The reinforcement of combustible polymeric binders with chemical fibres containing an antipyrene makes it possible to improve the resistance to combustion of not only the fibre by itself but also of the polymer matrix.[35–38]

Questions concerning the theory and technology of the preparation of the antipyrene-modified, so called fire-proofed fibres have been described in numerous publications and inventions.[39–83] It is possible to differentiate the following methods whereby resistance to combustion can be imparted to chemical fibres: surface treatment of the fibres with antipyrenes, the introduction of antipyrenes into the polymer before the formation of the fibres, and chemical modification. Various phosphorus-, chlorine-, bromine-, and nitrogen-containing compounds or their synergistic mixtures are used for this purpose.

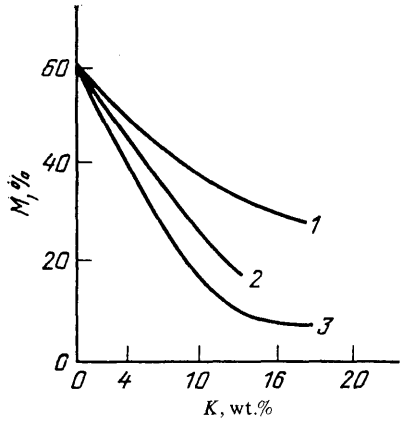

Figure 1. Dependence of the weight loss by the PCM (M) on the amount of inhibitors (K):[37] 1) PAN fibre + SF-342A composition modified with DBPP, Br + P being present in the binder; 2) AN/VC fibre + SF-342A, Cl forming part of the composition of the fibre; 3) PAN fibre modified with DBPP + SF-342A, Br + P being present on the fibre.

The employment of synthetic resins for reducing the combustibility of PCM reinforced with combustible chemical fibres (PAN, VF, PE) is relatively ineffective, since it requires the introduction into the material of large amounts of an antipyrene, which increases its cost and at the same time impairs its physicomechanical properties. In such compositions, it is desirable to introduce the antipyrene not into the polymeric binders but together with the reinforcing fibre.[35–38,84–91] For example, PCM based on anilino-phenol-formaldehyde resin SF-342A and PAN fibres fire-proofed by impregnation with dibromopropyl phosphate (DBPP) is characterised, compared with other materials containing the same amount of DBPP in the binder, by a weight loss smaller by a factor of two (Fig.1, curves *1* and *2*), a lower rate of propagation of the flame, an ignition point higher by 20 K, and an increase in the oxygen index (OI), characterised by the minimum oxygen content in the oxygen–nitrogen mixture ensuring the candle-like combustion of materials and expressed in volume percentages (or volume fractions), from 28 to 34%.

Analogous results have been obtained for phenolic compositions containing antipyrenes with different efficiencies. The Br + P mixture of combustion inhibitors, which is more effective than Cl, reduces the weight loss to a greater extent following the ignition of materials in air when these antipyrenes are introduced into the composition together with the reinforcing fibre [Br + P was introduced with the PAN fibre modified by DBPP, while Cl was introduced together with the reinforcing system comprising a mechanical mixture of PAN and the AN/VC copolymer fibres (Fig.1, curves *2* and *3*)].

However, the Cl entering into the composition of the reinforcing fibre reduces the combustibility of PCM to a greater extent than Br + P introduced into the phenolic resin as part of the composition of DBPP (Fig.1, curves *1* and *2*).

The greater inhibition of the combustion of PCM after the introduction of the antipyrene with the fibre can be explained by the fact that the antipyrene permeates from the fibre to the layer of polymer matrix, protecting thereby both the fibre itself and the polymeric binder against combustion. This has been confirmed experimentally on model PCM specimens prepared by casting in ED-20 epoxide resin lavsan fire-proofed with tricresyl phosphate (TCP).[37] The study of the specimens by scanning electron microscopy combined with X-ray spectroscopic analysis revealed the presence of phosphorus in the boundary layer of the polymer matrix adjoining the fibre over distances exceeding the maximum thickness (5 μm) of the layer of binder in PCM produced by the direct pressing method. The number of pulses recorded over a period of 30 s and characterising the phosphorus content in the specimen was 34 in the reinforcing fibre itself and on moving away from the surface of the fibre into the layer of polymer matrix to distances of 1, 7, 10, 17, and 40 μm the numbers of pulses were respectively 32, 28, 23, 16, and 0.

The antipyrene introduced with the binder permeates into the structure of the reinforcing fibre less effectively and inhibits mainly the combustion of the polymer matrix.[86] This is indicated by the increased weight loss in the combustion of PCM observed when the content of the PAN fibre is increased from 30 to 60% with an unchanged content of the antipyrene introduced into the composition together with the binder (Table 1).

III. INTER-RELATION BETWEEN THE CHEMICAL COMPOSITION OF THE REINFORCING FIBRES AND POLYMERIC BINDERS, AND THE THERMAL STABILITY AND COMBUSTIBILITY OF THE POLYMERIC COMPOSITE MATERIALS

The dependence of the thermal stability and combustibility of unfilled polymers on their chemical structure has been noted in a number of studies.[92–94] It has been shown that (a) there is a correlation between the yields of the coke residue (CR) formed on pyrolysis and the OI of the polymers not containing inhibitors of flame reactions:[92]

$$\mathrm{OI} \times 100 = 17.5 \pm 0.4\,\mathrm{CR};$$

(b) the tendency towards the formation of coke is an additive characteristic of the polymer and can be estimated from the

contributions of the functional groups constituting the polymer units:[92]

$$CR = \frac{\sum(TFC)_i \times 12}{M} \times 100\%,$$

where TFC is the tendency of the group i to form coke expressed in carbon equivalents per polymer unit and M is the molecular weight of the unit; (c) there is a relation between the OI and the heat of combustion per gramme of the test substance:[92]

$$OI = 1.9/\Delta h_{comb},$$

but the relation does not hold for a series of materials, including cellulose, polyacrylonitrile, etc.;[92] (d) there is a relation between the OI and the elemental composition of the polymer.

Table 1. Weight losses in the combustion of PCM containing bromine and phosphorus introduced with the binder.[86]

Br + P content in binder wt.%	Weight loss (%) in different compositions		
	60% PAN fibre + 40% SF-342A resin	50% PAN fibre + 50% SF-342A resin	30% PAN fibre + 70% SF-342A resin
0	60	59	52
2	58	57	46
5	58	50	36
10	49	38	27
15	45	31	—

The thermophysical and thermochemical properties of the fibres have a decisive influence on the characteristics of the thermal degradation and combustion of composite materials reinforced with chemical fibres, such materials constituting multicomponent systems. For example, the temperature of the degradation of the PCM reinforced with PVC and PAN fibres, a mechanical mixture of PAN (60 wt.%) and PVC (40 wt.%) fibres, and AN/VC copolymer fibre is higher by 20–50 K than the temperature of the degradation of the unfilled epoxide resin. The degradation temperatures are directly related to the thermal stabilities of the reinforcing fibres, which can be arranged in the following sequence in terms of this parameter: PAN > PAN + PVC mixture > AN/VC copolymer > PVC.[38]

One of the main characteristics of combustion is the rate of the latter. It can be expressed as the mass velocity characterising the burning up of the material. The rates of pyrolysis of materials under different conditions, including the temperature regimes which obtain on combustion, have been determined from the mass velocity of the degradation reduced with respect to the current mass of the specimen for which the given mass velocity has been found, i.e. with respect to the quantity $\dot{m}/m$, where $\dot{m} = dm/d\tau$, m is the current mass of the specimen in grammes, and τ is the duration of the test in seconds.[38]

The introduction of fibres into epoxide compositions lowers by a factor of 1.5–2 the rate of their pyrolysis and increases by a factor of 2–3 the yields of coke. On the other hand, the presence of fibres in phenolic PCM increases the rate of pyrolysis by a factor of 1.5–3 and lowers the yield of coke by 30–50%. However, the rate of pyrolysis of the material is determined to a large extent by the chemical composition of the fibres, which follows from the fact that the rate of pyrolysis of the unfilled epoxide resin is higher by a factor of 4 than that of the phenolic resin, while the rates of pyrolysis of PCM based on these binders differ by only 20–50%. The same character of the variation of the rate of pyrolysis and of the yield of coke can then be noted for both epoxide and phenolic PCM reinforced with identical chemical fibres (Table 2).[38,87]

Table 2. The mass velocities of the pyrolysis of PCM and the yield of coke at different temperatures:[38]

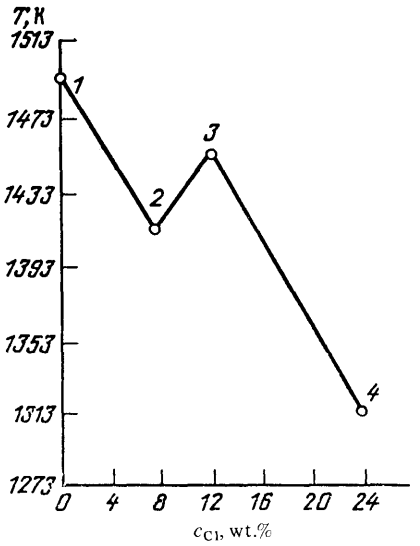
Reinforcing fibre	Temperature, K				
	673	773	873	973	1073
	Epoxide PCM				
PAN	0.64; 60.0	0.98; 31.0	1.54; 30.0	1.96; 26.5	2.44; 25.0
PVC	0.5; 56.0	0.94; 21.5	1.26; 16.0	1.8; 15.0	2.22; 14.0
AN/VC copolymer	0.65; 47.0	1.15; 27.0	1.75; 23.5	2.4; 21.5	3.0; 20.0
PAN + PVC mixture	0.4; 56.0	0.9; 35.0	1.4; 30.0	1.9; 28.0	2.35; 25.0
ED-20 without fibre	0.4; 53.0	2.5; 25.0	2.8; 9.0	3.35; 9.0	3.9; 9.0
	Phenolic PCM				
PAN	0.45; 79.0	0.78; 64.5	1.1; 61.5	1.4; 58.0	1.6; 55.0
PVC	0.35; 68.5	0.65; 64.5	0.98; 60.0	1.3; 55.0	1.5; 50.0
AN/VC copolymer	0.35; 73.0	0.8; 51.5	1.3; 49.5	1.8; 48.0	2.3; 46.0
PAN + PVC mixture	0.4; 71.0	0.7; 58.0	1.0; 54.0	1.3; 52.0	1.6; 50.0
SF-342A without fibre	0.08; 85.0	0.2; 80.0	0.4; 76.0	0.8; 60.0	1.0; 87.0

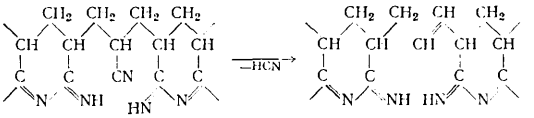
*The first figure represents the mass velocity of pyrolysis (s^{-1}) and the second the yield of coke (wt.%).

The chemical composition of the fibres in PCM influences also the temperature in the flame zone, which depends to a large extent on the composition of the pyrolysis gases from the reinforcing fibres.[38] For example, the flame temperature in the combustion of PCM based on PAN fibres is higher by 30 K than in the combustion of the unfilled epoxide resin. The observed dependence of the flame temperature on the amount of chlorine in the reinforcing fibres is complex (Fig.2): in the combustion of materials reinforced with the AN/VC copolymer fibre containing 13% of chlorine, it is higher than in the combustion of PCM based on the mechanical mixture of PAN + PVC fibres (60 and 40 wt.% respectively), containing 9% of chlorine. This is associated with the higher content of the combustible HCN in the pyrolysis gases of the AN/VC fibre compared with the gases evolved on pyrolysis of the mechanical mixture of PAN + PVC fibres (Fig.3).[89] These data show that the combustibility of the material depends not only on the composition but also on the structure of the reinforcing systems.

The ignition delay time is determined by the heat changes accompanying the degradation of the reinforcing fibres.[88] The unfilled epoxide resin has an ignition delay time of 1.3 s. The introduction of PAN fibres into the composition lowers the ignition delay time to 1.0 s, since the degradation of the fibre itself is characterised by an appreciable heat change (Fig.4, curve *3*). The ignition delay times of the PCM reinforced with chlorine-containing fibres, a mixture of

PAN and PVC fibres, which are degraded with smaller heat changes than the PAN fibre (Fig.4, curves *1* and *2*), are longer and amount to 1.8 and 2.2 s respectively. The maximum ignition delay time (2.6 s) is characteristic of PCM with the AN/VC copolymer fibres, whose degradation in the initial stage takes place endothermically (Fig.4, curve *4*).[88]





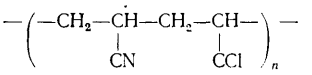


Figure 2. Dependence of the flame temperature (T_f) of epoxide PCM on the chlorine concentration c_{Cl} in the reinforcing fibres:[38] 1) non-reinforced ED-20 epoxide resin; 2) PAN + PVC; 3) AN/VC; 4) PVC.

chain with formation of double bonds via the reaction[99]

The introduction of chlorovinyl groups into the polyacrylonitrile molecule,

prevents its cyclisation, since steric hindrance due to the appearance of unconjugated nitrile groups arises. This increases the amount of uncyclised sections and hence the yield of HCN.[89]

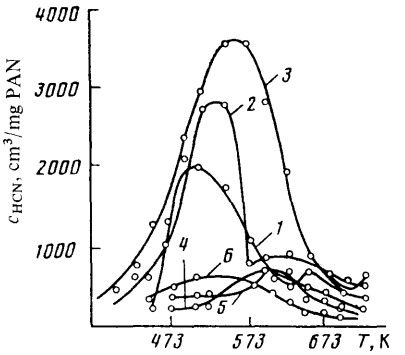

Figure 3. Dependence of the yield of HCN c_{HCN} on the pyrolysis temperatures of various fibres and composite materials based on them:[89] 1) PAN fibre; 2) AN/VC fibre; 3) PCM based on the AN/VC fibres; 4) mechanical mixture of PAN + PVC fibres; 5) PCM based on the PAN + PVC mixture of fibres; 6) PAN fibre modified with 2,3-dibromopropyl phosphate.

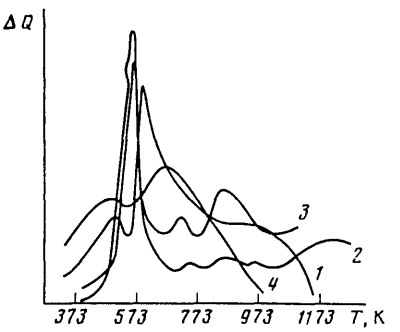

Figure 4. Differential thermal analysis curves for different fibres (Q are the heat changes):[89] 1) PVC fibre; 2) PAN + PVC mechanical mixture; 3) PAN; 4) AN/VC copolymer fibre.

IV. REDUCTION OF THE HCN TOXICITY OF THE PYROLYSIS GASES FROM POLYMERIC COMPOSITE MATERIALS REINFORCED WITH POLYACRYLONITRILE-CONTAINING FIBRES

The polyacrylonitrile-containing fibres used to reinforce resins evolve toxic gases, including HCN, on pyrolysis.[95-97]

A decrease in the HCN toxicity of PCN can be attained in several ways. Thus the amount of HCN evolved from the PAN fibres can be reduced by using graft copolymers of PAN with cellulose. In the pyrolysis of such fibres, the yield of HCN is appreciably reduced owing to a change in the mechanism of the thermal decomposition of PAN: the water evolved on pyrolysis of cellulose hydrolyses the nitrile groups, as a result of which NH_3 is evolved instead of HCN.[98] The AN/VC copolymer fibres used for reinforcement afford an even higher yield of HCN than the PAN homopolymer fibres (Fig.3, curves *1* and *2*).[89] This phenomenon has been explained by the fact that heating of PAN fibres entails complex chemical reactions and structural transformations: cyclisation, aromatisation, and depolymerisation,[97] while the evolution of HCN in the temperature range 473–823 K takes place mainly from the uncyclised sections of the

The second method of reducing the yield of HCN involves the use of a mechanical mixture of the PAN + PVC fibres.[92] Thus the yield of HCN from a mixture of 60 wt.% PAN and 40 wt.% PVC fibres is lower by a factor of ~6 compared with the AN/VC copolymer fibres with the same content of polyacrylonitrile (Fig.3, curves *2*

and *4*). In this reinforcing system, PVC accelerates catalytically the cyclisation of PAN, which reduces the evolution of HCN.[89] The yield of HCN from phenolic PCM reinforced with a mixture of PAN + PVC fibres is close to that observed in the pyrolysis of the reinforcing mixture of fibres (Fig.3, curves *4* and *5*). On the other hand, the yield of HCN from PCM reinforced with the AN/VC copolymer fibres is higher than for the reinforcing fibres (Fig.3, curves *2* and *3*). This has been explained by the different chemical mechanisms of the degradation of the above reinforcing systems, leading to a difference between the degradation reactions of the PCM based on them.

According to differential thermographic (DTA) data (Fig.4), an exothermic peak characteristic of the PAN cyclisation process is observed in the thermal degradation of both PAN fibres and the mixture of PAN + PVC fibres in the same temperature range.[89] For an AN/VC copolymer fibres, an endothermic peak characteristic of the dehydrochlorination processes is observed in the same temperature range, while the exothermic peak corresponding to cyclisation is displaced towards higher temperatures. Since the degradation of the phenolic resin occurs at higher temperatures compared with the AN/VC fibres, the HCl evolved in the dehydrochlorination process accumulates in the bulk of the material, leads to the depolymerisation of PAN, and increases the yield of HCN compared with that observed from the AN/VC fibres alone.[89]

An effective method of reducing the amount of HCN involved consists also in modifying the PAN fibres with dibromopropyl phosphate $(CH_2-Br-CHBr-CH_2O)_3PO$ (Fig.3, curve *6*).

Table 3. The yield of water and HCN in the pyrolysis of fibres.[86–88]

Fibre	c_{H_2O}, cm^3/mg PAN at different temperatures, K				c_{HCN}, cm^3/mg PAN at different temperatures, K			
	423	523	623	723	523	623	723	823
PAN	155	210	150	80	1050	2600	480	180
PAN + 11 wt.% (Br + P)	75	520	710	320	310	750	220	55

V. THE MECHANISM OF THE ACTION OF ANTIPYRENES IN POLYMERIC COMPOSITE MATERIALS

It has been established[93] that various compounds containing isotypical combustion inhibitors have different types of influence on the combustibility of polymers. Bromine-, chlorine-, and phosphorus-containing antipyrenes or their synergistic mixtures exert an inhibiting effect on a series of specific PCM.[37,38,84–89]

The bromine + phosphorus system introduced into the composition of the PAN fibres fire-proofed with dibromopropyl phosphate acts on phenolic PCM [86–88] and alters the course of the reactions in both condensed and gas phases. The composition of the pyrolysis gases changes under these conditions—the water content c_{H_2O} increases and the HCN content c_{HCN} diminishes (Table 3), the amount of heat evolved is reduced, which slows down the reaction in the gas phase, the flame temperature T_{fl} diminishes, the ignition temperature T_i increases, and the yield of coke falls slightly (Table 4).

Table 4. Characteristics of the thermal degradation and combustion of PCM (1 : 1 fibre : resin ratio).[86–88]

Composition	Coke residue (%) at different temperatures, K					T_i, K	T_{fl}, K	OI, %
	673	773	873	973	1073			
PAN + SF-342A	79.0	64.5	61.5	58.0	55.0	1383	1537	27
[PAN + 11 wt.% (Br + P)] + SF-342A	71.0	60.5	56.5	55.0	54.0	1437	1483	34

The introduction of antimony trioxide (Sb_2O_3) into PVC fibre + epoxide resin + polyethylenepolyamine compositions slows down the smoke formation process, increases the yield of coke, lowers the weight loss on combustion, and increases the OI and the ignition temperature (Table 5).[90,91]

Table 5. The influence of Sb_2O_3 on the characteristics of the combustion of epoxide PCM reinforced with PVC fibre.[93,94]

Combustion inhibitor and its content, wt.%	OI, %	Weight loss, %	T_i, K	Yield of coke (%) at different temperatures, K		
				773	873	973
Cl (23.9)	29.0	67.0	1392	21.5	16.0	15.0
Cl (23.9) + Sb_2O_3 (10)	38.0	10.5	1440	29.0	25.0	23.0

In compositions with a phenolic resin reinforced with the AN/VC copolymer fibres, the action of Sb_2O_3 is manifested by an increase (almost by a factor of 2) in the amount of coke residue, a decrease in smoke formation, and a decrease in the weight loss on combustion.[86,88]

Chemical Principles of the Biotechnology of the Preparation of Fuel

S.D.Varfolomeev, S.V.Kalyuzhnyi, and D.Ya.Medman

The chemical aspects of the biotechnology of the preparation of fuels together with the potential resources and possibilities of the biofuel technology are described. The present state of research into the preparation of biogas (mixture of methane and carbon dioxide), ethanol, acetone, butyl alcohol, and hydrogen from the biomass is examined. The technological features and economic aspects of the processes listed above are analysed.
The bibliography includes 213 references.

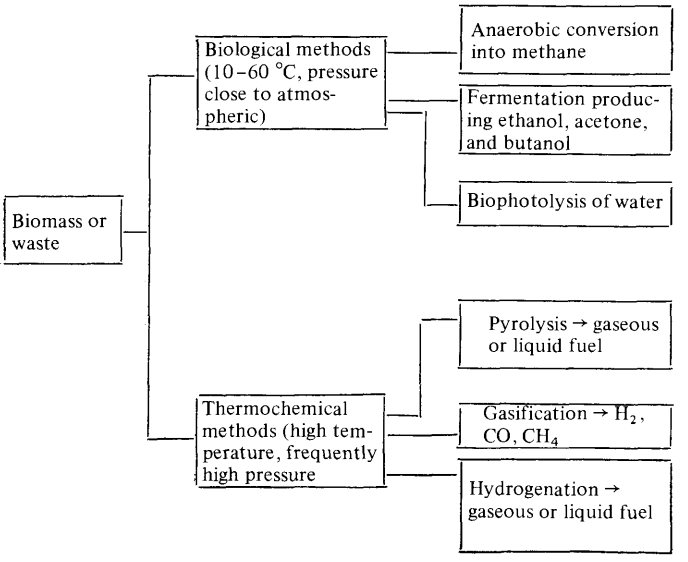
VI. Conclusion 700

The last decade has been characterised by an increasing interest in the problem of the application of renewable sources of energy. One of the main aspects of this research is associated with the use of solar energy. In recent years, biotechnological methods for the conversion of solar energy into fuel have developed significantly. The world interest in this problem is high, numerous symposia, conferences, and seminars being held annually.

A new scientific and technical field concerned with "fuel from the biomass" has been developed fairly vigorously in our country.[1-6] A number of projects have reached the level of technical solutions, whereas other are passing through the stage of laboratory research and experimental tests.



I. POTENTIAL RESOURCES AND POSSIBILITIES OF THE BIOFUEL TECHNOLOGY

The biomass is the cheapest form of renewable energy which can be accumulated on a large scale. By the term biomass, we understand any materials of biological origin, metabolic products, and the organic waste formed in the course of their processing. The daily increment in the biomass on Earth is 200 billion tonnes, which have an energy equivalent of 3×10^{21} J.[7,8]

The systems for the conversion of energy by preparing biofuels are fairly varied and include processes involving the preparation of methane, hydrogen, ethanol, methanol, butyl alcohol, and acetone as well as a number of other components of interest as fuel materials. The overall possibilities of the biofuel technology are fairly considerable and have been discussed in a review.[9]

The products derived from natural vegetation, agricultural waste, a wide variety of industrial waste and waste produced by the municpal economy and finally the crops specially grown in the so called "energy plantations" (sugar cane, manioc, potatoes, plankton, etc.) are potential raw materials for the production of biofuel.

The energy content of certain types of fuel, waste, and biomass are presented in Table 1. The simplest method of extracting energy from many materials is their combustion. Other methods of processing the initial raw material are presented in the Scheme below:

Estimates of the potential contribution of biofuel to the overall energy provision to the community are of fundamental importance. Evidently, biofuel technology may serve as a basis of new power engineering in the developing countries which have relatively poor energy resources but are located in zones with a high bioproductivity. Estimates of the percentage contribution of biofuels in highly developed countries are the subject of lively discussion in the literature.

The utilisation of the biomass in the USA amounts nowadays to 2% of the total energy consumption (1.5 quad g^{-1} or 1.6×10^9 GI g^{-1}).† Various estimates for the year 2000 range from 4 quad g^{-1} (4.2×10^9 GI g^{-1}) to 17 quad g^{-1} (1.8×10^{10} GI g^{-1}). The latter quantity amounts to 15-20% of the total energy production in the USA.[11]

† 1 quad corresponds to 10^{15} British Thermal Units, each of which is equal to 1.06×10^9 GI. This quantity corresponds to approximately 50 million tonnes of coal [Ed.of Translation].

Considerable attention has been devoted to prospects for the utilisation of renewable energy sources in europe. The problem of the preparation of biogas which has been subjected to a detailed and thorough analysis for various European countries.[10-12] The principal conclusion reached in these investigations is that biofuels will play a significant role in the power generation in these countries. By the year 2000, the contribution of the biotechnology of the preparation of fuel to the overall energy requirements of the countries in the Common Market will be 5–10%. For comparison, we may point out that the production of hydroelectric energy in the overall energy balance is only 2%.

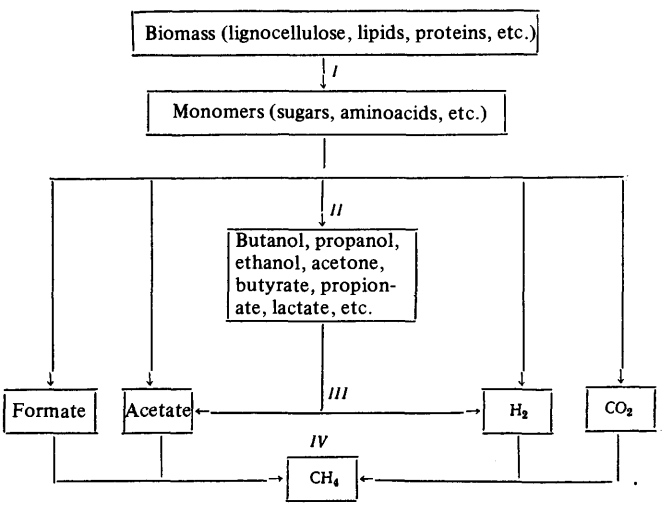
Table 1. The energy contents of certain types of fuels, waste, and biomass.[10]

Fuel	Energy content, MJ kg^{-1}	Biomass and waste	Energy content, MJ kg^{-1}
Coal	29 3	Typical biomass	14.0
Coke	28.4	Bacteria	22.7
Dry ash-free peat	21.0	Algae	20.0
Air-dry peat (25% H_2O)	16.3	Straw (15% H_2O)	14.2—15.5
		Dry straw	17.0
Brown coal	14.7	Grassy materials	17.5
Lignite, commercial fuel	26.8	Natural plants	18.3
		Wet wood	16.0
Unrefined petroleum	42.3	Dry ash-free wood	18.7
Diesel fuel	41.0		
Petrol	43.5	Unpurified waste	9.0—11.0
Kerosine	45.6—47.8	Fuel waste	14.7—15.6
Purified gas	41.0	Cattle manure	21.4
Natural gas[a]	31.7—39.8		
Coking gas[a]	16.1	Pig manure	20.0
Hydrogen[a]	12.1	Monosaccharides	15.5
Methane[a]	37.7	Polysaccharides	17.6
Biogas (60% CH_4)[a]	22.3	Lignin	31.1
Methanol	22.4	Protein	23.9
Ethanol (95%)	28.2	Fat	31.4
Ethanol (100%)	29.7	Carbohydrates	16.7—17.6
Isopropyl alcohol	33.0	Unpurified fibre	18.8—19.7
n-Propyl alcohol	33.6		
n-Butyl alcohol	36,2		

[a]Energy content in MJ m^{-3}.

The role of the biomass in the energy supply in the countries of Latin America has been analysed and it has been shown that 10–20% of the overall energy requirement in these countries will be met by employing the biomass and the biotechnology for its conversion into fuel.[13]

The energy programme in China has been discussed[14,15] and it has been shown that up to 30% of the energy provision in that country will be achieved by employing biofuels.



The ecological problems of the utilisation of the biomass and the advantages associated with it have been discussed.[16]

II. BIOGAS

The technology of the preparation of biogas (a mixture of 50–80% of methane and 20–50% of carbon dioxide) by the anaerboic conversion of various types of plant raw materials and organic waste has been developed to the greatest extent.[17-20] At the present time, studies in this field are being prosecuted both within the framework of fundamental research into the formation of methane by complex microbial populations and within the framework of the creation of an improved technology for the intensification of the process.

1. Principles of the Preparation of Methane

The anaerobic conversion of the biomass into methane (methane fermenation) is a complex multistage decomposition of a wide variety of organic materials under anaerobic conditions under the influence of bacterial flora, whose final result is the formation of methane and carbon dioxide. According to modern ideas, the anaerobic conversion of virtually any biomass into methane proceeds via four successive stages: the stage involving the hydrolysis (cleavage) of complex biopolymer molecules (proteins, cellulose, lipids, etc.) into simpler molecules, for example, monomers: aminoacids carbohydrates, etc.; the stage involving the fermentation of the resulting monomer to still simpler substances—lower acids and alcohols; the acetogenic stage (the formation of H_2, CO_2, formate and acetate), and then directly the methanogenic phase, which leads to the final cleavage product—methane:[19,21]

The study of the kinetics of methanogenesis from various substrates (cellulose, hemicelluloses, monosaccharides, ethanol, methanol, butyrate, and acetate) has been described in a number of communications,[21-29] kinetic schemes have been devised, and computer models describing processes involving the formation of methane in such systems, in the presence of natural methanogenic microbial populations, the *Methanobacillus kuzneceovii* system, and the pure *Methanosarcina vacuolata* have been constructed. As an example, Fig.1 illustrates the dynamics of the anaerobic conversion of glucose into methane in the presence of the methanogenic *Methanobacillus kuzneceovii* system. The overall experimental data accumulated as a result of the study of this process are summarised by the following kinetic scheme:

$$C_6H_{12}O_6 + H_2O \rightarrow 2H_2 + 2CO_2 + C_2H_5OH + CH_3COOH,$$
$$C_2H_5OH + H_2O \rightarrow CH_3COOH + 2H_2,$$
$$CH_3COOH \rightarrow CH_4 + CO_2,$$
$$CO_2 + 4H_2 \rightarrow CH_4 + 2H_2O.$$

The first two reactions are formed by a non-methanogenic microorganism via the Embden–Meyerhof pathway and the third and fourth reactions are performed by acetate- and water-utilising methanologens.

A mathematical model of the process, consisting of a system of nine non-linear differential equations, has been devised on the basis of the proposed kinetic scheme.[27-29] The adequacy of the proposed model has been tested by solving the so called direct problem. On the other hand, the solution of the reverse problem made it possible to determine from the available experimental data the kinetic parameters and constants for the conversion of glucose into methane. Mathematical calculations have confirmed the satisfactory quality of the description of the experiment.

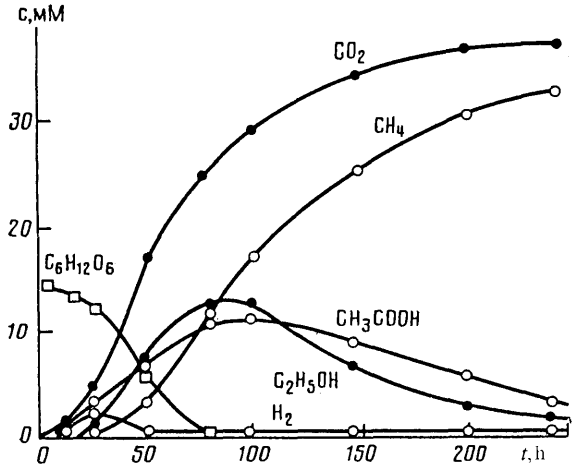


Figure 1. Dynamics of the anaerboic conversion of glucose in the presence of the *Methanobacillus kuzneceovii* system of microorganisms.[24]

Methane fermentation can occur in the temperature range from 10° to 65 °C. It has been shown that thermophilic methane fermentation (45–65 °C) is 2–3 times faster than mesophilic fermentation (25–30 °C), the change in temperature influencing only the rate of the process but not the qualitative composition of the product formed.

The acid generating stage, determined by the activity of the primary anaerobes, occurs at pH from 5 to 6.5–7 and is characterised by an intense growth of bacteria which ferment free carbohydrates. This period is accompanied by a decrease in the content of carbohydrates in the medium, a decrease in the pH of the medium, and an increase in the overall content of volatile aliphatic acids represented by formic, acetic, propionic, butyric, and other acids. Propionic and butyric acids predominate during this period.[17,21,30] The microbiological and biochemical processes in this stage have so far been studied inadequately.[17,20,34]

Among the large group of acid generating bacteria, acetogenic, lactic acid, and butyric acid bacteria as well as producers of caproic and succinic acids, ethanol, butanol, and other lower alcohols and ketones are of special importance (in the literature, this entire group is frequently referred to as solvent synthesising bacteria).

A definite interest has arisen in recent years in a comprehensive investigation of anaerobic bacteria active in the acid generating stage, which are important not only from the standpoint of methane generation but also because they are direct producers of biofuel substances.

2. Methane Forming Bacteria

Methanogens are obligatory anaerobes sensitive to oxygen. The oxidation–reduction potential of the medium used for their growth is -300 mV and less.[31] More than 45 species of methane forming bacteria are known at the present time.

Depending on the species, methanobacteria, can use a limited number of substrates as sources of energy (Table 2). Among them acetate is the most important, occupying the first place among precursors (more than 75%).[17,23-29,32-35] Acetate is followed by carbon dioxide,[26-29,36-38] formate, methanol, [22,23,41] methylamines,[42] methylcobalamin,[17] and carbon monoxide.[17] According to the available data, no other carbon compounds support the growth of methane forming bacteria.

Table 2. Chemical reactions effected by methanogens.[54]

Chemical reaction	ΔG_0° relative to CH_4 kJ mol^{-1}
$CO_2+4H_2\rightarrow CH_4+2H_2O$	−139
$4HCOO^-+4H^+\rightarrow CH_4+2H_2O+3CO_2$	−119
$4CO+2H_2O\rightarrow CH_4+3CO_2$	−186
$CH_3COO^-+H^+\rightarrow CH_4+CO_2$	−31
$4CH_3OH\rightarrow 3CH_4+CO_2+2H_2O$	−103
$4CH_3NH_2+2H_2O\rightarrow 3CH_4+CO_2+2NH_3$	−75
$2(CH_3)_2NH+2H_2O\rightarrow 3CH_4+CO_2+2NH_3$	−74
$4(CH_3)_3N+6H_2O\rightarrow 9CH_4+3CO_2+4NH_3$	−75

Methanogenic bacteria convert 90–95% of the carbon used into methane in order to accumulate energy for constructive metabolism via the coupled generation of a transmembrane potential and only 5–10% of the carbon is converted into the biomass. By virtue of the above feature, up to 80–90% of the organic matter decomposed in the course of the development of the methanogenic consortium is converted into gas.[17]

In mixed cultures, methane-forming organisms can be readily determined with the aid of fluorescence microscopy:[43-44] they give rise to either a green fluorescence by virtue of the F_{420} factor or a blue fluoresence by virtue of 7-methylpterin[45] (see below).

