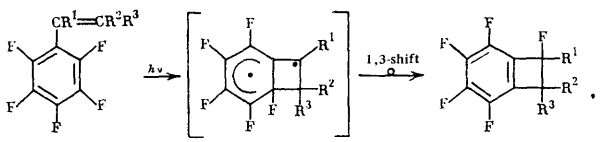
In order to account for the preferential formation of perfluoroindan in the copyrolysis of perfluoro-*p*-cresol and perfluoro-*p*-thiocresol with tetrafluoroethylene,[32] a mechanism has been proposed according to which a 1,3- or 1,5-sigmatropic shift of a fluorine atom takes place in the corresponding σ-complexes (I) with formation of the isomeric σ-complex (II). The stabilisation of the σ-complex (II) with abstraction of the trifluoromethyl radical leads to perfluoroindan. An analogous mechanism has been proposed also to explain the formation of 1,1,2,2,3,3,5-heptafluoroindan together with hexafluoroindan and 1,1,2,2,3,3,4-heptafluoroindan in the copyrolysis of *o*-fluorophenol with tetrafluoroethylene in proportions of 1 : 2.5 : 2.2 respectively:[33]



It has been suggested that the migration of a fluorine atom occurs also in the high-temperature reaction of nitrobenzene with hexafluorobenzene[34] in which 2,2',3,4,5,6-hexafluorobiphenyl was detected mass-spectrometrically:

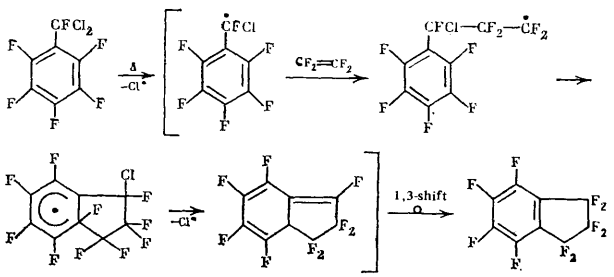


The formation of the same product has been detected in the reaction of benzoyl peroxide with hexafluorobenzene.[35]

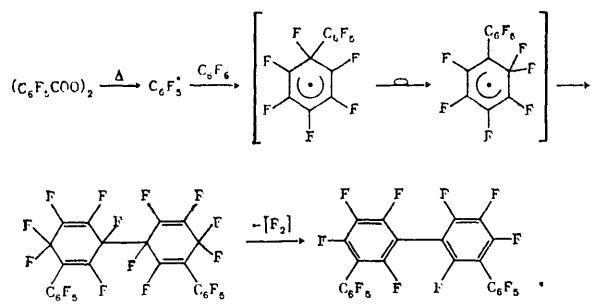


A similar migration of a fluorine atom has been proposed recently to account for the mechanism of the photocyclisation of 1-fluoro[5]helicene:[36]

The photolysis of hexafluorobenzene in the presence of 2,3-dimethylbut-2-ene leads mainly to the product (III), whose formation is apparently associated with the 1,3-migration of a fluorine atom from the ring to the side chain in the intermediate biradical:[37]

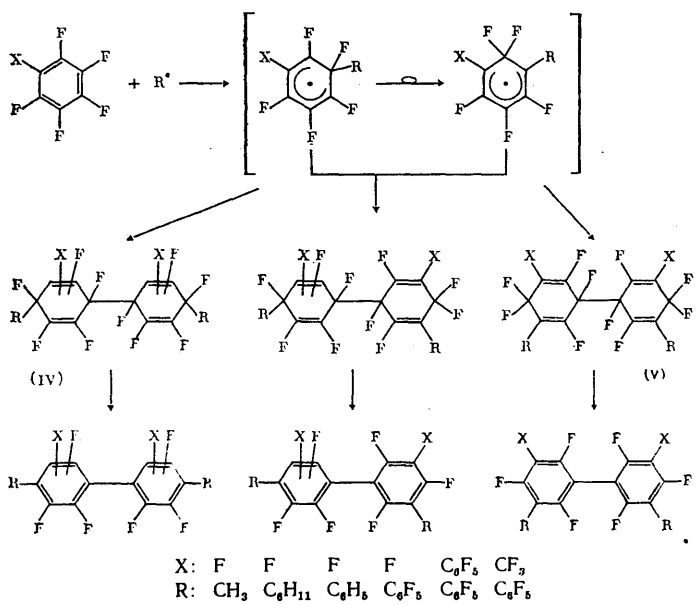


The migration of a fluorine atom has also been observed in the photocyclisation of polyfluorinated alkenylbenzenes in the gas phase,[38] leading to the formation of fluorine-containing benzocyclobutenes:



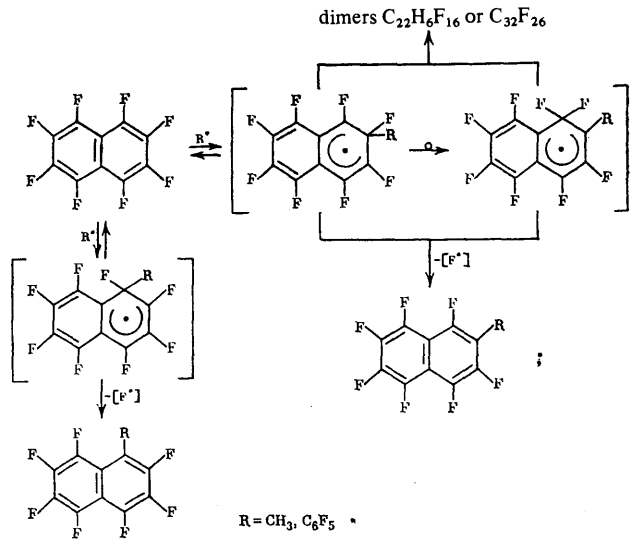
The migration of a fluorine atom can occur as a 1,3-sigmatropic shift concerted with the cyclisation process or following the latter, although the authors do not rule out the possibility of a repeated 1,5-shift of a fluorine atom.

Similar cyclisation with migration of a fluorine atom to the side chain has been observed also in the copyrolysis of pentafluoro(trichloromethyl)benzene with chlorotrifluoroethylene[39] and of αα-dichlorohexafluorotoluene with tetrafluoroethylene:[40]



2. The 1,2-Migration of a Fluorine Atom in Cyclohexadienyl Radicals

Ten years ago the 1,2-migration of a fluorine atom in radicals was still regarded as impossible.[41] During the intervening period, a series of studies providing experimental evidence that such migration is achievable under certain conditions have been published. The 1,2-migration of a fluorine atom in cyclohexadienyl raidcals, formed in the radical reactions of aromatic polyfluoro-compounds, has been studied in greatest detail. The rearrangement of cyclohexadienyl radicals with migration of a fluorine atom was first observed in a study of the interaction of hexafluorobenzene with pentafluorobenzoyl peroxide at 200 °C.[42] The defluorination of the mixture of products of this reaction having the composition $C_{24}F_{22}$ led to the formation of perfluoro-*mm'*-quaterphenyl in a quantitative yield, which provided grounds for the assumption that its precursor is perfluoro-3,3'-diphenyl-1,1',4,4'-tetrahydroquaterphenyl—the dimer of the σ-complex resulting from the addition of the pentafluorophenyl radical to hexafluorobenzene. Evidently, this dimer cannot be obtained by the dimerisation of the primary σ-complex but is the product of the dimerisation of the secondary σ-complex formed on rearrangement with migration of a fluorine atom from the geminal site in the cyclohexadienyl radical to a neighbouring position:



An analogous rearrangement takes place in the cyclohexadienyl radical formed in the reaction of hexafluorobenzene with phenyl,[43] methyl,[44] and cyclohexyl[45] radicals and also in the reactions of octafluorotoluene[46] and decafluorobiphenyl[47] with the pentafluorophenyl radical:

X: F F F F C_6F_5 CF_3
R: CH_3 C_6H_{11} C_6H_5 C_6F_5 C_6F_5 C_6F_5

In the cyclohexadienyl radicals formed by the addition of perfluoroalkyl radicals[44,48,49] or the pentafluorobenzoyloxy-radical[42,50] to aromatic polyfluoro-compounds, a rearrangement with migration of a fluorine atom does not take place. The general character of the rearrangement of polyfluorinated cyclohexadienyl radicals with 1,2-migration of a fluorine atom has been confirmed by the results of the reaction of octafluoronaphthalene with the methyl and pentafluorophenyl radicals:[51]

A characteristic feature of these reactions is a relatively high yield of 2-substituted octafluoronaphthalene derivatives, which can be attributed to the reversible addition of the methyl and pentafluorophenyl radicals to the aromatic ring and the consequent possibility of the interconversions of the isomeric σ-complexes. The irreversible removal from the equilibrium of the σ-complexes formed when these radicals are added to the 2-position in octafluoronaphthalene, as a result of a rearrangement with migration of a fluorine atom from the geminal site in the cyclohexadienyl radical to the 1-position, ensures the accumulation of more stable σ-complexes, whose defluorination actually affords 2-substituted heptafluoronaphthalenes.

A kinetic scheme for the interaction of aromatic polyfluoro-compounds with radicals has been analysed for the reaction of hexafluorobenzene with the cyclohexyl radical.[45] It follows from this analysis that the rearrangement is a unimolecular process, since the ratio of the yields of the products (IV)/(V) (see the scheme above) is a linear function of the concentration of the cyclohexyl radical R', which depends on the initial concentration c_0 of the source of this radical:

$$(IV)/(V) = K[R^{\cdot}] = f(c_{0\ \text{peroxide}}).$$

The analogous analysis performed on the assumption of a bimolecular rearrangement gives rise to the ratio (IV)/(V) which is independent of the radical concentration. The experimental data show that in reality the product ratio (IV)/(V) varies with the concentration of di-t-butyl peroxide.

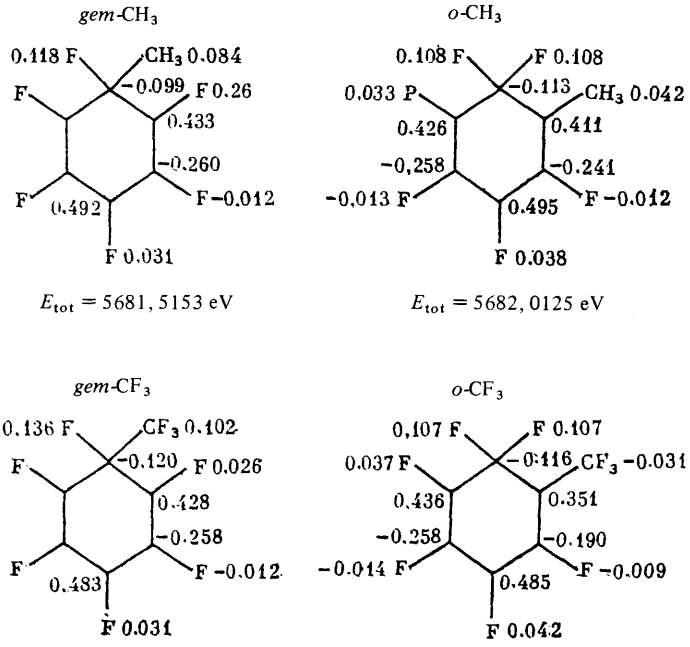
The dependence of the degree of rearrangement on the reaction temperature and the concentration of the source of the radical has been established for the interaction of hexafluorobenzene with the phenyl, pentafluorophenyl, and cyclohexyl radicals.[44] An increase in the reaction temperature increases the degree of the rearrangement. With an increase in the concentration of the source of the radical,

the lifetime of the radical σ-complexes diminishes as a result of the increase in their concentration in solution and there is a consequent decrease in the degree of rearrangement.

Assessment of the role of factors associated with the structure of the geminal site in polyfluorinated cyclohexadienyl radicals in a rearrangement with migration of a fluorine atom has shown that the possible contribution by the steric hindrance in the geminal site of the σ-complexes is extremely insignificant. The influence of the concentration of the source of the radical on the degree of rearrangement is the same for the σ-complexes formed by the addition to hexafluorobenzene of both the methyl and cyclohexyl radicals, which have similar polarities, but differs appreciably as regards its steric requirements[44] (See Table).

Estimation of the contribution of steric effects to the driving forces of the rearrangement.[44]

Concentration of di-t-butyl peroxide, M	Degree of rearrangement	
	$CH_3^{\cdot}$	cyclo-$C_6H_{11}^{\cdot}$
0.77	0.29	0.27
0.42	0.50	0.32
0.38	0.58	0.47
0.33	0.85	0.58
0.19	1.12	0.68



In order to estimate the influence of the nature of the substituents at the geminal site on the stability of the radical σ-complex, the total energies E_{tot} and the distribution of the spin densities in the rearranged and non-rearranged σ-complexes of the methyl and trifluoromethyl radicals with hexafluorbenzene were calculated.[44] The calculations were performed by the unrestricted Hartree–Fock method in terms of the INDO approximation with the standard parametrisation of Pople and Segal.[52] The bond lengths and angles optimal for fluorinated cyclohexadienyl radicals, obtained[53] by INDO calculations with the same parametrisation, were used.

The results of the calculation (see Figure), show that, when the methyl radical adds to hexafluorobenzene, the rearranged σ-complexes are more stable than the non-rearranged complexes by 11.6 kcal mol^{-1}, whereas in the case where hexafluorobenzene is attacked by the trifluoromethyl radical, the reverse situation obtains—the non-rearranged σ-complexes are found to be more stable (by 3.8 kcal mol^{-1}).

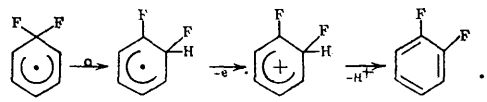
The ratio of the unpaired electron densities in various positions in the unsaturated part of the non-rearranged σ-complexes of the methyl and trifluoromethyl radicals with hexafluorobenzene are virtually the same, whereas for the geminal sites appreciable differences are observed on passing from the non-rearranged σ-complexes to the rearranged complexes: when the methyl radical adds on, a greater fraction of the spin density is found to be concentrated on the fluorine atoms of the difluoromethylene group at the geminal site, whereas in the case where the trifluoromethyl radical is added the fraction of spin density on the fluorine atoms of the geminal site is smaller than in the non-rearranged σ-complex.

Thus the results of the calculations show that the rearrangement may be caused by the energy gain on formation of the geminal unit with two fluorine atoms. The increase in the C–F bond strength as the geminal fluorine atoms accumulate has been described in the literature[54] and there exist data indicating the higher stability of the polyfluorinated arenium ions having two fluorine atoms in the geminal unit compared with isomers containing in the geminal unit substituents other than fluorine atoms.[55]

Although the difluoromethylene group is saturated, nevertheless it exhibits an electron deficient character.[56] For example, perfluoroalkanes form complexes with electron-donating solvents.[57] In the analysis of the electronic effect of the difluoromethylene group, Liebman used these data to justify treating it as an analogue of the carbonyl group.[58]

E_{tot} = 5681, 5153 eV E_{tot} = 5682, 0125 eV

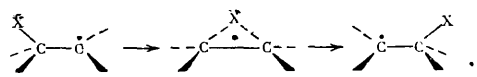
E_{tot} = 7777, 9177 eV E_{tot} = 7777, 7468 eV



Distribution of spin density and total energies of polyfluorinated cyclohexadienyl radicals.[44]

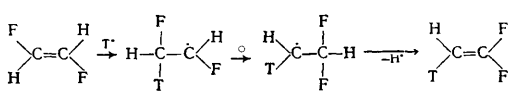
If this approach is applied to the analysis of the stability of radical σ-complexes, then in the case where the geminal unit contains two fluorine atoms, the σ-complex can be regarded as a substituted phenoxy-radical after the replacement of the difluoromethylene group by the carbonyl group. The relatively high stability of different substituted phenoxy-radicals has long been known.[59]

In those cases where the geminal unit contains a fluorine atom and a substituent with a high electronegativity (perfluoroalkyl and pentafluorobenzoyloxy-groups), the electron-accepting properties of the unit produced remain extremely powerful. There exist literature data demonstrating the capacity of the trifluoromethyl group for conjugation with the radical centre.[60] On the other hand, the replacement of a fluorine atom in the difluoromethylene unit of a polyfluorinated radical σ-complex by an electron-donating substituent (the methyl or cyclohexyl group) should apparently lead to a sharp weakening of the electron-accepting properties of the saturated unit. These differences do in fact determine to some extent the possibility of the rearrangement of fluorinated radical σ-complexes with migration of a fluorine atom from the geminal unit to a neighbouring position.



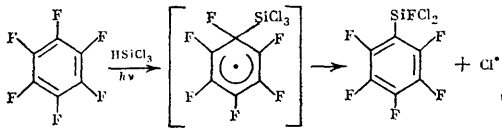
Burdon and Parsons[61] invoked the 1,2-shift of a fluorine atom in radical σ-complexes to explain the formation of fairly large amounts of aromatic polyfluoro-compounds in the reaction of benzene with $CsTlF_4$. Their calculation of the energy

of the cyclohexadienyl radicals by the CNDO/2 method showed that the stage involving the 1,2-migration of the fluorine atom is exothermic.



The authors believe that this is a key stage in the fluorination of aromatic compounds despite the fact that, in their view, it is prohibited from the standpoint of orbital symmetry rules. However, such prohibition tends to be regarded as absolute. The driving force of the rearrangement can apparently have a purely thermodynamic nature associated with the fact that the radical formed as a result of the rearrangement is much more stable than the initial radical.

In 1981 French workers published a theoretical study[2] of free-radical migration. They carried out a calculation by the STO-3G RHF method for a series of 1,2-rearrangements of β-substituted ethyl radicals. The difference between the energies of the β-substituted ethyl radical and the symmetrical bridge structure, adopted as the transition state in the process, was adopted as the energy barrier to the reaction:



The calculation for the 1,2-shift of a fluorine atom, like that for the 1,2-shift of a hydrogen atom and groups such as OH, NH_2, and CH_3 yielded a very high barrier to the reaction (F = 107 kcal mol^{-1}, H = 88 kcal mol^{-1}). The authors believe that the activation energies for these rearrangements are much higher than the activation energies for processes such as recombination, transfer, etc. and that this is the reason why these rearrangements have not been detected experimentally. The authors were probably unaware of either the results of studies on the radical reactions of aromatic polyfluoro-compounds,[42-51] discussed above, or of a study[62] of the 1,2-shift of a fluorine atom in the 1,2-difluoroethyl radical obtained as a result of the addition of tritium to *trans*- and *cis*-1,2-difluoroethylenes:

It is also noteworthy that the method employed by Fossey and Nedelec[2] yields barriers to the rearrangements which are much too high. A calculation has been recently carried out for the 1,2-migrations in free radicals by the MNDO SCF-MO method.[63] The barriers to the rearrangement calculated in the above study are much lower than in the previous investigation[2] and agree with experimental data for rearrangements known in the literature. Unfortunately, the authors[63] did not carry out a calculation for the 1,2-migration of a fluorine atom.

In the literature, there are several further examples involving the 1,2-migration of a fluorine atom in reactions which can proceed via the formation of free radicals. Thus the photochemical interaction of hexafluorobenzene with trichlorosilane[64] leads mainly to dichlorofluoro(pentafluorophenyl)-silane:

It has been suggested that the formation of this product is associated with a rearrangement in the initial σ-complex of the trichlorosilyl radical with hexafluorobenzene. It was later shown that such rearrangement is a common reaction in the series of organosilicon compounds:[23]

$$ClCH_2CF_2SiCl_3 \xrightarrow{\Delta} ClCH_2CFClSiFCl_2 \xrightarrow{\circ} ClCH_2CCl_2SiF_2Cl\ .$$

The photochemical exchange of hydrogen and fluorine atoms is observed in the photolysis of isomeric difluoroethylenes:[65]

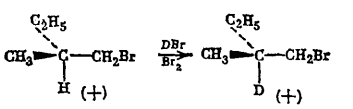
$$CFH{=}CFH \underset{}{\overset{h\nu}{\rightleftarrows}} CF_2{=}CH_2\ .$$

The mechanism of such exchange has not so far been investigated.

3. Comparison of the 1,2-Migration of a Fluorine Atom with the 1,2-Migration of Other Halogen Atoms

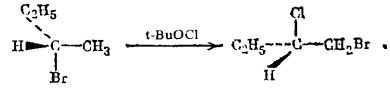
In contrast to the 1,2-migration of a fluorine atom, the 1,2-migration of other halogen atoms, in particular chlorine and bromine, in radicals is well known. Thus the 1,2-migration of a chlorine atom in alkyl radicals is very common:[1,66,67]

$$XCCl_2\dot{C}YCH_2Z \xrightarrow{\circ} X\dot{C}ClCClYCH_2Z\ ,$$
$$X{=}H,\ F,\ Cl,\ CH_3\quad Y{=}H,\ Cl,\ Br,\ CH_3\quad Z{=}Br,\ CCl_3,\ SR\ .$$



The data accumulated permitted the claim that this migration takes place intermolecularly and theoretical calculations[2,65] have shown that the 1,2-migration of a chlorine atom proceeds via a bridged transition state with a relatively low energy barrier (26.4 kcal mol^{-1}).[65] A series based on the relative stabilities of the radicals has been constructed,[6,7] its left-hand side coinciding with the familiar series based on the relative stabilities of hydrocarbon radicals (primary < secondary < tertiary):

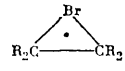
$$RCH_2 < R_2CH < R_3C < RCHCl < R_2CCl < RCCl_3\ ,$$



It is noteworthy that in the case of possible competition between the 1,2-shifts of a chlorine or a fluorine atom, the shift of a chlorine atom always takes place:[68,69]

$$CH_2{=}CH{-}CCl_2F + \dot{C}Cl_3 \rightarrow CCl_3CH_2\dot{C}HCCl_2F \xrightarrow{\circ}$$
$$\rightarrow CCl_3CH_2CHCl\dot{C}ClF \xrightarrow{t\text{-}BuNO} CCl_3CH_2CHClCClF{-}N(O\cdot){-}Bu\text{-}t.$$

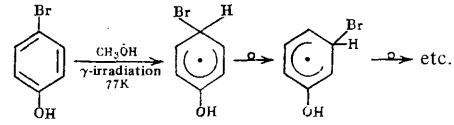
The 1,2-migration of a bromine atom in alkyl radicals occurs at even higher rates than the migration of chlorine. Analysis of literature data[70] has led to the conclusion that the rates of these rearrangements can reach values >10^8 s^{-1} for chlorine and >10^{10} s^{-1} for bromine. The 1,2-migration of a bromine atom is not as common a process as the 1,2-migration of a chlorine atom probably because the β-bromoradicals can decompose fairly readily with formation of unsaturated compounds. The problem of "bridged" radicals is very closely related to the problem of the mechanism of the 1,2-migrations of bromine and chlorine atoms. It has been shown that in radical reactions of bromoalkanes the bromine atom is involved in anchimeric cooperation with the abstraction of a β-hydrogen atom.[1,70] This is manifested, for example, in radical reactions of optically active bromoalkanes. Thus the deuterium exchange reaction involving (+)-(*S*)-1-bromo-2-methylbutane proceeds with full retention of optical activity:[70]



Asymmetry can be fully retained also in processes accompanied by the 1,2-migration of a bromine atom, for example, in the chlorination of (+)-(*S*)-2-bromobutane:[70,71]

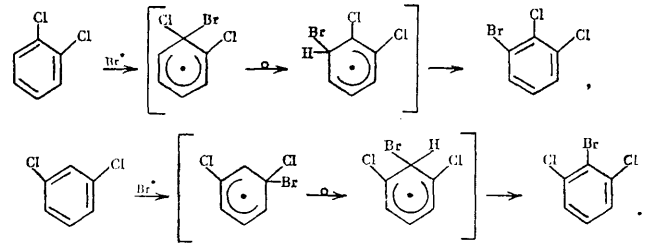
Like the bromine atom, the chlorine atom is also involved in anchimeric assistance in the abstraction of a β-hydrogen atom, although to a lesser extent than bromine. Thus the racemisation of the intermediate chloroalkyl radical takes place to an appreciable extent in the bromination of (+)-(*S*)-1-chloro-2-methylbutane.[70] Similar anchimeric assistance has not been detected for the fluorine atom. The radical fluorination of (+)-(*S*)-1-fluoro-2-methylbutane leads to complete racemisation.[70]

These results can be explained by the formation in the intermediate β-bromo- and β-chloro-radicals of a bridged structure in which the rotation about the C_α–C_β bond is to a large extent hindered and the stabilisation of such a radical leads to the retention of asymmetry in the reaction products.



Analysis of the EPR spectra of β-chloroethyl radicals showed that the chlorine atom is in the eclipsed conformation with respect to the *p* orbital of the radical centre. Hence, it has been suggested that the radical has an asymmetric bridged structure.[72,73] In the β-fluoroethyl radical, the angle between the *p* orbital and the C–F bond is 50°.[72,74] These data agree with calculations by the MNDO method.[75] The different structures of the β-chloroethyl and β-fluoroethyl radicals are caused, according to the authors, by a combination of steric and electronic factors.[72,75]

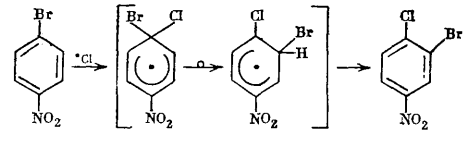
Hudson[76] estimated from the standpoint of the perturbation theory the stabilisation of radicals as a result of bridge formation for β-halogenethyl radicals:



$-\Delta E$ (kcal mol^{-1}): I (7.54) Br (2.97) Cl (0.22) F (— 1.30) O (—0.72) .

These data show that bridge formation is unfavourable for fluorine and oxygen atoms. According to the author, this is caused mainly by the large difference between the energies of the interacting orbitals, which diminishes on passing from fluorine to bromine and iodine. The ease of the 1,2-migration of a halogen atom varies in the same direction. Thus it is apparently possible to distinguish three energy factors influencing the ease and direction of the 1,2-migration of a halogen atom: (1) the degree of interaction of the *p* orbital of the radical centre with the halogen atom; (2) the dissociation energy of the C–Hal bond in the β-halogenoethyl radical, which decreases from fluorine to bromine (46.3 kcal mol^{-1} for fluorine, 22.0 kcal mol^{-1} for chlorine, and 7.9 kcal mol^{-1} for bromine[2]); (3) the relative stabilities of the radicals formed.

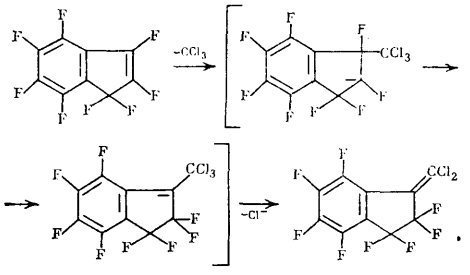
Several examples of the migration of bromine and chlorine atoms in cyclohexadienyl radicals are also known. Thus the γ-irradiation of methanol solutions of bromobenzene and *p*-bromophenol at 77 K generates cyclohexadienyl radicals with bromine atoms in the geminal unit.[77] Analysis of the EPR spectra of these radicals shows that the bromine atom "rotates" around the ring via a rapid 1,2-shift (the lifetime in this state is $<10^{-7}$ s):



In his analysis of the work of Belgian chemists[79] on the photobromination of dihalogenobenzenes, Traynham[78] drew attention to the fact that 1,2,3-trihalogenobenzenes constitute an appreciable proportion of all the isomeric trihalogenobenzenes formed. He suggested that radical unco-σ-complexes are formed and that the halogen undergoes 1,2-migration in these σ-complexes:

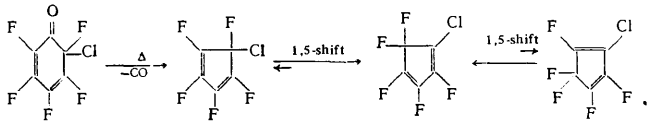
The Belgian scientists, who did not agree with this interpretation of their results, carried out a thorough investigation of the isomeric composition of the products of the photobromination of *o*- and *m*-dihalogenbenzenes.[80] They showed that the reaction products contain only 3-bromo-1,2-dichlorobenzene (reaction of *o*-dichlorobenzene) and 2-bromo-1,3-dichlorobenzene (reaction of *m*-dichlorobenzene). However, the formation of these products fits within Traynham's scheme, while the absence of other isomeric 1,2,3-trihalogenobenzenes can be accounted for by the different capacities for migration of chlorine and bromine atoms (Br > Cl).

Yet another process in which the 1,2-migration of the halogen in cyclohexadienyl radicals has been demonstrated is the free-radical chlorination of *p*-halogenonitrobenzenes:[81,82]



The structure of the rearranged product of this reaction also indicates the greater ease of the 1,2-migration of a bromine atom compared with a chlorine atom.

---o0o---



Thus analysis of the literature data shows that, whereas the migrations of a fluorine atom in neutral compounds are fairly common reactions and are consistent with modern theoretical views, the shifts of a fluorine atom in the intermediate species proceed via a fairly high energy barrier and require further theoretical consideration.

Most data available for the migration of a fluorine atom in intermediate species concern migrations in free radicals and, in particular, the 1,2-shift of a fluorine atom in cyclohexadienyl radicals. However, hitherto it is impossible to distinguish all the factors influencing the direction and energetics of the process. Presumably the energy of the 1,2-migration of a fluorine atom in radicals is intermediate between those of the 1,2-migrations in cations and anions. Although there is no experimental proof in the literature of the occurrence of the 1,2-shift of a fluorine atom in cations, Burdon and Parsons[61] believe that the 1,2-shift of a fluorine

atom in arenium ions is possible. Calculation by the CNDO/2 method of the relative energies of the isomeric arenium ions has shown that the stage involving the 1,2-shift of a fluorine atom is exothermic, but such a rearrangement should take place via a high energy barrier. It is believed that[61] it is achievable in the temperature range 200–500 °C. As regards the 1,2-shift of a fluorine atom in anions, the latter can apparently take place via a lower energy barrier than in the case of radicals and cations. Admittedly, in the latter case the interpretation of experimental data is hindered by the ease of abstraction of a fluoride ion from the anions. Nevertheless, for certain isomerisations proceeding with participation of anions, it is possible to postulate an intramolecular mechanism. For example, the formation of 1-dichloromethyleneperfluoroindan on interaction of perfluoroindene with sodium trichloroacetate can be represented as the result of isomerisation with formal 1,2-migration of a fluorine atom in the intermediate anion, although one cannot rule out pathways via the consecutive abstraction and addition of the fluoride anion:[83]

During the preparation of the manuscript for publication, several studies concerning the migration of a fluorine atom appeared in the literature. Thus the thermal 1,5-shift of a fluorine atom has been invoked[84] to account for the isomeric composition of the chloropentafluorocyclohexadienes formed on thermolysis of chloropentafluorocyclohexadienone:

Mal'tsev et al.[85] studied the isomerisation of bis(trifluoromethyl)carbene to perfluoropropene. The initial carbene was detected by IR spectroscopy in an argon matrix at 12–40 K:

$$(CF_3)_2C: \xrightarrow[\text{1,2-shift}]{} CF_3CF{=}CF_2 .$$

A study of the 1,2-migration of a fluorine atom in the 1,1,2-trifluoroethyl radical has been published recently.[86] The authors used the method proposed previously,[62] which consists in the addition of tritium atoms to fluorinated olefins:

$$CF_2{=}CHF \xrightarrow{T^{\cdot}} \dot{C}F_2{-}CHFT \xrightarrow{\circ} CF_3{-}\dot{C}HT \xrightarrow[-[F^{\cdot}]]{} CF_2{=}CHT .$$

Kotaka and Sato[86] explained by the 1,2-migration of a fluorine atom in the 1,1,2-trifluoroethyl radical the results of an earlier study[87] in which the formation of $CF_3CH_2CH_2CF_3$ was observed when a hydrogen atom was added to trifluoroethylene. Scott and Jennings[87] discussed the results of a calculation by the INDO method of the activation energies for the 1,2-migration of fluorine and hydrogen atoms in the radicals $\dot{C}F_2$–CHFT and $\dot{C}$FH–CFHT and suggested that in the excited radicals the 1,2-migration of a fluorine atom and not a hydrogen atom is energetically more favourable.

Steric Structuring of Polyolefins by Chemical Methods

U.D.C. 678.74.01:53:541.459

I.V.Konoval, N.G.Konovalenko, and S.S.Ivanchev

The present state of the problem of the steric structuring of polyolefins by chemical cross-linking agents (organic peroxides, azo-compounds, and organo-silanes) is examined. The structure formation mechanisms, the process conditions, the requirements which must be met by cross-linking agents, the factors determining the properties of cross-linked polymers, as well as the prospects for the development of the method are discussed.
The bibliography includes 28 references.

VI. Conclusion 80

I. INTRODUCTION

The steric structuring (cross-linking) of polyolefins is one of the principal ways of modifying their structure, which makes it possible to improve their operating characteristics and to extend the temperature range and types of applications of polyolefins.

Steric structuring is achieved by different methods: by radiation or ultraviolet light or with the aid of chemical cross-linking agents. The radiation structuring method does not as a rule require the introduction of special additives into the polymer. However, its application requires cumbersome and expensive apparatus and the maintenance of safety conditions. At the present time chemical structure formation is the commonest and most convenient procedure in practice and is employed in two principal versions: (1) the cross-linking of polyolefins with the aid of radical-forming agents (peroxides and azo-compounds) and (2) the cross-linking of polyolefins by organosilanes. The structuring of polyolefins by peroxides has been known for a long time. Organosilanes began to be used for this purpose more than 10 years ago, while azo-compounds have been applied only in recent years.

Despite the evident advances in the industrial use of chemical structuring, the theoretical aspects of the problem, in particular, the kinetics and mechanism of the process have not as yet been duly developed. The point is that the cross-linking reaction of polyolefins occurs either in the solid polymer or in its melt. It is known[1] that the structural-physical state is the most important factor influencing the chemical process in polymers. Structural microinhomogeneity of polymers is due to the inhomogeneity of the distribution of additives and reactants in the polymer system, the spatial localisation of the physical processes and chemical reactions in certain regions of the polymer, and also the dependence of the kinetic parameters on the kinetics of the molecular motions and molecular-relaxation properties of the polymer.[1] However, the kinetics and mechanisms of chemical structuring have so far been scarcely investigated from these standpoints.

There are extensive literature data concerning the structures and properties of cross-linked polyolefins, their relation with the initial compositions, and the determination of the kinetic parameters for the decomposition of peroxides and for the structure formation process. However, a considerable proportion of the results are unsuitable for the analysis of the state of the problem.

II. THE MECHANISM AND KINETICS OF THE CROSS-LINKING OF POLYOLEFINS BY CHEMICAL METHODS

The mechanism of cross-linking by radical forming agents has been investigated only in relation to organic peroxides. According to existing ideas,[2] it includes radical formation by the homolytic decomposition of the peroxide, the transfer of the radical activity to the polyolefin macromolecule by the abstraction of a hydrogen atom from the latter, and the recombination of the polyolefin macroradicals with formation of carbon–carbon cross-links:

$$I \xrightarrow{k_1} 2\dot{R}\,, \tag{1}$$

$$\dot{R} + PH \xrightarrow{k_2} \dot{P} + RH\,, \tag{2}$$

$$\dot{P} + \dot{P} \xrightarrow{k_3} P{-}P\,, \tag{3}$$

Apart from the three main elementary reactions, there is a possibility of the occurrence of radical side reactions, for example, the radical-induced decomposition of the peroxide, the fragmentation of the macroradicals, their interaction with low-molecular-weight radicals, disproportionation, etc.:

$$\dot{R} + I \xrightarrow{k_4} \dot{R}' + R\sim\,, \tag{4}$$

$$\dot{P} + I \xrightarrow{k_4} \dot{R}' + P\sim\,, \tag{5}$$

$$\dot{P} \xrightarrow{k_6} P_{=} + \dot{P}'\,, \tag{6}$$

$$\dot{P} + \dot{P} \xrightarrow{k_3'} \text{products of disproportionation of macroradicals,}$$

$$\left.\begin{aligned} \dot{P} + \dot{R} &\xrightarrow{k_7} \\ \dot{R} + \dot{R} &\xrightarrow{k_8} \end{aligned}\right\} \text{products of the recombination and disproportionation of radicals,} \tag{7, 8}$$

where $P_{=}$ is a macromolecule with a double bond.

The rate-limiting stages of the cross-linking process are the consecutive reactions (1) and (2). Part of the peroxide, decomposing via a mechanism other than the unimolecular mechanism, is effectively lost as regards the structuring process.[3] The presence or absence of the induced decomposition is determined by the nature of the cross-linking agent, other conditions being equal.

From the standpoint of the final result, two elementary reactions are decisive: the recombination reaction (3) and the degradation reaction (6) of the polymer radicals. Depending on the structure of the polymer radicals, reaction (3) leads to linear growth, branching, or cross-linking of the macromolecule; reaction (6) entails degradation. The preferential occurrence of each of these reactions depends to a large extent on the efficiency of the steric structuring process, i.e. on the number of cross-links arising in the polymer as a result of the decomposition of one peroxide group. For example, in polyethylene the polymer radicals almost always recombine with formation of cross-links. Polymers containing tertiary carbon atoms tend to undergo degradation.

The study of the transformations occurring on decomposition of benzoyl peroxide in polyethylene, polypropylene, and polyisobutylene made it possible to derive general kinetic equations, which take into account the possibility of the simultaneous occurrence of the structuring and degradation reactions in polyolefins.[4]

1. For the unimolecular decomposition of the peroxide [reaction (1)]:

$$\Delta n = K_s[I]_0(1 - e^{-k_1 t})/k_1 - K_d\{[I]_0(1 - e^{-k_1 t})/k_1\}^{1/2} .$$

2. For the chain composition of the peroxide [reaction (4)]:

$$\Delta n = K_s \frac{2.303 \lg \{e^{k_1 t}(k_c[I]_0/k_1 + 1) - k_c[I]_0/k_1\} - k_1 t}{k_c} - K_d\left\{\frac{2.303 \lg \{e^{k_1 t}(k_c[I]_0/k_1 + 1) - k_c[I]_0/k_1\} - k_1 t}{k_c}\right\}^{1/2} .$$

3. For the chain decomposition of the peroxide [reaction (5)]:

$$\Delta n = K_s \frac{2k_1}{k_c^2}\left[(a+1) - \frac{A(a+1)}{A(a+1)-a} - 2.303 \lg \frac{A(a+1)-a}{A}\right] - K_d\left\{\frac{2k_1}{k_c^2}\left[(a+1) - \frac{A(a+1)}{A(a+1)-a} - 2.303 \lg \frac{A(a+1)-a}{A}\right]\right\}^{1/2} ,$$

where Δn is the change in the concentration of bonds in the polymer, $K_S = k_1 k_3/(k_3 + k'_3)$ the structuring constant,

$$K_c = k_1^{1/2} k_6/(k_3 + k'_3)^{1/2}$$

the degradation constant, k_c the rate constant for the chain decomposition of the peroxide, $[I]_0$ the initial peroxide concentration, t the time, $a = k_c[I]_0^{1/2}/k_1$, and $A = e^{k_1 t/2}$.

The equations take into account, on the one hand, the possibility of both the unimolecular and chain decomposition of the peroxide and, on the other, various types of radical termination. However, these equations are nevertheless specific in character and, like the mechanism presented above [reactions (1)–(8)], did not take into account the structural-physical characteristics of the polymer, its molecular weight distribution, and the role of the cage effect in the system and of the delay transfer in the transport of the reacting species—radicals and molecules. The necessity to take these factors into account is indicated by experimental data. For example, the rate of radical reactions in low density polyethylene (LDPE) is higher by two orders of magnitude than in high density polyethylene (HDPE).[5] The introduction of identical amounts of the cross-linking agent, other conditions being equal, leads to the formation of a larger number of cross-links in HDPE than in LDPE (Fig. 1).[6]

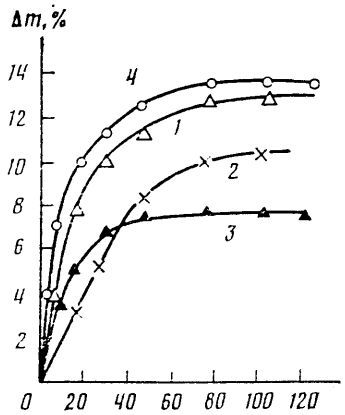

Figure 1. Kinetic curves for the swelling (at 140 °C) in *p*-xylene of HDPE (curves *1*–*3*) and LDPE (curve *4*) specimens cross-linked by di-t-butylperoxyisopropylbenzene. The content of peroxide (%): 1) 1.5; 2) and 4) 2.0; 3) 3.0.

Table 1. The efficiency of the cross linking of linear polyethylene (d = 0.960 g cm^{-3}) by dicumenyl peroxide at the initial gel formation point (at 150 °C).[7]

Polymer	$10^{-3}M_w$	M_w/M_n	c^{**}, mmol kg^{-1}		Efficiency of cross linking***, %
			experiment	calculation

*Polymers 1–10 contain less than 0.07 of a vinyl group per 1000 carbon atoms. The mixture of polymer 10 with dicumenyl peroxide was freed from oxygen in an atmosphere of nitrogen before the reaction. Polymer C contains 0.5 of a vinyl group per 1000 carbon atoms and H represents the hydrogenated polymer.

**Here c is the concentration of dicumenyloxy-radicals.

***The ratio of the calculated and real peroxide concentrations at the beginning of gel formation.

The study of the characteristic features of the cross linking of linear polyethylene[7] in the presence of dicumenyl peroxide showed that the efficiency of cross linking, the yield of the product of the thermolysis of the peroxide, and the preferential occurrence of one of the competing reactions are

significantly influenced by the presence of a vinyl group in the system, whose carriers may be both the peroxide decomposition products and the polyolefin. This is expressed, in particular, by the considerable discrepancy between the theoretical amount of cumenyloxy-radicals, calculated from the Flory–Stockmayer relation, and its experimental amount ensuring the same efficiency of cross linking[7] (Table 1). The kinetic parameters of the cross linking by peroxides depend on the concentration of active oxygen in the system, the nature and concentrations of the components, and the process temperature (Fig.2).[6] Furthermore, the rate of cross linking and the yield of the cross-linked polymer are influenced by the pressure;[8] it may be that the observed effect is caused by the decrease in the activation volume of the reaction.[9]

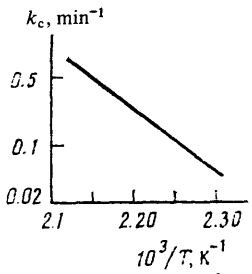

Figure 2. Temperature dependence of the rate constant for the cross linking of polyethylene with the density $d = 0.960$ g cm^{-3}.[6]

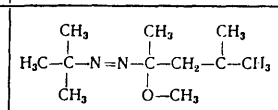
The examples considered clearly indicate the imperfection of the existing ideas about the mechanism of the cross linking of polyolefins by organic peroxides, as they fail to take into account a whole series of significant factors.

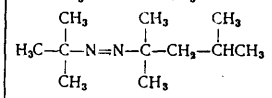
The cross linking of polyolefins by azo-compounds has been studied still less. It has been assumed for a long time[10] that azo-compounds cannot serve as initiators of the cross linking of polyolefins, because the radicals formed on decomposition of the majority of them [via reaction (1)] are incapable of abstracting hydrogen from the polyolefin macromolecule. However, when the polymer system contains double bonds (ethylene–propene–diene copolymers, their mixtures with saturated polyolefins, etc.), structuring can occur as a result of the addition of primary radicals with dissociation of double bonds according to the mechanism[10]

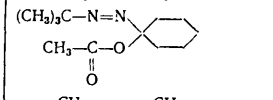
$$R + CH_2{=}CH{-}R'{-}CH{=}CH_2 \rightarrow R{-}CH_2{-}\dot{C}H{-}R'{-}CH{=}CH_2 ,$$

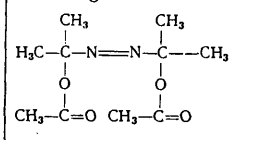
$$R{-}CH_2{-}\dot{C}H{-}R'{-}CH{=}CH_2 + PH \rightarrow R{-}CH_2{-}CH_2{-}R'{-}CH{=}CH_2 + \dot{P} ,$$

$$R{-}CH_2{-}CH{-}R'{-}\dot{C}H{=}CH_2 + P \rightarrow R{-}CH_2{-}\underset{\displaystyle P}{CH}{-}R'{-}CH{=}CH_2 ,$$









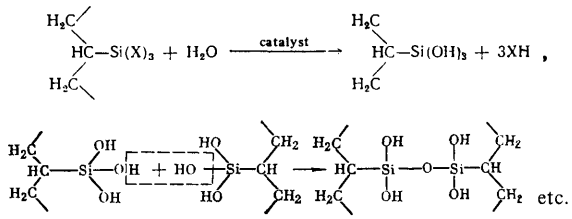
$$R{-}CH_2{-}\underset{\displaystyle P}{CH}{-}R'{-}CH{=}CH_2 + \dot{R} \rightarrow R{-}CH_2{-}\underset{\displaystyle P}{CH}{-}R'{-}CH{-}CH_2{-}R ,$$

$$R{-}CH_2{-}\underset{\displaystyle P}{CH}{-}R'{-}\dot{C}H{-}CH_2{-}R + P \rightarrow R{-}CH_2{-}\underset{\displaystyle P}{CH}{-}R'{-}\underset{\displaystyle P}{C}{-}CH_2R .$$

Thorough investigation of the mechanism is still to come, but it is already clear that the use of azo-compounds makes it possible to avoid degradation [reaction (6)] in the structuring of polyolefins containing tertiary carbon atoms. Furthermore, additional possibilities arise for increasing the efficiency of the action of the cross-linking agent as a result of the use of mixtures of azo-compounds, or regulating the duration and extent of the structuring process, etc.[10] Table 2 presents certain azo-compounds recommended for the cross-linking of polyolefins.

Whilst having a series of undoubted advantages, which include high strength of the finished article, resistance to cracking and the action of organic solvents and mechanical stresses at high temperatures, the possibility of varying its properties over a wide range, the uniformity of its structuring throughout its volume, etc., cross linking by radical forming compounds also suffers from significant disadvantages. In the first place, one should note the possibility of the premature cross linking of the material already in the stage where the cross-linking agent is introduced into the polymer. Another disadvantage is the limited choice of methods suitable for the preparation of the finished articles and the compositions undergoing cross linking. The use of organosilanes as cross-linking agents makes it possible to eliminate some of these disadvantages and provides a fundamentally new solution to the problem.

Table 2. Azo-compound cross-linking agents.[10]



Name		Formula	Temperature, °C	
chemical	commercial		τ = 10 h	τ = 12 h
2-t-Butylazo-2-methoxy-4-methylpentane	Luazo-135		135	155
2-t-Butylazo-2,4-dimethylpentane	Luazo-148		148	168
1-t-Butylazo-1-acetoxycyclohexane	Luazo-165		165	187
2,2-Azobis-2-acetoxypropane	Luazo AP		189	215

Notation: τ is the decomposition half-life of the azo-compound.

The mechanism of the cross linking pf polyolefins by organosilanes has been described in the literature in the most general form and we are unaware of any far reaching studies on the process kinetics. According to the available data, the cross linking of the polyolefins includes two main reactions: the grafting of the organosilane of the type $R_nSIX_{(4-n)}$ to the polyolefin and subsequent structuring of the modified polymer in the presence of water and a hydrolysis catalyst[11] [X = hydrogen, a halogen, or a radical (alkyl, aryl, arylalkyl, cycloalkyl, alkylamine, arylamine, etc.); R = radicals with olefinic double bonds containing 2–12 carbon atoms; n = 1, 2]. It has been suggested[12] that the grafting of the silane to the polyolefin can be represented as follows in a general form:

$$\sim CH_2{-}CH_2{-}CH_2 \sim + RSi(X)_3 \rightarrow \sim CH_2{-}\underset{\displaystyle Si(X)_3}{\overset{\displaystyle H}{C}}{-}CH_2 \sim ,$$

and the second stage can be represented schematically by

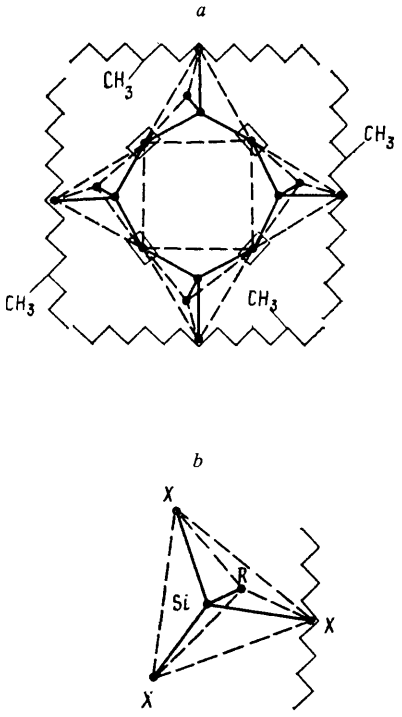


Figure 3. The configuration of the cross-linking nodes: *a*) the node linking four macromolecules, the centres of the intermolecular interaction of the silane substituent being indicated by rectangles; *b*) schematic illustration of the position of substituents capable of participating in the cross-linking process.

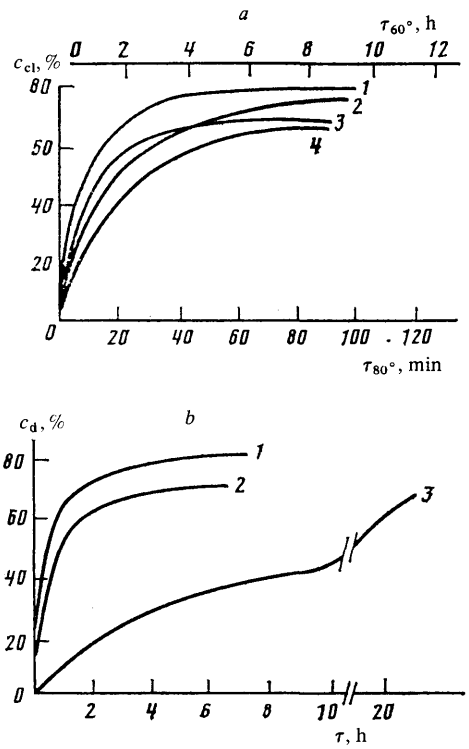
A polyolefine modified by silane is a polyfunctional compound which constitutes a kind of cross-linking centre capable of binding several macromolecules at once. Under these conditions, the four substituents in the silane molecule capable of being joined to macromolecules and to one another form a tetrahedron with the silicon atom at the centre (Fig.3*b*).[13] In the polymer there are usually three reactive substituents. However, as can be seen from Fig.3*a*, on average only two substituents are involved in the structuring process. Structuring by silanes results in the formation of polymers whose properties differ from those of polyolefins cross-linked by organic peroxides, which is caused to a large extent by the difference in the nature of the cross-link (–Si–O–Si–C instead of –C–C–) and in the functionality of the nodes of the network.[13]

The silane is usually grafted to the polyolefin by the mechanochemical degradation method using one of the familiar procedures for the processing of polymers. The best results have been obtained in a Banbury blender and on a rolling machine.[12] The conditions in the mechanical treatment depend on the type of polymer, its molecular weight, the required degree of grafting, and the type of equipment.[11] The efficiency of the grafting process can be increased by introducing into the polymer substances capable of generating free radicals (peroxides and azo-compounds). The content of the radical forming compound is determined by the type of polyolefin and the required degree of grafting, but it should not be so large that the polymer is cross-linked.



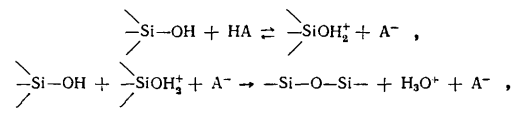


Figure 4. Dependence of the content of the cross linked-fraction c_{cl} in the composition on the structuring process conditions: *a*) Moldex S-181 in water: 1) at 80 °C; 2) at 60 °C; 3) and 4) Moldex S-161 under analogous conditions [$\tau_{60°}$ (h) and $\tau_{80°}$ (min) are the times during which the compositions are kept in water at 60° and 80 °C]; *b*: 1) Moldex S-181 at 40 °C and 90% humidity; 2) Moldex S-161 under the same conditions; 3) Moldex S-161 at 25 °C [τ is the exposure time (h)].[12]

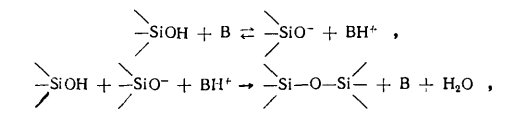
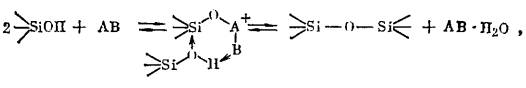
The polymer modified with a silane is hydrolysed by atmospheric moisture even at room temperature. Nevertheless, in order to accelerate the reaction, the cross linking is frequently carried out in an aqueous medium at 40–90 °C in the presence of a catalyst or by treatment with water vapour at a temperature ≥100 °C. The limiting cross-linking density achieved under these conditions does not then change (Fig.4). The hydrolysis catalysts can be inorganic



and aliphatic acids, organic bases (ethylamine, dibutylamine, and piperidine), orthotitanate esters, chelates, and metal carboxylates. Depending on the nature of the catalyst, the following mechanisms have been proposed for the formation of the siloxane linkage:[12]

(a) in the presence of acids:



where A is the acid anion;

(b) in the presence of alkali:

where B is the base;

(c) in the presence of neutral salts:

Among the multiplicity of catalysts for cross linking by organosilanes, preference is given to organotin compounds such as dibutyltin dilaurate, dibutyltin diacetate, and dibutyltin dioctanate. These compounds are neutral salts, exhibit a high catalytic activity, and do not generate a corrosive medium.[11,12]

The grafting and structuring stages can be combined by introducing into the system additives forming water in the course of their chemical interaction with the components of the system.[12] Polyolefins with any density and any parameters of the fluidity of the melt can be subjected to structuring by organosilanes.

III. THE REQUIRMENTS WHICH MUST BE MET BY CROSS-LINKING AGENTS

The essential requirements which must be satisfied by the agents for the cross linking of polyolefins are determined primarily by the mechanism of the cross-linking process, its kinetic features, and the way in which it is achieved. Furthermore, there exist a series of technical and economic requirements, common to all types of chemical cross-linking agents: stability and low volatility under the conditions where they are combined with the polymer, volatility and lack of toxicity of the thermolysis products or the products of the interaction with the components of the composition, and ready availability of the raw material; for radical forming agents, a high rate of decomposition (decomposition half-life 4–6 min) at a temperature exceeding by 40–60 °C the temperature at which they are introduced into the polymer is sufficient.

Reactions (1) and (2) determine the principal requirement which must be met by peroxides as cross-linking agents: the ability to generate radicals which are sufficiently active in reactions involving the abstraction of hydrogen from the polymer chain. It is known that the activity of radicals in hydrogen abstraction reactions depends both on their intrinsic structure and on the structure of the elements of the macrochain.[7,8] In the cross-linking reactions of polyolefins, it is preferable to use peroxides generating alkoxy-radicals on decomposition. The study of the behaviour of a series of asymmetric peroxides of the type R–O–O–R′ in a cross-linking process showed that t-butyl cumenyl peroxide exhibits the maximum efficiency. Its decomposition results in the formation of t-butoxy- and cumenyloxy-radicals, which decompose in their turn to methyl radicals and correspondingly to acetone and acetophenone.

Among peroxides with different structures—peracids, peracetals, perketals, peresters, hydroperoxides, and dialkyl and diacyl peroxides—tertiary dialkyl peroxides satisfy most fully the requirement specified. The optimum conditions for the technological cross-linking process and the optimum characteristics of the cross-linked polyolefins are ensured by dicumenyl peroxide, which is widely used on an industrial scale. The mechanism and kinetics of its thermal decomposition have been studied in fair detail.[14] The formation of the highly toxic actophenone in the thermolysis of dicumenyl peroxide has led to the search for other peroxides combining all the positive qualities of dicumenyl peroxide with the absence of toxic decomposition products. Such cross-linking agents proved to be certain bifunctional peroxides. The recommended temperatures of their mixing with the polymer (T_{mix}) and the cross linking temperatures (T_{cl}) as well as the efficiencies (f) of the cross linking of LDPE are indicated below:[15]

	T_{mix}, °C	T_{cl}, °C	f
Di-t-butyl peroxide	up to 100	150	–
Dicumenyl peroxide	up to 120	160	0.61
1,3-Di-t-butylperoxyisopropylbenzene	up to 130	170	–
1,4-Di-t-butylperoxyisopropylbenzene	up to 130	170	–
n-Butyl-4,4′-di-t-butylperoxyvalerate	up to 110	150	–
1,1-Di-t-butylperoxy-3,3,5-trimethylcyclo hexane	up to 100	140	–
2,5-Di-t-butylperoxy-2,5-dimethylhexane	up to 130	170	0.29
2,5-Di-t-butylperoxy-2,5-dimethylhex-3-yne	up to 130	170	0.74

The possibility of the cross linking of polyolefins by two-component cross-linking systems generating radicals in the course of the oxidation-reduction reaction is of definite interest. The cross-linking system consisting of a hydroperoxide and a variable valence metal ion may serve as an example.[16] The low activation energy for the interaction of the hydroperoxide with a variable valence metal ion makes it possible to carry out the structuring process at lower temperatures and to avoid the premature cross linking of the polymer. The rate of the process can be regulated by varying not only the temperature but also the content of the metal. The advantage of such systems, consisting in lowering the temperature of the cross linking process, proved at the same time to be their disadvantage, since they can initiate structuring only during the preparation and formation of the mixtures. However, this principle of the formation of macroradicals ensures contact between the components via diffusion at the required stages of the process. When it is applied to the preparation of thin-layer materials, the cross-linking temperature is appreciably reduced, which makes it possible to cross-link polyethylene films at temperatures which do not induce their deformation.

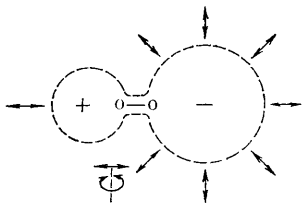
The *meta*- and *para*-isomers of di-t-butylperoxyisopropylbenzene or their mixture (peroxymon) have come to be most widely used. The diperoxy-derivatives of ketones and tri- and tetra-peroxides of different structure can be used as cross-linking agents.[17] However, the methods of their synthesis are as a rule complex, the raw materials are difficult to obtain, and the polyolefins cross-linked by them do not manifest any significant advantages in their properties. For this reason, the above group of peroxides can be of interest only for the investigation of the influence of the

structure and functionality of the peroxide on the mechanism and kinetics of the cross-linking process. The hypothesis that the bifunctional di-t-butylperoxyisopropylbenzene can be more efficient in the cross linking of polyolefins than dicumenyl peroxide has not been confirmed experimentally.[18]

Subsequently it was shown[19] that there is a possibility of the stepwise decomposition of peroxy-groups in diperoxides. The activation energy for the decomposition of the second peroxy-group is greater (E_1 = 152 kJ mol^{-1}, E_2 = 161 kJ mol^{-1}) and the rate of decomposition is lower—$k^1_{decomp} = 58 \times 10^{-5}$ s^{-1} and $k^2_{decomp} = 30 \times 10^{-5}$ s^{-1} at 150 °C (for comparison, we may recall that the values determined under analogous conditions for dicumenyl peroxide are E = 153 kJ mol^{-1} and $k_{decomp} = 53 \times 10^{-5}$ s^{-1}).[19] The observed features are due to the differences in the structures of the peroxide complexes and in the stability of the radicals formed on decomposition of the first and second peroxy-groups.[19] These differences cause the reduced efficiency of the cross linking of polyolefines in the presence of di-t-butylperoxyisopropylbenzene compared with dicumenyl peroxide in the temperature range 140–160 °C. An increase in temperature reduces the difference.

It had been postulated earlier that the mechanism of the thermal decomposition of peroxides remains unchanged on passing from model systems to the polymer.[20] However, in the light of the existing ideas about the mechanisms of solid-phase reactions,[1] this hypothesis must be regarded as erroneous and as associated with the low accuracy of the experiment.

Specific requirements which must be met by cross-linking agents are closely related to the problem of the introduction and decomposition of radical-forming compounds in polyolefins.



IV. THE CONDITIONS IN THE STRUCTURE FORMATION PROCESSES

Radical-forming cross-linking agents can be introduced into polyolefins by different methods: (1) by stirring into a polymer melt, (2) by the diffusion method, (3) by dry mixing, and (4) by the internal synthesis of the cross-linking agent.[21] As an example of the use of the last method, one may quote the synthesis of di-t-butyl peroxalate from tetraalkyl hydroperoxide and oxalyl chloride directly in the bulk of the polymer.[23]

Silanes can be introduced into the polymer melt or can be dispersed on the surface of the polyolefin. Hydrolysis catalysts are introduced into the composition in different ways: before the start of the reaction involving the grafting of the silane to the polyolefin, during this reaction, or after it has been completed; by mixing the components; by diffusion; by treating the grafted copolymer with an aqueous suspension, emulsion, or solution of the catalyst.[11]

Until recently, only thermolysis has been used to decompose the peroxide into the free radicals. The application for this purpose of an ultrahigh frequency electromagnetic field (microwave mixing or, what amounts to the same thing, UHF mixing, UHF cross linking) has opened up new possibilities.[22] Cross linking by exposure to a UHF field can be achieved in three ways.

1. Decomposition in the UHF field of peroxides, for example, t-butyl peroxybenzoate or di-t-butyl peroxyterephthalate. The peroxide decomposes as a consequence of the instantaneous absorption of energy from the UHF field, usually at a frequency of 2450 MHz, in accordance with the scheme

2. The use of weakly polar peroxides and auxiliary substances highly active in a UHF field, such as halogenohydrocarbons, carbon black, triallyloxy-*s*-triazine, etc. The molecules of the auxiliary substances absorb the energy of the UHF field and transmit it to the peroxide molecules. The polymer composition being cross linked in the UHF field is heated uniformly to the temperature at which the thermal composition of the peroxide begins.[21]

3. The use of auxiliary substances highly active in a UHF field and of weakly polar products forming complexes with them. As a result, the peroxide molecules are always in the immediate vicinity of the molecules of the auxiliary substances which transmit to them the absorbed energy from the UHF field, so that the thermolysis of the peroxide is possible at a lower temperature of the polymer.

There is as yet little information in the literature about the mechanism of the microwave cross linking, the decomposition of peroxides in a UHF field, and the effect of auxiliary additives, the kinetic process parameters, etc. Only the influence of the nature of the peroxide and of the auxiliary additives on their activity in the UHF field and on the degree of structuring of the polyethylene has been noted and the dependence of the rate of cross linking on the concentration of the peroxide, the initial temperature of the polymer composition, and the duration of the action of the UHF field has also been observed.[22,23] Nevertheless, the advantages of the method of the microwave cross linking of polyolefins are already evident: the decreased energy requirement for the process, the decrease in the length of the industrial production line and of the cooling zone, and the possibility of cross linking a thick-walled article. Furthermore, the decomposition of polar peroxides to weakly polar products has a favourable effect on the dielectric characteristics of the structured polymers (when di-t-butyl peroxyterephthalate is used for polyethylene, the tangent of the dielectric loss angle tan $\delta = 1.5 \times 10^{-4}$ at 20 °C and a frequency of 100 Hz, while the dielectric constant is ε = 2.34).[22] The possibility of cross linking articles regardless of their thickness is the main advantage of the method and is responsible for its vigorous development and industrial application.[22]

V. THE CONSTITUTION AND PROPERTIES OF COMPOSITIONS UNDERGOING CROSS LINKING

The influence of the constitution of the compositions undergoing cross linking on their properties can be examined fully enough only in relation to polyolefins structured by organic peroxides, since these have been most thoroughly investigated.

A real composition undergoing cross linking is a complex polymer system, which contains as a rule stabilisers, accelerators, fillers, and modifying agents which are not always inert towards the cross-linking agents or free radicals. The antioxidant preventing degradation is an obligatory component of cross-linking compositions based on polyolefins. The structuring and inhibited thermal oxidation reactions

proceed via a radical mechanism, so that, when the polymer contains simultaneously a peroxide and an antioxidant, the latter interacts with the radicals formed on decomposition of the cross-linking agent. The reaction products inhibit the cross-linking reaction and reduce the efficiency of the structuring process. Apart from reactions (1)–(8), there is then a possibility of the occurrence of the following elementary reactions:[20]

$$\dot{R} + YH \xrightarrow{k_9} \dot{X} + RH \qquad (9)$$

$$\left.\begin{aligned} \dot{Y} + \dot{Y} &\xrightarrow{k_{10}} \\ \dot{P} + \dot{Y} &\xrightarrow{k_{11}} \end{aligned}\right\} \text{reaction products.} \qquad (10),\ (11)$$

For the steric structuring by peroxides, the relative reactivity of the antioxidant can be estimated with the aid of the relation (Fig.5):[20]

$$\left(\frac{[i]}{[i']}\right)^{1/2} = rk\frac{[YH]}{[PH]} + k$$

where [YH] and [PH] are the amounts of the antioxidant in the polymer (moles), k is the ratio of the rate constants characterising the cross-linking reactions of the stabilised and unstabilised polyolefins, r is the relative reactivity of the antioxidant, and [i] is the amount of peroxide which induces the formation of the same number of cross-links in the unstabilised polyolefins as the amount [i'] in the stabilised polyolefin.

Thus the relative reactivity of the antioxidant can be estimated from the ratio of [i] and [i']. The reactivity of antioxidants of the phenolic type is higher than that of antioxidants of the amine type. The values of r and k for the polyethylene–dicumenyl peroxide system are presented below; the data obtained using 1,3-di-t-butylperoxyisopropylbenzene are indicated in brackets:[23]

	r	k
N-Cyclohexyl-*N*-phenyl-*p*-phenylenediamine	60	1.02
NN'-Diphenyl-*p*-phenylenediamine	90	0.97
NN'-Dinaphthyl-*p*-phenylenediamine	160(280)	0.99(0.90)
2,2'-Methylenebis(6-t-butyl-4-methylphenol)	540(600)	0.91(0.86)
4,4'-Thiobis(6-t-butyl-3-methylphenol)	1500	0.83

In order to intensify the peroxide cross-linking process, one may introduce into the composition cross-linking coagents, whose role is usually fulfilled by sulphur or polyfunctional monomers [divinylbenzene, trialkyl cyanurate, tri(hydroxymethyl)propane trimethacrylate, pentaerythrityl tetramethacrylate].[2]

The introduction of a filler also influences the kinetic structuring parameters, since the rates of the elmentary reactions occurring on the filler surface and in the bulk of the polymer are different.[21] This difference is caused by the selective adsorption of the reactant at the interface and by the involvement in the reactions of the functional groups of the filler. The adsorption interaction of peroxides with the filler surface may be abolished by introducing additives (for example, poly-1,2-dihydro-2,2,4-trimethylquinoline) which are adsorbed first on the filler surface.

Fillers containing on their surfaces acid centres (carbon black, kaolin, etc.) induce an ineffective (non-radical) decomposition of the peroxide. This reduces the efficiency and density of the cross linking and the physicomechanical characteristics of the structured polymer are altered (Table 3).

Table 3. The physicomechanical characteristics of cross-linked filled LDPE (d = 0.917 g cm^{-3}, dimethyl peroxide content 2.5 wt.%).[17]

Filler	c_f, %	σ_b, MPa	l, %	$\Delta\Sigma$*, %
—	—	14.5	500	45.0
Chalk	10.0	12.0	350	30.0
Chalk	20.0	13.5	300	23.0
Talc	10.0	11.0	360	23.0
Kaolin	20.0	8.0	120	83.0
Kaolin	30.0	9.0	100	60.0

Notation: c_f is the content of the filler, σ_b the breaking stress on extension, l the relative elongation at rupture, and $\Delta\Sigma$ the deformation under a load of 5 N at 200 °C.

*The cross-linking density was estimated from the degree of deformation.

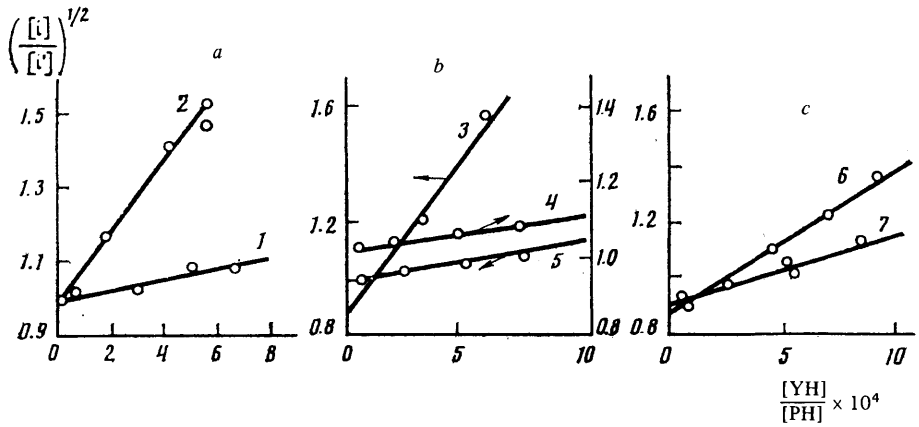


Figure 5. Dependence of $\{[i]/[i']\}^{1/2}$ on the antioxidant/polyethylene concentration ratio;[20] cross-linking agents: *a*) and *b*) dicumenyl peroxide; *c*) 1,3-di-t-butylperoxyisopropylbenzene; antioxidants: 1) and 7) *NN'*-dinaphthyl-*p*-phenylenediamine; 2) nickel dibutyldithiocarbamate; 3) 4,4'-thiobis(6-t-butyl-3-methylphenol); 4) *N*-cyclohexyl-*N'*-phenyl-*p*-phenylenediamine; 5) *NN'*-diphenyl-*p*-phenylenediamine; 6) 2,2'methylenebis(6-t-butyl-4-methylphenol).

The properties of cross-linked polyolefins are determined by a multiplicity of factors, the most important of which is the cross-linking parameter. In a number of studies, use has been made of the concept of the cross-linking density, which is either identical with the concept of the cross-linking parameter or is expressed as (a) the concentration of the effective chains, (b) the number of cross-linking sites referred to 1000 carbon atoms, and (c) the molecular weight of the section of the chain included between two nodes (M_C).[6,13]

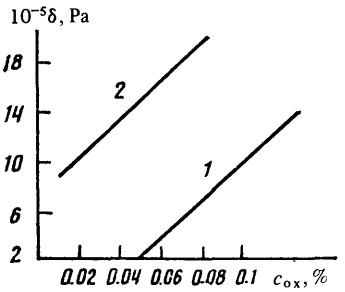

Figure 6. Dependence of the cross-linking density (estimated from the modulus of shear δ) of polyethylene with different densities on the content of active oxygen c_{ox} in the system: 1) d = 0.924 g cm^{-3}; 2) d = 0.960 g cm^{-3}.

The cross-linking parameter of polyolefins is determined by the process temperature, the concentration of active oxygen (Fig.6), the structural-morphological characteristics of the polymer, and the nature and concentration of other ingredients of the composition.[24] With increase in the cross-linking parameter, the relative elongation[24] and density of the polyolefins decrease (Fig.7) (according to Voight,[13] the relative elongation does not change) and their deformability by mechanical loads also diminishes (Fig.8). The content of the gel fraction changes little as the cross-linking density is varied (Fig.9). The point is that, even for low values of the latter, the extractable part of the polymer is small. Theoretically two cross-linking nodes per mass-average macromolecule are sufficient for the formation of an insoluble gel, but, depending on the molecular weight distribution (MWD) of the polyolefin, the content of the gel fraction may be different for the same cross-linking parameter.[25]

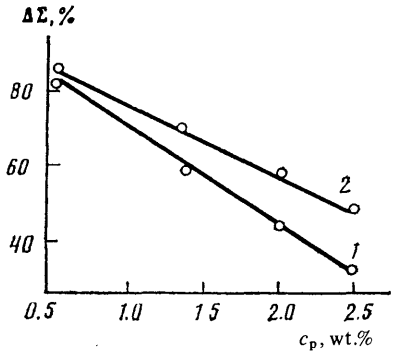

Figure 8. Dependence of the degree of deformation $\Delta\Sigma$ of cross-linked LDPE under a load of 5 N at 200 °C on the peroxide concentration c_p: 1) 2,5-di-t-butylperoxy-2,5-dimethylhexane; 2) 2,5-di-t-butylperoxy-2,5-dimethylhex-3-yne.

Since the main field where cross-linked compositions are used is the electrotechnical industry, it is necessary to know the factors determining their dielectric characteristics. These include the content, volatility, and polarity of the components of the polymer composition. An increase in polarity and a decrease in volatility impair the dielectric parameters.

The degree of crystallinity and the size of the unit cell of the cross-linked polyolefin are independent of the type and content of the peroxide.[26,27] Thus, whereas the degree of crystallinity is about 65% for LDPE (d = 0.917 g cm^{-3}), the value for the same polymer cross-linked in the melt by 2,5-di-t-butylperoxy-2,5-dimethylhexane or 2,5-di-t-butylperoxy-2,5-dimethylhex-3-yne is 33–37% for a peroxide concentration in the composition of 0.5–4.5%. The average size of the crystallites is 70 Å.[27] It is of interest to elucidate whether the structuring process occurs preferentially in the amorphous or crystalline phases of the polymer. So

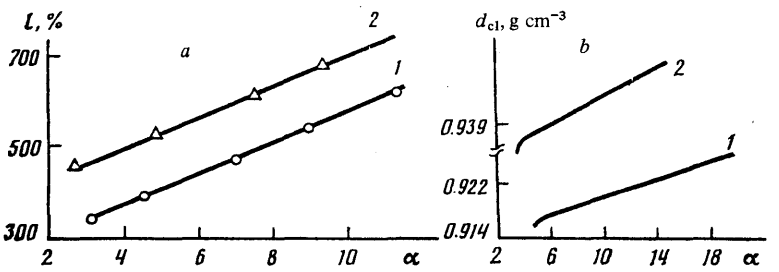

Figure 7. Dependence of the relative elongation l (a) and the cross-linking density d_{cl} (b) of cross-linked polyethylene with different densities [1) d = 0.924 g cm^{-3}; 2) d = 0.960 g cm^{-3}] on the swelling coefficient α determined at 140 °C.[6]

far there is no unanimous view concerning the character of the distribution of the cross-links between the phases of polyolefins. However, there is hardly any point in considering the probability of the occurrence of the structuring process in a particular phase[28] in those cases where it takes place in the polymer melt and the phase structure is established after the completion of the structuring process on cooling the specimen.

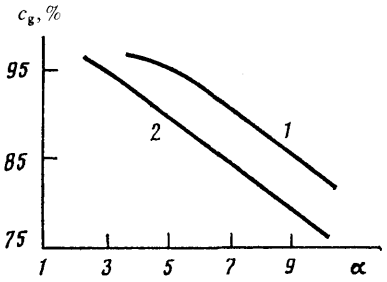

Figure 9. Dependence of the content of the gel fraction c_g in polyethylene with different densities on the swelling coefficient α:[6] 1) d = 0.960 g cm^{-3}; 2) d = 0.924 g cm^{-3}.

VI. CONCLUSION

We examined above the current state of the problem of the steric structuring of polyolefins by chemical methods. The questions of the technology, the specificity and importance of which require special consideration, were not considered.

At the present time, it is evident that the method of cross linking polyolefins or organic peroxides in the thermal decomposition of the latter occupies a leading position as regards its industrial application and practical value. It is also the method which is the most thoroughly investigated. The successive development and improvement of this method requires, firstly, the study of the mechanism of the thermal decomposition of organic peroxides in polyolefins and model hydrocarbons for the critical analysis of the mechanism adopted for the structuring process; secondly, the development and organisation of the industrial manufacture of effective new-generation structuring agents are needed. It is also useful to investigate the structuring effect of mixtures of organic peroxides as one method for increasing the efficiency of the process and for improving the technology.

From the standpoint of industrial application, the structuring of polyolefins by organic peroxides in the course of their decomposition by a UHF field is the most advanced application. The development of this application requires the study of the kinetics and mechanism of the microwave cross linking and the development and industrial application of polar peroxides.

The method of structuring polyolefins by organosilanes has a series of undoubted advantages, which has led to its vigorous industrial application (approximately 25 companies are engaged in this problem in Western Europe alone), despite the fact that it has been comparatively little studied. However, the method has limited applicability, mainly for the cross-linking of thin-walled articles, for example, in the manufacture of tubes, oriented films, packing materials with an increased resistance to moisture and corrosive media and with a reduced gas permeability, and for the insulation of wires and cables. The mechanism of structuring by organosilanes and the composition–structure–properties relation have been little investigated.

Overall, the compositions undergoing cross linking should be the subject of vigorous studies on the basis of modern theoretical approaches and using modern methods for the investigation of the kinetics, structures, and properties of polymers, which will ensure the successful development of this field and the preparation of materials with valuable properties.

Electrophoretic-electrochemical Deposition of Polymers and Metals

Yu.F.Deinega and Z.R.Ul'berg

The physicochemical principles of the formation of composite polymeric and metallopolymer coatings by the electrodeposition of polymer dispersions in water and electrolyte solutions are described. The electrophoretic and electrophoretic-electrochemical mechanisms for the formation of the polymer and metallopolymer coatings are examined. The role of the chemisorption interaction of the polymers and colloidal metals in increasing the protective properties of the coatings is demonstrated. The new phenomenon of "electrophoretic" polarisation and its influence on the electrode processes are considered.
The bibliography includes 100 references.

I. INTRODUCTION

The use of electric fields to form dispersed structures has been acquiring increasing importance. Particles can be oriented in electrical fields along their geometrical or molecular axes and directional movement of the particles and the interaction of polarised particles leading to structure formation can be achieved. These effects are used in electrodeposition processes,[1-4] in the manufacture of materials with anisotropic properties,[5] in the purification of liquids by electrofiltration,[6] and for controlling the mechanical properties of dispersed systems.[7]

The use of electric fields to create composite materials and coatings has opened up wide possibilities. Together with the rapid development of traditional fields of electrotechnology such as electroplating and galvanoplastics, the formation in the electric field of composite coatings based on polymers, metals, and non-metals is being applied to an increasing extent in this type of technology.

Three main trends can be distinguished in this field. The process involving the formation of coatings from solutions of oligomeric electrolytes in a constant electric field—the electrodeposition method—was developed at the beginning of the 1960's.[1-3] It is based on the formation in the electric field of a water-insoluble deposit on the anode and its subsequent thermohardening with formation of a three-dimensional polymer network from the oligomer. The mechanism of the formation of films bound by adhesion to a support includes also the formation of local bonds between groups of polymer molecules and the surface of the support.[4,5]

Numerous studies designed to create combined electrochemical coatings, which are compositions consisting of metals, alloys, and substances dispersed in them, were carried out in the same period.[6,7] The dispersed substances are refractory borides, carbides, nitrides, silicides, graphites, carbonaceous materials, abrasive powders, and lubricants. The coatings are formed as a result of the electrolytic segregation of the metal (matrix), the parallel processes involving the adhesion of the particles of the disperse phase to the matrix and their growth into the latter.

In recent years, there has been a sharp increase of interest in electrophoresis as a method of preparation of coatings formed from dispersions of various substances—polymers, metals, oxides, and natural materials.[8-12] The possibility of the simultaneous deposition and orientation of particles of different nature in order to obtain composite and especially metallopolymer coatings is of special interest.[13,14]

The introduction of colloidal metals into polymers, accompanied by the chemisorption interaction of the macromolecules with the active centres on the surfaces of the colloidal metal particles, leads to the formation of metallopolymers.[15,16] Two-phase systems stable as regards aggregation, in which the metal is uniformly distributed within the polymer, arise under these conditions. The character of the interaction of the macromolecules with the surfaces of the highly dispersed particles is determined by the chemical nature of the polymer and the metal. The macromolecules can be distributed on the surfaces of metals in the form of fixed adsorption layers, forming covalent, ionic, and coordinate bonds with the surface metal atoms.[17,18]

The formation of metallopolymer coatings in the electric field is based on the simultaneous occurrence of two processes—the electrophoretic deposition of polymer dispersions (solutions) and the electrolytic segregation of colloidal metals or alloys.[19-21] The successful development of this important branch of the electrotechnology of coatings has been promoted by fundamental studies in colloid chemistry during recent years. The creation of a theory of the polarisation of the electrical double layer and of its kinetic model, the development of a theory of the stability and coagulation of colloidal systems in an electric field, and the prediction and discovery of a number of new non-equilibrium electrokinetic phenomena—dipolophoresis, diffusiophoresis, and non-linear electrophoresis[22-26]—should be included among them.

The above theoretical developments constitute the basis of the study of the electrophoretic transport of colloidal particles, their polarisation interaction in an electric field (electrocoagulation), and electrochemical coagulation in the diffusion layer, which determine the mechanism of the formation of polymer coatings. Colloidal-chemical factors determine the possibility of regulating the conditions in the electrochemical reduction of ions and the electrocrystallisation of colloidal metal deposits.

This review considers the main principles and the mechanism of the formation of metallopolymer coatings and materials. The development of this branch of electrotechnology involves the solution of a number of problems in colloid chemistry, electrochemistry, and the physical chemistry of filled polymers. They include (1) the study of the mechanism of the formation of the charge on polymer particles and the possibility of regulating it (in connection with the electrophoretic transport and aggregation of particles on the electrode), (2) the study of the electrophoretic deposition of dispersions, especially the drift of the particles to the electrode, and of

the mechanism of the coagulation of polymer dispersions under the influence of the electric field and products of electrochemical reactions in the diffusion layer, (3) the study of the influence of the electrophoretic deposition of colloids on the polarisation of the electrode and the electrocrystallisation of the metal, (4) the study of the electrode reactions determining the deposition of metals and polymers on electrodes with a metallopolymer coating, and (5) the study of the interaction of polymers and metals in joint electrodeposition and heat treatment.

II. ELECTROPHORETIC DEPOSITION OF POLYMER DISPERSIONS

The electrophoretic deposition of dispersions includes the following stages: the charging of the polymer particles; their movement to the electrode accompanied by their aggregation in space; the coagulation of the particles in the region near the electrode; the heterocoagulation and adhesion of the particles to the electrode.

The electrodeposition of polymers from solutions involves, firstly, the movement to the electrode of macroions (polyelectrolytes) or ionised aggregates and, secondly, loss of solubility by them in the region near the cathode on interaction with precipitant ions.[3,9] Presumably, the polymer segregation process subsequently proceeds analogously to the way that this occurs in electrophoresis, including coagulation, heterocoagulation on the electrode, and the formation of a deposit which is a colloidal structure consisting of globular particles. It is important to note that both processes involving deposition from aqueous media are controlled by electrode reactions in which water is decomposed and the electrodes ionised, as a result of which an electrolyte concentration gradient is created, which is responsible for the segregation of the polymer in an insoluble form and its subsequent coagulation.

Three main mechanisms of coagulation in the electrodeposition of dispersions and the electro-osmotic compaction of the deposits formed are known at the present time: (1) electrochemical; (2) electrocoagulation; and (3) accumulative. The role of each depends on the specific physicochemical properties of the dispersed systems in the layer near the electrode and the parameters of the external electric field.

1. The Electrocoagulation Mechanism

The formation of a deposit on the electrode in an electric field is associated with the stability of dispersed systems characterised by the potential energy curves for the interaction between the particles or, in other words, by the balance of the forces acting between them. A quantitative description of the interaction of dispersed particles based on the general concept of the wedging pressure has been proposed.[24,25] Under certain conditions, two minima can appear on the overall potential energy curve for the interaction (for large and small distances between the particles) and a maximum can appear for intermediate distances. This character of the curve can be explained by the fact that the molecular and ionic-electrostatic interaction forces depend in different ways on the distance between the macroparticles: the former decrease in accordance with a power law and the latter decrease exponentially. The depth of the nearest potential well $U_{\min} \gg kT$ is determined by the degree of compensation of the molecular attractive forces by the Born repulsive forces.[26]

Coagulation, corresponding to a deep first minimum, leads to the formation of aggregates at the surface of the particle, which do not decompose after the external electric field has been switched off (irreversible coagulation). When a sufficiently high potential barrier exists, the electric field is responsible for the fixation of the particles, which corresponds to the second minimum on the potential curve. Depending on the depth of this minimum, the aggregation of the particles is reversible or irreversible.[4,27-29]

It has been shown[30] that the formation of the electrophoretic coating in the electric field is determined by the action of ionic-electrostatic forces, the repulsive forces of the non-overlapping non-deformed double layers, the dispersion attractive forces, and the dipole–dipole forces, which are manifested over distances $S = 2 + h/a$, where a is the radius of the spherical particle and h the distance between the particles. If the distances are less than a, the forces are converted into the more powerful multipolar forces due to repeated mutual polarisation, manifested solely over short distances. Allowance for the polarisation forces leads to the appearance (or deepening) of a second minimum, the depth and the coordinate of which are determined, other conditions being equal, by the strength of the active electric field.

For not unduly strong fields, where the deformation of the weakly overlapping double layers can be neglected, the total energy of the interaction between the particles is

$$U_e = U_i + U_m + U_E . \qquad (1)$$

A formula for the calculation of ionic-electrostatic repulsion U_i of the particles corresponding to arbitrary values of ϕ_δ for $\varkappa a \gg 1$ and $\varkappa a \cong \varkappa h \gg 1$ has been proposed[31] (a is the particle radius, $\varkappa$ the Debye shielding radius, and ϕ_δ the Stern potential). The molecular attraction energy U_m, expressed as a function of the distance between the particles, can be determined from the Hamaker formula for spherical particles.[32] The dipole–dipole attraction U_E can be calculated from the formula proposed by Estrela-Lopez et al.[30] The uniformity of the coating is determined by the uniformity of the packing of the particles in the film. More favourable conditions for this are created in reversible coagulation corresponding to the second minimum on the energy curve, whereupon the particles retain their ability to migrate in the film as a result of the interaction with the field and with the nearest neighbours and to fill uniformly all the cavities.[33,34] It has been shown[30] that the role of the dipolar forces increases with increasing size of the particles of the disperse phase. As the electric field strength increases, the depth of the second minimum also becomes more marked and the distance between the particle diminishes. Thus the increase in the electric field strength leads to the growth of the cohesive forces and to the compaction of the structure of the deposits.

Calculation of the potential curve for the interaction of the particles of a dielectric, semiconductors, and metals in the absence of a field and in an electric field showed that the increment in the energy of the attraction of the polarised particles under the influence of the field promotes the complete disappearance of the potential barrier.[11] At the same time, for a sufficiently high barrier, the imposition of the electric field induces the appearance of deep secondary minima responsible for further aggregation of the particles and the formation of the deposit. With increase in the electric field strength, the depth of the second minimum likewise rises.[35] In the study of the processes involving the formation of an electrophoretic coating in the region of the second minimum, it is necessary to take into account the

collective interaction of the particles in a limited or constrained volume.[4,36] Such conditions are satisfied by the layer near the electrode with an increased concentration of the disperse phase, where the particles are separated by distances comparable to their radius, which increases the attractive forces between them.[37]

In order to carry out the electrophoretic deposition, it is necessary that the electric field strength and the duration of its action should be must less than certain critical values.[38] The time necessary for the occurrence of coagulation processes is called the "critical time" τ^*. The ideas concerning the critical time have been developed in a number of studies.[11,39,40] According to Us'yarov and co-workers,[27,28] in the general case τ^* is the average statistical time required for the formation of fairly large aggregates. However, the main stage determining τ^* is the formation of a strong bond between two particles. On the basis of the slow coagulation theory allowing for the change in the concentration of particles in the space near the electrode and under conditions where a doublet is formed in the remote well, τ^* can be determined:[41]

$$\tau^* = \frac{\sum^{i} \exp\left[U(\varphi)_{max}/RT\right] \Delta\varphi_i}{64\pi^2 D r^3 N_x} , \qquad (2)$$

where r is the radius of the particle, $U(\phi)_{max}$ the potential barrier of the interaction, $\Delta\phi_i$ the specified range of values of the angle between the direction of the field and the axis of the induced dipole, D the diffusion coefficient of the particles, and N_x the concentration of the particles in the layer near the electrode.

Together with the critical time, an important characteristic of the electrodeposition process is the "critical electric field strength" E^*, i.e. the field strength for which the formation of the coagulation structure begins. It has been shown[41] that $\tau^* \propto E^{-2}$, i.e. E^* and τ^* are inter-related quantities which are functionally linked to the parameters of the system and the electrodeposition conditions. The determination of these quantities requires allowance for the polarisation interaction; otherwise there is a possibility of large discrepancies between the calculated and experimental values.[42] Examination of the aggregation of particles from the standpoint of slow coagulation[43] suggests that each pair of particles which have collided forms a doublet. The critical electric field can be estimated from the formula

$$E^* = \frac{4\pi\sigma_0}{\varepsilon_0} , \qquad (3)$$

where σ_0 is the electrical conductivity of the medium and ε_0 the dielectric constant. The aggregation of particles in the layer near the electrode is accelerated not only by an increase in the electric field strength but also following an increase in the concentration of the suspension.[41]

The question of the interaction of the particle with the surface of the electrode is no less important. It follows from the heterocoagulation theory that the optimum deposition conditions are ensured for unlike charges of the electrode and the particle.[44] When the signs of the charges are identical, the wedging pressure plays an appreciable role.[41] The interaction of the particle with the electrode is regarded[45–47] as the result of the attraction due to the image forces, which are dipolar in nature. A formula has been obtained according to which the dipolophoretic attraction becomes significantly greater than the electrophoretic force with decrease in the distance to the electrode surface. The attractive forces are proportional to the radius of the particle raised to the sixth power.

The role of the electrocoagulation mechanism in the formation of coatings in aqueous organic media was tested experimentally by investigating the dependence of the yield of the deposit on the polarisation of the particles of the disperse phase.[48] In the isopolarisation state, the polarisation criterion is described by the expression

$$\mathrm{Rel}_{iso} = \frac{\cosh\frac{\varphi_\delta}{2} - 1}{\varkappa a} = \frac{1}{2} . \qquad (4)$$

The electrophoretic deposition of an aerosol dispersion in isopropyl alcohol—water mixtures with an increasing water content has been investigated.[48] In the absence of dipolar interaction between the particles and the electrode, in the isopolarisation state the yield of the deposit formed via the electrocoagulation mechanism is minimal. Studies have shown that a change in the composition of the dispersion medium can serve as a fine instrument for varying the contribution of the electrocoagulation and the electrochemical mechanisms to the electrophoretic deposition of dispersions. Thus it is possible to regulate the process involving the formation of the coatings and the structure and properties of the latter.

2. The Electrochemical Mechanism

The electrochemical mechanism presupposes the formation, in the zone near the electrode, of an excess electrolyte concentration front which spreads into the surrounding space; these ideas date back to two studies.[38,49] In the above mechanism the critical time τ^* is interpreted as the time necessary to create the threshold electrolyte concentration at which the stability of the system decreases and the particles coagulate on the electrode in conformity with the Deryagin–Landau–Verwey–Overbeek (DLVO) theory.[24,25,50,51] The excess electrolyte concentration in the diffusion layer at the electrode c_{el} tends to the initial concentration c_0 under conditions such that the concentration of ions changes as a result of diffusion and electromigration:[49]

$$c_{el} \to c_0 = \frac{2}{\pi^{1/2}} \frac{It_m}{SF} \left(\frac{\tau}{D}\right)^{1/2} , \qquad (5)$$

where I is the current, t_m the transport number of the ions M^+, D the diffusion coefficient of the ion pair M^+OH^-, S the electrode surface area, F the Faraday, and τ the deposition time.

The formula for τ^* can be represented in the form

$$\tau^* = pI^{-2} = qU^{-2}\sigma^{-2} \qquad (6)$$

where p and q are constants, U is the potential, and σ the conductivity of the suspension. Thus the critical time is inversely proportional to the square of the potential of the electrodes and to the conductivity of the suspensions. The experimental confirmation of these relations is one of the proofs of the validity of the theory considered. The DLVO theory, developed for systems with a conducting dispersion medium, can also be used to calculate parameters which determine the stability of dispersions in the region near the electrode in a weakly conducting non-polar dispersion medium.[38,49]

The ideas concerning the role of the electrochemical mechanism of the coagulation of particles in the formation of a deposit were developed further in other investigations.[2,52,53] Analysis of the experimental and theoretical data shows that the electrophoretic deposit is formed in two stages and that the process includes the transition from reversible to irreversible coagulation and also an increase in the concentration of the

polymer and electrolyte species in the diffusion layer near the electrode. Electrochemical coagulation can therefore take place via a concentration mechanism (determined by the compression of the electrical double layer) and a neutralisation mechanism (associated with a decrease in the charge).

The degree of reversibility of the coagulation and hence the thickness and strength of the deposit are determined by the spatial-temporal distribution of the coagulating ions in the zone near the electrodes. The relations illustrated in Fig.1 give an idea of the processes involving the formation of deposits from the polymer particles.[53] The factor determining the kinetics of the formation of the deposit is the change in the overall concentration of the coagulating ions, in the given instance hydroxide ions. With increase in the electrolyte content in the diffusion layer (Fig.1*a*, curve *1'*), the dimensionless electrokinetic potential $\tilde{\zeta} = (F/RT)\zeta$ decreases (curve *1*) owing to the compression of the double layer.

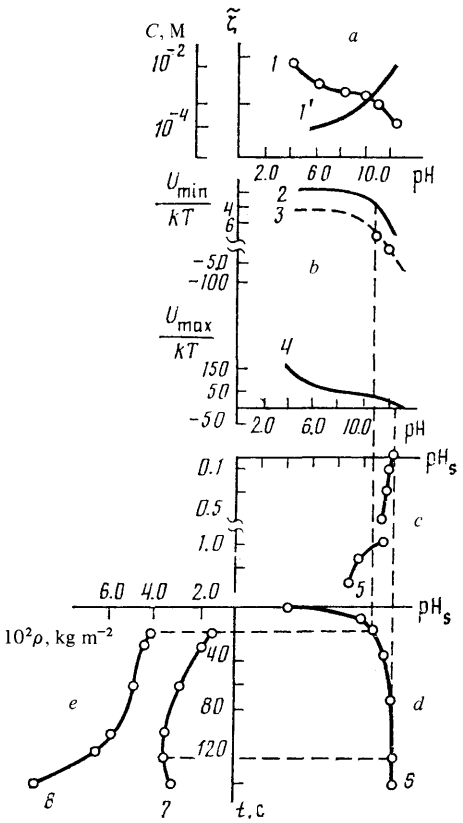

Figure 1. *a*) Dependence of the electrokinetic potential (ζ) of the particles of an epoxide oligomer (curve *1*) and of the electrolyte concentration (curve *1'*) on the pH; *b*) dependence of the energy of the interaction of a particle doublet under the usual conditions (curve *2*) and under constrained volume conditions (curve *3*) and of the potential barrier preventing aggregation (curve *4*) on the pH; *c*) variation of the pH of the dispersion in the layer near the electrode with the distance *l* to the electrode 40 s after the onset of deposition; *d*) variation of the pH in the layer near the electrode with deposition time; *e*) dependence of the yield of the deposit (ρ) formed as a result of irreversible aggregation only (curve *7*) and as a result of the joint reversible and irreversible aggregation (curve *8*) on deposition time.[53]

The decrease in the potential ζ in coagulation of the concentration type deepens the remote potential well (Fig.1*b*, curves *2* and *3*) and decreases the potential barrier (curve *4*). The probability of the long-range (reversible) and short-range (irreversible) coagulation of the particles increases correspondingly. The first stage in the deposition process is intense reversible coagulation. After 20 s, the pH increases from 3.8 to 11.0 near the electrode (Fig.1) to 8.0 at a distance of 0.3 mm from the electrode. The subsequent increase in pH is determined by the balance between the formation of OH^- ions in electrolysis and their consumption in diffusion and migration processes. At a distance $l = 0.5$ mm from the electrode, the pH has constant values, while in the presence of polymers the pH decreases appreciably (Fig.1*c*).

At pH 11.0 the ζ potential is 0.9 (Fig.1*a*, curve *1*) and the potential barrier U_{max} is still fairly high (Fig.1*b*, curve *4*). However, the binding energy of the particles U_{min}, determined by the depth of the remote potential well recalculated to give the number of nearest particles, is entirely sufficient for their mutual fixation (Fig.1*b*, curve *3*). The fraction of the reversible deposit exceeds appreciably that of the irreversible deposit (Fig.1*e*). The deposit is readily peptised after the removal of the field.

With increase in the electrodeposition time and with increase in pH at the electrode surface from 11.0 to 12.2, the ζ potential falls to 0.45 (Fig.1*a*, curve *1*). This threshold value of the ζ potential corresponds to the onset of irreversible coagulation. The potential barrier preventing the coagulation of particles then disappears (Fig.1*b*, curve *4*). The yield of the irreversibly coagulated deposit at high pH becomes a maximum (Figs.1*c*, 1*d*, and 1*e*). The overall yield of the deposit also increases (Fig.1*e*, curve *8*); with increase in pH, the reversible coagulation begins at a certain distance from the electrode and the deposit is partly formed from aggregates weakly bound to the electrode. The amount of the irreversibly coagulated deposit then falls.

Analysis of systems with the neutralisation type of electrochemical coagulation showed that their principal feature is a large contribution by irreversible coagulation to the deposit formation process.[54] The deposition from such dispersions proceeds almost without a critical time.

Systems with the concentration type of electrochemical coagulation are more plastic in the sense that there is a possibility of controlling the kinetics of the deposit formation on the electrode, but the process is in this case longer and the amount of deposit formed is smaller than in systems of the neutralisation type. The concentration systems are most suitable for the preparation of high quality electrophoretic deposits. The electrochemical purification of the liquid is best performed by the electrochemical coagulation of the neutralisation type.

3. The Accumulative Mechanism

The electrophoretic deposit is formed via the accumulative mechanism as a result of the coagulation of particles at the electrode under the influence of the forces developed by the external electric field and the molecular attraction forces. It has been suggested[55] that the process involving the preparation of a deposit by the electrophoretic method is analogous to the sedimentation of particles in the gravitational field. The role of the electric field is to supply particles to the electrode and to compact the deposit on the electrode surface. According to the accumulative theory,[55] a distinctive feature of this mechanism is the direct proportionality of the critical deposition time τ^* to the square of the field strength and its inverse proportionality to the concentration

of particles. This mechanism makes a significant contribution to the formation of a deposit from concentrated systems and in the case of dilute dispersions it is manifested in the zone near the electrode to a greater extent the higher the content of the disperse phase under the constrained volume conditions. The principle postulates and conclusions concerning the accumulative mechanism have been described in detail.[1,55,56]

All three deposit formation mechanisms are accompanied by the electro-osmotic compaction of the deposit,[11] which is an additional factor in the formation of the coating. The electro-osmotic component must be manifested appreciably as the deposit becomes denser and its thickness increases. It alters the distribution of the concentration of the particles in the region near the electrode, which leads to the appearance of a clarified layer of dispersion medium at the upper boundary of the deposit being formed. The liquid in the layer moves upwards and entrains the dispersed particles of the suspension, some of which contribute to the growth of the electrophoretic deposit. It has been shown[57] that the electrokinetic potential calculated from the flow rate of the medium in concentrated suspensions approaches the ζ potential determined by the electro-osmotic method. Thus the formation of the electrophoretic deposit is accompanied by the electro-osmotic migration of the dispersion medium, which promotes, on the one hand, an increase in the density of the layer of suspension near the electrode and, on the other hand, it inhibits the motion of the particles, since it is directed in opposition to it. Estimation of the electro-osmotic compaction forces showed that they increase with increasing concentration of the dispersion phase.[57]

4. Cataphoretic Deposition of Polymer Dispersions

In the conclusion of this Section, we shall consider the characteristic features of the electrophoretic deposition of polymer dispersions on the cathode (for aqueous organic suspensions of epoxide and phenol-formaldehyde oligomers).[48] The character of the electrochemical coagulation—neutralisation or concentration—plays a significant role in the deposit formation process. The results of the study of the electrophoretic deposition of the epoxide oligomer via the concentration mechanism and of the phenol-formaldehyde oligomer via the neutralisation mechanism from an aqueous organic medium are presented in Table 1. Evidently there are fundamental differences in the formation of deposits via the two mechanisms.

The deposition of the epoxide oligomer begins after a critical time, amounting to 20 s, has elapsed, which is associated with the attainment in the diffusion layer of the pH necessary for coagulation (in the given instance 11.0). It is noteworthy that coatings based on the epoxide oligomer are formed in two stages: reversible and irreversible coagulation. The duration of the first stage is between 20 and 50 s and that of the second between 60 and 120 s. The two-stage nature of the deposition process is a necessary precondition for the preparation of a uniform coating, since favourable conditions for the distribution of particles over the entire area of the electrode are created in reversible aggregation. The deposit is fixed in the irreversible coagulation stage. The phenol-formaldehyde oligomer is deposited immediately without a critical time.[48] The formation of the coating is caused mainly by irreversible coagulation. A common feature of the systems investigated is the formation of a deposit within the limits of the diffusion layer. In the course of the formation of the deposit, the ratio of its components, formed as a result of the reversible and irreversible coagulation, changes with time and there is an overall tendency towards an increase in the yield of the polymer. The ratio of the reversible and irreversible aggregations makes it possible to determine the parameters of the deposition process (cathodic current density, deposition time, and field strength) for which the optimum properties of the coating are attained.

Table 1. Parameters of the processes involving the electrophoretic deposition of polymers from an aqueous organic medium via the concentration and neutralisation coagulation mechanisms.

t, s	pH_s	$10^2\rho_1$, kg m^{-2}	$10^2\rho_2$, kg m^{-2}	l, mm	δ, mm
Epoxide oligomer*					
2	6.50	0.45	0.60	0.70	0.01
5	8.60	0.80	0.96	0.80	0.016
10	9.80	1.1	1.30	0.85	0.018

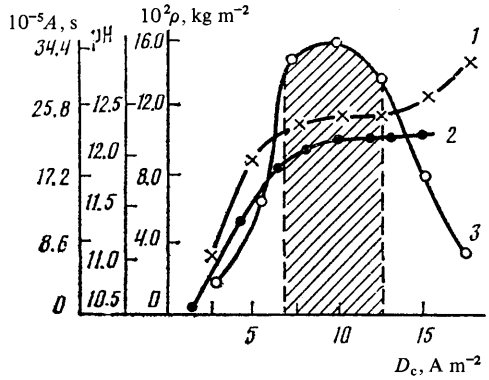

Figure 2. Dependence of the yield (ρ) of the electrophoretic deposit of an epoxide oligomer (curve *1*), of the pH of the layer near the electrode (curve *2*), and of the corrosion stability (A) of the coatings (curve *3*) on the cathodic current density.[48]

Fig. 2 presents the dependence of the yield of the deposit of the epoxide oligomer, the pH of the diffusion layer, and the corrosion stability of the coatings on the cathodic current

density. Since the electrode deposition process is an electrode reaction, I = const. is a necessary condition. The cathodic current density D_c is chosen so that it is possible to regulate the conditions in the electrochemical reactions determining the course of the coagulation processes. The increase in D_c in the initial section is accompanied by a parallel increase in the pH of the diffusion layer, the yield of the deposit, and the corrosion stability of the coatings in a chamber with 100% humidity. The increase in the amount of deposit and the pH ceases after the attainment of pH 12.2. The region $D_c = 7-12$ A m^{-2}, corresponding to the maximum stability of the films in the corrosion medium (shaded in Fig. 2), also corresponds to the transition from reversible to irreversible coagulation (pH 12.2). The decrease in the anticorrosion stability at $D_c > 12$ A m^{-2} is associated with the intensification of the electrochemical reactions, the spreading to the bulk phase of the increased electrolyte concentration front, and the deposition on the electrode of the large aggregates of particles formed under these conditions. This entails the growth of the yield of the deposit and the simultaneous increase in its porosity. Thus there is a direct relation between the deposit formation conditions, the relative contributions of the reversible and irreversible coagulation, and the corrosion stability of the coatings (Fig. 2 and Table 1). The methods for the preparation of composite polymer coatings with anticorrosion, protective-decorative, and electrically insulating properties have been described.[58-62]

III. ELECTRODEPOSITION OF POLYMERS AND METALS

1. The Mechanism of the Formation of Metallopolymer Deposits

The metallopolymer deposits are formed as a result of the simultaneous electrodeposition of polymer dispersions and the electrochemical segregation of the metal. The electrophoretic precipitation of the polymer deposit and the interaction of the particles of the disperse phase in the zone near the electrode play a decisive role in this process. The electrodeposition and electrocrystallisation of the metal depend in their turn on the kinetics of the formation of the polymer layer on the electrode. The structure of the metallopolymer deposit is determined by the character of the polarisation and chemisorption interactions between the polymer and metallic particles.

In this connection, we shall consider the mechanism of the formation of metallopolymer coatings from the standpoint of the influence of surfactants and polymers on the discharge of metal ions and the formation of colloid deposits. The process involving the formation of the metallopolymer deposit on the electrode begins with the formation of a polymer layer through which metal ions move to the electrode as if through a membrane. The supply of ions to the electrode surface is the rate-limiting stage. The influence of the polymer layer on the metal ion reduction process is determined by the concentration of the disperse phase, the charge on the polymer particles, their size, and the deposition conditions. The conditions governing the creation of a controllable flux of metal ions migrating to the cathode and the interaction between the particles of the segregated polymers and metals determine the composition and structure of the deposits.

The homocoagulation and heterocoagulation interactions between the polymer and metallic particles depend on the colloidal-chemical properties of the system and on the deposition conditions.[1] If the polymer particle is deposited on a metallic particle (heterocoagulation) in the formation process, then the growth of the metallic particle is greatly inhibited. In the case where the polymer particles interact mainly with one another during deposition (homocoagulation), metallic particles are formed and grow freely. The relative contributions of homocoagulation and heterocoagulation are determined by the balance between the electrophoretic (F_{ef}) and dipolophoretic (F_d) forces. When a deposit is formed from dispersions characterised by high electrokinetic potentials of the particles, low electrolyte concentrations, and the quantity Rel > 1, it is found that $F_d/F_{ef} > 1$. The active inhibition of the electrocrystallisation of the metal under these conditions makes it possible to segregrate the metal in the form of particles of highly dispersed powders uniformly distributed within the polymer. In the codeposition of particles of the epoxide oligomer and lead, the latter are produced with an irregular form and their size is 0.1–0.3 μm.[1]

In the electrodeposition of dispersions with a low ζ potential and with the parameter Rel ≪ 1, we have the ratio $F_d/F_{ef} < 1$. The structure of the deposit changes significantly in this case, since the polymer being deposited inhibits to a lesser extent the growth of metallic particles. They are needle-shaped and their size is up to 2–5 μm. Under these conditions, there is a possibility of obtaining coatings with a high metal content (up to 90–96%) and a thickness up to 100 μm, since the metal dendrites formed are conducting.

The ideas described above concerning homocoagulation and heterocoagulation can explain the results obtained in the experimental study of the codeposition of polymers and metals. A general tendency is an increase in the yield of the deposit with increasing concentration of the disperse phase and charge on the particles and a decrease in the metal content of the latter. An increase in the electrolyte concentration naturally diminishes the potential and also increases the parameter a and decreases Rel. Dipolophoresis and electrophoresis promote the homocoagulation of the polymer particles. The growth of metallic particles is not blocked, which increases the metal content in the deposit.

With increase in the concentration of polymer particles and their charge, the simultaneous occurrence of dipolophoresis and electrophoresis promotes the interaction of the polymer and metallic particles, i.e. heterocoagulation. The effect, involving the blocking of the electrode surface and of the metallic particles by the polymer particles, leads to the appearance of a new form of overpotential, which we have called the electrophoretic overpotential. The electrophoretic overpotential influences the electrocrystallisation of the metal as a rule to a much greater extent than the adsorption of a surfactant on the electrode.[18,63,64-67]

Fig. 3 illustrates the polarisation curves for a copper electrode in 0.032 M $Cu(HCOO)_2$ solution containing a biquaternary ammonium compound and a dispersion of the organosilicon oligomer. The joint action of the surfactant and the polymer results in the discharge of the copper ions under the conditions of appreciable cathodic polarisation. At low current densities, a shift of the polarisation curves towards negative potentials is already observed: by 220 mV in the presence of the surfactant and by 480 mV in the presence of the polymers. When the quaternary ammonium compound (Fig. 3, curve *2*) and the disperse phase (curves *3–5*) are introduced, the current maxima on the curves are reduced and sections appear along which the current depends little on the potential. This indicates an increase in the activation energy necessary for the penetration of metal ions through the polymer layer and their discharge on the electrode.

The electrophoretic polarisation depends directly on the colloidal chemical properties of the dispersions deposited, which determine the relative contributions of homocoagulation and heterocoagulation in the deposit. Table 2 presents the most typical data characterising the codeposition of dispersions and colloidal metals. The electrophoretic polarisation increases with increasing ζ potential of the polymer particles. The increase in the electrokinetic potential increases in its turn Rel and heterocoagulation.[18] For example, the increase in the ζ potential of the epoxide oligomer particles from +36.2 mV to +115.5 mV corresponds to a change in Rel from 0.12 to 0.87.

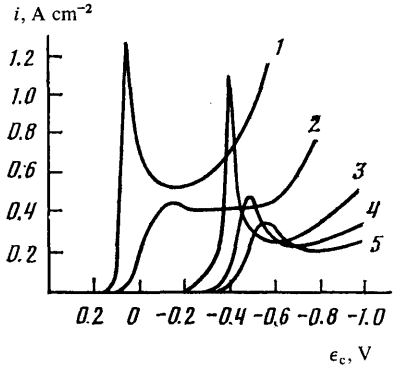

Figure 3. Cathodic polarisation curves for a copper electrode: *1*) in 0.032 M $Cu(HCOO)_2$ solution; *2*) ditto with added 0.5 mm surfactant; *3*) ditto with added disperse phase [*3*) 0.125%; *4*) 0.25%; *5*) 0.50%][83] (*i* is the current density and ϵ_c the potential).

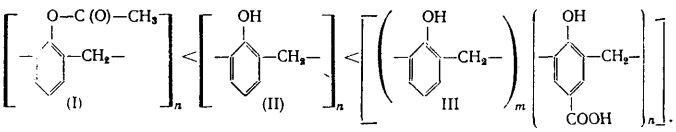
Table 2. The influence of the ζ potential of the epoxide oligomer particles and their concentration on the polarisation of the electrode in codeposition with lead [electrolyte 0.005 M $Pb(HCOO)_2$].[19,68]



ζ potential, mV	Shift of polarisation curves, V	Concentration of disperse phase, wt.%	Shift of polarisation curves, V	Yield of polymer component, mg cm^{-2}
−36.2	0.8	0	0.1	0
+43.7	0.9	0.06	0.35	6.4
+54.0	1.1	0.31	1.4	8.3
+84.8	1.3	0.94	1.9	10.1
+115.5	1.6	2.25	2.6	12.8
		2.6	3.3	12.1

The next factor determining the effectiveness of the increase in the overpotential of the segregation of metals in the formation of the metallopolymer deposit is the increase in the concentration of the disperse phase in the electrolyte solution.[68] Thus the increase in the epoxide oligomer concentration increases the polymer content in the metallopolymer deposit and leads to the growth of the lead reduction overpotential, which is indicated by the shift of the polarisation curves towards negative potentials by 3 V (Table 2); under these conditions the metal is produced in a highly dispersed state.

The effective activation energy for the discharge of lead ions increases from 28 to 74 kJ mol^{-1} with increase in the concentration of the disperse phase from 2.5 to 5 wt.%.[18] This is accompanied by a decrease in the size of the metal particles from 2–3 μm to 0.2–0.5 μm and a change in the crystal structure; the size of the blocks of the mosaic falls from 1590 to 200 Å.

Not only the polarisatio. interaction between the polymer and metallic particles but also the chemisorption interaction processes between them play an important role in the establishment of the conditions governing the polarisation of the electrode. In the process involving joint segregation on the electrode, the epoxide oligomers interact with the surface of the lead particles with opening of the epoxide rings.[15] For example, a 2.2 V cathodic shift of the polarisation curves has been observed for epoxide oligomers containing 2.2% of epoxide groups, while in the presence of an epoxide content of 21.8% the shift was by 3.4 V other conditions being equal. The displacement of the epoxide groups in the oligomer chain by hydroxy-groups reduces this effect to 0.7–0.9 V.

Analogous results have been obtained in the electrodeposition of dispersions of phenol-formaldehyde oligomers and zinc.[65,66] When oligomers with hydroxy- and carboxy-groups and oligomers in the chains of which these groups have been replaced by ester moieties are used, the zinc electrocrystallisation overpotential increases in the sequence

The chemisorption interaction between the polymer and metallopolymer particles has two important consequences: firstly, together with the increase in the ζ potential of the polymer particles and in their concentration, this is a fine instrument for regulating the degree of dispersion and the structure of cathodic metal deposits and, secondly, as will be shown below, the formation of surface compounds and the shielding of such surfaces of metallic particles constitute the basis of corrosion stability of metallopolymer coatings.[1,56]

An increase in polarisation and hence a decrease in the metallic particle size have been noted in the codeposition of zinc with phenolformaldehyde oligomers of type (III) with increase in their content of carboxy-groups from 2 to 16%.[67] The increase in polarisation indicates a significant change in the rates of both principal stages of the metal segregation process: the penetration of metal ions to the electrode and their discharge.

The change in the polarisation of the electrode is caused by the joint influence of the biquaternary ammonium salts and polymer particles on the parameters of the electrical double layer and the diffusion layer at the electrode. The adsorption of surfactants plays an important role in the initial period of the formation of the metallopolymer deposit, influencing the electrical double layer at the electrode surface.[64] As a rule, the formation of the adsorption layer is accompanied by a decrease in the exchange current and an increase in the surface coverage, which reaches the limiting value of 0.87 at a surfactant concentration of 2 M.[64]

Thus examination of the data obtained permits the conclusion that the characteristic feature of the segregation of the metal in the formation of the metallopolymer deposit consists in the fact that it occurs under the conditions of very pronounced adsorption and electrophoretic concentration polarisation. The rate-limiting stage of the process becomes the diffusion of metal ions M^{2+} through the polymer layer.

The diffusion boundary layer is localised within the deposit. A steady state reaction is established after the attainment of a constant thickness of the latter. Up to this instant, the process is non-stationary, the thickness of the diffusion layer increases with time, and the balance between the rate of the electrochemical discharge of metal ions and the rate of their supply and also between the concentrations of the discharging ions and ions diffusing into the solution is disturbed. The electrochemical reaction proceeds in accordance with the general laws of the diffusion kinetics of heterogeneous processes in solutions.[71,72] The thickness of the diffusion layer reaches ~500 μm under the conditions of the electrophoretic deposition of polymers and the electrochemical segregation of the metal, which agrees with data obtained in an unstirred solution[73] and is close to the values which have been obtained in the study of processes involving the electrophoretic deposition of polymers (Fig.1). The principal characteristic feature of the formation of such a layer in a combined process consists, in contrast to the processes involving the segregation of pure metals, in slow diffusion into the bulk phase and an appreciable accumulation of OH^- ions in the layer near the electrode.

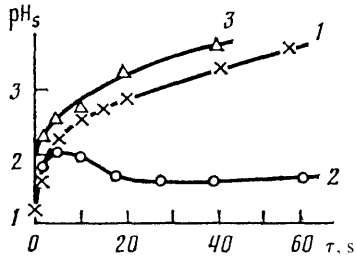


Figure 4. Dependence of pH_S on the electrodeposition time (τ) for a dispersion of a phenol-formaldehyde oligomer (curve *1*), lead (curve *2*), and the metallopolymer deposit based on them (curve *3*).[74]

The principal differences between the formation of the diffusion layer on deposition of metals, polymers, and metallopolymers are illustrated in Fig.4, characterising the variation of the pH in the layer near the electrode (pH_S) as a function of the process time in the codeposition of dispersions of phenol-formaldehyde oligomers and lead from solutions of lead sulphamate.[74] Studies of the variation of the pH of the layer near the electrode (pH_S) showed that the formation of a polymer film, which prevents the diffusion of OH^- ions into the bulk of the solution, leads to an increase in the pH of the diffusion layer compared with the segregation of the pure metal (without the polymer), which retards the onset of the stationary state. Analogous results have been obtained in the deposition of other resins, including the aminoformaldehyde resin.[56] An increase in pH_S leads to the segregation of metallic deposits with different phase compositions and the formation of hydrates and basic salts.[1,18,74]

The character of the diffusion processes and hence the mechanism of the formation of metallopolymer deposits are determined mainly by the relative contributions of the electrophoretic and electrochemical depositions. A transition from metallopolymer deposits to composite electrochemical coatings with a high metal content can be achieved by regulating them by varying the concentration of the disperse phase, the charge on the particles, and the concentration of the electrolyte. In the first case, the polymer is deposited preferentially: the rate of its electrophoretic deposition exceeds the rate of the electrochemical segregation of the metal.[75] Then the parameter A, characterising the ratio of the segregated polymer and metal, assumes the value $A \leqslant 0.25$. This corresponds to the conditions for electrodeposition from dilute electrolytes and to increased electrokinetic potentials of the particles in the dispersions and their concentrations (mechanism I). By varying these parameters, it is possible to equalise the rates of electrodeposition of polymers and metals and to obtain deposits of a constant composition, with respect to thickness, and a uniform structure. If the rate of segregation of the metal exceeds the rate of deposition of the polymer, composite coatings are formed, consisting of a metallic matrix in which the polymer particles are distributed (mechanism II). The presence of a kinetic potential of the polymer particles in concentrated electrolyte solutions indicates the important role of electrophoretic transport of the particles of the disperse phase in the formation of metallopolymer electrochemical coatings via mechanism II.[76,77]

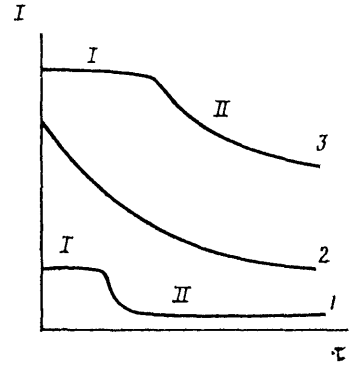

Figure 5. Schematic illustration of the dependence of the current on the time required for the deposition of polymers (curve *1*) and metallopolymer deposits from dilute (curve *2*) and concentrated (curve *3*) electrolytes.

The differences between these two processes, the first of which is determined by diffusional kinetics and the second by electrochemical kinetics, are revealed when the dependences of the current I on the deposit formation process time are compared (Fig.5). The joint deposition of the polymer and the metal via mechanism I (curve *2*) is characterised by the absence of a critical time, which is the case in the electrophoretic deposition of the polymer (curve *1*) and by an appreciable decrease in the current. The decrease in τ^* is promoted by an increase in the electrolyte concentration (OH^-) even in the first seconds as a result of electrode reactions and the rapid segregation of the metallic deposit. The sharp decrease in the current can be explained by its proportionality to $\tau^{1/2}$, which is associated with the shielding effect of the polymer deposit and with the decrease in the diffusion of M^+ ions through the polymer layer formed.

The presence of a horizontal section on the curve in the codeposition of metals and polymers from concentrated electrolytes (Fig.5, curve *3*) is associated with the preferential

segregation of the metal. The extent of the first horizontal section is limited by the time during which the composition and conductivity of the deposit remain constant. The conditions under which the resistance of the film is independent of time in the initial deposition stage, which ultimately determines that the current is independent of time, have been estimated.[75] In the deposition process, these conditions break down and, after a certain time interval, the deposit is formed under conditions where $I \propto \tau^{1/2}$, in conformity with mechanism *I*. These ideas have been confirmed by data obtained from layer-by-layer analysis.[74] The greatest metal content in the metallopolymer deposits obtained in the deposition of the phenol-formaldehyde oligomer from concentrated zinc sulphate solutions has been detected in the lower layers, the upper layers being enriched in the oligomer (Table 3).

Table 3. Results of the layer-by-layer chemical analysis of metallopolymer coatings.[74]

Coating deposition time, s	5	10	17	25	30
Thickness of coating, μm	4	6—7	10—12	14—16	20—22
Zinc content, wt.%	92	87	82	78	69

The occurrence of the conditions for diffusional kinetics in the formation of metallopolymer coatings via mechanism I follows from the estimation of the diffusion of metal ions in the deposit formation process from the equation for nonstationary diffusion for planar electrodes.[75] Here it was assumed that (1) the thickness and mass of the deposit are limited by the conditions for adequate ionic conductivity in the pores within the deposit, i.e. by the presence of metal ions in a polar dispersion medium, (2) the main bulk of the ions are supplied to the electrode surface through the polymer layer via diffusion, (3) the rate of deposition of the polymer exceeds the rate of segregation of the metal ($A \leq 0.25$), and (4) since diffusion takes place in a porous body, i.e. is independent of the migration of the dispersion medium, convective diffusion is ruled out.

The boundary conditions are determined by the fact that, after a certain time has elapsed, the concentration of ions on the electrode surface becomes zero because their diffusion through a film of large thickness is impossible. The film is formed in the presence of M^+ ions being discharged simultaneously with the deposition of the polymer.

For thin films under the conditions of long deposition times, the relation between the film thickness and the deposition time is given by the equation[7]

$$l = \left(\frac{2Dc_0\tau}{M}\right)^{1/2}, \qquad (7)$$

where *M* is the concentration of metal ions within the moist film, c_0 their concentration at the electrode surface, and *D* the diffusion coefficient of the ions. This relation has been confirmed experimentally in a study of the codeposition of an epoxide oligomer with lead.[75] The thickness of the deposit and the Faraday current are described by $l \propto \tau^{1/2}$ and $I \propto \tau^{1/2}$ respectively.

In the electrochemical reduction of metals in polymer dispersions stabilised by surfactants, the conditions for the transport not only of ions but also of polymer particles, i.e. the ζ potential, change. The introduction of small amounts of polyvalent electrolytes (10^{-5}—10^{-4} M) into the polymer dispersions stabilised by added surfactants increases the electrokinetic potential of the polymer particles as a result of the additional adsorption of the codeposited cations M^{2+}.[78] This possibility has been justified theoretically in a study[79] where it was shown that the degree of sorption of the codeposited ions is determined by the product $z\phi_\delta$ (where *z* is the valence of the ion) and diminishes sharply for $\overline{\phi}_\delta > 3$—4 as a result of the enhancement of the electrostatic repulsion. The sharp decrease in the ζ potential of the particles and in the stability of the system as regards aggregation occur for electrolyte concentrations 10^{-3}—10^{-2} M. Furthermore, the introduction of electrolytes into polymer dispersions, stabilised by surfactants, can promote an increase in the electrokinetic potential of the particles as a result of the additional adsorption of the surfactant on their surface and the compaction of the adsorption layer.[80—82] As a rule, with increase in the electrolyte concentrations, the ζ potentials pass through a maximum. The characteristic features of ion transport under these conditions are associated with the fact that the particles of the disperse phase behave as ion carriers, which makes a definite contribution to their diffusion to the electrode. The efficiency of the ion transport is determined by the magnitude and sign of the charge on the particles (ϕ_δ) and by the degree of adsorption of the surfactant.

Table 4. Dependence of the diffusion coefficient *D*, the thickness of the diffusion layer δ, and the thickness of the coating *l* on the electrolyte composition in the formation of a metallopolymer coating based on an organosilicon oligomer and copper.[63,64]

Parameter	Copper formate	Copper formate + 0.5% of oligomer dispersion	Copper formate + 0.5% of oligomer dispersion + surfactant at different concentrations, mM			
			0.13	0.50	1.00	3.00
$10^6 D$, $cm^2 s^{-1}$	1.62	2.37	1.90	1.53	1.42	1.12
$10^2 \delta$, cm	0.326	0.457	0.366	0.295	0.274	0.216
$10^2 l$, cm	—	—	0.34	0.28	0.26	0.22
$10^3 i_d \tau^{1/2}$	14.5	16.8	15	13.5	13.0	11.5

The estimation of the diffusion coefficients from Sand's equation, which is valid for linear semi-infinite diffusion,[83] showed that the introduction of particles of an organosilicon oligomer increases the diffusion coefficient of the Cu^{2+} ions (Table 4). The results obtained suggest that this effect is associated with the transport of ions by polymer particles. With increase in the surfactant concentration and hence in the positive ζ potential of the particles, the effect involving an increase in the diffusion coefficient of the Cu^{2+} ions disappears. Apparently a phenomenon somewhat similar to that of micellar catalysis, described in the literature,[84] takes place here, but, instead of surfactant micelles, the ion carriers are polar particles stabilised by such micelles. When the system contains ionogenic surfactants and cations, the charge on the particle is generated as a result of the competitive adsorption of both types of species.

The introduction of biquaternary ammonium compounds decreases the degree of adsorption of the cations on the surface of the particles.[64] With increase in the surfactant content and hence in the ζ potential, the additional sorption of the codeposited cations becomes impossible, which decreases the diffusion coefficient by a factor of two (Table 4). The

limiting diffusion current i_d changes analogously. Evidently there is a correlation between the diffusion coefficient D and the thickness of the diffusion layer δ. Comparison of the values of δ with the thickness of the coatings l shows that the coatings are formed within the limits of the diffusion layer.

The steady increase in the diffusion of the ions M^{2+} entails a decrease in the potential at which the metal is segregated at low concentrations of the disperse phase and an acceleration of the deposit formation process.[85,86] Apart from the intensification of ion transport to the electrode by virtue of the involvement of the polymeric carriers in the process, this phenomenon can be accounted for by the enhancement of the diffusion under the conditions of the simultaneous segregation of the metal and polymer particles. The formation of a three-dimensional-network of dielectric particles can lead to the deformation of the electric field strength lines in the interelectrode space and hence to an intensification of the field in the gap between the particles.

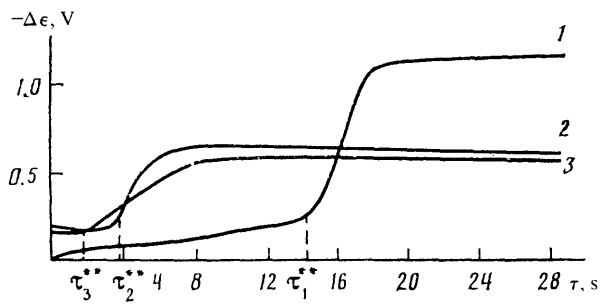

Figure 6. Time variation of the potential of a copper electrode (galvanostatic conditions) in 0.032 M $Cu(HCOO)_2$ solution containing 1% of the disperse phase and also different amounts of a surfactant [*1*) 0%; *2*) 0.75%; *3*) 2%] (D_c = 8.9 A m^{-2} is the cathodic current density).

Yet another important aspect of the mechanism of the joint deposition of polymer and metal dispersions is noteworthy. It consists in the fact that the presence of polymer particles in the diffusion layer promotes, like surfactants, a change in the electrode potential and hence in the energy parameters of the metal segregation process. In the electrophoretic-electrochemical codeposition of an organosilicon oligomer and copper in the presence of an uncharged oligomer dispersion, the electrode potential shifts appreciably towards negative values after the transient time has elapsed.[63] In the codeposition of copper with dispersions whose particles have a high ζ potential, the electrode potential diminish by a factor of 2–3 with increase in the polymer concentration (Fig. 6, curves *1* and *3*). The electrode reactions begin at higher potentials of the cathode and require an appreciable polarisation, the contributions of its individual components changing in different stages of the process. At a low current density, where the M^{2+} ions are reduced at constant (or nearly constant) potentials, the rate of the electrochemical reaction is apparently lower than the rate of diffusion of ions to the electrode surface. An appreciable overpotential, due to charge transfer, is observed. The study of the temperature dependence of the rate of the electrochemical reaction at different current densities showed that the overpotential associated with the formation of a new phase also makes a significant contribution.[64]

The nature of the overpotential and the possibility of regulating it throughout the deposit formation process determine the structure of the layer of the deposited material. At current densities close to or exceeding the limiting values, copper is deposited on the cathode in the form of a dense layer in the course of a short period equal to the transient time τ^{**}, which, as can be seen from Fig. 6, is appreciably reduced with increase in the charge on the polymer particles (τ_1^{**}, τ_2^{**}, and τ_3^{**} respectively). After the time τ^{**} has elapsed, the concentration of the discharging ions in the region near the cathode falls, the potential shifts towards more negative values, and copper is subsequently deposited in a non-compact form.

Thus, by altering the concentration of the particles of the disperse phase and their charge, it is possible to regulate the parameters of the diffusion layer and hence the reduction of the metal ions. It becomes possible to carry out the electrocrystallisation process under conditions of increased activated inhibition and high polarisation.

In connection with the formation of metallopolymer coatings via mechanism II, the phenomenon of the electrophoretic mobility of polymer particles in concentrated electrolyte solutions merits a separate discussion. The presence of the electrokinetic potential in dispersions with a high electrolyte content requires a new approach to the treatment of the mechanism of the formation of the electrical double layer. At the present time, there exist several hypotheses.[76,87] In the presence of ionogenic surfactants, the increase in the electrophoretic mobility of particles with increase in the electrolyte concentration can be associated, as stated above, with increase in the surface charge density as a consequence of the adsorption of the surfactant.[18,81,88] Presumably the potential around a charged particle in concentrated electrolyte solutions will oscillate and its dependence on concentration will therefore have a complex non-monotonic character.

On the basis of ideas concerning the disruption of the solvate layer by electrolytes, presumably an increase in the electrolyte concentration entails a shift of the slip plane, separating the stationary and mobile parts of the double layer, towards the interface.[89] It has been suggested that the solvate layer is disrupted faster with increasing electrolyte concentrations than the diffuse layer is compressed.

Allowance for the different solvent powers of the solvate layer in relation to anions and cations demonstrated the possibility of increasing the potential of the solvated particles in concentrated electrolyte solutions and the appearance of an electrostatic stability factor of a new type.[90] Studies on these lines are important both for the development of a technology for the deposition of coatings and for the solution of the problem of the stability and generation of the charge on dispersed systems in concentrated electrolyte solutions.

IV. THE STRUCTURE AND PROPERTIES OF METALLOPOLYMER COATINGS

The extensive possibilities for regulating the composition and structure and hence also the properties of metallopolymers permit their use as effective anticorrosion, antifriction, and electrically conducting coatings. The advantages of anticorrosion metallopolymer coatings over polymer coatings arise from the fact that the protective properties of polymers are supplemented by the protective or inhibiting effect of the corresponding metals. The strength and stability of the metallopolymer coatings are as a rule higher than those of

the polymer coatings. Two-layer protective-decorative coatings can be obtained from electrically conducting metallopolymer compositions by electrodeposition.

Metallopolymer coatings are multicomponent systems containing a mixture of oligomers and polymers together with colloidal particles of metals and alloys. Their electrophoretic-electrochemical codeposition on the electrode is in essence the first stage in the formation of the coating. The properties of the composite metallopolymer material formed under these conditions are determined to a large extent by its subsequent hardening at elevated temperatures and mainly by the interactions between the polymeric components and the surface of the metal particles. The segregation of the metal particles, which have an active surface, together with the polymer promotes an increase in the fraction of chemisorption bonds in the system. The nature of the polymer and the type and number of functional groups play the main role in this process.

As a result of the thermal interaction of the oligomers and polymers with the surfaces of colloidal metallic particles, various surface compounds with bonds of different types are produced.[15,16] Ionic bonds (polysulphide) or M–O–C bonds of the covalent type (epoxide and polyester oligomers, polyethylhydrosiloxane) are formed in polymers containing groups with locally concentrated charges. Polymers containing tervalent nitrogen, for example, acrylic oligomers [sic], are capable of interacting with the atoms on the surface of the metallic particles with formation of coordinate bonds. If the polymers contain ether, ester, and hydroxy-groups [polyether and phenol-formaldehyde oligomers and poly(vinyl acetate)], then there is a possibility of their interaction with the surface to form dipole–dipole, ion–dipole, and hydrogen bonds.

Studies on processes involving the formation of metallopolymer coatings from mixtures of oligomers and oligomer–polymer mixtures showed that in this case the compatibility and the interaction of the polymeric components play an important role.[15] The most satisfactory physicochemical properties of the coatings are then attained for the ratio of the components which corresponds to the range of their compatibility or the formation of graft copolymers in the system.

The study of the structure and properties of metallopolymer coatings is part of the general problem of the formation of composite polymeric materials containing fillers of different kinds.[15,16,91] The mechanism of the action of fillers consists in the general case in the fact that in their presence adsorption on the surface of solid particles results in the formation of ordered polymer layers, which play the role of crystallisation centres in crystallising polymers, and of regions determining the structure formation in the entire system in amorphous polymers; the capacity of oligomers and monomers for polymerisation is also important.[92,93] According to modern ideas concerning filled polymer systems, the presence of such layers increases the heterogeneity of the system and improves its mechanical properties as a result of the decrease in the energy of cohesion in boundary layers and the possibility of the relaxation of stresses.[94]

Metallopolymer coatings consist of a polymer base in which metallic particles are distributed. Typical structures of composite metallopolymer deposits are illustrated in Fig. 7. Fig. 7*a* represents a coating obtained by the electrophoretic-electrochemical deposition of dispersions of epoxide and polysulphide oligomers and lead on a steel plate (D_c = 9 A m^{-2}, deposition time 120 s). The ratio of the polymer components is 8.5 : 1.5 and the concentration of the metal is 60 wt.%. The bulk of the oligomers exist in the form of globules 500–1000 A in size. The interaction of the polymers with the colloidal metallic particles on the surface of the latter results in the formation of compacted polymer layers (Fig. 7*b*). They are clearly observed after etching the coating in active oxygen (Fig. 7c). The chemisorption interaction and the formation of surface compounds at the metal–polymer boundary have been confirmed by IR spectroscopic studies.[15,16]

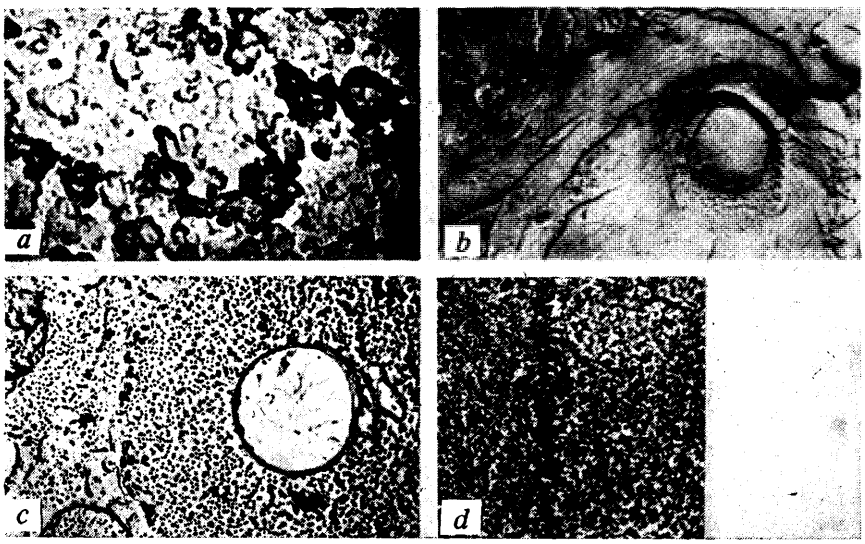

Figure 7. Electron micrographs:[12] *a*) a metallopolymer coating (magnification ×8400); *b*) region near a metallopolymer particle (magnification ×70000); *c*) ditto after etching; *d*) metallopolymer coating on which a profile line has been drawn.

It has been established by X-ray diffraction studies that the partial deformation of the crystal lattice of the metal (for example, reflections characteristic of the β-form of zinc appear) and the change in the packing density of the coatings are a consequence of the chemisorption interaction at high metal concentrations in the metallopolymer coatings.[67]

The formation of interfacial boundary layers of polymers on the surfaces of metallic particles is an important factor, which tends to impart anticorrosion properties to the coatings. Their corrosion stability is associated not only with the inhibiting and protective properties of the metals but also with the hindrance of the access to electrolytes as a consequence of the shielding of the surfaces of the coatings by the surface compounds formed. The degree of perturbation of the corrosion process is then determined by the composition of the coating.

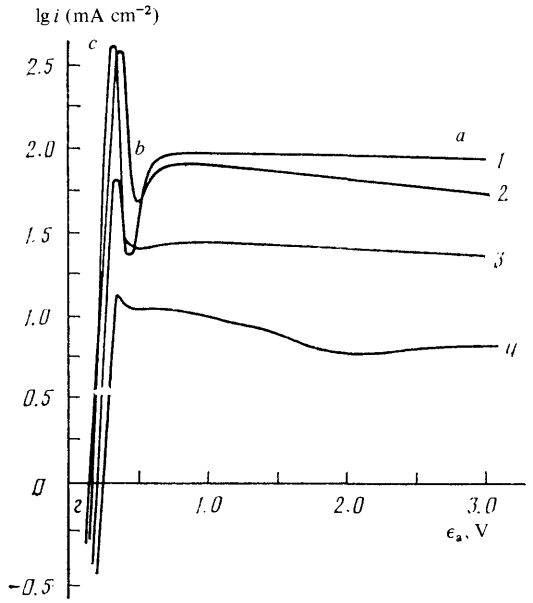

Figure 8. Polarisation curves for the anodic dissolution of copper electrodes in a solution of 200 g litre^{-1} $CuSO_4$ and 90 g litre^{-1} of H_2SO_4: *1*) unprotected electrode; *2)–4)* electrodes with a metallopolymer coating based on an organosilicon oligomer with copper contents of 80, 64, and 44% respectively.[64]

The protective properties of the metallopolymer coatings can be illustrated by comparing the electrochemical behaviour of copper electrodes without a coating and with a metallopolymer coating based on an organosilicon oligomer and copper. Fig. 8 presents the results of a potentiometric study of such electrodes.[64] The metallopolymer coatings were produced by the simultaneous deposition of copper and an emulsion of an organosilicon oligomer (D_C = 7.5 A m^{-2}, τ = 180 s). For small deviations of the equilibrium potential of the electrodes into the anodic region, a sharp rise in the current is observed. After the attainment of certain critical current and potential, the electrodes are passivated. The polarisation curves *1* and *2* are characterised by a maximum and a minimum (points *b* and *c*). The "*ab*" region corresponds to the active dissolution of the metal and the "*cd*" region corresponds to its passive state; the copper dissolution process almost ceases under these conditions. The maximum on the curves is reduced with increasing content of the polymer in the metallopolymer layer and almost disappears for a copper content of 44%, while the passivation potential is reached at lower current densities: at 315.2 mA cm^{-2} for the copper electrode and at 12.6 mA cm^{-2} for the metallopolymer electrode with a copper content of 15%. The rate of corrosion of the copper electrode is 5–6 times greater than that of the metallopolymer coating containing 44% of copper.

The retardation of the dissolution of electrodes with coatings based on oligomers having the COO^-, NH_3^+, $H_2C—CH—$ (O), etc., functional groups is very marked. At lead and copper concentrations in the range 55–68% and zinc and cadmium concentrations in the range 68–73%, the dissolution of the metal ceases almost completely.[12,64] With increase in the metal content in the coating, the shielding of the surface diminishes and, furthermore, the adhesion of the coating to the support is weakened. The conditions for the preparation of metallopolymer coatings based on the above metals and also epoxide and polyether resins as well as organosilicon and polyether varnishes have been described.[12,18,64,70,96]

The metallopolymer coatings with the optimum composition obtained to date have corrosion stabilities superior to those of polymer coatings and the corresponding galvanic coatings (Table 5).

Table 5. The corrosion and mechanical stabilities of polymer, metallic, and metallopolymer coatings.[18]

Composition of coating	Σ, mm	A_1, days	A_2, days
Polymer coating based on E-41 and E-30 epoxide resins	1–2	70	60
Galvanic coating based on lead	—	90	78
Metallopolymer coating based on a mixture of epoxide resins with 60% of lead	1	110	96

Notation: Σ is the bending strength, A_1 the stability in 3% NaCl solution, and A_2 the stability in a chamber with 100% humidity.

The corrosion stability of metallopolymer coatings is greater the stronger the bond between the functional groups of the oligomer and the metal, for example, zinc.[74] It has been noted[95] that, when phenol-formaldehyde oligomers are used, the region of the maximum stability in corrosive media shifts towards higher metal concentrations as the bond between the polymer and the metal weakens in the sequence inner complex (chelate) > ionic > coordinate (via amino-groups) > donor–acceptor (via the OH group) > no chemical bond (ester group). The decrease in the number of epoxide rings on formation of metallopolymer coatings based on epoxide oligomers and the Zn–Pb alloy is accompanied by a sharp fall of corrosion stability.[18,98]

The dependence of the corrosion stability of coatings based on phenol-formaldehyde oligomers and zinc on their content of carboxy-groups passes through an extremum.[74,97,99] This is associated with the fact that, in the region of maximum corrosion stability of the coatings, the concentration of

the functional groups corresponds to the most favourable combination of two mechanisms of protection: the protective mechanism and the insulating mechanism involving the formation of surface compounds.

The introduction of colloidal metals into polymer coatings makes it possible to improve considerably the physicomechanical properties (to increase the adhesion and impact strength) and antifriction properties (to decrease the coefficient of friction and the wear of the material).[15] The thermal and electrical conductivities of metallopolymer coatings can be regulated within wide limits by varying the concentrations of the metals.

The electrical conductivity and the enhanced corrosion stability of metallopolymer materials permit their use as anticorrosion layers (primer) on which polymer compositions or industrial paints, for example, VAS-1162 and EP-2100, are subsequently electrodeposited. Data typical for two-layer metallopolymer–polymer coatings are presented in Table 6 for two industrially manufactured materials (VAS-1162 and EP-2100) with metallopolymer anticorrosion layers (primers) based on lead and the lead–copper alloy. The stability of such a system comprising two-layer coatings during their tests in chambers with 100% humidity and a 5% salt mist is higher by a factor of 2–3 than that of the single-layer industrial coatings of the same thickness (Table 6).

Table 6. The corrosion stabilities of polymer and metallopolymer coatings in a chamber with a 5% salt mist (NaCl)*.[98]

Composition of coating		τ, h
layer II	layer I	
Industrial materials: VAS-1162	—	176
EP-2100	—	176
Lead-based (60 wt.%) metallopolymer primer	VAS-1162	520
	EP-2100	520
Metallopolymer primer based on a lead–copper alloy (60%)	VAS-1162	>615
	EP2100	>615

*The thickness of the coatings was 45 μm.

Table 7. Dependence of the dielectric strength of polymer and two-layer metallopolymer-polymer coatings on the deposition time.[59]

Type of coating	Dielectrical strength (kV) for different deposition times (min)					
	0.5	1.0	1.5	2.0	2.5	3.0
Polymer coating based on a mixture of the E-30 and E-41 epoxide resins	0.8	1.5	1.75	2.0	1.8	1.4
Two-layer coating (first layer—metallopolymer based on a mixture of resins and lead; second layer—mixture of epoxide resins).	2.0	2.7	3.2	3.5	3.7	3.8

An important application of two-layer metallopolymer-polymer coatings involves the creation of highly effective electrically insulating coatings. The results of tests of the electrical strength of polymer and metallopolymer-polymer coatings are presented in Table 7. For the same thickness (40 μm), the dielectric strength of composite two-layer coatings is increased by a factor of two.[12,59] The presence of the metallopolymer layer ensures an increase in adhesion to the support and hence an improvement in the anticorrosion properties and also in the homogeneity, uniformity, and the specified thickness of the coatings along the edges of the given articles.

The electrically insulating properties of the two-layer coatings do not change after periodic alternation of the polarity of the electric field.

---o0o---

Thus the simultaneous use of two classical phenomena—electrophoresis and electrolysis—had led to the development of new methods of formation of metallopolymer structures and materials. The possibility of regulating the kinetics of electrode processes with the aid of the electrophoretic deposition of polymers–electrophoretic polarisation—is of considerable interest from the standpoint of the electrochemical preparation of metallic powders and the anodic passivation of metals.

Further development of this field requires the solution of a number of problems in colloid chemistry, electrochemistry, and the physical chemistry of filled polymers, which include the problems of the stability of dispersed systems in electric fields, of the electrocrystallisation of metals in polymers, and of the interaction of polymers with colloidal metals.

Trends in the Development and Tasks of Modern Quantum Chemistry†

N.D.Sokolov

The main advances are surveyed and the principal trends in the development of modern quantum chemistry are noted. The intensification of the linkage between theoretical and experimental research is emphasised. The tasks in various branches of quantum chemistry of greatest current interest are analysed. The electron clouds and the electronic processes in molecules and solids, intermolecular interaction, intramolecular dynamics, elementary processes in gas and condensed phases, and phenomena determined by the non-adiabatic electronic-nuclear interaction are examined. The tasks associated with the development of a theory of the application of physical research methods in chemistry and also those concerned with the applied quantum chemistry, namely theoretical materials science and quantum molecular biology, are discussed. The role of computer modelling is emphasised and the trends in the development of quantum-chemical methods are briefly analysed.
The bibliography includes 269 references.

I. INTRODUCTION

Quantum chemistry was born as the science of the electronic structure and reactions of molecules in the gas phase based on quantum mechanics. At the same time, these quantum-mechanical methods have come to be used to explain spectroscopic and other physical properties of molecules. However, experiment required the theory to explain the structure, properties, and reactions not only of molecules as such but also of substances in the liquid and solid states. Together with quantum mechanics, it became necessary to start using the methods of statistical and mathematical physics and computer mathematics for the solution of these problems. Thus modern quantum chemistry is a broad science located between chemistry and physics whose subject is theoretical study of the structure, properties, and transformations of substances at the atomic-molecular level with the aid of methods of quantum mechanics, statistical physics, computational mathematics, and mathematical physics.

---

†Expanded text of the report read on 2nd February 1987 at the All-Union Coordinating Conference on Quantum Chemistry (Chernogolovka).

1. Strengthening of the Linkage between Theory and Experiment

Still comparatively recently, in assessing the contribution of quantum chemistry to chemical sciences it was pointed out that it explained many chemical phenomena and regular features, created the system of concepts and the language of modern chemistry, and imparted a physical significance to the existing chemical ideas. These were indeed major advances. However, the success and the role of present-day quantum chemistry are much greater. It is able not only to explain but also to predict the possibility of the existence of new chemical compounds and materials and their structure and properties, as well as new effects, and to calculate the characteristic parameters of molecules which are inaccessible to experiment or can be determined experimentally with difficulty. Quantum chemistry proved able to solve also more complex problems: to recommend, for example, the optimum synthesis of a new compound with specified properties, to indicate how one can measure, in principle, any characteristic parameter or property, and to assist in planning a new experiment. Problems which are ultimately very relevant to practical applications, to the creation of the new engineering, are being solved with increasing frequency. All this characterises the new stage in the development of quantum chemistry. Its role in modern chemistry has changed significantly.

Thus one of the main trends in the development of modern quantum chemistry is strengthening of the linkage with experiment. Whereas 20–30 years ago, the bulk of the literature on quantum chemistry was devoted to methodological developments and trial calculations, nowadays most of the theoretical studies are associated with a specific experiment, with its interpretation, or with predictions. This is due to several causes. On the one hand, quantum-chemical methods have been greatly improved, having reached a level of development where they can really satisfy many of the requirements of experimenters. There has been enormous growth in the power of modern computer techniques. The application of methods of mathematical physics, which make it possible to find solutions to quantum-chemical problems in a closed form or to bring them to the stage where it is rational to resort to computers, has become more effective. The application of methods of statistical physics has been expanded, which gave rise to the possibility of obtaining results in a form which can be compared directly with experiment.

On the other hand, the above tendency is associated with colossal progress in physical experimental methods and their application in chemistry. However, the application of new physical research methods in chemistry is based on special theoretical developments. Quantum chemistry has been concerned to an increasing extent with the solution of this problem.

The increasing role of physical research methods in chemistry led to an enhancement of interest by quantum chemists in the physical properties of molecules. The existence of this trend is already evident from the following example: at the Vth International Congress on Quantum Chemistry in 1985 (Canada), among the new reports delivered by invitation, whose selection is usually made on the basis of a sober assessment of what is new, about 60% were devoted to physical problems important for chemistry and the remaining 40% were concerned with chemical tasks and problems significant for both chemistry and physics (methodological studies).

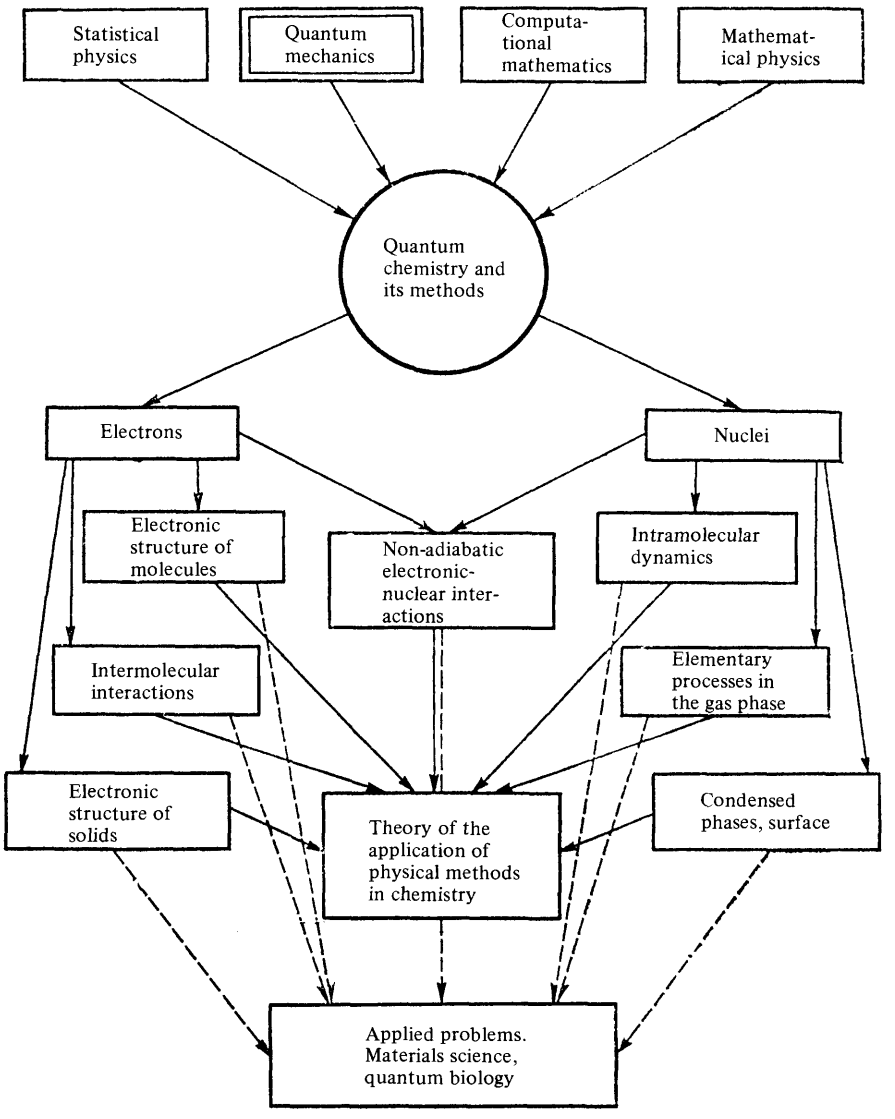
The main cause of the strengthening of the linkage between quantum chemistry and experiment is ultimately determined by practical requirements: new experiments and new experimental methods are essential for the solution of problems of practical importance. A theory applied to chemistry, namely quantum chemistry, must provide a basis for such experiments and methods and an interpretation of the results.

A vital task for theoreticians is to carry out investigations in close contact with experimenters. In practice this has by no means always been achieved, but it is known that the joint investigations by theoreticians and experimenters always greatly assist in the successful outcome of research.

The Figure presents a schematic illustration of the structure of modern quantum chemistry. Quantum mechanics has made the main contribution to the development of its methods. Statistical physics, computer mathematics, and mathematical physics also play a significant role. Quantum-chemical investigations based on the adiabatic approximation are divided into two fields: the study of electron clouds and the study of the motion of atomic nuclei. The first includes the electronic structure and electronic processes in molecules and solids and intermolecular interaction. The second field embraces the intramolecular dynamics of nuclei, the elementary processes in the gas phase, and the dynamics of the processes in condensed phases and at interfaces. It is known that there exist many systems and phenomena to the description of which the adiabatic approximation is inapplicable and account must be taken of non-adiabatic electronic-nuclear interaction. A separate bunch of quantum chemistry is devoted to such systems.

The development of theories of the application of physical research methods to chemistry, which is related to the fields mentioned above, is a very important component of quantum chemistry. The solution of applied problems is a comparatively new branch of quantum chemistry, which, however, is of very great current importance. In particular it embraces the large field of materials science. Many applied problems are being solved successfully with the aid of computer modelling. One of the most important problems of this kind involves the development of quantum molecular biology.

Some of the most important problems of modern quantum chemistry, in each of the fields mentioned above, are characterised briefly below. The examples quoted are illustrative. In conclusion, the general trends in the development of quantum chemical methods are briefly analysed.



II. ELECTRON CLOUDS

1. Electron Clouds of Molecules

One of the quantum-chemical problems of greatest current importance involves the establishment of a relation between the properties of molecules and their electronic structure. The most important chemical property of molecules is their reactivity. An enormous amount of experimental data, characterising the relation between the reactivity and the electronic structure of molecules has accumulated in this field. There have been major advances also in the theoretical treatment, such as, for example, the principle of the conservation of orbital symmetry of Hoffmann and Woodward,[1] the concept of frontier orbitals,[2–4] and the principle of isolobal analogy.[5,6] The principal trend in the development of the modern theory of reactivity involves an increase in the number and improvement in the quality of calculations of the potential energy surfaces (PES) of reacting systems. Quantum-chemical calculations of the transition states (the saddle point on the PES) and calculations of the directions of motion of atomic nuclei in the given molecular configuration make it possible to predict the reaction path and the nature of the

final products. Hundreds of PES have been calculated[7-14] and the mechanisms of many reactions have been determined with a high degree of probability, which has made it possible to estimate the kinetic parameters necessary for the calculation of their rates. This branch of the theory of reactivity has been very fruitful and in the immediate future will probably influence significantly synthetic chemistry (mainly organic chemistry).

On the other hand, many problems of chemical reactivity have been solved at an empirical level without theoretical justification or have not been solved at all. Thus various empirical rules of different kinds, many of which lack theoretical justification and the limits of the applicability of which are not known, are widely used in organic chemistry. As regards the reactivity of molecules, quantum chemists are therefore faced by a broad field of activity which is of great interest to experimenters. We shall indicate several questions which await an answer. For example, how can one justify the Brønsted–Polanyi–Semenov rule and to what factors are the observed deviations from this rule related:[15] when does the nucleophilic substitution reaction proceed via the S_N2 mechanism and when does it involve the formation of a radical-ion; why do some reactions proceed in general via a concerted mechanism, while others involve intermediate stages; in what cases are metastable intermediate complexes formed; what is the influence of low-lying electronically

The structure of modern quantum chemistry.

excited states on the rates of reaction; how can one increase the selectivity of chemical reactions, i.e. how can one avoid their occurrence via a multiplicity of channels leading to the formation of side products and greatly complicating the manufacturing process and increasing its cost. (We may note that, for certain types of major chemical manufacturing processes, an increase in the yield of product by 2–3% would result in an annual saving equivalent to the cost of construction of a new large factory!)

Various approaches can be usefully resorted to for the solution of numerous problems of the theory of the reactivity of chemical compounds. Together with the calculations of the PES mentioned above, semiquantitative approaches are of interest for specific reactions:[7–14] the construction of semiempirical PES[10] or the estimation of diabatic terms modelling certain cross-sections through the PES for the reacting system.[15] Calculations of the electronic structure and properties of the intermediate formations, which are not susceptible or are little susceptible to experimental study, are also important.

It is noteworthy that, as a result of the improvement of experimental techniques, many chemical reactions known previously only in solutions have now been investigated also in the gas phase;[16,17] this makes possible the comparison of the results of the calculation of reactivity with the "pure" experiment.

There are many problems in the theory of electronic structure which are not related directly to reactivity but are important for chemistry. They include, for example, the development and application of the model of "additional spherical electron density",[18] which justifies the Lewis–Sidgwick rule. According to this rule, electronic configurations resembling those in inert gas atoms are especially stable in coordination compounds. Calculations of the electronic structure of compounds with heavy atoms taking into account relativistic effects are very important. It is now clear that, without taking the latter into account, it is impossible to explain satisfactorily either the chemical or physical properties of compounds of the actinides, lanthanides, and other elements with a high anionic number.[19,20] Many characteristic features of compounds with heavy atoms are influenced, in a manner which is not yet fully understood, by the presence in these atoms of a large number of closely spaced energy levels.[20–23] In general, the theory of chemical bonding involving the atoms of heavy elements still has to be constructed. The nature of the metal–metal bonds,[24,25] the structure of compounds involving variable-valence metal atoms,[26] and many others have to be investigated.

Among the physical methods for the study of matter, the most important information about the electronic structure of molecules is provided by spectroscopic methods: spectroscopy in the visible, ultraviolet, and X-ray regions, X-ray and photoelectron spectroscopy, Auger spectroscopy, EPR, and NQR. The task of quantum chemistry is primarily a correct interpretation of the wide variety of information obtained by these methods: data on the energies of electronic transitions, the form, intensity, and polarisation of electronic, vibronic, and rovibronic spectra, their fine structure, their behaviour in external fields, and many others. Calculations of the energies of excited electronic states as a function of nuclear coordinates (PES) are of special interest. The modern quantum-chemical methods so far permit the calculation with an adequate accuracy of the structure and spectra only of small molecules.[14,21] However, their characteristics are important for the solution of many practical problems.

The development of laser techniques during the last decade has allowed the investigation of many fast chemical, physical, and biophysical processes on the nanosecond and picosecond time scales. The development of the appropriate theories is essential for the interpretation of these experiments. Theoretical study of the rates of the transfer and capture of the electronic excitation energy of molecules, calculations of the lifetimes of excited states in relation to radiative and non-radiative decompositions, and the study of the pathways and rates of relaxation processes are of special interest: the calculations of the ionisation, autoionisation, and dissociation cross-sections of molecules and the cross-sections of their excitation and superexcitation by single-photon and multiphoton irradiation and other types of ionising radiation, the cross-sections of the resonance and non-resonance light scattering, etc. are also important. The solution of these problems, which characterise the leading front of present day science of the interaction of radiation with electron clouds, is necessary for the construction of a theory of elementary reactions, the development of theories of vibronic interactions, the usual and laser photochemistry, radiation chemistry, and plasma chemistry, for the calculation of the conditions governing the operation of molecular, excimer, and chemical lasers, etc.[27–34]

The modern spectroscopic methods are characterised by a high resolving power and a high sensitivity. This imposes enhanced requirements on quantum-chemical calculations. It is important to be able to calculate fine effects for the understanding of which it is necessary to resort to the entire range of procedures of modern theoretical physics. The high sensitivity of modern spectroscopic instruments has made it possible to observe a series of previously unknown or little investigated metastable species, the nature, structure, and properties of which have to be studied jointly by experimenters and quantum chemists. Such species have been detected in gas-phase chemical reactions, electrical discharges, and by the action of strong electromagnetic fields and ionising radiation in plasma, space, etc.

2. Intermolecular Interactions

The theory of intermolecular interactions has always attracted the attention of scientists because of the role which such interactions play in various physicochemical phenomena in both gaseous and (especially) condensed media.[35] During the last 10–15 years, the theoretical research in this field has advanced appreciably in connection with the creation and development of a series of new effective experimental methods for the investigation of the interaction of molecules in the gas phase.[36] These studies yielded extensive new information about the intermolecular interaction, which, on the one hand, required theoretical interpretation and, on the other, served as a basis for checking calculations.