Fairly important data have been obtained by investigating rRNA. It was found that methane-forming bacteria differ from all other organisms in terms of their 16S RNA nucleotide sequence.[46,47] In addition, methane-forming bacteria differ sharply from other organisms as regards the composition of the electron transferring agent as well as a series of coenzymes. The processes involved in their metabolisms also have characteristic features.[41,47]

On this basis and primarily as a result of the studies of the 16S rRNA, methane-forming bacteria are regarded as a special branch in the evolution of organisms and are classified as archebacteria.[46]

3. The Mechanisms of the Formation of Methane

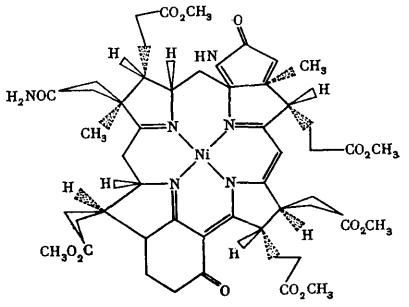
The biosynthesis of methane is the main reaction leading to the generation of the energy necessary for the development of the cell. The universal scheme for the formation of methane by bacteria was first proposed in 1976 by Barker, who combined processes involving the biosynthesis of methane from H_2/CO_2, formate, acetate, and methanol:[48]

Since it had been shown even earlier that formate, formaldehyde, and methanol are not intermediates released into the culture medium in the course of the formation of methane from CO_2, the authors suggested that these C_1-compounds, reduced to different extents during their transformation into methane, should be linked to one or several compounds "X". Vigorous biochemical and physicochemical studies during the last 10–15 years made it possible to elucidate to an appreciable extent the nature of the compounds "X". In the first place, at least six unique coenzymes were isolated from methanogens and identified. These coenzymes are hardly encountered in other species of bacteria.

The compound

$$HS{-}CH_2{-}CH_2{-}SO_3^- \ .$$

which was called coenzyme M (CoM), was the first to be discovered and its involvement in the formation of methane was demonstrated. Coenzyme M can combine with a methyl group, being thereby converted into methyl coenzyme M ($CH_3SCH_2CH_2SO_3^-$). The latter plays a central role in the terminal stage of the formation of methane, which is associated with the demethylation of $CH_3-S-CoM$:[47]

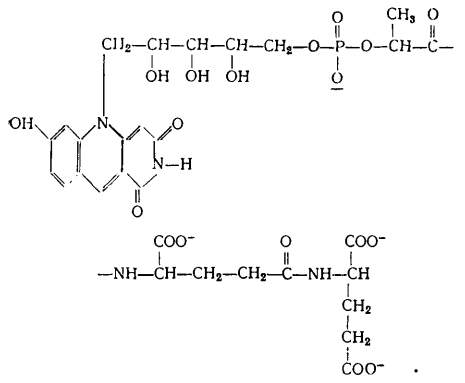


$$CH_3{-}S{-}CoM + 2H^+ + 2\bar{e} \xrightarrow[\text{methylcoenzyme M reductase}]{\text{comp. A, comp. B, } Mg^{2+}\text{, ATP}} CH_4 + HS{-}CoM \ .$$

This formally simple reaction is catalysed by an involved complex of enzymes and cofactors.[51] Component A is a protein complex exhibiting a hydrogenase activity. Four components were isolated from this complex: three proteins (A_1, A_2, and A_3) and the coenzyme FAD.[52] A_1 is an oxygen-resistant hydrogenase, which uses coenzyme F_{420} as the substrate. The hydrogenase A_1 may be identical with the F_{420}-reducing hydrogenase whose isolation has been described by Jacobson et al.[53] Compounds A_2 and A_3 are oxygen-labile proteins. It has been suggested that A_2 may participate in the reduction both at a formal level and as the activator methyl coenzyme M of the reductase system.[54] The function of A_3 is still not understood.

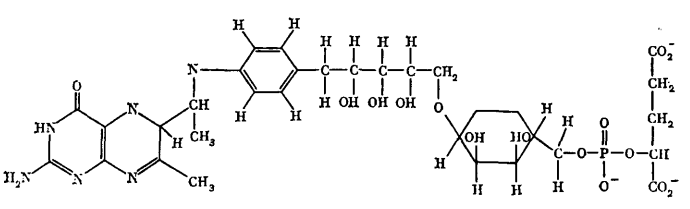
Component B is an oxygen-sensitive, thermally stable cofactor,[51] which has a molecular weight of about 1000 D and which contains an adenosine residue.[54] Catalytic amounts of ATP and Mg^{2+} are required for the functioning of the methyl coenzyme M reductase system. ATP probably activates enzymes or the coenzymes linked to the enzymes via acylation and phosphorylation reactions.[55]

Methyl coenzyme M reductase is an oxygen-stable protein consisting of three subunits and having a maximum absorption near 425 nm.[56] Two molecules of the recently discovered factor F_{430} function as prosthetic groups.[57]



The factor F_{430}, given this name after the observation of its characteristic absorption maximum at 430 nm,[58] is a nickel-containing tetrapyrrole.[59–65] The structure of this chromophore, modified by methylating the carboxymethyl and carboxyethyl groups, has been established by Pfaltz et al.:[66]

The factor F_{430} usually forms ~1 : 1 complexes with coenzyme M and the complex is usually designated by $CoMF_{430}$.[67]

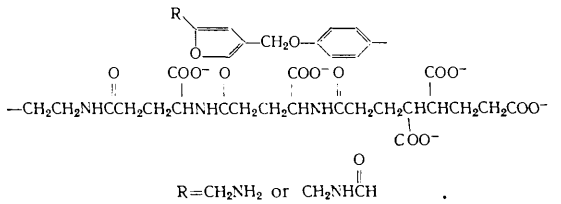


The function of $CoMF_{430}$ has not been ultimately established. From the chemical standpoint, this compound most probably functions as an electron transferring agent.[54]

The formation of methane from carbon dioxide represents the transfer of eight electrons from hydrogen to CO_2. Data obtained in the isotope fractionation of *M. thermoautotrophicum* have shown that H^+ from water is converted into methane, that H_2 serves solely as an electron donor, and that carbon dioxide is used in the gaseous form.[70,71] The coenzyme F_{420}, which has been given this designation on the basis of its fluorescence maximum in the oxidised form, first described in 1972 and having a low oxidation-reduction potential [E_0 = –0.34 V with respect to the normal hydrogen electrode (n.h.e.)], functions in this process as the electron transferring agent:[72–73]

This compound is the primary electron acceptor of hydrogenase,[39,53,53] formate dehydrogenase,[75–77] and F_{420}-dependent NADP-reductase[78] and is an electron donor in the terminal strage of the reduction of CO_2. Furthermore, F_{420} is an electron donor for two critical reactions in cell synthesis effected by pyruvate dehydrogenase and α-ketoglutarate dehydrogenase.

In 1978 experiments with labelled $^{14}CO_2$ showed that, over a period from 2 to 20 s, 25–50% of the label is bound into a compound giving rise to a bright yellow fluorescence.[36] These results suggested that the compound, later identified as 5,10-methenyl-5,6,7,8-tetrahydromethanopterin (5,10-methenyl-THF),[80] is an intermediate in the reduction of CO_2 to CH_4. After incubation under non-reducing conditions, 5,10-methenyl-THMP is converted into a compound which now exhibits a blue fluorescence and is a metabolic precursor of 5,10-methenyl-THMP (it does not contain the C_1 unit derived from CO_2). This compound has been called methanopterin.[81] Methanopterin has been isolated from the *Methanobacillus thermoautotrophicum* cells in 1983.[82] Its structure was determined in 1984 by high-resolution NMR spectroscopy (500 MHz)—by two dimensional ^1H and ^{13}C NMR:[83]



Methanosarcina barkeri contains another methanopterin derivative, which was called *sarcinapterin*. Its difference from methanopterin consists in the presence of glutamic acid joined to α-hydroxyglutaric acid.[81]

Brief incubation of the *M. thermoautotrophicum* cell suspension with $H^{13}CO_3^-$ (in a hydrogen atmosphere) and subsequent isolation of 5,10-methenyl-THMP showed that the label is present as the methenyl (=CH−) group.[54]

Thus methanopterin behaves as a C_1-transferring agent in two consecutive stages of the reduction of CO_2, which is manifested by the formation of methylene-THMP and methyl -THMP respectively.[54] These processes have been confirmed experimentally.[79,84]

Direct demonstration of the role of methanopterin in the reduction of CO_2 to methane has been achieved in a study[15] where it was shown that the absorption of CO_2 stimulated by coenzyme M and the so called RPG effect (see below) require the concerted action of two compounds stable with respect to oxygen and heating, one of which is methanopterin. The second compound, called the CDR-factor (the carbon dioxide reducing factor), was discovered in 1982 [86] and is yet another coenzyme in methanogens; the CDR-factor is encountered in two forms, namely as the free amine and as a formamide:

It has been suggested that in the latter case the formyl group originates in CO_2, since this form is in fact accumulated in the reaction mixture on incubation in an atmosphere of H_2 and CO_2 in the absence of methanopterin. This shows that the CDR-factor acts as a C_1-transferring agent before the THMP-derivative. Another name for the CDR-factor can also be encountered in the literature, namely methanofuran.[83] CO_2 is activated by the energy derived from ATP.[89] Reductive carboxylation is the energetically preferred type of CO_2 fixation.

The explanation of the socalled RPG effect, the sharp increase in the rate of reduction of CO_2 after the addition of $CH_2-S-CoM$ to the reaction mixture, is important.[90] This effect is produced also by a series of what are at first sight heterogeneous compounds: serine,[54] formaldehyde, hydroxymethylcoenzyme M,[91] pyruvate, L-ketoglutarate, L-malate, and isocitrate.[92] A common property of these compounds is that they can all function as donors of C_1-intermediates at different stages of the reduction process: of the formyl group (pyruvate, L-ketoglutarate, malate, and isocitrate), of the =CH− group (serine, formaldehyde, and hydroxymethylcoenzyme M), and of the methyl group ($CH_3-S-CoM$). Furthermore, the RPG effect clearly indicates a direct relation between the terminal (reduction of $CH_3-S-CoM$) and initial (activation of CO_2) stages of methanogenesis.[47,91]

Despite the fundamental correctness of the scheme proposed for methanogenesis by Barker, it is nevertheless too general in character. During the last 30 years, several attempts have been made to make this scheme more concrete,[46,48] but inadequate knowledge of the biochemistry of methanogens made it impossible to go outside the framework of general considerations and postulates. It was not until 1984 that Keltjens, having summarised the latest data, proposed a molecular model of the formation of methane from CO_2 and hydrogen.[54]

The basis of the Keltjens model is that CO_2 is activated by the methylreductase system (Fig.2). The one-electron reduction of the complex CH_3SCoMF_{430} leads to the formation of methane and a highly active thiyl radical, which activates and captures CO_2 with formation of a thiocarboxy-radical. The possibility of the existence of a thiyl radical in molecular methane-forming systems has been demonstrated experimentally.[69] The thiocarboxy-radical is subjected to attack by the CDR-radical coupled with one-electron reduction, which results in the formation of a complex of thiocarbamate, the CDR-factor, and $CoMF_{430}$ (Fig.2). Yet another one-electron reduction stage leads to the formation of the formamide form of the CDR-factor and the liberated thiyl radical. The subsequent stages involve the transfer of the formyl group of THMP and the formation of methyl-THMP. They take place with consumption of four electrons and the intermediate formation of methenyl- and methylene-THMP. Methyl-THMP is a relatively weak methylcarbonium (CH_3^+) donor. In order to be transferred to the thiyl radical, the CH_3^+ ion must be initially reduced to the methyl radical. This may be the function of component B of the methylcoenzyme M reductase system (Fig.2).

After the addition of the RPG-effectors, the increase in the degree of reduction of CO_2 is caused, as already mentioned, by the donation of C_1 units, which ultimately leads to an increase in the concentration of the thiyl radicals necessary for the binding of CO_2. However, the RPG-effect is transient apparently for two reasons: reaction of radical trapping agents and the exhaustion of the C_1 intermediates in the reduction of CO_2 for the synthesis of cell carbon.

Above we examined in detail the metabolism and biochemical characteristics of the methanogenic organisms specialising mainly in the conversion of H_2/CO_2 and/or formate. The metabolism and biochemical features of the organisms whose main substrates are acetate, methanol, and methylamines have been investigated to a much lesser extent, which can be explained both by the smaller number of organisms of this group and by certain methodological difficulties in their cultivation and investigation.[42,43] Hitherto it has been firmly established by the tracer atom method and certain other procedures that a common terminal methyl group transferring agent is coenzyme M for all methanogens.[36,50,93–96] It has been suggested that the primary recipients of the methyl group may be methanopterins or corrinoids, while the further transfer of the methyl group takes place as in the reduction of CO_2 with hydrogen.[93,97]

There exist two basic mechanisms of the transformation of acetate into methane and CO_2. The mechanism I, also referred to as the acetoclastic mechanism,[98,99] was described above and involves the cleavage of acetate in such a way that the methyl group is converted into methane and the carboxy-group is converted into CO_2. The mechanism II was proposed in 1936 by Barker and Van Neel and is a two-stage process.[100] Acetate initially decomposes to hydrogen and CO_2, which is then followed by the reduction of CO_2 with hydrogen. According to Van Neel's hypothesis, all the potential methanogenic substrates are initially converted into oxidised products and CO_2 and methane are formed as a result of the reduction of CO_2.[100] These two mechanisms can be differentiated using ^{14}C-labelled substrates.

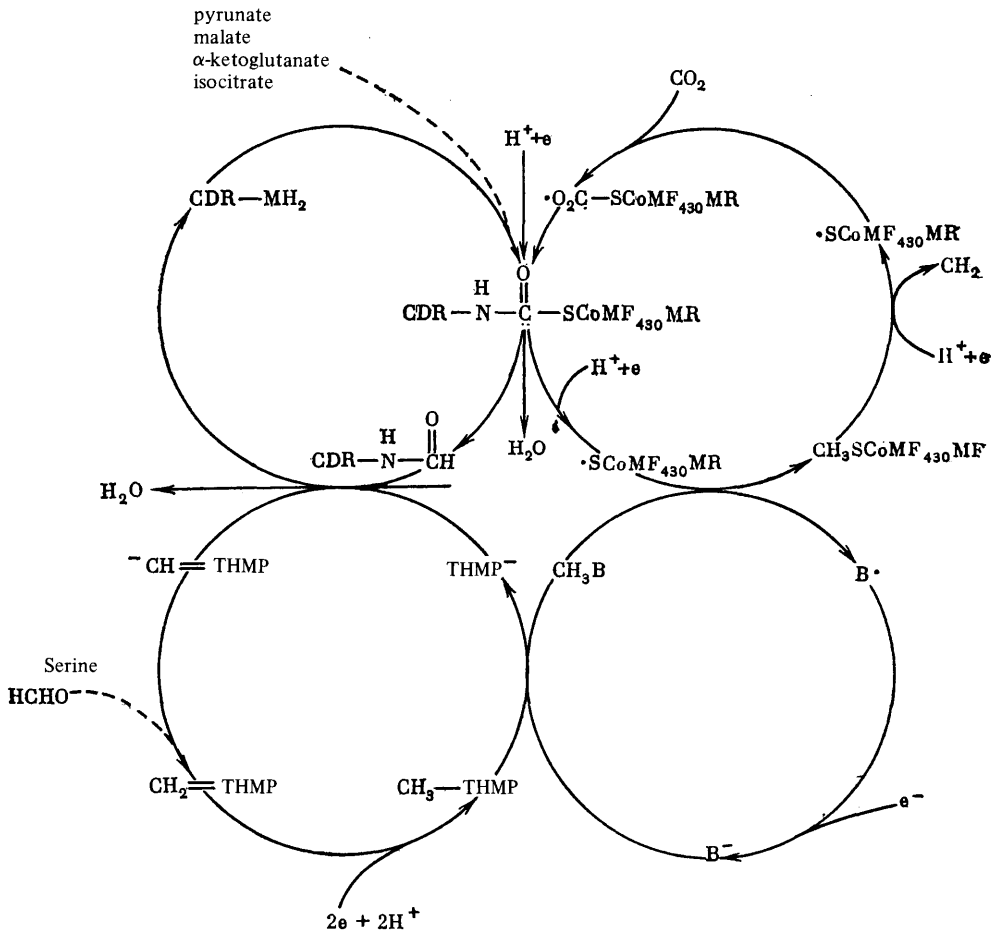


Figure 2. Keltjens molecular model for the reduction of CO_2 to methane.[54]

Numerous experiments have demonstrated that pure cultures belonging to the *Methanosarcina* family and also *Methanotrix soengenii* convert acetate via the mechanism I.[98,101,102] There is also no doubt that formate, methanol, and methylamines converted into methane by pure cultures of methanogens via the mechanism I.[46] Van Neel's hypothesis has been confirmed for other substrates, such as alcohols (C_2 and higher) and aliphatic acids (C_3 and higher), but subject to its significant modification which is that the conversion of these substrates takes place with participation of not one but several micro-organisms. The interaction of several micro-organisms takes place as a result of a process which has come to be called the interspecies hydrogen transfer.[103] This phenomenon was first demonstrated for an ethanol oxidising culture, the micro-organism called *Methanobacillus omelianskii*.[103] A similar interaction of cultures has been demonstrated in the methanogenic degradation of cellulose and hemicellulose,[21,104] glucose,[24–26,105] butyrate,[21,106,107] propionate,[108] acetate,[109] and also methanol, ethanol, and acetate by the methanogenic association of micro-organisms *Methanobacillus kuzneceovii*.[23–26,108,110] Interspecies hydrogen transfer is especially important in the anaerobic degradation of aliphatic acids, since their oxidation can proceed, for thermodynamic reasons, only at very low partial pressures of oxygen in the system, which is in fact ensured by the activity of hydrogen consuming organisms.[111–113]

Methanogens have played an enormous role in the genesis of natural gas on Earth. It has been demonstrated by geochemical analytical methods that more than 80% of gas deposits of industrial importance in the USSR consist of biological methane which has accumulated in such colossal amounts during billions of years of the activity of methanogens.[17] The advances in modern biotechnology permit the hope that in the near future it will be possible to replace a considerable proportion of the extracted natural gas by the industrial synthesis of methane.

4. Technological Principles of the Preparation of Biogas

The phenomenon of the evolution of combustible gas on decomposition of organic material under anaerobic conditions has been known for a long time. The first practical application of biogas dates back to the end of the XIXth century when in 1885 in the English city of Exeter methane obtained from a septic tank was used to illuminate streets.[114]

The first-scale factory for the manufacture of biogas was constructed in 1911 in Birmingham for the sterilisation of the solids from the sewage in that city. The methane formed was converted

into electrical energy. At the present time there exist a number of examples of the use of methane tanks in various countries of the World, this field of biotechnology passing through a period of intense development at the present time.[1,5,10,11,14]

The industrial preparation of biogas from organic waste has a number of advantages:[5]

(1) The heat generating capacity of biogas amounts to 20–28 MJ m^{-3} (0.7–0.8 kg of conventional fuel); the processing of 1 tonne of organic matter (dry weight) yields up to 800 m^3 of biogas.

(2) The process takes place periodically, semiperiodically, and continuously in large-scale reactors whose volume ranges from several cubic metres to thousands of cubic metres. The reactors are as a rule simple to construct.

(3) Methane fermentation achieves the effective purification of sewage and the processing of waste from animal husbandry and the cultivation of plants and of active sludge leads to the preparation of sterile high-quality fertilisers and to the complete mineralisation of nitrogen and phosphorus.

(4) The high coefficient of the conversion of the energy of organic substances into biogas, reaching 90%.

(5) Biogas can be used very effectively also directly as a fuel or can be converted with 83% efficiency into electrical and thermal energy by means of gas generators.

(6) In the anaerobic processing of waste, it is possible to obtain valuable biologically active compounds, for example, vitamin B_{12}, together with biogas.

A critical analysis of the economic problems associated with the introduction of biogas technology has been carried out.[115] It has been shown that the manufacture of biogas may be economically justified only when a series of conditions are observed: there must be a supply of raw materials with minimum and negligible transport and storage costs; there must exist a system for the utilisation of the gas without its accumulation and storage; there must exist a cheap source of low-potential heat for the heating and thermostatting of the methane tank.

Studies directed to the conversion into biogas of the waste from animal farms, which is regarded as an integral component part of modern animal farming industry, are of greatest practical interest.[116] The large-scale application of biogas technology makes it possible to solve in one process three inter-related problems—the preparation of a fuel, the conversion and sterilisation of waste, and the preparation of concentrated fertilisers.

An improved technology for the conversion of waste from the animal farming industry has been described.[117,120]

The rate-limiting stage in the preparation of biogas is the degradation of the biomass to oligomeric and monomeric components. Studies designed to intensify the depolymerisation processes by various methods are being prosecuted on these lines. One of the latest aspects of this field is associated with the use of ionising radiation. It has been shown that preliminary irradiation of biomass with γ-rays can intensify severalfold the methane formation process.[29,121]

Studies are being carried out on the automation and control of the methane generating process. For example, a correlation has been discovered between the productivity of the methane generator and the content of the coenzyme F_{420}. Methods have been developed for the determination of F_{420} in mixtures and procedures have been proposed for the estimation of the "methane generating force" of a mixed culture in terms of the content of coenzyme F_{420}.[123]

Fundamentally new possibilities in the biotechnology for the preparation of fuel are associated with the development of methods for the biogasification of peat.[124] Large deposits of peat fuel are known to exist in many countries, the development of their use being held back by the lack of an ecologically acceptable technology.

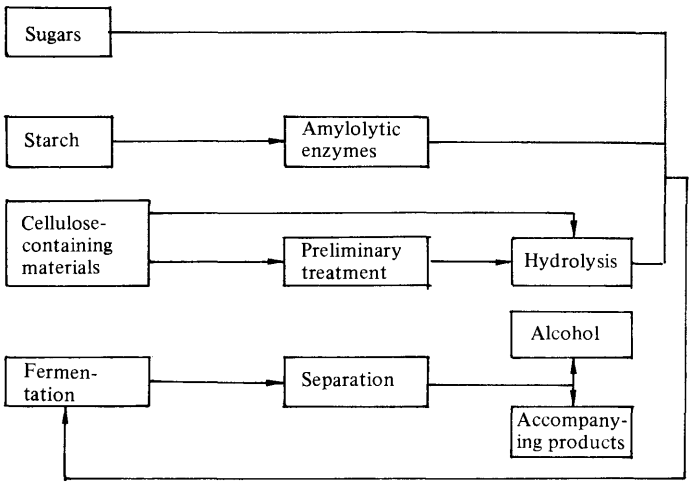
The first attempts to convert peat into biogas date back to the 1920's.[125] At the present time several projects designed to obtain biogas from peat are being developed. The project being developed by the Institute of Gas Technology (Chicago, USA), which has been called the "Biotherm Gas-process", provides for the combination of the conversion of peat into methane with participation of stages involving biological and thermochemical gasification.[126,127]

A second project, work on which is being carried out by the Dynatech Company (USA), provides for the chemical processing of peat with alkali coupled with an oxidative process and subsequent anaerobic conversion into biogas.[128,129]

The technical-economical parameters of various processes, including traditional processes have been compared and it has been shown that both projects may reach the stage of an economically significant technology in the immediate future. The main possibilities for the improvement of the technology are associated with the development of methods for the preliminary treatment of peat involving the improvement of its capacity for biodegradation.[124]

The rates of methane formation have been compared[130] for cellulose and hemicellulose in mesophilic and thermophilic decomposition processes. In the mesophilic process (35 °C), the degree of conversion of hemicellulose was higher than that of cellulose, but hemicellulose was converted significantly less effectively compared with cellulose under the conditions of thermophilic decomposition (55 °C). The rates of formation of gas from hemicellulose-containing materials are 0.3–0.6 of a volume of biogas per volume of the reactor per day for a methane content of 52–63% as a function of the process conditions.

The attempts to combine in a single system the generation of atomic energy and biogas are of great interest. There have been reports according to which a system for the preparation of biogas, based on the use of the heat of the cooling water, has been created within the framework of an atomic electric power station in Belgium. Algae converting biogas in the subsequent methanogenic stage have been cultivated using the low-potential discarded heat from the electric power station in water reservoirs.[131,132]



The present state of the biogas industry in the world has been surveyed in a number of reviews.[5,10,11]

III. ETHANOL

1. Chemical Principles of the Synthesis

With increasing deficiency of liquid mineral fuels, it has become necessary in many countries to replace petroleum by ethanol as a fuel, in the first place for the needs of automobile transport. The sources of raw material for the manufacture of fuel ethanol are plants with a high sugar content (sugar cane, sugar beet, etc.), starch (potatoes, maize, etc.), grain crops, as well as a wide variety of cheap plant materials of the lignocellulose type.

The biotechnological preparation of ethanol can be represented schematically as follows:

Only part of this scheme, based on the use of starch or sugars (molasses) as the initial raw material, has so far been realised on a wide scale. Low grade maize (corn) starch is thinned with α-amylase at a high temperature (80 °C, 20–30 min), hydrolysed with glucoamylase to soluble sugars (mainly glucose), and this is then followed by the yeast fermentation of glucose to ethanol, which is subsequently fractionally distilled.[133]

The rate-limiting stage in the conversion of the cheap cellulose-containing raw material is the hydrolysis stage (cellulose is approximately 100 times more difficult to hydrolyse than starch). At the present time, three principal methods of hydrolysis of cellulose are in the process of development and compete with one another: (1) with dilute inorganic (sulphuric) acids at a high temperature; (2) with concentrated inorganic acids (sulphuric, hydrochloric, or hydrofluoric acid) at a low temperature; (3) enzyme hydrolysis at a low temperature. Each method has definite advantages and disadvantages.

When concentrated acids are used, high rates of hydrolysis of cellulose are achieved, but problems associated with the recovery of the acids and the corrosion of the equipment arise.

Processes using dilute acids require high temperatures in order to attain technological rates of conversion of cellulose, but the rate of decomposition of glucose increases at the same time and equipment is again corroded.[143,144]

Enzyme hydrolysis does not suffer from the above disadvantages, but at the present time the cost of cellulases (enzymes hydrolysing cellulose) is fairly high. Furthermore, the attainment of high degrees of conversion of cellulose frequently requires an intense preliminary treatment to decompose the lignin shell and to convert cellulose from the crystalline to an amorphous state. Other problems in enzyme hydrolysis consist in the inhibition of cellulases by the hydrolysis products and in the inactivation of enzymes.

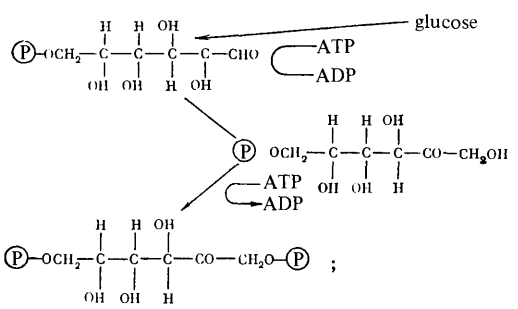
In general, hydrolysis with dilute acids makes it possible to achieve only 50–60% yields of glucose, while hydrolysis with concentrated acids or a multistage process involving the decrystallisation of cellulose (the Tsao–Purdue process) is potentially capable of reaching yields of 90%. The yield of glucose in enzyme hydrolysis depends greatly on the type of preliminary treatment (mechanical milling, delignification with solvents, treatment with live steam, preliminary hydrolysis of hemicelluloses with dilute acid) and can vary from less than 50% to more than 90%.[134–140]

Jones and Semrau[134] carried out an economic analysis of the cost of the final product (ethanol) for different methods of hydrolysis of cellulose. None of them has economic advantages, compared with the preparation of ethanol from grain, which has been traditional in the USA. However, the economic situation can change significantly if furfural, the principal side product of the acid hydrolysis of wood, becomes commercially significant as a chemical agent.[134]

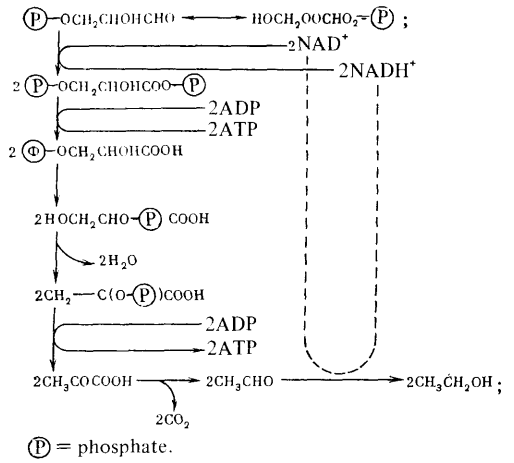
The use of various component of the biomass not susceptible to alcohol fermentation is being studied in this connection. An interesting aspect of such research is associated with the development of methods of preparation of monomers from the biomass.[141,142] Thus a procedure has been described for the preparation of 2-vinylfuran—the component capable of serving as a basis for new polyvinyl polymers.

The use of a hybrid process, in which a dilute acid is employed for the preliminary treatment and separation of the corresponding fraction of wood (mainly the hemicellulose fraction), while enzymic hydrolysis is used to convert the residual cellulose into glucose, also appears very promising.[154]

Partial degradation of cellulose can likewise be achieved with the aid of a number of physical methods, for example, by treating cellulose with live steam or with γ-radiation. The effect on the enzyme and acid hydrolysis of the preliminary treatment [with radiation] of the biomass has been investigated and it has been shown that, for doses greater than 10 Mrad, bagasse (the residue from sugar cane after the juice has been pressed out) is degraded; bagasse irrigated with a dose of 100 Mrad affords 2–4 times more glucose than the non-irradiated specimen. Irradiation influences the acid hydrolysis to a greater extent than the enzyme hydrolysis.[145–147]



The second stage in the processing of cellulose—the conversion of carbohydrates into ethanol—is one of the oldest microbiological processes used by man:



$$C_6H_{12}O_6 \rightleftharpoons 2C_2H_5OH + 2CO_2 .$$

The coefficient of the conversion of energy in this reaction is 98%.

The mechanism of the microbiological preparation of ethanol is fairly complex, but it has been investigated in great detail at the microbiological and biochemical levels[1] (see Scheme 1).

Scheme 1

(P) = phosphate.

On a technological scale, sugars are fermented to ethanol as a rule by yeast (*Candida brassicae, Candida utilis, Saccharomyces cerevisiae, etc.*). The theoretical yield of ethanol is 51 wt.% of the initial concentration of glucose, while the practical yield is 47 wt.% as a result of the growth of the yeast and the formation of side products. The inactivation of yeast by high concentrations of ethanol (in excess of 10–12%) creates many problems and for this reason methods for the extraction of ethanol from the culture medium are being vigorously developed.[148] In this sense, much hope is associated with the bacteria *Zymomonas mobilis* which ferments sugars twice as fast as yeast.[149] Thus the *Z. mobilis* cells immobilised in calcium alginate pellets afforded at the outlet from the reactor 102–116 g litre h^{-1} of ethanol for an incoming concentration of glucose of 200 g $litre^{-1}$.[150]

The idea of direct effectively single-stage conversion of polysaccharides into ethanol has gained wide currency in recent years. Thermophilic anaerobic bacteria are very promising in this connection: they do not require aeration, grow at high (60–65 °C) temperatures, grow rapidly on cellulose and exhibit a high metabolic activity, contain the complete set of enzymes of the cellulase complex, and ferment cellulose and sugars with formation of a limited spectrum of metabolites: ethanol, lactate, H_2, and CO_2.[137] These bacteria also have a number of advantages characteristic of thermophilic organisms in general. Thus at high temperatures there is, firstly, a decrease in the solubility of oxygen and other gases which lowers their toxic effect and increases the time during which anaerobic conditions are maintained, secondly, the viscosity of the solutions diminishes and the solubility of the substrates increases, which improves their accessibility to enzymes, and finally and thirdly, the volatility of ethanol increases, which permits its continuous distillation using a low vacuum, reducing thereby its inhibiting effect.

The technological application of thermophilic anaerobic bacteria is limited by a number of disadvantages: the lack of balance in the cellulase enzyme complex; the relatively low yield of ethanol to the fermented sugar molecule; the increased sensitivity to ethanol (as a rule their metabolism is almost completely suppressed already in the presence of 0.5% of ethanol in the medium); the low capacity to ferment the products of the hydrolysis of hemicelluloses.[137]

The natural strains of micro-organisms suitable for the direct conversion of plant raw material into ethanol require at the present time an improvement in their biological characteristics. This can be achieved by methods involving the selection of the appropriate mutants by the creation of recombinant strains with specified properties by genetic engineering and also by searching for new natural strains and by the selection of micro-organisms suitable for joint cultivation. The development of improved methods of preparation of ethanol, the creation of new strains of micro-organisms tolerant to an increased ethanol content and a low pH have been described.[152,153]

2. Technological Features and Economics

Brazil has the greatest experience in the use of ethanol as a fuel. The National Alcohol Programme (PROALCOOL), adopted by the Brazilian government in 1975, was the outcome of almost half a century's research in this field. The principal aim of this programme was to reduce the import of petroleum by partly replacing petrol by ethanol and made provision for the manufacture by 1985 of 107 billion litres of ethanol annually.[156] The source of alcohol was in this instance the fermentation of sugar obtained from sugar cane.[155] It is noteworthy that Brazil as a whole has successfully fulfilled these plans. The campaign conducted in that country in favour of replacing petrol by alcohol has enabled Brazil to save 2 billion dollars per year. The results of the Brazilian experiment for the development of systems for the preparation of fuel ethanol from sugar cane are described in a report by Khan and Fox.[157]

As already mentioned, the manufacture of ethanol from grain is the traditional procedure in the USA, the cost of such alcohol being 42 cents per litre.[134] The use of grain as the substrate is explained by the low prices and certain surpluses in the production of mainly maize grain.[157,158] These factors as well as the energy crisis led to the adoption in the USA of a national alcohol programme designed mainly to produce gasohol (90% of petrol and 10% of ethanol).[159] The popularity of this new fuel was due to its satisfactory anti-knocking properties (10–12% of ethanol is equivalent to 1–2 cm^3 of tetraethyl-lead per gallon)[159] and its economy—the consumption of gasohol is smaller by 25.3 g km^{-1} than that of non-ethylated petrol.[160]

Among the developments in the acid hydrolysis of lignocellulose materials, attention must be concentrated on the process developed at the New York University.[134] In order to obtain technologically acceptable rates of hydrolysis of wood by dilute sulphuric acid and in order to reduce the losses resulting from the decomposition of sugars at a high temperature, the process is carried out under continuous conditions with a short (10 s) residence time in the high-temperature zone in a specially designed reactor for a temperature of 232 °C and a pressure of 34.02 atm. Insoluble substances lignin, unreacted cellulose, ash components, and gypsum) are separated from the resulting suspension and the solution obtained, containing soluble sugars at a concentration of 10–11 wt.%, is supplied periodically into the reactor, where it is fermented to ethanol by yeast. The recycling time is 48 h. The concentration of ethanol at the outlet is 5.2 wt.% or 6.5 vol.%. The last stage is the distillation of ethanol.[134]

Economic calculations carried out for a factory with a productivity of 914.6 million litres of ethanol annually have shown that for an overall capital investment of about 132 million dollars the calculated cost of the ethanol would be 72 cents per litre. Thus it is seen from the calculation that the cost of the ethanol obtained by acid hydrolysis is fairly high and such technology cannot at present develop without government subsidies.

A group of scientists at the Michigan University have recently proposed a new process for the hydrolysis of wood with the aid of gaseous hydrogen fluoride. Dry wood is treated at a reduced pressure for 1 h. This results in the formation of glucosyl fluoride (up to

99% yield) from cellulose. Next, glucosyl fluoride is hydrolysed with water (1 h, 140 °C) with formation of glucose and hydrogen fluoride. The latter is recycled by evacuation or with the aid of slight heating and its residues in the solution are neutralised with calcium carbonate. The CaF_2 deposit is treated with sulphuric acid in order to achieve a more complete recyclisation of HF. The principal products of the process are glucose and lignin. The glucose is subsequently fermented to ethanol. The estimated cost of glucose is 12 cents per kilogram of which 7.5 cents represents the cost of the initial wood.[161] Unfortunately, there have been no communications so far about the scale of this process.

The entire wide variety of scientific and technological solutions of the problems concerning the enzymic conversion of cellulose into ethanol in the USA can be reduced to three basic processes.

(1) The use of separate reactors for the accumulation of cellulases, hydrolysis of cellulose, and the fermentation of sugars to ethanol (the Army Laboratory at Natick).

(2) The use of a separate reactor for the accumulation of cellulases and the combined process involving the conversion of cellulose into sugars and the fermentation of the sugars formed to alcohol (Gulf Oil Chemicals Co.—Arkansas State University).

(3) The use of a single reactor for the direct conversion of cellulose into ethanol with the aid of one or several species of microorganisms (Massachusets Institute of Technology).

The technology of the Gulf Oil Chemical Co. has been most thoroughly developed from the standpoint of technique and economics. Cellulose is hydrolysed by the cellulose enzymes of the fungus *Trichoderma reesei* and the sugars formed are fermented to ethanol by the cells of *Candida brassicae*.[135,162,163] It was proposed to scale up this technological process in three stages and a factory for the combined processing of 3000 tonnes of dry waste per day is to be built in the last stage, which is planned for the end of the 1980's. Apart from the production of 200 million litres of absolute alcohol annually, the factory will generate also 52.5 MW of electrical energy annually as a result of the combustion of the unused cellulose. The total cost of the planned factory is 230 million dollars. The commercial cost of the alcohol produced will be 58 cents per litre.[135]

The laboratory in Natick in collaboration with the New Brunswick Company constructed a pilot plant where wood is treated with steam and then hydrolysed by cellulases obtained by the deep culture of a mutant strain of *T. reesei* in a separate 400 litre fermenter. The sugars formed are fermented in a 250 litre reactor to give alcohol, which is distilled. The lignin and the unreacted cellulose are burnt. The apparatus has been automated to the highest possible extent for analysis and control.[134,164]

The process economics has been analysed for a factory with a productive capacity of 100 million litres of 95% ethanol annually, processing 495 000 of town waste containing 375 000 tonnes of cellulose. The capital investment in the construction of this factory is expected to be 83.5 million dollars and the intrinsic cost of ethanol is to be 42 cents.[135,164] According to other data, the intrinsic cost of ethanol from this process is 55 cents per litre.[134]

The process developed by the Massachusets Institute of Technology (MIT) is based on the employment of mutant strains of the thermophilic bacteria *C. thermocellum* and *C. thermosaccharolyticum* for the direct preparation of ethanol from agricultural cellulose-containing waste. In the laboratory experiments, the yield of alcohol reached 85%.[165] A disadvantage of this development is the relatively low rates of conversion of cellulose into ethanol. The economic analysis carried out was based on plans for a factory using the MIT technology processing 1500 tonnes of maize stems per day and capable of producing ~100 million litres of ethanol annually. The intrinsic cost of the ethanol is 28 cents per litre, while the cost of the raw material is 30 dollars per tonne. The capital outlay on the construction and operation of the factory is 34.4 million dollars.[135]

The Tsao–Purdue process is based on the preliminary treatment of cellulose-containing materials consisting in the dissolution of the cellulose fraction in cyclohexane, ethylenediamine, and concentrated phosphoric, sulphuric, and hydrochloric acids with subsequent precipitation of cellulose already in an amorphous form with methanol or water.[166] Recently the Tsao–Purdue process was criticised because of the considerable technical complexities in scaling up and is believed to be economically unfavourable.[135]

The Aietick Canadian Company developed an effective method for the preliminary treatment of lignocellulose materials for subsequent hydrolysis. Here Mason's method (or the co called steam explosion) is used, where live steam under pressure permeates into the biomass, whereupon the ordered structure of lignocellulose is broken down as a result of instantaneous decompression and then converted into a loose amorphous mass. The lignin then melts and can be readily separated from the cellulose fraction. Furthermore, such treatment results in the extraction of the hemicellulose fraction, which passes to water after the condensation of steam. Cellulose is hydrolysed by the enzyme preparations from *T. reesei* C-30 and *A. niger*. Under these conditions, 90–95% of cellulose and 80–85% of hemicellulose are converted into sugars in 100 h at 45–50 °C. The fermentation of the resulting glucose to ethanol takes place in 95% yield. The yield of ethanol is 270 litres from 1 tonne of wood. Xylose is not fermented by yeast and its concentrated solution serves after evaporation as a commercial product under the name "Feed molasses". If an effective fermentation of xylose to alcohol is also achieved, then the yield of ethanol may be 360 litres per tonne of wood. The lignin remaining after hydrolysis is used for the manufacture of phenol-formaldehyde plastics and adhesives.

Technical-economical calculations for the factory planned by the Aietick Company, designed to process 250 tonnes of lignocellulose daily with a productivity of 30 million litres of ethanol per year, have shown that the overall capital investment will be in the region of 10 million dollars and the cost of the ethanol will be 45 cents per litre.[133,135] One of the Canadian companies is planning to expand the factory in Manitoba which is already producing ethanol from barley by the Aietick process.

An analogous project has been developed by another Canadian firm—Stake Technology. Its difference from the Aietick process consists in the application of a continuous preliminary treatment of the lignocellulose raw material.[133,135]

The combined approach in Canada to the utilisation of biomass has also been manifested in the development of integrated agricultural projects including, for example, the growing of maize and the production of beef and fuel ethanol.[167]

The French government set aside in 1981 the sum of 26 million dollars for a programme designed to develop the manufacture of gasohol. It is proposed that the realisation of this programme by 1990 will enable France to satisfy the national requirements for transport fuel to the extent of 25–50%. It is planned to produce ethanol from wood, straw, and artichokes; the fermentation of the glucose syrups by immobilised cells will be combined with the removal of ethanol by extraction to prevent the inhibition of the process.[168]

In Japan interest in the preparation of ethanol from the biomass arose in the 1950's. Japanese technologists developed three processes for the hydrolysis of cellulose-containing raw material by concentrated acids at atmospheric pressure and a temperature not exceeding 100 °C.[169] Unfortunately the Japanese investigators were unable to eliminate fully the disadvantages characteristic of the hydrolysis by concentrated acids and more attention has been devoted to enzymic hydrolysis in the national project for the preparation of fuel ethanol, which has been executed by the Ministry of International Trade and Industry between 1980 and 1986. Japanese investigators have reported that they devised a very simple method for the enzymic conversion of cellulose-containing materials into sugars and the preparation of low cost sugars and ethanol with a considerable saving of energy.[135,155]

Scientific and technological activity in the development of processes for the preparation of fuel ethanol from biomass has also been manifested in India, Finland, Italy, Sweden, Austria, Australia, New Zealand, South Africa, Mauritius, and other countries.[114,170,171]

IV. THE ACETONE–BUTYL FERMENTATION

Interest in the preparation of organic solvents by a microbiological procedure has arisen anew recently. Examination of past history shows that interest in the acetone–butanol–ethanol fermentation waned and waxed anew, such interest determining the possibility of utilising the final fermentation products and also stimulating the research in this field.

The first major improvements in the process for the conversion of carbohydrates into butanol, acetone, and ethanol on an industrial scale were achieved during and after the First World War. The need for acetone was very high, which led to the rapid development of its manufacture. At the same time, butanol was not of much value and its storage and utilisation presented difficulties. However, after a time it was discovered that butanol is an extremely valuable chemical product and some of its esters came to be used in the manufacture of automobile varnishes and in other branches of industry.

It is essential to note that the USSR has been a pioneer in the development of the microbiological acetone-butyl industry, the scientific principles of which were developed by Academicians Shaposhnikov and Ierusalimskii.

The principal processes achieved on an industrial scale before the Second World War were the fermentation of the waste from the industrial manufacture of starch and molasses and the industrial processing of maize. Whether or not the industry was economical depended mainly on the cost of the raw material and after the Second World War the microbiological synthesis of solvents was abandoned in most countries as economically unfavourable in connection with the development of the production of synthetic solvents from cheap petroleum.[172,173]

The growing cost of the petroleum processing products during the 1970's stimulated the creation of more sophisticated technologies for the preparation of butanol. A commercially viable manufacturing process was developed on the basis of the fermentation of sugar cane molasses by a *C. acetobutylicum* culture.[174]

Butanol has effective characteristics as a fuel. By mixing up to 50% of butanol with petrol, a satisfactory fuel is produced.

The cultures used for the acetone–butanol fermentation consist of the *C. acetobutylicum* species and are distinguished, apart from morphogolical differences, also by the carbohydrate medium which they convert, by the rate of fermentation, by the type of nitrogen-containing nutrient substances required, and by the ratio of the solvents obtained.

The search for new strains is associated with the need to employ raw materials which are cheaper and more readily available than the expensive carbohydrates. The possibility of obtaining butanol from hydrolysed pine wood was investigated with the aid of *C.acetobutylicum* NC113-2951.[176] The fermentation was carried out at 30 °C for 5–7 days. The amount of hydrolysate obtained was 30 g litre^{-1} (4% of xylose, 6% of mannose, 2% of galactose, and 88% of glucose). The main hydrolysate was decolorised and steam-treated only in a combined process, which led to the removal of inhibitors and made it possible to obtain up to 1.6 g litre^{-1} of butanol which is equivalent to 90% of the yield of the product in relation to the carbohydrates adsorbed. However, during decolorisation the hydrolysates lost up to 30% of the sugars present. The use of a combination of cation- and anion-exchange resins for the purification of the hydrolysates made it possible to increase the yield of butanol as a result of subsequent fermentation (5.7 g litre^{-1} or 17% of the carbohydrates employed).

A *C. acetobutylicum* ATCC 324 culture was used to determine the optimum conditions for the preparation of butanol and acetone from acid buttermilk.[177] The culture of the above producer is capable of utilising several carbohydrates, including lactose, with formation of butanol, acetone, and ethanol in proportions of 6:3:1. The maximum synthesis of solvents was observed when sterile buttermilk was used in the fermenter without stirring. After 120 h, the pH fell to 5.2 and the concentration of solvents reached 9.2 g litre^{-1} and that of the residual lactic acid in the medium was 2.5 g litre^{-1}. Treatment in an autoclave and the absence of stirring increased the yield of solvents. Periodic fermentation of whey ultrafiltrate, glucose, lactose and galactose as carbon sources, by *C. beijerinckii* made it possible to compare the conditions for the preparation of butanol from the whey ultrafiltrate with those in its preparation from other substrates and to determine the optimum process parameters.[178]

The main aspects of the research on the improvement and reduction of the cost of the manufacture of butanol in our country involve the replacement of the expensive alimentary raw material (flour) by a non-alimentary raw material (for example sugar beet, molasses). Use of the *C. acetobuylicum*, strain S, culture, which made it possible to alter the solvent ratios and to obtain a fairly high yield of butanol (69–72%) for a content of residual sugar from 0.6 to 0.3%, is promising. The process terminates after 42 h, the content of the solvents at the end of the process amounting to 15.07 g litre^{-1} and including 11.03 g litre^{-1} of butanol, 3.38 g litre^{-1} of acetone, and 0.6 g litre^{-1} of ethanol.[179]

The utilisations of various sugars from hemicellulose hydrolysates by *C. acetobutylicum* have been compared.[177] A 90% yield of butanol can be observed in the fermentation of glucose. Five other sugars ensured the formation of butanol in decreasing amounts: cellobiose > mannose > arabinose > xylose > galactose.

An important problem involves the search for strains ultilising cellulose. It was found that only two out of 21 of the solvent producing *Clostridium* species strains tested exhibit a cellulolytic activity.[180] Furthermore, subsequent investigations revealed that the same strains exhibit endoglucanase and cellobiase activities, but their overall activity is insufficient for the hydrolysis of crystalline cellulose.

The biochemical principles of the anaerobic metabolism have been elucidated in fair detail and described in a number of studies.[181–183] *C. acetobutylicum* metabolises glucose to pyruvic acid via the

Embden–Meyerhof pathway with formation of two molecules of ATP and two molecules of NADP. Acetyl-CoA, CO_2, and H_2 are formed as a result of the phosphoroclastic pyruvate cleavage reaction. The amount of hydrogen in *C. acetobutylicum* varies as a function of the presence of NADH-ferredoxin oxidoreductase.[184] The acetyl-CoA formed is converted into acetate (ATP is synthesised), ethanol (two molecules of NADH are required), and acetoacetyl-CoA, which is either transformed into acetone or is reduced (two molecules of NADH are needed) to butyryl-CoA. *C. beijerinckii* reduces acetone to isopropyl alcohol.[185] It had been suggested earlier that the formation of butyrate is associated with transferase activity, but the latest studies have demonstrated that the main metabolic pathway proceeds via butyryl phosphate and the formation of ATP.[186,187] Butyryl-CoA is subsequently reduced to butanol with participation of two NADH molecules. The hydrogen, evolved in the first stages of the conversion of glucose, is consumed in the formation of NADH used to reduce the butanol.

It is known that in the course of the growth phase in the periodic cultivation of *C. acetobutylicum*, the main products are acetic and butyric acids, hydrogen, and CO_2. The acids are reassimilated when the cultivation pH falls and are converted into solvents with simultaneous consumption of the sugar. There exists the view that the accumulation of butyrate in the medium activates a new fermentation system, which leads to the formation of acetone and butanol and disturbs the usual mechanism of the cycle. The transition from the acid to the synthesis of the solvent can be partly accounted for by the latest enzymological studies at the level of the enzymes of these two phases. It has been shown that the activity of phosphate acetyltransferase and acetylkinase was greatly reduced and that of phosphate butyryltransferase vanished during the stage involving the synthesis of the solvent by *C. acetobutylicum* ATCC824.[187] A similar situation has been observed for *C. acetobutylicum* DS 14: the butyraldehyde and butanol dehydrogenase activities were determined only for cells synthesising the acetone–butanol mixture.[186] The same phenomenon has been observed for *C. beijerinckii*.[185] *C. acetobutylicum* possesses a transferase system which transfers the acetoacetyl-CoA from the cycle to the synthesis of acetoacetate and the latter can be decarboxylated to acteone. Acetate(butyrate):CoA transferase is an enzyme with a broad substrate specificity, which also exhibits a higher activity in the butanol synthesising cells than in the cells synthesising acid.[174,186] The decarboxylation of acetoacetate to acetone stimulates the transferase reaction via the well known acetoacetate decarboxylase, which is again induced only in the butanol synthesising cells.[174,186,187]

The synthesis of the reduced final products depends on the reducing potential of the cell. During the acid phase in the periodic culture portions of them are lost in the form of H_2. In the synthesis of the solvent, two moles of NADH are formed per mole of glucose and a certain amount of the former is also produced from the reduced ferredoxin. Consequently, in order to increase the amount of butanol, it is essential to increase the total amount of NADH. This can be achieved, for example, by inhibiting the hydrogenase at the acid formation stage[145] or via continuous cultivation in the solvent formation stage. The maximum theoretical yields from 1 g of glucose are 0.41 g of butanol, 0.32 g of acetone, and 0.5 g of ethanol. Thus, in the formation of a mixture of these products, the maximum theoretical yield depends on the product ratio. If this ratio is 6:3:1 (butanol–acetone–ethanol), which is typical, the maximum theoretical yield of solvents is 0.39 g g^{-1}.

It has been established that at a high pH mainly acids are synthesised whereas at a low pH an acetone–butanol mixture is formed. The optimum pH for the synthesis of solvents varies as a function of the strain and the cultivation conditions, lying as a rule in the range 4.0–6.0.[180,189] This is apparently associated with the fact that acetoacetate decarboxylase has a pH optimum in the region of 5.0.[190] Furthermore, the pH influences the ratio of the dissociated and undissociated forms of acetic and butyric acids and it is known that only the undissociated form permeates through the cell membrane.[191]

However, these conclusions cannot be applied to all the butanol synthesising *Clostridium* species. Significant synthesis of butanol by *C. beijerinckii* PI 13436 is attained at pH 6.8 and neither an acid concentration nor a pH which might be correlated with the onset of the formation of butanol were observed.[185] The synthesis of butanol by *C. acetobutylicum* NCIB 8052 (ATCC 824) can be induced at pH 7.0 by adding high concentrations of acetate and butyrate (100 mM each)[192] and in certain *C. acetobutylicum* cultures, isolated in Egypt, the final pH did not prevent the synthesis of butanol (20 g $litre^{-1}$) down to 6.4.[193] Whatever the process mechanism, the addition of acetate and butyrate to the periodic culture influences the time of the onset of synthesis,[185,192,194] the final product ratios, and the concentration and yield to an extent which cannot depend exclusively on the simple conversion of the acids into the acetone–butanol–ethanol mixture.[194]

An important factor in the formation of the acetone–butanol mixture is the concentration of the carbon source. Unduly low glucose concentrations[186,196,197] afforded as a result only acids. In a periodic culture, the organisms did not enter into the butanol formation phase under these conditions and in continuous systems the substrate concentration must be not less than 5 g $litre^{-1}$.[198]

Detailed studies of the kinetics of the formation of products were carried out by chemostatic cultivation with limiting glucose, nitrogen, and phosphate.[199] The specific rate of consumption of glucose increased with increase in the rate of dilution. An increase in the rate of dilution increased the rate of formation of acid, which did not appear at low rates of growth. A completely different picture obtained as regards the rate of formation of acetone, butanol, and ethanol. It has been shown that their amounts increase with increasing rate of dilution up to a certain point (0.1–0.2 h^{-1}) and then again decrease rapidly. Extrapolation indicates the formation of an acetone–butanol mixture at a zero rate of growth. Thus the synthesis of butanol is only partly associated with growth. If the butanol-synthesising cells are again placed in a buffer solution, they continue to synthesise the solvents. Thus non-growing cells can be used for the prolonged preparation of butanol.[198,200]

A weak point in acetone–butanol fermentation is the low concentration of the target products (about 2%). Solvents, especially butanol, are toxic to bacterial cells. In test experiments, the rate of growth of *C. acetobutylicum* ATCC 824 was 50% inhibited at a butanol concentration of 7–13 g $litre^{-1}$, an acetone concentration of 40 g $litre^{-1}$, and an ethanol concentration of 50–60 g $litre^{-1}$.[201] Complete growth inhibition was observed in the presence of 14–16 g $litre^{-1}$ of butanol and 70 g $litre^{-1}$ of acetone and ethanol. The lower concentration limit at which no decrease in the rate of growth takes place is 4.4–8 g $litre^{-1}$ of butanol. Other strains responded analogously to organic solvents and in certain cases they are even more sensitive than the strain 824. For a culture of *C. acetobutylicum* P 262, the addition of 10 g $litre^{-1}$ of butanol virtually stopped growth.

The difference between the inhibiting concentrations of the solvents can be accounted for by the differences in the hydrophobic properties of the alcohols.[202] The lipid layers in the cell membranes are acted upon by the solvents. It has been shown that butanol (0.5–1.5 vol.%), added to the lipid fraction obtained from cells in

the middle of the exponential phase of the growth of the *C. acetobutylicum* ATCC 824 strain, appreciably increases the mobility of the spin-labelled hydrocarbons in lipid dispersions or, in other words, butanol leads to the "thinning" of the lipid double layer.[203] It has been established that the composition of the lipid acyl chains changes, on passing from the exponential to the stationary growth phase to one with a higher percentage content of saturated chains. The addition of butanol (0.5–1 vol.%) to the cultures influences the composition of the chains in the same way. It has been concluded that the ability to increase the percentage content of saturated aliphatic acids in the membrane in response to the increase of the butanol level acts against the "thinning" effect of the latter.[203]

C. acetobutylicum is sensitive not only to butanol but also to acetic and butyric acids. The inhibiting effect by acids is correlated with the intercellular concentration of undissociated structures and with the pH.[204] A twofold decrease in the rate of growth occurs in the presence of 8–15 g litre^{-1} of acetic acid and 6–13 g litre^{-1} of butyric acid.[201]

At the present time, industrial fermentation with periodic cultivation has approached the limit of the biological possibilities of the cultures employed. For example, the Weisman strain of *C. acetobutylicum*, cultured in a 90 m^3 periodic fermenter on sugar cane molasses, affords an overall yield of solvent of 19.5 g litre^{-1} in the proprotions 6:3:1 (butanol–acetone–ethanol) after 30–34 h in 0.3 g g^{-1} yield and with a productivity of 0.6 g litre^{-1} h^{-1}. For comparison, we may note that the best result obtained on a laboratory apparatus with glucose as the source of carbon is as follows: overall yield of the acetone–butanol mixture 18.4–21.3 g litre^{-1} and a productivity of 0.3–0.9 g litre^{-1} h^{-1}.[205]

The change from periodic continuous cultivation regimes made it possible to increase the productivity in acetone–butanol fermentation. A two-stage chemostatic cultivation of *C. acetobutylicum* DS 1731, optimised with respect to pH and temperature, has been described.[199] The first stage was carried out at a rate of dilution D = 1.25 h^{-1} (37 °C, pH 4.3) and the second stage at D = 0.03 h^{-1} (33 °C, pH 4.3). The stream of synthetic medium contained 0.1 g litre^{-1} of KH_2PO_4 and 54 g litre^{-1} of glucose. These conditions permitted the complete utilisation of the carbon source, affording a yield of the final product of 18.2 g litre^{-1} [4.87:12.78:0.78 (g litre^{-1}) acetone–butanol–ethanol mixture].

Chemostatic cultivation of *C. acetobutylicum* ATCC 824 with glucose limitation (50 g litre^{-1}) and the use of a complex medium at D = 0.1 h^{-1} gave an overall solvent yield of 15.9 g litre^{-1} [5.4:9.5:1 (g litre^{-1} acetone–butanol–ethanol mixture]; a butanol yield of 0.32 g g^{-1} and a productivity of 2.56 g litre^{-1} h^{-1} were achieved at D = 0.22 h^{-1}. The high productivity of this system is associated with the high concentration of the biomass as a result of the employment of a complex medium. Evidently the productivity can be increased still further by recirculating the biomass.

The continuous formation of acetone and butanol can also be achieved by employing immobilised cells. In order to reduce the losses of activity, a technique designed to meter the neutrient substances has been developed.[198] Using this technique, the continuous production of an acetone–butanol mixture in the presence of *C. acetobutylicum* ATCC 824 cells immobilised on the calcium alginate gel or adsorbed on beechwood chippings has been achieved.[198] In the system with adsorbed cells, the best results were attained for D = 0.2 h^{-1}: the solvent yield was 6.3 g litre^{-1}, the butanol yield 0.33 g g^{-1}, and the productivity 1.2 g litre^{-1} h^{-1}. These are highly promising figures bearing in mind that the rate of growth of the micro-organisms was not raised to the maximum and the medium was not optimised.

The growing cells of *C.beijerinckii* MD 27.6 were immobilised in a calcium alginate gel for the continuous preparation of butanol and isopropyl alcohol. The medium contained glucose and a yeast extract. The best result was obtained for D = 0.3 h^{-1}: an overall solvent yield of 9–10 g litre^{-1} and a productivity 1.5 g litre^{-1} h^{-1}.

Thus, despite the fact that the acetone–butanol fermentation is one of the first purely microbiological processes developed at the industrial level, the renewal of interest in this manufacturing process can be justified only if a number of problems, capable of resulting in economically viable results, are solved. The use of an improved technology, such as continuous cultivation and immobilised cells, can increase the productivity of the fermentation. The attempts to solve the problem of the toxicity of butanol and acetone and to increase the yield of the products synthesised have been concentrated on the adaptation and selection of tolerant strains and also on the creation of various mutants in the study of the genetic control of the production of butanol. At the present time, studies have been published on the development of methods for genetic analysis which make it possible to manipulate the corresponding genes for the creation of strains capable of more productive synthesis of solvents and of altering their ratio .

It is noteworthy that the acetone–butyl fermentation is a waste-free industrial process. The carbon dioxide of hydrogen formed during fermentation can be regarded as secondary products. Carbon dioxide, liquid and solid, is used in the food industry and hydrogen is employed as a fuel or in methane formation processes. The liquid waste from industry containing riboflavin, vitamins, and protein is used as cattle feed.

V. HYDROGEN

An important natural phenomenon, which is of great interest from the standpoint of the conversion of energy, was discovered in 1942.[206] After adaptation to the dark, under anaerobic conditions, the cells of microscopic algae begin to evolve hydrogen vigorously in the course of several hours. Since the microscopic algae are capable of producing molecular oxygen in the light, there exists the possibility, in principle, of employing the mechanism of photosynthesis for the biophotolysis of water with conversion of light energy into a form of fuel.[1]

In recent years, the phenomenon involving the formation of hydrogen by microscopic algae has been investigated in a series of laboratories. The present state of this problem has been discussed in review articles.[1,2,206,207] There exist several examples of laboratory processes leading to the formation of hydrogen. The use of thermophilic algae *Mastigoladus laminosus* has been described.[208] The system for the formation of hydrogen acted in the course of several days with an efficiency in the utilisation of the energy of sunlight of 2.7%. The algal culture was projected against the action of oxygen with the aid of a mixture of argon, nitrogen, and CO_2.

The blue-green algae, exhibiting both hydrogenase and nitrogenase activities, are of interest in this sense. The limitation in the supply of nitrogen promotes the formation of hydrogen by a factor of 2.5–3.5 compared with the normal conditions.[133] The experiments performed with the blue-green algae *Anabaena cylindrica* showed that the yield of hydrogen increases by ~70% on periodic illumination (10 s period). An apparatus for the manufacture of

hydrogen has been created under laboratory conditions in which a suspension of algae circulated between dark and illuminated zones.[209]

The practical use of the phenomenon of the photoevolution of hydrogen by microscopic algae has not as yet been achieved in view of the low efficiency of the evolution of hydrogen under stationary conditions. It may be that further studies and the optimisation and increase in the process efficiency will create conditions for the technological exploitation of this phenomenon.

Experiments performed on photosynthesising bacteria have shown that the best candidates for the preparation of hydrogen are the purple bacteria and cyanobacteria. It has been reported that the use of immobilised cells of photosynthesising bacteria made it possible to achieve a productivity in the evolution of hydrogen of 40 ml H_2 per gramme of the dry cells per hour.[210] Fairly high productivities—180 ml H_2 from a litre of the culture medium per hour—have also been achieved by the continuous cultivation of the purple bacteria *Rhodospirillum rubrum* on a medium with lactate.[211]

At the end of the 1970's and the beginning of the 1980's, studies on artificial photosynthesis were also prosecuted vigorously.[1,68,76,213] Best results were attained on artificial systems containing illuminated chloroplasts and enzyme preparations of bacterial hydrogenases. Such systems were capable of evolving hydrogen at rates up to 94 μmol H_2 per milligramme of chlorophyll per hour in the course of several hours.[212]

The genetic modification of the photosynthesising organisms, the study of their biochemical pathways, the increase of the hydrogenase and nitrogenase activities, and the optimisation of the nutrition, illumination conditions, and immobilisation of micro-organisms are all ways leading to an increase in the efficiency of the photosynthesis and its industrial application.[133]

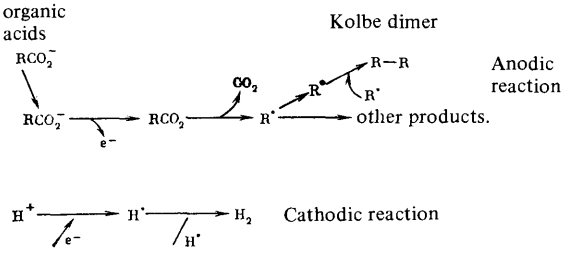
The ability of certain chemotropic organisms to evolve molecular hydrogen was also noted a fairly long time ago. Subsequently, this phenomenon was investigated in detail in our country and abroad. The present state of the problem has been analysed in detail.[79]

Hydrogen-forming micro-organisms are common in nature and hydrogen can be formed from carbohydrate compounds, including starch and cellulose and from aminoacids and ketoacids.

On complete decomposition of glucose solely to CO_2 and H_2, the limiting energy conversion efficiency of 99% can be achieved theoretically:

$$C_6H_{12}O_6 + 6H_2O \rightarrow 6CO_2 + 12H_2,\ \Delta G_0' = -260\ \text{kJ mol}^{-1}.$$

In practice, under the conditions of clostridial fermentation the process proceeds with formation of acetate or acetate and butyrate apart from CO_2 and H_2:



$$C_6H_{12}O_6 + 4H_2O \rightarrow 2CH_3COO^- + 2HCO_3^- + 4H^+ + 4H_2,$$
$$\Delta G_0' = -206{,}6\ \text{kJ mol}^{-1};$$
$$C_6H_{12}O_6 + 2H_2O \rightarrow CH_3CH_2CH_2COO^- + 2HCO_3^- + 3H^+ + 2H_2,$$
$$\Delta G_0' = -255{,}2\ \text{kJ mol}^{-1}.$$

In the first case, 33% of the energy stored in glucose is converted into hydrogen form and in the second 16.7% is converted. This is determined by the fact that a considerable proportion of the energy remains in the aliphatic acids.[1] In order to increase the efficiency of the energy transformation, the aliphatic acids formed can be converted into fuel by the Kolbe electrolysis.[118] The process has been vigorously investigated by the Dynatech Company (USA).[133]

Organic acids are selectively extracted from the culture liquid by kerosine and are re-extracted with an aqueous solution. Organic acids are converted into liquid and gaseous fuel via the reaction

$$2CH_3CH_2CH_2COOH \rightarrow C_6H_{14} + 2CO_2 + H_2.$$

The fundamental anodic and cathodic reactions in the electrolysis are presented below:

The alkanes formed can serve as an effective fuel for internal combustion engines and the mixture of hydrogen and Co_2 produced is used for the generation of elecricity.

Anaerobic bacteria, which are capable of forming ethanol together with hydrogen, are also of definite interest. A new thermophilic hydrogen-forming culture, isolated in hydrothermal sources in Kamchatka, which decomposes glucose in accordance with the equation

$$C_6H_{12}O_6 + H_2O \rightarrow 2H_2 + 2CO_2 + C_2H_5OH + CH_3COOH,$$
$$\Delta G_0' = -201{,}44\ \text{kJ mol}^{-1},$$

has been described.[119] In this system the efficiency of the transformation of energy (of the overall energy into the hydrogen and ethanol forms) is 79%.

One of the latest advances in the preparation of hydrogen from water involves the creation of microbiological systems for the biophotolysis of water on the basis of cultrues of micro-organisms coupled via their metabolites.[122,175] Laboratory tests of a system for the photodecomposition of water into hydrogen and oxygen by sunlight with the separate formation of the gases have been carried out and completed. Productivities up to 0.5 litre H_2 per litre of the medium per hour (correspondingly 0.25 litre O_2 per lite of the medium per hour) have been obtained.[175]

In conclusion of this Section, one may note definite advances in laboratory studies of photobiological processes leading to the formation of hydrogen and also the creation of several demonstration plants. The scaling up of these processes still remains a complex biotechnological task, but the colossal advantages of the hydrogen power engineering inspire the hope that studies on these lines will continue and will bring about the expected practical results.

VI. CONCLUSION

The recent years have been characterised by an increasing interest in the development of renewable energy and raw material sources. Biotechnological processes occupy an important place in these projects. National programmes in fuel and biotechnology are being actively developed in the USA, Great Britain, France, Brazil, Japan, Canada, China, and other countries.

During the last ten years, studies on the utilisation of biosystems for the synthesis of fuel-type compounds with a high energy content have been carried out in a number of countries, including the USSR. These investigations have been directed towards the creation of a fundamentally new energy technology using renewable energy sources, in the first place solar energy.

At the present time two categories of systems capable of contributing significantly to the energy supply of the country are considered as likely prospects.

The first generation bioenergy technology presupposes the wide-scale industrial introduction of methanogenesis, which has now reached the level of technical solutions. The process represents anaerobic microbiological conversion of cellulose-containing materials into a mixture of methane and carbon dioxide. The quantitative characteristics of this process have not been investigated, the pathways leading to the transformation of the substances in a complex sequence of reactions have been studied, the key intermediates have been discovered, and a mathematical model and methods for the regulation of methanogenesis have been created for the first time.

The large-scale application of the biogas technology makes it possible to solve three inter-related problems—the preparation of the fuel, the concentration of organomineral fertilisers, and the problem of the protection of the environment against biological contamination (agricultural waste). By utilising the waste in the USSR alone, it should be possible to obtain up to 150 million tonnes of conventional fuel, which fully covers the future energy needs of agriculture.

At the present time agriculture consumes 60–62 million tonnes of petroleum products. By generating biogas, the agricultural industry can attain self-sufficiency in terms of energy.

The preparation of fuel ethanol and the acetone–butanol mixture from cellulose may make a significant contribution.

The second generation bioenergy technology is associated with the creation of a large-scale process for the biophotolysis of water—the reaction leading to the decomposition of water into hydrogen and oxygen by sunlight. At the present time, a reaction of this kind is achievable on the basis of microbiological cultures coupled via their intermediate compounds.

The complexities in the creation of systems for the transformation of solar energy involve the necessity to occupy large territories by technical constructions. Because of this, the constructions must be as simple as possible, should be convenient to use, and should not require expensive materials.

It has been suggested that biopower engineering plants will develop in the period 1990–2000, which will create a new power enginnering technology using high-energy and ecologically pure fuel. After sufficient development, processes of this category will meet a significant proportion of the energy needs of the community.

The Influence of Surface Microstructures on the Physicochemical Properties of Oxides

A.I.Leonov, Yu.P.Kostikov, and V.S.Strykanov

Published data on the role of defects and the microstructures formed on them in the chemistry of solid oxides have been examined. The conditions of formation, stability, and breakdown of the microstructures obtained on the external surface, at the phase boundaries, and in the inter-crystallite layers in polycrystalline solids have been described. It has been shown that surface compounds have an activating and an inhibiting action on the kinetics of solid-phase chemical reactions and on the thermomechanical and electrophysical properties of oxide materials.
The bibliography contains 74 references.

I. INTRODUCTION

The study of surface microstructures is becoming one of the principal research fields in solid state chemistry and physics. All heterogeneous catalytic reactions take place on a surface, and progress in heterogeneous catalysis depends on the study of the composition, structure, and energetics of surface microstructures. The properties of metallic and non-metallic constructional materials are determined to a large extent by the phase boundaries and the grain boundaries, which are the most important structural elements. The study of the influence of defect microstructures (dislocations, grain boundaries, and phase boundaries) on the electronic processes in semiconductors is extremely important. Surface structures have an extremely marked influence on the kinetics of crystal growth and the habit and degree of perfection of crystals.

In the present review, published data on the role of surface microstructures in the physical chemistry of oxides have been systematised, and a critical analysis has been carried out. The dependence of the

properties of microstructures on the chemical character and concentration of impurities and on temperature, and the formation of non-equilibrium (intermediate) compounds in solid-phase chemical reactions as a consequence of the defect character of the structure, have been examined. Data on the influence of microstructures on the kinetics of the sintering of ceramic masses, the deformation of materials at high temperatures, and the electrophysical properties of doped oxides have been discussed.

II. METHODS FOR STUDYING THE SURFACE AND THE INTER-PHASE BOUNDARIES

Widely employed methods of analysis—chemical analysis, X-ray diffraction, spectroscopy, microscopy— do not give the required information on the properties of a surface and micro-volumes. The present section gives brief characteristics of some of the most informative methods for the analysis of a surface, the grain boundaries, and the phase boundaries in ceramic materials.