The main task of the theory of intermolecular interaction involves the study of potential energy surfaces in both ground and electronically excited states. The relevant information can be obtained experimentally only in the simplest one-dimensional cases, mainly for the ground electronic states. For problems associated with the study of the physical properties of molecular complexes, liquids, solutions, and clusters, it is in many cases sufficient to know the PES in the vicinity of the equilibrium position for the ground electronic state. For the theory of elementary processes, especially chemical and photochemical ones, the theory of chemical laser systems, and the solution of many other problems, it is essential to know the changes in potential energy over a wide range of variation of nuclear coordinates for both ground and electronically excited and ionised states taking into account the possibility of the existence of several reaction channels.[7–14]

The study of the effect of the molecules of the medium (the solvent) on the rate of the chemical reaction constitutes an independent problem. Disregarding the questions concerning the dynamic action of the medium (see subsection 3 of Section III), the solution of this problem reduces to the calculation of a multidimensional PES taking into account the molecules of the medium. Model calculations have made it possible in a number of instances to take this phenomenon into account qualitatively.[7,37] Here the natural question arises what number of solvent molecules must be taken into account. At first sight it may turn out that this number should be very great, especially when the reacting system is charged, since Coulombic forces decrease slowly with distance. However, recent experiments involving the study of the multistage solvation of ions in the gas phase have shown that the nearest ligands play the main role in this process and that the influence of more remote ones may be neglected.[16,17] The qualitative difference between gaseous and solvated systems is determined in many instances by the action of only a single ligand. Hence it apparently follows that, in theoretical estimates of solvation effects in both thermodynamic and kinetic problems, the treatment can be restricted in most cases to clusters comprising a small number (6–8) of ligands. A model calculation of the potential energy curve for proton transfer in the $FH...NH_3$ system shows that for the gas phase this curve has only one minimum while for the solution, when account is taken of the hydration shell of this complex consisting of six water molecules, a second fairly deep minimum appears.[38] The question of the influence of solvation on elementary processes requires thorough investigation.

In certain cases interesting conclusions concerning the influence of intermolecular interaction on the rate of reaction can be reached without any calculation. For example, the reaction $Cl_2 + Br_2 \rightarrow 2ClBr$ is known to be symmetry-prohibited (it requires a high activation energy[1]). However, the same reaction involving the van der Waals complex $(Cl_2)_2$ takes place readily, since the symmetry prohibition has been removed.[39] Application of the orbital symmetry conservation rules to reactions involving van der Waals complexes may prove useful also in other cases.

It has been frequently suggested that the form of the activated complex for a bimolecular reaction resembles that of the corresponding stable molecular complex. Such similarity would be important because the form of the latter complex can be determined experimentally. However, it has been found that in general no such similarity exists.[39] The problem of the theoretical analysis of the conditions under which it can nevertheless occur therefore arises.

An important task of the theory is also the study of the changes in various characteristic parameters and properties of molecules under the influence of their interaction: on formation of molecular complexes, especially hydrogen-bonded complexes, in solvation, adsorption, etc.[36,40]

An increasing amount of experimental data, indicating the important role of cooperative (multispecies) interactions of molecules in condensed phases, has accumulated in recent years.[36,41,42] Such interactions are manifested by the nonadditivity of the interaction energy and the sharp changes in vibrational spectra, equilibrium geometry, and other characteristics of the molecules on passing from a dimer to an aggregate. The theory of the cooperative interactions of molecules is as yet far from being complete.

3. The Electronic Structure of Solids

During the last two decades, the theory of the solid state has developed vigorously. We shall not be concerned with the general problems of the solid state physics and shall characterise briefly only some of the problems of the theory of the electronic structure of solids relevant to chemistry. These include in the first place problems associated with the properties of the surface.

The creation in the 1970's of a series of new extremely effective methods for the experimental investigations of the surface led to an unprecedented advance in theoretical research into the electronic structure and properties of the surfaces of solids and interfaces. Among the new methods designed to investigate the composition, geometry, and electronic structure of surfaces, mention should be made of slow electron diffraction, photoemission,[43] the spectroscopy of energy losses by electrons,[44] photoelectron and X-ray electronic spectroscopy,[45–47] etc. In connection with the development of these methods, many specific theoretical problems, whose formulation would have been premature in the absence of these methods, have arisen.

One such problem involved the determination of the difference between the electronic structures and the arrangements of atoms in the surface layer and in the bulk of a crystal and also the elucidation of the way in which these characteristics change under the influence of adsorption and local defects. It is also important to know how adsorbed molecules and defects influence the position of the local energy levels, the density of states, the form of the photoemission spectrum, etc.[43]

In connection with one of the most important problems in chemistry, that of heterogeneous catalysis, numerous tasks involving the theoretical study of the adsorption of molecules, molecular fragments, and various intermediate complexes on the active centres of catalysts have arisen.[48–50] Analogous calculations are also necessary for the theory of metal complex catalysis.[51–53] The accumulation of calculated data on the steric orientation of the adsorbed molecules and the nature of their bond with the active centre, the relative adsorption energies of different species on different centres with different types of orientation, the rearrangement of the surface in adsorption, and the interaction of adsorbed molecules is very important. In particular, such calculations can assist in the search for the optimum catalytic reaction pathway. Calculations of the characteristic parameters of adsorbed molecules and other species, namely the frequencies of the electronic and vibrational transitions, dipole moments, and distribution of electron density, as well as various NMR and EPR parameters, are also important for the interpretation of data obtained by physical research methods.[54]

The study of the electronic structure not only of the surface but also of the bulk of the solid, i.e. the local states and defects in the bulk phase, their excitations, ionisation, tunnel recombination, autoionisation, luminescence, etc., is likewise of interest for chemistry.[52,55,56]

The development of the theory of electronic structure and electronic processes in organic crystals with a quasi-one-dimensional structure constitutes a separate problem.[57,58] In a number of instances such structures, which include, in particular, oriented polymers with conjugated bonds,[59] have completely unusual dielectric, conducting, and magnetic properties.

Methodologically, one of the main trends in the development of the theory of the electronic structure of solids is the endeavour to transfer to this theory the methods and approaches developed in the theory of the electronic structure of molecules. This applies in the first place to the treatment of the properties which are determined to a significant extent by the short-range order and local characteristics of the structure—point defects in the bulk phase and on the surface, the presence of adsorbed atoms and molecules, optical and X-ray excitations, etc. The joint application of the methods of the theories of molecular and

solid state structures will undoubtedly prove useful in the treatment of the properties of non-crystalline solids and alloys, the stability of materials with respect to the action of radiation, corrosion, etc. The cluster model, within the framework of which the methods of the theory of the electronic structure of molecules are also applied, has been used successfully in the study of these properties.[60,61]

It is noteworthy that in the theory of the electronic structure of solids, as in the theory of molecules, clear models play an important role. For example, the representation of molecular orbitals by a linear combination of atomic orbitals makes it possible to describe many features of the structure and a number of properties of not only molecules but also of solids.[62,63] Further development of clear representations of the electronic structures of solids is therefore useful, especially for experimenters.

III. DYNAMICS OF THE MOTION OF NUCLEI

1. Intramolecular Dynamics of Nuclei

Under the influence of the development and wide-scale application of new physical research methods, the theoretical study of the dynamic properties of substances has greatly intensified. The intramolecular dynamics of nuclei occupies an outstanding place in such research.

Until recently, in the study of intramolecular non-radiative processes most attention was devoted to electronic relaxation. In recent years, the research into the vibrational and rotational relaxation of molecules has grown appreciably, which is directly related to advances in the development of the laser technique. By virtue of these advances, the dynamics of various intramolecular processes,[64-72] including isomerisation, decomposition, tunnelling, relaxation time, etc., have become susceptible to detailed investigation.

The study of the exchange of vibrational energy is of primary interest.[64,70,71] A definite amount of energy, calculated to produce a local excitation of a specific vibrational mode, is imparted with the aid of a laser to a molecule having a very low rotational and vibrational temperature. The creation of such a non-equilibrium distribution under the conditions of a high vacuum can lead to the dissociation of the molecule if the rate of this reaction is higher than the rate of redistribution of the additional energy among other vibrational degrees of freedom, i.e. than the rate of intramolecular vibrational randomisation (stochastisation). The task of the theory is to facilitate with the aid of calculations the search for the selective vibrational excitation of the molecule in which this condition would be fulfilled. Calculations can help to elucidate the causes of the observed deviation from the experimental data of the rates of photoinitiated dissociation calculated on the basis of a statistical model.[73] The deviations can be caused by the incomplete randomisation of the energy, kinematic effects, insufficiently accurate calculations of the PES, etc. Calculations not only of the PES but also of the vibrational energy levels for the ground and electronically excited states, the constants for the anharmonic and kinematic interactions of modes, the probabilities of energy transfer between the modes, etc. are therefore necessary. Questions of this kind are part of the broader problem of the relation between the ergodic and random motions in the molecule, a problem which should be solved by means of the joint efforts of experimenters and theoreticians (see, for example, Noid et al.[74] and Krivoshei et al.[75]).

The problem of the influence of the non-equilibrium distribution of energy on the rate of unimolecular decomposition of molecules does not arise solely in connection with laser excitation. A non-equilibrium distribution can arise for different reasons; in particular, it is created in the course of the reaction itself. It can be neglected only in terms of the rapid mixing (randomisation) approximation. The development of these problems is of very urgent interest for chemical kinetics.[76,77]

A series of theoretical problems in intramolecular nuclear dynamics and as regards the structure of electron clouds are related to the increase in the sensitivity and resolving power of spectroscopic instruments. Thus the improvement of the resolution of the rotational and vibrational-rotational spectra to 10^{-3} cm^{-1} for a line width up to approximately 5×10^{-4} cm^{-1} imposes new requirements on the accuracy of the calculations and interpretation of the spectra.[67,78-80] To characterise the complexity of this problem, we may mention the high-resolution laser IR spectrum of the comparatively simple ion H_3O^+: approximately 100 transitions have been detected for this ion in the region of 3500 cm^{-1} in plasma cooled with liquid nitrogen, whereas in plasma cooled with liquid air an additional ~240 transitions were observed, but these have not as yet been interpreted.[67] The interpretation of such complex spectra requires the development of new computational methods, such as, for example, the method of computer modelling. New approaches have also arisen in the calculations of the force constants of molecules.[81]

The problem of the calculation of the vibrational spectra of non-rigid molecules, in particular molecules with pseudo-rotation,[82,83] molecules with conformational transitions, etc. is also of urgent interest. In the treatment of such spectra, it is necessary to solve the problem of the motion of atomic nuclei in a field with a complex potential.[84,85]

Many new fairly puzzling data concerning the dynamics of strong hydrogen bonds have appeared in recent years. These findings have not as yet been explained satisfactorily within the framework of a single approach. Such phenomena include, for example, various "anomalous" isotope effects for geometrical parameters,[86] the frequencies and intensities of stretching and deformation vibrations,[87,88] etc.

A number of interesting theoretical problems in intramolecular dynamics have arisen in connection with NMR.[89,90] Here information about the character of the motion of nuclei (for example, about their hindered rotation) is extracted with the aid of the theory of the NMR line form.[91]

2. Dynamics of Elementary Processes in the Gas Phase

The main task of the theory of elementary processes in a gas is the elucidation of the mechanisms of these processes and the calculation of the corresponding rate constants. Knowledge of the latter permits the calculation of the rates of complex multistage chemical reactions, the determination of the pathway followed in the degradation of energy and of the rate of such degradation in photochemical processes, calculations for laser gas-phase systems, processes in plasma, ultrasonic flow, etc. The experimental determination of the elementary constants, especially at high temperatures, is frequently difficult. The role of the theory is especially great in this instance. The study of the dynamics of gas-phase reactions is not important solely for practical purposes; investigation of such reactions makes it possible to learn about the mechanisms of the chemical reaction in a "pure" form uncomplicated by the influence of the medium.

As in the theory of molecular structure, theoretical investigations of elementary processes in the gas phase have received a new stimulus during the last decade by experiments using the new technology, in the first place lasers. Here it must

be emphasised that successful experimental studies of chemical reactions became possible by virtue of their combination with theoretical calculations.

The elementary processes, the calculation of the cross-sections of which is urgently necessary, are extremely varied. They include processes involving the transfer of electronic, vibrational, and rotational energy, charge transfer, ionisation, and decomposition, photodissociation, substitution, etc. reactions,[34,92,93] Many processes take place non-adiabatically.[94,95] The tunnel effect sometimes plays an important role.[96] Whereas two decades ago measurements were made mainly of the cross-sections of processes averaged with respect to rates and the quantum numbers of the initial and final species, in recent years the new technology has made it possible to measure cross-sections with a high resolution with respect to energy in molecular beams, the dependence of the cross-sections on the quantum numbers, the distribution of the products with respect to quantum states, etc. New requirements as regards the quality of the theory have therefore arisen. Thus it has become clear that, when the vibrational relaxation of molecules is considered, account must be taken of the change in their rotational state; it is important to take into account the anharmonic and Coriolis interaction of the modes, the occurrence of the van der Waals interaction of molecules which have collided, and the possibility of their chemical reaction.[97-99] Interesting problems arise in the interpretation of the results of the study of the transfer of rotational energy in beams taking into account the changes in the projection of the angular momentum.[100]

One of the new tasks of the theory of elementary processes consists in finding the transverse cross-sections of chemical reactions between species one of which (a molecule) was subjected beforehand to selective vibrational or rotational excitation.[101,102] For example, it is known that the reaction $N_2O + Cu \rightarrow N_2 + CuO$ on the surface of copper under the conditions of the excitation by a laser of the antisymmetric longitudinal vibrational of the N_2O molecule is 5×10^3 times faster than the thermal reaction on the same surface at 363 K.[101] It has been observed that the rates of the $N_2^+ + Ar$ and $H_2^+ + Ar$ reactions are a maximum on excitation of a specific vibrational level in the initial molecule; this maximum is apparently associated with the resonance (still incompletely understood) between the vibrations of the initial and final molecules.[103] Such resonance-induced increase in the rate of reaction has been observed in certain cases also for a specific translational energy of the species which have collided.

It is of interest to interpret theoretically the experimentally observed appearance of two maxima on the curve describing the dependence of the population of the rotational levels of the product molecules on the rotational quantum number of the initial molecule, which apparently indicates the existence of two decisive configurations of the activated complex (for example, in the reaction $MgH_2 \rightarrow MgH + H$).[103] It is also urgently necessary to obtain an answer to the question in what cases does the distribution of energy in the intermediate state become statistical and in what cases is there sufficient time for the reaction to occur before the randomisation of the energy.

A weak point in the theory of elementary processes is the calculation of the PES, which is usually performed with an inadequate accuracy. As regards the dynamics of the process itself, extremely effective methods have been developed for its treatment, which in the presence of a sufficiently accurate PES make it possible to achieve satisfactory estimates of the collision cross-sections. The calculations of cross-sections based on the solution of the Schrödinger equation have been most widely used (see the relevant reviews[92,104-106]). The success of the calculations of the rates of reaction depends to an appreciable extent on the successful choice of the curvilinear coordinates in terms of which the problem is solved.[106,107]

A number of other quantum-chemical methods of the collision theory are in the stage of intense development (see the reviews[108,109]). Together with these methods, trajectory calculations have become fairly common[110-113] in which classical trajectories of the motions of the representative point of the reaction are calculated with the aid of Newton's equation on a specified PES under different initial (quantum) conditions. In order to obtain the rate constant, the flux of particles is averaged over the thermal distribution. Allowance for quantum effects (tunnelling, interference, resonances) requires a more sophisticated calculation. The corresponding method is called semiclassical.[114]

However, it is necessary to recognise that the application of the above methods to systems with more than three atoms involves considerable computational difficulties. The statistical method for the calculation of reaction rates—the transition state method—has therefore come to be widely used. This method requires much less detailed information about the PES than the other methods.

The principal disadvantage of the initial transition state theory[115] was that no account was taken in it of the trajectory of the reverse motion on the PES of the representative points of the reaction towards the initial state, as a result of which the calculated rate constant was overestimated.[116] Furthermore, an insufficiently complete account was taken of tunnelling. A weak point of the theory was also the hypothesis of the separation of coordinates corresponding to different degrees of freedom and the neglect of the anharmonicity of the vibrations in the calculation of the vibrational partition functions. The subsequent development of the theory was directed mainly towards the elimination of these disadvantages.[117-123] As a result, a general transition state theory was developed, the central place in which is occupied by allowance for the trajectories of the reverse motion with the aid of a variational procedure (see the review of Truhlar et al.[124]).

We may note that the transition state theory is not always applicable to reactions in solution, because it does not take into account the stochastic character of the molecular motion (see the following subsection).

3. Dynamics of Elementary Processes in Condensed Phases and at Interfaces

For a long time the influence of the medium on elementary chemical processes in the liquid phase was taken into account in the majority of theoretical studies mainly in terms of the static approximation where only the change in the profile of the reaction path under the influence of the interaction with solvent molecules is taken into consideration.[125,126] The dynamic character of the influence was taken into account inadequately. For example, in the investigation of the kinetics of electron transfer by Marcus no account was taken of the Brownian character of the motion of the system in the formation of the activated state; only the reorganisation of the solvent and its influence on the activation energy were taken into consideration.[125] In a number of other studies, the charge transfer process was treated as non-adiabatic within the framework of a fairly special model.[127,128]

Later two approaches came to be used for the treatment of elementary processes in the liquid phase: the model based on the Brownian character of the motion of the reacting system along the reaction pathway (Kramers[129]) and the generalised Langevin equation.[130] According to the latter, the motion of the representative point in the liquid phase takes place under the influence of a random force in the presence of time-dependent friction. A common feature of these approaches is allowance for the deactivating influence of the collisions of the reacting molecules with the molecules of the medium, which diminishes the rate constant compared with the value calculated from the transition state theory. It has been shown recently that the two approaches are in essence equivalent.[131] An adiabatic theory of charge transfer has been developed within the framework of the Kramers model.[132–137] The generalised Langevin equation combined with the formalism of the time correlation function has found extensive application in the treatment of various reactions (see the relevant reviews[138–142]). Proton transfer processes[143–144] isomerisation reactions,[144–147] atom transfer reactions,[148] etc.[147,149–152] have been investigated. This branch of the theory of liquid phase reactions undoubtedly merits constant attention and development.

One of the fundamental problems in liquid-phase kinetics involved the solution of the problem of the character of the breakdown of the equilibrium distribution of the populations of the energy levels under the influence of the reaction. An experimental solution of this problem has become possible by virtue of the development of the laser technique.[32] It is important to understand how such breakdowns affect the rate and mechanism of the process.

New possibilities for the development of research into elementary processes in the condensed phase have arisen as a result of the application of picosecond and subpicosecond laser spectroscopy[153] and especially the method of laser-induced fluorescence.[154] Comparatively recently it has become possible to measure with the aid of ultrashort light pulses the rate of ultrafast elementary processes with durations in the range 10^{-11}–10^{-15} s.[155–157] Measurements of the characteristic times of the collisions of molecules in the liquid phase, of the redistribution of energy between different degrees of freedom in the excited molecule, of the times required for the dissipation of the excitation energy, of the intermolecular and intramolecular transitions of the electron and protons, of photodissociation, of the redistribution of atoms in the molecular system, etc. have been initiated. The application of this technique has led to a revolution in the study of ultrafast processes and made it possible to achieve a series of exceptionally interesting investigations.[153–156] For example, it has been shown that the rate of the intramolecular transition of an electron is controlled by the molecular motion.[157] This conclusion is based on the observation of proportionality between the relaxation time of the electronic transition and the corrected dielectric relaxation time of the medium. On the basis of results of similar measurements, it is possible to model confidently the corresponding processes.

Definite progress in the theory of liquid-phase reactions may be expected in connection with the application of the methods of molecular dynamics and in general of computer modelling, naturally subject to a sufficiently realistic approximation of the PES.[158–160] These methods have been used successfully in the study of not only elementary processes but also of molecular spectra.[158–160] We may note, however, that the dynamic effect of the liquid medium on the form and width of the bands in the rotational and vibrational spectra of molecules[161–163] and also in the EPR and NMR spectra[164,165] has already been successfully investigated for a long time on the basis of model approaches with the aid of methods of theoretical physics.

The computer modelling methods have found applications also in the study of the structure and dynamic properties of solids.[166]

One of the most important problems in quantum chemistry involves the study of the dynamics of elementary processes on the surfaces of solids.[167–170] It has already been demonstrated comparatively recently that the atoms distributed on the surface cannot as a rule be regarded as immobile when gas-phase molecules collide with them. However, the number of degrees of freedom which must then be taken into account is much greater than in calculations on the collisions of molecules with one another. Therefore theoretical study of the collisions of molecules with the surface has become appreciably more complicated. The first problem which arises here involves, as for a liquid medium, the determination of the minimum number of molecules which must be explicitly taken into account in the calculations on elementary processes on the surface. It is then necessary to find the PES. The main difficulty in the treatment of processes involving the collision of molecules with the surface is the inapplicability of the standard Born distorted wave method because the interactions are strong and the velocities of the molecules are low. Furthermore, a number of problems are associated with the need to take account of a large number of interacting reaction channels; it is difficult to take into account the quantum effects, especially for light atoms (interference, tunnelling), and also the energy exchange between molecules and phonons both in the bulk phase and on the surface. Nevertheless, many dynamic problems of the interaction of gas species with the surface of a solid have been solved successfully.[167–171] For example, the dynamics of the adsorption of diatomic ions on the surface of a metal, the reactions of oxygen atoms with the surface of carbon-containing platinum,[172] the dynamics of the recombination of hydrogen atoms on tungsten,[173] the adsorption of atoms taking into account relaxation processes,[174–178] the dynamics of adsorption in the presence of interaction with phonons,[179,180] the migration of atoms along the surface,[181] and other processes have been investigated.

A number of interesting problems in the dynamics of surface processes arise in connection with the development of new research methods. Among the latter, mention may be made of the molecular beam method,[167] desorption with angular resolution stimulated by electrons and phonons,[182] the spectroscopy of the energy losses by the electrons scattered by the surface,[44,183] Raman spectroscopy,[184] and other methods.

The promising nature of the method of the laser-induced fluorescence,[154] which provides unique detailed information about the distribution of energy in different stages of the reaction, in particular, for a reaction on the surface and in desorption, about the concentration and nature of radicals appearing in heterogeneous catalysis, and about other processes, which is extremely important under experimental conditions when other spectroscopic methods are inapplicable, must be specially emphasised. Such information should play a primary role both in the formulation of the theoretical problem of the dynamics of surface phenomena and in comparing the theory with experiment. We may note that the generalised Langevin equation has been used with some success for the description of the dynamics of the surface–gas system.[167,172,185]

The study of the dynamics of elementary processes plays an important role in the theory of catalysis (see, for example, Kiselev and Krylov,[186] Chapter 5). Here the initial problem is to discover the elementary stages comprising the catalytic process. It is known that even seemingly simple reactions, for example the catalytic synthesis of methanol,[187] involve a large number of intermediate stages. Theoreticians can assist in the analysis of reactions of this type by studying not only the PES but also the dynamics of individual stages. However, calculations for

only the simplest processes are in fact possible at the present time. Some of these were mentioned above.

In addition, it is useful to involve quantum chemists in the solution of fundamental interrelated problems of catalysis: concerning the mechanism of the decrease in the activation energy and of the change in the reaction pathway under the influence of catalysts and also in seeking an answer to the most important question how to avoid multichannel occurrence in catalytic reactions and how to reduce the amount of side products. Enzyme catalysis is known to be an example of high selectivity (see, for example, Refs.188–190). A high selectivity of the reaction implies that it is faster along one channel than along another. This optimum reaction pathway is probably associated with the self-organisation of the system, which presumably reduces to the choice of the most "favourable" sequence of stages and the optimum mutual orientation of the components of the reacting system in combination with the optimum character of their activation at each stage of the process. The natural question arises why these conditions are fulfilled in enzyme catalysis with such unvarying rigour. For this reason, modelling, especially computer modelling, of the possible mechanisms of the catalytic action of enzymes (and also of ordinary catalysts) constitutes an important task in quantum chemistry.

When the temperature is sharply reduced, the rates of many chemical reactions in the solid state are known to decrease initially in accordance with the Arrhenius law after which they cease to depend on temperature and the reaction proceeds at a low rate, which, however, is higher than the rate corresponding to the Arrhenius equation at the given temperature.[191,192] The existence of this low-temperature limit has been explained by Gol'danskii[192] by a tunnel reaction mechanism. However, the problem cannot be regarded as entirely elucidated. Its solution requires calculations for specific models. For example, Bazilevskii and co-workers[193,194] proposed a model for the ionic polymerisation reaction in crystalline formaldehyde in which the polymer chain propagation stage, which determines the rate of the entire process, takes place with a "favourable" mutual orientation of the molecules and involves very slight atomic displacements. If the height of the corresponding potential barrier is then fairly small, the atomic displacements can in general occur via both the tunnel mechanism and over the barrier. At a low temperature, the rate of reaction can then be determined both by the low tunnelling probability and by the low probability of the realisation of the "favourable" orientation of the molecules. In the absence of a barrier, only the second cause will naturally operate. At the usual temperatures, the reaction proceeds via another (activated) pathway, since the latter is faster. Fairly correct calculations have been performed for hydrogen transfer reactions[195] and the quantum nature of the low-temperature limit of the reaction rate has been demonstrated (see also Refs.72, 123, and 196).

IV. NON-ADIABATIC ELECTRONIC-NUCLEAR INTERACTIONS

It is known that the behaviour and properties of atomic-molecular systems can be largely treated in terms of the adiabatic approximation. However, under certain conditions the adiabatic separation of the electronic and nuclear motions is illegitimate. Studies in recent years have shown that in any molecular system there is a possibility of a situation where it is essential to take into account the non-adiabatic electronic-nuclear interaction, i.e. the situation where the electrons and nuclei must be regarded as a single dynamic system.

The interaction of nuclei and electrons is manifested in different ways for bound and unbound states. In the former case, the interaction is referred to as vibronic. It can be disregarded if the characteristic vibration frequency ν_{vibr} is much lower than the frequency ν_{el} corresponding to the electronic transition between the ground and first excited states. The limiting situation, which infringes this condition, occurs when the electronic energy states are degenerate ($\nu_{el} = 0$) in a certain region or at one point in space. If the degeneracy is associated with the symmetry of the system, then, according to the Jahn–Teller theorem, the symmetrical configuration of the nuclei proves to be unstable because of the mixing of the electronic states by nuclear displacements. Depending on the nature of the degeneracy, two or more distorted configurations will be stable. Such manifestation of the vibronic interaction is referred to as the Jahn–Teller effect.[197,198]

Thus, in the situation indicated, the Jahn–Teller effect actually determines the real structure of the molecular system and also its dynamics and certain physical and chemical properties which depend on the structure. During the last 20 years, manifestations of the Jahn–Teller effect have been observed in many compounds with the aid of various experimental methods: EPR, IR, Raman, and UV spectroscopy, photoelectron spectroscopy, and studies of the polarisability and magnetic susceptibility of substances. The Jahn–Teller effect is significant in crystal chemistry and influences structural phase transitions (the cooperative Jahn–Teller effect), especially the transitions associated with the spontaneous polarisation of crystals (ferroelectric phase transition). The theory explains satisfactorily the observed effects and has been used successfully in many instances for prediction.[197–202] A model of the fusion of solids has been recently proposed[203] on the basis of the Jahn–Teller effect.

The vibronic interaction is manifested also in those cases where ν_{el} is non-zero but is of the same order of magnitude as ν_{vibr}.[197,198] The corresponding effect is frequently referred to as the pseudo-Jahn–Teller effect. This situation is frequently encountered, for example, in molecules which are in highly excited electronic Rydberg states[199] and in compounds with transition metals.[21–23,26] Thus, in the energy range from 0 to 0.54 eV, the iron molecule $Fe_2(^7\Delta_u)$ has 112 electronic states.

With the aid of the pseudo-Jahn–Teller effect, it is possible to explain in many instances the shape of the molecule—for example, the stability of the planar form of the ammonia or methane molecule.[204] It is also noteworthy that the mathematical formulation of a theory of this effect helped to justify and extend the Woodward–Hoffmann orbital symmetry conservation rules.[205] Furthermore, it is also possible to obtain other useful results of a qualitative character; for example, one can explain the characteristics of the mutual influence of ligands, the relative stabilities of the isomers of coordination compounds, the geometrical features of metalloporphyrin molecules, etc.[204] In certain cases, recommendations concerning the formulation of the experiment in order to observe a new phenomenon follow from the theory.

The main task in the future application of the vibronic inter action theory lies apparently in the field of chemical reactions. It may be hoped that the existing theory will permit a deeper understanding of the mechanisms of elementary chemical reactions. The applications of the theory to the solution of certain problems in materials science (see below), in the theory of structural phase transitions, and in other applied problems, may prove very useful. At the same time, it is important to improve the theory itself: to learn to perform calculations correctly in the presence of a large number of

closely spaced states, in the presence of the spin–orbit interaction, etc.[22,23,206]

The manifestation of non-adiabatic conditions for unbound states, for example, in collisions between molecules, consist in the fact that, under its influence, any regular system can under certain conditions undergo a non-radiative transition with a finite probability from one electronic energy state to another having the same symmetry. For this, it is essential that the nuclei (the "slow" subsystem) should fall within the region of the configuration space where these energy states are at fairly short distances from one another and the rate at which the nuclei move is not too low. This effect plays a primary role in non-radiative transitions, in electronic relaxation, in the theory of non-elastic and reactive collisions, etc.[29,34,94,95,207] Situations are encountered in which non-adiabatic transitions occur between vibronic energy states, and not simply between electronic states, under the influence of a strong vibronic interaction.[99]

It has been demonstrated in recent years that, by analogy with the theory of the non-adiabatic transitions in atom–molecule collisions, it is possible to devise a theory of the interactions of radiation with molecules.[208,209] This analogy is based on the concept of quasi-energy.[210] In the theory, which has so far been constructed for diatomic molecules, a wide variety of situations are observed, not all of which are encountered in atom–molecule collisions. This applies, for example, to the resonance Raman scattering, hot luminescence, and related phenomena, which can be treated from a single standpoint.[211]

The problems associated with non-adiabatic transitions are extremely varied. If one considers molecular collisions, then it is important to learn to calculate the probabilities of non-adiabatic transitions for multidimensional PES. Hitherto, theoretical studies have been restricted to cases where the PES depends only on one or at most two coordinates.[29] In certain cases more stringent requirements are imposed on the accuracy of the calculations of the PES, for example when the region of the quasi-intersection of the energy states is calculated. A fairly high accuracy is then essential for a reliable calculation of the probabilities of non-adiabatic transitions taking into account tunnelling.[29]

With the aid of the model of non-adiabatic transitions between quasi-energy surfaces, it is possible to formulate the important problem of the dynamics of electronically excited polyatomic molecules. For this purpose, it is necessary to extend the dynamic theory of non-resonance Raman scattering developed for diatomic molecules.[209,211] Further development of the theory of the interaction of a strong alternating field with molecules,[212] the dynamic theory of multiphoton processes in atoms and molecules,[213] etc. is also important. In particular, such a theory can indicate a way of determining the parameters of the non-adiabatic linkages in molecules from experimental scattering intensities and phase relations.

V. DEVELOPMENT OF THEORIES OF THE APPLICATION OF PHYSICAL RESEARCH METHODS TO CHEMISTRY

Theory has always played a significant role in the development of ways of applying physical methods to chemistry. It is sufficient to recall the Debye method for the determination of the electrical dipole moments or the theory of optical spectra without which molecular spectroscopy would simply not exist and which has in fact become the basis of the theory of molecular structure. Hundreds of such examples could be quoted. The corresponding theories have become an inseparable component of quantum chemistry. Among recent studies along these lines, mention should be made of the theoretical justification of the multipulse NMR method, which made it possible to resolve the fine structure of NMR spectra of solids and which has proved exceptionally important to chemistry,[214,215] the development of a theory for the investigation of the character of molecular motion in a condensed medium with the aid of a paramagnetic label,[216] and proof of the possibility of using the angular anisotropy of the Auger spectra for the investigation of the geometry of surface layers and adsorbed molecules.[217]

The appearance of a new physical method useful for chemistry frequently begins with the discovery of some kind of physical phenomenon which serves as the basis for a new research method after the appropriate theoretical interpretation. Theoreticians sometimes suggest how an existing method should be modified or amplified in order to apply it to chemical objects and to obtain a new type of information. Several theoretical problems whose solution may culminate with the creation of new experimental research methods in chemistry are quoted below as examples.

(1) Physicists have learned how to obtain beams of polarised electrons. The diffraction of such beams by the surface of a solid can undoubtedly yield unique information about the magnetic and spin states of the surface. However, it has so far been possible to obtain polarised beams only at very low temperatures and in an ultrahigh vacuum and the intensity of the beams has been low.[218] This very greatly restricts the scope of their application. The task for quantum chemists is, on the one hand, to find systems which polarise electrons under less severe conditions and ensure a sufficiently high intensity of the beams and, on the other hand, to develop a theory of the diffraction of polarised electrons in relation to chemical problems.

(2) It has been recently discovered that, when fast molecular ions pass through films, their electron clouds are "stripped off" and the molecule decomposes into charged fragments which fly apart under the influence of Coulombic forces ("Coulombic explosion").[219] The angular and energy distributions of these fragments can, generally speaking, reflect both the structure of the initial molecular ions and the properties of the film. It is extremely likely that the development of the appropriate theory will permit the creation of a new research method.

(3) The method for the indirect detection of electron magnetic resonance (IDMR), for example, detection with the aid of luminescence, made it possible, by virtue of its high sensitivity, to obtain much unique information about the intermediate species in chemical reactions, about the mechanism of the transfer of valence, etc.[220,221] It is promising and feasible to apply the IDMR method to the study of a process involving charge transfer between ions in the liquid phase. It is also of interest to examine the question of the specific features of the application of the IDMR method to the study of processes on the surface of a solid. It is natural to begin the solution of these problems with the development of appropriate theories.

(4) It is known that, under the conditions of a shock wave in the solid phase, many interesting effects are observed, for example, intense polarisation of the specimen, a change in the direction and rate of reactions, etc.[222,223] Apart from high pressure, a high temperature is characteristic of a shock wave. It would be very attractive to create a theoretical model of such processes and to show experimenters what experiments should be formulated in order to test the model and then to explain the observed effects at the molecular level and possibly to create a new method for the investigation of shock waves.

(5) Laser chemistry has so far taken only the first steps. It is known that the chemical action of the laser beam can involve not only the selective excitation of vibrations but also the excitation of the electron cloud.[224] For example, appropriate action by a laser entails the ready occurrence of the reaction[225]

$$Na + HgCl_2 \rightarrow NaCl + HgCl$$

The laser method for the separation of isotopes is based on the selective excitation of electrons. The task for quantum chemistry is to develop a detailed mechanism of the reactions of the laser-excited species and to recommend how experiments should be set up in order to achieve the catalytic action of the laser beam on chemical reactions.

VI. APPLIED PROBLEMS

1. Materials Science; Computer Search for New Compounds and Materials

As mentioned above, quantum chemistry has always served as the foundation which ensured the development of new ways of investigating matter and even the creation of whole branches of natural science, which ultimately has had enormous practical importance. It is sufficient to recall molecular spectroscopy mentioned above, which would be unable to solve many applied problems without the appropriate quantum-chemical theory. However, apart from such indirect influence on practice, quantum-chemical methods are resorted to with increasing frequency for the direct solution of specific applied problems, for example, the problems arising in materials science. One may quote a series of examples where quantum-chemical calculations proved useful in determining the relation between the macroscopic properties of materials and their atomic-molecular structure and ultimately in the solution of technological problems.

We may mention the calculations of diffusion coefficients in solid materials as one such example. These calculations are of special interest if the study of diffusion is hindered as a consequence of say, high radioactivity. Theoretical investigation of diffusion at the atomic-molecular level is also important in order to be able to understand the mechanics of the process and to create a basis for the treatment of more complex transport processes.[226] A model calculation of the activation energy for the diffusion of helium in nickel made it possible to understand the nature of the potential barrier and to elucidate the role of electronic relaxation and of the degree of involvement in the process of various electron layers of the nickel atom.[226,227]

Calculations of the physical characteristics of impurities and of their influence on the properties of materials are also important. For example, the geometrical and energy characteristics of the impurity centre, its influence on the intrinsic defects in the solid, etc. have been calculated by quantum-chemical methods. Such calculations for impurity carbon in iron helped to explain many effects important for engineering.[226]

Quantum-chemical methods have helped in the solution of certain problems of interest for the theory of solar cells, for example, the probabilities of the non-radiative decomposition of excitons in solid hydrogen fluoride have been calculated.[226]

An interesting quantum-chemical calculation has been performed to elucidate the mechanism of the oxidation (and inactivation) of a graphite moderator in a nuclear reactor. Calculations showed that the oxidation takes place at defects on the graphite surface and that the diffusion to these defects of molecules such as those of H_2O and CH_4 is much faster than the diffusion of oxygen. The addition of a small amount of, for example, methane to the coolant (CO_2) slows down the oxidation of graphite, because methane rapidly occupies its active centres.[226]

Quantum-chemical calculations have made an important contribution to the solution of the problem involving the search for the optimum accumulator (carrier) of hydrogen as a source of chemical (fuel) and nuclear energy.[228] Transition metal alloys are usually employed for this purpose. Calculations permitted the determination of the maximum possible store of hydrogen in the given alloy and showed, in particular, that amorphous bodies are capable of carrying more hydrogen than crystals of similar composition.

The development of the theory of the Jahn–Teller effect led to the prediction of a practically important phenomenon—giant magnetostriction.[201,229] The theory has been confirmed experimentally.[230]

One may point to a striking example where quantum chemistry played an important role in the solution of one of the fundamental problems in the physics of elementary particles—in the determination of the true mass of the neutrino at rest. Kaplan and co-workers[231,232] investigated the rearrangement of the electron clouds of a number of molecules of tritiated hydrocarbons and certain other compounds occurring on β-decomposition. The results of the calculations were used to interpret experiments designed to find the rest mass of the neutrino.[233] Analogous but more accurate calculations were subsequently performed by other workers.[234,235]

An increasing tendency to calculate by quantum-chemical methods the stability and properties of compounds which have not yet been synthesised, to make recommendations for the optimisation of the conditions and pathways leading to the synthesis of new medicinal preparations, etc. has been observed in recent years. For example, the stability of the C_{60} molecule, which, in view of its spherical shape has been called footballene, has been demonstrated theoretically.[236,237] Its stability was predicted as early as 1973 by the Hückel method.[238] Footballene has not yet been synthesised, but there are experimental data confirming its existence and high stability.[239,240] We may also note that quantum-chemical calculations have helped in the synthesis of a new effective antibiotic—quantamycin.[241] According to the recommendation arising from the quantum-chemical calculations, it has the composition and structure such that the negative qualities of its analogue (lincomycin) are eliminated.

The computer assisted search for new chemical compounds and materials with properties specified beforehand and the development of the optimum methods of their synthesis will undoubtedly be expanded still further in the immediate future Computer modelling will also be directed to the search for means of protecting materials against radiation,[242] the study of their behaviour under extreme conditions, and the solution of many other problems important for practical purposes.[243]

2. Quantum Molecular Biology

One of the most important fields in which quantum chemistry has been applied is molecular biology. During the last decade, considerable progress has been seen in this direction and has been represented increasingly at international congresses and conferences on quantum chemistry; conferences devoted specifically to this topic have also been organised. Analysis of the relevant questions is outside the

scope of our task. However, in order to demonstrate the specific features of this extensive field, we shall quote one example.

The striking selectivity of photochemical biosynthesis is known: under natural conditions, billions of tonnes of green matter are generated each spring in several weeks virtually without waste, while under laboratory conditions in analogous processes the yield of the required product reaches no more than 50%. The question arises what is the mechanism of this surprising single-channel nature of the process (purity of the biosynthesis), which is comparable to the selectivity of the action of enzymes. Quantum chemistry should help in the solution of this problem.

The specific features of molecular biology and the exceptional advances in gene engineering give grounds for the expectation that the use of biomaterials and biotechnology is more promising for the creation of the new generation of electronic computers[244] than that of the usual chemical compounds and methods.[245] Theoretical analysis of the possible versions of the structure of the constituent elements of a biocomputer is a task of current importance, to the solution of which modern quantum chemistry can make a definite contribution.

It must be emphasised that many major problems in molecular biology and pharmacology can be solved and are already being solved with the aid of computer modelling. These problems include, for example, the prediction of the biological activity of chemical compounds.[246,247] The simplest version of such predictions is as follows. The structures of a series of compounds, already known as active in the desired sense, are calculated quantum-chemically, the structural and electronic feature characteristic of the given activity are established, and new compounds having these features are then synthesised.

VII. DEVELOPMENT OF QUANTUM-CHEMICAL METHODS

As mentioned above, effective research methods have now been developed in various fields of quantum chemistry. Powerful procedures have been created in the theory of elementary processes in the gas phase, in the theory of magnetic, electronic, and vibrational relaxation of condensed phases, theoretical methods for reactions in solutions, theories of the interaction of matter with radiation, and many others have been greatly developed. Considerable efforts by theoreticians and mathematicians have been directed to the solution of the many-electron problem. Here studies have been prosecuted in two directions: (a) the improvement of semiempirical computational methods; (b) the development of effective non-empirical computational methods (calculations from first principles—*ab initio*). *Ab initio* methods have been developed mainly by expanding the initial basis set of one-electron functions in order to achieve the maximum possible approach to the Hartree–Fock limit and to develop effective methods for taking into account the correlation of electrons.[248]

At one time it appeared that non-empirical calculations should displace the semiempirical methods, because the former are more rigorous and in the limit yield accurate results. However the improvement of *ab initio* methods was very slow: on average (according to the data over a period of 20 years) the size of the systems in which it was possible to take into account correlation effects increased only by one and a half electrons per year.[249] The chemistry of large molecules therefore developed independently of these calculations. Furthermore, it was found that, as the non-methods are improved and the number of electrons in the system is increased, there is a catastrophic growth in the necessary computer time, which leads to a dramatic increase in the cost of calculations. When ultrafast computers (supercomputers) are used, the machine time is shortened, but the cost of the calculations does not fall but actually increases (approximately by a factor of 100) as a consequence of the increase in the cost of the work of the computer per unit time.[250]

Thus the view that *ab initio* calculations on molecules with a high degree of accuracy are not promising for the majority of chemical fields, since such calculations have to be confined in practice to comparatively small molecules, merits consideration. The problem of the development of sufficiently effective semiempirical methods, which would be comparatively cheap and "fast" and which would reproduce correctly the principal characteristics of molecular systems therefore comes to the fore. Certain promising approaches to the improvement of semiempirical computational methods have been published recently. For example, on the basis of the idea put forward by Burshtein and Isaev,[251] Dewar[250] proposed a new version of a semiempirical method, which is almost free of the most significant disadvantages of the previous versions.

It is possible to find in the literature a number of convincing examples where the semiempirical calculations, using the already existing methods, proved to be extremely useful and were found to have a predictive power (see, for example, Refs. 252–262), although, as is well known, not all the properties of molecules can be reproduced with equal adequacy by such calculations.

Together with this, there remains naturally the task of finding new methods for the solution of the many-electron problem. Such methods are essential in the first place for calculations on very large molecules, for which entirely satisfactory methods have not yet been created.[263] It may be that here one should abandon the standard procedure involving a simple extension of the models existing for small molecules and that an attempt should be made to find new modelling methods. The method of the density functional[264–267] merits attention. One cannot rule out the possibility that progress in computational quantum chemistry will be achieved using approaches in which wave functions do not appear at all.[263] Mention should also be made of a promising but more specific possibility of studies where new (sometimes quite unexpected) relations are established between different properties of molecules or physical quantities, without solving the Schrödinger equation, on the basis of general theorems such as the Hellmann–Feynman theorem or the hypervirial theorems.[268]

The following comment should also be made concerning non-empirical calculations and the prospect of obtaining with their aid highly accurate results. As the calculation becomes more accurate, there is a gradual abandonment of simple models. In the limit of the "accurate" calculation, the clarity of the results is completely lost; as in the case of an experiment, the latter must be re-interrupted anew, since otherwise the result of the calculation will be merely a "dead" numerical value. In other words, even after very extensive computerisation of quantum chemistry the physical model will not lose its heuristic role. The development of science during the last 10–20 years confirms this view. It is sufficient to recall, for instance, the role which orbital symmetry conservation rules[1] or the concept of frontier orbitals[2–4] have played and are playing in the development of chemistry. Such generalisations are perhaps more important for progress in science than hundreds of other laborious calculations.

The same may be said also about other ways of applying computers in quantum chemistry. The method of molecular

dynamics and the method of statistical sampling (the Monte Carlo method) can only supplement but not replace studies based on physical models. Clearly, there exist very complex processes which cannot be investigated by procedures other than those involving computer modelling.

It is known that the computer itself does not generate directly new physical or chemical ideas. It is a means for the completion of the development of a new idea or a new method and in this sense computers play a very important but subsidiary role in the development of science. At the same time, one should also bear in mind two factors. In systematic studies using a computer, the investigator acquires a new ("computer") form of thinking: a computer experiment suggests to him an effective way of solving the problem which is in essence associated with the computer. Thus, a kind of feedback is generated. The Luzanov method—the method for the operator reduction of the density matrix—may serve as an example of such a situation.[269] It is based on the idea of developing a mathematical apparatus for taking into account the correlation effects which could be readily translated into machine language. The specific features of computers suggested that an algebraic apparatus can serve for this purpose. With its aid, the author was able to develop a method which takes into account effectively configuration interaction without an explicit use of wave functions.

The second factor is associated with the fact that the computer is in essence an effective instrument for carrying out a kind of computer experiment. If one expects from such an experiment not a simple individual numerical value of some kind of parameter but a broader kind of information about the test system, then as in any experiment, the results have to be interpreted after the completion of the calculations. Such interpretation can lead to the appearance of new representations and new ideas important for the solution of the problem as a whole and in this way the computer can prove to be an indirect source of new ideas.

Fundamental ideas in quantum chemistry are known to have appeared before the invention of computers. Among them one may include the Heitler–London method (1927), the idea of molecular orbitals [Hückel, Mulliken (1930–1932)], the crystal field–ligand field theory [Boethe, Van Vleck (1929–1935)], the self-consistent field method [Fock (1930)], the Jahn–Teller theorem (1937), the transition state method [Eyring, Polanyi (1935)], the Kramers method in the theory of reactions (1940), and others. Unfortunately one should note that by no means all the major ideas were properly understood and adopted sufficiently rapidly. This happened with ligand field theory, whose principles are being introduced into chemistry only after 25 years had elapsed since the first publications; the Jahn–Teller theory appeared in the scientific literature for more than a quarter of a century as an elegant artifice without experimental confirmation and application; the Kramers method remained unknown to chemists for more than 30 years. As a result of the last factor, virtually no account was taken for a long time of dynamic effects, as mentioned above, in the theory of reactions in solutions. The task for theoreticians apparently consists, in particular, in helping the penetration of new ideas into practical experimental research.

---o0o---

It follows from the foregoing that quantum chemistry has been playing an increasingly important role in the development of chemistry as a whole and has been making increasing contributions to practical research and to new technology. This mission of quantum chemistry is being achieved in conjunction with experiment. The task is to strengthen comprehensively such linkages with experiment, to strengthen the influence of theory on experimental research, and to seek new ways of applying physical research methods in chemistry. At the same time it is necessary to improve quantum-chemical methods and to develop effective and cheap methods for calculations on molecular systems. It is to be expected that the general trends in the development of quantum chemistry in the coming years will involve the theory of chemical reactions, theoretical materials science, and molecular biology. The advances in the development of these theories during the coming decades may prove comparable to the advances in the theory of molecular structure during the last 20–30 years.

Layered Silicates as Catalysts

M.I.Rozengart, G.M.V'yunova, and G.V.Isagulyants

The structure of layered silicates, mainly smectites, and the synthesis of similar minerals, including fixed clays with pores exceeding in size the inlet apertures in zeolites are examined. Such clays are capable of catalysing the reactions of even large molecules, having a kinetic diameter in excess of 1.0 nm, which cannot penetrate into zeolite cavities for steric reasons. Certain reactions occuring in the presence of layered and fixed clay minerals are considered.
The bibliography includes 184 references.

I. INTRODUCTION

Clays, which form part of the group of natural layered aluminosilicates, have long been used for the purification and clarification of petroleum fractions by virtue of their adsorption properties. Much later clays came to be used as catalysts of organic reactions.

The advances in catalysis in the presence of amorphous aluminosilicates[1] and then synthetic crystalline aluminosilicates (zeolites)[2-6] diverted attention from the application of clays as catalysts and greatly weakened the interest in research on these lines. However, during the last decade, numerous studies have again been published on the application of layered silicates as catalysts of organic reactions.[7-11] This was promoted by the brilliant successes in the synthesis of minerals, including clay minerals, and the appearance of new refined methods for the determination of their structure and properties. A new class of catalysts, which are called "pillared sheet silicates" and also cross-linked or fixed layered silicates, were created in the 1970s. There is virtually no information about them in the Soviet literature. The appearance of fixed layered silicates, including clays, coincided with the time when interest was aroused in compounds resulting from intercalation in layered substances such as graphite,[8-12] clays,[7-11] phosphates, and certain other compounds of quadrivalent metals.[8]

Layered silicates, including clays, constitute three-quarters of the sedimentary rocks in the Earth's crust.[13] Their deposits have been created as a result of the weathering of hyperbarites, basalts, granites, and especially volcanic ash, glasses, tuffs, and different types of pumice. The principal chemical components of layered silicates are SiO_2 (30–70%), Al_2O_3 (10–40%), and H_2O (5–10%). Among the clay minerals constituting the basis of clays, which have found applications as adsorbents and catalysts, mention should be made of the kaolinite $[Al_4](Si_4O_{10})(OH)_8$.[9,10] Various smectites, capable of swelling, including the dioctahedral smectites[9,10] (see Fig. 2 below), montmorillonite $M^{n+}_{x/n}[Al_{4-x}Mg_x](Si_8)O_{20}(OH)_4$ and beidellite $M^{n+}_{x/n}[Al_4](Si_{8-x}Al_x)O_{20}(OH)_4$, and the trioctahedral smectites hectorite $M^{n+}_{x/n}[Mg_{6-x}Li_x](Si_8)O_{20}(OH, F)_4$ and saponite $M^{n+}_{x/n}[Mg_6](Si_{8-x}Al_x)O_{20}(OH)_4$ are of greatest interest. Vermiculites, which swell with much more difficulty, as well as the micas muscovite $K_2[Al_4](Si_6Al_2)O_{20}(OH)_4$ and phlogopite $K_2[Mg_6](Si_6Al_2)O_{20}(OH)_4$, where M are exchangeable cations are also layered silicates; the cations forming part of the composition of the octahedral layer are enclosed in square brackets (see Section II) and the cations forming part of the composition of the tetrahedral layer are indicated in round brackets (again see Section II). In reality, the composition of real clay minerals may differ from the idealised formulae quoted above. Furthermore, clays usually contain different admixtures: carbonate, gypsum, iron oxides, etc. as well as plant or animal residues. All the most important properties of clays and clay minerals depend mainly on the chemical and mineral composition and the proportions of different grain sizes.

Pure montmorillonite clays (bentonites), industrial deposits of which exist in various regions of the USSR, have acquired the greatest practical importance as sorbents and catalysts. Mainly montmorillonites and hectorites, both natural and synthetic, constitute the basis of a new type of fixed layered aluminosilicate catalysts.

II. THE STRUCTURE OF LAYERED SILICATES

The majority of layered silicates are made up mainly of two structural fragments:[16-19] a network of silicon–oxygen tetrahedra SiO_4 (the *T*-network) and the network of aluminium-oxygen octahedra $Al(O, OH)_6$ (the *O*-network). In the ideal model, it is assumed that the sizes of the tetrahedra and octahedra are comparable, the Si^{4+} ions being located in the centres of the tetrahedra whose vertices are occupied by oxygen ions. Each O^{2-} ion, lying in the basal plane (the plane comprising oxygen triads lying at the bases of the tetrahedra) of the *T*-network, made up in accordance with the hexagonal motif, joins together two tetrahedra (Figs. 1*a*, 1*b*, and 1*c*). The octahedra, in the centres of which aluminium or magnesium ions are located, sometimes substituted by the ions of other elements, have edges in common, on which there are two common oxygen ions, and form the *O*-network, also in accordance with a hexagonal motif (Fig. 1*d*). Depending on the valence of the cations and on the degree of occupation of the *O*-positions by them, dioctahedral networks arise (Fig. 2). The octahedra in the dioctahedral networks are populated mainly by tervalent cations (Al^{3+}, Fe^{3+}), pairs of such octahedra meeting at a common lateral edge; trioctahedral networks include predominantly bivalent cations and three octahedra meet at a common lateral edge in each case.

The Si^{4+} cations in the *T*-network can be isomorphously substituted by Al^{3+}, Fe^{3+}, etc. ions, while the Al^{3+} ions in the *O*-network can be similarly substituted by Mg^{2+}, Fe^{2+}, Li^{+}, etc. ions. The substitution of a cation by an ion with a lower valence leads to the appearance of one negative charge in the layer, which creates conditions for the manifestation of acid properties by the clays. In those cases where charge-compensated substitution takes place, for example, the substitution of $2Al^{3+}$ by $3Mg^{2+}$, the charge of the layer does not change [see Barrer[7] (p.538) and also Osipov[18]].

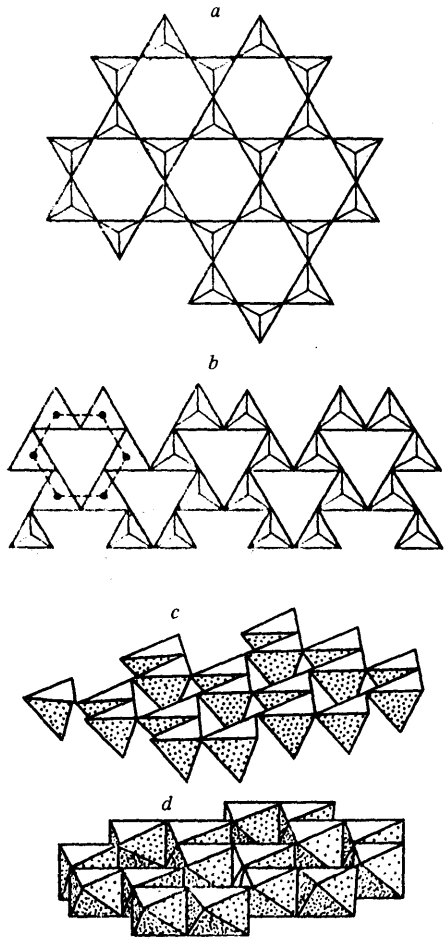

Figure 1. Models of the principal structural fragments of layered silicates:[7,8,17] *a*) and *b*) tetrahedral silicon–oxygen networks (*T*-network) (in the hexagonal motif in Fig.1*b*, the dots indicate the apical oxygen atoms of the tetrahedra and the dashed lines designate their hexagonal disposition); *c*) *T*-network in the axonometric representation; *d*) octahedral network (*O*-network) in the axonometric representation.

The *T*- and *O*-networks are joined together via the O^{2-} ions, forming layers made up of two, three, and more networks (Figs.3 and 4) constituting the basis of various clay minerals. All the vertices of the tetrahedra in each *T*-network are rotated towards the *O*-network. Kaolinite, for example, belongs to structures made up of two-network layers (1:1) and containing one *T*-network and one *O*-network in each case. Smectites (montmorillonites, hectorites, and hydromicas), vermiculites, as well as micas have a structure in which two *T*-networks are joined to an *O*-network between them (2:1, *TOT*-minerals). The distance *d* from the *T*-network of one layer to the *T*-network of an adjoining layer arranged in the same way and the size Δd of the gap between the layers are characteristic parameters of layered silicates (Figs.3 and 4).

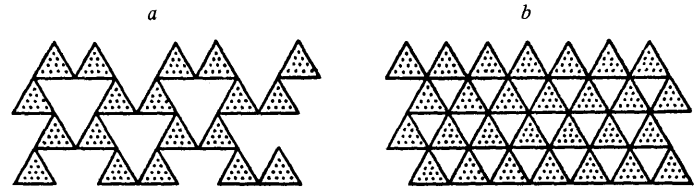

Figure 2. Types of octahedral networks:[16,17] *a*) dioctahedral; *b*) trioctahedral (only the upper faces of the octahedra are represented).

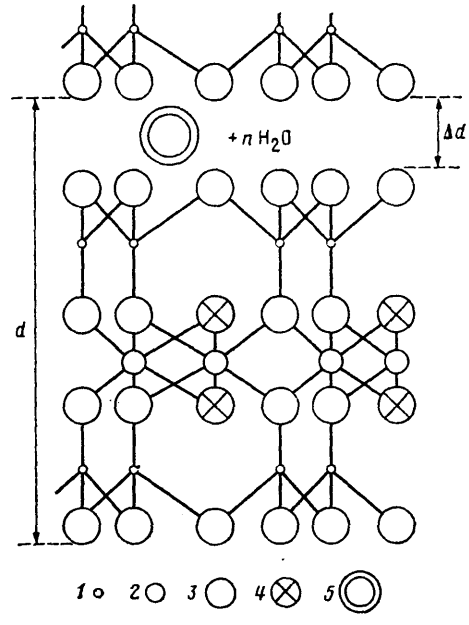

Figure 3. Schematic representation of the structure of montmorillonite:[7,8] 1) Si; 2) Al; 3) O; 4) OH; 5) intercalated cations.

In real clay minerals, the bases of the tetrahedra are not located in one plane, the cations being displaced relative to the tetrahedra and the pattern of the *T*-network differing from the ideal hexagonal motif. The octahedra are frequently flattened in the direction at right angles to the

planes of the networks. A twist in the arrangement of the octahedra in the dioctahedral network in the plane coplanar with the basal plane has been noted, which also distorts the planar surface and its hexagonal motif.[16] This influences strongly the structure of layered silicates: the dimensions of the tetrahedra and octahedra cease to be comparable, the surfaces of the octahedra become non-coplanar, and the basal surfaces of the layers acquire an irregular wavy structure.

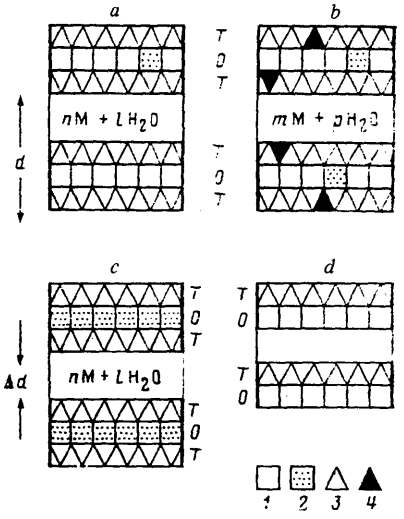

Figure 4. Schematic representation of the structures of certain layered silicates according to Frank-Kamenetskii et al:[16] *a*) montmorillonite; *b*) hectorite; *c*) vermiculite; *d*) kaolinite; 1) aluminium–oxygen octahedron; 2) magnesium–oxygen octahedron; 3) silicon–oxygen tetrahedron; 4) aluminium–oxygen tetrahedron; M = intercalated cations.

In the layered silicates having the *TOT*-structure, the gap between the layers is made up of the isotypical surfaces of the *T*-networks, which are held by the dispersion forces of the silicon–oxygen tetrahedra and by the electrostatic forces arising between the negative charges of the opposite layers and the cations (mostly Na^+ and Ca^{2+}) located between them. Depending on their size, the cations are fully or partly "pressed" into the free space between the tetrahedra, generating an additional force drawing the layers together. In terms of this capacity, the ions can be arranged in the series Li < Na < K < Mg < Pb < NH_4 < Co < Al[19] (p.179). However, this sequence frequently breaks down. Thus if the sizes of the cation and of the apertures of the *T*-network are similar, then such a cation is held more strongly.

The space between the layers in many layered minerals having the *TOT*-structure, such as smectites, vermiculites, etc. contains a certain number of water molecules involved in the formation of the mineral. These molecules prevent the collapse (complete adhesion) of the layers. The layered and two-dimensional primary porous structure arises in this way (it is denoted in the literature by 2*D* or 2*d* in contrast to the three-dimensional 3*D* or 3*d* porous structure of zeolites).

Cations are also located on the lateral surfaces of the crystals. Like the interlayer cations, these can be readily exchanged for a wide variety of inorganic and organic cations. Furthermore, as a result of the abrupt termination of the *T*- and *O*-networks, valence-unsaturated atoms capable of adsorbing ions and molecules are formed on the lateral surface. It has been suggested that up to 80% of the exchangeable cations are present in the interlayer space and up to 20% on the lateral surface[7] (p.537).

The crystals of clay minerals are joined together into small scale-like, ribbon-like, or tubular particles sometimes of colloidal size, which tend to aggregate and generate a secondary porous structure between the particles.[8,20,21] Table 1 presents data on the shapes and dimensions of the particles of certain clay minerals.

Table 1. The shapes and dimensions of the particles of certain layered silicates.[7,9]

Mineral	Shape of particles	Particle size, μm
Kaolinite	Hexagonal plates, frequently well formed, sometimes elongated	Width 100–4000; thickness 50–2000
Montmorillonite	Poorly differentiated shapes, rarely hexagonal, characteristic tendency towards formation of aggregates of particles	Diameter up to 1000 and above; thickness 1–20
Hectorite	Thin elongated plates	Length up to 3000; width ~100; thickness 1–2 and above

The occurrence of reactions between organic substances in the interlayer space in smectites at high temperatures (in excess of 200 °C) is prevented by the dehydration of the clays and the collapse of the layers induced by this. The temperature-dependent limitations imposed by the collapse can be overcome by introducing into the interlayer space thermally stable bulky cations which act as a kind of pillar and fix the layers at a specific distance preventing them from adhering closely after the removal of water or a solvent. This way of fixing the layers made it possible to create a new class of aluminosilicate catalyst—pillared sheet silicates.

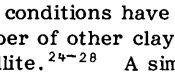
III. THE SYNTHESIS OF LAYERED SILICATES

Clay minerals of constant composition, contaminated to a minimal extent by extraneous impurities (which is especially important for the development of catalytic systems), can be obtained synthetically. Layered silicates are synthesised under hydrothermal conditions (100–400 °C) or by fusing together mixtures of the initial oxides at 800–1500 °C.

The results of studies on the hydrothermal preparation of kaolin, montmorillonite, pyrophyllite, and other clay minerals at an increased pressure have been summarised in a review.[22] The conditions in the formation of montmorillonite have been examined and its properties described.[23] Montmorillonite is formed in alkaline media and the results of the synthesis are appreciably influenced by magnesium (in contrast to other cations).

It has been established that the dioctahedral montmorillonite is formed with a relatively small MgO content in the mixture of the initial oxides. With increase in the MgO content

in the mixture, a small admixture of a trioctahedral smectite is formed initially and this is followed by the appearance of large amounts of the latter. In order to obtain a well crystallised product, the hydrothermal treatment is carried out for several (6–7) days.[31] A decrease in the duration of the hydrothermal treatment entails a proportionate decrease in the exchange capacity of the mineral.[31] The influence of temperature and pressure on the formation of montmorillonite in the SiO_2–Al_2O_3–H_2O[29] and SiO_2–Al_2O_3–MgO–H_2O [30] systems has been studied in detail and the regions corresponding to the formation of montmorillonite and other minerals have been described with the aid of phase diagrams.[30] Depending on the pH of the mixture, it is possible to obtain a clay mineral with the *TO*- or *TOT*-structure. Thus the addition of HCl to the initial mixture leads to the formation of kaolinite, while the addition of NaOH induces the formation of montmorillonite.[32]



Hydrothermal conditions have also been used in the synthesis of a number of other clay minerals, for example, kaolinite and beidellite.[24–28] A simple method of synthesis of various clay minerals from a mixture of natural sand (or artificially precipitated SiO_2) and aluminium hydroxide (or $AlCl_2$) has been described.[32] The methods of synthesis of the so called "fluorotetrasilicate micas", in which some or all the hydroxy-groups have been replaced by fluorine atoms, have been developed vigorously in recent years,[33–36] especially by Japanese investigators. The fluorotetrasilicate micas constitute the basis of catalysts of a new type with a high thermal stability. The fluorohectorites obtained after the replacement of OH groups by fluorine are stable up to 800 °C [7] (p. 469). The OH groups can be replaced by fluorine atoms also in the hydrothermal treatment of a freshly prepared smectite with a solution of NH_4F or other water-soluble fluorine compounds.

Much attention has been devoted to the synthesis and study of the catalytic properties of the so called mica-montmorillonite,[37–40] which consists of a multilayered mineral with a random packing of mica and montmorillonite layers and an overall mica content ranging from 1/6 to 5/6. This mineral is frequently synthesised in such a way that it contains transition metal ions,[41–43] mainly nickel ions,[41,42] in the octahedral network. The composition of the product obtained by Heinerman's method[41] corresponds to the chemical formula $(Al_{1.08}Ni_{4.38})(Si_{6.62}Al_{1.38})O_{20}(OH)_{3.24}F_{0.76}(NH_4)_{1.38}$. As mentioned above, to prevent the layers from sticking together on raising the temperature, they are fixed at an appropriate distance.

The fixation of clays was first proposed more than 30 years ago.[44] In order to attain a constant porosity in clays, tetraalkylammonium ions have been used. However, the prospects for the employment of clay minerals in order to develop catalysts of a new type arose only when the fixation was achieved with the aid of inorganic compounds, namely the oligomeric aluminium and zirconium and then bismuth, chromium, etc. hydroxo-cations (Table 2). The insertion of an oligocation in clay minerals takes place fairly readily as a result of exchange with the interlayer cations. At the same time, in the presence of an excess of Al_{13} oligocations, the amount of bound aluminium calculated per unit cell varies within narrow limits (2.78–3.07), is not correlated with the charge determining the exchange capacity of the clay, and is independent of the charge distribution among the layers, which is extremely non-uniform in smectites and can vary from layer to layer by a factor of two.[60,61] This led to the hypothesis[62] that the adsorption of the oligocation entails the formation of a more or less uniform monolayer of polyoxo-cations on the surface of the clay. In this case the distance between the pillars is determined by the radius of the hydrated cations, which can in fact account for the uniform distribution of the pillars in the interlayer space after the dehydration of the fixed smectite.

The introduction of aluminium and zirconium oligocations leads to the formation of thermally stable clays exhibiting molecular-sieve and catalytic properties and having a specific surface of 200–500 $m^2\ g^{-1}$ and an interlayer gap Δd in excess of 0.9 nm.[49,50,63–68]

Table 2. Compounds used for the fixation of clays.

Name	Formula	θ, °C *	Refs.
Tetraalkylammonium	Alk_4NH	<250	[7, 44]
Bicyclic amines		<250	[45, 46]
Fe(II) and Cu(II) metal chelate complexes	$[Fe(2,2'\text{-bipyridyl})_3]^{2+}$; $[Cu(1,1'\text{-phenanthroline})_3]^{2+}$	<450	[47, 48]
Al oligocations	$[Al_{13}O_4(OH)_{24}(H_2O)_{12}]^{7+}$; $[Al_{26}O_8(OH)_{52}(H_2O)_{20}]^{10+}$	>500	[49]
Zr oligocation	$[Zr_4(ON)_{12}(H_2O)_{12}]^{4+}$	~800	[50–52]
Bi oligocation	$[Bi_6(OH)_{12}$	>500	[13]
Cr oligocation	—	>500	[53, 54]
SiO_2 polymers	—	>600	[55–58]
Nb and Ta complexes	$[M_6Cl_{12}]^{2-}$	>600	[59]

* Thermal stability of fixed clays (natural clay is stable up to ~200 °C[7]).

As can be seen from Table 2, fixation increases the upper limit to the thermal stability from 200° to 550–800 °C. The fixation of clay minerals by oligomeric hydroxo-cations makes it possible to obtain aluminosilicates with a regular structure, the size of the cavities in which is significantly greater than in coarsely porous zeolites, including faujasites. This led to the possibility of using fixed clays for the catalytic reactions of large molecules, to which the internal surface of zeolites is inaccessible.

The aluminium oligocation (known in the U.S. industry as "chlorohydrol") is used most widely as a fixing agent and has been more thoroughly investigated than other such agents. It can be obtained by various methods: by dissolving metallic aluminium in a boiling solution of $AlCl_3$ [69] or in an NH_4Cl solution[70] and by hydrolysing $AlCl_3$ dissolved in water with sodium carbonate (either solid or in solution) at 90–100 °C.[71] The use of different aluminium salts yields similar results.[62] It has been suggested that the principal species in the aluminium oligocation is the so-called Keggin cation $[Al_{13}O_4(OH)_{24}(H_2O)_{12}]^{7+}$,[69,72] consisting of a central tetracoordinate Al^{3+} ion surrounded by twelve AlO_4 octahedra joined via the common edges.

In order to increase the molecular weight of the oligocation, chlorohydrol is subjected to ageing by boiling the solution for 1–48 h or by treating it with ammonia, alkali, and metallic magnesium.[66] The Al_{13} oligocation then dimerises with formation of the cation $[Al_{26}O_8(OH)_{52}(H_2O)_{20}]^{10+}$.[66]

The zirconium oligocation is obtained by hydrolysing zirconyl chloride $ZrOCl_2.8H_2O$ in sodium carbonate solution. After the solution has been aged for 24 h, an oligomer having a molecular weight of ~1000 is obtained.[66] The method of fixation of clays described by Vaughan et al.[66] has been used virtually without change in many investigations.

The high thermal stability of the smectites fixed by the Al_{13} and especially Zr_4 oligocations is attributed to the formation of metal oxide clusters as a result of the dehydroxylation of the hydroxo-cations at an elevated temperature. In the case of the Al_{13}-montmorillonite, this reaction proceeds in accordance with the mechanism[73]

$$[Al_{13}O_4(OH)_m \cdot p\,H_2O]^{n+} \rightarrow 6.5\,Al_2O_3 \cdot q\,H_2O + n\,H^+$$

However, there is no information about the structure of the cluster (the so called pillar) or about the disposition of the protons in the oxide compound.

Chromium is also included among the metals capable of forming oligocations.[53,54] The transparent solution of the chromium oligocations obtained from chromium nitrate and ammonium hydroxide is violet in colour. The bentonite fixed by such cations has a specific surface of 165 $m^2\ g^{-1}$ and a micropore volume of 0.03 $cm^3\ g^{-1}$ and d amounts to 1.2–1.4 nm (0.96 nm in the initial clay).

There have been reports[74–76] of the synthesis of Fe-fixed smectites prepared using the trinuclear hydroxoacetatoiron(III) nitrate complex $[Fe_3(OAc)_7(OH)_2(H_2O)].NO_3$. After the clay has been heated, the complex cations, introduced by ion exchange, are converted into oxides, which serve as the pillars; the value of d established is 1.66 nm.

Although fixation with the aid of polynuclear hydroxo-cations makes it possible to obtain stable clays with a large free space between the layers, the number of elements capable of forming the oligomers is limited. Ways of extending the number of fixing agents are therefore being sought. For example, the silicic acid obtained by the hydrolysis of silicon acetylacetonate cations in the interlayer gap[56,57] or of polychlorosilanes[58] can be introduced into montmorillonite. In such cases the clay is usually allowed to swell beforehand in an organic solvent (amine or alcohol). After heat treatment, the inserted SiO_2 is capable of maintaining the layers at a distance of 1.26 nm from one another; the specific surface of the clay fixed by silica and measured with respect to nitrogen is 240 $m^2\ g^{-1}$.

It has been suggested that aluminium and zirconium as well as aluminium and silicon copolymers be used for fixation.[66] The properties of catalysts prepared on the basis of clay minerals cannot be improved by the fixation of the latter. Thus a decrease in the activity of the catalyst was noted[77] when a copolymer of aluminium and silicon was used as the fixing agent. The hydrolysis and oxidation of the cations $Nb_6Cl_{12}^{2+}$ and $Ta_6Cl_{12}^{2+}$ make it possible to obtain fixed clays with an interlayer gap $\Delta d > 1.0$ nm. These clays are stable up to 400 °C.[59]

Whereas the fixation of clay minerals determines their primary interlayer porosity, the secondary porosity between the clay particles depends greatly on the conditions in the drying of the fixed mineral.[62] Thus drying in air gives rise to a product in which the size of the external secondary pores is 0.6–0.9 nm, while the mineral dried by subliming water from the specimen frozen beforehand is capable of adsorbing molecules with a kinetic diameter† greater than 1.0 nm. It has been suggested that drying in air entails close layer-by-layer adhesion of the mineral particles and the volume of secondary pores becomes small. Drying by sublimation promotes a disordered agglomeration of the particles, which gives rise to a larger free pore volume between them.

†The kinetic diameter[62] or the critical diameter[7] (p. 293) is the diameter of the van der Waals section through the molecule.

IV. CERTAIN PHYSICOCHEMICAL PROPERTIES

The most characteristic and important property of clay minerals, especially montmorillonites and to a lesser extent hectorites and vermiculites, is their ability to swell both in water and water vapour as well as in certain polar organic liquids. The molecules of the substances inducing the swelling are inserted into the interlayer space and move the layers apart. For example, when one, two, or three layers of water molecules are inserted in montmorillonite, d increases from 0.95 to 1.24, 1.54, and 1.9 nm respectively. The montmorillonite in which the intercalated cations have been exchanged for Sr^{2+} can give rise to several intercalation compounds with butyrolactone (single-layer, two-layer, and three-layer), for which d is 1.3, 1.8, and 2.3 nm respectively.[19]

Some workers believe that paraffinic hydrocarbons are not sorbed by smectites containing small intercalated cations[7] (p. 434). According to other data,[15] intercalation does occur, but extremely slowly, and traces of moisture are essential for this purpose. Apparently, the presence of intercalated water leads to the delocalisation of alkali metal cations and intensifies their polar effect on hydrocarbons. The nature of the intercalated cation, which is important for the adsorption of polar compounds, does not influence appreciably the intercalation of n-alkanes.[78] Evidently the adsorption of saturated hydrocarbons is not due to ion exchange; their insertion in the space between the layers in smectites can be accounted for from the standpoint of the interactions of the molecular dipoles, induced by the mineral ions, with the surfaces of the clays.[15,78,79] There are data showing that the Ca- and NH_4-montmorillonites do not sorb n-hexane.[79] However, montmorillonite with intercalated $CH_3NH_3^+$, $(CH_3)_4N^+$, and $(C_2H_5)_4N^+$ ions sorbs saturated hydrocarbons, while montmorillonite containing a quaternary ammonium base with a long chain, for example, the didodecyldimethylammonium ion, adsorbs selectively paraffinic and aromatic hydrocarbons, and is used in gas–liquid chromatography.[7]

The intercalation of C_6–C_{10} paraffins in fixed clays takes place fairly readily,[81] is independent of temperature and the number of carbon atoms in the molecule, and leads to the filling of 50–60% of the pore volume. The heats of sorption in such clays are much lower than in zeolites and the rate of diffusion of the sorbates is several times higher.

The study of the adsorption of hex-1-ene on the Cr^{3+}-exchange montmorillonite by IR spectroscopy[82] shows that the alkene is protonated in this instance and that the 2-carbonium ion formed is linked to the primary coordination sphere of the intercalated cation. One of the hydrogen atoms in the water molecules in this primary sphere is involved in the formation of strong hydrogen bonds with the silicate layers, while others do not form such bonds and are directed into the interlayer space. These hydrogen atoms are in fact labile and protonate the alkene molecule.

Benzene and its substituted derivatives as well as tetralin and naphthalene are fairly readily intercalated in certain smectites, forming even a double layer.[78,83] The interaction of benzene with Cu^{2+}-montmorillonite results in the formation of coloured complexes:[84,85] in the green complex, benzene retains its aromatic character, while in the red complex its aromaticity is infringed, since the π-electrons become localised.[84,85]

Non-aromatic non-polar molecules are intercalated very slightly or not at all in layered silicates containing intercalated cations of small diameter, for example, Na^+ and Ca^{2+}. On the other hand, in the presence of large cations, for

example, the Cs^+ ion, intercalation takes place to an appreciable extent[7] (p.436). Another smectite, Ca-montmorillonite, swells effectively in saturated alcohols and glycols, which are capable of displacing water from the interlayer space, including water hydrating the cations. When a single layer of C_4–C_{18} alcohol molecules is intercalated in the smectite, the hydrocarbon group is arranged parallel to the basal plane (Fig. 5a). The hydrogen of the hydroxy-group is linked to the oxygen of the *T*-network via a hydrogen bond. On the other hand, if many molecules are intercalated, they are arranged almost at right angles to the basal plane (Fig. 5b) and the hydrogen atoms of not only the hydroxy-group but also of the methyl group at the opposite end of the chain form a hydrogen bond with the oxygen of the second *T*-network. With increase in the length of the hydrocarbon chain of the alcohol, the distance between the layers therefore increases. The layers move apart to an even greater extent after the intercalation of aliphatic acids.

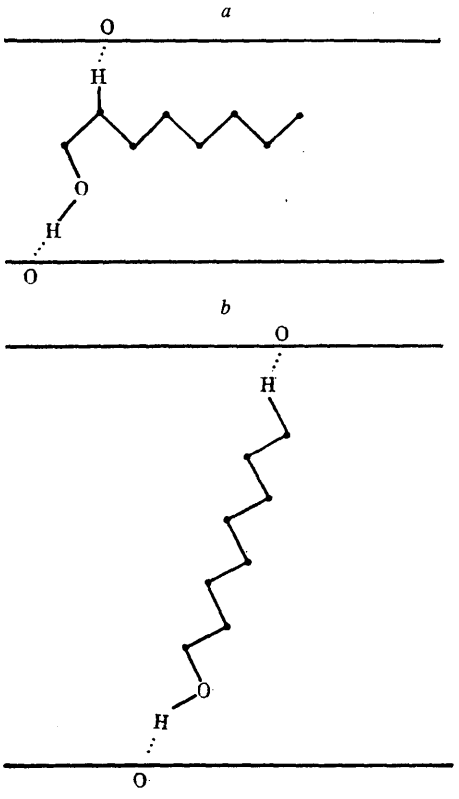


Figure 5. Models of the arrangement of n-alcohols in the interlayer space:[86] *a*) for the single-layer intercalation of the alcohol; *b*) for the maximum intercalation.

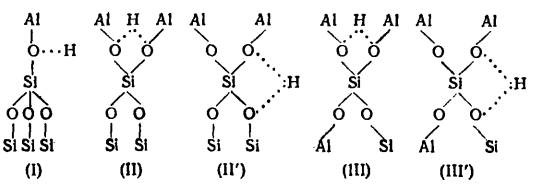
The removal of water and of intercalated organic substances, for example, on heating unfixed layered silicates, leads to a marked decrease in the interlayer space (the layers adjoin one another closely), which hinders the subsequent intercalation of substances and sometimes completely rules it out. On the other hand, if the inorganic intercalated cations have been exchanged for the ions of quaternary ammonium bases, then, after the removal of the intercalated substances, for example, water or alcohols, the distance *d* remains the same as before swelling[7] (p.461): the bulky ions prevent the layers from sticking together.

The ability of the intercalated cations to exchange, which was already mentioned in Section III, is important for the chemistry of layered silicates. The cation exchange takes place mostly in aqueous salt solutions, which can be achieved also in non-aqueous solutions, for example, alcoholic solutions. With increase in temperature, the rate of exchange also rises, but the exchange capacity diminishes, since some of the compensating cations move deeper into the network.[21] The exchange capacity diminishes particularly markedly when the specimen is heated above 300–400 °C; after such heating, the exchange capacity of clays is not as a rule restored, since the mineral is partly decomposed.

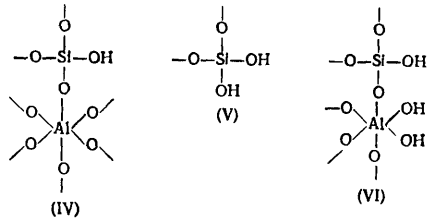


V. THE NATURE OF THE ACTIVE SURFACE

It follows from the data described in Section II that the active surface of layered silicates is extremely inhomogeneous. It is based on the basal surface of the *T*-networks with the lower valence cations built into these and the *O*-networks, which generates negative charges in the layer, the latter being neutralised by the intercalated cations. These *T*-networks bound both the crystal as a whole (part of the external surface) and the individual layers of the *TOT*-structure (internal surface). Another part of the external surface is made up of the lateral surface of the layers made up of the valence-unsaturated atoms of the *T*- and *O*-networks. Although the lateral surface of the cleaved layers does not exceed 20% of the total specific surface of the layered silicate (see Section II), nevertheless it has an appreciable influence on the character of the adsorption and of the catalytic action of the layered silicates.

It is known that the surface of a pure silicon–oxygen compound, for example quartz or ignited silica gel, is neutral. (Freshly prepared silica gel, heat-treated at a temperature not exceeding 500 °C, exhibits a weak acidity and catalyses the reactions of hexatrienes via an acid mechanism[87,88]). On isomorphous substitution of an Si^{4+} ion by Al^{3+}, the resulting aluminosilicate acquires acid properties, the nature of which is the same for all aluminosilicates, including zeolites; it has been most thoroughly investigated for the latter.

The aluminium atom inserted into a hydroxylated silicon–oxygen surface draws the electrons in the Al–O–Si–O–H group towards itself in an effort to fill its unoccupied *p* orbital, which polarises the –O–H bond[4] and, in the interaction with a water molecule, leads to the formation of an additional proton centre.



On the basis of quantum-chemical calculations for cluster models and the study of the IR spectra of aluminosilicates, it has been suggested[89,90] that there are several types of acid centres in both amorphous and crystalline aluminosilicates:

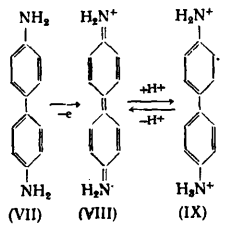
The highly acid centres are linked to the terminal siloxane OH group. The acidity of the bridging OH groups in centres of type (I) and especially (II) and (III) is somewhat reduced. The acid centres of types (II) and (III) can exist in the isomeric forms (II) and (II') and (III) and (III').

It is to be expected that acid centres are also present in layered silicates. The distance between them in such silicates usually exceeds the size of the aluminium ion and even the radius of action of the valence bonds.

Valence-unsaturated atoms, giving rise to single (IV) and paired (V) and (VI) Brønsted acid centres differing in strength, appear on the lateral surface of the layers, especially when the crystal is cleaved:

(IV) (V) (VI)

The hydroxy-groups in (VI) can become capable of either cation exchange or anion exchange depending on the pH of the medium[9] (p.25). Furthermore, there are Lewis acid centres in montmorillonite both on the lateral surface of the crystal and on the basal surfaces.

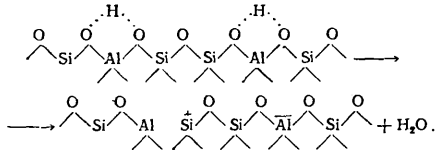


Acid centres arise in layered silicates also as a result of the interaction of water with intercalated cations, especially tervalent cations:

The degree of dissociation increases with increase in the polarising power of the cation in the sequence K < Na < Mg < Al.[93,94] In the presence of a large amount of water, the polarisation effect, arising when water is acted upon by the cation, weakens, since the influence of the cation is dissipated among a larger number of molecules and the pH of the medium approaches the values characteristic of the ion in solution. However, the concept of such a major role of exchange cations in generating the acidity of layered silicates has been questioned[18] (p.33). The hydroxy-groups of minerals can also serve as centres for the adsorption of polar organic compounds. Brønsted acidity predominates on clays containing 0.5–1.0% of water. For a lower level of hydration, the strength of the acid centres increases and the clay behaves more like a Lewis acid.[95,96]

The study of the interaction of clays with various amines led to the elucidation of the nature of the catalytic activity of layered silicates. Acid–base and oxidation-reduction reactions, leading to the formation of coloured radical-cations, take place when certain amines are adsorbed on clays.[97] The acid–base mechanism is especially characteristic of acid-washed clays. These clays act as proton donors, because their activity is greatly suppressed by treatment with bases, for example, ammonia. Oxidation-reduction reactions are relatively insensitive to treatment with acids and bases, but they are appreciably influenced by the presence of reducing agents such as $SnCl_2$.

The study of different types of treatment showed that colour reactions of clays with aromatic amines proceed with participation of Lewis and Brønsted acid centres. The reaction of benzidine with layered silicates has been most thoroughly investigated:[86,92]



(VII) (VIII) (IX)

The proposed reaction mechanism involves electron transfer from the initial diamine (VII) (i.e. its oxidation) to the mineral with formation of the blue radical-cation (VIII) (a semiquinone). The stability of the colour can be explained by the conjugation of the unpaired $2p_z$ electron of the nitrogen atom with the π-electron system of the aromatic ring enhanced by the resonance of both rings. The blue colour is observed only at pH 2.5–6. At pH < 2, the proton adds to the unshared electron pair of the nitrogen atom in the radical-cation, giving rise to the yellow radical-dication (IX).

The adsorption of sodium polyphosphate or reductive treatment of the clay inhibits the colour reaction only partially. Its complete inhibition occurs only when both these factors act simultaneously. The hypothesis was put forward on this basis[86,92] that the diamine is oxidised on the valence-unsaturated aluminium atoms on the lateral surface, the process being inhibited specifically by polyphosphates, and on Fe^{3+} ions located in the octahedral network which react with the diamine in the interlayer gap via the *T*-network.

The similarity of the chemical nature of layered silicates and other aluminosilicates suggests that they all contain isotypical active centres and not only acid active centres. Thus strong electron-accepting centres, formed by the triply charged Si^{3+} and Al^{3+} ions of the defect structures, as shown below in the two-dimensional scheme for zeolites and aluminosilicates,[98,99] should arise on the lateral surfaces of layered silicates, particularly in the case of mechanical cleavage of the layers or in topochemical reactions occurring when smectites are heated and in the presence of the strain in the Si–O–Si and Si–O–Al linkages induced by this:

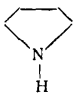
Indeed the presence of oxidation-reduction centres, whose number increases with increasing heat treatment temperature of the mineral, has been established by EPR using diphenylamine, anthracene, and chloranil probes[90] (p.55). Their presence in layered silicates has been suggested, as mentioned above, on the basis of the study of the colour reactions.

VI. CATALYSIS IN THE PRESENCE OF LAYERED SILICATES

In recent years there has been a growth of interest in clays as catalysts of various processes and at the present time numerous catalytic reactions involving their participation are known. Certain examples of catalytic reactions carried out in the presence of layered silicates as well as specific reactions with participation of large molecules on fixed clay minerals are presented in Table 3. The majority of these reactions have not been investigated in the presence of other aluminosilicates, including zeolites.

Clays, acting mainly as acid catalysts, initiate a wide variety of reactions of hydrocarbons, such as cracking, β-elimination, the shifts of the methyl group, and others. The catalytic properties of clays have also been investigated in connection with the elucidation of the genesis of petroleum. For example, the conversion of n-octacosane $C_{28}H_{58}$ in the presence of montmorillonite has been investigated.[102] Heating at 375 °C led to the formation of alkanes and olefins of smaller size, the yield of n-alkanes increasing and that of

branched and cyclic alkanes and aromatic hydrocarbons falling with increase in the duration of heat treatment. The olefins formed in the cracking process underwent isomerisation, rearrangement, and cyclisation.



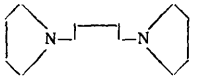


Table 3. Catalytic reactions in the presence of clays.

Field of application	Examples		Catalyst	Refs.
	starting materials	products		
Study of the genesis of petroleum. pyrolysis	Kerogen	–	Montmorillonite	[100, 101]
Ditto	Higher paraffins	–	Argillaceous rocks	[102]
"	Higher aliphatic acids	Hydrocarbons	Bentonite	[103]
Cracking of petroleum fractions	Distillates, gas oils	–	Bentonite clays	[104, 105]
Ditto	Various petroleum fractions	–	(0.5–4%) Al_2O_3/bentonite, with HNO_3	[106]
"	Higher paraffins	–	Ni-mica-montmorillinite	[107–109]
"	Gasoils, high-molecular-weight compounds in petroleum residues	–	Al-, Al-Zr-, Zr-, Al-Si-, and Si-fixed montmorillonite	[53, 55–57, 63–68, 110–115]

The hypothesis that aliphatic acids are precursors of the petroleum n-paraffins stimulated research into the catalytic decomposition of aliphatic acids. Thus, the decomposition of behenic acid $C_{21}H_{43}COOH$[103] on bentonite in the presence and absence of water at 200 °C yielded C_3–C_5 hydrocarbons. The total amount of saturated hydrocarbons increased with increase in the duration of heat treatment (90–760 h), while the yield of olefins fell. According to the authors,[103] the decarboxylation reaction is catalysed by the Lewis centres located on the lateral surfaces of montmorillonite, while the cracking is associated with the Brønsted acidity.

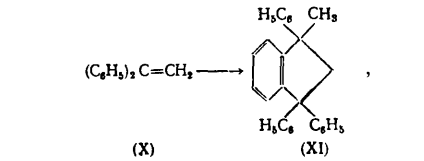
The ability of clay minerals to effect the cracking of petroleum fractions is well known.[105] However, the development of methods whereby clays can be fixed has led to new possibilities for the creation of catalysts for the conversion of high-molecular-weight compounds with a kinetic diameter >0.9 nm,[110] which are present in heavy petroleum fractions. The active catalysts for the cracking of the heavy raw material (petroleum residues, coal liquefaction products, coal tar) should have pores larger than 0.8 nm and a large internal surface.[111] The advantages of the fixation of clay minerals are manifested precisely in the cracking of large molecules. Thus the zeolite Y in the Ce-form and the fixed Ce-montmorillonite both sorb alkylbenzenes with a kinetic diameter <0.9 nm [including cumene (0.68 nm), t-butylbenzene (0.68 nm), *m*-diisopropylbenzene (0.79 nm), and tricyclodecane (0.81 nm)] and large differences between the activities of the two catalysts are not observed.[110] On the other hand, the degree of cracking of dodecahydronaphthalene (with a kinetic diameter of 1.15 nm) on fixed Ce-montmorillonite (in which the size of the inlet apertures and pores is 1.6–1.9 nm) is higher by several orders of magnitude than on the zeolite Ce-Y (with a size of the inlet apertures of 0.9 nm), on which the sorption of this compound is sterically hindered.

With decrease in the degree of cross-linking from 2.0 to 1.6 mmol of Al per gram of the Ce-montmorillonite, the activity of the fixed clay increases still further.[112] The explanation is that, under the conditions of incomplete exchange, a large amount of free space remains between the layers and is sufficient for the penetration of the reactants into the interlayer space and at the same time a certain number of cations remain and polarise the molecules of the residual water with formation of protons. In such cross-linked montmorillonite, the distance between the pillars is 1.1 to 1.9 nm, depending on the degree of cross-linking (the distances were determined from the adsorption of planar condensed aromatic compounds), while the distance between the layers is 0.8–1.0 nm. Further decrease in the degree of cross-linking to 1.25 nm lowers the thermal stability of the catalyst and decreases the total pore volume and leads to the loss of catalytic activity.

Wide-scale studies have been carried out[113] on the application to petroleum processing of montmorillonites fixed by aluminium or zirconium oligocations. However, the montmorillonite fixed by the Al_{13} oligocation lost its activity rapidly in the cracking of gasoil as a consequence of not only coke formation but also of the breakdown of its structure. With increase in temperature from 560° to 760 °C, the specific surface of the clay fixed by the Al_{13} oligocation gradually fell from 200–300 to 55 $m^2 g^{-1}$.[114] The deactivation caused by the formation of coke can be avoided by introducing into the catalyst small amounts (0.05%) of palladium and by carrying out the reaction in a stream of H_2.[134] Judging from the literature data,[134,178] by varying the conditions in the preparation of the specimens, especially from synthetic hectorite, it is possible to increase greatly the stability of the catalyst. Under optimum conditions, it is possible to obtain a catalyst whose specific surface remains fairly large (130 $m^2 g^{-1}$) even at 800 °C.[178] However, one should note that there is little information about the thermal stability of the catalysts of the new type considered here—fixed clay minerals.

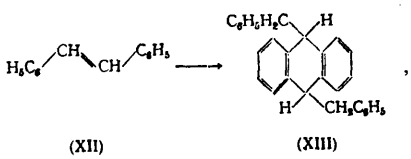
The stability of the montmorillonite cracking catalyst is also increased by adding to it 30% of the zeolite HY.[115] It has been suggested that the mica-montmorillonite mentioned above be used as a component of the cracking catalyst.[109,119] There are data concerning the application of clays, including fixed clays, to the hydrocracking of paraffinic hydrocarbons, from C_{10} upwards, and the hydroisomerisation of the C_4–C_5 hydrocarbons,[67,115,119,171,175] and also as carriers of catalysts for the hydropurification of heavy petroleum raw material.[125] Molybdenum catalysts deposited on bentonite showed a much greater activity in the hydrocracking of diphenylmethane and the hydrodesulphurisation of dibenzothiophen than those deposited on Al_2O_3. However, the activity of the Mo/Al_2O_3 catalyst was much greater in the hydrogenation of 1-methylnaphthalene.

Layered silicates have been used to alkylate aromatic compounds.[126–132] The overall characteristics of the alkylation process on clays and zeolites are the same. The reaction is usually carried out[159] at temperatures up to 400 °C and pressures ranging from 20 to 50 atm in order to maintain the reaction mixture in the liquid phase. The aromatic hydrocarbon:olefin molar ratio was varied from 2:1 to 15:1 in different investigations.[127,129] The alkylation of phenol requires a somewhat lower temperature—in the range 100–200 °C,[129,132] but in each specific case the reaction conditions depend on the catalyst used and on the type of alkylating agent. In the alkylation of benzene with ethylene under flow conditions on the Al_{13}-fixed montmorillonite (384 °C, contact time 10 s, benzene:ethylene molar ratio 7:4), the degree of conversion of ethylene into alkylbenzenes (diethylbenzene and ethylben-



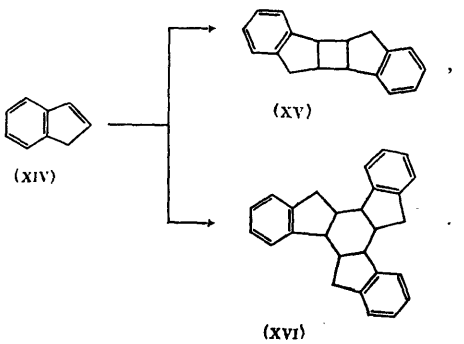
zene in proportions of 16:1) was 25.4%.[159] On montmorillonite in the H-form, treated with tetraethoxysilane, ethylbenzene was formed in 13% yield in a static system (40 atm. 200 °C, 2.5 h).[128]

Natural smectite clays (hectorite, saponite) in the cation-exchange form are used to alkylate benzene by higher olefins.[130] Under optimum conditions, the yield of the corresponding alkylbenzenes (with respect to the olefin) reaches 50%. Clays containing a cation with the highest Pauling electronegativity (Al^{3+}, In^{3+}, Cr^{3+}) are the most active. Minerals in which the cation has an electronegativity less than unity are inactive in the alkylation reaction. In the alkylation of phenol with chloro-octane (150–155 °C, 20 h) in the presence of natural bentonite, the yield of octylphenol (with respect to the alkane) reaches 92%.[132] Overall, comparative tests of the zeolitic catalysts H–ZSM and of fixed bentonite[179] showed that the latter is most suitable as the catalyst of the alkylation of benzene by olefins.



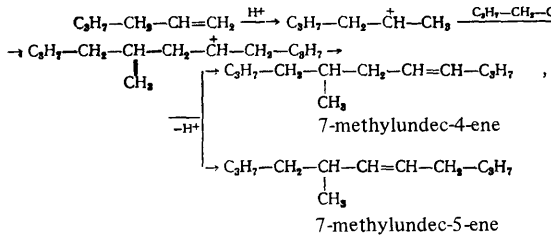
Dealkylation of isopropylnaphthalene[62] has been investigated in the presence of the Al-fixed montmorillonite dehydrated by the vacuum sublimation of a frozen specimen or by drying the specimen in air at room temperature. The reaction was carried out in a flow reactor at 300–400 °C and with a contact time of 0.6–3.6 s. The initial activities of the two specimens were similar (conversion 90–100%), but the catalyst dried by sublimation proved to be much more stable, The specimen dried in air rapidly lost its activity as a consequence of coke formation.

The transalkylation[124,163] and disproportionation[125,134] reactions of aromatic hydrocarbons have been carried out on bentonite activated by H_2SO_4 and on fixed smectites. A number of other catalytic reactions of hydrocarbons in the presence of clays are also known: hydrogenation,[136] dehydrogenation,[142,143] hydration of olefins,[146] oxidation,[8,45] etc.



Studies of the dimerisation, oligomerisation, and polymerisation of olefins in the presence of layered silicates are of interest. As in the case of cracking, the use of layered and especially fixed silicates in these reactions makes it possible to introduce into the reaction or obtain large molecules:[8,149]

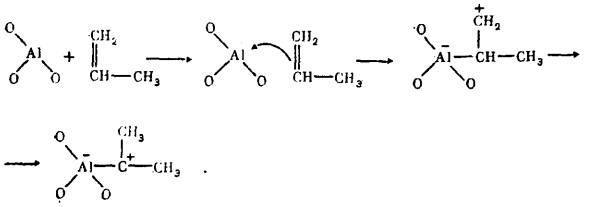
(X) (XI)



(XII) (XIII)

(XIV) (XV) (XVI)

For example, 1-methyl-1,3,3-triphenylindene (XI), whose molecule contains four aromatic rings, has been obtained[149] by dimerising 1,1-diphenylethylene (X) on Cu^{2+}-montmorillonite. The even larger 9,10-dibenzyl-9,10-dihydroanthracene (XIII) molecule is formed on the same catalyst from *trans*-stilbene (XII).[8] The dimerisation and especially the trimerisation of indene (XIV) leads to compounds (XV) and (XVI),[8] which cannot be obtained in comparatively narrow pores and cannot emerge from pores of moderate size and coke is gradually formed. Admittedly, one cannot rule out the possibility that such molecules can be assembled from the monomers on the lateral surface of the smectite crystal carrying acid centres of different strengths.



The mechanism of the dimerisation of olefins can be represented as follows in relation to hex-1-ene:[148]

7-methylundec-4-ene

7-methylundec-5-ene

Evidently, the oligomerisation of olefins under mild conditions can also be considered from the standpoint of the proton-donor mechanism. However, according to Occelli et al.,[152] the oligomerisation of propene on a fixed bentonite at temperatures up to 400 °C proceeds with participation of Lewis acid centres, which predominate on the surface even at temperatures above 300 °C. In this case, the reaction begins with the interaction of a highly active Lewis acid centre with a propene molecule and the formation of a stable π-complex. Electron transfer to an unoccupied orbital of the aluminium atom leads to the appearance of a σ-complex in which the propene fragment carries a positive charge:

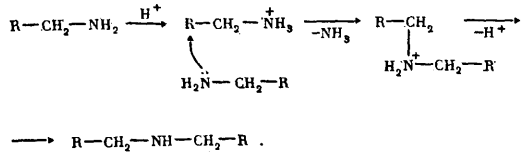
After the addition of a propene molecule to this carbonium ion, chain propagation begins.

The elucidation of the cause of the activity of clays in polymerisation reactions[157–160] was assisted by a study of the interaction of leuco-bases with clay minerals.[92] This investigation resulted in the development of a donor–acceptor mechanism of the interaction of organic compounds with clays,[86,92,180] an example of which is presented in Section V.

The activity of montmorillonite in the styrene polymerisation reaction is appreciably suppressed after treatment with polyphosphates,[160] which is explained, as for the colour reactions (see Section V), by the presence on the lateral surface of electron-accepting (Lewis) centres consisting of aluminium atoms in an octahedral coordination. Since the polymerisation reaction has features characteristic simultaneously of free-radical and ionic mechanisms, it has been suggested[160] that electron transfer from the adsorbed styrene to aluminium results in the appearance of a radical-cation, which is rapidly converted into a dimer. Both the radical-cation and its dimer initiate the process, but the polymerisation itself proceeds via a cationic mechanism. Alcohols and amines inhibit

the polymerisation: being stronger Lewis bases, they are adsorbed preferentially.[158]

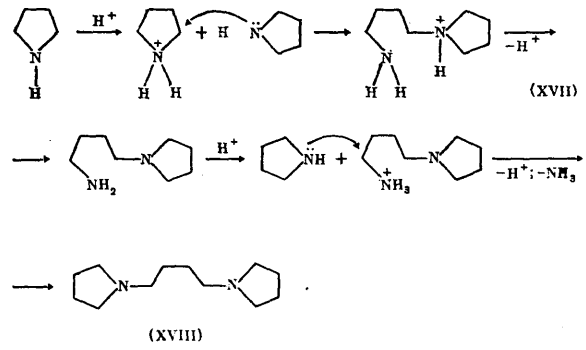
On the other hand, it has been suggested[181] that Brønsted and not Lewis acidity is responsible for the initiation of the polymerisation. However, whereas alkaline treatment suppresses the polymerisation completely, the adsorption of triphenylmethyl chloride on the Lewis centres on the lateral surfaces only reduces the yield of the polymer. It would therefore be an oversimplification to relate the activity of montmorillonite to its Lewis or Brønsted acidity only.



Various reactions of olefins, alcohols, thiols, and amines on layered silicates at low temperatures have been studied recently.[182] The reactions of olefins with water and alcohols afford ethers, those with carboxylic acids give rise to esters, and those with thiols produce thioethers (sulphides). Olefins do not react with amines on layered silicates.

It is noteworthy that the formation of an ether from an olefin and water requires an intermediate stage in which an alcohol is formed.[164] This reaction takes place with participation of the intercalated water after the exhaustion of which the reaction ceases; the catalyst cannot be regenerated. Smectites containing an exchange cation with the maximum polarising effect (Al^{3+}, Fe^{3+}, Cr^{3+}) exhibit the highest activity. However, the greatest selectivity in the formation of ethers has been attained on Cu^{2+}-exchange montmorillonite. For each cation, there is an optimum content of the intercalated water for which the yield of the ether is a maximum. The optimum $Cu:H_2O$ ratio for Cu^{2+}-montmorillonite is 1 : 12.[171]

The reactions of alcohols on layered silicates, which proceeds via an acidic mechanism, lead to the formation of ethers, alkenes, and alkene dimers.[163] Primary alcohols then give rise preferentially to ethers, secondary alcohols yield mainly alkenes, while tertiary alcohols give rise to alkenes and their oligomers exclusively. The fixation of montmorillonite and beidellite by the Al_{13} oligocation (d then increases to 1.8 nm) leads to a sharp fall in their catalytic activity in the reaction involving the formation of ethers from alcohols and of esters from an olefin and a carboxylic acid.[27]

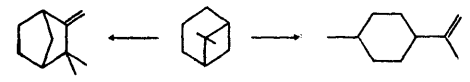


The reaction of benzyl alcohol on Cu^{2+}-montmorillonite takes place in an interesting manner:[62,163] polyphenylenemethylenes containing between 10 and 100 phenylenemethylene fragments are formed. The reaction of an aromatic thiol is of the same type.[170] The dimerisation of epoxyethane on Cu^{2+}-montmorillonite leads to the formation of a cyclic ether—dioxan.[109,182]

The reaction in which secondary amines are formed from primary anions on Cu^{2+}- or Al^{3+}-montmorillonite[172] has also been considered from the standpoint of a proton mechanism:

The formation of alkenes from amines was not then observed.

The rate of conversion of 2-alkylamines and cyclic amines is higher than that of 1-alkylamines (aniline is known to form complexes with clays,[172] but the nucleophilic substitution reaction does not occur). Cyclic secondary amines, for example, pyrrolidine, also split off ammonia in the presence of the Cr^{3+}-exchange montmorillonite, but in this case three amine molecules are involved in the reaction:[172]



(XVII)

(XVIII)

With increase in reaction time, the yield of compound (XVIII) increases and that of compound (XVII) falls, which indicates the intermediate character of the latter. The formation of piperidine and pyridine from acetylene and ammonia has been observed on bentonite activated with H_2SO_4.[173]

It is noteworthy that certain compounds react on layered silicates in a way which is different from that on zeolites. For example, α-pinene affords up to 20% of camphene and a large number of polymers on layered silicates, 50–62% of camphene has been obtained under industrial conditions on clays treated with acid, while on a synthetic zeolite the main product is dipentene:[183]

Camphene α-Pinene Dipentene

The "chemistry of C_1 compounds", which is based on the reactions of methanol and the synthesis gas, has acquired considerable importance in research and for practical purposes in all countries during the last decade. The possibility of using layered silicates as catalysts in this field has therefore been frequently investigated. For example, olefins, mainly having the C_2–C_4 composition, have been obtained from methanol in high yields on montmorillonites—both containing different exchange cations and fixed.[174–177] In this reaction too, the activity of the catalysts is related to their acidity. Preliminary treatment of the clay which enhances its acid properties, such as for example, the exchange of the Na^+ and Ca^{2+} cations for Ti^{4+} ions, greatly increases the degree of conversion of methanol.[174] Certain questions of the mechanism of the formation of higher olefins from methanol on zeolites have been examined in detail.[184] The similar nature of the active centres on zeolites and layered silicates (see Section V) suggests that the reactions on the latter proceed via the same mechanism.

---o0o---

The data presented in this review show that the uses devised in recent years for layered silicates, in particular clays, in the preparation of catalysts have greatly expanded the scope of catalysis, mainly acid–base catalysis. This is due to the ready availability and low cost of the widely occurring natural raw material, the thermal stability of fixed clays, and the possibility of accelerating with their aid the reactions of large molecules. The latter is especially important at the present stage of development of the chemical, petrochemical and coal-chemical industry, which requires the creation of a

waste-free ecologically clean industry and hence the development of processes for the utilisation of the heavy residues remaining after the processing of different types of organic raw material containing large molecules.

Metal Complex Catalysis of Electrode Processes

O.N.Efimov and V.V.Strelets

A new field of application of metal complexes for the acceleration of electrode processes is examined. The general principles of the design of metal complex electrocatalytic systems are analysed and the results of studies carried out during the last 10 years on the electrochemical reduction and oxidation of various organic and inorganic substrates are surveyed.
The bibliography includes 177 references.

I. INTRODUCTION

During the last 30 years, considerable advances have been made in metal complex catalysis (MCC) and have had a strong influence also on other types of catalysis; heterogeneous enzyme catalysis and electrocatalysis. This influence is due to the high theoretical level of understanding of the processes undergone by the substrate in the coordination spheres of metal complexes—in particular, in the case of homogeneous MCC, where it has been possible in many cases to elucidate the sequence of the elementary reactions, to isolate or identify spectroscopically the intermediate compounds, to follow the changes in the oxidation states of the metals during the catalytic process, and to achieve a quantum-chemical description of the character of the bond between the substrate and the metal.[1,2]

Together with the fundamental importance of MCC for the generation of fundamental ideas referring to catalysis as a whole, the practical advantages which it can ensure play a significant role. This applies in the first place to the comparatively mild reaction conditions in solution (low temperature and pressure), low sensitivity to impurities and catalytic poisons, the accessibility of the active centres to the interaction with the substrate, and finally the possibility of controlling the catalytic system by altering the ligand environment of the metal complex and the composition of the medium. In many cases, homogeneous catalysts are superior to heterogeneous catalysts as regards selectivity, being at the same time much more readily available.

The principles of MCC can be readily transferred to the catalysis of electrochemical reactions. In particular, metalloporphyrins have been used successfully to carry out electrocatalytic hydrogen reduction reactions in fuel cells in order to replace or reduce significantly the consumption of expensive metals.[3] However, the application of MCC in electrosynthesis, which has developed most recently, is of greatest interest. One can point out a series of factors which make the combination of MCC with electrochemistry particularly attractive to specialists in both fields. These are in the first place the possibility of replacing at the electrode strong oxidants and reductants, which are frequently expensive and difficult to obtain and furthermore contaminate the reaction mixture by their conversion products. By carrying out a redox reaction at the electrode, it is possible to influence within wide limits its rate by regulating the electrode potential, and to ensure the transfer of any number of electrons without altering the composition of the medium, which is especially important in many-electron reactions. The possibility of lowering the overpotential at the electrode and of increasing the current density by means of MCC are in their turn attractive to electrochemists. Finally, special mention should be made of the fact that MCC can ensure the occurrence of chemical reactions which are altogether impossible in the absence of metal complexes, for example the reduction of nitrogen or carbon monoxide. Furthermore, one should add that the modern methods for the investigation of electrode processes, namely various types of polarography, cyclic voltamperometry, and various pulse methods make it possible to achieve a fairly complete description of the mechanism of the catalysis when combined with electrolysis at a controlled potential and spectroscopic methods.

The statement of the well known electrochemist Baizer[4] that there are unlimited possibilities for an investigator working at the junction of organic chemistry, electrochemistry, and catalysis is fully applicable to metal complex electrocatalysis (MCE). Investigators can use pure methods for the introduction and removal of electrons, procedures for the deposition of potential catalysts on electrode matrices, the advantages of adsorption on electrodes which depends on the electric field, a large set of solvents, and, if necessary, supporting electrolytes which exert a specific influence on the electrode processes and the behaviour of intermediate species in solution.

The trend towards an increase in the number of studies involving the use of metal complexes in electrocatalysis observed in recent years requires systematic treatment of the accumulated data in this essentially new field. It is necessary to understand the methodology of the selection of metal complex electrocatalysts, the general principles of their functioning, and the possibilities and prospects for their use in electrochemical reactions of various substrates. This review is in fact devoted to the consideration of these questions.

II. GENERAL PRINCIPLES

In terms of the mechanism of their action, metal complex catalysts of electrosynthesis can be divided into two main groups. The first includes metal complexes whose coordination spheres remain unchanged throughout the catalytic cycle and electron transfer takes place via an outer sphere mechanism without the formation of an intermediate complex between the substrate (A) and the catalyst (the redox pair P/Q):

$$\begin{gathered} P+e \rightleftharpoons Q, \\ Q+A \rightleftharpoons P+B, \\ B \rightarrow C\ . \end{gathered}$$

It has been suggested that this type of MCE be called redox catalysis.[5] The functions of the redox catalyst (other names: redox transferring agent, mediator) consist in electron transfer from the electrode to the substrate, after which the primary product B of the reduction of the substrate is converted into the final product C already in the course of the chemical reaction. When B is rapidly and irreversibly converted into C, the substrate may be reduced under the conditions of homogeneous electron transfer in the direction opposite to the standard potential drop ($E^0_{P/Q} > E^0_{A/B}$),[6] which greatly extends the scope of redox catalysis. Evidently a gain is achieved using redox catalysts only when they are capable of being rapidly regenerated at the electrode and with high yields at potentials more positive than those of the direct electrochemical reduction of the substrate or less positive than the potentials of its direct electrochemical oxidation, are stable, and can interact rapidly with the substrate. Thus this type of MCE can be usefully employed if, by restorting to homogeneous electron transfer, one increases the rate of the process as a whole by transferring the process to the bulk of the solution and by reducing the overpotential of the electrochemical reaction and also if substrates for which homogeneous redox reactions occur for one reason or another at higher rate than heterogeneous reactions participate in the process.

The second group of catalysts includes metal complexes with the participation of which electron transfer from the electrode to the substrate takes place via an inner sphere mechanism with formation of an intermediate complex between the catalyst and the substrate (PA or QA). The mechanism of the action of these catalyats can be represented in a simplified form by the following schemes:

$$\left.\begin{array}{l}\overrightarrow{P + A \rightleftharpoons PA}\\ PA \xrightarrow{e} PB \rightarrow P + C\end{array}\right|$$

or

$$\left.\begin{array}{l}\overrightarrow{P + e \rightleftharpoons Q}\\ Q + A \rightleftharpoons QA\\ QA \xrightarrow{e} QB \rightarrow P + C\end{array}\right| .$$

Since the reactions of the substrate in the coordination sphere of the metal complex assume the main role in the catalytic cycle, this type of MCE can be usefully defined as coordination electrocatalysis. The electrochemical stage and the chemical reaction of the substrate are coupled with participation of the catalyst–substrate complex and the function of the catalyst consists in the binding and activation of the substrate in the coordination sphere of the metal complex as a result of which the reactivity of the substrate in the electron exchange reaction with the electrode increases. In contrast to redox catalysis, in coordination MCE, P or Q must be coordination-unsaturated or must contain ligands which are kinetically labile in substitution reactions. This is essential for the formation of the intermediate complexes PA and QA.

The choice of a specific metal complex for coordination MCE is appreciably facilitated by the availability of extensive information on the complex formation reactions and activation of substrates which are kinetically inert in redox reactions.[1,2] Having chosen a suitable metal complex which binds the substrate and activates it in its coordination sphere, one can proceed to the solution of practical problems in the coupling of the electrode and chemical reactions. This strategy is evidently idealised but in the subsequent description of this approach it will be illustrated by a number of examples.

In coordination MCE, the metal complex can be immobilised on the electrode surface, for example, by adsorption and special fixing methods,[7] or can be present in the bulk of the solution. The electron exchange between the electrode and the catalyst–substrate complex can then take place either directly or with participation of redox transferring agents. In particular, if the reaction centre in the immobilised coordination catalyst exchanges electrons slowly with the electrode, then the efficiency of this process can be increased by the additional immobilisation on the electrode surface of a redox transferring agent capable of rapid electron exchange both with the electrode and with the reaction centre. As will be shown below, this approach, which has been developed in bioelectrocatalysis for the coupling of enzymes in electrochemical reactions,[8] can be used successfully also in coordination MCE.

In conclusion, we may note that coordination MCE is in fact the only method for the involvement in electrochemical reactions of substrates whose direct oxidation-reduction at the electrode is difficult or does not occur at all. Attention will therefore be concentrated in the present review on precisely this type of MCE.

III. THE MAIN ELECTROCHEMICAL REACTIONS CATALYSED BY METAL COMPLEXES

1. Dehalogenation of Organic Halides

The problem of the dehalogenation of organic halides RX, where R = aryl or alkyl and X = Cl, Br, or I, is of not only theoretical but also of applied importance, because many halides accumulate in the waste from industrial organic synthesis. The direct electrochemical reduction of alkyl and aryl halides is usually carried out at potentials more negative than −1.5 V.†[4] The pattern changes significantly when the complexes of certain transition metals capable of reacting with RX to form more readily reducible compounds are introduced into the electrolyte solution. The reductive dehalogenation of RX can then be performed at considerably more positive potentials, usually at the potentials of the regeneration of the metal complex active in relation to RX. The complexes catalytically active with respect to RX can be arbitrarily divided into three groups: the phosphine, tetra-azamacrocyclic, and polypyridyl complexes. We shall consider each of these groups.

The tetraphosphine complexes of zerovalent nickel $NiPn_4$, electrochemically generated by the two-electron reduction of Ni^{2+} or NiX_2Pn_2 in the presence of an excess of phosphine Pn, catalyse the electrochemical reduction of RX (R = alkyl or benzyl) and ArX (Ar = aryl) with formation of a mixture of the corresponding hydrocarbons (RH or ArH), dimerisation products (R–R or Ar–Ar) and, in the case of alkyl halides, also the alkenes R(−H).[9–11] The reduction takes place at Hg, Pt, Au, or carbon glass cathodes in a diaphragm electrolyser in various solvents [EtOH, tetrahydrofuran (THF), MeCN, etc.]. The ratio of the products depends significantly on the nature of the solvent but not of the electrode. Thus, in the catalytic electrochemical reduction of ArX in an alcoholic medium, the only product is the corresponding ArH, while in THF or in its mixtures with hexamethylphosphoramide (HMP) the product is a mixture of ArH and Ar–Ar, the

† All the potentials are quoted in this review relative to the aqueous saturated calomel electrode.

material yield of biaryl increasing to 70–95% with increase in the HMP content.[9] The electroanalytical study of this reaction permitted the conclusion that the mechanism of the dehalogenation of aryl halides can be represented as schematically as follows:[9]

$$Ni^{2+} \xrightarrow{2e;\ Pn} NiPn_4 \xrightarrow{ArX} ArNiXPn_2 \xrightarrow{2e;\ H^+} Ar^- + NiPn_4,$$
$$Ar^- \xrightarrow{H^+} ArH$$
$$Ar^- + ArNiXPn_2 \rightarrow Ar{-}Ar + X^- + NiPn_4.$$

As a result of the oxidative addition of RX to $NiPn_4$, the intermediate formation of the organonickel σ-derivative $RNiXPn_2$, the stability and further reaction pathways of which depend significantly on the nature of the solvent and the halide, has also been postulated for alkyl halides.[10] Tributyl- and triphenyl-phosphines[9,10] and the diphosphines of the type of bis(diphenylphosphino)ethane (dppe) [12] are used in this reaction.

The study of the mechanism of the electrochemical reduction of 1-iodobutane, 1-iodo-2,2-dimethylpropane, benzyl chloride, and PhBr at an Hg cathode in MeCN in the presence of catalytic amounts of $[Ni(PPh_3)_2(MeCN)_4]^{2+}$ and an excess of PPh_3 led to the conclusion[13] that the active species in relation to RX is also the electrochemically generated $Ni(PPh_3)_4$ and that the subsequent reaction of $RNiX(PPh_3)_2$ (I), formed as a result of oxidative addition, depends on the nature of the organic halide and proceeds in accordance with one of the possible schemes

$$(I) \xrightarrow{e} [RNi(PPh_3)_2X]^- \rightarrow R{-}R + Ni(PPh_3)_4 + X^-,$$
$$(I) \rightarrow Ni(PPh_3)_3X + R^{\cdot} \rightarrow R{-}R + RH + R(-H)$$

via a hydride complex i.e.

$$(I) \rightarrow R(-H) + [Ni(PPh_3)_2(H)X] \rightarrow Ni(PPh_3)_3X + RH + H_2$$

with subsequent electrochemical regeneration of $Ni(PPh_3)_4$. The same complex can promote the electrochemical reduction of allyl halides in MeCN to hexa-1,5-diene with a current yield of 85–95%.[14] The formation of the nickel(I) π-complex $(\pi\text{-}C_3H_5)Ni(PPh_3)Cl$, whose subsequent one-electron reduction is accompanied by the cleavage of the C–Ni bond with regeneration of the catalyst and the formation of the anion X^- and the radical $C_3H_5^{\cdot}$, dimerising with formation of hexadiene, has been proposed as an intermediate in the oxidative addition of the substrate to $Ni(PPh_3)_4$. An important condition for the occurrence of this electrocatalytic reaction is a tenfold excess of PPh_3 relative to Ni^{2+}, which is the initial ion for the preparation of $Ni(PPh_3)_4$.

Together with the diphosphine complexes of nickel, the product of the reversible one-electron reduction $[Rh(dppe)_2]^+$ also exhibits a catalytic activity in the dehalogenation reaction.[15] In the absence of the substrate, the $RH(dppe)_2$ generated electrochemically at the Hg cathode reacts with the solvent [dimethyl sulphoxide (DMSO), MeCN, etc.] to form the hydride $RhH(dppe)_2$, while in the presence of cyclohexyl chloride, a mixture of cyclohexane and cyclohexene is formed. The detection of dicyclohexylmercury as a side product indicates that the reaction proceeds via the intermediate formation of the free cyclohexyl radical.

The phosphine complexes of zerovalent nickel can also be used to carry out more complex reactions with participation of RX. For example, it has been shown[16] that, in *N*-methylpyrrolidinone or a THF–HMP mixture (Au-cathode), the complex $[Ni(Pn_2R'X]^-$, where R′ = ethylene, propene, or styrene and X = Cl, Br, or I, generated by the reduction of Ni^{2+} in the presence of a threefold excess of Pn = PPh_3 and an alkene, reacts with halogenobenzenes to form the corresponding arylalkenes via the mechanism (for example, when R′ = C_2H_4)

$$NiPn_2X_2 + R' \xrightarrow{2e} [NiPn_2R'X]^- \rightleftharpoons \text{«PhNiX»} \xrightarrow{Et_3N} PhCH{=}CH_2 + Ni(0) + Et_3NHX$$

Olefins are arylated as a result of the reversible oxidative addition of PhX with formation of the organonickel complex "PhNiX" of unknown structure, which decomposes irreversibly to form the arylalkene. The process becomes catalytic only in the presence of a base (Et_3N), which apparently promotes the elimination of HX.

Another example of the use of RX for the preparation of more complex products is the electrocatalytic synthesis of arylacetic and arylpropionic acids.[17] These acids are formed as a result of the electrochemical reduction of the corresponding benzyl halides at an Hg cathode in a CO_2-saturated aprotic medium (mixtures of THF with HMP or *N*-methylpyrrolidinone) in the presence of catalytic amounts (10%) of diphosphine complexes of zerovalent nickel or zerovalent palladium. The products are formed via the following proposed mechanism (L = diphosphine):

$$ML_2 \xrightarrow[-L]{RX} RMXL \xrightarrow[-X^-]{2e} RML^- \xrightarrow{CO_2;\ L} RCO_2^- + ML_2$$

The material yield of acids is 20–50% and bibenzyls are formed as side products.

Another group of complexes catalysing the electrochemical reduction of RX consists of square planar nickel(II) and cobalt(II) complexes with tetra-azamacrocycles (L) or Schiff bases. Thus it has been shown[18] that the complexes NiL^{2+} in an aprotic medium [MeCN, dimethylformamide (DMF), DMSO, etc.] undergo reversible one-electron reduction to the stable complexes NiL^+, which undergo an oxidative addition reaction with RX (2-bromo-octane, 2-bromo-2-methylheptane, etc.) to form the organonickel compounds $[RNi(L)Br]^+$ (II), whose subsequent fate depends on the nature of R. For primary RBr, the dehalogenation products RH, R(–H), and R–R are formed as a result of the competing reactions

$$(II) + RBr \rightarrow R{-}R$$

and

$$(II) \xrightarrow{e} R^- \xrightarrow{H^+} RH),$$

while secondary and tertiary RBr are dehalogenated exclusively via the radical mechanism[18]

$$((II) \rightarrow R^{\cdot} \rightarrow RH + R(-H) + R{-}R)$$

The dehalogenation reaction is catalytic and takes place at potentials corresponding to $E^0(NiL^{2+/+})$. It is of interest to note that the introduction of any substituents into L shifts $E^0(NiL^{2+/+})$ to the anodic region, the maximum effect being generated by substituents at the N atoms of the ligand, which makes it possible to lower the RBr reduction potentials down to −1 V.[18] The main products of the dehalogenation of RBr in the presence of nickel(II) complexes of Schiff bases are the corresponding dimers R–R, which shows that the reaction proceeds mainly via a radical mechanism.[19]

The tetra-azamacrocyclic complexes CoL^{2+} [20,21] and the cobalt(II) complexes of Schiff bases[22] exhibit an analogous catalytic activity in the dehalogenation of RX at the potentials of the Co(II/I) redox transition. For example, in the dehalogenation of BuX (X = Cl or Br) in the presence of the electrochemically generated bis(salicylideneiminato)cobalt(I) $[Co(salen)]^-$, the main product is 2-methylpropene. The formation of alkylcobaloxime (sic) [BuCo(salen)] as a side product indicates, according to the authors,[22] the intermediate formation of the butyl radical.

The formation of alkylcobaloximes (sic) [RCo(salen)] in the reaction of $[Co(salen)]^-$ with RX has been used for the electrocatalytic carboxylation of organic halides.[23] Electrolysis of alkyl and benzyl chlorides [R = $PhCH_2$, $Ph(CH_3)CH$, $PhCH{=}CHCH_2$, $CH_3CH{=}CHCH_2$ etc.] at the Hg cathode in the presence of the [Co(salen)] catalyst in a THF–HMP mixture

saturated with CO_2 at atmospheric pressure leads to the formation, after the hydrolysis of the catholyte, of the carboxylic acids RCO_2H in a material yield of 50–97%. In a moist solvent with an H_2O content of $(1–5) \times 10^{-2}$ M, the yield of acids falls somewhat, simultaneously with the appearance in the product of the corresponding RH and R–R. The formation of acids is not observed for aliphatic halides (bromopropane) or bromostyrene, but acids are formed from aryl halides after the replacement of the cobalt complex by $Ni(Ph_3P)_4$. It has been suggested[23] that the formation of acids can be described by the following scheme:

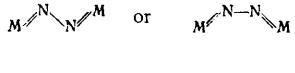
$$[Co\,(salen)] \overset{e}{\rightleftharpoons} [Co\,(salen)]^- \xrightarrow{RX} [RCo\,(salen)] \xrightarrow{2e;\ CO_2} RCO_2^- + [Co\,(salen)]$$

The reaction proceeds either via the intermediate formation of an adduct of CO_2 with alkylcobaloximes or via the attack on CO_2 by the carbonium ion formed on dissociation of [RCo. .(salen)]. In the light of these data, it is appropriate to mention a study[24] in which it was shown that the two-electron multistage reduction of alkylcobaloximes [RCo(dmg)Py] (where R = alkyl or benzyl, dmg = dimethyl glyoximate, and Py = pyridine) is accompanied by the formation of a dealkylated cobalt(I) complex whose two-electron reoxidation regenerates the initial alkylcobaloxime in a material yield of 60–95%. In the case of optically active groups R, the oxidation-reduction process involving the initial complex is accompanied by the complete inversion of configuration. A mechanism of the cleavage of the Co–R bond in the reduction of alkylcobaloximes, according to which the axial group R, split off in the form of R$^\cdot$ or R$^-$, remains reversibly bound to cobalt(II) or cobalt (I) complexes as a result of its transfer to the nitrogen atom of the equatorial dmg ligand, has been proposed on the basis of the data obtained. It is quite possible that, in the course of the synthesis of carboxylic acid,[23] the reduction of [RCo(salen)] is also accompanied by the transfer of R to the axial ligand with the simultaneous liberation of a coordination site for a CO_2 molecule. After the coordination and activation of CO_2, the reverse transfer of R takes place, but this time to a CO_2 molecule with formation of a carboxylate ion.

The complexes, which are structural models of vitamin B_{12}, can apparently be used also for involving alkyl halides in other interesting reactions, for example, in reductive cross-coupling. Thus the electrolysis of a mixture of ethyl iodide and acrylonitrile in MeCN at a carbon electrode polymerically modified by the 3,5-diaminobenzoyl derivative of vitamin B_{12} results in the selective formation of valeronitrile.[25] The complex $Ni(teta)^{2+}$ (where teta = hexamethyltetra-azacyclotetradecane) catalyses the electrochemical dehalogenation of RX (for example, 1-bromo-octane) with formation of RH (30%), R–R (45%), and R(–H) (20%).[26,27] After the additional introduction of activated olefins (CH_2 = CHY, where Y = Ar, CN, CO_2Et, etc.) into the catholyte together with RX, the cross-coupling products RCH_2CH_2Y are found to be formed. This reaction is not catalytic, since the complex $[Ni(teta)X_2]^+$ formed is electrochemically inactive.[26]

The third group of compounds catalysing the reductive dehalogenation of RX includes the polypyridyl complexes of Group VIII metals. It has been shown[28,29] that $Co(bipy)_3^{2+}$ (where bipy = 2,2′-bipyridyl) in MeCN catalyses the reductive dimerisation of allyl halides to hexa-1,5-diene. The hexadiene is formed at the redox potentials of $Co(bipy)_3^{2+/+}$, i.e. at potentials more anodic by 1.2 V than the potential of the reduction proper of allyl chloride at a platinum electrode.[29] The oligomers $-[CH_2CH(CH_2Cl)]-_n$ are formed together with the hexadiene. The same reaction can be carried out also in an aqueous medium.[30]

The formation of the hexadiene has likewise been observed in the electrochemical reduction of allyl bromide in MeCN in the presence of $Ni(bipy)_3^{2+}$ and a tenfold excess of the ligand.[31] Alkyl and aryl bromides are dehalogenated with formation of mainly the dimers R–R in DMF in the presence of the $Ni(phen)_3^{2+}$ catalyst (where phen = 1,10-phenanthroline).[32]



The electrochemical dehalogenation of alkyl and aryl halides can be carried out at a cathode subjected to preliminary modification with the reduction products of the metal complexes. Thus 1-bromo-octane is dehalogenated in DMF in the electrolyser fitted with aluminium electrodes but without a diaphragm, where the cathode is coated by an iron-containing deposit.[33] The dehalogenation of RBr is then achieved at potentials more anodic by 0.9 V than at the aluminium cathode. Under analogous conditions, a cathode coated by the deposit formed in the electrochemical reduction of $Ni(acac)_3$ catalyses the dehalogenation of aryl and benzyl halides.[34]

1,1-Dibromo-2-phenylcyclopropane is dehalogenated with formation of 1-bromo-2-phenylcyclopropane (90%) and phenylallene (10%) in the presence of catalytic amounts of $CrCl_3$. The reduction is carried out at a lead cathode in DMF at the potentials of the $Cr^{3+/2+}$ redox transition, which are more annodic by 2 V than the potentials of the electrochemical reduction proper of the halide.[35] Examples of other reactions involving the electrodehalogenation of organic halides catalysed by metal complexes can be found in Tanaka's review.[36]

2. Reduction of Molecular Nitrogen and Nitric Oxide

The problem of the fixation of nitrogen under mild conditions has attracted the constant attention of investigators during the last 20 years. Although the biological fixation of nitrogen has long been known, the mechanism of this most important reaction remained unknown until recently. The attempts to find simple chemical reactions permitting the reduction of nitrogen to ammonia close to biological conditions have been frequently undertaken, but they encountered difficulties associated with the necessity to rupture the exceptionally strong triple bond in nitrogen (920 kJ mol^{-1}).

Theoretical study has shown[37] that in protic media the most economical pathway (in the sense of energy expenditure) involves the activation of nitrogen in the linear dinuclear complex M...N=N...M, which tends to weaken appreciably the N≡N bond. The best catalytic properties should be manifested by metal ions with the d^3 electronic configuration, for example, Mo^{3+} and V^{2+}. With their participation, the many-electron reduction of nitrogen to N_2H_4 and NH_3 can take place without the intermediate formation of the thermodynamically extremely unfavourable diimide N_2H_2 under conditions with a more uniform distribution of energy among different stages. Such equalisation of the energy relief is achieved by the stabilisation of the intermediates formed in the reduction of nitrogen, as a result of the "conjugation" effect, i.e. the overlap of the *d* orbitals of the metal and the *p* orbitals of nitrogen, for example, in hydrazine derivatives

which have a planar configuration.

The creation of a metal complex electrocatalyst should include the search for a suitable complex $M(d^3)$ capable of activating nitrogen via the coordination mechanism described above and of reacting either directly at the electrode or with participation of a suitable catalytic transferring agent.

The first attempts to set up electrochemical systems for the reduction of nitrogen were based on the use of the nitrogen-fixing hydroxide system $Ti(OH)_3$–Mo(III) in a methanolic alkaline solution. In this system, molybdenum(III) played the role of a catalyst activating nitrogen and titanium(III) played the role of the reductant.[38] The available information about the involvement of a large number of Ti^{3+} ions in electron transfer to the active centre[38] permitted the hope that it would be possible to use Ti^{3+} as the catalytic transferring agent in amalgam or electrochemical reduction. Indeed the introduction of sodium amalgam into the system made it possible to increase appreciably the yields of N_2H_4 and NH_3,[39,40] the formation of nitrogen fixation products being observed already at 20 °C, while in the absence of the amalgam the reaction was carried out at temperatures above 80 °C. The relatively slow reduction of hydrazine in this system and the kinetics of the accumulation of ammonia showed that the fixation products are formed via parallel pathways.[40]

The results obtained in the amalgam reduction of nitrogen made it possible to proceed to direct electrochemical reduction at a mercury cathode in the same system.[41] It was found that the maximum yield of products is attained at a current density of 0.5 mA cm^{-2} or a potential of −1.86 V, i.e. under the conditions for the formation of sodium amalgam on the electrode.[42] At more positive potentials, the rate of reaction decreased exponentially with decrease in the absolute potential, in conformity with the slow discharge theory, while at more cathodic potentials the absorption of charged hydroxide species was hindered. When the mercury cathode was replaced by a rotating amalgamated copper electrode (3000 rev min^{-1}), the electrochemical nitrogen reduction reaction became selective with respect to hydrazine. This was explained[43] by the short contact times between the activated species and the electrode surface as a consequence of which the transfer of six electrons with formation of ammonia became less probable than the four-electron reduction of nitrogen to hydrazine.

The study of the electrochemical behaviour of titanium(III) and titanium(IV) chlorides in methanol made it possible to discover conditions under which the solution remained homogeneous even at a relatively high alkalinity (guanidine buffer, $pK = 13.6$) and titanium(IV) was reduced to titanium(III).[44] The introduction of molybdenum(III) did not affect the homogeneity of the solution. The formation of N_2H_4, catalysed by this system, in electrolysis in a diaphragm electrolyser (a mercury pool at the bottom serving as the cathode at a nitrogen pressure of 30 atm) began at −1.6 V, which corresponded to the half-wave potential for the reduction Ti(IV) + e → Ti(III). The composition of the medium had a significant influence on the rate of reaction.[45,46] The increase in the concentration of alkali as a result of the evolution of hydrogen at the cathode led to a decrease in the rate of formation of N_2H_4, which, however, increased again to the previous value after the introduction of water. It was assumed that the active species in the reduction of nitrogen were heteronuclear titanium(III) and molybdenum(III) complexes; furthermore, the titanium(III) complexes might have played the role of electron transferring agents. The catalytic system containing the components in the proportions Ti/Mo = 3 remained active during electrolysis for more than 14 h.

Similar results were obtained in the amalgam reduction of nitrogen in the titanium(III)–molybdenum(III)–catechol (H_2.Cat) system in an aqueous medium.[47] Catechol forms stable complexes with titanium ions, which remain stable in aqueous media over a wide pH range (from 5 to 13) and which react reversibly at the electrode:

$$Ti(cat)_3^{3-} + e \rightleftharpoons Ti(cat)_3^{4-};\ E^0 = -1.4V.$$

Molybdenum ions also form soluble complexes with catechol, whose composition depends on the pH of the medium and the method of preparation.[48,49] The most active system in the fixation of nitrogen can be obtained by reducing the initial $Ti_2(SO_4)_3$ or Na_2MoO_4 solution with a gradual increase in the alkalinity of the latter from pH 3–4 to pH 7 during electrolysis as a result of the evolution of hydrogen. Under these conditions, the reduction reaction Mo(VI) + e → Mo(V) is accompanied by the dimerisation $2Mo(V) \rightarrow [Mo(V)]_2$ according to polarographic data. The dinuclear dimolybdenum(V) complexes of catechol are reduced irreversibly under the conditions of electrolysis at a controlled potential, forming apparently polynuclear molybdenum(III) complexes. The yield of hydrazine and ammonia in the titanium(III)–molybdenum(III)–catechol system passes through a maximum for the ratio Ti/Mo = 6. In the absence of titanium(III) as well as in all the systems enumerated, molybdenum(III) exhibited a very weak catalytic effect, which made it possible to obtain only traces of hydrazine and ammonia.

The possibility of the electrochemical reduction of nitrogen in aqueous media in the presence of molybdenum complexes was first noted by Zueva et al.[50] However, these data as well as data on the amalgam reduction of nitrogen in methanol solutions, catalysed by molybdenum carbonyl complexes,[51] were poorly reproducible, although the fact itself of the formation of hydrazine was not open to doubt. Reproducible results were achieved using molybdenum(III) complexes as the catalysts, obtained by reducing molybdenum(V) in alkaline methanol solutions in the presence of magnesium ions.[52] The electrochemical[53–55] and kinetic[53,56] study of this system showed that the composition of the species active with respect to nitrogen includes molybdenum(III) and magnesium and that the catalytic complex functions in a state corresponding to its adsorption on the surface, although the catalyst is fairly rapidly deactivated during the reaction. The only nitrogen reduction product was hydrazine.

These results served as a basis in the search for molybdenum(III) complexes capable of being strongly adsorbed on the amalgam surface as a result of the surface activity of the ligand. After numerous surfactants of various nature had been tested, it was possible to observe an appreciable and satisfactorily reproducible increase of the catalytic activity of molybdenum(III) in the presence of dipalmitoylphosphatidylcholine (DPPC).[57] A characteristic feature of the structure of the DPPC molecules, which belong to the class of phospholipids, is a combination of hydrophobic "tails" (palmitic acid residues) with a dipole "head", incorporating the negatively charged phosphate group and the positively charged quaternary ammonium group. Capacitance measurements have shown[58,59] that the DPPC molecules form an adsorption layer on the negatively charged surface of the mercury electrode, being arranged vertically with the "head" towards the surface and the hydrophobic "tails" towards the solution. It has been suggested[56] that the active species is a dinuclear dimolybdenum(III) complex stabilised as a result of interaction with the phosphate (or carbonyl) groups in the adsorbed DPPC. The identical activation energies (~36 kJ mol^{-1}) for the formation of N_2H_4 and NH_3 show that, in the parallel reactions in which these products are formed, there apparently exists a common rate-limiting stage. This stage may be electron transfer from the amalgam to the active complex with formation of a molybdenum derivative of hydrazine (N_2^{4-}). This process is facilitated by the synchronous transfer of protons from the solvent via the hydrophobic layer of DPPC and the formation of the fragment $N_2H_n^{(4-n)-}$. At nitrogen pressures in excess of 50 atm, when the rate of formation of N_2H_4 and NH_3 ceases to depend on pressure, the yield of products calculated relative to the sodium content in the amalgam is approximately 2%.

Further improvement of this catalytic system was achieved by introducing tertiary phosphines, in the presence of which an appreciable catalytic effect was observed already at atmospheric nitrogen pressure.[60] The cocatalytic effect of phosphines was attained only in the presence of a phospholipid; their joint (synergistic) action increased the rate of reaction by a factor of three compared with its rate in the absence of the phospholipid, so that it was virtually identical with the rate of biological fixation of nitrogen (0.1–1 of a N_2 molecule per second per active centre). At a nitrogen pressure of 50 atm, the N_2H_4 concentration reached 2.6×10^{-2} M and the yield relative to the sodium in the amalgam which reacted was 20%.

Recently the fixation of nitrogen in the molybdenum(III)–DPPC–phosphine catalytic system was achieved also under the conditions of electrolysis at a mercury cathode.[61] Although the structure of this multicomponent and most active of all the known nitrogen-fixing systems is still not clear in its details, its investigation by cyclic and a.c. voltamperometry[54,55,62] has to some extent thrown light on the functions of the individual components. Thus it has been suggested that in the adsorption layer there are two types of molybdenum(III) complexes, one of which, containing only molybdenum, binds and activates nitrogen (activator) but exchanges electrons with the electrode only slowly.[62] The second complex—a molybdenum–magnesium complex—does not activate nitrogen but exchanges electrons with the electrode and the activator rapidly and reversibly and thus can function as a redox transferring agent, which is essential for the coupling of the electrochemical and chemical stages of the catalytic process. As a result of the strong adsorption properties of the transferring agent, its concentration on the amalgam surface greatly exceeds the content of the activator. The phospholipid coordinated to the activator increases the degree of adsorption of the layer and approximately equalises the surface concentrations of both components, maintaining them in the proportions optimum for the effective functioning of the catalytic system. The incorporation of the activator in the lipid film specifies a fully defined spatial disposition of the active centre, relative to the electrode on amalgam surface, and, furthermore, it prevents the deactivation of the catalyst during the reaction of the kind observed in the system without a phospholipid.[53] Coordination to phosphines enhances the electron-accepting properties of the transferring agent (and possibly also the activator), which should increase the rate of electron transfer from the amalgam to the substrate. Overall, the creation of a sterically ordered activator–transferring agent–outer electron source (amalgam or electrode) system lowers the energy barrier to electron transfer to the coordinated nitrogen molecule, as a result of which a catalytic effect comparable to the rate of an enzyme process is achieved.

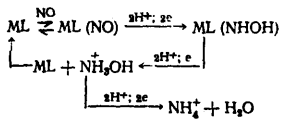
Among other metal complexes catalysing the electrochemical reduction of nitrogen in protic media (water, THF–CH_3OH mixture), mention may be made of the clusters $[Fe_4S_4(SPh)_4]^{2-}$ and $[Mo_2Fe_6S_8(SPh)_9]^{3-}$.[63] Electrolysis in the presence of these complexes at $E = -1.7$ V, atmospheric nitrogen pressure, and 20 °C leads to the formation of NH_3 in a current yield of 1.6%.

Mention may also be made of studies on the reduction of N_2 to NH_3 in aqueous hydrochloric acid solutions in the presence of molybdenum complexes and zinc chloride[64] and on the direct reduction of N_2 at an iron cathode in alkaline solutions[65] with a current yield of ammonia not exceeding 1%. The detection of small amounts of ammonia must be checked carefully by carrying out parallel experiments with an inert gas or $^{15}N_2$. Without such a check, there is a possibility of erroneous conclusions about the feasibility of the reduction of nitrogen in particular systems. How likely is the risk of such an error is demonstrated by a study[66] in which it was shown by means of a repeated test in an inert gas atmosphere that the NH_3 detected in the electrochemical and photoelectrochemical reduction of nitrogen at an iron semiconductor (GaP) cathode is formed as a result of the reduction of the admixtures of nitrates and nitrites in the reagents employed. The reduction of nitrogen reported in studies[64,65] where no such check was made is therefore open to doubt.

The main disadvantage of all the electrochemical systems for the reduction of molecular nitrogen known at the present time is the low current yield of ammonia and hydrazine. This is associated with the occurrence of the parallel hydrogen evolution reaction whose rate is significantly higher.

Overall, studies on the electrochemical reduction of nitrogen in protic media are of great theoretical interest and have laid the foundations for future technologies for the synthesis of NH_3 and N_2H_4 under mild conditions. However, it must be recognised that these studied have not so far gone beyond the framework of purely laboratory methods.

Systems incorporating a powerful chemical reductant (organomagnesium, organolithium, and organoaluminium compounds, lithium tetrahydroaluminate, and metallic magnesium) and a transition metal compound capable of forming a complex with molecular nitrogen, which were discovered by Vol'pin and Shur in 1964,[67] served as a basis for the development of a nitrogen reduction process in aprotic media. The final products of the reduction of nitrogen in these systems are compounds of the nitride type, whose hydrolysis can yield ammonia. In the presence of aprotic Lewis acids, the amount of bound nitrogen exceeds by a factor of tens and hundreds the amount of catalyst used.



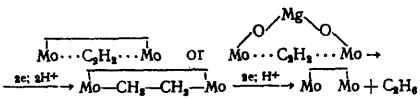
A series of electrocatalytic systems have been proposed,[68] the most effective of which makes it possible to obtain about 3 moles of ammonia per mole of a titanium compound when nitrogen is blown through a cell with an aluminium anode and a nichrome cathode filled with a solution of naphthalene and titanium and aluminium isopropoxides in dimethoxyethane. The reaction mechanism was not investigated, but it has been suggested that naphthalene fulfils the function of a redox transferring agent, aluminium isopropoxide plays the role of the Lewis acid, and the catalyst is the alkoxy-derivative of titanium(II).

A fundamentally new approach to the direct synthesis of organonitrogen compounds, especially aromatic amines,[67] from molecular nitrogen presupposes either the insertion of nitrogen in a metal–aryl bond or direct nucleophilic attack on the nitrogen ligand by a carbanion with subsequent reduction of the ArN=N group coordinated to the metal. Stable diazoalkane, diazenide, and hydrazide derivatives, from which free amines can be isolated by degradative methods, have been obtained by the direct alkylation and acylation of the nitrogen ligand.[69]

The degradative isolation of substituted hydrazines and amines from the hydrazido- and diazenido-complexes of molybdenum and tungsten can be replaced by the electrochemical reduction of these complexes at mercury or platinum cathodes in an aprotic medium using the traces of water in the solvent as the source of protons.[70,71] *N*-Aminopiperidine[70] and 5-amino-4-cyanopyrazole [71] were then obtained in 60–70% yields. Although this approach is very attractive, the problem of creating a continuous catalytic cycle for the synthesis of amines from molecular nitrogen is still far from being solved. The principal difficulties which must be overcome are associated with the appreciable contribution of side reactions and also with the difficulty of regenerating the initial complexes and isolating the target product from the reaction mixture without decomposing the catalytic system.

The interest in the problem of the electrocatalytic reduction of NO is associated with the attempt to utilise under mild conditions the nitrogen oxides contained in the waste gases from many chemical industries. In contrast to the known methods for the heterogeneous reduction of NO with H_2, CO, or NH_3 (see, for example, Seiyama et al.[72]), the electrochemical utilisation of NO does not require high pressures and temperatures. Successful attempts have been made both at the direct electrochemical reduction of NO and at its electrochemical reduction in the presence of metal complexes with formation of N_2O, N_2, NH_2OH, N_2H_4, and NH_3 as the products.[72,73]

In weakly acid aqueous solutions in the presence of transition metal (Fe^{2+}, Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, etc.) complexes of ethylenediaminetetraacetate (EDTA), the electrochemical reduction of NO at the semiconducting GaAs electrode is accompanied by the selective formation of NH_3 (degree of conversion 22–31%) at room temperature and atmospheric pressure.[74] Similar results have been obtained at a platinum electrode ($E = -1.8$ V) using FeL_3^{2+} complexes (L = phen or bipy) as the catalyst; the degree of conversion of NO into NH_3 is 74–84%.[75] Finally, the selectivity of the conversion of NO into NH_3 at a carbon glass electrode modified with cobaltphthalocyanine reaches 92% (current yield 63%), while at a platinum electrode modified with poly(4-vinylpyridine)iron(II) (a redox catalyst), it does not exceed 2%.[76] This indicates that the reduction of NO proceeds via the coordination, rather than the redox-catalytic, mechanism. Presumably the coordination of NO to the metal is accompanied by a shift of electron density to the NO molecule, which activates it and results in its reduction. The mechanism for the reduction of NO to NH_3 catalysed by a metal complex (ML) can then be represented, for example, in the following manner:[75,77]



3. Reduction of Compounds with Triple Bonds

The reduction reactions of acetylene, the cyanide ion, nitriles, and isonitriles can be usefully removed to a separate chapter, since they are frequently regarded as model reactions for the reduction of molecular nitrogen, because these substrates are isoelectronic with nitrogen molecule and are in the main electrochemically inactive.

In the series of compounds with multiple bonds whose reduction is catalysed by molybdenum(III) complexes, acetylene is the most convenient substrate for the investigation of the kinetics and mechanism of the electrocatalytic reaction, since the hydrocarbons formed in it can be readily analysed by gas chromatography and the ratio of the products is extremely sensitive to the structure of the catalytically active species. The cysteine complexes of molybdenum(III) catalyse in aqueous solutions (pH 8–10) the electrochemical reduction of acetylene to ethylene and ethane in the proportions $C_2H_4 : C_2H_6 = 0.8$ and in these and other systems, which will be discussed below, ethylene is not reduced and thus ethane is formed from acetylene without the emergence of the ethylene derivative from the coordination sphere of the catalyst.[78,79]

Molybdenum(III) citrate complexes exhibit a similar catalytic activity.[80] It has been suggested[79,80] that a vacancy for the coordination of acetylene (C_2H_2) is liberated as a result of the dissociation of the oxo bridge bonds between the molybdenum(III) ions in the dimeric complex formed on reduction of the initial cysteine or citrate complexes of molybdenum(V). This conclusion agrees well with the fact that the stable complex Na_2MoO_4 (EDTA), in which such dissociation of the bonds after the reduction of molybdenum(VI) to molybdenum(III) does not occur, is catalytically inactive.[79] However, the replacement of the oxo bridges by the more labile sulphide bridges in $Na_2Mo_2O_3S$ (EDTA) or $Na_2Mo_2O_2S_2$ (EDTA) makes the dissociation of the bridge bonds again possible and catalytic activity appears. This entails an increase in selectivity with respect to ethane and the attainable product ratio $C_2H_4 : C_2H_6 = 0.2–0.3$ differs sharply from the ratio characteristic of the cysteine and citrate complexes.

When magnesium ions are introduced into the system containing molybdenum(III) citrate complexes, the current yield of the reaction products becomes quantitative and the selectivity with respect to ethane increases,[80] which suggests that the mutual approach of two molybdenum(III) ions as a result of the appearance of an elongated bridge, made up of a bidentate carboxylate ligand or the magnesium ion, creates a possibility for the linear coordination of C_2H_2 between the molybdenum ions, which is similar to the coordination of nitrogen examined above and favours a more far-reaching reduction of acetylene to ethane via the intermediate dimolybdenum derivative:

In the products of the amalgam reduction of C_2H_2 in the presence of molybdenum(III) and tungsten(III) citrate complexes, appreciable amounts of methane, propane, and propene were detected together with C_2H_4 and C_2H_6.[81,82] The formation of methane (CH_4) indicates an increase in the lifetime of the dimetallic ethane derivative M=CH–CH=M because of the weakening of the proton-donating properties of the medium, as a result of which its further reduction with cleavage of the carbon–carbon bond becomes possible.[81] It has been suggested that this cleavage is accompanied by the formation of carbenoid intermediates of the type $M=CH_2$, whose secondary reactions with C_2H_2 lead to the appearance of propane and propene in the reaction products.[82]

In all the electrocatalytic systems enumerated above, the rate of reaction depended exponentially on the cathode potential and thus the rate-limiting stage is electron transfer from the electroce to the catalytically active species containing a coordinated acetylene molecule. In contrast to this, in the system incorporating the catechol complexes of titanium(III) and molybdenum(III), the rate of reaction no longer depended on the cathode potential and was approximately an order of magnitude higher than in the system without titanium(III).[83] As in the amalgam reduction of nitrogen,[47] it has been suggested that $Ti(cat)_3^{3-}$ functions as the catalyst transferring electrons from the electrode to the catalytically active species in the bulk of the solution.

The iron-molybdenum cofactor isolated from nitrogenase has been used[84] as the catalyst for the electrochemical reduction of C_2H_2. The main product of electrolysis at a mercury cathode in the borate buffer (pH 9.6) at $E = -1.8$ V was C_2H_4 with a current yield of 2%. Nitrogenase also catalysed this reaction but only in the presence of adenosinetriphosphate and methylviologen as the catalytic transferring agent, since the direct electron transfer from the electrode to the active centre of the enzyme was prevented by its protein environment.

The stoichiometric reaction involving the reduction of C_2H_2 to C_2H_4 by a synthetic analogue of ferredoxin containing a cluster with the cubane structure, i.e.

$$2\,[Fe_4S_4(SR)_4]^{3-} + C_2H_2 + 2H^+ \rightarrow 2\,[Fe_4S_4(SR)_4]^{2-} + C_2H_4\ ,$$

where R = Ph or p-MeC_6H_4,[85] has been used to set up an electrocatalytic cycle in which the reduced form of the cluster was constantly regenerated at a mercury cathode:[86]

$$2\,[Fe_4S_4(SR)_4]^{2-} \overset{2e}{\rightleftharpoons} 2\,[Fe_4S_4(SR)_4]^{3-} \xrightarrow{C_2H_2;\ 2H^+} 2\,[Fe_4S_4(SR)_4]^{2-} + C_2H_4\ .$$

The conclusions concerning the role of iron sulphide and iron molybdenum sulphide clusters in the electrocatalytic reactions must be treated with caution, since the dissociation or decomposition of the cluster into low-molecular-weight fragments is possible in their reduction. In particular, in methanolic solutions of $FeCl_2$ (or $FeCl_3$) and Li_2S, sodium amalgam reduces C_2H_2 to C_2H_4 and C_2H_6 with an activity close to that of the cluster $[Fe_4S_4(SBu)_4]^{2-}$, which decomposes under the conditions of amalgam reduction.[87]

The modification of the surface of the electrode prepared from polymeric sulphur nitride $(SN)_x$ by molybdenum ions (possibly via their binding to the surface sulphur atoms) made it possible to obtain an electrode on which acetylene was selectively reduced to ethylene with a quantitative current yield and which exhibited an activity exceeding that of nitrogenase.[88]

Electrocatalytic systems based on molybdenum complexes have also been used to reduce other substrates with triple bonds. Thus, in the presence of molybdenum(III) citrate complexes at a mercury cathode at a potential of −1.8 V, the cyanide ion is reduced to NH_3 and CH_4; furthermore, C_2 and C_3 hydrocarbons are produced in smaller amounts.[89] In the reduction of CH_3CN in the same system, propane and propene were found together with the main products C_2H_6 and NH_3, which indicates the dissociation of the C–C bond in the activated CH_3CN molecule with the intermediate formation of, apparently, the carbenoid fragment $Mo{=}CH_2$ and the growth of the carbon chain in its interaction with the next CH_3CN molecules.[90] The formation of amines in these systems was not observed.

The iron sulphide and iron molybdenum sulphide clusters already mentioned catalyse the reduction, in a protic medium, of methyl isonitrile to CH_4, C_2H_4, and C_2H_6 and of acetonitrile to C_2H_6 and NH_3.[91] Under the same conditions, the azide ion is reduced to N_2H_4, NH_3, and N_2,[92] while N_2H_4, NH_3, and RNH_2 are formed from RN_3 (R = CH_3 or HOC_2H_4).[93] The reduction can be carried out, in particular, in an aqueous borate buffer solution (pH 10) at a chemically modified electrode prepared by depositing the $(Bu_4N)_3[Mo_2Fe_6S_8(SPh)_9]$ cluster from solution in acetonitrile onto the surface of an electrically conducting support. However, the activity of this electrode decreases with time as a consequence of the deposition of the cluster from the electrode surface.[93]

4. Reduction of Carbon Oxides

The creation of catalysts for the low-temperature reduction of carbon monoxide and dioxide is of potentially very great importance, since, as the coal, petroleum, and natural gas resources are exhausted, carbon monoxide may becomes a source of raw material for the synthesis of various organic compounds.

A review has been devoted[94] to questions of the coordination chemistry of CO_2 and its biological, chemical, photochemical, and electrochemical activation. The amalgam or electrochemical reduction of CO_2 in the absence of metal complexes can lead to various products of the type of formate,[95] oxalate,[95,96] and many other organic compounds (tartrate, glycolate, etc.),[94] depending on the conditions (the material of the electrode, solvent, etc.).

The purely electrochemical reduction of CO_2 is an energy consuming process, since the formation of the radical-anion $CO_2^{\cdot-}$, which is the primary product of the conversion of CO_2, takes place at potentials of approximately −2 V.[94] The situation may change significantly when metal complex catalysts are used. The possibility of involving CO_2 in the electrolytic carboxylation of organic halides was already mentioned previously.[17] Another reaction catalysed by metal complexes is the reduction of CO_2 to CO. The tetra-azamacrocyclic complexes of cobalt[97] and nickel,[98] $Re(bipy)(CO)_3Cl$,[99] $[Ru(bipy)_2.(CO)_2]^{2+}$,[100] RhL_2Cl (where L = diphosphines),[101] etc. serve as catalysts. The reaction is carried out in aqueous organic or aqueous media at atmospheric or elevated CO_2 pressures at different electrodes (mercury, carbon glass, platinum, etc.). The reduction prduct is the CO + H_2 mixture and under optimum conditions the current yield of CO reached 90–100%. In an alkaline medium, formate is formed together with CO.[100]

The electrolysis is carried out at the electrochemical reduction potentials of the metal complexes. In all cases, these potentials are more cathodic than the thermodynamic potentials of the reduction of CO_2 to CO.[94] The metal complexes retain their catalytic activity for a long time.[98–101] It has been suggested[99] that they play the role of redox catalysts in this reaction. However, it may be thought that, since this reaction is in fact the reverse of the metal complex-catalysed conversion reaction of water gas (CO + H_2O),[102] the function of the catalyst consists not only in electron transfer from the electrode to the CO_2 molecule but also in preliminary coordination and activation of the latter. The absence of formate from the products indicates, according to the authors,[99] that hydride derivatives capable of reducing CO_2 to formate are not formed in the reduction of the metal complexes.

The complex $Rh(bipy)_2^+$, electrogenerated from $[Rh(bipy)_2.(CF_3SO_3)]^{2+}$ in acetonitrile at the potentials of the $Rh(bipy)_2^{0/-}$ redox transition (E^0 = −1.55 V), reduces CO_2 catalytically at atmospheric pressure to formate with a current yield of 64%.[103] The formation of the product is described by a stoichiometric scheme with participation of the cations of the supporting electrolyte Bu_4N^+:

$$Bu_4N^+ + CO_2 \overset{2e}{\rightarrow} HCO_2^- + Bu_3N + CH_2{=}CHEt\ .$$

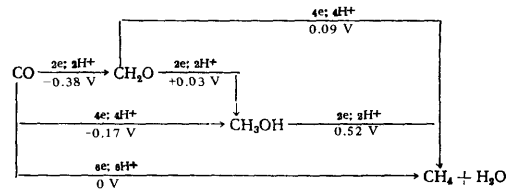
It was shown in the same study that the complex $Ru(trpy).(dppe)$ [where trpy = 2,6-di(2-pyridyl)pyridine], electrogenerated by the irreversible two-electron reduction of $Ru(trpy)(dppe)Cl^+$, catalyses, under analogous conditions at E = −1.4 V, the reduction of CO_2 in accordance with the stoichiometric scheme

$$Bu_4N^+ + 2CO_2 \overset{2e}{\rightarrow} Bu_3N + CH_2{=}CHEt + CO + HCO_3^-\ .$$

It is suggested that the catalytic activity of metal polypyridyl complexes is due to the possibility of their electrochemical reduction accompanied by the ejection of the $CF_3SO_3^-$ or Cl^- anions and the appearance in the coordination sphere of a free site for the binding of CO_2. The subsequent reduction of CO_2 in the coordination sphere leads to products whose nature depends significantly on the basicity of the intermediates in the reduction of CO_2. The polypyridyl ligands, which play the role of a kind of "electron reservoir", apparently have an important function in the catalytic activity of these complexes.[103]

The cluster $[Fe_4S_4(SR)_4]^{2-}$ (where R = Ph or $PhCH_2$), which has the cubane structure and is a model of ferredoxin, catalyses in DMF at $E = -1.7$–2.0 V the electrochemical reduction of CO_2 on mercury with formation of formate, oxalate, and carbon monoxide as the products.[104] The same products are formed also in the non-catalytic electrochemical reduction of CO_2 but at much more cathodic potentials (−2.4 V). Furthermore, whereas the non-catalytic reduction of CO_2 leads mainly to the oxalate, the principal product in the catalytic process is formate (selectivity up to 93%). By varying the composition of the electrolyte, it is possible to drive the process towards the required product.

Thus the use of transition metal compounds capable of forming complexes with CO_2 can ensure the operation of a particular catalytic reduction mechanism. The reduction of CO_2 to formaldehyde, methanol, and hydrocarbons is more promising. For a number of reasons, it is desirable to carry out the reaction in protic media. Only the first steps have been taken along these lines. Thus it has been shown[105] that reduction of CO_2 with zinc amalgam catalysed by VO^{2+} ions in acid aqueous solutions (pH 2.5) leads to the formation of formaldehyde, methanol, and methane together with formic acid. In the presence of titanium ions, aluminium amalgam reduces CO_2 selectively to CH_2O alone under the usual conditions.[106] The reaction proceeds within a narrow pH range in the vicinity of 3.5, which enabled the authors[106] to put forward the hypothesis that the catalytically active species is formed by the association of two titanium ions.



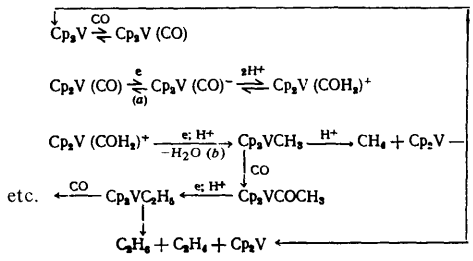
The molybdenum(III) complex of catechol catalyses the electrochemical reduction of CO_2 at a mercury cathode to C_1–C_3 hydrocarbons.[107] The reduction was carried out in an aqueous buffer solution (pH 7) under the conditions of galvanostatic electrolysis (i = 7 mA cm^{-2}). The reaction is accompanied by the vigorous evolution of hydrogen and the overall yield of hydrocarbons does not exceed 0.2%. It is of interest that the formation of oxygen-containing products of the reduction of carbon dioxide (CO, CH_2O, HCO_2H, and CH_3OH) was not observed and the rate of reaction increased by a factor of 5 after the introduction into the system of $Ti(cat)_3^{3-}$, which is itself inactive in relation to CO_2. It has been suggested that CO_2 is reduced in the coordination sphere of Mo(III) via a mechanism involving inner sphere catalysis without the emergence of intermediates into the bulk of the system. This system is of interest also because outer sphere redox catalysis takes place in it together with the inner-sphere catalysis, since $Ti(cat)_3^{3-}$ fulfils the function of an agent transferring electrons from the cathode,[47,83] The formation of C_1–C_3 hydrocarbons was observed also in the reduction of CO_2 catalysed by $[Fe_4S_4(SR)_4]^{2-}$.[104]

Other classes of transition metal complexes catalysing the electrochemical reduction of CO_2 are metallophthalocyanines and metalloporphyrins. This question has been considered in greatest detail by Tarasevich and Radyushkina.[3] The main reduction products are oxalic and gluconic acids. One may also mention a study[108] in which it was shown that $VO(acac)_2$ in acetonitrile catalyses the electrochemical reduction of CO_2 at the potentials at which the corresponding vanadium(II) complex is generated, but the reduction products were not identified.

Thus the possibility of the formation of complexes of CO_2 with transition metal compounds and the possibility of the inner sphere electron transfer to the coordinated CO_2 molecule at much more anodic potentials than in the purely electrochemical reduction demonstrate that MCE is promising in various carbon dioxide conversion reactions.