1. *X-Ray spectral microanalysis (XMA)* is based on the study of the X-ray emission spectra; the emission is excited in the specimen being analysed by an electron probe with a diameter of $0.7-1$ μm on the surface of the specimen. XMA can be used to determine all the elements from Li onward; the sensitivity is ~1 at.% for the light elements, and ~0.1 at.% for the middle and heavy elements. The spatial resolution is $1-3$ μm, because of the scattering of the exciting electron beam in the massive specimen. The thickness of the specimen is much greater than the mean free path of the electrons with an energy of $5-20$ keV usually employed in XMA.[1]

XMA can be used to carry out the local (within $1-3$ μm) qualitative and quantitative analysis of a substance with an accuracy of ~2 rel.%, to study the distribution of elements over the surface of a specimen, to study the reaction at a phase boundary, and to determine diffusion characteristics.

For XMA, the specimen should have a well polished surface, in order to observed its microstructure in a metallographic microscope and, which is more important, in order to carry out quantitative analysis, since the surface relief influences the intensity of the X-ray emission recorded. There are no restrictions on the electrophysical characteristics of the specimens.

2. *Scanning electron microscopy* makes it possible to study the topography of the surface of a specimen, its microstructure, and its domain structure in the case of ferromagnetics and ferroelectrics. When the back-reflected scattered electrons are recorded, the image produced gives information on the distribution of the elements on the surface of the specimen, particularly if the atomic number of the element concentrated at the grain boundaries differs considerably from that of the basic compound.[2] The attainable resolution is 10 nm.[3] The scanning electron microscope gives a resolution of ~1 μm when operating under X-ray microanalysis conditions.

3. *Scanning transmission electron microscopy (STEM)* can be used to study the microstructure and the morphology of the intergranular formations, and to determine the structure of phases by microdiffraction. The attainable spatial resolution is $\sim 3-5$ nm. A characteristic of STEM is that it is possible to carry out routine microanalysis with a spatial resolution of ~20 nm.[4,5] This high resolution is made possible by the use of electron beams with a field emission cathode, which make it possible to obtain an electron probe with a diameter $\leqslant 10$ nm on the surface of a specimen. Since STEM uses specimens whose thickness ($150-650$ nm) is smaller than the mean free path of the electrons in the specimen, the broadening of the beam in the specimen as a result of scattering is slight, and the diameter of the region analysed is $2-3$ times the diameter of the probe on the surface of the specimen.[6] The broadening also depends on the thickness of the specimen, the energy of the electron probe, and the characteristics of the target—atomic number, atomic mass, and density. Quantitative X-ray spectral analysis is difficult, so that the results of microanalysis by STEM must be regarded as only a qualitative demonstration of enrichment of the grain boundary.[5]

The preparation of specimens for STEM is tedious and complicated, since it is necessary to reduce the thickness of the specimen to ~100 nm. Chemical etching and etching by ion bombardment are used for this purpose. The preparation of the specimens may have a significant influence on the results, since in chemical etching, selective etching of different phases may take place, and in etching by ion bombardment, the atomisation of different elements is irregular[3] and the temperature of the specimen increases considerably, so that chemical reactions may take place with a change in the phase composition of the specimen. This must be borne in mind when discussing the results of microanalysis by STEM.

4. *Auger electron spectroscopy (AES)* is based on the analysis of the Auger electrons emitted by the specimen when it is irradiated by a beam of electrons with an energy of $1-3$ keV. The depth of removal of the Auger electrons varies from 0.4 nm to 3 nm, depending on their kinetic energy.[3] The AES data therefore carry information on the surface layer of the specimen.

AES makes it possible to determine the qualitative and approximate quantitative composition of the surface (all elements except H and He); its sensitivity corresponds to $\sim 10^{-2}$ monolayer. Under scanning conditions it is possible to study the distribution of the elements over the surface of the specimen; the spatial resolution in this case is determined by the diameter of the exciting beam of electrons, and is usually $5-20$ μm. The most interesting feature is the possibility of observing the Auger spectra directly during the ion etching of the specimen; this makes it possible to obtain the distribution of elements along the depth and to obtain information on the reactions taking place in the region of a phase interface. No special preparation of the specimens is required; in the study of dielectrics, difficulties are encountered, associated with the charging of the surface.

5. *X-Ray photoelectron spectroscopy (XPES)* or electron spectroscopy for chemical analysis (ESCA) is based on the analysis of the photoelectrons emitted by the specimen when it is irradiated by a monochromatic beam of X-rays. The depth of removal of the photoelectrons is several nanometres, that is spatial ESCA, like AES, carries information about the surface of the specimen. XPES has no spatial resolution over the surface, since it is extremely difficult to focus the X-ray beam to a diameter smaller than 1 mm.

XPES makes it possible to carry out the qualitative and quantitative analysis of a surface and to determine all the elements of the periodic system with a sensitivity of ~0.1 at.% (for uniform distribution of the element being determined) and an uncertainty of not more than 10 rel.%.

A significant advantage of XPES is the simplicity of quantitative analysis, since there is no inter-element influence in the determination of any elements. Special preparation of the specimens is not required, and there are no restrictions on the electrophysical properties of the specimens. The methods are more informative when XPES and AES are used together.

6. *Secondary ion mass spectroscopy (SIMS)* is based on the analysis of the secondary ions emitted by a target when it is bombarded by a beam of primary ions with an energy of 1–20 keV. The secondary ion mass spectrum contains differently charged monatomic ions of the main substance, the ions of polyatomic clusters, and the ions of impurities and chemical compounds, and the interpretation of the mass spectrum is tedious. A significant advantage of SIMS over other methods is its high sensitivity, from 10^{-7} at.% to 10^{-9} at.%.

The recording of the mass spectra with constant etching of the surface of the specimen makes it possible to obtain the distribution of the elements being determined along the thickness of the surface layer; the resolution along the layer (with allowance for the physical factors restricting the resolution—the roughness of the surface, the formation of etching facets or cones, and atomic mixing) is ~10 nm.

In the ion micro-probe, in the study of the distribution of elements over the surface of the specimen, the spatial resolution is determined by the size of the ion probe (1–10 μm). Preliminary preparation of the specimens is not required. The analysis of dielectrics is difficult, because of charging of the surface.

7. *Autoradiography (ARG)* is based on the recording of the distribution of a radioactive isotope in the specimen being studied from the blackening of photoemulsion applied to the specimen (or a photographic plate), under the influence of nuclear radiation. For contact radiography, the spatial resolution is ~20 μm, and for radiography with applied emulsions combined with electron microscopy the resolution is ~1 μm. ARG gives information on the diffusion characteristics of the phase boundaries and grain boundaries.[7] Any material can be studied by autoradiography. The restrictions are related to the selection of a radioactive isotope of the element being studied, suitable for radiography.

A detailed comparative analysis of methods for studying a surface has been given in a published review.[8]

III. THE FORMATION OF THE MICROSTRUCTURES ON DEFECTS IN OXIDES CONTAINING AN IMPURITY, AND THEIR PROPERTIES

Natural minerals and oxides used in technology contain non-controlled impurities or specially intoduced additives (mineralisers, activators, modifiers), which form microstructures as a result of internal adsorption on defects. Table 1 gives the compositions of microstructures in oxides, determined by XPES and using electron and ion micro-probes.

X-Ray electron studies of polycrystalline oxides[9] containing small quantities of impurity (0.01–1 mole %) showed that in the specimens $MgO-[Al_2O_3]$, $SnO_2-[CaO]$, $TiO_2-[CaO]$, and $TiO_2-[BaO]$, the compounds $MgAl_2O_4$,[9–12] $CaSnO_3$,[14] $CaTiO_3$, and $BaTiO_3$ [9] respectively are formed as local microstructures in the region of the defects. The synthesis temperature was 1650–1800 K. The composition of the surface was determined from the integral intensity of the analytical lines $Mg2s_{1/2}$, $Ca2p_{3/2}$, $Ba3d_{5/2}$, $Al2s_{1/2}$, $Ti2p_{3/2}$, and $Sn3d_{5/2}$ with allowance for the photo-ionisation cross-sections.[27]

The results of an X-ray electron study of the polycrystalline oxide MgO containing small quantities of added Al_2O_3 are given in Fig.1.[10] With increase in the Al_2O_3 concentration from 0.4 mole % to 2 mole % in the surface layer there was a decrease in the concentration of Mg in octahedral coordinatoin [binding energy E_b(Mg. $2s_{1/2}$) = 87.5 eV], indicating the formation of spinel $MgAl_2O_4$.

Table 1. The formation of microstructures on defects containing impurities (0.01–1 mole %).

Oxide	Impurity	Microstructure	Refs.
MgO	Al_2O_3	$MgAl_2O_4$	[9–11]

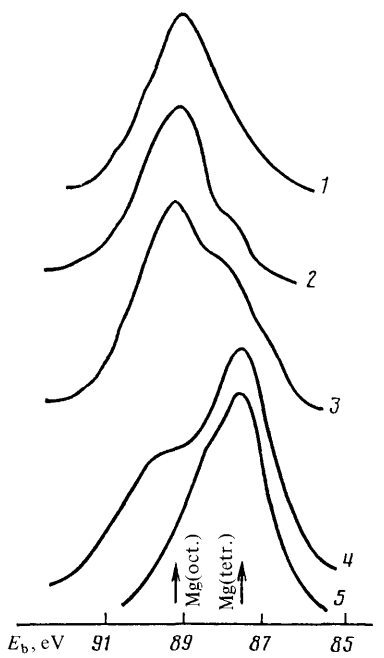

Figure 1. Mg2*s* X-ray electron spectra: *1*) MgO, *2–4*) MgO containing 0.4, 0.8, and 2.0 mole % Al_2O_3 respectively, *5*) $MgAl_2O_4$ (spinel).[10]

The ratio Al/Mg in the surface layer with a thickness of ~8.0 nm, found from the intensities of the Mg and Al lines, is 0.3, whereas in spinel, Al/Mg = 2. This lack of agreement is apparently due to the formation of spinel as local inclusions in an MgO matrix both along the depth of the layer and over the surface of the specimen, and the observed value of the Al/Mg ratio is the averaged value. Electron-microscope studies[11] showed that the formation of spinel involves the accumulation of crystals with dimensions of 0.5–10 μm, distributed in disordered fashion in the surface layer.

The dependence of the surface formations in a CeO_2 ceramic on the concentration of added La_2O_3 has been studied experimentally.[10] The $Ce3d_{5/2}$ spectrum in CeO_2 has characteristic lines with E_b = 882.3 eV and E_b = 882.6 eV. When CeO_2 contains added La_2O_3, a new $Ce3d_{5/2}$ line appears, with E_b = 381.3 eV, which can be assigned to a surface compound. The enrichment in La_2O_3 of a surface layer with a thickness of 8–10 nm, established from the intensities of the Ce and La lines, corresponds to an approximately five-fold increase in the La_2O_3 concentration relative to the average value for the specimen. In the surface film with a thickness of several atomic layers (1–1.5 nm), the La_2O_3 concentration is probably even greater, as a result of chemisorption. With increase in the La_2O_3 concentration, the line due to the new compound becomes stronger, and the lines with E_b = 882.3 eV and 882.6 eV become weaker. These data indicate that the introduction of La_2O_3 into CeO_2 leads to the formation on the surface of the CeO_2 granules of a micro-phase in which the states of the Ce atoms differ significantly from their states in CeO_2. According to the equilibrium diagram of the $CeO_2-La_2O_3$ system,[28] CeO_2 and La_2O_3 form restricted solid solutions. No chemical compounds are formed in this system. Thus in the $CeO_2-La_2O_3$ system, the chemistry of the surface micro-phases differs from the chemistry of the macro-phases. The compound formed was not identified.

Table 1 shows that, on the defects, microstructures are formed as chemical compounds which have been identified in the equilibrium diagrams ($MgAl_2O_4$, $CaTiO_3$, etc.)[9] or as compounds which are unstable in macro-volumes, for example $La_2(Cr^{VI}O_4)_3$.[9,20] In the systems with restricted solid solutions $SnO_2-Nb_2O_5$, SnO_2-NiO, SnO_2-ZnO,[9,16] and SnO_2-TiO_2, the micro-phases and the macro-phases differ in the concentration of the dissolved component.[9,15] The microstructures may be produced on the surface, and also along the boundaries of crystals and blocks and on dislocations, that is in the zones in which defects are concentrated. The crystallographic properties of the main oxide and the impurity play an important role in the formation of microstructures. The distribution coefficients of the impurities vary over a wide range, and depend on the concentration of the impurity, the nature of the interaction between the impurity and the defects of the matrix, and on temperature.

X-Ray electron spectroscopy has been used[12] to study a specimen of aluminium oxide containing 0.06 mole % MgO and 0.002 mole % CaO. The concentrations of the impurities determined along the grain boundaries were 0.2 mole % MgO and 3.4 mole % CaO, corresponding to enrichment coefficients $K = [MgO]_{boundary}/[MgO]_{bulk}$ = 3.3 and $K = [CaO]_{boundary}/[CaO]_{bulk}$ = 1700. Magnesium oxide forms surface microstructures consisting of non-stoichiometric spinel in the form of isolated units, whereas calcium oxide is distributed uniformly along the boundaries and is concentrated in several atomic layers of the surface of the crystals. A decrease in the segregation of calcium oxide is observed with increase in temperature.

In titanium oxide specimens containing added barium oxide,[9] the surface layer with a thickness of 8–10 nm was enriched in barium oxide; with increase in the concentration of the additive in the specimen, although its concentration in the surface layer increased, the distribution coefficient K decreased. In the surface layers, BaO was present as local formations with the composition $BaTiO_3$.

In the SnO_2-CaO system, the compounds $CaSnO_3$ and Ca_2SnO_4 are formed.[29] Quantitative X-ray electron analysis of the surface showed that the coefficient of enrichment of the surface layer of the specimens in calcium oxide reached 520 at a CaO additive concentration of 0.01 mole %, and 7.8 at a CaO concentration of 10 mole %.[30] In the surface layer, the tin is present as tin(IV) in an octahedral environment of oxygen atoms [SnO_6; $E_b(Sn3d_{5/2})$ = 486.7 eV], as in SnO_2. The Ca atoms have cubo-octahedral coordination, similar to that observed in $CaSnO_3$. For $CaSnO_3$ and $CaTiO_3$, $E_b(Ca2p_{3/2})$ = 347.2 eV; for CaO with calcium in octahedral coordination, the value is 346.3 eV. The $Ca2p_{3/2}$ spectrum of the compound Ca_2SnO_4, which contains calcium ions in two non-equivalent positions, is the superposition of the spectra of $CaTiO_3$ and CaO. Thus the coordination of the Ca atoms changes from octahedral in CaO to cubo-octahedral in $CaSnO_3$. Moreover, XPES data obtained with a positive charge on the surface showed that the specimens with a low CaO concentration contain two phases in the surface layer—SnO_2 (continuous layer) and $CaSnO_3$ (local formations).

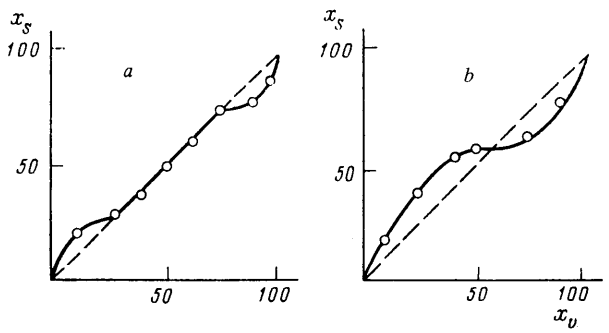

Figure 2. Composition of the surface layer of specimens in the SnO_2-TiO_2 system at different heating temperatures: *a*) 1373 K, *b*) 1673 K; x_v and x_s are the volume and surface concentrations of TiO_2.[15]

The SnO_2-TiO_2 system[15] is characterised by much smaller surface enrichment coefficients than the SnO_2-CaO system. At a concentration of 0.1 mole % TiO_2 in tin(IV) oxide, the enrichment coefficient is 11, and with the addition of 0.1 mole % SnO_2 to the TiO_2 matrix the coefficient is 50. Fig.2 gives the dependence of the composition of the surface of the specimen on its bulk composition in the SnO_2-TiO_2 system. At a heating temperature of 1373 K in the range of bulk compositions 25–75 mole % TiO_2, the surface layer is two-phase, and its composition corresponds exactly to that of the macro-volume. In the regions adjoining the pure components of the system, the surface layer is single-phase, and its composition differs from that of the bulk. Increase in the heating temperature to 1673 K leads to the formation, throughout the entire composition range, of a single-phase surface layer, whose composition differs from that of the bulk. Thus in this system, surface solid solutions TiO_2-SnO_2 are formed, and the range of their existence is broader than that for the bulk phases.

The distribution of added SiO_2 in polycrystalline SnO_2 is characterised by the following parameters.[15] With change in the quantity of added SiO_2 from 0.1 mole % to 5.0 mole %, the enrichment coefficient changes from 320 to 12. The coordination numbers of tin and silicon remain unchanged. The surface layer of the specimens is two-phase throughout the composition range.

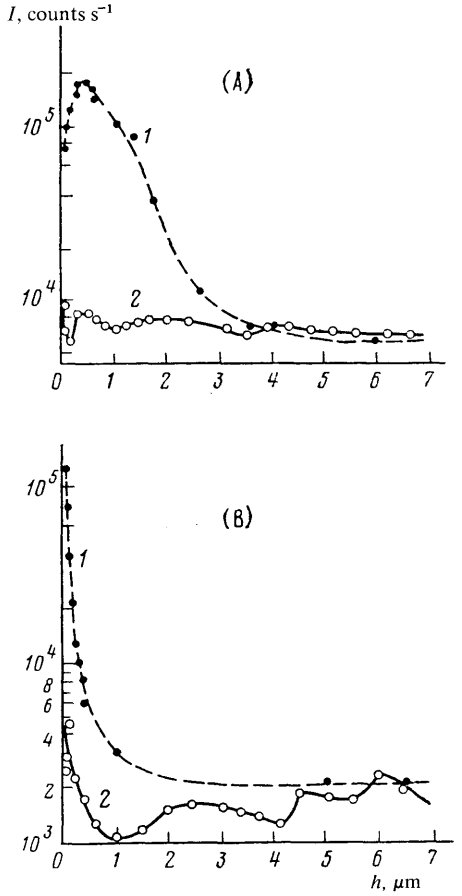

Figure 3. Mass-spectrometric microanalysis of the distribution of Al in slowly cooled (*1*) and quenched (*2*) MgO specimens containing 0.187 mass % Al (*A*) and 0.006 mass % Al (*B*); *h* is the depth of the layer analysed, *I* is the number of counts in 1 s, ^{27}Al.[11]

If the impurity forms continuous solid solutions with the oxide matrix (isomorphous systems), the internal adsorption of the isomorphous impurity is slight, $K \simeq 1$. The compounds NiO and MgO form a continuous series of solid solutions.[29] An XPES analysis of polycrystalline magnesium containing NiO showed that the concentration of nickel oxide in the surface layer is practically the same as that in the bulk.[9] The $Ni2p_{3/2}$ and $Mg2s_{1/2}$ binding energies in the surface layer of the specimen are the same as in the pure oxides. This indicates that solid solutions of NiO in MgO are formed both in the surface layer and in the bulk.

The stability and concentration of the microstructures on the defects change with change in temperature. The dependence of the surface segregation of Al_2O_3 in MgO on the thermal treatment conditions has been studied.[11] Single crystals of magnesium oxide containing 0.187 mass % and 0.006 mass % Al in solid solution [specimens (A) and (B) respectively] were heated in air for several hours at a temperature of 2073 K. Half of the specimens were subjected to air quenching by ejection from the furnace, and the rest were cooled in the furnace over a period of several hours. The results of the experiments are given in Fig.3. In the specimen cooled slowly (A), the maximum concentration of Al was established at a depth of less than 1 μm from the surface. Microscope and mass-spectrometric analyses showed the formation of local inclusions of spinel in the surface layers. The quenched specimen showed little change in the concentration of aluminium in the layer next to the surface, and no heterogeneous formations were detected. At high temperatures, desorption and solution of Al_2O_3 in the bulk of the MgO crystal take place. On slow cooling, segregation of Al_2O_3 developed on the defects, and the formation of microstructures with the composition $MgAl_2O_4$ was observed. Similar processes took place in the (B) specimens. Comparison of the curves for specimens (A) and (B) shows that the depth of formation of the microstructures increases with increase in the concentration of impurity.

The kinetics of the segregation of Al_2O_3 on the defects in an MgO matrix have been studied.[31] The rate of separation of Al_2O_3 from the $MgO-Al_2O_3$ solid solution and the formation of spinel along the grain boundaries increase with increase in the concentration of the dissolved component. The process is controlled by diffusion.

Table 2. Primary products of the chemical reaction in oxide mixtures.

Systems	Primary products	*A*	Refs.
$MgO-Al_2O_3$	$MgAl_2O_4$	1:1, 1:13	[34]
$CaO-Al_2O_3$	$CaAl_2O_4$	3:1, 12:7, 1:1, 1:2, 1:6	[34]
$SrO-Al_2O_3$	$SrAl_2O_4$	3:1, 2:1, 1:1, 1:2, 1:6	[34]

Note. *A* is the molar ratio of the oxides in the final products.

*Ln = La, Ce, Pr, Nd.

**Solid solution based on ZrO_2.

An X-ray electron study[9,14] of polycrystalline tin(IV) oxide containing small quantities of added calcium oxide showed that the surface layer with a thickness of 8–10 nm is enriched in calcium oxide; the enrichment coefficient *K* reached values of 520 and 7.8 for concentrations of the additive of 0.01 mole % and 10 mole %

respectively. The surface was two-phase; the SnO_2 matrix contained local formations of $CaSnO_3$. The formation of the surface layer and its stability at high temperatures were studied. The surface layer was removed by grinding. The specimens were heated to different temperatures, kept for 1 h, and then subjected to air quenching to preserve the distribution of the additive, established at the given temperature. After each thermal treatment, the spectra of the surface of the specimen were recorded, and their intensities were used to calculate the Ca/Sn ratio. At low heating temperatures with treatment for 1 h, the surface structure did not form at all. The maximum segregation (Ca/Sn = 0.53) wa attained at 1773 K. At higher temperatures, the reverse process, that is the solution of the microstructure in the matrix, took place.

The depth (thickness) of the surface formations in crystalline oxides varies over a wide range and depends on the nature and concentration of the impurities present in the surface structures. Fig.3 shows that the boundaries of the surface formations, facing into the crystals, have an indistinct "diffuse" form. With increase in the concentration of impurity, the depth of segregation increases. The depth of segregation of the impurities at the grain boundaries also depends on temperature, and increases with increase in the latter.[32]

The surface and the grain boundaries of oxides have an electric charge, as a consequence of the presence of an excess of ions of a given sign.[32] This surface charge is compensated by ions of opposite sign, which are formed close to the surface and extend to a depth of 2–10 nm.

IV. THE RELATIONSHIP BETWEEN THE CHANGE IN THE DEFECT CHARACTER AND THE SEQUENCE OF CHEMICAL REACTIONS IN MIXTURES OF SOLID OXIDES

Solid-phase reactions generally take place in several stages. Irrespective of the reagent ratio in the original mixture, the intermediate reaction product is a definite compound.[13,17,22,34–37] Examples of these reactions are given in Table 2.

It has been suggested[34] that the compound with the highest crystallisation temperature is formed first. This rule is not confirmed by a number of reactions, however. For example, in mCaO + $n$$Al_2O_2$, mMgO + $n$$TiO_2$, and $m$$Y_2O_3$ + $n$$Al_2O_3$ mixtures, irrespective of the component ratio, the compounds $CaAl_2O_4$, $MgTiO_3$, and $YAlO_3$ respectively are formed in the first stage of the reaction. According to the equilibrium diagrams of the $CaO-Al_2O_3$, $MgO-TiO_2$, and $Y_2O_3-Al_2O_3$ systems,[29] the compounds formed first are not the most refractory. The physicochemical factors causing solid-phase reactions to take place in stages have been studied.[20]

Comparison of the formation of microstructures in oxides containing impurities (Table 1) and the primary reaction products of the corresponding oxides in solid-phase reactions (Table 2) shows that defects play a definite role in these processes. In reacting oxide mixtures, the compounds formed first are those which are also produced on defects in the oxides.[20] For example, in mMgO + $n$$Al_2O_3$, mCaO + $n$$SnO_2$, mCaO + $n$$TiO_2$, and mBaO + $n$$TiO_2$ mixtures, irrespective of the component ratio, the compounds $MgAl_2O_4$, $CaSnO_3$, $CaTiO_3$, and $BaTiO_3$ respectively are formed first. On the other hand, in the same systems, but at concentrations of the second components from 0.01 mole % to 1 mole % (see Table 1), the compounds $MgAl_2O_4$, $CaSnO_3$, $CaTiO_3$, and $BaTiO_3$ respectively are formed as local microstructures on defects.

In a 2CaO + SnO_2 mixture at temperatures of 1200–1500 K, reactions take place to give the primary product $CaSnO_3$, and when the reaction mixture contains sufficient calcium oxide, this product reacts further with it to give the compound Ca_2SnO_4.[34]

Solid-phase chemical reactions are accompanied by a change in the defect character of the reacting mixture. According to Ref.34, the chemical reaction involves a number of elementary processes: covering of the surface, breakdown of the crystals and disordering as a result of surface and bulk diffusion, actual chemical reaction, an increase in the specific surface of the reacting substances, subsequent formation of a defect crystalline product, and removal of the defects in the crystal lattice of the compound formed. At definite stages, these processes lead to an increase and then a decrease in the defect character of the reacting mixture.

In the synthesis of compounds with the garnet structure $A_3B_5O_{12}$, where A = Ln, Y, and B = Al, Fe, the solid-phase reactions in the $3A_2O_3$ + $5B_2O_3$ mixtures take place with the formation of monoclinic $Y_4Al_2O_9$ and cubic $YAlO_3$ as intermediate products.[22,36] For this reason, it is difficult to obtain the pure product $A_3B_5O_{12}$.

An X-ray electron spectroscopic study[20] of the synthesised compound $Y_3Al_5O_{12}$ in the surface layer of a specimen with a thickness of 7–10 nm established the ratio Y/Al = 1.03 ± 0.05, which corresponds to the compound $YAlO_3$. The $Al2s_{1/2}$ binding energy in the surface layer is 119.2 ± 0.1 eV. In the compounds $YAlO_3$ and $LaAlO_3$, aluminium is in octahedral coordination, $E_b(Al2s_{1/2})$ = 119.3 ± 0.1 eV. For aluminium in tetrahedral coordination in sodalite $3NaAlSiO_4.NaCl$, E_b = 118.2 ± 0.1 eV. In the garnet structure, Al occupies tetrahedral positions. On the surface of the specimen with the composition $Y_3Al_5O_{12}$, aluminium was detected in octahedral coordination. The composition of the surface and the octahedral coordination of aluminium indicate that microstructures of the compound $YAlO_3$ are formed in the defect surface layer of the specimen with the composition $Y_3Al_5O_{12}$. $YAlO_3$ microstructures may also be produced along the boundaries of the crystals and blocks and on dislocations, that is in the zones where defects are concentrated. Thus in the $3Y_2O_3$ + $5Al_2O_3$ reaction mixture, the intermediate compounds $YAlO_3$ and $Y_4Al_2O_9$ are formed in the initial period of intensive defect formation.

In the systems given in Table 2, the intermediate reaction products of the oxides are generally found on the corresponding equilibrium diagrams. The formation on defects of new microstructures with compositions and structures differing from those of the equilibrium compounds is also possible, however. An example is provided by the $Cr_2O_3-La_2O_3$ system.

In an La_2O_3 + Cr_2O_3 mixture at a temperature of 873 K, phases corresponding to the chromate $La_2(CrO_4)_3$ and the chromite $LaCrO_3$ were detected in addition to the original oxides[20,22] (Fig.4). The kinetic curve *3* (the formation of the intermediate chromate) has a maximum indicating the predominant formation of chromate in the initial stage of the reaction of chromium(VI) according to the scheme

$$1.5Cr_2O_3 + 2.25O_2 + La_2O_3 \rightarrow La_2(CrO_4)_3.$$

The course of curve *3* is determined by two factors: the change in the defect character of the reaction mixture, which is responsible for the production of the maximum, and the presence of lanthanum oxide, which binds Cr^{VI} in a chemical compound.[20]

XPES has established the formation of metastable microstructures $xCr_2O_3.yCrO_3$ on defects in a Cr_2O_3 matrix,[38] the concentration of which decreases with increase in temperature and with decrease in

the oxygen pressure in the gaseous medium.[21] Metastable microstructures influence the reactivity and catalytic activity of substances, and the sintering and recrystallisation of solids.[10,16,20,21,39]

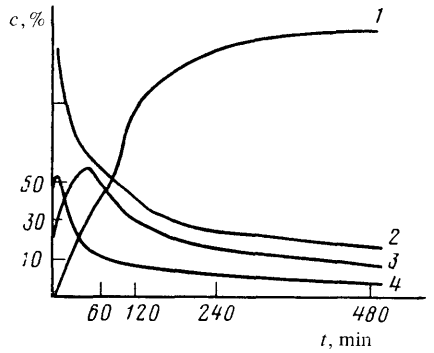

Figure 4. Kinetics of the reactions in an $La_2O_3 + Cr_2O_3$ mixture in air at 873 K; *c* is the concentration: *1*) $LaCrO_3$, *2*) La_2O_3, *3*) $La_2.(CrO_4)_3$, *4*) Cr_2O_3.[20,22]

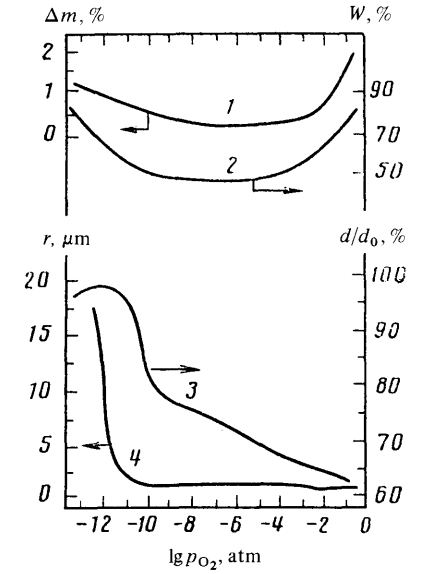

Figure 5. Change in the volatility, reactivity, sintering, and collective recrystallisation of chromium oxide on the partial pressure of oxygen:[21] *1*) mass loss (Δm) after 1 h at 1870 K;[40] *2*) quantity (*W*) of bound chromium oxide formed by the reaction $MgO + Cr_2O_3 = MgCr_2O_4$ after 1 h at 1620 K;[21] *3*) relative density (d/d_0) of chromium oxide specimens, sintering at 1870 K, 1 h;[40,41] *4*) size of the crystals (*r*), heating at 1970 K for 1 h.[21]

The results of studies[21,40–42] of the dependnece of the properties of chromium oxide and its compounds on the partial pressure of oxygen are given in Fig.5. The most intensive mass loss by a specimen of chromium oxide at a temperature of 1873 K (curve *1* in Fig.5) takes place at an oxygen pressure of 1 atm. This high volatility is due to the following features. At increased temperatures, chemical adsorption of oxygen on Cr_2O_3 crystals takes place,[21,43] to give oxygen-containing surface compounds of chromium with an increased valence $CrO_{1.5+x}$ (CrO_3, CrO_2), which are highly volatile. With decrease in the partial pressure of oxygen, the volatility of the specimens decreases. In the oxygen pressure range $10^{-3}-10^{-5}$ atm, the surface compounds $CrO_{1.5+x}$ become unstable, and their concentration decreases, and with further decrease in p_{O_2} they may may not be formed.

At low partial pressures of oxygen ($10^{-10}-10^{-13}$ atm), the volatility of the specimens increases again. Under these conditions, chromium oxide dissociates on the surface of the particles according to the scheme

$$^2/_3Cr_2O_3 \rightleftarrows {}^4/_3Cr + O_2 .$$

The rate of the reaction $MgO + Cr_2O_3 \rightarrow MgCr_2O_4$ (curve *2*) and the volatility of chromium oxide (curve *1*) change in the same sense with change in the partial pressure of oxygen. The activating factors in these processes are, firstly, the formation of the surface compounds $CrO_{1.5+x}$ at a high oxygen pressure of $10^{-2}-1$ atm, and, secondly, the predissociation of Cr_2O_3 at a low oxygen pressure of $10^{-10}-10^{-13}$ atm.

The rates of the sintering (curve *3*) and collective recrystallisation (curve *4*) of chromium oxide in oxygen (1 atm) and in air are reduced considerably. After heating at temperatures of 1870–2020 K for 1 h in the gaseous media indicated, the specimens remain porous and finely crystalline. Intensive sintering and crystal growth begin at oxygen pressures of $10^{-10}-10^{-11}$ atm and $10^{-11}-10^{-12}$ atm respectively. This effect of the surface compound $CrO_{1.5+x}$ is determined by the thermodynamic conditions on the surface of the particles. The formation of $MgCr_2O_4$ from the oxides at 1273 K takes place with $\Delta H = -10.3$ kcal and $\Delta G = -8.1$ kcal mole^{-1}.[21] The heats of sintering of the oxides are apparently comparable with the heats of the change from the amorphous to the crystalline state (1–3 kcal mole^{-1} [21]). The heats of collective recrystallisation are probably of the same order of magnitude as the energies of polymorphic transformations (0.01–1 kcal mole^{-1} [21]). The heat of adsorption of oxygen on the surface of chromium oxide, calculated from the equilibrium isobar, is 3.7 kcal mole^{-1}.[21]

The suppression of the sintering and recrystallisation of chromium oxide by adsorbed oxygen ($p = 1$ atm) is possible if ΔG_0, that is the thermodynamic potential of the formation of the surface compound $CrO_{1.5+x}$, is greater than the thermodynamic potential of the sintering or collective recrystallisation (ΔG_s) of chromium oxide: $\Delta G_a > \Delta G_s$, where ΔG_a relates to the adsorption of oxygen (here, the absolute values of the thermodynamic potentials are understood). The thermodynamically more stable surface compound prevents the decrease in the surface which takes place on sintering and collective recrystallisation. If the partial pressure of oxygen is lowered to values at which $\Delta G_a < \Delta G_s$, intensive sintering and recrystallisation of chromium oxide begin, as observed experimentally. The activation of the formation of chromium spinel at $p_{O_2} = 1$ atm is due to the fact that $\Delta G_0 > \Delta G_a$. The higher activity of the surface compound $CrO_{1.5+x}$ is due to the fact that its dissociation pressure is higher than that of Cr_2O_3. The dissociative activation of the surface compound reaches a maximum value at thermodynamic equilibrium, that is on fulfilment of the condition $\Delta G = RT \ln(p_{O_2}/p^*) = 0$, where p^* is the dissociation pressure of the surface compound $CrO_{1.5+x}$.

In the high-temperature synthesis of oxide materials, the water vapour which is always present in the furnace atmosphere is adsorbed on the oxide particles and activates the physicochemical processes taking place. A study[4] of the influence of the presence of oxygen and water vapour on the kinetics of the reactions of the oxides MgO, CaO, BaO, and ZnO with Al_2O_3 and of CaO with quartz and amorphous silica showed that at increased temperatures in an oxygen atmosphere and more particularly in the presence of water vapour the oxides are more reactive than in a vacuum. The surface complexes formed, MO_{n+x} or $MO_n.xH_2O$, activate crystallisation and sintering and increase the reactivity of the material.[44]

V. THE MECHANISM OF THE ACTION OF IMPURITIES IN SINTERING, AND THE DEFORMATIONAL PROPERTIES AND THERMAL STABILITY OF OXIDE MATERIALS

The mechanism of the activating and inhibiting action of impurities on physicochemical processes in solids is not completely clear, and a single theory has not been developed. The most widely accepted model is that in which disorder is produced in the lattice of the matrix by ions with a different valence as a result of a change in the concentration of vacancies in the anion or cation sublattices. Many experimental data are difficult to explain using this model, however.

As shown in sections III and IV of the present review, impurities react with defects of the matrix and in micro-volumes to form compounds differing in their composition, structure, and energy from the defect-free regions of the matrix. Thus real solids are microheterogeneous systems. To investigate the mechanisms of the processes taking place in these systems, it is necessary to study the chemical composition, structure, and energy state of the formations in local micro-volumes.

The effect of added Ln_2O_3 (Ln = lanthanide) on the kinetics of the sintering of cerium oxide has been studied.[10,13,45] According to the equilibrium diagrams,[13,29] these oxides in the concentration range 0–10 mole % Ln_2O_3 studied react with cerium oxide to form solid solutions with the fluorite structure. The results of experiments to study the influence of added lanthanum oxide on the shrinkage of cerium oxide are given in Fig.6. The Ln_2O_3 impurity forms a chemical compound on the defects of the CeO_2 matrix (see Table 1). The formation of the microstructure should pass through a stage involving the formation of a eutectic, depending on the concentration of the additive.

In the primary sintering of mechanical mixtures of the powders (curve *1* in Fig.6), when the additives have not yet penetrated into the cerium oxide particles, the effective concentration of the additive on the surface of the cerium oxide particles is much greater than that corresponding to its final (equilibrium) distribution (curves *2* and *3* in Fig.6), and the critical state of the microstructures is produced at a lower actual concentration of the additive (0.5 mole % Ln_2O_3). On the second and third heating of the specimens (curves *2* and *3* in Fig.6), the maximum intensities of sintering correspond to an additive concentration of 1.25 mole % Ln_2O_3. With further increase in the additive concentration of 1.25 mole % Ln_2O_3. With further increase in the additive concentration (> 1.25 mole %), a decrease in the rate of sintering is observed, and the additive acts as an inhibitor (range of the stable state of the microstructures). With increase in the sintering temperature to 1873 K, the shrinkage maximum becomes flatter, and at 1923 K the additive activates the sintering throughout the concentration range studied. As shown in section III, the stability and concentration of the microstructures changes with change in temperature. At 1923 K, the microstructures "dissolve" in the CeO_2 matrix.

The results of experiments[45] to study the influence of single (Sm_2O_3) and combined (Sm_2O_3 + Gd_2O_3) and (Sm_2O_3 + Gd_2O_3 + Y_2O_3) additives on the sintering of cerium oxide show that the effect of the added mixtures is additive, since the valences are the same, and the structures of the electron levels and the ion dimensions are similar: $R(Sm^{3+})$ = 0.97 Å, $R(Gd^{3+})$ = 0.94 Å, $R(Y^{3+})$ = 0.97 Å.[45] In the mixtures containing (98 – *x*) mole % CeO_2 + 2 mole % La_2O_3 + *x* mole % Sm_2O_3, increase in the samarium oxide concentration is accompanied by a regular decrease in the shrinkage of the cerium oxide specimens. The reason for this behaviour of the mixtures is that lanthanum oxide forms more stable microstructures than samarium oxide. The change in the shrinkage when the complex additives La_2O_3 + Y_2O_3(Sm_2O_3) are used[45] is similar to that when only lanthanum oxide is added. Preferential internal adsorption of lanthanum oxide apparently takes place as a result of the higher energy of interaction with the defects of the matrix for lanthanum ions compared with yttrium or samarium ions.

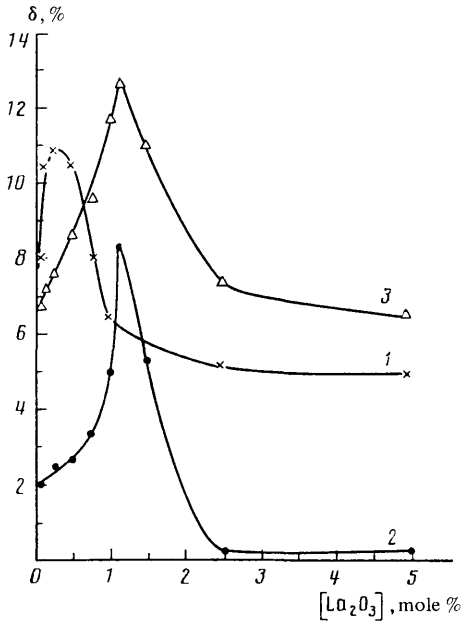

Figure 6. Dependence of the linear shrinkage (δ, %) of cerium dioxide on the concentration of added La_2O_3: *1*) first sintering (1673 K, 0.5 h); *2*) second sintering (1673 K, 2 h); *3*) third sintering (1773 K, 2 h).[10,45]

The results of experiments on the sintering of mixtures with the composition (80 – *x*) mole % CeO_2 + 20 mole % Nd_2O_3 + *x* mole % La_2O_3 in which *x* varied from 0 to 5 show that at the concentration indicated, the additives have an inhibiting action on the sintering of cerium oxide. A maximum was not observed, and the system showed only a regular poorly defined decrease in the rate of shrinkage, indicating that the effect of the reagents is additive. These experiments indicate that the added oxides M_2O_3 (from La to Yb, and also Y) react with the same defects of the CeO_2 matrix.

The properties of a modified cerium oxide ceramic have been studied.[39,47,48] In the range of additive concentrations 0.5 to 1.25 mole % La_2O_3, an extremal change in properties was observed. The processes of sintering, deformation, and crystal growth took place at maximum rates. The ceramic with the composition indicated had the optimum catalytic activity in the dehydrogenation of isopropyl alcohol.[49] With both decrease and increase in the additive concentration, the rate of sintering, deformation, and catalytic activity decreased, with corresponding changes in other properties.

Analysis of the results indicates a single mechanism of action of the microstructures on the processes being considered. The highest activity is observed when the thermodynamic state of the microstructure corresponds to the critical state where $a^0 = a_m$, $\Delta G_d = RT \ln(a^0/a_m) = 0$, where ΔG_d is the change in free energy on dissociation of the microstructure, a^0 and a_m the activity of the additive in the bulk of the crystal and in the microstructure respectively, R the gas constant, and T the temperature.

When the concentration of the impurity in the solid is lower than the equilibrium concentration and $a_m > a^0$, $\Delta G_d = RT \ln(a^0/a_m) < 0$, the microstructure is not formed, so that the additive does not have an activating effect.

The rate of deformation of the cerium ceramic is determined by the concentration of La_2O_3 in it. The efficiency of the influence of the microstructures formed by the impurities also depends on the temperature of the thermomechanical testing.[47,48]

With increase in the temperature of testing from 1473 K to 1573 K, the rate of deformation changes in different ways for specimens with different compositions. The fluidity increases considerably in the specimens containing 1.25 mole % La_2O_3, and is practically unchanged in the ceramic containing 5 mole % La_2O_3. With increase in temperature, the intensity of the relaxation processes evidently increases to the greatest extent in the thermodynamically unstable microstructures.

The increased thermal stability of the specimens containing 0.5 to 1.25 mole % La_2O_3 can be attributed to the high rate of the relaxation processes in the microstructures. According to phenomenological theory,[48,50] the stability of a material to thermal shock is due to the interaction of three forms of energy: the energy of elastic deformation, the surface energy, and the kinetic energy associated with the formation and growth of cracks. Expressions giving the relationship between the surface energy and the thermal stability of a material are given below. The Griffiths stress σ_g required to create cracks with dimensions c is related to the surface energy by the equation $\sigma_g^2 = 2\gamma E/\pi c$, where γ is the surface energy of the material, and E the modulus of normal elasticity.[48,50] The maximum temperature differential for which growth of cracks does not take place is given by

$$\Delta T = \left(\frac{2\gamma}{\pi c E}\right)^{1/2} \frac{1 + 2Nc^2}{\alpha}$$

where N is the number of cracks in the material on unit area, and α the coefficient of thermal expansion. In Ref.50 it is recommended that a material with a high surface energy be selected for articles subjected to thermal shock during use.

In the region of the critical state ($\Delta G_d = 0$), substances of different character show a heat capacity maximum;[51] as a result, the substances acquire an excess of energy by absorbing heat from the surrounding medium.

Under the conditions being considered, the surface structures in specimens of a CeO_2 ceramic containing 0.5 – 1.25 mole % La_2O_3 apparently have an excess of energy compared with the microstructures in specimens with either higher or lower La_2O_3 concentrations.

The catalytic action of the additives is due to the fact that the surface complexes in the critical state, formed as a result of the reaction of the substrate with the catalyst, have the highest reactivity and act as active centres in the transformation of the substrate.[39]

The microstructures forming restricted solid solutions on defects, and their influence on the thermomechanical properties of oxide ceramic materials, are examined below. In the $TiO_2 - Ta_2O_5$ system, XPES established[10] that in a surface layer with a thickness of 8 – 10 nm, tantalum is present as tantalum(V) in an octahedral environment of oxygen ions, as in Ta_2O_5.

Increase in the additive concentration is accompanied by an increase in the concentration of Ta_2O_5 in the surface layer, but its distribution coefficient decreases.[10]

[Ta_2O_5], mole %, in the bulk	0.001	0.1	3.0	5.0	10.0
[Ta_2O_5], mole %, in the surface layer	0.02	0.5	8.0	10.0	15.0
Distribution coefficient (K)	20	5	2.6	2	1.5

Experimental data[25] indicate that Ta_2O_5 dissolves in titanium oxide as the rutile-like compound $Ti^{III}TaO_4$. The possible formation of a solid solution in the $TiO_2 - Ti^{III}TaO_4$ system when titanium dioxide is added is due to the reduction of rutile in air at a temperature above 1370 K and the stabilisation of Ti^{III} when introduced into the solid solution.

At low concentrations (1 – 4 mole % Ta_2O_5), the additive had an inhibiting action on the sintering, and also lowered the fluidity and thermal stability of the ceramic at high temperatures. At a higher concentration of the additive, the rate of sintering, deformation, and thermal stability of the specimens increased. The dependence of the properties of the TiO_2 ceramic on the Ta_2O_5 concentration is given by curves with minima, correlating with the corresponding relationship for the free energy of the restricted solid solution.[46]

Similar relationships were established[16] in a study of the sintering of SnO_2 containing added Nb_2O_5. Increase in the concentration of added Nb_2O_5 from 0 to 0.05 mole % leads to suppression of the sintering; the shrinkage decreases from 11% to 6.3%. With further increase in the Nb_2O_5 concentration, intensification of the sintering is observed. Analysis of the X-ray electron spectra of specimens with the composition 99.8 mole % SnO_2 + 0.2 mole % Nb_2O_5 and 98 mole % SnO_2 + 2 mole % Nb_2O_5 showed enrichment of the surface layer in niobium by factors of 27 and 7 respectively. The energy parameters and valences of the Sn^{4+} and Nb^{5+} ions in the surface layer were the same as in SnO_2 and Nb_2O_5. In the surface layer of the tin(IV) oxide specimen, the added Nb_2O_5 forms restricted solid solutions, which are supersaturated at a concentration of 0.5 mole % or more Nb_2O_5. The solubility of Nb_2O_5 in SnO_2 is ~3 mass %.[52] Similar surface microformations were found in the $SnO_2 - ZnO$ system.[16] The surface phase consists of a solid solution with restricted solubility, with a higher concentration of the dissolved component, compared with the solid solution in the bulk.

Studies of various properties of an SnO_2 ceramic containing added ZnO showed that at concentrations of 0 – 0.5 mole % ZnO the shrinkage and thermal stability of the specimens remained unchanged, but the rate of sublimation decreased, corresponding to the existence of stable solid solutions in the surface layers. At ZnO concentrations greater than 0.5 mole %, its activating influence increased as a consequence of the decomposition of the surface solid solutions.

One promising method for preparing oxide materials with specified properties is by using modifying agents. Depending on their thermodynamic state, the microstructures formed by the impurities

may have either an activating or an inhibiting action on the physicochemical processes in the oxides in the synthesis and application of ceramic materials. If the impurity forms a chemical compound on the defects in the matrix, the formation of the micro-structure should take place via the stage of eutectic formation, depending on the concentration of the additive. Thermodynamic analysis[46] shows that the eutectic has the highest free energy, and the micro-formations in the eutectic state have the maximum reactivity. The critical state of the microstructure is reached at a definite concentration of the additive.

When the impurity forms solid solutions on the defects, activation is achieved in the critical state of the system, corresponding to supersaturation of the restricted solid solutions.

The established regularities of the formation of microstructures make it possible to use micro-additives to control the sintering and recrystallisation of dispersed solids, and also to produce specified properties such as the deformation, thermal stability, and ageing of ceramic materials at high temperatures.[9,10,16,39]

VI. SURFACE MICROSTRUCTURES AND THE PROTECTION OF CERAMIC MATERIALS FROM REDUCTION

One of the most important tasks in materials science is the production of ceramic condenser materials permitting high-temperature annealing in media with a low partial pressure of oxygen without loss of the dielectric properties. This task follows directly from the problem of replacing electrodes of valuable metals in ceramic condensers by electrodes of non-noble metals, whose annealing can be carried out only in a protective atmosphere with a low partial pressures of oxygen.

The processes taking place in the synthesis of materials permitting annealing in gaseous media with a low oxygen pressure have been described using the theory of point defects and the method of quasi-chemical reactions.[53–55] In the works cited, the equilibrium state of the point defects is assumed *a priori*, and the influence of impurities and additives on the properties of the material is regarded as a displacement of the equilibrium according to the law of mass action applied to the point defects. This model does not take account of physicochemical processes and the formation of surface microstructures.

XPES data[24,56] show that when additives which protect calcium titanate from reduction are introduced, the surface of $CaTiO_3$ granules has the composition $3CaO.TiO_2$, that is it differs from calcium metatitanate. The increase in the stability of the $CaTiO_3$ ceramic to reduction must be related to the formation of a surface structure which is enriched in CaO and which has an equilibrium oxygen pressure lower than that in the moist hydrogen used for annealing the ceramic. So long as reduction does not affect the surface phase, reduction of $CaTiO_3$ in the bulk does not take place, but the non-doped material may be reduced to a considerable extent under these conditions. The reduction begins at the surface, that is the defect zone, which moves into the depth during the process. The surface structure $3CaO.TiO_2$ formed increases the thermodynamic stability of the surface and the grain boundaries. Increase in the temperature of annealing and decrease in the partial pressure of oxygen in the furnace lead on prolonged treatment to reduction of the surface structure and the material in the bulk.

Similar results were obtained in a study of the protection of $SrTiO_3$ from reduction by adding SrO, BaO, MgO, and Ga_2O_3.[57] According to XPES data, in the specimens containing added Ga_2O_3, after heating in moist hydrogen, the surface layers of the ceramic did not contain gallium, because of the reduction of Ga_2O_3 to Ga_2O, which volatilised. Thus in the specimens in which titanium was replaced by gallium, the surface of the strontium titanate granules was enriched to the composition $\sim 7SrO.TiO_2$.

Examination of the reduction process from the viewpoint of surface phase formation makes it possible not only to obtain a consistent explanation of available experimental data but also to make specific technological recommendations for the production of materials which can be heated in media with a low partial pressure of oxygen.

VII. THE INFLUENCE OF SURFACE STRUCTURES ON THE ELECTRICAL PROPERTIES OF CERAMIC MATERIALS

Oxide materials with dielectric, semiconducting, or highly conducting properties with electronic or ionic carriers are synthesised by controlling the chemical character and concentration of impurities. The mechanism of the action of the impurities has been insufficiently studied, however.

The titanium-containing compounds TiO_2, $CaTiO_3$, $SrTiO_3$, and $BaTiO_3$ and solid solutions based on them are widely used in electronics. The properties of TiO_2 containing Ta_2O_5 have been studied.[58] In Ref.59 it was suggested that the semiconducting properties of doped titanium dioxide are due to the production of titanium(III), but the reasons for its appearance were not established. Magnetochemical and XPES data [58] showed that Ta_2O_5 dissolves in titanium dioxide to give the rutile-like compound $Ti^{III}TaO_4$. The possible formation of a solid solution when titanium dioxide is doped is due to the reduction of rutile in air at a temperature above 1370 K and the stabilisation of Ti^{III} in the solid solution.[13] The formation of the $TiO_2-Ti^{III}TaO_4$ solid solution leads to a decrease in the specific electrical resistance of the specimens by factors of 10^8-10^{10} at concentrations of 0.1–5 mole % Ta_2O_5. When the limit of the solubility of Ta_2O_5 in TiO_2 at the grain boundaries is exceeded, decomposition and oxidation of the $TiO_2-Ti^{III}TaO_4$ solid solution takes place to give dielectric layers with the composition $TiO_2 + TiTa_2O_7$ on the surface of the granules. Thus the extremal concentration dependence of the conductivity of TiO_2 doped with Ta_2O_5 is due to two competing reactions: the formation and decomposition (oxidation) of the $TiO_2-Ti^{III}TaO_4$ solid solution.[57]

The influence of the combined additives Nb_2O_5 and BaO on the electrophysical properties of TiO_2 has been studied.[60] When the niobium(V) cations are added, the specific electrical resistance of the material decreased from 10^{13} Ω.cm to 100 Ω.cm at 300 K. Auger spectroscopy detected the segregation of barium along the grain boundaries of the titanium dioxide ceramic; the distribution coefficient of barium reached 150. The action of the added Nb_2O_5 was explained[60] using the disordering model:

$$Nb_2O_5 = 2Nb_{Ti}^{\cdot} + 2e^- + 4O_O + {}^1/_2O_2$$

where $Nb_{Ti}^{\cdot}$ is the cation occupying a cation site in the TiO_2 lattice; O_O an oxygen ion in a normal position (in a lattice site); and e^- an electron. This approach is inadequate, since it does not reveal the detailed mechanism of the physicochemical processes taking place in the reaction between the impurity and the matrix.

Niobium is an analogue of tantalum, and the formation and decomposition of the $TiO_2-Ti^{III}NbO_4$ solid solutions and the redox processes $Ti^{IV} \rightleftarrows Ti^{III}$ evidently determine the electrophysical properties of doped titanium dioxide. In Refs.58 and 61–64 it was shown

that the extremal dependence of the electrophysical properties of barium titanate when it is doped with the oxides of the lanthanides and the group V elements, so-called donor additives, is due to two competing processes in the barium titanate ceramic. On the one hand, semiconducting solid solutions containing titanium(III) [for example $Ba_{1-x}Y_x(Ti^{IV}_{1-x}Ti_x)O_3$] are formed, and on the other hand, oxidation and decomposition of the solid solutions take place (for example to give the compounds $BaTiO_3$ and $Y_2Ti_2O_7$), beginning on the surface and along the grain boundaries, as a result of which surface dielectric layers are produced. These physicochemical processes determine the extremal change in the properties of doped barium titanate: the magnetic susceptibility maxiimum, the dielectric–semiconductor transitions, and the existence of a positive temperature coefficient of electrical resistance close to the Curie point.

Materials whose properties are determined by the surface phases are used in electronics. These materials are used to prepare posistors (semiconducting ceramic devices having a positive temperature coefficient of electrical resistance), varistors (devices for which the dependence of the current on the voltage is appreciably non-linear), and condensers with an inter-granular capacity, in which a superhigh effective dielectric constant is produced since the capacities are included at the boundary of each granule. A ceramic for varistors based on zinc oxide has been studied repeatedly by electron microscopy. The segregation of Bi in a $ZnO-Bi_2O_3$ ceramic has been detected[65] at the boundary between the granules of the main material. The chemical form of the additive (MnO or MnO_2, CoO or Co_2O_3) has a significant influence on the distribution of the cations at the grain boundary and in the phase between the granules, and hence on the recrystallisation and microstructure of the specimen.[66] This is undoubtedly due to the formation of different surface structures when the oxides of metals in different oxidation states are added. Thus the monoxides MnO and CoO form solid solutions with ZnO, whereas when MnO_2 and Co_2O_3 are added, the spinels Zn_2MnO_4, $ZnMn^{III}_2O_4$, and $ZnCo_2O_4$ may be formed at the ZnO grain boundaries.

In an $SrTiO_3$ ceramic containing added Bi_2O_3, enrichment of the surface regions of the granules in Bi to a depth of up to 25 nm has been detected.[67] The influence of additives forming surface structures on the melting point of the layer at the grain boundaries, which plays a decisive role in crystallisation processes, has been noted.[68] It is suggested that selective fusion takes place, when the additives dissolve (fuse) the titanium dioxide which is always present in strontium titanate ceramic, with almost no change in the volume of the granule. An analysis of a large amount of experimental material led to the conclusion[69] that in a ceramic based on $SrTiO_3$ with added glass-forming oxides (Bi_2O_3, PbO, SiO_2): a) the second phase is concentrated in "pockets" at contacts between three granules; b) in general, the structure at the intergranular boundary is the same as that in the bulk, and the foreign ions merely enrich the outer layers of the granules; and c) the measured physical properties of the ceramic are determined by the oxidised layers of the granules on the semiconducting granule, and not by the second vitreous phase.

In the ferroelectric $BaTiO_3$, impurities (Bi, Zr) enrich the surface of the granules; the formation of a ferroelectric domain structure is suppressed in the granules, apparently as a result of the distortion of the $BaTiO_3$ lattice taking place on solution of the impurities.[70]

The development of methods for analysing a surface has made it possible to obtain direct experimental proof of the decisive role of surface structures in the production of various materials: ceramics for electronics,[71] electrode materials for fuel cells,[72] electrodes for the photolysis of water,[73] and semiconducting materials for devices with a Schottky diode.[74]

—o0o—

Thus the study of the formation of surface microstructures and their influence on physicochemical processes in solids is an important research field. The nature of the influence of small quantities of impurity on the properties of a matrix is not completely clear, and contradictory explanations of the observed phenomena have been published. Theoretical studies are required in this field. The methods of physicochemical analysis used at present do not give exhaustive information on the properties of surface microstructures, so that it is necessary to improve further the methods for the quantitative analysis of the chemical composition, the determination

The Paramagnetic Hydrophilic Probing of Colloidal Systems by NMR Spectroscopy

Yu.E.Shapiro

The principal results of the use of a hydrophilic paramagnetic probe in ^{1}H, ^{13}C, and ^{31}P NMR spectroscopy to study the structure, stability, and local density of packing of colloidal systems have been examined. The magnetic properties of the ions of *f*- and *d*-metals used as shift and relaxation probes have been discussed. Methods for estimating the stability of micelles and the conformation of the polar fragments of the molecules of surface active substances (SAS) on the surface of micelles and vesicles have been described. Particular attention has been paid to the study of dynamics, the compositional asymmetry of lipid membranes, the analysis of their interaction with physiologically active compounds, and the structure of biocolloidal systems.
The bibliography contains 134 references.

I. INTRODUCTION

NMR spectroscopy is one of the most effective methods for determining the structure of organic compounds and also supermolecular formations such as micelles, liposomes, and other complex colloidal aggregates. The informative character of NMR spectra, particularly proton NMR spectra, however, is lowered considerably because the nuclei of aliphatic groups not adjoining electronegative atoms give signals with similar chemical shifts. In addition, there are a number of factors leading to the broadening and the mutual overlap of the signals in the NMR spectra of colloidal systems. The most important of these are the presence of spin multiplets, dipole–dipole relaxation in the interaction of directly coupled nuclei, intermolecular association, the low fragmentary mobility of aliphatic chains, microheterogeneity, and the appreciable viscosity of dispersions.[1]

To overcome these difficulties and increase the informative character of the NMR spectra of colloidal systems, Soviet authors[2-9] proposed the method of hydrophilic shift and relaxation paramagnetic probes—the ions of *f*- and *d*-metals having an unpaired electron.

The influence of paramagnetism on the characteristics of nuclear resonance was detected by Bloembergen and Dickinson.[10] The characteristics of NMR in paramagnetic systems have been summarised in a number of reviews and monographs.[11-16] The interaction between the paramagnetic centre and the nucleus whose magnetic resonance is being observed is revealed in the isotropic hyperfine shift,[17] the change in the nuclear relaxation times T_1 and T_2,[18] and the nuclear polarisation of the spins as a consequence of the Overhauser effect.[19] These phenomena give information on the electronic and geometric structures of the ligands joined to the paramagnetic centres.

1. The Paramagnetic Shift

The isotropic shift of the signals in the NMR spectra of paramagnetic substances is the sum of two types of interaction: contact and pseudo-contact.

The Fermi contact shift takes place if the spin density of the unpaired electron is delocalised, and transferred to the nucleus through a system of chemical bonds. The contact shift obeys the Curie law, and for a one-spin state with an isotropic *g*-tensor it is described by the equation:[10]

$$\frac{\Delta H}{H_0} = -\frac{Ag\beta^2}{g_N\beta_N}\frac{s(s+1)}{3kT}$$

where A is the hyperfine interaction constant, g_N the nuclear *g*-factor, β_N the nuclear magneton, H_0 the intensity of the external magnetic field, β the Bohr magneton, g the Lande factor, k the Boltzmann constant, T the absolute temperature, and s the the spin-quantum number of the electron.

The contact shift of the signal is observed with the condition $T_{1e}^{-1} \gg A$, where T_{1e} is the electronic spin–lattice relaxation time. The contact shifts are large for the nuclei of oxygen and nitrogen directly coordinated to a paramagnetic centre, and also for carbon chemically bound to these atoms. For atoms at a greater distance and, commonly, for all protons, the contact contribution is small, and the observed paramagnetic shifts are pseudo-contact in character.[11-16]

The pseudo-contact shift of a signal is determined by the dipole–dipole interaction of the spins of the unpaired electron and the nucleus. It depends on the electron configuration of the paramagnetic ion, the magnetic anisotropy of the ligand field, and temperature. For axial symmetry of the complex, the pseudo-contact shift is given by the McConnell–Robertson equation:[17]

$$\frac{\Delta H}{H_0} = -\frac{\beta^2 s(s+1)}{9kT}(g_\parallel^2 - g_\perp^2)\frac{3\cos^2\theta - 1}{r^3} \qquad (1)$$

where $g_\parallel$ and $g_\perp$ are the components of the *g*-tensor of the magnetic anisotropy parallel to and perpendicular to the principal axis of the complex, r the distance from the paramagnetic centre to the nucleus, and θ the angle between the radius vector $\vec{r}$ and the principal axis of the complex.

The dependence of the pseudo-contact shift on the geometry of a complex, described by Eqn.(1), makes it possible to assign the signals in the spectrum of a ligand of known structure and to solve the inverse problem, that is from the known assignment to obtain information on the geometry of a molecule.[5,11-17]

2. Paramagnetic Broadening

In the presence of a paramagnetic centre, broadening of the NMR signals is observed, due to the increased rate of relaxation of the nuclear spin and the influence of exchange between the bonded and free molecules of the substrate. The spin–lattice T_1 and spin–spin T_2 relaxation times for nuclei with a spin of 1/2 in the presence of a paramagnetic centre are given by the Solomon–Bloembergen equations (2) and (3):[18]

$$\frac{1}{T_1}=\frac{2}{15}\frac{(\beta_N g_N \beta g)^2 s(s+1)}{r^6}\left(\frac{3\tau_c}{1+\omega_I^2\tau_c^2}+\frac{7\tau_c}{1+\omega_s^2\tau_c^2}\right)+\frac{2}{3}s(s+1)\left(\frac{A}{\hbar}\right)^2\frac{\tau_e}{1+\omega_s^2\tau_e^2} \quad (2)$$

$$\frac{1}{T_2}=\frac{1}{15}\frac{(\beta_N g_N \beta g)^2 s(s+1)}{r^6}\left(4\tau_c+\frac{3\tau_c}{1+\omega_I^2\tau_c^2}+\frac{13\tau_c}{1+\omega_s^2\tau_c^2}\right)+ + \frac{1}{3}s(s+1)\left(\frac{A}{\hbar}\right)^2\left(\frac{\tau_e}{1+\omega_s^2\tau_e^2}+\tau_e\right) \quad (3)$$

where ω_I and ω_s are the Larmor precession frequencies of the nucleus and the electron, and $\hbar = h/2\pi$ is Planck's constant.

The first terms of these equations are due to dipole–dipole interaction and depend on the distance r between the nucleus being observed and the paramagnetic centre. This interaction is determined by the correlation time of the electron–nucleus dipole interaction τ_c. The second terms, which are independent of r, are characterised by the correlation time of the contact interaction τ_e. The correlation times are defined as

$$\tau_c^{-1}=\tau_R^{-1}+\tau_s^{-1}+\tau_M^{-1}+\tau_D^{-1}$$
$$\tau_e^{-1}=\tau_s^{-1}+\tau_M^{-1}$$

where τ_R, τ_s, τ_M, and τ_D are the correlation times corresponding to the rotational motion, the relaxation of the electron spin, chemical exchange, and diffusion exchange respectively.

The relaxation times are influenced only by variable effects for which the correlation time has the same order of magnitude as the period of the Larmor precession of the nuclear spins.

II. THE HYDROPHILIC PROBING OF MICELLAR DISPERSIONS

The rapid decrease in the contribution of dipole–dipole interaction to the relaxation rates T_1^{-1} (2) and T_2^{-1} (3) with distance to the paramagnetic centre (r^{-6}) and the absence of its angular dependence make ions with high values of A and T_e (Mn^{2+}, Ni^{2+}, Cu^{2+}, Co^{2+}, Gd^{3+}, etc.) valuable probes for structural studies. These ions are used as hydrophilic relaxation probes both to characterise the stability and local denisty of packing of micelles formed by different surface-active substances (SAS) and also to estimate the spatial orientation of the polar fragments in their structure.

1. Estimation of the Stability of Micelles

The stability of micellar aggregates is of fundamental interest both for solving the problems of micellar catalysis and in cell biochemistry. The estimation of the stability of micelles by the hydrophilic relaxation paramagnetic probe method[2–9] is based on the Dill–Flory statistical lattice model of the micelle.[20]

Paramagnetic cations can form dynamic complexes with the polar groups of SAS, oriented in micelles into the aqueous phase. The relaxation of the protons of definite fragments of the SAS molecule takes place only on the collision of the hydrated ion and the fragment of the molecule. It is therefore possible to determine whether the hydrophilic paramagnetic ions are in contact with definite parts of the molecule. An analysis[7,21–23] of the ^1H NMR spectra of micelles of sodium, copper, cobalt, and vanadyl dodecyl sulphate showed that not only the protons of the CH_2–SO_4^- groups but also the protons of the $(CH_2)_{10}$ chains and CH_3 groups collide effectively with Cu^{2+}, Co^{2+}, VO^{2+}, and lanthanide ions. These collisions may take place either as a result of the penetration of the ions into the micelles or as a result of the diffusional movement of the hydrocarbon chains into the Stern layer.[20,23,24]

The penetration of the hydrophilic ions into the hydrophobic nucleus of a micelle might be assumed in a model[25] containing water in the hydrophobic nucleus. The untenability of this model of "aqueous channels and cavities" within the micelle was proved, however, by the correspondence between the mechanisms of the extinction of the fluorescence of pyrene on ions in solution and in a micellar dispersion of sodium dodecyl sulphate in water,[26] and also by the difference between the experimental ratios of the spin–lattice relaxation times T_1 for the ^{13}C nuclei and the ratios calculated using the model of "aqueous cavities".[27] It has been proved convincingly[28,29] that in the micelle, only three or four methylene groups of the hydrocarbon chain of the SAS, counting from the polar head, are hydrated. Thus water is capable of penetrating into the hydrophobic nucleus of a micelle to a depth of only 0.4–0.5 nm. The positions at which water is localised in micro-emulsions (Tween-81–n-hexadecane–H_2O) have been determined by ^1H, ^2H, and ^{13}C NMR spectroscopy using Tb^{3+} and $Fe(CN)_6^{3-}$ ions as paramagnetic probes.[30] It was shown that the water molecules do not penetrate into the hydrophobic regions of the micro-emulsions. In addition, EPR spectroscopy detected hydrated Mn^{2+} ions only in the Stern layer of aqueous micelles of manganese dodecyl sulphate.[31]

These experimental data provide a reliable basis for estimating the stability of micelles using a relaxation probe.[32–36] The difference in the broadening of the signals from different molecular fragments of SAS in the presence of hydrophilic relaxation probes characterises the degree of stability of the micelle. The magnitude of the increase in the difference between the half-widths of the signals from groups close to the Stern layer (for example α-CH_2) and the terminal CH_3 groups of SAS molecules when paramagnetic ions (Mn^{2+}) are introduced into the dispersion of micelles.[32,34] This is confirmed by the experimentally established increase by two orders of magnitude in the difference in the relaxation rates ΔT_1^{-1} for the ^{13}C nuclei of the α-CH_2 and CH_3 groups of sodium dodecyl sulphate with increase in its concentration in water above the critical concentration for micelle formation (CCM) in the presence of Mn^{2+} ions.[27] The difference in the relaxation mechanisms is attributed to the increase in the constant for complex formation by Mn^{2+} ions with sodium dodecyl sulphate molecules on going from the solution to the micellar system.

Table 1 gives the values of the stability criterion for a number of micelles formed by the potassium salts of aliphatic acids.[34] Table 1 shows that the most stable micelles are formed by potassium stearate, and also by a mixture of synthetic aliphatic acids and sodium alkyl sulphonate, used in industry as emulsifiers in polymerisation.[32] The stability of the micelles decreases with decrease in the length of the hydrocarbon chain and increase in its unsaturated character. The influence of leuconol on the stability of micelles formed by the potassium salts of alkyl-substituted benzylbenzoic and aliphatic acids has been studied.[33,34] It was shown using Mn^{2+} ions that leuconol itself does not form micelles in water, and breaks down the micelles formed by other SAS.

On the other hand, if SAS molecules are capable of forming aggregates in the micelle structure, the stability of the micelles is increased. Aggregates of this kind with an average lifetime of ~10 ms and a stoichiometry which depends on temperature were detected in mixed micelles of sodium alkyl sulphonate and potassium dehydroabietate.[32] The influence of the stability of a layer of SAS adsorbed by the polymeric and monomeric particles on the micro-block character of emulsion copolymers was demonstrated in Refs.34, 37, and 38, and its influence on the rate constant of copolymerisation in Ref.33.

Table 1. Difference in the half-widths of the ^1H NMR signals of the α-CH_2 and CH_3 groups of SAS dispersions (0.1 M in D_2O)[34] and the values of the stability criterion.

SAS	$(\Delta\nu_{1/2}^{\alpha\text{-}CH_2}-\Delta\nu_{1/2}^{CH_3})$, Hz		Increase in $(\Delta\nu_{1/2}^{\alpha\text{-}CH_2}-\Delta\nu_{1/2}^{CH_3})$ when Mn^{2+} is added, Hz
	without Mn^{2+}	10^{-5} M Mn^{2+}	
Potassium stearate	0.70	2.70	2.00
Potassium palmitate	0.23	0.71	0.48
Potassium myristate	0.65	0.86	0.21

Potassium linoleate	0.08	0.40	0.32
Potassium linolenate	0.07	0.32	0.25
Mixture of synthetic aliphatic acids	0.83	2.57	1.74
Sodium alkyl sulphonate	3.1	4.4	1.3

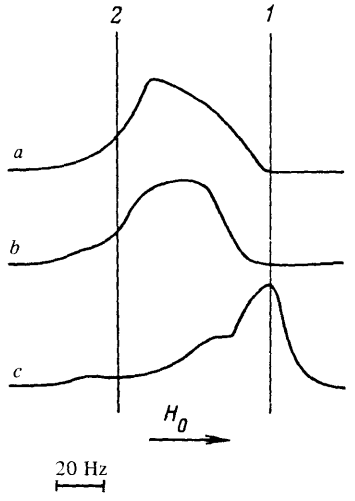

Figure 1. Form of the ^1H NMR signal of the oxyethyl protons in a 5% solution of Triton-X-100 in water in the presence of $TbCl_3$ (*a*), $Tb(NO_3)_3$ (*b*), and $Tb(ClO_4)_3$ (*c*); *1*) position of the signal of free polyhethylene glycol 1000 in the presence of these salts, *2*) position of the signal in the absence of the salts.[42]

An analysis of the characteristics of the bonding of paramagnetic ions to sodium dodecyl sulphate micelles in water[23,39] made it possible to put forward a method for measuring CCM from the cobalt-induced shift of the ^1H NMR signals of the SAS.[40] With increase in the concentration of the SAS above the CCM in the presence of Co^{2+} ions, a sharp increase in the chemical shift of the signals from the alkyl chains is observed, relative to the signal of acetone added to the system as standard. This phenomenon can be attributed to the sorption of the Co^{2+} ions in the Stern layer on micelle formation.