The involvement of carbon monoxide in catalytic reactions leading to the synthesis of organic compounds has long formed an industrial application. It is sufficient to point out the processes involving the formation of synthol via the Fischer–Tropsch reaction, the carbonylation of methanol with formation of acetic acid, the conversion of water gas, etc.[2] On the other hand, the reactions involving the electrochemical conversion of CO began to be investigated comparatively recently. This is because the electrochemical reduction of carbon monoxide takes place at extremely negative potentials, since the thermodynamics of this process are apparently determined primarily by the potential corresponding to the reduction of CO to the radical-anion $CO^{\cdot-}$. Thus CO can be reduced chemically only with the Na–K alloy in THF.[109] After the hydrolysis of the reaction mixture, the glycolate and oxalate anions as well as $C_3O_3^{2-}$ are then formed as the final products. The electrochemical reduction of CO at pressures of several hundreds of atmospheres at a steel cathode under the conditions of galvanostatic electrolysis leads to the formation of squaric acid $C_4O_4H_2$.[110] Apparently, in liquid ammonia (−50 °C), in the presence of 0.1 M KI, carbon monoxide is reduced at various cathodes at potentials close to the potentials at which the solvated electron (e_S^-) is generated.[111] However, the attempt at a preparative electrochemical reduction of CO under these conditions failed. Only the reduction of CO by electrogenerated e_S^- leads to the formation of the dimeric anions $C_2O_2^{2-}$, which are precipitated as a deposit of the salt $K_2C_2O_2$.

The use of many-electron reactions should significantly improve the energetics of the reduction of carbon monoxide. The thermodynamics of the reduction of CO to the simplest organic compounds confirms this.



Despite the favourable thermodynamics, the direct amalgam or electrochemical reduction of CO at a mercury cathode is impossible, apparently because of kinetic limitations. The picture changes significantly when CO is coordinated to transition metal complexes, i.e. under the conditions of coordination electrocatalysis, where the catalyst–substrate complex with an activated CO molecule is reduced.

The fruitfulness of this approach was first demonstrated in relation to the vanadocene-catalysed amalgam reduction of CO with formation of C_1–C_4 hydrocarbons.[112–116] It was shown[112,113] that Cp_2V effectively catalyses the reduction of CO with sodium amalgam even at room temperature and atmospheric CO pressure in aprotic solvents (DMF, THF, etc.) containing diethylbarbituric acid or a phenol as the proton donor. The main product is methane (85–95%) and the remainder consists mainly of saturated C_2–C_4 hydrocarbons. Under optimum conditions, more than 100 molecules of hydrocarbons are formed per catalyst molecule and the periodic introduction of consumable reagents into the system (amalgam, CO, and a proton donor) makes it possible to achieve a continuous process.[112] This reaction is a kind of electrochemical analogue of the Fischer–Tropsch synthesis, proceeding with participation of the adsorbed catalyst and being characterised by the transfer of the first electron to the coordinated substrate molecule in the direction opposite to that of the standard potential drop, since $E^0[Cp_2V(CO)^{0/-}] = 2.3$ V and the amalgam potential is approximately −2.1 V.[114] We may note that this is the first case of endoergic electron transfer[6]

in MCE, known to us, which has been demonstrated experimentally. Vanadocene also catalyses the evolution of oxygen, as a result of which the current yield of hydrocarbons does not exceed 10%.[114]

Both reactions (the reduction of CO and the evolution of H_2) take place in the adsorption layer without the emergence of the intermediate reduction products into the bulk of the solution and their kinetics is described taking into account the surface and not the bulk-phase concentration of the catalyst. Carbon monoxide is reduced at potentials which are insufficient for the intermediate formation of the hydride Cp_2VH^-, which makes it possible to rule out the hydride mechanism of the reduction of CO and explains the absence of CH_2O and CH_3OH from the reaction products.[113,114] Finally, the formation of C_2–C_4 hydrocarbons and also the growth of the hydrocarbon chain in the Fischer–Tropsch synthesis take place as a result of the insertion of CO in the metal–alkyl bond in the intermediate alkyl complexes Cp_2V–Alk,[115] which yet again indicates the retention of the general characteristics of MCC in electrocatalysis. The catalytic cycle of the vanadocene-catalysed electrochemical reduction of CO can be represented schematically as follows:[115,116]

Stage (*a*) is endoergic and occurs because of the presence in the cycle of the rapid and irreversible stage (*b*) in which the C–O bond is ruptured.

The efficiency of metal complex electrocatalytic systems depends significantly on the stability of the catalyst. Thus, together with vanadocene, other electrochemically generated metallocenes of Group VB and VIB metals likewise catalyse the electrochemical reduction of CO in aprotic solvents containing proton donors, but the catalytic activity of systems based on them decreases to zero fairly rapidly.[117] This is due to the metastability of the complexes Cp_2M (M = Nb, Mo, or W) responsible for the coordination of CO.

The advantage of electrocatalytic reactions in theoretical research consists in the possibility of using electrochemical methods for their investigation. For the electrochemical reduction of CO catalysed by metallocene dichlorides, it has been possible not only to identify by electrochemical methods the primary products of the interaction of the catalyst with CO and to reach a conclusion about the nature of the catalytic activity of the species, but also to elucidate the cause of the differences between the catalytic activities of the complexes Cp_2MCl (M = Ti, V, Nb, Mo, or W), which consists in the different stabilities of the metallocenes or their cations responsible for the coordination of CO, and also to characterise the kinetic thermodynamic regions where these are stable.[117,118] The thermodynamics of the region corresponding to the stability of catalysts is an important factor which must be taken into account in the development of metal complex electrochemical systems. Without taking it into account, one can over-reduce or, conversely, oxidise the catalyst, which would alter the electronic configuration of its constituent metal, making it unfavourable for the coordination of the substrate, so that the catalyst loses its activity. The studies where the possibility of predicting the thermodynamic stability of neutral and ionic metal complexes on the basis of tabulated ionisation potentials of the corresponding metals has been demonstrated in relation to sandwich and wedge-sandwich metal complexes, catalytically active in numerous reactions,[67,122] merit attention in this connection.[119–121]

The electrochemical reduction of CO to C_1–C_3 hydrocarbons can be achieved also in aqueous solution ($6 < pH < 13$) using the catechol complex of molybdenum(III) adsorbed on the mercury cathode as the catalyst.[123] As in non-aqueous media, the main product is methane (80–90%) and the overall current yield of hydrocarbons is a fraction per cent, since the main bulk of the electricity is consumed in the parallel H_2 evolution reaction catalysed by the same molybdenum(III) complexes. The efficiency of this system increases appreciably after the introduction of $Ti(cat)_3^{3-}$, which is manifested by an increase in the rate of reaction and in the current yield of the hydrocarbons to 15%.[124] The kinetic and electrochemical studies of this system have led to the conclusion that the catalytic species in relation to CO is a carbonyl complex of molybdenum(III) and the reversible $Ti(cat)_3^{2-/3-}$ pair functions as a redox catalyst. Thus, when a redox catalyst is introduced into the system, electron transfer also to molybdenum(III) complexes, activating the CO molecule but having no direct contact with the electrode, becomes possible as a result of which the overall rate of reaction increases. This is an excellent example of the combination of coordination catalysis [activation and inner-sphere reduction of CO in the presence of the molybdenum(III) complex] and redox catalysis [electron transfer by the $Ti(cat)_3^{3-}$ complex to the molybdenum(III) carbonyl complex] which leads to an increase in the catalytic efficiency of the system.

The electrocatalytic reduction of CO by metal complexes can yield not only hydrocarbons but also oxygen-containing products. At room temperature and atmospheric pressure, CO is reduced selectively in aqueous solutions (pH 3.5) to methanol at a platinum electrode modified by the complex $[Fe^{II}(CN)_6]Fe^{II}K_2$ (A) at $E = -0.9$ V.[125–127] Methanol is also formed at a non-polarised cathode, the process being accompanied by the oxidation of the complex (A) to $Fe^{II}(CN)_6 . Fe^{III}K$ (B). It has been suggested that the CO molecule is activated as a result of its incorporation into the coordination sphere of the anion $[Fe(CN)_6^{4-}]$ with displacement of CN^- and the formation of $[Fe(CN)_5(CO)]^{3-}$ and the subsequent reduction of CO in MeOH via a redox catalytic mechanism [the catalyst is the (A)/(B) redox pair].[125,126]

There are relatively few data on the electrochemical oxidation of CO catalysed by metal complexes. One can only mention a study[128] where it was shown that in aqueous solutions of HX (X = Cl, Br, or I) the complex $[Rh(CO)_2X_2]^-$ catalyses the oxidation of CO to CO_2 on carbon glass at potentials of approximately 0.4 V. This reaction is thought to be promising for use in fuel cells.

5. Oxidation of Water and Organic Compounds

The oxidation of water to oxygen is a complex many-electron process, which gives rise to certain requirements to be met by the metal complex catalyst of this reaction, which are extremely similar to the requirements imposed on the catalysts of the reduction of nitrogen: it is necessary that the metal complex should be able to "switch over" the reaction from the thermodynamically unfavourable one-electron mechanism to the more favourable many-electron mechanism.[129–131] Only then do the thermodynamics of the overall oxygen formation reaction become sufficiently favourable. By analogy with natural photosynthesis, it has been suggested[129]

that the metal complex should consist of a dinuclear or tetranuclear cluster, each atom of which is capable of accepting respectively two electrons or one electron, such acceptance being reversible since only then is it possible to achieve an efficient operation of the catalyst. Polynuclear complexes can also be used, but in this case the oxidation of water would proceed via the intermediate formation of a peroxy-derivative. However, this would happen only if the metal atom in the complex is capable of changing its valence by two units.

The use of such approaches[132,133] showed that simple hydroxo-complexes of iron(II) and cobalt(II) are effective catalysts of the electrochemical oxidation of water. This is due to the ability of these metals to change their valence by two units with formation of highly reactive M(IV) complexes, oxidising water to the peroxide, which is rapidly oxidised further under these conditions or decomposes catalytically at the electrode, affording oxygen. The mechanism of the electrocatalytic oxidation of water with participation of hydroxo-complexes of iron and cobalt (MOH^+) can be represented by the scheme[132,133]

$$M^{II}OH^+ \xrightleftharpoons{2OH^-} M^{II}(OH)_3^- \xrightarrow{-2e} M^{IV}(OH)_3^- \rightarrow M^{II}OH^+ + H_2O_2 \quad . \qquad (1)$$

The catalytic process is apparently of a mixed bulk-phase–surface character although the appearance of a catalytic oxidation wave on the voltage–current plots even at Fe^{2+} and Co^{2+} concentration in the range 10^{-8}–10^{-6} M indicates a significant contribution of the bulk-phase process.[132]

The development of catalysts for the oxidation of water is important also from the standpoint of the solution of the problem of its photocatalytic oxidation. In particular, using iron and cobalt hydroxo-complexes, some of the first catalytic systems for the oxidation of water with high quantum yields under the influence of visible light have been developed.[134,135] Detailed kinetic study led to the conclusion[136–139] that the mechanism of the catalytic action of the hydroxo-complexes in the reactions involving the oxidation of water by one-electron oxidants is more complex than the one represented by the overall Eqn.(1).

In subsequent studies, whose authors attempted to use the complexes of the same transition metals but with other ligands are homogeneous catalysts of the electrochemical and chemical oxidation of water, the high activity of even traces of the hydroxo-complexes led, in our view, to an erroneous interpretation of the data obtained. Thus it has been concluded[140] that the hypothetical complex $[Fe(bipy)_2(bipyH)(OH)]^+$ is a catalyst of the electrochemical oxidation of water. However, here no account was taken of the fact that in alkaline media the initial complex $Fe(bipy)_3^{2+}$ hydrolyses with formation of amounts of $FeOH^+$ which are quite sufficient for the appearance of a catalytic effect.[132] An analogous error was most probably made also by Zamaraev and Parmon[141] and Nord et al.[142] in studies of the chemical oxidation of water by one-electron oxidants. The solutions of iron and cobalt complexes with various ligands which they used as "catalysts" almost always contain traces of the corresponding hydroxo-complexes or hydrolyse with their formation. It has been shown[143,144] that such trace amounts are entirely sufficient for the observed catalytic effect.[141,142]

It has been reported[145,146] that the dinuclear complex $[(bipy)_2(H_2O)Ru^{III}ORu^{III}(H_2O)(bipy)_2]^{4+}$ (C) oxidises water to oxygen during its electrochemical four-electron oxidation to $[(bipy)_2(O)Ru^{V}ORu^{V}(O)(bipy)_2]^{4+}$ in an acid medium. However, the authors note that the initial complex is destroyed during the catalytic reaction. It is entirely possible that the complex $RuO_2.xH_2O$, which is known to catalyse effectively the chemical and electrochemical oxidation of water to oxygen in an acid medium,[147] is formed in the course of the degradation. Furthermore, the complex (C) catalyses the chemical or electrochemical reactions in which Cl^- is oxidised to Cl_2.[148,149] In particular, this has been the cause of the erroneous conclusion[145] that the dimer (C) is catalytically active in the electrochemical oxidation of water, since traces of Cl^- ions were present in the electrolyte solution.

Thus, despite certain advances associated with the detection of the catalytic activity of the hydroxo-complexes or iron(II) and cobalt(II),[132,133] the problem of the development of metal complex catalysts for the electrochemical oxidation of water is still far from being solved.

Organic compounds can be oxidised with participation of a number of transition metal ions in the highest oxidation states (Co^{3+}, Ce^{4+}, MnO_4^-, Mn^{3+}, $Cr_2O_7^{2-}$, Tl^{3+}). Some of these reactions can be used to set up an electrocatalytic cycle in which the transition metal ion is regenerated in the initial state by oxidation at the anode. It is by no means always convenient to regenerate the oxidant in the presence of the substrate and this operation is frequently performed in a separate electrolyser and the substrate is then oxidised in another reactor. Analysis of the reactions using electrochemically generated oxidants is outside the framework of the present review. The necessary information about this question can be secured from a monograph[150] and another review.[151] We shall deal only with two examples of the use of metal complexes in oxidation reactions. One of them refers to the application of polypyridyl complexes of ruthenium(IV) as the catalytic transferring agents in the oxidation of organic compounds (S) [152] in accordance with the mechanism

$$[(trpy)(bipy)RuO]^{2+} + S + H_2O \rightarrow [(trpy)(bipy)RuOH_2]^{2+} + S{=}O$$
$$\uparrow \qquad\qquad -2e;\ -(E = 0.6\text{–}0.8\ V) \qquad\qquad \downarrow$$

The oxidation is carried out in a diaphragm electrolyser at a carbon glass anode in phosphate (pH 7) or borate (pH 9) buffer solutions at a metal complex concentration of about 10^{-3} M. Under these conditions, it is possible to oxidise 2-propanol to acetone, toluene to benzoic acid, *p*-xylene to terephthalic acid, and cyclohexene to *p*-benzoquinone via the intermediate formation of 2-cyclohexanone. The oxidation can be carried out using not only a dissolved metal complex but also one which was immobilised beforehand on the anode surface.[153]

The second example refers to the cathodic reactions in which oxygen is activated with participation of metal complexes or transition metal ions. Such activation can be achieved by reducing oxygen to hydrogen peroxide and regenerating from the latter the $OH^{\cdot}$ radical via the reaction of H_2O_2 with Fe^{2+} ions (Fenton's reagent). Electrocatalytic systems for the oxidation of polymethylbenzenes to the corresponding aldehydes[154] and also of aliphatic C_5–C_{30} hydrocarbons and 3-methylpentane to ketones[155] have been constructed in accordance with this principle. The electrolysis is carried out in hydrochloric acid solutions at a mercury cathode, the solution being saturated with oxygen. The following mechanism of the catalytic cycle has been proposed:[154]

$$\left.\begin{array}{l} Fe^{3+} \xrightarrow{e} Fe^{2+} \\ O_2 \xrightarrow{2e;\ 2H^+} H_2O_2 \end{array}\right\} \rightarrow Fe^{3+} + OH^{\cdot} \xrightarrow[-H_2O]{PhCH_3} PhCH_2^{\cdot} \xrightarrow{O_2}$$
$$\rightarrow PhCH_2OO^{\cdot} \rightarrow PhCHOOH \xrightarrow[-Fe^{3+};\ -OH^{\cdot}]{Fe^{2+}} PhCHO \quad .$$

The electrochemical activation of oxygen in hydrocarbon oxidation reactions has been achieved also via electron transfer to an iron–porphyrin complex deposited on the surface of a graphite electrode.[156] The electrode was impregnated with a benzene solution of iron-tetraphenylporphyrin chloride and

dried *in vacuo*. Hexane and 1,2-dimethylcyclohexane were oxidised to the corresponding hexanols under the conditions of potentiostatic electrolysis at $E = -1.5$ V in acetonitrile containing 10% of the hydrocarbon and 5×10^{-2} M acetic anhydride. The current yield of the alcohol was 7%. During the electrolysis, the system lost its activity and after 2 h the reaction ceased completely because the iron-porphyrin was completely washed off the cathode. It has been suggested that the oxidation of hydrocarbons (RH) at this electrode is described by the following consecutive reaction scheme (Pr = porphyrin):

$$\begin{array}{c} \mathrm{PrFe^{III} \xrightarrow{e} PrFe^{II} \xrightarrow{e} PrFe^{I}} \\ \downarrow O_2 \qquad \downarrow O_2 \\ \mathrm{PrFe^{III}O_2^- \xrightarrow{e} PrFe^{III}O_2^{2-} \xrightarrow[-AcO^-]{Ac_2O} PrFe^{III}OOAc \xrightarrow{-AcO^-}} \\ \rightarrow [\mathrm{PrFe^{IV}=O}]^+ \xrightarrow{KH} \mathrm{PrFe^{III}} + \mathrm{ROH}. \end{array}$$

The oxo-complex $[PrFe^{IV}=O]^+$ serves as the hydrocarbon oxidising agent. Overall, the catalytic cycle can be regarded as an electrochemical model of cytochrome P-450.

---o0o---

Thus the use of metal complexes in the catalysis of electrode processes make it possible to reduce the energy consumption and to ensure the occurrence of electrochemical reactions of substrates which are electrochemically inactive or are discharged at electrodes with a high overpotential. The metal complex-catalysed reductive dehalogenation reactions are promising for practical applications, in particular, for the decontamination of waste water containing toxic organic halides and for the solution of certain problems in fine organic synthesis, including the synthesis of carboxylic acids from alkyl and aryl halides and carbon dioxide. The successful development of catalysts for the electrochemical oxidation of nitrogen and carbon monoxide, which make it possible to reduce these substrates at low cathodic potentials and to increase thereby the current yield of the products, enables us to count on fundamentally new possibilities in the electrosynthesis of hydrazine from N_2 and of organic compounds from CO (i.e. a raw material which is non-traditional for electrochemistry) at low pressures and temperatures. The use of metal complexes for the catalysis of electroprocesses in photoelectrochemical solar energy converters (catalysts of the oxidation of water) and current sources (catalysts of the reduction of CO and CO_2 and also of the oxidation of alkanes and CO) is also promising, although one must admit that the development of catalysts for these processes has not as yet gone beyond the framework of laboratory research.

The results presented in this review demonstrate only a small fraction of the possibilities which have arisen in metal complex electrocatalysis with a skilful combination of the principles of electrochemistry and homogeneous and heterogeneous catalysis with ideas derived from modern inorganic and organometallic chemistry. One may hope that the development of this undoubtedly promising field will lead to the discovery of many fundamentally new catalytic reactions and may possibly serve for the creation of new industrial processes.

During the preparation of the present review, there has been a sharp growth of the number of studies on the electrocatalytic reduction of CO_2 to CO. The complexes $\{Pd[PhP.(CH_2CH_2PPh_2)_2]R_3P\}^{2+}$ (where R = MeO, Et, Ph, or CH_2OH),[157] $Ni(bipy)_3^{2+}$, $Ni(dppe)_3^{2+}$,[158] $Re(CO)_3LCl$ (where L = bipy and its substituted derivatives),[159–162] $Ni(teta)^+$, and Co(salen) [163] have been used as catalysts in acetonitrile in the presence of various proton donors. Significantly more attention has been devoted in these studies to the electroanalytical investigation of the mechanism of the catalytic action of the metal complexes. In particular, it has been shown[157] that the key stage in the electrocatalytic cycle is the insertion of CO_2 in the Pd–H bond of the hydride complex formed as an intermediate in the electrochemical reduction. It has been noted[159,161,162] that the efficiency of the catalytic action and the stability of the complexes fixed on electrode-supports by electropolymerisation methods, by incorporation in a polymer matrix, etc. is significantly enhanced. The electrodes modified with an insoluble $K_2Fe[Fe(CN)_6]$ film catalyse the reduction of CO_2 and CO to methanol in an aqueous medium in the presence of water-soluble iron, nickel, cobalt, and chromium complexes.[164,165] The complex $Ru(bipy)_2.(CO)_2^{2+}$ catalyses the selective reduction of CO_2 to $HCOO^-$ in acetonitrile in the presence of $Me_2H_2N^+$ or PhOH as proton donors.[166] Individual examples of the catalysis of CO_2 reduction reactions and also of the dehalogenation of RX by phosphine, polypyridyl, and macrocyclic nickel complexes may be found in Troupel's paper.[167]

The possibility, in principle, of reducing nitrogen by protonating the complex $[W(N_2)_2(dppe)_2]$ with toluene-*p*-sulphonic acid in THF with subsequent electrochemical reduction of the resulting hydrazido-cation $[W(NNH_2)(p\text{-}MeC_6H_4SO_3).(dppe)]^+$ in an atmosphere of N_2 with formation of NH_3 and the regeneration of the initial dinitrogen complex has been demonstrated.[168,169] The products of the reduction of Cp_2TiCl_2 in THF and methanol catalyse the electrochemical reduction of N_2 to NH_3.[170] The current yield of ammonia does not exceed 1.5% and the results have not been confirmed by blank experiments (in an argon atmosphere) in experiments using $^{15}N_2$.

In an aqueous medium, macrocyclic cobalt and nickel complexes catalyse the electrochemical reduction of NO_3^- to hydroxylamine,[171] while water-soluble iron porphyrinates catalyse the reduction of NO_2^- to N_2O, NH_3, and NH_2OH;[172,173] the nitrosyl complex [Fe(NO)Pr] has been proposed to an intermediate in the last reaction.[173] A review[174] has been devoted to the consideration of the electrochemical oxidation reactions of organic compounds, H_2O, Cl^- and the reduction of NO_2^- catalysed by polypyridyl complexes of ruthenium and osmium. Other reviews[175–177] deal with studies in which metal complexes are used as redox transferring agents.

The Oxidation-reduction Stage in the Nitration Reaction

A.S.Morkovnik

The mechanism of the nitration of aromatic compounds in which the initial stage is the oxidation of the aromatic substrate to the radical-cation is examined. Certain general preconditions, which make such a mechanism feasible, and also the available experimental evidence for its operation are analysed.
The bibliography includes 219 references.

I. INTRODUCTION

The reactions of organic compounds with electrophiles are known to begin with electron transfer from the substrate to the reactant and the formation of radical-cation (RC) of the organic compound:[1,2]

$$RH + E^{\cdot} \rightarrow RH^{+} + E^{-} \rightarrow \text{products}.$$

The oxidation-reduction stage in reactions of this type is frequently masked by the rapid subsequent reactions of the RC and the electrophile reduction product, which is a manifestation of the non-radical character of the overall process.[1,2] In such cases, the study of the reaction mechanism involves considerable experimental difficulties and its determination makes it necessary to resort to various indirect data apart from the investigation of the kinetics. These difficulties are a consequence of fundamental limitations characteristic of classical kinetics which make it impossible to obtain direct information about the fastest stages of chemical reactions. As a result, in the words of Hoffmann,[3] with the aid of kinetic studies it is possible to obtain "only the lower limit... to the number of stages in a reaction sequence and hence to the number of intermediate species".

The question of electron transfer as a possible elementary step in the reaction arises, in particular, in the study of the nitration of aromatic compounds. The energies of the highest occupied molecular orbitals (HOMO) of aromatic compounds are frequently close to or even exceed the energies of the lowest unoccupied molecular orbitals (LUMO) of the electrophiles involved in the nitration, which creates a possibility for an exoergic one-electron transfer in the direction from ArH to the electrophile in the case of activated aromatic substrates.

The experimental study of this problem, first formulated in the 1940's–1950's,[4-7] became possible only recently as a result of the advances achieved in the study of the RC of aromatic compounds ArH^{+}. Although the data obtained hitherto do not provide an exhaustive answer to the question of the role of the RC in nitration reactions, they nevertheless permit the conclusion that significant progress has been achieved in the solution of this problem. Some of these data are difficult to explain from the standpoint of classical ideas about the nitration mechanism[8] and are therefore of fundamental importance.

It is noteworthy that the problem of electron transfer as a possible stage in electrophilic substitution in aromatic compounds has already been frequently discussed.[9-16] However, it has not been the subject of a special detailed examination in relation to nitration. This factor and also the significant progress in the study of electron transfer processes in ArH–nitrating agent systems, which has occurred in recent years, made it desirable to write the present review devoted to the role of RC in nitration reactions.

II. THE FORMATION OF THE RADICAL-CATIONS OF AROMATIC COMPOUNDS UNDER NITRATION CONDITIONS AND THEIR CONVERSION INTO NITRO-COMPOUNDS

1. One-Electron Oxidation of Aromatic Compounds By Nitrating Agents

The oxidation reactions of aromatic compounds under the influence of nitrating agents are extremely varied and have long been known.[17] However, the possibility of the simplest of them, namely the one-electron oxidation of aromatic substrates in which the latter lose one π electron and are converted into highly active RC, has been demonstrated only recently:

$$ArH \xrightarrow[-e]{\text{nitrating agent}} ArH^{+}$$

The range of ArH capable of reacting in this way is fairly wide and according to the available data includes aromatic compounds with strong and moderate reducing properties, such as naphthalene,[18] sterically hindered phenols,[19] various aromatic amines,[20-23] and certain heterocyclic compounds.[20,21,24-27]

The formation of RC has been most often demonstrated by the usual spectroscopic methods. In a series of reactions of activated aromatic compounds with nitrating agents, RC were isolated preparatively in the form of salts with weakly nucleophilic anions[22,27-29] (Table 1). The formation of extremely unstable RC, such as, for example, the RC derived from toluene (its lifetime in 2 M $HClO_4$ solution is less than 3.3×10^{-7} s [30]) by these procedures is difficult or impossible. An indirect sign of the formation of such species is the presence

in the reaction product of biaryls (dehydrodimers), which usually arise on dimerisation of the RC: [20,31]

$$2ArH^{+\cdot} \rightarrow \overset{+}{A}r(H) - \overset{+}{A}r(H) \rightarrow Ar - Ar + 2H^+$$

An alternative reaction, which also leads to biaryls, involves the attack on the substrate by the arenium cation ArH_2^+ or $ArHNO_2^+$. [32–34]

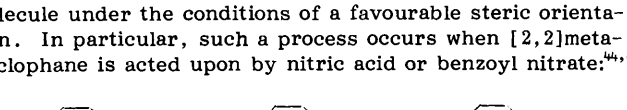

Table 1. The yield of radical-cations in reactions involving the one-electron oxidation of aromatic compounds by nitrating agents.

ArH	Nitrating agent	Solvent	W*, %	Method of determination	Refs.
Phenothiazine	HNO_3	CH_3CN	70	spectrophotometry	[20]
Phenothiazine	HNO_3	$HClO_4$	78	isolation of RC salt	[20]

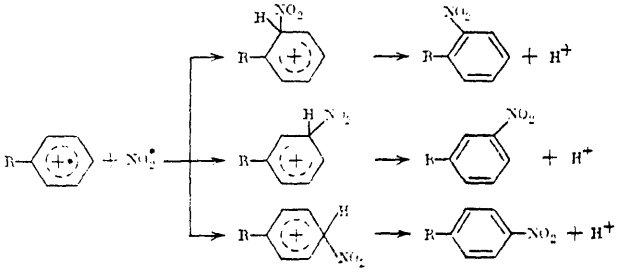
NNN'N'-Tetramethylbenzidine	HNO_3	CH_3CN	10	spectrophotometry	[20]
Tri-*p*-tolylamine	HNO_3	$ClCH_2CH_2Cl$	79	spectrophotometry	[21]
N-Methylcarbazole	HNO_3	$HClO_4$	95	from the yield of the biaryl RC	[40]
N-Methylcarbazole	HNO_3	CF_3COOH	24	from the yield of biaryl	[20]
1,3-Diphenyl-2-pyrazoline	HNO_3	$HClO_4$	97	from the yield of the biaryl dication	[40]
1,3,5-Triphenyl-2-pyrazoline	NO_2BF_4	CH_3CN	30	from the yield of biaryl	[23]
NN-Dimethylaniline	HNO_3	$HClO_4$	66	from the yield of the biaryl dication	[22]
NN-Dimethylaniline	NO_2BF_4	CH_3CN	12	from the yield of the biaryl dication	[23]
6-Methoxy-1,3-dimethyl-1,2-diaza-1*H*-phenalene	$NaNO_2$	CH_3COOH	75	isolation of the RC salt	[27]

*The yield of the RC estimated from the maximum observed concentration of the RC in the ArH–nitrating agent system or the preparative yield of the RC salt or biaryl. In the last case, the yield is quoted on the assumption that the biaryl is formed as a result of the dimerisation of the RC.

Biaryls are formed as side or main products in the nitration of alkylbenzenes, [35–37] diphenylene, [38] furan, [39] 9-methylcarbazole, [20,40] *NN*-dimethylaniline, [22,31,41] aminonaphthalenes, [42] and derivatives of 1-phenyl-2-pyrazoline [20,40] and 2-acetyl-1-phenylpyrazolidine. [43] It has been established that dehydrodimerisation of alkylbenzenes proceeds without the involvement of the protonated form of the hydrocarbons. [36]

The "cross linking" of the aromatic nuclei under nitration conditions occurs also when they are fragments of a single molecule under the conditions of a favourable steric orientation. In particular, such a process occurs when [2,2]metacyclophane is acted upon by nitric acid or benzoyl nitrate: [44,45]



(I)

The initial stage in these reactions leads in all probability to the oxidation of compound (I) to the RC, since it is known [46–48] that the RC of [2,2]metacyclophanes are readily converted into tetrahydropyrenes. Analogous processes have been observed [49] also in the nitration of [3,2]metacyclophanes.

The one-electron oxidation of aromatic compounds by nitrating agents constitutes in many instances an independent reaction leading to the formation of RC as the final product, sometimes in a nearly quantitative yield [25,27,28,40] (Table 1).

2. The Conversion of the Radical-Cations of Aromatic Compounds into Nitro-Compounds

The RC are converted into nitro-derivatives when they are acted upon by nitrogen dioxide [formed in Ar–H–oxygen compounds of nitrogen(V) systems as a result of the reduction of the nitrating agent by the substrate] or the nitrite ion. In the latter case, the initial stage of the reaction is usually the one-electron reduction of the RC by the nucleophile: [50–52]

$$ArH^{+\cdot} + NO_2^- \rightarrow ArH + NO_2^{\cdot}$$

$$ArH^{+\cdot} + NO_2^{\cdot} \rightarrow ArNO_2 + H^+$$

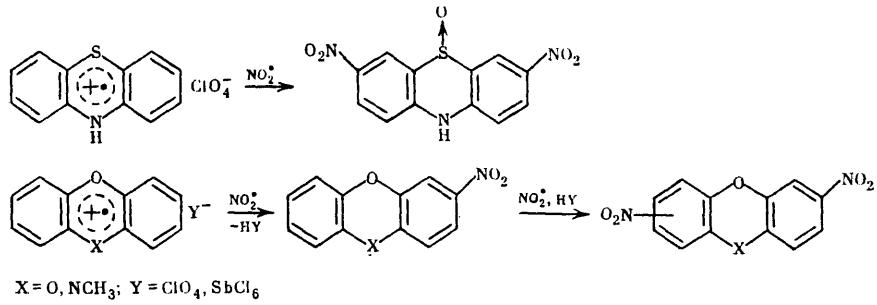
$$2ArH + 3NO_2^{\cdot} \rightarrow 2ArNO_2 + NO^{\cdot} + H_2O$$

The recombination of the RC with $NO_2^{\cdot}$ should be regarded as a special case of little investigated reactions of the following type: [53–58]

$$ArH^{+\cdot} + R^{\cdot} \rightarrow ArHR^+ \rightarrow ArR + H^+$$

The RC dimerisation processes are related to these reactions. [50,59] The results of studies of the interaction of the RC with nitrogen dioxide, carried out mainly in recent years, will be examined below.

Initially an attempt was made to achieve the reactions of RC with nitrogen dioxide by subjecting aromatic compounds to one-electron oxidation (chemical or electrochemical) in the presence of $NO_2^{\cdot}$. The nitration of naphthalene [60] and mesitylene [61] observed under these conditions was interpreted as a result of the recombination of the RC of the hydrocarbons with nitrogen dioxide in accordance with the scheme



$$ArH \xrightarrow{[Ox]} ArH^{+\cdot}$$

$$ArH^{+\cdot} + NO_2^{\cdot} \rightarrow ArHNO_2^+ \rightarrow ArNO_2^{\cdot} + H^+$$

[Ox] = $Ce(NH_4)_2(NO_3)_6$, or the anode; ArH = naphthalene or mesitylene.

However, the quantitative oxidation of the initial compounds to the RC was not ensured under these conditions, since the hydrocarbons reacted too slowly with the one-electron oxidants. [62] They underwent much faster direct nitration by nitrogen dioxide, which is catalysed by the strong acids accumulating in the $ArH–NO_2^{\cdot}–[Ox]$ system. This process has in fact been the source of nitroarenes (at least of the bulk of the latter). [62] Thus the data quoted above [60,61] neither confirmed nor disproved the possibility of the recombination of the RC with nitrogen dioxide.

Unambiguous evidence for the ability of the RC to react with $NO_2^{\cdot}$ was obtained using stable RC. [22,25,51,63,64] It was found that even RC with a comparatively low reactivity are capable of reacting with $NO_2^{\cdot}$ to form nitro-compounds. The objects of studies were the perchlorates of the RD derived from phenothiazine, [63] *N*-methylphenoxazine, [22] the hexachloroantimonate of the RC obtained from dibenzo-*p*-dioxin, [25] and the hexafluorophosphates of the dimeric RC derived from naphthalene, [51] mono- and di-methylnaphthalenes, [64] pyrene, [64] and perylene. [52] In the case of the first three RC (the reactions were carried out in acetonitrile), nitro-products corresponding to attack on the RC at positions with the maximum unpaired electron density were obtained: [25,65]

X = O, NCH_3; Y = ClO_4, $SbCl_6$

The direct nitration of the corresponding heterocyclic compounds leads to analogous results.[22,25,63]

Table 2. The selectivity of the direct nitration of hydrocarbons of the naphthalene series (ArH) and of the recombination of the corresponding dimeric RC of the type $(ArH)_2^+$ with nitrogen dioxide.[64]

ArH	Nitration conditions	Yields of products of mononitration of ArH in individual positions, %					Distribution of spin density in RC
		1	2	4	5	8

Note. A) An excess of the RC salt was treated with nitrogen dioxide in CH_2Cl_2 at −70—−20 °C; B) nitration of ArH with nitrogen tetroxide in CH_2Cl_2 at 20 °C; C) nitration of ArH with acetyl nitrate in acetic anhydride at −30 °C; D) nitration of ArH with nitric acid in acetic acid at 25 °C; E) nitration with nitronium tetrafluoroborate in CH_2Cl_2 at 25 °C.

The dimeric RC obtained from hydrocarbons of the naphthalene series recombine with $NO_2^\cdot$ to form mixtures of mononitro-derivatives, which have the same qualitative composition as the products of the direct nitration of the corresponding hydrocarbons,[64] for example:

$$(C_{10}H_8)_2^{\cdot+}\,PF_6^- + NO_2^\cdot \rightarrow \alpha\text{-}C_{10}H\text{-}NO_2 + \beta\text{-}C_{10}H_7NO_2 + C_{10}H_8 + HPF_6\,.$$

The quantitative compositions of the nitration products differ significantly in the two cases (Table 2). Compared with the direct nitration, the reactions of dimeric RC with $NO_2^\cdot$ are usually distinguished by greater regioselectivity. However, the RC of 1,4-dimethylnaphthalene gives rise to a high yield of 1,4-dimethyl-2-nitronaphthalene, whereas the nitration of 1,4-dimethylnaphthalene with acetyl nitrate or nitrogen tetroxide usually results in the preferential formation of the 5-nitro-derivative and the products of nitration in the methyl group. It must be emphasised that the conditions of the direct nitration of naphthalene hydrocarbons and their dimeric RC (temperature, acidity of the medium, composition of the ions present, etc.) have frequently differed significantly, which precludes in many instances final conclusions concerning the identity or non-identity of the regioselectivity of the two processes.

Monomeric RC of the naphthalene series are much more reactive than the dimeric RC.[66,67] One can therefore expect that they will recombine with $NO_2^\cdot$ faster than the dimeric RC and with a lower regioselectivity, which, however, may approach the selectivity of the usual nitration of naphthalene and its methyl derivatives. Unfortunately, an experimental test of this hypothesis is hindered by the extreme instability of this RC.

It has been suggested[64] that the reactivity of the RC with respect to $NO_2^\cdot$ decreases sharply with decrease in the electrochemical oxidation potentials of the corresponding ArH and of the RC of aromatic substrates having potentials less than 1.7 V relative to the normal hydrogen electrode do not interact with nitrogen dioxide. However, it has been shown[68] that the rates of reaction of the stable RC of tri-*p*-anisylamine and tri-*p*-bromophenylamine with an N_2O_4 solution are approximately the same despite the very large difference between the oxidation potentials of the corresponding amines (~0.7 V). The effective rate constants are 0.33 and 0.25 litre$^{1/2}$ mol$^{-1/2}$ s^{-1} at 20 °C (the reactions are of first order with respect to RC and of order 0.5 with respect to N_2O_4). Furthermore, the RC of tri-*p*-tolylamine proved to be much more reactive than the RC of tri-*p*-bromophenylamine (by a factor of 10^2),[68] whereas under conditions where the oxidation-reduction potential of the ArH/ArH^+ pair plays a decisive role one would expect the opposite relative reactivities of these RC. One cannot rule out the possibility of a parallel variation of the reactivity of the RC with respect to nitrogen dioxide and of their tendency to dimerise with formation of doubly protonated iaryls.

Nothing is known at present about the rate of reaction of highly active short-lived RC with $NO_2^\cdot$ in solution, but it has been established that in the gas phase such reactions are very rapid. The rate constant for the recombination of the dimeric RC derived from benzene with nitrogen dioxide is 2.4×10^{-11} cm^3 molecule^{-1} s^{-1} under these conditions.

The monomeric RC of toluene and *p*-xylene react somewhat more slowly and the reaction of the RC of naphthalene is much slower.[69,70]

The joint anodic oxidation of 1,4-dimethoxybenzene and the nitrite anion yielded 1,4-dimethoxy-2-nitrobenzene,[71] whose formation was explained by the recombination of the RC of 1,4-dimethoxybenzene with nitrogen dioxide:

$$p\text{-}CH_3OC_6H_4OCH_3 \xrightarrow{-e} p\text{-}CH_3OC_6H_4OCH_3^{+\cdot},$$

$$NO_2^- \xrightarrow{-e} NO_2^{\cdot},$$

$$p\text{-}CH_3OC_6H_4OCH_3^{+\cdot} + NO_2^{\cdot} \xrightarrow{-H^+} CH_3O\text{-}C_6H_3(NO_2)\text{-}OCH_3.$$

A parallel variation of the ease of substitution of a particular hydrogen atom by the nitro-group on treatment with $NO_2^{\cdot}$ and of the unpaired electron density at the corresponding carbon atom has been observed for the dimeric RC of naphthalene and 1,8-, 2,3-, and 2,6-dimethylnaphthalenes (see Table 2). More or less pronounced deviations from this type of variation occur for the RC of other naphthalene hydrocarbons.[64] These data justify the hypothesis that the distribution of the unpaired electron density on the RC is an important but not the only factor determining the isomeric composition of the nitro-products formed from the RC and nitrogen dioxide.

Table 3. Comparison of data for the nitration of aromatic compounds and the distribution of unpaired electron density in their RC.

ArH	Position in ArH at which nitration occurs preferentially	Position with maximum unpaired electron density in the RC
Benzonitrile	3 [74]	3 [75]
Nitrosobenzene	4 [76]	3 [77]

Phenothiazine	3 [99]	3 [65]

*The data were taken from the handbook "Beilsteins Handbuch der organischen Chemie", Vierte Verlage, Springer Verlag, Berlin.

Note. Numbers in square brackets denote references (Ed. of Translation).

The partial addition of $NO_2^{\cdot}$ to the *unco*-positions in the RC apparently has an appreciable influence on the ratio of the nitro-isomers formed in a number of instances. Evidently, in such cases a greater or smaller proportion of the nitration products should be formed from the *unco*-σ-complex and the isomeric composition of the nitro-product does not reflect the true reactivities of the individual positions in the RC.

It is of interest to trace also the relation between the distribution of the unpaired electron density in the RC $ArH^{+\cdot}$ and the position of the nitro-group in the nitration of ArH, such relation having been postulated previously.[72,73] The data in Table 3 (see also Table 2) show that the situation in this case is analogous to that examined above for the dimeric RC of the naphthalene series. Here too the most probable cause of the absence of an unambiguous relation between the unpaired electron density in the RC and the position of the nitro-group is the formation in the nitration reaction of *unco*-σ-complexes, which mask the true reactivities of the different positions in the ArH.[11] The complicating influence of this factor is apparently minimal for the positions in the ArH corresponding to the maximum unpaired electron density in the RC (Tables 2 and 3) and as a rule aromatic compounds are nitrated preferentially precisely in these positions. This rule can evidently be used to predict the positional selectivity in electrophilic aromatic nitration reactions.

One may predict the existence also of other factors which disturb the relation between the unpaired electron density in the RC and the positional selectivity of the nitration reaction. One of these factors can be seen in the nitration of secondary aromatic amines. *N*-Nitramines, which are converted into products of the nitration of the aromatic ring via the nitramine rearrangement, are intermediates in such reactions.[100] The preferential nitration of the amine in the *o*-position relative to the amino-group is usually a consequence of this mechanism,[101] although the unpaired electron density in the RC of aromatic amines is as a rule a maximum in the *p*-position (see Table 3). The unexpected nitration of nitrosobenzene in the *p*-position (in its RC, the unpaired electron density is a maximum in the *m*-position) is in all probability associated with the occurrence of the reaction via the intermediate formation of the hydrated form of the substrate.[102]

The coincidence of the most reactive position in the aromatic compound with the site where the maximum unpaired electron density is located in the RC, usually observed, creates additional possibilities for predicting the characteristic features of the electronic structure of the RC on the basis of data for the nitration of the corresponding ArH. For example, the nitration of vinylarenes in an unsaturated substituent[103,104] indicates an increased unpaired electron density in the vinyl group in the RC of vinylarenes. This is also indicated by the anomalous character of the dimerisation of such RC (unlike other RC of the type $ArH^{+\cdot}$, they dimerise via the exocyclic β-carbon atoms[105,106]) and by the result of a quantum-chemical calculation for the styrene RC.[107]

In the nitration of *m*-disubstituted benzenes in which one substituent is a powerful *ortho*- and *para*-directing agent and the other is a *meta*-directing agent, the influence of electron-donating substituents usually predominates.[108] It is natural to expect that the unpaired electron density in the RC of the aromatic compounds indicated will be a maximum in the *o*- and *p*-positions relative to the electron-donating group. The available data show that this is indeed the case. For example, for the RC of *NN*-dimethyl-3-nitroaniline,[81] the hyperfine interaction constant, which is directly proportional to the spin density is 5.9 and 6.3 G respectively for the *o*- and *p*-positions relative to the dimethylamino-group, while for the *m*-position it does not exceed 1.8 G.

The data examined indicate the possibility, in principle, of nitration via the intermediate formation of the RC, because they demonstrate that aromatic compounds can be converted

under the nitration conditions into the RC and the latter can be converted into nitro-compounds.

III. NITRATION OF AROMATIC COMPOUNDS BY THE NITRONIUM CATION

1. Nitration in the Gas Phase

Being a powerful oxidant,† the nitronium cation in the gas phase readily abstracts a single electron from the molecules of aromatic compounds such as benzene and its derivatives, converting them into the RC.[70,110] The subsequent recombination of the products of the one-electron transfer leads to a σ-complex, which is deprotonated on collision with molecules of bases B, forming the nitro-product.[70,111] Direct addition of the nitronium cation to benzene and its derivatives does not occur under these conditions:[70]

$$ArH + NO_2^+ \rightarrow ArH^{+\cdot} + NO_2^{\cdot} \rightarrow ArHNO_2^+ \xrightarrow[-BH^+]{B} ArNO_2$$

(here and henceforth B represents the base.) The electron transfer occurs in virtually every collision of the reacting species. The radical recombination stage is significantly slower and limits the rate of formation of the σ-complex.[70] The data presented confirm the validity of the quantum-chemical calculations,[7,112,113] indicating the possibility of electron transfer in nitration by the nitronium cation.

Thus, in the gas-phase nitration of aromatic compounds, the substrate RC is the primary reaction product and the σ-complex is the secondary product.

2. Nitration in Solution

The oxidising properties of the nitronium cation in solution can be characterised by the $NO_2^{\cdot}/NO_2^+$ oxidation-reduction potential, which is ~1.6 V in acetonitrile[114,115] and ~1.9 V in nitromethane[116] (relative to the normal hydrogen electrode). The rate of nitration of aromatic compounds by the nitronium cation increases with decrease in the ionisation potential, reaching a limit which is determined by the diffusion of the reacting species.[72,117] On the basis of the data of Coombes et al.,[117] the limiting ionisation potential can be estimated as being of the order of 8.8–9.0 eV.

The question of the mechanism of the liquid-phase nitration by the nitronium cation is at present controversial. Many experimental data obtained in the study of this reaction can be explained satisfactorily by a heterolytic mechanism in which the initial stage is the formation of the π-complex $ArH...NO_2^+$ with the nitro-group located at one of the π-bonds of the aromatic ring.[118] However, facts also exist which provide grounds for the hypothesis that the reaction can proceed via electron transfer.[9,13,60,74,113,118,119]

Perrin's communication,[60] which has aroused a lively discussion, quotes a number of arguments in support of the occurrence of this stage in the nitration of aromatic substrates more reactive than toluene by the nitronium cation. According to this study,[60] the reaction mechanism includes in this instance the formation of the short-lived radical pair $[ArH^{+\cdot}NO_2^{\cdot}]$ and its geminal recombination in the solvent cage:

$$ArH + NO_2^+ \rightarrow [ArH^{+\cdot}NO_2^{\cdot}] \rightarrow \underset{\sigma\text{-complex}}{ArHNO_2^+} \xrightarrow[-BH^+]{B} ArNO_2$$

One of the main arguments in support of this mechanism is that naphthalene is nitrated to give the usual mixture of mononitronaphthalenes in its oxidation at the anode in the presence of nitrogen dioxide.[60] It has been suggested that the nitration of naphthalene in the given instance is a result of the recombination of the naphthalene RC formed at the anode with $NO_2^{\cdot}$. However, it was soon established that this process proceeds virtually without the participation of the electrochemically generated RC.[62]

According to Eberson and Radner,[115] the nitration by the nitronium cation proceeds preferentially via the heterolytic (polar) pathway and only to an insignificant extent via the radical-ion pathway involving the outer-sphere electron transfer. It has also been suggested that, firstly, the relative contributions of these reaction pathways depend on the $ArH/ArH^{+\cdot}$ oxidation-reduction potential, and secondly, that the homolysis of the σ-complexes is an additional source of the $ArH^{+\cdot}$ RC and, thirdly, that the regioselectivities of the attack on ArH by the nitronium cation and on $ArH^{+\cdot}$ by nitrogen dioxide are in general different:

$$ArH + NO_2^+ \begin{cases} \rightarrow ArH^{+\cdot} + NO_2^{\cdot} \\ \downarrow\uparrow \\ \rightarrow ArHNO_2^+ \xrightarrow[-BH^+]{B} ArNO_2 \end{cases}$$

Consequently, some of the nitro-products are formed, according to Eberson and Radner,[115] via the following reaction sequence:

$$\underset{(A)}{ArHNO_2^+} \rightarrow ArH^{+\cdot} + NO_2^{\cdot} \rightarrow \underset{(B)}{ArHNO_2^+} \rightarrow ArNO_2$$

where (A) and (B) are mixtures of isomeric σ-complexes differing in their composition. For this nitration pathway, the positions of the nitro-groups will be determined by the free-radical recombination stage and the set of the first two stages can be regarded as a kind of variant of the inner-sphere electron transfer.[120] There are a series of arguments in support of this view.

(1) The selectivity in the nitration of naphthalene by nitronium tetrafluoroborate ($\alpha/\beta \cong 15$) is not identical with the selectivity in the reaction between the dimeric napthalene RC and nitrogen dioxide ($\alpha/\beta \cong 40$).[51]

(2) The rate constants for the outer-sphere electron transfer from ArH to NO_2^+, calculated using the Marcus equation,[115] are much smaller than the corresponding rate constants for the nitration of ArH. The calculated constants depend on the $ArH/ArH^{+\cdot}$ oxidation-reduction potentials and vary within extremely wide limits (from ~10^{-16} litre mol^{-1} s^{-1} for benzene to ~10^6 litre mol^{-1} s^{-1} for ferrocene).

(3) The attempts to observe the chemically induced dynamic nuclear polarisation in nitration by the nitronium cation were unsuccessful.[121,122]

The different selectivity of the nitration in the $C_{10}H_8$–NO_2^+ and $(C_{10}H_8)_2^{+\cdot}$–$NO_2^{\cdot}$ systems apparently mean that the dimeric RC does not participate significantly in the nitration of naphthalene by the nitronium cation. However, this fact by itself does not justify the confident conclusion that the more reactive[66,67] monomeric naphthalene RC does not participate in the above reaction, because the selectivity in its recombination with nitrogen dioxide is unknown and there is no reason to suppose that it should be the same as that for the dimeric RC. Account must also be taken of the complex formation reaction between the nitronium cation and the solvent,[123,124] the decrease in the reactivity of NO_2^+ induced by this phenomenon (approximately by an order of magnitude[123]),

† The electron affinity of the nitronium cation can be estimated as being above 9 eV on the basis of the ionisation potential of nitrogen dioxide.[109]

and a probable change in the geometrical configuration of NO_2^+ on which the results of calculations of the rate constant for electron transfer between ArH and NO_2^+ depend decisively. It is also essential to take into account data[125] from which it follows that the rates of nitration of aromatic comounds by the nitronium cation may be appreciably lower than has usually come to be assumed (for example, at least by two orders of magnitude in the case of anisole).

The homolysis of σ-complexes is indeed possible. However, it is doubtful if this reaction can serve as an effective source of RC in the ArH–NO_2^+ systems: examination of data for the chemistry of the $ArHNO_2^+$ cation[126–132] creates the impression that these species are incapable of homolysis occurring readily enough to be able to compete with their deprotonation to nitro-derivatives.

According to Fukuzumi and Kochi,[74] like other electrophilic aromatic substitution reactions, nitration by the nitronium cation begins with the formation of a charge-transfer complex (CTC) between the reacting species, in which inner-sphere electron transfer takes place subsequently from the substrate of the reactant. The electron transfer is then regarded as a consequence of the thermal electronic excitation of the CTC, and the electronically excited state of the CTC is identified as the radical pair $[ArH^+E^\cdot]$:

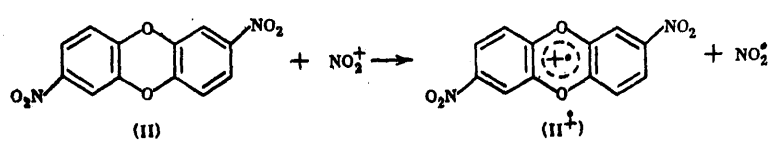
$$ArH + E^+ \rightarrow ArH\cdots E^+ \xrightarrow{h\nu} [ArH^+E^\cdot] \rightarrow \underset{\sigma\text{-complex}}{ArHE^+} \rightarrow ArE + H^+$$

where E is the electrophile, including NO_2^+.

In particular, the linear dependence of the activation energy for electrophilic substitution on the energy of the charge-transfer bands in the spectrum of the complex $ArH\ldots E^+$ and also of the reaction constants ρ in the Brown equation on the quantities $\Delta h\nu_{st}/\Delta I$ characterising the rate of variation of the energy of the charge transfer band ($h\nu_{st}$) with the ionisation potential I of ArH supports this mechanism.[74]

The electron transfer mechanism described is analogous to that proposed previously.[133–136] From the standpoint of the ideas of the above investigators,[74,133–136] the thermal transfer of an electron thus proceeds analogously to its phototransfer. The most important difference consists in the fact that the electron phototransfer, being a Franck–Condon process, leads to the formation of a radical pair in a non-equilibrium unrelaxed state and therefore requires a much greater energy expenditure than the thermal transfer.[74,136–138] Comparison of the ArH/ArH^+ and $NO_2^\cdot/NO_2^+$ oxidation-reduction potentials[115] shows that, for aromatic compounds with low ionisation potentials, the energy levels of the complexes $ArH\ldots NO_2^+$ and $ArH^+\ldots NO_2^\cdot$ should be similar or that their ratio should be actually reversed.

The main reason why the calculation of the rate constants for the outer-sphere electron transfer from ArH to NO_2^+ leads to unduly low values of the latter is the appreciable energy of the reorganisation of the NO_2 group necessary for the electron transfer.[115] The component associated with the change in the internuclear angles of the NO_2 fragment on transition from the linear nitronium cation to the bent nitrogen dioxide molecule makes the dominant contribution to this energy. The unfavourable influence of this factor is apparently markedly weakened in electron transfer via the inner-sphere mechanism, since there is reason to believe that the NO_2 group then passes from the linear to the angular state already in the complex formation stage.[139] In general, the transition from the outer-sphere to the inner-sphere mechanism is frequently accompanied by a marked increase in the rate of electron transfer (up to by a factor of 10^9 [140]).



For aromatic amines, sulphides, and ethers, there exists yet another pathway to the formation of the radical pair $[ArH^+NO_2^\cdot]$, which has apparently not been discussed in the literature. The molecules of these compounds are attacked by the nitronium cation in the first place at the heteroatom having an unshared electron pair.[141] The homolysis of the ammonium, sulphonium, and oxonium cations formed under the conditions can evidently lead to the radical pair indicated:

$$ArXR_n + NO_2^+ \rightarrow Ar\overset{+}{X}R \rightarrow ArXR_n^+ + NO_2^\cdot$$
$$\qquad\qquad\quad |$$
$$\qquad\qquad NO_2$$
$$X = N, O, S$$

The experimental confirmation of the possibility of the one-electron oxidation of aromatic compounds in the ArH–NO_2^+ system is hindered by the low stability of the RC, their ability to recombine with $NO_2^\cdot$, and, in particular, by the fact that in the case of the most active RC the recombination of the radical pairs $[ArH^+NO_2^\cdot]$ can apparently occur in the solvent "cage" without the emergence of the radicals into the bulk of the solution.

Examples of the oxidation of aromatic substrates to the RC by nitronium tetrafluoroborate have been described,[18,23,25] but one cannot be certain that the nitronium cation is in fact the oxidant in these reactions, since the reactant usually contains an admixture of the nitrosonium cation, which is difficult to separate and which is capable of oxidising these substrates

The results obtained for 2,7-dinitrodibenzo-*p*-dioxin (II) are of interest in this connection.[142] When compound (II) is treated with nitric acid in concentrated sulphuric acid, the radical-cation (II^+) is formed. Under these conditions, the nitrosonium cation does not oxidise the dioxin (II). Consequently a one-electron oxidant, superior in its strength to the nitrosonium cation, exists in the HNO_3–H_2SO_4 system (or can be formed in the presence of ArH). Since nitric acid is almost fully converted into the nitronium cation (the most reactive oxygen compound of nitrogen) under the conditions indicated above, it was concluded that the cation is responsible for the oxidation of the dioxin (II) to the RC:[142]

(II) (II^+)

The reaction discovered is the most convincing of experimental evidence for the ability of aromatic compounds to be oxidised in solution to the RC by the nitronium cation.

One can thus conclude that the role of the electron transfer in liquid-phase reactions involving the nitration of aromatic compounds by the nitronium cation is less clear than in the gas-phase reaction. However, here too there can be hardly any doubt about the possibility of the intermediate formation of the RC. Nevertheless the question of the extent to which the RC participates in these reactions is general and must still be regarded as open.

IV. CATALYTIC NITRATION

We shall now consider another large group of nitration reactions—the reactions occurring without the participation of the nitronium cation and catalysed by nitrous acid.# This nitration pathway is characteristic of aromatic compounds having fairly low ionisation potentials and activated with respect to electrophilic substitution.[3] The catalytic nitration reactions frequently occur under autocatalytic conditions, since the nitration catalyst is usually formed in the course of the reaction itself. In a pure form, they occur in media containing virtually no nitronium cations.

The mechanism of the catalytic reaction is often described in terms of a scheme involving nitration via nitrosation:[3]

$$ArH + HNO_2 \rightarrow ArNO + H_2O$$
$$ArNO + HNO_3 \rightarrow ArNO_2 + HNO_2, \text{ etc.}$$

It has been suggested that the initial formation and subsequant accumulation of nitrous acid in the ArH–HNO_2 systems occur as a result of the reduction of nitrous acid in oxidation-reduction side reactions. However, a number of experimental data, in particular the intermediate formation of the σ-complexes of $ArHNO_2^+$ in certain autocatalytic reactions[144,145] and also the preferential nitration of phenol in the *o*-position on treatment with dilute nitric acid (the nitrosation of this compound takes place almost exclusively in the *p*-position[146]) cannot be explained satisfactorily within the framework of this mechanism. Furthermore, there exist quite a few activated aromatic compounds§ whose nitrosation is unknown and many of them apparently do not enter into this reaction at all. Nevertheless, such compounds usually readily undergo autocatalytic nitration.

It has been shown recently that the autocatalytic nitration of *NN*-dimethylaniline[31] and phenol[147]—the classical substrates in the nitrosation reaction—and also naphthalene[148] cannot be explained in terms of the nitration mechanism involving reaction via nitrosation, at least in strong acids.

Two mechanisms are nowadays considered as the most probable. Firstly, one mechanism involves catalytic nitration initiated by the one-electron oxidation of the substrate,[31,40,145,148,149] whose possibility is due to the ability of the lower oxygen compounds of nitrogen ("nitrous acid") to effect the one-electron oxidation of activated aromatic compounds. The second mechanism involves nitration in which the active species is the electrophile $N_2O_4.NO^+$,[64] formed from nitrogen tetroxide and the nitrosonium cation.

The subsequent Sections will deal with the reactions involving the one-electron oxidation of aromatic compounds by the nitrosonium cation, their role in the formation of RC in the ArH–HNO_3 system and in autocatalytic nitration, and also the mechanism of nitration with participation of $N_2O_4.NO^+$.

1. The Nitrosonium Cation as a One-Electron Oxidant in Reactions with Aromatic Compounds

Until recently, the possibility of the one-electron oxidation of aromatic compounds by the nitrosonium cation had hardly been taken into account. This cation was regarded exclusively as a nitrosating agent interacting with aromatic substrates via a heterolytic mechanism. The limitations of this treatment became clear in recent years when the ability of the nitrosonium cation to accept one electron from the molecules of aromatic compounds has been demonstrated:

$$ArH + NO^+ \rightarrow ArH^+ + NO^\cdot$$

Reactions of this type were initially observed for readily oxidisable ArH of the amine type, namely phenothiazine,[150] phenoxazine,[40,151] *NNN'N'*-tetramethyl-*p*-phenylenediamine,[21] and derivatives of 9,10-dihydrophenazine.[21] It was later shown that polycyclic aromatic hydrocarbons also react similarly with NO^+.[18,22,115,152,153] For example, on reaction with nitrosonium perchlorate in trifluoroacetic acid, naphthalene is converted initially into the monomeric RC, then into the dimeric RC, and finally into a mixture of hydrocarbons having the polynaphthylene structure:[152,153]

$$C_{10}H_8 + NO^+ \rightarrow C_{10}H_8^+ + NO^\cdot$$
$$C_{10}H_8^+ + C_{10}H_8 \rightarrow (C_{10}H_8)_2^+$$
$$(C_{10}H_8)_2^+ \rightarrow \rightarrow C_{10}H_7 - (C_{10}H_6)_n - C_{10}H_7$$

In contrast to readily oxidisable substrates, naphthalene reacts with the nitrosonium cation fairly slowly, which can be explained by the endoergic character of the electron transfer in this case (calculation yields $\Delta G_0 = 13.1$ kcal mol^{-1} [115]). The reaction can be conveniently followed from the evolution of nitric oxide, whose yield is ~90% with respect to the initial nitrosonium salt.[153] These data show that the nitrosonium cation is almost incapable of nitrosating naphthalene.

Fluorene, triphenylmethane, and thiophen also interact with nitrosonium perchlorates with liberation of nitric oxide,[153] which indicates the one-electron oxidation of the substrates in these cases too. It is of interest that *NN*-dimethylaniline—an aromatic compound which readily undergoes electrophilic nitrosation—behaves in relation to the nitrosonium cation primarily as a one-electron reductant.[22,31]

Calculations by the Marcus equation of the thermodynamic kinetic characteristics of processes involving the one-electron oxidation of aromatic compounds by the nitrosonium cation[115] support the view that the formation of the RC is a result of the direct electron transfer from the π-system of the substrate to the electrophile.

Aromatic compounds of the benzen-type, which are oxidised with difficulty, hardly interact with the nitrosonium cation under the usual conditions (if one disregards the formation of a charge-transfer complex).[154,155] Calculations have shown[115] that the inertness of the nitrosonium cation with respect to such substrates is mainly due to thermodynamic causes (the oxidation-reduction equilibrium is very strongly displaced towards ArH and NO^+). It is therefore not surprising that the hexafluorophosphate of the hexafluorobenzene RC readily

---

All the lower oxygen compounds of nitrogen analytically determined as nitrous acids are designated for convenience by the term "nitrous acid".[143] The nitrosonium cation has come to be regarded as the most reactive component of nitrous acid.

§ Here and henceforth, this term is used to designate compounds containing aromatic nuclei activated with respect to electrophiles (aromatic amines, alkoxyarenes, polycyclic arenes, etc.).

reacts with nitric oxide, oxidising it to the nitrosonium cation:[156]

$$C_6F_6^+PF_6^- + NO^\cdot \rightarrow C_6F_6 + NO^+PF_6^-$$

In the gas phase the oxidising properties of the nitrosonium cation are more pronounced than in solutions and under these conditions it readily oxidises benzene to the RC.[157,158] The appreciable weakening of the oxidising properties of NO^+ in solution compared with the gas phase is caused by its strong solvation (the calculated hydration energy of NO^+ is ~80 kcal mol^{-1} [159]).

Other lower oxygen compounds of nitrogen can in all probability also function as one-electron oxidants in relation to aromatic compounds, because they frequently possess pronounced oxidising properties. For example, the electron affinity of nitrogen dioxide (3.1 eV [160]) is close to the electron affinity of powerful oxidants such as chlorine and bromine, while the calculated standard oxidation-reduction potential of the $NO_2^-/NO_2^\cdot$ pair is ~1 V in water.[161]

2. Autocatalytic One-Electron Oxidation of Aromatic Compounds by Nitric Acid

When aromatic compounds are oxidised to the RC by dilute nitric acid, which contains hardly any nitronium cations, the nitrosonium cation usually functions as the one-electron oxidant.[22,31,40,145,151,162] Reactions of this type are autocatalytic and are characterised by an induction period. The latter factor is caused by the absence of the nitrosonium cation from the reaction mixture in the initial period of the interaction. A special case of these reactions are those described by the overall equation[22,40,151]

$$3ArH + HNO_3 + 3H^+ \rightarrow 3ArH^+ + NO^\cdot + 2H_2O \quad (1)$$

For example, the oxidation of phenothiazine and phenoxazine by nitric acid in 57% perchloric acid, which leads to the RC perchlorates and nitric oxide in 75–80% yield, proceeds in accordance with this scheme.[40,151] Reactions (1) usually occur as independent reactions for the stoichiometric reactant ratio or in the presence of a deficiency of nitric acid. When an excess of HNO_2 is used, the nitration of ArH is usually observed.[22,28,29,40] The relatively unreactive forms of nitrous acid do not play a significant part in the oxidation of ArH, because in strong acids, where reactions (1) were carried out, they are converted into the nitrosonium cation.[163]

The reduction of dilute nitric acid by activated aromatic compounds is apparently similar to the cathodic reduction of this reactant, which is also autocatalytic.[164] Reactions (1) can be regarded as a kind of chain process in which the chain propagation stage is described by Eqns.(2) and (3):[40,165]

$$ArH + NO^+ \rightarrow ArH^+ + NO^\cdot \quad (2)$$

$$NO^\cdot + 0.5HNO_3 + 1.5H^+ \rightarrow 1.5NO^+ + H_2O \text{ , etc.} \quad (3)$$

The multiplication coefficient of the one-electron oxidant (NO^+) in this scheme is 1.5, which ensures the occurrence of one-electron oxidation with self-acceleration. The initial formation of the nitrosonium cation in the reaction mixture and hence the chain initiation take place in all probability as a result of the reduction by the aromatic substrate of the nitronium cation present at a vanishingly low concentration.

Eqn.(3) describes the autocatalytic regeneration of the nitrosonium cation from nitric oxide, which is the reverse of disproportionation of nitrous acid.[166,167] This process is catalysed by nitrous acid and proceeds with intermediate formation of nitrogen dioxide.[167]

In the case of unstable RC, the autocatalytic oxidation of ArH in accordance with Eqn.(1) is masked by the subsequent reactions of these radicals, for example, by their dimerisation. Dimeric products are obtained in the oxidation of *NN*-dimethylaniline,[22,31] 9-methylcarbazole,[40] and 1,3-diphenyl-2-pyrazoline [40] by nitric acid. As an example, we shall consider the reaction of *NN*-dimethylaniline with HNO_3 in 57% perchloric acid, which leads to the *NNN'N'*-tetramethylbenzidinium dication (IV) and nitric oxide in yields of ~80%:[22]

$$3C_6H_5N(CH_3)_2 + HNO_3 + 3H^+ \rightarrow 3C_6H_5\overset{+}{N}(CH_3)_2 + NO^\cdot + 2H_2O$$

$$2C_6H_5\overset{+}{N}(CH_3)_2 \rightarrow (CH_3)_2N\text{–}C_6H_4\text{–}C_6H_4\text{–}N(CH_3)_2 + 2H^+$$

(III)

$$3\,(III) + 2HNO_3 + 6H^+ \rightarrow 3\,(CH_3)_2\overset{+}{N}{=}C_6H_4{=}C_6H_4{=}\overset{+}{N}(CH_3)_2 + 2NO^\cdot + 4H_2O$$

(IV)

The overall reaction equation is

$$6C_6H_5N(CH_3)_2 + 4HNO_3 + 6H^+ \rightarrow 3\,(IV) + 4NO^\cdot + 8H_2O$$

Anthracene reacts with nitric acid in 57% perchloric acid in a manner different from that of the reactions of *NN*-dimethylaniline, 9-methylcarbazole, and 1,3-diphenyl-2-pyrazoline, affording anthraquinone as the final product. The initial stage of the reactions is probably the same as for the compounds quoted above:[22]

$$3C_{14}H_{10} + HNO_3 + 3H^+ \rightarrow 3C_{14}H_{10}^+ + NO^\cdot + 2H_2O$$

This is supported by the formation of nitric oxide from nitric acid in a high yield. The anthracene RC is converted into anthraquinone as a result of its interaction with water in the presence of an excess of the oxidant.[168–170] The ability of NO^+ to oxidise anthracene to the RC has been established.[115] An analogous interpretation of the formation of anthraquinone in the nitration of anthracene with nitrogen tetroxide has been given in another study.[171]

The analogy between the autocatalytic one-electron oxidation of activated aromatic compounds by nitric acid and the reactions involving the oxidation of certain inorganic substances by the same reagent is striking. The dissolution of metallic silver on interaction with nitric acid in 57% perchloric acid[40] and the oxidation of bivalent iron to the tervalent state[172] can serve as examples of such processes:

$$3Ag + HNO_3 + 3H^+ \rightarrow 3Ag^+ + NO^\cdot + 2H_2O$$
$$3Fe^{2+} + HNO_3 + 3H^+ \rightarrow 3Fe^{3+} + NO^\cdot + 2H_2O$$

3. Autocatalytic Nitration Initiated by One-Electron Oxidation

The mechanism of nitration of this type involves two couple stages: the autocatalytic oxidation of the aromatic compound to the RC and the conversion of the RC into the nitro-produc as a result of its recombination with nitrogen dioxide.[31,40,145,148,165] The autocatalytic character of these reactions therefore arises in the one-electron oxidation stage, in the course of which an electron is transferred from the aromatic substrate to the nitrosonium cation or to some other form of nitrous acid.

When the conditions in the interaction of the reactants do not favour the recombination of the RC with nitrogen dioxide, the reactions occurring in the ArH–HNO_3 system are restricted to the one-electron oxidation of the aromatic compound. As already mentioned, the formation of the nitroproducts is promoted by the use of an excess of nitric acid.

Such influence by the excess of the reagent can be accounted for by the increase in the concentration of nitrogen dioxide in the reaction mixture as a consequence of the more effective absorption of nitric oxide by nitric acid. In the ideal case, where they entire nitric oxide formed in accordance with Eqn.(1) is oxidised to the dioxide, the one-electron oxidation of ArH can be described by Eqn.(4) and the autocatalytic nitration can be described by Eqns.(4) and (5):

$$ArH + HNO_3 + H^+ \rightarrow ArH^{+\cdot} + NO_2^{\cdot} + H_2O \quad (4)$$

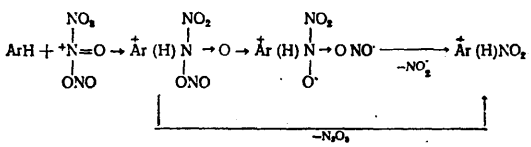
$$ArH^{+\cdot} + NO_2^{\cdot} \rightarrow ArNO_2 + H^+ \quad (5)$$

According to the literature,[31,149] the autocatalytic nitration reactions initiated by the one-electron oxidation are of first order with respect to the substrate, although a fractional order has been quoted (1.5).[148] The order with respect to nitric acid is variable, diminishing with increase in its concentration from 1 to 0.[31,148,149] This finding has been explained by the change of the rate-limiting stage when the reactant concentration is altered. At higher concentrations, the electron transfer from ArH to the one-electron oxidant becomes such a stage, while at low concentrations the oxidation of nitric oxide by nitric acid becomes rate-limiting.

The mechanism of the autocatalytic nitration initiated by the one-electron oxidation corresponds to a true autocatalytic process, since in this case the accumulation of the catalyst does not require the occurrence of any side reactions. In this respect, it differs from the mechanism involving nitration via nitrosation, in which the accumulation of nitrous acid can be achieved only as a result of side reactions.

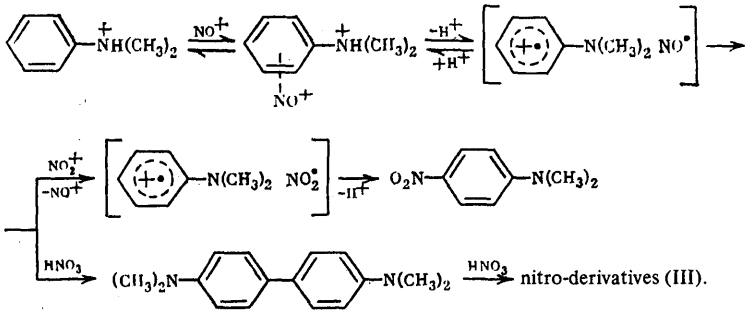
The nitration of *NN*-dimethylaniline by nitric acid in 75–80% sulphuric acid is an example of an autocatalytic reaction which exhibits a number of specific features.[31] These include a fairly high concentration of the nitronium cation in the reaction mixture and the complete protonation of the initial amine. The reaction products are mainly *NN*-dimethyl-*p*-nitroaniline and nitroderivatives of *NNN'N'*-tetramethylbenzidine in proportions which depend on the acidity of the medium. The base, formed apparently as a result of the unusual deprotonation of the protonated amine by the nitrosonium cation, enters into the reaction.[31] A nitration mechanism with participation of not only the nitrosonium cation but also of the nitronium cation has been proposed:

It is noteworthy that this mechanism can be only specific in character. In principle, it is applicable solely to the nitration of sufficiently basic aromatic compounds which are almost wholly protonated under the reaction conditions. If the reaction mixture contains an appreciable concentration of the non-protonated substrate, then evidently in this case the substrate can react mainly with the nitronium cation, which is more reactive as an electrophile than the nitrosonium cation by ~14 orders of magnitude.[173]



The products of the autocatalytic nitration of *NN*-dimethylaniline,[174] *p*-nitrophenol,[175,176] mesitylene,[122] and durene[177] (labelled with $H^{15}NO_3$ nitric acid) in sulphuric or trifluoroacetic acid exhibit a chemically induced dynamic polarisation of the ^{15}N nuclei, which has been explained by the formation of nitro-derivatives from the radical pairs $[ArH^{+\cdot}NO_2^{\cdot}]$.

There is now no doubt that the autocatalytic one-electron oxidation of ArH can be the initial stage of the autocatalytic nitration of activated aromatic compounds.



4. The Mechanism of the Autocatalytic Nitration with Participation of $N_2O_4.NO^+$

A new mechanism has been proposed recently for the autocatalytic nitration catalysed by the cation $N_2O_4.NO^+$ [64,178] whose existence has not so far been confirmed. It is assumed that this cation, tentatively formed from nitrogen tetroxide and the nitrosonium cation, is directly involved as the nitrating species:

$$N_2O_4 + NO^+ \rightarrow N_2O_4 \cdot NO^+$$

$$\overset{+}{Ar}(H)NO_2 + N_2O_3 \rightarrow ArNO_2 + HNO_2 + NO^+$$

nitro-derivatives (III).

(III)

The oxidation of nitrous acid by nitric acid regenerates nitrogen tetroxide (and hence also the catalyst). The above mechanism explains the chemically induced dynamic nuclear polarisation effect in the catalytic nitration reactions by the intermediate formation of radical pairs in the homolysis of the primary σ-complex at the N–O bond.

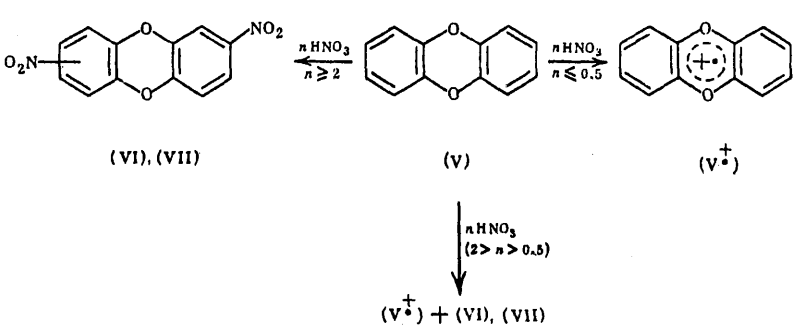
The determination of the applicability of the mechanisms examined evidently required further studies. Nevertheless, it is already clear that the mechanism involving nitration via nitrosation can be excluded from consideration for catalytic nitration reactions of a number of aromatic hydrocarbons (for example, naphthalene), since such compounds are either hardly nitrosated or they react with nitrosating agents too slowly.

V. THE CHANGE IN THE MODE OF REACTION AFTER A CHANGE IN THE REACTANT RATIO

As already mentioned, in certain cases the use of a deficiency of the nitrating agent makes the RC of the substrate the final product of the reaction of the latter. This is associated with the uncoupling of the multistage radical-ion nitration process in the part of the mechanism between the first and subsequent stages, which is induced by unfavourable conditions for the conversion of the RC into the nitration product. The influence of this factor decreases rapidly with increase in the mole fraction of the reactant in the initial reaction mixture. This can result in an additional change in the composition of the reaction product corresponding to the transition from the one-electron oxidation to nitration after a comparatively small change in the reactant ratio.[22,25,28,29]

A characteristic example is provided by the nitration of dibenzo-*p*-dioxin (V) in trifluoroacetic acid.[25] For the reagent : substrate molar ratio $n \geq 2$, this compound reacts rapidly with nitric acid, being converted into a mixture of 2,7-dinitrodibenzo-*p*-dioxin (VI) and 2,8-dinitrodibenzo-*p*-dioxin (VII) in a high yield. The nitration is accompanied by the appearance of a rapidly vanishing blue colour characteristic of the RC ($V^{+\cdot}$). On the other hand, for $n = 0.3–0.5$, the RC is the final reaction product (in ~90% yield). The range of values of n from 2 to 0.5 corresponds to a smooth transition from nitration to one-electron oxidation:

For a specified value of n, variation of the concentrations of the starting materials does not entail significant changes in the ratio of the RC and the nitro-compounds.



The fact that the dinitro-derivatives (VI) and (VII) are also formed in the presence of a deficiency of nitric acid implies that the introduction of the second nitro-group is faster than that of the first. This anomaly can apparently be explained by the higher reactivity of the RC of the mononitro-derivative of dioxin compared with ($V^{+\cdot}$) under conditions where the introduction of both groups is limited by the rates of recombination of the above RC with $NO_2^{\cdot}$.

A mixture of the dinitro-compound (VI) and (VII) is obtained also in the reaction of a known salt of the radical-cation ($V^{+\cdot}$) with nitrogen dioxide.[25] The introduction of the second nitro-group is undoubtedly catalysed in this case by the strong acid formed in the RC mononitration stage (cf. Eberson et al.[62]).

In the nitration of compound (V) by nitrogen tetroxide in trifluoroacetic acid, the same features are observed as in the nitration with nitric acid.[25] For the reagent : substrate molar ratio $n = 0.25$, the RC ($V^{+\cdot}$) formed is stable, while for $n \geq 1.5$, it is converted into a mixture of the nitro-compounds (VI) and (VII) in a high yield. The values of n between 0.25 and 1.5 constitute an intermediate region. The limiting value $n = 1.5$ corresponds to the stoichiometry of the dinitration of aromatic compounds by nitrogen tetroxide.[25,179]

A radical-ion mechanism has also been proposed for the nitration of aromatic compounds by nitrogen tetroxide in neutral solvents. It has been suggested that the initial stage of the nitration involving this mechanism is the oxidation of the substrate to the RC by nitrogen dioxide.[171] However, it has been suggested[64] that the operation of this mechanism is unlikely because nitrogen dioxide is a poor one-electron oxidant (the electron exchange in the $NO_2^{\cdot}$–NO_2^- system is relatively slow). The formation of the RC when aromatic compounds having pronounced reducing properties are acted upon by nitrogen tetroxide can be explained[64] by the oxidation of ArH by the nitrosonium cation arising as a result of the isomerisation of N_2O_4 to the nitrosyl nitrate form.

A dependence of the composition of the reaction product on the reagent : substrate ratio, analogous to that examined above, obtains also in the nitration of phenothiazine,[28,29] *N*-methylphenoxazine,[22] and probably *NN*-dimethylaniline[22] by nitric acid.

VI. NITRATION OF AROMATIC COMPOUNDS BY TETRANITROMETHANE AND METAL NITRATES

1. Thermal Nitration by Tetranitromethane

Tetranitromethane (TNM) is a mild nitrating agent[180] and a moderately strong oxidant (electron affinity 1.3 eV,[180] electrochemical reduction potential in methanol 0.7 V,[181] calculated oxidation-reduction potential in water 0.9 V relative to the normal hydrogen electrode[182]).

The interaction of aromatic compounds with TNM begins in all probability with electron transfer from the substrate to the reagent within the ArH...TNM CTC:

$$ArH + C(NO_2)_4 \rightarrow ArH\cdots C(NO_2)_4 \rightarrow ArH^{+}\,C(NO_2)_4^{-}$$

The decomposition of the TNM radical-anion formed leads to nitrogen dioxide,[180] which subsequently reacts with the RC and the excess substrate:

$$C(NO_2)_4^{-} \rightarrow C(NO_2)_3^{-} + NO_2^{\cdot}$$

$$ArH^{+} + NO_2^{\cdot} \xrightarrow{-H^{+}} ArNO_2$$

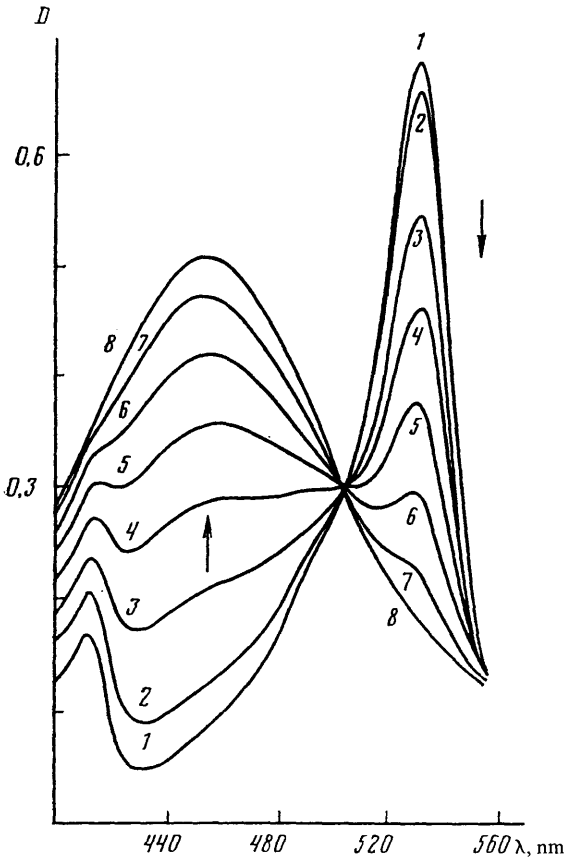
The rate-limiting stage of the nitration can be both electron transfer and the conversion of the RC into the nitro-product. The latter variant is most favourable for demonstrating the reaction mechanism and obtains in the case of the least active RC.

An example of the reactions in which electron transfer is not the rate-limiting stage is provided by the nitration of *N*-methylphenoxazine (VIII).[22,26] In this reaction, the initial aromatic compound is oxidised rapidly and with a high yield to the RC, which is subsequently converted comparatively slowly into *N*-methyl-3-nitrophenoxazine (IX).

The Figure presents the spectra of the (VIII)–TNM system in the visible region, demonstrating the conversion of the RC into the nitro-compound. The presence of the isosbestic point confirms the conclusion that the RC is located on the nitration coordinate. The nitro-compound (IX) can also be obtained by treating a known salt of the RC (VIII^{+}) with nitrogen dioxide or TNM.[22]

It is noteworthy that the reaction of the oxazine (VIII) with TNM is the first example of nitration where direct evidence has been obtained for the intermediate formation of the substrate RC and it has been shown that this nitration pathway is the main one.

The reactions of TNM with the phenyl derivatives of magnesium, tin, and mercury are also of the oxidation-reduction type, but in this case the aromatic compounds are hardly nitrated. The main product of these reactions is benzene.[183,184] The above finding has been explained by the specific properties of the organometallic RC, namely by their ability to fragment readily with formation of neutral free radicals.[183,184] The fragmentation is so rapid that there is insufficient time for the RC to recombine with nitrogen dioxide:



$$C_6H_5M + C(NO_2)_4 \rightarrow C_6H_5M^{+} + C(NO_2)_4^{-} \rightarrow C_6H_5^{\cdot} + M^{+}C(NO_2)_3^{-} + NO_2^{\cdot}$$

$$C_6H_5^{\cdot} \xrightarrow{Solv} C_6H_6$$

$$C_6H_5^{\cdot} + NO_2^{\cdot} \rightarrow C_6H_5NO_2$$

$M = C_6H_5Mg,\ C_6H_5Hg,\ (C_6H_5)_3Sn$; Solv = solvent.

The low yield of nitrobenzene indicates a low probability of the recombination of the radicals $C_6H_5^{\cdot}$ and $NO_2^{\cdot}$ in solutions.[183,184]

Electronic absorption spectra describing the conversion of the *N*-methylphenoxazine RC into *N*-methyl-3-nitrophenoxazine on nitration of *N*-methylphenoxazine with TNM in 97% acetic acid.[22] The absorption band with λ_{max} = 412 and 533 nm are due to the RC and that at 450 nm is due to the nitro-derivative. The initial concentrations of the reagent and the substrate were 5×10^{-3} and 5×10^{-4} M respectively; the thickness of the cell l = 0.1 cm. Spectra recorded under the following conditions: 1) 1 min after mixing the initial solutions; 2) after 2.5 min; 3) after 21 min; 4) after 51 min; 5) after 1 h 27 min; 6) after 2 h 7 min; 7) after 2 h 54 min; 8) after 3 h 53 min.

2. Photochemical Nitration with Tetranitromethane

Under the usual conditions, TNM does not react with aromatic compounds difficult to oxidise such as benzene, naphthalene, etc. or reacts with them very slowly.[185] However, it readily forms charge-transfer complexes with these compounds, whose irradiation with light at the wavelength corresponding to the charge-transfer band leads to the electron transfer:[186]

$$ArH + C(NO_2)_4 \rightarrow ArH\cdots C(NO_2)_4 \xrightarrow{h\nu} [ArH^{+}C(NO_2)_3^{-}] + NO_2^{\cdot}$$

One may therefore expect that nitration of the relatively unreactive ArH would be accelerated in the light. It has been shown for *N*-ethylcarbazole [187] that such influence by light does indeed occur.

The photochemical nitration of anthracene with TNM leads to a 9-nitroanthracene, which has been explained by the recombination of the 9-anthryl free radical with $NO_2^{\cdot}$.[188] However, one cannot rule out the possibility that the anthracene RC, whose formation in the course of the reaction is not open to doubt, in contrast to the 9-anthryl radical, participates in the formation of the nitro-derivative together with nitrogen dioxide.[188]

3. Nitration with Metal Nitrates

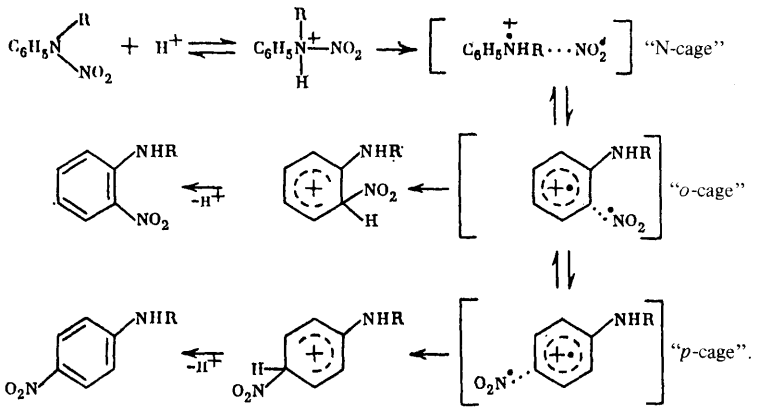
Among all the metal nitrates, the strongest nitration agents are salts with pronounced oxidising properties[189–196] such as titanium(IV), zirconium(IV), iron(III), and copper(II) nitrates and cerium ammonium nitrate. Some of these salts are such powerful oxidants that under the usual conditions they oxidise even alkanes[193] and water.[195]

The study of the nitration of aromatic compounds with titanium(IV) nitrate led to the conclusion that the nitrate salt is involved directly in the reaction.[191] Under comparable conditions, anhydrous metal nitrates can be superior to nitric acid as regards their nitrating capacity.[191,192] These facts indicate that nitration with metal nitrates can proceed via a specific mechanism and not necessarily via a trivial pathway involving the hydrolysis of the salt.

According to a recently proposed mechanism,[197] in the nitration of arenes by cerium ammonium nitrate,[192] the nitronium cation, formed in the interaction of the initial compounds, is the active species. Together with nitration, the oxidation of arenes to the RC by the cerium(IV) cation,[198] which is regarded as a side reaction,[197] has also been noted. However, the question of the role of the RC in such reactions and even more so in nitration by metal nitrates is not in general quite so simple, because there is a possibility of the formation of nitro-products from the RC when they interact with nitrate anions:

$$ArH + M(NO_3)_n \rightarrow ArH^{+}NO_3^{-} + M(NO_3)_{n-1}$$
$$ArH^{+} + NO_3^{-} \rightarrow \rightarrow ArNO_2$$

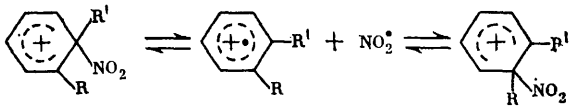
Such a nitration mechanism has been proposed in a study[199] of the nitration of *N*-methylphenoxazine (VIII). Heating of this compound in propanol with iron(III) or copper(II) nitrate leads to a satisfactory yield of the 3-nitro-derivative (IX). The formation of the phenoxazine RC is observed in the cold. The known radical-cation salt ($VIII^{+}\cdot ClO_4^{-}$) also gives rise to the nitro-compound (IX) on heating in propanol with tetrapropylammonium or potassium nitrate.



A number of facts indicate indirectly that this nitration pathway is possible also for other aromatic compounds. For example, it has been shown that the one-electron oxidation of benzene by cobalt(III) trifluoroacetate in the presence of potassium nitrate leads to nitrobenzene.[200] The electrochemical oxidation of anthracene in the presence of the tetrabutylammonium nitrate supporting electrolyte as the potential corresponding to the oxidation of anthracene to the RC affords a mixture of 9-nitro-, 9,10-dinitro-, and 4,9-dinitro-anthracene.[201] Under these conditions, the supporting electrolyte is oxidised only at an appreciably higher potential.

Although the mechanism of the conversion of the RC into nitro-compounds on interaction with NO_3^{-} is as yet not clear, the very fact of the occurrence of such reactions is not open to doubt. One of them has been described in a study[202] where it was shown, in an investigation of the action of nucleophiles on the RC of dibenzo-*p*-dioxin, that treatment of the perchlorate salt of this RC with potassium nitrate leads to 2-nitrodibenzo-*p*-dioxin. In contrast to the RC of dibenzo-*p*-dioxin, the thianthrene RC, which has a similar structure, reacts with the nitrate anion to form thianthrene *S*-oxides.[203]

The nitration of aromatic compounds by palladium nitrate proceeds via a specific mechanism, which is indicated by the unusually high level of *m*-substitution in the nitration of toluene and chlorobenzene by this reagent.[204] The partial rate factors for the attack of toluene by $Pd(NO_3)_2$ are 0.3 (*o*), 1.3 (*m*), and 3.0 (*p*). The partial rate factors for the palladisation of toluene by bivalent palladium salts are close to these values:[205] 0.28–0.95 (*o*), 1.44–1.87 (*m*), and 1.64 to 4.47 (*p*). It is logical to suppose that the nitration of aromatic substrates by palladium nitrate involves the intermediate formation of organopalladium compounds.



VII. THE RADICAL-ION MECHANISM OF THE NITRAMINE REARRANGEMENT AND THE ISOMERISATION OF NITROARENIUM CATIONS

The radical-ion mechanism of the nitramine rearrangement, involving the homolysis of the protonated form of nitramine with formation of the amine RC and nitrogen dioxide followed by the recombination of these radicals, has been justified in a number of studies:[206–209]

This mechanism is supported by the observation of the CIDNP effect in one of the reactions of the type considered[210] and also by the results of measurements of the $^{15}N/^{14}N$ and $^{14}C/^{12}C$ kinetic isotope effects.[211]

The isomerisation of the nitroareneium cations $ArRNO_2^+$ with the migration of the nitro-group along the perimeter of the aromatic ring is usually regarded as an intramolecular process.[132] However, one cannot rule out the possibility that in certain cases it can proceed via a radical-ion pathway similar to the mechanism of the nitramine rearrangement:[60]

From the standpoint of thermodynamics, the homolysis of nitroarenium cations is preferable to the alternative pathway involving their dissociation into ArH and NO_2^+ in those cases where the ArH have fairly low ionisation potentials. This conclusion is based on the results of the calculation of the ΔG_0 corresponding to electron transfer from various aromatic compounds to the nitronium cation.[115] The possibility of the radical-ion pathway leading to the isomerisation of nitroarenium cations is supported by data for the capacity for homolysis.[212] However, it is not as yet clear whether this reaction pathway can be the main one.

---o0o---

Thus studies in recent years have shown that the ideas about electrophilic nitration according to which it is a purely heterolytic process can no longer claim to be universal. An increasing number of facts have been appearing which do not fit within the framework of these ideas and which show that radical species such as radical-cations and nigrogen dioxide can play an important role in nitration. On the other hand, these facts do not conflict with the classical mechanism of nitration as regards the role of the σ-complexes as the direct precursors of the nitro-derivatives. For practical purposes, it is extremely significant that free radicals serve as a source of not only nitro-products but also (by virtue of their high reactivity) of various side products. It is not difficult to note that the observed evolution of ideas about the nitration mechanism is a specific manifestation of the more general trend towards a separation of the concepts of heterolytic and electrophilic (nucleophilic) substitution. As a result, the fact that a reaction belongs to the class of electrophilic (nucleophilic) substitution reactions is no longer a basis for its automatic inclusion in the series of heterolytic reactions. In the field of nucleophilic aromatic substitution reactions, this has been reflected, in particular, by the establishment of the $S_{RN}1$ radical-nucleophilic substitution mechanism.

The studies designed to discover the role of electron transfer in nitration are naturally far from being completed. One can suppose that they will ultimately lead to the development of clear experimental criteria for a radical-ion mechanism and will provide an answer to the question of its specific contribution in the overall set of aromatic nitration reactions.

During the preparation of the article for publication, a series of new studies concerning the role of the oxidation-reduction stage in nitration reactions have been published, in particular a monograph[213] and a review,[214] which contain sections devoted to these reactions. It has been shown[215] that the regioselectivity of the nitration of naphthalene with nitric acid in trifluoroacetic acid, expressed by the ratio α : β of the mononitronaphthalenes formed, depends significantly on temperature and, when the latter is reduced, it reaches values characteristic of the recombination of the dimeric naphthalene radical-cation with nitrogen dioxide. This fact and also the detection of the radical-cation indicated above in the $C_{10}H_8$–HNO_3–CF_3COOH system have been interpreted as evidence for the radical-ion mechanism of the nitration of naphthalene.

The complex oxidation reactions occurring in the interaction of a series of compounds of the dihydropyridine series with nitric acid have been explained by the oxidation of these compounds to the RC and the recombination of these species with nitrogen dioxide via the oxygen atom of the latter.[216]

The mechanism of the nitration of aromatic compounds by nitrogen tetroxide, whose initial stage is the heterolysis of N_2O_4 to form the nitrosonium cation, has been discussed.[217] Other pathways leading to nitration by this reagent presumably involve its homolysis to nitrogen dioxide. The latter can oxidise aromatic substrates to the RC,[218,219] which, as already mentioned, are capable of being converted into nitrocompounds under the influence of $NO_2^{\cdot}$. It has been demonstrated by pulse methods[218,219] that the electron transfer from *NNN'N'*-tetramethylbenzidine, *N*-methylphenothiazine, and metiazinic acid to $NO_2^{\cdot}$ in polar medium is extremely fast: the corresponding rate constants are of the order of 10^7–10^8 litre mol^{-1} s^{-1}. According to the available data,[178] there is also a possibility of the free-radical attack on aromatic substrates by nitrogen dioxide, characterised by a low positional selectivity and also leading to nitro-derivatives.

Selenonium Compounds and Their Applications in Synthesis

N.N.Magdesieva

The review gives a systematic account and surveys the results of studies in the chemistry of selenonium compounds (salts, ylides, ylide-salts, diylides, and imides). The methods of synthesis of selenonium compounds, their structure, their behaviour in reactions with electrophiles and nucleophiles, and also their reactions under conditions of thermolysis and rearrangements are considered.
The bibliography includes 95 references.

I. INTRODUCTION

Selenonium compounds contain a fragment with a tricoordinate positively charged selenium atom; they include selenoxides, selenimides, selenonium salts, selenium ylides, and also bis-onium compounds (ylide-salts and di-ylides) containing, together with the selenonium fragments, also fragments based on other heteroatoms (nitrogen, phosphorus, arsenic, and sulphur). The present review does not include data from the chemistry of selenoxides, because the reactivity of the latter has been described in detail in a series of reviews published in recent years.[1-3]

The sharp growth of interest in the chemistry of selenonium compounds (salts, ylides, and ylide-salts) in recent years is due to their ready availability and high reactivity, which as a rule greatly exceeds the reactivity of the corresponding sulphonium compounds and in many cases has no analogy in the chemistry of the onium compounds of Group V and VI elements. The interest of chemists in these compounds is associated not only with their importance for theoretical organic chemistry but also with the real possibility of their practical use as convenient active synthons for fine organic synthesis, the majority of the reactions with the participation of which proceed stereospecifically and regioselectively.

This review gives a systematic account and surveys the results of studies on the development of the methods of synthesis, the structures, physicochemical properties, and reactivities of selenonium compounds (salts, ylides, ylide-salts, diylides, and also selenimides) during the last 15 years. Until 1972, the chemistry of these compounds was hardly investigated and there have been only individual studies on the synthesis of selenonium salts, which have been surveyed in a monograph.[4]

Wherever possible, the reactivities of selenonium systems have been compared with sulphur compounds of analogous structure.

II. SELENONIUM SALTS

The first and most general method of synthesis of selenonium salts involves the alkylation of selenides with alkyl halides, α-bromoacids and their esters, and α-bromoketones.

Alkyl diphenylselenonium tetrafluoroborates have been obtained by alkylating diphenyl selenide with alkyl halides in the presence of a stoichiometric amount of silver tetrafluoroborate:[5]

$$Ph_2Se + \begin{matrix} R^1 \\ R^2 \end{matrix}\!\!>\!CHX \xrightarrow{AgBF_4} Ph_2\overset{\oplus}{S}e\text{-}CH\!<\!\begin{matrix} R^1 \\ R^2 \end{matrix}\ \overset{\ominus}{B}F_4$$

$R^1 = R^2 = H$, X = I; $R^1 = H$, $R^2 = Me$, X = Br; $R^1 = R^2 = Me$, X = I

The alkylation of a selenide containing the trifluoromethyl group has been described:[6]

$$PhSeCF_3 \xrightarrow{MeI,\ AgBF_4} Ph\text{—}\overset{Me}{\overset{|}{\overset{\oplus}{S}e}}\text{—}CF_3\ \overset{\ominus}{B}F_4$$

A convenient method of synthesis of selenonium salts containing the benzyl group involves the methylation of selenides with trimethyloxonium tetrafluoroborate and also with methyl fluorosulphonate,[7] for example:

$$RCH_2SePh \xrightarrow{\overset{\oplus}{Me_3}O\ \overset{\ominus}{B}F_4} RCH_2\overset{\oplus}{\underset{|}{S}}ePh\ \overset{\ominus}{B}F_4$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\quad Me$$

R = Ph, *p*-ClC_6H_4, *m*-ClC_6H_4, *p*-MeC_6H_4.

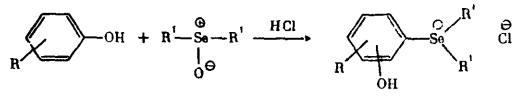
Unsaturated selenides are smoothly alkylated with methyl fluorosulphonate:[8]

$$\underset{SePh}{\overset{|}{\overset{|}{\text{—CH=C}}}}\!<\!\begin{matrix} R \\ R^1 \end{matrix} \xrightarrow{MeSO_3F} \underset{\oplus SeMe}{\overset{|}{\overset{|}{\text{—CH=C}}}}\!<\!\begin{matrix} R \\ R^1 \end{matrix}\ SO_3^{\ominus}F$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\quad Ph$$

R = H, Me; $R^1 = C_6H_{13}$, C_8H_{17}

Diaryl selenides are arylated with iodonium salts in the presence of copper(II) benzoate:[9]

$$Ph_2Se + \overset{\oplus}{Ar_2}\overset{\ominus}{I}AsF_6 \xrightarrow{Cu\,(II)} ArPh_2\overset{\oplus}{S}e\ \overset{\ominus}{A}sF_6 + ArI$$



Ar = Ph, *p*-t-BuC_6H_4, *p*-MeC_6H_4, 3,4-$Me_2C_6H_3$

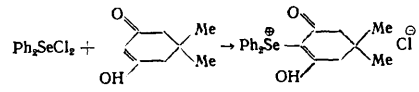
Diaryl selenides readily react with t-butyl hypochlorite:[10]

$$Ar_2Se + t\text{-}BuOCl \rightarrow Ar_2\overset{\oplus}{S}eOBu\text{-}t\ \overset{\ominus}{Cl}.$$

Methods of synthesis of selenonium salts on the basis of organic derivatives of selenium(IV), namely selenoxides, diorganoselenium dihalides, and selenium halides and oxides halides, are known. A method of synthesis of dialkyl- or

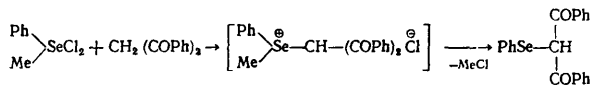
alkylphenylhydroxyphenylselenonium chlorides by the reaction of phenols with selenoxides and hydrogen chloride has been developed:[11]

R = Me; R' = Me, Et, Ph



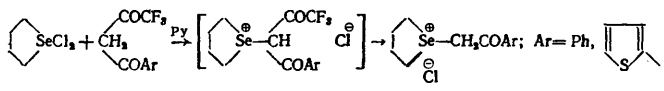
Tri-*p*-tolylselenonium chloride has been obtained by the reaction of toluene with selenium dioxide in the presence of sulphuric acid.[12]

Triarylselenonium salts have been synthesised from selenium oxide chloride and arylmagnesium bromides:[13]

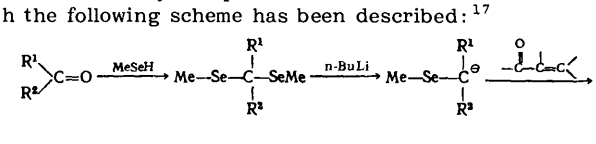


$$RC_6H_4MgCl + SeOCl_2 \xrightarrow{HX} (RC_6H_4)_3\overset{\oplus}{S}e\overset{\ominus}{X}$$

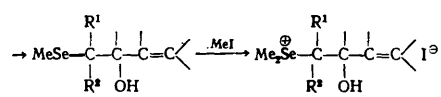
X = Cl, Br, I; R = H, *o*-Me, *m*-Me, *p*-Me.



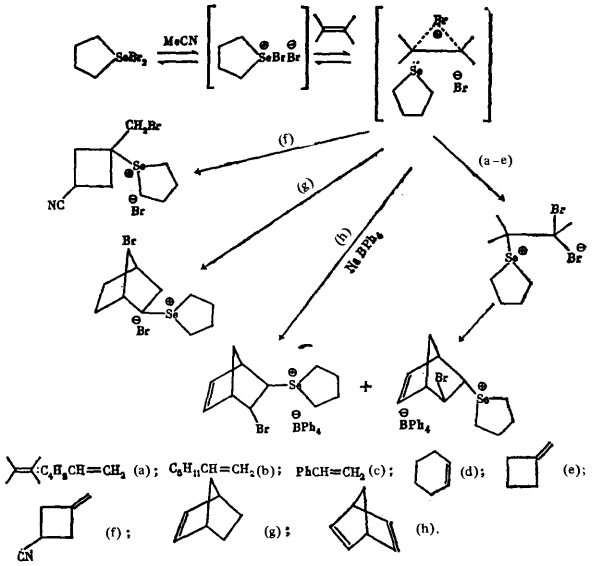
The synthesis of triarylselenonium salts by the reaction of diarylselenium dichlorides with activated arenes has been described.[20] Diphenylselenium dichloride reacts with dimedone to form a selenonium salt. The ease of this reaction is due to the fact that the enolic proton in the fixed *trans*-enol structure of dimedone can promote the polarisation of the Se–Cl bond:[14]



In the reaction of methylphenylselenium dichloride with dibenzoylmethane, the intermediate selenonium salt is demethylated:[15]



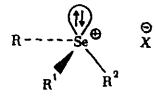
In the case of β-diketones containing the trifluoroacetyl group, the cleavage of the intermediate diketoselenonium salts by a nucleophile (Py or $Cl^{\ominus}$) proceeds differently, which can be accounted for by the large positive charge on the carbonyl carbon atom of the CF_3 group of the diketoselenonium salt:[16]



The synthesis of γδ-unsaturated β-hydroxyselenonium salts from carbonyl compounds and a selenol in accordance with the following scheme has been described:[17]

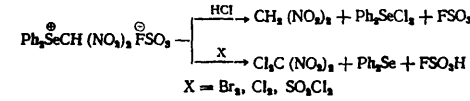
$R^1 = R^3 = H$, Me; $R^1 = H$, R^2 = Me; $R^1 = H$; $R^2 = Me(CH_2)_6$—

A method of synthesis of a new type of selenonium compounds, namely β-bromoselenonium salts, based on the interaction of tetramethylselenium dibromide with olefins having different structures (acyclic, cyclic, and skeletal), has been developed recently.[18] The electrophilic addition of tetramethyleneselenium dibromide to acyclic and cyclic olefins proceeds *trans*-stereospecifically with formation of 2-bromoalkyltetramethyleneselenonium bromides together with dibromoalkanes. The addition of tetramethyleneselenium dibromide to norbornene is accompanied by a rearrangement as a result of a 7,2-hydride shift and the addition to norbornadiene takes place with formation of a 3 : 1 salt mixture comprising 2-*endo*-bromo-3-*exo*-(tetramethyleneselenonium)- and 2-*exo*-bromo-3-*endo*-(tetramethyleneselenonium)-norbornene bromides:



Dinitro-substituted selenonium salts have been obtained by protonating diphenylselenonium dinitromethylide with inorganic acids having a weakly nucleophilic anion:[19]

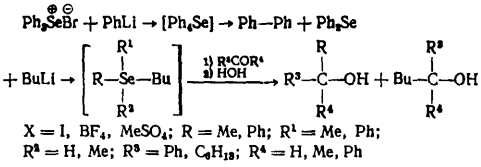
$$Ph_2\overset{\oplus}{S}e\overset{\ominus}{C}(NO_2)_2 + HX \rightleftharpoons Ph_2\overset{\oplus}{S}eCH(NO_2)_2\,\overset{\ominus}{X}$$



X = SO_3F; BF_4; F

The selenium atom in selenonium compounds is in the sp^3-hybrid state and the selenonium group therefore has a pyramidal structure:

A series of optically active selenonium salts have been obtained, whose stability indicates a high barrier to inversion at the selenonium chiral centre.[21] X-Ray diffraction,[22] UV spectroscopic,[23] IR spectroscopic,[24] and ^{77}Se NMR [25] data as well as the electrical conductivities of aqueous solutions of selenonium salts and the ability of the salts to exchange readily their anions[26] have confirmed their ionic structure. Selenonium tetraphenylborates are soluble in organic solvents, which makes it possible to use them in homogeneous reactions.[27] Selenonium salts with two electron-accepting groups are unstable and readily decompose.[28]

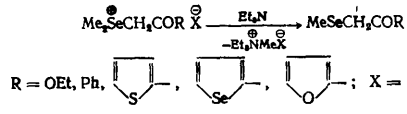


On treatment with electrophiles, diphenyl(dinitromethyl)-selenonium salts are cleaved at the Se–CNO_2 bond:[19]

X = Br_2, Cl_2, SO_2Cl_2

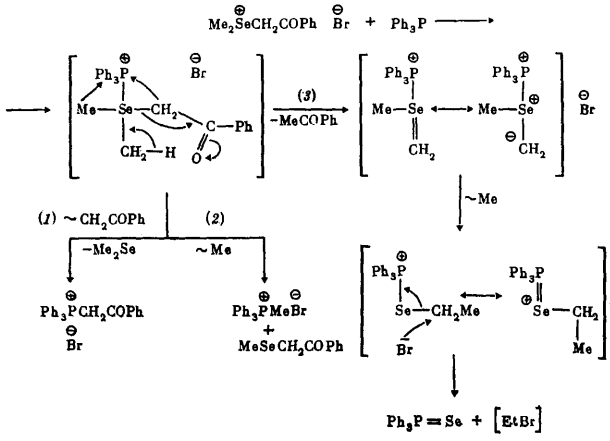
Reactions with nucleophiles are most characteristic of selenonium salts. On treatment with organolithium compounds, the intermediate σ-selenuranes undergo further

reactions: [29]

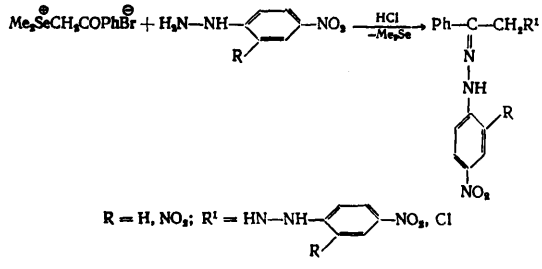


The last reaction can be used to synthesise tertiary alcohols.[29]

The photochemical reaction of triphenylselenonium tetrafluoroborate with triphenylphosphine via a radical mechanism has been described: [30]

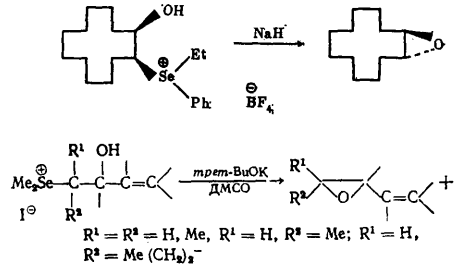


The homolytic character of the dissociation of the bond in the initial selenonium salt is confirmed by the fact that the reaction does not proceed in the dark and that benzene is formed as a side product. [30]

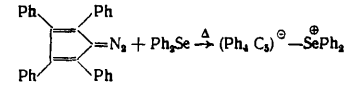


The interaction of arylacyl- and alkoxycarbonyl-methyl-(dimethyl)selenonium salts with nucleophiles (tertiary amines, substituted hydrazines, and triphenylphosphine) has been investigated. The demethylation of selenonium salts with triethylamine, which takes place with formation of α-methylselenocarbonyl compounds, is a convenient method of their synthesis: [27]

The reaction of dimethylphenylacylselenonium bromide with triphenylphosphine apparently proceeds via the primary attack by the nucleophile on the selenium atom with the subsequent migration of the phenylacyl or methyl group from selenium to phosphorus (pathways 1 and 2) and the elimination of acetophenone from the σ-selenurane intermediate (pathway 3): [27]

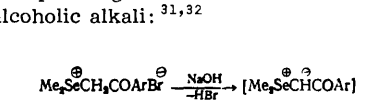


The interaction of dimethylphenylacylselenonium bromide with substituted hydrazines is accompanied by the elimination of dimethyl selenide: [27]

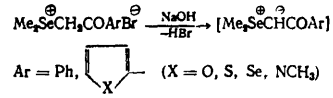


The reactions of selenonium salts with bases are very important. They are the basis of a general preparative method of synthesis of unstabilised selenium ylides and also of monostabilised ylides containing one electron-accepting group at the ylide carbon atom.

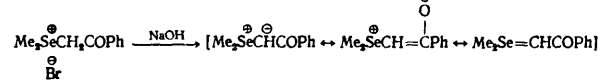
Treatment of β-hydroxyselenonium salts with bases results in a stereospecific reaction involving the intramolecular nucleophilic substitution of the selenonium group with formation of epoxides, [33] including αβ-unsaturated epoxides: [17]



III. UNSTABILISED AND MONOSTABILISED SELENIUM YLIDES

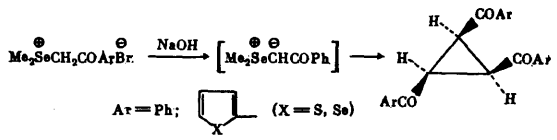


A general preparative method of synthesis of monostabilised selenium ylides involves the interaction of their conjugate acids with bases [31,32] or the decomposition of diazocompounds in the presence of selenides, [33,34] which takes place via the formation of a carbene: [35]

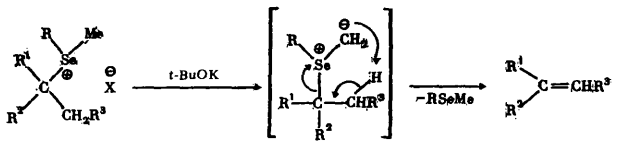


Potassium t-butoxide is normally used to generate unstabilised selenium methylides *in situ*: [6]

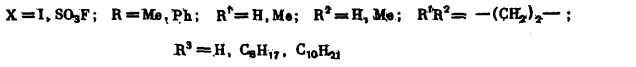
Monocarbonyl-stabilised selenium ylides are obtained *in situ* when the corresponding selenonium salts are treated with aqueous or alcoholic alkali: [31,32]



Only one selenium monoketoylide, namely dimethylselenobenzoylmethylide, has been isolated. It is an extremely labile crystalline compound, whose IR spectrum indicates the involvement of the carbonyl group in the declocalisation of the charge on the ylide carbanion: [31]



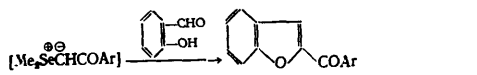
In the light or on slight heating, dimethylselenonium benzoylmethylide decomposes via a carbenoid mechanism with formation of *trans*-tribenzoylcyclopropane. [31] This reaction

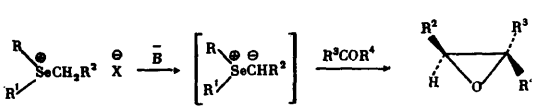


is a convenient method of synthesis of heteroaroylcyclopropanes:[36]

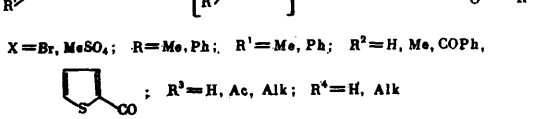
Unstabilised selenium ylides usually do not form carbenoid decomposition products. However, when benzylselenonium salts were treated with sodium amide, small amounts of *trans*-stilbene, which is formally a product of the dimerisation of phenylcarbene, were isolated.[37]

The reaction involving the intramolecular cleavage of unstabilised selenonium ylides is used to synthesise various olefins including sterically hindered olefins:[8]





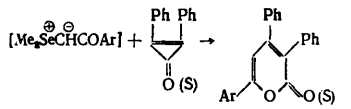
As a rule, unstabilised and monostabilised selenium ylides are not isolated but are used *in situ*, being generated from salts in the presence of the substrates with which the reaction is carried out.

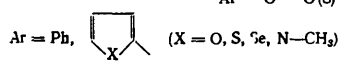


As carbenoid species, monostabilised selenium ylides are more nucleophilic than their sulphur analogues and they readily interact with electrophiles. The most convenient and productive method of carrying out the reactions of ketoselenonium ylides with electrophilic substrates involves the use of a two-phase system: chloroform–water with sodium hydroxide as the base. The ylide generated in the aqueous phase on treatment of the selenonium salt with alkali is immediately extracted chloroform. The salt which failed to react remains in the aqueous phase, which suppresses the secondary reaction of the ylide with the salt leading to a triarylcyclopropane.

The reactions of carbanions with electrophiles in a two-phase system are carried out[38] in the presence of a phase transfer catalyst. The reactions of selenium ylides do not as a rule require special catalysis.

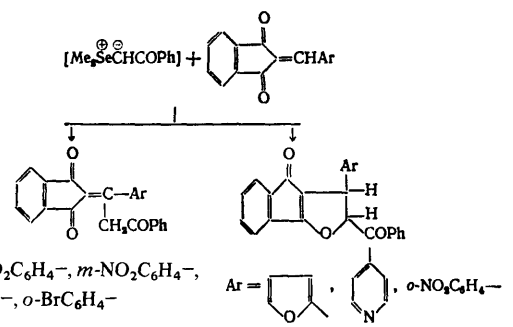
The selenonium ylides stabilised with a phenylacyl[39] or cyclopentadienyl group[34] react with nitrosobenzene to form the corresponding nitrones. The reactions of selenium ylides with various carbonyl compounds lead to oxirans having the *trans*-confirguration[40–42] and the reactions with salicylaldehyde lead to 2-aroylbenzofurans:[41]



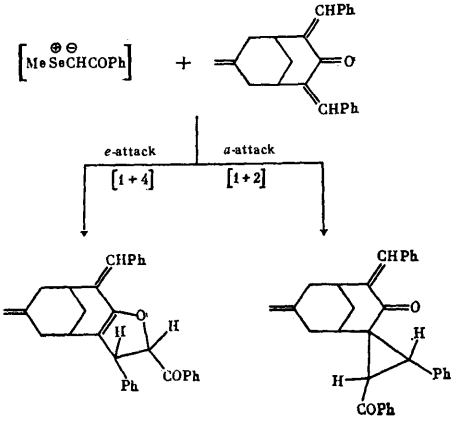


The interaction of selenonium ylides with activated multiple bonds usually begins as the Michael addition, the subsequent reactions of the betaines formed as a rule involving the elimination of the readily removed selenonium group as a result of intramolecular nucleophilic substitution.

A convenient preparative method of synthesis of trisubstituted α-pyrones and α-pyranthiones by the [3 + 3]dipolar cycloaddition of selenium monoketoylides to diphenylcyclopropenone or its thio-analogue has been developed:[32]

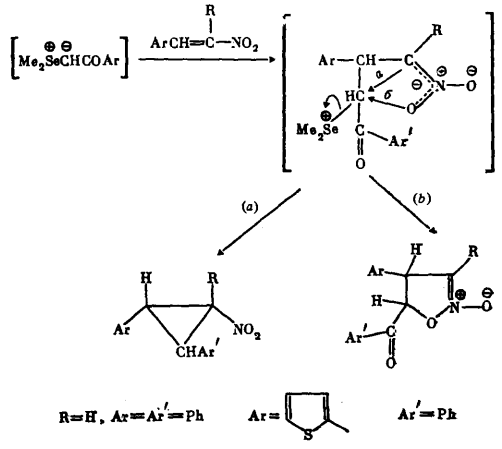


The reactions of cyclic selenium diketoylides, namely dimethylselenonium diketoylides formed from dimedone and indan-1,3-dione, with diphenylcyclopropenone can be used to synthesise condensed α- and γ-pyrones.[43]



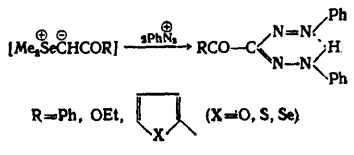
The interaction of selenium monoketoylides with activated acetylenes (dialkyl acetylenedicarboxylate or dibenzoylacetylene) leads to the formation of the corresponding trisubstituted furans.[44,45]

In contrast to sulphur ylides, the reactions of selenium monoketoylides with *para*-substituted 2-benzylideneindan-1,3-diones, having a conjugated bond system, begin with nucleophilic attack by the ylide carbon atom on the activated double bond. The betaine formed in this reaction splits off dimethyl selenide and, depending on the character of the substituent in the benzylidene group, either a 1,2-hydride shift takes place with formation of the Michael addition product or the dihydrofuran ring is formed. The reaction takes place stereoselectively and only the *cis*-isomers of dihydrofurans are formed:[46]

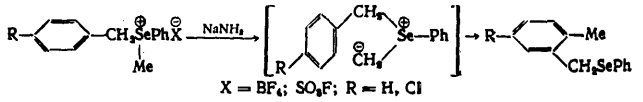


The reaction of selenium monoketoylide with dibenzylidene derivatives of a series of ketones (acyclic, cyclic, and bicyclic) in which both [1 + 2]- and [1 + 4]-cycloaddition is possible, have been investigated. It has been established that the interaction of selenium ylide with dibenzylidene derivatives of acetone, cyclopentanone, and cyclohexanone takes place as [1 + 2]cycloaddition to one of the double bonds of the dieonone with formation of two isomeric cyclopropyl ketones. In the case of the dibenzylidene derivative of bicyclo[3.3.1]ionan-3-one, the type of reaction, i.e. [1 + 2]- or [1 + 4]-cycloaddition, is determined by the direction of attack by the selenonium ylide (axial or equatorial). The attack by the ylide from the equatorial side relative to the given cyclohexane ring leads to the formation of the dihydrofuran ring as a consequence of the mutual approach of the carbonyl oxygen atom and the ylide carbon atom in the transition state. On the other hand, the attack from the axial side leads to the oxygen and ylide carbon atoms moving apart in the transition state and the formation of a three-membered ring becomes preferable. The reaction

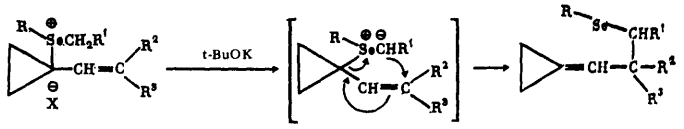
takes place stereospecifically with formation of cyclopropane having the *cis*-configuration and of the *cis*-isomer of dihydrofuran:[47]



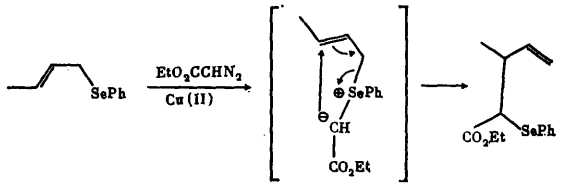
In all the cases investigated, the reaction involves only one benzylidene group.



The conjugated nitro-olefins, in which there is a possibility of both [1 + 2]- and [1 + 4]-cycloaddition with formation of substituted cyclopropanes or isoxazoline *N*-oxides, constitute a convenient model for the study of reactions involving the cycloaddition of selenium ylides to an activated multiple bond. A necessary and sufficient condition for the occurrence of a reaction of the [1 + 4]-cycloaddition type is the presence of a substituent in the α-position relative to the nitro-group in the initial nitro-olefin. The nature of the substituent (alkyl, aryl, heteroaryl, or halogeno-) does not then influence the mode of reaction. The reaction takes place stereoselectively and is a convenient preparative method of synthesis of trisubstituted isoxazoline *N*-oxides in the *trans*-configuration:[48]

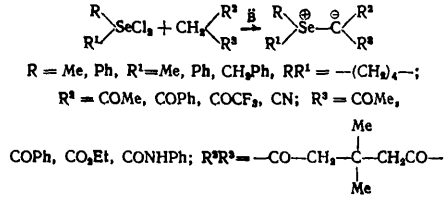


Among the electrophiles having the electrophilic centre at a heteroatom, detailed studies have been made of the interaction of selenonium acylmethylides with benzenediazonium chloride.[49] In contrast to phosphorus, nitrogen, and sulphur ylides, this reaction takes place with formation of 3-keto-1,5-diphenylformazans and constitutes a preparative method of their synthesis:



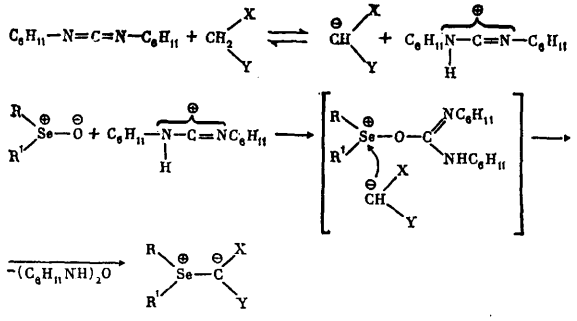
The [2,3]sigmatropic rearrangement of benzylselenonium ylides on treatment of the corresponding salts with sodium amide in liquid ammonia has been described:[37]

The [2,3]sigmatropic rearrangement of allylselenonium ylides is used to synthesise olefins:[9]



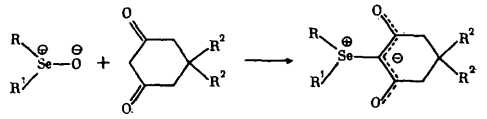
An analogous rearrangement has been observed on treating allyl selenide with diazoacetic ester in the presence of copper(II) sulphate:[33]

Thus unstabilised and monostabilised selenium ylides are convenient and very active reagents for the synthesis of various classes of organic compounds. Their ylide bond $\geq\bar{C}-\overset{+}{Se}<$ is weaker than the $\geq\bar{C}-\overset{+}{S}<$ bond in sulphonium ylides. R_2Se is a group which is more readily eliminated than R_2S. All the reactions with participation of selenonium ylides takes place under mild conditions. In terms of their behaviour, selenium ylides resemble nitrogen ylides more than sulphur ylides.



IV. DISTABILISED SELENIUM YLIDES

Distabilised selenium ylides have been obtained in satisfactory yields by condensing diorganoselenium dichlorides with compounds containing an active methylene group in the presence of a base (sodium ethoxide, potassium hydroxide, pyridine, alumina):[14,50–53]

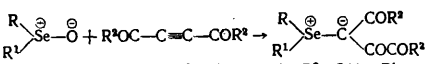


A general convenient preparative method of synthesis of distabilised selenium ylides involves the condensation of selenoxides with compounds containing an active methylene

group in the presence of dicyclohexylcarbodiimide: [16,51,52,54]

$R=R^1=Ph$; $R=Ph, R^1=PhCH_2$; $R=R^1=-(CH_2)_4-$, $X=Y=-CO-CH_2-C(Me)_2-CH_2-CO-$; $X=Y=COPh$; $X=COPh, Y=COCF_3$; $X=COCF_3, Y=CO$-(thienyl)

The asymmetric synthesis of a number of optically active selenonium diketoylides by the reaction of cyclic β-diketones with selenoxides in the presence of camphor-10α-sulphonic acid and anhydrous sodium sulphate has been achieved: [55]

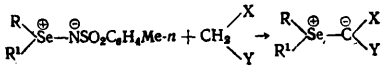


R = Ph, α-naphthyl, *o*-MeC_6H_4; 1,2,3-$Me_3C_6H_2$; R^1=Me, Ph; R^2=H, Me

Selenonium nitroylides have been obtained by this method: [19,56]

X = NO_2, CO_2Me, COPh; R=Ph, $PhCH_2$; $R_2=-(CH_2)_4-$

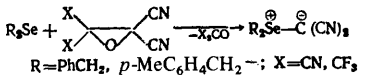
It is also known that selenoxides form selenium ylides by reaction with dimethylacetylenedicarboxylate [57,58] and dibenzoylacetylene: [59]



R=Me, R^1=Ph; R=R^1=$PhCH_2$, Ph; R^2=OMe, Ph

Selenium dicyanomethylides have been obtained by the reaction of selenoxides with tetracyanoethylene: [57]

R=$PhCH_2$, *p*-$MeC_6H_4CH_2-$



A method of synthesis of distabilised selenonium ylides from readily available selenimides and compounds with active methylene groups has been developed: [54]

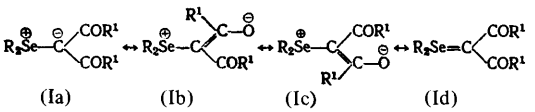
R = R^1 = $PhCH_2$, Ph; $RR^1=-(CH_2)_4-$, X, Y=CN, COOMe, COMe, SO_2Ph

The rate of this reaction depends on the stability of the ylides formed.

Selenonium dicyanomethylides have been obtained by the reaction of selenides with activated oxirans: [57]

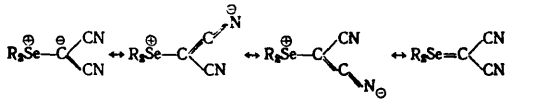
R=$PhCH_2$, *p*-$MeC_6H_4CH_2-$; X=CN, CF_3

Only one example of the synthesis of selenonium ylides from the ylides of other elements is known: [56]



R = $PhCH_2$; $R_2=-(CH_2)_4-$

The yield of the ylides in this reaction depends on the nucleophilicity of the selenide used.

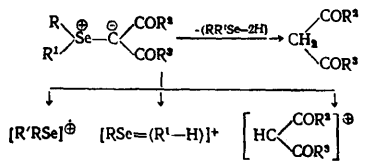


X-Ray diffraction data are available for only two distabilised selenium ylides: diphenylselenonium diacetylmethylide [56] and tetramethylselenonium dimedonylide. [60,61] These ylides have a trigonal pyramidal structure, at the apex of which the selenium atom is located.

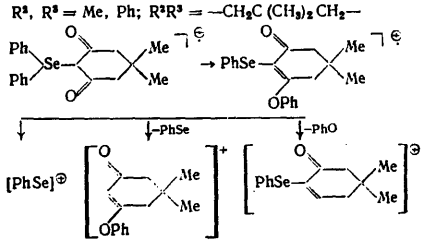
Analysis of the bond lengths between the selenium atom and the ylide carbon atom and also of the bond lengths in the electronegative substituents indicates the involvement of electron-accepting groups in the declocalisation of the negative charge on the carbanion. [53,61] The IR. spectra of the distabilised selenonium ylides convincingly confirm this. [16,52]

The contribution of the dipolar resonance structures (Ib, c) and (IIb, c) to the ground state is extremely significant for selenonium diketo- and dicyanomethylides:

(Ia) (Ib) (Ic) (Id)



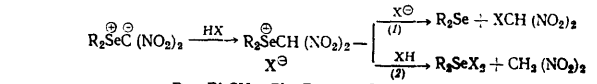
(IIa) (IIb) (IIc) (IId)



The selenium–ylide carbon bond lengths found in the distabilised selenium ylides [53,61] and also the ^{77}Se NMR data for these compounds [25] suggest a difinite contribution by the double bond character and the possibility of the formation of a $p_\pi-d_\pi$-bond using the selenium *d* orbital. [62] The contribution of the structures (Id) and (IId) in the selenium ylides is smaller than that of the analogous structures in sulphur ylides.

In aprotic solvents, the carbanionic fragment of selenonium ylides has the *W*-conformation, which has been confirmed by ^1H NMR and dipole moment data. [15]

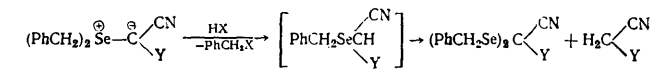
On electron impact, selenium diketoylides decompose at the $\overset{+}{>}Se-\bar{C}<$ bond together with the migration to the anionic residue of the ylide of hydrogen or the group (in the case of diphenylselenonium dimedonylide) linked to the selenium atom: [63]



R = Ph; R^1 = Me, Ph; $RR^1=-(CH_2)_4-$; R^3, R^3 = Me, Ph; $R^2R^3=-CH_2C(CH_3)_2CH_2-$

With the exception of nitroylides, [19] the distabilised selenium ylides are extremely stable compounds resistant to the action of various nucleophiles: aqueous and alcoholic alkali, [51,52] amines, [50] and alkali metal alkoxides. [51] As a consequence of the delocalisation of the charge on the ylide carbon atom over two electron-accepting groups, their nucleophilicity is significantly lower than that of unstabilised and monostabilised selenium ylides. However, reactions with fairly powerful electrophiles and compounds containing activated multiple

bonds are characteristic of the distabilised selenium ylides; thus, they afford the corresponding hydrochlorides, which lose HCl near their melting points.

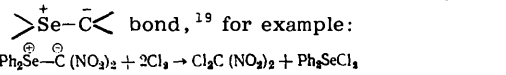


Selenonium dinitromethylides are protonated reversibly by inorganic acids containing weakly nucleophilic anions.[9] On treatment with acids having nucleophilic anions, the $\gtrless\overset{+}{S}e-\bar{C}\lessgtr$ bond dissociates. The intermediate salt is then capable of being cleaved at the $\gtrless\overset{+}{S}e-CH\lessgtr$ bond not only by the nucleophile counterion (pathway *1*) but also by the electrophilic molecule of the acid (pathway *2*):[19,56]

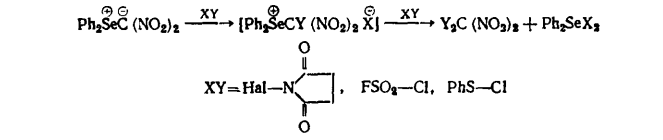
$R = RhCH_2$, Ph; $R_2 = -(CH_2)_4-$; X = Cl, Br

The preferred reaction pathway depends on the nucleophilic properties of the counterion; on passing from HCl to HBr, the contribution of pathway *1* increases.

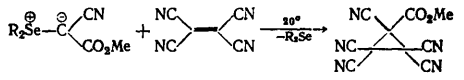
Dibenzylselenonium dicyano- and cyanomethoxycarbonylmethylides are cleaved by acids only at the $\gtrless\overset{+}{S}e-CH_2Ph$ bond:[28]



X = Cl, Br, NO_3, HSO_4, CF_3COO, $ClCH_2COO$; Y = COOMe, CN

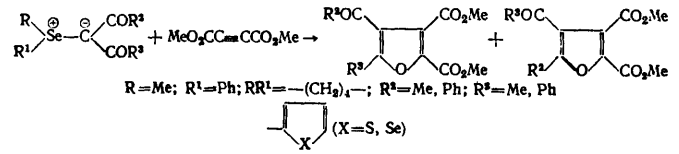


On the other hand, diphenylselenonium trifluoroacetylbenzoylmethylide is cleaved at the $\gtrless\overset{+}{S}e-\bar{C}\lessgtr$ bond on treatment with hydrogen chloride:[16]

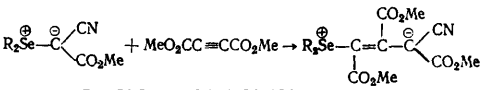


On interaction with powerful electrophiles (Cl_2, Br_2, SO_2Cl_2), diphenylselenonium nitroylides are also readily cleaved at the $\gtrless\overset{+}{S}e-\bar{C}\lessgtr$ bond,[19] for example:

Compounds with a "positive" halogen and benzeneulphenyl chloride also react with selenonium nitroylides under mild conditions, two "electrophilic" components of the reagent being joined to the carbanionic fragment, as in the interaction of distabilised ylides with acids:[19]

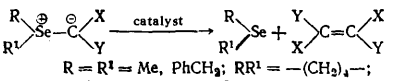


Distabilised selenonium ylides do not as a rule react with αβ-unsaturated ketones. However, substituted cyclopropanes have been obtained by the reaction of selenium cyanomethoxycarbonylmethylides with the highly electrophilic tetracyanoethylene:[57]



$R = PhCH_2$, p-$MeC_6H_4CH_2$.

The interaction of selenonium diketoylides with dimethyl acetylenedicarboxylate leads to tetrasubstituted furans:[50]

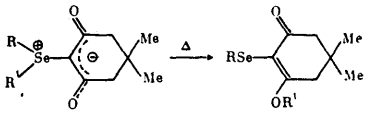


The reaction of selenium cyanomethoxycarbonylmethylides with dimethyl acetylenedicarboxylate results in the formation of only betaines, probably as a consequence of the reduced electrophilicity of the methoxycarbonyl group:[50,57]

$R = PhCH_2$, p-$MeC_6H_4CH_2$; $R_2 = -(CH_2)_4-$

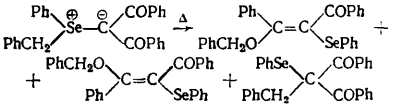
Distabilised selenium ylides readily decompose into the corresponding selenides and the products of the dimerisation of the carbanionic fragment on treatment with catalysts: tetramethylthioureas,[64] thioamides,[65] and episulphides:[66]

$R = R^1 = Me$, $PhCH_2$; $RR^1 = -(CH_2)_4-$;
X = CN, Y = CN, COOMe, COOEt



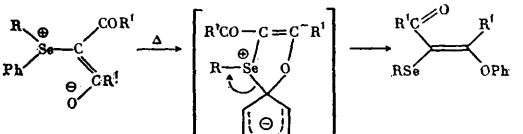
The mechanisms of all these reactions involve the initial attack on the thioderivatives by the ylides carbon atoms and the elimination of the selenide.[64-66]

Selenonium dinitromethylides are known to react with thiourea as follows:[56]



The course of the reaction depends greatly on the structure of the groups attached to the selenium atom. Thus, whereas in the case where $R_2 = -(CH_2)_4-$ a thiuronium ylide is formed in a high yield, when $R = PhCH_2$ the product is a 1:1 complex with thiourea, and in the case where R = Ph the reaction does not occur at all.

Under relatively mild conditions (refluxing in benzene or xylene), selenonium diketoylides rearrange with migration of the benzyl or phenyl group to the oxygen atom:[67]



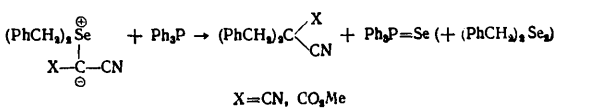
$R = PhCH_2$, Ph, Me; $R' = PhCH_2$, Ph

Only in the case of benzylphenylselenonium benzoylmethylide was the product of the Stevens rearrangement isolated together with that of the *O*-migration of the benzyl group:

The rearrangement of benzylphenylselenonium diketoylides apparently takes place stepwise via the formation of a radical pair and its subsequent recombination within a cage.

The migration of the phenyl group in methylphenyl- and diphenyl-selenonium diketoylides takes place via a mechanism involving intramolecular nucleophilic substitution in the benzene ring:[67]

R = Me, Ph; R^1 = Ph, $R'_2 = -CH_2-C(CH_3)_2-CH_2-$

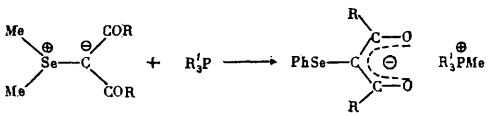


The capacity of the groups attached to the selenium atom for migration decreases in the sequence $PhCH_2$ > Ph > Me.[67]

Thermolysis of cyclic selenium diketoylides in the presence of copper(II) sulphate apparently proceeds via the formation of carbenes. As a result of the interaction with the initial ylide, the carbene is converted into the corresponding tetrasubstituted ethylene: [68]

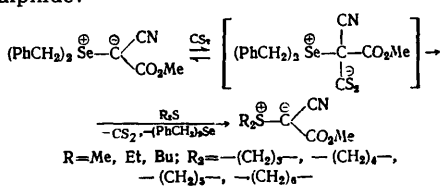
R, R^1=Me, Ph; R^2_2=—$CH_2C(CH_3)_2CH_2$—, *o*-C_6H_4—

The main pathway in the reaction of distabilised dibenzylselenonium ylides with triphenylphosphine involves the elimination of selenium with formation of triphenylphosphine selenide: [69,70]

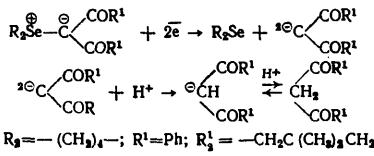


X=CN, CO_2Me

On the other hand, the reaction of dibenzylselenonium tosylimide proceeds with formation of triphenylphosphonium tosylimide: [70]



Triphenylphosphine and tris(dimethylamino)phosphine demethylate diketoylides with formation of phosphonium salts of enols: [71]



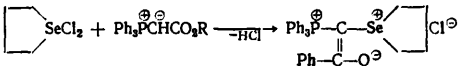
R=Ph, R_2=—$CH_2C(CH_3)_2CH_2$—, R^1=Ph, Me_2N

Dibenzylselenonium cyanomethoxycarbonylmethylide undergoes transylidation by dialkyl sulphides in the presence of carbon disulphide: [70]

R=Me, Et, Bu; R_2=—$(CH_2)_3$—, —$(CH_2)_4$—, —$(CH_2)_5$—, —$(CH_2)_6$—

In the polarographic reduction of stable selenium ylides at a dropping mercury electrode in dimethylformamide, the electrochemical cleavage of the carbon–selenium bond consists of two consecutive stages: [72]

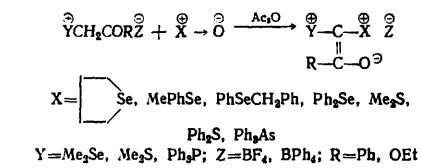
R=Ph; R_2=—$(CH_2)_4$—; R^1=Ph; R^1_2=—$CH_2C(CH_3)_2CH_2$—



After electrolysis and treatment of the catholyte with water, dimedone and diphenyl selenide were detected in the reaction mixture. In the second stage, the dianions are apparently protonated with the initial formation of monoanions, which then combine with a proton and afford dibenzoylmthane and dimedone respectively.

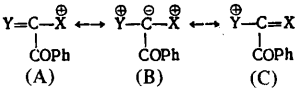
V. BIS-ONIUM SELENIUM COMPOUNDS

The bis-onium compounds of selenium are ylide-salts and diylides containing, together with the selenonium fragment, onium fragments based on other heteroatoms (nitrogen, phosphorus, arsenic, selenium, and sulphur).



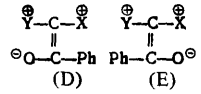
1. The Ylide-Salts of Selenium with Onium Groups at the Ylide Carbon Atom

The first attempt to synthesise ylide-salts containing the selenonium group involved the reaction of diorganoselenium dichlorides with alkoxycarbonylmethylenetriphenylphosphoranes. [73,74] Only in the case of selenolane dichloride, was the intermediate bis-salt resistant to the action of the nucleophilic chloride ion and a stable ylide-salt was obtained: [74]

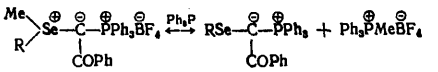


The reaction of diphenylselenium dichloride yields the corresponding α-chlorophosphorane and the reactions of the dichlorides of methylphenyl- and benzylphenylselenium involve the dealkylation of the intermediate bis-salt and the formation of α-phenylselenomethylenetriphenylphosphorane. [74]

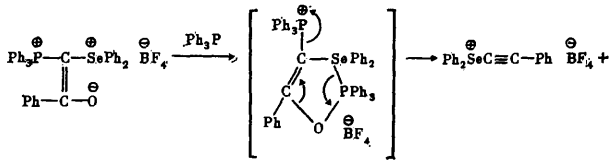
A general preparative method of synthesis of selenium ylide-salts is the condensation of onium salts containing an active methylene group with diorganyl selenoxides, sulphoxides, and arsenoxides in the presence of acetic anhydride. The yield of the ylide-salts depends on the nucleophilicity of the initial oxide: [75–77]



An essential condition for this reaction is the presence of sufficiently acid protons of the methylene group in the initial onium salt ($pK_a \approx 6–9$). [75] The phenyl groups attached to the onium atoms both in the initial salts and in the corresponding oxides give rise to steric hindrance to this interaction. [75,76] The high stability of the ylide-salts can be explained by the delocalisation of the negative charge on the carbanion over three centres: the two onium atoms and the carbonyl oxygen atom. This decreases the nucleophilicity of the ylide carbon atom. The ylide-salts are weaker nucleophiles than the acetate ion.

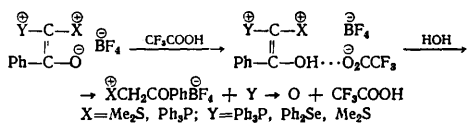


The structure of the cations of the phenylacylide-salts can be described by the set of mesomeric structures (A)–(C): [77]

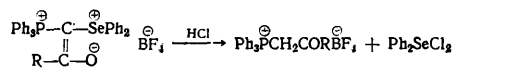


The onium groups of the phenylacylide-salts can be arranged in the following sequence in terms of their ability to stabilise the carbanion: $Ph_2S > Ph_3P > Ph_2Se > Ph_3As > Me_2S \approx$ MePhSe > Me_2Se. According to Ir and ^{1}H and ^{77}Se NMR spectra, [25,75–77] when the onium groups differ greatly (X = Me_2Se and Y = Ph_3P), the *trans*-structure (D) is formed with a considerable contribution by the structure (A), but, when the abilities of the onium groups to stabilise the carbanion are similar (X = Me_2S and Y = MePhSe), the ylide–salt consists of the *cis*- and *trans*-isomers (D) and (E).

The phenylacylide-salts containing the selenonium and triphenylphosphonium groups are demethylated on fusion with triphenylphosphine, forming Se-substituted phosphoranes: [78]

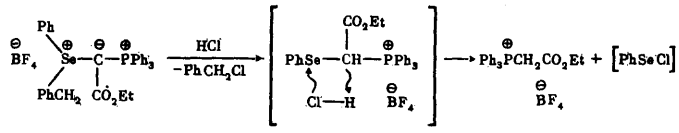


The ylide-salts without readily eliminated groups at the onium atom react differently. In this case, there is nucleophilic attack by triphenylphosphine on the selenium atom with subsequent elimination of triphenylphosphine and triphenylphosphine oxide and the formation of ethynylselenonium salts: [77]



+ $Ph_3P{=}O$ + Ph_3P

Trifluoroacetic acid protonates phenylacylide-salts at the oxygen atom and the bis-salts obtained in this process are readily hydrolysed: [79]

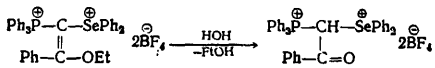


X=Me_2S, Ph_3P; Y=Ph_3P, Ph_2Se, Me_2S

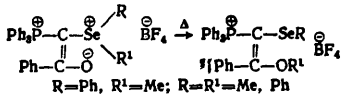
The electrophilic cleavage of the phenylacylide-salts of selenium with hydrogen chloride [76,77] take place analogously to the corresponding reaction of dinitromethylselenonium salts: [56]

R=OEt, Ph

The interaction of benzylphenylselenonium ylide-salts with hydrogen chloride is accompanied by their dealkylation: [76]

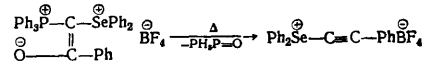


Selenonium phenylacylide-salts are alkylated at the oxygen atom [80] with formation of the (*E*)-isomer of the corresponding bis-salt with the *trans*-disposition of the triphenylphosphonium group or, in the absence of the latter, of the selenonium group, relative to the alkoxy-group:



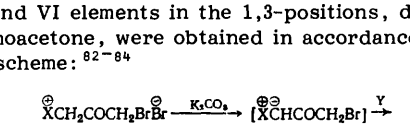
X=Me_2S, Y=Ph_2Se; X=Me_2Se, Y=Ph_3P;
X=Ph_2Se, Y=Ph_3P.

The bis-salts formed are readily hydrolysed by moist ether, for example: [80]



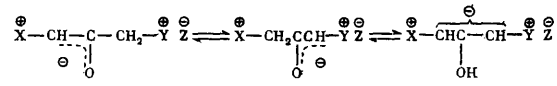
The thermolysis of selenonium phenylacylide-salts is accompanied by the migration of the methyl or phenyl group from the onium fragment to the oxygen atom as a result of the attack by the nucleophilic oxygen on the electrophilic carbon atom of the onium group. This results in the preferential formation of the (*E*)-isomer of the corresponding αβ-disubstituted triphenylstyrylphosphonium tetrafluoroborate with the *trans*-disposition of the triphenylphosphonium and alkoxy- or phenoxy-groups. The Stevens rearrangement has never been observed in such cases: [81]

R=Ph, R^1=Me; R=R^1=Me, Ph



The intermolecular Wittig reaction with formation of ethynylselenonium tetrafluoroborate occurs in the rearrangement of a diphenylselenonium phenylacylide-salt: [77]

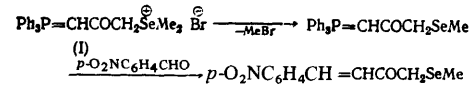
2. Selenium Ylide-Salts with Onium Groups in the 1,3-Positions



The presence in one molecule of an ylide-salt of two different onium groups in the 1,3-positions makes it possible to compare directly the degrees of their involvement in the stabilisation of the carbanion.

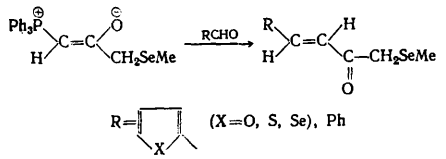
Ylide-salts containing two different onium centres with Group V and VI elements in the 1,3-positions, derived from 1,3-dibromoacetone, were obtained in accordance with the following scheme: [82-84]

X=Ph_3P, Py; Y=Me_2Se, MeS, Py, Ph_3As



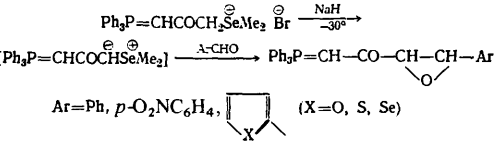
The existence of three tautomeric forms is theoretically possible for these salts: [83]

(A) (B) (C)

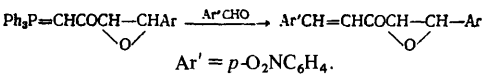


It was established from UV, IR, and ^1H, ^{31}P, ^{13}C, and ^{77}Se NMR data that the ylide-salt (I), containing together with the triphenylphosphonium group also the dimethylselenonium group (X = Ph_3P, Y = Me_2Se) exists in solution predominantly as the single tautomeric form (A) with an ylide phosphorane fragment. The ylide-salt containing the pyridinium and dimethylselenonium groups (X = Py, Y = Me_2Se) exists in solution in the form of an equilibrium between the two tautomeric forms (A) and (B) having the pyridinium ylide or salt fragment. The presence of the third form has not been detected. [25,82-84]

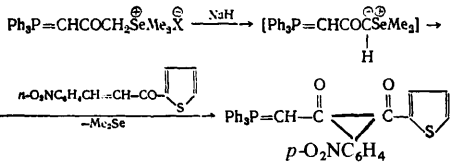
The ylide-salt (I) (ω-triphenylphosphoranylideneacetonyldimethylselenonium bromide) does not undergo the Wittig reaction, in contrast to the usual phosphorus ylides, as a consequence of the decrease in the nucleophilicity of the ylide carbanion under the influence of the selenonium group in close proximity. In the interaction with *p*-nitrobenzaldehyde, this ylide-salt forms a selenium-substituted αβ-unsaturated ketone. Under the influence of the nucleophilic bromide ion, the most electron-deficient $\gtrless$Se–Me bond is apparently cleaved under the reaction conditions and the resulting selenium-substituted phosphorane then enters into the Wittig reaction with *p*-nitrobenzaldehyde: [85]



The ylide-salt (I) with selenonium and phosphonium groups in the 1,3-positions is readily demethylated by triethylamine with formation of methylselenoacetylmethylenetriphenylphosphorane which exists as the (*Z*)-conformer in $CHCl_3$: [84]

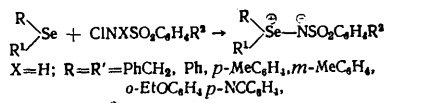


This phosphorane readily enters into the Wittig reaction not only with the reactive *p*-nitrobenzaldehyde but also with less reactive aromatic or heteroaromatic aldehydes, forming the corresponding αβ-unsaturated ketones having the *trans*-configuration and containing the Me–Se group: [84]

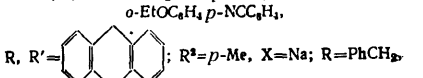


Bases such as sodium carbonate or hydroxide do not deprotonate the ylide-salt (I), although their basicity is sufficient for the formation of selenonium ketoylides from the corresponding selenonium salts. [31,32] When the ylide-salt (I) was treated with sodium hydride, a di-ylide was obtained *in situ* and its reactions with electrophiles—aromatic aldehydes and αβ-unsaturated ketones—were investigated. [82,85] Thus the reactions with aromatic aldehydes afford ketomethylenetriphenylphosphoranes containing the oxiran ring:

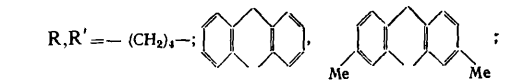
The selenonium ylide fragment in the di-ylide is more nucleophilic than in monoketoylides and reacts more readily with aromatic aldehydes. [82,85] The phosphorane formed under these conditions enters into the Wittig reaction under more severe conditions:



The C–P ylide bond remains unchanged in the reaction of the di-ylide with 2-(*p*-nitrophenyl)-1-(2-thenoyl)ethylene: [82,85]

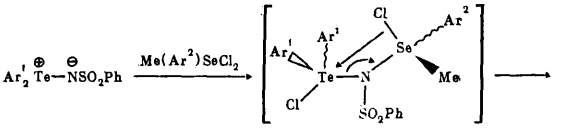


Thus, in the reactions with electrophiles, the selenurane and not the phosphorane fragment is more reactive in the di-ylide formed on deprotonation of the ylide-salt (I). The high reactivity of the di-ylides having this structure makes it possible to use them in organic synthesis, because, by selecting onium groups with different stabilising capacities and different reaction conditions, it is possible to achieve the selective interaction of a particular ylide fragment with electrophiles.



VI. SELENIMIDES

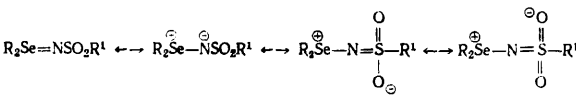
Selenimides have been synthesised by treating organic selenides with *N*-chlorosulphonamides or their sodium salts: [86–88]



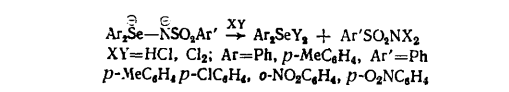
Selenimides are obtained in satisfactory yields by the condensation of selenoxides with sulphonamides and carboxylic acid amides: [51,88,90]

The occurrence of this reaction requires the presence of sufficiently strong electron-donating groups in the oxide and of electron-accepting groups in the amide. [90]

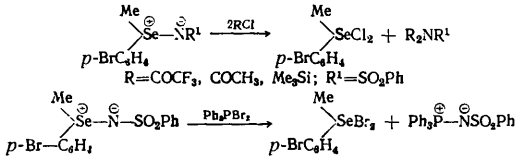
The reaction of *N*-(benzenesulphonyl)tellurimides with arylmethylselenium dichlorides affords *N*-benzenesulphonylselenimides and diaryltellurium dichlorides.



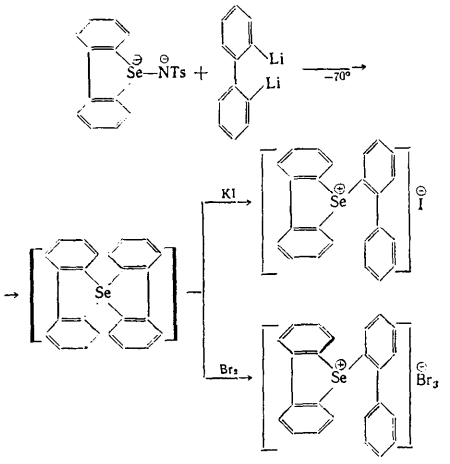
The possibility of such conversion of tellurimides into selenimides is due to the greater tendency of tellurium, compared with selenium, to form tetracoordinate compounds: [94]



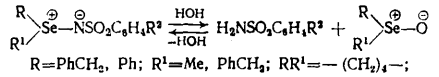
IR and UV-spectroscopic and ^{1}H NMR data indicate a dipolar structure of *N*-arenesulphonylselenimides with a considerable contribution to the ground state of the molecule by resonance structures with a positive charge on the selenium atom: [91]



Selenimides with a chiral selenonium group have been synthesised. The pyramid of the onium selenium atom in selenimides has a high inversion barrier. [91]

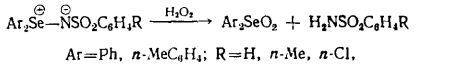


Measurements of the pK_a for selenimides have shown that their basicity is close to that of the anils of aromatic aldehydes. [91] Selenimides are stable compounds resistant to the action of aqueous alkalis and water at 20 °C. However, after prolonged heating with an aqueous 2 *N* solution of sodium hydroxide, they hydrolyse to selenoxides and arenesulphonamides. [87] Diaryl selenimides are readily cleaved by hydrogen chloride or chlorine at the $\overset{+}{\text{Se}}-\bar{\text{N}}$ bond: [87]

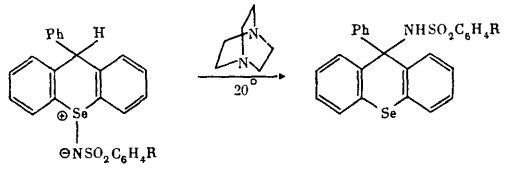


Selenimides react similarly also with acyl chlorides, triphenylphosphine dibromide, and chlorotrimethylsilane: [92]

solution of the latter with aqueous potassium iodide or bromine leads to its cleavage products: [86]



When aqueous solutions of selenides are heated, reversible hydrolysis takes place with formation of selenoxides and the corresponding amides: [87,88]



R=PhCH$_2$, Ph; R^1=Me, PhCH$_2$; RR^1=—(CH$_2$)$_4$—;
R^2=H, *n*-Cl; *o*-NO$_2$; *n*-NO$_2$

This reaction is accelerated in the presence of sodium hydroxide or silica gel. [87] Selenimides are oxidised by hydrogen peroxide or nitrogen dioxide and afford diarylselenones after subsequent treatment with water: [87]

Ar=Ph, *n*-MeC$_6$H$_4$; R=H, *n*-Me, *n*-Cl,
o-NO$_2$, *n*-NO$_2$

The reaction of *N*-arenesulphonylselenimides with 1,4-diazabicyclo[2.2.2]octane at 20 °C in benzene takes place quantitatively with formation of 9-arenesulphonamido-9-phenylselenoxanthenes, while hydrolysis on a silica gel plate (TLC) affords 9-phenylselenoxanthene 10-oxide: [93]

R=H; *n*-Me

Thus the data presented in this review show that in the last 15 years the chemistry of selenonium compounds has developed vigorously, particularly in recent years.

On the basis of selenonium compounds, in the first place the reactive and readily available selenium ylides, new preparative methods of synthesis have been developed for various classes of organic compounds: tertiary alcohols, olefins with different structures, including sterically hindered olefins, α-methylselenocarbonyl compounds, phosphoranes containing the methylseleno- or epoxy-group, heteroaroylcyclopropanes, nitrones, ketoformazans, oxirans, furans, condensed dihydrofurans, isoxazoline *N*-oxides, etc.

Various processes of the type of [1 + 2]-, [3 + 3]-. or [1 + 4]-dipolar cycloaddition with participation of selenium ylides, which in most cases proceed regioselectively and stereospecifically, are of special interest among the reactions of selenonium compounds.

All this shows that there are great prospects for the application of selenonium compounds in specific fine organic synthesis. One can undoubtedly expect the discovery of new reactions with participation of selenonium compounds, which will find practical applications. This will in its turn enhance the interest in the chemistry of selenonium compounds from the standpoint of their involvement in selective chemical processes.

The rapid development of the chemistry of organoselenium compounds is also indicated by the fact that, during the preparation of the manuscript of the review for publication, a monograph devoted to this topic appeared in the literature. [95]

The Structure of Polymeric Colloid Particles and the Effect Associated with It

V.I.Eliseeva

The results of studies on the morphology and phase structure of polymeric colloid particles formed in the latex copolymerisation and seeded polymerisation of various monomeric compositions are surveyed. The role of the polar interactions at the interface and of the mobility of polymer molecules as factors influencing the location of the functional groups, the orientation of the macrochains, and the inversion of the polymer phases in the colloidal particles is discussed. The relation between the structure of the particles, on the one hand, and the colloidal behaviour of the system, the mechanism of film formation and the physical properties of the segregated polymers, on the other, is examined.
The bibliography includes 122 references.

I. INTRODUCTION

Synthetic latexes in which the disperse phase consists of different chemical nature and the dispersion medium is water are typical polymeric colloids. Latexes are thermodynamically unstable hydrophobic colloids with a large interface characterised by different types of interfacial interactions. There has been a constant growth of interest in the industrial application of latexes. This is associated with the favourable factors in the technology of their manufacture and applications, the low cost of the petroleum raw material, and other familiar advantages of polymeric materials without organic solvents. The expansion of the range of latexes designed for different purposes is therefore one of the tasks in the chemistry and technology of polymers of current interest.

Vigorous studies have been carried out in recent years on the methods for the modification of latexes obtained from industrial monomers. One of the promising aspects of such research is the specific regulation of the internal structure of the colloidal particles of the polymer, without altering or altering only slightly its composition, and the determination of the relation between the structure of the particles, on the one hand, and the properties of the latexes and the polymers isolated from them, on the other.

Several reviews have been devoted to the morphological consideration of latexes consisting of heterogeneous particles. Latexes with the "core–shell" particle structure, used for the preparation of impact-resistant polymers,[1] and latexes with particles consisting of interpenetrating polymer networks, which are used to absorb sound and to extinguish vibrations,[2] have been examined. However, a systematic survey of the physicochemical characteristics of the formation of the structure of the polymer particles at their large interface with a polar medium is lacking in these reviews. This aspect of the research has become increasingly apparent in the studies carried out during the last 5–10 years, which have been partly described in a recent review.[3]

The morphology and structure of polymer particles with a diameter D_r = 50–500 nm are established during latex polymerisation where the macromolecules formed in them are fairly mobile because of the presence in the particles of the monomer, whose concentration is determined by the thermodynamic equilibrium conditions[4] and the monomer content in the reaction system.