Similar studies carried out for non-ionogenic SAS[41] make it possible to probe their aqueous micelles.[42] For example, the observed anisotropy of the shift indeced by Tb^{3+} ions in the ^1H NMR spectra of Triton-X-100 and Triton-X-305 in water (Fig.1) was related to the existence of a salt concentration gradient along the thickness of the oxyethyl layer, depending on the counter-ion. These results agree with fluorescence measurements[43] and indicate that the penetrating power of electrolytes into micelles of non-ionogenic SAS is determined by electrostatic interactions at the micelle–water boundary.

VO^{2+}, Cu^{2+}, and Co^{2+} ions have been used[21,22,44] to study the micellar catalysis of the exchange of water protons in the coordination sphere of cations. This micellar catalysis has been related to the existence of an electrostatic potential on the surface of a sodium dodecyl sulphate micelle.[21] Micro-emulsification of this system with toluene leads to an increase in the rate of exchange.[22,44]

As paramagnetic centres for the analysis of colloidal systems it is possible to use iminoxyl markers, as has been done for micelles of ionic SAS containing phenoxy-groups.[45] Finally, it is possible to carry out the NMR probing of micelles by making use of the shifts induced by magnetically anisotropic (usually aromatic) substances and solvents.[46,47] The efficiency of these methods, however, is much lower than that of the hydrophilic paramagnetic probe, and the methods have not been developed.

2. Determination of the Conformation of SAS Molecules in the Structure of Colloidal Systems

Since the rates of relaxation of the nuclei and the induced shift of their signals in the NMR spectra depend on the distance r to the paramagnetic centre [Eqns.(1)–(3)], it is possible to estimate the preferred conformation and spatial orientation of the polar fragment of an SAS molecule in the structure of a colloid.[5,35,36,48,49] For small SAS molecules it is also possible to determine the conformation of the alkyl chains.[50,51] The conformation of the polar fragment generally remains unchanged on going from the SAS monomers in water to the micelles.[35,49] Thus the introduction of Mn^{2+}, Pr^{3+}, or Eu^{3+} into a dispersion of N-carbalkoxymethylene-2-methyl-5-vinylpyridinium bromides when their concentrations in water were above and below the critical concentration of micelle formation (CCM_1) showed that the conformation of the SAS molecule relative to the CH_2–COO bond remains eclipsed. However, on going from spherical to asymmetric micelles above CCM_2, the torsional angle increases, the conformation is no longer eclipsed, and the pyridine ring moves out of the plane of the monolayer.[35]

Similar changes in conformation in polymorphic transformations were detected in aqueous dispersions of mono-, di-, and triallylammonium salts with the general formula $(CH_2=CH\text{–}CH_2)_nN(CH_3)_{3-n}\cdot CH_2COORBr^-$, where n = 1–3, and monomers basxed on methacryloyloxyethylammonium salts $CH_2=C(CH_3)COOC_2H_4\overset{+}{N}(CH_3)_2\cdot CH_2COORBr^-$, where R = $C_{10}H_{21}$–$C_{16}H_{33}$.[36]

The magnitude of the selective broadening of the signals in the ^1H NMR spectra of anisotropic micelles, and an analysis of the structure of SAS molecules using models, made it possible to use Eqn.(3) to estimate the preferential conformation of the polar fragment (Fig.2). The areas corresponding to the molecule, calculated for these conformations, show good agreement with those determined experimentally

at a water–air interface.[36] The stabilisation of the monolayer on going from asymmetric micelles to a lamellar structure is accompanied by the movement of the methacrylate and N-methyl groups into the aqueous phase.[36,48] This is indicated by the increased broadening of the signals from the corresponding fragments when Mn^{2+} ions are introduced (Table 2). The conclusions reached about the relationship between the conformation and spatial orientation of the polar fragments of surface-active monomers and their polymorphism in water made it possible to understand the regular features of their emulsion polymerisation.[35,36,48,52]

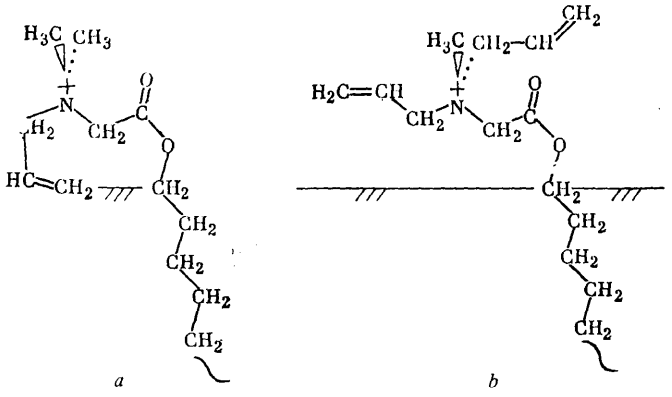

Figure 2. The conformation of alkylammonium SAS in asymmetric micelles: *a*) $n = 1.3$; *b*) $n = 2$.[36]

Table 2. Values of the broadening induced by Mn^{2+} cations for the ^1H NMR signals of dispersions of N-cetyl-N,N-dimethylmethacryloyloxyethylammonium bromide in water.[36]

Proton group	$\Delta\Delta\nu_{1/2}$, Hz*	
	asymmetric micelles	lamellae
CH_3 (terminal)	0.01	0.02
$(CH_2)_n$	4.28	0.60
CCH_3	1.04	1.50
$\overset{+}{N}CH_3$	1.50	2.45
α-CH_2	8.06	broadened
=CH(trans)	5.18	broadened
=CH(cis)	5.18	broadened

*$\Delta\Delta\nu_{1/2} = \Delta\nu_{1/2}([Mn^{2+}] \neq 0) - \Delta\nu_{1/2}([Mn^{2+}] = 0)$.

An analysis of the conformations of the alkyl fragments of sodium dibutyl phosphate in solution and in a micelle using Ni^{2+} and VO^{2+} ions[50] made it possible to select the most probable conformations of the POCCCC chain. Table 3 shows that the probability of a number of conformers increases on going from the SAS solution to the micelles. The use of Mn^{2+} ions as paramagnetic probes showed that the alkyl fragments of the SAS do not enter the aqueous phase. The first segment of the chain has an almost *trans* conformation, although the conformation of the subsequent segment is the same as in the liquid hydrocarbon.[51]

Thus polymorphic transformations in colloidal systems produce a change in the conformation of not only the hydrophilic but also the hydrophobic fragments of the SAS molecule.

Table 3. Probabilities of the alkyl chain conformers of sodium dibutyl phosphate.[50]

Conformer	P	
	monomer	micelle
TTT	0.132	0.200
$TTG^+ + TTG^-$	0.067	0.086
$TG^+T + TG^-T$	0.057	0.086
$G^+TT + G^-TT$	0.057	0.062
$TG^+G^+ + TG^-G^-$	0.029	0.037

Note: *P* is the probability of the conformer, *T* is the *trans*-rotamer, and *G* the *gauche* rotamer.

III. THE HYDROPHILIC PROBING OF LIPOSOMES

The method of hydrophilic paramagnetic probing opens up extensive possibilities for the study of the structure and molecular dynamics of lipid membranes, which are closed lamellae. It makes possible the differential observation of the signals from molecules situated on the external and internal surfaces of a bilayer vesicle.[2–6,8,9] From the ratio of the integral intensities of these signals it is possible to estimate the size of the membrane particles, and also to detect asymmetry of the molecular composition, that is differences in the distribution of lipids, proteins, and other components between the external and internal surfaces of a membrane. The method makes it possible to estimate the conformation and spatial orientation of the polar fragments of lipid molecules facing the aqueous phase. It makes it possible to study the processes of trans- and inter-membrane transfer of ions, lipid molecules, proteins, and all possible biologically active compounds.

Various aspects of the application of the hydrophilic paramagnetic probing of vesicles and biological membranes have been reviewed.[9,53–58]

1. The Differentiation of the Surfaces of Membranes by NMR Spectroscopy and the Estimation of the Dimensions of Liposomes

The testing of the bilayer character of liposomes of amphoteric lipids in water can be carried out using paramagnetic lanthanide ions.[3–5,8,9,59–73] and for anionic lipids using divalent manganese ions[2,3,6,9,74–82] or inorganic anions[46,80–83] which do not bring about flocculation of the colloidal system.

When shifting ions are introduced into the external volume of a dispersion of phosphatidylcholine (PC) in water, subjected to ultrasonic treatment, the ^1H NMR spectrum (Fig.3c) shows two signals from the protons of the polar group. The chemical shift of one of these signals coincides with that of the signal from the "pure" dispersion (Fig.3*a*), and corresponds to polar groups facing into the vesicle. The other is due to external polar groups coordinated to the lanthanide ions.[3,9,59,60] The directions of the shift of the signals are of opposite sign, and the broadening effect of the ion is determined by the absolute magnitude of the anisotropy factor of the magnetic susceptibility.[9,60]

A similar differentiation of the internal and external surfaces of a vesicle can be carried out from the ^{13}C [8] (Fig.4) and ^{31}P [4] (Fig.5) spectra. The observed ratios of the integral intensities of the external and internal signals from the polar groups (I_{ext}/I_{int}) are 2.09 for PC and 2.03 for sphingomyelin (SM) in water. [9]

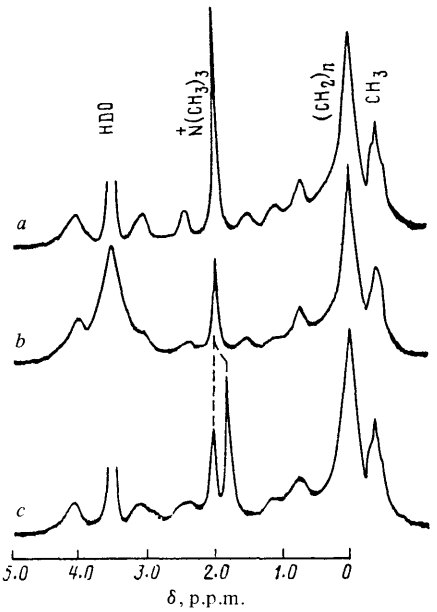

Figure 3. ^{1}H NMR spectra of a 5% dispersion of egg PC subjected to ultrasonic treatment: *a*) in D_2O; *b*) after the addition of 10^{-3} M $MnSO_4$ or *c*) 10^{-2} M $Eu(NO_3)_3$ to the external volume of the specimen.[3]

Nd^{3+} and Eu^{3+} ions have been used[61-63] to test the bilayer character of liposomes of synthetic saturated PC (C_{10}–C_{16}) and phospholipids containing polymerised itaconic acid fragments. Increase in the length of the alkyl chains in the PC molecules leads to the formation of more stable vesicles.[61] The addition of dipalmitoyl-lecithin, bis(2,4-octadienoyl)-PC, or cholesterol to unstable vesicles of itaconate-containing phospholipids gives two kinds of stable bilayer liposomes with diameters of 40 nm and 140 nm.[62,63]

By placing in the vesicles and in the external medium different paramagnetic probes (for example Pr^{3+} and Eu^{3+}) which shift the signals from the polar groups to weak and strong fields respectively, it is possible to make the method highly sensitive and at the same time to follow processes taking place on the external and internal surfaces of the bilayer.[64,65]

The influence of paramagnetic probes on the thermal phase transformations in aqueous dispersions of lipids has been studied.[59,67-70] For example, for dipalmitoyl-lecithin the introduction of Pr^{3+} ions raises the phase transition point by 3–5 K.[59,67]

The systematic error of the determination of the ratio I_{ext}/I_{int} at ^{31}P nuclei,[73] produced as a result of the decrease in the nuclear Overhauser effect (NOE) on the signal from the nuclei in contact with the paramagnetic probe, with decoupling from the protons does not exceed 10% for PC.[9] To obtain a more accurate result, it has been suggested that the dispersion be titrated with a relaxation probe (Mn^{2+}, Ni^{2+}, Gd^{3+}) by recording the ^{1}H [2,3,74,75] or ^{31}P [74-77] NMR spectra. It should be noted that the measurement of the ratio of the intensities in Ref.74 was incorrect; instead of the peak intensities, the integral intensities should have been measured.[76]

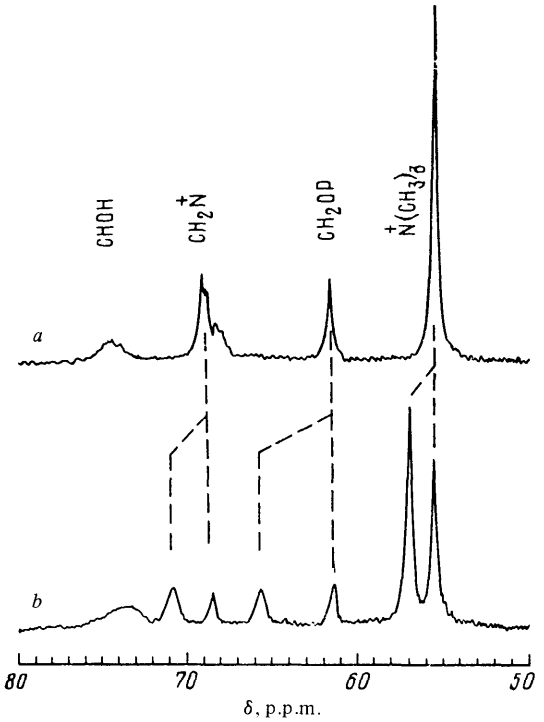

Figure 4. Range of the choline signals of the ^{13}C {H} NMR spectrum of a 20% SM dispersion subjected to ultrasonic treatment: *a*) in D_2O; *b*) after the addition of 5 x 10^{-2} M $Pr(NO_3)_3$ to the external volume of the specimen.[8]

Fig.6 shows that the dependence of the intensity of the ^{31}P signal on the concentration of Mn^{2+} in the external volume comes to a plateau corresponding to the intensity of the signal from the internal phosphate groups.[76,77] For phosphatidylinositol (PI), I_{ext}/I_{int} is 2.50.

Since according to X-ray diffraction data the thickness of the bilayer is 3.6 nm,[78] the external diameters are 24 nm for vesicles of PC and SM, and 19 nm (±1 nm) for vesicles of PI.[9] The values obtained agree with the results obtained by other methods.[79]

The titration of a system containing bilayer vesicles of PC gives two ^{1}H NMR signals from $\overset{+}{N}(CH_3)_3$ groups (the spectra were recorded at 250 MHz).[80] The signal from the internal $\overset{+}{N}(CH_3)_3$ groups is displaced by 0.01–0.02 p.p.m. towards higher fields. The magnitude of the shift increases with the time of ultrasonic treatment of the dispersion. Measurement of the relaxation times T_1 of the ^{13}C nuclei of the external and internal $\overset{+}{N}(^{13}CH_3)_3$ groups of enriched PC[71] showed that this shift is due to a difference in the packing and mobility of the molecules on the external and internal surfaces of the bilayer. This was previously noted in a study[81] using Mn^{2+} ions,

and not Yb^{3+} ions, as in Ref.71. Two-component ^{13}CO [8] and ^{31}P [77,82] signals were also obtained in the spectra of phospholipid vesicles. The observed influence of the density of packing of the molecules on the magnitude of the chemical shift[80,81] made it possible to discriminate the NMR signals (500 MHz) from monomers, micelles, and vesicles of PC, phosphatidylaminoethanol (PA), and SM using Pr^{3+} cations.[72] In these systems the vesicles were obtained without ultrasonic treatment by adding short-chain phospholipids.

A method has been proposed[34] for estimating the average dimensions and number of bilayers n in multilayer liposomes. The integral intensity of the signal from the polar groups, remaining in the titration with Mn^{2+} ions, makes it possible to determine the ratio I_{ext}/I_{int}. This ratio depends on n and R/d, where R is the external radius of the liposome, and d the thickness of the bilayer. It was shown that the ratio of the lengths of the alkyl chains in lipid-like SAS determines the structure of the liposome. Thus for liposomes of N-cetyl-N,N-diallyldodecylacetoammonium bromide with an average diameter of 1000 nm, $n = 13 \pm 1$, whereas liposomes of N-dodecyl-N,N-diallylcetylacetoammonium bromide with an average diameter of 25 nm are bilayer.

2. Factors Influencing the Lifetime of the Hydrophilic Probe in the Bound State

The lifetime of the paramagnetic probe in the state combined with the membrane determines the magnitude of the induced shift of the signals in the NMR spectra. The point of binding of the paramagnetic ions is the phosphate group of the phospholipid molecule.[4,5,8] The maximum number of Mn^{2+} ion binding positions on the surface of a PC membrane is 0.005 per PC molecule,[85] and the corresponding number for the lanthanides (Pr^{3+}, Nd^{3+}) is 0.13.[59] The presence of a single shifted signal in the NMR spectra when the lanthanides are introduced into a phospholipid dispersion indicates a high rate of lateral exchange of the ions between the binding position. The lifetime of the ions in the bound state is independent of their concentration in solution, but decreases with increase in the PC concentration from 0.17 s (at 0.06 M PC) to 0.02 s (at 0.18 M PC).[9] The lifetime of the probe in the bound state is a maximum at pD = 3.5 and decreases on heating.[9]

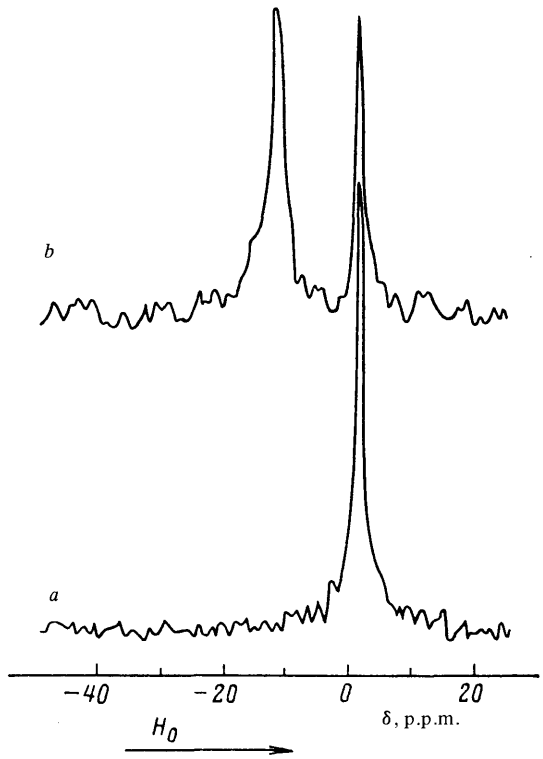

Figure 5. ^{31}P $\{^1H\}$ NMR spectra of a 10% dispersion of egg PC subjected to ultrasonic treatment: *a*) in D_2O; *b*) after the addition of 10^{-2} M $Pr(NO_3)_3$ to the external volume of the specimen.[4]

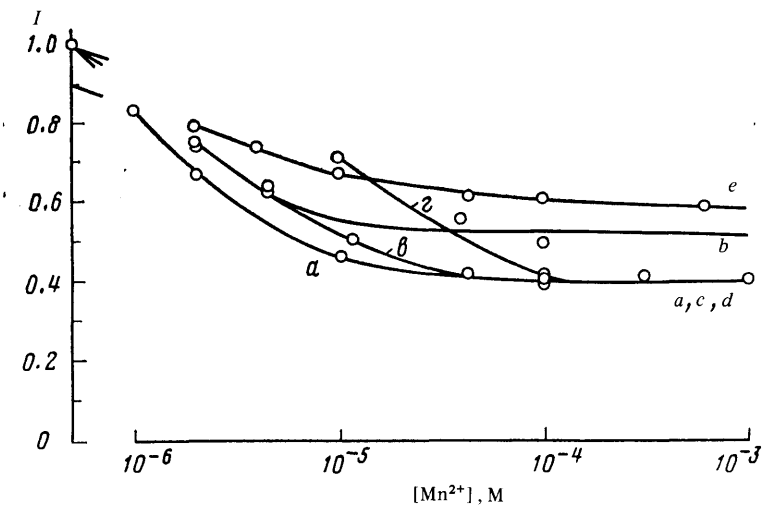

Figure 6. Dependence of the integral intensity (I) of the ^{31}P NMR signal on the Mn^{2+} concentration for dispersions of 0.08 M PI (*a*);[73] 0.05 M (PC + PG) mixture, 1:1, mole/mole, *b*) PC, *c*) PG; and the corresponding dependence for the $\overset{+}{N}(CH_3)_3$ ^1H NMR signal for dispersions of 0.05 M PC (d) and a (PC + PG) 1:1 mole/mole mixture (*e*)[71] in D_2O.

The inclusion of anionic lipids (PI and phosphatidytlserine PS) in the lipid bilayer leads to an increase in the paramagnetic shifts of the signals from the polar groups.[8,76,77] These lipids, by giving the surface of the bilayer a negative charge, influence the distribution of ions in the Stern layer of the vesicle. As a result, the lifetime of the probe in the bound state increases.[9] The same phenomenon is responsible for the influence of inorganic anions on the magnitude of induced shifts.[4,8,46,53,86,87] In this case, however, the redistribution of the ions takes place as a result of the selective Langmuir adsorption of anions on the surface of the lipid bilayer.[87] The ratio of the anion binding constants K correlates satisfactorily with the ratio of the electrophoretic mobilities of liposomes in the presence of these anions (Table 4).[86,87]

Table 4. Electrophoretic mobility of PC liposomes in solutions of different potassium salts and the constants of the Langmuir adsorption isotherms for different anions (300 K, pD = 6).[87]

Anion	Mobility, $\mu m\ s^{-1}\ V^{-1}\ cm$	Δ, p.p.m.	K, $mole^{-1}$
Cl^-	−0.15±0.01	0 15±0.01	1.67±0.45
NO_3^-	−0.46±0.03	1.01±0.02	4.03±0.26
SCN^-	−1.85±0.11	0.99±0.01	23.7±1.1
SO_4^{2-}	1.25±0.09	−0.43±0.01	14.9±0.2

3. Determination of the Conformation and Spatial Orientation of Polar Fragments

The dipole–dipole broadening of the signals in the NMR spectra of colloidal systems prevents the direct use of spin–spin coupling constants to estimate the conformation of polar groups. Thus in Refs.5, 8, and 49 the conformation and spatial orientation of phosphorylcholine zwitterions on the surface of vesicles were determined using the relative pseudo-contact shifts induced by Eu^{3+}, Pr^{3+}, and Yb^{3+} for the signals in the ^1H and ^{13}C NMR spectra. The experimental values of the shifts together with the values calculated from Eqn.(1) for all possible 54 P–O, O–C, and C–C bond rotamers (Fig.7) were plotted on maps of the relative induced shifts of the ^{13}C and ^1H nuclei (Fig.8).

The main contribution to the conformation of the zwitterion is made by the *trans*-forms 111, 211, 611 (70–83%),[5,49] and their probability increases with the degree of unsaturated character of the hydrocarbon chains and with increase in temperature. This is apparently related to the increase in the area corresponding to the SAS molecule[28] and agrees with D and ^{31}P NMR data.[88]

The conclusions obtained are confirmed for O–C bond rotamers by an analysis of the vicinal spin–spin coupling constants $^3J_{POOCC}$ [49] and $^3J_{POCH}$,[89] found without the introduction of a paramagnetic probe. Thus paramagnetic ions have no significant influence on the conformation of a polar group on the surface of a vesicle, so that the fears expressed on this account in Refs.15 and 90 are unfounded.

In micelles of lysolecithin and glycerophosphorylcholine diacetate, instead of the *gauche* forms 132 ≡ 123 and 323 ≡ 532, the different set 523 ≡ 332 is produced,[49] in agreement with the results of studies[91,92] in which a paramagnetic probe was not used.

The fact that the NMR signals from the phosphorylcholine nuclei and from the CH_2CH_2CO groups of the aliphatic acid chains have induced shifts with different directions indicates, in accordance with Eqn.(1), that for all selected conformations the phosphorylcholine zwitterion is arranged parallel to the membrane surface.[5,8,49] This conclusion was subsequently confirmed by other methods: measurement of the ^{31}P NOE in vesicles,[93,94] the ^{31}P NMR of oriented bilayers,[95,96] neutron diffraction (for PC),[97] X-ray diffraction (for PA),[98] measurement of the anisotropy of the ^{31}P shift and D NMR for both PA[99] and PC,[100,101] and quantum-chemical calculations.[102] Thus paramagnetic ions do not alter the orientation of a polar group at the phase interface.[5,9,49,103]

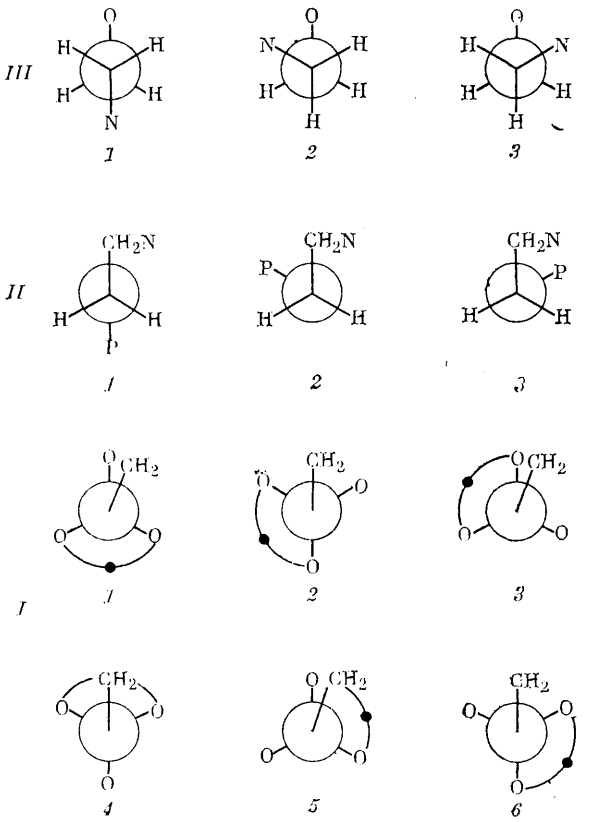

Figure 7. Rotamers of the phosphorylcholine group with respect to the bonds P–O (I), O–C (*II*), and C–C (*III*).[49].

From this it follows that it is not correct to transfer the conclusion about the normal arrangement of the zwitterion on vesicles, obtained for planar bilayers.[104,105] It was noted above that on going from non-closed lamellar structures to bilayer liposomes, the spatial orientation of the polar fragment changes from normal to the surface of the bilayer to planar.[36]

The main reason for the stabilisation of the unfolded *trans*-conformation and the planar orientation of the phosphorylcholine zwitterion on the surface of the vesicle is apparently the intermolecular interaction between the phosphate and $\overset{+}{N}(CH_3)_3$ groups of neighbouring molecules.[49,102] This conclusion is of fundamental importance for an understanding of the molecular organisation and functioning of biological membranes.

4. The Exchange of Lipid Molecules and the Compositional Asymmetry of Membranes

Liposomes, like micelles, are dynamically stable structures. The molecules of SAS in liposomes are extremely mobile, however. They take part in three types of transfer: lateral diffusion,[106] trans-membrane transfer,[107] and inter-membrane transfer.[76] The ratio of the rates of these processes depends on the structure of the lipid molecules and the colloidal system, the molecular composition of the bilayer, and external factors (temperature, ionic strength, the presence of transport proteins, etc.). This ratio determines the possible formation of liposomes with an asymmetric composition of the external and internal monolayers, and also of molecular clusters in the monolayer.

The hydrophilic paramagnetic probe method is the most effective both for the study of the three types of molecular exchange[5,65,76,77,108-110] and in the analysis of the molecular topography of colloidal systems.[64,65,73-77, 111-114]

The rate of the trans-membrane transfer of lipid molecules is low. The time constant of the process is greater than 2.2×10^4 s for egg PC[107] (determined by the spin probe method) and 4.3×10^4 s for [N−$^{13}CH_3$] dioleoyl PC[108] (determined from the penetration of Pr^{3+} ions through the bilayer) at 350 K. This rate can be increased, however, by modelling the bilayer by a system of inverse micelles[5,109] or by introducing small quantities of lysolecithin (LPC) and peroxides.[65,110]

In Refs.5 and 109, the rates and thermodynamic parameters of exchange were found using a mixture of inverse micelles of PC in benzene, with and without Mn^{2+} or Pr^{3+} ions in the solubilised aqueous vesicle.

The kinetics of the trans-membrane transfer of molecules of PC[110] and PI[65] in the presence of LPC or peroxides has been studied by introducing Pr^{3+} or Yb^{3+} ions on the outside of the vesicles. The use of a double probe technique[64] showed that in the transfer of PI molecules the decrease in the induced shift of the signal from the external $\overset{+}{N}(CH_3)_3$ groups is accompanied by an increase in the shift of the signal from the internal groups. The results obtained for both inverse micelles and vesicles indicate that the trans-membrane transfer of the molecules is cooperative in character.

Inter-membrane exchange by lipid molecules is initiated either by a transport lipid-binding protein or by LPC.[76,77] The analysis of the kinetics of the process was based on the increase in the induced paramagnetic shift of the signals from the polar groups when molecules of

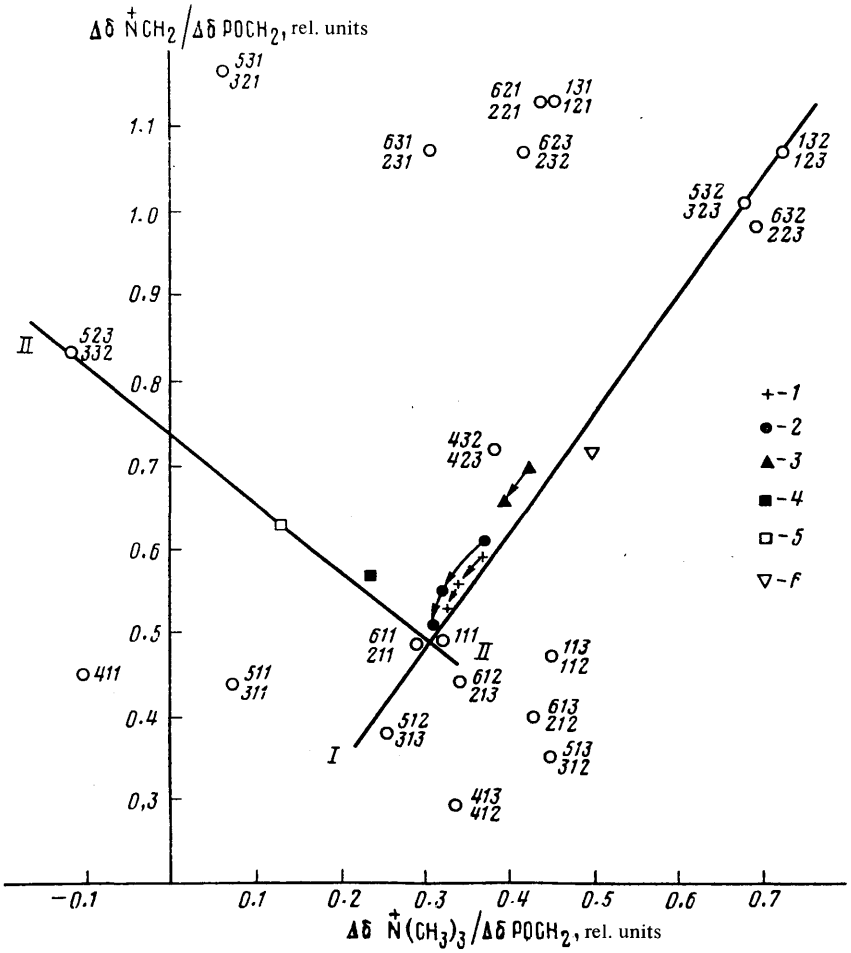

Figure 8. Map of the induced shifts for the ^1H nuclei of the zwitterion: *1*) egg PC, *2*) dioleoyl-PC, *3*) dipalmitoyl-PC, *4*) lysolecithin, *5*) glycerophosphorylcholine diacetate, *6*) stearylphosphocholine.[49]

an anionic lipid (PI) were built into the bilayer (Figs.9 and 10). The change in the magnitude of the induced shift and the ratios I_{ext}/I_{int} give information on the mechanism of inter-membrane exchange.

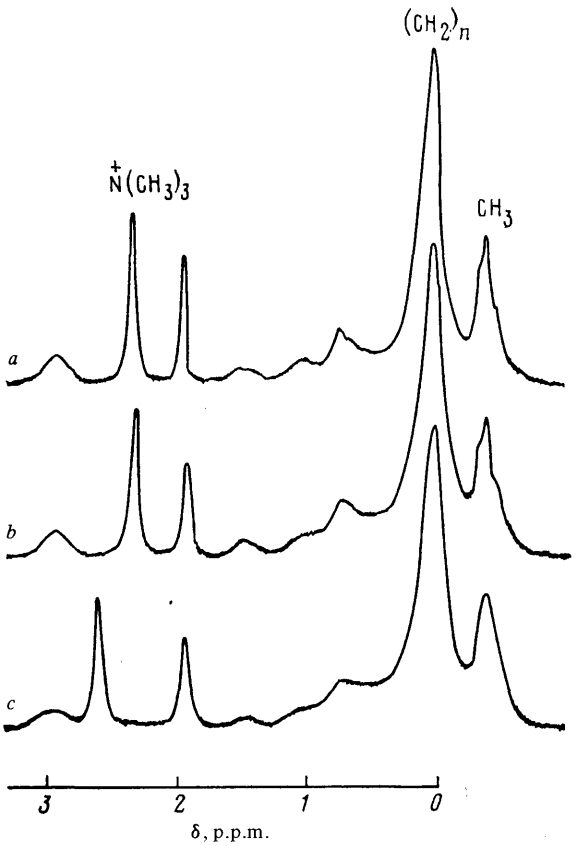

Figure 9. ^{1}H NMR spectra of phospholipid dispersions in D_2O after the addition of 10^{-2} M Pr^{3+} to the outside: *a*) PC vesicles, *b*) mixed vesicles of PC and PI before and *c*) after the exchange of PI by the action of a transport protein (323 K).[77]

In the exchange, vesicles with an asymmetric distribution of lipids are formed (Fig.11). In the spontaneous exchange of PC and PI molecules[65] or in the presence of a PI-transporting protein, PI is exclusively built into the external monolayer.[77] If the system contains micelles of LPC, PI is localised chiefly in the internal monolayer. Monomolecular exchange takes place in the first case, and cooperative exchange in the second. The $^{13}C[N-{}^{13}CH_3]$ NMR spectra of palmitoyl LPC, built into vesicles of dioleoyl-PC, in the presence of Dy^{3+} showed that LPC itself is localised in the external monolayer of the vesicle.[111]

The curvature of the bilayer also leads to an asymmetric distribution of lipids. In mixed PC–PG vesicles, the phosphatidylglycerol (PG) molecules are present chiefly on the external surface,[74,75] as shown by ^{31}P and ^1H NMR with Mn^{2+} This distribution is difficult to understand, since other anionic lipids of PS[64,82] and PI[61] are situated chiefly in the internal monolayer, as indicated by more accurate data with two probes, Pr^{3+} and Eu^{3+} (Fig.10). This distribution is attributed to the more compact packing of the molecules in the internal monolayer, as a result of which the bulky polar fragments of PC are more effectively arranged in the external monolayer. With increase in the concentration of PC or PI, however, the electrostatic forces of repulsion displace an increasing number of molecules of the anionic lipids into the external layer, and the asymmetry of the membrane decreases.[64,65]

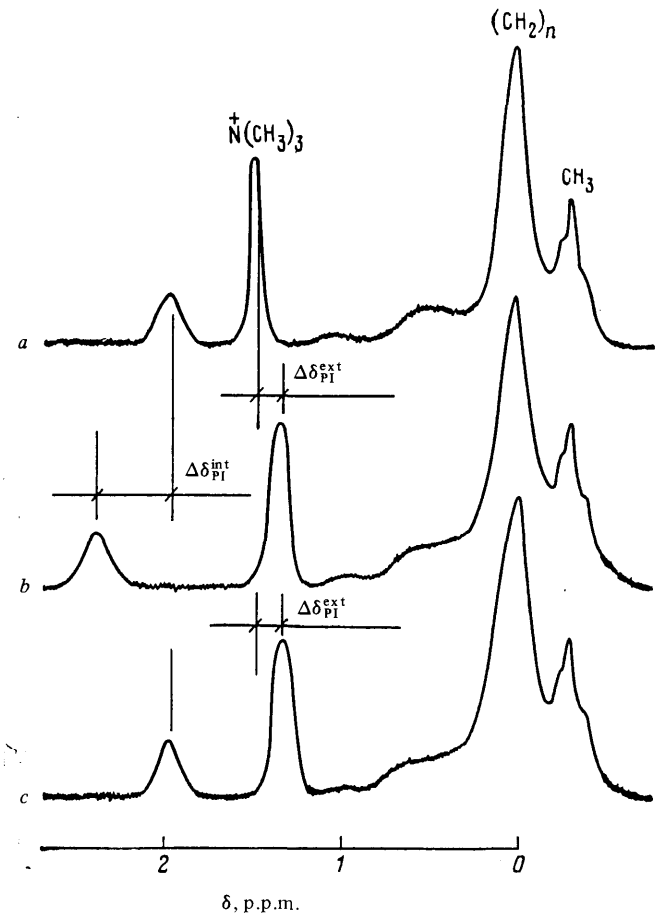

Figure 10. ^{1}H NMR spectra of phospholipid dispersions in D_2O: *a*) PC vesicles, *b*) mixed vesicles of PC and PI, subjected to ultrasonic treatment, *c*) vesicles of PC with spontaneously built-in PI after the combined incubation of vesicles of PC and PI for 5.8 x 10^4 s at 296 K, containing 10^{-2} M Pr^{3+} inside and 10^{-2} M Eu^{3+} outside.[65]

The asymmetry of the distribution of cholesterol in vesicles of PC was also first detected using a paramagnetic probe (Pr^{3+}).[112] Cholesterol is present in the external monolayer in vesicles of unsaturated PC, and is distributed throughout the vesicles of saturated PC.[113] The constant for the spontaneous inter-membrane exchange of cholesterol is 0.0117 min^{-1}.[113]

The rate of the lateral diffusion of cholesterol depends on the molecular structure of the PC.[53,114] Thus if the liposomes contain simultaneously molecules of the SS-, SU-, and UU-types (S and U represent respectively saturated and unsaturated alkyl chains), the cholesterol is more frequently in contact with molecules of the UU-type than with molecules of the SU- or SS-type. Thus if the membrane contains PC of different types, the cholesterol is present chiefly in the phase containing the more unsaturated molecular forms of PC.

5. Analysis of the Interaction of Liposomes with Low-Molecular-Weight and Biologically Active Compounds

The above example of the study of the behaviour of cholesterol molecules in the structure of liposomes indicates the promising possibilities provided by the use of the paramagnetic probe method to investigate the nature of the interaction of physiologically active compounds with a membrane. Most studies are based on the use of the effect on the trans-membrane transfer of lanthanide cations of ionophors,[66,115-117] local anaesthetics,[118,119] and other physiologically active compounds,[76,77,120] as in the case of LPC.[110]

The transport of Pr^{3+}, Eu^{3+}, Yb^{3+}, and Dy cations through a bilayer has been studied using the ionophor X-537A,[115] alamethicin,[116] the ionophor A23187 of the nigericin type,[117] glycophorin,[66] the local anaesthetics tetracaine, procaine, and lidocaine,[118] isoprenoids,[119] and sodium taurocholate.[120] Here, the lanthanide cations act as physiological analogues of calcium. The activation energy of the process is 85 kJ $mole^{-1}$.[119]

A different method has been proposed for determining the kinetics of the transport of Na^+ and Li^+ by the ionophor monensin using Gd^{3+} as relaxation probe. Since the order of magnitude of the rate of transfer was the same as that of the rate of relaxation of the ^{23}Na and ^7Li nuclei, the mobility of the ions made a contribution to the relaxation time. The values found, $\nu_{Na} = 4$ nm s^{-1} and $\nu_{Li} = 0.035$ nm s^{-1} correspond to the affinity of the ionophor for cations.[121]

^{13}C-enriched lipids have been used for the paramagnetic hydrophilic probing of the distribution of aliphatic acids in vesicles of PC with a pH gradient.[58] The relaxation probe Mn^{2+} established that the 1-anilinonaphthalene-8-sulphonate molecule is localised on the surface of the vesicles.[122]

IV. THE STRUCTURE OF BIOCOLLOIDAL SYSTEMS

The transport of ions through a membrane barrier plays a fundamental role in the vital activity of cells. It is equally important, however, to establish the mechanism of lipid–protein interaction and the behaviour of combined water in colloidal systems. The characteristics of the introduction of polypeptides (poly-L-glutamic acid, poly-L-leucine)[123] and a transport protein[76,77] into a liposome have been studied using Eu^{3+} and Pr^{3+} ions and ^1H and ^{31}P NMR spectroscopy. It was established that the mosaic model is applicable to bilayer vesicles. According to this model, the protein "icebergs" in the membrane float in a lipid sea. The mosaic model was also found to be applicable to blood serum lipoproteins,[124-127] the structure of which was determined by ^{13}C and ^{31}P NMR spectroscopy using Eu^{3+} ions and built-in [N–$^{13}CH_3$]-PC and -SM and 1,2-(1-oleoyl-^{13}C)-PC.[124,125] Experiments with the hexacyanoferrate(III) anion and Nd^{3+} [126] confirmed the published conclusions[124,125] that all the mobile $\dot{N}(CH_3)_3$ groups of the phospholipids in both low-density and high-density lipoproteins are situated on the external surface of the globule (Fig.12). The incomplete broadening of the ^{31}P signals in the spectra of lipoproteins in the presence of Mn^{2+} ions (80% in high-density lipoproteins and 50% in low-density lipoproteins)[127] may be due to an error in the organisation of the experiment resulting from the competition with the powerful Complexone ethylenediaminetetraacetic acid.

Mn^{2+} ions have been used to determine the location of the membrane proton of erythrocyte ghosts.[128] Comparison of the broadening of the signals in the ^1H NMR spectra of model membranes of PC

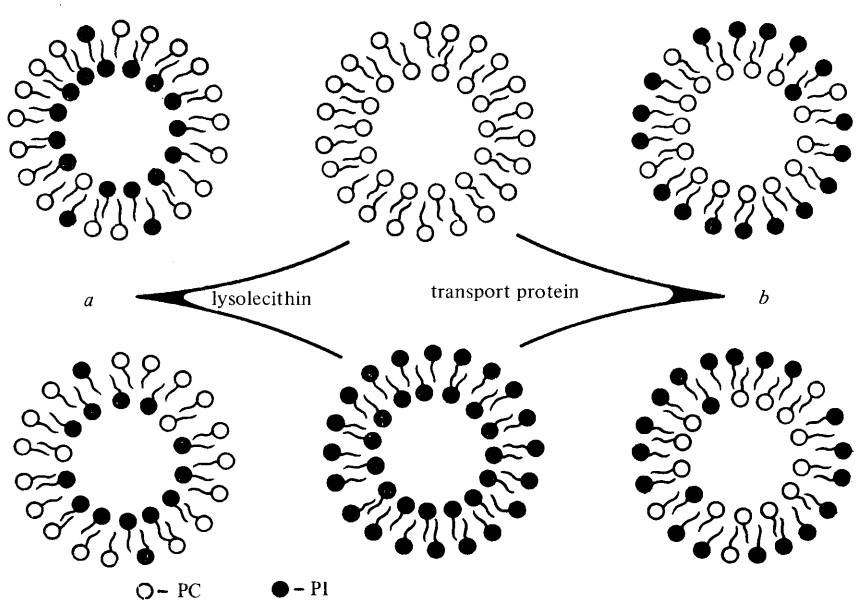

Figure 11. Diagram of inter-membrane exchange under the influence of: *a*) LPC, and *b*) a transport proteins.[53]

and the erythrocyte ghosts showed that the protein is situated on the surface of the biomembrane. This agrees with the results of an analysis of the membrane of sarcoplasm reticulum using an iminoxyl probe from its broadening effect on the ^{1}H and ^{13}C NMR signals.[129]

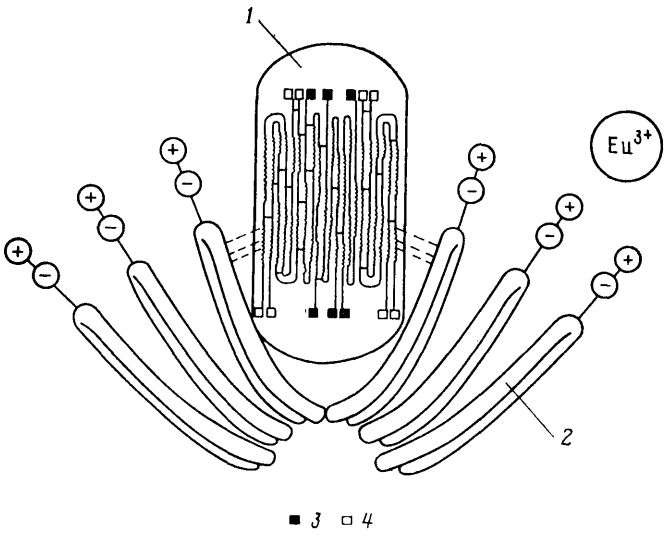

Figure 12. Model of a high density lipoprotein: *1*) protein, *2*) mixture of PC and SM, *3*) apoprotein I, *4*) apoprotein II.[125]

^{31}P NMR spectroscopy has been used[130] to measure the rate of the penetration of paramagnetic ions into heart cells. The penetration of Mn^{2+} ions made it possible to diagnose ischaemia.

Relaxation paramagnetic probes have been used many times[56-58,132,133] to study the behaviour of water in biological systems. In the first of these studies, Mn^{2+} ions were used to identify the signals from free and combined (intracellular, 4 p.p.m.) water in native rabbit sciatic nerve.[131] All other studies used similar methods. One of the most interesting is a study[132] in which NMR spectroscopy was used to investigate the intercellular transport of water in the roots of wheat plants. The introduction of Mn^{2+} ions into the space outside the cell makes it possible to eliminate from consideration the vacuolar transport of water and to control the symplast path. It is known that manganese is necessary for the liberation of oxygen in photosynthesis in the chloroplast membrane. The state of the manganese ions combined with the membrane was estimated using the values of the spin–lattice relaxation time T_1 of the protons of the water in a suspension of the thylakoid membranes of chloroplast.[133] It was shown that the manganese atoms have oxidation states II and III.

A large number of studies have been devoted to the investigation of the structure and topography of colloidal protein systems using paramagnetic hydrophilic propbes.[14,15] These studies, which are all of the same type, will not be characterised, but the results of one such study, where the possibilities provided by the method were most fully used, can be considered.[134] The authors cited used Mn^{2+}- and Cr^{3+}-ATP probes to determine the distances to different regions of carbamoyl-phosphate synthetase (CPS) by ^{1}H, ^{13}C, ^{15}N, ^{6}Li, ^{7}Li, and ^{31}P NMR spectroscopy (Table 5). These results gave the first topographical map of the environment of the substrates and the positions of the activator ions and allosteric modifiers in the CPSA dimer from *E.coli*.

Table 5. Distance from the ions Mn^{2+} and Cr^{3+}-ATP (r) to the nuclei of the ligand in the complex of CPS from *E.coli*.[134]

Mn^{2+}-ligand			Cr^{3+}-ATP-ligand		
ligand	nucleus	r, nm	ligand	nucleus	r, nm
Glu	^{13}C (5)	0.86±0.06	Glu	^{13}C (5)	0.70±0.05
$Co(NH_3)_4$-ATP	^{31}P ($\alpha\beta$); ^{31}P (γ)	0.66±0.04; 0.64±0.04	HCO_3^-; NH_4^+	^{13}C; ^{15}N	0.47±0.03; 0.74±0.05
Li^+	^{7}Li; ^{6}Li	0.75±0.04; 0.80±0.05	—	—	—

Thus the use of paramagnetic shift and relaxation hydrophilic probes combined with traditional methods of studying colloidal systems by NMR spectroscopy opens up extensive possibilities for the analysis of their structure and molecular dynamics. The results obtained by this method are of fundamental interest for establishing the mechanisms of micellar catalysis and emulsion polymerisation. The method has made it possible to study a wide range of properties of membrane systems, important both for the investigation of the molecular structure and mechanism of the functioning of cell membranes and for the development of membrane technology.

Spectroscopy of Molecules and Molecular Complexes Dissolved in Liquefied Gases: Structure and Reactivity

Ya.M.Kimel'fel'd

The application of the absorption spectroscopy (IR and UV) of solutions in liquefied elemental gases (N_2, O_2, Ar, Kr, and Xe) to the study of reactivities and reaction mechanisms is examined. The design of cryostats and the method of preparation of solutions are described and data on the solubilities of molecules in liquefied gases are presented. The characteristic features of the spectra of diatomic and polyatomic molecules in cryosolutions are analysed. The possibilities of the method in the investigation of unstable molecular complexes and in the elucidation of the nature of the spectra of the hydrogen-bonded complexes formed are demonstrated. The specific features of the non-linear absorption of IR radiation by molecules in the cryosolutions are discussed and a number of photochemical reactions in cryosolutions are described. It is shown that the method is promising for the solution of problems of laser chemistry in the condensed phase.
The bibliography includes 101 references.

I. INTRODUCTION

Liquefied noble gases are transparent in the range from the vacuum ultra-violet region to the far infrared, while liquefied oxygen and nitrogen have only weak absorption bands in the middle infrared region. For this reason, solutions of molecules in liquefied gases have been traditionally investigated by methods of absorption optical spectroscopy. The latest review devoted to the IR spectroscopy of solutions in liquefied gases was published in 1973 by Bulanin[1] and describes fairly completely aspects such as the solubility of the simplest molecules in O_2, N_2, and Ar and the design of optical cryostats. It is emphasised that the low solubility is compensated by the possibility of studying very thick layers of solutions, up to 10 metres. The review reaches conclusions about the characteristics of the IR spectra of solutions of molecules in liquefied gases: the frequency shifts relative to the frequencies in the gas phase are smaller (on average down to 5 cm^{-1}) than in any other environment, for example, in matrices; the integral band intensities are close to those in the gas phase; the widths of the bands of polyatomic molecules are usually less than 5 cm^{-1}; as a result of the narrowing of the band, the IR spectrum at 90 K contains much more information than that at low temperature in a traditional solvent, for example, in CCl_4. The presence of particular groups in the molecule, the stoichiometry of the molecule, its symmetry, and even its geometry can therefore be determined from the IR spectrum.[2]

During the last one and a half decades, numerous studies have been published in which krypton and xenon were also used as solvents. At elevated pressures (up to 50–60 atm), it is possible to carry out experiments over a wide temperature range, up to 0 °C. Naturally, this made it possible to dissolve more complex molecules, such as, for example, decamethylferrocene.[3] It became possible to investigate not only molecules but also complex formation reactions, photochemical processes, etc. Studies on the effect of laser radiation on molecules in cryosolutions began to be prosecuted on a broad front. Finally, the wave length range in which spectra are obtained has been extended—from far to near infrared and further to the vacuum ultraviolet region of the spectrum. Overall, the specific features of a simple cryosolution made it possible to obtain new information about intramolecular and intermolecular processes.

II. METHODS

It has been noted[4] that the spectroscopy of solutions in liquefied elemental gases has much in common with the familiar low-temperature matrix isolation method. However, the latter method is not suitable for the investigation of weak absorption bands because of the difficulties in the preparation of specimens with a fairly large thickness and due to the light scattering by the matrix; also this procedure does not yield quantitative information about the concentration of the impurity molecules and hence about the intensity of the spectral bands. Furthermore, the solution is in a high-pressure cell and the reacting gases cannot leave the reaction space, as happens in the matrix isolation method where the measurements are performed under high vacuum. Furthermore, in the matrix experiment there is a spectroscopic problem—the band splitting associated with the positions of the molecules in the matrix. It arises because the isolated molecules can exist in different environments in the solid matrix and the IR bands are frequently split. It is therefore sometimes impossible to distinguish the matrix splittings from spectral effects associated with changes in the molecule. The

essential feature of the method of preparation of solutions in liquefied elemental gases, including N_2 and O_2, is that the solute is introduced into a closed volume cooled as a rule with liquid nitrogen (we shall designate the word liquid by the symbol L, e.g. LN_2), and the solvent gas is condensed. Bulanin[1] described two types of optical cryostats—with horizontal and vertical optical axes. A cryostat of the second type (Fig.1), developed at the Institute of Physics at the Leningrad State University, which makes it possible to carry out experiments with thicknesses of absorbing layers up to 40 cm as a result of the double passage of the IR radiation through the solution, is particularly effective. Since the cryostat window is not in contact with the cold solution and its temperature is always close to room temperature, it can withstand high pressures (up to 60–70 atm), which permits the coverage of the temperature range 80–270 K using liquefied N_2, O_2, Ar, Kr, and Xe (Fig.2).[5]

Rebiai et al.[6] used a fairly effective design of a cryostat with a horizontal optical axis. It was made almost entirely of brass in order to reduce the effect of thermal stresses. An additional shielding chamber was placed over the chamber with the specimen. It can be filled with a cooling agent, which permits the maintenance of a constant temperature in the test solution without its boiling. The specimen chamber as well as the shielding chamber are attached to the upper lid of the cryostat via stainless steel tubes having a low thermal conductivity.

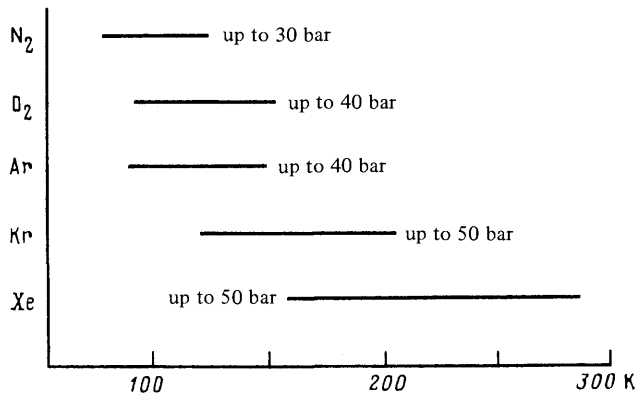

Figure 2. Region of the existence of the liquid phase of cryosolvents.[3]

In order to be able to investigate the largest possible number of substances in such solutions, their inadequate solubility must be compensated by the large thickness of the layer investigated. A novel design of multipass cell has been developed by Jeannotte and

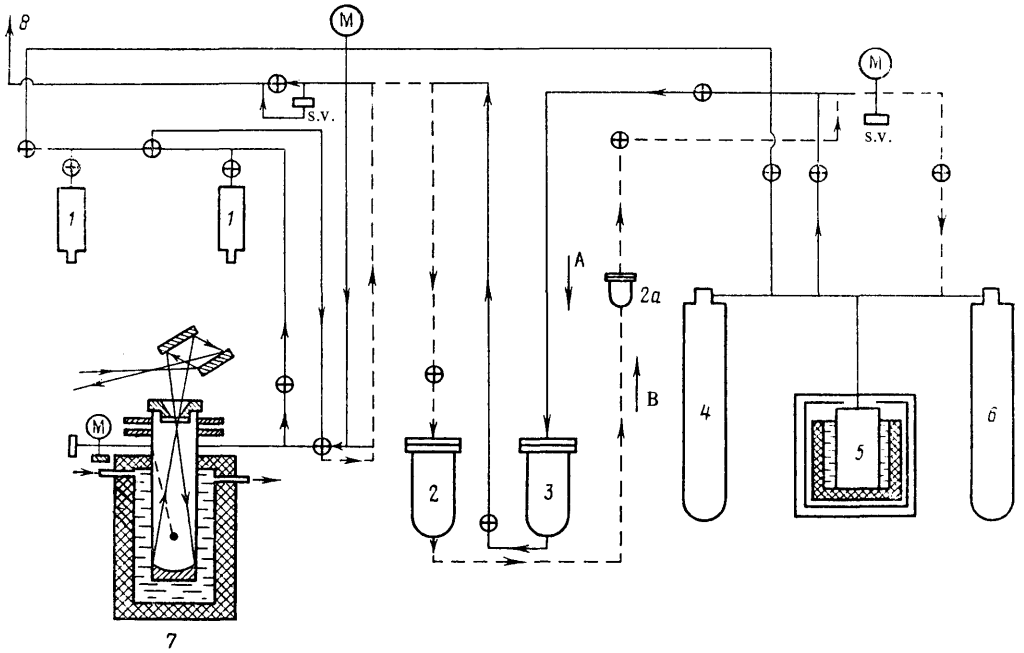

Figure 1. Schematic illustration of the apparatus for cryospectroscopy:[11] (1) vessels for the storage of the test compounds; (2), (2a), and (3) absorber systems; (4)–(6) vessels for the collection and storage of the inert gases; (7) cryostat; (8) forced evacuation; s.v.—safety valves; M—manometers; ⊕—valves; A—forward flow of the condensible gas admitted into the cryostat; B—reverse flow of the condensible gas being collected in the gas collector.

Overend.[7] The path length was varied from 0.3 to 2.1 m in 0.6 m steps. Since there are difficulties in sealing the windows under conditions where the temperature is reduced repeatedly, a cell was produced with a single window through which both the incoming and outgoing beams pass. As in the previous versions, the familiar White cell design was used. The internal 1.5 litre volume of the cell was surrounded with gaseous helium by altering the pressure of which it was possible to regulate the cooling with liquid nitrogen in the outer volume. For an optical path length of 1.5 m, LAr is entirely transparent and the transmittance of the cell over the entire IR range investigated in not less than 95%.

A design has been proposed[8] in which a change in the thickness of the optical layer by an order of magnitude is achieved without interfering with White's scheme by rotating plane illuminating mirrors placed outside the limits of the volume with the liquefied gas.

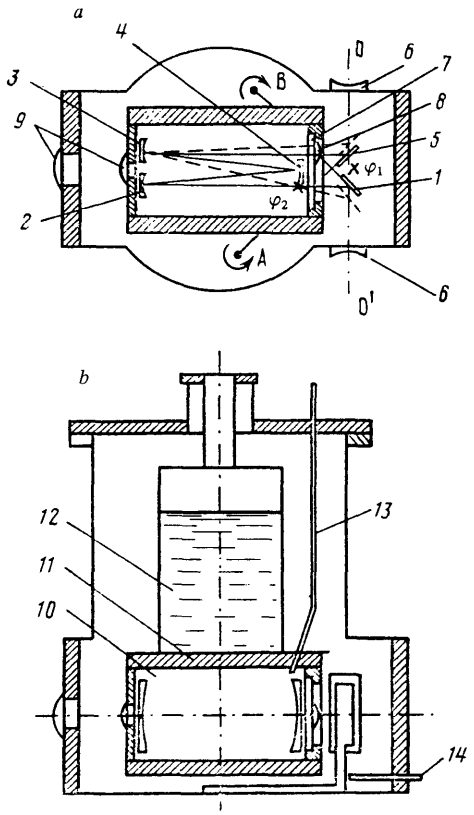

Figure 3. Schematic diagram of the cryostat:[8] (a) horizontal section: (1) and (5) plane mirrors; (2)–(4) spherical White cell mirrors; (6) scattering lenses; (7) window; (8) collector; (9) lenses; (b) vertical section: (10) cell with specimen; (11) copper jacket; (12) cooling vessel; (13) inlet for test substance; (14) component controlling the mirrors (1) and (5).

A schematic horizontal section through the cryostat with a representation of the path followed by the beam is illustrated in Fig.3*a*. The retuning of the optical scheme for two passes is achieved by rotating the plane mirror *1*, whereupon light falls immediately on the exit White cell mirror *3* (dashed line) and then, by rotating the plane mirror *5*, it is directed on to the OO' axis.

The vertical section through the cryostat is shown schematically in Fig.3*b*. The test solution is in cell *10*, which consists of a tube with an internal thread for the attachment of White cell mirrors.

Melikova[8] noted the advantages of the cryostat compared with previous designs.[1,7] Firstly, a thick optical layer is ensured for a small volume of the specimen (300 ml), achieving thereby not only economy as regards expensive solvent gases (especially xenon), but also a uniformity of temperature in the cell. Secondly, there is a possibility of adjusting the optical layer in the same specimen by an order of magnitude without the need to move any optical components in the liquefied gas. Thirdly, it is possible to work with standard spectroscopic apparatus without additional illuminating devices.

The preparation of solidified optically transparent solid solutions is of special interest, since the dissolved molecules are then in a field of known symmetry. Solid specimens, obtained by freezing liquefied noble gases, can be more crystalline than those obtained by the direct condensation of the gases. Fairly thick specimens of dilute solid solutions are sufficiently transparent for absorption spectroscopy. If the solid solutions are contained in a cell where it is possible to maintain an excess pressure of solvent vapour, the temperature can be raised up to the melting point of the solid specimen, in contrast to the matrix isolation method. The design of the corresponding cryostats has been developed by Maier.[9] In order to obtain a solid solution in xenon (it will be designated by SXe), the bottom of the cell with an optical path length of 1.3 cm is cooled to −117 °C, which is approximately 5 °C below the freezing point of pure xenon, and the top of the cell is maintained near −107 °C. Since the crystal grows upwards, the temperature of the top of the cell is slowly reduced until the crystal fills the cell. This solidification process usually lasts 4 h. The solid specimen obtained is transparent without any visible defects. Depending on the purpose of the experiment, the solid specimen is kept either several degrees below the melting point of the xenon or is cooled to lower temperatures.

Spectroscopic studies on liquid cryosystems using large optical path lengths impose extremely severe requirements on the purity of the liquefied gases.[10]

For systematic studies using expensive gases such as xenon and krypton, it is essential to make provision for a closed solvent circulation cycle (Fig.1). The purification of the gas involving the removal of the substance dissolved in the previous experiment is carried out in zeolite-filled columns and the transfer of the gas, without losses, from the cryostat to the storage compartment is achieved by recondensation in the vessel *5* cooled with liquid nitrogen.[11]

The simplest method of separation of the solutions involves the filling of the cryostat volume in the 1 : 1000 or 1 : 10 000 gas mixture, its subsequent condensation, and the addition of the solvent gas. In the measurement of the band intensities,[12] solutions of known concentration, known beforehand to be below that corresponding to saturation, were prepared by liquefying in the cryostat reference gas mixtures with the test substance.

The experiments with solutions in elemental gases are performed in the same way as those with traditional solutions. When nitrogen oxides were dissolved in LXe, the solution was constantly agitated with a magnetic stirrer, which actuated a Teflon-coated rod placed at the bottom of the cell.[13] The NO concentration in the solution depends on temperature and the NO partial presure over the

solution. In order to obtain the required concentration, an elevated NO pressure was used.

An interesting method of preparation of ozone solutions in LAr has been proposed.[14] Ozone was obtained directly in a cryostat with BaF_2 windows by irradiating LO_2 with light from a mercury lamp. The solutions in LAr were prepared by condensing AR in the cryostat after slow distillation of oxygen from a solution of O_3 in LO_2. This method makes it possible to transfer O_3 almost completely to LAr.

Cryostats with a vertical optical axis are specially convenient for the preparation of solutions of solid compounds:[3] the powder is poured into the cryostat in a stream of dry argon, the upper flange with a window is attached, argon is evacuated whilst cooling, the solvent gas condenses, and the solution is repeatedly caused to boil by releasing the pressure. One can assume that the specimen taken for the experiment dissolved if the spectrum did not change as a result of the subsequent ebullition of the solution. To accelerate the dissolution, the solution is vigorously bubbled with the gaseous medium.

III. THE SOLUBILITY OF MOLECULES IN LIQUEFIED GASES

The solubilities x of various compounds in cryogenic liquids are of independent interest for many technological problems. For example, CO_2, hydrocarbons, and NO_2 solidify during the liquefaction of air. A method has been proposed[15] for the calculation of the solubilities of solids in cryosolvents. The decisive factors in the approach described are the interaction of solute with the solvent and the melting point of the solute, its fugacity, and activity coefficient. The calculated solubilities in LO_2 [16] of different classes of compounds are given below in mole fractions (m.f.): alkanes (from methane to hexane) from 1 to 1×10^{-4}, alkenes (from ethylene to hexene) from 1 to 2×10^{-2}, acetylene 5×10^{-2}, benzene 1×10^{-4}, methanol 6×10^{-2}, CO_2 1×10^{-3}, H_2S 1×10^{-3}, NO 1×10^{-2}, NO_2 2×10^{-6}, and Kr 3×10^{-1}. The calculated solubilities of solid hydrocarbons, with the exception of methane, are higher by one and a half to three orders of magnitude than those obntained experimentally.[16] The regularities found in the solubilities of homologous series can be seen. The solubilities of alkanes and alkenes decrease with increase in molecular weight. The solubility of acetylene, which tends to form associated species, is lower than those of ethylene and isobutene. The solubilities x of olefins in LN_2 were determined by IR spectroscopy.[17] The analytical bands selected were those of ethylene ($\nu = 2168$ cm^{-1}; $\nu_{1/2} = 9.5$ cm^{-1}), propene (2034 cm^{-1}; 1.5 cm^{-1}), and but-1-ene (995 cm^{-1}; 4.0 cm^{-1}); the values of x proved to be 6×10^{-3}, 1×10^{-3}, and 1.5×10^{-4} m.f. respectively at 80 K. The solubility of olefins in LO_2 is higher by 1–4 orders of magnitude than in LN_2. Careful preparation of the saturated solution, including its bubbling with He and the measurement of the IR spectra both on heating and cooling, made it possible to determine the solubility x of linear molecules with an error in the range 15–20%: in LO_2, x is 4.3×10^{-6} for CO_2, 5.6×10^{-4} for COS, and 1.4×10^{-4} m.f. for N_2O, while x for CS_2 in LAr is 5.6×10^{-7} m.f.[18] The solubilities x of alkynes are much less satisfactorily reproducible. The following values of $10^6 x$ (in m.f.) have been obtained in LAr at 90 K: 5.4 for $HC{\equiv}CH$, 2.3 for $CH_3C{\equiv}CH$, 2.2 for $C_2H_5C{\equiv}CH$, 0.25 for $CH_2{=}CH{-}C{\equiv}CH$, and 0.16 for $HC{\equiv}C{-}C{\equiv}CH$.[19] The solubilities x of hydrocarbons containing between 5 and 8 carbon atoms in LAr have been determined[20] and have been found to lie in the range $0.3-30 \times 10^{-6}$ m.f. The parameters x in LAr and LO_2 proved to be similar. In practice this is important, since solutions in LO_2 are explosive.[4]

The values of x for certain substances have been determined from electronic absorption bands.[21] The high absorption coefficient in the UV region makes it possible to carry out measurements at lower concentrations and hence to determine x for a wider range of compounds. The list of substances and the values of x (in m.f.) found for them are as follows: 4×10^{-9} for pyrimidine in LKr, 3×10^{-10} for pyrazine in LKr, 1.4×10^{-8} and 7×10^{-10} for pyridine in LKr and LAr respectively; 5×10^{-7} for NH_3 in LAr and LKr; 5×10^{-6} and 2.2×10^{-7} for acetone in LKr and LAr; 1.1×10^{-6} for CH_3I in LAr; 7×10^{-6} and 4.5×10^{-8} for toluene in LAr and LN_2; 9×10^{-6} and 2.2×10^{-7} for benzene in LKr and LAr. A mole fraction of 2.4×10^{-3} has been quoted for I_2 in LXe.[22] Since the mole fraction x varies exponentially with temperature ($\lg x = a - b/T$), the heat of solution can be found. For the series of substances investigated, it varies from 2 to 7 kcal mole^{-1}. The solubility of toluene in LKr exceeds by more than an order of magnitude that in LAr and the solubilities of CS_2 and CH_3I in LN_2 are at least an order of magnitude lower than in LAr. Agreement between the values of x calculated by the method of Preston and Prausnitz[15] and the experimental values on the assumption that there is no interaction is achieved only for simple systems, while for solutions of toluene in LN_2, for example, the discrepancy amounts to several orders of magnitude. This makes it possible to determine the parameter characterising the interaction in solution.

Unusually high solubilities x of water in LN_2 (1×10^{-5}) and LO_2 (1×10^{-5}) have been reported.[6] Particles of ice were ground in the liquid solvent and the solution was then filtered into the cell, the degree of saturation of the solution being deterined by the intensity of the grinding. According to the authors, spectroscopic data confirm that solutions of monomolecular water were obtained. However, the frequencies quoted for the stretching vibrations of water $\nu_1 = 3605$ and $\nu_3 = 3707$ cm^{-1} are very close to those known for CO_2 in solution in LN_2 (see Section V), while the D_2O frequencies differ fairly considerably from the frequencies of this molecule in the gas phase.