The latex polymerisation begins with the generation of polymer-monomer particles (PMP) in the bulk of the aqueous phase. The possible regions where they are generated may be micelles made up of the emulsifying agent,[5,6] the molecular solution of the monomer in water,[7–9] and microdrops of the monomer.[10–12] This depends on the molecular solubility of the monomer in water, the ratio between this quantity and the colloidal solubility of the monomer in the emulsifying agent micelles, the types of the emulsifying agent and the initiator employed,[13] and the intensity of the hydrodynamic influence on the system.[14,15] With increase in the size of the PMP and depending on the chemical nature of the monomer, the recipe, and the way the process is carried out, various structural and physicochemical changes can occur in them: orientation of the macromolecules, separation and inversion of the phases, and the formation of transitional layers between them. Furthermore, the primary particles may undergo flocculation, heteroflocculation, and coalexcence. Changes of this kind lead to the formation of the final structure of the latex particles.

Attempts have been made at a theoretical consideration of the influence of the interface on the distribution and orientation of the macromolecules in the PMP.[16,17] Thus the idea of a gradient in the distribution of the density of the polymer in the bulk of the PMP, determined by the thermodynamic equilibrium conditions for the macromolecules in the particle, has been introduced.[16] On the basis of the concept of the increase in the free energy of restriction of the volume of the macromolecule between two surfaces in close proximity,[18] it has been assumed[16] that a uniform distribution of the macromolecules throughout the entire volume of the PMP is unlikely; they should migrate from the interface (which is assumed to be impermeable), where their conformational freedom and entropy are low, to the central region of the particle, where the macromolecules can assume the more favourable conformation of a statistical coil. Hence follows the model involving the ancapsulation of seed particles in the monomer after the attainment of the equilibrium degree of swelling.

A one-dimensional model of the distribution of the density of flexible long-chain molecules at an impermeable surface has been examined[19] as a function of the distance from the surface and of the energy of their attraction to the surface. It has been shown, that for an adsorption energy in excess of $0.693kT$, most of the segments of long-chain molecules are near the surface, while for a lower interaction energy, the density of their distribution is zero in this region. Evidently, for polar macromolecules or hydrophobic macromolecules containing hydrophilic units, the PMP–aqueous phase interface cannot be regarded as impermeable. For a freely jointed hydrophobic macromolecule containing a small fraction of hydrophilic units, the criterion of the entry of the latter into the aqueous phase has been determined theoretically.[17]

The polymerisation of polar monomers entails a limited flocculation of the PMP,[20–23] which is associated with the reduced energy of the adsorption of the emulsifier in such systems. The particles of the final latexes, consisting of aggregates of tens and hundreds of primary particles, are characterised by complex "grainy" structures. When they contain carboxy-groups, they decompose in an alkaline medium as a consequence of the ionised groups of the macromolecules and can be dispersed by vigorous stirring. This results in the formation of extremely highly dispersed polymeric colloids (D_r = 10–50 nm) with unique film-forming properties.[24,25]

The structure of the particles becomes much more complex on passing from latexes comprising homopolymers and copolymers to latexes made up of composite polymers, which were obtained by the successive polymerisation of individual monomers or their mixtures. In the heterogeneous particles formed, the chemical composition and topographic distribution of the individual polymers depend on their thermodynamic compatibility, the interaction with the aqueous phase, and the way in which the polymerisation is carried out. A change in the order of introduction of individual monomers into the reaction system influences significantly the chemical and physical structure of the resulting polymer and hence its macroscopic properties.[26] To be able to control the structure of the particles in order to obtain latexes and polymers with the necessary properties or in order to create in them regions with a specified reactivity, the introduction of individual monomers in stages during the synthesis has come to be used in industry.

This review is devoted to the morphology and phase structure of latex particles, the factors influencing them, and the effects associated with these factors. An attempt is made to give a systematic account of a wide variety of data which have accumulated in the scientific literature on these questions. In dealing with the physicochemical characteristics of the formation of colloidal particles and polymers, attention was concentrated on the role of the interfaces and molecular interactions at these interfaces in the heterogeneous system—latexes, particles, and films.

II. THE MORPHOLOGY OF THE PARTICLES WITH FUNCTIONAL GROUPS AND ITS INFLUENCE ON THE ADSORPTION CHARACTERISTICS OF THE COLLOIDS, THE POLYMERISATION KINETICS, AND THE STRUCTURE OF THE FILMS

1. The Morphology of Latex Particles and the Methods for its Investigation

Various physical, physicochemical, and chemical methods are used to investigate the morphology of particles. A universal method for the study of the shape, morphology, and phase structure of particles is electron microscopy (EM). The use of scanning EM made it possible to observe the structure of the surfaces of particles, especially those of immunolatexes.[27] The improvement of the preparatory technique in transmission EM (etching of the preparations and the use of specific reagents interacting with individual polymers) permitted the characterisation of the supermolecular organisation of the polymer and the identification of the topographical distribution of the individual polymers in the bulk of the particles. This possibility is due to the increase in the scattering of electrons as the polymer becomes more compact or when heavy metal atoms are introduced into it, which leads to a contrast effect.

In order to discover the supermolecular organisation of the polymer, the method involving the low-temperature etching of the specimens with active oxygen, obtained in an electrodeless high-frequency discharge, has been developed.[28] The less dense portions of the polymer are then rapidly destroyed, which makes it possible in many instances to discover the morphology of the polymer. Osmium tetroxide has come to be used widely as a specific reagent for polymers containing a carbon–carbon double bond.[29,30] Its introduction into the polymer increases the electron scattering[31] and leads to a greater contrast in particles whose composition includes a diene polymer. Preliminary treatment of the polymer particles containing carboxy- or ester groups with hydrazine hydrate or hydroxylamine, which interact with such groups, followed by increasing the contrast in the preparations with osmium tetroxide makes it possible to determine the topographical distribution of the polymer (for example, an acrylic polymer) in the bulk of the particles.[32]

In order to determine the content of poly(methyl acrylate) in the bulk of heterogeneous particles, the NMR method has been used: the content of this polymer in the solution obtained by the gradual hydrolysis of particles of polyacrylates with alkali was determined.[33] Methods involving the conductimetric and potentiometric titration of latexes with dilute solutions of alkali have been used to characterise the morphology of the particles of carboxylated polymers.[34] The concentration of the carboxy-groups located on the surface was determined from the characteristic points of inflexion in the titration curves. The fraction of the individual polymer in the surface region of the particles can be estimated by the adsorption titration of the latex with an emulsifier.[35] This method is based on the fact that the adsorption area of the molecule of the given emulsifier is a characteristic quantity for each individual polymer.[36,37]

Since the structure of the particles is preserved in the polymers isolated from the latexes,[26] it has been inferred in a number of studies from the properties of the latex polymers and films: from their spectroscopic,[8,38,40] mechanical,[41] relaxation,[42,47] and other physical characteristics. Thin-layer chromatography of the polymer solution in tetrahydrofuran on plates coated beforehand with silica gel has also been used to determine the phase structure of the composite particles of the poly(butyl acrylate)–polystyrene system (to determine the content of the grafted polymer).[48]

Previously it was regarded as self-evident (see, for example, Refs. 49–52) that the properties of particles are statistically uniform throughout the bulk and their behaviour in film formation is therefore determined mainly by the elasticity of the polymer. This idea was based, in particular, on electron microscope data for the surfaces of latex films, from which it followed that their structural element is the latex particle. However, it was shown later that, depending on its chemical nature and the character of its interaction with the aqueous phase, the polymer is organised in the particles in the form of some kind of supermolecular formation.[28,38] This is clearly demonstrated by the electron photomicrographs of the

particles and replicas from the surfaces of "etched" films[28] illustrated in Fig.1.[53]

The difference between the structures of the particles influences significantly the colloidal behaviour of the latexes[54,55] and the physical properties of the films.[41,56] This difference is manifested when the functional groups of different chemical nature are introduced into the given polymer by the copolymerisation method. It is significantly smoothed out after the reprecipitation of the latex films from an organic solvent, in which the initial structure of the polymer is altered.[56] The introduction of functional groups by homophase and not latex polymerisation has a much smaller influence on the physical properties of the polymer.[57]

2. Characteristic Features of the Copolymerisation in Colloidal Systems and the Morphology of the Particles Formed

One of the widely used methods for the modification of latex polymers involves the introduction of a small proportion of functional groups into their macromolecules by the copolymerisation method. The strengthening of the polymer and the improvement of its adhesion properties are achieved in this way and the ability to be cross-linked as well as other specific features are imparted to the polymer.

The copolymerisation in latex systems has its specific features distinguishing it from the homophase process, so that the structure and composite composition of the resulting macromolecules can differ significantly. Even in the copolymerisation of hydrophobic monomers, when the process takes place in a single phase (PMP), the effective copolymerisation constants depend on the interfacial resistance to mass transfer in the PMP of the monomers undergoing copolymerisation.[58] The diffusion-dependent limitations of the copolymerisation of the monomers in the PMP acquire special importance when the process is carried out under semicontinuous conditions providing for the gradual introduction of the monomer into the reaction system. Thus it has been shown for butyl acrylate and styrene that the effective copolymerisation constants and hence the structures of the macrochains differ as a function of the rate of introduction of the monomers.[59,60]

In the case of monomers whose solubilities in water differ appreciably, the copolymerisation reactions take place in several zones: in the aqueous solution, in the bulk of the particles, or on their surface. Depending on the contribution of each reaction, the effective copolymerisation constants differ to a greater or lesser extent from the constants in homogeneous processes. This has been demonstrated for the copolymerisation of methyl acrylate with methacrylic acid,[61] of chloroprene with methyl methacrylate,[62] and of methyl acrylate with vinyl acetate.[63]

The characteristic features of the structure of the macromolecules formed on copolymerisation in a colloidal system of a hydrophobic monomer with a small fraction of a hydrophilic monomer are significantly reflected in the morphology of the latex particles and polymers.

Theoretical examination of the behaviour at the oil–water interface of a one-dimensional freely jointed macromolecule consisting of hydrophobic units and a small proportion of hydrophilic units made it possible to define[17] the criterion governing the entry of the latter into the aqueous phase, which depends on the ratio of the potential energies of the two types of units in the oil and aqueous phases. This study permits the conclusion that, on formation of a flexible copolymer molecule at the interface between water and the hydrophobic monomer, copolymerising with a small proportion of a hydrophilic monomer, for a certain value of the partition coefficient of the latter between the phases, the hydrophilic units should emerge onto the surface of the PMP, influencing the conformation of the copolymer molecules. Thus, when the mobility of the macromolecules in the PMP is high, which is promoted by the presence of the monomer, a high polarisation temperature, and the flexibility of the polymer chains, the possibility arises of the assumption by them of an energetically most favourable conformation, which corresponds to the endeavour of the hydrophilic groups to emerge onto the interface with the aqueous phase.

So far numerour experimental data have accumulated, indicating the endeavour of the highly polar groups contained in the macromolecules to become concentrated on the surface of the particles, which is reflected in the colloidal behaviour of the latexes and in the physical properties of the polymers

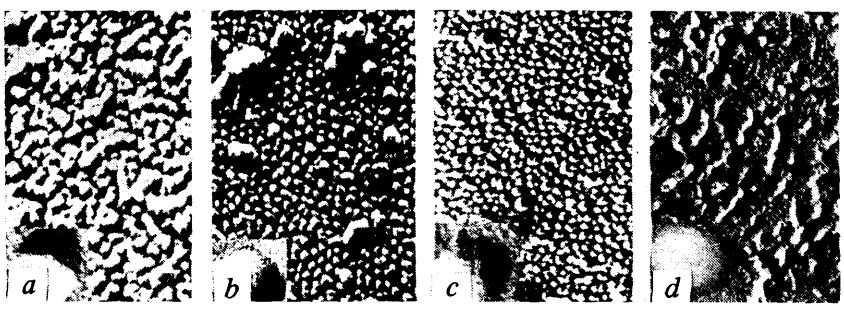

Figure 1. Electron photomicrographs of the replicas from the films: *a*) poly(alkyl acrylate); *b*) copolymer of alkyl acrylate with 3 mole% of methacrylic acid (MAA); *c*) copolymer of alkyl acrylate with 5 mole% of MAA; *d*) copolymer of alkyl acrylate with 5 mole% of the MAA amide after etching with oxygen. The electron photomicrographs of the initial latex particles are shown in the corners of the photomicrographs of the films.[53]

isolated from them.[64-66] The preparation of stable latexes in the absence of emulsifiers is based on this feature. Such latexes are formed when charged groups, forming part of the composition of the macromolecules (SO_4^-,[67-69] NR_3^+,[70] COO^- [71]) are concentrated on the surface, which occurs when the polymerisation is initiated by radical-ions or when a small proportion of an ionisable comonomer participates in the copolymerisation.

The concentration of the hydrophilic functional groups on the surface of the particles is greater the more hydrophilic the comonomer containing them. Thus, conductimetric and potentiometric titration studies of the distribution of the carboxy-groups of acrylic (AA) and methacrylic (MAA) acids in the particles of their copolymers with ethyl acrylate (EA) showed that in the case of AA the degree of concentration of these groups in the surface zone of the particles is higher than in the case of the more hydrophobic MAA, which diffuses more readily into the bulk of the particles.[34] In the copolymers of butadiene (Bd) with styrene (St), only some of the carboxy-groups of AA and MAA are distributed on the surface of the particles and for MAA their concentration in the bulk phase is higher.[72] The influence of the hydrophilicity of the unsaturated acid and its distribution in the particles has also been demonstrated in a study of the copolymerisation of St with itaconic, acrylic, and methacrylic acids: the first, most hydrophilic acid polymerised in the aqueous phase, the second is concentrated on the surface of the particles, and MAA, being most hydrophobic, is distributed in the bulk of the particles.[73]

3. The Influence of the Functional Groups of the Polymer on the Colloidal Properties of Latexes, the Polymerisation Kinetics, and the Structure of the Films

The localisation of the polar groups of the polymer on the surface of the particles hinders the adsorption of the emulsifier by the latter. This has been demonstrated in a study of the kinetics of the adsorption of sodium alkanesulphonate (by measurement of the electrical conductivity of the system) in the benzoyl peroxide-initiated polymerisation of butyl acrylate (BA) and its copolymerisation with 3 mole% of MAA, the amide of MAA, and *N*-hydroxymethylamide of MAA.[55]

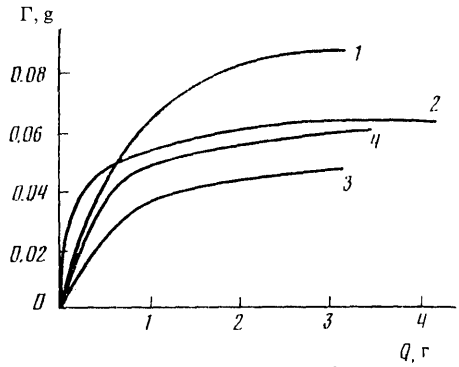

Figure 2. Dependence of the degree of adsorption Γ of sodium alkanesulphonate on the mass *Q* of the polymer formed in the polymerisation process: 1) BA; 2) BA–MAA (3 mole%); 3) BA–MAA amide (3 mole%); 4) BA–MAA *N*-hydroxymethylamide (3 mole %). Initial concentrations: 0.167 wt.% of sodium alkanesulphonate in the aqueous phase and 0.1 and 1 wt.% of benzoyl peroxide and t-dodecanethiol relative to the weights of the monomers respectively.[55]

The degree of adsorption of the emulsifier in the copolymerisation of BA with MAA amide is smaller approximately by a factor of two than in the homopolymerisation of BA (Fig.2). This has been explained by the mosaic structure of the surface of the copolymer particles, which is partly occupied by polar groups.[55] The mosaic structure of the particles of copolymers with unsaturated acids has been confirmed experimentally by the EM method, the carboxy-groups being labelled with uranyl acetate.[65] The presence of ionised carboxy-groups in the surface layer of the particles lowers the degree of adsorption of the emulsifier to a greater extent the higher the concentration of such groups. This has been demonstrated by the adsorption titration of the carboxyl-containing poly(ethyl acrylate) latexes with sodium dodecylbenzenesulphonate (at high pH).[66]

The localisation of the polar groups of the polymer on the surface of the particles also influences the polymerisation kinetics. This has been demonstrated by a dilatometric study of the polymerisation of BA and of its copolymerisation with 3 mole% of the MAA amide and *N*-hydroxymethyl amide.[55,64] Fig.3 shows that the copolymerisation is faster than the homopolymerisation. In view of the small fraction of the hydrophilic comonomer, the observed effect can be explained by the increasing hydrophilicity of the surface of the particles, which lowers the interfacial tension and hence increases the concentration of the monomer in the bulk of the PMP.[4]

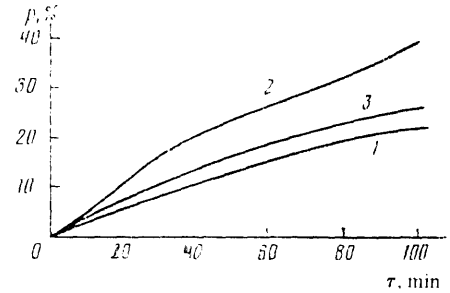

Figure 3. Variation of the degree of conversion *p* with time τ in the polymerisation process: 1) Ba; 2) BA–MAA amide (3 mole %); 3) BA–MAA *N*-hydroxymethylamide (3 mole %).[55] The polymerisation conditions are the same as in Fig.2.

When the surface of the particles is made hydrophilic by the introduction into the latter of highly polar groups, the resistance of latexes to aggregation in the cyclic freezing–thawing process increases,[61,74] and it becomes possible to synthesise colloidally stable latexes in the absence of an emulsifier.[75]

The localisation of polar functional groups on the surface of the particles (Fig.4*a*) promotes their interaction, both with one another and with the coreagent introduced into the aqueous phase, on contact between the particles in the film formation process. As a result, the structure of the film produced is a kind of globular network (Fig.4*b*). An advantage of this structure is an increase of the strength and thermal stability of the polymer. Thus films with a viscous flow temperature of 220 °C and a tensile strength of 60 kg cm^{-2} are formed on drying under room conditions from the latex of the copolymer of EA with 6.6 mole% of *N*-hydroxymethylmethacrylamide, which is capable of forming strong hydrogen bonds,[76] while the EA homopolymer exists in the viscofluid state even at room temperature [T_g = −20 °C].[40]

The study of the relaxation properties and dynamic characteristics of such films showed that they are strong three-dimensional networks, which do not break down on swelling in water at 75 °C.[41] Bearing in mind that chemical bonds are not formed between the hydroxymethylamide groups under the conditions indicated, the appearance of the network can be explained by the formation of hydrogen bonds between the "outer" groups coming into direct contact in the formation of the film. The structure formed under these conditions resembles that of a two-phase composite material: within the continuous phase, which is a network compacted by hydrogen bonds, consisting of the surface layers of colloidal particles and constituting a smaller proportion of the overall mass of the polymer, there are "cores", constituting a kind of filler, which are made up mainly of the linear polymer. The transition from a layer with a high degree of cross-linking to the linear polymer is continuous, so that one cannot speak of a true interface.

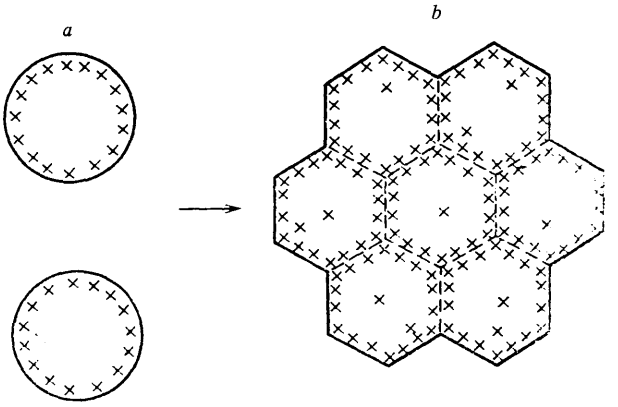

Figure 4. Schematic illustration of the structures of the particles (*a*) and films (*b*) of a hydrophobic latex polymer containing hydrophilic functional groups.

On deformation of composite materials of this kind, the mechanical properties of the continuous phase play a much more important role than would correspond to its volume fraction. Since, owing to the high density of the hydrogen bonds, the network has a high modulus of elasticity, the system as a whole also has a higher modulus of elasticity than the polymer with a uniform distribution of the same number of hydrogen bonds throughout its volume would have had. The chemical cross-linking process in such systems proceeds in an unusual manner: there is an optimum content of functional groups corresponding, as shown by approximate calculation, to the complete surface coverage by them for which the most complete cross-linking is achieved.[41]

In the latex copolymerisation of a hydrophobic monomer with another hydrophobic comonomer containing functional groups (glycidyl methacrylate, siloxanes), the latter are distributed statistically in the bulk and on the surface of the particles. Therefore, as a rule an increase in their concentration in the polymer induces a monotonic change in the degree of cross-linking, strength, and water resistance.[77]

Colloidal microgel particles approximately 10 nm in diameter, in which the reactive groups (double bonds) are present both within and on the surface of the particles, are of special interest. They are obtained by the polymerisation of divinyl monomers.[78,79] The cross-linking of the polymer in the copolymerisation process is apparently the cause of the small particle size in view of the insignificant swelling of the PMP in the monomer. Because of the small size of the colloidal particles, their reactivity is very high, since the functional groups, most of which are located on the large interface, are readily accessible to the coreagents.

4. The Morphology of the Particles and Films of a Polymer Containing Functional Groups Interacting Chemically with Water

The chemical interaction of the functional groups introduced into the polymer with water also leads to inhomogeneity of the composition of the particles. This is because the

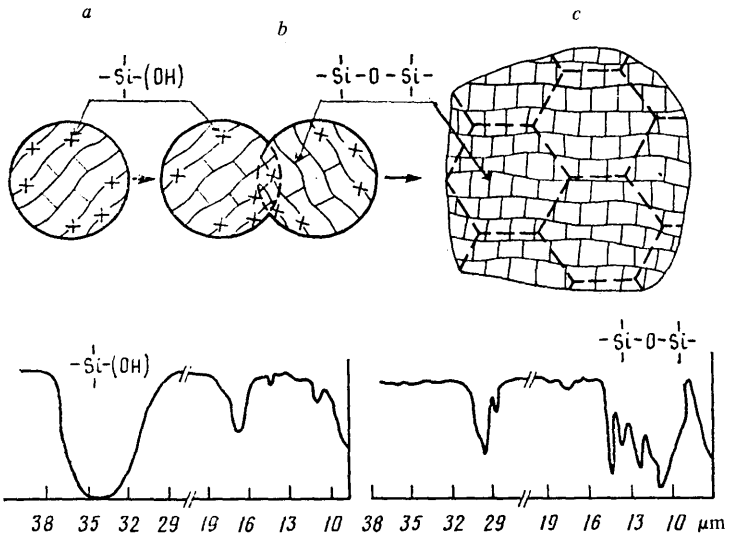

Figure 5. The mechanism of the formation of a film from the polymer latex incorporating siloxane: *a*) latex particles; *b*) coalescence of particles on drying of the latex; *c*) film structure. Above—schematic illustration of film formation; below—corresponding IR spectra.[82]

contribution and degree of the reaction of such groups, reacting on the surface of the particles, are greater than in the bulk phase. Thus the copolymerisation of acrylic and vinyl monomers with a small amount of siloxane leads to the formation of particles of the "core-shell" type, in which the structures of the polymer in the surface zone and in the bulk of the particles are different.[80-83]

This difference has been explained by the ability of alkoxysiloxanes to undergo hydrolysis and condensation reactions, whose relative contributions depend on the concentration of water in the reaction zone.[81,82] It has been shown by IR spectroscopy that, in the copolymerisation of vinyl chloride with vinylidene chloride and a small proportion of methacrylate-triethoxymethylsiloxane (0.2–0.8 mol%), the alkoxysilyl groups in the particles hydrolyse and undergo partial condensation; the latter apparently occurs in the nuclei of the particles, where the water concentration is minimal.[82] One may therefore assume that the copolymer particles consist of a nucleus comprising a polymer with a three-dimensional structure cross-linked by interchain $\geq$Si–O–Si$\leq$ bonds and of a shell made up of a linear polymer containing the hydroxysilyl $\geq$Si(OH) groups. Such morphology of the particles ensures their coalescence when the latex dries (latexes whose particles consist of only a cross-linked polymer with a three-dimensional structure are known not to form a strong film, because the coalescence of the particles is difficult). On further removal of water during the film formation process, the hydroxysilyl groups present in the film "matrix" condense with formation of oxygen bridges between the macromolecules and the polymer is thus cross-linked by chemical bonds throughout the bulk of the film. This process is illustrated schematically in Fig. 5. Film forming cold hardening latexes are obtained in accordance with this principle.

The presence of a small fraction of an alkoxysilane is appreciably reflected in the colloidal properties of the latex, inducing a decrease in particle size and this effect becomes more pronounced with increase in the concentration of the alkoxysilyl component. It may be that this is associated with the decrease in the monomer concentration in the partially cross-linked particle, which results in its growth, and also with the weakening of the particle coalescence process in cross-linked polymers.[81]

The data presented in this Section show that the interface in the vicinity of which the particles are formed plays a major role in the formation of their structure. The balance of the polar and dispersion interactions between the growing macromolecules and the aqueous phase determines the distribution of the functional groups on the surface or in the bulk of the particles. The localisation of the polar groups on the surface of the particles affects the polymerisation kinetics, the colloidal characteristics of the latexes, and the structure and properties of the films formed. Chemical interaction with water of the functional groups, distributed predominantly in the surface zone of the particle, leads to the inhomogeneity of the composition of the latter and affects the characteristic features of the mechanism of the formation from them of films having three-dimensional structures.

III. THE PHASE STRUCTURE OF COMPOSITE PARTICLES AND ITS RELATION WITH THE MORPHOLOGY AND PROPERTIES OF POLYMERS AND FILMS

Latexes with particles consisting of several polymers of different chemical nature† are used to impart particular properties to the composite materials isolated from them—impact strength, impermeability to sound, hardness, and low film formation temperature. They are obtained by two- or multi-stage polymerisation: the "seed" latex is synthesised initially and then the second, and if necessary, the third etc. monomers are polymerised in its presence. Depending on the method used to carry out the second and subsequent stages, the composite particles are formed in each seed particle, or as a result of the heteroflocculation of the new particles with the seed particles, or by a combination of both processes.

The polymers isolated from latexes with composite particles consist of a matrix in which the second polymer is dispersed. It is linked to the matrix by chemical bonds or by transitional layers of intermediate composition or solely via the physical interpenetration of the polymer chains. The physical state of the two phases depends on the purpose of the material: in impact resistant plates there is a vitreous matrix and an elastic nucleus, in film forming latexes, there is a rigid nucleus and an elastic matrix, and vibration damping systems are obtained from latexes having particles which consist of interpenetrating networks of two polymers. In general, the morphology of such materials is determined by many factors—the structure of the units of the macromolecules, their steric structure, the size and disposition of individual domains, etc. The possible combination of factors can be extremely varied and can depend on the choice of the monomers and the polymerisation method.

1. The Mechanisms of the Formation of the Phase Structure of the Particles of Composite Polymers

From the standpoint of the topochemistry of polymerisation, the phase structure of particles consisting of two polymers (1 and 2) is formed to a first approximation either on polymerisation of the monomer (monomers) 2 within the seed particles of the polymer 1 or as a result of the heteroflocculation of the seed particles of the polymer 1 with the new particles of the polymer 2 formed outside them. In the former case, the polymerisation is carried out after the seed particles have been swollen in the monomer 2 and the attainment of a thermodynamic equilibrium distribution of this monomer in PMP is very important for the formation of the phase structure of the particles. The formation of the particles via the second mechanism is characteristic of semicontinuous conditions in the polymerisation of monomers appreciably soluble in water and is not associated with the attainment of the equilibrium swelling of the seed particles in the monomer 2, depending significantly on the content of the emulsifier in the system.

(a) *Polymerisation in the bulk of the seed particles swollen in the monomer.* Seeded polymerisation, which is used to produce most of the impact resistant polymers (ABS-plastics), is carried out in two stages: initially a latex of the elastomer 1—butadiene (Bd) or the Bd–St copolymer—is obtained and then one polymerises in its presence the monomers 2—acrylonitrile (ACN) and St—absorbed by the seed particles 1.[84] In the second stage, the polymerisation takes place in the swollen particles. It has been suggested that the growing polymeric ACN–St radicals are grafted to the double bonds of the elastomer and the grafted polymer layer strengthens both polymer phases. The particles of such latexes are characterised by a complex morphology: a concentric shell of the polymer 2 is formed on the surface of the seed particles of the polymer 1; the polymer 2 is incorporated in the form of inclusions also in the nuclei of the composite particles produced.[84]

†Below, such particles will be referred to as composite.

There exist different views on the mechanism of the formation of the structure of composite particles of the "core-shell" type. The commonest view is that the polymers 1 and 2 are imcompatible[85,86] or that the solubility of the polymer 1 in the monomer 2 is limited.[87] However, it has been shown experimentally that such a structure is formed also for completely compatible polymers, namely in the seeded polymerisation of St containing a small amount of Bd[16] or of tritiated St[88] on a styrene latex after the attainment of thermodynamic equilibrium swelling of its particles in the monomer. The polymer formed in the second stage was identified in the former case by labelling Bd with osmium tetroxide and in the latter case the autoradiographic method was used. The morphology of the particles formed in this process can be seen from the electron photomicrograph in Fig. 6.[88]

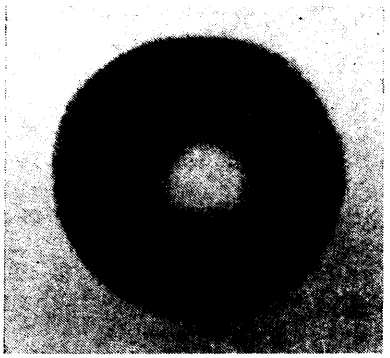

Figure 6. Electron photomicrograph of a section through a latex particle obtained as a result of the St–Bd (0.7%) seeded polymerisation on a polystyrene latex.[88]

In order to explain the result, the authors put forward the hypothesis that the distribution of the monomer in the PMP obeys the laws of microthermodynamics and not macrothermodynamics. Theoretical estimation of the influence of the particle–water interface on the thermodynamics of the dissolution of the polymer in the colloidal particles on the assumption that the macromolecule is attached via one end to an impermeable and inert surface[18,19] led to the conclusion that, in the thermodynamic equilibrium swelling of the polymer in the solvent, segments of the macromolecule tend to be repelled from the surface, leaving an excess of the solvent near it. Since the macromolecules in a latex particle are attached via the terminal SO_4^- group to the surface of the particles,[89] the majority of the segments of the polymer 1 in its particle subjected to equilibrium swelling in the monomer 2 are localised in the central region and the monomer 2 tends to be concentrated in the peripheral zone, as a result of which a gradient of its concentration is established in the bulk of the particles. The polymerisation of the monomer 2 therefore takes place preferentially in the peripheral zone of the particles, which in fact leads to the formation of the "core–shell" structure even when the monomers 1 and 2 are completely miscible.

The idea of a monomer concentration gradient in the particle which has undergone equilibrium swelling conflicts with the classical theory of latex polymerisation, which postulates a uniform distribution of the monomer in the PMP.[85] However, it is believed[16] that the experimental data on the kinetics of the polymerisation of St (the duration of the constant rate period, the rate, and the number of radicals per particle) agree with the main postulates of the theory[90] if the treatment is based on the corresponding model. The morphology of the PSt particles (Fig. 6) is difficult to explain from the standpoint of a uniform distribution of the monomer in the PMP. In the latter case, it was necessary to assume the presence of forces which promote the diffusion of the macromolecules, formed in the second stage, towards the periphery of the particles. Such a phenomenon could occur under conditions where there is a considerable difference between the polarity of the monomers formed in the two stages (see below), which is ruled out in the case under consideration. For a uniform distribution, one would have to expect the appearance of a "cellular" structure of the type of inclusions of one polymer in the other. The appearance of inclusions when the polymers 1 and 2 are incompatible may be a consequence of the entry of the radical of the monomer 2 into the seed particles of the polymer 1, the radical serving as the centre for the independent polymerisation of the monomer localised in a medium with a high viscosity.[91]

The formation of inclusions can lead to the formation of non-spherical particles, which has been observed in the seeded polymerisation of St on a butadiene–styrene latex and of a mixture of vinyltoluene with Bd on a styrene latex.[91] The formation of inclusions in composite latex particles is indicated by the results of a number of studies[45–47] in which the structure of the polymers isolated from latexes obtained by the seeded polymerisation of various monomers, namely vinyl acetate, alkyl acrylates and methacrylates, and MAC, was investigated by relaxation methods.

In the non-equilibrium swelling of the seed particles in the second monomer, this restriction of the diffusion of the latter into the particles during the polymerisation can itself be the cause of the formation of the "core–shell" structure. For example, in the polymerisation of St, which is usually carried out at 65–70 °C where the seed particles are in a vitreous state, the process in the bulk of the particles is retarded and may cease altogether as a result of the limitation of the diffusion of the monomer—it migrates into the shell of the particle.[92] On raising the temperature to 90 °C, the polymerisation shifts into the bulk of the particles.[93] This difference is reflected both in the process kinetics and in the structure of the particles formed.

When the monomer 2 is introduced gradually into the seed latex of the polymer 1 (semicontinuous polymerisation conditions), the preferred zone in which the process takes place becomes the shell of the seed particle enriched in the monomer.[94]

The conversion of the monomer in the seed latex should be important both for the polymerisation of the second monomer and for the phase structure of the particles of the final latex. Thus, when the polymerisation of alkyl acrylates and polystyrene particles compared after 100 and 80% conversion of St, it was shown that in the latter case the process is faster and the shell enriched in the alkyl acrylate is bound more strongly to the cores of the composite particles.[95] These effects can be explained by the fact that, when the conversion is incomplete, the polymerisation of alkyl acrylate or its copolymerisation with St proceed from the very beginning in the viscous medium of the swollen PMP (gel effect) and that a fairly thick transitional layer of the copolymer arises between the two polymers. The presence of a transitional layer of a grafted or statistical copolymer in the composite particle, between the nucleus and the shell, is very important for the strength of the combination of the segregated polymers 1 and 2.

In the seeded polymerisation of St on the poly(butyl acrylate) latex, the amount of grafted polystyrene depends on the method used to introduce St. The monomer can be introduced in three different ways: after the preliminary equilibrium swelling of the seed particles in it, all at once, or gradually at a constant rate. The grafting takes place in all cases but it attains the maximum extent (25%) when St is introduced at once, this being followed by the values obtained in equilibrium swelling (16%) and under the conditions of the gradual introduction of the monomer (7.7%).[48] This difference has been attributed[48] to the different mobilities of the molecules of the monomer absorbed by the seed particles: when St is introduced gradually, its degree of absorption is lowest, which reduces the mobility of the molecules and the degree of grafting, while in the other two cases the above parameters are correspondingly greater. Under the conditions of a low degree of grafting, the appearance of "dumb-bell-shaped" particles was observed during the storage of the latex and was explained by phase separation. Such particles were not formed when the degree of grafting was increased. All the latexes obtained by seed polymerisation afforded on drying transparent films, while the films obtained in a mixture of homopolymer latexes readily cracked and became turbid. This indicates the important role of the transition layer (grafted copolymer) between the imcompatible polymers in the film formation process.

In particular, systems used as vibration damping polymers are obtained by seeded polymerisation.[96] Interpenetrating polymer networks (IPN), obtained by the polymerisation of a monomer containing a cross-linking agent located within the particles of the seed latex of the cross-linked polymer swollen in the cross-linking agent, permit the attainment of this effect. The cross-linking agents are bimonomers of the type of dimethacrylate-ethylene glycol, divinylbenzene, etc., which are used in small amounts (~0.4%), so that excess cross-linking should not prevent the moulding and fusion of the composite material isolated from it.

The degree of phase separation and the size of the phase domains in such systems are limited by the compatibility of the polymers and by the degree of cross-linking and are controlled by the chosen composition of the reaction mixture. Even when polymers with similar solubility parameters are obtained jointly, the individual domains can consist of different polymers and may make their individual contributions to the properties of the composite material, influencing its operation characteristics. Thus a relation has been established between the composition of structured acrylate-methacrylate polymers obtained in the first (ethyl methacrylate–EA copolymer) and second (BA–EA copolymer) polymerisation stages, on the one hand, and the width of the temperature range of the effective attenuation of sound, on the other.[97]

The study of the dynamic characteristics of composite materials of the type of IPN in the temperature range from −110° to 170 °C shows clearly that they depend not only on the nature of the polymers but also on the phase structure and morphology of the particles.[98]

In the systems examined, the initial latex particle contains two cross-linked polymers, and systems in the particles of which only one of the grafted polymers is cross-linked are also classified as IPN.[99] They can be obtained, for example, by the seeded polymerisation of MMA on the latex of the MMA–1,3-butylene dimethacrylate copolymer.

Systems of this type have been obtained to increase the impact strength of poly(vinyl chloride) obtained by emulsion polymerisation.[100] In the polymerisation of the St–MMA mixture on seed latexes of the Bd–St and BA–ethylene glycol dimethacrylate copolymers with particle diameters in the range 50–200, a structure of the "core–shell" type is formed regardless of the solubility parameters. The character of the shell arising from the very beginning of the process depends on the degree of adsorption saturation of the surface of the seed particles by the emulsifier, i.e. on the emulsifier concentration in the system. For a low degree of saturation (under 25%), an upper layer of non-uniform thickness is formed; for a high degree of saturation, the shell is formed as individual surface growths and a new fraction of particles is produced. In order to form a concentric shell, it is necessary to achieve the optimum degree of adsorption saturation on the surface of the particles for which the maximum degree of grafting is believed to be achieved.[100]

(b) *Polymerisation with formation of new particles.* In the seeded polymerisation of St on the polystyrene latex, new particles may appear, which, depending on the emulsifier concentration, can flocculate with the seed particles or can be retained as an individual fraction.[101] In the two-stage seeded polymerisation of the BA–MAA mixture, the formation of new particles was observed when the monomers and the emulsifier were gradually introduced into the reaction system. As these particles appear, they flocculate with the seed particles of poly(methyl acrylate) (PMA)[43] or PSt[44] in such a way that the total number of particles hardly changes (Fig.7). Flocculation takes place because the newly formed monomer-enriched particles are less stable than the seed particles.

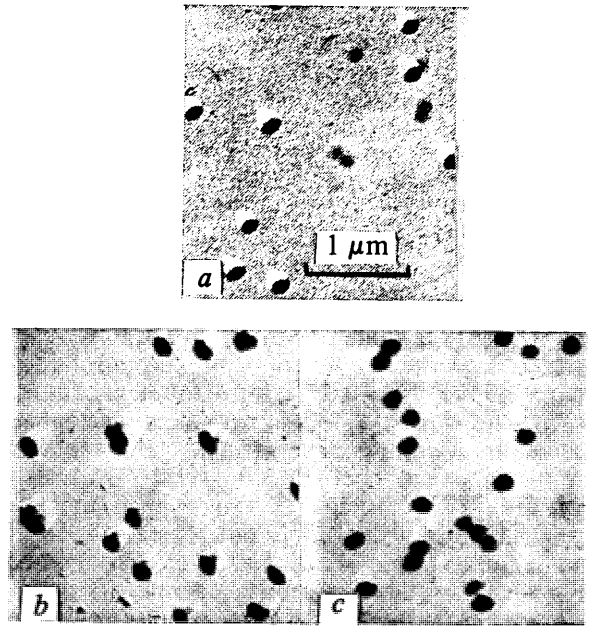

Figure 7. Electron photomicrographs of the particles formed in the BA–MAA seed polymerisation on a PMA latex with gradual introduction of the monomers: *a*) seed latex; *b*) second stage; *c*) final latex.[43]

This results in the formation of composite particles consisting of the polymers obtained in the first and second stages, which are located in the core and in the peripheral zone respectively. A study by the dielectric relaxation method of the PMA–P(BA–MAA) polymers isolated from the latex[43] showed that the particles produced consist mainly of two segregated polymers, PMA and P(BA–MAA), and a small

fraction of a copolymer having the intermediate composition P(MA–BA–MAA), which is apparently located at the interface between the segregated polymers. This copolymer, which plays the role of a transitional layer, might have been produced at the beginning of the second stage as a result of the copolymerisation of the second monomer with the residual monomer of the seed latex.

2. The Influence of the Compatibility of the Polymers and the Phase Structure of the Composite Particles on the Properties of Polymers and Films

The influence of compatibility on the properties of composite latex polymers and films has been investigated in binary systems with satisfactory (PMA–PVA), limited (PMA–PMMA), and poor (PMA–PSt) compatibility.[26] The systems were obtained by mixing the homopolymer latexes, by the joint polymerisation of a pair of monomers, and by seed polymerisation, which was carried out after the equilibrium swelling of the seed latex in the second monomer.

The study of the temperature dependence of the modulus of shear of the specimens showed that the presence of a more rigid component does not have an appreciable effect on the T_g of polymers with limited compatibility within a wide concentration range. Thus $T_g \cong 4°$, which is close to T_g for PMA, has been found for the PMA–PMMA composition with component ratios (by weight) from 75:25 to 50:50, obtained either from a mixture of homopolymer latexes or by seeded polymerisation. The value $T_g \cong 15°$ was found for the statistical MA–MMA copolymer having the composition (by weight) 75:25, which is in good agreement with the calculated value.

Hence, it has been concluded that the composite materials obtained contain fairly large regions of segregated polymers and that the latex particles retain their individuality in the isolated polymers and films.[26] This has been confirmed by data obtained for the fully compatible PMA–PVA polymers: for the ratio 50:50 by weight, two regions were observed in which there was a marked change in the modulus of shear—at 6 °C, which is close to T_g for MA, and at 32°, which corresponds to T_g for PVA. In the seeded polymerisation of the incompatible polymers investigated, grafting occurred, which ensured the formation of a transparent film from the latex at room temperature. The copolymer latexes obtained under these conditions did not exhibit a film forming capacity and mixing of the homopolymer latexes resulted in the formation of cloudy films. The latter demonstrates yet again that the transitional copolymer layer between the segregated incompatible polymers in the particles is very important for the film formation process. Such a layer affects also the strength of the polymer. Thus it has been established that the presence of a small fraction (several per cent) of the grafted ethylene–styrene copolymer in the polyethylene–polystyrene incompatible polymer mixture greatly increases the strength of the composite material.[102]

Data concerning the fomation of films from latexes with composite particles of rigid incompatible polymers are of interest. Such latexes with two-layer monodisperse particles have been synthesised by the emulsifier-free seeded polymerisation of St on a PMMA latex.[103] The films, obtained by fusing the particles, were distinguished by a high mechanical strength and transparency provided that the particle diameter did not exceed 200 nm. With increase in particle size (D_r > 300 nm), the fused films become appreciably cloudy. This can apparently be accounted for by the formation on fusion of smaller particles of the PSt–PMMA diffusion layer between the phases, whose thickness is comparable to the particle diameter; with increase in the relative volume of the incompatible polymer phases, the influence of the transitional layer diminishes.

The mechanical properties of the PMMA–PEA films (D_r = 290–370 nm), obtained by drying, under normal conditions, latexes with two-layer particles comprising vitreous and elastic polymers with limited compatibility, as well as the minimum film formation temperature (MFT) depend on the ratio of the polymers and on the morphology of the particles.[104] Fig. 8 shows that, for the same MMA content in the polymer (about 50%), the MFT for the copolymer latex is 30 °C, while the corresponding temperatures for the latexes obtained by the seeded polymerisation of MMA on PEA and of EA on MMA are respectively about 70° and 0 °C depending on which of the polymers—vitreous or elastic—constitutes the film matrix. Similarly the modulus of elasticity corresponding to 100% extension of certain films made from latexes with particles having a two-layer structure exceeds by a factor of 4 the modulus of the copolymer film. The data obtained show that the film forming properties of the latexes are affected not only by the structure of the polymer (composite polymer, copolymer) but also by the order in the distribution in the bulk phase of the particles of the segrated polymers. This order can change as the films age during the attainment of thermodynamic equilibrium.[105]

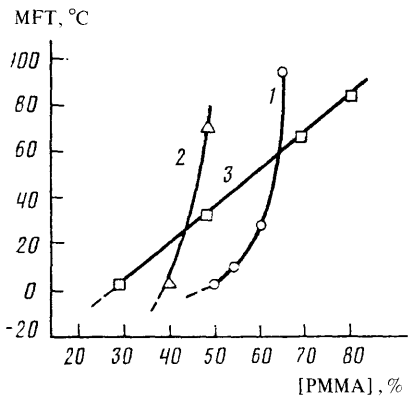

Figure 8. Dependence of the MFT for the latex on the particle structure: 1) PMMA in the core and PEA in the shell; 2) PEA in the core and PMMA in the shell; 3) statistical EA–MMA copolymer.[104]

The marked dependence of the film forming and mechanical properties of the films on the structure of the particles has been observed for latexes obtained by the semicontinuous polymerisation of the MA–BA–MAA, MMA–BA–MAA, and St–BA–MAA compositions.[42,44] The tensile strength and its change after the prolonged storage of the latex films obtained by seeded polymerisation differ significantly from the analogous characteristics of statistical copolymer dilms and latex films formed from mixtures of latexes of the corresponding polymers, as can be seen from Fig. 9. In order to elucidate the causes of this difference, a study has been made of the structure of the films by the dielectric and spin–lattice relaxation methods.[42]

As an example, Fig. 10 presents the temperature variation of the tangent of the dielectric loss angle (tan δ) at different frequencies for MMA–BA–MAA (50:45:5) polymer films obtained both from a mixture of latexes (curve 1) and from a

latex of the same polymers synthesised by seeded polymerisation (curves *2*, *2'*, *2''*, and *2'''*). At a frequency of 1 kHz, the range of tan δ_{max} for the film consisting of the mixture of latexes is entirely symmetrical (curve *1*). The temperature variation of tan δ for the specimen consisting of the latex obtained by seeded polymerisation (curve *2*) is of a different character: the range of tan δ_{max} is displaced towards high temperatures and is asymmetric. Analysis of the temperature variations recorded at a frequency of 1 Hz showed that, on heating and dissolution of film 2 in an organic solvent, the asymmetry increases and the range of tan δ_{max} values is divided into two peaks corresponding to tan δ_{max} for the initial copolymer and the copolymer enriched in MMA (curves *2'*, *2''*, and *2'''*), which indicates the presence in the latex particles obtained by seeded polymerisation of a transitional copolymer layer whose chemical composition is intermediate between those of the nucleus and the shell. It is formed at the beginning of the second stage as a result of the copolymerisation of the residual monomer of the seed latex with the monomers introduced in the second stage. On dissolution of the film in an organic solvent, this layer is removed from the interface between the segregated polymers and is segregated itself in a separate phase, which has been confirmed also by electron microscope data[106] (p.80).

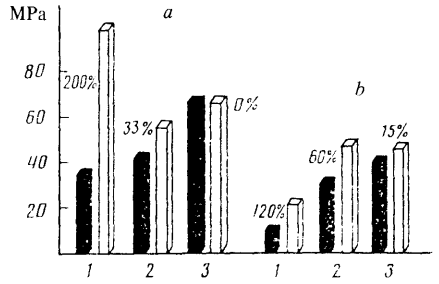

Figure 9. Breaking stress in the rupture of films made from latexes obtained by different methods before (filled columns) and after (open columns) prolonged storage[106] (p.124). Polymers: *a*) St–BA–MAA; *b*) MA–BA–MAA; the latexes were obtained by copolymerisation (*1*), by mixing the latexes (*2*), and by seeded polymerisation (*3*). The numerals in the diagram denote the increments in strength during the storage of the film.

The removal of the transitional layer from the interface between the segregated polymers lowers the mechanical strength of the films. Thus, after reprecipitation from an organic solvent of the film obtained by the seeded polymerisation of the latex having the general composition P(MMA–BA–MAA), its resistance to rupture is reduced almost by 30%[106] (p.94). The reprecipitation of a film having the same composition but obtained from a mixture of latexes does not alter its strength. Thus the presence at the interface of the composite particle of a transitional layer having an intermediate chemical composition increases the strength of the films: the presence of this layer improves the thermodynamic compatibility of the polymers in the core and the shell and intensifies the interchain interactions. The second cause of the increase in the strength of the films obtained from particles with the "core–shell" structure consists in the ordered distribution in them of a highly dispersed filler formed from the cores of the particles, which does not occur in the blended film. This improves the surface contact between the filler and the "shell"—the film matrix, on which interfacial interactions strengthening it take place.[107]

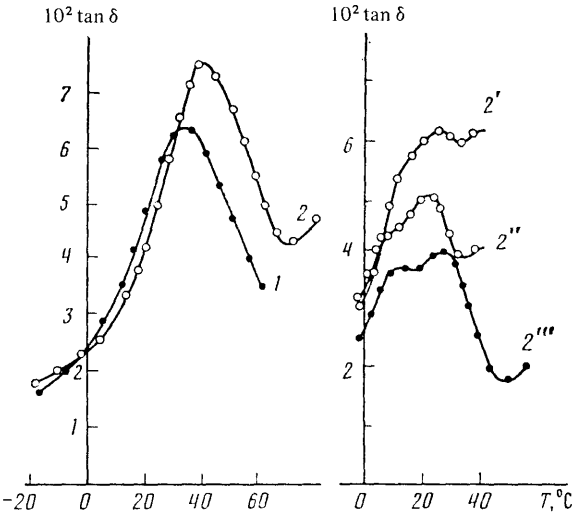

Figure 10. Temperature variation of tan δ at frequencies of 1 kHz (curves *1* and *2*) and 1 Hz (curves *2'*, *2''*, and *2'''*) for MMA–BA–MAA films formed in different ways: 1) from a mixture of the PMMA and P(MMA–BA–MAA) latexes; 2) and 2') from latexes obtained by the seeded polymerisation of the MAA–BA–MAA mixture on a PMMA latex; 2'') from the latex 2 after heating at 70 °C; 2''') from the latex 2 after reprecipitation from dioxan.[42]

The structures of the latex particles and films obtained by the joint and seeded polymerisation can be represented schematically, as shown in Fig.11. These schemes make it possible to understand the difference between the physical properties and behaviour of these materials after a long time has elapsed (Fig.9). The equilibrium structure of films produced from linear polymer latexes with homogeneous particles, obtained by the joint polymerisation of hydrophobi monomers, is produced in the course of the mutual diffusion of the molecules between the particles and the uncoiling of the macromolecules, which is accompanied by an increase in the strength of the films as a result of the increase in the number of intermolecular contacts[51] (Figs.9*a*–*1* and 9*b*–*1*). In films produced from latexes obtained by seeded polymeristion,[43,44] the mutual diffusion of the molecules is restricted in space mainly by the thickness of the layers of the elastic polymer between the nuclei of the filler. In the case of the vitreous state of the latter, equilibrium is attained already in the film formation process and subsequently the strength of the film does not vary with time (Fig.9*a*–*3*). In the case of an elastic filler, partly compatible with the matrix, limited mutual diffusion of the macromolecules takes place in the films as a function of time, which is accompanied by some increase in the strength of the film with time (Fig.9*b*–*3*).

The presence of a highly dispersed filler which is a foreign polymer limits the mutual diffusion process also in films made from blended latexes, but to a much smaller extent than in the case of films produced from latexes obtained by seeded

polymerisation, which can apparently be explained by the disordered distribution of the filler particles and the absence of transitional layers in the contact zone. The strength of the blended films increases with time (Figs. 9a–2 and 9b–2).

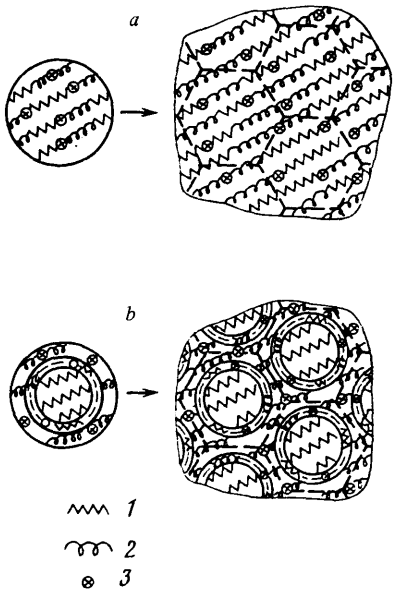

Figure 11. The phase structure of the particles and films formed from latexes obtained by the copolymerisation (a) and seeded polymerisation (b) methods: 1) PMMA; 2) PBA; 3) MAA.

The data presented in this Section on the phase structure of composite latex particles indicate a wide variety of factors influencing it and its relation with the properties of the polymers isolated from the latexes. The phase structure of the particles formed in seed polymerisation depends on the physical state and structure of the polymer of the seed latex, the parameters of its interaction with the monomers introduced in the following stage, the rate at which they are introduced, the degree of swelling of the seed particles in them, and the concentration of the emulsifier in the system, i.e. both on thermodynamic factors and on the specific features of the latex polymerisation process.[108] This process results in the formation of mixed structures, grafted copolymers, interpenetrating polymer networks, and segregated polymers in the form of concentric regions of the "core–shell" type.

In order to obtain graft polymers and systems of the INP type, the method of seed polymerisation with the simultaneous introduction of the monomers into the system is used preferentially. In the absence of an excess of emulsifier, this promotes the occurrence of polymerisation in the PMP formed initially[109] and the most complete chemical interaction (grafting) of the polymers.[48] The use of a semicontinuous seeded polymerisation method with gradual introduction of the monomers, in which equilibrium swelling of the seed particles in the latter is not attained, is a procedure for the specific formation of the particle phase structure of the "core–shell" type also when chemical bonds are not formed between the segregated polymers. The thickness of the shell and the degree of phase separation of the segregated polymers are regulated by choosing the ratio of the monomers in the first and second stages and the degree of conversion of the monomer in the seed latex.

In order to obtain a continuous film made up of composite particles consisting of polymers with different T_g, the bulk phase content of the more elastic component should be not less than 30–40%.[26] Such films are elastic polymer matrices filled with a highly dispersed filler consisting of a rigid polymer; they have a two-phase structure and thus differ significantly from the latex films incorporating homogeneous elastomer particles which ultimately form a single continuous phase.[49–52] The formation of a strong film from the latex always involves the formation of irreversible contacts at the initial interface between the particles, which is attained in the case of homogeneous particles as a result of the mutual diffusion of the macromolecules. The formation of a strong latex film consisting of heterogeneous particles requires in addition the attainment of an irreversible contact between the matrix and the filler. If there is no chemical binding, this takes place as a result of the formation of chemical or diffutional transitional layers between the segregated polymers. The strength of the two-phase films compared with the single-phase films of the same composition is greater owing to interfacial interaction; the MFT decreases simultaneously as a result of the localisation of the elastic component within the film matrix formed from the shells of the particles. Diffusional processes as well as reversible deformation, ensuring the elasticity of the system, are restricted in two-phase films by the thickness of the layers of the elastic matrix between the "cores" of the highly dispersed filler.

IV. LAYER FORMATION AND PHASE INVERSION IN COMPOSITE PARTICLES AND THE PROPERTIES OF THE "INVERTED" LATEXES AND FILMS

1. Effects Associated with the Separation of Phases into Layers

As stated above, one of the processes leading to the formation of composite particles is the polymerisation of the monomer 2 in the particles of the monomer 1 which had been swollen in it. In the final stage of the polymerisation, as the second polymer incompatible with the first is formed, phase separation takes place in the particles and is accompanied by a change in the shape of the particles and the segregation of a new highly dispersed fraction from them. When sufficiently strong transitional layers are formed between the components, the fragmentation of the particles is not observed.[48,110–113]

In composite particles having the same composition, the phase separation effects depend on the polymerisation method. Thus, in the seeded polymerisation of St on PMA, PEA, and PVA latexes, spherical particles are formed in most cases. However, after the preliminary equilibrium absorption of St in the seed latex, the particles acquire a "raspberry-like" shape and fragment at the end of the process: PSt domains appear initially in the seed particles and, after the attainment of 95% conversion, combine into cores which are subsequently segregated in the form of highly dispersed particles.[110] The latter explains the non-spherical shape of the particles and the intense local stresses arising in them as the latex is shaken in the polymerisation process.[110] When St was introduced gradually into the PBA or St–ethylene glycol dimethacrylate latex, the formation of "raspberry-like" particles was also observed but these did not break up on heating and shaking the latex. The transitional layers formed in this

process apparently ensure adequate adhesion of the segregated polymers. Conditions have been found (temperature, phase ratio) under which semispherical particles with cavities in their interior are formed as a result of the seeded polymerisation of St on PBA.[111,112] The observed effect is explained by phase separation: part of the polymer, enriched in PBA, "slips out" from the overall particle during the polymerisation process owing to inadequate adhesion.

The films obtained from latexes comprising particles of two incompatible polymers, with sharply different T_g, undergo a radical change in their physical properties as a result of heat treatment.[113] Thus, when films made from latexes obtained by the seeded polymerisation of St on the PEA latex were heated at a temperature above the T_g of the more rigid polymer (PSt), a change in their mechanical, adhesion, and optical characteristics was observed. The initial films were elastic, were characterised by a high adhesion capacity, and exhibited rainbow colours in both transmitted and reflected light; after heating, they became rigid, did not adhere to the support, and became cloudy. After reprecipitation from an organic solvent, there was no longer any change in the properties of the same films as a result of heat treatment. The thermal sensitivity of the films is controlled by altering the relative contents and the T_g of the constituent polymers. This effect can be explained by the morphological changes occurring in the latex film on heating, namely separation into layers and phase inversion: in the unheated film, the matrix is PEA, which ensures its elasticity and high adhesion capacity; after heating, the continuous phase becomes PSt, as a result of which the strength increases but the elasticity and adhesion capacity diminish. This phenomenon, which has also been observed by Kast,[114] is apparently associated with the free energy gained by the system as a result of the combination of the highly dispersed fraction of the polymer into larger domains and into one continuous phase.

2. The Influence of the Polarity of the Polymer on the Morphological Changes in Composite Particles

Stable latexes at a 30% concentration are formed in the emulsifier-free polymerisation of St on seeding the PEA latex subjected to preliminary hydrolysis in such a way that the surfaces of the seed particles contain carboxy-groups at a specified concentration with the ratio PEA : PSt = 2.5 : 47.5. Hydrolysis of the ester groups of PEA is achieved in the polymerisation of EA in an acid medium generated by the decomposition of the initiator—a persulphuric acid salt.[115]

Matsumoto and co-workers[71,115] investigated the mechanism of the formation of stable particles by electron microscopy at different stages of the polymerisation of St on the PEA latex taken in proportions of 1 : 1. At the beginning of the polymerisation, a fraction of fine PSt particles appears in the PEA seed particles, while at the end of the process particles of the type of "confetti" are produced (Fig.12). The authors explain this morphological picture by the diffusion of St radicals from the aqueous phase to the surface zone of the seed particles, where they grow by absorbing styrene: the macromolecules formed are combined into domains incorporated in the PA phase. Since particles in the form of "confetti" were not formed on replacement of St by the more polar MMA, it was concluded that the polarity of the polymer affects the phase structure of the composite particles. On the other hand, the stability of the polystyrene emulsifier-free latex, obtained by the polymerisation of St on the hydrolysed PEA latex, has been explained[71,115] by the distribution of the latter on the surface of the PSt particles and the orientation of the carboxy-groups at the interface with the aqueous phase.

The distribution of polymers in the bulk phase and on the surface of the particles as a function of the polymer polarity has been investigated in relation to the seeded polymerisation of compositions based on MA, MMA, and St.[35] The method involving the adsorption titration of the latexes with a solutin of sodium dodecyl phenylmethanesulphonate, the adsorption area of the molecules of which had been determined beforehand for homopolymer latexes, was used. It depends on the polymer polarity and amounts to 214, 133, and 53 Å^2 respectively. For statistical copolymers, this area is additive. The polymerisation conditions were chosen so that the number of particles did not change during the process. In the polymerisation of St on the PMMA seed latex, the ratio of these components in the surface zone of the particles did not correspond to their overall ratio in the system, as happens in copolymerisation: the concentration of PMMA on the surface of the particles was higher than in the system as a whole.

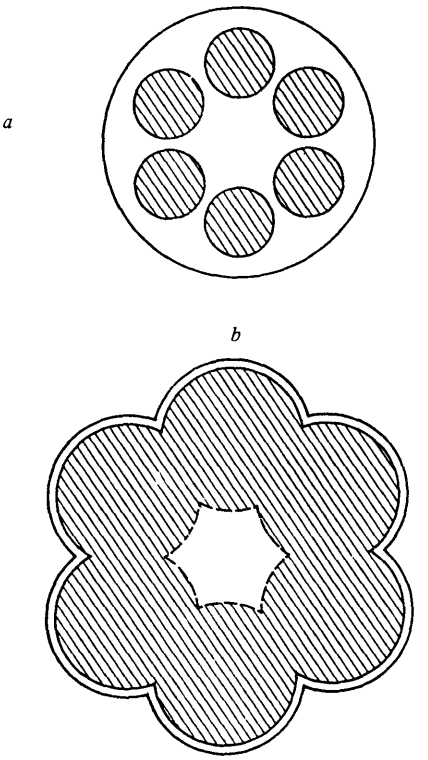

Figure 12. The shape of the particles formed in the seeded polymerisation of St on a PEA latex at the beginning (*a*) and end (*b*) of the process; open regions—PEA; shaded regions—PSt.[71,115]

The authors explain this behaviour[35] by the greater hydrophilicity of MMA compared with St. The hydrophilic properties were characterised by data on the interfacial tension of the polymer solutions in the same monomer at the interface with the aqueous phase. It proved to be 26.5 dyn cm^{-1} for the PSt/St solution and 12.6 dyn cm^{-1} for the PMMA/MMA solution. These data show that PMMA is adsorbed preferentially at the interface with the aqueous phase, compared

with PSt. An analogous but more clear-cut morphological picture was observed when the more polar PMA was used as the seed latex.

In a study of the seed copolymerisation of chloroprene (CP) and MAA (95:5) on the butyl methacrylate (BMA)–MAA (95:5) copolymer latex under the conditions of the gradual introduction of the monomers, the phenomenon of phase inversion in the colloidal particles was observed.[116] By following the mechanism of their formation with the aid of electron microscopy and contrasting the diene component with osmium tetroxide (Fig.13), it was shown that the PCP, formed in the second polymerisation stage in the form of domains (Fig.13*b*) or a separate phase (Fig.13*c*), is concentrated on the surfaces of the polyacrylate seed particles and is incorporated in their cores, the polymer of the seed latex then disintegrates and emerges onto the surfaces of the composite particles (Fig.13*d*) in the form of domains. Thus phase inversion takes place during polymerisation in the composite particles. This phenomenon has been explained by the free energy gained by the system on passing from the P(CP–MAA)–aqueous phase interface in the particles to the P(CP–MAA)–P(BMA–MAA) interface in the composite particles and the P(BMA–MAA)–water interface in the aqueous phase. The latter can be explained by the fact that the polarity (the contribution of the polar interactions to the interfacial tension) of PBMA is higher than that of PCP, the two polarities amounting to 0.18 and 0.11 respectively.[117]

Such phase inversions affect significantly the properties of latexes and films. This is indicated by the comparison of the properties of the latex described and the latex having the same composition but obtained by polymerisation in the opposite sequence. In the latter case, phase reversal does not occur and both latexes are characterised by similar morphologies of the particles.[118] The properties of latexes having the same composition but obtained with the monomers introduced in different order differ significantly: the "non-inverted" latex does not exhibit frost resistance, while the "inverted" latex withstands seven freezing (to −30 °C) and thawing cycles.[118]

The frost resistance of the inverted latex is apparently associated with the high concentration of carboxy-groups[119] and non-freezing water[120] on the surface of the particles. The concentration of carboxy-groups on the surface of the particles can be a result of their spontaneous energetically favourable orientation at the interface with the aqueous phase. Such orientation takes place during the disintegration of the P(BMA–MAA) copolymer of the seed latex and its emergence onto the surface in the form of domains. In the shells of the "non-inverted" latex particles, the carboxy-groups are distributed at random (in the second stage of the copolymerisation of BMA with MAA) and their concentration on the surface of the particles is lower. This hypothesis is confirmed by the significant increase in the strength and the sharp decrease in the absorption of water by the "inverted" latex film, which can be accounted for by the higher concentration of the interparticle hydrogen bonds formed between the carboxy-groups when the particles come into contact during film formation and hence by the denser structure of the film.

It has also been shown that, in the seeded polymerisation of Bd–St on the carboxylated EA–MAA (90:10) copolymer latex, phase inversion takes place in the second stage of the process in the particles, as a result of which the hydrophobic polymer comes to be located within the particles and the more hydrophilic polymer is in their peripheral zone.[121] The degree of emergence of the carboxylated polymer onto the surface of the particles has been investigated by the potentiometric titration method and it has been established that it depends on the molecular weight of the polymer. In the presence of $CHBr_3$ as the chain transfer agent, which is used to regulate the molecular weight in both stages, 92% of the MAA introduced was found on the surface of the particles, while in its absence the corresponding figure was only 69%. This is evidently associated with the greater mobility of the macromolecules with a lower molecular weight, which facilitates their emergence onto the surface of the particles.

The phenomenon of phase inversion in particles has been observed also in the seed polymerisation of acrylic monomers, which are characterised by different solubilities in water.[33] The MA–MAA (90:10) mixture was polymerised on the EA–MAA (90:10) copolymer seed latex and the EA–MAA (90:10) mixture was polymerised on the MA–MAA (90:10) copolymer seed latex. The ratio of the polymers was 1:1 in both cases. It has been shown with the aid of the NMR and

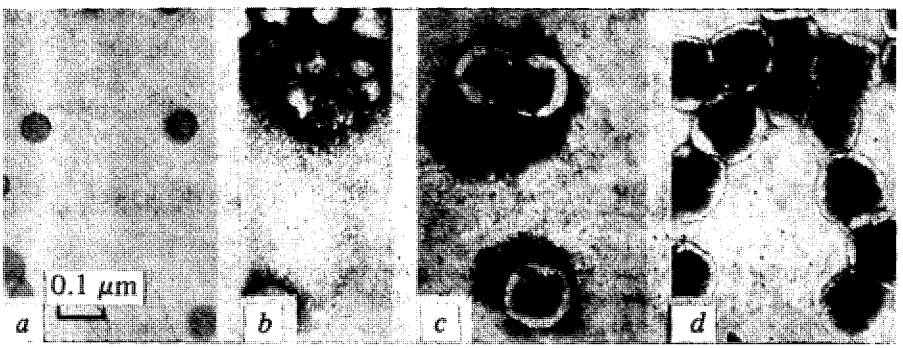

Figure 13. Electron photomicrographs of the particles formed in the CP – MAA seeded polymerisation on a P(PMA–MAA) latex; *a*) seed latex; *b*) and *c*) second stage of the polymerisation process; *d*) final latex.

acid titration methods that the peripheral zone of the particles of both latexes contains only PMA, while the core contains PEA and PMA, i.e. the more polar polymer is always present in the shell of the particles regardless of which monomers were polymerised in the first and second stages. Thus phase inversion occurred in the particles in the second case, as in the other systems described above.

Not only the polarity but also the physical state of the polymers is important for the phase transformations of this kind during latex polymerisation. Evidently the decrease in the Gibbs free energy, which promotes the "drawing" of the hydrophobic polymer into the interior of the particles, is possible only when the macromolecules of the seed and second polymers exhibit a sufficiently high translational mobility, i.e. when the polymerisation temperature T_{pol} is higher than the T_g of the polymers.

This conclusion has been confirmed in a study of the mechanism of the formation and phase structure of the particles of composite polymers obtained by the semicontinuous seeded polymerisation of CP on the PEA, PMMA, and PSt latexes.[122] The polarity of the polymers was estimated from the interfacial tensions of the monomers at the interface with water; in the cases indicated, they amounted to 16.9, 17.8, and 35.0 dyn cm^{-1} respectively. The physical state of the polymer in the polymerisation process was inferred from the differences $\Delta = T_g - T_{pol}$, which were 60, -65, and -60 K respectively. The selected polymers of the seeding latexes were either in the same vitreous state under the polymerisation conditions but differed in polarity (PSt, PMMA) or their polarities were similar but they existed in different physical states (PMMA, PEA). It was shown that, in the polymerisation of CP in the presence of all the seed latexes, PCP are formed initially (Fig.14), behaving differently in different cases. In the PCP–PSt composition, they aggregate into more stable particles, forming a separate fraction, apparently as a consequence of the sharp difference between the chemical natures of the polymers. In the PCP–PMMA composition, the PCP particles are adsorbed on the surface of the PMMA particles, forming a dense non-uniform shell: the rigidity of PMMA prevents the PCP domains from penetrating into the

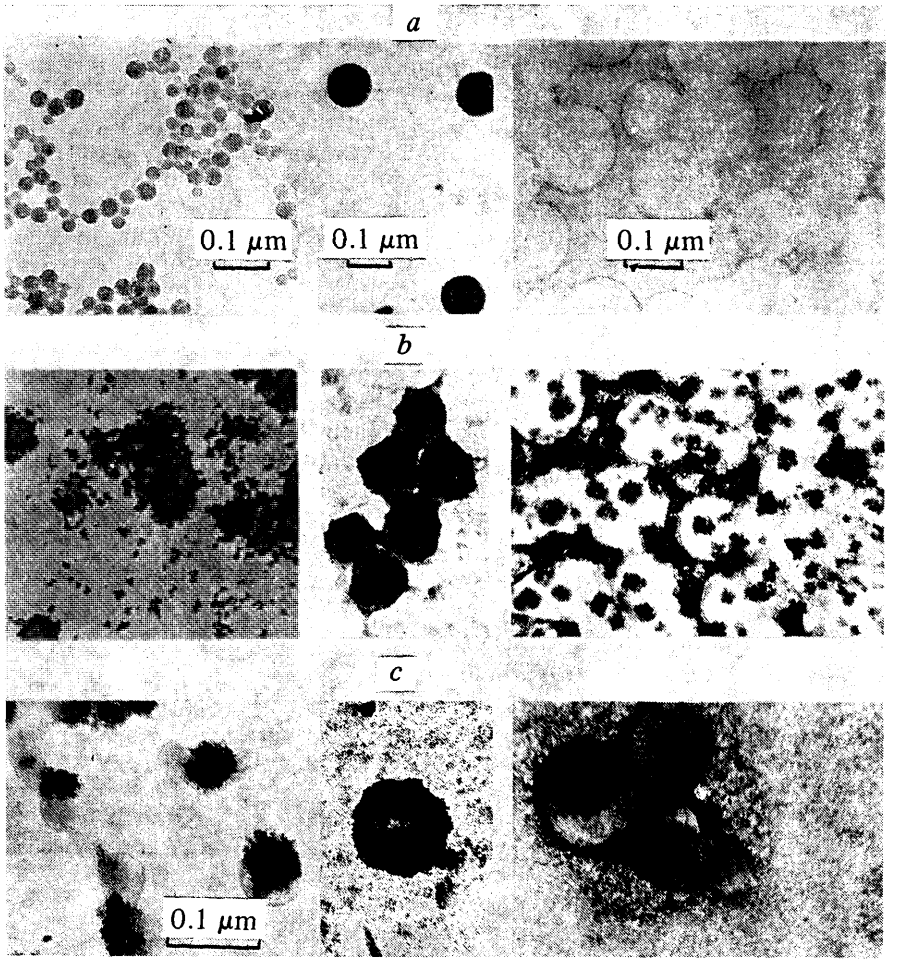

Figure 14. Electron photomicrographs of the particles formed in the seeded polymerisation of CP on PSt (*1*), PMMA (*2*), and PEA (*3*) latexes: *a*) seed latex; *b*) second stage; *c*) final latex.[122]

bulk of the particles, as happened in the case of PBMA (Fig.13). Finally, in the PCP–PEA composition, the PCP domains penetrated into the bulk of the seed particles, forming a discrete phase in the latter: in terms of polarity, PEA is close to PMMA, but during the polymerisation process it exists in a viscofluid state, as a result of which it does not prevent the "drawing" of the PCP domains into the bulk of the hydrophobic particles which is determined by thermodynamic factors.

The data presented in this Section show that the phase structure of the composite colloidal particles can undergo significant changes during polymerisation depending on the compatibility, polarity, and the physical state of their constituent polymers.

If the polymers are incompatible and a strong contact between them is not attained, phase separation takes place in the bulk of the particles: a discrete polymer phase appears, which can lead, under certain conditions, to a non-spherical shape of the particles, the segregation from them of a new highly dispersed fraction, and the formation of semispherical particles with cavities.

When the difference between the T_g of the incompatible polymers is large, the latexes with composite particles form thermosensitive films whose physical properties change sharply as a result of heat treatment. This is caused by the inversion of the polymer phases in the two-phase film, whose driving force arises from the endeavour of the system to reduce the area of the interface.

When the difference between the polarities of the polymers is large and the mobility of their macromolecules is adequate, phase displacement can occur in the polymerisation process of a kind such that, regardless of the sequence in which the monomers are introduced into the reaction system, the more polar component is on the surface of the particles. This phenomenon is associated with the gain of free energy on formation of a colloidal system with a smaller interfacial tension and entails an increase in the resistance of the latexes to aggregation.

---o0o---

Summarising the data described in the review, one may reach the following conclusion. A characteristic feature distinguishing hydrophobic polymeric colloids—latexes and other hydrophobic sols—is the complexity and wide variety of the structures of the particles, which depends both on the chemical nature of the polymer and on many factors associated with the conditions governing their formation in the two-phase polymerisation system. The colloidal behaviour of the latexes and the kinetics of the latex polymerisation depend on the structure of the particles which have been formed and are being formed respectively. Being retained in the polymers and films isolated from the latexes, the structure of the particles has a decisive influence on their physical properties. In this sense, the most typical are the latexes of polymers modified by functional groups and the latexes of composite polymers. The presence of an interface with the aqueous phase, on which colloidal polymer particles are formed, is an important factor in both cases, which influences the orientation, packing, and distribution of the polymer molecules and domains, if the forces acting at this interface (dipolar interactions, hydrogen bonds) can compete with the intramolecular and intermolecular interactions of the macromolecules, i.e. if the macromolecules in the PMP are sufficiently mobile.

The physicochemical film formation process, which has been investigated for the latexes of elastomers with homogeneous particles,[49,52] in the case of latexes with heterogeneous particles must be considered taking into account the structure of the latter, where not single-phase but two-phase polymer systems with characteristic properties are formed as a result of the combination of the particles.

Topological Indices in Organic Chemistry

M.I.Stankevich, I.V.Stankevich, and N.S.Zefirov

The numerical characteristics of molecular structures, called topological indices, which are used for the quantitative description of the structures of organic compounds, are examined. The method of topological indices is analysed as one of the procedures for determining the relation between the structure of chemical compounds and their properties.
The bibliography includes 164 references.

I. INTRODUCTION

The search for regularities in the type of variation of different properties of molecules as a function of their structure belongs to the so called "structure–property" problem which has long attracted the attention of chemists.[1-2] The solution of this problem even for an individual fairly narrow range of compounds is extremely important.[3] The observed regularities can be used for the systematic treatment of molecules of a given class, for the prediction of the properties of hypothetical molecules, and for the search for new compounds with a specified set of properties. Furthermore, they can also prove useful in the development of a theory which would explain the phenomenon under consideration and would provide a key to the understanding of the mechanism of the action of biological active compounds.

In order to find quantitative relations between structure and property, various mathematical modelling methods are used, their choice being determined by the type of chemical compounds, their state of aggregation, and the property being analysed. Procedures for the description of molecular structures occupy a special place among these methods.

The description of molecular structure can be detailed to different extents. Thus the overall formula shows how many and what atoms are contained in the molecule. The structural formula contains information also about the way in which these atoms are linked to one another. Finally, the specification of the coordinates of the atomic nuclei in space makes it possible to construct three-dimensional models of molecules. With the aid of quantum-chemical calculations, it is possible to obtain additional information about the distribution of electron density in the molecule. The physicochemical parameters reflecting the molecular structure indirectly are used in many cases to characterise the molecules.

Modern experimental research methods make it possible to determine fairly reliably the geometry and different physicochemical characteristics of molecules. However, such methods are applicable only to substances which actually exist and not to all substances. In those cases

where experiment is difficult, one can use quantum-chemical calculations of the geometrical and energy characteristics of molecules. Such calculations are still inferior as regards accuracy to experimental data and, moreover, they are associated with considerable computational difficulties. More formal and simpler methods, based on the description of the molecular structure by the structural formula, are therefore also used nowadays to solve the "structure–property" problem. In this topological method for the description of molecular structure, account is taken only of the types of atoms and of the character of their bonding to one another, but the metric characteristics of the molecule are neglected.

The methods based on the analysis of the structural formula in order to discover the relation between the structure and property have long been used in theoretical organic chemistry. For example, the additive schemes employed to estimate the physicochemical properties of hydrocarbons, based on the concept of a numerical characteristic of the property investigated in the form of the sum of the contributions by atoms and bonds, are widely known.[4,5] Further development of the topological approach led to the appearance of various modifications of simple additive schemes associated with allowance for a non-valence interaction, the use of more complex structural fragments, the application of non-linear functional relations between the property and the structural parameters,[6–10] etc. This made it possible to extend significantly the list of properties investigated and also to analyse compounds with a structure more complex than that of hydrocarbons.

The development of the topological approach is associated to a large extent with the application of the methods of graph theory,[11] since the structural formula of a molecule is equivalent to the corresponding molecular graph. The analysis of the structural formula which must be carried out within the framework of the "structure–property" problem therefore reduces to the treatment by the methods of the theory of graphs of the corresponding abstract mathematical structure—the molecular graph (MG). Weighted MG are usually employed in structural chemistry.[10] The weighting factors for the vertices and edges are chosen in order to take into account the differences between the types of atoms and bonds. The weighted graph is defined by the adjoining matrix $A = (a_{ij})$, $(i,j = 1,\ldots,n)$, where a_{ii} is the weighting factor of the ith vertex, $a_{ij} = a_{ji}$ the weighting factor of the edge (i,j), $a_{ij} = a_{ji} = 0$ if the vertices i and j are not connected by an edge, and n is the number of vertices in the graph. The form of the adjacency matrix depends, generally speaking, on the way in which the vertices of the graph are numbered. However, different numbers characterising its structure and independent of the way in which the vertices are numbered can be attributed to each graph. Such numbers are called the invariants of the graph or structural constants. Examples of the graph invariants are the number of vertices, the number of edges, the number of paths of equal length, the determinant of the adjacency matrix, etc. In organic chemistry, the invariants of weighted molecular graphs are called topological indices (TI). Topological indices have found a wide variety of applications in structural chemistry. In particular, they can be used to code chemical information, in designing a chemical experiment, in the theory of the atomic structure and reactivity of molecules, and for the quantitative description of chemical structures in the analysis of the relation between the structure of a molecule and its properties. In the present review, we shall discuss the last two applications of the TI.

As a rule, in order to establish a relation between the structural parameters $x_i, \ldots, x_k$ (in the given case topological indices) and the numerical characteristics of a property "y", a functional relation of the type $y = a_0 + \sum_i a_i x_i$, where a_i are unknown constants determined by the method of least squares, is sought. The quality of the model constructed is characterised by the regression parameter s (the standard deviation of the regression line; $s \geq 0$) and r (the correlation coefficient; $0 \leq r \leq 1$). In more general cases, non-linear functional relations are used.[12]

Another approach to the "structure–property" problem associated with TI is also possible. Its essential feature consists in the fact that the concept of "distance" between the structures is introduced on the basis of the TI, making it possible to estimate the similarity of the structures and to relate it to changes in the property considered. Furthermore, TI are used as structural descriptors in the solution of the "structure–property" problem by other methods, for example, by the image recognition method.[12]

The approach to the solution of the "structure–property" problem based on TI has a number of advantages, which include, firstly, the simplicity and rapidity of the calculation of TI even on small computers and, secondly, the non-empirical character of the indices and the possibility of obtaining them directly from the structural formula. The latter is especially significant when one is dealing with the estimation of the properties of hypothetical structures for which there are no experimental data whatsoever.

The method of topological indices, based on the formal description of the molecular structure, suffers also from an evident disadvantage: not all the characteristic features of the molecular structure are taken into account. Nevertheless, in many cases TI are satisfactorily correlated with both steric parameters (molecular volume, molecular refraction, the surface area of the molecule) and the electronic parameters (ionisation potentials, electron affinity, polarisability, chemical shifts in NMR spectra, spin density, etc.). Furthermore, in constructing TI one can take into account not only the topology of the molecule but also certain features of its electronic and steric structures, the weighting factors for vertices and edges of the MG being appropriately selected.

One should also note that TI are usually obtained with the aid of formal operations on the MG. It is therefore not always possible to achieve a satisfactory physical interpretation of certain TI and to explain the correlation obtained with their aid even at a qualitative level. In the solution of the specific problems with the aid of the TI method, the problem of the motivated [subjective?] selection of topological indices arises.

However, in certain applied fields, in particular in the search for new biologically active substances,[12,13] a fairly complex situation arises, associated with the necessity to synthesise and investigate a large number of chemical compounds. Therefore any even indirect considerations which enable the investigator to solve *a priori* the question of the structures which can have the required properties or those which need not be considered at all is of great interest. The TI method can be used in the solution of problems of this type as a "coarse filter" for the preliminary sorting of molecules.

Recently there has been considerable growth of interest in topological indices. Numerous publications on this topic have been published in which increasing numbers of new TI have been introduced (see, for example, Bonchev[14]). Naturally, the abundance of TI combined with the lack of a single theory makes it difficult to understand them, promotes the appearance of speculative publications in this field, and even to some extent discredits the TI method.

The main aim of the review is to carry out an approximate classification of the TI described in the chemical literature, to give an account of the general principles of the construction of TI, and to analyse the real possibilities of the TI

method as a procedure for the description of chemical structures in the solution of the problem of the "structure–property" relation. The review also discusses the relation between different indices and their interpretation. The individual Sections are devoted to the discussion of correlations of TI with physicochemical properties and with the biological activity of certain classes of compounds known from the literature.

There exists a series of foreign reviews devoted to the use of TI in structural chemistry.[14–19] However, these publications cover inadequately the different applications of TI and provide as a rule merely a description of the factual data without its analysis.

II. TOPOLOGICAL INDICES AS QUANTITATIVE CHARACTERISTICS OF MOLECULAR STRUCTURES

This Section gives a brief description of the principal ways of constructing TI used in the analysis of molecular structure.

1. Invariant Sets of Molecular Graphs

We shall denote by G an arbitrary molecular graph. Different sets of numbers (numerical sets) can correspond to the graph G, characterising its structure and being independent of the numbering of the vertices. Each such set $\mathfrak{M}$ will be called an invariant set (IS) of the graph G assuming, to make the treatment concrete, that its elements are arranged in a decreasing sequence. For example, the set of the elements of the adjoining matrix $A=(a_{ij})$ of the graph G as well as the set of degrees of vertices v_i, where

$$v_i=\sum_{j,j\neq i} a_{ij}.$$

are invariant sets. When the weighting factors of the edges are equal to the multiplicities of the corresponding bonds, the quantity v_i is equal to the number of edges incident with the vertex i and related directly to the valence of the ith atom.

Together with the adjacency matrix, other matrices corresponding to the graph G can be used to construct its IS. The distance matrix $D = (d_{ij})$ $(i,j = 1, \ldots, n)$, whose element d_{ij} is equal to the distance between the ith and jth vertices, is most often used in structural chemistry. The quantity d_{ij} is defined as the minimum number of edges which must be traversed when moving along the edges of the graph from the ith vertex to the jth. The set of elements of the matrix D, the set of the distance degrees of the vertices d_i, where

$$d_i=\sum_j d_{ij},$$

and also the spectra of the matrices A and D are IS. Other examples of IS will be examined below.

A whole family of different TI corresponds to each IS $\mathfrak{M}$. We shall describe several ways of constructing TI of this type.

First method. Suppose that the IS $\mathfrak{M}$ of the graph G consists of k elements $m_1, \ldots, m_k$. We shall select an arbitrary symmetrical function $F(x_1,\ldots,x_k)$ of k variables (the values of this function do not change in arbitrary transpositions of the arguments). The quantity $F(m_1,\ldots,m_k)$, regarded as the value of the function F on the graph G, is a TI corresponding to $\mathfrak{M}$. For example, if $\mathfrak{M}$ consists of the element of the adjacency matrix A of the graph G, $k = n^2$ (where n is the number of vertices of the graph G), and

$$F(x_1,\ldots,x_k)=\sum_i x_i,$$

then $F(m_1,\ldots,m_k)$ is equal to the sum of all the elements of the matrix A. If the graph G is simple, i.e. A is a matrix consisting of zeros and ones [a(0,1)-matrix] and $a_{ii}=0$, then $F(m_1,\ldots,m_k) = 2q$, where q is the number of edges of the graph. By altering the form of the function F, it is possible to construct a whole series of other TI also related to the given IS $\mathfrak{M}$. . In yet another example, we may specify a TI generated by the function

$$F_a=\sum_i \delta(x_i),$$

where $\delta(x_i) = 1$ for $x_i = a$ and $\delta(x_i) = 0$ for $x_i \neq a$, a being a fixed number. The value of the function F_a at the point $(m_1,\ldots,m_k)$ is equal to the number of elements of the set $\mathfrak{M}$ identical with a. Thus, if $a = 2$ and the IS consists of the elements of the matrix D, then the value of the function F_a is equal to twice the number of pairs of the vertices of the graph located at a distance of 2.

Second method. We differentiate in the graph G the subgraphs G_j of a specific type with the same numbers of vertices m $(m < n)$. We relate to the subgraph G_j the IS $\mathfrak{M}_j$ consisting of k elements: $m_1^{(j)},\ldots,m_k^{(j)}$. We select a symmetrical function $F(x_1,\ldots,x_k)$ of k variables. For each subgraph G_j, we find the value of $F(m_1^{(j)},\ldots,m_k^{(j)})$ and then we determine the TI equal to the sum of these quantities. In particular, if $F(x_1,\ldots,x_k) \equiv 1$, then the TI determined by the method described is equal to the number of subgraphs of the given type.

Third method. New TI can be obtained from those already known by adding, multiplying, subtracting, and dividing the latter. Finally, it is possible to construct a multi-index—an ordered sequence of simple indices.

The TI described above characterise the graph as a whole. Such TI are represented in many cases as the sums of the numerical characteristics of different structural fragments, for example, the vertices or edges of the MG and these characteristics are independent of the numbering of the vertices of the fragment. Some of these invariants, called TI of the local type, are of independent interest and are used in the solution of various problems in theoretical chemistry. For example, the local TI determined as the matrix elements of different functions of the adjacency matrix are used in the theory of the electronic structure of conjugated molecules.

2. Indices Related to the Distance Matrix D

Correct estimates of the dimensions and degree of branching of the molecule are important in the estimation of a number of physicochemical properties of compounds, for example, the boiling point or melting point, because the energy of intermolecular interactions actually depends to a considerable degree on these parameters. In the topological approximation, mainly indices characterising the "size and form" of the graph are used for the solution of this problem. Some of them are directly related to the distance matrix D. This approach was first applied by Wiener,[20] who suggested that two TI, W and p, defined in terms of the distances between the vertices of the corresponding molecular graphs, be used for the comparison of the carbon skeletons of saturated hydrocarbons. The index p is equal to the number of pairs of vertices the distance between which is 3 and W is equal to the sum of the distances between all pairs of vertices of the graph G. The number W, usually called the Wiener index, is expressed in terms of the elements of the distance matrix D by the formula

$$W=\frac{1}{2}\sum_{i,j}d_{ij}.$$

The index W can also be written in the form

$$W=\sum_{j}jg_j,$$

where g_j is the number of pairs of indices separated from one another by the distance j, i.e. the number of elements d_{kl}, $(k<l)$ in the matrix D equal to j.[21] The number p is identical in the given instance with the quantity g_3. The polynomial

$$W(x)=\sum_{j}x^jg_j,$$

introduced by Altenburg,[22] is sometimes used to characterise the distances between the vertices of the MG which can occur in the graph. In terms of the $W(x)$ polynomial, the Wiener index is calculated by the formula

$$W=\frac{dW(x)}{dx}\Big|_{x=1}.$$

The distance matrix is also used to determine the distance polynomial

$$D(x)=(-1)^n\det(D-xE),$$

where E is a unit matrix.[23] This polynomial is the invariant polynomial of the graph.

The indices $J(G)$ and $D^{(k)}$, associated with the matrix D, are described by the formulae†[13]

$$J(G)=\frac{q}{1+c}\sum'(d_id_j)^{-1/2}$$

$$D^{(k)}=\left[\left(\sum_i g_i\cdot i^k\right)\Big/\left(\sum_i g_i\right)\right]^{1/k};\ k=1,2,3,4,$$

where q is the number of edges and c is the cyclomatic number which in the case of simple graphs is equal to $q-n+1$.

In constructing certain TI, the concept of the centre of the graph is used.[11] The centre of the graph is defined as follows. For each vertex of the graph, one calculates initially the quantity $e_i=\max_j d_{ij}$, where i is the number of the vertex. The quantity e_i is called the eccentricity of the ith vertex. Then, among all the numbers e_i, the smallest is selected: $r(G)=\min_i e_i$. This number is called the radius of the graph. By definition, the centre of the graph is understood as the set of vertices whose eccentricity is $r(G)$. For example, the tree has a centre consisting of one or two connected vertices.[11] The centric TI for the tree is determined by means of the following procedure. In the first step, all the first degree vertices (pendant vertices) and the edges incident with them are cut off from the tree. In the second step, all the first degree vertices and the edges incident with them are again cut off from the subgraph obtained in the first step. This procedure is continued until finally only the central vertices of the tree remain. We shall denote by Δ_i the number of vertices eliminated in the ith step and shall put

$$B=\sum_i\Delta_i^2.$$

The quantity B is called the centric Balaban index.[24] The normalised (B') and binormalised (B'') centric indices are also defined in terms of the index D:

$$B'=0.5(B-2n+u),\ B''=2B'((n-2)^2-2+u)^{-1},$$

where $u=0.5\,[1-(-1)^n]$. A definition of the TI B_c, also related to the concept of the centre of the graph, has been proposed.[25] The index B_c is defined in terms of the formula

$$B_c=\sum_i r_i^2,$$

where r_i is the distance from the ith vertex to the centre. The centric indices B and B_c can also be defined in a different way in terms of the IS of the graph. Suppose that the set $N=(i_1,\ldots,i_k)$ consists of the numbers of central vertices. For each vertex i, one finds its distance from the centre $r_i=\min d_{ij}$ (j N; $r_i=0$ for the central vertices). The set of such numbers r_i constitutes the IS. Next the symmetrical function

$$F=\sum_{i=1}^{n}x_i^2,$$

defined by this IS, is calculated. As a result, one obtains the topological index B_c. The calculation of the index B reduces the calculation, for this IS, of the number of elements equal to $a=0,1,2,\ldots$.

The invariants of the graph, associated with the distances matrix D, have also been discussed in two other studies.[26,27]

We may note that the TI defined above refer to a simple molecular graph. In order to take into account heteroatoms and multiple bonds, the distance matrix D, constructed taking into account the weighting factors attributed to the vertices and edges of the MG, was introduced.[28] The elements of the matrix D were determined from the formulae

$$d_{ii}=1-\frac{6}{z_i}\ \text{and}\ d_{ij}=\sum\frac{1}{b_{kl}}\frac{36}{z_k\cdot z_l},$$

where z_j is the nuclear charge of the jth atom and b_{kl} the multiplicity of the bond (k,l); $b_{kl}=1$, 2, 3 or 3/2 depending on whether the bond is respectively single, double, triple, or aromatic. The summation is extended over all the bonds (k,l) forming the shortest path between the ith and jth vertices. The question of certain modifications of the distance matrix D in the presence of multiple bonds is also discussed in the above study.[29] In particular, it is suggested that a weighting factor equal to the bond length be attributed to each edge of the corresponding molecular graph.

3. Indices Based on the Invariant Set of Degrees of Vertices

Here we shall discuss certain TI which are defined in terms of the degrees of the MG vertices. Indices of this type can be easily calculated both for simple and weighted graphs. For this reason, they belong to the class of the most popular TI in theoretical chemistry. We shall indicate initially a series of indices (M_1,[30] P,[31] I,[14] and Q[24]) which are defined with the aid of symmetrical functions of degrees of the graph vertices of the type

$$\sum_i x_i^2,\ \prod_i x_i,\ \sum_i x_i$$

$$M_1=\sum_{i=1}^{n}v_i^2,\ P=\prod_{i=1}^{n}v_i,\ I=\sum_{i=1}^{n}v_i=2q,$$

$$Q=0.5\sum_{i=1}^{n}(v_i^2-2v_i)+1=0.5M_1-2q+1.$$

†In the formula for $J(G)$ and henceforth, the prime before the summation symbol implies that the summation is carried out with respect to all the edges (i,j).

We shall now assume that the edges have been selected as the subgraphs of the graph G in order to determine the indices. Using various symmetrical functions of two variables $F(x_1, x_2)$, it is possible to determine a series of TI which depend on the degrees of the vertices of the graph G. For example, the indices f, M_2, and χ have been introduced:[30,32,33]

$$f = {}'\sum(v_i + v_j - 2),$$

$$M_2 = {}'\sum v_i v_j,$$

$$\chi = {}'\sum(v_i v_j)^{-1/2}.$$

The quantity χ is called the molecular connectivity index or the Randić index,[33] M_2 is the Gutman index,[30] and f is the Platt index.[32] An extension of the structural parameter χ has been proposed;[34] the resulting index is called the index of molecular connectivity of order h. This graph invariant ${}^h\chi$ is determined from the formula

$${}^h\chi = \sum(v_{i_1}, v_{i_2}, \ldots, v_{i_{h+1}})^{-1/2} \text{ (along paths of length } h),$$

where $h \geq 1$ is a fixed integer and v_{i_k} is the degree of the vertex i_k along the given path of length h ($k = 1, \ldots, h$). Evidently, ${}^1\chi = \chi$.

The index ${}^h\chi$ was further modified[35,36] by differentiating in the graph G tree-like subgraphs G_j of a special type, each containing h edges. A certain number δ_i (for example, $\delta_i = v_i$) is ascribed to each vertex i of the graph G. Then the quantity

$$F(\delta_{j_1}, \ldots, \delta_{j_{h+1}}) = \prod_{k=1}^{h+1} \delta_{j_k}^{-1/2},$$

is calculated for each subgraph G_j with the vertices $j_1, \ldots, j_{h+1}$. The numbers $F(\delta_{j_1}, \ldots, \delta_{j_{h+1}})$ are then summed over all the subgraphs G_j. In order to take into account multiple bonds and heteroatoms, it has been suggested[36,37] that the quantities

$$\delta_i = z_i^v - r_i \quad \text{or} \quad \delta_i = (z_i^v - r_i)/(z_i - z_i^v - 1),$$

where z_i and z_i^v are respectively the total number of electrons and the number of valence electrons in the ith atom and r_i is the number of hydrogen atoms linked to the ith atom, be used as the numbers δ_i. The connectivity indices obtained in this way may be called the valence connectivity indices and are denoted by ${}^h\chi^v$.

However, cases are possible where atoms of one kind, forming bonds of different types with their neighbours, cannot be distinguished with the aid of the number δ_i. For this reason, a "perturbation" connectivity index has been introduced.[9] Instead of δ_i, in each construction use was made of the numbers δ_i^p, which are determined from the equation $\Gamma\overline{\delta^p} = \overline{\delta}$, where $\overline{\delta^p}$ and $\overline{\delta}$ are column vectors with the components δ_i^p and δ_i ($i = 1, \ldots, n$), respectively and $\Gamma = (\gamma_{kl})$, where $kl = 1, \ldots, n$, is a square matrix. The matrix elements γ_{kl} satisfy the conditions $\gamma_{kk} = 1$ and $\gamma_{kl} = 0$, provided that the vertices k and l are not connected. In the remaining cases, the γ_{kl} are selected empirically. Examples of correlations of different physicochemical properties with the "perturbation" connectivity index for a special selection of the elements of the matrix Γ (for example, for $\gamma_{kl} = \gamma_{lk} = 0,1$) have been published[9] and it has been noted that the quality of the correlations is higher than in the case where "non-perturbation" quantities δ_i are used.

The index χ has also been modified in a study[38] whose authors introduced the concept of the lth order connectivity K_l, where $l = 2,3$, using the following formula to find this quantity:

$$K_l = {}'\sum((v_i a_i v_j a_j) b_{ij})^{-1/2},$$

where ${}^l v_i$ is the number of second-order ($l = 2$) or third-order ($l = 3$) neighbours of the vertex i, the number a_i characterises the type of the ith atom, and b_{ij} is the (i,j) bond order. The indices ${}^1\chi$, ${}^2\chi$, f, and M_1, determined for weighted graphs, have been discussed.[29]

In the case of weighted graphs, the problem of the choice of the weighting factors for the vertices and edges arises. Some of the ways of introducing the weighting factors were discussed above. One of the possible variants of the distribution of the weighting factors among the vertices of the graph, associated with the method of potentials,[40] has been proposed.[39] A number u_i, called the potential defined by the formula

$$u_i = \sum_{j=1}^{n} h_{ij} h_{jj},$$

where $i = 1, \ldots, n$ and the h_{ij} are the elements of a non-degenerate matrix $H = (h_{ij})$, which depend in a special way on the elements of the adjoint matrix, is attributed to each vertex. The topological index is defined by the expression

$$\prod_{i=1}^{n} u_i \text{ [39].}$$

Certain TI which depend on the degrees of the vertices, can be represented as functions of the TI associated with more complex fragments. For example, $f = 2N_2$, where f is the Platt index and N_2 the number of paths on the MG whose length is 2 (the quantity N_2 has been introduced as the TI in the study of Gordon and Scantlebury[41]). On the other hand, if the degrees of the graph vertices do not exceed 4, then the index N_2 is linearly related to the index Q and the index M_1: $Q = N_2 - n + 2 = 3 - 2n + 0.5M_1$. For acyclic graphs,

$$\sum(v_i - 1)v_i \text{ [16].}$$

The index N_2 has been used to construct a new topological index ${}^2\kappa$ on the basis of the formula

$${}^2\kappa = \frac{2N_{2,\max} \; N_{2,\min}}{N_2^2},$$

where $N_{2,\max} = 0.5(n-1)(n-2)$ and $N_{2,\min} = n - 2$ are the values of N_2 for a simple chain and a star respectively and n is the number of vertices of the graph.[42]

The MG fragments corresponding to paths whose lengths are greater than 2 have also found applications in the construction of TI.[8,43-45] For example, it has been suggested that the sequence of numbers $N_1, \ldots, N_k$, where N_i is the number of paths of lengths i on the MG, be used to code chemical structures.[43-45] The "distance" d between the structures can be determined in terms of the numbers N_i by means of one of the formulae

$$d^2 = \sum_i (N_i - N_i')^2 \text{ and } d = \sum_i (N_i - N_i') \log_2 \frac{N_i}{N_i'},$$

which makes it possible to classify these structures in terms of the extent to which they approach a certain standard structure. In many cases the sequence of structures obtained in this way is consistent with the character of the changes in the properties.[43,45]

4. Indices which Depend on the Spectroscopic Characteristics of the Graph

A series of TI used in the analysis of molecular structures are related directly to the eingenvalues λ_j, where $j = 1, \ldots, n$, of the adjacency matrix A of the molecular graph.

The numbers $\lambda_1, \ldots, \lambda_n$ form the spectrum of this graph and are identical with the set of zeros of the characteristic polynomial:[23]

$$R(G, x) = (-1)^n \det(A - xE) = x^n + a_1 x^{n-1} + \ldots + a_n .$$

The spectrum of the graph is an IS and the coefficients of the polynomial $R(G,x)$ are symmetrical functions of the eigenvalues. Therefore any coefficient of the polynomial $R(G,x)$ can be used as the TI. In particular, the sum of the absolute coefficients of the polynomial

$$\sum_i |a_i| .$$

is also a TI. For acyclic graphs, this quantity is identical with the Hosoya index Z:[46]

$$Z = \sum_k p(G,k) ,$$

where $p(G,k)$ is the number of ways of selecting k edges of the graph in such a way that no two of them have common vertices. The Hosoya indices used for the estimation of the physicochemical properties of hydrocarbons have been tabulated.[47,48]

Individual eigenvalues, the sums of non-negative eigenvalues, etc. are also used as the TI.[44,49,50] For example, the maximum eigenvalue is used as the characteristic of the degree of branching of the molecule.[49] The relation between the coefficient of the polynomial $R(G,x)$ and other invariants of the MG has been discussed.[23] The spectroscopic characteristics of MG have found applications in the theory of the electronic structures of conjugated systems. These questions are considered in greater detail in Section IV.

5. Information Topological Indices

One of the ways of comparing molecular structures in terms of the topological approximation consists in the calculation for each of them the number of structural fragments of a specific type and subsequent comparison of these quantities. Since the structural fragments of one type can differ in terms of some feature, they can be classified further with different degrees of detail. We shall assume that a certain criterion has been selected for the classification, which leads to the subdivision of the set of the chosen structural fragments X, consisting of n elements, into k equivalence classes X_i, and

$$n = \sum_i n_i ,$$

where n_i is the number of elements in the set X_i. Definite information about the molecular structure, which can be characterised quantitatively, is associated with each selection of the numbers $(n_i, \ldots, n_k)$. The quantity n_i/n can be regarded as the probability of finding the fragment from the class X_i in the structural formula of the molecule considered. Therefore, for a quantitative assessment of the information about the molecular structure contained in the set of numbers $(n_1/n, \ldots, n_k/n)$, use is made of the entropy of the distribution of the probabilities $\bar{I}$ and the associated quantity $I = n\bar{I}$, which are calculated from the formulae

$$\bar{I} = -\sum_i \frac{n_i}{n} \log_2 \frac{n_i}{n} , \quad I = \bar{I}n = n \log_2 n - \sum_i n_i \log_2 n_i .$$

The quantities $\bar{I} \geq 0$ and $I \geq 0$ can be used to estimate the degree of inhomogeneity of the set of the selected structural fragments of the molecule. This method of interpretation is based on the following properties of the entropy: for the most inhomogeneous subdivision (i.e. when $n_i = 1/n$, $i = 1, \ldots, n$), the quantity $\bar{I}$ assumes its maximum value, which is $\log_2 n$, while for the most homogeneous subdivision (i.e. when one of the numbers n_i is 1 and all the others become zero), $\bar{I}$ attains its minimum value, which is zero. The function $\bar{I}$ is sometimes referred to as the average information content of the given subdivision and I is the information content of the subdivision. The use of such terminology is associated with the fact that in information theory formulae of a similar type are used to characterise the amount of information contained in a message of a special type. The specification of the number n_i/n can be interpreted as a message about the composition of the set X. Furthermore, the formula for the index $\bar{I}$ is analogous to the expression for the thermodynamic entropy.[51]

At the present time, a series of TI, referred to as the information TI, are used in structural chemistry. All these indices are constructed in accordance with the principle described above: initially a certain set X, consisting of the structural fragments of the molecular graph, is selected and then it is subdivided into equivalent classes X_i and the quantities I and $\bar{I}$, which depend on the chosen set of structural fragments and the criterion constituting the basis of the subdivision of the set X into classes, are calculated. We may note that the methods used to construct quantities of the type I and $\bar{I}$ fit within the general scheme for the construction of TI described in subsection 1. In this case, the set $= (n_1/n, \ldots, n_k/n)$ is an IS and the symmetrical function F has the form

$$F(x_1, \ldots, x_k) = -\sum_i x_i \log_2 x_i .$$

We shall deal brirefly with certain TI of the information type used in the analysis of molecular structures.

(a) Allowance for the atomic composition in the wide variety of types of chemical bonds. The information indices were first used in theoretical chemistry in a study[52] where the assembly of all the atoms of the molecule was considered as a set X and the assembly of atoms of a single type i were treated as the subsets X_i. The degree of inhomogeneity of the elemental composition was characterised by the information-theoretic index I_{at}. Subsequently the index I_{at} was modified;[53] apart from the elemental composition, account was taken also of the valence of the atoms. The inhomogeneity of the molecular structure was then estimated with the aid of the Morowitz formula

$$I_{MOR} = I_{at} + \sum_i n_i \log_2 t_i ,$$

where the numbers t_i are calculated from the valences of atoms of the ith kind. The index I_B, characterising the variety of chemical bonds, was determined analogously:[54]

$$I_B = B \log_2 B - \sum_i B_i \log_2 B_i ,$$

where B_i is the number of bonds of type i (for example, single, double, and triple) and B is the total number of bonds.

(b) Allowance for the symmetry of the molecular graph. It has been suggested[55-57] that the vertices of the graph be subdivided into equivalence classes in such a way that the vertices of different classes cannot be interconverted whatever the automorphism of the graph. For example, it is possible to combine in a single class vertices having the same degrees, the same number of second neighbours, etc. The "finest" subdivision is generated by the orbits of the group of automorphisms of the graph. The information index I_{orb} corresponds to such subdivision into classes. In order to characterise the molecular structure, the sum of the automatic and orbital indices has been introduced:[55]

$$\bar{I}_{RASH} = \bar{I}_{at} + \bar{I}_{orb}.$$

(c) Chromatic information index. The graph G is said to be k-colourable if its vertices can be coloured by k colours in such a way that each vertex has neighbours of another colour only.[11] The vertices of a graph coloured in this way can be divided into non-intersecting classes. The elements of each class have the same colour and are not connected. The smallest number $k = k(G)$ for which k-colouring of the graph is possible is called the chromatic number and the corresponding subdivision into classes is called the chromatic resolution of the vertices.

Suppose that V is the chromatic resolution of the vertices of the graph and $n_i(V)$ the number of vertices in the ith class [$i = 1, \ldots, k(G)$]. The chromatic information index has been introduced:[58]

$$\bar{I}_{chr} = \min_{V} \left\{ -\sum_{i=1}^{k(G)} \frac{n_i(V)}{n} \log_2 \frac{n_i(V)}{n} \right\}$$

and $\bar{I}_{chr}$ and $\bar{I}_{orb}$ have been compared. In particular, it has been shown that, for monocyclic structures of any size, $\bar{I}_{orb} = 0$, since all the vertices belong to the same orbit of the group of automorphisms of the graph, but $\bar{I}_{chr} \neq 0$ for such graphs. However, for certain molecular graphs, $\bar{I}_{chr} = \bar{I}_{orb}$. The chromatic index can be determined analogously also for the edges. Chromatic information indices have been used in the analysis of the properties of alternant hydrocarbons. The conditions for the existence of the Kekulé structure of aromatic hydrocarbons have been formulated in terms of the chromatic indices.[14]

(d) The matrices of the graph and information indices. The set of the elements of the adjoint matrix A of order n, whose elements are zero or one, can be subdivided into two classes consisting respectively of zeros and ones. If n_1 and n_2 are the numbers of elements in these classes and $n^2 = n_1 + n_2$, then the quantity

$$\bar{I}_A = -\sum_{i=1}^{2} \frac{n_i}{n^2} \log_2 \frac{n_i}{n^2}$$

characterises the inhomogeneity of the composition of the set of the elements of the matrix A. The information indices can be constructed analogously for the edge adjacency matrix, the cycle matrix, the incidence matrix, etc.[14,59] Information indices have been used in a number of studies to analyse the structure of IS consisting of the degrees of the vertices $\{v_i\}$ or the distance degrees of the vertices $\{d_i\}$. Any two elements having equal values were assigned to the same class. The information indices corresponding to these subdivisions were denoted by ${}^{V}I_A^E$ and ${}^{V}I_D^E$ respectively. The information index I_{conn},[59] defined on the bases of the edge adjacency matrix, can be constructed analogously: the non-zero elements of the matrix are subdivided, for example, into the orbits of the group of automorphisms of the matrix. If $n_{c,i}$ is the number of elements in the ith orbit and n_c the total number of non-zero elements in the matrix, then

$$\bar{I}_{conn} = -\sum_{i} \frac{n_{c,i}}{n_c} \log_2 \frac{n_{c,i}}{n_c} .$$

(e) The use of compound topological indices for the construction of TI of the information type. Some of the topological indices considered above are represented by the sum of local or integral TI. Such indices can be conveniently referred to as compound. For example, the Wiener (W), Hosoya (Z), and the Randić (χ) indices as well as the Balaban centric index B are compound. New indices of the information type have been derived in a series of studies on the basis of these TI. In their construction, the set of components whose sum yields the initial TI was subdivided into classes in some way. For example, the Wiener index W, which can be written in two equivalent forms, i.e.

$$W = \sum_i i g_i = \frac{1}{2} \sum_{i,j} d_{ij},$$

has been used to construct the indices I_D^W, $\bar{I}_D^W$, I_D^E, $\bar{I}_D^E$, I_D^M, and $\bar{I}_D^M$, which are defined by the following formulae:[14,16,19]

$$I_D^W = W \log_2 W - \sum_j g_j j \log_2 j; \quad \bar{I}_D^W = -\sum_j g_j \frac{j}{W} \log_2 \frac{j}{W};$$

$$I_D^E = \frac{n(n-1)}{2} \log_2 \frac{n(n-1)}{2} - \sum_i g_i \log_2 i;$$

$$\bar{I}_D^E = -\sum_j \frac{2g_j}{n(n-1)} \log_2 \frac{2g_j}{n(n-1)};$$

$$I_D^M = 2W \log_2 2W - \sum_i d_i \log_2 d_i;$$

$$\bar{I}_D^M = -\sum_i \frac{d_i}{2W} \log_2 \frac{d_i}{2W} .$$

In these formulae, g_j is the number of pairs of MG vertices at a distance j and d_i the distance degree of the ith vertex. Analogous expressions have been constructed also for the indices B, Z, and χ, for example:[16]

$$\bar{I}^Z = -\sum_k \frac{p(G,k)}{Z} \log_2 \frac{p(G,k)}{Z} .$$

(f) Information indices and long range effects. As stated in subsection 3 of this Section, TI which depend on the structure of different coordination spheres of the MG vertices (for example, the indices K_l for $l = 2,3$) are used in theoretical chemistry. In this subsection we shall consider a series of information-theoretic indices of analogous types. The definition of these TI is based on the subdivision of the set of graph vertices into equivalent classes, in which the character of the immediate environment of the vertices, including their degree and the multiplicity of the corresponding edges, is taken into account in detail.

Two vertices i and j belong to the same class if, firstly, they correspond to atoms of the same type and have equal degrees; secondly, each of these vertices has the same number of first neighbours $i_1, \ldots, i_m$ and $j_1, \ldots, j_m$; thirdly, there exists a mutually unambiguous mapping of the set of vertices $i_1, \ldots, i_m$ on the set of vertices $j_1, \ldots, j_m$, $i_\alpha \leftrightarrow j_\beta$, for which the vertices i_α and i_β correspond to atoms of the same type; fourthly, the orders of the vertices i_α and j_β are identical, i.e. $\nu_{i_\alpha} = \nu_{j_\beta}$; fifthly, the multiplicities of the edges (i, i_α) and (j, j_β) are identical. Only TI of information-theoretic type have been compared with this type of sub-division of the vertices of the molecular graph into equivalence classes:[60-72] ${}^1IC$ (Information Content), ${}^1SIC$ (Structural Information Content), ${}^1CIC$ (Complementary Information Content), and ${}^1BIC$ (Bonding Information Content), which are defined by the formulae

$${}^1IC = -\sum_i \frac{n_i}{n} \log_2 \frac{n_i}{n}; \quad {}^1SIC = \frac{{}^1IC}{\log_2 n};$$

$${}^1CIC = \log_2 n - {}^1IC; \quad {}^1BIC = {}^1IC/\log_2 q .$$

In these formulae, n is the number of graph vertices, n_i the number of vertices in the ith equivalence class, and q the number of graph edges. The index ${}^1CIC$ characterises the deviation of the topological index ${}^1IC$ from its maximum value ${}^1IC_{max} = \log_2 n$. The differences between other coordination

spheres can be taken into account analogously, which leads to the indices ${}^{k}IC$, ${}^{k}CIC$, ${}^{k}SIC$, and ${}^{k}BIC$;[64] the symbol k characterises the order of the coordination sphere.

Together with the information topological indices ${}^{k}IC$, etc. mentioned above, use is also made of "weighted" information indices[73] based on the subdivision of the graph vertices into the equivalence classes described above. However, in this case a weighting factor equal to the van der Waals volume of the corresponding atom is attributed to each vertex and then the weighting factors of the vertices referring to the same class are added together and the index

$$ {}^{k}IC_v = -\sum_{i=1}^{j} \frac{v_{is}}{v_s} \log_2 \frac{v_{is}}{v_s} \text{ and } v_s = \sum_{i=1}^{j} v_{is} , $$

where v_{is} is the sum of the weighting factors of the vertices of the ith class and j is the number of classes, is calculated. The topological indices ${}^{k}SIC_v$, ${}^{k}BIC_v$, and ${}^{k}CIC_v$ are determined analogously.

We may indicate yet another information index I_{sym}, which is used to characterise the molecular structure but is not topological in the generally accepted sense. The definition is based on allowance for the molecular symmetry and has been proposed in a study[74] where the following criterion of the equivalence of atoms was introduced: the atoms are assumed to be equivalent if they are interconverted by some kind of operation involving the symmetry point group of the molecule.

6. Other Topological Indices

The adjoint matrix of the graph $A = (a_{ij})$ can be used to construct certain other matrices, which are useful in finding new IS and hence also other TI. For example, in the method of potentials, which is used to establish the isomorphism of graphs,[40] the matrices $L = (l_{ij})$ and $H(h_{ij})$, where $l_{ij} = -a_{ij}, (i \neq j)$, $l_{ii} = \nu_i + 1$, and $H = L^{-1}$, are defined. The matrix $D^H = (d_{ij}^H)$ with the elements $d_{ij}^H = 0.5(h_{ii} + h_{jj}) - h_{ij}$ has been introduced.[39] The matrices L, H, and D^H have been used to define new topological indices:

$$ \prod_{i \neq j} d_{ij}^H, \det L, \det H. $$

We may mention several further graph invariants, which are discussed in the mathematical literature[11,23] but which have not so far found application in theoretical chemistry as TI: the numbers of the vertex and edge coverings, the vertex and edge independence numbers, thickness, edge connectivity, deformability, and certain others. In conclusion we may note one other TI for simple graphs, which is known as the minimum binary code.[33] For its construction, each adjoint matrix of the graph is formulated and a single row of length n^2 made up of zeros and ones. Each such row can be regarded as the binary formulation of a certain number. The smallest of all these numbers, corresponding to the adjoint matrices, is in fact referred to as the minimum binary code. We may note that the calculation of such a code for large matrices is fairly laborious.

7. Relation between the Topological Indices and Their Comparison

As shown above, hitherto numerous TI of different kinds have been defined. Most of them have found application in the analysis of molecular structure and in the construction of correlations between structure and property. Some of these TI are linked by simple relations. The examples of such functional relations have been discussed above. Undiscovered relations of some kind probably exist also in many other cases. The results of testing the approximate equalities of the type $T_i = a + bT_j$ for certain pairs of topological indices T_i and T_j have been reported.[75] The constants a and b were fitted by the method of least squares. Such analysis has been carried out for TI of three series of hydrocarbons—alkanes, polyalkylbenzenes, and monocyclic structures. It has been shown[75] that approximate linear relations with a fairly high correlation coefficient r ($0.84 \leq r \leq 0.99$) exist between the indices W, Z, χ, N_2, λ_1, and M_1. On the basis of such an investigation, one can postulate that the indices of one group carry approximately the same information about the structure of compounds of the given classes.

Certain indices, for example, I_D^W and I^Z, can be fitted by second degree polynomials in terms of Hosoya (Z) and Wiener (W) indices as well as other TI.[76]

We shall now proceed to the estimation of the quality of the TI. In coding chemical structures with the aid of TI, it is desirable that different structures should receive different index codes. However, one cannot establish a mutually unambiguous correspondence between the set of square symmetrical matrices, describing the topology of the molecule, and the set of real numbers. It is therefore always possible to select two different structures having the same values of the TI. Consequently, any TI is degenerate with respect to structures of some kind. Topological indices are usually compared in terms of their capacity to "differentiate" compounds of a certain class, i.e. in terms of the degree of their degeneracy. TI are usually employed to differentiate isomeric compounds. For example, the Balaban index $J(G)$[13] is subject to a comparatively small degree of degeneracy. Such degeneracy appears for alkane isomers only in molecules where the number of carbon atoms is greater than 20. In order to obtain TI with a smaller degree of degeneracy, superindices, equal to the sum of simpler TI, or multi-indices, which constitute an ordered sequence of topological indices, are used.[14,47] The question of the degeneracy of different TI has also been discussed in a number of publications.[13,16,77–80]

The effectiveness of 19 TI, used to identify chemical structures, has been investigated.[81] The quantity $e = n/N - t/T$, where n is the number of different values of the index in an assembly of N structures and t and T are the average time of the calculation of the index and the time required to test the isomorphism criterion respectively, has been used as a characteristic of the effectiveness of the TI. Indices defined in the method of potentials[39] and the Randić index[33] have been recognised as the most effective. One TI is regarded as "better" than another (in the estimation of the given physical property) if the correlation equation obtained with its aid is more accurate.

8. Topological Indices as Characteristics of the Shape and Size of Molecules

It has been suggested that certain TI be used to characterise the degree of branching and the shape of molecules.[19] According to intuitive ideas about the degree of branching for a specified number of vertices, the chain and star graphs have the least and most branched structures respectively. In terms of the degree of branching, the remaining structures occupy an intermediate position between them. Certain indices considered above, for example W, χ, B'', λ_1, and ${}^{2}\kappa$ have the property involving their assumption of the smallest (or greatest) value for the chain and of the greatest (or smallest) value for the star.# It has therefore been

#See also L.B.Kier, Quant.Struct.-Act.Relat., 1987, 6, 8.

suggested that they be regarded as measures of the branching of the structure. Another piece of evidence in support of the selection of these branching characteristics is the existence for a number of TI of relations of the type

$$T_j = a + bn + cn_1 + dn_2 \text{ [75]},$$

where n_1 is the number of branching points, n_2 the number of side chains connected to the main chain, and a, b, c, and d are constants.

Topological indices also vary in parallel with molecular size. It has been noted that,[82] for a series of compounds, the van der Waals volume of the molecule varies linearly with molecular refraction (MR) and determines the value of the latter to the extent of 90%. Correlations have been found[82] between MR and TI, i.e. relations of the type $R = a + bT_j$, for 17 TI and it has been concluded that the van der Waals volume can be estimated fairly accurately with the aid of the indices W and M_2 and the two information indices I_D^E and I_D^W.[83]

III. THE USE OF TOPOLOGICAL INDICES FOR THE ESTIMATION OF PHYSICOCHEMICAL PROPERTIES OF COMPOUNDS

The traditional methods for the estimation of physicochemical properties of compounds are based on additive schemes. In the classical theory of chemical structures, it is postulated that certain physicochemical properties of organic compounds (for example, the heat of formation, the boiling point, the polarisability, the dipole moment, etc.) can be calculated as the sum of the contributions ε_i, ε_{ij}, and ε'_{kl}, corresponding to the effective atoms i, the bonds (i, j), and pairs of valence- non-bonded atoms (k, l) of the corresponding molecules.[4] In the simplest case, this approach presupposes a fairly detailed classification of the vertices and edges of the MG and is based on the hypothesis that the contributions ε_x for fragments x of one type are independent of the choice of the molecule of the class under consideration.

This additive scheme for the calculation of molecular properties permits a series of modifications. Thus, one of the versions of additive schemes reduces to the representation of the numerical value y of the given property of a chemical compound by the linear function

$$y = \sum_i a_i k_i,$$

defined on the basis of the corresponding MG. In this formula, the index i characterises a MG fragment of a specific type, which can have a fairly complex structure, k_i is the topological index equal to the number of such fragments, and a_i is the contribution by each fragment of the ith class to the given property; the numbers a_i are independent of the choice of compounds. As an example, we may point out that the heats of formation of alkanes ΔH^0_{298} can be calculated approximately from the formula

$$\Delta H^0_{298}, \text{ (kcal mol}^{-1}) = 16.625 + 4.158N_1 + 1.074N_2 - 0.431N_3,$$

where N_i is the number of paths of lengths i on the MG corresponding to the carbon skeleton of the molecule.[8]

We shall now discuss the results of other studies in which different modifications of the simple additive model have been realised. In most of them, the physicochemical properties of alkanes are discussed. We may note that certain properties of hydrocarbons are satisfactorily correlated with the number of carbon atoms.[84-89] Thus the heats of atomisation and molar refractions of normal alkanes vary linearly and the boiling point and density vary non-linearly with the number of carbon atoms. However, the properties of branched hydrocarbons can no longer be described in terms of the single parameter n, since in this case the degree of branching of the molecule also plays a significant role.[10]§ Wiener has suggested in a number of studies[20,90-93] that properties of alkane isomers such as molar refraction, molar volume, the boiling point, the heat of formation, etc. be described with the aid of equations of the type

$$y - y_0 = a(W - W_0) + b(p - p_0),$$

where y is the numerical value of the given property, W the Wiener index for the MG corresponding to the carbon skeleton of the molecule, p, g_3 the so called polarity number, y_0, w_0, and p_0 are the corresponding characteristics for a normal alkane, and a and b are constants which depend on the property investigated. The value of the index W is interpreted as a quantity characterising the degree of branching of the isomer. For example, the following formula has been obtained[20] for the boiling points of alkanes t:

$$t - t_0, ^\circ\text{C} = \frac{98(W - W_0)}{n^3} + 5.5(p - p_0),$$

where

$$t_0 = 745.42 \log(n + 4.4) - 689.4; \; W_0 = \frac{1}{6}(n^3 - n); \; p_0 = n - 3,.$$

The correlations of the type described above have been analysed,[32] which has led to a conclusion concerning the cases where such indices can be usefully employed. Thus it has been shown that the heat of formation and molar refraction are best described in terms of the invariants f and p (f is the Platt index) and the heat of evaporation, the boiling point, and the molar volume can be most usefully described in terms of the indices p and W. The heats of formation of alkanes are most accurately described by a three-parameter correlation with the indices p, W, and f. Subsequently the Wiener index was used to estimate the properties of other hydrocarbons also. Relations between the Wiener index, on the one hand, and the boiling and melting points, surface tensions, viscosities, densities, and refractions of alkanes, alkynes and alkenes, as well as the boiling points of arenes, on the other have been published.[18,21] The index W has found applications also in other branches of physical chemistry: for the estimation of the width of the forbidden gap in the π-electronic spectra of conjugated micromolecules,[94,95,96] in chromatography,[94,97,98] and in crystal theory.[99,100]

In a number of studies, the Hosoya index has been used to estimate the thermochemical properties of hydrocarbons of this type.[46-48] A linear correlation between the boiling points of alkanes and both the index Z and the index

$$P = \prod_i v_i \text{ [31]}.$$

has been reported.[31] The index Z has also been used to estimate the bond orders and π-electron energies in conjugated hydrocarbons.[101,102]

It has been shown that the octane numbers of acyclic hydrocarbons can be estimated fairly satisfactorily in terms of the centric indices B, B', and B'' (especially the binormalised index B'').[103] The introduction of an additional parameter—the number of carbon atoms or the molecular weight of alkanes—increases the accuracy of the estimate.

Among other TI used to estimate the physicochemical properties of compounds, the connectivity index $^1\chi$ and its varieties, especially $^2\chi$, $^1\chi^v$, and $^2\chi^v$, have enjoyed the greatest popularity. Relations have been obtained[9,10,33,104,105]

between these quantities and various physicochemical properties. We shall quote several examples of such equations. It has been shown [33] that the heat of formation of alkanes ΔH_f^0 can be described approximately by the formula

$$\Delta H_f^0 \text{ (kcal mol}^{-1}) = 12\chi - 11n - 9,$$

where n is the number of carbon atoms in the molecule. An equation relating the heats of atomisation of monohydric alcohols ΔH_a to the connectivity index χ and the number of non-hydrogen atoms n has been published:[10]

$$\Delta H_a \text{ (kcal mol}^{-1}) = -21.926 + 22.275\Delta\chi + 559.975\chi_n,$$
$$(r > 0.9999;\ s = 1.01;\ N = 19)$$

where $\Delta\chi = \chi - \chi_n$ and $\chi_n = 0.5(n-3) + 2^{1/2}$ is the connectivity index for a normal alcohol. It has been noted that the separation of the contributions by the group OH and the carbon skeleton to χ, i.e. the use of two independent parameters χ^{OH} and χ^{C} instead of the sum χ, reduces the standard error s by 30–40%. The density d of carboxylic acids can be estimated in terms of the parameters $1/\chi$ and $^3\chi$ by means of the formula[10]

$$d(\text{g cm}^{-3}) = 0.7546 + 0.4358\chi^{-1} + 0.0252^3\chi \quad (r = 0.983;\ s = 0.014;\ N = 20).$$

Notation. N is the number of compounds and r the correlation coefficient.

The topological index χ proved to be useful in chromatography for the estimation of retention indices.[104,105] However, in this case, together with χ, it is necessary to use also other topological characteristics of the molecule, describing its size, for example, the number of paths of length 3 or the number of six-membered rings in aromatic hydrocarbons.[104]

We shall now proceed to information TI. It has been shown that the Morowitz index I_{MOR} is correlated with the entropies and heats of formation of organic compounds of different classes.[14,106] Equations of the type

$$y = a + bn + cI_D^W + dI_D^W n,$$

where a, b, c, and d are constants, have been used to estimate the molecular volumes and properties of hydrocarbons such as heats of formation, oxidation, and evaporation and the boiling points.[16,94,107] A relation between the index I_D^W for alkylbenzenes and their chromatographic retention parameters has also been reported. Analogous relations have been obtained likewise for the index I_D^E in the case of o-dialkylbenzenes and isoalkanes.[108] The index I_D^M has found an application in the estimation of different thermochemical properties of alkylbenzenes.[109] There is an equation[14] relating the heat of evaporation ΔL_{298} of alcohols and the index I_{orb}:

$$\Delta L_{298} \text{ (kcal mol}^{-1}) = 0.265 I_{orb} + 8.566 \quad (r = 0.989;\ s = 0.414;\ N = 15).$$

A linear relation has been established between the entropies of alkanes, alkenes, alcohols, and organic acids and the information index I_{sym}.[74] Other examples of the use of information topological indices have been discussed in a monograph.[14]

Table 1 summarises data on some of the relations described in the literature between the connectivity indices and various physicochemical properties.

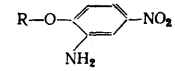
IV. TOPOLOGICAL INDICES AND BIOLOGICAL ACTIVITY

One of the most important applications of TI involves their use to establish quantitative relations between the structure and biological activity of molecules. Biological activity is usually estimated in terms of the molar concentration of the substance necessary to attain a specified level of biological activity. Various parameters are used as characteristics of biological activity, including LD_{50} (or LC_{50}), representing the dose which destroys 50% of the organisms tested, the dose ED_{50} of the antagonist which lowers by 50% the effect of the standard dose of the agonist, the concentration *MIC* of the inhibitor which suppresses the growth of the experimental biological object to a minimal level, the molar concentration I_{50} of the inhibitor which reduces the rate of the enzyme-catalysed reaction by a factor of two, etc.[12] The hydrophobicity parameter lg *P* (*P* is the partition coefficient of the given compound between water and a lipid-simulating phase, usually 1-octanol) as well as the Hammett and Taft constants, reflecting the electronic and steric structures, are most often used as empirical parameters in the study of the relation between structure and activity. An extensive bibliography on the methods used to establish a relation between structure and biological activity has been published[12,40,119] and the principal molecular characteristics used to solve this problem have been described.

Among the TI used to investigate biological activity, the molecular connectivity indices, especially the Randić index χ, have found the most extensive applications. We shall consider certain examples of the use of indices of this type.

A correlation between lg *MBC* and the index χ has been found by Kier et al.[34] from the results of Agin et al.[120] for a series of anaesthetics (aliphatic alcohols, ketones, ethers, amines, phenols, heterocycles, and hydrocarbons):

$$\lg MBC = 3.55 - 0.762\chi \quad (r = 0.983;\ s = 0.390;\ N = 36).$$



Here *MBC* is the minimum blocking concentration of the anaesthetics for isolated muscle or nerve fibres. We may note that a relation between lg *MBC* and the polarisability α has been discovered for the given group of compounds[120] and a correlation has been found[34] between α and χ. These facts have served as the basis of the above equation relating lg *MBC* and χ.

Certain relations between the index χ and biological activity have been discussed.[115,121,122] The discovery of linear correlations between χ and lg *P* and also between lg *P* and the biological activity of aliphatic alcohols made it possible to establish a linear relation between χ and biological activity.[115] The narcotic effect of alcohols on the larvae of certain crustaceans and the inhibition of the movement of tadpoles have been considered as a manifestation of the biological activity of such substances. For aliphatic alcohols, ethers, esters, ketones, and carbamates, relations have been found between the index χ and the non-specific narcotic activities of the above compounds on tadpoles ($N = 36$).[121] The dependence of the non-specific toxic activity of monofunctional alcohols, ethers, and ketones on fungi of a particular species and the index χ ($N = 45$) was considered in the same study. A linear correlation has also been reported[121] between the index χ for a series of compounds and the inhibition of the enzymes succinate oxidase, thymidine phosphorylase, and butyrylcholinesterase. Thus an equation of the following type has been obtained for a series of saturated and unsaturated aliphatic alcohols, ketones, phenols, aniline, and pyridine, which inhibit succinate oxidase:

$$-\lg I_{50} = 0.916\chi - 1.582 \quad (r = 0.966;\ s = 0.169;\ N = 13).$$

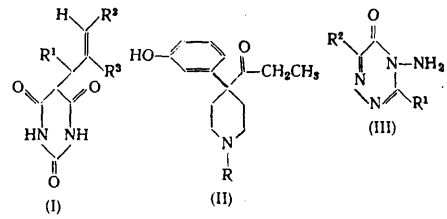
Quadratic correlations between lg I_{50}, lg LC_{50}, and quantities such as lg *P* and χ have also been described. Such correlations have been observed, for example, in estimations of the bactericidal activities of alkylbenzylmethylammonium salts and of the narcotic activities of 5,5-dialkylbarbituric acids on certain animal species.[16,63,122]

Correlations between the connectivity indices and parameter of types of biological activity such as non-specific narcotic activity, enzyme inhibition, bactericidal activity, toxicity, and anaesthesising activity have been examined in a monograph.[10] The possibility of estimating the taste and smell of substances with the aid of topological characteristics of molecular structure has been discussed in the same publication. Thus the relative sweetness *RS* of nitroanilines of the type

is expressed in terms of the parameters $^1\chi$ and $^1\chi^v$ in the following manner:

$$\lg RS = 0.350\,{}^1\chi + 0.694\,{}^1\chi^v - 3.856 \quad (r = 0.953;\ s = 0.222;\ N = 9).$$

According to one of the theories of smell, the smell of a substance is determined by the shape and size of its molecule.[12] It has been suggested[10] that molecular shape be characterised by the parameter χ/n and the hypothesis was put forward that substances having identical smells should have similar values of χ/n. To confirm this hypothesis, a list of structurally different substances having the almond smell and similar values of χ/n is quoted.[10]



Together with the first-order connectivity index, higher-order connectivity indices have been considered in a number of studies.[10,123] For example, the topological index $^2\chi^v$, calculated for phenol derivatives, has been used to analyse their antifungal activity characterised by the parameter *MIC*.

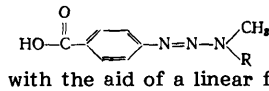
We shall now consider other topological indices. A series of correlations between the indices I_{orb} and I_{sym}, on the one hand, and the inhibition of enzymes, alcohols, and their non-specific narcotic activity and toxicity, on the other, has been discussed in a monograph.[14]

Systematic studies on the "structure–biological activity" problem, based on the information indices *IC*, *SIC*, *BIC*, and *CIC*, have been carried out.[60–73,124] The relation between the structure and toxicity of ethers, characterised by the parameter LD_{50}, has been analysed.[60] The quantities $^1\chi$, $^1\chi^v$, χ^v, *W*, *IC*, *SIC*, *CIC*, I_D^W, and $\bar{I}_D^W$ were used as the TI and it was established that the most suitable structural characteristic among those quoted is the index $^1\chi^v$ in this instance. A correlation equation of the following type has been obtained in terms of the TI:

$$\lg LD_{50} = -0.7207\,{}^1\chi^v - 1.3868 \quad (r = 0.938;\ s = 0.246;\ N = 15).$$

The indices *IC*, *CIC*, $^1\chi$, $^1\chi^v$, I_D^W, $\bar{I}_D^W$, and *W* as well as the parameters lg *P* and the van der Waals volume V_W have been used as structural characteristics to estimate the anaesthesising activities of barbiturates.[61] Four groups of biologically active molecules have been investigated by Basak et al.:[63] alcohols (toxicity); barbiturates (anaesthetic (I); ketobemidones (analgesics) (II), and triazinones (herbicides) (III). There were all characterised with the aid of the indices *W*, *IC*, *SIC*, *CIC*, I_D^W, $\bar{I}_D^W$, $^1\chi$, and $^1\chi^v$.

(I) (R^1,R^2,R^3 = alkyl groups)



(II) [$R = CH_3(CH_2)_n$, where $n = 0, ..., 9$]

(III) ($R^1 = SCH_3$; R^2 = alkyl groups)

It was established that the most convenient structural characteristics in such cases are the indices CIC and $\bar{I}_D^W$ and the most suitable type of functional relation is quadratic.

The indices IC, SIC, and CIC are used to characterise derivatives of piperidine (inhibition of butyrylcholinesterase), barbiturates (hyponotic activity), alkanes (toxicity), aliphatic alcohols (local anaesthesia, narcotic effect on crustacean larvae), and a mixed group of compounds which are tranquillizers.[66-68]

The antitumour activity of triazenes of the type

has been estimated with the aid of a linear function of two variables lg P and ^2BIC.[124] The same type of biological activity has been considered in a study[69] where a wider set of parameters was used, namely lg P, V_W, IC, and SIC. The index SIC is also useful in the analysis of the biological activity of triazinones (herbicides) and N-alkylnorketobemidones (analgesics).[70] The higher-order indices ^kCIC, ^kIC, and ^kSIC, where $k > 1$, have been used[64] to analyse the biological activity and structures of a series of organic compounds. In particular, correlations of the type lg $LD_{50} = ay^2 + by + c$ between the toxicity of barbiturates (LD_{50}) and characteristics such as lg P, W, I_D^W, $\bar{I}_D^W$, $^1\chi^v$, ^2SIC, ^2CIC, and $^1\chi\lambda$ have been described. The most accurate correlation has been obtained using the indices ^2SIC and ^2CIC.

In some of the studies enumerated above, it is emphasised that the use of TI as structural parameters instead of characteristics such as lg P leads to more accurate correlations. The presence of several correlations, obtained in terms of different structural parameters, for the same property makes it possible to identify those which are most significant for the given property. Hypotheses concerning the mechanism of the action of active compounds can be constructed on the basis of such analysis.

The application of the index $^2\kappa$ (see above) in the quantitative estimation of the properties of chemical compounds has been discussed.[142] For example, it has been suggested that the index $^2\kappa$ be used as the characteristic of the molecular shape; it has been shown that, for similar values of $^2\kappa$ (i.e. for similar shapes), the substances have similar smells. A relation has been established between $^2\kappa$ and the bactericidal activity of phenol derivatives with halogenoalkyl substituents:

$$\lg PC = 1.817\,{}^2\kappa - 0.131\,({}^2\kappa)^2 - 2.899 \quad (r = 0.955;\ s = 0.27;\ N = 49),$$

where PC is the minimum concentration of the substance inducing specified biological effects in 10 min. The index $^2\kappa$ has also been used[142] to estimate the sweetness of nitro- and cyano-anilines.

Together with the TI mentioned in this Section, a series of topological indices, originating from the study of the electronic structures and chemical reactivities of biologically active compounds with the aid of topological approximations of quantum chemistry, have also been used in estimating biological activities. This field developed most vigorously in the 1960's and it has been described in detail in a monograph.[125]

V. QUANTUM-CHEMICAL METHODS AS A SOURCE OF TOPOLOGICAL INDICES

1. The Hückel Method and Graph Theory

In the examples considered previously, the TI arose as a rule as a result of the formal analysis of the structure of the molecular graph. Such analysis was supplemented in many instances by qualitative considerations concerning the choice of criteria for the estimation of the degree of branching or compactness of the molecule. In this Section, we shall discuss TI which appear naturally within the framework of certain mathematical models used to investigate the electronic structures of molecules. We shall follow in relation to one such model how the solution of the problem of the electronic structures of conjugated molecules reduces to the analysis of the TI of certain MG.

A molecule with a system of conjugated double or triple bonds contains as a rule a fairly extended planar fragment, which makes it possible to sub-divide the electronic system into two parts—the σ- and π-components—and to investigate each system independently.[125-128] Later we shall consider only the π-electron system assuming that it exists in a certain effective field generated by the atomic nuclei, the electron inner shells, and the σ electrons participating in the formation of localised two-centre σ-bonds. In the case of conjugated hydrocarbons, the number of π electrons is usually the same as the number of carbon atoms forming the conjugated part of the molecule. The structure of the conjugated part can be described by a molecular graph in a simplified form. It is obtained from the complete MG by removing the vertices corresponding to univalent substituents.

The properties of a system incorporating m π electrons are known[125-128] to be described in terms of one-electron energy levels ε_k and the corresponding molecular orbitals

$$\psi_k(r) = \sum_{j=1}^{m} c_j^{(k)} \varphi_j(r),$$

where $\phi_j(r)$ is an atomic $2p_z$ orbital centred on the jth atom of the conjugated part of the molecule. We shall denote by $\mathbf{c}^{(k)}$ the unit vector with the components $c_1^{(k)}, ..., c_m^{(k)}$. Then, in the case of hydrocarbon systems, the vectors $\mathbf{c}^{(k)}$ and one electron energy levels are found by solving the system of equations $H\mathbf{c}^{(k)} = \varepsilon_k \mathbf{c}^{(k)}$, where $H = \alpha E + \beta A$, E is the mth order unit matrix, A the adjoint matrix of the MG describing the conjugated part of the molecule, and α and β are the Coulombic and resonance integrals. For heteroatomic systems, the matrix A must be replaced by the adjoint matrix of the weighted MG.

We shall denote by λ_j (where $j = 1, ..., n$) the eigenvalues of the matrix A arranged in decreasing order. The one-electron energy levels ε_j can be then represented in the form $\varepsilon_j = \alpha + \lambda_j\beta$, where $\beta < 0$. The eigen-vectors of the matrices H and A are identical. The energy of the ground state of the system with an even number of m of π electrons can be calculated in terms of λ_j by the formula

$$\varepsilon_\pi = 2\sum_{j=1}^{m/2} \varepsilon_j = m\alpha + 2\beta \sum_{j=1}^{m/2} \lambda_j .$$

The density matrix P, whose elements are

$$p_{ij} = 2\sum_{k=1}^{m/2} c_i^{(k)} c_j^{(k)},$$

is defined in order to analyse the distribution of electron density. The diagonal element p_{ii} of the matrix P is called the π-electron density at the ith atom, while the non-diagonal element p_{ij}, corresponding to atoms linked by valence bonds, is called the order of the π-bond (i,j). The elements of the matrix P are TI of the local type and in terms of these TI

the formula of the total π-electronic energy of the ground state of a conjugated system containing heteroatoms can be formulated as follows:

$$\varepsilon_\pi = \sum_i \alpha_i p_{ii} + \sum_{i \neq j} p_{ij}\beta_{ij} ,$$

where $\alpha_i = H_{ii}$ and $\beta_{ij} = H_{ij}$ are respectively the Coulombic and resonance intervals. It can be shown[127] that the elements of the matrix P characterise the response of a π-electron system to small perturbations leading to changes in one of the parameters α_i or β_{ij} and can be found as partial derivatives of ε_π with respect to the corresponding parameters α_i and β_{ij}. The use of the topological indices p_{ij} for the interpretation of data on the chemical reactivity of conjugated molecules is based on this property.[127]

In the case of hydrocarbons, the expression for the energy of the ground state ε_π includes as a rule only non-negative eigenvalues λ_j of the corresponding MG. The energy levels ε_j located below the Coulombic integral α correspond to such eigenvalues. The energy levels ε_j satisfying the inequality $\varepsilon_j < \alpha$ are called bonding.[125] The term "antibonding" is used to characterise the energy levels to which $\lambda_j < 0$ correspond. On the other hand, if $\lambda_j = 0$, then $\varepsilon_j = \alpha$; such an energy level is referred to as non-bonding. If the number of bonding orbitals is $m/2$, then it is said that the π-electron system has a closed (in the Hückel sense) electron shell.

The character of the electron shell of conjugated hydrocarbons can be interpreted in terms of the topological index $\omega = n_+(G)/m$, where $n_+(G)$ is the number of positive eigenvalues of the molecular graph G. If $\omega = 1/2$, then the molecule has a closed (in the Hückel sense) electron shell. For $\omega > 1/2$, there is a deficiency of π electrons and, when $\omega < 1/2$, there is an excess of π electrons. The presence of a closed π-electron shell in a conjugated hydrocarbon molecule is attributed to the stability of the π-electron system and the molecule as a whole.[125–127] Qualitative conclusions used[126–139] for *a priori* estimates of the possibility of the existence of chemical compounds are based on this precise hypothesis. The results of studies[135–139] where the problem of the existence of polyhedral C_n carbon clusters is discussed are based to a large extent on the criterion specifying whether or not the electron shell is closed in the Hückel sense.¶

It follows from the data described in this Section that the study of the electronic structure of conjugated systems in terms of the Hückel π-electron approximation reduces to finding a series of invariants of molecular graphs corresponding to conjugated systems. We shall indicate the most important of these quantities: the eigenvalues of the MG $\{\lambda_j\}$, the sum of the positive eigenvalues

$$\lambda_+ = \sum_{\lambda_j > 0} \lambda_j$$

the π-electronic charges on the atom p_{ii}, and the π-electron bond orders p_{ij}. A more complete list of the TI used in the Hückel method can be found in Table 2.

The TI used for the purpose of classification occupy a special place in the theory of conjugated systems. They include, for example, the conjugation energy and the topological resonance energy (TRE). The latter was introduced by Aihara[140] and Gutman et al.[141] and has been used to estimate the relative stabilities and degrees of aromaticity of conjugated molecules. The topological resonance energy is determined in terms of the zero values of the so called acyclic polynomial in the construction of which use is made of the combinatorial properties of the coefficients a_j characterising the polynomial $P(G,x)$ of the molecular graph G. It can be shown[23] that each coefficient a_j represents the sum of the contributions corresponding to special subgraphs of the graph G. Among the subgraphs, there are those which contain cyclic components. We shall denote by a_j' the sum of the contributions introduced into the expression for a_j solely by the subgraphs which do not contain cyclic components. The polynomial $P(G,x)$ with the coefficients a_j' is called acyclic.[141] It has only real roots and is regarded as the characteristic polynomial of the hypothetical π-electron system with the same number of π electrons as in the initial system. The difference between the energies of the ground states of these two systems is called the topological resonance energy. These questions are discussed in greater detail in the review of Graovac et al.[142] Certain new TI used to estimate the degrees of aromaticity[144,145] have been compared.[143]

Table 2. Certain topological indices used in the Hückel method.[126]

Topological index ($m = 2k$)	Name	Application
$\lambda_1, \ldots, \lambda_m$	Eigenvalues of the MG adjacency matrix	Calculation of one-electron energy levels $E_i = \alpha + \beta\lambda_i$; interpretation of photoelectron and UV spectra
$\lambda_+ = \lambda_1 + \ldots + \lambda_{m/2}$	Sum of positive eigenvalues of the MG adjacency matrix	Calculation of the energy of the ground state of the π-electron system ($E_\pi = m\alpha + 2\beta\lambda_+$); estimation of the relative stabilities of the conjugated systems; calculation of the resonance energy
$p_{ij} = 2\sum_{k=1}^{m/2} c_i^{(k)} c_j^{(k)}$	Elements of the density matrix: p_{ii} is the π-electron density at the atom i and p_{ij} at the π-electron bond order	Bond orders—estimation of bond lengths, force constants, and chemical reactivity; p_{ii} elements-estimation of the dipole moments and reactivities
$F_i = N_{\max} - \sum_{j \neq i} p_{ij}$	Free valence index	Used as the reactivity index in radical substitution reactions; $N_{\max}$ is the maximum permissible value of $\sum_{i \neq j} p_{ij}$ for atoms of the given type
$\lambda_{m/2}$, $\lambda_{m/2+1}$; $\{c_i^{(m/2)}\}$, $\{c_i^{(m/2+1)}\}$	The smallest positive and the greatest negative eigenvalues of the MG adjacency matrix and the corresponding eigenvectors	Estimation of the first ionisation potential, electron affinity, and the energy of the first electronic transition; polarography; theory of chemical reactivity

Notation: $m = 2k = N$ is the number of centres in the conjugated systems, where N is the number of π electrons; $\lambda_j \neq 0$ for $j = 1, \ldots, m$.

Various correlations between TI (of the Hückel type) and different physicochemical properties of conjugated molecules have been described fairly completely in monographs.[125–127] The usefulness of the Hückel method for the interpretation of the photoelectron spectra of polycondensed aromatic hydrocarbons has been discussed.[146] It has been shown for more than 250 compounds that the potentials of ionisation from the upper π-energy levels can be fitted with an adequate accuracy (the standard deviation does not exceed 0.1 eV) by analytical

¶ See also D.J.Klein, W.A.Seitz, and T.G.Schmalz, Nature, **1986, 323, 703.**

expressions whose form is determined by the one-electron energy levels and the bond orders.

Quantities such as the eigenvalues of the MG, the elements of the density matrix, and other characteristics of the molecular systems can be readily calculated with the aid of a computer. However, these data, many of which have been compiled in handbooks (see, for example, Streitwieser and Brauman[147]), are difficult to interpret directly in structural terms. Nevertheless such interpretation is of interest for the understanding of the sources of the appearance of definite functional relations between the structure of the molecule and its properties. The field associated with the search for relations between the results of Hückel calculations and clear characteristics of molecular graphs has therefore developed fairly vigorously in recent years.[142] For example, a complete series of approximate formulae of different degrees of complexity has been obtained for the sum of the positive eigenvalues of the MG, which, as mentioned above, is linearly related to the total π-electronic energy. A catalogue of the most convenient of these together with estimates of their accuracy has been published.[148,149] Analogous formulae have been obtained for the maximum eigenvalue and also for the difference between the smallest positive and greatest negative eigenvalues of the adjoint matrix.[150–152] The latter quantity is of interest for the estimation of the spectroscopic characteristic of conjugated molecules.

The mathematical model of the electronic structures of unsaturated molecules described in this Section can be extended also to the case where it is necessary to take into account all the valence electrons (for example, to saturated systems). One of the possible extensions has been proposed in studies[153,154] where the investigation of the electronic structure of molecules in terms of the valence approximation reduces to the analysis of the spectroscopic characteristics of weighted graphs of a special type. The vertices of these graphs correspond to different hybrid orbitals constructed from atomic functions of the *s* and *p* types.

2. Relations between Certain Topological Indices of the Quantum-Chemical Type

As mentioned above in Section II, a series of TI are linked by simple functional relations. Some of these relations are empirical and have been established by the method of least squares. Similar relations have been obtained in a number of studies[10,95,96,155–158] between certain topological indices defined in the Hückel method and indices which do not have a direct bearing on the method (such as, for example, the connectivity indices, the Wiener numbers, and others). It has been shown[155] that, for conjugated hydrocarbons, the first-order connectivity index $^1\chi^v$, determined from the formula

$$^1\chi^v = {\sum_{i,j}}' (\delta_i^v \delta_j^v)^{-1/2},$$

is fairly satisfactorily correlated with the total π-electronic energy. In this formula $\delta_i^v = z_i^v - h_i$, where z_i^v is the number of valence electrons of the *i*th atom and h_i the number of univalent substituents of the given atom. Relations of an analogous type have been established[156] between the charges on the atoms and the Mulliken bond orders obtained by the extended Hückel method for aliphatic hydrocarbons, on the one hand, and the atomic connectivity indices χ_i^v, found from the formula

$$\chi_i^v = \frac{1}{2}{\sum_{j}}' (\delta_i^v \delta_j^v)^{-1/2},$$

on the other. Such formulae are useful, since they make it possible to imitate fairly simply the results of calculations of the electronic structure of molecules by MO methods, which cannot be carried out without using modern computers.

A series of TI appear naturally when another quantum-chemical method is used—the valence bond method[159] and some of its modifications.[144,145] Methods of this type are based on the construction of a many-electron wave function in the form of a linear combination of many-electron basis functions of a special type. In the case of the π-electron approximation, where only the π orbital is taken into account for each atom, a certain spin pairing scheme for the π electrons associated with the corresponding carbon atoms corresponds to each basis function. This scheme can be described in terms of the graph theory. Only electrons corresponding to atoms linked by valence bonds are usually combined in pairs. Each such scheme is described by a Kekulé graph. It consists of a set of connected two-vertex subgraphs MG (edges), which cover the vertices of the initial graph and have no common vertices in pairs. The Kekulé graph can be related to a structural formula with single and double bonds. Suppose that an approximate wave function ψ_k corresponds to each such structural formula. Then the total wave function ψ can be formulated as the linear combination

$$\psi = \sum_k a_k \psi_k.$$

The numbers a_k are called the weighting factors of the structures and are treated as variational parameters. The procedure described above is usually employed to investigate the stability of bicyclic benzenoid hydrocarbons and their heteroanalogues. On the basis of qualitative considerations, it can be shown that, among the isomers of benzenoid hydrocarbons, the greatest stability should be shown by the isomer to which corresponds the greatest number of Kekulé structures.[159]

The following procedures are used to estimate the bond strength. The number of all the Kekulé structures is found. Then the edge, for example (i,j), corresponding to a bond C–C in the initial molecule, is selected in the MG. Next this edge together with the edges incident with it are excluded from the MG. We shall denote the number of Kekulé structures in the graph obtained in this way by k_{ij}. The ratio $\tilde{p}_{ij} = k_{ij}/k$ is called the Pauling bond order.[160,161] It has been established that, for alternative hydrocarbons not containing four-membered rings and non-bonding energy levels (which is equivalent to the validity of the inequality $\det A \neq 0$, where A is the adjoint matrix), this quantity can be calculated from the formula

$$\tilde{p}_{ij} = \sum_{\lambda_k > 0} c_i^{(k)} c_j^{(k)} / \lambda_k,$$

where $c_i^{(k)}$ are the components of the *k*th eigenvector of the adjoint matrix A. The quantity on the right-hand side was introduced by Ham and Ruedenberg[161] and is called the Ham and Ruedenberg bond order. A number of other relations between TI, used in various quantum-chemical methods, have also been discussed (see, for example, Hosoya and Hosoi[157]).

The examples presented in Sections II and V show that there are simple relations, determined ultimately by the combinatorial properties of the initial MG, between TI which are at first sight of different nature. The search for various systems of independent TI, in terms of which it would be possible to calculate any other TI, is therefore of interest. The solution of this problem would make it possible to construct various correlations more effectively and with better justification and to predict the properties of compounds which have not yet been synthesised.

---o0o---

Two main aspects of the problem of topological indices can be distinguished. The first is associated with the development of effective methods for the coding of molecules, which is of great interest in connection with the use of information-search systems for different purposes. The second aspect refers directly to the search for sets of structural fragments of molecules which are responsible for the manifestation of particular physicochemical properties of concrete compounds and to the discovery of regularities in the character of their variation.

It appears at first sight surprising that the properties of a substance can be predicted with the aid of simple mathematical models of the kind described in this review. However, experience shows that the properties of many chemical compounds, whose molecules have "like" structural fragments, are indeed similar. Furthermore, one should bear min mind that, in selecting the coefficients a_i in functional relations of the type

$$y = a_0 + \sum_i a_i k_i,$$

between the numerical values of a certain property and the structural characteristics expressed in terms of TI, one takes into account implicitly not only the geometrical parameters of individual molecules (more precisely certain average characteristics) but also the features of the structure of the substance as a whole. The same property can be described in terms of different TI, which leads to unlimited possibilities for the search with the aid of computers for relations between changes in the properties of a substance and the topological characteristics of the molecular structure.† In practice, preference should be given to simpler and more accurate relations which can be used even when it has not been possible to justify reasonably the relations discovered. In his Nobel Lecture, Richard Feynman said "the only true physical description of a phenomenon involves the interpretation of the significance of the quantities in an equation from the standpoint of the experiment or, more precisely, a method of applying equations to experimental results. Once this is admitted, then the best way of creating a new theory is to guess at equations without paying attention to physical models or a physical explanation".[164] From our point of view, the method of topological indices is precisely such an approach, which makes it possible to "guess" equations relating structure to property in those fields of structural chemistry where a sufficiently reliable theory has not yet been developed or the applications of a theory encounter considerable computational difficulties.

Lanthanide Oxide Sulphides

Yu.L.Suponitskii, G.M.Kuz'micheva, and A.A.Eliseev

A systematic account is given of the methods of preparation of oxide sulphides having the composition Ln_2O_2S (where Ln = lanthanide, Sc, or Y) in the form of polycrystalline materials, single crystals, thin films, and ceramics. The crystal-chemical, thermal, thermodynamic properties of the oxide sulphides are considered.
The bibliography includes 117 references.

I. INTRODUCTION

Compounds having the composition Ln_2O_2S, where Ln = lanthanide, Sc, or Y, are known for all the lanthanides without exception and also for scandium and yttrium. They occupy an intermediate position between the oxides and sulphides of the corresponding elements. All these groups of compounds are structurally related as regards either their crystal lattices or individual structural fragments. The practical aspects of the application of lanthanide oxide sulphides have attracted in the first place the continued attention of investigators and a broad spectrum of materials based on them have already been created: powders (ceramics), single crystals, thin layers, and films.

The polycrystalline oxide sulphides or solid solutions based on them, in the first place lanthanum oxide sulphide activated with Nd, Er, Tm, and Yb, are highly effective anti-Stokes phosphors (with green and blue glow) and can be used, in the form of phosphor coatings emitting in the IR part of the spectrum, to make light emitting diodes, digital and alphanumeric indicators and indicator panels, and colour television. In the USSR and other countries, methods have been developed for the growing of single crystals of lanthanum oxide sulphide activated with Nd, Er, and Yb. Combined studies on such single crystals—structural, optical, mechanical, and spectroscopic (the luminescence characteristics of laser emission)—have demonstrated their likely usefulness by the creation of low-threshold microlasers and unified light diodes. However, the difficulties in the growing of single crystals of a high quality have not as yet been overcome.

This review is devoted to the consideration of the questions concening the formation of point defects in the oxide sulphide and their thermal and thermodynamic properties, which will fill the existing gap in the literature.

II. METHODS OF SYNTHESIS

Apparently the first lanthanide oxide sulphide obtained was lanthanum oxide sulphide. Subsequently extensive patent literature appeared on the methods of synthesis of the oxide sulphides and phosphors based on them.

Studies by investigators in many countries, especially France, the USA, Finland, the USSR, etc., have been devoted to the methods of preparation of the oxide sulphides and have found extensive applications in the technology of phosphors. The methods of synthesis are distinguished by wide variety. All the known procedures reduce in essence to two schemes which are chemically fundamentally different. In the first scheme, the sulphur is introduced into the initial sulphur-free oxygen compound of the lanthanide by some kind of sulphur-containing reagent, as a rule a sulphide or elemental sulphur. In the second scheme, the initial sulphur-containing lanthanide compound is reduced, oxidised, or decomposed to the oxide sulphide. We shall consider the existing methods of synthesis of oxide sulphides in conformity with the schematic arrangement which we have proposed.

1. The Introduction of Sulphur into Lanthanide Oxide Compounds

The introduction of sulphide sulphur can be achieved by treatment with various compounds, using elemental sulphur,[1-6] hydrogen sulphide,[2,3,7-10] carbon disulphide,[11] sulphides,[5,7] ammonium or sodium thiocyanate,[5] and thioacetamide[11] (Table 1).

In the general form, the chemical reactions take place in accordance with the scheme

$$Ln_2O_3+RS\rightarrow Ln_2O_2S+RO\,,$$

where R is the group of the "sulphiding" agent. Depending on the conditions and the reagents, one of the variants of the solid-phase, liquid-phase, or gas-phase syntheses is achieved.

When elemental sulphur is used, lanthanide oxides are treated with its vapour in an inert medium in one or two stages.[1-6] In the latter case, the synthesis is carried out initially at low temperatures (400–450 °C), which is then followed by annealing at 500–800 °C (Table 1). Oxide carbonates, oxalates, formates, etc. can be used instead of the oxide.[1]

When sulphur is introduced with the aid of carbon disulphide, it is also possible to obtain oxide sulphides, but these not only contain admixtures of substances which have failed to react but are also contaminated with carbon.[11-13] The introduction of sulphur by hydrogen sulphide in a stream of argon (nitrogen) with added water vapour is carried out at higher temperatures (1100–1150 °C)[1-3,8,9] and, in the case of CeO_2, at 1300 °C.[3]

The introduction of sulphur by gaseous reagents, which takes place at the solid–gas interface, leads to the appearance of a sulphide sulphur concentration gradient in the

bulk of the oxide sulphide grain, to its non-uniform content in particles of different size, and also to the formation of non-stoichiometric phases.

Table 1. Preparation of the oxide sulphides by the "sulphiding" method.

Initial compound	"Sulphiding" agent	Side products	t °C	τ, h	Medium	Refs.

Y_2O_3	Y_2S_3	Y_2S_3	1000	100	vacuum	[5]

Notation: t is the temperature and τ the duration of the synthesis. [a] The synthesis is carried out in two stages. [b] The method is used in industry. [c] The temperature of the synthesis of Ce_2O_2S is 500 °C. [d] Ln = Gd—Lu or Y; the temperature and the duration of the synthesis depend on the nature of Ln. [e] The yield of the oxide sulphide is 35%. [f] The temperature of the synthesis of Lu_2O_2S is 780 °C. [g] The yields of lanthanum, praseodymium, neodymium, samarium, and europium oxide sulphides are 95—98%; Ce_2O_2S and Pm_2O_2S were not investigated.

The degree of conversion increases significantly when the synthesis is performed in the melt of the "sulphiding" agent. A mixture of the lanthanide oxide with sulphur and sodium carbonate is heated at 1100 °C.[14—19] The reaction begins with the formation of sodium polysulphides from sodium carbonate and sulphur. These polysulphides melt and then introduce the sulphur into the lanthanide oxide with formation of the oxide sulphide. An advantage of the method is the evolution of carbon dioxide on decomposition of sodium carbonate, the dioxide protecting the oxide sulphide against oxidation. The method of introducing sulphur into oxides by sodium sulphite in an inert medium is closely related to the above procedure.[20] At high temperatures, sodium sulphite disproportionates to the sulphate and the sulphide, the melt of the last compound reacting with the lanthanide oxide. The maximum yield of the oxide sulphide (88—95%) is obtained at 1100 °C, after 1 h, and for the ratio $Na_2SO_3 : Ln_2O_3 = 4 : 1$. The reactivity of the oxide in the "sulphiding" reaction depends on the position of the metal in the series of lanthanides. Manashirov and Semikhova[20] divided the oxides into three groups in terms of their reactivities: the maximum reactivity is shown by the oxides of elements ranging from lanthanum to gadolinium, which form oxide sulphides at 1100 °C; ytterbium, lutetium, cerium, and yttrium oxides, which form appreciable smounts of oxide sulphide only at 1350 °C, have been assigned to the second group; the oxides of the remaining lanthanides produce a mixture of the oxide sulphide and the oxide which failed to react at 1100 °C.

The oxide sulphides are also obtained by the sealed tube method, the oxides being heated in an excess of thioacetamide at 1200 °C.[11] In the solid phase, the "sulphiding" agent is as a rule the sulphide of the same lanthanide.[5,7,21—24] The mixture of pressed oxide and sulphide, with 20% excess of the latter, is sintered for a long time at 1300—1500 °C in a medium protecting from oxidation (*in vacuo*). The oxide sulphides obtained by this method must also be freed from the excess sulphide. The oxide sulphide having the composition $Ce_4O_4S_3$, namely $Ce_2^{3+}Ce_2^{4+}O_4S_3$, in which the cation has a mixed valence, can be obtained by the sealed tube method in which sulphur is introduced into CeO_2 by the Ce_2S_3 + S mixture at 550—600 °C.[22] Analysis of the method based on the introduction of sulphur into the oxygen compound of the lanthanide shows that the oxide sulphides formed are as a rule contaminated and that they must be subjected to additional purification in order to remove the initial compound which failed to react, or side products.

2. The Reduction of Sulphates and Sulphites

A widely used method of synthesis of the oxide sulphides involves the reduction of lanthanide sulphates, oxide sulphates, or sulphites with hydrogen,[25—33] carbon monoxide,[34—42] or natural gas[29] (Table 2). When sulphates are used, oxide sulphates are formed initially and are then reduced in accordance with the scheme

$$Ln_2O_2SO_4+4CO \rightarrow Ln_2O_2S+4CO_2.$$

If the lanthanide can exhibit an oxidation state of +2, then the sulphate is reduced consecutively: initially to $LnSO_4$, according to data for $Eu_2(SO_4)_3$,[37] then to $Ln_2O_2SO_4$, and finally to Ln_2O_2S. The reduction can be carried out either by the pure reductant or by its mixture with an inert carrier (argon, nitrogen). During the synthesis, the sulphur

Table 2. Preparation of the oxide sulphides by reducing sulphates and sulphites.

[a] Natural gas (550—650 °C) was also used as the reductant. [b] Eu_2O_2S is not formed under these conditions.

oxides are reduced to elemental sulphur. An advantage of the method considered is the high rate of reaction and the relatively low temperatures of the synthesis, particularly when sulphites are used (Table 2). A single-phase product not requiring additional purification is then formed. Evidently the method can be applied in a continuous process. When the nitrogen–hydrogen mixture is used, there is no harmful waste.

3. The Oxidation of the Sulphides

The formation of oxide sulphides has been observed in the oxidation of lanthanide sulphides in air.[6,43–47] The partial oxidation of Ln_2S_3 by treatment with a mixture of water vapour and air leads to the formation of a mixture of the oxide sulphide with the sulphide and the oxide, but, at a rigorously fixed temperature, it has been possible to obtained the stoichiometric lanthanum oxide sulphide by the method of vapour phase hydrolysis.[48] The formation of oxide sulphides has been established in the oxidation under relatively mild conditions of thin films of LnS or Ln_2S_3.[46,47] The oxide sulphides are also formed *in vacuo* or in an inert medium if there is an admixture of oxygen[21,46–49] (Table 3). The formation of the oxide sulphides in the oxidation of the sulphides with sulphur(IV) dioxide[31] and carbon dioxide[4,12,50] has been noted.

[a] The sulphides of the yttrium subgroup elements are oxidised to the oxides.
[b] The intermediate $Ce_2O_2S_2$ is formed in the oxidation of CeS.
[c] Prolonged heating.

A special method of synthesis of the oxide sulphides having a non-stoichiometric composition has been proposed.[51,52] In the thermal decomposition of the thiocarbamide complexes of lanthanide acetates and propionates in an inert medium, the thiocarbamide group rearranges to the thiocyanate group and oxide sulphides having the compositions $Ln_2O_{2.6}S_{0.4}$ and $Ln_2O_{2.4}S_{0.6}$ are formed at 300–335 °C. The stoichiometric oxide sulphides are produced when homogenised mixtures of the metal carboxylate and thiocarbamide, taken in proportions of 1:3, are heated for 1 h at 300–320 °C. The product, which is contaminated with carbon, must be heated in a stream of dry CO_2 at 600–650 °C.

Thin films of the oxide sulphides, for example, Sm_2O_2S, are formed as a result of the deposition of $(CH_3)_4C_6H_{10}Sm$ + S from the gas phase at 700 °C onto a SiC support.[53] Ceramic specimens of the oxide sulphides can be obtained by heating pressed Ln_2O_2S powders at 700–1300 °C and a pressure of $(9.8–19.8) \times 10^4$ kPa for 1–5 h.[19]

Apparently lanthanum oxide sulphide was the first compound of this kind to be obtained in the single crystal state.[54] The greatest advances in this field have been achieved at the end of the 1970's and the beginning of the 1980's.[24,55–60] Different versions of the method of direct recrystallisation from solution in the melt (the Bridgman–Stockburger, Czochralski, etc. methods) are used to obtain the single crystal, the procedure involving the creation in the crucible of an inert gas counterpressure (with argon or an argon–hydrogen mixture at a pressure of 300–1500 kPa).

4. Mixed Oxide Sulphides

Oxide sulphides containing two and more lanthanides have been known for a fairly long time and are obtained by the same methods as the oxide sulphides of the individual lanthanides. However, during the last decade there has been much interest in the mixed oxide sulphides containing, apart from the traditional lanthanide, also another element, as a rule a *d* or *p* element, whose chalcogenides are used to a greater or lesser extent to prepare semiconducting materials.

The methods of synthesis of such mixed oxide sulphides are based on the familiar procedures for the preparation of "simple" compounds.[61] Mixed lanthanide oxide sulphides containing Cu(I), Ag(I), Ga, In, Ge(IV), Sn(IV), Pb(II), As(III), Sb(III), Bi(III), Cr(III), and V(III) as the second element have been synthesised hitherto.[62,63]

III. CRYSTAL-CHEMICAL PROPERTIES

1. Crystal Structure

Compounds having the general formula $(LnO)_nX$, containing the lanthanide and oxygen (Ln = lanthanide, X = oxygen, chalcogenide, halide, carbonate, orthoborate, etc. ions), have a common feature involving the presence in the structure of the $(LnO)_2^{2+}$ "complex ion", first considered by Caro.[64] This complex has a tetrahedral structure. The oxygen atom is at the centre of the tetrahedron in the sp^3-hybridised state and the corners of the tetrahedron are occupied by lanthanide ions. However, the "complex ion" cannot be identified in all the compounds containing a lanthanide and oxygen. Kuz'micheva et al.[65] specified a series of conditions for the presence or absence of such an ion in the compounds $(LnY)_2X$. The main one is the existence in the structure of different crystallographic positions for the X and Y atoms.

By combining with one another, the $(Ln_4O)_n$ tetrahedra form layers. Laruelle[66] noted that two structures of the layer are possible (Fig.1): a trigonal structure in which the triangular base of each tetrahedron is parallel to the layer, and a tetragonal structure in which the orthogonal edges of the tetrahedron are located in the planes bounding the layer. Thus the entire wide variety of the structural types of the lanthanide oxide chalcogenides is ensured by different types of alternation of the anionic lattices with layers of the $(Ln_4O)_n$ tetrahedra oriented either in accordance with the trigonal law, as happens in La_2O_2S, or in accordance with the tetragonal law, which obtains in Nd_2O_2Te. The different structures arise as a result of the formation of a superstructure, monoclinic or orthorhombic distortions, and also displacements.

A relation which makes it possible to determine the symmetry of the tetrahedral layers constituting the basis of a

particular compound has been derived[65] from the close packing principles:

$$0.78 < \frac{r + R_t}{r + R_o} < 0.96 ,$$

where r is the ionic radius of the lanthanide for a coordination number of 7 and R_t and R_o are the oxygen radii for coordination numbers 4 and 6 respectively.

If the ratio of the sums of the radii is less than 0.78, compounds of the type $(LnO)_2X$ crystallise in structural types based on the tetragonal symmetry of the layer; if it is in the range 0.78–0.96, then they are based on trigonal symmetry, and if the ratio is greater than 0.96, then the "complex ion" cannot be identified in the compound containing a lanthanide and oxygen.

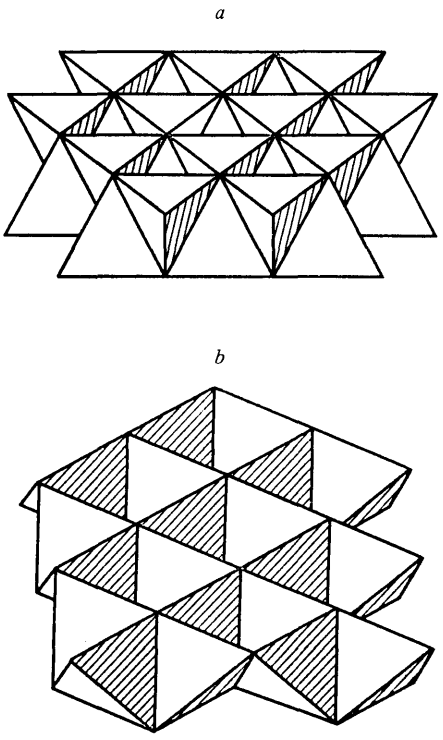

Figure 1. Trigonal (*a*) and tetragonal (*b*) construction of the $(LnO)_n^{n+}$ layer in the La_2O_2S and Nd_2O_2Te structure respectively.[62]

The structure of the lanthanide oxide sulphides having the composition Ln_2O_2S is based on a tetrahedral layer with trigonal symmetry and they are all isostructural for the entire series of lanthanide metals.[17] The structure of La_2O_2S can be derived from that of Ce_2O_3 by replacing an oxygen atom in the octahedral environment by a sulphur atom.[67] Fig. 2 presents projections of the La_2O_2S structure onto the xy and yz basal plane and also the coordination polyhedra around the La atoms.

Investigators have frequently attempted to refine the structure of Ln_2O_2S. One of such refinements has been carried out by means of the X-ray diffraction analysis of La_2O_2S : Nd single crystals, obtained by Czochralski's method,[55] on an autodiffractometer.[64] Polycrystalline Ho_2O_2S [69] and Nd_2O_2S [70] have been investigated by neutron diffraction at 300 and 4 K respectively. The thermal and positional parameters were refined as in the previous study. The large error in the determination of the thermal isotropic factors or even their negative values in the case of Nd_2O_2S can be explained by the presence in the specimen of a second phase, namely $Nd_2O_2S_2$:[70] no explanation has been found for Ho_2O_2S.[69] An attempt has been made to refine the multiplicity of the positions of sulphur in Ho_2O_2S.[70] The desirability to refine the populations of the different positions by sulphur atoms was justified by the possibility of the partial substitution of sulphur by oxygen. It was found that the population exceeds the multiplicity [number?] of the positions occupied, which can be in no way accounted for by the substitution of sulphur by oxygen. Nevertheless the refinement of the sulphur content made it possible to reduce somewhat the R factor.

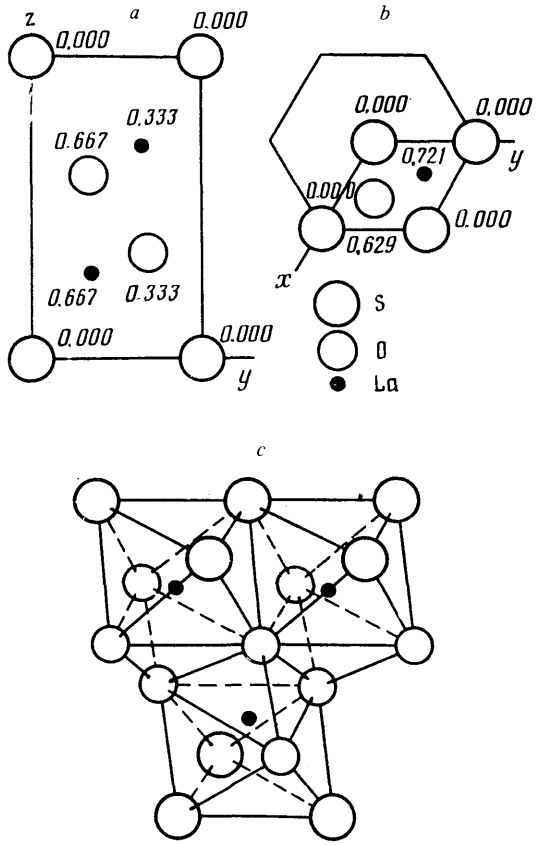

Figure 2. Projection of the La_2O_2S structure onto the yz (*a*) and xy (*b*) planes and the interlinking of the polyhedra around the La atoms (*c*). The numbers indicate the height along the $x(z)$ axis.

The structures of La_2O_2S : Ln single crystals, obtained by the modified Stockburger–Bridgman method,[57] have been investigated[71,72] on an autodiffractometer. According to the X-ray diffraction data, the crystals have a deficiency of sulphur and the metal, while the population of the oxygen sites is excessive.[71] Allowance for the partial incorporation

of sulphur in the oxygen sublattice and for the incorporation of oxygen in the sulphur sublattice (on the assumption that the sites are filled to the maximum extent) made it possible to reduce the *R* factor and to obtain crystal-chemically acceptable formulae of the compounds.[72] In the calculation of the difference electron density, a maximum was observed for the 0 0 1/2 site. This region of "concentrated" electron density was interpreted as interstitial atoms of neutral sulphur, occupying approximately 5% of these positions. However, one cannot rule out the possibility that lanthanum ions (or the ions of another lanthanide) are located at a low concentration in these positions.† These results were confirmed by the study of La_2O_2S : Ln single crystals by the chemical and neutron activation methods and by hydrostatic weighing.[72]

Thus crystal-chemical formula of lanthanum oxide sulphide can be written in the general form

$$La_{2-x}[\ ]_xO_{2-y}[\ ]_yS_{1-z}[\ ]_z\,(S_w^0)$$

where [ ] denotes vacancies here and henceforth. The formation of the principal point defects in La_2O_2S can be described by the following equation (in terms of the Kröger–Wink notation[73]):

(a) Schottky disordering reaction;

$$0 \rightleftarrows 2V_{La}^{\cdot\cdot\cdot} + 2V_O^{\cdot\cdot} + V_S^{\cdot\cdot}.$$

(b) Frenkel' disordering reaction:

$$La_{La}^{x} + V_i^{x} \rightleftarrows La_i^{\cdot\cdot\cdot} + V_{La}^{\prime\prime\prime},$$

$$S_S^{x} + V_i^{x} \rightleftarrows S_i^{x} + V_S^{x}.$$

(c) Interfacial reactions at the crystal–vapour interface:

$$S_S^{x} \rightleftarrows 0.5S_2(gas) + V_S^{\cdot\cdot} + 2e^{\prime},$$

$$O_O^{x} \rightleftarrows 0.5O_2(gas) + V_O^{\cdot\cdot} + 2e^{\prime}.$$

(d) Antistructural defects or atoms at "foreign" sites:

$$S^{x} + V_O^{x} \rightleftarrows S_O^{x},$$

$$O^{x} + V_S^{x} \rightleftarrows O_S^{x}.$$

In the equations the dots, primes, and crosses denote positive and negative charges and neutral atoms respectively.

In principle there is a possibility of the formation of partly ionised or neutral defects[74] (for example, apart from the $V_S^{\cdot\cdot}$, $V_O^{\cdot\cdot}$, and $V_{La}^{\prime\prime\prime}$ forms, the vacancies can exist as $V_{La}^{\times}$, $V_{La}^{\prime\prime}$, $V_{La}^{\prime}$, $V_S^{\times}$, $V_S^{\cdot}$, $V_O^{\times}$, and $V_O^{\cdot}$). In this case the equations for defect formation presented here are supplemented by others. It has been shown[75,76] that, under the influence of pressure, the lanthanum oxide sulphide specimens change colour: at a low pressure, the colour of the specimens becomes pink, i.e. a colour centre, the so called *F*-centre $(V_S^{\cdot}, e^{\prime})^{\times}$, is formed.

The results obtained for the defect formation have served as the basis of the mechanisms of diffusion in lanthanum oxide sulphide# and also of a high-speed method for the determination of the composition and the extent of defect formation according to X-ray diffraction data.§

2. The Region of Homogeneity

The La–O–S ternary system has not so far been fully investigated. The phase regions and the phase crystallisation conditions are unknown. Only the liquidus line for the compositions of the La_2S_3–La_2O_3 quasi-binary section (Fig.3),[77] having two maxima, has been determined. One of the maxima corresponds to La_2O_2S with a melting point of 2080°, which agrees well with the value found previously (2070 °C).[54] The second maximum corresponds to the composition La_2OS_2, which melts at 1960 °C.

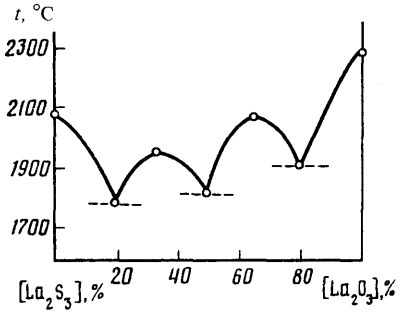

Figure 3. The liquidus in the La_2S_3–La_2O_3 system.[77]

In a study of the La_2S_3–La_2O_3 system,[78] the specimens were obtained by the method inovlving the solid-phase sintering of lanthanum sesquioxide and sesquisulphide *in vacuo* or in an atmosphere of argon (pressure 1–2 atm) at 1100–1200 °C for 4 h. A broad region corresponding to the existence of the lanthanum oxide sulphide phase having the composition

$$La_{2\pm x}O_{2\pm y}S_{1\pm z}$$

was established from the X-ray diffraction data. In the region of homogeneity, the plots of the variation of the lattice periods (Figs.4*a* and 4*b*) have a point of inflection corresponding to the composition La_2O_2S. The decrease in the periods on passing from La_2O_2S to La_2O_3 can be associated both with the subtraction of sulphur and metal via the

$$La_{2-x-2/3}[\ ]_{2x}O_2S_{1-x}[\ ]_x,$$

mechanism and with the substitution of sulphur by oxygen: $La_2O_2(S_{1-x}O_x)$. In the composition range La_2O_2S–La_2S_3, the decrease in the lattice period can be explained by the subtraction of oxygen and the metal, i.e.

$$La_{2-x-2/3}[\ ]_{x-2/3}O_{3-x}[\ ]_xS,$$

and also by the substitution of oxygen by sulphur, i.e. $La_2(O_{2-x}S_x)S$. The type of the solid solutions was established by measuring the density of the test specimens. Its variation within the limits of the region of homogeneity corresponds exactly to the substitution mechanism (Fig.4*c*). The composition $La_2O_{2.14}O_{0.86}$ corresponds to the boundary of the region of homogeneity on the La_2O_3 side, while the composition $La_2O_{1.71}S_{1.29}$ (1100 °C, 0.1 Pa) corresponds to the boundary on the La_2S_3 side (Fig.4*a*). At 1200 °C, the boundary specimens have the compositions $La_2O_{1.81}S_{1.18}$ and $La_2O_{2.09}S_{0.91}$ (Fig.4*b*), but one can hardly speak of a narrowing of the region of homogeneity with increase in temperature, because the results obtained vary within the limits of the accuracy of the phase analysis. Furthermore, there are

§See G.M.Kuz'micheva, I.V.Perepelkin, and A.A.Eliseev, Zhur.Neorg.Khim., 1986, **31**, 2527 [Russ.J.Inorg.Chem., 1986(10)].

no grounds for the assumption that the defect-free crystal lattice with fully occupied atomic sites corresponds to the composition La_2O_2S.

Analysis of studies on the Ln–S–O systems, where Ln ≠ La, can also be of definite interest.[21,104] One of these has been devoted to the investigation of the Dy–S–O system in the region of homogeneity of dysprosium oxide sulphide.[21] Homogeneous specimens of dysprosium oxide sulphide having the general formula $Dy_2O_{2+x}S_{1+x}$ were synthesised by heating in a vacuum furnace (p < 0.1 Pa) mixtures of Dy_2O_3 and Dy_2S_3 at 1300 °C for 5 h and at 1600 °C for 3 h. The region of homogeneity in the temperature range 1300–1600 °C (for quenched specimens) hardly varies and extends from 19 (in the case of $Dy_2O_{2.05}S_{0.95}$) to 23 at.% of sulphur ($Dy_2O_{1.85}S_{1.15}$). The variation of only the period c was observed in this composition range, while the period a remains constant within the limits of the error of the determination (±0.003 Å). This character of the variation of the lattice parameter of Dy_2O_2S with the sulphur content indicates the formation of substitutional solid solutions in the concentration range indicated.

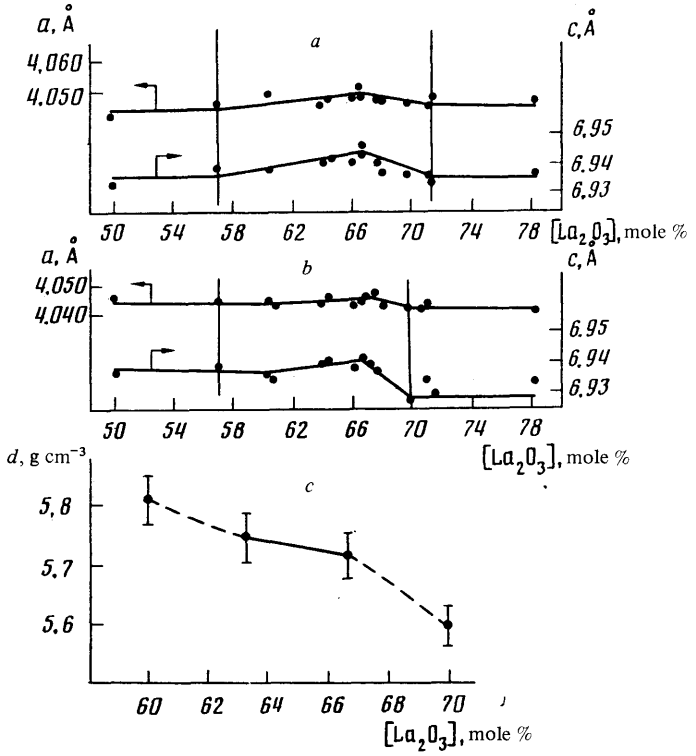

Figure 4. Variation of the lattice periods (a, b) and of the densities (c) of lanthanum oxide sulphide at 1100 °C (a) and 1200 °C (b and c) *in vacuo* along the La_2S_3–La_2O_3 section.[78]

IV. SOLID SOLUTIONS IN THE Ln'_2O_2S–Ln''_2O_2S SYSTEM

A number of studies[8,29,40,79–81] have been devoted to solid solutions of the type $(Ln', Ln'')_2O_2S$. In particular the La_2O_2S–Ln_2O_2S systems, where Ln = Nd, Sm, Eu, Gd, Dy, Yb, Lu, or Y, have been examined.[40] Total miscibility has been observed only in the La_2O_2S–Nd_2O_2S and La_2O_2S–Sm_2O_2S systems, while in the remaining systems there are two-phase regions. The possibility of the existence of solid solutions is determined by the ratio of the ionic radii: a continuous series of solid solutions are formed for

$$[R(La^{3+}) - R(Ln^{3+})]/R(Ln^{+3}) < 9\%$$

Apart from the $(La, Ln)_2O_2S$ systems, Leskela[38] also investigated systems based on yttrium oxide sulphide: Y_2O_2S–Nd_2O_2S and Y_2O_2S–Eu_2O_2S (Fig.5). The above dimensional criterion is valid also in this case: in the former system ($\Delta R/R$ = 9.2%), a limited miscibility is observed, while in the latter ($\Delta R/R$ = 5.2%) the miscibility is complete. The specimens for the investigations were prepared by the reduction of coprecipitated lanthanide sulphates with carbon monoxide at 800 °C.

It has been stated[40] that the limit of the two-phase regions as well as the lattice period depend on the method of preparation of the $(Ln', Ln'')_2O_2S$ powders. Indeed the miscibility in the La_2O_2S–Y_2O_2S specimens obtained by "sulphiding" in a stream of $0.2H_2S + 0.8N_2$ (1200–1250 °C) a homogeneous mixture of coprecipitated lanthanide oxide powders[79] is somewhat different from that in the analogous system described by Leskela and Ninisto.[40] This difference cannot be explained by the different temperature of the synthesis, because the two-phase region does not become narrower on raising the temperature from 800 °C [40] to 1200 °C [79] and its width remains unchanged, the region being merely displaced towards La_2O_2S. On the other hand, the lattice periods of individual oxide sulphides in the La_2O_2S–Gd_2O_2S system, found in the above two investigations,[40,79] are identical, although a different value has been obtained for the La_2O_2S–Y_2O_2S system.

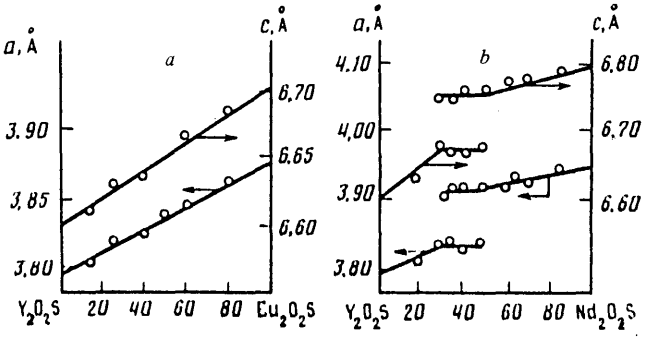

Figure 5. Variation of the lattice periods as a function of the composition of the Y_2O_2S–Eu_2O_2S (a) and Y_2O_2S–Nd_2O_2S (b) systems.[40]

Completely different results for the miscibility of the oxide sulphides have been published in a study[88] where the existence of a continuous series of solid solutions in the La_2O_2S–Ln_2O_2S systems (Ln = Pr, Eu, or Yb) was discovered. The $(La, Pr)_2O_2S$ solid solutions were obtained by oxidising a mixture of the polysulphides in a stream of $H_2 + H_2O$ (3 vol.% H_2O) for 3–4 h at 520 °C. The $(La, Eu)_2O_2S$ and $(La, Yb)_2O_2S$ specimens were obtained by introducing sulphur in the liquid phase into the corresponding solid solutions of the oxide carbonates (500–700 °C, 4–5 h). The lattice periods of the individual oxide sulphides in these systems, quoted in the above investigations,[40,79] are the same within the limits of experimental error and the temperatures of the synthesis are similar.

An attempt has been made[82] to calculate the binodal curve for the decomposition of the solid solutions in the La_2O_2S–

Ln_2O_2S systems by the method of Urusov and co-workers[83,84] in order to elucidate the influence of various factors on the width of the region of homogeneity. The calculation is based on the principle that the Gibbs free energy of mixing tends to a minimum, which also determines the state of equilibrium in the isomorphous mixture; the vibrational and configurational entropies were taken into account. This calculation made it possible to explain the discrepancies between the limits of miscibility in the La_2O_2S–Ln_2O_2S systems and to demonstrate the marked dependence of the limits of the region of homogeneity on the method of preparation of the solid solutions, which determines the common structural unit and the degree of defectiveness of the initial components.

V. THERMAL AND THERMODYNAMIC PROPERTIES

The oxide sulphides Ln_2O_2S occupy an intermediate position, as regards composition, in the Ln_2S_3–Ln_2O_2S–Ln_2O_3 series. They differ from the sulphides by a greater thermal stability in an oxidising medium but are greatly inferior to the oxides in this respect. The thermal stability of the oxide sulphides in an inert medium (argon) has been determined for both the individual and the erbium-, ytterbium-, and neodymium-activated lanthanum oxide sulphide.[85,86] Lanthanum oxide sulphide is stable up to 1450 °C, but, starting from 1500 °C, when the specimens have been maintained for 1 h under the given conditions, the stoichiometry of the oxide sulphide phase changes. At higher temperatures the oxide sulphide evaporates and dissociates; the composition of the gas phase is complex and has not been established unambiguously. Fused lanthanum oxide sulphide is gradually depleted in sulphur and its loss reaches 30% after the melt has been allowed to stand for 5 h.[55]

The thermal properties of the oxide sulphides on heating in an oxidising medium (air) have been studied by many investigators.[30,81,87–93] It has been established by various methods of thermal analysis (thermogravimetric, derivatographic measurements, and differential thermal analysis) that the oxide sulphides are oxidised by air directly to the oxide sulphates $Ln_2O_2SO_4$. However, it has been observed by the derivatographic method that praseodymium, europium, and gadolinium oxide sulphides are oxidised in air in two stages.[90,92,93] The oxidation of Gd_2O_2S in the first stage is accompanied by the formation of an intermediate oxide sulphite phase having the composition $Gd_2O_2SO_3$. Presumably, the oxide sulphite is formed initially as an intermediate in the oxidation of praseodymium and europium oxide sulphides. The oxide sulphites of the above metals are stable within a narrow temperature range and are oxidised to the oxide sulphates at a higher rate than the oxide sulphides.[92] The fact that the formation of the oxide sulphites has not been observed in all the cases investigated confirms their thermal instability. In pure oxygen, the oxidation of oxide sulphides is rapid. The temperatures of the onset of the activation of Ln_2O_2S and the temperature ranges where these compounds are oxidised to the oxide sulphates differ by 80–100 °K in the above studies, which can be explained by the different purities of the specimens, the different conditions in their preparation (disc or powder), and the different methods of investigation, i.e. the specific features of the study of the heterogeneous system under non-equilibrium conditions.

The temperature ranges of the stability and of the onset of oxidation of lanthanide oxide sulphides are arranged systematically in Table 4. Overall, the polycrystalline lanthanide oxide sulphides are stable in air up to 450–500 °C, but Ce_2O_2S begins to oxidise already at temperatures above 180 °C.[7] The rate of oxidation at the beginning of the process is low, but, above a certain temperature limit which depends on the type of the lanthanide, it increases sharply. The temperature of the onset of oxidation increases in the sequence La_2O_2S–Lu_2O_2S, Y_2O_2S, occupying an intermediate position in the middle of the series. The oxide sulphates, the final sulphur-containing products of the oxidation of the oxide sulphides, are more stable; their stability decreases in the sequence La–Lu, Y occupying the position after Dy. When the rate of heating is reduced from 10 to 1 K min^{-1}, the temperatures of the onset of the oxidation of La_2O_2S and Y_2O_2S decrease from 765–770° to 620–640 °C. The stability of the oxide sulphides is influenced by the degree of crystallinity of the specimens. After they have been kept in an inert medium (nitrogen), the temperature of the onset of oxidation increases by ~100 K and the rate of oxidation falls.

Table 4. The oxidation temperatures of the lanthanide oxide sulphides.

Notation: t_o is the temperature of the onset of oxidation and t_d the decomposition temperature of the oxide sulphate.

[a] The composition of a continuous solid solution is quoted.
[b] The composition of a solid solution with limited miscibility is quoted.
[c] Two-stage oxidation.

The thermal oxidation of solid oxide sulphide solutions depends on the type of the solid solution (Table 5). The continuous solid solutions (Eu_2O_2S–Y_2O_2S) are oxidised as individual compounds. The temperature of the onset of

oxidation then diminishes with increase in the content of the less stable component and the temperature limits of the stability of the oxidised phase increase, i.e. a dependence of the thermal stability on the mole fractions of the components of the pseudobinary system is observed. The solid solutions with limited miscibility (when the difference between the ionic radii of the lanthanide is greater than 10%) are oxidised to the oxide sulphates in two stages and the oxide sulphate phases also decompose into two stages.

In view of the instability of the oxide sulphides in oxidising and inert media at elevated temperatures, the determination of their melting points involves considerable experimental difficulties. The melting points of many oxide sulphides are therefore either unknown or have been determined with inadequate accuracy. The melting points indicated in the literature (Table 6) indicate, with the apparent exception of the melting point of La_2O_2S, the temperature range of the fusion of oxide sulphates rather than characterising the individual compounds.

Table 6. The melting points of the oxide sulphides.

The phase equilibria in the oxide sulphide systems have been studied only for the La–S–O system.[77,94] The equilibrium compositions of the La_2O_3(B), LaS_2, La_2S_3, $La_2O_2SO_4$, La_2O_2S, and $La_2O_2S_2$ phases coexisting at 800 °C have been established[94] (Fig.6). These data confirm the formation of La_2O_2S, detected previously in a study of the T–x section of the diagram for the La_2S_3–La_2O_3 system.[77] The above studies[77,94] are at present the only fundamental investigations which have been made on the phase equilibria in the oxide sulphide systems.

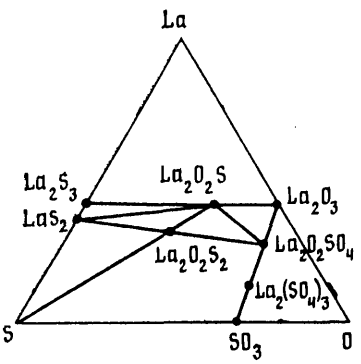

Figure 6. Isothermal section through the phase diagram for the La–S–O system (at 1073 K).[94]

The knowledge of the thermodynamic properties makes it possible to determine the conditions under which perfect oxide sulphide single crystals can be grown, for example, from their melts. Since the melts dissociate with evolution of gases which also contain elemental sulphur, the thermodynamic parameters are essential for calculations of the equilibrium pressure of the gas phase over the melt.

In an experimental study of the thermochemical properties of the oxide sulphides, it has been established that,[93,97–99] in a sulphuric acid solution of cerium(IV) sulphate, the oxidation proceeds in accordance with the equation

$$Ln_2O_2S(cryst.) + Ce(SO_4)_2(soln) + H_2SO_4(soln) \rightarrow$$
$$Ln_2(SO_4)_3(soln) + Ce_2(SO_4)_3(soln) + S_{orthorhomb} + H_2O(soln).$$

The enthalpies of these reactions have been measured by calorimetric methods and the standard enthalpies of formation of lanthanum, praseodymium, neodymium, and samarium oxide sulphates have been determined. The enthalpies of formation of europium and gadolinium oxide sulphates listed in Table 7 were calculated from the enthalpies of solution of the compounds in aqueous hydrochloric acid saturated with hydrogen sulphide (Table 7). The calculated enthalpies of formation of the oxide sulphides[100,101] differ from the experimental values by 85–100 kJ mol^{-1}. Consequently the theoretically deduced probable dissociation reactions of La_2O_2S [102] and the excess pressure of the gas phase over the melt necessary in order to be able to grow single crystals must be regarded as approximate.

[a] Approximate entropies obtained by different workers.
[b] The adjustment of the values of Δ_fH^0(298.15 K) and $\Delta_fG^0(T, K)$ for self-consistency is impossible owing to the lack of the temperature variation of the heat capacities of Ln_2O_2S and $Ln_2O_2SO_4$; the calculation of Δ_fH^0(298.15 K) from the temperature variation of $\Delta_fG^0(T, K)$ is also impossible for the same reason.

A tensimetric study of the CeO_x–CO–SO_2 equilibrium[103] and of the Eu_2O_3–H_2S–H_2–CO system[10] made it possible to calculate for the reactions

$$2CeO_2(cryst.) + 4CO(gas) + SO_2(gas) \rightarrow Ce_2O_2S(cryst.) + 4CO_2(gas)$$
(900–1400 °C)
$$4EuS(cryst.) + 2O_2(gas) \rightarrow 2Eu_2O_2S(cryst.) + S_2(gas)\ (900°).$$

the equilibrium pressures of the gaseous components and the Gibbs free energies of formation of cerium and europium oxide sulphides, which are also listed in Table 7.

The oxidation of the oxide sulphides in accordance with the equations

$$Ln_2O_2S(cryst.) + 2O_2(gas) \rightarrow Ln_2O_2SO_4(cryst.),\ Ln = Ce, Y;$$

$$Ln_2O_2S(cryst.) + 0.5O_2(gas) + 2Ag(cryst.) \rightarrow Ln_2O_3(cryst.) + Ag_2S(cryst.),$$
$$Ln = La, Nd\text{-}Dy,$$

has been studied thermodynamically by an e.m.f. method using an oxygen ion solid electrolyte based on zirconium oxide.[105-110] The temperature dependence of the Gibbs free energy of the first of the above reactions has been found. The thermodynamic properties of the oxide sulphides (Table 7) and their enthalpies of oxidation (Table 8) were calculated by the present authors from the relations obtained. The values found made it possible to plot thermodynamic diagrams for the coexistence of the oxide, sulphide, and oxide sulphide phases[111-115] as a function of the partial pressures of O_2 and S_2 (Fig.7).

Table 8. The enthalpies of the oxidation of the oxide sulphides via the reactions $0.5\ Ln_2O_2S(cryst.) + O_2(gas) \rightarrow 0.5Ln_2O_2SO_4(cryst.)$.

[a] Estimated quantities.
[b] At 1285 K.
[c] At 1380 K.

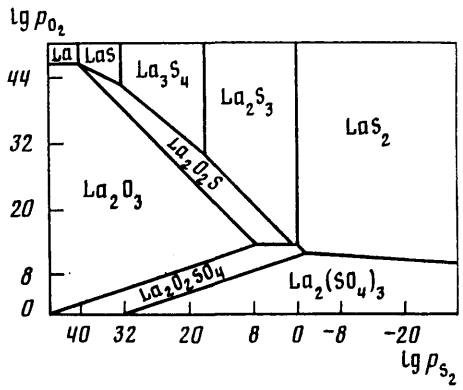

Figure 7. Isothermal section through the phase diagram for the La–S–O system (at 1100 K).

The standard entropies of the oxide sulphides have been estimated in a number of studies.[93,97,116,117] The values obtained have been used to calculate standard thermodynamic functions (Table 7) and, in particular, the Gibbs free energies, from which the equilibrium constants and the equilibrium vapour pressures of sulphur necessary for the selection of optimum conditions for the growing of perfect single crystals were calculated.

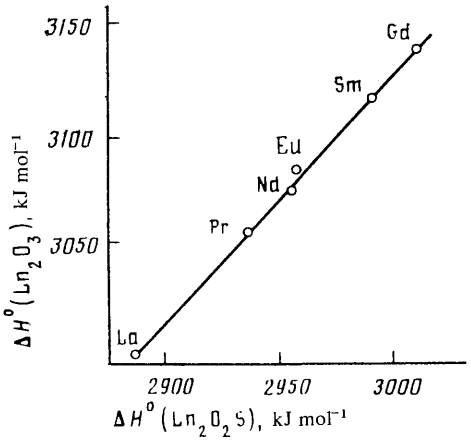

Figure 8. Relation between the crystal lattice energies of the lanthanide oxides and oxide sulphides.

Comparison of the thermodynamic functions of the oxide sulphides, sulphides, and oxides shows that the energies of formation of the compounds increase in the sequence Ln_2S_3–Ln_2O_2S–Ln_2O_3. This sequence agrees in principle with the increase in thermal stability and melting points. The rule of additivity does not then hold when sulphur is replaced by oxygen. Thus the complete oxidation of the sulphide to the oxide ($La_2S_3 + 4.5O_2 \rightarrow La_2O_3 + 3SO_2$) results in the evolution of 120 kJ per mole of S, while the oxidation of the oxide sulphide to the oxide ($La_2O_2S + O_2 \rightarrow La_2O_3 + SO_2$) is accompanied by the evolution of 100 kJ per mole of S. Analogous thermodynamic properties in the series of lanthanide oxides and oxide sulphides vary in parallel, which is illustrated, in particular, in Fig.8.

---o0o---

As can be seen from the data presented, the methods of synthesis and the crystal chemistry of the oxide sulphides have been investigated fairly completely. The thermodynamics of the lanthanide, scandium, and yttrium oxide sulphides have been investigated to a lesser extent. There are no consistent values of the principal thermodynamic functions and no reliable melting points, which could be used to characterise newly obtained compounds. Bearing in mind the applied importance of the oxide sulphides, namely their generally established application in the technology of phosphors, as well as the possible new fields where they may be used in the desulphurisation of metallic melts and steels and in the removal of sulphur and its gaseous compounds (H_2S, SO_2) from furnace gases and gaseous fuel, the necessity for further investigation of the high-temperature chemistry and thermodynamics of the oxide sulphides becomes understandable.

Oxidative Condensation of Methane—a New Pathway to the Synthesis of Ethane, Ethylene, and Other Hydrocarbons

Kh.M.Minachev, N.Ya.Usachev, V.N.Udut, and Yu.S.Khodakov

During the last five years, the chemistry of methane has been enriched by the possibility of obtaining C_2 and other hydrocarbons as a result of the oxidative condensation of methane in the presence of a series of catalytic systems. The availability of the starting materials (CH_4 and O_2) leads to extensive prospects for the replacement of the petroleum raw materials by natural gas in single-stage syntheses of valuable compounds and in the first place ethylene. This review gives a systematic account of the results of the selection of effective catalysts and surveys the information leading to the elucidation of the mechanism for the formation of the products of the extensive oxidation and oxidative condensation of methane. The bibliography includes 118 references.

III. The mechanism of the oxidation reactions of methane 227

I. INTRODUCTION

Methane has long attracted the attention of chemists as the starting material for the synthesis of valuable products,[1] but its high stability hinders its processing.[2] At the present time the bulk (more than 90%) of the natural gas extracted is used as fuel, although there exist industrial methods for the conversion of methane into a synthesis gas, chloro-derivatives, and acetylene.[3] The activation of CH_4 molecules, for example, for the manufacture of acetylene, is achieved at high temperatures (about 1500 °C),[1] which is due to the thermodynamic factors governing this process.

In connection with the problem of involving methane in chemical reactions studies[4-6] on its activation under comparatively mild conditions by transition metal complexes are of considerable interest. Thus at 90–120 °C and a methane pressure of 100 atm, methane is oxidised in an aqueous solution of $PtCl_4^{2-}$ and $PtCl_6^{2-}$ to CH_3OH and CH_3Cl with stoichiometric reduction of platinum(IV) to platinum(II).[4] Studies[6] on the oxidation reactions of methane under the influence of oxygen, especially its oxidation to methanol and formaldehyde, have a clear-cut practical purpose.[6] In the presence of one of the most active molybdenum-containing catalysts at 450 to 500 °C and a pressure of 50 atm, the yields of CH_3OH and CH_2O relative to the methane which has reacted reach 50–75% and 4–8% respectively for an overall conversion of methane up to 3.5%. Methods for the gas-phase oxidation of methane by atmospheric oxygen with added initiators (nitrogen oxides) are also known,[6] but the low yield of the target products hinders their practical application. In order to increase the selectivity of the formation of methanol and formaldehyde, it has been suggested[6] that N_2O be used as the oxidant, which makes it possible to avoid the extensive oxidation of methane, although the degree of conversion of the latter does not then increase and amounts to ~2%.

In the oxidation of methane with N_2O in the presence of high-silica zeolites, the formation of aliphatic and aromatic hydrocarbons is observed at a reaction temperature of 300 to 600 °C.[7-12] The dependence of the yield of hydrocarbons of different classes on temperature and on the degree of elimination of metal cations from zeolites shows that methanol, the primary methane oxidation product,[8] undergoes reactions characteristic of catalysis by high-silica zeolite (HSZ).[7] It is noteworthy that the replacement of N_2O by oxygen under the same conditions leads to the formation of the products of the extensive oxidation of methane.[8] Studies[13-15] on the oxidative coupling of methane to substances whose molecules contain methyl groups (toluene, acetonitrile) are of interest; this results in the formation of vinyl derivatives (styrene, acrylonitrile). As in the previous case, oxygen-containing methane oxidation products (CH_3OH, CH_2O) probably enter into the coupling reaction, but their yield is unfortunately low.

A new aspect of the methane chemistry arose as a result of studies by Mitchell[16-18] and Keller and Bhasin[19] in which C_2 and other hydrocarbons were detected after methane had been allowed to come into contact with the oxides of a number of metals at temperatures above 600 °C. The formation of, for example, ethane under these conditions takes place via the oxidative condensation of methane:

$$2CH_4+[O]\rightarrow C_2H_6+H_2O\,.$$

The participation of oxygen (in the given instance of the oxygen from the oxide, which plays the role of a solid oxidant) is an essential condition for the elimination of thermodynamic limitations to the formation of the C–C bond from the CH_4 molecules.[19]

The results of the above studies[16-19] stimulated research into the oxidative condensation of methane, which has led to the discovery of a direct pathway to the preparation from natural gas of a number of hydrocarbons and especially ethylene, whose synthesis had been based hitherto on the processing of petroleum raw material. The present review surveys and gives a systematic account of the results obtained in the selection of catalytic systems for the oxidative condensation of methane and analyses data concerning the conditions and mechanisms of the reactions leading to the formation of C_2 and other hydrocarbons from methane.

II. CATALYSTS OF THE OXIDATIVE CONDENSATION OF METHANE

The deliberate search for effective catalysts of the effective condensation of methane, which has been prosecuted simultaneously by many research groups in the USSR, Japan, the USA, and the Federal Republic of Germany, established the principal features of the catalytic reactions of methane in the presence of systems of different chemical composition. Among the catalysts investigated, three main classes, embracing oxide systems, oxide systems with alkaline additives, and catalysts containing halogen compounds, may be

distinguished. This classification reflects not only the greater complexity of the catalytic systems but also takes into account their greater effectiveness in the formation of C_2 and other hydrocarbons in the oxidation reactions of methane.

1. Oxide Systems

The results of a systematic study[19] of the oxidative condensation of methane in the presence of various oxides deposited on α-Al_2O_3 in amounts of 5–10 wt.% were published in 1982. The reaction was carried out in the presence of catalysts subjected to preliminary treatment with oxygen. The highest activity in the formation of C_2 hydrocarbons (ethane and ethylene) was shown by manganese, thallium, cadmium, and lead oxides (Table 1). Catalysts containing Zn, Ti, Zr, Mo, Fe, Cr, W, Cu, Ag, Pt, Ce, and V proved to be less active. According to the authors,[19] the reaction proceeds with participation of the oxygen from the oxide, as a result of which CH_3 species are formed on the surface of the catalyst, whose interaction leads to the formation of C_2H_6 molecules. Ethane can in its turn undergo oxidative dehydrogenation to ethylene. In order to regenerate the oxide after it has been in contact with methane, it must be treated with O_2-containing gas at the reaction temperature.

Table 1. The activities of certain metal oxides deposited on α-Al_2O_3 in the oxidative condensation of methane to ethane and ethylene at 800 °C[19]

Metal	Conversion of CH_4, %		
	w.r.t. C_2 hydrocarbons	CO_x	total
Initial carrier	0.2	1.6	1.8
Mn	5.0	6.0	11.0
Cd	4.0	6.0	10.0
Sn	0.4	8.0	8.4
Tl	3.0	3.8	6.8
Pb	2.0	2.6	4.6
Bi	0.4	4.0	4.4

The syntheses of C_2 hydrocarbons from methane under conditions where methane, an inert gas, and O_2 are supplied in succession have been proposed in patents.[20–30] Antimony, germanium, bismuth, lead, indium, and manganese oxides deposited on SiO_2 were used as catalysts, which functioned essentially as solid oxidants. At 700–800 °C the conversion of methane and the selectivity in the formation of C_2 hydrocarbons were 0.25–1.06 and 38.5–83.3% respectively. The successive introduction of the reactants into the catalytic zone evidently prevents the attainment of a satisfactory efficiency of the process, although the selectivity with respect to the C_2 hydrocarbons is relatively high.

Hinsen and Baerns,[31–34] investigated the possibility of the oxidative condensation of methane in the presence of O_2 on Pb-, Bi-, Sb-, Sn-, and Mn-containing catalysts. Among these systems, 34 wt.% PbO/γ-Al_2O_3 proved to be the most active catalyst. In its presence at 750 °C and for methane and O_2 contents in the reaction system of 50.9 and 5.2 vol.% respectively, the overall yield of C_2H_6 and C_2H_4 was about 5%. With increase in the PbO concentration in the catalyst, the selectivity in the formation of methane condensation products also increases (Fig.1), which has been attributed to the blocking of the acid centres on the carrier responsible for the extensive oxidation of the hydrocarbons.[34] The surface area of the catalyst also depends on the PbO content, diminishing from 166 $m^2\ g^{-1}$ (for the pure carrier) to 6 $m^2\ g^{-1}$ in the presence of 47 wt.% PbO/γ-Al_2O_3, which is evidently induced by the sintering of the catalyst at the reaction temperature. The influence of the nature of the carrier on the stability of the lead catalysts has been noted.[35] The use of aluminium and titanium oxides makes it possible to obtain systems whose catalytic properties do not change after use for 20–25 h; the lifetime of the SiO_2-based catalyst is significantly shorter, which is due to the loss of lead compounds and the sintering of the catalyst.

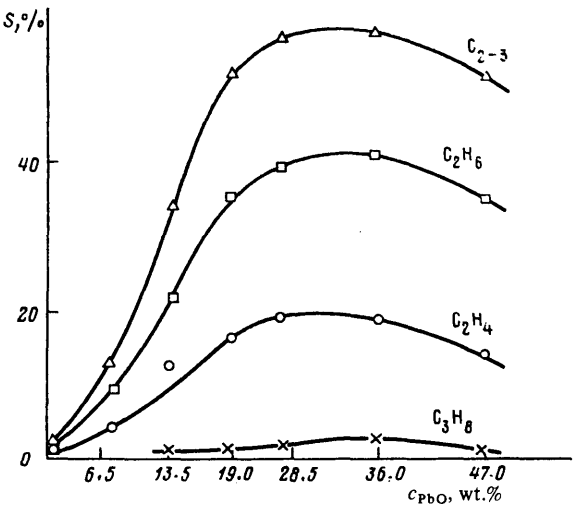

Figure 1. The selectivity S in the formation of the products of the oxidative condensation of methane in the presence of PbO/γ-Al_2O_3 with different contents c_{PbO} of PbO;[80] T = 740 °C; p_{CH_4} = 70.9 kPa; p_{O_2} = 7.1 kPa.

The increase in the process selectivity in the presence of lead systems is promoted by the increase in the reaction temperature and in the CH_4: O_2 ratio.[31] Together with C_2 hydrocarbons, the reaction products contain very small amounts of formaldehyde and propene; the extensive oxidation products were represented mainly by carbon dioxide. Only in the case of Sb_2O_3/SnO and Mn/Al_2O_3, which accelerated mainly the extensive oxidation process, did the selectivity in the formation of CO exceed 5%.[31]

Minachev et al. showed[36,37] that the efficiency of the manganese systems in the oxidative condensation of methane can be significantly increased by replacing the γ-Al_2O_3 carrier by silica gel. In the presence of Mn/SiO_2 containing the optimum amount of manganese in the form of the oxide (10 wt.%), at 750 °C and a volume flow rate ν of the supply of the gaseous mixture of 1000 h^{-1}, and for the CH_4: air = 0.65 molar ratio, the conversion of CH_4 into C_2H_4 + C_2H_6 is 6.3%.[36] The possibility of the oxidative condensation of methane in the presence of Mn/SiO_2 has been confirmed.[38] Although PbO/γ-Al_2O_3 [31] and Mn/SiO_2 [36] have similar activities with respect to the overall yield of C_2 hydrocarbons, they differ appreciably as regards selectivity in the formation

of ethane and ethylene. The $C_2H_4 : C_2H_6$ molar ratio exceeds 1.3 for the manganese catalyst, while for the $PbO/\gamma\text{-}Al_2O_3$ catalyst it is in the range 0.23–0.95. Overall, the composition of the C_2 hydrocarbons formed depends, as will be shown below, not only on the nature of the catalyst but also on the reaction conditions.

The study of the catalytic properties of a large group of pure oxides at 700 °C, for the low $O_2 : CH_4 = 0.022$ molar ratio, and for a high dilution of the reaction mixture with helium (82%) established the following activity series: Sm > Pb > Bi > Ho > Gd > Fr > Tm, Yb, Y > La, Nd, Eu, Dy, Lu, Ca > Zn > Pr, Tb, Ce, Sc, Ge, In, Sn. Under these conditions, the lanthanide oxides exhibit a selectivity with respect to C_2 hydrocarbons greater than 75% and for the most active Sm_2O_3 the selectivity reaches 93%. It is noteworthy that in the presence of Sm_2O_3 the yield of C_2 hydrocarbons does not diminish even after the catalyst has been used for 180 h.[39] The appreciable activity of lanthanide oxides has been confirmed (for Sm_2O_3 and La_2O_3) by a number of data.[40–44] It has been observed that the efficiency of La_2O_3 increases after the addition of alumina[44] and increase in the fraction of the amorphous phase of the catalyst. According to Imai et al.,[44] the active centres for the oxidative condensation of methane are linked to aluminium ions dispersed in La_2O_3.

The ability of systems based on alkaline earth metals to accelerate the synthesis of C_2 hydrocarbons from methane has been demonstrated in a number of studies.[45–50] For the individual magnesium, calcium, strontium, and barium oxides, a steady increase in activity and selectivity with increase in the atomic weight of the metal is observed[45] (Table 2). On passing from MgO to BaO (750 °C), the yield of C_2H_4 and C_2H_6 increases from 4.4 to 15.2%, while the selectivity increases from 11.7 to 45.4%. It has been noted[45] that in the presence of SrO and BaO the reaction products contain no CO_2 during the first hours of the operation of the catalyst, which is associated with the conversion of the oxides into the carbonates. Comparison of the oxide and carbonate catalysts under identical conditions demonstrated the similarity of their properties in the oxidation (Table 2). The possibility of increasing both the activity and the selectivity of the catalyst by a preliminary heat treatment at 1000 °C (Table 2), which reduces the surface of the oxide by a factor of ~4, has been demonstrated for MgO.[48] The catalytic properties of alkaline earth metal oxides are also influenced by other factors, which is indicated by the increase in the activity of MgO after adding a small amount of barium compound (0.2 mole %) (Table 2), which is accompanied by the increase in the surface area of the catalyst from 70 to 200 $m^2\ g^{-1}$.[48]

Thus the oxidative conversion of methane into C_2 hydrocarbons can occur in the presence of a wide variety of oxide catalysts. It is difficult to differentiate any group of metals which is greatly superior in terms of activity and selectivity. Nevertheless, one may note that, with rare exceptions, there are no literature data concerning the use of oxide catalysts containing *d* transition metals, which exhibit a high activity for the extensive oxidation of hydrocarbons.[51,52]

2. Oxide Systems with Added Alkali Metal Compounds

The modifying effect of added alkali metals on catalysts of different processes, including the partial oxidation of organic substances, is widely known.[53] The increase in the activity and selectivity of the catalyst by alkali metals is due to a number of causes, the main ones being the neutralisation of the acid centres of the carrier, the alteration of its adsorption characteristics, the weakening of the bonds between oxygen and the active components, and prevention of coke formation.[53]

Table 2. Catalytic properties of the catalysts of the oxidative condensation of methane containing alkaline earth metals.

The promoting effect of alkali metal additives on catalysts of the conversion of methane has been observed under conditions where methane and O_2 were supplied consecutively[54–79] and simultaneously.[80–98] For example, when methane came into contact with manganese systems modified by Li, Na, K, Rb, and Cs additives, the yield of the methane oxidative condensation products was higher than for the unpromoted solid carriers.[25,26] The conversion of methane, determined 2 min after the start of the experiment at 800 °C, was 7% in the presence of 10 wt.% Mn/SiO_2 with a selectivity in the formation of hydrocarbons of 55.6%. The addition of 1.7 wt.% Na (as the acetate) to the catalyst increases the conversion of methane and the process selectivity to 9 and 89.9% respectively. It has been noted[37,54] that the efficiency of the manganese systems investigated depends on the nature of the promoting additive and carrier and also on the method of their preparation.

The addition of Na (as sodium nitrite) to PbO/Al_2O_3 in an amount up to 4 wt.% increases the catalyst selectivity by ~10%, while the overall conversion of methane passes through a maximum when the Na_2O content in the catalyst is approximately 2 wt.%[80] (Fig.2). According to Hinsen et al.,[80] the

effect of Na is due to the neutralisation of the acid centres of the carrier, which, as already mentioned, promote the extensive oxidation of hydrocarbons. Accordingly, the promoting effect of added Na is manifested to a greater extent for catalysts prepared on the basis of acid carriers (γ-Al_2O_3, aluminosilicate).[80] The important role of the acid–base properties of the carrier is indicated by results[35] according to which the efficiency of the lead catalyst increases sharply when acid carriers are replaced by alkaline ones (CaO, SrO, BaO, and especially MgO).

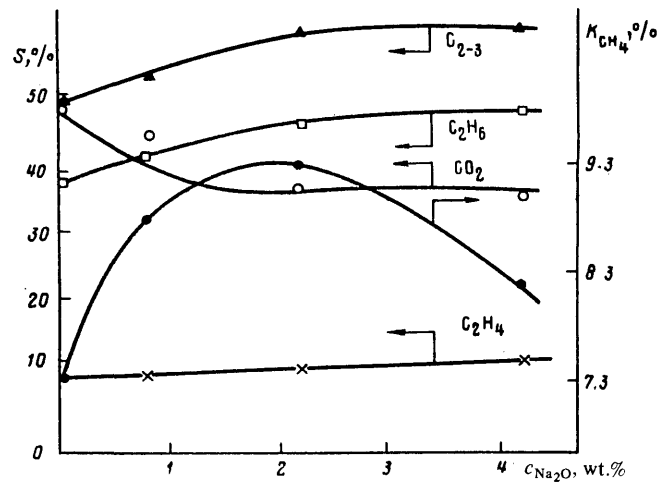

Figure 2. The influence of the alkaline additive on the catalytic properties of the 22 wt.% PbO/γ-Al_2O_3 catalyst in the oxidative condensation of methane;[80] T = 750 °C; p_{CH_4} = 70.9 kPa; p_{O_2} = 7.1 kPa; K_{CH_4} = conversion of methane.

Table 3. Oxidative condensation of methane in the presence of the 10 wt.% Mn/carrier catalyst[37] (T = 750 °C; molar ratio CH_4: air = 0.65; ν = 1000 h^{-1}).

Carrier	K_{CH_4}		S w.r.t. $C_2H_6 + C_2H_4$, %	Molar ratio C_2H_4:C_2H_6
	total	to $C_2H_6 + C_2H_4$		
γ-Al_2O_3	14.9	0.4	2.6	0.08
SiO_2	20.6	6.3	30.6	1.31
NaHSZ (X = 71)*	25.6	13.3	51.9	2.18
NaY (X = 4,4)	17.3	4.1	23.8	1.22
NaA (X = 2)	17.9	3.7	20.7	1.01

*$X = SiO_2/Al_2O_3$ (molar ratio).

The influence of alkaline components must be taken into account when materials such as zeolites, whose composition usually includes Na^+ cations, are used as carriers.[37] The higher efficiency of the Mn/NaHSZ zeolitic catalyst, compared with Mn/SiO_2, is probably associated with this factor (Table 3). The properties of zeolitic catalysts whose structures break up at the methane oxidative condensation temperature (700 to 800 °C) apparently depend also on the aluminium content in the zeolite. With decrease in the SiO_2/Al_2O_3 ratio in the carrier, i.e. with increase in the aluminium content, the yield of the C_2 hydrocarbons falls, although it still remains higher than in the presence of the γ-Al_2O_3-based catalyst (Table 3).

Systematic study of the effect of alkali metal additives on the Mn/SiO_2 catalysts[81] showed that the greatest promoting effect is exhibited by sodium (Table 4). At 800 °C and ν = 2000 h^{-1} in the presence of Mn/SiO_2 containing 4 wt.% Na, the yield of ethane and ethylene reaches 16.9% for a selectivity in the formation of C_2 hydrocarbons greater than 70%. The addition of lithium as the acetate to Mn/SiO_2 also increases the overall conversion of methane (to 25.4%), but the process becomes less selective owing to the increase in the yield of CO_2. Other alkali metals (K and Cs) increase the selectivity of the catalysts but lower their activity. The modification of Mn/SiO_2 by alkaline earth metal (Mg and Ca) compounds reduces appreciably the conversion of methane and the selectivity in the formation of C_2H_4 and C_2H_6 (Table 4). The effect of added alkali and alkaline earth metals on the properties of manganese catalysts[37,81] may be due to the decrease in the acidity of the catalytic systems and also to changes in the valence state of manganese and in the strength of the Mn–O bond.

Table 4. Catalytic properties of 10 wt.% Mn/SiO_2 with added 4 wt.% of alkali metal or alkaline earth metal (M) acetates in the oxidative condensation of methane[81] (T = 800 °C; molar ratio CH_4: air = 0.55; ν = 2000 h^{-1}).

The promoting effect of alkali metals has been observed for samarium,[82] zinc,[83] and bismuth oxides deposited on various carriers.[84] The characteristics of the variation of the catalytic properties of Sm_2O_3 and ZnO after the addition of alkali metal (Li, Na, K, Rb, and Cs) compounds are similar. The efficiency of the promoting additive decreases in both cases with increase in the atomic weight of the alkali metal.[82,83] In interpreting the effect of alkali metal additives, one should bear in mind that the promoting agent (Li), deposited on an inert carrier (SiO_2), is inactive in the conversion of methane (Fig. 3). The addition of 20 mole % of Li to Sm_2O_3 makes it possible to convert up to 21% of methane at 750 °C into C_2 hydrocarbons with a selectivity of 57%. This yield of C_2H_4 and C_2H_6 persists in the range of promoting agent concentrations from 10 to 30 mole %, while the maximum selectivity in the oxidative condensation of CH_4 is observed for 5–10 mole %.[82] According to Matsuura et al.,[83] an increase in the activity and selectivity of ZnO is observed when the fraction of Li in the catalyst is increased to 12.5 mole %; further growth of its concentration (up to 40 mole %) does not alter the catalytic properties of ZnO. The highest yield of C_2 hydrocarbons (23.9%) for a selectivity of 66.8% in the presence of Li/ZnO is obtained for a high dilution of the reaction mixture with helium (>80 vol.%) and for the molar ratio CH_4:O_2 = 2.[83]

Important results concerning the nature of the promoting effect of alkali metal additives have been obtained.[85,86] The $[Li^+O^-]$ centres containing active oxygen have been detected by EPR in MgO-based catalysts of the oxidative condensation of methane with added lithium carbonate. These centres are formed only at temperatures above 500 °C in an atmosphere of an O_2-containing gas. Their concentration increases significantly with increase in the partial pressure of O_2 to 13.3 kPa (Fig. 4). According to the authors,[85,86] the $[Li^+O^-]$ centres participate in abstracting H atoms from CH_4 with formation of methyl radicals:

$$[Li^+O^-] + CH_4 \rightarrow Li^+OH^- + CH_3^\cdot .$$

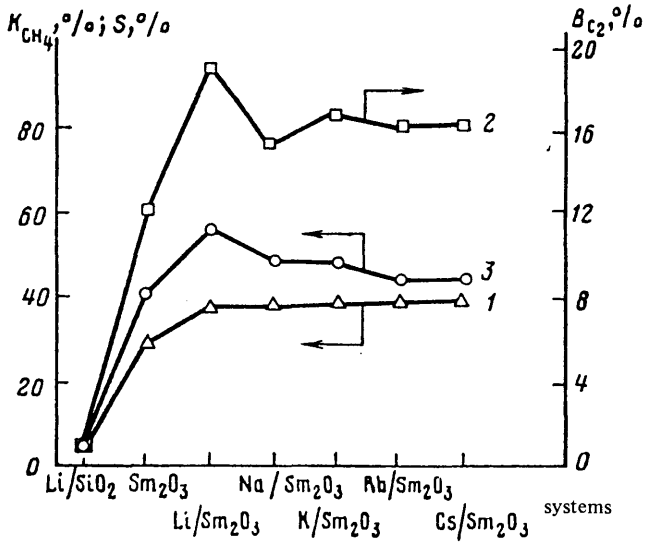

Figure 3. The effect of alkaline additives (20 mole %) on the conversion of methane (curve *1*), the yield *B* (curve *2*), and selectivity (curve *3*) in the formation of C_2 hydrocarbons in the presence of Sm_2O_3 catalysts of the oxidative condensation of methane;[82] T = 750 °C; p_{CH_4} = 5.1 kPa; p_{O_2} = 2.1 kPa; p_{He} = 94.1 kPa.

The $CH_3^\cdot$ radicals are intermediates in the reactions involving the partial and extensive oxidation of methane. The regeneration of the active centres of Li/MgO takes place after the dehydration of Li^+OH^- and the adsorption of O_2, accompanied by the dissociation of the O–O bond. Since these processes are endothermic, they take place at high temperatures.[86] Among the catalysts investigated, the 7 wt.% Li/MgO catalyst proved to be the most active. In its presence at 720 °C and for the molar ratios of the reaction mixture components $CH_4 : O_2 : He$ = 2 : 1 : 23, the yield of C_2 hydrocarbons reached 19% for a selectivity of 50.3%. The Li/MgO system can serve as an example of the direct involvement of the promoting agent (the alkali metal) in the formation of active centres for the oxidative condensation of methane.

According to the data of Moriyama et al.,[87] added sodium nitrate has the greatest promoting effect on MgO, the effect of the nitrates of other alkali metals (Li, K, Rb, Cs) being less marked. In the presence of the catalyst with the optimum composition (15 mole % Na/MgO) at 800 °C and for the volume ratios CH_4 : air : He = 1 : 2.5 : 33.3, C_2 hydrocarbons are formed in 22.4% yield and with a selectivity of 56.8%. The increase in the Na content lowers significantly the thermal stability of the MgO crystal lattice: after heat treatment at 800 °C, the surface area of MgO is 70 $m^2\ g^{-1}$, while for the specimens with 15–20 mole % Na it is only 1–2 $m^2\ g^{-1}$. The authors[87] suggest that the reactions involving the generation of $CH_3^\cdot$ radicals, the extensive oxidation of the hydrocarbons, and the destruction of methyl radicals take place on the catalyst surface. A decrease in the area of the catalytic system retards the last two reactions to a greater extent, which increases the yield of the C_2 hydrocarbons and the process selectivity. The promoting effect of the alkali metal additive is apparently caused, together with other factors, by the modification of the carrier, which leads to the optimum morphology of the catalyst surface.

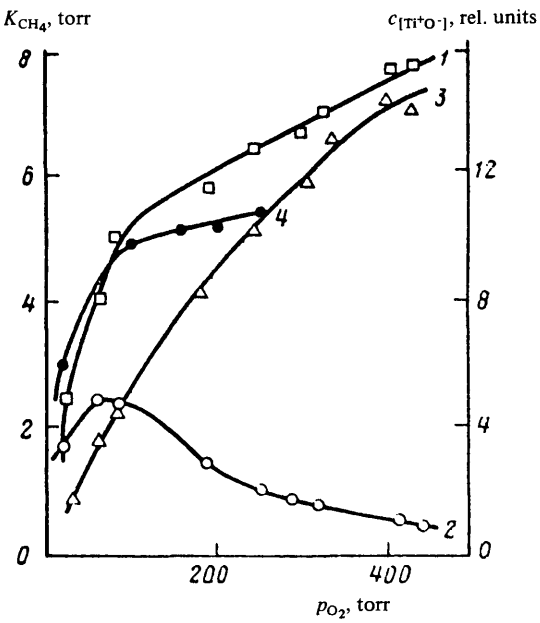

Figure 4. Dependence of the conversion of methane and of the concentration of the $[Li^+O^-]$ centres on the partial pressure of O_2:[86] 1) overall conversion of methane; 2) conversion into $C_2H_6 + C_2H_4$; 3) conversion into $CO + CO_2$; p_{CH_4} = 300 torr; T = 620 °C; catalyst—7 wt.% Li/MgO.

There are literature data[45,88,89] showing that the compounds of other alkaline earth metals (Ca, Sr, Ba) are also sensitive to alkali metal additives. Thus it has been shown that the catalytic properties of MgO and CaO modified with 5 mole % of Li, Na, K, or Cs[88] vary similarly: the yield of C_2H_4 and C_2H_6 and the selectivity in their formation decrease with increase in the ionic radius of the alkali metal (r_{M^+}). These relations have been explained taking into account the results of the X-ray diffraction analysis of the specimens heat-treated at 950 °C. If r_{M^+} is smaller than or equal to the radius of the alkaline earth metal (M^{2+}), then substitutional solutions with healing of the defects in the cationic sublattice are formed. On the other hand, when $r_{M^+} > r_{M^{2+}}$, then M^+ can enter the interstices, which increases the defectiveness

of the MO lattice as far as its conversion into the amorphous form. The latter promotes the adsorption of CO_2 and hence the blocking of the catalyst surface, which reduces its activity.[88] These considerations concerning the role of the conversion of the MO lattice into the amorphous form and the chemisorption of CO_2 in the deactivation of the catalyst differ from the hypotheses put forward by Aika et al.,[45] As already mentioned (Table 2), the formation of $BaCO_3$ from BaO under the conditions of oxidative condensation does not influence the yield of C_2 hydrocarbons, while the addition of Li, Na, K, or Rb compounds to $CaCO_3$ increases somewhat its activity but reduces its selectivity with respect to C_2H_4 and C_2H_6.[45]

On the basis of the data examined, one may conclude that the increase in the efficiency of the majority of catalysts of different nature as a result of the modification by alkali metal additives can be due to a number of causes. In acid systems, their effect is associated with the neutralisation of the acid centres accelerating the extensive oxidation of hydrocarbons. The interaction of alkali metal compounds with the catalysts at high temperatures (700–1000 °C) probably induces various changes in the crystal lattice and in the state of the catalytic surface. This usually leads to the conversion of the catalyst into an amorphous form and its sintering, which ensures the formation of the optimum surface of the catalytic system. Furthermore, alkali metal cations apparently promote the formation of centres containing active oxygen by creating defects and altering the effective charge on the ions localised on the catalyst surface.

Table 5. Catalytic properties of Sm_2O_3 modified by lithium compounds[99] (T = 750 °C; p_{CH_4} = 5 kPa; p_{O_2} = 2 kPa; p_{He} = 94 kPa).

Catalyst	K_{CH_4}, %		S, %	molar ratio $C_2H_4:C_2H_6$
	total	to $C_2H_4 + C_2H_6$		
Sm_2O_3	30.2	12.4	41.2	1.24
$LiBr/Sm_2O_3$	30.4	11.6	38.2	1.98
$LiCl/Sm_2O_3$	28.8	19.9	69.0	5.39
LiF/Sm_2O_3	26.5	13.9	52.6	1.00
$LiOH/Sm_2O_3$	38.2	19.5	51.1	1.09
$LiNO_3/Sm_2O_3$	37.5	19.5	51.9	1.17
Li_2CO_3/Sm_2O_3	41.2	22.3	54.1	0.95

3. Halogen-Containing Catalysts

The study of various catalytic systems promoted by alkali metal salts showed that their catalytic properties depend significantly on the nature of the anion of the added salt.[81,99–102] In the presence of Sm_2O_3,[99] the yield of the oxidative condensation products increases from 12.4% to 19.5–22.3 after the introduction of lithium chloride, hydroxide, nitrate, or carbonate (Table 5). The addition of LiBr and LiF hardly alters the conversion of methane into C_2 hydrocarbons. With the exception of the bromide, lithium compounds increase the selectivity in the formation of C_2H_4 and C_2H_6, the selectivity of $LiCl/Sm_2O_3$ being highest (69%). It is striking that the C_2 hydrocarbons formed in the presence of this catalyst consist mainly (to the extent of 84.4%) of ethylene. The fraction of ethylene in the presence of other catalysts is appreciably lower and is less than 50% for Li_2CO_3/Sm_2O_3. It has been suggested[99] that the observed effects are caused by the suppression of the extensive oxidation of the hydrocarbon by the added LiCl.

The fact that the addition of alkali metal salts to oxide catalysts having different chemical compositions induces similar changes in their activity and selectivity in the oxidative conversion of methane is important for the understanding of the nature of the catalytic action of the systems considered.[81,99,100] Indeed, as for samarium oxide modified by lithium compounds,[99,101] the efficiency of manganese catalysts[81] increases significantly after the introduction of sodium salts into their composition (Table 6). The nature of the halides influences also the proportions of the methane oxidative condensation products (Tables 5 and 6). For example, catalysts modified by LiF and NaF are inferior to other halogen-containing systems as regards selectivity in the formation of C_2H_4. Analogous behaviour has been observed[100] also for NiO + LiX (X = F, Cl, or Br). The addition of lithium and sodium chlorides induces the highest promoting effect; for $(Mn + NaCl)/SiO_2$, the yield of C_2 hydrocarbons reaches 25.8% for a selectivity in their formation of 77.5% (Table 6). The simultaneous increase in the activity and selectivity of the manganese catalyst cannot be explained solely by the suppression of the extensive oxidation of hydrocarbons, as suggested for $LiCl/Sm_2O_3$.[99,100] The Cl^- ions present in the catalyst are probably converted as a result of oxidation-reduction reactions into organochlorine compounds, which accelerate the formation of C_2H_4 and C_2H_6.

Table 6. The influence of the nature of the anion of the added sodium salt on the catalytic properties of Mn/SiO_2 in the oxidative condensation of methane[81] (T = 800°; molar ratio CH_4: air = 0.55; v = 2000 h^{-1}).

Salt	K_{CH_4}, %		S, %	Molar ratio $C_2H_4:C_2H_6$
	total	to $C_2H_4 + C_2H_6$		
—	16.4	8.0	48.6	5.7
CH_3COONa	23.9	16.9	70.5	20.1
NaF	22.3	9.8	43.9	2.9
NaCl	33.3	25.8	77.5	17.4
NaBr	26.8	19.2	71.6	26.4

The change in the catalytic properties of a number of transition metal oxides (Table 7) as a result of their modification by added LiCl has been investigated.[100,101] It must be emphasised that the individual oxides propagated only the extensive oxidation of methane under the selected conditions, while $LiCl/SiO_2$ did not exhibit an appreciable activity in the conversion of methane.[100] The combination of LiCl and metal oxides (with the exception of Fe and Cr) affords effective catalytic systems. Thus, in the presence of LiCl/Mn oxide, the conversion of methane into C_2 hydrocarbons is 30.6% for a selectivity of 64.7%. A high content of C_2H_4 in the methane oxidative condensation product is characteristic of all the catalysts (Table 7) and depends on the partial pressure of the reactants. In the case of LiCl/Mn oxide, the decrease of $p_{CH_4+O_2}$ from 85.5 to 7.65 kPa increases the fraction of C_2H_4 in the C_2 hydrocarbons from 67 to 92% with the simultaneous increase in the overall $C_2H_4 + C_2H_6$ yield by a factor of ~2.[100,101] The importance of the chloride component in the catalytic systems is also indicated by the decrease in the activity of LiCl/NiO with time, which is caused, according to the authors.[100,101] by the removal of LiCl from the catalytic zone. Patent data concerning the possibility of the activation by methylene chloride of the $NaMnO_2/MgO$

solid oxidant used in the cyclic conversion of methane agree with this finding.[103]

The efficiency of alkaline earth metal (Mg and Ca) oxides, in the presence of which the degree of conversion of methane into C_2H_4 and C_2H_6 at 800 °C is ~5%, increases after the addition of LiCl.[100] This is especially notable for the MgO systems: the yield and the selectivity in the formation of C_2 hydrocarbons increase from 4.8 to 19.4% and from 22.4 to 69.7% respectively, i.e. LiCl exhibits simultaneously a promoting effect and suppresses the extensive oxidation of methane. In the case of the oxides SiO_2 and Al_2O_3, which are inactive in the oxidative condensation of methane, the addition of LiCl increases the yield of C_2 hydrocarbons to only 3.6–3.7%.[100] The overall conversion of methane increases by a factor of ~2 (to 26.7%) on passing from Al_2O_3 to $LiCl/Al_2O_3$, mainly as a result of the formation of CO_2. This is the only example of the anomalous influence of LiCl on the catalytic properties of oxide systems in the oxidation reaction of methane.

Table 7. The influence of LiCl (20 mole %) on the catalytic properties of transition metal oxides[101] (T = 750 °C; p_{CH_4} = 5.1 kPa; p_{O_2} = 2.55 kPa; p_{He} = 93.7 kPa).

Metal	K, %		S, %	B, %	
	CH_4	O_2		$C_2H_4 + C_2H_6$	C_2H_4
Ti	17.6	40	82.8	14.6	13.6
Cr	26.1	85	0	0	0
Mn	47.3	95	64.7	30.6	28.1
Fe	22.2	92	0	0	0
Co	48.0	91	35.6	17.0	15.4
Ni	25.9	57	71.8	18.6	14.5
Cu	49.5	80	20.6	10.2	10.2
Zn	22.0	49	68.9	15.2	9.4

The above results[100,101] make it possible to compare the influence of the nature of alkali metals, whose chlorides have been used to modify nickel, samarium, and europium oxides. In the presence of nickel catalysts with 20 mole % MCl (M = Li, Na, or Cs), the yield of C_2 hydrocarbons decreases from 18.6% (Table 7) to 6.2% and to 5.9% with increase in the atomic weight of M. The fraction of C_2H_4 in the methane condensation product diminishes at the same time from 78.0 to 58.0 and to 42.4%, although a parallel variation of the selectivity in the series of these catalysts is not observed. Systems based on Eu_2O_3 and containing LiCl and NaCl hardly differ as regards the yield of C_2H_4 and C_2H_6 but the selectivity of the catalyst with added NaCl is somewhat higher than for the specimen promoted with LiCl. Among the Sm_2O_3 catalysts modified with sodium, potassium, and caesium chlorides, the Na and Cs systems proved to be the most active. The KCl/Sm_2O_3 catalyst exhibits a higher selectivity with respect to C_2 hydrocarbons while being inferior to other Sm_2O_3 systems in terms of the overall conversion of methane (by a factor of ~2). These data show that lithium and sodium chlorides have the greatest promoting effect, although the nature of the carrier also plays a significant role in this case.

Bivalent and tervalent metals [metal halides] deposited on pumices, kieselguhr, and titanium, zinc, magnesium, and calcium oxides can be used as the active components of the halides in the preparation of halogen-containing catalysts of the oxidative condensation of methane.[102] At 750 °C and for the volume ratio CH_4:air = 2:1, $BaBr_2$, $MgCl_2$, $CaCl_2$–$MgCl_2$, $CaCl_2$–LiCl–$CeCl_3$, and $CaCl_2$–LiCl–$PrCl_3$ deposited on pumice exhibit a high efficiency. The yield of the methane condensation products in the presence of these systems is in the range 13–15% for a selectivity of 80–90%. Catalysts which consist of melts of individual salts or mixtures with alkali metal halides (LiCl, CsCl, KBr, and KI) on carriers show a lower activity under the same conditions. The high concentration of C_3 and C_4 hydrocarbons in the methane condensation products obtained in the presence of a series of catalysts with bivalent metal halides is striking. Thus the fraction of butenes is 46.8 and 24.1% respectively in the presence of $BaBr_2$/pumice and $CaBr_2/MgO$. The selectivity of the systems considered with respect to C_3 and C_4 hydrocarbons depends on the nature of the salts and carriers used. For catalysts obtained by depositing $BaBr_2$ on pumice, CaO, ZnO, and silicon carbide, the content of C_3 and C_4 hydrocarbons in the methane condensation products is reduced from 46.8 to 33.9%, which indicates the possibility of regulating the degree of the oxidative condensation of methane by varying the composition of the catalyst.

Thus the efficiency of halogen-containing catalysts in the oxidative condensation is greater than that of other catalytic systems. The promoting function of the halide components is due to a number of factors. Their involvement in the formation of intermediates in the oxidative condensation of methane and in the suppression of processes involving the extensive oxidation of hydrocarbons appears to be extremely probable. The latter factor is indicated, in particular, by the results of studies of the deactivation by the chloro- and bromo-derivatives of methane and ethane of palladium and platinum catalysts of the extensive oxidation of methane.[104] These chloro- and bromo-derivatives are adsorbed preferentially on the centres responsible for the activation of oxygen reacting with methane. Additional evidence in support of the concept of the inhibition of the extensive oxidation of hydrocarbons is provided by data indicating a sharp change in the selectivity of the oxides of a series of transition metals in the oxidation reaction of methane after the addition of halide salts, which leads to the preferential formation of the products of the oxidative condensation of methane. On the other hand, these systems are more effective than non-transition metal halides deposited on inert carriers, which indicates the interaction of the halide component with transition metal compounds under the catalytic conditions. Such interaction apparently induces the formation of active halogen species promoting the condensation of methane. This agrees with the decrease in the activity of the catalysts as a result of the loss of the halide component and the possibility of an increase in their activity following the addition of volatile halogen compounds to the reaction mixture. A high content of ethylene in the C_2 hydrocarbon formed is characteristic of the catalysts considered, i.e. the presence of halogens influences different stages of the catalytic process, including the stages responsible for the appearance of different proportions of the methane condensation products.

III. THE MECHANISM OF THE OXIDATION REACTIONS OF METHANE

Comparison of the properties of catalysts of different classes makes it possible to discover a series of common features of the oxidative condensation of methane. The most important factor is that C_2 hydrocarbons are formed in the presence of all the catalysts only at temperatures above 550–600 °C. Fig. 5 presents typical temperature variation of the yield of the products of the extensive and partial

oxidation of methane in the presence of a manganese catalyst.[37] Up to 600 °C, the only products are carbon oxides and water and under these conditions the oxygen in the gas mixture is almost fully converted (to an extent greater than 95%). At higher temperatures, the formation of C_2H_6 and C_2H_4 is observed, their yield increasing up to 800 °C. At the same time there is an increase in the selectivity with respect to the C_2 hydrocarbons and the oxidative condensation of methane becomes the dominant process at temperatures above 750 °C. It is noteworthy that, in the presence of Mn/NaHSZ at 700–800 °C, ethylene is formed in greater amounts than ethane, which may be associated with the increase in the rate of dehydrogenation of ethane on passing to high temperature.

The character of the oxidative conversion of methane is determined, apart from reaction temperature, by the contact time and the ratio of the components of the reaction mixture.[37,80,83,105] The kinetic relations (Fig. 7*a*) obtained for low conversions of O_2 on Sm_2O_3 [105] show that the selectivity with respect to C_2 hydrocarbons increases steadily with decrease in p_{O_2} and approaches 100% for $p_{O_2} < 0.3$ kPa. The increase in the selectivity in the oxidative condensation of methane and in the rate of formation of the methane conversion products is favoured by an increase in p_{CH_4} (or in the ratio $CH_4:O_2$), which is clearly manifested in the range of p_{CH_4} from 0 to 30 kPa (Fig. 7*b*).

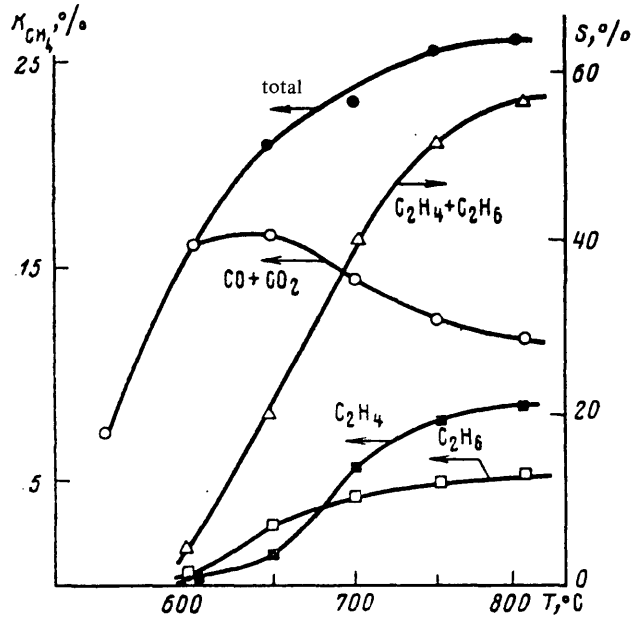

Figure 5. The influence of temperature on the yield of the products of the oxidation reactions of methane:[81] 10 wt.% Mn/NaHSZ ($X = 71$); molar ratio CH_4:air = 2:3; ν = 1000 h^{-1}.

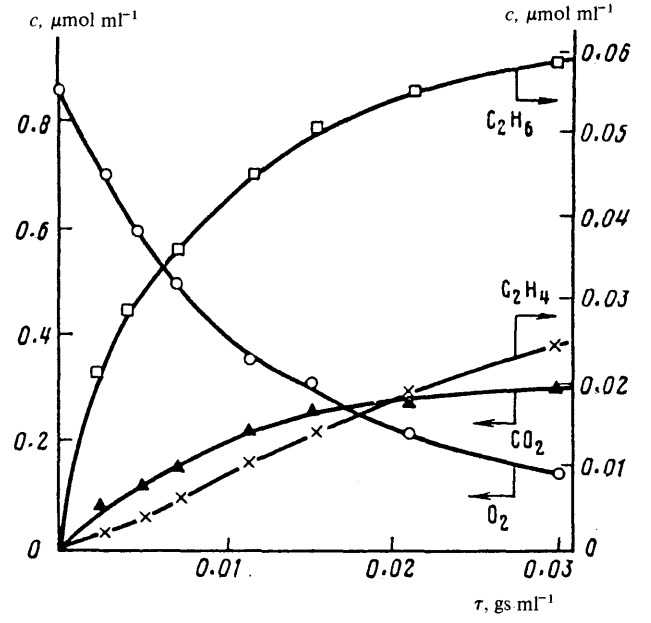

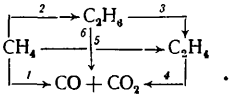

Figure 6. Dependence of the yield of the products of the oxidative condensation of methane on the contact time τ on PbO/γ-Al_2O_3;[80] T = 700 °C; c_{CH_4} = 5.0 mol ml^{-1}; p_{CH_4} = 40 kPa.

It has been shown for the PbO/γ-Al_2O_3 [80] and Li/MgO [86] catalysts that an increase in the contact time τ leads to an increase in the yield of the products of the extensive and selective oxidation of methane. In the presenece of the lead system (Fig. 6), the yield of ethylene varies linearly over the entire range of values of τ and the conversion of CH_4 into C_2H_6 after long contact times tends to a limit. This increases the ratio C_2H_4/C_2H_6, indicating the consecutive formation of C_2H_4 from C_2H_6. It has been noted for Li/MgO [86] that the curves for the formation of the methane oxidation products at 620 °C do not pass through the origin of coordinates. Since diffusion-dependent obstacles are unlikely on Li/MgO in view of the low surface area of the catalyst (2 m^2 g^{-1}) and the absence of micropores, the authors[86] attribute the observed variation to the possibility of the reaction of methane via a chain mechanism.

The composition of the products formed as a result of the extensive oxidation and the oxidative condensation of methane suggests a mechanism reflecting the following possible reactions of the hydrocarbons:

The contribution of the individual reactions to the overall processes can be inferred from data obtained in studies[86,105] of the reactions of individual hydrocarbons under the conditions of the oxidative condensation of methane. The results of experiments on the oxidation of CH_4, C_2H_6, and C_2H_4 in the presence of Sm_2O_3 are presented in Table 8. The initial C_2H_6 and C_2H_4 partial pressures correspond to the pressures of these substances in the mixture obtained on oxidation of methane. Evidently the main bulk of CO and CO_2 is formed as a result of the direct oxidation of methane (see Scheme

above, reaction 1), which is consistent with data for Li/MgO, in the presence of which the yield of CO and CO_2 in the oxidation of methane is greater by a factor of 3.6 than in the oxidation of ethane. The fact that the CO and CO_2 partial pressures are somewhat smaller in the oxidation of C_2H_4 (Table 8) than in the oxidation of C_2H_6 indicates a greater involvement of ethane in the extensive oxidation reaction (reaction 5) than that of ethylene (reaction 4).

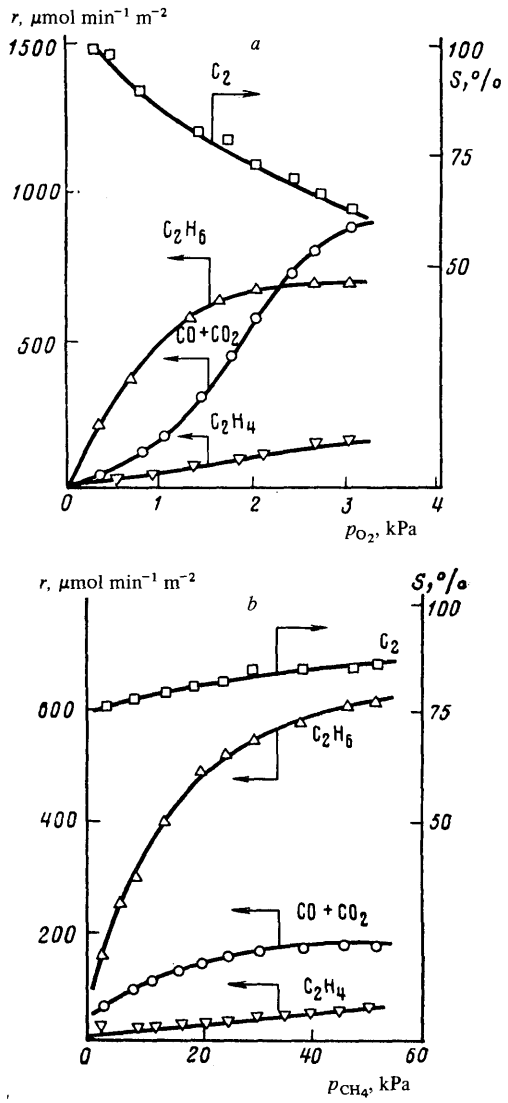

Figure 7. The influence of the partial pressures of O_2 (*a*) and CH_4 (*b*) on the rate of formation of the products of the oxidative conversion of CH_4 (*r*) and on the selectivity with respect to C_2 hydrocarbons;[105] catalyst—Sm_2O_3; T = 700 °C; p_{CH_4} = 18.2 kPa; p_{O_2} = 0.98 kPa.

Comparison of the rates of formation of C_2H_4 from CH_4 and C_2H_6 (Table 8) shows that they differ little, i.e. that C_2H_4 is formed from ethane—the primary product of the oxidative condensation of methane, and not via reaction 6 (see Scheme).

Table 8. The partial pressures of the methane oxidation products over Sm_2O_3 [105] (T = 710 °C; mass of Sm_2O_3 = 3.3 mg; v = 37.5 ml min^{-1}).

Initial hydrocarbon	Partial pressures of compounds, kPa					
	O_2	CH_4	C_2H_6	C_2H_4	CO_2	CO
CH_4	$9.2\cdot10^{-1}$	7.7	$1.2\cdot10^{-2}$	$1.6\cdot10^{-4}$	$1.1\cdot10^{-2}$	$0.2\cdot10^{-3}$
C_2H_6	$9.2\cdot10^{-1}$	0	$1.3\cdot10^{-2}$	$2.0\cdot10^{-4}$	$9.5\cdot10^{-4}$	$2.4\cdot10^{-4}$
C_2H_4	$9.2\cdot10^{-1}$	0	0	$2.0\cdot10^{-6}$	$6.4\cdot10^{-6}$	0

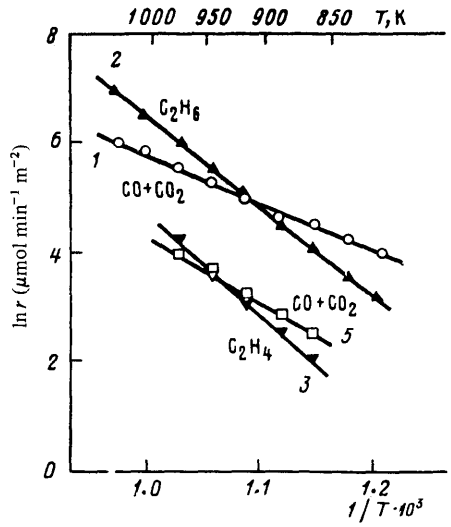

Figure 8. The Arrhenius relations for the extensive and selective oxidation reactions of CH_4 (lines *1* and *2*) and C_2H_6 (lines *3* and *5*) in the presence of Sm_2O_3 [105] (the numerals correspond to the numbers of the reactions presented in the Scheme); p_{CH_4} = 18.2 kPa; p_{O_2} = 0.98 kPa.

The apparent activation energies E_{act} calculated from the data in Fig. 8 [105] for the extensive oxidation of CH_4 and C_2H_6, the oxidative condensation of CH_4 to C_2H_6, and the oxidative dehydrogenation of C_2H_6 to C_2H_4 in the presence of Sm_2O_3 are respectively 66, 94, 135, and 173 kJ mol^{-1}. The higher values of E_{act} for the formation of C_2H_6 and C_2H_4 compared with E_{act} for the extensive oxidation of hydrocarbons show that an increase in temperature promotes the selective conversion of methane into C_2 hydrocarbons. An important factor is that such differences have been discovered for a whole series of catalysts containing lead,[80] barium, cadmium, tin, antimony, and thallium[89,106] oxides. Under comparable conditions, the E_{act} for the selective conversion of methane are within a narrow range of values for catalysts of different chemical nature. Consequently, the mechanism of the formation of C_2 hydrocarbons can include stages characteristic of a wide range of catalytic systems, for example, the formation of CH_3 radicals on the surface of the catalyst and their transfer to the gas phase.[86] The heterogeneous-homogeneous mechanism is supported by the similarity of the E_{act} for the formation of C_2 hydrocarbons and methyl radicals,[89,106] whose existence has been confirmed by EPR.[47,107]

The important role of the $CH_3^{\bullet}$ species in the oxidative conversion of methane is indicated by data for isotope exchange between CD_4 and CH_4 in the presence of oxide catalysts.[84,108] It was found that only one hydrogen atom exchanges in the adsorption–desorption cycle of the CH_4 molecule, which has been explained by the dissociative reaction of CH_4 on the surface of the oxide with formation of the $CH_3^{\bullet}$ and $H^{\bullet}$ species. The removal of hydrogen is facilitated by the formation of C_2H_6 from the $CH_3^{\bullet}$ radicals, so that the active catalyst should combine, according to the authors,[84] the functions ensuring the dissociation of CH_4 and the oxidation of $H^{\bullet}$.

Nowadays the majority of investigators believe that the active centres of the oxide catalysts on which the $CH_3^{\bullet}$ species are generated contain oxygen in one state or another.[86,105,109,114] Thus the formation of $CH_3^{\bullet}$ radicals is regarded[109] as a result of the interaction of CH_4 with the oxygen in the crystal lattices of the oxides. This conclusion is based on the fact that the amount of oxygen incorporated in the reaction product after CH_4 has been in contact with the solid oxidant exceeds the amount of oxygen in the surface layer by a factor of 10–20, i.e. the oxygen present in the bulk of the oxide enters into the reaction. Under the catalytic conditions, the main bulk of the $CH_3^{\bullet}$ radicals are probably formed with participation of the oxygen in the surface layer of the oxide, whose loss is made good by the O_2 from the gas phase. As already mentioned, the active centres in Li/MgO [86] are regenerated by the reaction of O_2 with the structural defects in MgO. This induces the appearance of the coordination-unsaturated O^- species, whose concentration is correlated with the content of Li^+ in the catalyst and with the rate of formation of the $CH_3^{\bullet}$ radicals (Fig. 4).

Another state of active oxygen has been detected on La_2O_3 after its treatment in an atmosphere of an O_2-containing gas at 650 °C and rapid cooling to −196 °C.[43] The EPR spectra of the oxide contained lines whose g-factors ($g_{\parallel} = 2.047$, $g_{\perp} = 1.994$) are characteristic of the superoxide ion O_2^-. The conclusion that diatomic oxygen species (O_2, O_2^-, or O_2^{2-}) participate in the dissociation of the C–H bond in the CH_4 molecule was reached[111,112] on the basis of kinetic studies of the oxidative condensation of CH_4 in the presence of Sm_2O_3. This agrees with the finding that the peroxides Na_2O_2, SrO_2, and BaO_2 are capable of oxidising methane to C_2 hydrocarbons at relatively low temperatures (200–450 °C).[113,114] The interaction of methane with the peroxide oxygen in Na_2O_2 involves the surface and deep layers of the Na_2O_2 lattice, which is indicated by the ratio of the oxygen in the reaction products and in the outer layer of the oxidant.[113] Comparison of the apparent E_{act} for the oxidative condensation of methane (59 kJ mol^{-1}) and decomposition of BaO_2 (142–192 kJ mol^{-1}) indicate the involvement of the peroxide ions O_2^{2-} in the reaction and not of the gaseous O_2 formed on thermal dissociation of BaO_2 [89,114] Thus the state of the active oxygen can be influenced by the nature of the promoting agent and the oxide employed. At the same time, for a number of catalysts, for example, those which contain chlorides, one cannot rule out the generation of the $CH_3^{\bullet}$ radicals when methane interacts with the halide components of the reaction system.[81,100]

The question of the site where the methyl radicals recombine has been confirmed in a number of investigations.[16,19,86,106] It has been suggested[19] that ethane is formed as a result of the dimerisation of the $CH_3^{\bullet}$ species on the surface of the solid oxidant with subsequent dehydrogenation of the adsorbed C_2H_6 to C_2H_4. Another view has been expressed[109] on the basis of kinetic data obtained in the cyclic oxidation of methane in the presence of Mn/SiO_2 (Fig. 9). Extrapolation of the relations presented shows that the selectivity in the formation of all the products (with the exception of ethane) tends to zero with decrease in contact time. The increase in the selectivity with respect to C_2H_6 under the given conditions has been explained[109] by the gas-phase interaction of the $CH_3^{\bullet}$ radicals, because strong adsorption of these species on the Mn/SiO_2 surface should also lead to the formation of C_2H_4 and the extensive oxidation products.

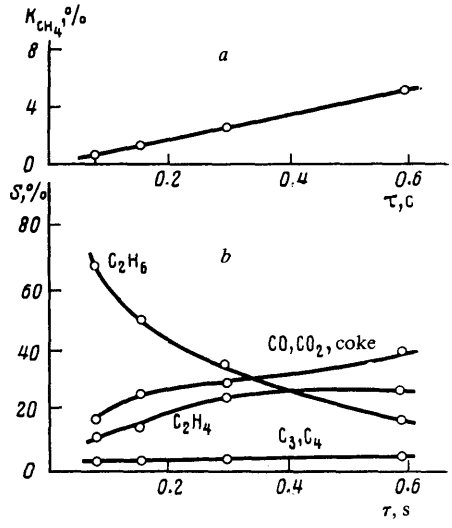

Figure 9. Dependence of the degree of conversion of methane and of the selectivity in the conversion process on the time of contact with the solid oxidant 5 wt.% Mn/SiO_2 at 800 °C [109] (data obtained 1 min after the start of the experiment).

The conclusion that the gas-phase dimerisation of the $CH_3^{\bullet}$ radicals takes place has also been reached by other investigators[86,106] who studied the catalytic conversion of methane in the presence of gaseous oxygen. According to the mechanism proposed,[86] after their appearance on the surface, the $CH_3^{\bullet}$ radicals pass to the gas phase, where they form C_2H_6. The methyl species can also interact with oxygen, affording the methylperoxy-radicals $CH_3O_2^{\bullet}$, which are intermediates in the extensive oxidation reaction. This agrees with the increased yield of CO and CO_2 following an increase in the partial pressure of O_2 [37,83,105] and also with the finding that the main bulk of carbon oxides are formed from methane under the conditions of the oxidative condensation of methane and not from C_2H_6 or C_2H_4 [86,105] (Table 8). It is noteworthy that the $CH_3O_2^{\bullet}$ species are fairly stable up to ~500 °C, as has been established in the gas-phase oxidation of methane by oxygen.[116] The decrease in the O_2 concentration and the increase in temperature therefore promote the decomposition of $CH_3O_2^{\bullet}$ into O_2 and $CH_3^{\bullet}$, which leads ultimately to an increase in the selectivity with respect to C_2 hydrocarbons.[43] The gas-phase oxidation is probably not the only pathway to the formation of CO and CO_2 under the conditions of the catalytic conversion of methane. The heterogeneous occurrence of the extensive oxidation process is indicated by the large amount of carbon oxides formed in the reaction of CH_4 with the solid oxidant in the presence of gaseous oxygen.[109] Lunsford and co-workers[86] assumed that extensive oxidation includes the interaction of the $CH_3^{\bullet}$ radicals with the O^{2-} ions

of the catalyst. Unfortunately there are insufficient data to infer the nature of the surface intermediates and the centres responsible for their extensive oxidation.

Together with the generation of the $CH_3^{\cdot}$ radicals and the formation of carbon oxides, the oxidative dehydrogenation of ethane can be attributed to reactions occurring on the surfaces of the catalysts. This is indicated indirectly by numerous data (see Section II) for the dependence of the C_2H_4/C_2H_6 ratio on the composition of catalysts used under identical conditions. In particular, the introduction of dehydrogenating additives (ZnO, NiO) into PbO/Al_2O_3 increases the fraction of ethylene in the products of the oxidative condensation of methane.[115] It has been suggested[89] that, when PbO/Al_2O_3 is used, ethane is formed from methane and ethylene is formed from ethane (in contrast to the extensive oxidation reaction) on the same active centres. According to Ito et al.,[86] the first stage in the dehydrogenation of C_2H_6 in the presence of Li/MgO takes place with participation of O^- ions and the $C_2H_5^{\cdot}$ radicals formed in this process are converted into C_2H_4 under the influence of the O^{2-} anion in the oxide lattice. As shown in the previous Section, the fraction of ethylene in the C_2 hydrocarbons formed in the presence of halogen-containing catalysts is much greater than in the presence of oxide systems. It has been suggested[100] that the dehydrogenation of C_2H_6 is accelerated in the gas phase by the $Cl^{\cdot}$ radicals, although this has not so far been confirmed directly.

Data indicating the formation of hydrocarbons containing three and more carbon atoms together with C_2H_6 and C_2H_4 are of undoubted interest both from the standpoint of the elucidation of the nature of the reactions occurring in the oxidative condensation of methane and from the practical point of view. C_3 and C_4 hydrocarbons are most frequently detected when the methane conversion is carried out under cyclic conditions.[109] Kinetic investigations have shown[109] that the increase in the duration of contact between methane and the solid Mn/SiO_2 oxidant increases the content of ethylene, propene, and butenes and reduces the fraction of ethane in the methane condensation products (Fig.9), which indicates the successive formation of C_2–C_4 olefins from C_2H_6. Furthermore, the yield of C_3H_6 and C_4H_8 increases appreciably when ethylene and propene are added respectively to methane. Hence it follows that the degree of the oxidative condensation of methane is controlled by the intensity of the reactions between the olefins formed and the $CH_3^{\cdot}$ radicals.[109] The absence of appreciable amounts of C_3 and C_4 hydrocarbons under the catalytic conditions may be associated with the high concentration of oxygen in the gas phase and on the catalyst surface, which promotes the extensive oxidation of these hydrocarbons and the intermediates involved in their formation. It may be expected that further study of the mechanism of the oxidative reactions in the CH_4–O_2–catalyst system will yield new results elucidating further the synthetic possibilities of the oxidative condensation of methane.

The solution of the problem of the activation of methane and of its selective conversion into valuable products is of fundamental and practical importance. The steadily increasing stream of information about the direct synthesis of C_2 and other hydrocarbons from methane shows that, in essence, a new field has been established in the chemistry of methane. There is no doubt that the practical application of the oxidative condensation of methane still requires the solution of a number of complex theoretical and applied problems. The improvement of the catalytic conversion of methane is associated in the first place with a deeper understanding of the reaction mechanism, of the nature of the active centres in the catalytic systems, and of their deactivation processes. However, considerable advances have already been made in the development of effective catalysts and in the selection of optimum conditions for the oxidative condensation of methane.

In the presence of the most active and selective catalysts, methane can be converted to the extent of 40% in a single pass with a selectivity of 70–80% with respect to C_2 hydrocarbons.[81,116] It is important that such results have been obtained for mixtures with high concentrations of the starting materials and at high volume flow rates. In many cases the C_2 hydrocarbons contain up to 95 vol.% of ethylene, which is of exceptional interest in connection with the steadily growing requirements for this product, whose world production will reach ~45 million tonnes according to predictions for 1990.[117]

The preparation of ethylene from natural gas will reduce the consumption of the petroleum raw material in this industry. Furthermore, the ethylene formed by the oxidative conversion of methane, can be almost fully converted, without being isolated from the gaseous mixture, into other olefins and aromatic hydrocarbons[118] in the presence of zeolites of the pentasil type.[7] Thus the oxidative condensation of methane opens a pathway to the synthesis of various compounds which are currently obtained by the processing of petroleum. The role of such processes will probably increase greatly in the future, because any depletion in the available resources of methane can be made good by the biochemical decomposition of a wide variety of organic substances.

The Reactions of Compounds with Halogenoimidoyl Groups

T.D.Petrova and V.E.Platonov

New data on the reactions of compounds of different classes containing the halogenoimidoyl group -N = C-Hal, including the reactions of both the halogen atom and the N = C bond, are surveyed.
The bibliography includes 310 references.

CONTENTS

I. Introduction 234
II. Nucleophilic substitution at the N = C bond 234
III. Elimination reactions 240
IV. Addition reactions 243

I. INTRODUCTION

The reactions of compounds with halogenoimidoyl groups $-N=\overset{|}{C}-Hal$ are extremely varied. The high mobility of their halogen atom and the ability of the N=C bond to enter into various reactions determine the possibility of using these compounds as precursors of derivatives of almost any type, including heterocyclic compounds. The ability to serve as sources of reactive intermediate ions extends still further their synthetic possibilities. It is therefore not surprising that reviews and monographs have been devoted to the study of these reactions.[1-3] However, after 1970, data for only individual types of compounds, in particular imidoyl fluorides and difluorides as well as fluorinated imidoyl halides,[4-6] hydrazonohalides, and halogenoazines[7-9] have been treated systematically. Some information about other compounds with halogenoimidoyl groups can be found in a series of comparatively recently published monographs[10-14] and reviews (1971–1973),[15-17] but they are not complete.

It appeared useful to give a systematic account of the extensive data on the reactions of compounds with the $-N=\overset{|}{C}-Hal$ groups published after 1970 and not included in the publications quoted above. This attempt was made in the present review. Bearing in mind the available review articles on the reactions of imidoyl difluorides and fluorides, only new data obtained in recent years are included. In the case of hydrazonohalides and halogenoazines, attention has been concentrated on studies after 1974 and 1977 respectively. Only a few examples of the reactions of compounds in which the halogenoimidyl group enters into the composition of a heterocycle or is attached to a heterocycle are presented. All the information about the reactivity of compounds with halogenoimidoyl groups has been divided into three groups corresponding to three main types of reactions: nucleophilic substitution reactions at the N=C bond, elimination reactions, and addition reactions. A common feature of these reactions is that they frequently do not stop after the formation of the primary products but proceed further and lead to a wide variety of final compounds, including heterocyclic derivatives.

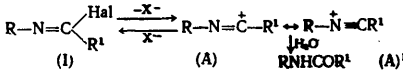
Only the chemical reactions of compounds with halogenoimidoyl groups are considered in this review. New data on some of their other properties can be found in other publications: ^{13}C and ^{15}N NMR spectra,[18-20] IR and Raman spectra,[10] data on the dipole moments, configurations, and conformations,[10,21-24] and quantum-chemical calculations.[10,25-28]

II. NUCLEOPHILIC SUBSTITUTION AT THE N=C BOND

In terms of its properties (bond length and bond energy, dipole moment), the N=C bond occupies an intermediate position between the C=O and C=C bonds. The reactions with nucleophiles have been investigated fairly adequately for activated vinyl halides and acyl halides, but simple azomethine systems have been investigated to a much lesser extent. However, by analogy with nucleophilic reactions of the C=O and C=C bonds, one can assume that nucleophilic attack on the N=C bond should lead to the formation of an anion or zwitter-ion, which can subsequently give rise to substitution, addition, and cleavage products. In halogenoimidoyl compounds there is in addition the possibility of the dissociation of the C–Hal bond and the formation of cationoid intermediates, which are also capable of undergoing various reactions.

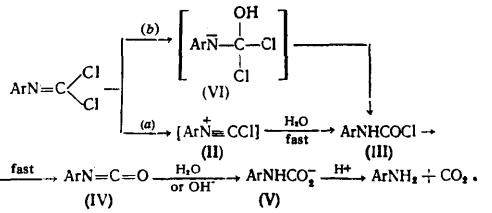
1. Reactions with O-Nucleophiles

(a) Hydrolysis



The hydrolysis of imidoyl halides with formation of amides is characteristic of compounds of this class.[29-39] Many imidoyl halides are extremely sensitive even to atmospheric moisture, as a result of which their isolation in a pure form is difficult and their formation in the course of reaction is inferred from the amide isolated. On the other hand, a convenient preparative method of synthesis of amides has been based on this finding.[40] However, this mode of the reaction is not unique. Thus the products of the hydrolysis of chloroformamidines are the corresponding ureas.[34,41-44] The hydrolysis of *N*- arylchloroformimidates or the corresponding chlorothioformimidates can lead to carbamates or their decomposition products—anilines, hydroxy-derivatives, and CO_2.[34] The hydrolysis of *N*-arylcarboimidoyl dichlorides takes place with formation of amino-derivatives of carbamates.[45] 4-Aminotetrachloropyridine is the only product of the acid hydrolysis of *N*-(2,3,5,6-tetrachloro-4-pyridyl)carboimidoyl dichloride.[46] *N*-(trichloromethyl)carboimidoyl dichloride reacts with water vigorously in a solvent or on heating until the decomposition is complete.[15]

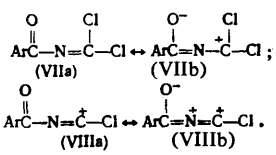
At the same time, the reactions of imidoyl halides with water do not always take place readily. Thus certain *N*-(pentafluorothio)chloroformimidates and the corresponding chloroformamidines proved to be fairly resistant to hydrolysis.[47] *N*-(Pentafluorophenyl)halogenoacetimidoyl chlorides



hardly interact with water even on being boiled.[37] Perfluoroalkylimidoyl iodides also do not hydrolyse under mild conditions.[48] Their conversion into the corresponding amides requires refluxing with 20% hydrochloric acid.

The hydrolysis of halogenoazines can afford various products, including ylidene hydrazides and heterocyclic derivatives, depending on their structure and the hydrolysis conditions.[8,49-52] On treatment with water, hydrazonohalides are converted into the corresponding hydrazides of cyclic products.[7,53-60]

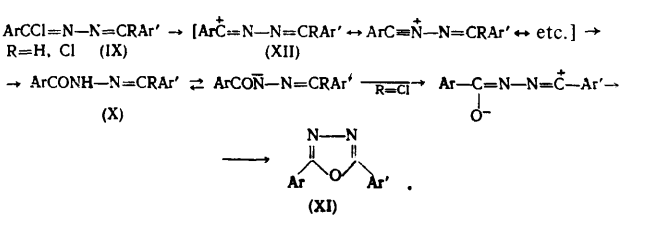
The mechanism of the hydrolysis of compounds with halogenoimidoyl groups has so far been studied fairly completely. Kinetic studies on imidoyl chlorides and dichlorides,[34,45,61] halogenoazines,[8,51,62] and hydrazonohalides[8,55-58] have shown that the unimolecular S_N1 mechanism with the dissociation of the C–Hal bond as the rate-determining stage is most characteristic of the hydrolysis of these compounds. The nitrilium ion (A), for which the contribution by the octet resonance structure (A)[1] predominates, is then formed as an intermediate:



However, this mechanism is not unique and can vary depending on the structure of the substrate, the reagent, and the medium. Thus the hydrolysis of *N*-arylcarboimidoyl dichlorides (I, R = Ar, R^1 = Cl) in solution in the 1:4 dioxan–water mixture at 25 °C and a pH of the medium up to approximately 12 is characterised by the Hammett constant $\rho = -2.30$, which indicates the operation of the S_N1 mechanism via the intermediate nitrilium ion (II) (pathway *a*):

This results in the formation of the carbamoyl chloride (III), which is rapidly converted into the isocyanate (IV). The addition of water to the latter and the decomposition of the resulting carbamate (V) gives rise to the observed reaction products.[45] As the concentration of OH^- ions increases, there is a direct attack by the hydroxyl on the substrate (pathway *b*) with formation of the tetrahedral intermediate of type (VI) (S_N2 mechanism, $\rho = +1.26$). The observed influence of the substituents in the arene ring on the rate of hydrolysis confirms the above findings.

The hydrolysis of *N*-aroylcarboimidoyl dichlorides (I, R = COAr, R^1 = Cl) takes place 10^3 times faster under similar conditions, although the rate via the S_N1 mechanism diminishes by a factor of 10^6. Only the bimolecular mechanism operates. The observed facts can be accounted for by the greatest sensitivity of *N*-aroylcarboimidoyl dichlorides to nucleophilic attack [see the structure (VIIb)] and also by the stabilisation of their negative charge adjoining the carbonyl group in the type (VI) intermediate and the destabilisation of the nitrilium ion postulated for the S_N1 mechanism [see the structure (VIIIb)]:[45]



In aqueous dioxan, the hydrolysis of *N*-aryl- and *N*-aroylbenzimidoyl chlorides in the corresponding chlorothioimidates and chloroformamidines (I, R = Ar or COAr, R′ = Ar′, SAr′, or NMeAr′, Hal = Cl) proceeds via the S_N1 mechanism. Under these conditions, *N*-arylimidoyl chlorides are 10^6 times more reactive. On the other hand, the bimolecular mechanism of the hydrolysis reaction is more characteristic of the corresponding chloroformimidates (I, R = Ar or COAr, R′ = OAr′, Hal = Cl) under similar conditions.[35,45] The tendency of *N*-arylchloroformimidates to hydrolyse via the S_N2 mechanism, in contrast to other *N*-arylimidoyl chlorides, is attributed to the influence of substituents at the imidoyl carbon atom on the formation and stabilisation of the developing carbonium centre, which varies in the sequence Ar > NMeAr > SAr > OAr. Compared with the sulphur atom, the oxygen atom stabilises the carbonium centre to a lesser extent owing to the mesomeric effect and destabilises it more because of the greater negative inductive effect. In all cases, the degree of cooperation with the formation of the carbonium centre as a result of the delocalisation of the positive charge is greater for the aromatic ring linked to the nitrogen atom than for that linked to the carbon atom, because the contribution of the octet resonance structure to the nitrilium ion predominates.

The S_N1 mechanism has been established for the hydrolysis in aqueous dioxan of the isomeric (*Z*)- and (*E*)-*O*-methylbenzohydroximoyl halides,[33] the (*Z*)-isomers hydrolysing almost 470 times faster than the (*E*)-isomers. This shows that the free electron pair at the nitrogen atom should be preferentially in the *trans*-position with respect to the leaving group in the formation of the intermediate nitrilium ion. The nature of this group affects the rate of hydrolysis. For bromine, the rate is much higher than for chlorine, which also confirms the S_N1 mechanism.

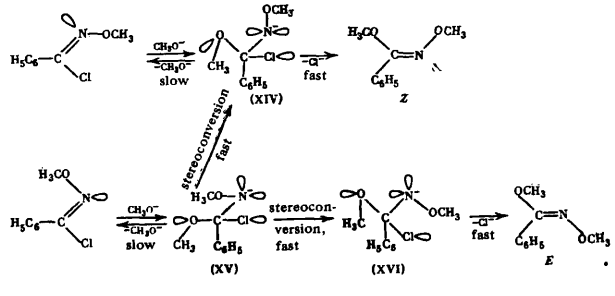
Compared with *N*-arylimidoyl halides, *O*-methylbenzohydroximoyl halides hydrolyse with more difficulty (at 120 °C compared with room temperature for imidoyl halides), which can be explained by the destabilisation of the intermediate nitrilium ion by the electronegative methoxy-group at the nitrogen atom.

It follows from kinetic data for the hydrolysis in an aqueous organic medium of halogenoimidoyl groups in halogenoazines[8,50,51] that for compounds of this type the mechanism can change, as for imidoyl halides, from the dissociative S_N1 mechanism to the associative S_N2 mechanism depending on the structure of the substrate and the medium. For example 1,4-diaryl-1-chloro, and 1,4-diaryl-1,4-dichloro-2,3-diazabuta-1,3-dienes (IX, R = H or Cl) are converted respectively into the hydrazides (X) and the oxadiazoles (XI) in aqueous dioxan; a similar slow stage, involving the unimolecular cleavage of the C–Cl bond and the formation of the stabilised nitrilium ion (XII), has been observed for compounds of both series:

In basic media, compounds of both series are subjected to direct S_N2 attack by hydroxide, but only provided that electron-accepting substituents are present in the arene rings. In other cases, the rate of reaction falls with increase in the concentration of OH^- ions.[50]

In the series of hydrazonohalides, studies have been made of the kinetics of the hydrolysis in an aqueous organic medium of *N*-arylhydrazonobromides[55-57] and *N*-amidinohydrazonobromides,[58] including those with the amidine group as part of the composition of the heterocycle.[59,60] It was shown that, as a rule, the hydrolysis proceeds in accordance with the S_N1 mechanism via the nitrilium ion (XIII):

$$R\overset{+}{C}{=}N{-}NR^1R^2 \longleftrightarrow RC{\equiv}\overset{+}{N}{-}NR^1R^2 \quad (XIII)$$



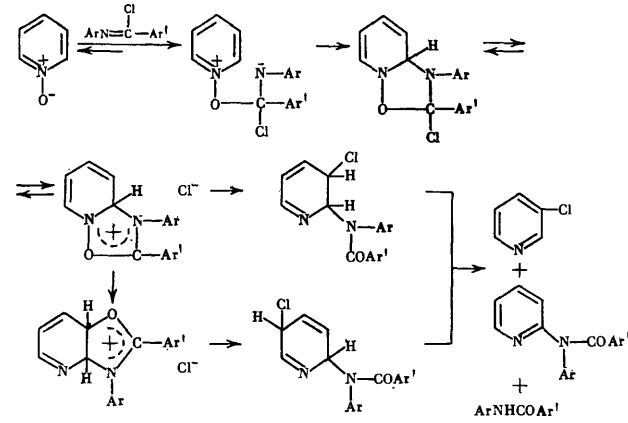
Electron-donating substituents at the imidoyl carbon atom (R) and the hydrazine nitrogen atom (R^1 and R^2) promote the formation of the nitrilium ion. Steric factors are also significant. Thus the rate of hydrolysis of *N*-arylhydrazonobromides with an alkyl group at the imidoyl carbon atom decreases with increase in the bulk of this group.[55] The hydrolysis of the hydrazonobromide group forming part of the composition of a heterocycle is difficult.[56]

(b) Reactions with Alcohols and Phenols

The familiar reaction involving the nucleophilic substitution of the halogen atoms in imidoyl halides and dihalides on treatment with alcohols or alkoxides, leading to the formation of the corresponding imidates, has been extended to new systems.[24,33,47,48,63-72] The interaction of *N*-(perfluoroisopropyl)acetimidoyl chloride with polyfluorinated alcohols has been carried out in the presence of trimethylamine,[66,72] while in the reactions of *N*-(pentafluorophenyl)carboimidoyl dichloride with alcohols and phenols, potassium carbonate has been used as the base.[64] It has been shown in relation to the interaction of *N*-arylbenzimidoyl chlorides and sodium phenoxides that aryl imidates can be obtained in satisfactory yields under the conditions of two-phase catalysis.[73,74] For a description of the reactions of *N*-trichloromethyl)carboimidoyle dichloride with alcohols and phenols, see Findeisen et al.[15]

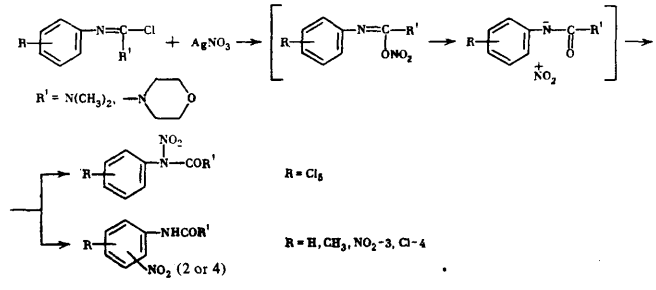
The substitution of halogens by alkoxy- and aryloxy-groups has also been described for halogenoazines[51] and hydrazonohalides.[62,75-77] The reaction of *N*-arylhydrazonohalides with *o*-aminophenols leads to 1,4-benzoxazine derivatives.[78]

Not only a kinetic but also a stereochemical study has been made on the reactions involving alkoxide substitution at the N=C bond for benzohydroximoyl chlorides[71] and benzohydrazonochlorides,[75] although in many cases the configurational instability of the azomethine systems hinders such study. The reactions of the (*Z*)- and (*E*)-isomeric *O*-methylbenzohydroximoyl chlorides with sodium methoxide in solution in the 10% methanol–90% dimethyl sulphoxide (DMSO) mixture are characterised by the Hammett constant $\rho = 1.90$ and proceed with retention of configuration to the extent of ≥95% for the (*Z*)-isomer and 77–≥95% (depending on the substituents in the arene ring) for the (*E*)-isomer. The *E* → *Z* isomerisation of the initial chlorides does not then take place. The data obtained agree with a bimolecular mechanism for the addition–elimination reaction, in which the rate-determining stage is nucleophilic attack by the alkoxide ion on the initial chloride with formation of a tetrahedral intermediate:



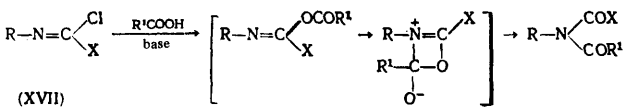
The stereochemistry and the relative rates of the reactions are interpreted in terms of the theory of the stereoelectronic control of the addition and elimination stages.[79] Accordingly, the loss of the chloride ion from the tetrahedral intermediate (XIV) is faster than the elimination of the methoxide ion with conversion into the initial compound or stereoconversion. The stereoconversion to the intermediates (XIV) and (XVI) proceeds more rapidly in the tetrahedral intermediate (XV).

A similar mechanism and stereochemistry have been established also for the reactions of *N*-arylbenzohydrazonohalides with the methoxide ion in methanol.[75]



(c) Reactions with *N*-Oxides and Silver Nitrate

The *N*-oxides of nitrogen heterocycles interact with benzimidoyl chlorides to form heterocyclic derivatives containing 2-acylamino-groups, which readily hydrolyse to 2-amino-derivatives without being isolated.[80-83] Apart from the acylamination reaction, the chlorination of the heterocyclic ring and in certain cases the formation of hydroxy-derivatives are observed. In the presence of bases, the yield of the acylamination products increases. The reactions with pyridine *N*-oxides have been most fully investigated.[80,81] One of the reaction schemes is presented below:

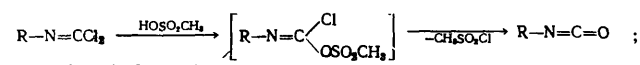


Ar = C_6H_5; Ar' = C_6H_5, $C_6H_4CH_3$-2, -3 and -4 etc.

Nucleophilic attack by the *N*-oxide oxygen on the electrophilic carbon atom of the imidoyl chloride and subsequent intramolecular addition of nitrogen in the 2-position in the pyridine ring leads to the intermediate, 1,2-dihydropyridine, which aromatises or undergoes a successive 1,5-sigmatropic shift and aromatisation. The primary products of the substitution of chlorine by the $-ONO_2$ group rearrange to nitroureas in the reaction of *N*-arylchloroformamidines with silver nitrate:[41]

(d) Reactions with Organic Acids

The reactions of salts of aromatic and aliphatic carxobylic acids or of the acids themselves with benzimidoyl chlorides or aryliminochloromethyl sulphides having the general formula (XVII) in the presence of bases take place via the nucleophilic substitution of the chlorine atom and the subsequent 1,3-migration of the acyl group from the oxygen to the nitrogen atom.[73,84] Satisfactory results have been obtained also under the conditions of two-phase catalysis:

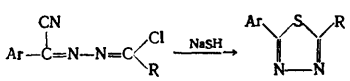


(XVII)

R=Ar, Alk; R'=Ar, Alk; X=C_6H_5, SC(Hal)$_3$

N-(Trichloromethyl)carboimidoyl dichloride reacts with aromatic, aliphatic, alicyclic, and heterocyclic carboxylic acids via the intermediate *N*-(chloroformyl) carboimidoyl dichloride in accordance with the scheme[15]

$$CCl_3{-}N{=}CCl_2 + R{-}COOH \rightarrow RCOCl + CO_2 + ClCN + HCl$$



In the reactions involving aliphatic sulphonic acids, the final product is *N*-chloroformyl isocyanate. Isocyanates are obtained also in the reactions of carboimidoyl dichlorides with methanesulphonic acid:[17,85-87]

R=ClCH$_2$, CHCl$_2$, COCl

2. Reactions with *S*-Nucleophiles

The reactions of compounds containing halogenoimidoyl groups with aromatic and aliphatic thiols or their salts take place readily, leading to products of the substitution of the imidoyl halogen atom by a thio-group.[66,68,73,75,88-91] In many instances the reaction does not stop at the thioimidate formation stage and proceeds further, affording cyclisation products, 2,5-Disubstituted 1,3,4-thiadiazoles have been obtained in this way from, for example, 4-chloro-1-cyano-2,3-diazabuta-1,3-dienes:[2]

Ar=C_6H_5, $C_6H_4CH_3$-2, C_6H_4Cl-4; R=CH_3, C_6H_4Cl-2.

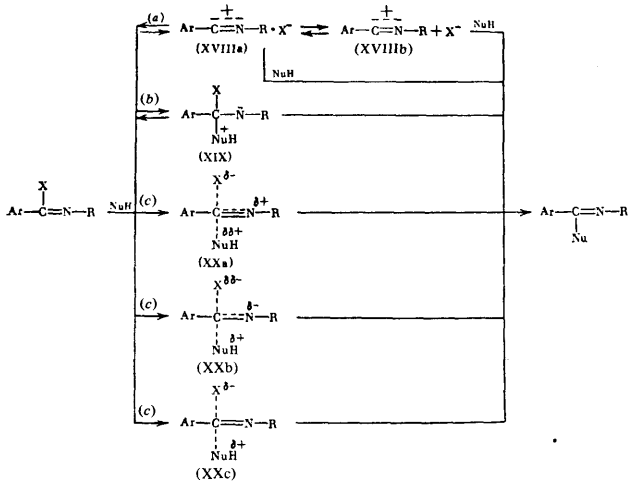
N-(Trifluoromethylthio)trifluoroacetimidoyl chloride, having two centres susceptible to nucleophilic attack (the imidoyl carbon atom and the sulphur atom), reacts with thiols as soft nucleophiles exclusively via the sulphenyl sulphur atom (the carbon atom is sensitive to attack by hard nucleophiles).[72]

Among other sulphur-containing reagents, phosphorus pentasulphide has been involved in the reaction, converting *N*-(dichloromethylthio)carboimidoyl dichloride into the corresponding isothiocyanate with a low yield.[93] The reactions of hydrazonohalides with various sulphur-containing reagents have been described by Shawali[9] and Hassaneen et al.[77]

3. Reactions with *N*-Nucleophiles

(a) Reactions with Amines

Primary and secondary amines. The reactions of compounds containing halogenoimidoyl groups with primary and secondary amines lead to the products of successive substitution of the halogen atoms at the imidoyl carbon atom by amino-groups. The compounds then formed are either entirely stable and can be isolated and characterised or they are unstable and undergo various conversions, in particular, carbodiimides or their tautomers (amidonitriles) and heterocyclic derivatives.



Stable substitution products have been isolated in the reactions of carboimidoyl dihalides,[41,45-97] imidoyl halides[37,48,65,72,95-109] hydrazonohalides,[59,77,91,110,111] and halogenoazines.[8] In certain cases trimethylsilyl derivatives of the amine were used for the reactions.[49,107]

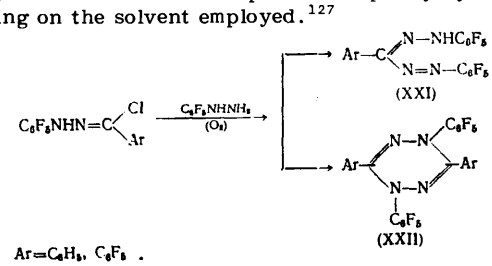
It is noteworthy that, in the reactions of carboimidoyl dichlorides with aromatic amines, it is frequently not possible to obtain the products of the substitution of one chlorine atom and guanidines are formed.[17,46] They are present in the reaction mixture even when the degree of reaction of the initial dichloride is low.

Amidonitriles are formed in the reactions of *N*-(*p*-chlorophenyl)- and *N*-(pentachlorophenyl)-carboimidoyl dichlorides with ammonia.[3] Conversion into a carbodiimide has been noted in the reaction of 2,4,6,6-tetrachloro-1,1,1-trifluoro-2-phenyl-3,5-diazahexa-3,5-diene with t-butylamine. In the analogous reaction with isopropylamine or primary aromatic amines, derivatives of 1,2-dihydro-1,3,5-triazine were obtained.[112] Heterocyclic compounds have also been synthesised from carboimidoyl dichlorides and chlorides by reaction with ethylenediamine,[113] anilines,[15,108,114] and *o*-phenylenediamines[30,94,115-117] and also in the reactions of halogenoazines with amines.[8,35]

Kinetic data have been obtained for the formation of amidines in the reactions of diarylamidoyl halides with aliphatic[100,105,106] and aromatic[98,99] amines in non-aqueous solvents of different polarity and also in the reactions of isomeric *O*-methylbenzohydroximoyl halides with aliphatic amines.[109] Analysis of the influence of the nature of the substituents in the diarylimidoyl halide, the structure and basicity of the amine, the nature of the solvent, salt effects, and the effect of the leaving group and of the activation parameters supports bimolecular nucleophilic substitution at the imidoyl carbon atom with participation of the C=N bond. The substitution takes place via different pathways: (a) the nucleophilic elimination–addition mechanism characterised by negative values of the Hammett constant ρ in which the attack by the nucleophile on the nitrilium cation intermediate (XVIII) formed initially, which can exist either as the ion pair (XVIIIa) [the S_N2(IP) mechanism] or as the ion (XVIIIb) [the $S_N2(C^+)$ mechanism], is rate determining;† (b) the nucleophilic addition–elimination mechanism ($Ad_N - E$ or S_AN) involving the formation of the tetrahedral intermediate (XIX) and characterised by a positive value of ρ; (c) a concerted S_N2 mechanism which is differentiated in terms of the degree of involvement of the C=N bond (in terms of the relative contributions of the degree of dissociation of the C–Hal bond and the degree of formation of the C–Nu bond) into a dissociative bimolecular S_N2 mechanism with a transition state of type (XXa), where the degree of loosening of the C–Hal bond predominates over the degree of formation of the C–Nu bond (negative ρ), an associative mechanism where the opposite relative contributions obtain (the state (XXb), and a mechanism with a symmetrical transition state (XXc) with identical degrees of formation and loosening of the bond.

†The notation S_N2(IP) and $S_C2(C^+)$ represents respectively the ion-pair bimolecular nucleophilic substitution mechanism and the bimolecular nucleophilic subsitution mechanism with participation of the free ion and has been taken from Ta-Shma and Rapport.[105]

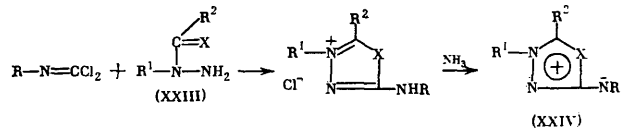
Pathways in which base, electrophilic, or bifunctional catalysis by an amine operates are also manifested, but their contribution to the overall process is small.



The $S_N2(IP)$ mechanism is preferable for the reactions of imidoyl halides having electron-donating substituents at the nitrogen atom with moderate nucleophiles and in solvents with a high solvating power, the version $S_N2(C^+)$ (pathway *a*) occurring for sterically strained nucleophiles. Pathway *b* is more characteristic of the reactions of substrates with electron-accepting substituents and strong nucleophiles. In intermediate cases, the diminution of the withdrawal of electron density from the azomethine linkage can be accompanied by the simultaneous operation of pathways *a* and *b*. Pathway *c* is less probable, but it cannot be rejected altogether especially since kinetic data do not always permit a clear-cut determination of the mechanism. For example, it is difficult to distinguish pathway *a* and pathway *c* with a transition state of type (XXa).[98]

The (*Z*)-isomers of *O*-methylhydroximoyl halides react with amines via an addition – elimination mechanism, while the (*E*)-isomers do not react.[109]

Tertiary amines are frequently used in the reactions of halogenoimidoyl compounds with nucleophiles in order to bind the HHal evolved or to generate ions (see below). However, instances of the addition of tertiary amines to halogenoimidoyl derivatives with formation of imidoylammonium salts are known. These reactions and their kinetics and mechanisms are described in detail elsewhere.[118–122]

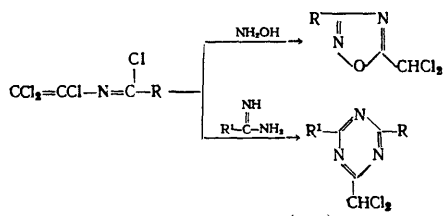


(b) The Reactions with Hydrazines and Their Derivatives

Hydrazines and their derivatives react with compounds containing halogenoimidoyl groups, forming stable primary products of the substitution of the halogen atom by the hydrazine residue[123–126] or the products of their further reactions. Thus mainly formazans (XXI) or tetrazines (XXII) are formed in the reactions of *N*-(pentafluorophenyl)-benzohydrazonochlorides with pentafluorophenylhydrazine depending on the solvent employed.[127]

Ar=C_6H_5, C_6F_5 .

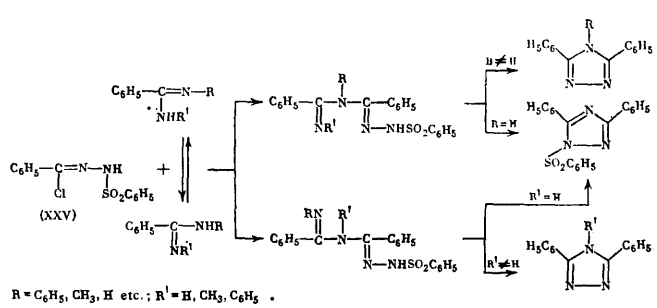
Tetrazines are the products of the reaction of *N*-(arenesulphonyl)carboimidoyl dichloride with methylhydrazine in the presence of methyl orthobenzoate.[128] Substituted 1,2,4-triazoles or 2,5-diaryltetrazoles have been obtained by the reaction of *N*-(polychlorovinyl)imidoyl chlorides[108,114] and 1,3-dichloro-1-dimethylamino-4-fluoro-2-azabutadiene[129] or *N*-(benzenesulphonyl)benzohydrazonochlorides[130] respectively with arylhydrazines. The primary products of the reactions of *N*-(aryl)- or *N*-(alkyl)-carboimidoyl dichlorides with α-acyl- or α-thioacyl-hydrazines (XXIII) are converted into cyclic mesoionic compounds of type (XXIV) on treatment with ammonia:[131–134]



X = O, S

R^1 = CH_3; R^2 = C_6H_5; R = $C_6H_4CH_3$-4, C_6H_4Cl-4, CH_3 .

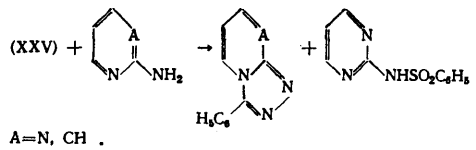
Mesoionic structures are also formed in the analogous reactions of 1,1-dibromo-2,3-diazadienes and *N*-aminobenzamidines.[125,134,135]



(c) Reactions with Hydroxylamine and Amidines

Carboimidoyl dichlorides and chlorides containing *N*-chloroalkenyl groups having α-chlorine atoms react with bifunctional nucleophiles, in particular, with hydroxylamine or amidines involving the substitution of an α-chlorine atom or the chlorine atom at the imidoyl carbon atom and affording various heterocyclic derivatives,[15,17,108,114] for example:

R=C_6H_5, C_6H_4Cl-4, $C_6H_4CH_3$-4, CCl_3 (etc.).

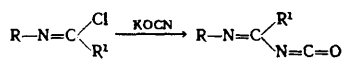


The reactions of *N*-(benzenesulphonyl)benzohydrazonochloride (XXV) with *N*-substituted amidines take place via a two-step mechanism involving the nucleophilic attack on compound (XXV) by two tautomeric forms of the amidine and subsequent cyclisation as a result of the nucleophilic attack by the amino-group on the iminocarbonyl carbon atom of the initial amidine in the intermediate compound. The final products are substituted 1,2,4-triazoles:[136]

R = C_6H_5, CH_3, H etc.; R^1 = H, CH_3, C_6H_5 .

2-Aminopyridine or 2-aminopyrimidine, which can be regarded as heterocyclic amidines, react analogously; the initial nucleophilic attack on the hydrazonochloride is by a ring nitrogen atom. This results in the formation of tri-

azolopyridines or triazolopyrimidines;

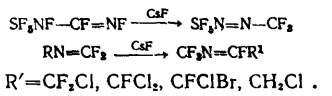


A=N, CH .

The reactions of other hydrazonohalides are similar.[137] Both linear and cyclic products are formed in the reactions of α-ketohydroximoyl chlorides with heterocyclic amidines.[138]

(d) Reactions with Azides and Cyanates

When compounds with a halogenoimidoyl group are acted upon by sodium azide, the halogen is replaced by the azido-group[57,139–143] and tetrazoles are formed.[51,84,139,144,145] The study of the kinetics of the reactions of isomeric acylbenzohydroximoyl chlorides with sodium azide in water showed that the reaction is bimolecular. When the (*Z*)-isomer is involved it takes place with retention of configuration, while in the case of the (*E*)-isomer it is ten times slower and the inversion of configuration is observed.[143]



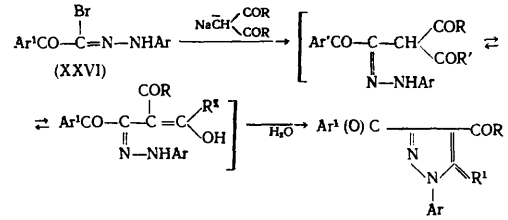
Open-chain imidoyl isocyanates, which have been little investigated, can be obtained by the reaction of imidoyl chlorides with potassium cyanates in the presence of crown-ether:[146]

R = iso-C_3H_7, C_6H_5 etc., R^1 = t-C_4H_9 .

4. Reactions with Halide Anions

The interaction of halogenoimidoyl compounds with the fluoride anion, whose source is as a rule caesium, potassium or sodium fluoride, has been most widely investigated. One of the reaction pathways involves the substitution of the imidoyl halogen atom by fluorine.[16,37,38,72,147–149] Under these conditions, other halogen atoms present in the molecule can also be substituted by fluorine[150,151] or these atoms alone are substituted if their mobility is higher than that of the halogen at the carbon atom of the N=C bond.[152] Another pathway in the reaction with alkali metal fluorides is isomerisation:[153,154]

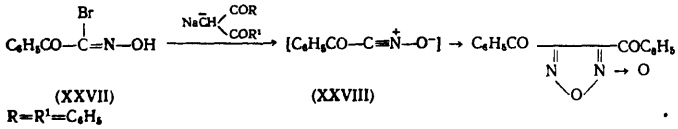
R′=CF_2Cl, $CFCl_2$, CFClBr, CH_2Cl .



Finally, the addition of the fluoride anion to the N=C bond leads to the formation of *N*-anions, which can be inferred either from direct spectroscopic observations[155,156] and the isolation of stable salts[157] or from the reaction products. The anions can undergo intramolecular rearrangements and cyclisations[150,158,159] or they can participate in intermolecular reactions, functioning as active nucleophiles.[137,160] Dimerisation processes also belong to the class of intramolecular reactions.[159,161,162]

A study[159] of the interaction of the fluoride anion with perfluoro-2,5-diazahexa-2,4-diene established that the formation of a particular product is influenced by the source of the fluoride anion and the reaction conditions, which determine the formation of products resulting from kinetic or thermodynamic control.

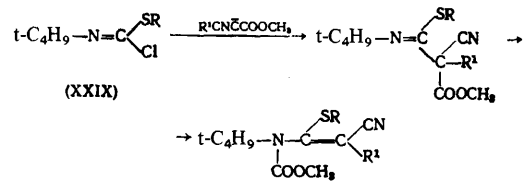
The *N*-anion CF_3NF^-, formed by the reaction of $FN=CF_2$ with caesium, potassium, or mercury fluorides, behaves as an active nucleophile in reactions with the initial compound or its *N*-chloro-analogue and also with perfluorocarbonyl fluorides, giving rise to different products.[163,164] The less stable and nucleophilic *N*-anion CF_3NCl^-, formed by the reaction of $ClN=CF_2$ with potassium or caesium fluoride, is oxidised by chlorine to CF_3NCl_2.[164] The reactions of the *N*-anions derived from perfluoroazacyclohexene and perfluorocyclohexadienes have also been described.[155,156]



5. Reactions with *C*-Nucleophiles

The interaction of imidoyl chlorides or hydrazonohalides with KCN leads to the products of the substitution of the halogen by the CN group.[91,165,166] Carbanions generated from compounds with active methylene groups can also function as *C*-nucleophiles:[167]

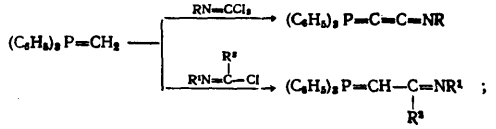
R=R^1=CH_3, C_6H_5; Ar=C_6H_5; Ar^1=C_6H_5; $C_6H_4NO_2$-4 .



In contrast to this, in the reaction of hydroximoyl bromide (XXVII) with a carbanion, the latter acts only on the base, which promotes the formation of the intermediate nitrile oxide (XXVIII):[88]

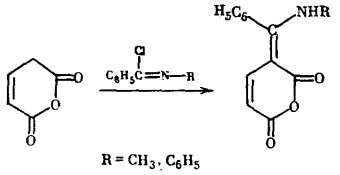
R=R^1=C_6H_5

The difference in the behaviour of the two types of compounds, (XXVII) and (XXVI), can be attributed to the different acidities of the O–H and N–H bonds and to the ease of formation of the nitrile oxide from compound (XXVII) and the nitrile imine from compound (XXVI).



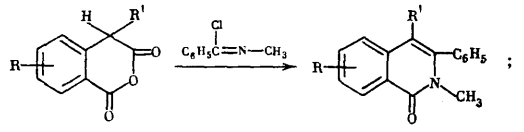
The interaction of chlorothioformimidates (XXIX) with carbanions derived from cyanomalonic esters leads to thioimidates which rearrange even at room temperature to the (*E*)- and (*Z*)-isomers of *N*-vinylcarbamates as a result of the 1,3-migration of the alkoxycarbonyl group:[168]

R=CH_3, C_6H_5; R^1=C_6H_5, $C_6H_4CH_3$-4 etc.



In the reaction of phenyl-lithium with *N*-(pentafluorothio)-chloroformamidine, the chlorine atom is substituted by the phenyl group.[47] Reactions with vinyl- and ethyl-magnesium bromides and also with aromatic and aliphatic magnesium bromide derivatives are described elsewhere.[42,89,171]

Carboimidoyl dichlorides react with methylenetriphenylphosphorane:[169,170]



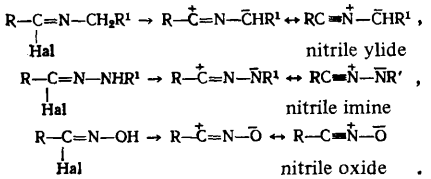
R=C_6H_5, CH_3, C_6H_{11} etc.; R^1=C_6H_5, $C_6H_4CH_3$-4;
R^2=C_6H_5, OCH_3, SCH_3 .

In reactions of glutaconic or homophthalic anhydrides with imidoyl chlorides, the initial nucleophilic attack on the imidoyl carbon ion is by the C(4) atom of the anhydride. The intermediate compounds of the aldol type are converted into the final products with and without the involvement of the anhydride component of the molecule:[172–174]

$R = CH_3, C_6H_5$

$R = H, OCH_3$ etc.; $R' = H, CH_3$.

6. Reactions with Other Nucleophiles



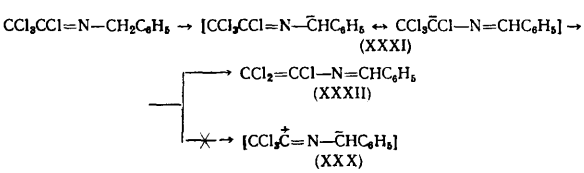
The reactions of imidoyl chlorides and hydrazonohalides with selenium compounds, leading to selenium heterocycles, have been described.[175,176] The mode of the reactions of imidoyl chlorides with di- and tri-alkyl phosphites[177,178] and also with phosphorus acid ester amides[179] depends unambiguously on the structure of the initial compounds and the reaction conditions. Imidoyl chlorides are converted into imines and amines on treatment with the $HFe(CO)_4^-$ anion in high yields,[180] while the reaction with the $C_6H_5COFe(CO)_4^-$ anion affords mesoionic 1,3-oxazol-5-ones.[181]

III. ELIMINATION REACTIONS

The elimination reactions of compounds with halogenoimidoyl groups have been fairly thoroughly investigated, particularly those which lead to highly reactive intermediate dipolar ions capable of interacting with various reagents to form new compound of many types. The wide scale use of halogenoimidoyl derivatives in organic synthesis, especially in the synthesis of heterocyclic compounds, is associated with precisely this feature.

1. The Formation of Ions and Their Reactions

When comounds with the halogenoimidoyl group are acted upon by strong bases, hydrogen halide is split off and dipolar ions of the following main types are formed:



nitrile ylide

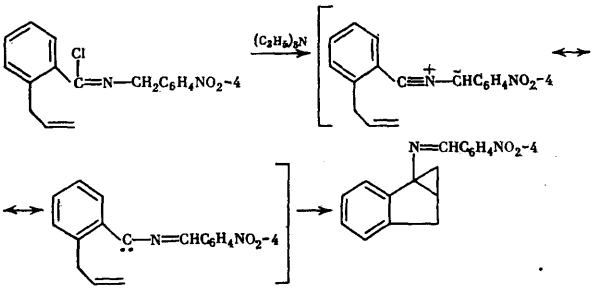
nitrile imine

nitrile oxide .

As a rule, these ions are formed only *in situ* and, depending on their structure and the reaction conditions, rapidly undergo intramolecular reactions or enter into intermolecular reactions with formation of dimers or the products of the reactions with other reagents present in the system.

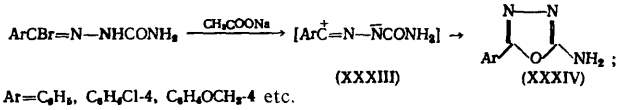
In the course of development of early research into nitrile ylides, the mechanism of the tautomeric transformation of *N*-(4-nitrobenzyl)benzimidoyl chloride, *N*-(benzyl)-4-nitrobenzimidoyl chloride, and of the nitrile ylides formed from them on treatment with triethylamine has been studied in greater detail and confirmed experimentally.[182] Treatment of *N*-(benzyl)trichloroacetimidoyl chloride with triethylamine does not lead to the expected nitrile ylide (XXX), because the mesomeric carbanion (XXXI) formed initially is converted into *N*-(benzylidene)perchlorovinylamine (XXXII):[183]

(XXXI)



(XXXII)

(XXX)



When the corresponding hydroximoyl chlorides were treated with triethylamine, acetonitrile oxide[184] and diphenylacetonitrile oxide[185] were obtained, the latter proving so stable that they could be isolated and characterised. Pentachlorobenzonitrile oxide is also extremely stable,[96] while pentafluorobenzonitrile oxide is unstable and readily dimerises. Silver nitrate has been used successfully to obtain the nitrile oxide from dichloroformaldoxime.[186] The attempt to obtain a nitrile imine from *N*-(benzenesulphonyl)benzohydrazonochloride was unsuccessful, which may be associated with the stability of the *N*-anion formed initially owing to the delocalisation of the negative charge on the electron-accepting benzenesulphonyl group.[136]

(a) Intramolecular Transformations of the Ions

The conversion of the nitrile ylide obtained from o-allyl-*N*-(*p*-nitrobenzyl)benzimidoyl chloride into a tricyclic compound as a result of the 1,1-cycloaddition of the carbene form of the nitrile ylide to the double bond may serve as an example of an intramolecular transformation:[187]

The intramolecular attack by the oxygen in the nitrile imine (XXXIII), which takes place as 1,5-dipolar addition, leads to the oxadiazole derivative (XXXIV):[188]

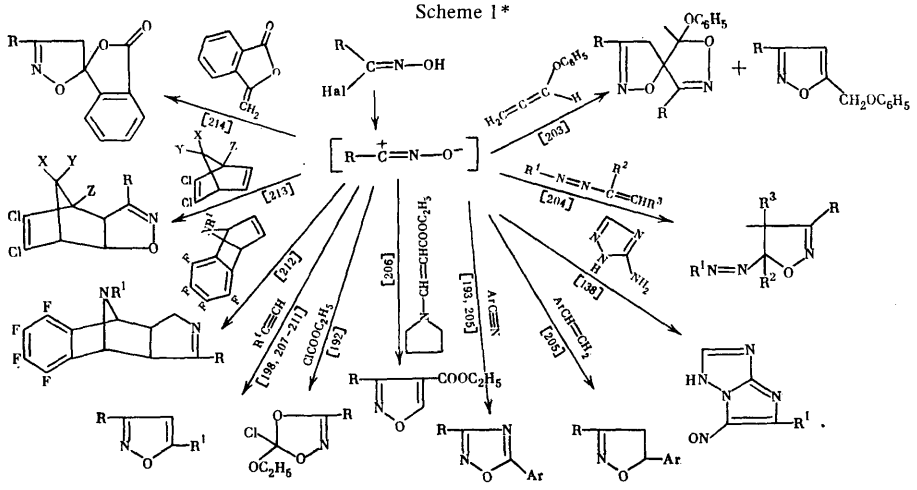
(XXXIII) (XXXIV)

$Ar = C_6H_5$, C_6H_4Cl-4, $C_6H_4OCH_3$-4 etc.

The nitronitrile imines formed as intermediates when the arylhydrazones of bromonitroformaldehyde are acted upon by sodium acetate in acetic acid isomerise to *N*-nitrosoaminoisocyanate, which is stable in the tautomeric cyclic mesoionic form of 3-aryl-1,2,3,4-oxatriazolate.[189,190]

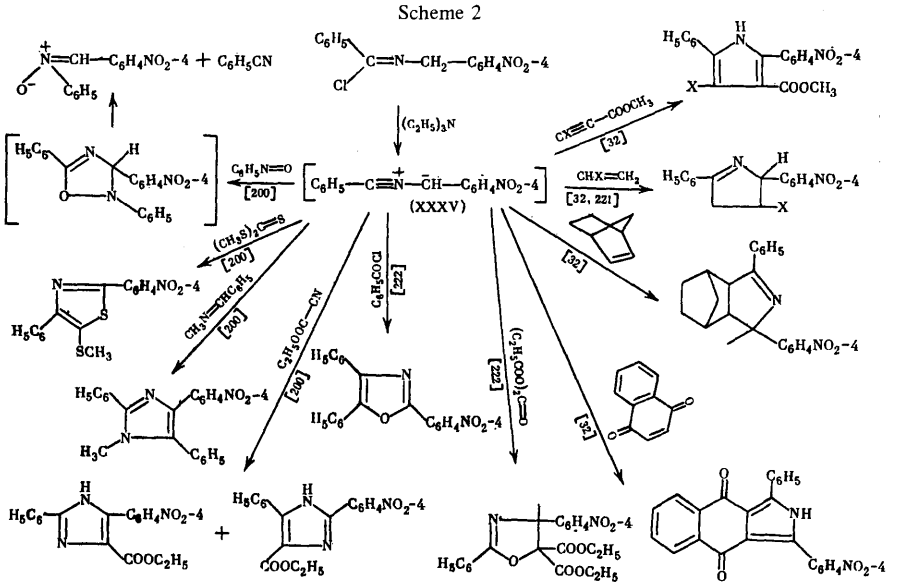
The nitrile oxides formed from benzohydroximoyl chlorides on treatment with iron pentacarbonyl are deoxygenated further to nitriles.[191]

(b) Intermolecular Reactions of the Ions



Dimerisation. The unstable nitrile oxides obtained from benzoylhydroximoyl halides[88,192] as well as acetonitrile oxide[184] and pentafluorobenzonitrile oxide[96] are converted into furoxan derivatives as a result of the 1,3-dipolar cycloaddition of one nitrile oxide molecule to the C≡N bond of another. Depending on the conditions under which trifluoroacetonitrile oxide is generated, its dimers are the corresponding dioxadiazine or furoxan.[193] Nitrile imines of the type $ArN^{-}-N=\overset{+}{C}-R$, where R = $COCH_3$, $COOC_2H_5$, or $COAr^1$, obtained from *N*-arylhydrazonohalides, dimerise to derivatives of 1,4-dihydro-1,2,4,5-tetrazine.[165,194]

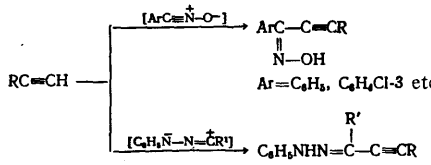
Interaction with dipolarophiles and other reactions. The important and widely investigated reactions of the intermediate nitrile ylides, nitrile imines, and nitrile oxides involve their dipolar [3 + 2]cycloaddition interaction with various dipolarophiles occurring with the closure of a five-membered heterocycle ring and leading to the formation of a wide range of a wide variety of heterocyclic systems. At the present time the range of dipolarophiles used is extremely wide. The cycloaddition reactions proceed with participation of the C=C, C≡C, C=N, C≡N, C=O, C=S, and N=O bonds. Some examples of the 1,3-dipolar cycloaddition reactions of nitrile oxides are presented in Scheme 1.



The reactions of nitrile oxides with other dipolarophiles have been described in a number of publications.[96,186,192,201,206,215–220] The 1,3-dipolar cycloaddition reactions of benzonitrile 4-nitrobenzylide are presented in Scheme 2. The reactions of the nitrile ylide (XXXV) with other dipolarophiles have been described by Huisgen and co-workers[32,222] and those of other nitrile ylides with dipolarophiles have been described by Padwa et al.[187] Scheme 3 presents the 1,3-dipolar cycloaddition reactions of nitrile imines. The reactions of nitrile imines with other dipolarophiles have been described in a series of publications.[194,199,202,212,228,230–232]

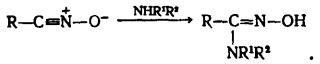
The mechanisms of these reactions have been described in a number of studies.[195–201] The most generally accepted point of view is that they take place via a concerted 1,3-di-

Scheme 1*



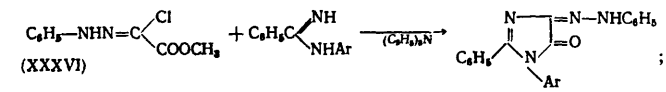
Scheme 2

Note. Numbers in square brackets denote references (Ed. of Translation).



polar cycloaddition mechanism. The dipolarophile activity and mode of addition have been considered within the framework of the molecular orbital theory. The regioselectivity of the reactions is attributed to the ambident nucleophilic character of the 1,3-dipoles.

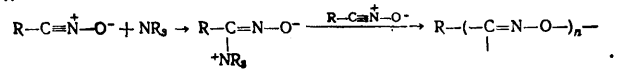
Nitrile imines and nitrile oxides are capable of entering not only into 1,3-dipolar cycloaddition but also into two-step 1,3-addition reactions with dienophiles, leading to acyclic products. For example, the reaction with acetylenes involves both processes and the second one leads respectively to acetylenic oximes or hydrazones:[195,198,202]



$R=C_6H_5$, $CH_2OC_6H_5$, $COOCH_3$; $R^1=CF_3$.

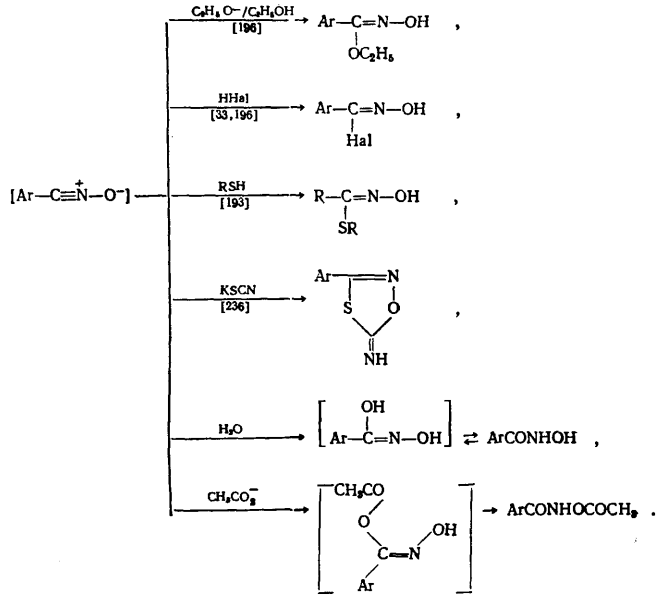
The reaction of nitrile imines and nitrile oxides with nucleophiles of different types (*N*-, *O*-, *S*-, and *C*-, and halogeno-nucleophiles) have also been investigated. The greatest number of publications refer to the reactions with *N*-nucleophiles. Primary and seconary amines react with nitrile oxides, affording amidoximes:[193,233,234]

Nitrogen-containing heterocyclic amino-derivatives are alkylated by nitrile imines at the most basic NH group of the ring and, if such a group is absent, at the NH_2 group.[226-228] Apart from the main product of cycloaddition to the C=N bond, 5-imidazolinones have been isolated in the reactions of the hydrazonochloride (XXXVI) with *N*-arylbenzamidines. Their formation is due to nucleophilic attack by the more basic amidine nitrogen atom (NHAr) of the electrophilic centre of the 1,3-dipole with subsequent ring closure involving a prototropic shift:[225]



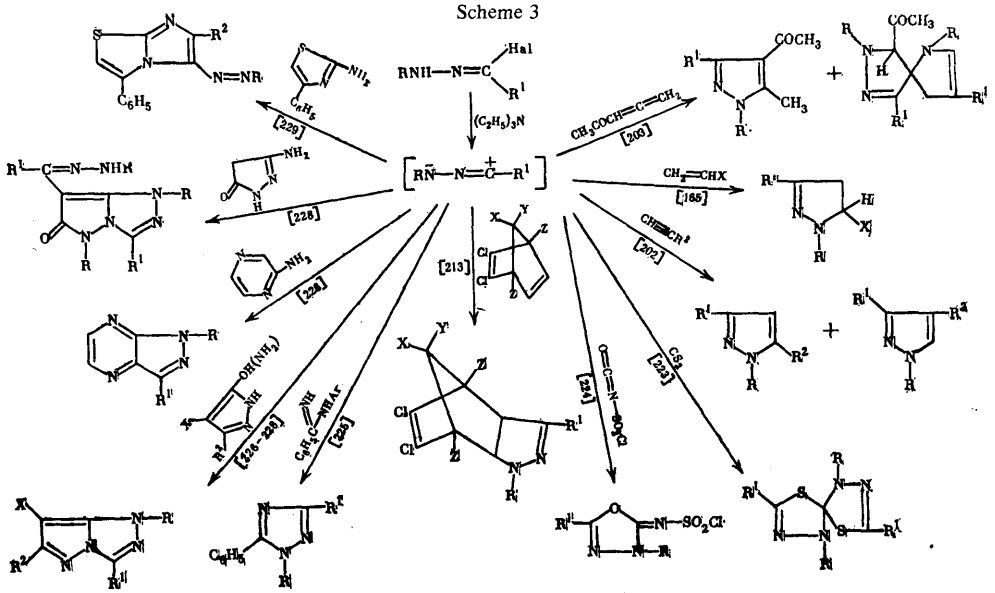
(XXXVI)

Ar=C_6H_5, $C_6H_4CH_3$-4 etc.



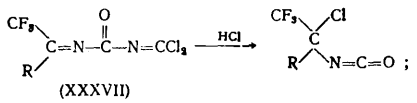
The reaction of nitrile imines with 1,1-diphenylhydrazine, carbohydrazides of the type $RCONHNH_2$, and the hydrazones of aromatic aldehydes and ketones involve the amino-group or proceed as 1,3-dipolar addition and lead to compounds of various types.[235]

Tertiary amines catalyse the polymerisation of nitrile oxides. They add to the nitrile oxides, giving rise to a zwitter-ion, which acts as a nucleophile on a second nitrile oxide molecule, etc.:[184,196]



Hydroximoyl azides are formed as a result of the reaction of nitrile oxides with the azide ion.[196]

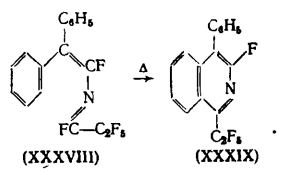
The interaction of nitrile oxides with *O*-, *S*-, *C*-, and halogeno-nucleophiles has been discussed in a number of studies.[33,193,196,197,233,236] "Open" oximes or the products of their further reactions are formed in these processes. Some of the reactions are presented below:



Scheme 3

2. Other Elimination Reactions

The familiar reaction involving the partial reduction of imidoyl chlorides to imines by treatment with tin dichloride has been used to convert a number of *N*-arylbenzimidoyl chlorides into aldehyde anils, from which aldehydes can be readily obtained in an acid medium.[237] In those cases where such a reductant cannot be applied, one can carry out the partial reduction under significantly milder conditions with the tris(t-butoxy)-derivatives of lithium aluminium hydride at a low temperature.[238] The reduction of imidoyl iodides with sodium tetrahydroborate leads to amines.[48] On treatment with magnesium in tetrahydrofuran (THF), *N*-(polyfluoroalkyl)- or *N*-(polyfluoroaryl)carboimidoyl dichlorides undergo reductive elimination of chlorine and the corresponding isocyanides are formed.[239]



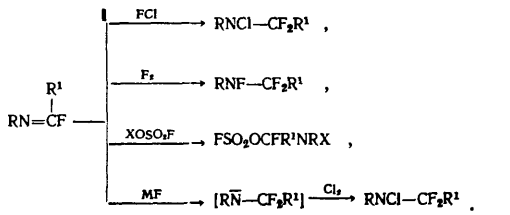
On heating with HCl, *NN'*-bisalkylideneureas of the type (XXXVII) split off chlorocyanogen with formation of α-chloroalkyl isocyanates:[240]

(XXXVII)

R=C_6H_5, C_6H_4Cl-4; $C_6H_4CF_3$-4 .

On thermolysis, imidoyl halides are converted into nitriles.[38,152,241] The high thermal stability of *N*-(pentafluorophenyl)carboimidoyl dichloride[161] and *N*-(pentafluorophenyl)chloroacetimidoyl chlorides[37] has been noted. Depending on the nature of the ring substituent, the thermolysis of benzohydroximoyl chlorides leads to nitriles, aryl isocyanates, or O-benzoylhydroximoyl chlorides.[242] *N*-(ω-bromopentyl)-benzimidoyl chloride undergoes fragmentation to ωω-dibromoalkane and benzonitrile on heating.[243] The azabutadiene (XXXVIII) splits off HF at 180–200 °C and is converted into the isoquinoline derivative (XXXIX):[244]

(XXXVIII) (XXXIX)

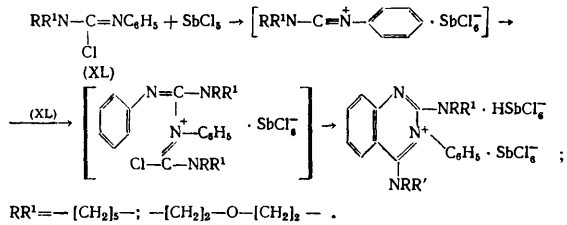


The thermolysis of compounds of the type $(RO_2C)_2N{=}N{-}CBrX$ (R = CH_3 or C_2H_5; X = Br or Cl) provides a new pathway to 2-halogen-1,3,4-oxadiazolin-5-ones which are difficult to obtain otherwise.[245]

Various chlorinated *SN*-heterocyclic systems are formed in the thermal dehalogenation reactions of polychlorinated imidoyl dichlorides and chlorides on treatment with sulphur.[246]

IV. ADDITION REACTIONS

1. The Action of Electrophiles and Radical Reagents

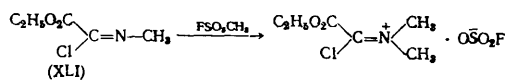


The reactions with electrophiles are less characteristic of compounds containing the halogenoimidoyl group than those with nucleophiles because of the electron-accepting properties of this group ($\sigma_m = 0.21$, $\sigma_p = 0.13$, $\sigma_I = 0.29$, $\sigma R = -0.08$[247]). However, such reactions are also known and in recent years their range has been appreciably extended. The interaction of halogenoimidoyl derivatives with the halogens,[248] including elemental fluorine,[249,250] chlorine monofluoride,[250–253] the highly electrophilic halogeno-derivatives of fluorosulphonic acid of the type $XOSO_2F$ (X = Cl, Br, or OSO_2F), the pseudohalogen $S_2O_6F_2$, and also moderately electrophilic halogeno-derivatives such as CF_3OCl and CF_3OF[164,148] has been investigated. These reactions involve the electrophilic or free radical addition of the reactants to the C=N bond. In many instances the reactions take place in the presence of alkali metal fluorides which promote the formation of the corresponding readily oxidisable *N*-anions:

The products of addition to the C=N bond are also formed in the oxidation of *N*-halogeno-, *N*-halogenoalkyl-, or *N*-pentafluorothio-imidoyl difluorides by trifluoromethyl hydroperoxide:[154,254,255]

$$RN{=}CF_2 + CF_3OOH \rightarrow CF_3OOCF_2{-}NHR$$

Lewis acids also enter into the addition reactions. This results in the formation of nitrilium salts,[243,256–259] which have been either isolated in a pure form or identified from the reaction products:

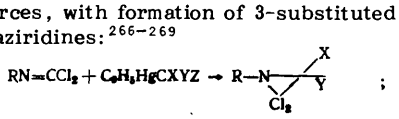


(XL)

RR^1=—$[CH_2]_5$—; —$[CH_2]_2$—O—$[CH_2]_2$— .

The interaction of SbF_3 with *N*-(chlorodifluoromethylthiosulphenyl)carboimidoyl dichloride is accompanied by the decomposition of the latter to chlorocyanogen and a disulphide.[260,261]

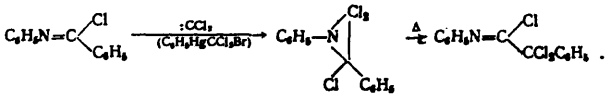
The imidoyl chloride (XLI) is alkylated by methyl fluorosulphonate to a reactive salt, whose formation has been detected from the ^1H NMR spectra and numerous reactions:[97]



(XLI)

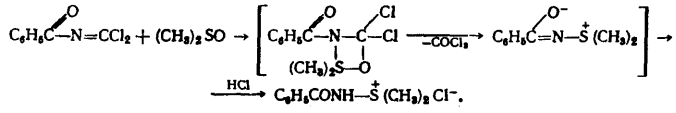
Treatment of imidoyl dichlorides with HF leads to the substitution of chlorine atoms by fluorine and addition to the C=N bond with formation of *N*-(trifluoromethyl)amino-derivatives.[157,262–264]

In the reaction of *N*-(t-butyl)carboimidoyl dichloride with bis(bistrifluoromethylamino-oxy)mercury, the final products resulted from the substitution of one or two chlorine atoms by the bistrifluoromethylamino-oxy-radical; the monosubstituted product can be converted into the disubstituted product by additional treatment with the mercury derivative.[264]



2. Cycloaddition

Aromatic and aliphatic carboimidoyl dichlorides enter into cycloaddition reactions with halogenocarbenes, obtained from mercury sources, with formation of 3-substituted 2,2-dichloro-1-phenylaziridines:[266–269]



R=C_6H_5 Z=Cl or Br X=F; Y=$COOC_2H_5$
X=Y=Cl
X=F; Y=Cl .

The aziridine derivative of *N*-phenylbenzimidoyl chloride isomerises to the corresponding imidoyl chloride already during isolation:[266]

N-Phenyltrichloroacetimidoyl chloride does not react with dichlorocarbene.[266] Nor could *N*-pentafluorophenylcarboimidoyl dichloride be made to react with high-temperature sources of dichloro- and difluoro-carbenes.[161]

The cycloaddition to the N=C bond takes place in the reaction of *N*-benzoylcarboimidoyl dichloride with dimethyl sulphoxide; however, the cyclic adduct if unstable and decomposes under the reaction conditions with elimination of phosgene:[270]

During the preparation of the manuscript for publication, kinetic data were obtained for the arylaminolysis reactions of *N*-methane- and *N*-benzene-sulphonylbenzimidoyl chlorides in acetonitrile which are consistent respectively with the ion-pair and addition-elimination mechanisms.[271,272] The mechanism of the salt formation reactions of *N*-alkylbenzimidoyl chlorides with pyridine bases has been investigated.[273] It has been shown that the salt formation reaction of *N*-phenylcarboimidoyl dichloride and cyclic tertiary amines is accompanied by dealkylation with ring opening in the case of small rings.[274] The interaction of *N*-arylcarboimidoyl dichloride with cyclic secondary amines has been described.[275] The hydrolysis of chloroformamidines, the reactions of imidoyl chlorides and thioimidates with thiocyanates, and substitution of the chlorine atom in hydroximoyl chlorides on treatment with various nucleophiles have also been described.[275-279] The products of the reactions of perfluoroisopropylacetimidoyl chloride with *S*-, *P*-, and *N*-nucleophiles have been obtained in order to investigate the stereochemical isomerisation at the N=C bond.[280] 1,3-Prototropic migrations have been noted in the phosphorylation of imidoyl chlorides containing a hydrogen atom at the α-carbon atom. Bases also promote the migration of the chlorine atom.[281] In the reactions of *N*-phenylchloroformimidates, *N*-phenylthioformimidates, and *N*-phenylamidines with salts of phosphorus(IV) thio-acids, the 1,3-migration of the $X=P(OR)_2$ group from the sulphur atom to the nitrogen atom has been observed in the imidoyl phosphorothioates formed initially. Thiocarbamates, dithiocarbamates, or thioureas were then obtained as the products.[282] In contrast to other *P*-nucleophiles, dialkyl phosphites react with imidoyl chlorides at the oxygen atom, affording imidoyl phosphites.[283] The 2,2-dichloromalonamides having the general formula $(R_2N-CCl=N-CO)_2CCl_2$, which have been little investigated, react with monofunctional nucleophiles to give the products of the substitution of two chlorine atoms at the amidine carbon atoms. In the reactions with bifunctional reagents, cyclisation to heterocyclic spiro-compounds takes place.[284] The use of halogenoimidoyl derivatives as promising starting materials for the synthesis of a wide variety of heterocyclic compounds, formed directly in the reaction with nucleophiles or via further reactions of the products, has been demonstrated in studies on the reactions with azides,[285-287] with amines and hydrazines,[288-290] with carbanions,[291] and with copper and silver acetylides.[292] The synthesis of heterocyclic compounds with the aid of reactions involving the [2 + 4] cycloaddition of dicyclopentadiene to perfluoroimidoyl fluorides[293] and the reactions of the intermediate dipolar ions—either via their intramolecular cyclisations[294-296] or via their 1,3-dipolar cycloaddition to polarophiles[297-312]—has also been described. New data on the characteristics of the formation of dipolar ions and their structure and reactivity have likewise been published.[297,305-307] Problems concerning the formation, structure, and stereospecificity of the reactions of nitrilium ions have been considered.[307,308] Data concerning a convenient method of reduction of imidoyl chlorides to aldimines by treatment with hydrogen in the presence of palladium complexes and the reactions of these compounds with organotin compounds have been published.[309,310]

General Principles and Characteristics of Cyclopalladation Reactions

V.V.Dunina, O.A.Zalevskaya, and V.M.Potapov

The factors influencing the ease and mode of the reactions involving the direct intramolecular cyclopalladation of organic ligands at sp^2- and sp^3-carbon atoms are analysed and the principal requirements which must be met by the structure of the ligand, the characteristic features of the coordination intermediates, and the experimental reaction conditions are considered. The bibliography includes 232 references.

V. Experimental conditions in the direct cyclopalladation reactions 261

I. INTRODUCTION

Cyclometallated complexes containing a comparatively reactive carbon–metal σ-bond stabilised by the additional coordination of the metal to a heterodonor atom of the same ligand are of great interest from several points of view. In the first place, cyclometallation processes are important as one of the ways of solving the most important current problems—that of the activation of the C–H bonds by transition metal compounds.[1,2] The study of the structures of stable cyclometallated complexes, which can be regarded as "frozen" intermediates in metal-catalysed chemical reactions, is a valuable source of information about the mechanisms of such catalytic processes.[3–5] The wide range of reactions with participation of cyclometallated compounds already known, which proceed with notable regio- and stereo-selectivity, leads to extensive possibilities for their synthetic application.[6–8] The cyclometallated compounds obtained in an optically active form can be used both for the synthesis of other chiral molecules,[9–12] and for the resolution of substrates with ligand properties,[13–18] and for the estimation of their optical purity.[19,20] Some of the cyclometallated complexes proved to be useful because of their liquid–crystal properties[21] or their high biochemical activity,[22,23] while others can be used to introduce heavy-atom and fluorescent labels into proteins and polypeptides.[24]

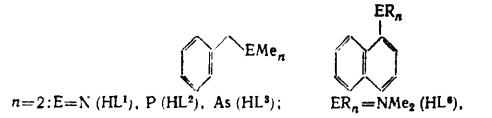
Since the synthesis of the first cycometallated complexes,[25] an enormous number of compounds of this class have been obtained (mono-, bi-, and tri-cyclic, mono-, di-, and trinuclear, and mono-, bis-, and tris-chelate) with metals having different electronic configurations (Pd, Pt, Ni, Rh, Ir, Ru, Re, Mn, Sn, etc.) and on the basis of a wide variety of ligands containing N, P, S, As, or O atoms as the heterodonors with M–C(sp^3) or M–C(sp^2) bonds involving an aliphatic, aromatic, olefinic, or acyl carbon atom; the complexes in which the M–C σ-bonds are stabilised by additional π-coordination can be formally also included in this class of compounds. A detailed discussion of each group of cyclometallated compounds is not of interest, especially since this has partly been done in review articles published previously,[26–42] which deal predominantly with data up to 1981. The analysis of the general principles of cyclometallation, which in the present review has been carried out in relation to the direct intramolecular cyclopalladation of ligands with heterodonor centres, is in our view of greater current interest.

Among all the known methods of synthesis of cyclopalladated complexes (CPC),[26] the direct palladation of a ligand coordinated beforehand via the heteroatom is the simplest and most convenient:

The terms "cyclopalladation"[43] or "*ortho*-palladation"—in the specific case of reactions involving the *ortho*-position in the aromatic ring of the ligand[44,45] were used to designate reactions of this type.

The ease and in many cases the very possibility of carrying out such processes depend on the structural features of the ligand and the intermediate coordination compounds and on the nature of the palladating agent and the reaction conditions. We have considered these factors in the present review.

II. PRINCIPAL REQUIREMENTS FOR THE STRUCTURE OF THE LIGAND



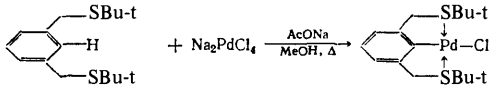
In order that the direct cyclopalladation of a particular ligand should be possible, its structure must satisfy a number of requirements concerning the nature of the heteroatom and its basicity, the possible size of the metallocycle, and the steric arrangement at the donor and metallated atoms within the chelate ring formed and outside it.

1. The Role of the Heteroatom

One of the necessary conditions for the successful palladation of a particular organic compound is the presence in the latter of a donor atom "directing" the reaction.[43,45–47] The formation of a transition metal–carbon σ-bond by direct metallation (without the preliminary coordination to the heteroatom) takes place in rare cases and is not characteristic of palladium. Intramolecular coordination to the heteroatom stabilises the C–Pd bond; the chelate effect is quite important in this connection. For example, the intramolecular cyclopalladation of azobenzene is 4×10^4 times faster than the intermolecular reaction of $PdCl_2$ with benzene;[48] the acceleration effect is associated with chelation via the azo-group, which converts the reaction from an intermolecular process to an entropically more favourable intramolecular process.

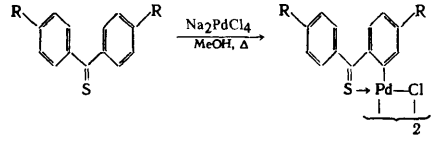
Preliminary coordination of the ligand to the transition metal atom is usually regarded as the first stage in the cyclometallation process.[45,48–51] It is therefore natural that the nature of the heteroatom should have a direct influence on the course of the reaction, which has in fact been confirmed by a whole series of facts.

The replacement of one heteroatom by another within the limits of the same general structure of the substrate can alter sharply its tendency to undergo cyclopalladation. For example, ligands of the types presented below form cyclopalladated complexes fairly readily (with $PdCl_4^{2-}$) only in the presence of a donor nitrogen atom—(HL^1) and (HL^6):[45,52–54]



n=2:E=N (HL^1), P (HL^2), As (HL^3); n=1:E=O (HL^4), S (HL^5)

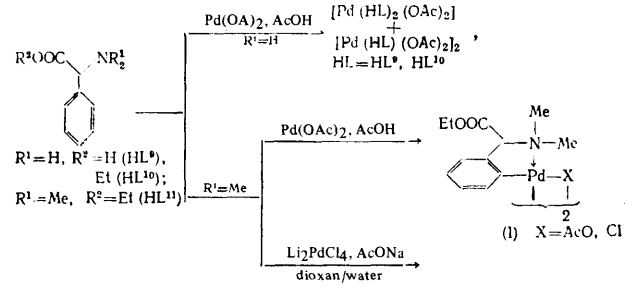
ER_n=NMe_2 (HL^6), PMe_2 (HL^7), SBu (HL^8)



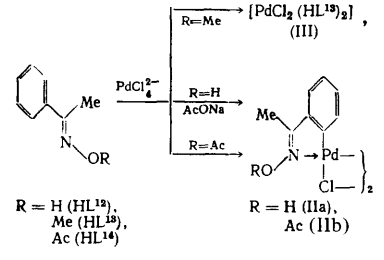
In the case of the dimethylphosphines (HL^2) and (HL^7) and arsine (HL^3), cyclopalladation does not occur and only coordination compounds of the type $[PdCl_2(HL)_2]$ are formed.[55–57] The introduction of oxygen, as in (HL^4), or sulphur, as in (HL^5) and (HL^8), as the donor atom also fails to stimulate metallation;[43,47,58] the thioether (HL^8) forms only a coordination compound. In their analysis of the failure of the attempts at the cyclopalladation of another *S*-donor ligand, namely benzyl phenyl sulphide, Takahashi et al.[59] concluded that the coordination of sulphur to palladium is so strong (compared with the analogous *N*-donor ligands) that it inhibits the further electrophilic substitution in the benzene ring under the influence of palladium(II). However, one should note that, when certain structural requirements and/or experimental conditions (see below) are observed, CPC based on phosphines[37] and thioethers[60,61] can be obtained.

In particular, the cyclopalladation process can be stimulated by doubling the number of thioether donor groups activating the *ortho*-position,[62,63] as happens, for example, in 1,3-di(*t*-butylthiomethyl)benzene:[63]

We may note that the monodentate analogue of this ligand is not metallated under the same conditions.



The degree of hybridisation of the donor atom has a significant influence on the ease of cyclopalladation. Thus, in contrast to the majority of thioethers (with the sulphur atom in the sp^3-hybrid state), which form only simple coordination compounds in the reactions with $PdCl_4^{2-}$ in methanol even on refluxing, thioketones[64–66] and thioamides[67–69] (containing a sulphur atom in the sp^2-hybrid state) undergo metallation comparatively readily under the same conditions. For example, CPC based on diaryl thioketones have been obtained:[66]

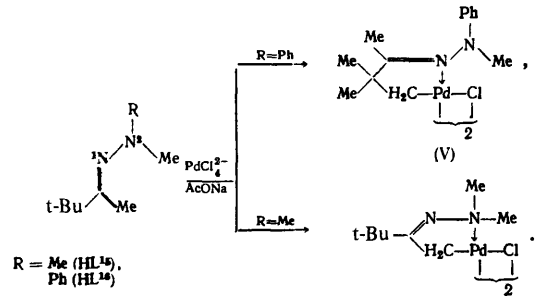


R=Me, MeO

The modification of the basicity of the initial ligand by altering the nature of the substituents at the heteroatom can also be significantly reflected in the rate and mode of the cyclopalladation reaction. For example, in view of the different reactivities of primary, secondary, and tertiary benzylamines, it has been suggested that the stronger *N*-coordination of the primary and secondary amines compared with the tertiary amine weakens the electrophilic properties of the metal to such an extent that this prevents the attack on the aromatic ring.[45]

Partly, for the same reason, it has not been possible to introduce into the *ortho*-palladation reaction either *C*-phenylglycine (HL^9) itself or its ethyl ester (HL^{10}), both containing a primary amino-group, while the *NN*-dimethyl derivative of the latter (HL^{11}) forms the CPC (I) both with palladium(II) acetate and with Li_2PdCl_4:[70,71]

This conclusion has also been confirmed by the comparative analysis of the reactivities of acetophenone oxime (HL^{12}), its *O*-methyl derivative (HL^{13}), and its *O*-acetyl derivative (HL^{14}) in the cyclopalladation reaction. The unsubstituted oxime (HL^{12}) undergoes *ortho*-palladation in the presence of sodium acetate with formation of compound (IIa), while its *O*-methyl analogue affords only the coordination compound (III) under these conditions:

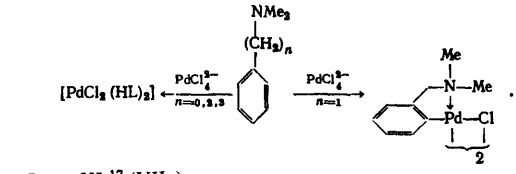


R = H (HL^{12}), Me (HL^{13}), Ac (HL^{14})

R = H (IIa), Ac (IIb)

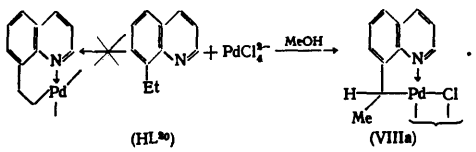
The authors explained this by the fact that the stronger coordination of (HL^{13}) to palladium(II), induced by the presence of the electron-donating Me group, reduces the formal charge on Pd(2+), preventing the electrophilic attack by the latter on the aromatic ring. On the other hand, (HL^{14}), in which the coordinating capacity of the nitrogen atom is reduced owing to the introduction of the electron-accepting acetyl group, forms the *ortho*-palladised complex (IIb) even in the absence of a base.[72]

The study[73] of the causes of the regiospecificity of the cyclometallation of a number of hydrazones of aliphatic ketones provides a striking example of the influence of the comparative basicities of the heterodonor centres on the mode of cyclopalladation. In particular, it has been shown that the metallation of pinacolone dimethylhydrazone (HL^{15}) takes place at the methyl group attached to the azomethine fragment with coordination of the metal via the N(2) aminonitrogen atom [compound (IV)], which is unusual for hydrazones:



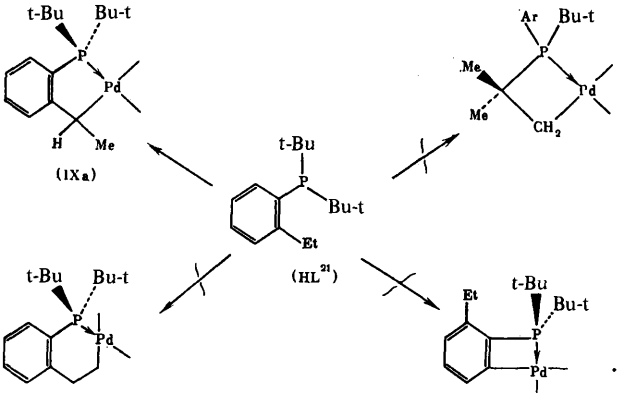
However, the introduction of the phenyl substituents at the N(2) atom, as in (HL^{16}), reduces its basicity (and hence its coordinating capacity), as a result of which the coordination of the metal via the azomethine N(1) atom becomes more favourable and, as a consequence of this type of preliminary coordination, the metallation of (HL^{16}) takes place at the methyl group in the t-Bu fragment [compound (V)].

Thus the presence of the heteroatom in the ligand is important for the stabilisation of the CPC formed, while the nature and the electron-donating properties of the heterocentre influence significantly both the reactivity of the metal and the mode of cyclopalladation.



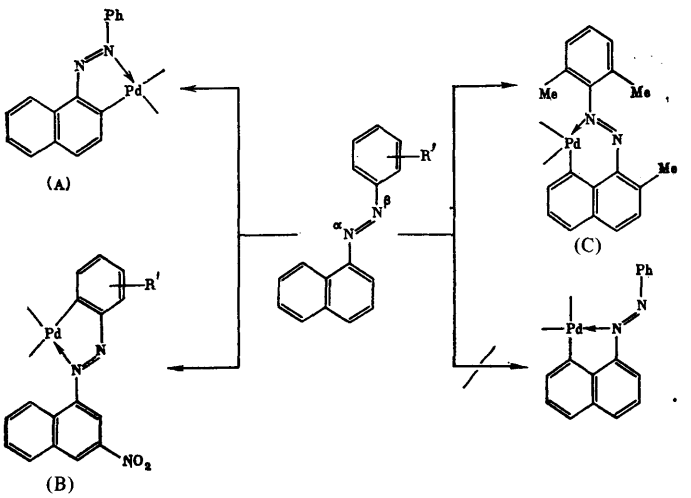
2. The Size of the Metallocycle

A clear-cut tendency towards the formation of a five-membered metallocycle is exhibited in the reactions involving the direct intramolecular cyclopalladation of the majority of organic ligands investigated. For example, in the series of amines of the type $Ph(CH_2)_nNMe_2$ (n = 0–3), only benzylamine (HL^1) is cyclopalladated, forming in this process the five-membered chelate ring (VIa);[45] the remaining ligands (HL^{17})–(HL^{19}) form only the simple coordination compounds (VIIIa–c):



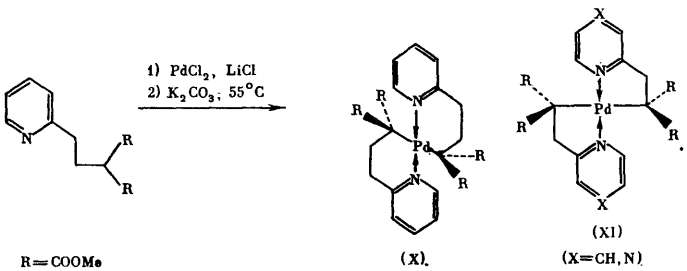
HL = HL^{17} (VIIa), HL^{18} (VIIb), HL^{19} (VIIc); n = 0 (HL^{17}), 1 (HL^1), 2 (HL^{18}), 3 (HL^{19})

In systems where there is a possibility of a choice between several modes of metallation, those leading to a five-membered metallocycle are as a rule realised. The dimeric CPC (VIIIa)[74–76] with a five-membered and not a six-membered metallocycle is formed in the palladation of 8-ethylquinoline (HL^{20}), despite the fact that a primary carbon atom is metallated more readily than a secondary carbon atom:[76]



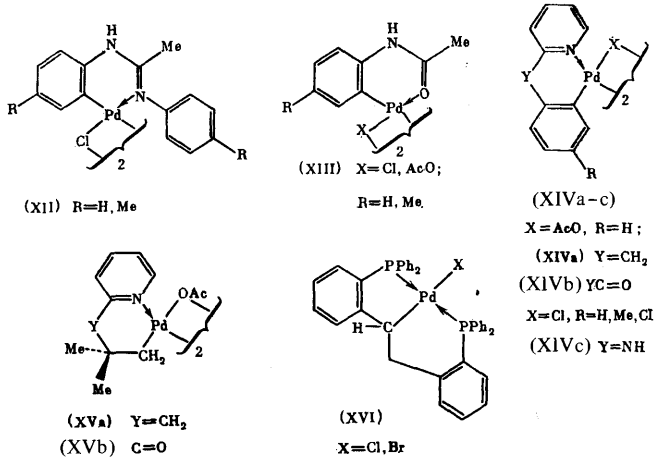
An analogous tendency has been observed also for *P*-donor ligands.[56,77,78] For example, several reaction pathways are possible for the cyclopalladation of the tertiary phosphine (HL^{21}): at the methyl group of the t-Bu fragment or in the free *ortho*-position in the benzene ring (with formation of four-membered metallocycles in both cases) and also the methyl or CH_2 group of the *ortho*-Et substituent (with formation of six- or five-membered rings respectively):

Despite the fact that the cyclopalladation at a secondary aliphatic carbon atom is more difficult than at a primary carbon atom (see below) or in an aromatic ring, the structure (IXa) with a five-membered metallocycle is produced in the experiment.[77]



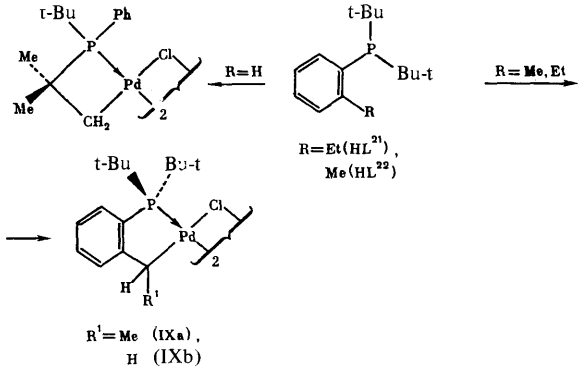
A marked tendency towards the formation of five-membered rings has been observed in a study of the behaviour of 1-arylazonaphthalenes under the conditions of the *ortho*-palladation reaction.[79–81] For ligands of this type, four versions of the closure of the metallocycle are possible, in principle, as a result of the presence of two donor nitrogen atoms and two aromatic rings suitable for metallation. In the absence of blocking groups, the reaction takes place preferentially via the C(2) atom of the naphthalene ring (A)[79] because of the greater accessibility of the N^{β} atom for preliminary coordination to the metal and the greater nucleophilicity of the naphthalene ring compared with the benzene ring; when strong electron-accepting substituents (the 3-NO_2 group) are introduced into the naphthalene ring and electron-donating substituents are introduced into the benzene ring, palladation at the benzene ring (B) becomes possible as a result of the change in the section involved in the preliminary coordination; a five-membered metallocycle is formed in both cases:

Only after the complete blocking by the methyl groups of all the sections suitable for the formation of five-membered rings (the 2′- and 6′-positions in the benzene ring and the 2-position in the naphthalene ring) is it possible to achieve



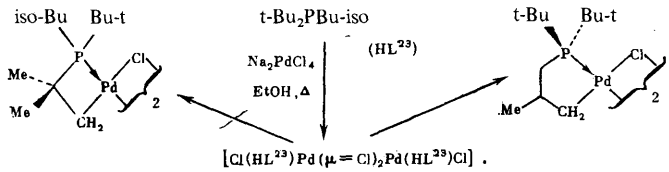
palladation in the *peri*-position in the naphthalene ring with formation of the six-membered metallocycle (C);[80] the involvement of the N^{β} atom in the structure (C) in coordination with the metal has been confirmed with the aid of ^{15}N NMR.[81]

It had been postulated earlier that the tendency by metals preferring the square-planar coordination to form five-membered metallocycles is associated with the necessity to maintain the ligand–metal–carbon intrachelate angle at a value near 90°.[82] The accumulated experimental data seem to confirm this "theory of five-membered rings". However, a recent comparison, based on X-ray diffraction analysis (XRA), of the structural features of complexes with five-membered[83,84] and six-membered[85] rings exhibiting the maximum structural similarity showed that the six-membered metallocycles can readily adjust to the requirement for a square planar environment of the metal; such complexes exhibit no unfavourable interactions and are obtained under the same conditions and with the same yields as their five-membered analogues.[85] The increase in the N–Pd–C intrachelate angle in structures of type (X) compared with (XI) is not accompanied by an appreciable loss of stability by the bis-chelates:[83-85]



Fairly numerous CPC with six-membered metallocycles, based on different classes of ligands with N, O, and P donor atoms and obtained by the palladation at both sp^2- and sp^3-carbon centres, are known at the present time. Such complexes have been obtained from *N*-arylamidines (XII),[86] acid *N*-arylamides (XIII),[86-88] 2-benzylpyridine (XIVa),[89,90] 2-benzoylpyridine (XIVb),[90,91] 2-anilinopyridine (XIVc),[92] 2-neopentylpyridine (XVa),[93] 2-pivaloylpyridine (XVb),[94] and 2,2′-bis(diphenylphosphino)bibenzyl (XVI).[95,96]

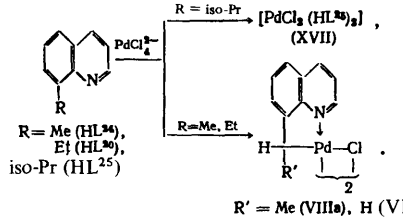
It is noteworthy that in all the cases presented above the formation of six-membered metallocycles is enforced, since the ligand structures do not provide more favourable alternatives.



Four-membered metallocycles are also known—they are formed as a result of the direct intramolecular cyclopalladation of certain phosphines containing the t-butyl group.[97-100]

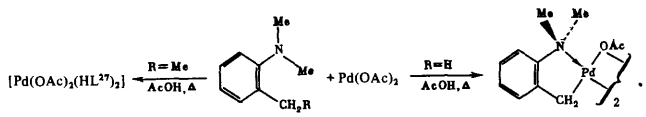
Nevertheless, here too the reaction pathway is enforced. When there is a possibility of the formation of a five-membered ring for ligands of this type, as happens, for example, in the case of (HL^{21})[77] or (HL^{22}),[78,101] the more favourable structure (IXa) or (IXb) respectively is in fact produced:

The cyclopalladation of di-t-butylisobutylphosphine (HL^{23}) also results in the formation of a five-membered and not a four-membered metallocycle:[102]



We may note that palladium(II) complexes with *N*-donor ligands, containing four-membered metallocycles, have not so far been isolated but the formation of such CPC has been postulated on the basis of spectroscopic data in a study of the mechanism of the amination of olefins in the presence of palladium compounds.[103]

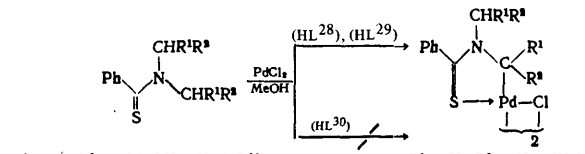
Thus, despite the fact that the formation of five-membered metallocycles in CPC is in general preferred, there is no evidence, in principle, against the formation of either six-membered or four-membered metallocycles.



Analysis of the literature shows that the possibility of cyclopalladation and also the ease and mode of reaction are in many respects determined by the steric features of the initial substrate. Depending on their disposition in the molecule and the class of organic ligand, bulky substituents can neither promote or hinder the cyclopalladation reaction.

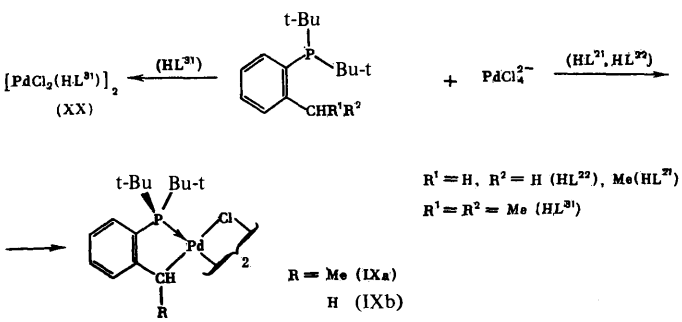
3. The State of the Palladated Carbon Atom

The problems of steric hindrance at the palladated carbon atom are especially acute in the direct metallation of aliphatic fragments. As was to be espected on the grounds of steric considerations, the ease of the cyclometallation of saturated carbon atoms decreases in the sequence primary > secondary > tertiary. For example, the palladation of 8-alkylquinolines takes place readily only when the 8-position contains a methyl group, as in (HL^{24}) and more slowly for the 8-ethyl derivative (HL^{20}); 8-isopropylquinoline (HL^{25}) forms only the coordination complex (XVII) under these conditions:[76,104]



Whereas the metallation of a secondary carbon atom has been achieved in this system, albeit with difficulty, in the case of *o*-alkyl-*NN*-dimethylanilines, the CPC (XVIIIa) has been obtained only from the corresponding toluidine (HL[26]); palladation at the secondary carbon atom of the ethyl substituent in the ligand (HL[27]) has not been observed under any of the conditions used:[105]

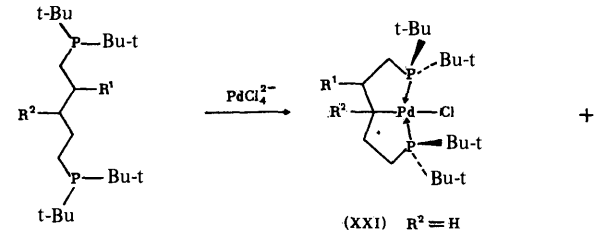
R = H (HL[26]), Me (HL[27]) (XVIII)*a*



Analogous features have been observed in the series of S- and P-donor ligands. The study of the cyclopalladation of a series of *NN*-dialkylthiobenzamides demonstrated[67] a significantly greater reactivity of the *N*-Me group [the yield of the complex (XIXa) was 94%] compared with the *N*–Et group [the yield of compound (XIXb) was 13%], whereas the *N*-iso-Pr substituent in the ligand (HL[30]) could not be metallated at all:

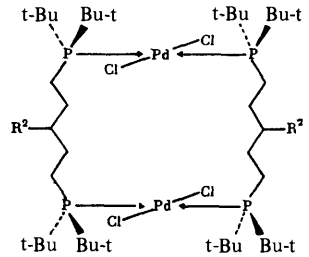
$R^1 = H$, $R^2 = H$ (HL[28]), Me (HL[29]); $R^1 = R^2 = Me$ (HL[30])

$R^1 = H$, $R^2 = H$ (XIXa) Me (XIXb)



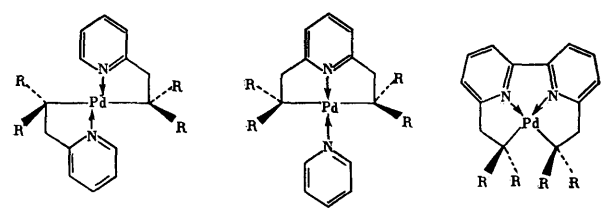
Palladation at a tertiary carbon atom in phosphines could not be achieved even in the presence of bulky substituents stimulating cyclometallation. Thus, whereas the cyclopalladation of di(t-butyl)-o-methylphenylphosphine (HL[22]) and di(t-butyl)-o-ethylphenylphosphine (HL[21]) takes place comparatively readily [structures (IXb) and (IXa)[77,78,101]], the ligand (HL[31]), containing the o-iso-Pr substituent, forms only the coordination complex (XX) under these conditions and the attempt to cyclopalladate it at elevated temperatures leads only to decomposition:[77]

$R^1 = H$, $R^2 = H$ (HL[22]), Me(HL[21])
$R^1 = R^2 = Me$ (HL[31])



R = Me (IXa) H (IXb)

Similar features have been observed also in the formation of bicyclic CPC from a series of long-chain diphosphines. CPC could not be obtained from 1,5-bis(di-t-butylphosphino)-3-methylpentane (HL[32]) apparently precisely because of the difficulty of metallating a tertiary carbon atom; in the case of the unsubstituted derivative (HL[33]) and the 2-methyl derivative (HL[34]), where the metallation takes place at the methylene group, the CPC are formed, although in a low yield. The main product of the reaction with (HL[33]) and the only product in the case (HL[32]) is the dinuclear *trans*-complex (XXII) with bridging diphosphine ligands.[106–108]

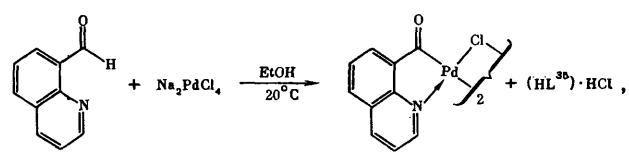


(XXI) $R^2 = H$

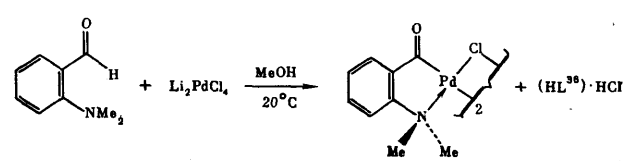
$R^1 = H$, $R^2 = Me$ (HL[32]), H (HL[33]);
$R^1 = Me$, $R^2 = H$ (HL[34])

(XXII) $R^2 = H$, Me

Cyclopalladation at a tertiary carbon atom takes place comparatively readily provided that the carbanionic centre thus produced is stabilised by electron-accepting substituents; this results in the formation of bis-chelate compounds (XXIII), bicyclic compounds (XXIV), or tricyclic compounds (XXV):[22,23,83,84]



(XXIII) R = COOMe

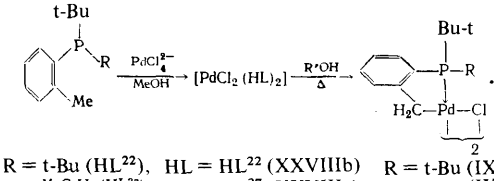


(XXIV) R = COMe, COOEt, CN

(XXV) R = COOMe, COOEt COOPr-iso

The ease with which the aldehyde functional group is palladised at the carbon atom is also noteworthy: acyl complexes are formed from aldehydes containing an additional donor group, in alcohol at room temperature without the introduction of an additional base:[109,110]

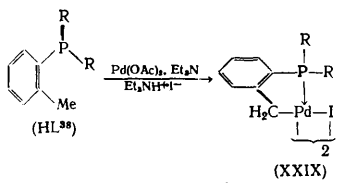
(HL[35]) (XXVI)



(HL[36]) (XXVII)

Thus a common feature is a decrease in the tendency towards cyclopalladation after the introduction of substituents at the carbon atom to be palladised; however, when such substituents are strongly electron-accepting, metallation is facilitated as a result of the increase in the acidity of the residual C–H bond and the resonance stabilisation of the carbanionic ligand.

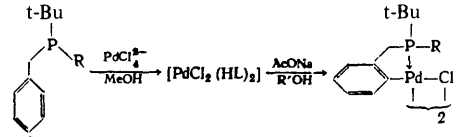
4. Substituents at the Donor Heteroatom



The steric hindrance at the donor heteroatom of the ligand can both promote and hinder its cyclopalladation. For tertiary phosphines, this process is greatly facilitated when bulky substituents are present at the phosphorus atom; for many of these compounds, an obligatory condition for successful cyclometallation is the presence of the t-butyl group.[56,77,78,97–101,111–113] This requirement refers to cyclopalladation both in the aromatic ring and in the aliphatic fragment. A far-reaching study of the cyclometallation of bulky phosphines has been carried out by Shaw and co-workers.[56,57,77,78,101,114–118] Comparison of the ease of the intramolecular palladation of the two phosphine ligands (HL^{22}) and (HL^{37}) in the coordination compounds (XXVIIIb, c) isolated beforehand showed that the rate of metallation of the ligand (HL^{22}), containing two t-butyl substituents at the phosphorus atom, is much higher than for the phosphine (HL^{37}), containing only one such bulky substituent:[78]

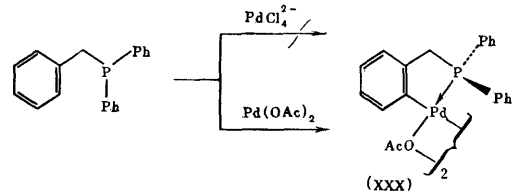
R = t-Bu (HL^{22}), o-MeC_6H_4 (HL^{37}); HL = HL^{22} (XXVIIIb), HL^{37} (XXVIIIc); R = t-Bu (IXb), o-MeC_6H_4 (IXc)

As an illustration of the lower tendency towards the cyclopalladation of arsines (compared with phosphines), we may note that ligands with an As donor atom, analogous to those described above, of the type $(t\text{-Bu})_n As(C_6H_4Me\text{-}o)_{3-n}$ (where $n = 1, 2$) do not undergo intramolecular metallation under the same conditions despite the introduction of even two bulky t-butyl substituents; heating of the *trans*-bis-complexes formed as intermediates with arsines coordinated as monodentate ligands via the heterodonor centre leads only to the segregation of zerovalent palladium.[119]



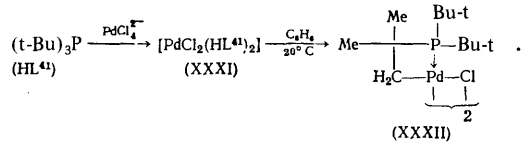
The cyclopalladation of tri(*o*-tolyl)phosphine (HL^{38}), which contains no t-butyl group, was considered for a long time to be impossible.[120] However, the formation of such CPC with (HL^{38}) (as a side product) was recently unexpectedly observed in the catalytic arylation reactions of conjugated polyenes, where the catalyst was the $Pd(OAc)_2$–(HL^{38})–Et_3N–$Et_3NH^+I^-$ system; the dimeric structure of the CPC (XXIX) with iodide bridges has been confirmed by X-ray diffraction analysis:[121]

(XXIX)



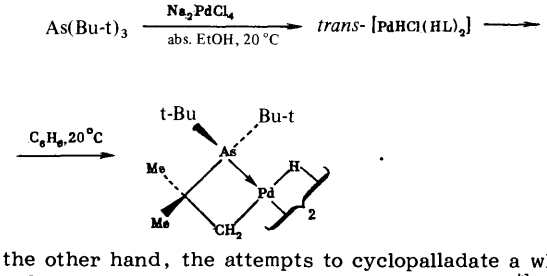
R = *o*-tolyl

An analogous stimulating effect of steric compression has been observed in the *ortho*-palladation of a series of benzylphosphines.[56] The rate of reaction decreases appreciably on passing from (HL^{39}) to (HL^{40}):



R = t-Bu (HL^{39}), $PhCH_2$ (HL^{40})

The *ortho*-palladation of phosphines not containing t-butyl substituents, for example, Me_2PCH_2Ph,[55] Ph_2PCH_2Ph, and $PhP(CH_2Ph)_2$,[122] does not occur at all under the same conditions. We may note that the *ortho*-palladated complex (XXX) based on Ph_2PCH_2Ph can be obtained only by using a more effective palladating agent—palladium(II) acetate:[112]

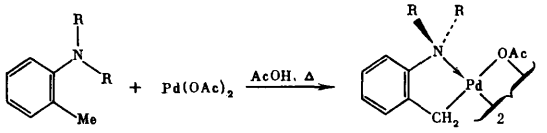


(XXX)

As was to be expected, in the case of tri(t-butyl)phosphine (HL^{41}), containing three bulky substituents, cyclopalladation takes place extremely readily: the bis-complex (XXXI) isolated beforehand is slowly converted into the cyclometallated compound (XXXII) even at room temperature in benzene,[98] the structure of the cyclometallated compound having been confirmed by X-ray diffraction analysis (XRA):[123]

(XXXII)

When three bulky t-butyl groups are introduced at the donor atom, intramolecular palladation of even an arsine ligand analogous to (HL^{41}) becomes possible, although in this case the reaction proceeds via a fundamentally different pathway with the intermediate formation of a stable hydride complex and its final product is the unusual hydrido-bridged dimeric cyclopalladated complex:[124]

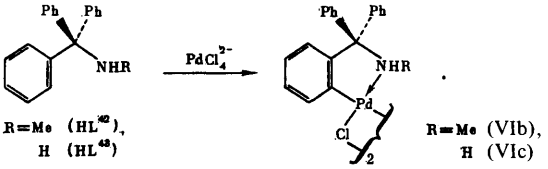


On the other hand, the attempts to cyclopalladate a whole series of less sterically hindered, compared with (HL^{41}), phosphines of the type of $R_2P(Bu\text{-}t)$ and $RP(Bu\text{-}t)_2$ (where R = Pr, Ph, or *p*-tolyl) were unsuccessful.[115] It follows from the calculation of the "cone angle" for such phosphines[98,115] that the steric compression in mixed alkylarylphosphines is much smaller than in (HL^{41}) and is insufficient to stimulate the formation of a four-membered metallocycle.

In his analysis of the causes of the effect of bulky substituents, which stimulate cyclometallation, Shaw[115] put forward several possible explanations. In the first place, we have the removal on metallation of unfavourable interactions between the phosphine and the adjoining ligand—for example, the halide in complexes of the type $[PdHal_2.(HL)_2]$. From the thermodynamic standpoint, the metallation

of bulky phosphines is accompanied by only a slight loss of rotational entropy, since rotation is strongly hindered even in ligands coordinated as monodentate species. If this is a kinetic effect, then one can assume that the free energy of activation for the metallation of sterically hindered phosphines is much lower than for the unhindered ligands as a consequence of entropic factors.

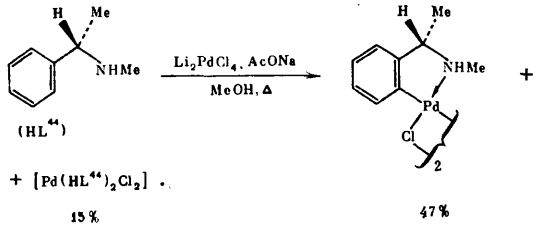
The "*gem*-dimethyl effect" is known in organic chemistry for small carbon rings ($n \leq 7$);[118] in the case of metallocycles involving larger atoms (phosphorus and metal) larger substituents are required for the stabilisation and easier formation of the rings, which results in the "*gem*-di-t-butyl effect".[118]



The characteristic features of the cyclopalladation of tertiary phosphines described above are not apparently characteristic of all types of ligands. Thus it is known[105] that the presence of bulky substituents at the nitrogen atom in *o*-alkylanilines hinders cyclopalladation: the replacement of *N*-methyl substituents by *N*-ethyl substituents decreases appareciably the yield of the CPC (XVIIIb) compared with (XVIIIa):

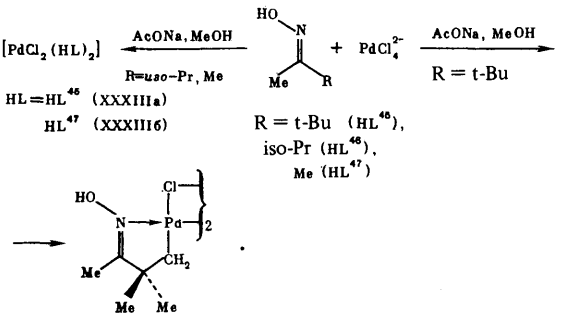
R=Me (XVIIIa) 70%
R=Et (XVIIIb) 8%

5. The Influence of Substituents in Other Fragments of the Ligand



Steric effects due to the presence of bulky substituents at non-donor atoms of the ligand have a significant influence both on the rate of the cyclopalladation reaction and on its mode. Bulky substituents at the carbon atoms forming part of the metallocycle as a rule accelerate the reaction.[52,59,98,125,126] A striking illustration of this conclusion is provided by the results of a study of the cyclopalladation of benzylamines.[52] It is known that primary and secondary benzylamines do not form CPC under the conditions of the Cope–Friedrich reaction.[45] However, when two phenyl substituents were introduced in the α-position in the benzyl ligand, it was possible to obtain the CPC (VIb, c) from not only the secondary amine (HL^{42}) but also from the primary amine (HL^{43}):[52]

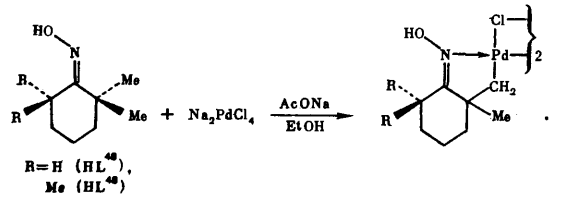
R=Me (HL^{42}), H (HL^{43})



R=Me (VIb), H (VIc)

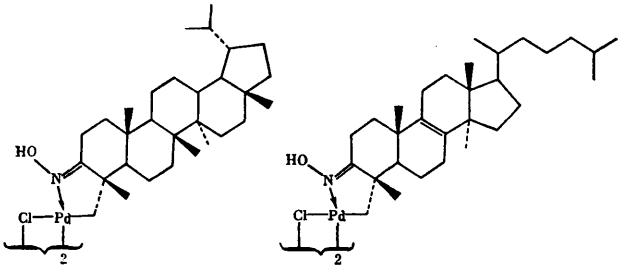
Later it was established[127,128] that a substituent in the α-position as small as the methyl group is quite sufficient for the successful cyclopalladation of secondary benzylamines:

It is noteworthy that the cyclopalladation of secondary amines is also facilitated with increase in the bulk of the substituent at the nitrogen atom: the *N*-isopropyl derivatives of α-methylbenzylamine and α-(2-naphthyl)ethylamine form CPC in 84 and 73% yields respectively.[127,128]



An obligatory condition in the cyclopalladation of oximes is the presence of the bulky t-butyl substituents at the keto-group,[125,126] for example, as in (HL^{45}); in its absence, as in (HL^{46}) and (HL^{47}), only the coordination compounds (XXIIIa, b) are formed:

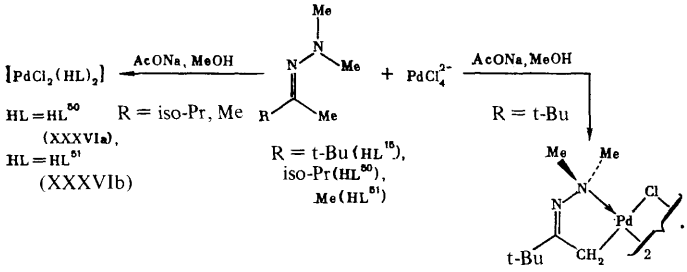
HL=HL^{45} (XXXIIIa)
HL^{47} (XXXIII6)



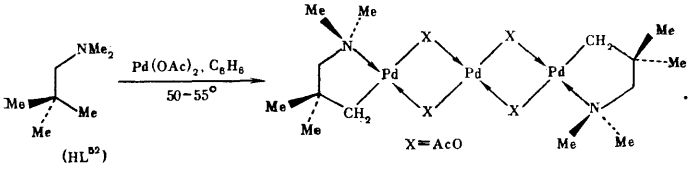
R = t-Bu (HL^{46}), iso-Pr (HL^{46}), Me (HL^{47})

Analogous features have been observed also for the oximes of cyclic ketones: (*E*)-2,2-dimethylcyclohexanone oxime (HL^{48}) and the strongly sterically hindered 2,2,6,6-tetramethylcyclohexanone oxime (HL^{49}) form CPC under standard conditions and in a high yield (~85%),[129] while the less sterically hindered 2-methylcyclohexanone oxime does not form cyclopalladation products:

R=H (HL^{48}), Me (HL^{49})



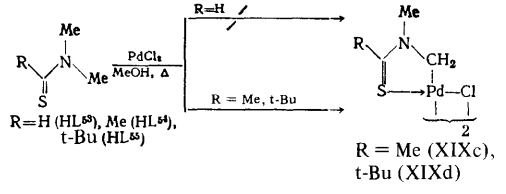
The possibility of the cyclopalladation of such fragments at the methyl group has been used successfully for the introduction of various functional groups into the non-activated methyl group in certain natural products, for example (*E*)-lupanone oxime[129] and lanost-8-en-3-one oxime[130] via the reactions of the corresponding CPC (XXXIV) and (XXXV):



(XXXIV) (XXXV)

The presence of the t-butyl group at the carbonyl carbon atom is also necessary for the cyclopalladation of hydrazones,[125,126] but under these conditions the methyl group of the –N=C– fragment is metallated as a result of the preliminary coordination via the nitrogen atom of the amino-group and not via the imino-nitrogen atom of the ligand (HL^{15}). The less sterically hindered ligands (HL^{50}) and

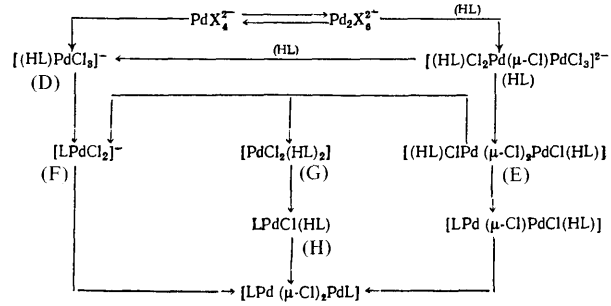
(HL[51]) form only the coordination compounds (XXXVIa, b):



The successful cyclopalladation of dimethylneopentylamine (HL[52]) is apparently in fact caused by the presence in the ligand molecule of the bulky t-butyl fragment (and also by the possibility of the closure of the preferred five-membered metallo-cycle); it is of interest to note that the reaction product is in this instance an unusual trinuclear complex:[131]

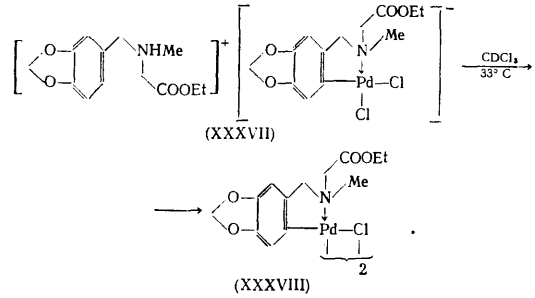
The successful cyclopalladation of 2-neopentylpyridine[93] and 2-pivaloylpyridine[94] with formation of the CPC (XVa,b) is accounted for by analogous causes; here the stimulating influence of the steric hindrance overcomes the unfavourable closure of six-membered metallocycles (see Section 2).

Bulky groups at non-donor carbon atoms promote the cyclopalladation reaction also in the case of *S*-donor ligands—thioamides[67,68] and thioketones.[64] For example, whereas it was impossible to introduce *NN*-dimethylthioformamide (HL[53]) into this reaction under any conditions, the corresponding thioacetyl derivative (HL[54]) is converted into the dimer (XIXc) after refluxing with $PdCl_2$ in methanol for 10 h in 49% yield; the replacement of the methyl group in the acid residue by the t-butyl group, as in (HL[55]), makes it possible to obtain the CPC (XIXd) in 94% yield after 1 h:[67]



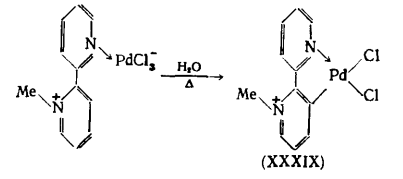
Thus the presence of bulky substituents at non-donor atoms in the ligands as a rule facilitates their cyclopalladation. The cause of this effect is analogous to the causes of the influence of the substituents at the donor phosphorus atoms in tertiary phosphines discussed previously (see above). Furthermore, the presence of bulky substituents in the ligand can lead to an enforced close approach by one of the protons to the metal atom within the framework of a simple coordination compound. Such interactions have been frequently confirmed by X-ray diffraction (see Section III).

III. STRUCTURAL CHARACTERISTICS OF THE COORDINATION INTERMEDIATES



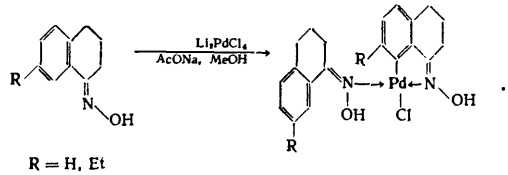
It has come to be assumed that the first stage in the cyclopalladation process is the coordination of the ligand to the transition metal atom. The alternative reaction mechanism—direct electrophilic metallation of the aromatic ring (analogously to the very familiar mercuration reaction) with subsequent chelation—is unlikely for metals in a low oxidation state to which palladium(II) belongs.[132]

The preliminary coordination of the initial ligand to the metal is acknowledged by the majority of investigators but the question of the specific structure of such coordination intermediates remains controversial. It apparently depends to a large extent both on the structure of the ligand and on the reaction conditions. For example, a study of the cyclopalladation of tertiary benzylamines[133] led to the postulation of several possible reaction pathways involving intermediates having different structures (Scheme 1):



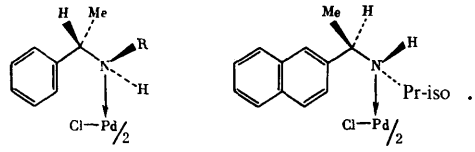
Scheme 1

Here X = Cl and (HL) and (L^-) are respectively the *NN*-dimethylaminobenzylamine ligands coordinated as a monodentate species and a 2*C*,*N*-chelated species. Some of the intermediate cyclopalladated and coordination compounds presented in Scheme 1 have been detected by spectroscopic methods or isolated in a pure state in the given and other ligand systems. For example, the mononuclear CPC (XXXVII) of type (F) has been isolated after treating the corresponding *NN*-disubstituted glycine ester with LiCl and $PdCl_2$ in methanol;[133] this compound is unstable and is converted already on dissolution in chloroform into the usual dimeric *ortho*-palladated complex (XXXVIII):



Stable mononuclear cyclopalladated compounds of type (F) are encountered comparatively rarely, but such a structure has been proposed, for example, for the product of the *ortho*-palladation of a cationic ligand—*N*-methyl-2,2′-bipyridylium (XXXIX):[134,135]

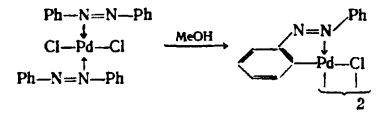
Complexes containing both a cyclopalladated ligand and a ligand bound as a monodentate species via the heteroatom [structure (H) in Scheme 1] have been isolated for certain reactant ratios in the *ortho*-palladation reactions of 1-tetralone



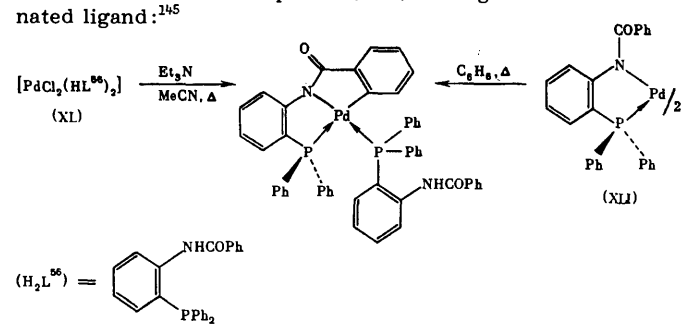
oximes:[136]

R = H, Et

Coordination compounds of type (G) belong to the class of the most typical stable intermediates—they have been isolated in a pure state in the cyclopalladation reactions of a wide variety of ligands: azobenzene,[50] hydrazones,[73] oximes,[72] aromatic primary amines,[137] sulphides,[60] thioamides,[69] tertiary phosphines,[78,98] and other ligands.[51,138] The isolation of coordination intermediates with tertiary benzylamines is hindered by the ready cyclometallation, but their 1:1 stoichiometry has been established with the aid of ^{1}H NMR even for the ratio $PdCl_4^{2-}$: $(HL^1) = 1:2$. Only one ligand is coordinated to the metal, while the other remains free.[139] It has been suggested that the first coordination intermediate is in this instance a dimeric coordination compound of type (E); the existence of the same type of intermediate has been suggested in the $Pd(OAc)_2$–(HL^1) system in $CDCl_3$.[133] However, kinetic and spectroscopic studies of the latter system in the presence of an excess of the ligand established[140] the rapid formation of a *trans*-bis-complex of type (G) (X = AcO), which is regarded as the initial state in the *ortho*-palladation reaction of (HL^1) in the given solvent.

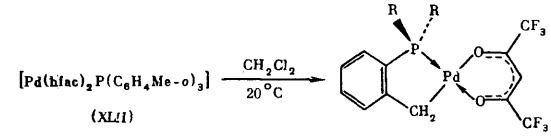


In the case of secondary benzylamines, whose tendency to undergo metallation is significantly reduced,[127,128] their coordination compounds of the *trans*-bis-type were isolated together with the cyclometallation products and were characterised by both spectroscopic and XRA methods:[141–143]



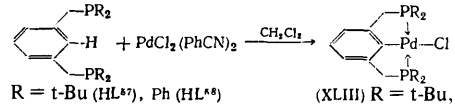
R = Me, iso-Pr

In the cyclopalladation of 1-tetralone oxime, the 1:1 stoichiometry of the intermediate was established by the ^{1}H NMR method and a dinuclear structure of type (E) and not an anionic structure of type (D) was attributed to it.[136] The formation of a similar dinuclear intermediate with the ligand coordinated as a monodentate species in the interaction of *trans*-$[PdCl_2(PhCN)_2]$ with the *N*-methyl-*N*-phenylhydrazone of pinacolene[73] even when a large excess of the ligand is used was attributed by the authors to the steric hindrance generated by the bulky substituents in the ligand. In other systems, there is a possibility of the formation of both mononuclear and dinuclear coordination intermediates depending on the reactant ratio. For example, complexes of types (E) and (G) have been isolated in the cyclopalladation reactions of di-t-butylisobutylphosphine[102] and pinacolone *NN*-dimethylhydrazone[73] for metal:ligand ratios of 1:1 and 1:2 respectively.

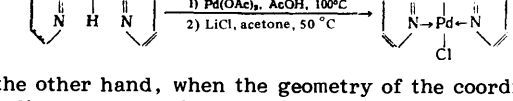


The most convincing evidence showing that the formation of coordination compounds with a monodentate ligand is one of the intermediate stages in the cyclopalladation process is provided by their ready conversion into CPC.[48,51,73,78,98,115,138,144], etc. Thus dichlorobis(azobenzene)palladium(II) can be readily converted into a cyclopalladated compound on heating[51] or by its simple dissolution in polar solvents (ethanol, methanol, aqueous dioxan):[48]

Several examples may be quoted to illustrate the wide variety of forms in which the first stage of the cyclopalladation process can take place (coordination via the heteroatom). Thus the *ortho*-palladation of the amidophosphine ligand (H^2L^{56}) can take place starting both with the traditional bis-complex comprising the ligand P-coordinated as a monodentate species, as in compound (XL), and with the bis-chelate compound (XLI) having an *NP*-coordinated ligand:[145]

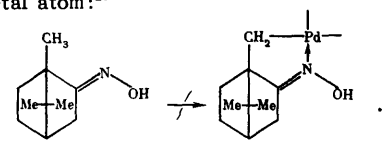


When palladium(II) bis(β-diketonates) are used to cyclopalladate bulky phosphines, pentacoordinated adducts of the type $Pd(hfac)_2(PR_3)$ (hfacH = 1,1,1,5,5,5-hexafluoropentane-2,4-dione) are formed as intermediates, one of which, formed in the reaction with tri(*o*-tolyl)phosphine, has not only been isolated but has also been characterised by XRA.[146] This phosphine is cyclopalladated by simply allowing a solution of the adduct (XLII) in dichloromethane to stand at room temperature:[146]



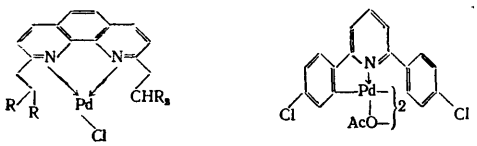
R = *o*-tolyl 47%

The ease and sometimes the very possibility of cyclopalladation depends significantly on the geometry of the complex with the ligand coordinated solely via the heteroatom. Thus it has been shown that complexes of the type *cis*-$[PdX_2(HL)]$ with the bidentate phosphines (HL^{57}) and (HL^{58}) are not converted into cyclometallated products, while the corresponding *trans*-complexes, in which the C–H bond has been activated in the vicinity of the metal atom, readily form CPC of type (XLIII):[147,148]



R = t-Bu (HL^{57}), Ph (HL^{58}) (XLIII) R = t-Bu, Ph

It may be that such activation of the central methylene group occurs also in the cyclopalladation of 1,3-di(2-pyridyl)-propane:[149]

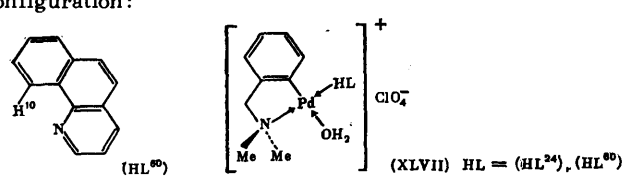


On the other hand, when the geometry of the coordination intermediate rules out for some reason a sufficiently close approach to the metal atom by the section to be metallated,

the metallation reaction becomes impossible. Thus, despite the formally close structural similarity of D-camphor oxime (HL^{59}) to the readily palladated pinacolone oxime,[125,126] all attempts to stimulate the conversion of its coordination complex *trans*-$[PdCl_2(HL^{59})_2]$ into the cyclopalladated derivative under various conditions were unsuccessful.[150] XRA of this complex established that the geometrical features of the molecule (especially the rigidity of the skeleton and the large Pd–N–C angles) prevent the methyl group from being close to the metal atom:[150]

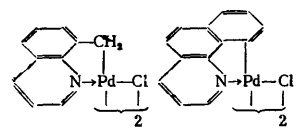
(HL^{59}) (XLV)

The impossibility of the repeated metallation of substituted phenanthroline ligands in the monometallated complexes (XLIV), although their bipiridyl analogues do form doubly metallated derivatives fairly readily, has been explained by the increased rigidity of the central heteroaromatic fragment:[23]



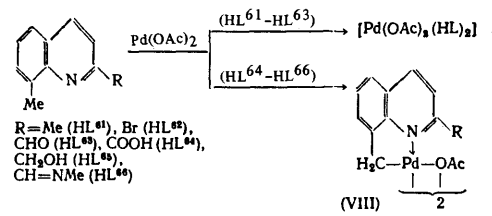
(XLIV) R = COOPr-iso (XLVI)

In their analysis of the causes of the failure of the attempt at the repeated palladation of 2,6-diarylpyridines, Selbin et al.[151] concluded on the basis of the XRA of the monopalladated dimer (XLVI) that, following the formation of the first strong, and therefore shortened, Pd–C σ-bond and also as a result of the increase in the Pd–C–C and C–C–C angles in the metallocycle with sp^2-carbon atoms, the metal "recedes" too far from the second aromatic ring and its metallation becomes impossible.



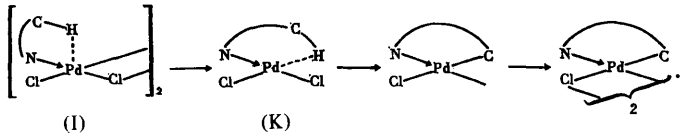
Analysis of the geometries of a number of coordination compounds on the basis of X-ray diffraction data demonstrated the occurrence in many palladium(II)[50,152] and also platinum(II)[153,154] complexes of specific intramolecular interactions which in fact make it possible to regard these complexes as possible intermediates in the cyclometallation of the corresponding ligands. A characteristic feature of the structure of the coordination compound of palladium(II) with azobenzene is an extremely close intramolecular contact of one of the chlorine atoms with the *ortho*-proton of the benzene ring and also fairly close contact (above and below the coordination plane) of the palladium atom with the *ortho*-protons of all four benzene rings of the ligands (two of these contacts are shortened).

Deeming and co-workers carried out a detailed study of the coordination chemistry of 8-alkylquinolines and benzo[*h*]-quinoline (HL^{60}) from the standpoint of the geometry of possible intermediates in the cyclopalladation reactions of these ligands.[86,104,155] In particular, they selected as test models the mononuclear *ortho*-palladated complexes of type (XLVII), in which the ligands investigated (HL^{24}) and (HL^{60}) are coordinated as monodentate species in the *trans-NN*-configuration:[155]



(HL^{60}) (XLVII) HL = (HL^{24}), (HL^{60})

It has been shown with the aid of ^1H NMR and also on the basis of the XRA of certain models that, in complexes of this type, one of the protons of the ligand coordinated as a monodentate species approaches the metal extremely closely: H(10) in the case of (HL^{60}) and the methyl group in the case of (HL^{24}). Such specific axial interactions in complexes with ligands coordinated as monodentate species are fully correlated in many cases with the pathway followed in the subsequent metallation: in the given instance, the ligands (HL^{24}) and (HL^{60}) are cyclopalladated in precisely the positions indicated above with formation of the dimers (VIIIa) and (XLVIII) respectively:[75,156]

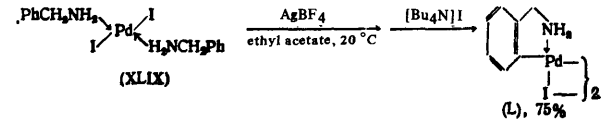


(VIIIa) (XLVIII)

However, despite the convincingly demonstrated reality of the axial interactions in the coordination compounds, it is still not clear for what position of the palladatable C–H bond relative to the coordination plane can its activation be the most effective. It has been suggested[155] that in square planar complexes of d^8 metals certain hydrogen atoms of the ligand are located above or below the coordination plane not as a result of bonding interactions but as a consequence of the endeavour to fill the unoccupied axial site, which reduces the repulsion. In particular, the much greater stability of the 7-methylquinoline complex compared with the analogous 8-methylquinoline compound clearly indicates the destabilising character of the enforced Pd...H–C interaction with the 8-methyl group of the ligand (HL^{20}). Further studies by these[76,86,104,156] and other[157] workers showed that the close axial approach by one of the protons of the ligand coordinated as a monodentate species does not always lead to the cyclometallation in this particular section. It is believed[104] that, under conditions where it behaves as an electrophile (which is in fact postulated in *ortho*-palladation reactions), the palladium atom should employ an unoccupied $d_{x^2-y^2}$ orbital, which requires cyclometallation in the coordination plane. The possibility of the activation of the C–H bond of the initial ligand in the coordination plane of the metal in cyclopalladation processes has been investigated by Deeming and co-workers,[76,104,156] who observed that the introduction of a substituent R in the 2-position in 8-methylquinoline can significantly modify the reactivity of the coordinated ligand. In the presence of groups such as Me, Br, and CHO in this position in the (HL^{61})–(HL^{63}) ligands, cyclopalladation does not take place, whereas for R=COOH, CH_2OH, or CH=NMe in the (HL^{64})–(HL^{66}) ligands, the latter are readily cyclopalladated at the 8-methyl group by palladium(II) acetate with formation of CPC of type (VIII):[158]

The authors suggest that the palladation of the 8-methyl group occurs only when the substituent R contains a [illegible] tive donor centre capable of participating in the [illegible] of the quinoline ligand (together with the quinolin[illegible] atom) and which thereby forces the 8-methyl group to approach the palladium atom in the coordination plane.

Spectroscopic analysis of the course of the *ortho*-palladation reactions of 1-tetralone oxime[136] and benzyldimethylamine[139] using low-temperature ^{1}H NMR spectra established that the axial and equatorial (within the coordination plane) orientations of the palladated C–H bond constitute two consecutive steps in the intramolecular metallation of these ligands:

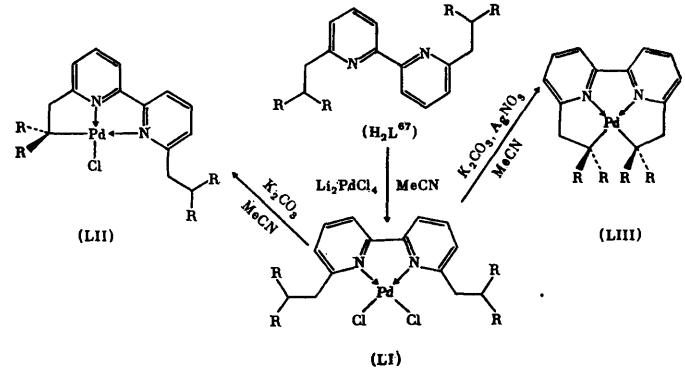


(I) (K)

In the case of tetralone oxime, it was possible to isolate from the aqueous medium at a reduced temperature (0 °C) the intermediate and most unstable (as regards cyclometallation) complex *cis*-$[PdCl_2(HL)].3H_2O$, whose spectroscopic characteristics indicate the location of the *ortho*-proton of the aromatic ring of the organic ligand in the coordination plane of the metal or close to it, which corresponds to a type (K) intermediate.[136]

The conversion of the intermediate (I) with an axial orientation of the C–H group into the intermediate (K) within the plane requires the liberation of one coordination site outside the metal. Pathways leading to the liberation of a coordination vacancy (in the given case apparently via the opening of the halide bridges) are not altogether clear, but there is no doubt about the importance of this stage in the cyclopalladation process.

Analysis of the kinetics of the cyclopalladation reactions of a series of substituted benzyldimethylamines by $Pd_2(OAc)_6^{2-}$ in acetic acid, led Sakodynskaya et al.[140] to the conclusion that the rate-limiting stage of the reaction is the formation of the coordination vacancy as a result of the dissociation of one of the acetate bridges in the adduct of the type $[(HL)(AcO)Pd(\mu\text{-}AcO)_2Pd(OAc)_2]^-$.

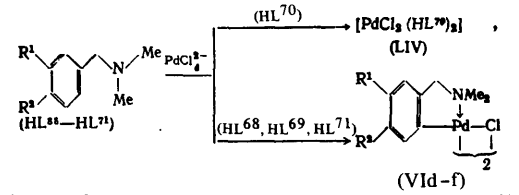


The most striking illustration of the importance of this stage in the cyclopalladation process is provided by the ready formation of the *ortho*-palladated dimer (L) with a high yield from the coordination complex (XLIX) when the latter is treated with two equivalents of $AgBF_4$, which effectively extracts iodide ions from the coordination sphere of the metal in the form of AgI:[159]

(XLIX) (L), 75%

This is particularly important because we are dealing with the palladation of the primary benzylamine which was for a long time believed to be impossible (see above). Naturally, the removal of halide ligands from the coordination sphere of the metal in the intermediate coordination compounds stimulates cyclometallation so effectively not only because of the liberation of the coordination vacancies but also as a result of the generation in this process of a stronger electrophile (Pd^{2+}), which is necessary for the second stage of the reaction—the electrophilic attack.

An analogous procedure has been used successfully to synthesise tricyclic CPC with two Pd–C(sp^3) σ-bonds in the *cis*-positions.[23] In the presence of sufficiently bulky substituents R in ligands of the type (H_2L^{67}), the coordination compounds (LI), isolated beforehand, are converted by bases only into monometallated derivatives (LII), while the introduction of $AgNO_3$ makes it possible to metallate both side chains with formation of compound (LIII):

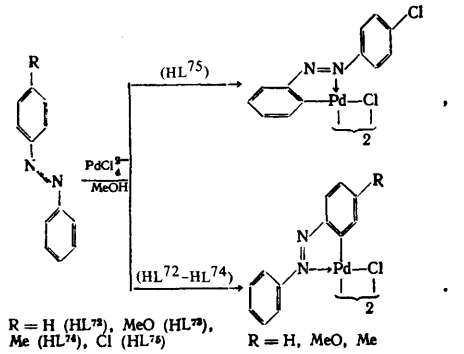


(LII) (LI) (LIII)

Compounds of type (LIII) with the *cis*(C)-geometry exhibit a high biochemical activity in relation to DNA,[160,161] while their *trans*(C)-analogues (LIII) have no biochemical activity.[22]

Although the studies discussed above do not provide a complete answer to the question of the mechanism of the activation of the C–H bond in the cyclopalladation process, they leave no doubt about the exceptional importance of the analysis of the structural features of the coordination compounds arising in the first stage of this process. The second stage of the process, the palladation proper, depends to a large extent on the electronic effects of the substituents in the ligand.

IV. ELECTRONIC EFFECTS IN CYCLOPALLADATION REACTIONS



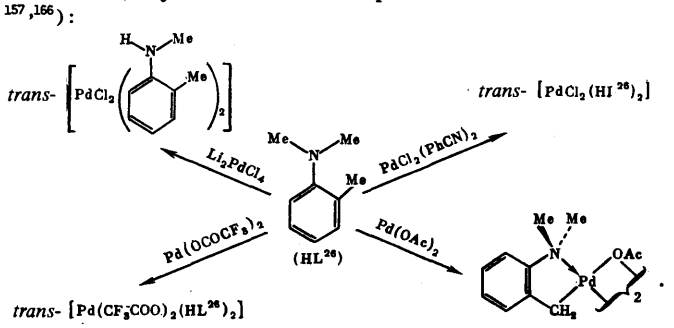
The electrophilic character of palladium(II) in the *ortho*-palladation reactions of various aromatic substrates is generally accepted and has been demonstrated experimentally. Electron-donating substituents (for example the methoxy- or methyl groups) greatly stimulate the *ortho*-palladation, while electron-accepting groups (for example, the nitro-group) partially or completely deactivate the aromatic ring. Such effects have been observed in the *ortho*-palladation reactions of benzylamines,[5,76,77,89] benzyl sulphides,[61] Schiff bases[162] and hydrazones,[163] and asymmetrically substituted azobenzenes[49,164] and 1-arylazonaphthalenes.[79,80] As an example, one may quote the results of a study of the behaviour of a number of benzyldimethylamines substituted in the aromatic ring.[45,165] While the ligands (HL^{68}) and (HL^{69}) with electron-donating substituents readily undergo *ortho*-palladation, the 3-nitro-derivative (HL^{70}) forms only the coordination compound (LIV). As an illustration of the marked acceleration of the reaction by several electron-donating substituents, one may recall the experimental conditions for the *ortho*-palladation of the ligand (HL^{71}): this benzylamine gives rise to the dimeric CPC (VIf) almost instantaneously at −78 °C in 95% yield:[165]

(VId-f)

R^1 = H, R^2 = MeO (HL^{68}, VId), Me (HL^{69}, VIe), NO_2 (HL^{70}); R^1 = MeO, R^2 = $MeSCH_2O$ (HL^{71}, VIf)

The study of the *ortho*-palladation of asymmetrically substituted azobenzenes,[49,164] 1-arylazonaphthalenes,[80] and dibenzyl sulphides[61] showed that both $PdCl_4^{2-}$ and $Pd(OAc)_2$ are electrophiles in these processes. The fact that palladation takes place preferentially in the aromatic ring of (HL^{73}) and (HL^{74}) having an electron-donating substituent and that of *p*-chloroazobenzene (HL^{75}) takes place exclusively in the unsubstituted phenyl group shows that the *ortho*-palladation occurs predominantly in that of the two aromatic rings which is more enriched in electrons:

R = H (HL^{72}), MeO (HL^{73}), Me (HL^{74}), Cl (HL^{75}) R = H, MeO, Me

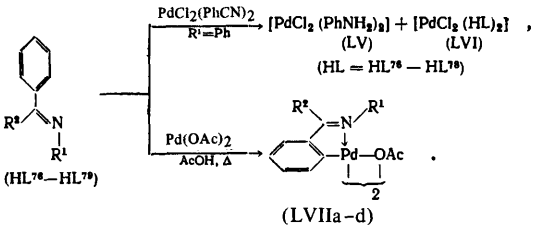


As was to be expected, the rate of *ortho*-palladation of compounds (HL^{72})–(HL^{74}) diminishes as a function of the nature of the substituent R in the sequence MeO > Me > H.[164]

V. EXPERIMENTAL CONDITIONS IN THE DIRECT CYCLOPALLADATION REACTIONS

Apart from the large number of structural factors influencing the ease and mode of cyclopalladation reactions, their success depends to a large extent also on the choice of conditions in the synthesis, namely on the nature of the palladating agent, the presence and nature of the base, the nature of the solvent, and the temperature and duration of the reaction.

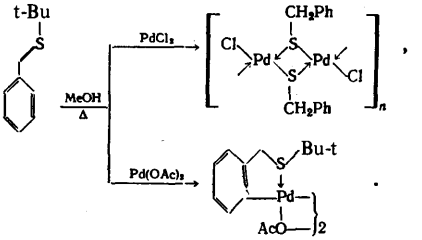
1. Palladating Agents



Both simple palladium(II) salts, namely $PdCl_2$ and $\{Pd(OAc)_2\}_3$, and coordination and chelate compounds of palladium(II), i.e. $M_2[PdCl_4]$ (M = Li, Na or K), $[PdCl_2(RCN)_2]$ (R = Ph or Me), $[Pd(acac)_2]$ (acacH = acetylacetone), and $[Pd(hfac)_2]$ are used as metallating agents in cyclopalladation reactions. The dependence of the reaction pathway on the nature of the metallating agents is clearly demonstrated by the reaction scheme for *NN*-dimethyl-*o*-toluidine (HL^{26}) under various conditions (only the main reaction products are indicated[105,157,166]):

trans- $[PdCl_2(HL^{26})_2]$ (HL^{26}) *trans*- $[Pd(CF_3COO)_2(HL^{26})_2]$

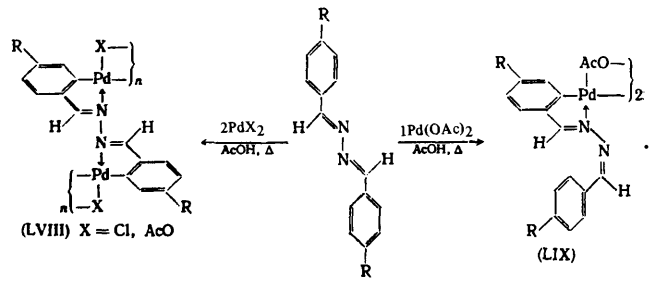
Historically the first method, proposed by Cope and Friedlich,[45] which is based on the interaction of the corresponding organic ligand with alkali metal tetrachloropalladate in the presence or absence of a base, is still used fairly widely for the synthesis of CPC.[44,45,52,165,167–169] Sometimes, the readily available palladium(II) coordination complex of benzonitrile *trans*-$[PdCl_2(PhCN)_2]$ is used for the cyclopalladation of organic compounds.[95,100,144,170] However, this method is not apparently distinguished by any advantages and does not always lead to the desired results.



Palladium(II) acetate, which is regarded as the best electrophile in aromatic substitution reactions[176] and is a milder reagent for readily hydrolysable ligands, frequently proves to be a more effective palladating agent.[89,91,104,112,166,171–175] For example, it is known that Schiff bases, especially the aniline derivatives (HL^{76})–(HL^{78}), are extremely sensitive to hydrolysis, which is appreciably accelerated when they are coordinated to a metal.[172,177] Thus, in the attempts to orthopalladate the ligands (HL^{76}) and (HL^{77}) with the aid of $[PdCl_2(PhCN)_2]$ in methanol[172] or of the ligand (HL^{76}) with $PdCl_2$ in aqueous dioxan,[177] the coordination compound of aniline (LV), formed as a result of the hydrolysis of the Schiff bases, was isolated as the main reaction product together with only small amounts of the coordination compounds (LVI) of the initial azomethines. The *ortho*-palladated compounds (LVIIa–d), based on the corresponding Schiff bases, were obtained only when $\{Pd(OAc)_2\}_3$ was used as the metallating agent in glacial acetic acid:[172]

(LVIIa–d)

R^1 = Ph, R^2 = H (HL^{76}, LVIIa), Me (HL^{77}, LVIIb), Ph (HL^{78}, LVIIc); R^1 = Me, R^2 = H (HL^{79}, LVIId)

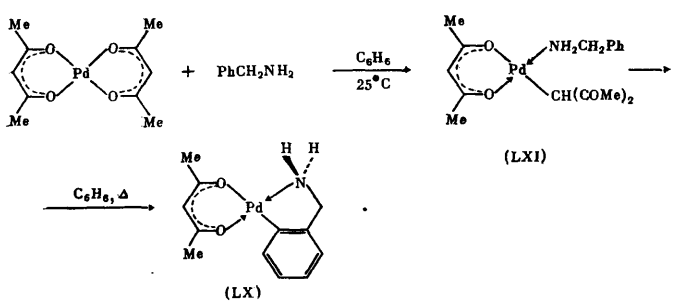


The *ortho*-palladation of benzyl t-butyl sulphide was achieved with the aid of palladium(II) acetate,[60] whilst all the attempts to cyclopalladate this ligand by treatment with Na_2PdCl_4 in alcohol (in the presence and absence of AcONa) or with $PdCl_2(PhCN)_2$ in dichloromethane or toluene were unsuccessful;[63] the use of $PdCl_2$ as the metallating agent leads to the dealkylation of the thioether ligand with formation of the polymeric complex $[\{Pd(\mu\text{-}Cl)(\mu\text{-}SCH_2Ph)\}_n]$:[60]

The successful *ortho*-palladation also of a series of less sterically hindered thioether ligands, namely benzyl izobutyl sulphide,[178] certain dibenzyl sulphides, and also dibenzyl sulphoxide,[61,179] with the aid of palladium(II) carboxylates as metallating agents is evidence for their high effectiveness.

By varying the palladating agent, it is possible to attain different degrees of metallation of ligands which provide several potential regions for this purpose. For example, in the reaction of benzylideneazines with $PdCl_2$, only the polymeric dicylcopalladised compounds (LVIII) are formed,[163] while in the reaction using $Pd(OAc)_2$ it is possible to isolate both the monometallated derivatives (LIX) and the dimetallate

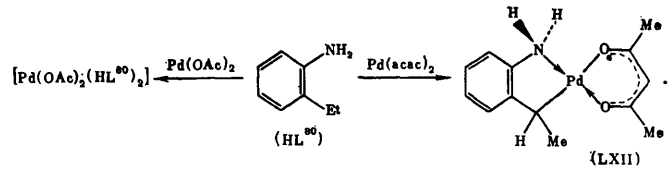
derivatives (LVIII) depending on the conditions:[180,181]



(LVIII) X = Cl, AcO (LIX)

The advantages of palladium(II) acetate as a palladating agent are especially evident in cyclometallation with participation of aliphatic fragments. For example, *NN*-dimethyl-*o*-toluidine (HL^{26}) is metallated by $Pd(OAc)_2$ with an almost quantitative yield, while under the conditions of the Cope–Friedrich reaction, the chloro-bridged analogue is formed in only 8% yield; the main process in the latter case becomes the dealkylation of the amine (HL^{26}) and the formation of the corresponding coordination compound.[105] When $Pd(OAc)_2$ was used, it was possible to synthesise the CPC (XVIIIb) from *NN*-diethyl-*o*-toluidine (see above), while on treatment with Li_2PdCl_4 the above ligand is not cyclopalladated at all.

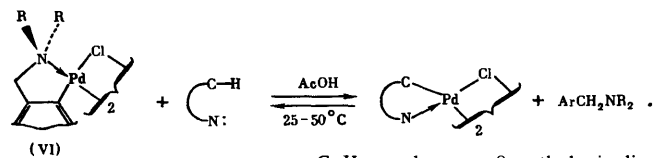
The possibility of the formation of not only the usual dinuclear but also of trinuclear cyclopalladated compounds should be noted as one of the complications associated with the use of the trimeric palladium(II) acetate for cyclopalladation. Thus, in a more detailed study of the structure of the primary product of the palladation of *NN*-dimethyl-*o*-toluidine, to which a dimeric formula had been attributed earlier[105,106] using mass-spectrometry, ^1H and ^{13}C NMR, and also specific synthesis, it was shown that the true structure of the complex formed in the reaction of (HL^{26}) with $\{Pd(OAc)_2\}_3$ in acetic acid is trinuclear with two pairs of bridging acetate ligands linking three palladium(II) atoms, two of which (the terminal atoms) are *CN*-chelated by the ligand (L^{26}).[182] This type of trinuclear structure was first established for the products of the cyclometallation of dimethylneopentylamine,[131] whose molecular weight in benzene corresponds to the trimer.



The use of the palladium(II) bis(acetylacetonate) complex as the palladating agent yielded unique results. In particular, with the aid of this reagent it has been possible to obtain the cyclopalladated complex (LX) based on the primary benzylamine,[137] whose metallation presents considerable difficulties:[45]

(LXI) (LX)

It has been suggested[137] that one of the causes of the successful cyclopalladation of this ligand may be the fact that $Pd(acac)_2$ fixes only one amine molecule. Furthermore, the intermediate (LXI) formed in the first stage contains a fairly labile C-bound acetylacetonate ligand, which functions as an effective proton acceptor, stimulating thereby the cyclopalladation reaction.



The cyclopalladation of primary *o*-alkylanilines presents special difficulties, since these ligands contain a "poor" coordinating centre (the primary aromatic amino-group) and an aliphatic fragment (the *o*-alkyl group—see above) which is difficult to metallate. Nevertheless, when palladium(II) acetylacetonate was used, it proved possible to achieve the cyclopalladation of *o*-ethylaniline (HL^{80}) at the secondary carbon atom with formation of the CPC (LXII):[137,157]

(HL^{80}) (LXII)

We may note that palladium(II) bis(hexafluoroacetylacetonate) has also been used successfully as a palladating agent[138] with the aid of which it has been possible to obtain CPC based on a wide variety of ligands: tertiary arylalkylamines, Schiff bases, thioamides, thioketones, and also thioethers, especially benzyl methyl sulphide, whose cyclopalladation presents certain difficulties[58] (see above).

A new method of synthesis of CPC, proposed by Yatsimirskii and Ryabov[90,183] and based on the ligand exchange reaction, is of undoubted interest. The fundamental difference from the procedures involving the direct cyclopalladation examined above consists in the use as the palladating agent of any available soluble *ortho*-palladated dimeric complex [for example, compounds (VIa, g)]:

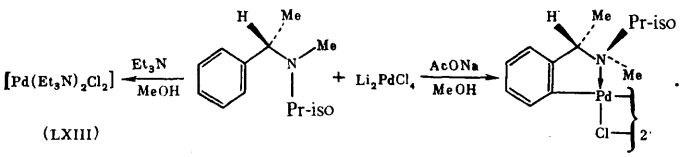
(VI)

Ar = Ph, R = Me (VIa), or Et (VIg);
Ar = ferrocenyl, R = Me

C–H = azobenzene, 8-methylquinoline, N: benzylideneaniline, 2-benzoylpyridine, *NN*-diethyl-4-nitrobenzylamine

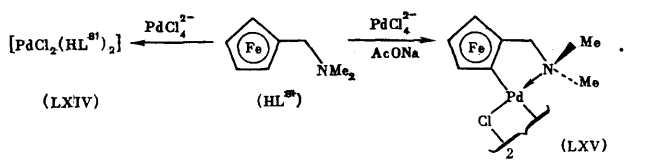
The ligand exchange reactions proceed under comparatively mild conditions (25–50 °C) but have to be carried out in the presence of acetic acid as the cosolvent. Among the CPC obtained by this method, compounds based on 2-benzyl- and 2-benzoyl-pyridine, containing six-membered metallocycles, and the complex with *NN*-diethyl-4-nitrobenzylamine merit special attention. The *ortho*-palladation of the last ligand, containing a benzene ring deactivated by an electron-accepting substituent, was achieved for the first time; this result makes it possible to regard the ligand exchange method as promising for the synthesis of metallocycles which are difficult to obtain under the conditions of the standard methods.

2. The Role of the Base in the Cyclopalladation Process



Cyclometallation in the reactions of the type considered here is coupled with the elimination of a proton from the ligand molecule:

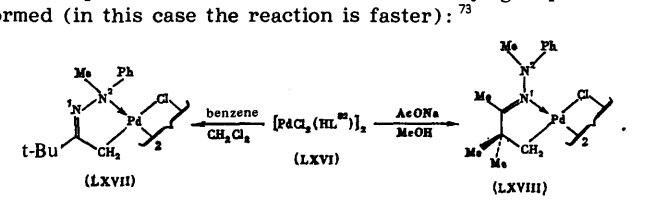
When the proton is evolved in the form a strong acid such as HCl, the problem of its neutralisation becomes especially acute. Sodium acetate[46,56,169,184–186] or aliphatic tertiary amines (for example, Et_3N and Bu_3N)[13,45,165] are usually



employed as the acceptor; in the cyclometallation of compounds with activated tertiary carbon atoms, K_2CO_3 has been used successfully as the base;[23] if the ligand has very marked basic properties, then an excess of this type of organic substrate is used to neutralise the HCl.[13,45,75]

Tertiary amines are apparently less universal as bases than sodium acetate. For example, in the cyclopalladation of sterically hindered tertiary α-arylalkylamines using triethylamine as the base, the latter competes successfully with the basic substrate for the metal and the main reaction product is its coordination compound (LXIII);[187] we may note that in the presence of sodium acetate such amines readily form CPC:[128,188]

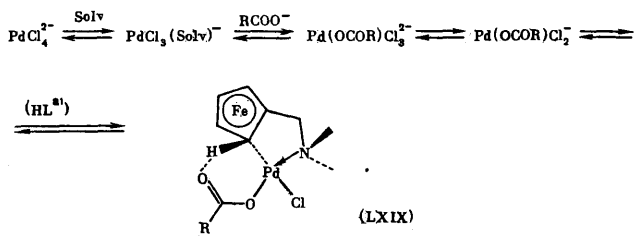
(LXIII)



Many systems are known in which the formation of cyclopalladated products in the absence of a base takes place with extremely low yields or the reaction does not occur at all. For example, the cyclopalladation of ferrocenyl ligands in the cyclopentadiene ring can in many cases be achieved only in the presence of sodium acetate despite the fact that this type of ring is more enriched in electrons than the corresponding phenyl derivatives.[46,169,184] Thus, whereas benzyldimethylamine forms the *ortho*-palladation product on treatment with Li_2PdCl_4 in the absence of a base (albeit with a low yield of 35%[45]), its ferrocenyl analogue (HL^{81}) affords under these conditions only the coordination compound (LXIV),[169,189] while the CPC (LXV) is formed only after the introduction of an additional base—sodium acetate:

(LXIV) (HL^{81}) (LXV)

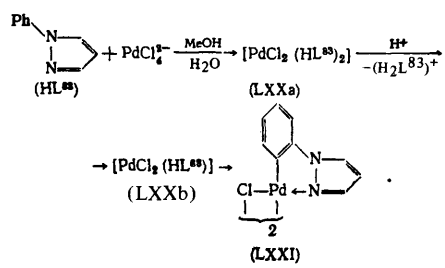
Analogous features have been observed when the results of the cyclopalladation reactions of 2-phenylpyridine[190] and 2-ferrocenylpyridine[184] were compared. Only in the presence of a base (sodium acetate), was it possible to obtain the CPC from a series of acetylhydrazones,[185,191] oximes,[72,125,126] pyrazoles,[192] and phosphines.[56,144]



In the cyclopalladation of the pinacolone *N*-methyl-*N*-phenylhydrazone (HL^{82}), the introduction of the base not only accelerates the metallation reaction but also alters its pathway. The intermediate dinuclear coordination compound (LXVI) with the *N*(1)-coordinated hydrazone in the absence of a base in non-polar solvents (benzene, dichloromethane) is slowly and spontaneously metallated at the CMe group and is converted into the CPC (LXVII), while in the presence of a base (sodium acetate) in methanol, the isomeric complex (LVIII) with a metallated t-butyl group is formed (in this case the reaction is faster):[73]

(LXVII) (LXVI) (LXVIII)

The structure of the two isomeric compounds (LXVII) and (LXVIII) has been confirmed by XRA.[193] The authors explained the change in the regioselectivity of this process as a function of experimental conditions by assuming that the complex (LXVI) with the *N*(1)-coordinated ligand (most of the initial hydrazone is bound in this form) participates in the reaction in the presence of a base; in the absence of a base, only the complex with the *N*(2)-coordinated ligand (present in the equilibrium mixture in a small amount) reacts, since the palladation then proceeds at the more active C–CH_3 group adjoining the azomethine bond.[73]



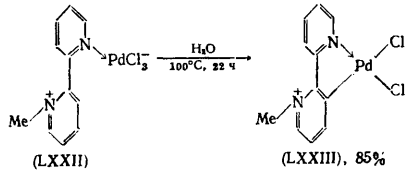
The role of sodium acetate in the cyclometallation reaction is apparently not limited to the simple neutralisation of HCl. When optically active salts of *N*-acetyl-α-aminoacids are used as bases, the cyclopalladated complex derived from *NN*-dimethyl-aminomethylferrocene (HL^{81}) is produced in an optically active form.[46] This example of the enantioselective introduction of planar chirality demonstrates unambiguously that the acid anion is directly involved in the transition state of the cyclopalladation reaction. It has been suggested[46] that the chiral carboxylate ion is inserted in the metallating agent during the cyclopalladation process and then enters into the composition of the bicyclic transition state (LXIX):

(LXIX)

Such asymmetric cyclopalladation reactions have found application in the synthesis of chiral di- and tri-substituted ferrocene derivatives[194] including ferrocenyl analogues of prostaglandins.[12]

There are exceptions to every rule and among cyclopalladation reactions there exists one which does not require the introduction of a base but does proceed in the presence of strong acids. Thus the cyclopalladation of 1-phenylpyrazole (HL^{83}) takes place in methanol in the presence of HCl or $HClO_4$.[43] The authors suggest that the acid is necessary in this case to remove (via protonation) one ligand molecule from the rapidly formed bis-complex (XXIIa). This is accompanied by the formation of the coordination-unsaturated intermediate (LXXb), which is then cyclopalladated with formation of compound (LXXI):

(LXXI)



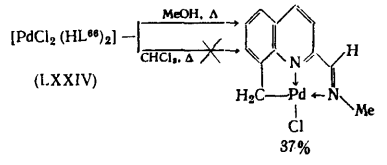
3. Other Experimental Conditions

Reaction conditions such as the nature of the solvent, temperature, and reaction time are quite important in the cyclopalladation of various organic ligands.

The solvent most widely used in reactions of the type considered is methanol.[45,67,72,76,77] Its role does not apparently reduce solely to increasing the solubility of the reactants, in particular, Li_2PdCl_4 and $PdCl_2(PhCN)_2$. The advantages

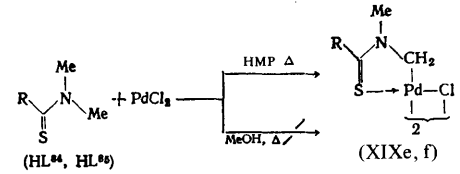
of polar solvents are probably based on the fact that they promote the creation of vacant sites in the coordination sphere of palladium(II) as a result of solvation. To illustrate this solvent effect, manifested in the stage involving the transition from the coordination compound to the cyclopalladated compound, one may recall the *ortho*-palladation of azobenzene[48] (see above), whose coordination complex is stable in non-polar solvents but is converted into the cyclopalladated compound after the simple addition of alcohol or aqueous dioxan.

The conversion of the palladium(II) coordination complex with a cationic ligand—*N*-methyl-2,2′-bipyridylium (LXXII)—into the cyclopalladated compound (LXXIII) requires a still more polar (aqueous) medium:



(LXXII) (LXXIII), 85%

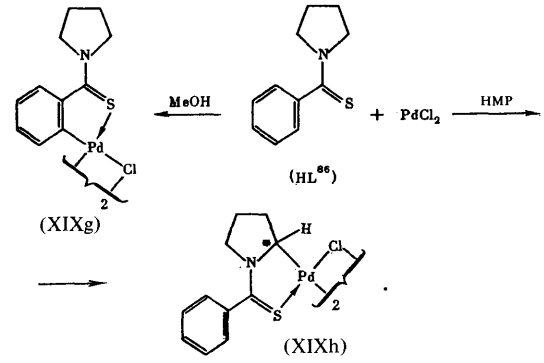
Cyclometallation does not occur on refluxing in alcohols (ethanol, 2-methoxyethanol).[134,135]



This reaction is especially surprising, since the positively charged pyridinium ring of the ligand is in this instance subjected to *ortho*-palladation (which is traditionally regarded as an electrophilic process).

The successful cyclopalladation of 8-methylquinoline-2-carboxaldimine (HL[66]), forming part of the composition of the coordination compound (LXXIV), in methanol and the absence of metallation products in chloroform (even at elevated temperatures) has been explained[76] as follows: by liberating a vacant site in the coordination sphere of palladium(II), methanol promotes the bidentate coordination of the ligand to the metal, which ensures the equatorial position of the 8-methyl group, necessary for the cyclopalladation in this fragment:

(LXXIV) 37%

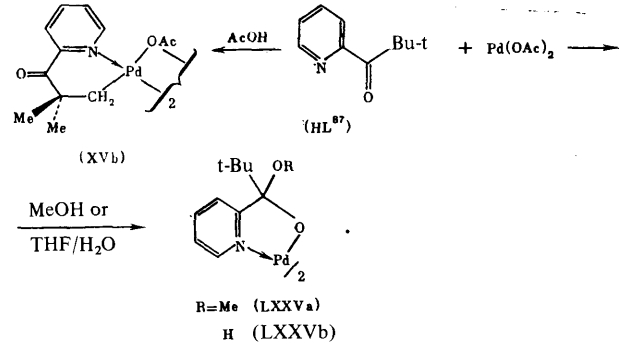


A similar solvation effect is probably the basis of the ready cyclopalladation in hexamethylphosphoramide (HMP) of certain thioamide ligands [for example, (HL[84]) and (HL[85])], which do not enter into this reaction in other solvents, especially in methanol:[67]

(HL[84], HL[85]) (XIXe, f)

R = PhCH=CH [(HL[84]), (XIXe)], —[(HL[85]), (XIXf)]

The nature of the solvent can influence not only the yield of the final product but also the pathway in the cyclopalladation reaction. For example, the cyclopalladation of *N*-thiobenzoylpyrrolidine (HL[86]) in methanol takes place in the aromatic ring with formation of the *ortho*-palladated complex (XIXg), whereas in HMP the α-methylene group of the pyrrolidine ring is subjected to metallation, affording compound (XIXh):[67,195,196]

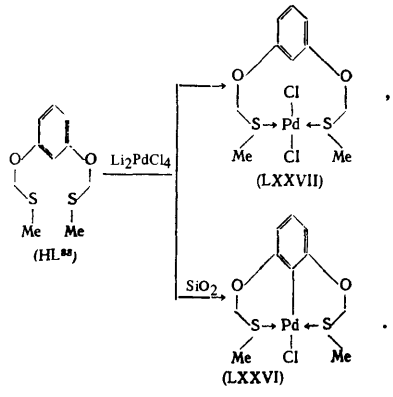


(XIXg) (HL[86]) (XIXh)

The successful resolution of the latter complex into enantiomers constitutes the best proof that the aliphatic fragment of the (HL[86]) is cyclopalladated.[195,196]

Apart from methanol and HMP, which have already been mentioned, some workers use aqueous dioxan[48,197] or 2-methoxyethanol[102] as effectively solvating solvents. Despite all the advantages of polar solvents, certain ligands are sufficiently reactive to enter into the cyclopalladation reaction even in weakly solvating solvents of low polarity such as benzene[137] and chloroform;[75,156] the reactions with palladium(II) acetate are carried out as a rule in glacial acetic acid.[89,172,173,198]

The importance of the correct selection of the solvent is illustrated by the following example. When the reaction of 2-pivaloylpyridine (HL[87]) with $Pd(OAc)_2$ is carried out in acetic acid, the usual dimeric cyclopalladation product (XVb) is formed,[94] whereas in methanol and in aqueous tetrahydrofuran (THF) the bis-chelates (LXXVa) and (LXXVb) are formed respectively as a result of the nucleophilic attack by the methoxide or hydroxide ions on the coordinated acyl fragment of the ligand (HL[87]):[199]



(XVb) (HL[87])

The required cyclometallation reaction time and temperature are determined by many factors: the class of ligand, its stereochemical characteristics, the nature of the palladating agent and solvent, etc. For example, whereas the *ortho*-palladation of the substituted benzylamine (HL[71]) in the aromatic ring activated by donor substituents takes place almost instantaneously even at −78 °C[165] (see Section IV), the cyclopalladation of *NN*-diethylthiobenzamide (HL[29]) is possible only after prolonged heating in HMP.[67] It is noteworthy that the increase in the reaction temperature and time frequently does not produce the desired result owing to the progressive formation of palladium black or the occurrence of other side processes.

Yet another way whereby the cyclopalladation reaction can be accelerated significantly and which is based on the catalytic action of silica gel merits mention.[62] As an example,

we shall quote the results of two attempts at the cyclopalladation of the bis-thioether ligand (HL^{88}): when the reaction with Li_2PdCl_4 is carried out in the presence of silica gel, the CPC (LXXVI) is formed in 95% yield, whereas in the absence of the Lewis acid under the same conditions the main reaction product is the coordination complex (LXXVII):[62]

Thus analysis of the literature data indicates a wide variety of factors influencing the mode and ease of the cyclopalladation reactions and also the structure of the cyclopalladated complex formed. However, a more far-reaching and detailed study of the causes of such effects and the mechanisms of reactions of the given type constitutes at the present time a task of fairly considerable current interest.

---o0o---

During the preparation of the manuscript for publication, a number of communications having a direct bearing on the topic of this review appeared in the literature.

Apart from the annual compilations of articles on the chemistry of palladium compounds,[200,201] Omae's monograph, summarising a series of review articles by the author published previously,[28,30,37-42] was published;[202] a review of this book[203] contains a series of serious critical comments.

Recently, there has been some progress in the research into the mechanisms of cyclopalladation reactions. It has been demonstrated by spectroscopic and kinetic studies of the *ortho*-palladation of a series of ring-substituted *NN*-dialkylbenzylamines that the reaction mechanism depends significantly on the nature of the solvent: in acetic acid, the rate-limiting stage is the opening of the acetate bridges in the polynuclear palladium acetate, while in chloroform the palladation proper of the amine takes place in the rate-determining stage within the framework of a pseudotricoordinate 14-electron intermediate.[204] The study of the kinetics and mechanism of the ortho-palladation of a series of 3,2′-annelated 2-phenylpyridines with bridges of different lengths by palladium bis(diketonates) suggested that the rate-determining stage of the process is not the attack by palladium(II) on the benzene ring but the subsequent deprotonation.[205]

The cyclopalladated ligand exchange reactions are finding increasing application in the synthesis of CPC of various types;[206-209] an advantage of this method is the preferential palladation of the more electron-accepting of the two ligands in the equilibrium process.[210,211] However, the ideas about the reaction mechanisms still remain contradictory: together with the dissociative mechanism, proposed on the basis of the study of the kinetics and thermodynamics of the reactions,[211,212] the possibility of the formation of mixed-ligand mononuclear bis-chelate CPC as key intermediates has also been discussed.[210] The final result is determined in both cases by the comparative stabilities of the Pd–C σ-bonds of the two palladium-containing heterocycles in relation to protonolysis.[213]

The problem of estimating the influence of various structural factors on the ease of cyclopalladation remains of current interest. Comparison of the behaviour of 1-phenyl- and 1-benzyl-substituted pyrazoles[214] and bornanopyrazoles[215] in the *ortho*-palladation reactions confirms the greater ease of formation of complexes with five-membered metallocycles: the 1-phenyl derivatives readily form CPC by reaction not only with palladium(II) acetate but also with Li_2PdCl_4, while 1-benzyl-substituted ligands afford only the coordination complexes. At the same time an increasing number of communications contradicting the idea of the absolute preference for five-membered palladium-containing heterocycles have been published. Thus the cyclopalladation of *N*-phenylbenzamidine by both $Pd(OAc)_2$ and Li_2PdCl_4 results in the formation of CPC with six-membered metallocycles as a result of metallation in the aniline ring and not the benzamidine ring, which might have led to the formation of a five-membered palladium-containing metallocycle; it has been suggested that this reaction pathway is caused by the greater electron density in the benzene ring of the aniline fragment.[216] For comparison, we may note that the *ortho*-palladation of substituted benzylideneanilines takes place in the aromatic ring of the benzylidene fragment.[217-219] An even more surprising result has been obtained in a study of the cyclopalladation of a series of benzylideneamines of the type $2,4,6\text{-}Me_3C_6H_2CH = N(CH_2)_nPh$ ($n = 0,1,2$),[220] which make it possible to compare simultaneously the tendencies towards metallation at the sp^2- and sp^3-centres and to estimate the importance of the size of the palladium-containing metallocycle formed. It was shown that in all the systems the metallation takes place at the *ortho*-methyl group (sp^3-centre) with formation of a six-membered palladium-containing metallocycle even if the alternative pathway involving metallation in the *ortho*-position in the benzene ring of the amine fragment (sp^2-centre) should have led to the formation of a five-membered ring (for $n = 1$). The nature of the factors which can compensate for the five-membered ring being preferred (compared with the six-membered ring) and for the preferred metallation of the sp^2-centre (compared with the sp^3-centre) remains obscure.[220]

The formation of six-membered metallocycles can be stimulated by introducing an additional (second) heterodonor centre: in contrast to the potentially bidentate 2-(1-methylbenzyl)pyridine, which is not metallated by $PdCl_4^{2-}$, the corresponding 2,2′-bipyridyl derivative readily forms a CPC with a tridentate *NNC*-coordinated ligand on treatment with Na_2PdCl_4 in aqueous HCl;[221] the structure of the complex has been confirmed by X-ray diffraction. It is suggested that the ready formation of CPC with six-membered palladium-containing metallocycles by potentially tridentate ligands of the NCN type {for example, 1,3-bis[1-(2-pyridinyl)-ethyl]benzene} is stimulated by the fact that metallation removes the stresses arising in the stage involving simple coordination via the terminal heterodonor centres.[222] We may note, within the framework of tricyclic systems with ligands of the CNNC type, the formation of not only six-membered but also seven-membered palladium-containing metallocycles proved to be possible.[223]

The possibilities arising from the modification of the cyclopalladation conditions for ligands with unfavourable structural features have been demonstrated in a number of investigations. As an illustration of the greater effectiveness of palladium(II) acetate compared with tetrachloropalladates,

one may mention that with its aid it has been possible to achieve the *ortho*-palladation of sterically unhindered benzyl methyl sulphide[224] and methyl α-naphthyl sulphide[225] and also the cyclopalladation in the aliphatic carbon centres of 2-t-butylbenzothiazole[226] and substituted benzylideneazine $(2,4,6\text{-}Me_3C_6H_2CH{=}N)_2$;[207] six-membered palladium-containing metallocycles are formed in the last case. Cyclopalladated complexes belonging to the series of substituted benzylidenebenzylamines have been synthesised in satisfactory yields by reaction with Li_2PdCl_4 only for a 1:1 reactant ratio, while in the case where a twofold excess of the ligand was used only the coordination complexes of the corresponding benzylamines were isolated as a result of hydrolysis.[227] With the same 1:1 stoichiometry and using $PdCl_2$ as the palladating agent, it has been possible to synthesise the CPC of substituted benzoylbenzylideneanilines.[228] An interesting example of the change in the metallation pathway as a function of the nature of the solvent is provided by two investigations:[211,212] when the reaction of the dibenzylamine ligand having two potential metallation regions, i.e. $3,4\text{-}(MeO)_2C_6H_3CH_2N(Me)CH_2C_6H_4NO_2\text{-}4$, with palladium(II) acetate is carried out in chloroform, the electron-enriched benzene ring is palladated, while in acetic acid the reaction involves the benzene ring containing the electron-accepting nitro-group. In the *ortho*-palladation reaction of α-phenyl-α-(2-pyridyl)toluene on treatment with palladium(II) acetate, a CPC with a six-membered palladium-containing metallocycle is formed only in acetic acid, while in benzene the reaction stops after the formation of the simple coordination *trans*-bis-complex.[229] The conversion of such coordination intermediates into CPC can be achieved either by heating in a suitable solvent—for example, chloroform[230] or ethanol[221]—or by introducing an additional equivalent of the palladating agent—for example, Li_2PdCl_4[215] or $PdCl_2$.[231] The synthesis of unusual dinuclear CPC with a single halide bridge from the *NCN*-chelated 2,6-bis(dimethylaminomethyl)phenyl ligand deserves to be mentioned.[232]

Photochemical Methods for the Construction of an Additional Four-membered Carbocycle in Steroids

A.V.Kamernitskii, V.N.Ignatov, and I.S.Levina

The photochemical methods for the synthesis of pentacyclic steroids with an additional four-membered carbocycle are considered. A systematic account is given of the available literature data on the [2 + 2] photocycloaddition of steroid enones and dienones to various alkenes and alkynes and also on the dimerisation of dienones and intramolecular cyclisation of steroid ketones.
The mechanism of the photolytic reactions is discussed and the stereo- and regio-specificity of the photocycloaddition are considered as a function of the structure of both the steroid and the alkene. It is shown that the pentacyclic steroids obtained are convenient intermediates for further modifications.
The bibliography includes 106 references.

I. INTRODUCTION

In the chemistry of steroid hormones, the modification of the skeleton of natural steroids is used to obtain compounds having a narrower and specific spectrum of biological activity, which gives rise to the possibility of their practical application. Among the numerous types of such transformed steroids, compounds containing an additional carbocycle are of great interest. The methods of their synthesis are fairly varied.

This review is devoted to the photochemical method of synthesis of steroids condensed with an additional four-membered carbocycle. Such pentaranes† exhibit an enhanced hormonal activity in many instances[2-15] and are also convenient intermediates for further modifications of the steroid skeleton.[16-22] Only the photochemical methods of synthesis of pentaranes are considered, because these methods frequently constitute almost the only possibility of the construction of a four-membered ring and the contribution of other methods of synthesis of similar structures (such as, for example, the cycloaddition of dichloroketen to steroid alkenes[23-26] or the intramolecular cyclisation of tosylates[27-29]) is small.

Photochemical [2 + 2]cycloaddition is a general method for the construction of pentacyclic steroids and, in contrast to the dark reactions, makes it possible to introduce the cyclobutane fragment into any site in the steroid molecule.

The main aim of the review is to demonstrate the synthetic possibilities of photochemical cyclisation to pentaranes and its stereo- and regio-specificity as a function of the structure of the steroid and alkene; special factors associated with the mechanism of the photoexcitation of the reacting molecules, their electronic state, etc. will not be discussed in detail. These questions have been dealt with quite fully in other publications.[30-34] The review contains data mainly referring to the last 18 years. Some information about the synthesis of cyclobutanosteroids up to 1970 can be found in a monograph.[35]

II. PHOTOCYCLOADDITION OF ALKENES TO STEROID ENONES

The interaction of photochemically excited enones and dienones with alkenes or alkynes usually leads to the formation of a four-membered carbocycle and frequently constitutes the most convenient or even the only available method of synthesis of such structures. In the steroid chemistry, the photocyclo-addition of various alkenes to αβ-unsaturated ketones# is a well-developed and convenient method for the introduction into the steroid molecule of an additional four-membered carbocycle, which is widely used at the present time.[36] Here it has been shown that this reaction leads to the formation of both *cis*-αα- and *trans*-αβ-cyclobutanes; insignificant amounts of the *cis*-ββ-isomers arising simultaneously are attributed to the epimerisation of *trans*-αβ-cyclobutanes under the reaction conditions.[37] The stereochemistry of the photoannelation can be explained on the basis of the general features of the interaction of an excited enone with an alkene in the ground electronic state: the attack by the latter takes place from the sterically less hindered α-region of the enone; (2) the *trans*-cyclobutane is formed as a result of the conformational inversion of the intermediate 1,4-biradical.[37-42]

The photocycloaddition of various alkenes to derivatives of testosterone (I) has been investigated[37] (Scheme 1); the yields of the isomeric cyclobutanosteroids (II)–(IV) obtained are listed in Table 1.

†The name "pentaranes"[1] is used for pentacyclic steroids containing an additional carbocycle.

#Here and henceforth we shall use the term "addition of alkenes (or olefins) to the more bulky steroid molecule".

Scheme 1

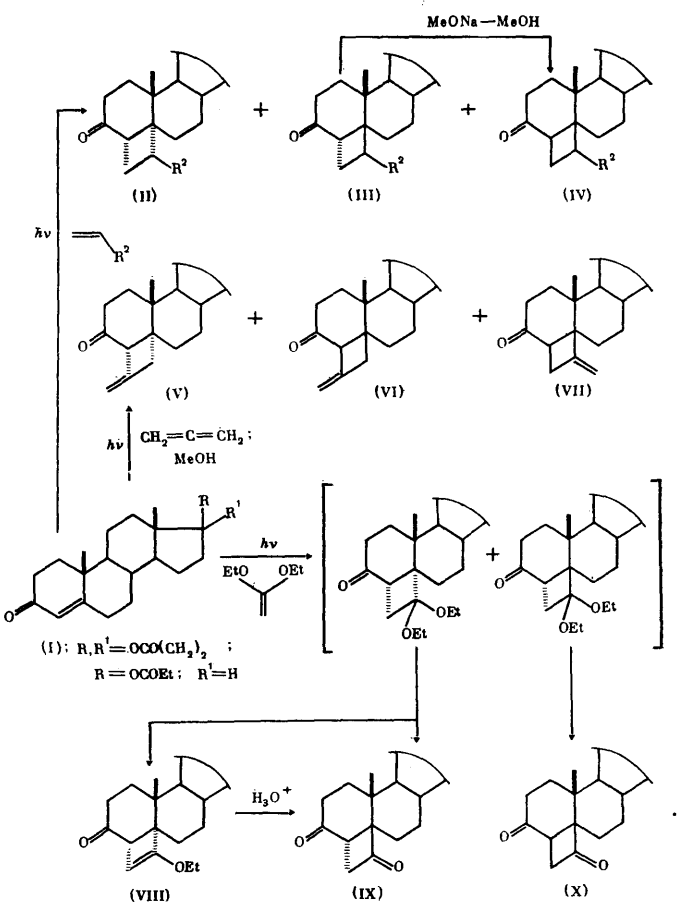

Table 1. The yields of the cyclobutanosteroids (II)–(IV).[37]

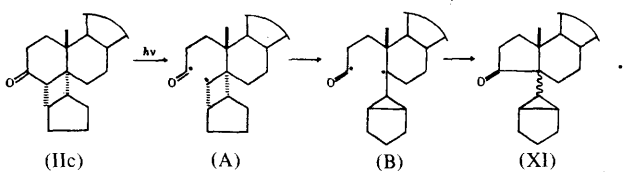
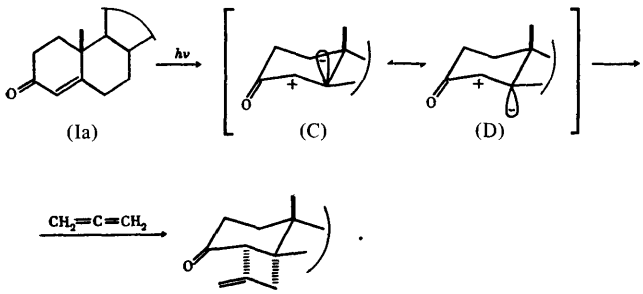


Olefin	Cyclic adduct, %		
	4α, 5α-(II)	4α, 5β-(III)	4β, 5β-(IV)
Ethylene	57	24—30	traces
Isobutene	76	12	traces
Cyclopentene	43	35	9
1-Acetoxycyclopentene	30	35	traces
Cyclohexene	40	25	12

It follows from the Table that ethylene adds to the steroid enone (I) affording the cyclic adducts (IIa) and (IIIa) with a high overall yield (81–87%), 4α,5α-cyclobutane (IIa) predominating in the mixture. Irradiation of a methanolic or ethyl acetate solution of testosterone propionate and ethylene also affords a mixture of compounds (IIa) and (IIIa) together with a small amount of the 4β,5β-epimer (IVa).[38,43] The high yields of the products of the reaction of the enone (I) with ethylene, which is a relatively unreactive alkene, can be explained by the fact that the steroid enone gives rise to a long-lived triplet state on irradiation.[44] In the reaction with a more electron-enriched alkene—isobutene—higher yields of 4α,5α-cyclobutane (IIb) were obtained. It was noted that the reactions with geminally substituted alkenes give rise only to cyclic adducts of the "head to tail" type (HT), while the reaction with cyclic alkenes affords only the *anti*-adducts,[37] although there are data[43] indicating the isolation of both the *syn*- and *anti*-isomers of the cyclic adduct of compound (I) with cyclopentene. The addition of allene to the enone (I) gives rise to a 5 : 1 mixture of compounds (V) and (VI); the reduction of the reaction temperature to −70 °C results in the exclusive formation of compound (V).[43]

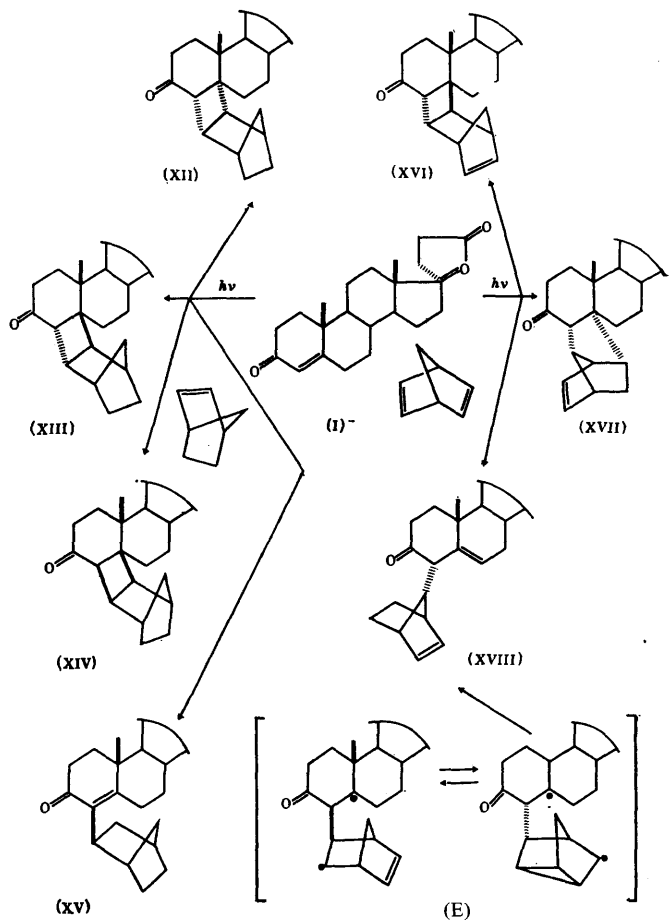
In order to account for the high structural specificity of the given reaction, the empirical "Corey rule"[45] that the "enone-unsaturated substrate" exciplex plays a decisive role, which has been developed for the series of aliphatic and monocyclic αβ-unsaturated ketones, has been successfully resorted to.[37]

The addition of 1,1-diethoxyethylene to compound (I) leads to a mixture of labile primary cyclic *cis*-4α,5α- and *trans*-4α,5β-adducts, which have been characterised as the cyclobutene (VIII) and the ketones (IX) and (X) (Scheme 1).[37]



It is of interest to note that 5-cyclopropyl-A-norsteroid (XI) has been isolated as a side product from the mixture of products of reaction of compound (I) with cyclopentene. The appearance of this steroid has been explained by the Norrish type (I) cleavage of cis-4α,5α-cyclobutane (IIc) with formation of the acylcyclobutyl biradical (A), which then rearranges to the cyclopropyl-substituted biradical (B) with subsequent stabilisation by conversion to the final compound (XI):[37]

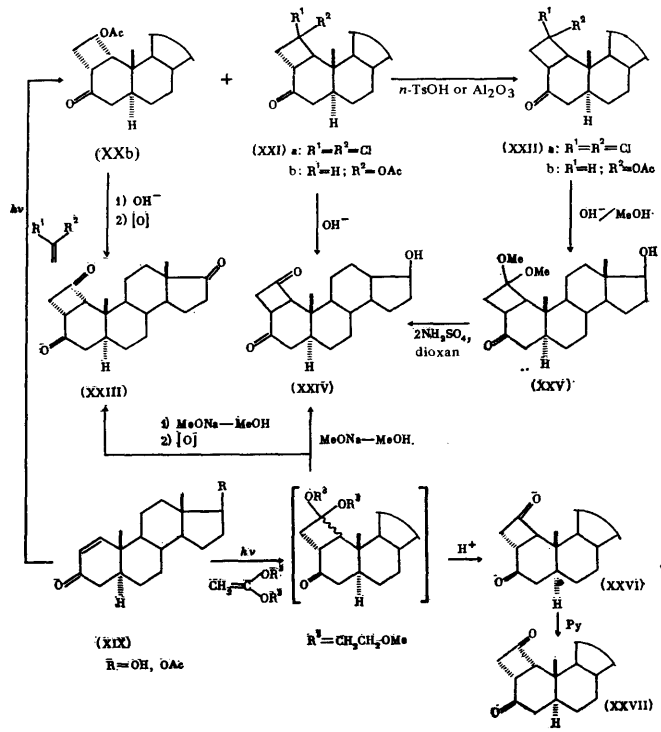
Extremely interesting results concerning the inversion of the stereospecificity of the photocycloaddition of alkenes to αβ-unsaturated ketones have been recently obtained by de Mayo.[43,46] It was found that irradiation of alkenes and testosterone or its propionate (I, R = OH or OCOEt), adsorbed on SiO_2 or Al_2O_3, leads to the preferential approach by the alkene to the β-region of the steroid molecule because the α-region is to a large extent blocked by the adsorbent molecules as a result of the preliminary adsorption of the steroid enone. It was shown that under these conditions the overall yield of the cycloaddition products increases. Thus, in the case of ethylene (R^2 = H, Scheme 1), the (IIa) : (IVa) = 42 : 58 mixture of cyclobutanes was obtained in a quantitative yield. *trans*-4α,5β-Cyclobutane (IIIa) was isolated only in trace amounts. Analogous results were obtained at a low temperature (−70 °C). The reaction of the testosterone propionate (I) adsorbed on SiO_2 with allene leads to a mixture of cyclic *cis*-4α,5α- and *cis*-4β,5β-adducts in the proportions (V) : (VI) = 1 : 1; the second regioisomer (VII) of the HT type was also isolated in an insignificant amount.[43] Thus the adsorption of the steroid enone on SiO_2 or Al_2O_3 prevents the conformational inversion of the intermediate biradical required for the formation of the *trans*-joined cyclobutanosteroids.



It is noteworthy that the structural specificity of the photocycloaddition of alkenes to αβ-enones is determined in the first place by the conformation of the enone reacting in the triplet state.[47] It has been shown in relation to cholest-4-en-3-one (Ia) that, of the two possible conformations (C) and (D) of the excited enone, the conformation (D) with the *trans*-disposition of the 19-CH_3 group and of the unpaired electron in the *p* orbital at C(5) is preferred. Accordingly, the cyclic adduct of the enone with allene should have a structure of the "head to head" type (HH), and the approach

of allene to the excited enone (Ia) from the α-region becomes preferred:

The addition of norbornene to the steroid enone (I) leads to a mixture of *cis*-4α,5α-cyclobutane (XII) (41%), the *trans*-4α,5β-epimer (XIII) (27%), the *cis*-4β,5β-adduct (XIV) (2%), and the adduct (XV) (17%)[48] (Scheme 2):

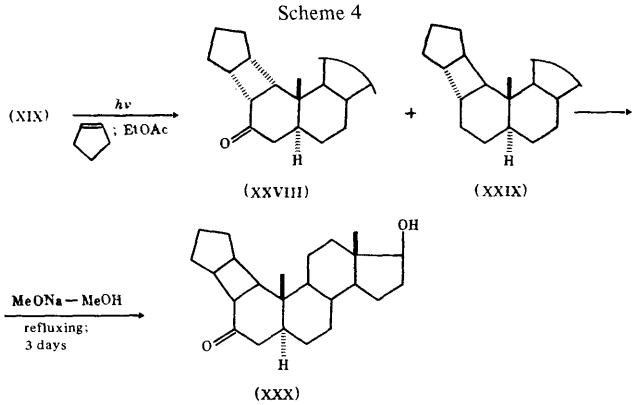


Scheme 2

The last adduct arises as a result of the 1,3-hydride shifts with formation of 4-norbornyl-3-keto-Δ⁵-steroid, which then isomerises to the Δ⁴-3-ketone (XV) in the course of the reaction. The appreciable stability of the *trans*-isomer (XIII) as regards epimerisation has been noted, which has been explained by the character of its conformation (the A ring is in the chair and not the boat form characteristic of the majority of 4α,5β-cyclobutanes,[31] which hinders the approach of the nucleophile to the 3-carbonyl group). The reaction of compound (I) with norbornadiene is fairly complex (cf. McCullough et al.[49]). *trans*-4α,5β-Cyclobutane (XVI) (10%) and two other products—(XVIII) (16%) and (XVIII) (53%)—were isolated from the mixture of substances (see Scheme 2). The formation of the last product has been explained by the steric hindrance to the rotation about the C(4)–C bond in the intermediate biradical (E).[48]

The cyclobutanosteroids condensed with the A ring in the 1- and 2-positions can be obtained by the photocycloaddition of olefins to Δ¹-3-ketosteroids. Literature data indicate a low reactivity of these enones compared with the Δ⁴-3-ketones. Thus it has been shown that ethylene, malic anhydride, and 1,1-difluoroethylene do not add to the series of androstane and pregnane Δ¹-3-ketones investigated.[50] However, irradiation of the Δ¹-3-ketone (XIX) in benzene solution containing 1,1-dichloroethylene led to a 16% yield of the substituted *trans*-1β,2α-cyclobutane (XXIa), which readily undergoes epimerisation at the C(2) centre, affording compound (XXIIa)[50] (Scheme 3). The stereochemistry of compound (XXIa) has been deduced from X-ray diffraction data. The hydrolysis of *trans*-1β,2α-cyclobutane (XXIa) and of its *cis*-1β,2β-isomer (XXIIa) yielded the same *cis*-1β,2β-cyclobutan-1′-one (XXIV). The reaction of the steroid enone (XIX) with vinyl acetate under analogous conditions led to a complex mixture of substances; after chromatographic separation, two products were isolated: *trans*-1β,2α-cyclobutane (XXIb) (21%) and *cis*-1α,2α-cyclobutane (XXb) (2%). Hydrolysis of the latter and subsequent Jones oxidation yielded 1α,2α-cyclobutan-1′-one (XXIII):

Scheme 3

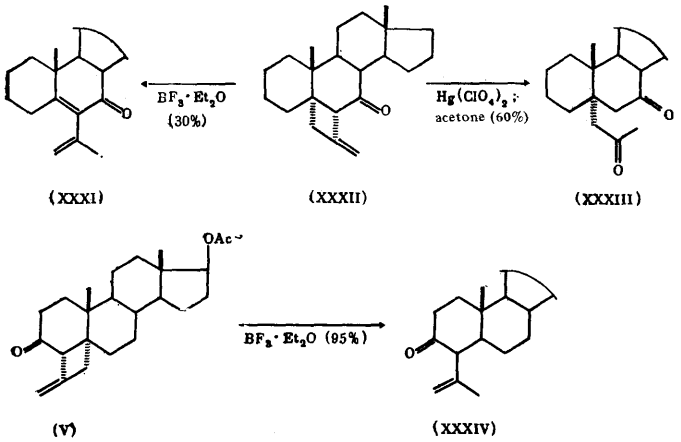


Thus the addition of substituted alkenes to Δ¹-3-keto-steroids leads to the formation of *trans*-cyclobuane adducts of the HT type with high regio- and stereo-specificity.

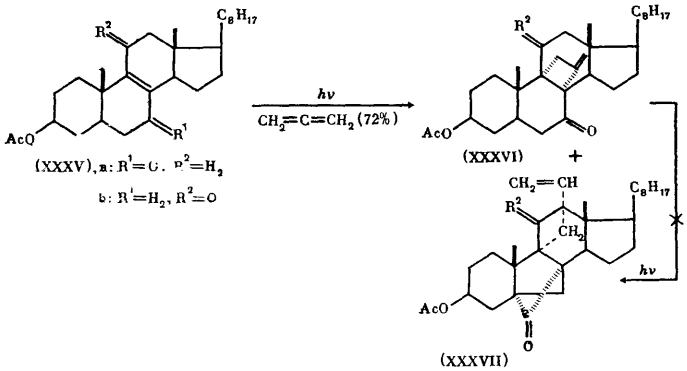
These adducts readily epimerise at the C(2) centre to form the more stable *cis*-1β,2β-cyclobutanosteroids.

The addition of cyclopentene to compound (XIX) led to the preferential formation of *cis*-1α,2α-cyclobutane (XXVIII) (56%) together with the usual *trans*-isomer (XXIX) (30%)[51]

(Scheme 4):



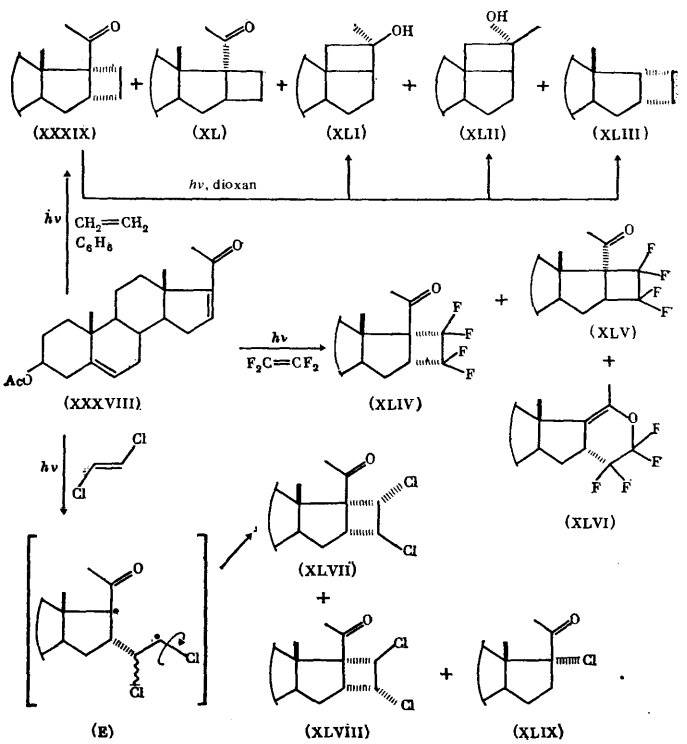
Scheme 4



The unusual stability of the last compound as regards epimerisation was noted here: the corresponding *cis*-1β,2β-isomer (XXX) was obtained only after prolonged refluxing of compound (XXIX) with MeONa in methanol. The isomeric 1β,2α-, 1α,2α-, and 1β,2β-cyclobutanones (XXVI), (XXVII), and (XXIV) were also obtained by adding ketene bis(2-methoxyethyl)acetal to compound (XIX) [51,52] (see Scheme 3). It is of interest to note that, whereas the acid-catalysed epimerisation of the *trans*-diketone (XXVI) leads to an equimolar mixture of compounds (XXIV) and (XXVII), heating of compound (XXVI) in pyridine affords only the *cis*-1α,2α-cyclobutanone (XXVII). [51]

Steroid enones substituted in the Δ^1-bond, for example the acetate of 17β-hydroxy-2-methyl-5α-androst-3-one, do not form cyclic photoadducts by reaction with alkenes at all, [50] which agrees with Corey's observation that such photochemical reactions are difficult for C(2)-substituted enones. [45]

6'-Methylene-5α,6α-cyclobutano-7-ketosteroid (XXXII) has also been described and its cleavage under various conditions has been investigated. [53,54] For example, when compound (XXXII) is refluxed in benzene in the presence of an excess of BF_3 etherate, the 6-isopropenyl-substituted 7-ketone (XXXI) is formed. Under analogous conditions, 4'-methylene-4α,5α-cyclobutane (V) gives rise to a high yield of the 4-isopropenyl-substituted 3-ketone (XXXIV). These products are apparently formed as a result of the electrophilic attack by the BF_3 etherate on the exocyclic methylene bond with subsequent opening of the cyclobutane ring. [53] The cleavage of methylenecyclobutane (XXXII) with mercury perchlorate in acetone leads to the diketone (XXXIII) in 60% yield. [54] These examples clearly demonstrate the possibility of using cyclobutanosteroids as intermediates for the transformation of steroids.

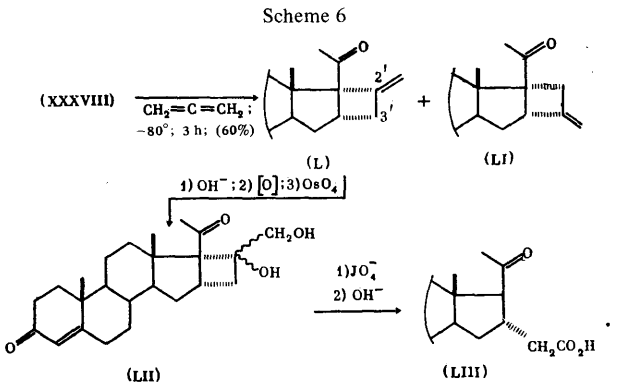


The 8α,9α-cyclobutanosteroid (XXXVI) has been obtained by the photoaddition of allene to 7-keto-$\Delta^{8(9)}$cholestene (XXXVa). The structure of the ketone (XXXVII) was attributed to the second compound arising under these conditions in ~20% yield:

Under analogous conditions, 11-keto-$\Delta^{8(9)}$-cholestene (XXXVb) does not react with allene. [55]

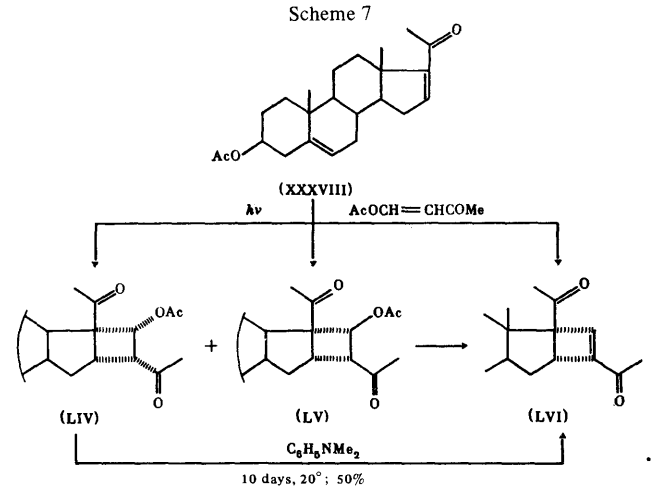
The 16-dehydro-20-keto-group in pregnanes is fairly reactive in photocycloaddition to various alkenes, which makes it possible to obtain the corresponding 16,17-cyclobutanosteroids. The first studies on their synthesis with participation of ethylene and its derivatives were published as early as the 1960's [56] and the formation of only *cis*-joined products with a significant predominance of the 16α,17α-isomers was demonstrated. [39,56] Thus, when ethylene is passed into an irradiated benzene solution of 16-dehydropregnenolene acetate (DPA) (XXXVIII), a mixture of 16α,17α- and 16β,17β-cyclobutanes (XXXIX) and (XL) is formed in proportions of ~7:1 (Scheme 5).

Scheme 5



After prolonged irradiation, the cyclobutanols (XLI) and (XLII) and the desacyl compound (XLIII) were detected as additional products in the reaction mixture. They were also obtained by the photolysis of the principal product (XXXIX) in dioxan. Under these conditions, the isomeric 16β,17β-cyclobutane (XL) is stable. The formation of compounds (XLI) and (XLII) was explained by the intramolecular attack on the 20-carbonyl group in an excited state by the vicinal 18-methyl group in the molecule of compound (XXXIX) and the formation of compound (XLIII) was accounted for by the abstraction of the acyl group. When the reaction is carried out in methanol, the yield and fraction of the main cyclic adduct (XXXIX) increased to 90%. When ethylene is passed through DPA absorbed on anhydrous SiO_2 at −70 °C, the overall yield of cyclic adducts rises to 70–85% with the simultaneous change in their stereochemistry in favour of an increase in the amount of the ββ-isomer: (XXXIX)/(XL) ≅ 1:1.[43]

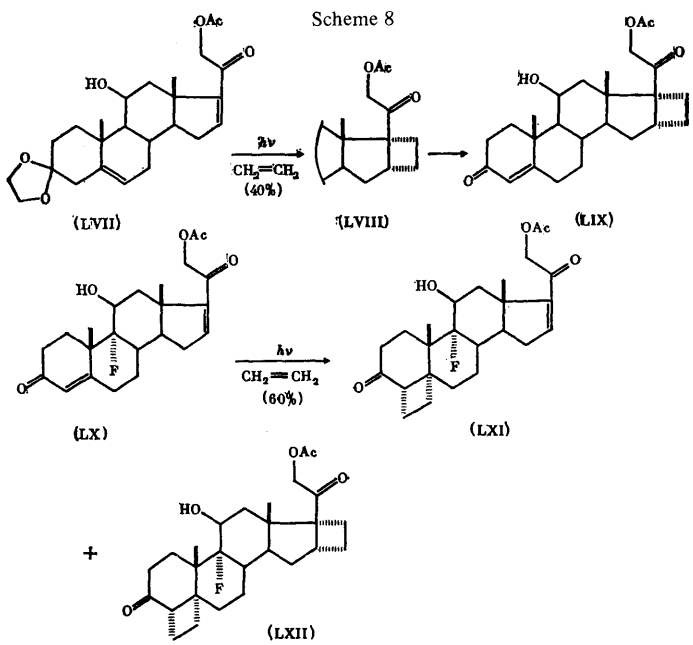
A high stereoselectivity of the cycloaddition has been observed also for the reaction of DPA with substituted alkenes,[2,39,57] which leads, for example, in the case of tetrafluoroethylene,[39] to a mixture of cyclic αα- and ββ-adducts (XLIV) and (XLV) in proportions of ~2:1 together with the formation of very small amounts of the dihydropyran (XLVI). The addition of *cis*- or *trans*-dichloroethylene to compound (XXXVIII) yields a mixture of substances of identical composition, from which *trans*-16α,17α-dichloro-compounds (XLVII) and (XLVIII) were isolated in proportions of ~1:1, differing in the configuration of the chlorine atoms. The 17α-chloropregnenolene (XLIX), detected in a very small amount, is apparently formed as a result of the direct addition of HCl to the initial enone (XXXVIII).[39] The fact that the *cis*- and *trans*-dichloroethylenes give rise to the same cyclic adduct agrees with the two-stage reaction mechanism via a biradical (F) (see Scheme 5); the rate of formation of the C(17)–CCl bond is evidently comparable to the rate of inversion of the C(2′)–Cl bond.



The photochemical reaction of DPA with allene is stereospecific and involves the formation of the 16α,17α-regioisomers (L) and (LI) in proportions of ~5:1 and an overall yield of ~60%[39] (Scheme 6):

Scheme 6

The structures of these compounds have been established with the aid of CD spectra in addition to certain chemical reactions with the main product (L). Thus its hydrolysis with subsequent Oppenauer oxidation afforded the corresponding Δ^4-3-ketone, whose hydroxylation with OsO_4 led to a mixture of diols (LII); successive treatment of these diols with OsO_4 and alkali yielded the familiar acid (LIII), which is formed via an intermediate stage involving the unstable cyclobutanone.[39] The photocycloaddition of 1-acetoxybut-1-en-one to DPA is of interest because both reactants can be in an excited state under the conditions of the photolysis. The cyclic 16α,17α-adducts (LIV) and (LV) in proportions of ~2:1 were then obtained together with a small amount of the cyclobutene (LVI). The latter was obtained after compound (LIV) had been kept for a long time together with dimethylaniline in solution in the $CHCl_3$–methanol mixture, although its diastereoisomer (LV) is stable under these conditions[58] (Scheme 7).



Scheme 7

The observed regiospecificity of the photochemical reaction conflicts with "Corey's rule",[45] because the preferential formation of cyclic adducts of the (EE) type should follow from an examination of the structures of the exciplexes. In order to account for this contradiction, one can postulate that the first reaction stage is the ordered orientation of the initial enones, which are in the ground state, after which the above coordinated complex undergoes photoexcitation with formation of the cyclic adducts (LIV) and (LV).[58]

The presence of substituents in the steroid skeleton of the molecule of compound (XXXVIII) does not reduce its reactivity in the photochemical reaction, but, when the Δ^4-3-keto-group is present together with the Δ^{16}-20-keto-

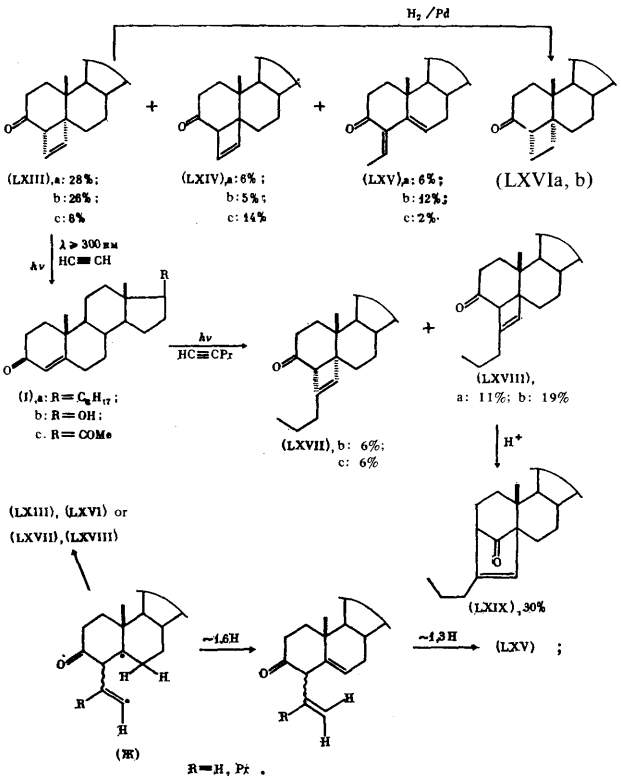
Scheme 8

group, cycloaddition takes place preferentially with participation of the former group. Thus it has been shown that the interaction of compound (LVII) with ethylene leads to a 40% yield of the 16α,17α-cyclobutane (LVIII), which is converted further into the Δ^4-3-ketone (LIX). On the other hand, the 4α,5α-cyclobutane (LXI) was obtained in 60% yield from the unsaturated 3,20-diketone (LX); the corresponding bis-adduct (LXII) was observed only in trace amounts in the mixture[56] (See Scheme 8).

It is of interest to note that in the monocyclic series cyclopent-2-enones exhibit a greater reactivity than cyclohex-2-enones.[59]

Thus, when account is taken of the data considered above, αβ-unsaturated ketosteroids can be arranged in the following sequence in terms of their reactivity: Δ^4-3-keto- > Δ^{16}-20-keto- > Δ^1-3-keto-. It must be emphasised that this series has been set up on the basis of a fairly limited set of steroid enones and one cannot therefore rule out the possibility that corrections will be introduced in connection with the appearance of new experimental data.

III. PHOTOCYCLOADDITION OF ALKYNES TO αβ-UNSATURATED KETOSTEROIDS



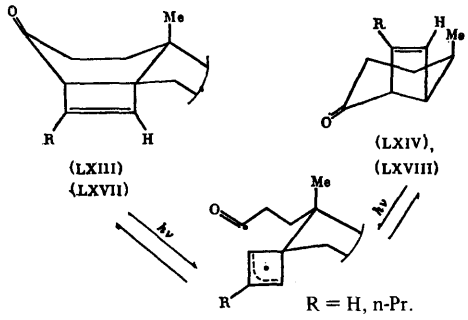
The photocycloaddition of alkynes to steroid enones gives rise to cyhclobutenosteroids with interesting synthetic possibilities. In view of their high strain, such structures undergo various transformations already under the conditions of the photolysis, which, when combined with certain dark reactions, leads to new ways of transforming steroids. Owing to the reduced nucleophilicity of the triple bond, alkynes are less reactive than alkenes in reactions involving addition to the excited enone. For example, it is known that the interaction of 2-cyclohexanone with vinylacetylene involves exclusively the double bond of the latter.[60]

When the steroid enones (Ia, b) are irradiated in ethyl acetate saturated with acetylene, mixtures of the diastereoisomers (LXIIIa, b) and (LXIVa, b) are formed in proportions of ~5:1 and in an overall yield of ~30%;[61] the reaction proved to be less stereoselective than the corresponding reaction with ethylene. On catalytic hydrogenation, the cyclobutenes (LXIIIa, b) afford the corresponding cyclobutanes (LXVIa, b) (Scheme 9).

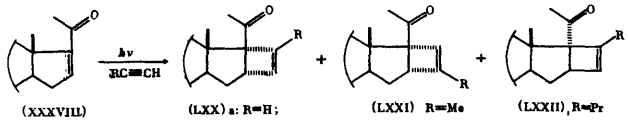
Together with the cyclic adducts (LXIIIa, b) and (LXIVa, b), the ethylidene derivatives (LXVa, b) were obtained in a yield of ~6–12%. The study of the cycloaddition of acetylene to compounds (Ia, b) under the influence of light with λ ≥ 320 nm, which is absorbed solely by the initial αβ-enone, the intramolecular inversion in the cyclic adduct being ruled out, showed that all three products (LXIII)–(LXV) are also formed under these conditions, from which the authors concluded that the reaction leads immediately to both diastereoisomers.[61] Analogous results were achieved in the photolysis of compound (Ib) together with pent-1-yne, which leads to stereoisomers of the type (LXVIIb) and (LXVIIIb).[62] The mechanism proposed for their formation, via the intermediate biradical (G) stabilised as a result of its closure to form cyclobutene or by disproportionation to 1,4-diene (H), also explains the appearance of the ethylidene-substituted compounds (LXV) (see Scheme 9).[61,63] The structures of the adducts (LXIIIa, b), (LXIVa, b), (LXVIIb), and (LXVIIIb) were established spectroscopically (NMR, CD), and also on the basis of X-ray diffraction data.[64]

The appreciable decrease in the overall yield of the cyclic photoadducts (LXIIIc) and (LXIVc), observed in the reaction of progesterone (Ic) with acetylene and pent-1-yne, and the inversion, compared with the cases examined above, of the stereospecificity of the addition, consisting in the preferential formation of ββ-isomers (LXIVc) and (LXVIIIc), are very remarkable.[62] The compounds discussed are interconverted under the influence of light λ ≥ 300 nm but are stable on irradiation with light having λ ≥ 320 nm. Since the photoaddition of both alkynes to compound (Ic) affords predominantly the 4β,5β-cyclobutenosteroids (LXIVc) and (LXVIIIc), the observed stereoselectivity is not a result of secondary reactions, but is caused, according to the authors,[62] by the influence of the acetyl group at C(17) via the mechanism of the long distance stereoelectronic effect.[65] This effect was noted for the first observation of this effect in the photochemistry of steroids.

Scheme 9



It follows from the data described that the empirical "Wiesner's rule", predicting the stereospecific course of the photoaddition of polycyclic–enones,[47] does not hold for alkynes, like "Corey's rule",[45] which predicts the structural specificity of this reaction.

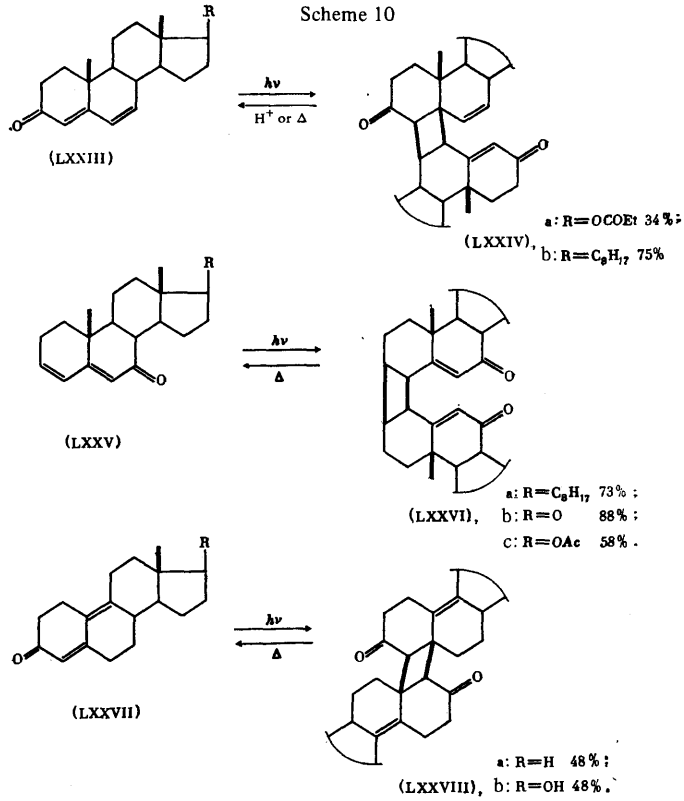


The cyclobutenosteroids (LXIIIb), (LXIVb), (LXVIIb), and (LXVIIIb) are extremely reactive compounds because of the presence of a strained double bond and the keto-group in their conformationally rigid structure. As noted above, on irradiation with light at λ ≥ 300 nm, they are interconverted via the 1,3-acyl shift mechanism, together with rapid polymerisation.[62,63]

The photoadducts considered can be converted into other steroids modified in the *A* ring. Thus, on treatment with TsOH, compound (LXVIIIb) gives rise to the bridged βγ-unsaturated ketone (LXIX) (see Scheme 9). Under analogous conditions, compound (LXIVb) does not undergo an isomerisation of this type.[62]

There exist data on the interaction of Δ^4-3-keto- and Δ^{16}-20-ketosteroids of the pregnane and corticoid series with different mono- and di-substituted actylenes.[4,66,106]

The cyclobutenosteroids (LXXa, b) and (LXXI) have been obtained by irradiating DPA [compound (XXXVIII)] in the presence of methylacetylene or acetylene.[33,103] The reaction proceeds stereospecifically from the region of the steroid molecule[67,68] and in the case of methylacetylene both regioisomers, (LXXb) and (LXXI), have been described. The interaction of DPA with pent-1-yne leads to a mixture of the stereoisomeric cyclic HH αα- and ββ-adducts (LXXc) and (LXXII) in proportions of ~10:1:[69,70]



The catalytic hydrogenation of the cyclobutenosteroids (LXXa–c) leads to the corresponding cyclobutane analogues.[13,69]

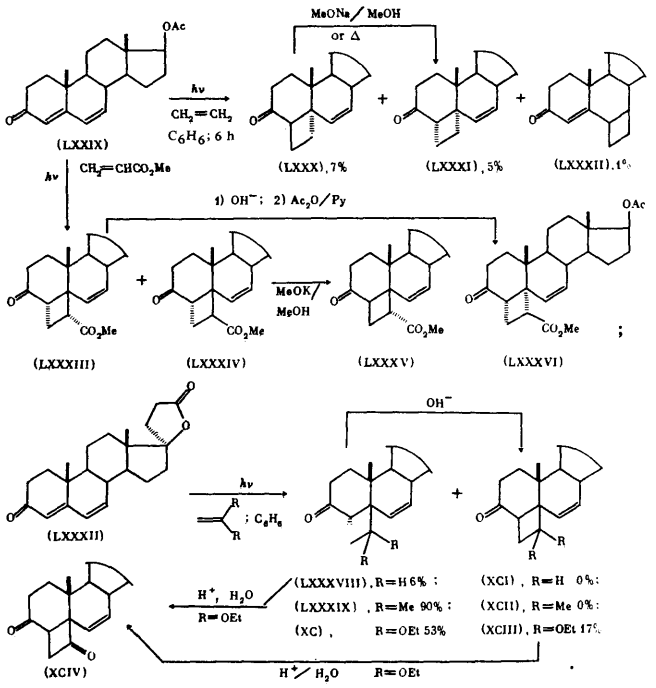
IV. PHOTODIMERISATION OF STEROID DIENONES

The photodimerisation of conjugated ketones can be regarded as one of the variants of the formation of a cyclobutane ring which has found an interesting application to the steroid series. Such photodimers were first obtained and characterised by two groups of workers at the beginning of the 1960's. Thus, after irradiating the androstadienone (LXXIIIa) derivative with UV light, Rubin et al.[71] isolated as the only reaction product a dimer to which the structure of the adduct (LXXIVa) of HT type was attributed on the basis of spectroscopic data and was subsequently confirmed[72] (Scheme 10).

Analogous dimerisation has been described[73] for cholestadienone: when compound (LXXIIIb) was irradiated, the photodimer (LXXIVb) was isolated in 75% yield. Thus the dimerisation proceeds in this case via the addition of the αβ-double bond (Δ^4) in one molecule of the dienone (LXXIII) to the γδ-bond (Δ^6) of the scond monomer. The dimerisation pathway is determined by the characteristic environment of the chromophore and steric factors play a decisive role here. For example, the dimerisation of the steroid $\Delta^{3,5}$-7-ketones (LXXVa–c) afforded in all cases high yields of only one regioisomer, namely (LXXVIa–c) of the HH type,[74] i.e. the product of the addition of the γδ-double bonds of both monomeric molecules of compound (LXXV). Apparently steric hindrance prevents the approach by the second bulky molecule of compound (LXXV) to the αβ-double bond of the first monomer, whereas on irradiation of compound (LXXVa) in cyclopentene the corresponding cyclic 5,6-adduct was isolated.[74] The rate of dimerisation of compound (LXXV) is much lower than the rate of dimerisation of compound (LXXIII). The photoirradiation of the dienone (LXXVII), in the molecule of which the γδ-double bond is sterically hindered, has also been investigated. This dienone affords a lower yield of the unstable dimer (LXXVIII), than the reaction involving the Δ^4-bonds alone.[5,75] In contrast to the 17β-hydroxy-$\Delta^{4,9}$-ketone (LXXVIIb), the 17β-acetoxy-derivative forms a dimer via a reaction of the HH type.[105] On heating in the crystalline state or in solution, the dimers (LXXIV), (LXXVI), and (LXXVIII) decompose with formation of the corresponding monomeric molecules.

Scheme 10

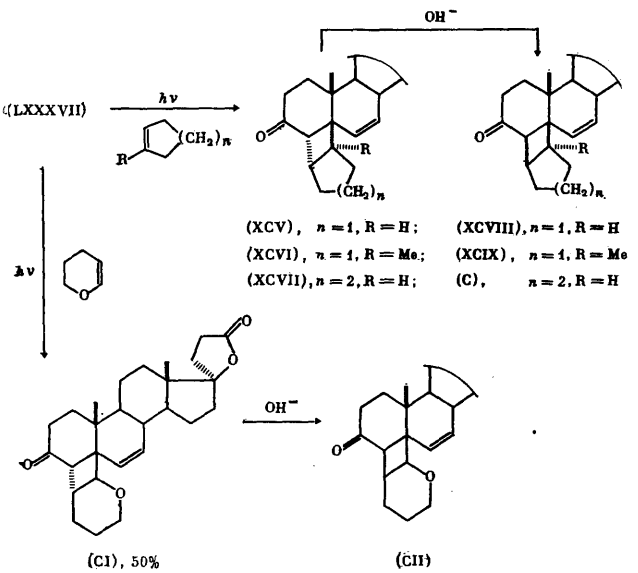
The nature of the excited state of the steroid βγ-hexadienone systems, including their triplet π,π* state, has been investigated quantum-chemically; the results of this study do not conflict with purely chemical conclusions concerning the structure of the dimers (LXXIV) and (LXXVI).[71, 73,76] It was shown in this connection that, whereas the positive charge is concentrated on the C(3) atom of the diene component of the steroid dienone, which is in the ground state, in the π,π* state the greatest positive charge is on the C(4) atom. In view of these considerations, the formation of a bond between the C(3) atom of one molecule and the C(4) atom of a second steroid dienone appears unlikely.[76]



V. PHOTOCYCLOADDITION OF ALKENES TO STEROID DIENONES

The photocycloaddition of various alkenes to steroid dienones proceeds in a more complex manner than for αβ-unsaturated ketosteroids and frequently leads to a complex mixture of adducts produced via both αβ- and γδ-double bonds of the initial dienone and differing in their structures

and stereochemistry depending on the mode of addition of the alkene.



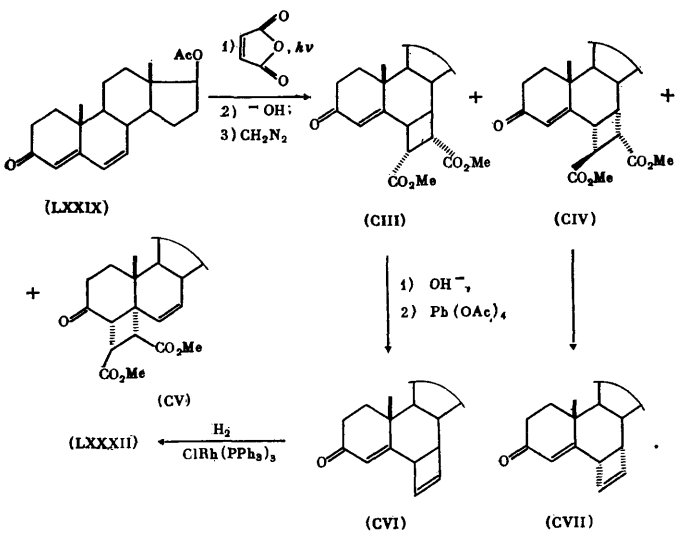
Ethylene is a relatively unreactive component of the [2 + 2]-photocycloaddition reaction. Irradiation of a benzene solution of the acetate (LXXIX) in an atmosphere of ethylene affords a low yield of *trans*-4β,5α- and *cis*-4α,5α-cyclobutanosteroids (LXXX) and (LXXXI) and also a 1% yield of the cyclic 6β,7β-adduct (LXXXII) [77] (Scheme 11):

Scheme 11

The structures attributed to compounds (LXXX)–(LXXII) are based on spectroscopic and certain chemical data. Thus *trans*-(LXXX) is known to isomerise readily to the *cis*-4α,5α-adduct (LXXXI) on treatment with sodium methoxide in methanol or thermally. The addition of ethylene to the $\Delta^{4,6}$-3-ketone (LXXXVII) has been achieved; [78] in this case the only product isolated (in 6%) yield was *trans*-4α-5β-cyclobutane (LXXXVIII), whose structure has been confirmed by data obtained by chiro-optical methods and also by the ready isomerisation to 4β,5β-cyclobutane (XCI). The photocycloaddition of a number of cyclic and acyclic alkenes to the ketone (LXXXVII) has also been investigated (see Scheme 11). The introduction of electron-donating substituents into the alkene molecule entails a sharp increase in the reaction rate and in the yield of cyclic adducts. [78] Thus isobutene adds to compound (LXXXVII) 20 times faster than ethylene and only *trans*-4α,5β-cyclobutane (LXXXIX) has been obtained in 90% yield. The addition of diethoxyethylene affords a 70% yield of a mixture of the adducts (XC) and (XCIII) in proportions of 3 : 1. The ready conversion of the *trans*-adducts into 4β,5β-isomers (XCI)–(XCIII) has been noted in all cases. The 4β,5β-cyclobutanone (XCIV) has been obtained by hydrolysing a mixture of cyclic adducts (XC) a and (XCIII). Cyclic alkenes also react with the photo-excited dienone (LXXXVII) (Scheme 12); for example, cyclopentene gives rise to only the one *trans*-adduct (XCV) in 50% yield, [38,78] while methylcyclopentene and methylcyclohexene react to form a mixture of the cyclic adducts (XCVI) and (XCIX), on the one hand, and (XCVII) and (C), on the other, respectively:

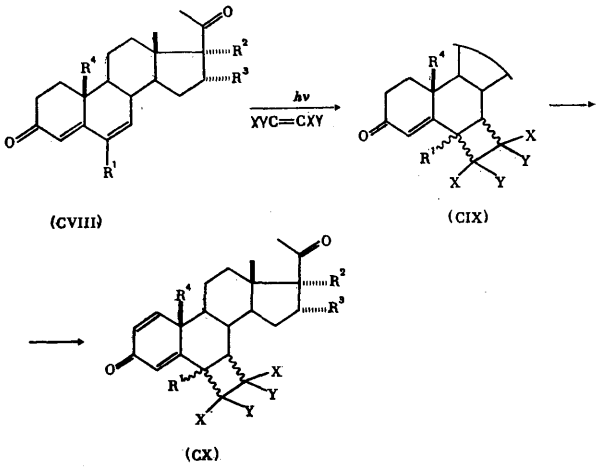
Scheme 12

The addition of dihydropyran to compound (LXXXVII) leads only to the *trans*-4α,5β-adduct (CI). All the *trans*-4α,5β-adducts (XCV)–(XCVII) and (CI) obtained readily isomerise to the *cis*-4β,5β-adducts (XCVIII)–(C) and (CII). [78]



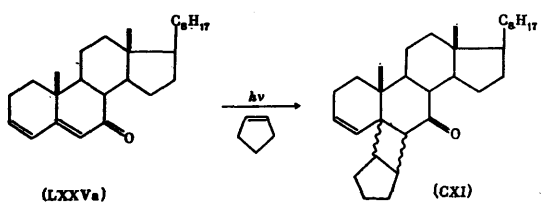
Thus the specificity of the photocycloaddition of alkenes to steroid $\Delta^{4,6}$-3-ketones, leading exclusively to *trans*-4α,5β-derivatives, has been noted in all cases.

The formation of the 4β,5β-epimer has been explained by the isomerisation of the *trans*-adduct during the photochemical reaction. Here it is assumed that, if the *cis*-adduct had in fact arisen as a result of cycloaddition, it should have had to possess the αα-structure. The stereochemical and orientational selectivity of the given reaction is explained by the fact that the dienone interacts in the excited singlet state, in contrast to the excited triplet state usually observed in photochemical cycloaddition reactions. [78]



The photoaddition of methyl acrylate to Δ^{6}-testosterone acetate (LXXIX) (Scheme 11), which proceeds in accordance with the [2*s* + 2*a*] scheme, leads to the *trans*-substituted cyclobutane (LXXXIII); the epimer (LXXXIV) was also isolated in the chromatographic separation. The hydrolysis and isomerisation of compound (LXXXIV) (MeOK–MeOH) with subsequent reacetylation leads to *cis*-4β,5β-cyclobutane (LXXXV). Under analogous conditions, *trans*-(LXXXIII) was converted into the diester (LXXXVI) (the given stereochemistry was attributed on the basis of some of its chemical and chiro-optical properties). [79] The photocycloaddition of cyclopentene to the dienone (LXXIX) adsorbed on silica gel has been investigated. [43] Apart from cyclic *trans*-4α,5β-adduct of the type of (LXXXVIII), which is the sole product of the reactions carried out in methanol, the corresponding cyclic 6,7-adduct is also formed in 30% yield in this instance. We may recall the photoaddition of maleic anhydride, reacting in the excited state, to Δ^{6}-testosterone acetate (LXXIX) in the ground state [77] (Scheme 13). Here the main product is that resulting from the addition to the γγ-bond of the steroid dienone—the diester (CIII) (55%) (obtained after the methanolysis of the primary cyclic adduct) and its 6α,7α-isomer (CIV) (19%). The yield of the photoadduct (XV), formed as a result of the addition to the αβ-bond, does not exceed 15%. The *exo*-disposition of the methoxycarbonyl groups has been attributed to compounds (CIII)–(CV).

The oxidation of compounds (CIII) and (CIV) by $Pb(OAc)_4$ leads smoothly to the cyclobutenes (CVI) and (CVII). The homogeneous hydrogenation of the former in the presence of Wilkinson's complex afforded the familiar[77] cyclobutane (LXXXII):

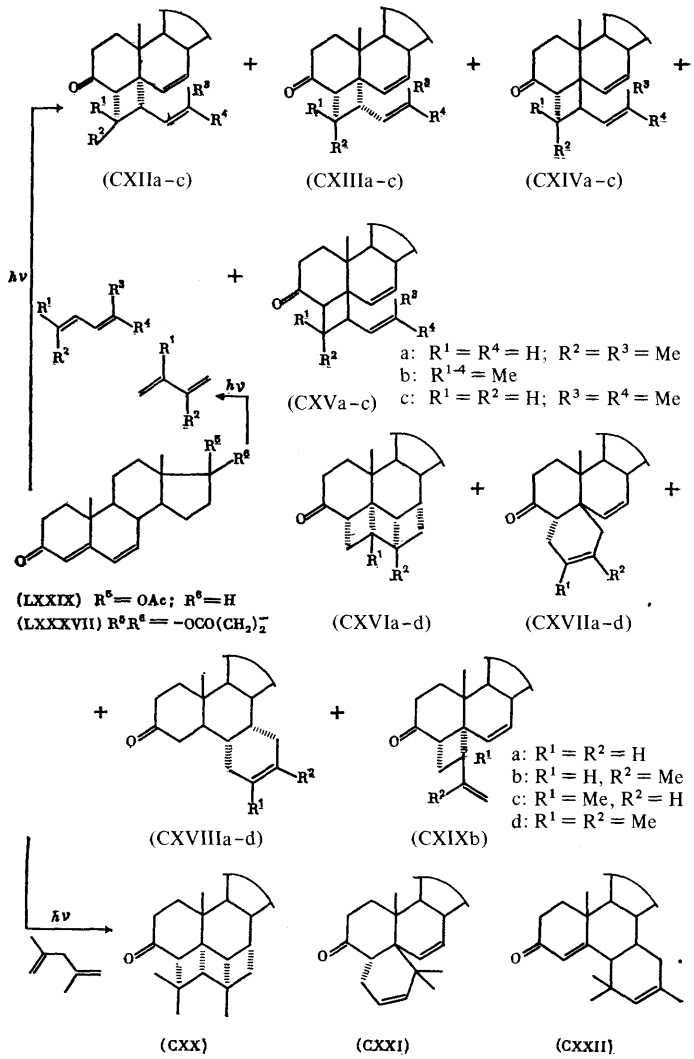


Scheme 13

A series of 6α,7α- and 6β,7β-cyclobutanopregnanes (CIX) and their 19-nor- and 17-, 16-, and 6-substituted analogues have been obtained by irradiating $\Delta^{4,6}$-3-ketopregnanes having the general formula (CVIII) in benzene in the presence of various alkenes; 4α,5α-,4β,5β-, and 4α,5β-cyclobutanes have also been mentioned as other products. The $\Delta^{1,4}$- derivatives (CX) have been obtained by chemical reactions of the cyclic adducts (CIX):[6]

The analogous 6,7-cyclobutanes of the androstane series have also been obtained.[7] The cyclic 4,5-adduct (CXI), whose stereochemistry has not been established, has been obtained by the cycloaddition of cyclopentene to cholesta-3,5-dien-7-one (LXXVa):[74]

Thus a characteristic feature of the photocyclisation considered is the ability of the steroid Δ^4- and $\Delta^{4,6}$-3-ketones in the π,π* state to form the *trans*-joined 4,5-cyclobutanosteroids, which differ significantly from the familiar results of the dark [2 + 2]cycloaddition; apparently it can be explained by the conformational flexibility of the *A* ring in the steroid systems considered (only the *cis*-adducts have been obtained for the *C* and *D* rings).



VI. PHOTOCYCLOADDITION OF DIENES TO STEROID DIENONES

It is well known that, when 1,3-dienes enter into a dark reaction with compounds containing an activated double bond, they give rise to the *cis*-products of the [2 + 2]- and [2 + 4]-cycloaddition.[80] On the other hand, the photoinduced addition of dienes leads to both *cis*- and *trans*-joined cyclic adducts. In the steroid series, this reaction has been investigated in detail by Lenz,[48,81-85] who showed that the 4,6-dien-3-ones (LXXIX) and (LXXXVII) interact with cyclic and ancyclic dienes (Table 2, Schemes 14 and 15), producing complex mixtures of substances, whose structures and stereochemistry and also composition depend on the structure of the diene and certain other factors. The results presented indicate that the isomeric cyclobutanosteroids are formed exclusively via the αβ-double bond (Δ^4-bond) of the initial steroid, which may be accounted for by its steric accessibility compared with the γδ-double bond. As can be seen from the data in Table 2, the ratio of the [2 + 2]- and [2 + 4]-adducts and the yield of the 4,5-cyclobutanosteroids depend in a definite manner on the conformation of the diene. Thus, in the reactions with transoid dienes (Table 2, compounds Nos.4–6), the yield of the isomeric cyclic 4,5-butanes (CXII)–(CXIV) is very considerable.[81,82] The 4α,5β-cyclobutanosteroids (CXIV) are converted into the 4β-epimers (CXV) in solution. On the other hand, butadiene and its 2-methyl and 2,3-dimethyl derivatives (Table 2, compound Nos.1–3) as well as *s-cis*-2,4-dimethylpenta-1,3-diene (Table 2, compound No.7) altogether fail to form cyclobutanes on reaction with steroid dienones [if one disregards the formation of compound (CXIXb) in 5% yield from isoprene]. In such cases the main reaction products are cyclic [2 + 4] adducts—the *trans*-4,5-cyclohexenosteroids (CXVII) and (CXXI) and the *cis*-6α,7α- and 6β,7β-cyclohexenosteroids (CXVIII) and (CXXII)[81-85] (Scheme 14).

Table 2. The yields of the cyclic adducts (%) in the photolysis of the dienones (LXXIX)* and (LXXVII)** in the presence of dienes.

No.	Diene	IP, eV	Yield of cyclic adducts, %					Refs.

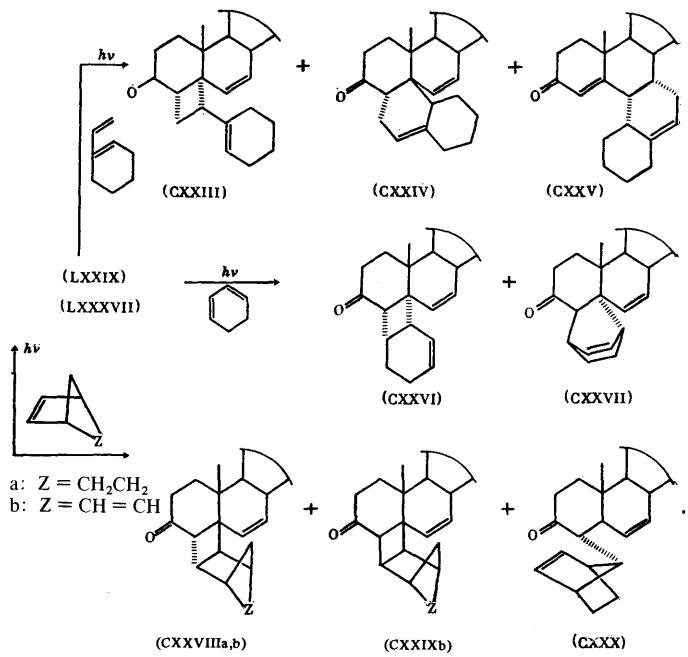
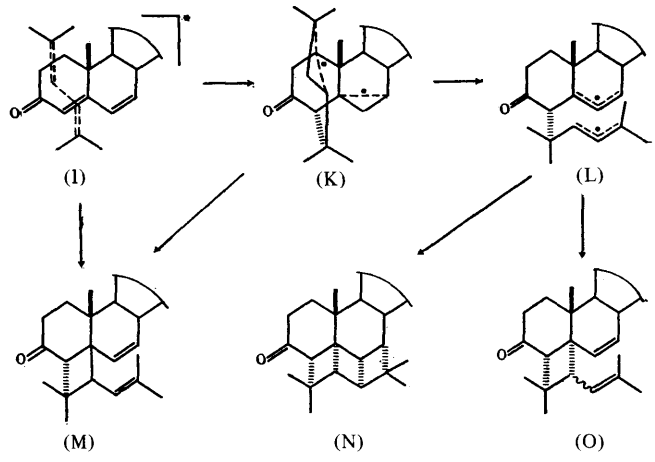
Scheme 14



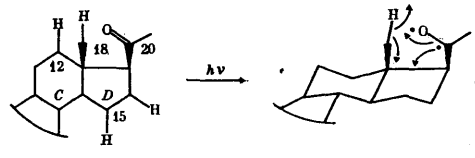
Vinylcyclohexene (Table 2, compound No.8) affords a mixture of cyclic adducts involving the Δ^4-bond: the 4α,5α-cyclobutane (CXXIII), the 4α,5β-cyclohexene derivative (CXXIV), and the product of the addition to the Δ^6-bond of the steroid dienone—compound (CXXV).[82] The interaction of the dienone with cyclohexadiene (No.9) leads exclusively to a mixture of the *cis*-4α,5α-cyclobutane (CXXVI) and the cyclic *trans*-4β,5α-adduct (CXXVII) [82] (Scheme 15).

The photocycloaddition of norbornene to the dienone (LXXXVII) leads to a 60% yield (Scheme 15) of the *trans*-4α,5β-cyclobutane derivative (CXXVIIIa), which is an exo-adduct according to X-ray diffraction data.[48] In contrast to the majority of *trans*-4α,5β-cyclobutanes, compound (CXXVIIIa) is converted into the corresponding 4β-epimer (CXXIXa) only after prolonged refluxing in methanol in the presence of sodium methoxide. Irradiation of compound (LXXXVII) in the presence of norbornadiene yielded three products: the 4α,5β- and 4β,5β-cyclobutanes (CXXVIIIb) and (CXXIXb) and the 4α-derivative (CXXX).



The most surprising result of the photocycloaddition of conjugated dienes to steroid dienones is the formation of "stepwise" cyclic [2 + 2 + 2 + 2]adducts (CXVI) and (CXX).[81-85] These compounds arise with a high regio- and stereo-selectivity. Thus the diene approaches exclusively the α-region of the steroid molecules, affording only a type HH adduct. Lenz[82] suggested that the possibility of the formation of the stepwise adduct depends on the ionisation potential (IP) of the diene. For IP smaller than 8.4 eV (Table 2, compound Nos.4 and 9), a product of this kind does not arise; furthermore, with increase of IP (Table 2, compound Nos.1 and 2), the yield of compound (CXVI) increases. Dienes with terminal substituents give rise to adducts of the HH type, for example, compound (CXX), while dienes with substituents at the centre of the molecule lead to a mixture of compounds (CXVIb, c).[81,82] One should also state that all the attempts to convert 4α,5α-cyclobutano-steroids (CXII) into the corresponding "stepwise" adducts were unsuccessful.[81]

Scheme 15

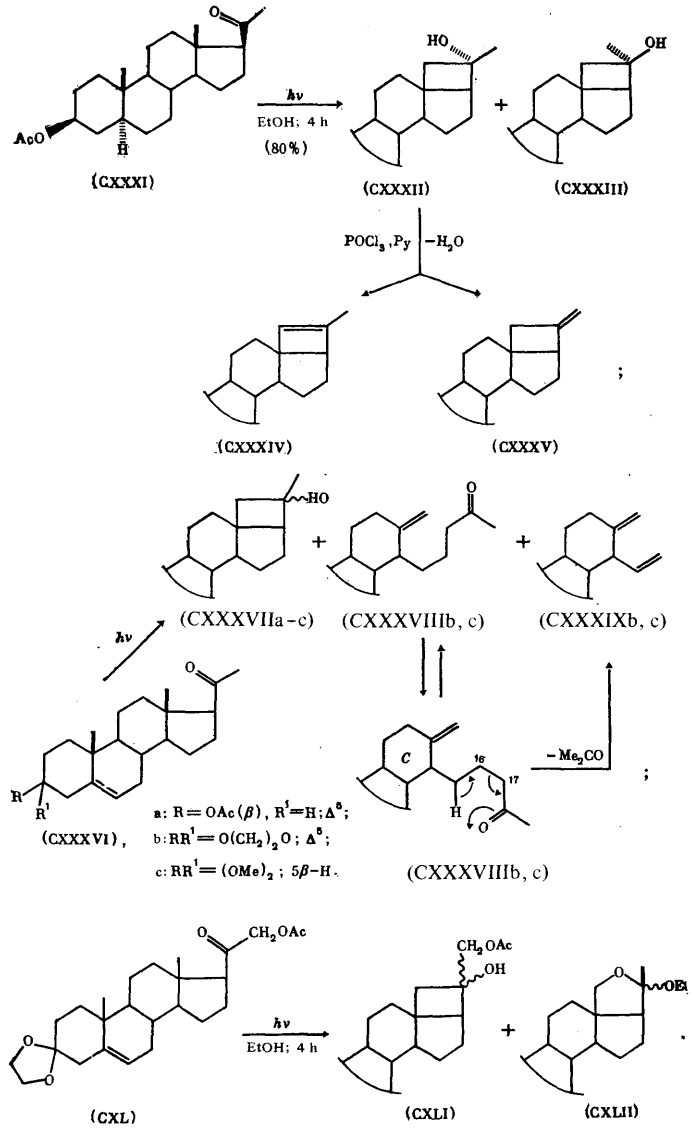


Since both the *cis*- and *trans*-cyclobutanes are formed as a result of the approach by the diene to the excited dienone in the α-region of the latter, the following reaction scheme has been proposed:[81] the photoexcited dienone interacts with the diene, to form an exciplex, in which a highly coordinating disposition of the reacting molecules obtains as a result of the adequately fixed chair conformation of the *A* ring and the presence of a pseudoequatorial current at C(4). In the complex (I), one of the double bonds of the diene is disposed orthogonally in relation to the Δ^4-bond of the dienone. Next there is a possibility of the direct formation of the *trans*-4α,5β-cyclobutanone (M), while the biradical intermediate (K) can generate, via a disrotatory transformation around the C(4α)—C bond, the allylic biradical (L), which is capable of forming the C(5)—C bond and this leads to both the *cis*-4α,5α-cyclobutane (O) and to synchronous

interaction of two allylic radicals with formation of the "stepwise" adduct (N):

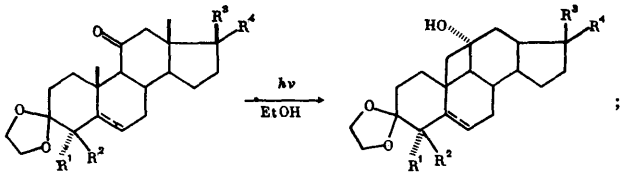
VII. INTRAMOLECULAR PHOTOCYCLISATION OF STEROID KETONES

Yet another variant of the synthesis of pentaranes with an additional cyclobutane ring uses the familiar ability of carbonyl compounds to undergo intramolecular photochemical reactions with the sterically close γ-hydrogen atom (Norrish type II reactions).[86] In the series of 2-keto-steroids, such interaction is possible, in principle, with the C(12), C(15), and C(18) centres. However, the 20-carbonyl and 18-methyl groups are most favourably disposed on purely steric grounds:



It has been shown that, when the 20-ketone (CXXXI) is irradiated in ethanol, a mixture of epimeric 13β,17β-cyclobutanols (CXXXII) and (CXXXIII) is formed in 80% yield in proportions of 3 : 1. A mixture of the alkanes (CXXXIV) and (CXXXV) was obtained by the dehydration of the 20α-epimer (CXXXII).[16,17] The structures of all these substances have been confirmed spectroscopically.[17]

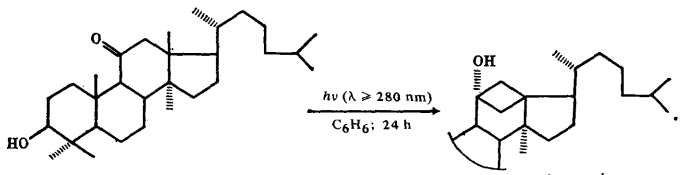
The replacement of ethanol by non-polar solvents leads to the retardation of the photocyclisation and a decrease in the yield of the reaction products.[17] Thus, irradiation of compound (CXXXVIa) in hexane afforded a 33% yield of a mixture of (CXXXVIIa) epimers; compounds (CXXVIIIb, c) were obtained analogously from compounds (CXXXVIb, c) together with appreciable amounts of the D-secosteroids (CXXXVIIIb, c) and (CXXXIXb, c).[17,87] Compounds (CXXXVIII) and (CXXXIX) evidently arise as a consequence of the occurrence of two competing and consecutive photo-retro-reactions (Norrish type II), leading to the dissociation of the C(13)–C(17) bond and then the C_{16}–C_{17} bond.[17,87]



The cyclosteroids (CXXXVII) have been used as intermediates in the introduction of functional groups at the C(18) centre in the synthesis of aldosterone and its analogues.[88,89] Isolated information about such hydroxycyclobutanosteroids is available in patents.[90,91]

Substituents in the α-position relative to the 20-carbonyl group affect the course of the intramolecular photocyclisation. Thus the acetoxyketone (CXL) proved to be less active than the ketone (CXXXVIb); its irradiation leads to an equimolar mixture of the isomeric cyclobutanols (CXLI) and the tetrahydrofuran derivative (CXLII). The formation of the latter can be explained by the interaction of the excited carbonyl moiety of the 21-acetoxy-group with the 18-methyl group.

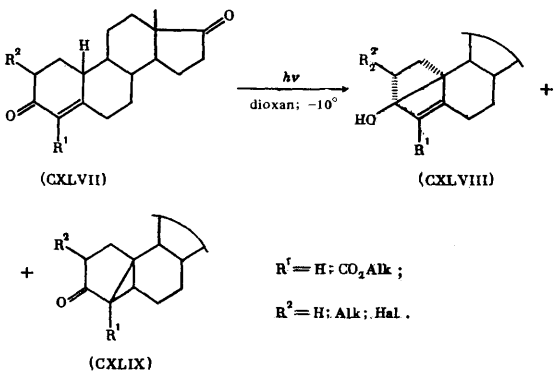
The extension of the reaction considered to the 11-keto-derivatives of steroids led to the synthesis of 11,19-cyclosteroids containing an additional four-membered ring condensed with the *B* and *C* rings.[92–96] Thus irradiation of the 11-ketones (CXLIII) in ethanol afforded 10β,11β-cyclobutanosteroids (CXLIV).[94,97,98] The yield of the latter depends to a definite extent on the presence of a substituent at C(4) and on the character of the junction of the *A* and *B* rings and is a maximum for the 4,4-disubstituted *A*–*B*-*cis*-compounds, because cyclisation in such steroids eliminates the steric interaction between the 4β-CH_3 and the 19-CH_3



groups in compound (CXLIII):

(CXLIII) (CXLIV)

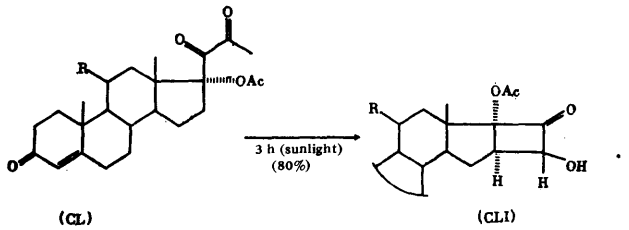
R^1 and R^2=H, Me; R^3, R^4=$O(CH_2)_2O$ or R^3=C_8H_{17}; R^4=H.



The character of the junction of the *C* and *D* rings and also the presence of the 14α-CH_3 group in the initial 11-keto-steroid affects the photocyclisation under consideration. Thus the Δ^{14}-11-ketosteroids form on irradiation the 11,8-cyclopropane derivatives;[99] the 11-ketone of the lanostane series (CXLV) is converted in ~20 yield into the 11β,13β-cyclobutanol (CXLVI):[100,101]

(CXLV) (CXLVI)

The cyclic 11,19-photoproducts in the series of triterpenoids have also been described.[92,93,102] It is noteworthy that the 11-keto-C-norsteroids do not undergo intramolecular cyclisation.[95]



The 19-nor-Δ^4-3-ketosteroids substituted in the *A* ring produce on irradiation a low yield of the 3,10-cyclobutanol compounds (CXLVIII) together with the 4,10-cyclopropane derivatives (CXLIX):[104]

(CXLVII) (CXLVIII)

(CXLIX)

The 16,17-cyclobutanosteroid (CLI), obtained in a high yield on irradiation of compound (CL) with sunlight, has also been described:[19]

(CL) (CLI)

---oOo---

Thus the review of the literature data on the synthesis of cyclobutanosteroids (pentaranes) by photochemical methods shows that the main process in the photochemical [2 + 2]addition of unsaturated substrates to the active double bonds in the steroid molecule is sometimes accompanied by the simultaneous reactions involving both the initial steroid and the primary cyclic adducts.

Mechanochemical Synthesis

C.Simionescu and C.V.Oprea

The mechanism and conditions in the mechanodegradation of certain homochain and heterochain polymers as well as mechanochemical graft and block copolymerisation, polycondensation, and mechanochemical complex formation processes are examined. These yield a virtually complete description of the behaviour of test polymers in mechanochemical processes; the possibility of altering the structure and properties of the initial polymers in the required direction is also discussed. Attention has been concentrated on homopolymerisation and copolymerisation reactions; it is shown that the reaction mechanisms and the structures of the polymers formed possess features determined by the nature of the activating influence (mechanical energy).
The bibliography includes 129 references.

I. ACTIVATION OF SOLIDS, INCLUDING POLYMERS, BY MECHANICAL ENERGY

1. Essential Features of the Process

Mechanochemistry is a science developing at the boundary between chemistry and mechanics: it is closely related also to other branches of science and engineering—physics, especially solid state physics, biophysics, physical chemistry, polymer technology, the chemistry and technology of inorganic substances, biochemistry, molecular biology, and bionics.

By selecting and reworking certain facts and laws taken from all these branches of science, mechanochemistry has in its turn put forward its own laws and conclusions, promoting the development and enrichment of the sciences related to it.

In the most general definition, mechanochemistry can be referred to as the science which deals with the study of the interconversions of mechanical and chemical energy in material bodies.[1-3] However, the creation of a single all-embracing hypothesis reflecting comprehensively all the aspects of the mechanochemical process must be based on the knowledge of the complex structure of the test object, which is determined by a number of levels of supermolecular organisation. The mechanochemical phenomenon includes two main components: the mechanochemical component, which determines the conversion of mechanical energy into chemical energy, and the chemomechanical component, which represents the liberation of mechanical energy as a consequence of chemical reactions.

Here one must bear in mind that it is extremely difficult to tell whether the mechanical action is the primary factor inducing the chemical reaction or whether it is merely an agent facilitating the action by the medium. The field of mechanical forces influences the probability of the initiation of various reactions and the latter in their turn determine the spatial disposition of the structural elements[4] (Fig.1).

The chemomechanical aspect of the phenomenon has been discovered as a result of studies by Kuhn[5] and Katchalsky[6] using artificial systems. Similar studies have been carried out also by other investigators.[8,9] These studies are of interest not only because of their current practical value but also because they model important biological phenomena such as the transport of matter through membranes or the contraction of muscle tissue, whose mechanisms have now been virtually demonstrated.[10-23] Different variants of the "mechanochemical machine" have been published, in which the LiBr and NaCl electrolyte concentration gradients and the pH values excite the expansion and contraction of protein (collagen) or cellulose fibres, which are thus able to set in mechanical motion a system of wheels in accordance with the transmission belt principle.[7]

The most complex process responsible for the liberation of mechanical energy in living organisms is the biomechanical process, which is cyclic in character. In muscle contractions, it takes place at the level of supermolecularly organised protein macromolecules, constituting macroscopic systems, which are excited mechanically by the work of the preceeding cycle. In this state, they become the site where chemical reactions (especially of the enzyme type) take place with the biological medium. Thus an isobaric and isometric mechanochemical transformation occurs (Fig.2). Its direct result is a change in the relative disposition of atoms and groups of atoms and also a change in the conformation of the macromolecules. The conformational changes occurring at the level of each macromolecule are manifested in contraction and expansion effects at the level of the supermolecular formation incorporating these macromolecules; as a result, this formation begins to perform mechanical work. The chemomechanical transformation in the cycle (2) is thus performed (Fig.2). The mechanical energy liberated acts on the supermolecularly organised macromolecules and the latter pass to a mechanically excited state and the biomechanical cycle is repeated.[23]

Consequently the mechanochemical process combines both the transformation of chemical energy into mechanical energy and of mechanical energy into chemical energy; the site where these transformations take place is the structure subjected to the given action. The mechanochemical and biochemical processes are now known and many aspects have been investigated; these processes have found important applications in life and engineering[1,2,23-28] (Fig.3).

2. The Step-wise and Activated Character of the Mechanical Process

The step-wise character of the mechanochemical process is manifested when it is considered at different levels of the supermolecular organisation. It is determined by the structural features of the polymer, which determine the specific character of the concentration of mechanical energy in specific chemical bonds located in the zone of defects with a statistical distribution at molecular, supermolecular-morphological, and structural-composition levels.

The micromechanics of the dissociation of chemical bonds can be studied successfully using the oriented polymer model of the greatest mechanical resistance to rupture (having the profile of fibre) or on a single crystal obtained by solid-phase polymerisation.[29] Such structures possess discrete formations, clearly separated in space, with a supermolecular organisation, whose transformation induced by the mechanical action can be estimated with the aid of the usual research methods. The mechanical model of such a structure can be represented as a set of macromolecules maintained in the longitudinal direction by dispersion forces, whose nature depends on the actual chemical structure of the polymer investigated (Fig. 4*a*).

For a correct separation of the phenomena occurring in the volume element under the influence of mechanical energy, account must be taken of the following factors. Real polymers (and material bodies in general) are characterised by a structural inhomogeneity, as a result of which the distribution of mechanical stresses is non-uniform. Since the determination of the magnitude of the stresses in chemical bonds is extremely difficult, one usually determines the variation of the rate constant for the dissociation of overstressed chemical bonds. It is then necessary to know the nature of the factors influencing the probability of the onset of chain mechanodegradation and the nature of the radical reactions initiated in this way.

Simplifying conditions, consisting, for example, of assuming that the stresses are distributed uniformly over each structural and chemical bond element, are usually resorted to in the calculations. For an analytical investigation of the phenomena occurring in a volume element (Fig. 4*a*), an isolated macromolecule, having the flat zigzag shape (Fig. 4*b*) characteristic of the majority of known polymers, is considered. As a result of the action of the stretching force P_1 on this macromolecule, the valence angles and chemical bonds are deformed. According to the condition adopted, the force is distributed in equal parts P_i which act on the

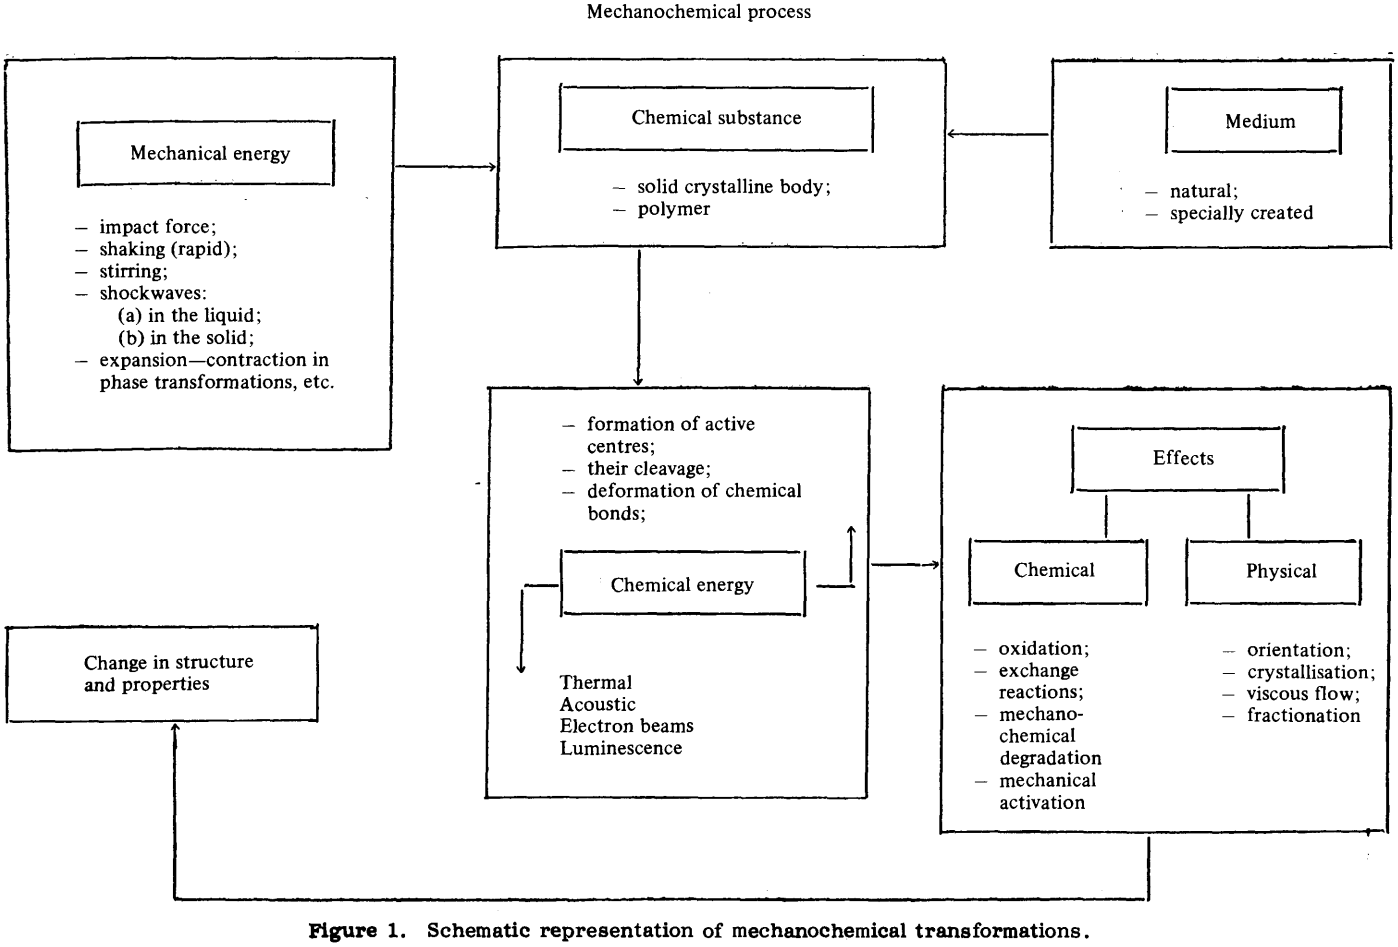

Figure 1. Schematic representation of mechanochemical transformations.

corresponding structural microelements consisting of not less than two chemical bonds (*1–2* and *2–3*) and a valence angle (*1–2–3*) (Fig. 4c) and can be divided into tangential ($P_{i,t}$) and normal ($P_{i,n}$) components. Despite the fact that the deformation of the valence angle is greater, the rupture takes place in the chemical bond. According to Natarajan and Reed,[39] we have

$$P_{t,\max} = \frac{P_{i,t,\max}}{\sin \rho_0} ,$$

where $P_{i,\max}$ is the force causing the dissociation of the chemical bond, $P_{i,t,\max}$ the tangential component at the instant of rupture balancing the resistance of the chemical bond, and ρ_0 the valence angle at the instant of rupture.

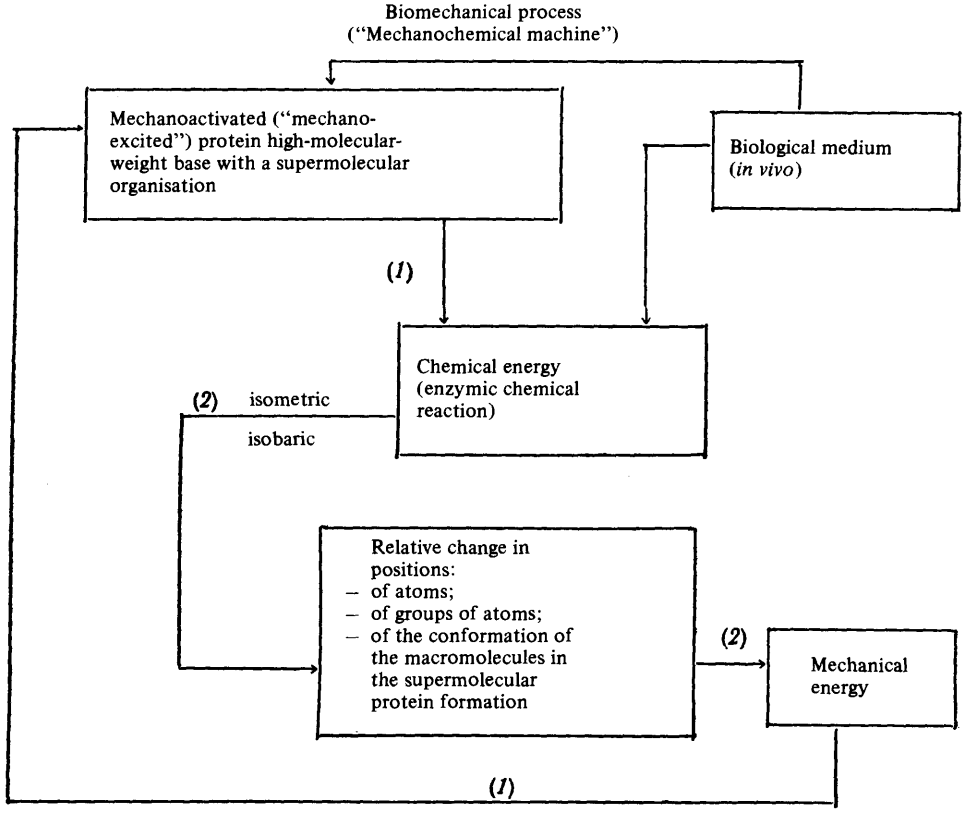
The break in the section *BC* (Fig. 4a) occurs when the latter is acted upon by a force which is determined by the length of the macromolecule with the maximum molecular weight ($P_{i,t,\max} = \Sigma n P_{i,t}$). Consequently, the chain length, expressed in terms of the number of component chemical bonds, is important for the occurrence of the rupture process. When the volume element contains macromolecules of critical length (which is much greater than the average length), its stability no longer depends on the energy of the interchain bonds but does depend on the chain length. For the critical chain lengths, the force developed is a maximum and causes the breaking of the chain, i.e. mechanocracking.

The breaking of the chains via mechanocracking is a chemical reaction but of a kind such that the participating kinetic and structural elements are not individual macromolecules but volume elements involved in the rupture. Therefore, despite the fact that the rupture occurs as a result of changes in the bonds at the atomic-molecular level, the mechanical process belongs, in essence, to the supermolecular level.

If the mass of the rupture volume element is denoted by X_2, then, after the absorption of a definite amount of mechanical energy Ω, the volume element is separated into two parts (X):[30]

$$X_2 + \Omega \rightarrow 2X .$$

The absorption of elastic energy leads to a bond dissociation volume element which is non-uniform in different regions. In those microvolumes where the potential energy becomes sufficient to overcome the energy barrier to the transition to the new state, an elementary breaking step, consisting in the transformation of the initial configuration state into another (final) state, takes place. At an intermediate stage, a configuration critical for the given conditions (corresponding to the maximum area under the potential energy curve) is attained, representing an unstable mechanoexcited complex. This complex is stabilised by the excess energy obtained by dissociation of a certain additional number of chemical bonds. The energy accumulated is then distributed among the vibrational and rotational degrees of freedom in accordance with



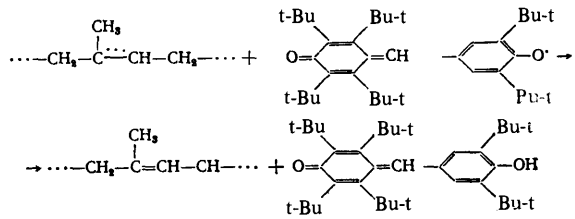


Figure 2. Schematic representation of a biomechanical process: 1) mechanochemical transformation; 2) chemomechanical transformation.

the requirements of the new configurations. Hence it follows that, in the bond deformation stage before rupture, the reactivity of the system increases with formation of mechano-excited states and free radicals, which arise as a consequence of the mechanocracking of the chemical bonds, occurring to a limited extent in the interior of the most activated micro-regions. The set of macroradicals, formed by a certain number of molecular breaks in the mechanoexcited micro-volume, leads to the appearance of an incipient microcrack.

The appearance of a mechanoexcited state and the formation of free radicals have been demonstrated by EPR studies and have been confirmed by the character of certain chemical reactions. For example, raw rubber deformed by stretching is oxidised more readily;[31–33] vulcanised rubber is ruptured more readily on exposure to ozone;[34] certain heterochain polymers are hydrolysed in the cold under the conditions of mechanical action, whilst under the usual conditions this process can occur only at elevated temperatures.[35,36] The mechanoexcited state in raw rubber enables the latter to react with stable radicals of the galvinoxyl type[37] in accordance with the scheme

When certain polyoxoamides are stretched in an inert medium in the cold, free radicals are obtained whose formation may be followed visually since they are coloured red. After the removal of the force, the active centres vanish and so does the colour, but the test specimens become insoluble in *m*-cresol.[38] The stretching of vulcanised rubber without additives at low temperatures (93–193 K) takes place with the appearance, before the onset of rupture, of fine gas

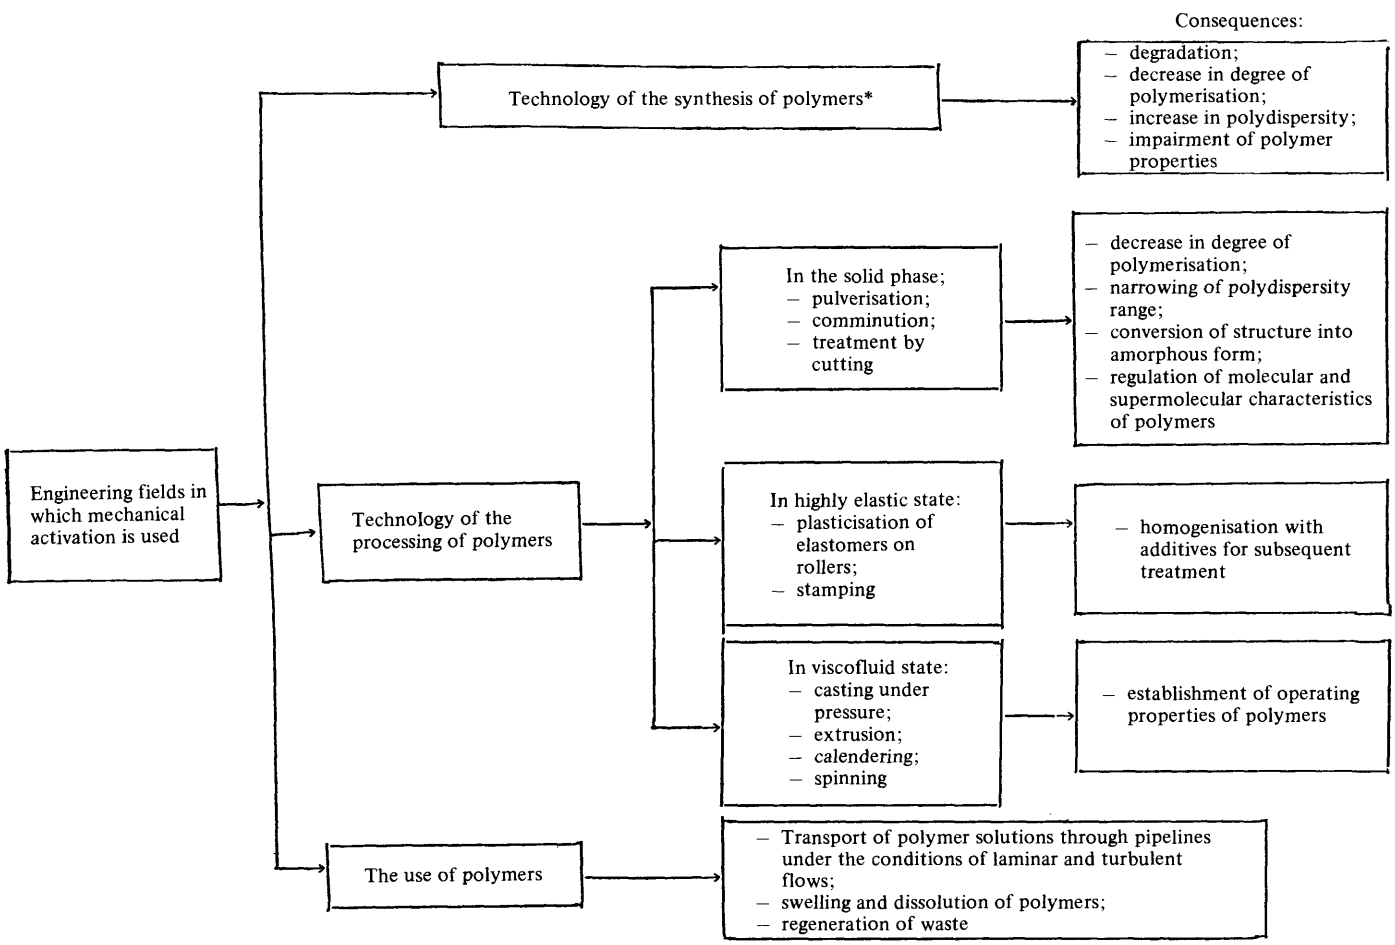

Figure 3. Technical applications of mechanochemical processes.

*Limited under the conditions of vigorous stirring of very viscous media.

bubbles on the surface of the specimens (the "foaming effect"), the gas being shown by chromatographic analysis to be hydrogen evolved on mechanical rupture of the chains. The stretching of the specimens at 93 K with the simultaneous recording of EPR spectra indicates the formation of free radicals. The amount of hydrogen evolved and the concentration of the radicals are correlated with the degree of structure formation in the elastomer and with the applied force (Fig.5 and Table 1).

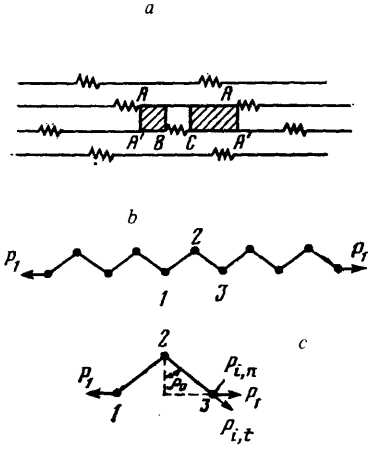

Figure 4. *a*) Mechanical model of a partly oriented polymer;[39] *b*) macromolecules subjected to the action of a force P_1; *c*) microelement subjected to the action of a force P_i.

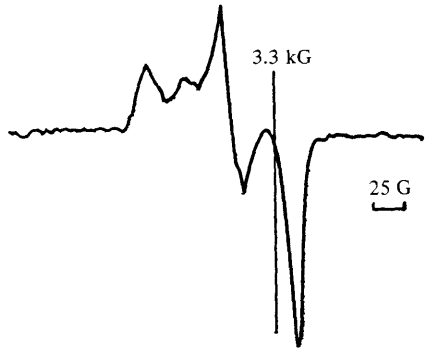

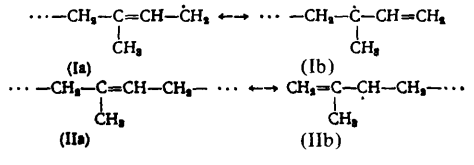

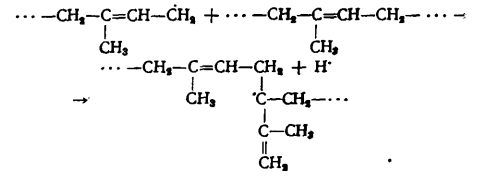

Figure 5. EPR spectrum, recorded at 200 K, of polyisoprene rubber stretched at 366 K.[39]

The results obtained show that the mechanical rupture of the chains takes place with participation of radicals in accordance with the scheme

and confirms the following mechanism:

The increase in the reactivity of the system at the deformation stage before rupture can be accounted for by the appearance of mechanoexcited states and free radicals and is defined by the term "mechanoactivation".

Table 1. Characteristics of polyisoprene rubber specimens stretched at 93 K.[39]

S, %	M_c	M_c^*	$10^{-17}a$, spins g^{-1}	l, cm^3 g^{-1}
1	11 158	10 668	4.0	28
2.5	6 082	5 370	8.9	47
4	4 385	3 850	9.5	50
6	3 364	2 934	11.1	60

Notation: M_C is the initial number-average molecular weight, M_C^* the molecular weight after the evolution of hydrogen, a the concentration of spins before rupture, l the amount of hydrogen evolved, and S the relative elongation of the specimen.

The accumulation of an increasing number of rupture volume elements generates a state promoting degradation; the free energy of the system then increases. For sufficiently high chemical potentials, the mechanochemical phenomena acquire quantitative characteristics to which corresponds the acceleration of all the chemical reactions possible in the given system by factors of tens.[40] The second step in the mechanochemical process, namely mechanocracking, takes place mainly via a radical chain mechanism at the atomic-molecular level. It results in the accumulation of degradation products with the minimum molecular weight (which is determined by the nature of the polymer and the medium, the parameters of the mechanical regime, and temperature), called the degradation limit ($\bar{M}_\infty$). The set of mechanocracking acts inducing the loss of functional properties by the polymer determines the mechanodegradation process.

The third step in the mechanochemical process proceeds mainly at the supermolecular level and consists in the reorganisation of the entire structure of the chain mechanism. This step consists of the following phases: (1) initiation occurring simultaneously with formation of incipient microcracks; this process begins already in the mechanoactivation stage (*A*, *B*, and *C* in Fig.6); (2) the growth of microcracks with formation of macrocracks from the latter (*E*); (3) the conversion of the macrocracks into the main crack capable, by virtue of its size, of generating, at its apex, stresses sufficient for the rupture of the structural element with formation of a new surface (*F* in Fig.6). At the macroscopic level, the specimen is ruptured. The rate of growth of the main cracks in the polymer v is expressed by the equation[41-44]

$$v = C \cdot \exp \frac{U_0 - \alpha\sigma}{RT} ,$$

where $c \cong 10^{10}$ cm s^{-1} is a constant, U_0 the activation energy for the growth of the main crack, α a coefficient taking into account the stresses appearing at the apex of the crack, σ the external load, R the gas constant, and T the temperature (K) at which the process takes place. The quantity U_0 is numerically equal to the activation energy for the dissociation of chemical bonds. At the instant of rupture, numerous active centres of the radical type appear as a result of the homolytic dissociation of macromolecular chains in the path of the main crack. After their stabilisation, new functional end groups are obtained, as is indicated by IR spectroscopic data.[45] The determination of the number of end groups on the surface of the main crack yielded 0.5×10^{22} cm^{-3}, which is approximately equal to the total number of chemical bonds in one cubic centimeter; consequently the surface of the main crack contains virtually only the ends of the chains.[48]

Both the incipient microcracks, which are active dynamic nuclei, and the main cracks are formed via the same mechanism, which consists in essence in the thermofluctuation rupture of chemical bonds activated by the stresses induced by the mechanical force applied from the outside.[41–47] The formation, growth, and spreading of the cracks via the mechanism indicated above are influenced signficantly by the presence of chemical agents penetrating into the depth of these cracks and accelerating the phenomena activated by the action of the force.

Consequently under the conditions of the stripping and fragmentation of the supermolecular and morphological formations in a solid polymer, the mechanical energy is consumed on the dissociation of interatomic bonds with formation of free radicals and also on the dissociation of ionic bonds (with the appearance of an electrical double layer), which can lead to the formation of new functional groups. Continuously renewed highly activated surfaces, constituting the basis for the initiation of numerous chemical reactions, are thus produced. The chemical reactions can be initiated either in the radical stage of the formation and growth of the cracks or later. The occurrence of these reactions is facilitated by the appearance of new functional groups and by the loosening of the structure of the specimen, which increases the accessibility of the active centres to chemical agents.

3. The Nature of the Primary Active Centres

Analysis of the elementary act in a mechanochemical process should have as its starting point the determination of the nature of the primary active centre appearing on decomposition of the mechanoexcited state.

The molecular transitions from the ground state to the activated state take place from a bonding orbital (π or σ electron) or from a non-bonding orbital (p electron) to an antibonding orbital (π^* or σ^* electron), which disturbs the distribution of the bulk of electron density. This tends to destabilise the chemical bond in the polymer.[47] The energy corresponding to excited states greatly exceeds the strength of any >C–C< chemical bond (Table 2), so that the recombination of the macroradicals generates insufficient energy to excite the neighbouring species (macromolecules, radicals).

Table 2. Electronic transitions for certain polymers (specimens in the form of films).

Polymer	λ_{max}, nm	$h\nu_{max}$, kJ mol^{-1}	Transition
Polyethylene	150	802	$\sigma \rightarrow \sigma^*$
Polybutadiene	180	670	$\pi \rightarrow \pi^*$
Polystyrene	187—200	461—645	[a]
Poly(methyl methacrylate)	214	561	$p \rightarrow \pi^*$
Poly(ethylene terephthalate)	290	415	$p \rightarrow \pi^*$
Poly(ethylene terephthalate)	240	502	[a]

[a] Taking into account the π-electron system.

For the idealised case of the dissociation *in vacuo* of chemical bonds of different types ranging from homopolar to purely ionic, two variants of such dissociation can be put forward:

$$\cdots\text{—}R_1\text{—}R_2\text{—}\cdots \longrightarrow \begin{cases} \cdots\text{—}\dot{R}_1 + \dot{R}_2\text{—}\cdots, \\ \cdots\text{—}\overset{(+)}{R}_1 + \overset{(-)}{R}_2\text{—}\cdots. \end{cases}$$

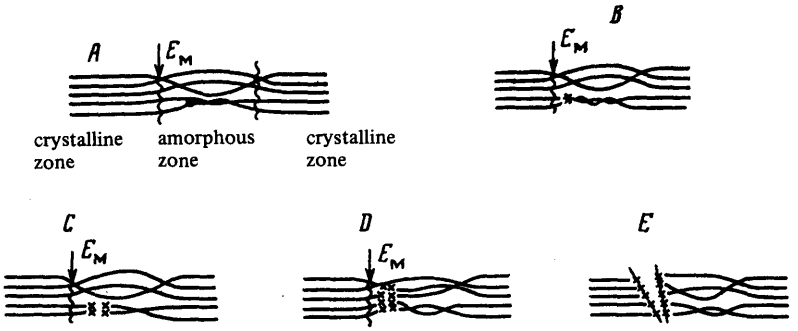

Figure 6. Stages of the mechanochemical process in the degradation of polymers (the arrow indicates the site where the mechanical energy E_m is concentrated—the junction of the crystalline and amorphous zones; the filled circle denotes a structural defect in the amorphous zone; the star denotes a structural defect mechanoactivated by the stress due to the action of mechanical energy E_m).

Positive ions or radical-ion centres with an energy level below that of the excited state appear with the greatest probability. Since the dissociation of $\ldots-R_1-R_2-\ldots$ into molecular ions requires an additional energy equal to 672 kJ mol^{-1} or even more, the above dissociation is more economical from the energetic standpoint than the homolytic dissociation.

After the formation of free radicals, the carbon–carbon bonds located in the α-position relative to the carbon atom with the unpaired electron proved to be to some extent stronger than in the ground state, while the bonds in the β-position are weaker. The subsequent rupture of the hydrocarbon chain containing the radical involves the formation of a double bond and the liberation of energy (250–280 kJ mol^{-1}). This shows that the activation energy is smaller for reactions of this type (Table 3).[47]

Table 3. The activation energies E_a for the rupture of chains containing a radical.[47]

Polymer	E_a, kJ mol^{-1}	Polymer	E_a, kJ mol^{-1}
Polyethylene	118	Poly(vinyl fluoride)	116
Polypropylene	102	Poly(vinylidene fluoride)	131
Polyisobutylene	76	Polytetrafluoroethylene	147
Polystyrene	85	Poly(vinyl acetate)	118
Poly(α-methylstyrene)	95	Poly(methylmethacrylate)	98
Poly(vinyl fluoride)	87	Poly(methyl acrylate)	85
		Polycaprolactam	117

The activation energies for the dissociation of bonds at the atom with the unpaired electron have been calculated by Kagya et al.[48] Free radicals are obtained as a result of the dissociation of chemical bonds not only in organic but also in organoelemental or inorganic polymers. The mechanical dispersion of quartz leads to the liberation of active species,[49–51] whose paramagnetic character has been demonstrated chemically or with the aid of paramagnetic nuclear resonance.[52–54] On mechanical dispersion of $SO_2/BaSO_4$, electrons in the form of *F* or *Y* centres were discovered not only at low temperatures.[2,27] An electrical double layer is formed via the dissociation of adhesion bonds on newly formed surfaces in contact, which generates a very intense electric field. The electrons leaving their initial positions move away from the newly formed surfaces into the bulk of the body, which leads to its electroexcitation. The electrical discharges induced by the activation of solid surfaces in contact and also of the newly formed surfaces liberate electrons which are capable of participating in subsequent mechanochemical reactions.[27]

II. REACTIONS INITIATED BY ACTIVE FRAGMENTS OBTAINED BY THE MECHANODEGRADATION OF POLYMERS

Studies on graft block copolymerisation have been undertaken because of the need to devise processes permitting the synthesis of compounds with the necessary predetermined properties. The aim of such research has been to obtain copolymers whose components would arise from significantly different polymers (natural and synthetic, polar, highly elastic, and rigid), so that the resulting compounds should combine the properties of the initial components.[55–59]

The mechanical activation of graft block copolymerisation is thought to be one of the most economically efficient ways of obtaining new products using the equipment generally adopted for the treatment of the initial polymers. Mechanical grafting was used initially to elucidate the character of the mechanism of the mechanochemical degradation of polymers[1,2,60–64] and only later as a method for the specific transformation of their structures and properties for practical purposes.[65–73]

1. Mechanical Grafting in a Polymer–Monomer System

The initiation of chemical reactions in a polymer–monomer system is due to the presence of radicals formed on cleavage of the polymer macromolecules subjected to mechanical treatment. In principle, the active primary centres should induce the formation of block copolymers in the presence of monomers. However, in practice, the simultaneous occurrence of graft polymerisation is observed, since chain transfer and in certain cases also cross-linking are unavoidable under the conditions of a radical mechanism. At the present time there are no methods which would make it possible to establish their specific contribution to the formation of the final product.

Table 4 presents only a few examples of the numerous systems investigated, which have a bearing on the specific alteration of certain properties of the polymer base. For example, non-polar polymers alter the character of the structure formation processes after grafting with the aid of acrylic acid, maleic anhydride, or a mixture of the above compounds to styrene, vinyl acetate, acrylonitrile, or methyl methacrylate.[68–72]

The improvement of surface-active properties has been achieved by grafting polar monomers to certain polymers of the polyamide[65] or polyester[66,67] type, which made it possible to overcome one of the main disadvantages of synthetic fibres—the lack of exchange of moisture with the external medium. Norbornene and SO_2 polymerise rapidly in the presence of mechanoradicals† formed, for example, from polyisobutene subjected to rapid stirring in solution. This reaction has been recommended as a method for the recognition of free radicals.[72]

2. Mechanochemical Grafting–Block Copolymerisation in a Polymer–Polymer System

A mixture of polymers has been most frequently jointly subjected to a treatment in order to improve technological and operating properties. In many cases the process conditions were the same as those usually employed in technological treatment and in some cases industrial equipment has been used.

In principle, the synthesis is initiated by the usual active fragments obtained by the rupture of macromolecules acted upon simultaneously by mechanical and thermal factors. The reactions of the active centres formed are as a rule subsequently complicated owing to mechano- and thermo-oxidative effects, which are unavoidable when the reaction takes place in the presence of atmospheric oxygen. By acting as a universal radical acceptor, atmospheric oxygen usually accelerates energetically initiated processes.

† Here and henceforth in the review the term mechanoradicals will be applied to radicals formed on mechanoexcitation.

Table 4. Graft block copolymers synthesised in a polymer–monomer system.

Table 5 presents a series of examples of the synthesis and properties of such products. The treatment of polyethylene (PE) and polypropylene (PP) was carried out both in the presence of certain polar rigid-chain polymers, such as, for example, ethylcelluloses (EC) or ε-polycaprolactam (PC),[74–75,80,81] and certain elastomers.[77–79] The PE/EC system was subjected to a thermomechanical action on a Bradenberg plastograph. It was then shown that the decisive factors in the formation of active centres are the component ratios, process time, and temperatures, while the occurrence of the process itself is influenced significantly by the presence of oxygen, which accelerates the primary radical reactions and leads to cross-linking (Fig.7).[74,75] The PE/PC system was treated by vibromilling at low temperatures

Table 5. Graft block copolymers synthesised in a polymer–polymer system.

Polymer base	Modifying agent	Conditions of treatment	Mechanochemical reaction	Result	Refs.
Polyethylene, low density	Ethylcellulose	Plasticisation on Brabender plastograph; $T = 165$ °C; in air	Graft block copolymerisation; structure formation	The polymer base becomes insoluble; calculation of the fluidity coefficient of the melt; improvement of dielectric properties	[74]

Notation: F_M = mechanical force, F_{cut} = cutting force.

($T = 0$– -40 °C). The rigidity of the system, which is the main condition for treatment in accordance with this principle, was ensured by the presence of a polyamide component and also by the temperatures employed.[76]

In both cases the main result of the mechanosynthesis is that the polyolefin base becomes insoluble in specific solvents. In the pairs investigated, PE is the component responsible for structure formation, while grafting-block copolymerisation increases the mechanical strength and thermal stability.[78–80] The impact strength and resistance to rupture of poly(vinyl chloride) (PVC) improved appreciably on coextrusion of plasticisation of this polymer on rollers in the presence of elastomers[84–87] (Tables 5 and 6).

The intense influences to which the PVC–elastomer systems are subjected during treatment on rollers favour the occurrence of the grafting–block copolymerisation–structure formation reactions (Table 6). An increase in temperature promotes mainly the occurrence of the structure formation reaction, which ensures an increase in the resistance to rupture, whilst maintenance at low temperatures stimulates mechanochemical grafting–block copolymerisation, which is responsible for an appreciable growth of impact strength. In all the cases investigated, it was possible to establish a 100% increment in the resistance to rupture and impact strength, which is an outstanding result bearing in mind that in the most common cases the factors which improve one of these characteristics impair the other. The solution of equations expressing the dependence of the mechanochemical properties of the reaction products on the thermomechanical conditions made it possible to establish the optimum conditions for the treatment of a PVC–elastomer mixture on rollers.[85–87]

Mechanosynthesis in a polymer–polymer system (in the case of the system comprising waste from rubber articles and thermoreactive resins) leads to the formation of materials with improved physicomechanical properties.[87–89]

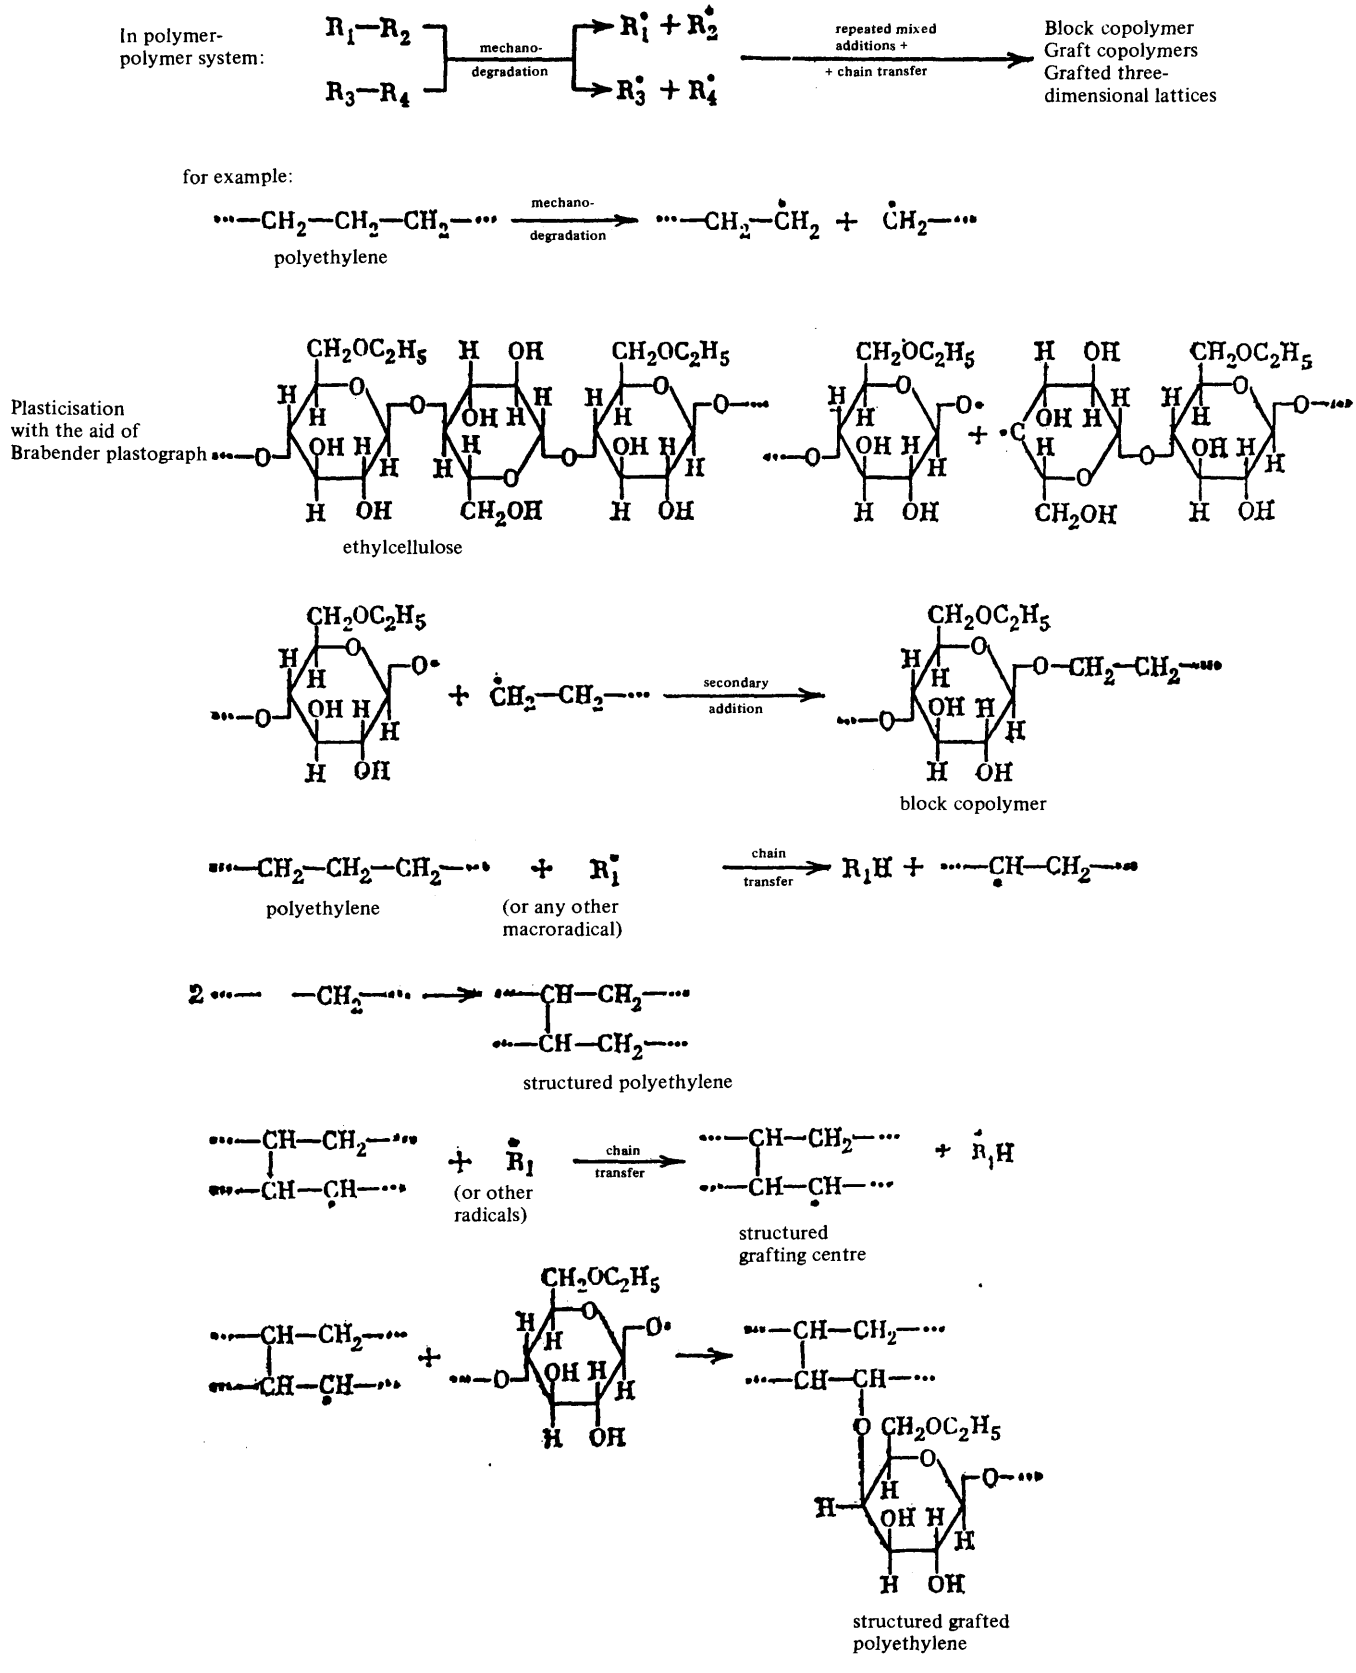

Figure 7. Mechanochemical reactions occurring in the mechanosynthesis in a polymer–polymer system.

III. REACTIONS INITIATED ON INORGANIC MECHANO-ACTIVATED SURFACES

1. Mechanochemical Grafting on Inorganic Surfaces

The mechanochemical activation of inorganic surfaces and the ability of such surfaces to activate chemical reactions have already long been known.[90-106] During the last decade, much attention has been devoted to the study of the mechanisms of these reactions and the elucidation of the nature of the centres inducing them.

Table 6. Variation of certain physicomechanical properties (%) of the PVC–elastomers systems as a function of the conditions of treatment*.[86-87]

Parameters of treatment on rollers*	Value of parameter	Nitrile rubber (SKN-18)		Polyurethane rubber	
		σ_p	a_k	σ_p	a_k
Duration of treatment, min (at $T = 170$ °C)	7	118	138	115	200
Ditto	14	117	258	115	136
"	21	116	233	115	156
Temperature of treatment, °C (for $\tau = 14$ min)	150	120	172	117	148
Ditto	170	117	258	115	136
"	190	115	90	119	216

Notation: σ_p is the resistance to breaking and σ_k the impact strength.
*For the system with 8% SKN and 2.5% PVC

The disintegration of ionic crystals such as those of $CaCO_3$, $BaSO_4$, rock salt, KCl, LiF, and CaF_2 leads to their activation, the degree of which has been estimated from their electron-donating capacity measured by EPR spectroscopy.[107] The surfaces obtained as a result of the grinding of the crystals are characterised by the emission of electrons and by the ability to initiate the grafting of certain vinyl monomers, especially styrene.[107-109]

The correlation between the change in the intensity of the electron emission during the mechanical breakdown *in vacuo* of ionic crystals (NaCl, LiF) and the degree of grafting of polystyrene to the newly formed surfaces indicates a shift in the development of these two effects, namely the grafting continues for a long time after the electron emission has ceased (Fig. 8). Consequently the initiation of the graft polymerisation is induced by the radicals generated on these surfaces by the electronic charges which persist for a long time after the rupture of the crystals.[107] Thus one may speak of an after-effect associated with the reactivity of the electrically charged active centres on the surfaces of the dispersed crystals.

In order to discover the nature of the active centres initiating polymerisation, a study was made of the influence of water vapour on the course of the grafting process. The moisture content of the crystal and the area of its contact surface with the monomer proved to be decisive factors for the process. For each type of crystal, there is a range of moisture contents within which the electrical potential and the degree of grafting reach a maximum. There exists therefore a selective catalytic influence exerted by the amount of water vapour which determines the reactivity of the inorganic surface newly formed as a result of the break up of the crystals.[110] On the other hand, the disintegration of such crystals *in vacuo* (10^{-6} mmHg) in the absence of moisture does not induce grafting. Consequently the adsorption of water vapour on electrical centres favour the formation of the polymerisation initiator. Under the influence of the static electricity on the mechanodispersed crystal surface, the water molecules dissociate and the resulting hydrogen ions ensure the cationic initiation of the polymerisation of styrene. The introduction of hydroquinone into the reaction medium does not disturb the grafting process, which is an additional argument in support of the cationic mechanism.

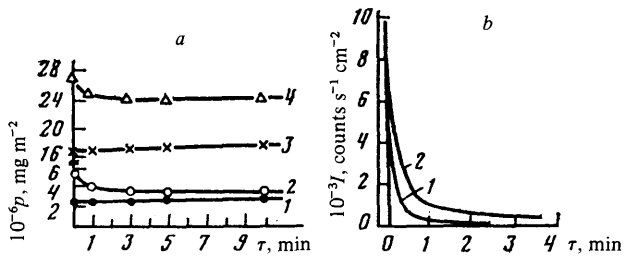

Figure 8. *a*) Dependence of the specific degree of grafting p of polystyrene on time τ after the breaking of the crystal in the liquid monomer and in argon with subsequent immersion in the monomer [1) and 2) NaCl; 3) and 4) LiF]; *b*) time decay of electron emission I from different crystals [1) NaCl; 2) LiF].[107]

Together with the grafting on the surface, homopolymerisation takes place on a limited scale; a radical mechanism has been attributed to such homopolymerisation on the basis of the observed consumption of hydroquinone. Presumably these two reactions—grafting and homopolymerisation—have a common initiation mechanism involving the active centres formed on the inorganic surface. In those cases where the degree of polymerisation of the grafted chains exceeds a certain specific value, the chains undergo homolytic rupture and the mechanoradicals formed combine with hydroquinone. Styrene, which is a nucleophilic monomer, should react with the positively charged centres formed as a result of the dissociation of water vapour. The polymer macromolecules should enter into a physical interaction with the negatively charged centres present on the surfaces formed.

This mechanism has been confirmed by the unipolar character of the charge arising on the surface produced by the breaking of the LiF crystals. When the crystals are broken into two parts, the corresponding rupture surfaces carry charges of opposite sign at the contact points, which results in the formation of a mosaic pattern in the charge distribution on the surface (Fig. 9).

The degree of grafting of styrene relative to the overall area of the negatively charged surface exceeds the degree of grafting relative to the area of the positively charged surface. Furthermore, fluorescence analysis of the products grafted on KCl powders established that the K and Cl contents in the grafted polystyrene are respectively 0.27 and 0.71%; this indicates the breakdown of the stoichiometric composition of the support, which can be explained by the irreversible

interaction of the polystyrene macromolecules with halide ions and the negatively charged centres on the newly formed surfaces of the crystal.

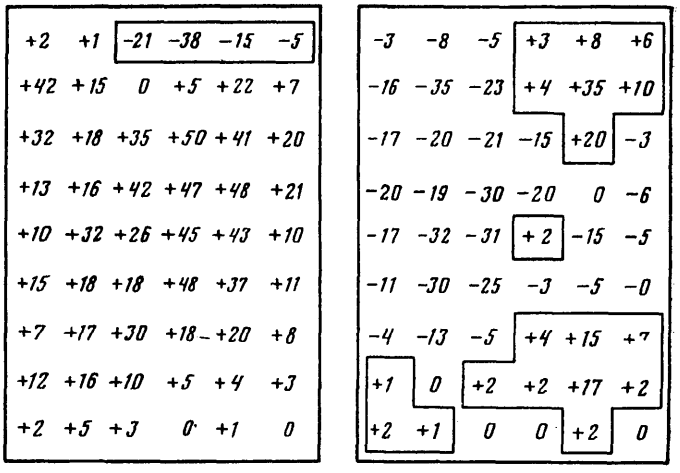

Figure 9. Topography of the distribution of electric charges on the surface of LiF crystals (5 × 10 mm² surface); the numerals indicate the charge intensity in 10^8 e cm^{-2}. [110]

The mechanochemistry of the quartz and sand surfaces is being vigorously investigated, but the existing contradictions have not yet been eliminated from this field. The main problem in the given instance is the elucidation of the nature of the active centres. It has been shown that, firstly, the mechanodispersion of quartz at a residual pressure of 10^{-3} to 500 mmHg in the presence of hydrogen at 80–400 K entails the dissociative chemisorption of hydrogen. [52–54] The active centres combining with hydrogen are formed both as a result of the mutual friction between these particles. The adsorbed hydrogen is firmly attached to the inorganic surface and its removal is possible only on raising the temperature to 600–700 K. On the basis of NMR and IR spectroscopic data, the reaction between quartz and hydrogen can be represented schematically as follows: [101]

$$\equiv Si-O-Si\equiv + H_2 \rightarrow \equiv SiH + SiOH \ .$$

The reaction is caused not only by radicals, which can be detected by EPR, but also by mechanoexcited $\equiv Si-O-$ bonds, since the total number of active centres on the surface is an order of magnitude higher than the surface concentration of free radicals (10^{13} cm^{-2} compared with 10^{12} cm^{-2}).

The primary act in the mechanochemical reaction between quartz and oxygen is the addition of O_2 to the radicals $\equiv \dot{S}i$ obtained on dissociation of the $\equiv Si-O-$ bond: [103]

$$\equiv Si-O-Si\equiv \xrightarrow[E_m]{} \equiv \dot{S}i + \dot{O}Si\equiv Si + O_2 \rightarrow SiOO^{\cdot} \ ,$$

$$\equiv SiOO^{\cdot} + {}^{\cdot}OSi \xrightarrow{\text{recombination}} \equiv SiOOOSi\equiv$$

peroxy-compound .

where E_m is the mechanical energy. The scheme presented above agrees with the consumption of oxygen and the concentration of paramagnetic centres. There is a possibility of the thermal decomposition of the final peroxy-compound:

$$\equiv SiOOOSi \xrightarrow{\Delta} \equiv SiOSi\equiv + O_2 \ .$$

This reaction explains the thermal desorption of oxygen at high temperatures.

Table 7. The adsorption characteristics of certain organic compounds in the vibromilling of sand.

Compound	s, Å²	$10^{-18}N_1$, molecules g^{-1}	$10^{-18}N_{50}$, molecules g^{-1}	N_1+N_{50}, m² g^{-1}
$CH_2=C(CH_3)COOCH_3$	34.3	3.0	4.9	2.7
$(CH_3)_2CHCOOCH_3$	36.1	2.1	1.3	1.2
$CH_2=CHCOOCH_3$	30.8	3.1	4.6	2.4

$CH_3COOC_2H_5$	32.5	2.7	1.0	1.2
$CH_2=CH(CH_2)_4CH_3$	41.4	1.6	0.57	0.91
p-C_7H_{16}	42.5	1.3	0.57	0.80
$(CH_3)_2CO$	28.9	3.3	1.2	1.2
p-$C_2H_5NH_2$	29.0	4.1	2.5	1.9
$(p$-$C_3H_7)_2NH$	40.7	2.8	1.6	1.8

Notation: s is the area of the molecules, N_1 the number of molecules adsorbed per mole of SiO_2, and N_{50} the same number after milling for 50 min.

The mechanical activation of the SiO_2 surfaces can also be accounted for by the grafting of certain vinyl and acrylic monomers in the vapour state (Table 7). [111] Under milling conditions, the monomers gradually polymerise on the solid surface. Oxygen exerts an inhibiting effect on this reaction, while the adsorption of the vapours of organic compounds has no influence on it whatsoever, which indicates a radical character of the process. Although free radicals were not detected under the experimental conditions (by EPR), milled sand contains numerous electrons in the surface traps while the adsorption of organic vapours induces exo-electron emission. [112] Homose et al. [111] therefore proposed a mechanism for the process which begins with electron transfer to the adsorbed monomer, attached to the surface by hydrogen bonds, with the subsequent formation of a radical-ion, which induces in its turn a reaction involving radicals.

2. Mechanochemical Homopolymerisation and Copolymerisation

Evidence confirming the idea that mechanical energy can induce the polymerisation reaction was obtained as a result of studies on polymers in the solid phase. Adler et al. [112] concluded that the elimination of rigorous order from the structure of the crystal lattice influences significantly the the rate of propagation of this type of polymerisation. With the aid of microscopy in polarised light, they demonstrated that polymerisation takes place precisely at the edges of the crystal irregularities. As the polymer is formed, the volume of the lattice diminishes and mechanical stresses appear in it favouring the dissociation of chemical bonds. Under these conditions, new active centres arise in the reaction medium and accelerates the polymerisation, which is initiated in most cases by radiation. Hence it follows that the mechanochemical act plays a significant role in the successful carrying out of the polymerisation process in the solid phase.

Another argument in support of the mechanochemical hypothesis concerning the solid-phase polymerisation is provided by experiment of Bamford et al. [113] involving the

grinding of acrylic and methacrylic acid crystals.[113] These crystals are subjected to a pressure of 1–5 atm directed at right angles to the axis of the crystal lattice. After irradiation with UV light, it was established that the polymerisation takes place without initiators precisely in the regions where the crystals were ground. Thus the idea was put forward that for this type of polymerisation the role of the mechanochemical act is not confined to that of an accelerating factor, because it can also induce initiation. Subsequently, using the energy of a high-intensity shockwave,[114,115] the ability of mechanical energy to induce true polymerisation involving all the stages of the chain mechanism was demonstrated.

Kargin and co-workers[116] used vibration dispersion for the polymerisation of a solid monomer—sodium acrylate. The authors assumed that the process was initiated by the concentration of mechanical energy on structural defects. The energy-induced transition of an electron located in the immediate vicinity of the COO^- group, involving an electron vacancy in one of the lattice sites, leads to the formation of a radical.

Under the experimental conditions used in the above study,[116] acrylamide did not polymerise, so the authors concluded that the ionic nature of the crystal lattice of the monomers plays a significant role.

A number of investigators[117–122] developed a polymerisation method which is activated by "mechanoinitiators"—inorganic crystalline salts with uncompensated electrons, the so-called "electron traps". Under the conditions of vibration dispersion, these electrons migrate to the newly formed surfaces and initiate polymerisation.

Subsequently it was possible to carry out the polymerisation and copolymerisation of a large number of a wide variety of monomers under the conditions of vibromilling without initiating additives. The starting materials (vinyl, acrylic, diene, and cyclic monomers or monomers which cannot be polymerised by the usual methods), were used in the solid (acrylamide, ε-caprolactam, etc.) or liquid state.[123–129]

Substitutional Carbonylation of Organic Compounds Catalysed by Palladium Complexes

Yu.V.Gulevich, N.A.Bumagin, and I.P.Beletskaya

The results of studies on the catalytic carbonylation of organoelemental compounds, organic halides, and other substrates of the type RX, in which X is substituted by CO during the reaction, are analysed. The mechanism of the action of palladium carbonylation catalysts is examined and the principal applications of the substitutional carbonylation reactions in organic synthesis are indicated.
The bibliography includes 141 references.

IV. Carbonylation of other organic substrates 311

I. INTRODUCTION

Among the selective methods for the preparation of oxygen-containing organic compounds, catalytic methods involving carbon monoxide play a special role. This industrially important field of homogeneous catalysis was founded as a result of the studies by Roelen[1] and Reppe[2] at the end of the 1930's and the beginning of the 1940's. Roelen showed that, in the presence of cobalt-containing catalyst, alkenes interact with CO and H_2 to form aldehydes with linear and branched structures containing one carbon atom more than the initial alkene:

$$RCH=CH_2+CO+H_2 \rightarrow RCH_2CH_2CHO+RCHMeCHO\,.$$

Reppe discovered a series of related reactions involving the carbonylation of alkenes, alkynes, and alcohols catalysed by carbonyl compounds of Group VIII metals. The products of these reactions are carboxylic acids, their derivatives, or alcohols, for example:

$$CH_2=CH_2+CO+H_2O \rightarrow EtCO_2H\,,$$
$$CH\equiv CH+CO+ROH \rightarrow CH_2=CHCO_2R\,,$$
$$MeCH=CH_2+CO+H_2O \rightarrow BuOH+CO_2\,.$$

After the publication of the above studies,[1,2] vigorous investigation of the reactions of organic compounds with carbon monoxide in the presence of transition metal complexes began. As a result, procedures such as the carbonylation of olefins, acetylenes, polyunsaturated compounds, alcohols, and nitrogen-containing compounds have been converted into large and independent branches of the catalytic chemistry of CO. The experimental data accumulated in this field as well as examples of the industrial use of the above reactions have been reflected in numerous monographs and reviews (see, for example, Refs.3–9).

The present review deals with the development of a comparatively new aspect of the chemistry of CO, which is of interest mainly for fine organic synthesis – the catalytic carbonylation of organoelemental compounds, organic halides, diazonium salts, arenes, and other substrates of the type RX (X = M, Hal, N_2BF_4, H, etc.). We have designated these reactions by the term "substitutional carbonylation", because the interaction of carbon monoxide with the substrates RX results in the substitution of the group X by the fragment CONu. Depending on the nucleophilic coreactant (Nu^-)

used, various carbonyl-containing products RCONu are formed—carboxylic acids and their derivatives, aldehydes, and ketones. Typical examples of such reactions are presented below:

$$RHal+CO+R_2'NH\rightarrow RCONR_2'+HHal,$$
$$RHgOAc+CO+R'OH\rightarrow RCO_2R'+HOAc+Hg,$$
$$RN_2BF_4+CO+R_4'Sn\rightarrow RCOR'+R_3'SnBF_4+N_2.$$

The complexes of a number of transition metals, namely palladium, nickel, cobalt, and rhodium, have been used as catalysts of the substitutional carbonylation of organic compounds. The substitutional carbonylation reactions have been studied most widely and in greatest detail under the conditions of homogeneous catalysis by palladium compounds. We have confined ourselves in the present review to other catalytic systems only when their application provides definite advantages compared with palladium complexes.

II. CARBONYLATION OF ORGANOELEMENTAL COMPOUNDS

Organic derivatives of many non-transition elements are known[3] to react with CO, forming a wide variety of oxygen-containing compounds. Unfortunately, such reactions can usually be achieved only under severe conditions (high CO pressure and temperature) and frequently proceed with a low selectivity. In many instances it is possible to overcome these difficulties by using palladium complexes as carbonylation catalysts. Catalytic carbonylation was first achieved for organic derivatives of mercury,[10] whose reactions with CO have now been most thoroughly investigated and have found applications in organic synthesis.

1. Reactions of Organomercury Compounds

It was noted in 1968[10] that, in the presence of stoichiometric amounts of $PdCl_2$, the aryl derivatives of mercury Ar_2Hg and ArHgCl interact with CO under very mild conditions: 1 atm and 20 °C. The reaction products are the acid chlorides ArCOCl when the carbonylation is carried out in an inert solvent or the esters $ArCO_2R$ when an alcohol is used as the coreactant:

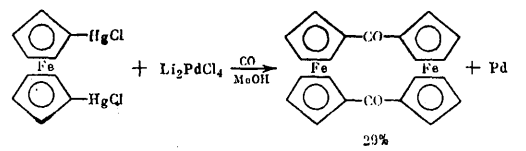
$$Ph_2Hg+PdCl_2 \xrightarrow[MeCN]{CO} \underset{21\%}{PhCOCl}+HgCl_2+Pd,$$
$$4\text{-}MeC_6H_4HgCl+PdCl_2 \xrightarrow[MeOH]{CO} \underset{27\%}{4\text{-}MeC_6H_4CO_2Me}+HgCl_2+Pd.$$

As a result of the reaction, palladium(II) passes to the zero oxidation state. The application of a suitable oxidant, for example, $CuCl_2$, makes it possible to regenerate palladium(II) ($Pd + CuCl_2 \rightarrow PdCl_2 + Cu_2Cl_2$) and make the carbonylation catalytic:

$$ArHgCl \xrightarrow[CuCl_2,\ HOAc]{10\%\ PdCl_2,\ 1\ atm\ CO} ArCO_2H,$$

Ar = 4-MeC_6H_4 (31%), 4-$HO_2CC_6H_4$ (56%),

In some cases, symmetrical diaryl ketones are formed in considerable amounts together with carboxylic acid derivatives (1—4 atm CO, 20 °C):[11]



$$PhHgCl \xrightarrow[CuCl_2,\ MeCN]{10\%\ LiPdCl_4,\ CO} \underset{22-40\%}{PhCOCl}+\underset{11-29\%}{Ph_2CO}.$$

Kasahara and co-workers[12,13] achieved for the first time the carbonylation of organomercury derivatives of non-benzenoid aromatic systems—ferrocene, furan, and thiophen (50 atm CO, 70—100 °C):

$$ArHgCl+Li_2PdCl_4 \xrightarrow[MeOH]{CO} \underset{30-35\%}{ArCO_2Me}+\underset{32-40\%}{Ar_2CO}+Pd,$$

where Ar = ferrocenyl, 2-furyl, 2-(5-methoxycarbonylfuryl), and 2-thienyl.

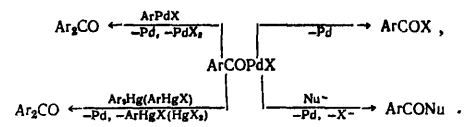
They used the method developed for the single-stage synthesis of [1.1]ferrocenophane-1,12-dione from readily available 1,1'-di(chloromercuri)ferrocene:[12]

29%

The reaction of arylmercury acetates with CO in the presence of $Pd(OAc)_2$ (one equivalent) and added sodium acetate (two equivalents) takes place selectively at 1 atm in methanol or trifluoroacetic acid and leads to the formation of the methyl esters or anhydrides of arenecarboxylic acids respectively in high yields,[14] for example:

$$PhHgOAc+Pd(OAc)_2 \xrightarrow[NaOAc,\ MeOH]{CO} \underset{88\%}{PhCO_2Me}+Hg(OAc)_2+Pd,$$
$$PhHgOAc+Pd(OAc)_2 \xrightarrow[NaOAc,\ CF_3CO_2H]{CO} PhCO_2Ac \xrightarrow[2)\ CH_2N_2]{1)\ H^+/H_2O} \underset{86\%}{PhCO_2Me}.$$

We may note that the initial organomercury compounds can be synthesised by mercurating the corresponding arenes with mercury(II) acetate and can be used in the subsequent carbonylation without isolating them from the reaction mixture.



The active intermediates in the reactions of arylmercury(II) compounds in the reactions with CO described above are undoubtedly organic palladium σ-complexes, formed in the first stages of the process:[15]

$$Ar_2Hg+PdX_2\rightarrow ArPdX+ArHgX,$$
$$ArHgX+PdX_2\rightarrow ArPdX+HgX_2,$$
$$X=Hal,\ OAc.$$

In a CO atmosphere, the arylpalladium complex is readily carbonylated, affording acyl derivatives:[16,17]

$$ArPdX+CO\rightarrow ArCOPdX.$$

The possible pathways in the subsequent conversion of ArCOPdX into the final carbonyl-containing organic products are presented in the scheme below:[10,11,18]

The reductive elimination of ArCOPdX leads to ArCOX. In the presence of a nucleophilic coreactant (Nu^-) in the reaction mixture, its interaction with ArCOX or with ArCOPdX produces the carboxylic acid derivatives ArCONu. Symmetrical diaryl ketones are formed in the reaction of the acyl complex with the initial organomercury compounds or with the σ-aryl derivative of palladium. Carbonylation of organomercury compounds is frequently complicated by oxidation processes, which lead to the side products Ar_2, ArCl, etc.

The reactions of aryl derivatives of mercury with CO, catalysed by phosphine complexes of palladium, are of great interest from the synthetic point of view. These reactions are fairly selective, and, in contrast to those examined previously, are catalytic in relation to the palladium complex in the absence of specially added oxidants. Thus, on catalysis with 0.5—2 mole% $PdCl_2(PR'_3)_2$ (R' = Ph or Bu), organomercury salts of the benzene and naphthalene series

interact with CO and alcohols to form esters of arenecarboxylic acids:[19,20]

$$ArHgX \xrightarrow[70-110^\circ C,\ ROH]{\text{"Pd", 4-10 atm CO}} ArCO_2R + Hg, \quad 30-99\%$$

X=OAc, O_2CCF_3

R=Me, Et, n-C_8H_{17}, iso-Bu, CH_2=$CHCH_2$, Ph

ArHgX containing chlorine, methoxy-, methoxycarbonyl, dimethylamino-, and acetamido-groups in the aromatic ring readily enter into the reaction. Primary unsaturated alcohols, allyl alcohol, and phenol can be used as the nucleophilic coreactants. We may note that the reaction is sensitive to steric hindrance: the use of sterically hindered organomercury compounds or secondary or tertiary alcohols reduces appreciably the yield of the ester and leads to the preferential formation of ArH and $ArCO_2H$.

The conversion of the organomercury compounds ArHgX and Ar_2Hg into symmetrical diaryl ketones has been achieved under very mild conditions (1 atm CO, 20 °C) by using a system comprising metal complex and nucleophilic (I^- ion) catalysts and by carrying out the carbonylation in inert solvents [hexamethylphosphoramide (HMP), tetrahydrofuran (THF), and acetone]:[21,22]

$$ArHgX \xrightarrow[Bu_4NI]{1\%\ PhPd(PPh_3)_2I,\ CO} Ar_2CO + HgX_2 + Hg, \quad 78-99\%$$

X=Cl, Br, OAc

$$Ar_2Hg \xrightarrow[Bu_4NI \text{ or } NaI]{0.5\%\ [Rh(CO)_2Cl]_2,\ CO} Ar_2CO + Hg, \quad 77-90\%$$

These reactions can serve as convenient methods of synthesis of substituted benzophenones $(YC_6H_4)_2CO$ (Y = H, 4-Me_2N, 4-H_2N, 4-MeO, 4-Me, 4-Cl, or 2-HO). The method is also applicable to the synthesis of heterocyclic ketones, which has been demonstrated for the conversion of 2-thienylmercury bromide into $(2\text{-}C_4H_3S)_2CO$.

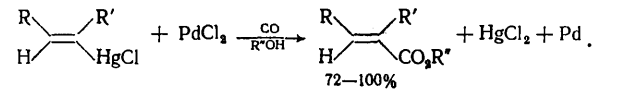
The mechanism of the carbonylation of aryl derivatives of mercury in the presence of phosphine complexes of palladium differs from that presented above. The catalytically active species in the given case is the zerovalent palladium derivative PdL_2 (L = phosphine ligand) obtained by the reduction of the initial palladium complexes by organomercury compounds. As an example, the scheme for the catalytic cycle involving the formation of diaryl ketones by the carbonylation of organomercury compounds in the presence of $PhPd(PPh_3)_2X$ is presented below:[22]

$$PhPdL_2X + RHgX \rightarrow PhR + HgX_2 + PdL_2,$$

$$RHgX + PdL_2 \rightarrow RPd(HgX)L_2 \rightarrow RPdL_2X + Hg;$$

or

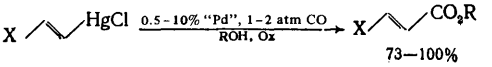
$$RHgPdL_2X$$



$$RPdL_2X + CO \rightarrow RCOPdL_2X$$

$$RCOPdL_2X + RHgX \rightarrow RCOPdRL_2 + HgX_2,$$

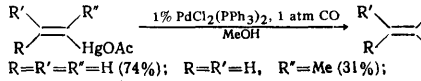
$$RCOPdRL_2 \rightarrow RCOR + PdL_2.$$



As a result of the oxidative addition of the organomercury salt to PdL_2 (the insertion of the zerovalent palladium complex in the Hg–C or Hg–X bond[23]) and the elimination of metallic mercury, the aryl derivative of palladium $RPdL_2X$ is obtained. The carbonylation of $RPdL_2X$ and the subsequent transmetallation reaction give rise to the diorganic complex $RCOPdRL_2$. The reductive elimination reaction of the latter leads to a ketone and the initial catalytically active PdL_2 species. We may note that the above scheme shows only one of the possible pathways leading to the formation of ketones in the carbonylation of organomercury salts. Clearly, the reaction involving the exchange between RHgX and $RPdL_2X$ can precede the insertion of CO in the C–Pd bond and metallic mercury may be eliminated in the last stages of the process. The addition of the iodide ion plays an important role. The I^- ion apparently accelerates[22] the exchange reaction of $RCOPdL_2X$ with RHgX (nucleophilic catalysis[24]) and facilitates the insertion of the zerovalent palladium complex in the Hg–C or Hg–X bond.

The use of vinyl derivatives of mercury as the initial substrates in the carbonylation reactions opens up pathways to the synthesis of αβ-unsaturated carbonyl compounds. Thus vinylmercury chlorides react with CO and $PdCl_2$ (one equivalent) in the presence of water or alcohols, forming αβ-unsaturated carboxylic acids or their esters in high yields (1 atm CO, -78–20 °C):[18]

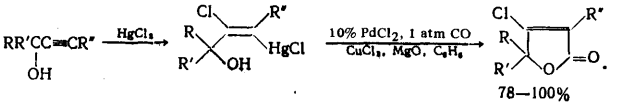
R, R′=Alk, Ar, vinyl; R″=H, Me, Et



The carbonylation takes place with complete retention of the configuration of the vinyl fragment. By adding oxidants for zerovalent palladium [copper dichloride[18] or iron(III) chloride[25]], it was possible to make the reaction catalytic:

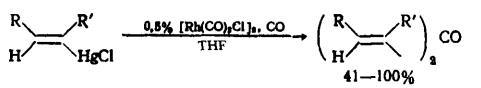
«Pd»=$PdCl_2$, Pd/C; Ox=$CuCl_2$, $FeCl_3$

X=Cl, Ph, Bu; R=H, Me, Et, Pr



The need to add oxidants disappears when the process catalysts are phosphinepalladium complexes:[19,20]

R=R′=R″=H (74%); R=R′=H, R″=Me (31%); R=R′=Ph, R″=H (36%)



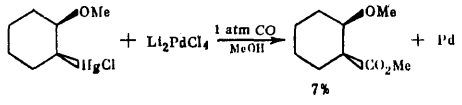
The cause of this phenomenon, which arises from the reaction mechanism, were considered in our previous communication in relation to the carbonylation of aryl derivatives of mercury.

If the organomercury compound contains the hydroxy-group, then under certain steric conditions the latter can behave as the nucleophile in the carbonylation process. Such a reaction results in intramolecular cyclisation, which leads to the formation of a lactone. This precise idea has in fact been the basis of an elegant method of synthesis of β-chloro-$\Delta^{\alpha\beta}$-butenolides, which involves two stages: the mercuration of propargyl alcohols and the subsequent carbonylation of the resulting organomercury derivatives:[26,27]

The yield of the lactone increases when the reaction with CO is carried out in the presence of magnesium, which binds the HCl evolved.

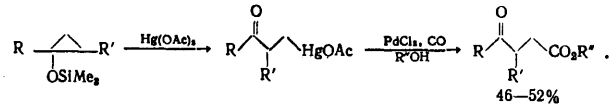
Symmetrical divinyl ketones have been synthesised by carbonylating vinylmercury chlorides at 1 atm at 25 °C in THF in the presence of a rhodium catalyst:[28]

R=H, Ar, Alk; R′=H, Alk



The possibility of using palladium complexes as catalysts in this reaction has not been investigated.

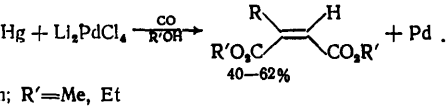
The interaction of alkylmercury compounds with CO has been studied comparatively little. The difficulty of carrying out the reaction is associated with the instability of the intermediate alkyl



complexes of palladium and other transition metals, which tend to undergo a rapid β-elimination reaction:

As a result of this side process, the yield of the carbonylation products is usually low:[29]

The undesirable elimination reaction can be avoided by using initial substrates containing an electron-accepting substituent in the β-position relative to the mercury atom. Thus β-acetoxymercuriketones interact with $PdCl_2$ (one equivalent) and alcohols in a CO atmosphere, forming γ-ketoacid esters in satisfactory yields:[30]

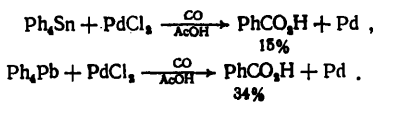


The carbonylation of alkylmercury(II) derivatives in methanol at an elevated CO pressure (2–63 atm), catalysed by $(Ph_3P)_3RhCl$, leads to methyl esters of alkanecarboxylic acids, the yield of the latter reaching 72%:[19,20]

X = OAc, Br
Alk = Et, n-C_6H_{13}, n-$C_{12}H_{25}$, $MeCO_2(CH_2)_2$, $BuCH(OMe)CH_2$, 2-methoxycyclohexyl

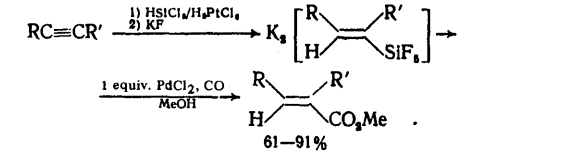
The examples presented make it necessary to revise the initial sceptical attitude towards the synthetic possibilities of the reactions of alkyl derivatives of mercury with CO and show that it is essential to investigate them more widely. The synthetic use of the stereoselectivity of this reaction, which proceeds with the preferential retention of the configuration at the carbon atom linked to the metal, is promising.[29]

Dialkynylmercurys interacts with CO in an alcoholic medium at 20 atm and 25 °C with formation of a substituted maleate as the main product:[31]



R=Et, Ph; R'=Me, Et

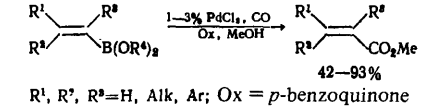
The authors believe that $RC{\equiv}CCO_2R'$ is formed in the first stage of the process and subsequently undergoes hydroalkoxycarbonylation.



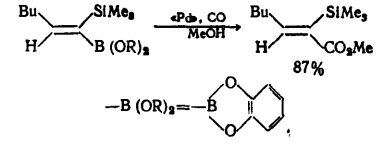
2. The Reactions of Other Organoelemental Compounds

The carbonylation of other organoelemental compounds has been studied to a much lesser extent.

Tetraphenyl-tin and tetraphenyl-lead react with CO and palladium chloride at 1 atm and 20 °C in acetic acid with formation of benzoic acid, but the yields are low in both reactions:

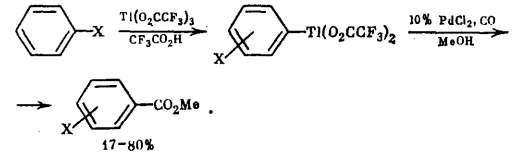


The carbonylation of the readily available vinyl derivatives of silicon–(*E*)-alkenylpentafluorosilicates– was achieved.[32] The reaction takes place stereospecifically and leads to high yields of the esters of (*E*)-αβ-unsaturated carboxylic acids (1 atm CO, 25 °C):



It is noteworthy that, in contrast to alkenylpentafluorosilicates, the corresponding alkenyltrialkylsilanes are relatively unreactive: they are carbonylated at a low rate. Phenyl- and benzylpentafluorosilicates do not interact with CO under the conditions investigated.

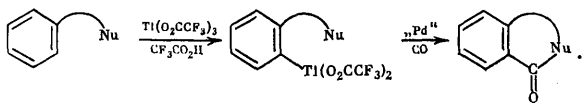
A convenient method of stereocontrolled synthesis of αβ-unsaturated acid esters, based on the reaction of alkenylboronates with CO and methanol in the presence of palladium chloride (1 atm, 0 to 50 °C), has been proposed.[33] The use of *p*-benzoquinone as the oxidant for zerovalent palladium makes this reaction catalytic:



R¹, R², R³=H, Alk, Ar; Ox = *p*-benzoquinone

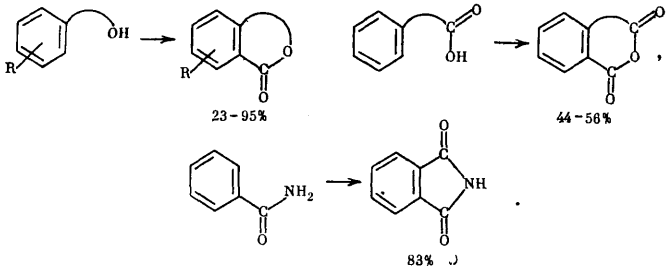
It is of interest that, when the initial substrate contains a silicon–carbon bond together with the boron–carbon bond, the former is not involved in the reaction:

The carbonylation of the monoaryl compounds of thallium $ArTl(O_2CCF_3)_2$ in methanol leads to the methyl esters of arenecarboxylic acid (1 atm CO, 20 °C):[34,35]

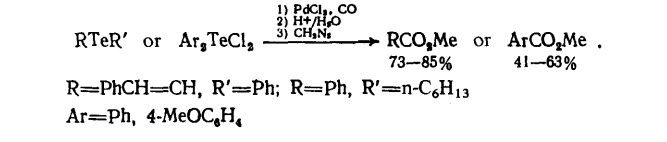


X = t-Bu, H, MeO, F, AcNH, H_2NCONH, PhCO

The reaction is catalytic with respect to palladium in the absence of specially added oxidants, because the thallium(III) salt, formed in the exchange interaction of organothallium derivatives with $PdCl_2$, regenerates the catalyst:



The initial arylthallium compounds can be obtained by the direct electrophilic substitution of thallium in arenes. This reaction is distinguished by high regioselectivity. Thus the fluorine atom and the t-Bu groups in methanol direct the attack by the thallium-substituting reagent almost exclusively to the *para*-position, while AcNH, PhCO, and other groups which are coordinated to the thallium(III) salt direct the attack to the *ortho*-position in the benzene ring. Among *ortho*-directing substituents, those which are capable of acting as nucleophiles in the carbonylation stage, for example CH_2OH, $(CH_2)_2OH$, CO_2H, $CONH_2$, etc. occupy a special



place. In this case the thallium substitution process and subsequent carbonylation result in intramolecular cyclisation:

The method has been used to synthesise a series of cyclic products—substituted γ- and δ-lactones, phthalic and homophthalic anhydrides, and phthalimide:[34,35]

The reaction of alkylbenzenes with CO (4—7 atm) in the presence of thallium trifluoroacetate and catalytic amounts of a palladium(II) salt leads to alkylbenzoic acids.[36] For example, a mixture of isomeric methylbenzoic acids has been obtained from toluene (*para*:*meta*:*ortho* = 91:5:4) in 81% yield relative to $Tl(O_2CCF_3)_3$ [Tl(III):Pd(II) ≃ 73:1]. The monoaryl derivatives of thallium(III), formed *in situ*, are in all probability intermediates in these reactions. The carbonylation of organic compounds of tellurium(II) and tellurium(IV) in the presence of stoichiometric amounts of $PdCl_2$ (1—20 atm CO, 20—30 °C) has been achieved in a recently published study:[37]

R=PhCH=CH, R′=Ph; R=Ph, R′=n-C_6H_{13}

Ar=Ph, 4-$MeOC_6H_4$

The reaction of the asymmetric telluride PhCH = CHTePh with CO leads mainly to an αβ-unsaturated acid ester, i.e. PhCH = $CHCO_2Me$. In the case of n-$C_6H_{13}TePh$, a benzoic acid derivative is formed, namely $PhCO_2Me$.

Thus the carbonylation of organoelemental compounds in the presence of palladium complexes makes it possible to obtain a wide variety of carbonyl-containing products. In many instances, these are chemoselective and stereoselective processes in which catalytic amounts of palladium compounds are used.

III. CARBONYLATION OF ORGANIC HALIDES

Not only organoelemental compounds but purely organic reagents can serve as sources of organic groups in substitutional carbonylation reactions catalysed by palladium complexes. Among such compounds, organic halides have found the widest application. The possibility of achieving reactions of this kind is based on the formation of σ-organopalladium compounds $RPdL_2X$ (L = ligand) as a result of the oxidative addition of the halide RX to a zerovalent palladium complex:[38—40]

$$PdL_n + RX \rightarrow trans\text{-}RPdL_2X + (n-2)L .$$

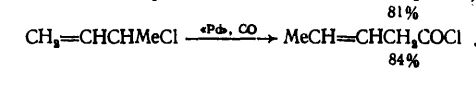
In view of the importance of the oxidative addition reaction for the understanding of the data described in this Section, we shall deal briefly with its main features.[40] Firstly, aryl and vinyl halides as well as benzyl, allyl, and certain other halides can be used in the reaction (in the case of alkyl halides containing a β-hydrogen atom, the organopalladium compounds formed are unstable and tend to undergo rapid β-elimination of palladium hydride). Secondly, the reactivity of the organic halides towards zerovalent palladium usually falls in the sequence RI > RBr > RCl. Thirdly, in the case of aryl halides, the rate of oxidative addition diminishes on passing from substrates containing electron-accepting groups to halogeno-derivatives containing electron-donating substituents. Fourthly, the reaction with vinyl halides proceeds with complete retention of the configuration of the vinyl group. Benzyl and allyl halides interact with zerovalent palladium complexes with the preferential inversion of the configuration of the carbon atom linked to the halogen. Finally, zerovalent palladium is used in the atomic state in the oxidative addition reactions. This can be achieved most simply by using zerovalent palladium complexes. As a result of oxidative addition, the coordination number of palladium increases by 2. Hence it follows that the initial zerovalent palladium complexes must be coordination-unsaturated or can readily dissociate under the reaction conditions.

The first communications concerning the carbonylation of organic halides under the conditions of catalysis by palladium compounds appeared in 1963—1964.[41—43] However, up to the middle 1970's, the number of studies were small and the initial substrates used were mainly allyl halides. The carbonylation occurred under severe conditions at high CO pressures and temperatures. Only after the discovery of the reaction involving the oxidative addition of organohalides to zerovalent palladium complexes[38] and the elucidation of the role which phosphine and certain other electron-donating ligands play in the stabilisation of intermediate organopalladium compounds, was it possible to reduce significantly the temperature and pressure at which carbonylation takes place and to extend the reaction to a wide range of organic halides.[44—48] Since then systematic research into the catalytic carbonylation of organic compounds began and this led to the development of new convenient methods of synthesis of a wide variety of carbonyl-containing products.

1. The Synthesis of Carboxylic Acids and Their Derivatives

The reaction of organic halides RX with CO catalysed by palladium complexes has found the widest application in the synthesis of carboxylic acids and their derivatives—esters and amides:

$$RX + HNu + CO \xrightarrow{«Pd»} RCONu + HX .$$



Nu=OH, OR′, NR'_2

Carbonylation without the addition of a nucleophilic coreactant has been least investigated and takes place under much more severe conditions with formation of carboxylic acid halide:

$$RX + CO \xrightarrow{«Pd»} RCOX .$$

For example, allyl chlorides and bromides interact with CO in the presence of a palladium catalyst at a pressure of 77—500 atm and a temperature of 80—150 °C in benzene or in the absence of a salt, forming the halides of αβ-unsaturated carboxylic acids.[42,43,49—51] The yield of the target product is fairly high under certain conditions and can become quantitative.[43] The palladium catalyst is usually added to the reaction mixture in the form of a π-allyl complex[43,50,51] or a palladium(II) salt.[42,49] The use of palladium black leads to the formation of a less active catalytic system.[43]

Despite the fact that the carbonylation can be accompanied by the allylic rearrangement, it is regioselective: only one product is obtained, in which the carbonyl group is linked to the least substituted carbon atom of the allyl fragment:[43,50]

In both reactions described above, the oxidative addition of the initial substrate to zerovalent palladium results in the formation of the same intermediate – bis(1-methyl-π-allylpalladium chloride).

In certain cases the carbonylation is complicated by the migration of the double bond in the acid halide from the βγ-position to the conjugated αβ-position:[49]

$$CH_2{=}CHCH_2Cl \xrightarrow{«Pd», CO} CH_2{=}CHCH_2COCl + MeCH{=}CHCOCl\ .$$

Allyl chlorides are less active than the corresponding bromides. Thus the rates of carbonylation of $CH_2=CHCH_2Cl$ and $CH_2=CHCH_2Br$ are in the ratio $1:\sim 0.08$ under identical conditions.[50] The structure of the allyl group also influences the reactivity of the halogeno-derivatives. The relative rates of the reaction increase in the sequence[50]

$$CH_2{=}CHCH_2Cl > MeCH{=}CHCH_2Cl \cong CH_2{=}CHCHMeCl > > \text{3-chlorocyclo-octene} \cong CH_2{=}CMeCH_2Cl > CH_2{=} {=}CHCHCl_2 \cong ClCH_2CH{=}CHCH_2Cl,$$

in the ratios 1:0.5: 0.04: 0.01.

The carbonylation of a mixture of allyl chloride and a conjugated diene leads to the formation of a derivative of the dienecarboxylic acid together with the chloride of a βγ-unsaturated acid,[50] for example:

$$CH_2{=}CHCH_2Cl + CH_2{=}CHCH{=}CH_2 \xrightarrow{«Pd», CO} \rightarrow \underset{36\%}{CH_2{=}CHCH_2COCl} + \underset{28\%}{CH_2{=}CH(CH_2)_2CH{=}CHCH_2COCl}.$$

Aryl, vinyl, benzyl, and alkyl chlorides, which are less reactive in the oxidative addition reaction, do not interact with CO under the conditions which are usually employed in the reactions of allyl chlorides.[43] The conversion of halogenoarenes into aroyl halides in the presence of palladium catalysts can be achieved at high temperature and CO pressures.[52,53] Thus arenecarboxylic acid fluorides have been obtained by carbonylating halogenoarenes at 300 – 350 °C and 600 – 900 atm in the presence of alkali metal fluorides:[53]

$$ArX + MF \xrightarrow[0.5-78\%]{«Pd», CO} ArCOF + MX,$$

"Pd" = $PdCl_2$ or Pd/C; M = alkali metals; X = F, Cl, Br, I

Summarising, one may say that the synthesis of the acid halides RCOX by the reaction of RX with CO is of limited importance and is applicable mainly to the synthesis of the halides of βγ-unsaturated acids from allyl halides. The catalytic cycle in the formation of RCOX apparently includes stages involving the oxidative addition of RX to zerovalent palladium, the insertion of CO in the C – Pd bond in the complex RPdX, and the reductive elimination of RCOPdX (we considered previously all the reactions of the palladium complexes incorporated in the cycle described). Under the conditions used in the synthesis of acid halides, palladium-containing intermediates readily decompose with the liberation of the relatively inactive palladium black. The reason for their instability is the absence from the reaction mixture of ligands capable of stabilising these palladium compounds. The deactivation of the homogeneous palladium catalyst necessitates the carrying out of the carbonylation of organic halides under very severe conditions. The carbonylation of allyl substrates is an exception, probably because of the high reactivity of allyl halides in the oxidative addition to zerovalent palladium and the stability of the π-allyl complexes of palladium obtained as a result of the oxidative addition.

The palladium catalyst can be stabilised in solution by adding phosphine ligands (other electron-donating ligands are used for this purpose more rarely). However, the acid halides RCOX cannot be obtained from RX and CO when the reacion is catalysed by phosphine complexes of palladium, because the oxidative addition of RX and the subsequent carbonylation of the resulting $RPd(PR'_3)_2X$ leads to the stable acyl derivative $RCOPd(PR'_3)_2X$,[17] which is incapable of reductive elimination. It was found that such acyl complexes readily react with certain nucleophiles. Thus the reaction with the alcohols R″OH yields the esters RCO_2R''.[48,54] This makes it possible to realise the catalytic cycle and to achieve the conversion of the halogeno-derivatives RX into the esters RCO_2R'' under the conditions of homogeneous catalysis by phosphine complexes of palladium:

$$RX + PdL_n \rightarrow RPdL_2X + (n-2)L,$$
$$RPdL_2X + CO \rightarrow RCOPdL_2X,$$
$$RCOPdL_2X + R''OH \rightarrow RCO_2R'' + HPdL_2X,$$
$$HPdL_2X + (n-2)L \rightarrow HX + PdL_n,$$
$$HX + B: \rightarrow BHX.$$
$$L = Pr'_3 \text{ and/or CO and B: } = \text{base}$$

The scheme presented reflects the generally accepted treatment of the mechanism of the alkoxycarbonylation of organic halides.[17,55] However, it is noteworthy that the available literature data do not rule out an alternative version of the mechanism of this reaction postulating the involvement in the catalytic cycle of the alkoxycarbonyl and not acyl complexes of palladium:[44]

$$RX + L_nPdCO \rightarrow RPd(CO)LX + (n-1)L,$$
$$RPd(CO)LX + R''OH + B: + L \rightarrow RPd(CO_2R'')L_2 + BHX,$$
$$RPd(CO_2R'')L_2 + CO + (n-2)L \rightarrow RCO_2R'' + L_nPdCO\ .$$

During the alkoxycarbonylation of RX, the strong acid HX accumulates and can cause the protolysis of the intermediate σ-organopalladium compounds[54] and may thereby exert an inhibiting effect on the course of the reaction. Organic or inorganic bases, among which tertiary amines,[44,47] potassium carbonate[56] and sodium acetates,[47] have found the most extensive application, are usually employed to remove the HX. One cannot rule out the possibility that the role of the base is also manifested in the reactivation of the nucleophile:[48]

$$R''OH + B: \rightleftarrows R''O^- + BH^+.$$

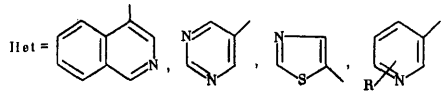
Aromatic halides are most often used as the initial substrates in the alkoxycarbonylation reaction, for example:[44]

$$ArX + BuOH \xrightarrow[100°C,\ Bu_3N]{1.5\%\ «Pd»,\ 1\ atm\ CO} \underset{46-96\%}{ArCO_2Bu}$$

X=Br, I; Ar=4-YC_6H_4 (Y=H, MeO, MeO_2C, NC), 2,6-$Me_2C_6H_3$, 1-naphthyl

The triphenylphosphine complexes of palladium $PdX_2(PPh_3)_2$ and $PhPd(PPh_3)_3X$ are effective catalysts of the process. In the case of aryl iodides, which are more reactive in oxidative addition than bromides, the reaction proceeds smoothly in the presence of palladium acetate (apparently Bu_3N plays the role of the weak stabilising ligand in this instance).

The reactivity of the halides depends on the structure of the allyl group and decreases in the sequence 4-NCC_6H_4Br > PhBr > 4-$MeOC_6H_4Br$ in the ratio 275:1:0.23 (the method of competing reactions). Judging from the half-life in the carbonylation reaction, iodobenzene is only slightly more reactive than bromobenzene. This probably shows that the oxidative addition is not the rate-limiting stage of the process.[44]† It is of interest that the steric hindrance generated by the *ortho*-substituents in 1-iodo-2,6-dimethylbenzene does not prevent the reaction: 2,6-$Me_2C_6H_3CO_2Bu$ was obtained in 63% yield.[44]



†According to Fauvarque et al.,[39] the reactivity of aryl bromides in the oxidative addition to zerovalent palladium is significantly lower than that of the corresponding iodides.

The methoxycarbonylation of aryl halides can be achieved successfully only at an elevated pressure: methyl benzoate is synthesised by the reaction of iodobenzene with methanol and CO at 3–14 atm.[47,56] Under milder conditions, (18 °C, 1 atm CO) the carbonylation takes place with a low yield.[48]

It has recently been possible to extend the reaction to heterocyclic halogenoderivatives.[57] The ethyl esters of isoquinoline-4-carboxylic, pyrimidine-5-carboxylic, and thiazole-5-carboxylic acids as well as those of substituted pyridine-carboxylic acids have been obtained in high yields:

$$\text{HetX} + \text{EtOH} \xrightarrow[100^\circ\text{C},\ Et_3N]{PdCl_2(PPh_3)_2,\ 7\ \text{atm CO}} \text{HetCO}_2\text{Et}$$

X = Br, Cl; 35–100%

Het = 

The tin and sodium alkoxides Et_3SnOMe and NaOMe can be used conveniently as the coreactant in the alkoxycarbonylation reactions of aryl iodides instead of alcohols:[58–60]

$$\text{ArI} + \underset{\text{or}\ \text{NaOMe}}{Et_3SnOMe} \xrightarrow[20^\circ C]{2\%\ PhPd(PPh_3)_2I,\ 1\ \text{atm CO}} \underset{75-99\%}{ArCO_2Me}\ .$$

Ar = 4-XC_6H_4 (X = H, MeO_2C, NC, NO_2), 1-naphthyl

The use of such powerful nucleophiles made it possible to convert ArI into $ArCO_2Me$ not only under very mild conditions but also at a high rate. Thus the carbonylation of 1-iodonaphthalene in the presence if NaOMe terminates after 4 h and leads to 1 $MeO_2CC_{10}H_7$ in 90% yield,[60] while that analogous reaction of 1-bromonaphthalene with $BuOH/Bu_3N$ does not go to completion even after 80 h: 46% of 1-$MeO_2CC_{10}H_7$; degree of conversion of 1-$C_{10}H_7Br$ 81%.[44]

The alkoxy-derivatives of aluminium,[61] boron,[62] titanium, and zirconium[63] are less reactive in the reactions with aryl halides and CO. The carbonylation in the $ArBr-E(OR)_n$ system can be achieved only at an elevated temperature in the presence of a zerovalent palladium complex (E = Ti) or a mixed catalyst containing zerovalent palladium and rhodium(I) complexes (E = Al, B, or Zr):

$$\text{ArBr} + \text{E(OR)}_n \xrightarrow[75-150\ ^\circ C]{\text{cat., 1 atm CO}} \underset{40-98\%}{ArCO_2R}$$

E = Al, B(n = 3); Ti, Zr (n = 4); cat. = 6% $Pd(PPh_3)_4$ or 6–8% $Pd(PPh_3)_4$ + 9–11% [(hexa-1,5-diene)RHCl]$_2$

Ar = XC_6H_4 (X = H, 4-MeO, 4-CH_2=CH, 3-Me), 1-naphthyl

R = Et, Pr, iso-Pr, Bu, t-Bu

Vinyl iodides and bromides interact with CO and ROH to form the esters of αβ-unsaturated carboxylic acids (1–87 atm, 60–125 °C):[44]

$$RR'C{=}CR''Y + BuOH \xrightarrow[Bu_3N]{1.5\%\ «Pd»,\ CO} \underset{58-95\%}{RR'C{=}CR''CO_2Bu}\ .$$

X=Br, I; «Pd»=$PdX_2(PPh_3)_2$

A mixture of geometrical isomers is usually obtained in which the product with retention of the configuration predominates. A decrease of temperature to 60–80 °C and the addition of an excess of triphenylphosphine make it possible to increase the stereoselectivity of the process, but the rate of carbonylation then falls markedly. Together with *cis-trans* isomerisation, the formation of side products is observed in some cases as a result of the migration of the double bond in the ester from the αβ- to the βγ-position.

The carbonylation of vinyl bromides in the presence of sodium, aluminium, boron, titanium, and zirconium alkoxides has been described only for individual examples.[59–63] The limited amount of experimental data precludes definite conclusions about the synthetic possibilities of these reactions.

The alkoxycarbonylation of allyl halides has been studied inadequately. The reaction is carried out in the presence of palladium catalysts not containing phosphine ligands under severe conditions (97–500 atm, 80–160 °C), which led to low yields of βγ-unsaturated carboxylic acid esters (29–52%).[41–43]

The methyl and butyl esters of phenylacetic acid were obtained in satisfactory yields by the carbonylation of $PhCH_2Cl$[47] or $PhCH_2Br$[56] catalysed by $PdCl_2(PPh_3)_2$. The reactions of benzyl halides can be complicated by the formation of side products as a result of the substitution of the halogen by the alkoxy-group, while in the case of substrates of the type ArCH(Alk)Hal, containing a hydrogen atom in the β-position in the alkyl chain, unsaturated compounds can be produced. Thus the carbonylation of α-bromoethylbenzene in the presence of methanol leads to methyl 2-phenylpropionate (49%), α-methoxyethylbenzene (24%), and styrene (12%).[64]

The interaction of propargyl chloride with CO in methanol is accompanied by the hydromethoxycarbonylation of the triple bond and affords methyl itaconate $CH_2=C(CO_2Me)CH_2CO_2Me$ in 66% yield.[65]

Yet another type of halide used as the initial substrates in the synthesis of esters comprises α-halogenoketones. Thus the synthesis of $PhCOCH_2CO_2Me$ (64%) by the reaction of $PhCOCH_2Br$ with CO in methanol has been described.[47]

The alkoxycarbonylation of halogeno-derivatives of saturated hydrocarbons (primary bromoalkanes) and also of phenylethyl bromide whose reactivity is similar to theirs has been achieved only recently[62,63] (1 atm CO, 90–150 °C):

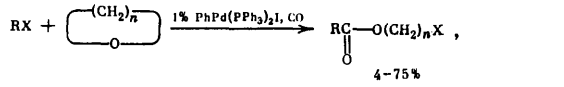
$$\text{RBr} + \text{E(OBu)}_n \xrightarrow{\text{cat., CO}} \underset{42-88\%}{RCO_2Bu}\ .$$

E = B (n = 3), Ti (n = 4); R = n-C_8H_{17}, n-$C_{12}H_{25}$, $PhCH_2CH_2$

cat. = 6% $Pd(PPh_3)_4$ (E = Ti) or 6% $Pd(PPh_3)_4$ + 9% [(hexa-1,5-diene)RhCl]$_2$ (E = B)

The diester $BuO_2C(CH_2)_6CO_2Bu$ (76%) is formed in the analogous reaction of $Br(CH_2)_6Br$ with $B(OBu)_3$.[62]

At high CO pressures, double carbonylation of organic halides can take place, which is of great interest as a method of synthesis of derivatives of α-ketoacids (150 atm CO, 15–120 °C):[66]

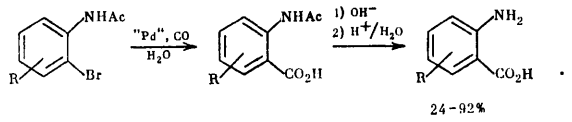


$$RX + R'OH \xrightarrow[Et_3N]{1\%\ «Pd»,\ CO} \underset{0-62\%}{RCOCO_2R'} + \underset{3-95\%}{RCO_2R'}\ .$$

RX=PhI, PhBr, 4-MeC_6H_4I, 4-$MeOC_6H_4I$, 2-iodothiophen, 5-bromothiazole, (*E*)-PhCH=CHBr

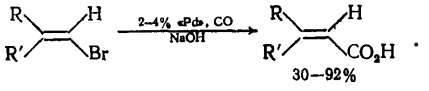
Under these conditions, the interaction of the halides RX with CO in alcohols leads to a mixture of the esters RCO_2R' and $RCOCO_2R'$, the mole fraction of the latter ranging from 0 to 91% depending on the nature of the initial reactants, the catalysts, and other factors. In order to increase the yield of α-ketoacid esters, it is essential to use as catalysts the complexes $PdCl_2L_2$, where L is the phosphine ligand with a conical angle of 145–170 °C (for example, Ph_3P, iso-Pr_3P, etc. and the process must be carried out at high pressures and low temperatures. It is recommended that the alcohols R'OH with R' = Bu, t-$BuCH_2$, iso-Pr, or cyclo-C_6H_{11} be used; when R' = Me, t-Bu, Ph, or $PhCH_2$, the only reaction product is RCO_2R'.

The ester $RCH(CO_2Et)CH_2CCl_3$ (29–60%) has been obtained together with CCl_4, RCH=CH, and CO in ethanol together with the products of the addition of carbon tetrachloride to the double bond of the initial alkene $RCHClCH_2CCl_3$ (16–33%).[67] It is not possible to extend this method to other organic halides.



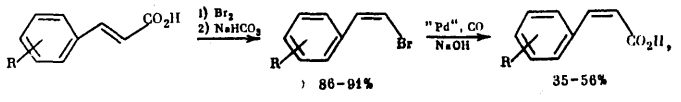
It has been proposed[68] that cyclic ethers, namely epoxides, oxetan, THF, and tetrahydropyran, be used as nucleophilic coreactants in the alkoxycarbonylation reaction (20 atm CO, 120–130 °C):

RX = PhI, PhBr, 4-AcC_6H_4Br, PhCH=CHBr, PhCH=$CHCH_2Cl$, $PhCH_2Cl$, $PhCOCH_2Cl$; $n = 2-5$



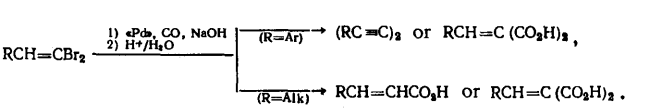
On passing from epoxides to less strained oxygen-containing heterocycles, the rate of carbonylation and the yield of products (esters of halogenohydrins) decrease sharply: oxiran > oxetan > THF > tetrahydropyran. The reactivity of tetrahydropyran does not differ from that of the acyclic dibutyl ether and the compound is almost inactive in this reaction.

The carbonylation of organic halides under the conditions of homogenous catalysis by palladium complexes is used widely in the synthesis of a wide variety of carboxylic acids. Thus the reaction of aryl halides (substituted bromobenzenes and 1- and 2-bromonaphthalenes) with CO(2–3 atm) and H_2O at 110–130 °C in the presence of the base Bu_3N and catalytic amounts of $PdX_2(PPh_3)_2$ (X = Cl or Br) or $Pd(PPh_3)_4$ leads to $ArCO_2H$ in a yield up to 94%.[69] The authors used the method to obtain anthranilic acids:



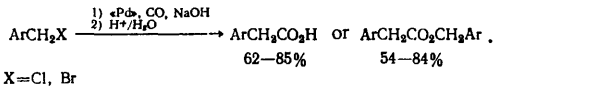
24–92%

The carboxylation of RX has been achieved[70-75] in a two-phase system: an aqueous solution of sodium hydroxide–organic solvent (C_6H_6, *p*-$Me_2C_6H_4$, CH_2Cl_2, or $EtCMe_2OH$). Tetrabutylammonium iodide,[70] tetrahexylammonium bisulphate,[72,74] benzyltriethylammonium chloride,[73,75] etc. were used as the phase transfer catalysts. We may note that the presence of a quatenary ammonium salt is not obligatory, at least in reactions with participation of benzyl halides.[72] Depending on the structurre of the halogeno-derivative RX, the following reactivity series were observed: $PhCH_2X$ > PhX and RI > RBr > RCl.[71] The carboxylation in a two-phase system usually takes place under very mild conditions. This is especially important in the reactions of halides of the vinyl type, because it makes it possible to convert them into αβ-unsaturated acids with the retention of both (*E*)- and (*Z*)-configurations of the vinyl group (1 atm CO, 20–50 °C):[73,75]



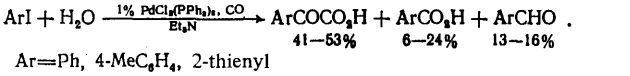
«Pd»=$Pd(PPh_3)_4$, $Pd(Ph_2PCH_2CH_2PPh_2)$;
R, R′=H, Ar, Alk

A convenient method of synthesis of *cis*-cinnamic acids from the corresponding *trans*-isomers is based on this reaction (1 atm CO, 20 °C):[73]

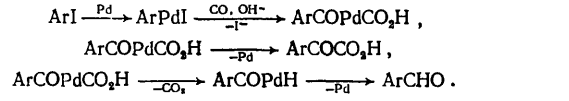


86–91% 35–56%

Depending on the nature of the initial dibromide the organic solvent employed, the interaction of 1,1dibromoalk-1-enes with CO leads to different products–diynes, αβ-unsaturated monoacids, or methylenemalonic acids (1 atm CO, 40–75 °C):[74]

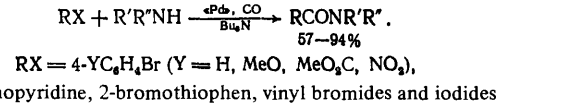


The carbonylation of benzyl halides in an aqueous sodium hydroxide solution–organic solvent system (1–5 atm CO, 20 to 95 °C) is used to synthesise arylacetic acids[70-72] and their benzyl esters.[72] The reaction pathway is determined mainly by the nature of the palladium catalyst and by the presence or absence of a quaternary ammonium salt (phase transfer catalyst):



X=Cl, Br

It is noteworthy that the product of the double carbonylation of the initial halides, namely $ArCOCO_2H$, as well as a small amount of the aldehyde ArCHO are obtained together with $ArCO_2H$ from aryl iodides and H_2O at a high CO pressure (150 atm CO, 40–80 °C):[76]



Ar=Ph, 4-MeC_6H_4, 2-thienyl

The mechanism of the formaion of the α-ketoacid and the aldehyde proposed by the authors is presented in the Scheme below (the ligands not involved in the reaction have been omitted from the Scheme):

The interaction of the halides RX with CO and the amines R′R″NH (1 atm, 100 °C), catalysed by 1.5 mole% of $PdX_2(PPh_3)_2$, leads to the carboxylic acid amides RCONR′R″.[45] Halogeno-derivatives of the aryl and vinyl types can be used as the initial substrates in the reaction. The amine base (Bu_3N) is as a rule added to neutralise, together with the amine reactant (R′R″NH), the acid HX evolved in the carbonylation reaction:

RX = 4-YC_6H_4Br (Y = H, MeO, MeO_2C, NO_2),
3-bromopyridine, 2-bromothiophen, vinyl bromides and iodides
R′R″NH=$PhNH_2$, $PhCH_2NH_2$, $(CH_2)_4NH$

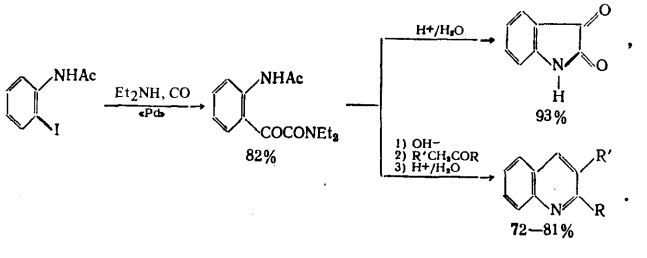
The conversion of organic halides into amides is achieved at a higher rate than that of the analogous alkoxycarbonylation reaction. For example, the amide $PhCONHCH_2Ph$ is formed 17 times faster in the reaction of PhBr with CO and $PhCH_2NH_2$ than the ester $PhCO_2Bu$ in the carbonylation of PhBr in the presence of BuOH.[45] It may be that this difference between the rates is the reason why the conversion of vinyl iodides and bromides into amides proceeds with complete retention of the configuration of the alkenyl group[45] in contrast to the alkoxycarbonylation of these compounds.[44]

It has been shown[60] that Me_3SnEt_3 reacts with ArI (Ar = Ph or 4-$NO_2C_6H_4$) and CO under very mild conditions (20 °C, 1 atm) with formation of $ArCONEt_2$ (82–90%). When the organo-tin nucleophile is replaced by the corresponding amine (Et_2NH), both the selectivity and the rate of the amide formation reaction decrease sharply.

Initially two fundamentally different mechanisms were proposed for the conversion of organic halides into amides in the presence of palladium catalysts[45] the acyl ($RCOPdL_2X$) or carbamoyl [$RPd(CONR'R'')L$] complexes of palladium were initially considered as intermediates (cf. with the alkoxycarbonylation mechanism described above). The experimental data obtained in later studies[59,60,77] showed that the reaction apparently takes place via the second pathway, i.e. the catalytic cycle in which the carbamoyl complexes participate is realised:

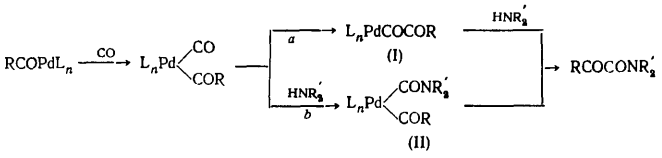
$$RX + PdL_n \rightarrow RPdL_2X + (n-2)L,$$
$$RPdL_2X + CO \rightleftarrows [RPd(CO)L_2]^+X^-,$$
$$[RPd(CO)L_2]^+X^- + R'R''NH + B: \rightarrow RPd(CONR'R'')L_2 + BHX,$$
$$RPd(CONR'R'')L_2 + (n-2)L \rightarrow RCONR'R'' + PdL_n,$$
$$L = PR_3 \text{ and/or } CO$$

Under certain conditions the reactions of organic halides with CO in the presence of primary or secondary amines lead to double carbonylation products – α-ketoacid amides (10 – 40 atm CO, 20 – 100 °C):[78,79]



$$RX + R'R''NH \xrightarrow[\text{«Pd»}, CO]{0.5-1\%} \underset{0-98\%}{RCOCONR'R''} + \underset{2-92\%}{RCONR'R''}.$$

X=Br, I; R=4-YC_6H_4 (Y=H, Me, MeO, Cl), 2-thienyl, 3-pyridyl, PhCH = CH



R'=R''=Me, Et, Pr, iso-Pr; R'R''= $(CH_2)_5$, $(CH_2)_2O(CH_2)_2$

The overall yield of the mixture of acid amides is 3 – 100%. The molar ratio RCOCONR'R''/RCONR'R'' varies within wide limits (0/100 – 98/2) and depends on a number of parameters. The formation of the α-ketoamide is promoted by the increase in the CO pressure, the decrease in the reaction temperature, the use of non-polar solvents.[78,80] The nature of the catalyst – a phosphinepalladium complex – plays a major role.[78] In the case of complexes with monodentate ligands – PdX_2L_2 and $PhPdL_2X$ – the relative content of RCOCONR'R'' in the mixture of products increases with increasing basicity of the phosphine L: $Me_2PhP > EtPh_2P > Ph_3P$. When the complexes PdU_2L, where L is a bidentate ligand of the type $Ph_2P(CH_2)_nPPh_2$, are used as the catalysts, the reaction selectivity calculated relative to RCOCONR'R'' diminishes as a function of *n* in the sequence 4 > 3 > 5 > 2. α-Ketoacid amides are obtained in high yields when RX is carbonylated in the presence of Et_2NH, Pr_2NH, or piperidine.[78-80] The reactions with weaker bases, namely Me_2NH and morpholine, and also with the sterically hindered iso-Pr_2NH afford mainly the monocarbonylation products.[78-80]

The method of synthesis of isatin and quinoline derivatives, proposed by Ozawa et al.,[81] is based on the double carbonylation of *o*-iodoacetanilide:

The acylpalladium complexes $RCOPdL_n$ (L = X, PR'_3 and/or CO), formed as a result of the oxidative addition of RX to zero-valent palladium and the subsequent interaction of $RPdL_n$ with CO, are undoubtedly active intermediates in the double carbonylation reactions considered. The conversion of $RCOPdL_n$ into α-ketoamides of carboxylic acids can be achieved in principle via two different mechanisms:[79,80] via the stage involving the formation of the acylformyl derivative of palladium (I) or of the acylcarbamoyl complex (II):

On the basis of a careful study of the reactions of the palladium complexes $RPdL_2X$, $RCOPdL_2X$, and $RCOCOPdL_2X$ (L = phosphine ligands), modelling the possible pathways in the catalytic process, it has been recently possible[77,82-84] to demonstrate that the double carbonylation of organic halides proceeds with participation of compounds (II) (pathway *b*).

It is of interest that not only primary and secondary but also tertiary amines can be used as the nucleophilic coreactants in the conversion of the halogeno-derivatives RX into amides (20 atm CO, 120 °C):[85]

$$RX + R'_2R''N \xrightarrow[CO]{0.6\%\ PhPd(PPh_3)_2I} \underset{11-75\%}{RCONR'R''} + R'X.$$

RX=PhI, PhCH=CHBr, EtI

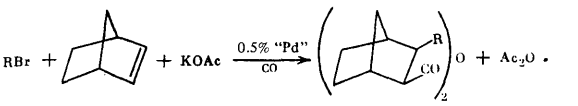
R'=R''=Et, Pr, Bu; R'=Et, R''=Ph

On passing from triethylamine to tripropyl- and tributyl-amines, which contain more bulky substituents, the yield of RCONR'R'' falls significantly. The fact that the carbonylation of EtI in the presence of $PhNEt_2$ proceeds with the selective dissociation of the N – Et bond and affords the *N*-ethyl-*N*-phenylamide of propionic acid in a high yield (75%) is noteworthy.

Non-activated iodoarenes and iodoarenes containing weak electron-accepting substituents interact with CO and organo-tin mercaptides to form thiolocarboxylic acid esters (1 atm CO, 20 °C):[58,59]

$$ArI + Et_3SnSR \xrightarrow[CO]{5-10\%\ PhPd(PPh_3)_2I} \underset{62-96\%}{ArCOSR}.$$

Ar=Ph, 4-ClC_6H_4, 1-naphthyl, 2-thienyl; R = Ph, Et

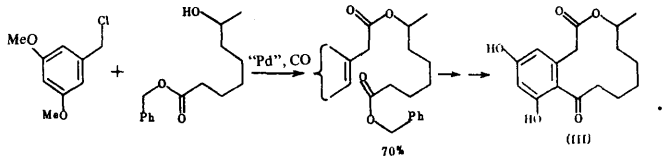


When the initial halide contains strong electron-accepting groups, ArCOSR cannot be obtained; the main reacion product is in this case the sulphide ArSR.

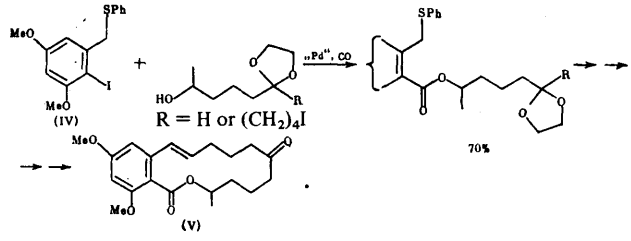
Aryl iodides have been converted into α-ketonitriles[86] (8 – 20 atm CO, 100 °C:

$$ArI + KCN \xrightarrow[CO]{1-3\%\ PhPd(PPh_3)_2I} \underset{45-92\%}{ArCOCN} + \underset{1-22\%}{ArCN},$$

Ar=4-XC_6H_4 (X=H, Me, MeO), 2-thienyl.

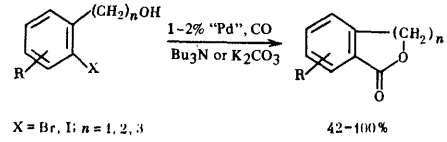


The carbonylation in the RBr – KOAc – norbornene (or norbornadiene) system, catalysed by tetrakis(triphenylphosphine)palladium, is accompanied by the insertion of both the alkene and CO in the C – Pd bond in the intermediate $RPd(PPh_3)_2Br$ (1 atm CO, 80 °C):[87]

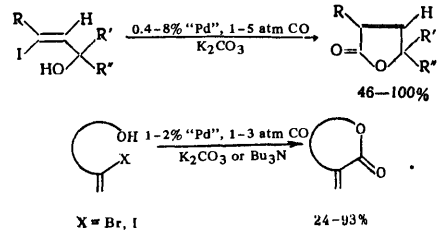


R = Ph, $PhCH_2$, MeO_2CCH_2, PhCH=CH, n-$C_6H_{13}CH$ = CH

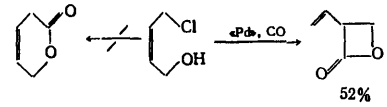
A mixed anhydride is apparently formed initially, but it is unstable and readily disproportionates. The reactions considered above have found application in fine organic synthesis.



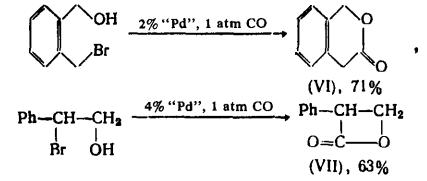
A method of synthesis of the macrolide(III) (curvularin), which is encountered in nature, has been developed. The key stage is the alkoxycarbonylation of 3,5-dimethoxybenzyl chloride:[88]



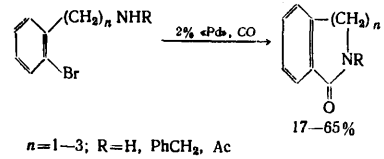
The dimethyl ether of zearalenone (V), a macrolide with a structure similar to that of curvularin, has been synthesised from the aryl iodide (IV) using a catalytic reaction:[89,90]



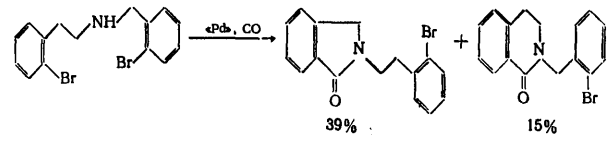
Hitherto, we have discussed the interaction of organic halides with CO and a wide variety of nucleophilic coreactants without dealing with the carbonylation of substrates containing a nucleophilic substituent (OH, NH_2, etc.) in the same molecule. On the other hand, the reactions of such halogenoderivatives with CO are of special interest from the synthetic point of view, because, unless this is prohibited by geometrical considerations, the latter can occur as intramolecular reactions leading to various heterocyclic compounds. For example, in the presence of an OH grup in the side chain of halogenobenzene, cyclisation takes place readily with formation of benzolactones (1–4 atm CO, 50–130 °C).[56,91] Special mention should be made of the possibility of obtaining in this way derivatives of the phthalide (n = 1) and 3,4-dihydroisocoumarin (n = 2) series, many of which are encountered in natural objects and exhibit biological activity:[35]



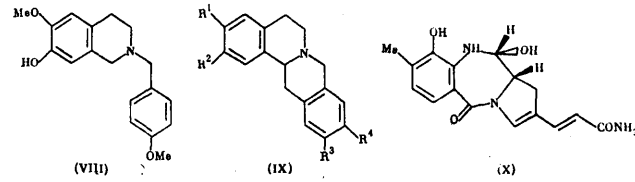
The reactions of vinyl halides, containing a hydroxy-group, have been used successfully for the synthesis of compounds of important classes such as $\Delta^{\alpha\beta}$-butenolides[56] and α-methylene-substituted γ-, δ-, and ε-lactones:[92,93]



It has been found[56] that a chloro-derivative of the allylic type—*cis*-4-chlorobut-2-en-1-ol—interacts with CO under very mild conditions (1 atm, 20 °C) in the presence of 4 mole% of $Pd(CO)(PPh_3)_3$ as the catalyst. The reaction leads to a four-membered ring lactone:

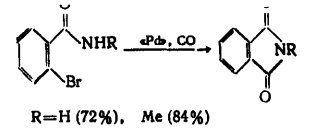


o-Bromomethylbenzyl alcohol and 2-bromo-2-phenylethanol react to form 3-isochromanone (VI) and the β-lactone of tropic acid (VII) respectively in satisfactory yields:[56]

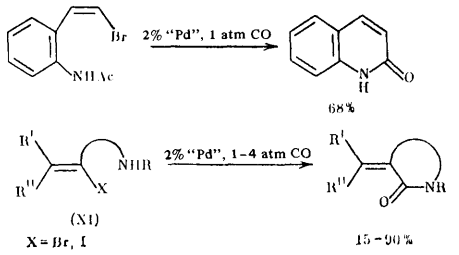


The conversion of *o*-(aminoalkyl)bromobenzenes into γ-, δ-, and ε-benzolactams hs been achieved[94,95] (1 atm CO, 100 °C):

When the intramolecular cyclisation can proceed via different pathways affording both six- and five-membered lactams, the latter is formed preferentially:[94]



The simplest alkaloids (VIII) and (IX), whose composition includes the tetrahydroisoquinoline system, have been synthesised using this elegant and convenient method for the construction of nitrogen-containing rings:[96,97]



Recently there has been a growth of interest in benzo-1,4-diazepines and their oxo-derivatives, among which substances active as tranquillisers, soporifics, and antibiotics have been discovered. A method has been developed for the synthesis of a series of physiologically active 1,4-benzodiazepines based on the cyclisation reaction catalysed by palladium complexes. One of the antibiotics synthesised in this way is anthramycin (X).[99]

o-Bromobenzamides interact with CO at 1 atm and 100 °C in the presence of the $Pd(OAc)_2$–PPh_3 catalytic system with formation of phthalimides:[95]

Vinyl halides are also used as the initial substrates in the synthesis of nitrogen-containing heterocyclic compounds. Thus the conversion of (*Z*)-*o*-acetamido-β-bromostyrene into 2-quinolone can be

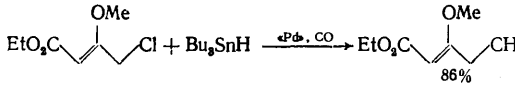
readily achieved.[95] The carbonylation of the vinyl derivatives (XI) leads to a wide variety of the substituted α-methylene-β-lactams, α-methylene-γ-lactams, and α-methylene-δ-lactams:[93,103,104]

The possible applications of this method in the synthesis of β-lactam antibiotics are being sought.[105]

2. The Synthesis of Aldehydes

The halogen in organic halides can be readily replaced by the formyl group using the carbonylation reaction.

In the presence of the synthesis gas ($CO:H_2$ = 1:1) and a palladium catalyst, iodo- and bromo-arenes of the benzene and heterocyclic series as well as vinyl derivatives are converted into the corresponding aldehydes in satisfactory yields.[46,106] The reaction takes place at approximately 100 atm and 80–150 °C in the presence of a base (a tertiary amine or pyridine):



$$RX + CO + H_2 \xrightarrow[65-99\%]{1-3\%\ «Pd»} RCHO\ .$$

«Pd»=PdX_2, $PdX_2(PPh_3)_2$; X=Br, I; R=Ar, vinyl.

In the case of vinyl halides, side products may be formed as a result of *cis–trans* isomerisation and the migration of the double bond. Substituents in halogenoarenes such as the cyano- and acetoxy-groups are not involved in the reaction. However, when an attempt was made to obtain *p*-nitrobenzaldehyde by formylating *p*-bromonitrobenzene, only polymeric products were isolated. In certain cases the reduction of the carbon–halogen bond is observed. Thus, the reaction of *o*-dibromobenzene leads to benzaldehyde (66%). However, in the reaction involving *p*-dibromobenzene, the normal product *p*-$(HCO)_2$.C_6H_4 with two aldehyde groups was obtained (74%).

The mechanism of the formylation of RX is in many respects analogous to the mechanisms of the reactions examined before: the active intermediate is the acyl complex of palladium $RCOPdL_2X$, the interaction of which with H_2 leads to the aldehyde RCHO.[46]

The use of tributyl-tin hydride as the reductant made it possible to convert organic halides into aldehydes under much milder conditions (1–3 atm CO, 50 °C).[107] Apart from aryl and vinyl iodides, allyl chlorides and benzyl bromide can serve as the initial substrate:

$$PhCH_2Br + Bu_3SnH \xrightarrow[75\%\ \ 12\%]{«Pd»,\ CO} PhCH_2CHO + PhMe\ .$$

«Pd»=$Pd(PPh_3)_4$

Formylation by the method of Baillargeon and Stille[107] is more chemoselective than the analogous reaction using synthesis gas: the methoxycarbonyl, keto-, and even nitro-groups are not involved in the reaction. In the reaction of *p*-bromoiodobenzene it is possible to achieve the selective substitution of iodine by the formyl group; the yield of *p*-bromobenzaldehyde reaches 88%. The formation of aldehyde is sometimes complicated by a side reaction involving the reduction of the initial halogeno-derivative RX to RH. For halogenoarenes containing strong electron-accepting substituents, this reaction may become the main one. For example, the formylation of *p*-$NO_2C_6H_4I$ leads to *p*-nitrobenzaldehyde (38%) and nitrobenzene (62%). Nevertheless, the yield of the aldehyde is usually high and in many cases reaches 90–100%.

Pri-Bar and Buchman[108] were able to replace tin hydride, which is sensitive to atmospheric oxygen, by the mild reductant poly(methylhydrosiloxane):

$$RX + [-SiMeH-O-]_n \xrightarrow[80-125°C]{«Pd»,\ 3\ atm\ CO} \underset{14-96\%}{RCHO}\ .$$

"Pd" = $Pd(PPh_3)_4$, $PdCl_2(PPh_3)_2$/polystyrene

RX = iodo- and bromo-arenes and benzyl bromide

$PdCl_2(PPh_3)_2$ deposited on cross-linked polystyrene is an effective catalyst. The immobilisaion of the palladium complex on a polymeric carrier made it possible, on the one hand, to retain the activity characteristic of the homogeneous catalyst and, on the other hand, to simplify significantly the problem of the separation of the palladium compounds from the reaction products.

The possibility of using HCOONa as the reductant in the formylation reaction (3 atm CO, 125 °C) has been demonstrated for iodo- and bromo-benzenes.[108] The yield of benzaldehyde was 80% and 58% respectively.

3. The Synthesis of Asymmetric Ketones

Carbonylation in the RX (organic halide)–R'M (organometallic compound) system, catalysed by palladium complexes, constitutes a convenient method of synthesis of asymmetric ketones:

$$RX + R'M \xrightarrow{«Pd»,\ CO} RCOR' + MX\ .$$

The reaction mechanism is in broad outline analogous to the mechanisms of the reactions considered in this Section. The first stage of the catalytic cycle is the oxidative addition of RX to the zerovalent palladium complex. The carbonylation of the $RPdL_2X$ formed and the subsequent interaction of the acyl derivative $RCOPdL_2X$ with R'M lead to the ketone RCOR' and the initial catalytically active zerovalent palladium species.

Tin derivatives have found the widest application as organometallic reagents in this reaction. They are resistant to the action of atmospheric oxygen and moisture, are readily available, and, what is most important, are inert not only in relation to the keto-group of the products COR' but virtually in relation to any important functional group. This permits the synthesis of ketones containing different substituents.

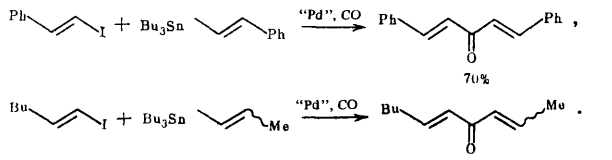
The carbonylation of the iodoarenes 4-XC_6H_4I in the presence of aryl-, vinyl-, phenylethynyl-, and alkyl-stannanes leads to the corresponding ketones in high yields (1–30 atm CO, 20–120 °C):[109,110]

$$4\text{-}XC_6H_4I + RSnR'_3 \xrightarrow[HMP]{«Pd»,\ CO} 4\text{-}XC_6H_4COR + ISnR'_3\ ,$$

X=H, Cl, MeO_2C, CN, NO_2; R=4-YC_6H_4 (Y=MeO, Me, H, Cl, NO_2), C_6F_5, 2-thienyl, H_2C=CH, PhC≡C, Me, Bu

"Pd" = $PhPd(PPh_3)_2I$, $(\pi\text{-}C_3H_5PdCl)_2$

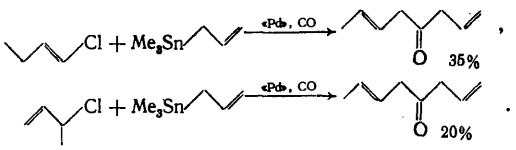
The reaction takes place under very mild conditions (1 atm CO, 20 °C) when it is catalysed by bis(π-allylpalladium chloride) (1 mole%).[110] In the reactions involving the most active tin compounds $RSnMe_3$ (R=CH_2=CH, 2-thienyl, or PhC≡C), the cross-coupling side product 4-XC_6H_4R is formed together with the carbonylation product. This undesirable process can be suppressed by carrying out the reaction in a less polar solvent–acetone.[111]



The halides of the heterocyclic series react analogously. Thus 2-C_4H_3SCOPh (95%) and 2-C_5H_4NCOPh (91%) have been obtained by carbonylating 2-iodothiophen and 2-iodopyridine in the presence of trimethylphenyltin.[111]

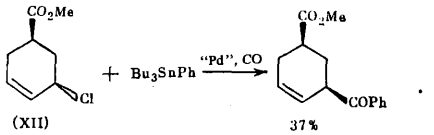
The reactions of β-bromostyrene with tetramethyltin,[109] of 1-iodohex-1-ene with tributylphenyltin, and of 1-iodopent-1-ene with $PrC{\equiv}CSnBu_3$ [112] at 4–30 atm CO and 45–120 °C lead to the corresponding αβ-unsaturated ketones in 46–62% yields. A method of synthesis of asymmetric divinyl ketones from vinyl iodides and alkenyltin derivatives (4 atm CO, 45–50 °C) has been developed:[112]

$$R^1R^2C{=}CR^3I + R^4R^5C{=}CHSnAlk_3 \xrightarrow{2\%\ «Pd»,\ CO} \rightarrow Alk_3SnI + R^1R^2C{=}CR^3CCH{=}CR^4R^5 \ (O;\ 45–93\%)$$



«Pd» = $PdCl_2L_2$, $PhCH_2PdL_2Cl$; L = PPh_3

We may note that the *trans*-configuration of the alkenyl group in the initial halide and the organostannane is retained in the reaction product. In the case of *cis*-organostannanes the carbonylation also takes place with the preferential retention of the geometry of the double bond, but the subsequent isomerisation of the ketone under the reaction conditions can lead to the *trans*-product, for example:



cis/*trans* = 6 24 h: *cis*/*trans* = 2.5
48 h: only *trans*-isomer, 62%

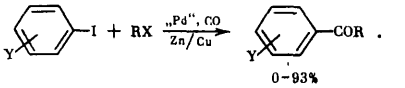
Allyl halides interact with aryl-, vinyl-, and allyl-trialkylstannanes at 4–52 atm CO with formation of βγ-unsaturated ketones.[113-115] Organotrimethylstannanes are usually employed in order to reduce the steric hindrance generated by the alkyl substituents in the organotin compound. The reactions of allyl bromides proceed less selectively than those of allyl chlorides. Although the carbonylation can be accompanied by the allylic rearrangement, it is regioselective: only one product is obtained in which the carbonyl grup is linked to the least substituted carbon atom of the allyl fragment:[114]

As shown for compound (XII), the stereochemical result of the reaction corresponds to inversion of the configuration at the carbon atom linked to the halogen:[115]

(XII) 37%

cis/*trans* = 26:74 *cis*/*trans* = 70:30

Vinylstannanes interact with allyl halides in a CO atmosphere with retention of both the *cis*- and the *trans*-geometry of the vinyl group.[115]



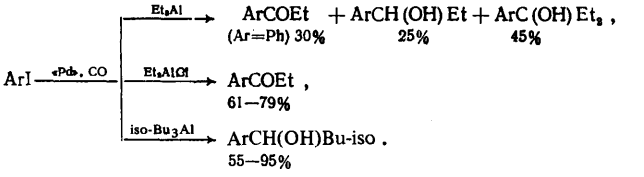
Benzyl chloride reacts with tetramethyltin and CO to form phenylacetone (86%).[109] *p*-Nitrobenzyl phenyl ketone has been obtained analogously in 85% yield from *p*-nitrobenzyl bromide and trimethylphenyltin.[110] The reaction of PhCHRBr (R = Me or Et) with R'_4Sn (R' = Me or Ph) and CO is complicated by side processes involving isomerisation and β-elimination,[116] for example:

$$PhCHMeBr + Me_4Sn \xrightarrow[120°C]{PdCl_2(AsPh_3)_2,\ 20\ atm\ CO} \rightarrow \underset{70\%}{PhCHMeCOMe} + \underset{4\%}{PhCH_2CH_2COMe} + \underset{14\%}{PhCH{=}CH_2}$$

Carbonylation in an α-halogenocarboxylic acid ester–organotin compound system constitutes a method of synthesis of β-ketoacid derivatives. Thus the reaction of ethyl α-bromoacetate with CO and tetraphenyltin leads to ethyl benzoylacetate (67%).[109] MeCH.(COMe)CO_2Et has been obtained from ethyl α-bromopropionate and tetramethyltin (62%).

The conversion of halogeno-derivatives of saturated hydrocarbons into ketones has been described for only one example: methyl iodide interacts with trimethylphenylstannane in a CO atmosphere to form acetophenone (94%).[110]

The organozinc compounds RZnX, obtained *in situ* from primary or secondary iodoalkanes or benzyl chlorides using the zinc–copper couple, react with aryl iodides at 1 atm CO in the presence of 1 to 2 mole% of $Pd(PPh_3)_4$.[117] The yield of the target product $YC_6H_4.COR$ is 56–93% for aryl iodides containing electron-donating substituents (Y = 4-MeO or 2- and 4-Me) and unsubstituted iodobenzene (Y = H), but in the presence of electron-accepting groups in the benzene ring of the halogenoarene (Y = 4-Br or 2-MeO_2C) it falls to 0–38%. It is also noteworthy that primary alkyl iodides are more reactive than secondary alkyl iodides:



X = I; R = Me, n-Pr, iso-Pr, iso-Bu, n-C_8H_{17}, cyclo-C_6H_{11}
X = Br; R = $PhCH_2$, 4-$ClC_6H_4CH_2$

Carbonylation in the RX–iso-Bu_2AlR' system under mild conditions (1 atm CO, 20–55 °C) can serve as a convenient method of synthesis of asymmetric ketones RCOR' of various classes:[118]

$$RX + \text{iso-}Bu_2AlR' \xrightarrow{1\%\ PdCl_2(MeCN)_2,\ CO} \underset{41–99\%}{RCOR'}$$

RX = 4-YC_6H_4I (Y = NO_2, NC, Cl, MeO, H), 2-iodothiophen, 4-$NO_2C_6H_4CH_2Br$, MeI
R' = Ph, PhC≡C, CH_2=CH

The reaction of aluminium trialkyls and dialkylaluminium chlorides with aryl iodides and CO (1 atm, 50 °C) takes place in a more complex manner.[119] Alkyl aryl ketones ArCOAlk obtained initially are capable of bineg reduced and alkylated by the initial organoaluminium compounds, affording, ArCH(OH)Alk and $ArC(OH)Alk_2$. Thus the carbonylation of iodobenzene in the presence of Et_3Al leads to a mixture containing the three products indicated in comparable amounts. The use of Et_2AlCl and iso-Bu_3Al as reactants made it possible to direct the process towards the preferential formation of a ketone or secondary alcohol respectively:

The ketones RCOC≡CR' are obtained from the halides RX and terminal acetylenes R'C≡CH (R' = Ph, $PhCH_2CH_2$, or Bu) in a CO atmosphere (20 atm, 80–120 °C).[120] The method is applicable over

a wide range of organic halides: substituted iodo- and bromo-benzenes, 1-bromonaphthalene, 2-bromothiophen, and vinyl bromides. In order to increase the yield of the ketone and to reduce the amount of the side products [$RC{\equiv}CR'$, $(R'C{\equiv}C)_2$], it is recommended that the complex $PdCl_2$ with the bidentate phosphine ligand 1,1'-bis(diphenylphosphino)ferrocene be used:

$$RX + R'C{\equiv}CH \xrightarrow[Et_3N]{1\%\ «Pd»,\ CO} \underset{47-93\%}{RCOC{\equiv}CR'}\ .$$

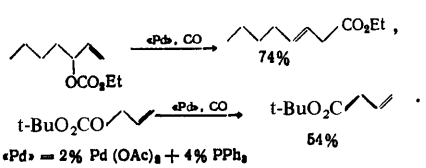
The reactions of aryl iodides with $RC{\equiv}CH$ at 1 atm CO and approximately 60 °C in the presence of the zinc–copper couple lead mainly to the enone $ArCOCH{=}CHR$ after the hydrolysis of the reaction mixture:[121]

$$ArI + RC{\equiv}CH \xrightarrow[2)\ H_2O]{1)\ cat.,\ CO,\ Zn/Cu} \underset{33-92\%}{ArCOCH{=}CHR} + \underset{0-26\%}{ArCOCH{=}CAr}R + \underset{0-44\%}{ArCOCH_2CHRCOAr} + \underset{0-23\%}{ArC{\equiv}CR}\ .$$

cat. = 2% $PdCl_2(PPh_3)_2$ + 4% $(C_6H_5)_2TiCl_2$

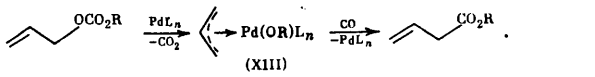
R=Ph, Bu; Ar=YC_6H_4 (Y=H, Me, MeO, Br), 2-thienyl.

The $ArCOC{\equiv}CR$ formed initially is apparently reduced by Zn/Cu to $ArCOCH{=}CRZnI$ whose subsequent interaction with water affords $ArCOCH{=}CHR$.[121]



The possibility, in principle of synthesising symmetrical diaryldiketones by carbonylating aryl iodides in the presence of palladium catalysts (8 atm CO, 111 °C) has been demonstrated recently[122] for the conversion of *p*-iodoanisole into *p*-bianisoyl:

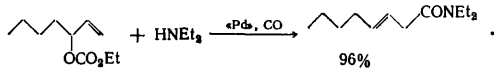
$$4\text{-}MeOC_6H_4I + Et_6Sn_2 \xrightarrow{1\%\ «Pd»,\ CO} \underset{71\%}{(4\text{-}MeOC_6H_4CO)_2} + Et_3SnI\ .$$



Thus the study of the reactions of organic halides with CO under the conditions of homogeneous catalysis by palladium complexes has led to the development of new convenient methods of synthesis of carboxylic acids and their derivatives, aldehydes, and symmetrical and asymmetrical ketones.

IV. CARBONYLATION OF OTHER ORGANIC SUBSTRATES

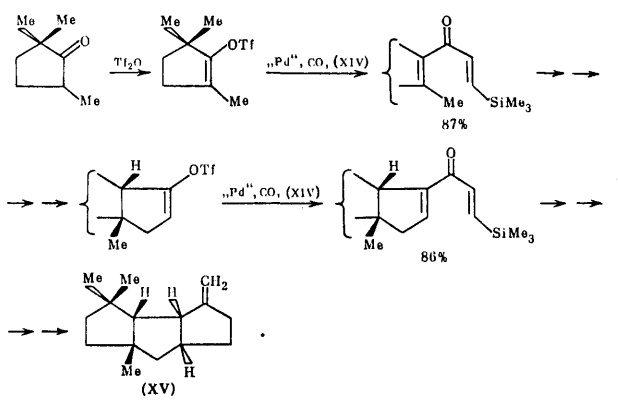
Not only organoelemental compounds and organic halides but also other substrates, capable of interacting with zerovalent palladium or palladium(II) complexes to form σ-organopalladium compounds, can serve as donors of organic groups in the carbonylation reaction. Thus, as early as the 1960's, it was shown[42,50] that ethers and esters of allyl alcohols react with CO in the presence of palladium catalysts. However, the severe conditions under which the process takes place and the low yields of the products precluded a wide-scale application of this synthetic method. Only much later was it found[123] that the readily available alkyl allyl carbonates exhibit a high reactivity: their carbonylation takes place under mild conditions (1–10 atm, 50 °C) and leads to βγ-unsaturated acid esters in satisfactory yields, for example:



The carbonylation is regioselective: only one product is formed in which the alkoxycarbonyl group is bound to the least substituted carbon atom of the allyl fragment. π-Allyl complexes of palladium (XIII), obtained as a result of the oxidative addition of allyl carbonates to zerovalent palladium on subsequent decarboxylation, are intermediates in the reactions considered:

(XIII)

When diethylamine is introduced into the reaction mixture as a nucleophilic coreactant, amides can be synthesised:[123]



The vinyl esters of trifluoromethanesulphonic acid (vinyl triflates) interact with CO and various organotin compounds (alkyl-, aryl-, vinyl-, ethynyl-, and allyl-trialkylstannanes) to form αβ-ketones (1–4 atm CO, 20–75 °C):[124]

$$RCH{=}CR'OSO_2CF_3 + R''SnAlk_3 \xrightarrow{3\%\ Pd(PPh_3)_4,\ CO} \underset{70-95\%}{RCH{=}CR'COR''}\ .$$

It is important to note that both the (*Z*)- and (*E*)-configurations of the alkenyl group in the initial vinyl stannanes are retained in the reaction. This constitutes an undoubted advantage of the given method compared with the analogous method of synthesis based on the carbonylation of vinyl halides[112] (see above). The ready availability of vinyl triflates, the methods of synthesis of which from the anhydride of trifluoromethanesulphonic acid and the corresponding ketones have now been thoroughly developed, is also important from the preparative point of view.

There has been an interesting communication about the synthesis of compound (XV) using (*E*)-1-trimethylsilyl-2-trimethylstannylethylene (XIV) (Tf = CF_3SO_2):[124]

The carbonylation of alcohols in the presence of palladium catalysts is of very limited importance and is applicable only to allyl derivatives.[41,42,50] The reaction proceeds with low yields at high CO pressures. Homogeneous catalytic systems based on rhodium compounds proved to be much more promising. Thus, in the presence of small amounts of added HI, certain carbonyl rhodium complexes are capable of catalysing the conversion of methanol into acetic acid at relatively low CO pressures (30–40 atm) (the active substrate is not the alcohol itself but the methyl iodide formed *in situ* by the reaction of methanol with HI; the interaction of MeI with CO and H_2O leads to acetic acid with the simultaneous regeneration of HI). This highly selective reaction served as the basis of a large-scale industrial process developed by the Monsanto Company.[8]

The wide scale synthetic possibilities of the reactions involving the carbonylation of arenediazonium salts have been demonstrated.[125-128] The interaction of arenediazonium tetrafluoroborates with sodium

carboxylates at 9 atm CO and 25 °C yields mixed anhydrides of the carboxylic acids:[125,126]

$$ArN_2BF_4 + RCO_2Na \xrightarrow{1\text{–}2\%\ Pd(OAc)_2,\ CO} ArCOCR \quad (O\ O;\ 28\text{–}86\%)$$

Ar = YC_6H_4 (Y = H, Me, MeO, Cl, Br, I, NO_2), 1-naphthyl

R = H, Me, Et, t-Bu, Ph

Heating of the mixed anhydrides to 100–120 °C *in vacuo* induces their disproportionation to $(ArCO)_2O$ and $(RCO)_2O$ in nearly quantitative yields.[126] It is of interest that substituents in ArN_2BF_4 such as chlorine, bromine, and even iodine are hardly involved during the carbonylation reaction. Thus an anhydride has been obtained from *p*-iodobenzoic acid in 86% yield relative to the initial diazonium salt.[125]

The reaction of PhN_2BF_4 with CO and alcohols ROH (R = Me, Et, Bu, or t-Bu) results in the formation of $PhCO_2R$ (0–21%) and $PhCO_2H$ (7–66%).[125]

In the presence of triethylsilane or better poly(methylhydrosiloxane), CO, and a palladium catalyst, the conversion of ArN_2BF_4 into ArCHO can be readily achieved (9 atm CO, 25 °C).[127] The formation of diazonium salts is a more chemo-selective process than the analogous reaction of halogenoarenes (see Section III): chlorine, bromine, and iodine atoms and acyl, alkoxycarbonyl, and nitro-groups are not reduced under the conditions used for the synthesis of aldehydes.

Asymmetric ketones can be obtained from ArN_2X and tetra-organostannanes in a CO atmosphere (9 atm CO, 25 °C):[128]

$$YC_6H_4N_2X + R_4Sn \xrightarrow[40\text{–}90\%]{2\%\ Pd(OAc)_2,\ CO} YC_6H_4COR + R_3SnX .$$

X = BF_4, PF_6; Y = H, 2-, 3- and 4-Me, 2- and 4-Cl, 4-Br, 4-F, 3- и 4-NO_2; R = Me, Et, Ph

We may note that the possibility of using arenediazonium salts ArN_2X as the substrates in various carbonylation reactions catalysed by palladium compounds is due to the ease of formation of the σ-organopalladium complexes $ArPdL_2X$:[125]

$$ArN_2X + PdL_n \rightarrow ArPdL_2X + N_2 + (n-2)\,L.$$

Diaryliodonium halides exhibit a high reactivity in the reactions with CO. Thus the alkoxycarbonylation of $[Ar_2I]X$ and their conversion into amides proceed under extremely mild conditions (1 atm CO, 20 °C) in the presence of 2 mole% of $PdCl_2$ and lead to quantitative yields of esters and amides respectively:[129]

$$[Ar_2I]X + ROH \xrightarrow[Bu_3N]{«Pd»,\ CO} \underset{\sim 100\%}{ArCO_2R} + ArI ,$$

$$[Ar_2I]X + PhNH_2 \xrightarrow[Bu_3N]{«Pd»,\ CO} \underset{\sim 100\%}{ArCONHPh} + ArI ,$$

X = Cl, Br, I; R = Me, Bu; Ar = YC_6H_4 (Y = H, 4-MeO, 4-Me, 4-t-Bu, 4-Cl, 3-NO_2), 2,4,6-$Me_3C_6H_2$.

The steric hindrance generated by the substituents in the aromatic ring does not prevent their reaction. For example, methyl 2,4,6-trimethylbenzoate has been obtained in 100% yield.

Symmetrical diaryl ketones are formed in the presence of reductants—copper or tin powder or best of all zinc dust (1 atm CO, 20 °C):[130,131]

$$[Ar_2I]X + Zn \xrightarrow{5\%\ Pd(OAc)_2,\ CO} \underset{38\text{–}68\%}{Ar_2CO} + \underset{90\text{–}100\%}{ArI} + ZnX_2 .$$

X = Cl, Br, I, BF_4; Ar = 4-YC_6H_4 (Y = H, Me, t-Bu, Cl, Br), 2,4,6-$Me_3C_6H_2$

The main side products are α-diketones $(ArCO)_2$ (up to 24%) and biaryls Ar_2 (up to 49%). The presence of electron-donating substituents in the initial diaryliodonium salt increases and that of electron-accepting groups decreases the yield of carbonyl-containing compounds. The catalytic cycle proposed by Uchiyama et al.[131] is presented schematically below:

$$[Ar_2I]X \xrightarrow[-ArI]{Pd(0)} ArPdX \xrightarrow[-ZnX_2]{Zn} Ar_2Pd + Pd(0) ,$$

$$Ar_2Pd \xrightarrow{CO} ArCOPdAr \xrightarrow{CO} (ArCO)_2Pd$$

$$\downarrow \qquad \downarrow \qquad \downarrow$$

$$Ar_2 + Pd(0) \quad Ar_2CO + Pd(0) \quad (ArCO)_2 + Pd(0) ,$$

The metallation of arenes by palladium(II) salts affords the σ-diorganopalladium compounds ArPdX,[132] which, as shown previously, are key intermediates in various carbonylation reactions catalysed by palladium complexes. The direct palladisation of aromatic compounds thus opens a pathway to their use as the initial substrate in the synthesis of carbonyl-containing products. The possibility of the practical realisation of this idea has been demonstrated in a number of studies.[36,133-140] It has been shown[133] that substituted benzenes as well as thiophen and furan react with palladium acetate and CO at 15 atm and 100 °C to form the corresponding carboxylic acids [the yields of the mixture of regio-isomers are given relative to $Pd(OAc)_2$]:

$$ArH + Pd(OAc)_2 \xrightarrow{CO} \underset{14\text{–}48\%}{ArCO_2H} + Pd .$$

ArH = C_6H_6, PhOMe, PhMe, PhCl, thiophen, furan

The sequence of the reactivities of the aromatic compounds (PhOMe > PhMe > C_6H_6 > PhCl) and the preferential *ortho-*, *para*-directing effect in the carboxylation reaction in the presence of *ortho*, *para*-directing substituents in the initial benzene (MeO, Me, Cl) indicates the electrophilic character of the process. The proposed mechanism of the carboxylation of arenes[133] is shown schematically below:

$$ArH + Pd(OAc)_2 \rightarrow ArPdOAc + HOAc ,$$

$$ArPdOAc + CO \rightarrow ArCOPdOAc ,$$

$$ArCOPdOAc \rightarrow ArCOOAc + Pd ,$$

$$ArCOOAc + HOAc \rightarrow ArCO_2H + Ac_2O .$$

It is of interest that, in the presence of certain organic halides, for example, 1,2-dibromoethane, the interaction of ArH with CO and $Pd(OAc)_2$ does not lead to carboxylic acids but affords their anhydrides $(ArCO)_2O$.[134]

According to the scheme presented above, in order to make the reaction catalytic it is essential to add an oxidant capable of converting the inactive zerovalent palladium into a palladium(II) salt. It has been suggested that $FeCl_3$,[135] $Tl(O_2CCF_3)_3$ (in this case the substrate may be an organothallium compound formed *in situ* and not the arene itself—see Section II),[36] $CuCl_2$,[136] $Na_2S_2O_8$,[137,138] and t-BuOOH[139] be used as the oxidants. However, the yield of the carbonylation product and the selectivity of the catalytic process are usually low, for example:[135,139]

$$C_6H_6 \xrightarrow[75\ ^\circ C\ t\text{-}BuOOH]{Pd(OAc)_2,\ 1\ atm\ CO} \underset{1300\%}{PhCO_2H} + \underset{1500\%}{Ph_2} + \underset{200\%}{PhOH} ,$$

$$MePh \xrightarrow[125\rightarrow 175^\circ C,\ FeCl_3]{PdCl_2,\ 48\ atm\ CO} \underset{520\%}{4\text{-}MeC_6H_4CO_2H} .$$

The yields are quoted relative to the palladium(II) salt.

The reaction of substituted arenes frequently yields mixtures of regioisomeric acids which are difficult to separate (1 atm CO, 75 °C):[139]

$$PhOMe \xrightarrow[t\text{-}BuOOH]{Pd(OAc)_2,\ CO} MeOC_6H_4CO_2H .$$

The yields, calculated relative to $Pd(OAc)_2$, of the *ortho*-, *meta*-, and *para*-products are 126, 8, and 123% respectively.

The interaction of substituted benzenes with palladium acetates in a CO_2 atmosphere also leads to aromatic acids.[140] In the presence of t-BuOOH, the reaction becomes weakly catalytic with respect to palladium (1 atm CO_2, 70 °C):

$$RPh \xrightarrow[t\text{-}BuOH]{Pd(OAc)_2,\ CO_2} RC_6H_4CO_2H\ .$$

R=Me (125%), H (127%), Cl (40%)

[the yields are quoted relative to $Pd(OAc)_2$]

Thus the carbonylation of arenes, which is of considerable interest because of the ready availability of the initial reactants, encounters major difficulties. The main problem is the low yield of the products and the low selectivity of the reaction.

Apart from arenes, the hydrogen atom can be replaced by CO only in the 1-position in terminal acetylenes (1 atm CO, 20 °C):[141]

$$RC{\equiv}CH + R'OH \xrightarrow[CuCl_2,\ NaOAc]{cat.\ Pd,\ CO} \underset{58-74\%}{RC{\equiv}CCO_2R'}\ .$$

R = n-C_5H_{11}, Ph, $PhOCH_2$; R'=Me, iso-Pr

The reaction is catalysed by 6 mole% of $PdCl_2$ using copper dichloride or *p*-benzoquinone as the oxidants.

The Kinetic Stability of Biscyclopentadienyl and Diarene Compounds of Transition Metals in the Thermal Decomposition Reaction

L.M.Dyagileva, E.I.Tsyganova, and Yu.A.Aleksandrov

Literature data on the kinetic stability of mononuclear metallocene and diarene derivatives of transition metals are described systematically and discussed. A relation between the reactivity of the π-complexes in the thermal decomposition reaction and their structure (the nature of the central metal atom, the σ-substituent, and the π-ligand) has been discovered, surface effects and the role of the adsorption of organometallic compounds in pyrolysis are examined, and problems of macrokinetics are discussed.
The bibliography includes 106 references.

I. INTRODUCTION

The study of the thermal stability of organometallic compounds (OMC) is of great theoretical and practical interest. The kinetic stability of mononuclear metallocene and diarene derivatives of metals is, together with their volatility, the fundamental characteristic determining the possibility of their practical use for the preparation of solid fuels,[1] various coatings,[2,3] and catalysts of many chemical processes.[4,5] Furthermore, a systematic analysis of the relevant literature data has not so far been carried out; in the present review, such an attempt is made for the first time.

Four aspects of the stability of OMC in synthesis–decomposition processes have been distinguished.[2,3] They embrace the molecular and electronic structure of organometallic compounds, their state of aggregation, their dynamics, and their interaction with energy and mass fluxes: the stability of an isolated molecule and of the decomposition products (quantum-chemical aspect), the stability of the sum of the molecules in equilibrium with their decomposition products (thermodynamic aspect), the rate of change in the equilibrium of the sum of the molecules (the kinetic aspect), and the phenomenon of mass and heat transfer in assemblies of molecules (macrokinetic aspect).

The quantum-chemical aspects of the stability of the molecules of certain π-complexes of metals[2,3,6-9] as well as the thermodynamic stability of metallocene and diarene derivatives of metals[2,3,10-17] have been described in the literature. An account has been given of the ideas concerning the stability of OMC in the synthesis–decomposition processes.[18]

The present review describes systematically, and surveys, experimental data on the kinetic and macrokinetic stability of mononuclear metallocene and diarene derivatives of transition metals in the thermal decomposition reaction. Questions concerning the reactivity of the OMC and its relation with the structure (the nature of the metal and ligand), the mechanism of the decomposition process, surface effects, adsorption, and the spatial localisation of the reaction are examined. In connection with the macrokinetic studies, the thermal decomposition reaction is considered taking into acount the heat and mass exchange. The kinetic parameters of the thermal decomposition of the OMC referring to the overall process are analysed and described systematically. These data have been analysed under comparable conditions. The review does not include any data on the deposition of metallic, oxide, and composite coatings obtained by the pyrolysis of OMC by the gas-thermal method, which have already been described systematically in the specialist literature[19,20] and in reviews[21,22] and also data on the photochemical decomposition of metallocenes.[23]

II. KINETICS OF THE THERMAL DECOMPOSITION OF THE π-COMPLEXES OF TRANSITION METALS

1. The Role of the Nature of the Central Metal Atom

The systematic study of the kinetics of the gas-phase decomposition of metallocenes began two decades ago with the investigation of the thermal stability of ferrocene and its substituted derivatives.[24,25] The kinetic study of the thermal decomposition of π-complexes has been carried out under static conditions by the manometric method and under dynamic conditions by a gas-chromatographic pulse method.[26] The apparent rate constants for the overall reaction, calculated for low degrees of decomposition where the influence of the products formed can be neglected, were used as a measure of the reactivity. The kinetic parameters were compared under comparable conditions in the temperature range where the kinetic regime operates.

The pyrolysis of ferrocene,[25] ruthenocene, and osmocene[27] is strikingly autocatalytic, the metal-containing solid phase serving as the catalyst. It has been established that, in vessels treated with pyrolytic iron, the kinetic stability of metallocenes of the iron subgroup increases with increase in the average dissociation energy of the ring–metal bond in the sequence ferrocene < ruthenocene < osmocene.[28]

In contrast to the iron-subgroup metallocenes, the pyrolysis of vanadocene,[29] chromocene,[30] manganocene,[30] cobaltocene,[31] and nickelocene[32] is described satisfactorily by first-order kinetic equations.

The nature of the central metal atom determines the kinetic stability of the mononuclear metallocenes[33,34] (Table 1).

Among metallocenes of the series of 3*d* metals, ferrocene, being an 18-electron complex,[2] exhibits the highest kinetic stability. The π-complexes of metals located to the left and to the right of iron in the Periodic Table are characterised respectively by a deficiency or

an excess of electrons at the central metal atom compared with ferrocene[7-9] and are less stable (Table 2).

Table 1. Kinetic parameters of the pyrolysis of the metallocenes Cp_2M (Cp = cyclopentadienyl) under static conditions*.[33,34]

Cp_2Os *	109	—	—	2.220	0.77

*The walls of the glass reactor were coated by the solid products of the pyrolysis of ferrocene.

For the electron-deficient complexes of 3*d* metals (vanadocene > chromocene > manganocene), the thermodynamic characteristics of the dissociation of the ring—metal atom bond (the average Gibbs free energy $\Delta\bar{G}$ and the average dissociation energy $\bar{D}$) and the kinetic stability vary in parallel. The contribution of the entropy change $\Delta\bar{S}$ to $\Delta\bar{G}$ is insignificant.[16] For the complexes of the metals in the iron triad, the decrease in thermal stability in the sequence ferrocene > cobaltocene > nickelocene is correlated with the decrease in the average dissociation energy in the above bond and with the population of the antibonding orbitals of the metallocene. In ferrocene, these orbitals are unoccupied, in cobaltocene they contain one electron, and in nickelocene they contain two electrons.[7]

Thus a monotonic variation of the kinetic stability of the metallocenes in the 3*d* series has not been observed:

$$Cp_2V > Cp_2Cr > Cp_2Mn \ll Cp_2Fe \gg Cp_2Co > Cp_2Ni.$$

In the Group VIII of the Periodic System, the kinetic stability of the metallocenes of the iron subgroup increases with increase in the atomic number of the metal.

The kinetic stability of the metallocene is not correlated with characteristics of the electronic structure such as the negative charge on the metal atom, the M—C bond indices,[9] and the number of unpaired electrons[8] and also no correlation is observed with the molecular structure (the M—C bond length[8]) and with the so called "decomposition temperature" which has no definite physical significance.[28,35]

The thermal stability of the diarene complexes of chromium, molybdenum, and vanadium increases with increase in the average dissociation energy of the six-membered ring—metal atom bond[36-38] (Table 3).

Table 3. Kinetic parameters of the gas-phase pyrolysis of diarene complexes of chromium, molybdenum, and vanadium.[36—38]

Compound	t, °C	E, kcal mol^{-1}	lg A (s^{-1})	$10^3 k$, s^{-1} (380 °C)
Dibenzenechromium	340—400	23.5±0.5	—	1.55
Di(ethylbenzene)chromium	320—400	25.0±1.0	5.7±0.4	2.26
(Ethylbenzene)(diethylbenzene)chromium	320—380	41.0±0.5	11.2±0.23	2.95
Di(ethylbenzene)molybdenum	340—400	42.1±0.6	10.9±0.2	0.69
Di(diethylbenzene)molybdenum	340—380	31.9±2.1	7.7±0.7	0.90
(Ethylbenzene)(diethylbenzene)molybdenum	340—400	36.9±1.4	9.4±0.5	0.93
Di(ethylbenzene)vanadium	360—480	22.3±0.5	3.8±0.4	0.22

The kinetic stability of the diarene derivatives of metals corresponds to the average dissociation energy, found by the thermochemical method, of the bond between the metal atom and the six-membered ring, which diminishes along the first series of transition elements and increases along the Group with increase in the atomic number of the transition metal.[12,13]

2. The Influence of the Substituent in Cyclic π-Ligands

The nature of the substituents in aromatic rings influences the kinetic stability of metallocene[25,35,39,40] and diarene derivatives of metals[37,38,41] (Tables 3 and 4). The activity of ferrocenes is attributed to the polar influence of the substituents and also to the stability of the radical formed on homolysis of the cyclopentadienyl ring—substituent bond. The influence of electron-donating alkyl substituents on the reactivity of the ferrocene nucleus is inductive in character, like the transfer of this influence via the iron atom to the other ring.[25] Little is known about the character of the influence of electron-accepting substituents on the thermal stability.

Under both static and dynamic conditions, the thermal stability of ferrocene increases with increase in the thermodynamic stability of the groups formed when the side chain is split off homolytically. The accumulation of t-butyl groups in the ferrocene nucleus increases the thermal decomposition rate constant to a much greater extent than the replacement of one alkyl group by another. This effect is especially pronounced on passing from heteroannular tri-t-butyl- and tetra-t-butyl-ferrocenes, in which the t-butyl groups are in different cyclopentadienyl rings of the ferrocene nucleus. Thus substitution of two hydrogen atoms by t-butyl groups in one cyclopentadiene ring of ferrocene increases the rate constant by a factor of 15, while the introduction of a further two t-butyl groups in the other ring increases the rate constant by a factor of 300. A similar relation can be traced also for ferrocenes with electron-accepting substituents. Evidently steric effects also play a decisive role in the kinetic stability of polysubstituted ferrocenes.

Analysis of data obtained shows that both electron-donating (alkyls) and electron-accepting (acetyl) substituents accelerate the decomposition of ferrocene. Here the introduction of one electron-accepting group lowers the thermal stability of ferrocene to a much greater extent than the introduction of any electron-donating group. Heteroannular polysubstituted ferrocenes with electron-accepting substituents are thermally the most stable. The introduction of an alkyl substituent into the cyclopentadienyl ring of nickelocene influences the reactivity to a lesser extent than in the case of ferrocene, the rate constant for the thermal decomposition of substituted nickelocene increasing by less than a factor of two.

The kinetic stability of the bisarene derivatives of chromium and molybdenum investigated hardly changes in the thermal decomposition reaction on passing from the diethyl to the triethyl and tetraethyl derivatives. This agrees well with the conclusion[13] that the influence of the alkyl substituent in the benzene ring of bisarene derivatives of metals on the average dissociation energy of the metal atom–ring bond is within the limits of experimental error.

Table 4. The influence of the substitutent on the rate of pyrolysis of metallocenes in closed and open systems.[34,36-38]

* V_{rel} is the ratio of the [pyrolysis?] rate constant to the rate constant for the decomposition of ferrocene at 550 °C.

3. The Influence of the Nature of the Cyclic π-Ligand

The reactivity of π-complexes of chromium is determined by the character of the ring linked to the metal atom. A comparative study has been made[42] of the kinetics of the thermal decomposition of the π-complexes of chromium with six-membered and five-membered cyclic π-ligands. It was shown that dibenzenechromium is less stable than chromocene. Thus dibenzenechromium and chromocene decompose at almost equal rates at 360° and 460 °C respectively (the rate constants are 0.35×10^{-3} and 0.48×10^{-3} s^{-1} respectively). It is known[16] that not only the average dissociation energy but also other thermodynamic characteristics of the metal–ligand bond dissociation ($\Delta\bar{G}$ and $\Delta\bar{S}$) diminish on passing from $(C_5H_5)_2Cr$ to $(C_6H_6)_2Cr$, the contribution of $\Delta\bar{S}$ to $\Delta\bar{G}$ being insignificant. Furthermore, these compounds decompose via different pathways: the radical pathway for $(C_2H_5)_2Cr$ and the molecular pathway for $(C_6H_6)_2Cr$. The latter pathway leads to the formation of chromium in an active state and to the autocatalytic acceleration of the decomposition of dibenzenechromium.

III. SURFACE REACTIONS IN THE PYROLYSIS OF ORGANOMETALLIC COMPOUNDS

1. The Spatial Localisation of the Reaction

Features characteristic of a homogeneous-heterogeneous process have been observed in the study of the pyrolysis of metallocenes[43] and bisarene derivatives of metals.[44] The rate of thermal decomposition of metallocenes of the iron triad (especially ferrocene and its alkyl derivatives) depends greatly on non-controllable changes in the state of the walls of the glass reaction vessel.

The metal-containing products of the pyrolysis of metallocenes exhibit an autocatalytic activity. The autocatalytic character of the decomposition of the iron subgroup metallocenes was noted above.[32,35] The rate constant for the pyrolysis of ferrocene on its own decomposition products is higher by three orders of magnitude than in clean glass vessels.[25]

The catalytic activity of the metal-containing solid phase segregated in the pyrolysis of metallocenes depends on the nature of the central metal atom. Pyrolytic osmium accelerates the thermal decomposition of osmocene to a greater extent than pyrolytic ruthenium accelerates the decomposition of ruthenocene, while pyrolytic iron is more active in the decomposition reaction of ferrocene than is osmium in the decomposition of osmocene. The catalytic activity of the pyrolytic metals in relation to the decomposition of ferrocene falls in the sequence osmium > iron > ruthenium.[27]

The solid products of the pyrolysis of vanadocene, chromocene, manganocene, cobaltocene, and nickelocene are less active and their catalytic effect is small and disappears during the experiment as a result of adsorption of cyclopentadiene on the active centres produced in the reaction. The absence of the autocatalytic acceleration in the thermal decomposition of the cyclopentadienyl derivatives of vanadium, chromium, manganese, cobalt, and nickel in clean glass vessels can be accounted for precisely by the decrease in the catalytic activity of the surface during the experiment.[34]

It has been shown[43] that, under static conditions, the heterogeneous decomposition of metallocenes on solid metal-containing products does not occur and the role of the heterogeneous processes reduces to initiating the gas-phase reaction, developing subsequently within the volume of the reactor. An analogous investigation of the surface effect in the pyrolysis of bisarene derivatives of metals[44] has demonstrated an appreciable dependence of the rate of reaction on both the nature and the area of the surface.

Coatings obtained by the pyrolysis of ditoluenechromium iodide, ferrocene, and carbonylruthenium chloride are the most active, accelerating the decomposition of the bisarene derivatives of chromium, molybdenum, vanadium by a factor of 30–50. The solid products of the pyrolysis of the diarene derivatives themselves and the nickel–carbon coating obtained by the decomposition of diisopropylnickelocene are less active coatings, accelerating the decomposition by a factor of only 3–5.

The rate of decomposition of the diarene derivatives of metals, except dibenzenechromium, depends to a large extent on the surface

area of the reaction vessel (Table 5). The effective rate constant for the decomposition of (ethylbenzene) (diethylbenzene)-chromium increases linearly with increase in the ratio of the surface area of the reactor to its volume.[37,44,45] The contribution of the homogeneous component to the overall process increases with increase in temperature and with decrease in the surface to volume ratio, while the contribution of the heterogeneous component actually falls under these conditions. The purely heterogeneous course of the process and a decrease in the kinetic stability of the diarene derivatives of metals have been observed when the thermal decomposition was carried out in a high vacuum.[45]

Table 5. The influence of the surface area on the rate constants for the pyrolysis of diarene complexes of metals in glass vessels.[37,44,45]

Compound	t, °C	S/v, cm^{-1}	$10^3 k$, s^{-1}

* "Packing" coated with pyrolytic chromium.

The kinetics of the heterogeneous thermal decomposition reaction of the diarenechromium π-complexes have been investigated in a stream of carrier gas[46,47] and also in closed and circulation systems.[48] In the kinetic region (305–350 °C), the order of the reaction changes from first to zero with increase in the OMC concentration, while in the diffusion region (360–600 °C) the reaction is first order. From the kinetic data presented,[48] one may conclude that the reactivity of the diarenechromium complexes changes little on passing from dibenzenechromium to its ethyl derivatives.

Thus the localisation of the reaction in space is determined by the experimental conditions on which depends the purely homogeneous, heterogeneous, or homogeneous-heterogeneous course of the process. Such conditions include the initial pressure and the concentration of the initial diarene derivatives of the metal,[45,48,49] the heterogeneous factor S/V (the ratio of the internal surface area of the reactor to its volume),[44,45] and the nature of the surface and the methods used to produce it.[44]

For the thermal decomposition of the diarene derivatives of chromium, molybdenum, and vanadium at the metal–ligand bond in a reactor of limited size with walls exhibiting a catalytic activity, a kinetic model has been proposed in which it is suggested that the reaction proceeds via a unimolecular mechanism complicated by phenomena involving the association of the OMC molecules or the formation of their complexes with the molecules of catalytic additives.[51] This model makes it possible to explain the experimentally observed dependence of the effective rate constant for the process on the initial pressure, the S/V ratio, the chemical activity of the surface of the reactor, and the degree of complex formation with the molecules of the catalytic additives.[52]

2. Adsorption Effects in Thermolysis

The high adsorption capacity of the OMC is widely known.[3,53] The adsorption of organometallic compounds and their decomposition products is one of the stages of the heterogeneous process influencing the rate and mechanism of the decomposition.

Two forms of adsorption have been observed by direct IR spectroscopic studies of the adsorption complexes of OMC[54-56] on surfaces modified by pyrolytic chromium: physical adsorption resulting from the ligand–surface interaction, chemical adsorption which is a consequence of the formation of a metal–surface or CO–surface (for OMC with carbonyl ligands) bond. On chemisorption, ferrocene forms charge-transfer complexes in the form of ferricenium[53,56] and ferrocenonium[56] cations.

A mechanism has been proposed for the catalytic decomposition of 1,1'-diethylferrocene on alumina involving its adsorption on the active surface centres with formation of the alkylferrocenium cation and its subsequent decomposition in the adsorbed state with segregation of an iron-containing solid phase having a polymeric structure.[57] The formation of σ- and π-complexes of cyclopentadiene following its adsorption on Group VIII metals has been observed spectroscopically.[58] The strong specific interaction of the surface chromium atoms, obtained by the decomposition of diarenechromium, with the six-membered rings of the substituted benzenes involving the formation of π-complexes has been demonstrated by gas chromatography.[59]

The influence of the adsorption of the OMC and of their decomposition products in the absence and presence of various additives on the rate of deposition and the properties of the resulting coating have been described in a number of studies.[60-64] The character of the intermolecular interaction of alkylferrocenes and (ethylbenzene) (diethylbenzene)chromium with the metallated and non-metallated surfaces under conditions approaching those in the thermal decomposition has been studied.[65] At temperatures above 200 °C on surfaces metallated by pyrolytic chromium, the contribution of the specific interaction of the diarenechromium molecules with the surface, leading to chemisorption, increases. Thus the isosteric heat of adsorption of (ethylbenzene) (diethylbenzene)-chromium on pyrolytic chromium at low degrees of coverages reaches 46 kcal mol^{-1}, while after the attainment of 20% coverage it falls to the limiting value of 27.5 kcal mol^{-1}. On the other hand, after its adsorption on quartz only non-specific adsorbate—adsorbent interactions (the isosteric heat of adsorption at 10% coverage is 1 kcal mol^{-1}) or weak interactions of the adsorbed diarenechromium molecules with one another (the isosteric heat of adsorption at a coverage above 10% is 5 kcal mol^{-1}) were observed. The following series based on the adsorption capacity of the compounds has been obtained from the heats of adsorption: (ethylbenzene) (diethylbenzene)chromium > ethylferrocene > ethylbenzene > benzene.[65]

Comparison of the adsorption capacities of ethyl- and butylferrocenes on quartz, pyrolytic iron, and chromium showed that the isosteric heats of adsorption at high coverages (starting from 20%) are similar (13.0 ± 0.5 kcal mol^{-1}), which is characteristic of physical adsorption.[65] Only at low coverages (5–10%) are strong specific interactions manifested between ethylferrocene (19.5 kcal mol^{-1}) and the most active centres on the surface metallated by pyrolytic iron, probably occurring with formation of charge-transfer adsorption complexes.

IV. MACROKINETICS OF THE THERMAL DECOMPOSITION

The study of the macrokinetics of the thermal decomposition of OMC has been undertaken in view of the practical interest in such compounds as sources of metallic and composite coatings.

In the decomposition of diarenechromium on a support in an open system at a constant rate of evacuation, the phenomenon of "peak" (maximum) rate of deposition of the coating, due to the change in the partial pressure of the OMC near the support owing to the increase in the concentration (pressure) of the volatile products liberted, has been observed.[3,6] The causes of the decrease in the rate of deposition are also the endothermicity of the thermal decomposition process and the decrease in the temperature of the support.[66-69]

There exist two types of conditions for the deposition of coatings from the vapour phase in the thermal decomposition of OMC[3,6,69-71]—monotonic and vibrational (including the conditions in a closed system)—which have been revealed by the changes in the pressure, the temperature of the support, and the rate of deposition of the coating. The vibrational phenomena and the causes of their appearance have been examined in detail.[3] The vibrational conditions lead to the appearance of a layered structure of the film with alternation of layers of the metal or metal carbide with different contents of carbon-containing products.

The kinetics of the growth of the layer of pyrolytic chromium in the decomposition of diarenechromium derivatives in a stream of an inert gas have been investigated[41] taking into account heat and mass exchange. The rate of growth was calculated with the aid of the model proposed by Patankar and Spalding[72] and Popov and Rabinovich[73] using the rate constants for the decomposition of the diarene derivatives of chromium in a stream of helium.[41] With increase in temperature in the deposition zone from 350° to 500 °C, the rate of growth of the chromium layer also increases, but the non-uniformity of the distribution along the length of the channel diminishes (the deviation from the uniform distribution increases from 2.6% to 36% respectively). With increase in the concentration of the diarene derivatives of chromium, the rate of growth also increases and the uniformity of the growing layer is improved. On the other hand, an increase in the flow rate of the gas mixture diminishes the rate of growth of chromium but the uniformity of its distribution along the length of the channel also improves. In order to attain high rates of growth of the coating, it is necessary to raise the concentration of the OMC introduced at a temperature in the deposition zone in the range 350°–400 °C and for the optimum flow rate of the gas mixture.

The influence of various factors (channel temperature, flow rate of gas mixture, concentration of the initial substance) on the distribution of the solid products of the pyrolysis of ethylferrocene along the length of the channel has been investigated analogously and the rates of growth of the layer of the iron-cross-linked polymer on the surface have been determined.[40] With increase in the pyrolysis temperature from 400° to 550 °C, an increase in the rate of growth and a decrease in the uniformity of the growing layer along the length of the channel are observed. An increase in the concentration of the ethylferrocene introduced leads to an increase in the rate of growth virtually without change in the uniformity of the growing layer along the deposition zone. An increase in flow rate of the gas mixture tends to decrease the rate of growth of the layer but improves significantly its uniformity (at flow rates of 1 and 3 litre min^{-2}, the deviation from uniformity at 400 °C is 8.4 and 0.1% respectively). The highest rate of growth of the coating combined with the best uniformity of the distribution is attained at 500 °C and for a flow rate of the gas mixture of 2 litre min^{-1}. These conclusions apply only to the given specific dimensions of the reactor, gas flow conditions, and the composition of the gas mixture.

V. THE MECHANISM OF PYROLYSIS

1. Thermal Decomposition Products and Pathways

The thermal decomposition of the π-complexes of transition metals is accompanied by the homopolar dissociation of the metal–ligand bond with formation of the metal and radicals or the metal and ligand molecules.[2,3] OMC whose ligands have an odd number of bonding electrons decompose via the radical pathway, while those having an even number of such electrons decompose via the molecular pathway.[64] The pyrolysis is usually a multistage process, the ease of the occurrence of which and the pathway followed are determined by the nature of the OMC, the metal–ligand bond dissociation energy, the ratios of this energy to the C–C and C–H bond dissociation energies in the ligand, the polarity of the metal–ligand bond,[2,3,6] and also the degree of shielding of the central metal atom by the ligands, i.e. by steric effects.[74]

A free radical mechanism, involving the homolytic cleavage of the metal–ligand bonds and the C–C and C–H bonds in the ligand, is usually proposed for the decomposition of the mononuclear cyclopentadienyl compounds of transition metals.

The main product of the non-extensive gas-phase pyrolysis of ferrocene is hydrogen, methane and carbon monoxide are formed from acetylferrocene, and ethane is formed from ethylferrocene. This agrees with the hypothesis that a hydrogen atom is initially abstracted from the ferrocene nucleus in the unsubstituted ferrocene and that the side chain (CH_3CO and C_2H_5) is split off from the cyclopentadienyl ring in the substituted ferrocenes.[25] The dependence of the yield of the main pyrolysis products of ferrocenes on the nature of the surface and on its area and also on the added inhibitors shows that the heterogeneous stages of the free-radical mechanism of the decomposition reaction are both the generation and destruction of the radicals.

The thermal decomposition of ferrocene in the condensed phase at relatively low temperatures is accompanied by the dissociation of the C–H bonds with formation of the pyrolysis product—biferrocenyl.[75] The same mechanism of the decomposition reaction—not at the metal—ligand bond but at the C–C and C–H bonds—has been proposed also for the decomposition of alkylferrocenes by electron impact.[76] At high temperatures, in the pyrolysis of ferrocene above 800 °C, the cleavage of the ring–metal atom bond is observed with formation of the cyclopentadienyl radical, which has been detected spectroscopically.[77] Indeed, cyclopentadiene has been found together with methane and ethylene in the products of the pyrolysis of ferrocene above 600 °C.[28]

The pyrolysis products of ruthenocene and osmocene have not been investigated. Only the existence of the dimeric forms of ruthenocene and osmocene in the gas phase has been established.[78] The main gaseous products of the pyrolysis of other metallocenes for low degrees of decomposition are cyclopentadiene, hydrogen, and methane.[33] The composition of the volatile products depends on the temperature and the degree of decomposition.

Apart from cyclopentadiene, naphthalene, and nickel, 9,10-dihydrofulvalene, which is the product of the recombination of the cyclopentadienyl radicals, has been found among the products of the pyrolysis of nickelocene[79] *in vacuo* under pulse conditions at 950 °C. The cyclopentadienyl dimer has also been detected[28] in the decomposition of cyclopentadienylcarbonylman- ganese. The main products of the decomposition of nickelocene in a stream of hydrogen[80] were cyclopentadiene, cyclopentene, and cyclopentane. The purity of the nickel segregated was 83–93%.

It has been suggested that the pyrolysis of metallocenes involves the abstraction of hydrogen from the cyclopentadienyl ring and the subsequent polyrecombination of the metal-containing radical. The metal-containing radicals formed are also capable of being dehydrogenated and of undergoing subsequent condensation, affording ultimately carbide-like structures.[2,32]

Apart from the metal-containing phases, substances have been detected in the pyrolysis products which appear as a result of the condensation of five-membered rings (ranging from the cyclopentadiene dimer to the pentamer) and also naphthalene, anthracene, phenanthrene, pyrene, and perylene.[32] Volatile products containing metal–carbon phases, tentatively assumed to be polymeric in nature, are also formed.[25,57]

The main reactions leading to the decomposition of unsubstituted metallocenes involve the cleavage of the ring–metal atom bond and the dehydrogenation of the metallocene, the contribution of the dehydrogenation reaction increasing in the sequences Cp_2Ni < Cp_2Co < Cp_2Fe and Cp_2Mn < Cp_2Cr < Cp_2V. The decrease in the contribution by the dehydrogenation reaction takes place in parallel with the decrease in the kinetic stability of the 3*d* metal metallocenes.[33]

The mechanism of the decomposition of the diarene derivatives of transition metals on heating[2,64,81-91] in a strong electric field,[92] in a high-frequency discharge,[93] and under the influence of electron impact[94] has been discussed widely in the literature. It is suggested that the process takes place almost quantitatively via a molecular mechanism involving the abstraction of ligands and the segregation of the metal.[2,3,64]

Gaseous compounds (hydrogen, methane, and C_2–C_5 paraffinic and olefinic hydrocarbons), liquid compounds (benzene, and ethyl-, diethyl-, and triethyl-benzenes), and solid compounds (biphenyl, terphenyl, ethyldiphenylcyclohexanes, carbon, metal carbides, and the metal) have been found in the products of the thermal decomposition of the diarene derivatives of vanadium, chromium, and molybdenum under static conditions. The main process involving the decomposition of the metal–ligand bond is accompanied by secondary ligand decomposition reactions[95,96] via catalytic dehydrogenation stages[87,88,95] and the subsequent formation of carbon-containing condensed products. It also proceeds via the elimination of methylene from the ligand side groups (for example, ethylbenzene), whose subsequent reaction leads to the formation of methane, carbon, and hydrogen.

In a flow system,[87,88,97] the primary ligand conversion reaction is also their dehydrogenation accompanied by the formation of aryl radicals whose recombination leads to the formation of biphenyls and other condensed substances which are dehydrogenated to carbon in the presence of the metal. Graphite has been detected in the condensation products by electron diffraction.[66] The amount of gaseous products in an open system is smaller by an order of magnitude than in a static system, the only gaseous product being hydrogen.

Thermographic and gas-chromatographic studies have shown[81] that the thermal decomposition of dibenzenechromium at the metal-ligand bond at reduced pressures takes place stepwise with the consecutive elimination of ligands, the energy of the abstraction of the first ligand being greater than that of the second.

Together with the preferential molecular decomposition of diarene derivatives of metals at the metal–ligand bond, radical decomposition takes place to some extent, proceeding via the $\pi-\sigma$ rearrangement of the initial compound[97,98] with formation of a hydrogen atom and aryl radicals. The formation of aryl radicals from the diarene derivatives of chromium, vanadium, and molybdenum has been demonstrated by their fixation on anthracene and ferrocene. A radical chain mechanism of the pyrolysis of di(ethylbenzene)chromium has also been proposed by Dudorov et al.[99]

2. Elementary Steps in the Thermal Decomposition Reaction

The common features of the radical and molecular mechanisms of the thermal decomposition of OMC proceeding with retention of the orbital symmetry (the Woodward–Hoffmann rule) and of the total spin of the system (the Wigner–Witmer rule) have been examined in detail by Razuvaev and co-workers.[2,3] A common feature of the radical and molecular decomposition pathways from the standpoint of the conservation rules, is that the most favourable activated state of the OMC molecule is the OMC triplet dissociating via the metal–ligand bond with formation of either a pair of radicals in the triplet state or ligand molecules and the metal in the excited triplet state.

A quantum-chemical description of the elementary step in the thermal decomposition at the metal–ligand bond has been achieved for diarenechromium[3,6,100] within the framework of the method of one-electron molecular orbitals. The dissociation of the metal–ligand bond can occur in an OMC molecule in an excited electronic state, arising when a light quantum is absorbed or as a result of the interaction with the medium. For dibenzenechromium, the energetically most favourable course of this reaction is via the triplet state of the OMC molecule with formation of the arene in the triplet state and of a chromium atom in a state other than the ground state. The possible pathways leading to the molecular decomposition of diarenechromium with migration of energy and the formation of the corresponding multiplet states have been examined[2] (p.105). The formation of excited chromium atoms imparts surface activity to the solid phase formed, which is manifested by the autocatalytic character of the decomposition of dibenzenechromium, improved adhesion of the chromium segregated to the material of the support, and its increased adsorption capacity. The decomposition of the arene in the triplet state (for example, to a carbene) induces secondary reactions.[3]

The metals segregated (especialy W, Mo, Re, Cr, and V) are capable of being coordinated to olfefins, arenes, and carbenes, forming intermediate complexes which undergo further reactions,[3] leading ultimately to metal carbide structures.[101-103] For example, carbene complexes can disproportionate to a carbyne complex with a metal–carbon triple bond and further to methane and the $-M\equiv C-$ carbide species.

The possibility of the decomposition of the OMC triplet into a singlet molecule (toluene from diethylbenzenechromium) and a carbene complex of the metal via the scheme

$$(CH_3CH_2C_6H_5)_2M \rightarrow 2CH_3C_6H_5 + CH_2{:} \rightarrow M \leftarrow {:}CH_2 \rightarrow$$
$$\rightarrow CH_2{-}M\equiv CH \rightarrow CH_4 + {-}M\equiv C{-}$$

has not been ruled out.[3,64]

The heterogeneous decomposition of the OMC of *d* metals on the surface in accordance wit the spin conservation rule (an analogue of the Wigner rule) takes place on active centres (AC) having unpaired electrons.[3] Such centres may be absorbed metal atoms, whose role is similar to that of free radicals in the homogeneous decomposition.

The decomposition of ferrocene with formation of iron in the ground state is possible when triplet AC, which may be chemisorbed iron atoms, are present on the surface:[3,63]

$$Fe(C_5H_5)_2(S) + AC(T) \rightarrow (C_5H_5)_2(S) + Fe(^5D_4) + AC(T),$$

where S is the singlet, T the triplet, and $^5D_4$ the ground state of iron.

The chemisorbed iron atoms, which are effective dehydrogenation catalysts, promote the formation of iron-cross-linked polymers, which has been frequently observed experimentally.[25,97] By suppressing the dehydrogenation reaction by adding hydrogen, it has been possible to obtain α-iron from 1,1'-diethylferrocene,[57] nickel from nickelocene,[80] and ruthenium from ruthenocene.[2]

Either the chemisorption of atomic chromium, or the cleavage of the benzene ring, or the dehydrogenation of the latter are necessary for the retention of the multiplicity of the OMC–AC system in the heterogeneous decomposition of the diarene derivatives of chromium.[63] In the presence of a catalyst (iodine, bromine, and sulphur),[3] which removes the spin prohibition, the decomposition of diarene-chromium proceeds with segregation of pure chromium and ethylbenzene without the cleavage of the latter.

- - - o 0 o - - -

The above analysis of the literature data revealed regularities in the variation of the kinetic parameters of the mechanism of the thermal decomposition of the test compounds as a function of the nature of the metal and the ligand and also the reaction conditions. The rate and mode of the thermal decomposition of the OMC investigated are determined by the nature of the reactant, mainly by its electronic temperature, the metal–ligand bond dissociation energy, and the ratios of this energy to the C–C and C–H bond dissociation energies in the ligand. Nor are there any grounds for the exclusion of the influence of steric factors on the kinetic thermal stability of the test compounds. The steric effect of the ligand on the stability of the complex, especially its quantitative aspect, have not been described in the literature. Nevertheless, in estimating the stability of the compound, it is essential to take into account also the steric effect together with the electronic influence.[104]

The decomposition reactions of the classes of comounds considered have not been found to be the same. A free radical pyrolysis mechanism via the homolytic cleavage of the metal–ligand bonds and the C–C and C–H bonds in the ligand has been proposed for mononuclear cyclopentadienyl compounds of transition metals. Predominantly molecular decomposition, involving the dissociation of the ring–metal bond or the elimination of a carbene and its stabilisation via coordination to the segregated metal and subsequent conversion of the carbene complex via known schemes, is characteristic of diarene compounds. The π–σ rearrangement, leading to the formation of radicals takes place to a slight extent in the decomposition of the diarene derivatives of metals.[105] It may be that the C–H bond dissociation process in the metallocenes is also preceded by the π–σ rearrangement, which has been detected for ferrocene by NMR.[106] However, from the standpoint of the conservation rules for the orbital symmetry and the total spin of the system, common features are observed in the radical and molecular mechanisms of the decomposition and also an analogy between the homogeneous and heterogeneous decomposition pathways.[3]

In recent years, a new field of study has begun to develop—the study of the adsorption of OMC and their volatile decomposition products on various surfaces, which determine the character of the interaction of the test compounds with the surface, and also the establishment of a correlation between the structure of the OMC and its adsorption capacity in relation to the metal-containing solid products of its own decomposition. However, these studies have only just begun, the range of compounds investigated is inadequate, and the nature of the adsorption complexes obtained has not been established. The importance of expanding the adsorption investigations is dictated by the fact that adsorption is one of the stages in the heterogeneous-catalytic decomposition which makes a definite contribution to the kinetics of the overall process.

In conclusion, it must be emphasised that the range of kinetic studies on the thermal decomposition of OMC is fairly narrow. Furthermore, the use of OMC is very promising in practice. The needs of modern technology for new materials in fact make it necessary to develop further the theoretical and experimental studies designed to determine the kinetics of the thermal decomposition of various OMC, whose knowledge is essential for the optimisation of the process leading to the formation of inorganic coatings and materials.

Oxidative Chlorination of Aliphatic Hydrocarbons and Their Chloro-derivatives

Yu.A.Treger, V.N.Rozanov, M.R.Flid, and L.M.Kartashov

The problems of the thermodynamics, the selection of catalysts, and the kinetics and mechanisms of the oxidative chlorination reactions of aliphatic hydrocarbons and their chloro-derivatives and the technological arrangement in the reactor unit are considered in relation to C_1-C_3 hydrocarbons.
The bibliography includes 154 references.

I. INTRODUCTION

Oxidative chlorination (or oxychlorination) is the hydrocarbon chlorination reaction occurring with participation of an oxidising agent, which is usually oxygen. The chlorinating agent is as a rule hydrogen chloride, the need to use large amounts of which has in fact been the cause of the development of the oxychlorination method.

The oxychlorination of a wide range of hydrocarbons and their chloro-derivatives has been described in the literature. The oxychlorination is carried out in the gas phase in the presence of a heterogeneous catalyst and also in the melt and in a catalyst solution.[1-5] Since it is most widely used, attention is concentrated in the review on the first of the above procedures. A number of studies have been devoted to oxychlorination in salt melts,[6-9] while oxychlorination in solutions of catalytically active salts has been described in detail in recently published reviews[10,11] and dissertations.[12,13]

Many publications have been devoted to the gas-phase heterogeneous-catalytic oxychlorination of hydrocarbons and their chloro-derivatives, covering many aspects of this problem[14,15] or its individual aspects, such as the selection of catalysts and the mechanism of their action,[16,17] the kinetics and mechanisms of the reactions,[18] the relevant technology and economics, and a review of the patent literature.[19,20]

The present article is devoted to the consideration of the current state of the problems of the thermodynamics, the selection of catalysts, and the kinetics and mechanisms of the oxychlorination reactions as well as the technological arrangement for the processes, mainly in relation to C_1-C_3 hydrocarbons and their chloro-derivatives, since the fundamental questions of theory and practice have been dealt with in studies on the oxychlorination of these compounds.

In terms of the mechanism, all the oxychlorination reactions can be subdivided into two large groups: (1) reactions which proceed via the intermediate oxidation of hydrogen chloride by oxygen to chlorine, which chlorinates the organic substrate; (2) reactions which do not require the preliminary oxidation of hydrogen chloride to chlorine. The substitutional oxychlorination reactions of alkanes (and chloroalkanes) belong mainly to the first group, whilst the second group includes the additive oxychlorination reactions of alkenes (and chloroalkenes):

$$2HCl + 0.5O_2 \rightleftarrows Cl_2 + H_2O,$$

$$RH + Cl_2 \rightarrow RCl + HCl,$$

$$\rangle C{=}C\langle + 2HCl + 0{,}5O_2 \rightarrow \rangle \underset{Cl\ Cl}{C{-}C}\langle + H_2O \quad .$$

Gel'bshtein[18] placed the chlorination of alkenes in a separate group:

$$\rangle C{=}C\langle_{H} + HCl + 0.5O_2 \rightarrow \rangle C{=}C\langle_{Cl} + H_2O \quad .$$

The reaction takes place at temperatures at which hydrogen chloride is oxidised and alkanes undergo substitutional oxychlorination, but there is no chlorine in the gas phase. It may be that the reaction proceeds via additive oxychlorination with subsequent dehydrochlorination. The elimination of hydrogen chloride is observed in high-temperature oxychlorination.[13] The additive oxychlorination of alkenes occurs at temperatures up to 300 °C (there is virtually no oxidation of hydrogen chloride to chlorine under these conditions), while the substitution oxychlorination of alkenes and alkanes takes place at temperatures above 350 °C.[1,14,15]

Processes involving the oxidative chlorination of ethylene to dichloroethane[1,14,20] and of ethylene, propene, and their chloro-derivatives to carbon tetrachloride, trichloroethylene, and tetrachloroethylene[21,22] have found extensive industrial application. The development of an oxychlorination technology in melts of metal chlorides and oxide chlorides has also been reported,[23,24] but there has been no information about its practical exploitation, which indicates difficulties in the industrial application of such a process.

We shall consider the individual aspects of the oxychlorination reactions.

II. THERMODYNAMICS

The reversible oxidation reaction of hydrogen chloride (the Deacon reaction) is of greatest interest from the thermodynamic point of view. The problems concerning the thermodynamics of this reaction have been examined in fair detail in earlier reviews.[1,14] The constants K_p and the degrees of conversion of HCl and O_2 decrease appreciably with increase in temperature. According to Arnold and

Kobe's data,[25] the following expression relating lg K_p to temperature is valid in the temperature range 200–2000 °C: lg K_p = 5881.7/T–0.93035 lg T + 1.3704 × 10^{-4} T–1.758 × 10^{-8} T^2–4.1744, or in a simplified form: lg K_p = 6104.0/T–7.0994. When the Deacon reaction and the chlorination reaction take place simultaneously, the reaction equilibrium shifts as a result of the consumption of chlorine, which may entail the virtually complete conversion of hydrogen chloride.[1]

III. CATALYSTS

Numerous studies have been devoted to the selection of new and the improvement of existing catalytic oxychlorination systems.[1,14,15] They concern the question of the choice of the most active and selective catalytic compositions, carriers, and methods for the preparation of catalysts and the stabilisation of their operation. Despite a number of advances achieved on these lines, copper(II) chloride, proposed as the catalyst for the oxidation of hydrogen chloride as early as the XIXth century, still remains the main constituent of the catalysts for the Deacon and oxychlorination reactions.

It is most likely that hydrogen chloride is oxidised in accordance with Scheme 1, which includes copper reduction and oxidation stages:[26,29]

Scheme 1

$$2CuCl_2 \rightleftarrows Cu_2Cl_2 + Cl_2 \text{ (gas)},$$
$$Cu_2Cl_2 + 0.5O_2 \text{ (gas)} \rightleftarrows CuO \cdot CuCl_2,$$
$$CuO \cdot CuCl_2 + 2HCl \text{ (gas)} \rightleftarrows 2CuCl_2 + H_2O \text{ (gas)}.$$

It has been suggested[27] that a peroxy-compound is formed in the reaction with oxygen in order to account for the observed second-order of the reaction with respect to copper monochloride:

$$2CuCl_2 \rightleftarrows 2CuCl + Cl_2 \text{ (fast)},$$
$$2CuCl + O_2 \rightarrow Cu_2O_2Cl_2 \text{ (slow)},$$
$$Cu_2O_2Cl_2 + 4HCl \rightarrow 2CuCl_2 + Cl_2 + 2H_2O .$$

The direct interaction of bivalent copper chloride with oxygen is unlikely in view of the positive value of ΔG for this reaction.[18,26-29]

Gel'bshtein and co-workers[30-32] did not consider the decomposition of bivalent copper chloride with evolution of chlorine, assuming that chlorine is evolved in two steps: in the adsorption of oxygen and in its subsequent interaction with the adsorbed hydrogen chloride (Scheme 2):

Scheme 2

$$[Cu_mCl_n] + 2HCl \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} [Cu_mCl_n \cdot 2HCl] \text{ (slow)},$$
$$[Cu_mCl_n \cdot 2HCl] + O_2 \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} [Cu_mCl_n \cdot 2HCl \cdot O_2] \text{ (slow)},$$
$$[Cu_mCl_n \cdot 2HCl \cdot O_2] + 2HCl \overset{k_3}{\rightleftarrows} [Cu_mCl_n] + Cl_2 + 2H_2O \text{ (fast)},$$
$$[Cu_mCl_n \cdot 2HCl] + Cl_2 \overset{k_4}{\rightleftarrows} [Cu_mCl_n \cdot 2HCl \cdot Cl_2] \text{ (fast)}.$$

One of the causes of the high catalytic activity of copper is its capacity for complex formation. It has been assumed that the interaction with oxygen does not go as far as the formation of copper oxide chloride but stops at the chemisorption stage. The oxidation reduction transformation of the copper cation in the Deacon reaction then proceeds in one stage – chloride ions transfer electrons to the absorbed oxygen via the copper cations, i.e. via a relay mechanism. Nevertheless, in the latest studies by the same workers[18,33] preference was given to the mechanism postulating the decomposition of $CuCl_2$ with evolution of chlorine.

The formation of univalent copper in catalytic systems has been established by the majority of investigators[26-29,33,34] and in many studies[26-29,33] the stages of Scheme 1 were investigated separately. Scheme 1 can serve as a good illustration of one of the first theories of catalysis, which explains the mechanism of the catalytic action by the formation of intermediate compounds, which are then converted into the reaction products with regeneration of the initial catalyst.

According to a series of data,[31,32,35-37] the first stage of the oxychlorination reaction of hydrocarbons, namely the oxidation of hydrogen chloride to chlorine, takes place at the same rate in the presence and absence of the hydrocarbon. Since the subsequent chlorination can proceed also without the participation of the catalyst, the main task in the development of a catalytic system for these reactions is the selection of the active component for the first stage.

Systems consisting of a carrier impregnated with copper chlorides and added chlorides of alkali, alkaline earth, lanthanide, and more rarely, other elements are most widely used as catalysts for the oxychlorination of methane.[38,39] A catalyst based on chromium oxide is also frequently employed.[40] An attempt has been made to combine the two familiar catalysts in the structure of the copper-chromium spinel $CuCr_2O_4$.[41,42] Catalysts based on iron[43] and its mixtures with copper, chromium, and alkali metals have also been described.[44] Rarer catalytic systems are also used: platinum, ruthenium, and potassium complexes on a carrier[45] and a mixture of palladium and lithium chlorides with added calcium, sodium, and potassium chlorides.[46]

The activities of the basic catalysts for the oxychlorination of methane enumerated above have been compared[42] and it has been shown that the most active catalyst is copper(II) chloride mixed with potassium and lanthanide chlorides. The attempts to bind copper in the spinel structure ($CuAl_2O_4$, $CuCr_2O_4$) and to use involatile copper compounds (CuF_2) were unsuccessful, since, under the conditions of an excess of hydrogen chloride and an elevated temperature, all these compounds are gradually converted into copper(II) chlorides.

It has been suggested[47] that copper be used in the form of the oxide, sulphate, nitrate, phosphate, stannate, plumbate, chromate, molybdate, vanadate, etc. in a mixture with compounds of the lanthanide elements. However, under oxychlorination conditions one may expect their gradual conversion into chlorides, so that the real catalytic system would not then differ from the traditional one.

Communications concerning the possibility of the oxychlorination of methane at relatively low temperatures (less than 200 °C) by using colloidal silicon dioxide as the carrier have appeared recently.[48-50] A salt melt without a carrier is frequently used for the oxychlorination of methane.[8,9,23,24,26]

It has been shown[15] that catalysts for the oxidative chlorination of ethane hardly differ from the systems used for the oxychlorination of methane.

Under the oxychlorination conditions, the mixture of the chlorides of copper, alkali metals, and a number of promoting agents is present as a rule on the carrier surface in the molten state.[1,14,15,30,35,51] It is noteworthy that the appearance of univalent copper in the system as well as the introduction into the latter of alkali metal chlorides reduces the melting point of the eutectic. This results in the formation of complexes having different chemical compositions[26-52] – $KCuCl_3$, K_2CuCl_4, K_2CuCl_3, and $K_2Cu_2Cl_6$. Lanthanide metal chlorides also greatly lower the melting point of copper(II) chloride.[53]

The melt of the active mass of copper and potassium chlorides on carriers of different chemical nature with different specific surfaces forms isolated inclusions having a thickness equivalent to 10–200 molecular layers in the extensive pore system of the carrier.[51,54,55]

Porous substances with a wide range of specific surfaces (from 0.5–1 to 200–500 $m^2\ g^{-1}$) are used as carriers.[1,14,15] The question of the selection of the carrier is fairly specific. As a rule carriers with larger surface areas are used to effect the process in a fluidised catalyst bed rather than with a stationary bed. This is because

coarsely porous carriers having a limited surface area, used to reduce the rate of side reactions, retain the melt poorly, which leads to the sticking together of the catalyst particles when reactors with a fluidised bed are employed and appreciably impairs the process parameters.[56,57]

It has been shown[30-32,35] that hydrogen chloride is oxidised in the bulk of the salt melt. Aglulin[35] believes that the chlorination proceeds, up to 425 °C, mainly via a heterogeneous mechanism on the surface of the salt melt, while at a higher temperature the process takes place predominantly via a heterogeneous–homogeneous pathway. Another worker[58] believes that the chlorination occurs mainly homogeneously in the gas phase.

An important factor in the choice of the oxychlorination catalyst is the minimisation of side reactions involving the extensive oxidation of alkanes and the oxychlorination reaction products (chloroalkanes) to carbon oxides. The side reaction is believed to be a catalytic process[58] and it is assumed that both the carrier surface free of the salt melt[54] and the surface of the salt inclusions[59] are responsible for the occurrence of this reaction.

It appears essential to consider the individual questions concerning the use of catalysts with copper chlorides in oxychlorination processes.

At the elevated temperature (250–500 °C) normally used for oxychlorination, copper chlorides are appreciably volatile: $\lg p(\text{mm Hg}) = -3550T^{-1} + 6.55$.[60] Carriers with various physicochemical properties are used and alkali metal chlorides forming complexes with the copper salt are introduced into the system[61] in order to reduce the volatity of the active components. All these procedures make it possible to lower by 1–2 orders of magnitude the volatility of copper and to form catalysts whose operation is stable.

The use of carriers and additives stabilising copper(II) chloride makes it possible, according to Kartashov et al.,[62] to retain the activity of the catalyst during 400–500 days of continuous operation. The problem of the loss of active components is especially acute when the process is carried out in a stationary bed where local superheating of the catalyst occurs. The volatilisation of copper chlorides can alter the catalyst selectivity as a function of time as a result of the change in the Cu:K ratio in the active salt mass.

Catalysts in which the copper cations are strongly adsorbed within zeolite pores[63,64] or are chemically bound in the catalyst structure (spinels)[41] are used to reduce the volatility of copper, but such catalysts have no advantages over the usual catalysts because of the gradual change in the catalyst composition under the influence of hydrogen chloride and the high temperature.[42,65]

The question of the influence of a number of other variable-valence metals on the catalytic activity of systems based on copper compounds is of great interest. These are in the first place iron, chromium, and nickel compounds, which have been patented as activators of the above catalytic system and individual oxychlorination catalysts[1,14,15] which can also be incorporated in the catalyst as a result of the metal exchange between the reactor surface and the catalyst.[66,67] The results of studies of the influence of these additives on the activity and stability of the operation of the catalyst based on copper chlorides are contradictory, especially as regards the iron compounds. In the oxidative chlorination of dichloroethane, the introduction of chromium, nickel, and iron chlorides into the catalyst increases the conversion of the reactants and raises the yield of the target products–trichloro- and tetrachloroethylenes[68]–by a factor of 1.5–2.

In the oxidative chlorination of methane,[69] there is a sharp increase in the yield of carbon monoxide in proportion to the increase in the content of iron(III) chloride in the catalyst. The degrees of conversion of methane and oxygen do not increase while that of hydrogen chloride diminishes, because hydrogen chloride is evolved in the combustion of chloromethanes. The introduction of chromium and nickel chlorides has almost no effect on the activity of the catalyst.

The most marked increase in the rates of the Deacon and substitutional oxychlorination reactions is observed when lanthanide chlorides are added to copper and potassium chlorides.[42]

Copper(II) chloride is the dominant catalyst in the additive oxychlorination reactions[1,14,15,19,70-72] which do not include the hydrogen chloride oxidation stage. The catalytic process can be illustrated schematically in relation to the oxychlorination of ethylene (Scheme 3):

Scheme 3

$$2CuCl_2 + C_2H_4 \rightarrow C_2H_4Cl_2 + Cu_2Cl_2 ,$$
$$Cu_2Cl_2 + 2HCl + 0.5O_2 \rightarrow 2CuCl_2 + H_2O .$$

The formation of univalent copper has been confirmed by X-ray diffraction data for the catalyst.[73]

In view of the wide-scale industrial use of the oxidative chlorination of ethylene, the choice of the appropriate catalysts is of great practical interest. Almost all the catalysts include, apart from copper(II) chloride, various additives, which depend on the process temperature. Allen and Clark[16] showed that the activity of the catalyst for the oxychlorination of ethylene increases appreciably when yttrium chloride is added. The useful life of the catalyst also increases under these conditions. Alumina is used preferentially as the carrier, but activated charcoal, silica gel, aluminosilicate, zeolites, and other carriers can also be used.[1,14,15]

The oxychlorination of ethylene in the presence of the catalyst with copper(II) chloride deposited on different carriers, including alumina or activated charcoal, takes place at 210–280 °C and the yield of 1,2-dichloroethane is at the level of 99%.[15,17] An increase in temperature promotes the acceleration of the substitutional oxychlorination and dehydrochlorination, which results in the formation of considerable amounts of vinyl chloride, polychloroethanes, and di-, tri-, and tetra-chloroethylenes.[1,74]

The choice of the carrier is very important for the activity of the catalyst. On the basis of the analysis of literature data, it has been concluded[1,14,15,20] that the greatest activity in the temperature range 200–260 °C is shown by catalysts based on alumina. An increase in temperature lowers the selectivity in the formation of dichloroethane and even leads to the loss of activity by the catalyst. It has been shown[75-78] that the activity and selectivity of the action of the catalyst depend to a great extent on the phase composition of the alumina. The use of η- or κ-Al_2O_3 [77] leads to an almost 100% yield of dichloroethane at 200–240 °C. According to Flid et al.,[75] when the process is carried out in a "fluidised" catalyst bed, it is useful to employ microspherical alumina containing the α-, θ-, and γ-forms in the proportions 1:2:4.

The content of the θ-phase of Al_2O_3 in the carrier plays a major role. The deposited copper(II) chloride reacts with it to form copper aluminates with spinel structures. The copper then exists on the surface both as $CuCl_2$ and as hydroxide chlorides, whose structure depends on the carrier. It is claimed[78] that the increase in the activity of the catalyst is associated with the increase in porosity, the content of the θ-phase, and the number of basic centres on the carrier surface.

The question of the effect of catalyst poisons on the ethylene oxychlorination catalyst is of great practical importance.[79] This problem has so far been inadequately investigated, but there are data showing that the activity of the catalyst decreases when sulphur compounds enter this system.[80,81]

It is claimed[80] that the deactivation is associated with the formation of the inactive copper sulphate and hence with the decrease in the content of copper(II) chloride in the catalysts, which leads directly to a decrease in activity.

The authors of the present review hold another view. It has been established[81] from IR spectroscopic data that copper sulphate is not formed under the reaction conditions. The impairment of the process parameters is associated, in our view, with the reduction of Cu^{2+} to Cu^{+} by sulphur dioxide and the reduction of copper(II) chloride by ethylene, which competes with the above reaction, and also with the blocking by the sulphur-containing ions of the centres on the carrier surface participating in the reaction. It has been suggested that the surface sulphur-containing structures be removed in order to restore the activity of the catalysts.[81]

It is of great interest to carry out the oxychlorination of ethylene at elevated temperatures (350–500 °C). Under these conditions, the process is performed in the presence of catalysts with the traditional mixture of the catalytically active components. The main difference consists in the employment of carriers more resistant to the action of high temperatures than alumina. They include primarily silica gel, α-alumina, and celite.[82] The possibility of using catalysts containing lanthanide metal chlorides together with copper and alkali metal chlorides has been considered.[82] The selectivity in the formation of vinyl chloride in the oxychlorination of ethylene at such temperatures reaches 92%.[83] The employment of the $CuCl_2-KCl$ catalyst on silica gel and of the $FeCl_3-KCl-La_2O_3$ catalyst on celite at 500 °C makes it possible to achieve a yield of vinyl chloride up to 50%.[15] At lower temperatures (370–430 °C) and when the $CuCl_2-KCl-PrCl_3$ catalyst on microspherical silica gel is used, the main products are tri- and tetra-chloroethylene (selectivity up to 80%).[84]

Vinyl chloride can be obtained also at temperatures in the range 200–300 °C by using primarily catalysts containing platinum group metal compounds together with copper and iron.[15,20,85-87] The presence of copper and iron compounds in the catalyst is evidently essential for the oxidation of the platinum group metals (Scheme 4):[87]

Scheme 4

$$C_2H_4 + PdCl_2 \rightarrow C_2H_3Cl + Pd + HCl\ ,$$
$$Pd + 2CuCl_2 \rightarrow PdCl_2 + 2CuCl\ .$$

The method of preparation of the catalyst has a great influence on its properties, including the selectivity and stability of its operation.[87] It has been established in the synthesis of the $Pd-Fe/Al_2O_3$ catalytic system that the optimum stability of operation of the catalyst is observed when the α- and θ-forms are present in the Al_2O_3,[87] which agrees with the data on the low-temperature oxychlorination described above.

The catalyst activity series for the formation of vinyl chloride is Pd > Rh > Pt > Ru; the highest selectivity has been achieved using palladium. A disadvantage of the catalysts described is the limited conversion of ethylene.

The main pathway in the oxychlorination of chloroethanes and chloroethylenes involves the formation of tri- and tetra-chloroethylenes.[1,15,20] The oxychlorination of chloroethylenes can be carried out in the presence of the catalyst described above at 200–300 °C and involves the addition of chlorine to the double bond.[1,88] An increase in the oxychlorination temperature to 400 °C makes it possible to obtain also tri- and tetra-chloroethylenes with fair selectivity (to an extent greater than 80%).[84,88] Tetrachloroethylene also can be obtained[89] by oxidising tetrachloroethane or other chloroethanes with a high chlorine content at 390 °C in the presence of the traditional oxychlorination catalyst.

Under the conditions of the high-temperature oxychlorination of chlorohydrocarbons of the ethane–ethylene series, the carrier has a much smaller influence on the properties of the catalyst. This applies especially to the process in a stationary catalyst bed. It has been shown[90] that the use of carriers greatly differing in chemical composition (Al_2O_3, SiO_2, $Al_2O_3-SiO_2$) and also in the specific surface and porosity in the oxychlorination of 1,2-dichloroethane leads to similar results as regards the conversion of the reactants and the selectivity in the formation of the target products.

Two main pathways must be distinguished in the oxychlorination of C_3 hydrocarbons: the synthesis of allyl chloride from propene and of organochlorine solvents (tri- and tetra-chloroethylenes, carbon tetrachloride) from different types of raw material.

In in the oxychlorination of propene in the temperature range 150–350 °C in the presence of the copper-based catalyst, the main product is 1,2-dichloropropane.[1,14,15,91] An increase in temperature leads to the appearance of appreciable amounts of allyl chloride in the products, but it also greatly accelerates the extensive oxidation side reactions and the loss of copper.

The principal procedure for increasing the selectivity in the formation of allyl chloride at relatively low temperatures (150–300 °C) involves the use of catalysts containing compounds of platinum group metals and tellurium. The possibility of the selective formation of allyl chloride at 180–240 °C in the presence of a catalyst containing platinum group metals on a carrier has been indicated.[90] The catalytic activity of the metals varies as follows: Rh > Pd > Pt > Ir > Ru; activated charcoal is the best carrier. It has been shown that the use of a mixture of platinum group metal, copper, and lanthanide chlorides[15,87,92] greatly increases the rate of reaction. The selectivity in the formation of allyl chloride reaches 90%. The mechanism of the action of the catalyst is analogous to that described for ethylene (see Scheme 4). The presence of platinum group metals in the catalyst virtually rules out the formation of 1,2-dichloropropane and the main side product is isopropyl chloride. The stability of the operation of this catalytic system is ensured by alkali metal chlorides, the best of which is sodium chloride[87,92] which does not impair the selectivity of action of the catalyst.

The use of tellurium compounds ensures a selectivity in the formation of allyl chloride at the level of 90% and above.[93] The presence of alkali metal chlorides lowers the selectivity and it is desirable that the catalyst should contain platinum group metal compounds in order to increase it.[94]

The oxychlorination of C_3 hydrocarbons and their chloro-derivatives is frequently carried out in order to obtain organochlorine solvents, traditional and modified catalytic systems being used for this purpose at temperatures which are as a rule above 350 °C. The reaction product consists of a complex mixture of hydrocarbons, the target products being tri- and tetra-chloroethylenes and carbon tetrachloride.[13,63,95]

IV. THE KINETICS AND MECHANISMS OF THE OXYCHLORINATION REACTIONS

It has been established in the course of a whole series of investigations[18,31,35,36] that the high-temperature oxychlorination proceeds via a stage involving the oxidation of hydrogen chloride to chlorine. The mechanism of the oxidation of HCl was described in the Section dealing with the catalysts and the kinetics of this reaction have been fairly well investigated.[18,29,30,etc] One can only state that the probabilities of the possible type of mechanisms of this reaction have been estimated[18] in accordance with the available experimental data.

Despite the definite differences between the postulated mechanisms of the Deacon reaction and even the disagreement concerning the region where it occurs (on the surface or in the bulk of the melt),[27,29,35] the rate of reaction r is described in all cases by equations of the following type after some simplification:

$$r = \frac{k\, p_{O_2}}{p_{Cl_2}}\ .$$

Until recently, the kinetics and mechanism of the oxychlorination of methane had been little investigated. It was established[96] that the chlorination of methane in the melts occurs at higher rates than the thermal process, the authors suggested that this takes place as a result of the iniation of the gas-phase process by the chlorine atoms evolved from the surface of the melt. This view was questioned[97] on the grounds that the rate of evolution of chlorine in the thermal decomposition is much lower than the rate of chlorination and also because of the difference between the selectivities in the gas-phase and catalytic chlorinations. This suggests that the chlorination of methane takes place predominantly directly in the melt.[97]

Other workers,[18,31,32,35] who have studied the kinetics and mechanism of the methane oxychlorination reaction in greatest detail, hold an analogous view. It has been shown that the oxidation of HCl takes place throughout the bulk of the melt with participation of $CuCl_2$ (see Scheme 2) regardless of the subsequent chlorination of methane, which is indicated by the same kinetics being observed when the reaction is studied in the presence and absence of methane.

It is believed[31,32,35] that the chlorination of methane up to 425 °C takes place on the surface of the melt predominantly via the interaction of methane with a polyhalide complex of the type ZCl_3, formed when molecular chlorine is chemisorbed by metal chlorides, Z being the free catalytic centre:

$$ZCl + Cl_2 \rightleftarrows ZCl_3 (ZCl \cdot Cl_2) ,$$

$$ZCl_3 + RH \rightleftarrows RCl + HCl + ZCl .$$

An increase in temperature increases the contribution of the reaction involving the thermal bulk-phase chlorination by free chlorine. It has been concluded[35] that the melt-free catalyst surface is virtually uninvolved in the chlorination reaction. The hypothesis has been put forward that metal chlorides inhibit the reaction in the bulk phase because of their greater affinity for chlorine.

Since the rate and kinetics of the chlorination of methane depend little in practice on the changes in the composition of the $CuCl_2-KCl$ system, the introduction of $LaCl_3$, or the replacement of $CuCl_2$ by LiCl, the authors suggest that the participation of variable-valence metal chlorides in complexes of the type ZCl_3 ($ZCl.Cl_2$) is not obligatory and that chlorination can take place on catalytic centres different from those which are essential for the oxidation of HCl.

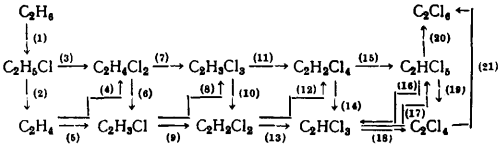
The reactions involving the oxidative and direct chlorination of methane in the presence of salt catalysts are described by the same kinetic equation,[31,32,35] i.e.

$$r = k p_{CH_4} p_{Cl_2}^{0.6} p_{O_2}^{n} ,$$

in which the order with respect to oxygen (n) varies with temperature from 0 to -0.25. Depending on the nature of the salt, the observed activation energy varies from 84 to 113 kJ mol^{-1}.

The use of semiconductor detector, mass-spectrometric, and molecular beam methods enabled Gel'bshtein and Bakshi[98] to justify the hypothesis of the heterogeneous-homogeneous character of the chlorination stage in the substitutional oxychlorination of alkanes.

The main side products in the oxychlorination of methane are carbon oxides. The rate of oxidation of methane and its chloro-derivatives is characterised by being first order with respect to the organic substrate and oxygen, while the ratios of the rates are $r(CH_3Cl) : r(CH_2Cl_2) : r(CHCl_3) : r(CH_4) : r(CCl_4) = 1 : 0.5 : 0.33 : 0.18 : 0.033$. The selectivity in the formation of CO increases with increase in the partial pressure of HCl.[32,35] The mechanism of the extensive oxidation reactions has been scarcely investigated.



The occurrence of the partial oxidation reactions of chloroethanes and chloromethanes as well as the formation of condensation products (carbon black formation) has been indicated in most studies. It has been established[99] that, at elevated temperatures in the absence of oxygen, carbon is deposited on the catalyst in the decomposition of chloromethanes. In the normal course of the process, the decomposition of condensation products were burnt off by oxygen with formation of oxides, which agrees with Mamedov's data.[63]

The kinetics of the oxychlorination of methane in the presence of the spinel copper–chromium catalyst have been described[100] and an equation has been obtained for the overall rate: $r = k p_{CH_4}^{0.8} p_{O_2}^{0.4}$, with an activation energy of 155 kJ mol^{-1}.

The kinetics and mechanism of the high-temperature oxychlorination of ethane, propane, and their chloro-derivatives have been studied in less detail because of its much greater complexity compared with the oxychlorination of methane. Only the formation of chlorine and its involvement in the reactions of the hydrocarbons are unquestionable.[1,15,36,37,98] According to the results of Gel'bshtein and Bakshi,[98] the chlorine formation and chlorination reactions take place on different active centres.

When account is taken of the subsequent reactions of the intermediates, the oxidative chlorination of ethane consists of a heterogeneous-homogeneous process, which proceeds via a series of parallel-consecutive chlorination and dehydrochlorination stages and is accompanied by the oxidation of the starting materials and intermediates to carbon oxides. The simplified mechanism of the formation of the reaction products can be represented as follows (Scheme 5):[36,37,101]

Scheme 5

Depending on the conditions, the process can be directed towards the formation of chloroethylene (vinyl chloride) or towards more chlorinated products.

In view of the large number of individual reactions, the oxychlorination of ethane has been studied in stages. The observed rates of reaction of ethylene, ethane, chloroethane, 1,2-dichloroethane, chloroethylene[36,37] and also the rates r_{16}, r_{18}, and r_{19} [106] are described satisfactorily by the equation

$$r_i = k_i p_i p_{Cl_2}^{0.5} . \qquad (I)$$

The rates of reaction of 1,1-dichloroethane depend solely on its partial pressure.

The following reaction pathways in Scheme 5 have been discovered:[18,56,57,102] (a) chloroethane is converted into 1,1-dichloroethane, 1,2-dichloroethane, and ethylene; (b) 1,2-dichloroethane is converted into 80% chloroethylene and 20% 1,1,2-trichloroethane; (c) ethylene, chloroethylene, and dichloroethylene are chlorinated only additively; (d) chloroethylene is formed as a result of the dehydrochlorination of both dichloroethanes; (e) 1,1,2-trichloroethane is formed from chloroethylene and 1,2-dichloroethane but not from 1,1-dichloroethane.

It has been shown[103] that the oxychlorination of ethylene and chloroethylene take place with participation of the catalyst. Ethane, chloroethane, and 1,2-dichloroethane react with molecular chlorine via a radical-chain mechanism, while the dehydrochlorination of 1,1-dichloroethane and the dissociation of chlorine into atoms take place with participation of the catalyst.[104]

According to some data,[105,106] 1,1,2-trichloroethane is formed via both 1,2-dichloroethane and via chloroethylene, while the relative contributions of these pathways depend in the first place on the volume of the gas phase in the reactor.[106]

The observed rate constant in Eqn. (I) depends on the nature of the organic substrate and decreases in the sequence $C_2H_6 > C_2H_5.Cl > C_2H_4Cl_2$ for saturated compounds. The activation energies for the conversion of the saturated (130 kJ mol^{-1}) and unsaturated

compounds (40–90 kJ mol^{-1}) differ very markedly, as a result of which the yield of alkenes increases with increase in temperature.

In the oxychlorination of hydrocarbons of the ethane–ethylene series, extensive formation of carbon oxides takes place. The rates of these reactions described [36,37] by the empirical equation

$$r_{CO+CO_2} = k_i p_i p_{O_2} p_{Cl_2}^{0.5} \quad .$$

The main contribution to the formation of carbon oxides comes from unsaturated compounds.[6,37,87,89] The introduction of one chlorine atom into ethylene increases the observed extensive oxidation rate constant by a factor of 7–8, while further increase in the chlorine content in the molecule diminishes the degree of combustion of chloroalkenes.[36,37]

The kinetics and mechanism of the high-temperature oxychlorination of C_3 chloroalkanes, which proceeds with formation of tri- and tetra-chloroethylenes and carbon tetrachloride, have been investigated.[13,63,95] In the oxychlorination of 1,2-dichloropropane by the $Cl_2 + O_2$ mixture in the temperature range 310–390 °C in the presence of the $CuCl_2$–KCl catalyst on a carrier, it has been established[13] that the rates of decrease in the amounts of all the reactants are described by the general equation

$$r = k_i p_{C_3H_6Cl_2}^{0.7} p_{Cl_2}^{0.3} (1 + p_{O_2}) \quad .$$

It has been suggested that the reaction take place both in the bulk phase and on the catalyst, which agrees with the results of studies on the high-temperature oxychlorination of ethane, ethylene, and their chloro-derivatives presented above.

The additive oxychlorination of alkenes takes place on catalysts with $CuCl_2$ at much lower temperatures (200–300 °C) than the oxychlorination of alkanes and does not involve the HCl oxidation stage (see Scheme 3). The kinetics of the oxychlorination of ethylene and propene have been studied on a series of catalysts under different conditions and have been described in detail in several reviews.[1,14,15,20,107] The empirical equations proposed for the reaction rates differ appreciably depending on the catalyst and the process conditions.

The first kinetic study of the oxychlorination of ethylene was carried out[108] on the $CuCl_2$–Al_2O_3 catalyst at 200–300 °C. The authors claimed that the rate of the process is independent of $p_{C_2H_4}$ but does depend on p_{O_2} and also that the reaction is inhibited by dichloroethane and HCl. In subsequent investigations, these conclusions were not in the main confirmed. It was found[107,109] that the rate of reaction depends in a complex manner on the partial pressures of ethylene, HCl, and oxygen and is described by a power equation of the type

$$r = k\, p_{C_2H_4}^{m} p_{HCl}^{n} p_{O_2}^{l} \quad . \qquad \text{(II)}$$

In the presence of the $CuCl_2$–KCl/silica gel catalyst in the region of limited conversions of ethylene, the parameters in Eqn. (III) are $m = 0.6$, $n = 0.2$, and $l = 0.5$. In the presence of a catalyst based on Al_2O_3 a direct dependence of the rate $p_{C_2H_4}$ and p_{O_2} ($m, l = 1$) and a weak dependence on p_{HCl} ($n = 0.3$) in the region of low oxygen pressures have been established; when $p_{O_2} \geqslant 0.01$ MPa, we have $l = 0$. An analogous picture ($m = 1$, $n = 0.2$, and $l = 0$) is observed when the $CuCl_2$/activated charcoal catalyst is used in the temperature range 130–180 °C; the selective formation of dichloroethane is possible only under the conditions of an excess of ethylene.

On the other hand, it has been stated[109] that, when an Al_2O_3-based catalyst is used, the rate of reaction depends on $p_{C_2H_4}$ and p_{O_2} but is independent of p_{HCl}, which is evidence, according to the authors, that the rate of reaction is limited by the stage involving the interaction of ethylene with oxygen on the catalyst surface.

The most complete idea about the kinetics and mechanism of the additive oxychlorination of alkynes has been put forward in studies by Gel'bshtein and co-workers.[110-112] The addition to the catalyst of alkali metal chlorides, capable of being coordinated to the copper cation as well as the adsorption of hydrogen chloride increase the electron density on the copper cation and thereby increase the dative component in the interaction of the copper cation with the olefin and at the same time weaken the Cu–Cl bond. The dissociation of two such bonds results in the addition of chlorine atoms to the olefin and in the corresponding reduction of the copper cation in the active centre.

The following mechanism of the reactions (Scheme 6) has been proposed for the oxychlorination of ethylene (at 250–340 °C in the presence of the $CuCl_2$–KCl catalyst on aluminosilicate or silica gel):[110,111]

Scheme 6

		(A)	(B)
$[Cu_mCl_n] + HCl \rightleftarrows [Cu_mCl_n \cdot HCl]$	(1′)	1	1
$[Cu_mCl_n \cdot HCl] + HCl \rightleftarrows [Cu_mCl_n \cdot 2HCl]$	(1″)	1	0
$[Cu_mCl_n \cdot 2HCl] + C_2H_4 \rightarrow [Cu_m^{2-}Cl_{n-2} \cdot 2HCl] + C_2H_4Cl_2$	(2)	1	0
$[Cu_m^{2-}Cl_{n-2} \cdot 2HCl] + O_2 \rightarrow [Cu_mCl_{n-2} \cdot 2HCl \cdot O_2^{2-}]$	(3)	1	0
$[Cu_mCl_{n-2} \cdot 2HCl \cdot O_2^{2-}] + C_2H_4 + 2HCl \xrightarrow{\text{fast}} [Cu_mCl_n] + C_2H_4Cl_2 + 2H_2O$	(4)	1	0
$[Cu_mCl_n \cdot HCl] + C_2H_4 \rightleftarrows [Cu_mCl_n \cdot HCl \cdot C_2H_4]$	(5)	0	1
$[Cu_mCl_n \cdot HCl \cdot C_2H_4] + O_2 \xrightarrow{+2O_2} [Cu_mCl_n] + 2CO_2 + 2H_2O$	(6)	0	1

$2C_2H_4 + 4HCl + O_2 \rightarrow 2C_2H_4Cl_2 + 2H_2O$ (A)

$C_2H_4 + 3O_2 \rightarrow 2CO_2 + 2H_2O$ (B) .

The numerals designating the stages and the stoichiometric numbers of these stages via pathways (A) and (B) are indicated to the right of the chemical equations.

If it is assumed that stages (1′), (1″), and (5) of Scheme 6 correspond to equilibrium, then the kinetic equations corresponding to the proposed Scheme and describing the rates of formation of 1,2-dichloroethane (r_A) and carbon dioxide (r_B) are as follows:

$$r_A = 2\,\frac{K_1' K_1'' k_2 p_{HCl}^2 p_{C_2H_4}}{1 + K_1' p_{HCl}\left[1 + K_5 p_{C_2H_4} + K_1'' p_{HCl}\left(1 + \frac{k_2 p_{C_2H_4}}{k_3 p_{O_2}}\right)\right]}, \qquad \text{(III)}$$

$$r_B = \frac{K_1' K_5 k_6 p_{HCl} p_{C_2H_4} p_{O_2}}{1 + K_1' p_{HCl}\left[1 + k_5 p_{C_2H_4} + K_1'' p_{HCl}\left(1 + \frac{k_2 p_{C_2H_4}}{k_3 p_{O_2}}\right)\right]} . \qquad \text{(IV)}$$

On the assumption that

$$K_1'' p_{HCl} \gg 1 + K_5 p_{C_2H_4}$$

Eqn.(III) assumes the form

$$r_A = 2\,\frac{K_1 k_2 p_{HCl}^2 p_{C_2H_4}}{1 + K_1 p_{HCl}^2\left(1 + \frac{k_2 p_{C_2H_4}}{k_3 p_{O_2}}\right)} ,$$

where

$$K_1 = K_1' K_1''$$

On the same assumption, Eqn. (IV) can be written in the form

$$r_B = \frac{K_1' K_5 k_6 p_{HCl} p_{C_2H_4} p_{O_2}}{1 + K_1 p_{HCl}^2\left(1 + \frac{k_2 p_{C_2H_4}}{k_3 p_{O_2}}\right)} .$$

Under conditions where $p_{O_2} \geqslant (p_{O_2})_{min}$ and $p_{HCl} \geqslant (p_{HCl})_{min}$, the rate of reaction is described by a simple first-order equation with respect to ethylene: $r = k_{obs} p_{C_2H_4}$.

The oxychlorination reaction of ethylene in the $CuCl_2$–KCl/γ-Al_2O_3 catalytic system has been investigated in detail.[113] The authors established that the maximum rate of formation of dichloroethane in the temperature range 220–300 °C corresponds to

a copper concentration in the catalyst of ~7.5%. The rate of formation of side products, in particular of ethyl chloride, CO, and CO_2, falls sharply with increase in the copper concentration. Kinetic studies confirmed the inhibition of the CO and CO_2 formation reactions by hydrogen chloride. It has also been shown that an increase in the Cu/K ratio lowers the activation energy for the dichloroethane formation reaction.

The kinetics of the oxychlorination of ethylene on the $PdCl_2-FeCl_3/\gamma\text{-}Al_2O_3$ catalyst at 230–280 °C have been studied.[87] The main products are chloroethylene and chloroethane whose rates of formation are described by Eqns. (V) and (VI):

$$r_{C_2H_3Cl} = k\, p_{C_2H_4}^{0.9}\, p_{O_2}^{0.6}\ , \qquad (V)$$

$$r_{C_2H_5Cl} = k'\, p_{C_2H_4}^{0.5}\, p_{HCl}^{0.8}\, p_{O_2}^{0.6}\ . \qquad (VI)$$

Analysis of Eqns. (V) and (VI) shows that chloroethylene and chloroethane are formed on different catalytic centres, since the orders with respect to HCl and C_2H_4 are different for these reactions.

The presence of zerovalent palladium and Fe^{2+} in the catalyst leads to an appreciable increase (by a factor of 2–3) in the degree of chemisorption of O_2. Evidently the catalyst surface is occupied by the palladium–iron complex with chemisorbed oxygen on which the main reaction products are in fact formed, which explains the identical reaction orders with respect to oxygen in Eqns. (V) and (VI).

The picture is similar in the oxychlorination of propene. The rate of reaction depends on the concentration of Pd and $PdCl_2$ in the catalyst and also on $p_{C_3H_6}$.[114] The kinetics of the oxychlorination of propene to 1,2-dichloropropane on the $CuCl_2-KCl/Al_2O_3$ catalyst have been studied.[112] The principal features are analogous to those obtained for ethylene. The rate of reaction at $p_{HCl} \geqslant 2$ kPa is described by the equation

$$r = k' p_{C_3H_6} \Big/ \left(1 + \frac{k' p_{C_3H_6}}{k'' p_{O_2}}\right)\ .$$

Depending on the conditions, the rate of the reaction is first order with respect to propene with an activation energy in the range of 90 kJ mol^{-1} or first order with respect to oxygen with an activation energy at the level of 30 kJ mol^{-1} (for zero reaction orders with respect to the other reactants).

V. THE TECHNOLOGY OF THE PROCESSES

This Section deals mainly with questions concerning the oxychlorination reactor—the most complex unit in the process.

In industrial practice the oxychlorination is carried out in different reactors,[1,14,15,20] for example on fluidised,[115, 116] and stationary catalyst beds,[117] and also in melts.[73] A highly isothermal process can be achieved in a fluidised bed, but, when the latter is employed, considerable complications arise in connection with the recovery of the catalyst, the corrosion of the heat exchange elements, the low conversion of the reactants, and the poor susceptibility to modelling. In reactors with a stationary bed considerable local superheating can occur, which leads to vigorous side reactions involving extensive oxidation. They are distinguished by an appreciably lower productivity but make it possible to achieve a high conversion of the reactants.[117,118]

The use of a combination of reactors with a fluidised bed (the first in the set-up for the process) and a stationary bed makes it possible[119] to create a set-up with a high productivity and a high conversion of the reactants.

Comparative study of the oxychlorination of methane in reactors with fluidised and stationary catalysts and also in the melt showed[120] that satisfactory results can be achieved under certain conditions.

When reactors with a fluidised catalyst bed are used, much attention is devoted to the conditions governing the fluidisation and mixing of the reactants. In order to eliminate the influence of backmixing and breakthrough in the form of bubbles, it was recommended that the reactor diameter be restricted to 100–500 mm,[121] which ensures minimal combustion as a result of uniform fluidisation without gas bubbles. In order to create set-ups with a high unit productivity, several tubes of this diameter are combined in a single jacketed tubular reactor. The removal of heat in the reactors is achieved with the aid of heat exchange elements[122] or by recycling the products.[123] To prevent the possibility of the decay of the reaction, it is recommended that the temperature of at least some of the heat exchange elements should differ from the temperature of the bed by not more than 25 °C.[122] Satisfactory mixing of the reactants promotes an increase in selectivity and is carried out directly in the fluidised bed,[115] in pre-mixers with a fluidised bed of inert materials,[124] or in special devices with a wide variety of designs.[125]

The oxychlorination stage is used mainly to establish processes, balanced with respect to chlorine, in which organochlorine products are obtained. The high-temperature chlorination is usually carried out in the first stage, while the hydrogen chloride from the chlorination stage is supplied to the oxychlorination stage, the products being either isolated from the reaction gas[126] or also supplied to the oxychlorination stage.[127] The supply to the oxychlorination stage of the same hydrocarbon raw material as in the chlorination stage is economically most efficient, since in this case there are no problems with the purification of hydrogen chloride.

Oxychlorination with a mixture of chlorine and oxygen or air is also known.[1,13,14,20,21,63,128,129] In this case the chlorination and oxychlorination reactions are combined in a single reactor; when polychlorides with a high chlorine content are processed under the conditions of a low heat change, this procedure is especially advantageous. Oxychlorination using chlorine takes place more vigorously, but, when C_2 and C_3 polychlorides are used, the contribution by extensive oxidation side reactions increases, in the first place owing to dehydrochlorination and the formation of alkenes which exhibit an increased tendency towards the formation of carbon oxides.[92,116] The yield of oxides is reduced by the means of an oxygen supply divided into sections along the height of the reactor[13,95,116,128,129] as a result of which the oxygen comes into contact not with the initial raw material but with more chlorinated hydrocarbons. The oxychlorination with a $Cl_2 + O_2$ mixture is carried out in reactors of all types, although it is assumed that the preferred variant involves the process being carried out in a pseudofluidised catalyst bed or in the melt.[13,128,129]

Processes in which hydrogen chloride is used have become the most common. There is also a possibility of employing hydrochloric acid.[130,131] The presence of large amounts of water vapour in the reaction mixture makes it possible to carry out the process successfully in a stationary bed—there is virtually no superheating of the catalyst in this case.[131] However, an excess of water vapour can also lead to the occurrence of side reactions. Thus reactions involving the formation of allyl alcohol, acrolein, and other oxygen-containing products are appreciably accelerated in the case of propene.[132] The interaction of chloroethylene with water vapour to form ethylene has been observed at temperatures above 450 °C.[133]

Air, air enriched in oxygen, and concentrated oxygen can be used as oxidants for oxychlorination.[128,129,134,135] The replacement of air by oxygen can greatly increase the productivity of the reactors, can simplify the condensation scheme by increasing the concentrations, and ultimately can reduce the intrinsic cost of the products. Under conditions where oxygen is used, the requirements for the removal of heat and conditions free from the risk of explosion become much more stringent, so that it is recommended that a reactor with a

fluidised catalyst bed be used for this purpose.[21,22,134,135] However, the possibility of the successful employment of concentrated oxygen also in reactors with a stationary bed has been demonstrated.[128,129] Provided that the conditions are chosen correctly, the selectivity in the formation of the target products is at the same level as in the case where air is used.

Oxidative chlorination has been used much less than the chlorination method because of the following disadvantages: (1) the volatility of the active components of the catalyst; (2) the formation of extensive oxidation side products ($CO + CO_2$) and the insufficiently high conversions of the reactants and yields of the target products (especially in the high-temperature process); (3) the pronounced corroding effect of the medium (catalyst, hydrogen chloride, chlorine, and water vapour at a high temperature).

The loss of copper(II) chloride from the catalyst is compensated by passing the initial reaction mixture through a melt or solid carrier containing copper(II) chloride.[136] When the oxychlorination is carried out in a fluidised bed, a constant amount of the catalyst is maintained by adding the solid carrier, copper in the form of the metal or a salt, and also an alkali metal as the chloride.[137]

In order to reduce the yield of carbon oxides and to improve the selectivity in the formation of target products, attempts are made in the first place to achieve the optimum temperature conditions in the oxychlorination reactions. It is recommended that the process be carried out in the presence of a (5–20)-fold excess of hydrogen chloride to maintain a uniform temperature in the catalyst bed.[138]

The attempts to organise temperature fields in reactors with a stationary catalyst bed by arranging the catalyst in order of increasing activity along the gas stream,[139] by a stepwise increase in the size of the catalyst particles,[140] and by increasing the tube diameter or by means of a higher temperature in each successive (along the gas stream) catalyst bed[141] are noteworthy.

The uniform mixing of active and low-activity catalysts increases[142] the yield of the target product by increasing the selectivity of the main reaction. The procedures described activate the process in the terminal part of the reactor and make it possible to achieve a high conversion of HCl.

It is also recommended that the catalyst be diluted by an inert material with a high thermal conductivity: graphite,[143] silicon carbide,[144] metals (nickel, molybdenum, cobalt, and silver) and their alloys,[145] and also the unimpregnated carrier.[146]

Only chloromethanes are recycled in the chlorination stage and only methane, oxygen, nitrogen, and carbon oxides are recycled in the oxychlorination stage in order to increase the degree of the useful employment of chlorine and to reduce the formation of side products.[147]

The greatest effect in reducing the extensive oxidation side reaction can be achieved by preventing contact between the hydrocarbon and oxygen by carrying out the process in two stages. In the first stage, the hydrocarbon is chlorinated with the aid of, for example, copper chloride, while in the second stage the reduced form of copper is oxidised by oxygen and hydrogen chloride. A melt of copper and potassium salts is usually employed to achieve such a process.[23,24,120,148] The low conversion of the hydrocarbons and the complexity of the equipment for transporting the melt should be included among the disadvantages of this method. In order to simplify the transfer of the catalyst from one stage to the other, it is suggested[149] that the traditional catalyst with $CuCl_2$ on a carrier be used. However, the formation of carbon oxides cannot be fully avoided even when a two-step scheme is used, since the oxidised form of the catalyst, coming into contact with the hydrocarbon, contains copper oxide chloride, which leads to the formation of carbon oxides.

Attempts have been made to reduce the corroding effect of the catalyst on the reactor material by selecting appropriately the carrier and the composition of the active mass,[150] but these improvements are not of fundamental importance. It has therefore been suggested that, when the process is carried out in a stationary bed, the surface of the tube should be coated with glass[140,151] or that a lined adiabatic reactor be employed.[152]

A procedure in which the oxychlorination process is initiated by means of a correct sequence in the supply of the reactants to the catalyst heated beforehand has been patented.[153] A method for the elimination of iron(III) chloride from the initial reactants[154] in order to maintain the activity and selectivity of the oxychlorination catalyst based on copper chlorides has also been proposed.

The above improvement in the technological set-up for the process permits the expectation of an expansion in the employment of the oxychlorination method at the present.

Stable Methylenequinones

A.A.Volod'kin and V.V.Ershov

Data obtained in studies on the chemistry of a vigorously developing class of conjugated compounds (methylenequinones) are surveyed. The structure of these compounds and the influence of substituents on their properties and reactivity are discussed. Typical methods of synthesis of methylenequinones are described and the mechanism of their formation as well as the interconversions of methylenequinones and the corresponding phenols in radical and heterolytic reactions are considered. The bibliography includes 144 references.

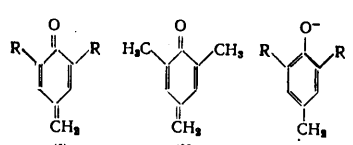
I. INTRODUCTION

Methylenequinones (quinone methides) are labile organic compounds belonging to the class of unsaturated cyclic conjugated ketones. The study of the properties of these substances has developed vigorously during the last decade primarily owing to the specificity of their structure, high reactivity, and the role which they play in many chemical and biochemical reactions.[1-3] Methylenequinones form part of the composition of plant pigments,[4] participate in the metabolism of natural products,[5] are used in medicine,[6] and are able to inhibit the thermo-oxidative degradation reactions of polymers.[7] Finally, the chemical properties of methylenequinones and phenols proved to be indissolubly linked, which is manifested most distinctly in the relation between sterically hindered phenols and the corresponding methylenequinones.[8]



The molecules of methylenequinones are characterised by a high degree of conjugation, lability of the π-electronic bond system, and the capacity for the delocalisation of electrons, which is reflected in the physical properties of methylenequinones and in the marked influence of substituents, particularly those attached to the carbon atom of the methylene unit, on the structure and chemical properties of compounds of this class. This review deals with the methods of synthesis and the properties of stable *para*-methylenequinones.

II. STRUCTURE, STABILITY, AND PHYSICOCHEMICAL PROPERTIES

The simplest methylenequinones are usually unstable. Hitherto they have not been isolated in a pure state. At the instant of formation, these methylenequinones either polymerise or interact with the medium. Their high reactvitiy is due primarily to the characteristic features of their structure. Analysis of calculated data on the structure of the simplest methylenequinones and their closest analogues—quinones and dimethylenequinones (quinodimethanes)—has shown that the ground state of methylenequinones can be both singlet and triplet.[9] The triplet states of *p*-dimethylenequinone and *p*-methylenequinone are biradicals of the dibenzyl or hydroxybenzyl type with a benzenoid (and not quinonoid) aromatic ring and one can therefore speak of the ground singlet (quinonoid) state of these conjugated compounds and of their transition triplet (benzenoid) state. Calculations on the singlet and triplet states of the *p*-dimethylenequinone molecule have shown[9-11] that in the former case it is diamagnetic and has a quinonoid structure, while in the latter state the molecule should be paramagnetic and should have a benzenoid structure with similar C–C bond lengths in the six-membered ring. The difference between the energies of the singlet and triplet states of *p*-dimethylenequinone is approximately 25 kJ mol^{-1}, so that *p*-dimethylenequinones can exist in the singlet state only at low temperatures, which is consistent with experimental data.[11] On the other hand, calculations have shown[9] that *p*-benzoquinone exists virtually in the singlet state and the probability of its transition to the triplet state is lower by a factor of 2.7 x 10^5 than for *p*-dimethylenequinone.

p-Methylenequinone occupies an intermediate position. The probability of its singlet–triplet transition is only 47 times lower than for *p*-dimethylenequinone and the difference between the energies of the singlet (quinonoid) and triplet (benzenoid) states is about 34 kJ mol^{-1}.[9] Thus the possibility of the conversion of *p*-methylenequinone into a biradical of the hydroxybenzyl type in the absence of factors stabilising the quinonoid bond system is fairly high. This in fact explains why the simplest (unsubstituted) methylenequinone does not exist under the usual conditions and polymerises during its preparation.[12-14]

The stability of methylenequinones increases significantly when one of the reaction centres, for example the oxygen atom, is sterically shielded. Naturally, this effect is manifested to the maximum extent for 2,6-di-t-butylmethylenequinone (I), which dimerises (at a concentration of 0.01 M) 10^3 times more slowly than 2,6-dimethylmethylenequinone (II).[15] The methylenequinone(I) can be isolated in a pure state, although at room temperature it undergoes an irreversible singlet–triplet transition in the course of several minutes with the subsequent formation of characteristic triplet methylenequinone conversion products.[16] The EPR spectrum of the compound in thetriplet state, measured at a concentration of 0.25 M, consists of three triplets and corresponds to the structure of the biradical (III):[17]

(I) (II) (III)

R = t-butyl group

The high degree of stabilisation of the quinonoid bond system of the methylenequinone is obtained as a result of the increase in the conjugation chain of the molecule. This effect is significant for

α-substituted (at the methylene unit) methylenequinones. Thus αα-dicyano-[18] and αα-diphenylmethylenequinones[19] can also be isolated in a pure state; they are less reactive than the methylenequinone (I).

Theoretically, on the basis of the calculation of the electron density and the bond order in the molecule of the simplest methylenequinone by the LCMO method, one may expect three $\pi-\pi^*$ transitions.[20] The most intense ($\lg\varepsilon = 4.05$) long-wavelength transition, corresponding to the wavelength $\lambda_{max} = 287$ nm ($\lambda_{max} = 282$ nm has been found experimentally), is associated with polarisation in the direction parallel to the symmetry axis of the methylenequinone molecule. Two other transitions, with $\lambda_{max} = 274$ nm and $\lambda_{max} = 229$ nm, associated with the polarisation of the molecule in the direction at right angles to the longitudinal symmetry axis, should have a low intensity. They have not been confirmed experimentally.[21] The difference between the λ_{max} of the substituted methylenequinones and the unsubstituted methylenequinone depends on the number and nature of the substituents and is an additive quantity. For any substituted methylenequinones, one can therefore calculate the maximum for the allowed $\pi-\pi^*$ transition from the positions and number of the substituents in the methylenequinone molecule. The wavelength of the main absorption maximum of the substituted methylenequinone is equal to the sum of the wavelengths of the main absorption maximum of the unsubstituted methylenequinone ($\lambda_{max} = 282$ nm) and the increments $\Delta\lambda$ characteristic of the substituents.[22] As can be seen from the data in Table 1, the α-substituents in the methylene unit of the methylenequinone molecule induce a much greater bathochromic shift than the ortho-substituents in the six-membered ring. Such additivity is in fact characteristic of methylenequinones, while in substituted benzoquinones the dependence of the bathochromic shift on the number and nature of the substituents is non-linear.[23].

Table 1. The increments due to the substituents for the calculation of the principal absorption maxima in the spectra of substituted methylenequinones.[8,22]

*From Ershov et al.[8]

Semiquantitative data on the π-electron delocalisation in the ground state have been obtained in a study of the ^{13}C NMR spectra of methylenequinones.[24,25] Analysis of the ^{13}C chemical shifts in the six-membered ring and in the methylene group of αα-disubstituted 2,6-di-t-butylmethylenequinones and 2,6-dialkyl-αα-diphenylmethylenequinones showed that the effect of the *ortho*-substituents arises predominantly (to the extent of approximately 80%) via the inductive mechanism, while the influence of α-substituents is associated mainly with conjugation (63–79%).

Depending on the electronegativity of the α-substituents, the carbonyl group of the methylenequinone can function both as an electron acceptor and an electron donor, which is reflected in the two diametrically opposed limiting structures (B) and (B)′, for example, of the molecules of αα-diamino- and αα-dicyano-2,6-di-t-butylmethylenequinones, in which the extent of intramolecular interaction is a maximum:[24]

(A) (B) (A)′ (B)′

On the other hand, in most of the other known methylenequinones the electron distribution obeys the rules for weak charge-transfer complexes, the energy transfer as a result of the intramolecular interaction is proportional to an ionisation potential function of the donor component molecule: $h\nu_i = \gamma I_d - \delta$, where ν_i is the absorption frequency for the ith bond, I_d the ionisation potential of the donor component of the methylenequinone molecule, and γ and δ are constants characterising the acceptor component of the methylenequinone molecule. The γ and δ constants are invariant for a series of αα-disubstituted 2,6-di-t-butylmethylenequinones (the correlation coefficient is $r = 0.967$).[24]

Measurement of the dipole moments of substituted methylenequinone in both ground (μ) and excited singlet (μ*) states confirmed the lability of the conjugated bond system in methylenequinone, which can be expressed by the corresponding contribution of the dipolar structure of type (B). In the ground state, this contribution is 9–18% and depends on the steric effects of the *ortho*-substituents, while in the first excited singlet state it increases to 25–40% and depends less on the character of the *ortho*-substituents in the methylenequinone molecule.[26]

The quantity $\Delta\mu = \mu^* - \mu$, characterising the degree of delocalisation of π electrons, has been found from the calculation and experimental data referring to the variation of the absorption maximum for a series of 2,6-dialkyl-αα-diphenylmethylenequinone in various solvents. The introduction of substituents into the methylene ring increases the dipole moment μ, whose value is correlated with the electrophilic substituent constants σ_p^+, including the inductive and conjugation effects:[27]

$$\mu = [(-7.55 \pm 1.2)\,\sigma_p^+ + 10.94] \cdot 10^{-30}\ (r = 0.993,\ n = 6)$$

The vibrational spectra of methylenequinones are close to those of quinones and quinolide compounds.[28,29] The IR spectra of methylenequinones contain the vibration frequencies of the conjugated carbonyl group, the latter being manifested as a rule by a doublet, and the intensity and positions of the frequencies in the spectrum depend on the nature of the α-substituents.[30,31]

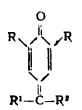
The application of model computational and experimental research methods makes it possible to interpret from a quantitative standpoint the IR spectra of various 2,6-dialkyl-αα-diphenylmethylenequinones and α-substituted 2,6-di-t-butylmethylenequinones.[32,33] It was found that the frequency ν_{CO} can be used to analyse the electronic interactions and the reactivities of the methylenequinones containing various substituents. The frequency ν_{CO} in the IR spectra of methylenequinones is correlated with the electrophilic constants of the substituents:

$$\Delta\bar{\nu}_{CO} = 9.41\ (\pm 0.58)\,\sigma_p^+ + 3.20\ (r = 0.973)$$

and the electronic effects therefore exert a decisive influence on ν_{CO} in methylenequinones. Furthermore, a two-parameter correlation, based on the inductive (σ_I) and the resonance components of the σ constant, has been established, which indicates approximately equal

contributions of the inductive and conjugation effects to the mechanism of the intramolecular interaction via the system of conjugated double bonds in the ground state of methylenequinones:

$$\Delta\bar{\nu}_{CO} = 9.47\,(\pm 2.03)\,\sigma_I + 9.50\,(\pm 0.79)\,\sigma_R^+ + 3.02\ .$$



The experimental results were confirmed by a calculation taking into account the dependence of $\bar{\nu}_{CO}$ on the solvent polarity (Table 2). By analysing the vibration frequencies of the carbonyl group and the integral intensities for a series of αα-diphenylmethylenequinones, the contribution of the steric effects to the mobilities of the electrons has been calculated for 2-monoalkyl- and 2,6-dialkylmethylenequinones:[33]

$$\bar{\nu}_{CO} = 35.6\Sigma\sigma_I - 9.1\Sigma\omega + 1625.5\,(r = 0.982)\,,$$

$$A_{CO}^{1/2} = -33.2\Sigma\sigma_I - 128.1\Sigma\omega + 141.1\,(r = 0.942)\,,$$

where ω is a quantity proportional to the van der Waals radii of the substituent and $A_{(CO)}$ is a quantity proportional to the integral intensity of the vibration frequency of the carbonyl group.

Table 2. The experimental and calculated vibration frequencies of the carbonyl group in α-substituted 2,6-di-t-butylmethylenequinones.[30,32]

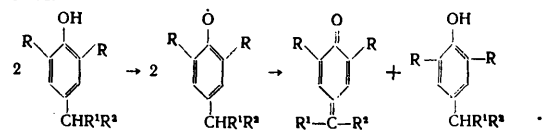
*From Volod'kin and Ershov.[30]

The vibration frequencies of the carbonyl group and the integral intensities diminish with increase in the van der Waals radii of the *ortho*-substituents, the delocalisation of the electrons due to the "*ortho*-effect" in 2,6-dialkylmethylenequinones being approximately 30% higher than in the 2-mono-substituted methylenequinones.

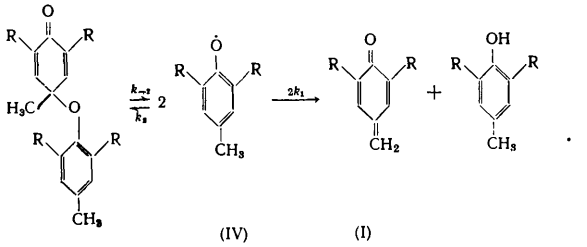
The specificity of the structure and properties of methylenequinones are also manifested in the ^{1}H NMR spectra of these compounds, in the first place as a consequence of the effect due to the hindered rotation about the exocyclic C=C bond.[34,35] This effect was observed for the first time in the analysis of the ^{1}H NMR spectra of substituted stilbenequinones[36] in which the non-equivalence of the *meta*-protons and the protons of the *ortho*-substituents is manifested. The non-equivalence of the ring protons of methylenequinones is associated with the different substituents in the α-position. At room temperature rotation around the exocyclic C=C bond is not observed. The study of the temperature dependence of the ^{1}H NMR spectra of α-substituted methylenequinones showed that the barrier to the intramolecular rotation about the C=C bond in such compounds is fairly high and the activation energy for this transition is greater than 105 kJ mole^{-1}. It has been suggested[35] that the rotation about the exocyclic C=C bond can take place via a biradical transition state:

According to the data of Mannchreck and Kolb,[37] the free electron pair of the nitrogen atom in the molecule of 2,6-di-t-butyl-α-dimethylaminomethylenequinone is coplanar with the cyclohexadiene ring. The ^{1}H NMR spectrum of this methylenequinone is temperature dependent as a consequence of the effects considered above, while the calculated low barrier to the intramolecular rotation about the C=C bond (60.7 kJ mol^{-1}) and the high barrier to the rotation about the C–C single bond (52 kJ mol^{-1}) show that the rotation about the C=C bond takes place via a dipolar transition state, which agrees well with the data considered previously:[24]



Thus analysis of the physicochemical data on the structure and the influence of substituents on the conjugated system of double bonds in methylene quinones permits a fairly clear-cut formulation of the condition for the stability of methylenequinones (the presence of substituents in the six-membered ring and at the carbon atom of the methylene unit) and makes it possible to deduce the reactivity of these compounds, a characteristic feature of which should be both radical reactions and electrophilic and nucleophilic 1,6-addition reaction by virtue of the presence in the molecule of two reaction centres: the nucleophilic centre at the oxygen atom and the electrophilic centre at the carbon atom of the methylene unit.[38]

III. THE FORMATION OF METHYLENEQUINONES

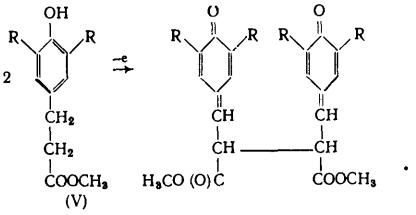


The relation between methylenequinones and phenols is manifested primarily in their interconversions caused by various chemical reagents and the methods of synthesis of stable methylenequinones are therefore mainly based on the reactions of substituted phenols.

The commonest method of synthesis of methylenequinones consists in the oxidation of phenols by variable-valence metal compounds (one-electron oxidation).[39-44] In the presence of α-hydrogen atoms in the molecule of the initial phenol, the phenoxy-radical formed initially disproportionates into methylenequinone and the initial phenol:

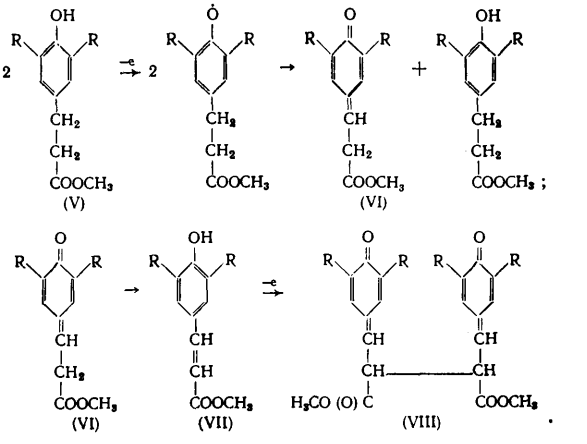
The kinetics of the decomposition of the majority of α-hydrogen-containing phenoxy-radicals are bimolecular. However, in the case of the 2,6-di-t-butyl-4-methylphenoxy radical (IV), the kinetics proved to be more complex, which has been the subject of many years' discussion concerning the mechanism of its decomposition. According to the initial view, the phenoxy-radical (IV) isomerises via a first-order reaction to a radical of the hydroxybenzyl type, whose recombination leads to the formation of dimeric compounds.[45-58] However, more recent data[49] confirm that the decomposition mechanism of the radical (IV) via the disproportionation reaction is general and it was found that the order of this reaction depends on the

concentration of the radical (IV). Such dependence is associated with the dimerisation reaction of the radical (IV) which takes place as a parallel process, which is reflected in the relation between the order of the reaction and the concentration of this radical:[50]



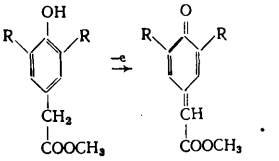
(IV) (I)

It was shown that, when $4K_2[PhO^{\cdot}] \gg 1$, where $K_2 = k_2/k_{-2}$, the decomposition of PhO$^{\cdot}$ is described by a first order law with $k_{eff} = k_1/2k_{-2}$, and, when $4K_2[PhO^{\cdot}] \ll 1$, the decomposition of PhO$^{\cdot}$ is a second order process with $k_{eff} = 2k_1$.



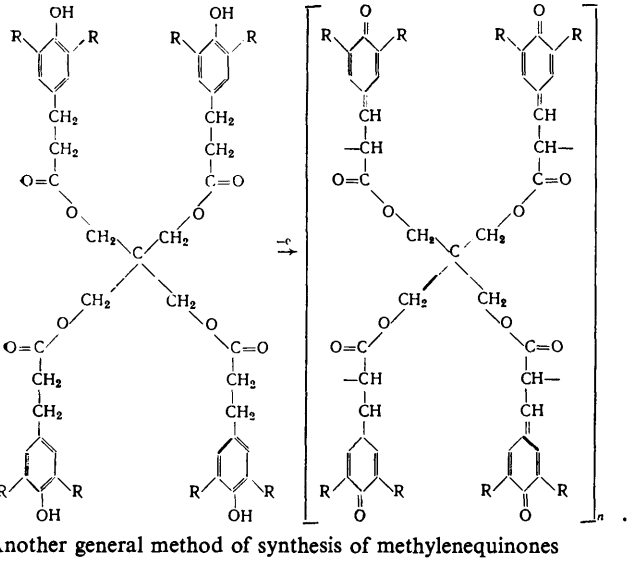
The duration and temperature of the oxidation of the initial substituted phenols are important factors influencing the attainment of the maximum yield of methylenequinones, which is usually associated with the high reactivity of the methylenequinones themselves and their involvement in parallel reactions. Thus the methylenequinone (I) is formed on oxidation of 2,6-di-t-butyl-4-methylphenol (concentration 0.15 M) after 10–15 min in 97–98% yield.[51] The increase in the duration of oxidation to 3–4 h lowers the yield of the methylenequinone (I) to 50% at the expense of its consumption via the spontaneous disproportionation reaction.

The processes in the oxidation of phenols containing hydrogen atoms in the β-position of the carbon chain can vary. For example, whereas the oxidation of 2,6-di-t-butyl-4-(β-phenylethyl)phenol results in the formation of only the corresponding methylenequinone,[52] oxidative dimerisation is observed in the oxidaion of β-(3,5-di-t-butyl-4-hydroxyphenyl)propionic acid:[53,54]

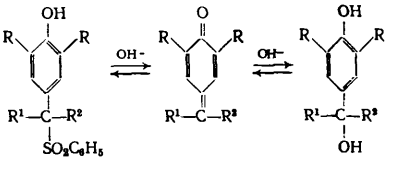


(V)

The study of the mechanism of the oxidation of methyl β-(3,5-di-t-butyl-4-hydroxyphenyl)propionate (V) showed that the methylenequinone (VI) formed in this case is unstable and isomerises spontaneously to the corresponding vinylphenol (VII), whose subsequent oxidation yields the oxidative dimerisation product (VIII). The overall mechanism of the oxidation of the ester (V) by one-electron oxidants can therefore be represented as follows:[55]

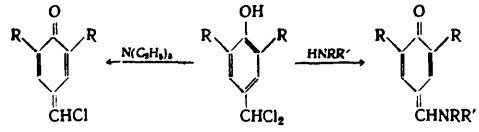


(V) (VI) (VI) (VII) (VIII)

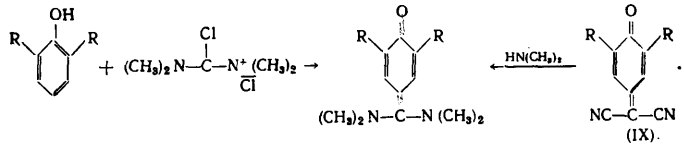


It is noteworthy that, in the oxidation of methyl (3,5-di-t-butyl-4-hydroxyphenyl)acetate, which contains no mobile β-hydrogen atoms, the stable 2,6-di-t-butyl-α-methoxycarbonyl methylenequinone is formed:[51]

Analogous reactions take place also with certain industrial phenolic antioxidants containing several fragments of a sterically hindered phenol in the molecule, for example in the oxidation of the pentaerythrityl ester of β-(3,5-di-t-butyl-4-hydroxyphenyl)propionic acid.[7] It was shown kinetically that in this case the destruction of the phenoxy-radicals takes place as a result of the intramolecular reactions of a biradical.[50,56]

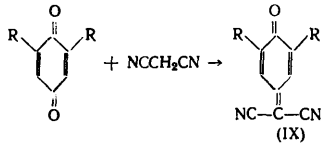


Another general method of synthesis of methylenequinones involves treatment with bases of phenols containing in the benzyl position halogen atoms,[57] the sulpho-group,[58-61] or the hydroxy-group.[62-64] This reaction can be regarded as a special case of the solvolysis of the phenol derivatives indicated, which terminates with the formation of a methylenequinone.[58,59] For example, the methylenequinone (I) is obtained in the reaction of 3,5-di-t-butyl-4-hydroxybenzyl halide with a trialkylamine.[52,56,65] In the general case, the solvolytic reaction in the presence of alkali is reversible and the reactivity of the initial phenols depends on their ability to form a methylenequinone, while the equilibrium constants are determined by the nature of the substituents in the benzyl position:[58,59]



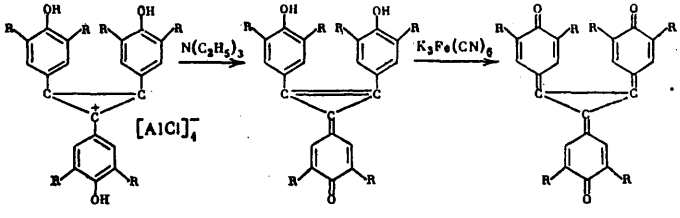
Consequently the yield of the methylenequinone is related to the equilibrium conditions in two reactions.[59]

The interaction of equimolar amounts of di-t-butyl-4-hydroxybenzyl halides with secondary amines also involves the intermediate formation of the corresponding methylenequinones, which are capable of reacting with an excess of the amine to form 3,5-di-t-butyl-4-hydroxybenzylamines.[66,67] However, the reactions of 3,5-di-t-butyl-4-hydroxybenzylidene dichloride with secondary amines terminate



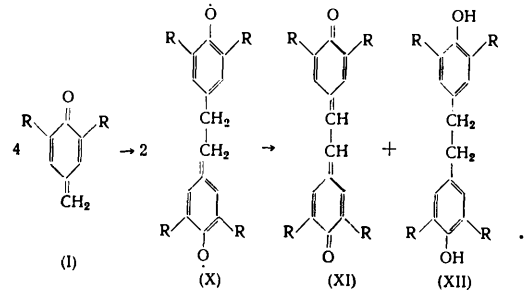
with the formation of 2,6-di-t-butyl-α-(*NN*-dialkylamino)methylenequinones; the above reaction with a tertiary amine yielded 2,6-di-t-butyl-α-chloromethylenequinone:[57]

A number of specific reactions leading to the formation of 2,6-di-t-butyl-α-(*NN*-dialkylamino)methylenequinones are known; for example, the condensation of 2,6-di-t-butylphenol with bis(dimethylamino)methyl chloride[68] and the aminolysis of 2,6-di-t-butyl-αα-dicyanomethylenequinone:[68,69]

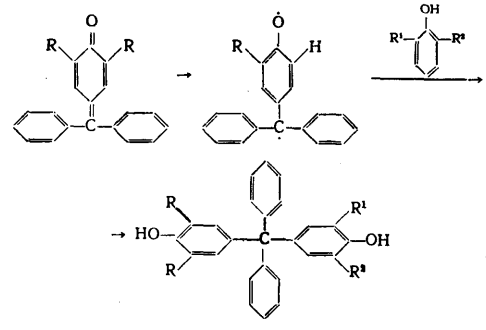


The methylenequinone (IX) has been obtained by condensing 2,6-di-t-butylquinone with malonodinitrile:[69,70]

The interaction of dichlorodiphenylmethane with 2,6-di-t-butylphenol leads to the formation of 2,6-di-t-butyl-αα-diphenylmethylenequinone.[71] Examples of the formation of αα-diphenylmethylenequinones in photochemical reactions have also been described.[72-75]

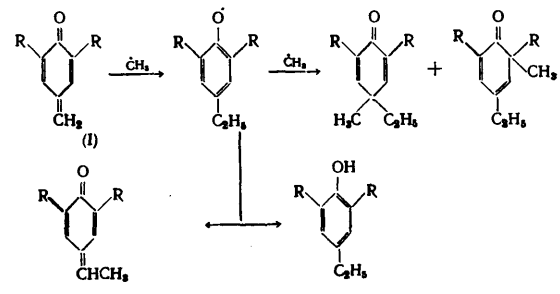


Compounds with a cross-conjugated bond system, which include several structural methylenequinone fragments, constitute a specific group. A general method of synthesis of polymethylenequinones is based on the condensation of 2,6-disubstituted phenols with derivatives of unsaturated cyclic hydrocarbons.[76-87] The complex of tetrachlorocyclopropene with aluminium chloride,[81,83,84,86] the complex of cycloheptatriene with fluoroboric acid,[78,80] and other cyclic unsaturated compounds[82,85] have found wide-scale applications for such purposes. For example, the condensation of 2,6-di-t-butylphenol with tetrachloropropene in the presence of aluminium chloride results in the formation of an adduct with three phenyl molecules, from which a derivative of methylenequinone containing also the aromatic rings of phenol is formed on treatment with a tertiary amine. On treatment with one-electron oxidants, the aromatic rings in such compounds are converted into the cyclohexadiene system with formation of a cross-conjugated bond system:[81]

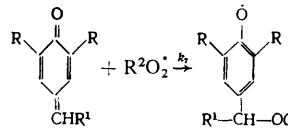


Compounds with such a bond system are relatively stable and can be isolated in a pure state. However, cross-conjugated methylenequinones exhibit very marked oxidising properties and some of them are capable of forming stable radical-anions.[83,84,86,87]

IV. RADICAL REACTIONS OF METHYLENEQUINONES



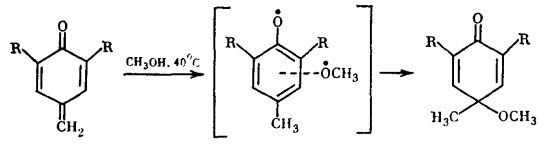
The radical reactions proper of methylenequinones in the form of biradicals (in the triplet state) are characteristic only of the simplest unsubstituted methylenequinones (polymerisation) and the methylenequinone (I), which dimerises spontaneously even in dilute solution with formation of the bisphenoxy-radical (X): Further reactions of this radical lead to a mixture of the stilbenequinone (XI) and dihydroxydiphenylethane (XII):[49,51,56,89]



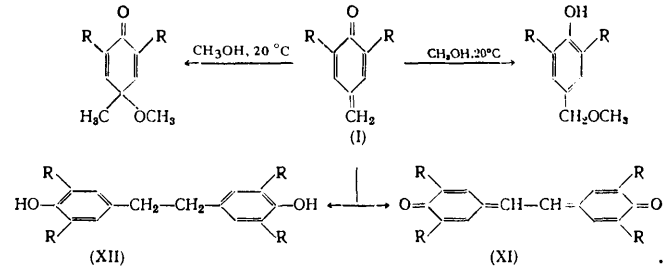
The formation of radical species in the disporportionation of the methylenequinone (I) has been confirmed by EPR.[17] For the stable αα-disubstituted methylenequinones, the singlet–triplet transition can be achieved only in photosensitised reactions. Thus, in the presence of excited benzophenone, 2,6-dialkyl-αα-diarylmethylenequinones react with 2,6-dialkylphenols via a radical mechanism with formation of di(hydroxyaryl)diphenylmethanes:[19]

Apart from the reactions indicated, many methylenequinones are capable of interacting directly with various radicals or of dehydrogenating organic compounds via a radical mechanism. Methylenequinones interact vigorously with alkyl radicals. In the model reaction of the methylenequinone (I) with methylradicals under the conditions of their constant generation as a result of the decomposition of t-butyl hydroperoxide by bivalent iron salts, the radical adds to the carbon atom of the methylene unit of the methylenequinone with formation of an intermediate phenoxy-radical, which is subsequently consumed, fully in conformity with the rules governing the behaviour of phenoxy-radicals, via a disproportionation reaction and via recombination with the methyl radicals present in excess:[56]

The possibility of using methylenequinones in the inhibited oxidation of organic substrates is based on their ability to participate in radical reactions. It follows from kinetic data for the inhibited oxidation of cumene or styrene that methylenequinones react fairly rapidly with peroxy-radicals $RO_2^{\cdot}$:[90]



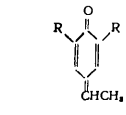
Quantitative estimation of the inhibiting effect of methylenequinones established that the quantity k_7 is independent of the concentration of the methylenequinone and that the phenoxy-radicals formed in this case do not therefore participate in propagating the oxidation chin. Comparison of the values of k_7 for methylenequinones and structurally similar phenols shows that the methylenequinones are somewhat less effective than the phenols in the reaction with phenoxy-radicals (Table 3). However, in this connection attention should be drawn to an interesting fact: the effectiveness of the bismethylenequinone (VIII)—the product of the oxidative dimerisation with the phenolic stabiliser (V)—is approximately equivalent to the effectiveness of the phenol (V) itself. Methylenequinones are effective inhibitors of the radical polymerisation of styrene (concentration 10^{-2} M, initial rate of initiation $w_i = 2.98 \times 10^{-7}$ mol litre^{-1} min^{-1}). The rate constants for the reactions of α-substituted 2,6-di-t-butylmethylenequinones with alkyl radicals are $0.8 \times 10^4 - 1.3 \times 10^5$ litre mol^{-1} s^{-1}, which is higher by 1–2 orders of magnitude than the rate constants for the reactions of the same methylene quinones with alkyl-peroxy-radicals.[91] It follows from the result of the same study that the bismethylenequinone (VIII) is equally reactive in the reactions with both alkyl and alkylperoxy-radicals.

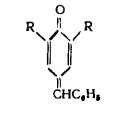


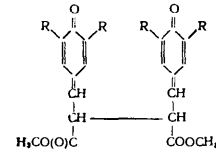
αα-Disubstituted methylenequinones with electronegative substituents do not inhibit the polymerisation of styrene and radical reactions are therefore not characteristic of methylenequinones of this type.

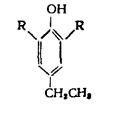
Methylenequinones are also stabilisers of the degradation of high-molecular-weight materials (polymers) and effectively inhibit the oxidation of polyolefins at high temperatures.[7,56] The inhibition of the thermo-oxidative degradation of polymers by methylenequinones is due to their ability to interact with both peroxy- and alkylradicals. This property in methylenequinones is of fundamental importance for the specific synthesis of effective stabilisers in the class of sterically hindered phenols, since the formation of methylenequinones in the primary step of the interaction of the polymeric radical $RO_2^{\cdot}$ with phenolic antioxidants depends on the structure of the sterically hindered phenol and the character of the substituents.

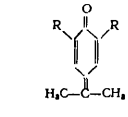
The simplest methylenequinones and the methylenequinone (I) are also capable of dehydrogenating certain organic compounds. For example, the methylenequinone (I) reacts with methanol in dilute solutions at 40 °C to form the methyl ether of the corresponding quinol, the phenoxy-radical produced being directly responsible for the formation of the ether:[51,92]

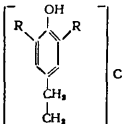




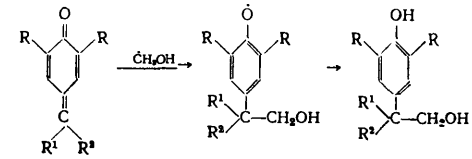








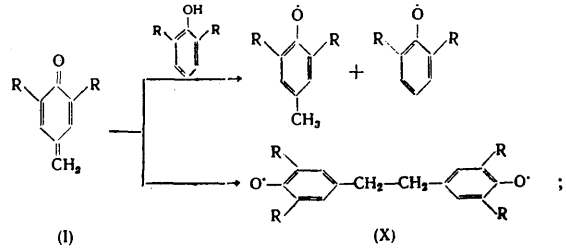
In addition, the formation of 3,5-di-t-butyl-4-hydroxybenzyl methyl ether, possibly via the competing reaction involving the heterolytic 1,6-addition of methanol, is observed. Together with the products of the interaction of the methylenequinone (I) with methanol indicated above, the characteristic products of the reactions of triplet methylenequinone are also formed—the stilbenequinone (XI) and dihydroxydiphenylethane (XII):



In the presence of catalytic amounts of an acid or alkali, only 3,5-di-t-butyl-4-hydroxybenzyl methyl ether is formed in this reaction.[93]

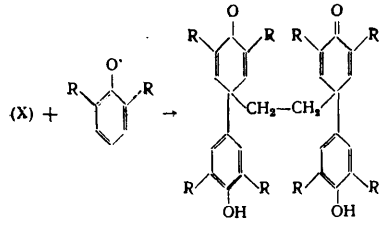
Table 3. The rate constants for the reactions of methylenequinones and phenols with peroxy-radicals $RO_2^{\cdot}$ in the inhibited oxidation of cumene and styrene.*

Inhibitor	k_7, litre mol^{-1} s^{-1}		Inhibitor	k_7, litre mol^{-1} s^{-1}	
	cumene	styrene		cumene	styrene
	$5.8 \cdot 10^3$	$1.4 \cdot 10^3$		—	$1.8 \cdot 10^2$
	$4.0 \cdot 10^4$	—		$4.0 \cdot 10^4$	$1.0 \cdot 10^3$
	$1.6 \cdot 10^4$	—		$2.9 \cdot 10^4$	—



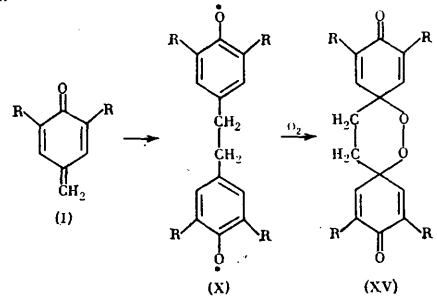
*Determined from the kinetics of the absorption of oxygen in the inhibited oxidation of the hydrocarbons in the presence of an oxidation initiator—azobisisobutyronitrile—at 60 °C.[90]

On irradiation with UV light (mercury lamp), methylenequinones react with methanol somewhat differently. According to the data of Yang et al.[94] and Matsuura and Ogura,[95] when a solution of the methylenequinone (I) or 2,6-di-t-butyl-αα-diphenylmethylenequinone (XIII) in methanol is irradiated, radicals are formed initially from methanol and then react with the methylenquinones. The reaction also proceeds via the phenoxy-radical formation stage:

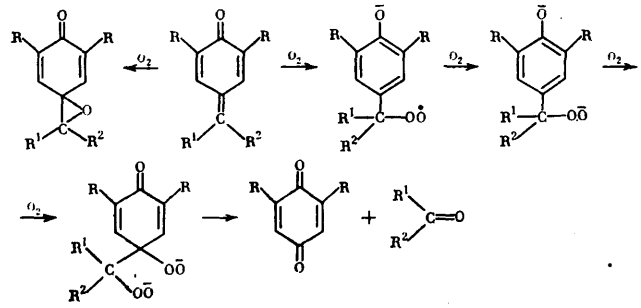


The formation of characteristic radical products has also been noted in the interaction of the methylenequinone (I) in the triplet state with 2,6-di-t-butylphenol[96] and vinylphenols.[97] These are multistage reactions. The phenol is initially dehydrogenated by the

methylenequinone with formation of two phenoxy-radicals, for example, the phenoxy-radical (V) and the 2,6-di-t-butylphenoxy-radical. As noted above, the methylenequinone (I) dimerises spontaneously with formation of the biradical (X), whose recombination with the 2,6-di-t-butylphenoxy-radical leads to the formation of compound (XIV) in 17% yield:[96]



(I) (X)



(XIV)

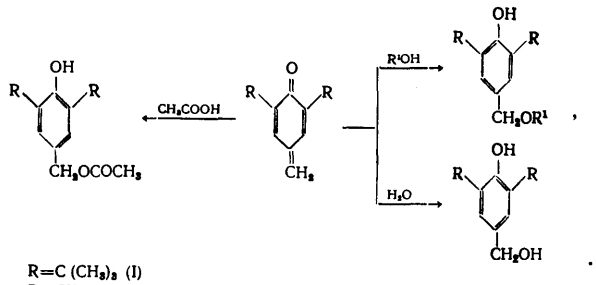
The majority of the known stable methylenequinones are inert in relation to oxygen. However, examples of the catalytic interaction of oxygen with substituted methylenequinones and its non-catalytic reaction with the methylenequinone (I), as a result of which the cyclic peroxide (XV) of the quinolide type is produced, are known. In the given instance, the biradical (X) participates in the reaction with oxygen:[98]

(I) (X) (XV)

In the catalytic oxidation of alkylmethylenequinones, the oxygen adds initially to the methylene carbon, as a result of which a mixture of oxygen-containing compounds is formed: quinols, the corresponding hydroperoxides, and other products.[88,99,100] For example, in the presence of cobalt compound, the reactions considered have a multistage mechanism and the final products are formed as a result of the occurrence of several stages involving the consecutive oxidation and fragmentation of the intermediate relatively unstable radical-ions, dianions of the quinolide type or having an aromatic structure:[101]

The selectivity of this oxidation depends on the nature of the catalyst and the solvent and temperature.

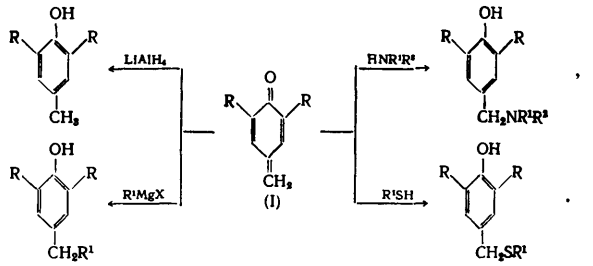
The typical radical reactions examined above are in fact characteristic of the biradical structure of methylenequinones. On the other hand, methylenequinones exhibit the properties of unsaturated carbonyl compounds with their characteristic heterolytic reactions. An example of a reaction characterising the methylenequinone system as a whole is the stepwise electrochemical reduction. The electron, interacting with the substrate, has the properties of both a radical and a nucleophile. As a nucleophile, the electron interacts in the course of the one-electron electrochemical reduction with the overall π-system of the methylenequinone molecule and passes to the lowest unoccupied molecular orbital. The spin density in the radical-anion formed is localised at the methylene carbon atom[102] and the latter therefore possesses the typical properties of radicals of the hydroxybenzyl type with their characteristic dimerisation processes.[51,56] On the other hand, in the initial step of the interaction between the methylenequinone and the electron, the general properties of methylenequinones as unsaturated carbonyl compounds are exhibited and these properties depend to a large extent on the presence and nature of the substituents in the methylenequinone molecule. For this reason, the electrochemical data for methylenequinones will be examined below in the Section devoted to the heterolytic reactions of these compounds.



V. HETEROLYTIC 1,6-ADDITION REACTIONS

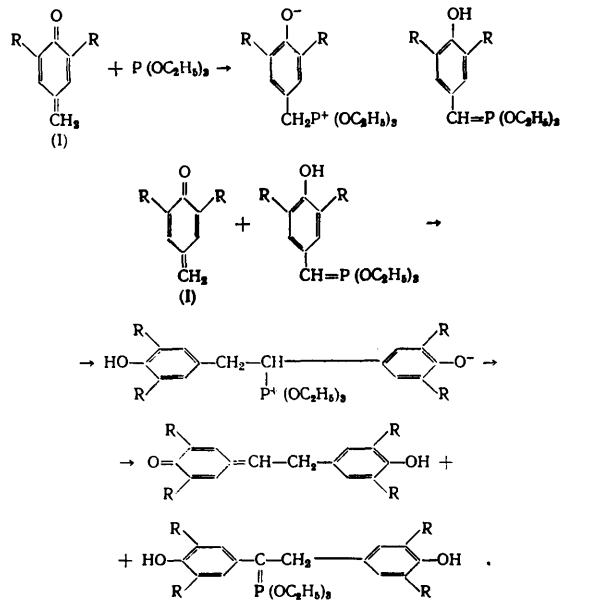
By virtue of the presence in the conjugated system of atoms with different electronegativities, the methylenequinone molecule contains two reaction centres: a nucleophilic centre which consists of the oxygen of the carbonyl group and an electrophilic centre which consists of the carbon of the methylene unit. Depending on the nature of the attacking agent, the reaction can be directed initially to either of the centres indicated. In both cases the result of the reaction is the same—1,6-addition with formation of phenol derivatives having functional group substituents. Nautrally, the reactions with electrophiles begin with the attack on the most electronegative oxygen atom of the carbonyl group incorporated in the conjugation system of the methylenequinone molecule. 2,6-Disubstituted methylenequinones readily react via the mechanism indicated with many electrophiles, which leads to different phenol derivatives with functional group substituents. Protic acids, water, and alcohols react with alkylmethylenequinones via the same pathway.

In dilute solutions, the methylenequinones (I) and (II) react with alcohols via a pseudofirst-order process and the rate of the latter depends quantitatively on the pK_a of the alcohols.[15,103-105] The hypothesis that associated alcohol species participate in the reaction has been justified kinetically.[105] The methylenequinone (II) is more reactive, its reaction, at a concentration of 10^{-2} M, with methanol being 550 times faster than that of the methylenequinone (I).[15] The rate constant for the reaction of the methylenequinone(II) with t-butyl alcohol (k = 1.2 x 10^{-8} s^{-1}) is smaller almost by three orders of magnitude than in the case of methanol (k = 3 x 10^{-5} s^{-1}) or ethanol (k = 4.5 x 10^{-5} s^{-1}); this methylenequinone reacts with acetic acid at a higher rate (k = 1.35 x 10^{-4} s^{-1}). The dependence of the rate of reaction of the methylenequinone (II) with water on its concentration corresponds to a fractional reaction order, because of the exclusive involvement of associated water species in the reaction.[105]

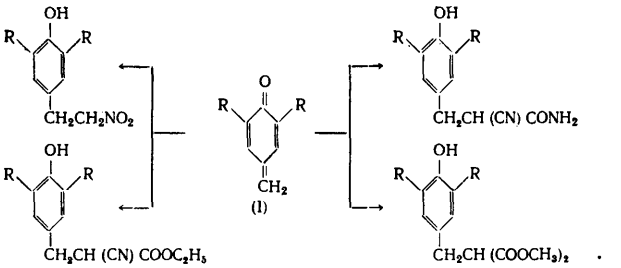


The kinetic features, examined above, of the reactions of 2,6-disubstituted methylenequinones with alcohols, protic acids, and water are valid for dilute solutions at a temperature not higher than 20 °C. Under these conditions, methylenequinones exhibit the properties of unsaturated ketones with their characteristic 1,6-heteroaddition

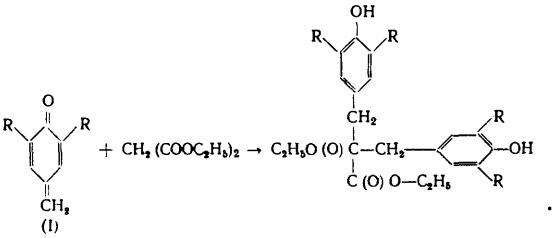
reactions:



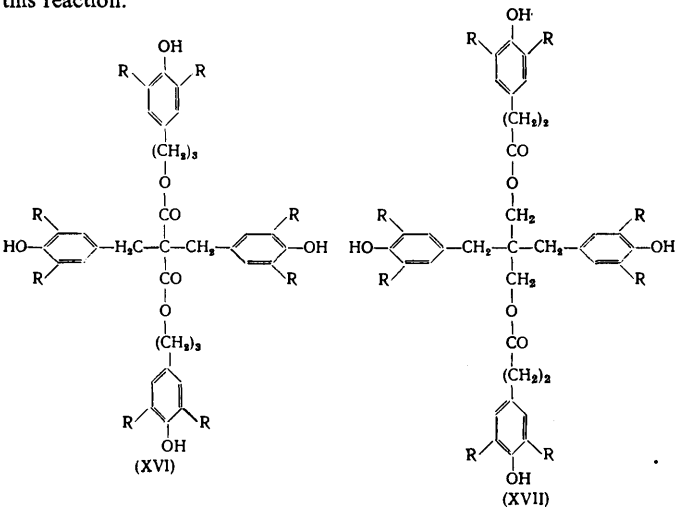
R=C (CH$_3$)$_3$ (I)
R=CH$_3$ (II)



Different workers have investigated most widely the reactions of the methylenequinone (I). which is formed as an intermediate in nucleophilic reactions and on oxidation of a number of derivatives of sterically hindered phenols.[15,30,88,93,106,107] Initially the addition of the nucleophilic species to the methylene carbon atom of the methyl-enequinone molecule also induces the conversion of the quinonoid bond system into an aromatic hydroxy-system and leads to the same reaction product as the initial addition of the proton of the acid reagent. Typical examples of such reactions are those of the methylenequinone (I) with mercaptans, amines, and Grignard reagents, the reduction by alkali metal hydrides, and other reactions:[30,108-112]



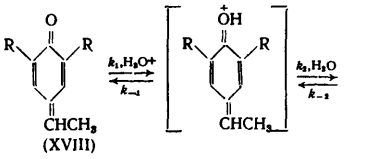
The methylenequinone (I) reacts specifically with triethyl phosphite. This is a multistage reaction:[113]



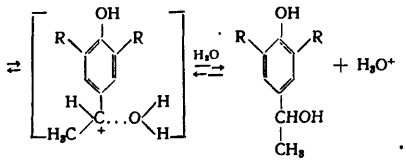
However, as a rule, in most reactions of methylenequinones with nucleophiles a high selectivity is retained, which makes it possible to use them for the synthesis of a wide variety of phenols with functional group substituents, in the first place in the synthesis of antioxidants for the stabilisation of polymers[8,108] and in biological research.[8,114] Thus nitromethane, malonic ester, cyanoacetamide, and cyanoacetic ester add to the methylenequinone(I) with a high degree of selectivity:[115,116]

The nature of the catalyst plays a significant role in the process selectivity. For example, in the presence of potassium t-butoxide, the methylenequinone (I) reacts with malonic ester to form a 1 : 1 adduct, while in the presence of sodium methoxide a 2 : 1 adduct is formed, namely bis(3,5-di-t-butyl-4-hydroxybenzyl)malonic ester:[116,117]

Effective polymer stabilisers (phenozans) have been obtained by this reaction:[117,118]

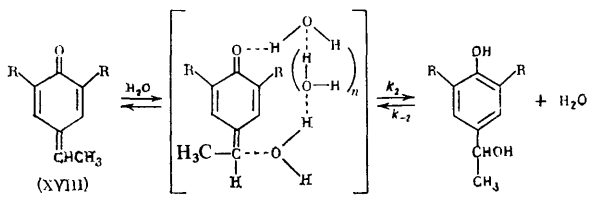


These structurally similar stabilisers are interesting because they behave differently in oxidation by one-electron oxidants. Whereas the oxidation of compound (XVI) leads to the formation of a stable methylenequinone, the oxidation of compound (XVII) involves oxidative dimerisation leading to an increase in the molecular weight of the antioxidant, which significantly improves its thermoprotective properties.[51]



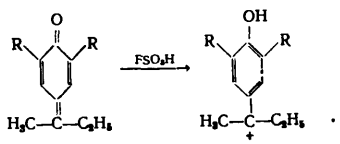
1. α-Alkylmethylenequinones

The homologues of methylenequinones containing alkyl substituents, the carbon atom of the methylene unit and t-butyl groups in the six-membered ring are relatively stable in a pure states. Reactions in the triplet state are no longer characteristic of these

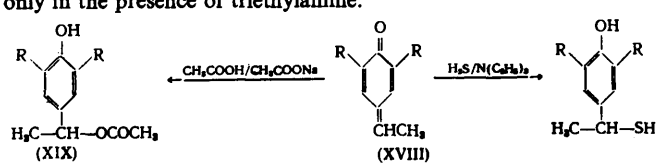


compounds but they retain a high reactivity in reactions with both proton-containing and nucleophilic agents. The effect of the pH of the medium on the mechanism of the 1,6-heteroaddition in reactions of α-alkyl-2,6-di-t-butylmethylenequinones with water is manifested more clearly than in the analogous reaction with the methylenequinone (I) or (II). The following mechanism operates in acid media (pH 2.4 – 5.1):[119]

(XVIII)



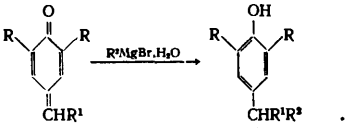
The reaction involving the addition of water to 2.6-di-t-butyl-α-methyl methylenequinone (XVIII) is reversible and the H_2O/D_2O isotope effect is 1.2 in an acid medium. In neutral media (pH 5.1 to 9.5) the transition state incorporates several water molecules and the reaction itself proceeds via the mechanism[119]



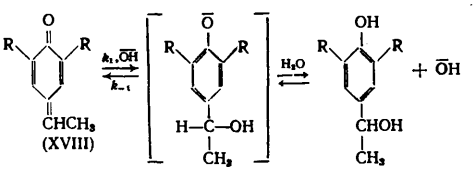
(XVIII)

The H_2O/D_2O isotope effect is 2.56.

The features of the behaviour of the methylenequinone (XVIII) in acid and neutral media examined are general and have been confirmed by other reactions of different α-alkyl- and αα-dialkyl-2,6-t-butylmethylenequinones with alcohols[120] and organic and inorganic acids.[121-124] The formation of the corresponding carbonium ion has been demonstrated by ^1H NMR in the reaction of 2,6-di-t-butyl-α-ethyl-α-methylmethylenequinone with fluorosulphonic acid at -40 °C:[125]



It is noteworthy that the appearance of carbonium ions in the reaction of α-alkylmethylenequinones with proton-containing reagents promotes the irreversible isomerisation of the methylenequinone structure to the aromatic structure of a vinylphenol (see below). The selectivity of many reactions with participation of α-alkylmethylenequinones therefore depends on the specific conditions and increases sharply with increase in the nucleophilicity of the reagent. For example, in the reaction of the methylenequinone (XVIII) with acetic acid, the corresponding 1,6-adduct—3,5-di-t-butyl-4-hydroxy-α-methyl benzyl acetate (XIX)—was obtained in 35% yield, while in the presence of sodium acetate the same reaction takes place more selectively and the yield of compound (XIX) is 90%. The methylenequinone (XVIII) reacts with hydrogen sulphide only in the presence of triethylamine:[30]



(XIX) (XVIII)