In spectroscopic studies, special measurements of x frequently were not made, but the solubilities can be inferred by comparing the intensities of the IR bands and the optical path lengths. If cells 1 cm long are used, then x is as a rule higher than 10^{-3} m.f., while for cells 10 cm long the solubilities are $\sim 10^{-4}$ m.f.; smaller values of x require greater optical path lengths. Thus a solution of monomeric formaldehyde in LXe with a concentration of $\sim 10^{-2}$ m.f. has been observed in a cell 1.3 cm^{-1} long;[23] the solidification of Xe does not alter greatly the solubility x. We may note that the preparation of such formaldehyde solutions makes it possible to observe the spectra of its monomeric form, although the molecular density of CH_2O in the solution is equivalent to a vapour pressure of 30 mmHg, while in the gas phase at a pressure in excess of 4 mmHg of CH_2O, polymerisation takes place rapidly.[23] The vapour pressures of comparatively heavy molecules are usually low. Thus it is only 7 mmHg for OsO_4 and, in order to obtain the IR spectrum of the gas, it is necessary to use cells with a large optical path length. On the other hand, the intensity of the IR bands of OsO_4 in solution in LXe in a cell 2.7 cm long is equivalent to a vapour pressure of 400 mmHg, i.e. the preparation of solutions of substances with a satisfactory solubility makes it possible to achieve a high molecular density. This facilitates the analysis of molecular impurities. Thus the IR spectrum of OsO_4 shows a fairly intense ν_3 band of the isotopic form, containing ^{18}O, at a concentration of only 4×10^{-6}.[23] The

high sensitivity of the cryospectroscopic method has found practical applications in the analysis of liquefied gases, for example, of liquid O_2, for molecular impurities. The sensitivity of the absorption spectroscopic analysis of cryosolutions actually achieved at the present time has reached the level approaching a mole fraction of 10^{-10}.[4]

IV. INFRARED SPECTRA OF SOLUTIONS OF DIATOMIC MOLECULES

The changes resulting from the transfer from the gas phase to the cryosolution can be seen in relation to the IR spectra of hydrogen halides in LXe.[24] The rotational branches are well manifested in the spectra of HCl, HBr, and HI in LXe. The *Q* branch has a high intensity, as in gases under high pressure. The distance between the rotational *P* and *R* branches is greater than expected. According to the authors, this can be associated with the superposition of induced *S* and *O* branches, which are not resolved from the *P* and *R* branches in the spectrum. The selection rules characteristic of the liquid are probably associated with the anisotropic fields, which induce a shift of the *J* states. In this sense, the rotational movements of HX in LXe are assumed to be not free. One can imagine that the diatomic molecules execute unhindered rotation in the course of a significant proportion of the rotation period and that, on collisions, random changes take place in the molecular angular momentum. Frequent changes in rotation caused by collisions usually lead to the suppression of the rotational structure. Compared with the gas phase, the initial sections of the HCl, HBr, and HI bands in LXe shift by 34, 29 and 17 cm^{-1} respectively, which amounts to ~1% of the energy of the level. The strongest effect involves an increase in the integral intensity of the bands compared with the free molecule: by a factor of 2.8 for HCl, 3.1 for HBr, and 44 for HI. According to the calculation carried out by the authors,[24] the effect of the dielectric medium can explain an increase in intensity only by a factor of 1.22 and they therefore sought an explanation in terms of an increase in the amount of ionic character of HX and assume that approximately 1/16 of an electron moves from the proton to the halogen when the molecule is dissolved even in LXe. However, it follows from Iogansen's studies that the strength of the intermolecular interaction is characterised by the intensity increment, i.e. not by the ratio but by the difference of the intensities in two different states. The increments for HI and HCl are similar. The low intrinsic band intensity of free HI is the reason for the increase in its intensity by a large factor on dissolution. The relative intensities of the components depend on the solvent. Thus, whereas the *Q* branch is not manifested at all as an individual maximum in the spectrum of the HCl solution in LAr, on passing to the solutions in Kr, Xe, and O_2, its intensity increases successively. On raising the temperature, weakening of the *Q* component and the strengthening of the *P* and *R* components are observed, while the integral intensities hardly change under these conditions. The integral absorption coefficients ($\times 10^8$ in $cm^2\ s^{-1}\ mol^{-1}$) of the bands of the principal vibrational transitions of HCl in the solutions are as follows: 19.4 in the gas phase; 48 (80 K) and 34 (120 K) in LN_2; 27 (90 K) in LAr; 34 (126 K) in LKr; 53 (165 K) in LXe; 47.2 (293 K) in CCl_4.[25] Analysis of the spectra of diatomic molecules in various solvents showed that LAr and LO_2 are spectroscopically the most inert and perturb the spectra of the solutes to a minimal extent.[4]

The second moments of the bands of hydrogen halides found from the experimental data, which have a bearing on the band width, have been compared to the theoretical values. A satisfactory agreement has been obtained for solutions in noble gases, oxygen, and CCl_4, which confirms the dominant role of the rotational movement of the hydrogen halide molecules in the above systems in the formation of their absorption band contours. Thus the temperature and not the medium determines the second moments of the hydrogen halide bands in solution and liquefied noble gases or simple molecules exhibit no unusual features compared with the usual solvents. This is also seen from the integral intensities of the bands due to simple molecules. On the other hand, the solvent influences the frequencies significantly. The HCl frequency in CCl_4 (2833 cm^{-1}) is significantly lower than in LXe (2850 cm^{-1}, 200 K). Bearing in mind that the frequency depends on temperature (~2 cm^{-1} for 20 K), the frequency in LXe is very close to that in the gas phase (2861 cm^{-1}).

Chesnoy[26] investigated the IR absorption spectra, fluorescence excitation spectra, and fluorescence spectra of HCl in LXe and SXe near the melting point of xenon. The main band and overtone in the excitation spectrum have similar contours: the *Q* branch is present for the liquid phase and absent for the solid phase. However, there are also differences: the rotational structure begins to appear in the overtone for the liquid phase and the *Q* branch for the solution has a lower intensity than in the main band. The author interprets the vibrational spectrum of HCl in LXe by postulating the existence of limitations to the free rotation of HCl and by regarding them as a perturbation. The disappearance of the *Q* branch from the spectrum of the solid solution indicates a high symmetry (the presence of a centre of symmetry) of the immediate environment.

In a more careful study of the band contours of hydrogen halides in liquefied noble gases as well as liquid SF_6, discrete rotational structure of the vibrational bands has been observed not only for the transition $(0 \rightarrow 2)$[26] but also for the fundamental.[27-29] A distinctive structure has been observed in the spectrum of an HF solution in LXe in the experimental temperature range (230–250 K). Numerous rotational components are also present on the wings of the HCl band. The latter become more explicit with increase in the concentration of the solution or in the optical path length. The attempt by the authors[29] to observe the rotational structure in the spectrum of an HCl solution in LAr failed, although the purely rotational absorption was observed for this solution in the long-wavelength IR spectrum.[30] The first resolved lines in both the near and far infrared components of the spectrum of the HCl solution in LKr corresponded to $J = 4$. The frequency shifts of the rotational components as a function of the density of the medium in the purely rotational spectra are appreciably smaller than in the vibrational-rotational spectra, which apparently reflects the contribution by the vibration. The linear variation of the shift as a function of the density breaks down on passing from the gas to the liquid phase, the shift becoming much greater. The widths of the purely rotational bands of HCl in LKr and LXe are 3 cm^{-1},[30] which means that they are several times narrower than the rotational components of the vibrational band.[29] The broadening of the rotational components in LAr is in fact most likely to prevent the manifestation of the fine structure of the spectrum. The results of the above study[29] have shown that the vibrational and rotational relaxation processes, which determine the band widths, exhibit different dependences on the density and that the rate of rotational relaxation increases to a greater extent for densities corresponding to the liquid solvent.

We confined ourselves to describing, as an example, the characteristic features of the spectra of solutions of hydrogen halides and in the following sections we shall also present data on the spectra of solutions of other diatomic molecules: CO, NO, H_2, N_2.

V. SPECTRA OF SOLUTIONS OF POLYATOMIC MOLECULES

1. Infrared Spectra

The rotation of polyatomic molecules such as CO_2, SF_6, etc., placed in cryosolution, is greatly inhibited by collisions with their environment, whilst their rotational movement is best described as diffusion. This results in a considerable narrowing of the vibrational-rotational contour of the band compared with that observed in the gas phase and greatly simplifies the IR spectra. The low temperature of the solutions in the cryosolvents and their great inertness lead to further narrowing of the spectral bands and a decrease in their overlap. This makes it possible to determine not only the frequencies of the principal vibrational transitions but also those of overtones and combination bands. In such solvents, it is also easier to measure the absolute and relative band intensities and isotope effects. At low temperatures, a significantly greater proportion of molecules are in the vibrational ground state, especially in the absence of low frequencies in the spectrum, and the interpretation of the spectrum becomes simpler as a result of the weakening of the bands due to hot transitions. The spectroscopy of cryosolutions of polyatomic molecules is a valuable research technique especially in those cases where the rotational fine structure of the vibrational band cannot be resolved in the gas phase.[12,31] Initially we shall present the results of the study of the IR spectra of solutions of the triatomic linear molecules CO_2, COS, CS_2, and N_2O in cryosolvents,[12] which clearly demonstrates the great possibilities of the method.

The following bands can be observed in the spectra of CO_2 dissolved in LO_2: 665 cm^{-1} (Π_u, ν_2), 2343 cm^{-1} (Σ_u, ν_3), 2277.5 and 3702.5 cm^{-1} (Σ_u, $\nu_1 + \nu_3$) and 3601.2 cm^{-1} (Σ_u, $2\nu_2 + \nu_3$). The weak 2277.5 cm^{-1} band, located near the most intense ν_3 band, corresponds to the isotopic modification $^{13}C^{16}O_2$. The relative intensity of these bands is consistent with the natural abundance of the ^{13}C isotope (1.13%). Since the 3601.2 and 3702.5 cm^{-1} bands are components of the Fermi resonance, the distance between the non-interacting levels $\Delta = 28.4$ cm^{-1} was determined from the ratio of the relative intensities:

$$\nu_1 + \nu_3/2\nu_2 + \nu_3 = \frac{\varkappa + \Delta}{\varkappa - \Delta}$$

($\varkappa$ is the observed distance between the interacting levels); under these conditions, the $10^0 1|W|02^0 1$ perturbation matrix element is 49.1 cm^{-1}, which agrees well with the value obtained for the gas.

The higher solubility of COS in LO_2 made it possible to record almost all the second- and third-order bands corresponding to transitions to non-degenerate levels. Fourth-order bands have also been observed: $4\nu_2$ and $2\nu_1 + 2\nu_2$. At 90 K, it is possible to observe a series of absorption bands in the spectrum of the COS solution which can be attributed to isotopic modifications with the ^{13}C, ^{18}O, and ^{34}S isotopes. The isotopic splittings calculated in terms of the harmonic approximation are close to the observed splittings and the relative intensities agree with the abundances of the isotopes within the limits of the error.

Comparison with the gas phase spectra shows that, on passing to the solution, the vibrational frequencies undergo a bathochromic shift. The maximum shift, reaching 9 cm^{-1} for COS, is observed for the ν_3 stretching vibration bands, which have the highest intensity. The shift of the overtone bands and combination bands is approximately equal to the sum of the shifts of the individual levels. It has been stated[12] that, in determining the anharmonic potential energy terms, the spectra of cryosystems make it possible to obviate the difficulties associated with the separation of the vibrational and rotational motions and the allowance for the vibrational-rotational interactions.

The absolute intensities (integral absorption coefficients) of the $\nu_3(CO_2)$ and $\nu_1(N_2O)$ bands have been measured in the spectra of solutions in LO_2. The observed values $A(\nu_3) = (35 \pm 2) \times 10^{-7}$ cm^2 s^{-1} and $A(\nu_1) = (29.5 \pm 1.0) \times 10^{-8}$ cm^2 s^{-1} do not differ from the data for the gas phase within the limits of the scatter of the literature values. Owing to the smallness of the refractive index of liquid oxygen ($n = 1.22$), the correction of Polo and Wilson, which takes into account the influence of the solvent on the absorption coefficient, is about 10%, i.e. does not exceed the error of the measurements of the band intensities in the spectra of gases.

The data obtained by Bertsev et al.[12] provide for the first time the initial information for a large number of compound and overtone bands essential for a rigorous formulation of the electro-optical problem.

Despite the inertness of LXe, the latter induces the (02^20) CO_2 transition with a frequency of 1324 cm^{-1} as a consequence of its interaction with CO_2.[10]

In connection with the study of the selective action of laser radiation on matter, there has recently been a growth of interest in the determination of data concerning the highest vibrational state of polyatomic molecules.[32] A reliable interpretation of the structure of the IR spectra of CF_3I involves considerable difficulties because of the existence of several low-frequency fundamental vibrations of this molecule. At room temperature, about half of the CF_3I molecules are in excited states, so that a series of bands due to hot $\nu_i \rightarrow \nu_k + \nu_i$ transitions are superimposed on each absorption band. The results of the study of the IR absorption spectrum of a solution of CF_3I in LAr at 90 K in the frequency range 200–4000 cm^{-1} have been published.[33] The frequencies, half-widths, and relative integral intensities of 70 vibrational bands have been determined and interpreted. The doublet in the region of 530 cm^{-1} has been interpreted as due to the Fermi resonance of two vibrational states, ν_5 and $2\nu_6$, which lead in its turn to the appearance of several other Fermi diads, namely ($\nu_5 + \nu_6$, $3\nu_6$), ($\nu_2 + \nu_5$, $\nu_2 + 2\nu_6$), ($\nu_3 + \nu_4$, $\nu_4 + 2\nu_6$) [This should be ($\nu_3 + \nu_5$, $\nu_3 + 2\nu_6$) or ($\nu_4 + \nu_5$, $\nu_4 + 2\nu_6$) (Ed. of Translation)], and ($\nu_2 + \nu_4 + \nu_5$, $\nu_2 + \nu_4 + 2\nu_6$). For the pairs of states enumerated above, the matrix elements of the interaction depend on the same cubic constant K_{566} in the expansion of the potential energy of the molecule in series in terms of the normal coordinates, the average value of the constant being $K_{566} = 9.0 \pm 0.1$ cm^{-1}. The resonance of the four fully symmetrical states ν_1, $2\nu_5$, $\nu_5 + 2\nu_6$, and $4\nu_6$, the matrix elements of the interaction of which are determined by the two cubic constants K_{566} and K_{155}, has also been observed. The cubic constant $K_{155} = 4.6$ cm^{-1} has been estimated. Certain anharmonicity constants have been found from the vibration band frequencies with a unique interprettion (in cm^{-1}): $X_{22} = -0.2$; $X_{23} = -1.6$; $X_{33} = -1.0$; $X_{24} = -6.3$; $X_{34} = -0.2$; $X_{25} = -1.0$; $X_{36} = -0.3$; $X_{26} = -0.5$; $X_{44} = -6.8$; $X_{56} - g_{56} + r_{56} = -3$; $X_{66} = 0.7$; $g_{66} = 0.2$; $g_{44} = 4.1$; $X_{46} + g_{46} = -0.9$. The analysis of the CF_3I spectrum at a low temperature led to the conclusion that the real band structure of the gas phase at room temperature is very complex. The spectrum in the region of the $\nu_1(CF_3I)$ vibration, in resonance with the radiation of the CO_2 laser with the aid of which it is possible to perform the selective dissociation of CF_3I with formation of the CF_3 radical is of special interest. The results of the study of Bulanin et al.[33] have shown that the number of energy states involved in the anharmonic interaction

increases rapidly with increase in the quantum number v_1 and, furthermore, transitions to degenerate states, among which the $v_1 + 2v_5$ transition should be the source of the intensity, are superimposed on the same region. Thus the strong interaction of the v_1, v_5, and v_6 vibrational modes combined with the low anharmonicity constants leads to the formation in the CF_3I spectrum of energy zones with a high density of states, promoting an effective excitation of this molecule by the laser radiation up to the dissociation limit.[33] The IR absorption spectra of $^{12}CH_4$ and $^{13}CH_4$ in solution in LAr have been interpreted similarly.[34]

The simultaneous IR transition, arising from $v_3(SF_6)$ and the fundamental O_2 vibration in SF_6 solution in LO_2 at 78 K, has also been observed.[35] The frequency of the 2490.6 cm^{-1} band is independent of the SF_6 concentration, while the absorption coefficient and the band half-width increase linearly with increase in the SF_6 concentration. The calculated frequency, obtained by adding together $v_3(SF_6)$ and the intrinsic frequency of O_2, is 2492.1 cm^{-1}. The observed value differs somewhat from the calculated ones since the latter are based on binary interactions and the low gas pressure limit, which are not fully legitimate for solutions in liquids.

The spectra of not only organic but also organometallic compounds in cryosolvents have been interpreted.[36] The structure of a molecule such as $Ru(CO)_5$ has not been reliably established from the IR spectra either in solution in n-hexane or on matrix isolation of solid N_2 even in the study of the ^{13}CO-enriched compounds, since the IR spectrum of the solution always consists of two broad bands and the complex character of the spectrum of the matrix-isolated $Ru(CO)_5$ is due to the matrix splitting. The IR bands of the $Ru(CO)_5$ dissolved in LXe at -60 °C are narrowed. Thus $v_{1/2}$ for the a_2'' band of the solution in LXe is 2.0 cm^{-1}, while that of the solution in n-hexane is 6.8 cm^{-1}. In the IR spectrum of $Ru(CO)_5$ enriched in ^{13}CO to the extent of 26.5%, 16 bands have been observed. The monosubstituted specimen, containing ^{13}CO in the equatorial position, should have the comparatively low C_{2v} symmetry and all its bands should be resolved in the IR spectrum. Gregory et al.[36] assigned the following bands to this isotopic specimens: a_1—2120.7 cm^{-1}, b_2—2038.9 cm^{-1}, a_1—2032.2 cm^{-1}, b_1—2001.6 cm^{-1}, and a_1—1964.0 cm^{-1}. The overall character of the $Ru(CO)_5$ spectrum is fully consistent with the D_{3h} molecular symmetry. The presence of 16 frequencies made it possible to determine all the force coefficients of $Ru(CO)_5$ (in N m^{-1}): K_{ax} = 1728.38; K_{eq} = 1653.28; $K_{ax,eq}$ = 27.57; $K_{eq,eq}$ = 34.82; $K_{ax,ax}$ = 48.09. The band intensities in the spectrum of $Ru(CO)_5$ in LXe have been calculated in terms of the local C—O dipole approximation, the results being in good agreement with experiment. The spectrum of ferrocene in solution in LXe has been interpreted similarly.[37]

Holland et al.[9] published IR spectra demonstrating the isotopic splitting of the BCl_3, SeF_6, OsO_4, MoF_6, and $TiCl_4$ bands in solid solutions and carried out a comparison of the results obtained in sputtered matrices, in the gas phase, and in liquid solutions. As an example, we may quote the data for BCl_3. In SKr (116 K) and SAr (84 K), the BCl_3 spectrum contains narrow bands of the split v_3 vibration and the doublet due to the degenerate v_3 vibration, which can be unambiguously assigned to $^{10}B^{35}Cl_3$ (983.2 and 985.6 cm^{-1}) and $^{11}B^{35}Cl_3$ (944.6 and 947.0 cm^{-1}) respectively. The frequencies of these bands decrease with decrease in temperature by approximately 0.04 cm^{-1} K^{-1} and can readily coincide with the CO_2 laser lines in the study of its selective action on BCl_3. Comparison with the gas phase spectrum indicates a much greater information content: $v_3(^{11}BCl_3)$ has 7 components in the solid phase and only two in the gas phase.

2. Ultraviolet Spectra

The influence of the solvent on the UV spectrum of the molecules has been demonstrated in relation to the $^1\Sigma_g^+ \leftarrow {}^1\Sigma_g^+$ absorption band of carbon disulphide in four solvents.[38] Compared with the solution in LAr, the band in LN_2 has undergone a hypsochromic shift by 75 cm^{-1} and the maximum of the continuous background envelope reaches 40% of the band maximum (instead of the 30% for the solution in LAr at the same temperature); consequently the vibronic maxima are broadened to a greater extent. The pattern for the solution in LXe is completely different: the band is very diffuse and its maximum has undergone a bathochromic shift by 1200 cm^{-1} and is located in approximately the same position as for the solution in hexane at room temperature. The complete disappearance of the vibronic structure in solution in hexane and its partial retention in LXe are noteworthy. This explains the possibility of the selective action of UV radiation on certain molecules dissolved in LXe and other elemental liquefied gases but not in molecular liquids. Clearly, from the standpoint of selectivity, LAr and LN_2 are preferable to LXe.

The vibronic structure of bands in the spectra of solutions in liquefied elemental gases is not retained for all molecules. Thus, on passing to the condensed phase, the vibronic band structure in the spectrum of acetone in the region of 195 nm becomes completely diffuse, the band positions being virtually the same in LAr, LXe, and hexane. Marked broadening of the vibronic components also occurred after the addition of gaseous Ar at a pressure of 130 atm. Such behaviour of the 195 nm acetone band shows that the upper state of this transition is mixed: Rydberg orbitals are also involved in it. Overall, the use of cryosolutions for the investigated $\pi \rightarrow \pi^*$ and $n \rightarrow \pi^*$ bands for a large series of compounds makes it possible to improve significantly the resolution of the fundamental vibrational structure.[39] On the other hand, although most of the structure characteristic of the gas is retained in the UV spectrum of OsO_4 solution in LXe,[23] it is also retained in other solvents (Ar, Kr, N_2O, CH_4, C_5H_{10}, CF_4, CF_3Cl, and BF_3). The frequencies of the band maxima are displaced by 2—10 nm compared with the spectrum of the gas phase, the shift depending on the type of solvent.

Fine structure has not been observed in the UV spectrum of CH_2O in the vapour phase, and the width of the spectral bands for the cryosolution is somewhat greater. Nevertheless, the UV spectrum of the CD_2O solution shows a major isotope shift compared with CH_2O used for the photolytic isotope separation.[23]

The vibronic structure of the ^1L_b absorption band of benzene dissolved in liquefied Ar (from 138 to 148 K), CF_4 (from 151 to 190 K), and Kr (from 122 to 160 K) has also been investigated.[40] Since the vibronic components of the band in the argon and Freon solutions are fairly narrow, while the majority of the "hot" transitions are frozen, it is possible to carry out a detailed analysis of the vibrational band structure and to refine the assignment of certain vibronic components.

VI. SPECTRA OF SOLUTIONS OF MOLECULAR COMPLEXES

The low temperature which can be attained in liquid elemental gases should permit the observation, under the conditions of infinite dilution, of the association of molecules which does not occur under

the usual conditions because the initial components are gases and the complex formation constant is small. The high inertness of liquefied noble gases is of decisive importance for the synthesis of weak complexes. The interaction of dissolved molecules with the environment under these conditions is significantly weaker than in traditional solvents. Naturally the components of the complex must dissolve effectively in the cryosolvent. By selecting the concentrations of the initial molecules, it is always possible to achieve a situation such that the equilibrium in the complex formation process can be observed under the experimental conditions and by altering the temperature its influence not only on the spectroscopic characteristics but also on standard thermodynamics can be determined.

The first study of this kind[41] dealt with the investigation of the system comprising $CHF_3(CDF_3)$ and $N(CH_3)_3$ in LAr and LKr. When the amine was added to the CHF_3 solution, the intensity of the ν_1 (3038 cm^{-1}) and ν_4 (1373 cm^{-1}) bands diminished and the bands disappeared in the presence of a large excess of the amine and were replaced by two other bands, at 3016 and 1404 cm^{-1}, which are associated with the corresponding vibrations in the hydrogen-bonded complex (HBC). The equilibrium constants of the association process in the temperature ranges 90–130 K for LAr and 120–160 K for LKr as well as the thermodynamic parameters $\Delta H^0 = 3.5 \pm 0.2$ kcal mol^{-1} and $\Delta S^0 = 15 \pm 2$ cal mol^{-1} K^{-1} were determined from the integral intensities of the ν_1 and ν_4 bands for CHF_3 and the ν_1 band for CDF_3. We may note that in the matrix isolation method the frequencies of the complex frequently cannot be obtained and the equilibrium cannot be observed. Studies on the HBC in cryogenic solutions have been prosecuted in two directions. The first[42,43] dealt with the study of the parameters of the bands of weak complexes which as a rule do not exist under the usual conditions. By virtue of the inertness of the liquefied noble gases, interactions which occupy an intermediate position between typical van der Waals interactions and a weak hydrogen bond can be studied in them. In the second direction,[11,43] the influence of the cryogenic solvent on the spectroscopic characteristics of moderately strong HBC, whose spectra are known both in the gas phase and in a traditional solvent, was investigated.

The results of measurements of the HCl, DCl, and HBr spectra in mixed solvents consisting of LAr with added N_2 or CO have been described.[42,44] In these systems, a narrow symmetrical band appears against the background of the broad band characteristic of solutions of hydrogen halides HX in LAr (see Section IV). The narrow band was assigned to the complexes of hydrogen halides with N_2 or CO, the intensity of the bands due to the free HX molecules decreasing with increase in the N_2 and CO concentrations. Thus, whereas HCl in LAr has a band at a frequency of 2869 cm^{-1} with a half-width of ~ 100 cm^{-1}, for the $HCl-N_2$ complex the frequency is $\nu = 2864$ cm^{-1} and $\nu_{1/2} = 11$ cm^{-1} and for the HCl–CO complex the frequency is $\nu = 2835$ cm^{-1} and $\nu_{1/2} = 9$ cm^{-1}. The narrowing of the HX bands has been explained by the rotation being hindered due to the greater moment of inertia in the complex. Complex formation influences the spectra of the molecules in the gas phase in a similar manner. The spectral parameters show that the interaction of the above diatomic molecules is local. The interaction between CCL_4 and HCl in LXe and LKr turns out to be similar. A narrow band appears in the IR spectrum at ~ 2840 cm^{-1} and it may be that it is in fact the local interaction which determine the contour of the HCl band in liquid CCl_4.[44]

Wek complexes of proton donors such as HBr, HF, $HC\equiv CH$, $CH_3C\equiv CH$, and HCN have also now been investigated.[45,46] the same behaviour has been observed as for the HCl complexes.

The complexes of olefins with HCl were classified as thermally unstable systems or systems unstable as regards their reaction (for example, with isobutene). Cooling to LN_2 temperatures makes it possible to investigate these complexes either as a result of suppressing the reaction or due to a sharp increase in the complex formation constant. The shift of the HCl bands on going from the complex with eithylene to that with trimethylethylene increases from 100 cm^{-1} to 260 cm^{-1}.[47,48] If the first can be assigned to weak HBC, then the second is due to moderately strong HBC. Together with the bathochromic band shift, another property of the band due to the HCl in the HBC is its higher intensity, by more than an order of magnitude compared with free HCl. The complex formation constants were determined at 77 and 95 K. The ΔH were calculated for this temperature range from the van't Hoff equation (Table 1). It was found that the experimental results satisfy well the relations between ΔH and $\Delta A^{1/2}$ and between ΔH and $\Delta\nu$, especially the latter. Thus the spectroscopic characteristics observed in the complex formation process make it possible to classify the complexes between HCl and olefins as typical HBC and to conclude that the interaction proceeds via the hydrogen atom. The entropy ΔS of complex formation amounted to 11 cal mol^{-1} K^{-1}. These characteristics of the olefin–HCl complexes in solution in LN_2 were found to be close to those obtained later[49] in solution in LAr: ν(HCl) = 2774 cm^{-1}, $\nu_{1/2} = 15$ cm^{-1}, and $\Delta H = 1.5 \pm 0.1$ kcal mol^{-1} for C_2H_4-HCl, ν(HCl) = 2732 cm^{-1} and $\nu_{1/2} = 20$ cm^{-1} for C_3H_6-HCl, and $\nu = 2679$ cm^{-1} and $\nu_{1/2} = 28$ cm^{-1} for C_4H_8-HCl. The HCl frequency is also somewhat higher for the solution in LAr compared with that in LN_2 and the band half-width is somewhat smaller.

Table 1. Parameters of the IR spectra and the enthalpies of complex formation for HCl–olefin systems in solution in liquid N_2.[47]

Proton acceptor	ν, cm^{-1}	$\Delta\nu$, cm^{-1}	$\nu_{1/2}$, cm^{-1}	$10^{-4}A$, litre mol^{-1} cm^{-2}	K_p(77 K), litre mol^{-1}	K_p(93 K), litre mol^{-1}	ΔH, kcal mol^{-1}		
							authors data (Ref. 47)	calc. from ΔA	calc. from $\Delta\nu$
—	2870	—	—	0.4	—	—	—	—	—

The data for complexes of HCl with olefins in solution permit a more correct comparison of the electron-donating properties of olefins and aromatic compounds, especially since the frequency of HCl (2685^{-1}) in the complex with hexamethylbenzene was determined in solution in LXe.[50] Comparison of the frequencies of the complexes with trimethylethylene and hexamethylbenzene shows that the decrease in frequency for the olefin is greater despite that the fact that its ionisation potential is higher (8.67 eV) than that of hexamethylbenzene (7.85). An intermediate case obtains for complexes of ferrocene and its methyl derivatives with HCl.[3]

Whereas the small width of the band of HCl in the weak C_2H_4-HCl complex is understandable, the fact that the band of the moderately strong $(CH_3)_2=CHCH_3-HCl$ complex remains narrow despite its significantly greater shift is unusual. This result led to the hypothesis that the marked broadening of the stretching vibration bands of the XH bond, observed in traditional solvents, is

not a universal property of the hydrogen bond but depends on the nature of the solvent. A study was therefore made in LKr and LXe of a series of HBC whose parameters were known for traditional solvents.

We selected the $CH_3CN-HCl$ complex as the principal object of study because of its adequate stability and high symmetry.[51] According to literature data, the HCl band half-width for the solution of this complex in CCl_4 is 275 cm^{-1}, while for the solution of HCl in CH_3CN it is 350 cm^{-1}. On the other hand, the spectrum of the gas phase complex consists of the principal HCl band with a half-width of 100 cm^{-1} and a weaker difference band, separated from the principal band by ~ 100 cm^{-1}. The band half-width for the HCl in the complex was estimated as ~ 70 cm^{-1} in solution in LXe ($T \simeq 165$ K) at HCl and CH_3CN concentrations of 3×10^{-4} and 6×10^{-3} M respectively,[51] i.e. much lower than in solution in CCl_4 and somewhat lower than in the gas phase. An even smaller value of $\nu_{1/2}$ (HCl) = 40 cm^{-1} has been obtained by Muradov and Tokhabze for $CH_3CN-HCl$ in solution in LXe.[44] The study of this complex in LKr showed that the HCl band becomes narrower ($\nu_{1/2} \simeq 35$ cm^{-1}) at the same temperature (165 K) and that cooling of the solution in LKr from 165 to 130 K leads to further narrowing of the band to 30 cm^{-1}. These data have been confirmed.[44] Thus cooling (from 290 to 130 K) and the change of solvent (from CCl_4 to LKr) narrowed the ν(HCl) band for the $CH_3CN-HCl$ complex by an order of magnitude. Previously this effect was not known. Subsequently, using CD_3CN and higher concentrations of the $CD_3CN-HCl$ complex,[11,43] it was possible to obtain for the solution in liquid Xe the overall and difference ν(HCl) $\pm$ ν_σ frequencies, where ν_σ is the frequency of the stretching intermolecular vibration of the hydrogen bond. This is a consequence of the narrowing of each band.

Table 2. The frequencies and widths of the ν(OH) bands of the binary hydrogen-bonded complexes in various media.[53]

In order to discover how general is the narrowing of the ν(XH) band on passing to an atomic solvent, a study was made[52] of a large number of heterocomplexes of methanol, trifluoroethanol, and perfluoro-t-butyl alcohol and their deuterio-derivatives with representatives of various classes of bases—olefins (C_3H_6), nitriles (CH_3CN), ethers [$(CH_3)_2O$], sulphides [$(CH_3)_2S$], ketones [$(CH_3)_2CO$], and amines [$(CH_3)_3N$] in solution in LXe and LKr in the temperature range 120–270 K. The ν(OH) frequency shifts from 70 to 500 cm^{-1} compared with the free alcohol, i.e. both weak and moderately strong complexes were investigated. Comparison with literature and own own[53] data shows that the ν(OH) band widths for the complexes of these alcohols in solution in the usual molecular solvents are greater by a factor of between 2 and 4 than in the atomic solvent at the same temperature (Table 2). On the other hand, the ν(OH) band widths of a gas-phase complex and the complex in LXe are approximately the same. Furthermore, the ν(OH) band widths of the complexes in solution in LXe and LKr are virtually the same in the same temperature range, which implies that the difference between the macroscopic parameters of the atomic solvents has little influence on the band width.

The influence of the solvent on the ν(OH) frequency is noteworthy: for all the complexes investigated, the frequency in LXe at 250–270 K is lower by 40–70 cm^{-1} than in the gas phase and higher by 30–40 cm^{-1} than in solution in CCl_4. In LKr, the ν(OH) frequency is higher by 10–20 cm^{-1} than in LXe at the same temperature.

The parameters of the ν_σ band, due to the intermolecular vibration of the (A...B) hydrogen bond itself, which is located in the far infrared, have also been investigated for a series of complexes of HCl with fluoro-alcohols in LXe and n-pentane at identical temperatures (165–250 K).[54,55] The band width proved to be ~ 30 cm^{-1} and was independent of the type of solvent. Such different types of influence of the atomic solvent on the ν(XH) and ν_σ band widths can be described by the theory developed by Sakun.[56] According to this theory, the broadening of the above band is due to different factors. The ν_σ band is formed under the influence of the oscillatory component of the motion of the A...B bond, while the width of the ν(XH) band and its structureless character are determined by the dissipative component of the A...B mode. The approximate equality of the ν(XH) band widths of the HBC in liquid noble gases and in the gas phase at similar temperatures indicates a weak interaction of the HBC with the atomic solvent. Presumably, in the atomic solvents, as in the gas phase, the ν(XH) band width is determined mainly by the contribution of the "hot" transitions of the ν_β deformation vibration. The principal difference in band shape should be the "smearing out" of the fine structure of the spectrum by the solvent. A decrease in temperature in LXe and LKr leads to the partial freezing out of the "hot" transitions and a decrease in their contribution to the ν(XH) band width with a temperature contaction coefficient of 0.1–0.3 cm^{-1} K^{-1}. More intense cooling, which is attainable in the matrix isolation method, leads to the almost complete freezing out of the "hot" transitions and in certain cases to a sharp narrowing of the band. For example, the width of the ν(OH) band of the complex of perfluoro-t-butyl alcohol with acetonitrile in the Ar matrix is only 10 cm^{-1}.[57] The observed temperature-induced shift of the ν(OH) band of the HBC investigated in LXe and LKr is 0.1–0.3 cm^{-1} K^{-1} and can be caused by a change in the contribution of the "hot" transitions as a result of cooling and hence a redistribution of the intensities within the limits of the band. the presence of the narrow ν(OH) and ν(OD) bands in the spectra of the series of complexes investigated made it possible to measure with a high degree of accuracy the isotope ratio, whose value for both weak and moderately strong HBC proved to be approximately equal to that for the free alcohol. The results obtained show that the isolated HBC do not exhibit an anomalously high anharmonicity. It is noteworthy that narrow ν(XH) bands are not always obtained in LXe and LKr, fairly broad bands remaining in the spectra of the complexes of acetone[50,52] and polymeric methanol.[50,58] Their width

can apparently be accounted for either by the presence of complexes of different composition or by their different structures.

The presence of a narrow ν(XH) band in the spectrum of the LXe solution made it possible to consider the problem of the site of coordination of HCl or perfluoro-t-butyl alcohol in complexes with a series of metallocene derivatives ranging from ferrocene to decamethylferrocene.[3,59] In principle, there is a possibility of coordination of both to the ring and to the metal atom. In both cases, the presence of only one ν(XH) band, displaced to lower frequencies, indicates the formation of a hydrogen-bonded complex of one type. the values of Δν and Δν for the interaction of ferrocenes with $(CF_3)_3COH$ are somewhat higher than for the interaction with HCl owing to the somewhat greater proton-donating capacity of the alcohol. In view of the similarity of the results for the HCl complexes with ferrocene,[3] olefins,[42,47] and aromatic compounds,[50] one can assume that the hydrogen bond is formed with the cyclopentadienyl ring and not with the metal atom. The same type of coordination is characteristic of the $(CF_3)_3COH$ complexes.

For carbonyl-containing cyclopentadienyl metal complexes, there are as many as three possible centres for the formation of a hydrogen bond: the π-ligand, the metal atom, and the oxygen atom of the CO group. When $(CF_3)_3COH$ is added to a solution of $CpMn(CO)_2$. .$P(iso\text{-}Pr)_3$ in LXe at 180 K, a band appears at 3415 cm^{-1}, indicating the formation of a HBC, in addition to the 3590 cm^{-1} free alcohol band.[60] The identification of the type of coordination was made on the basis of the changes in the region of the CO vibrations. The IR spectrum of a solution of $CpMn(CO)_2P(iso\text{-}Pr)_3$ in LXe contains bands at 1935 and 1873 cm^{-1}, while in the spectrum of its complex with alcohol the bands are shifted to 1931 and 1835 cm^{-1}. On the basis of the bathochromic shift of ν(CO), Lokshin et al.[60] concluded that the oxygen atoms of the carbonyl groups are involved in the hydrogen bond. When the spectrum at 180 K was subtracted from the spectrum at 165 K, two further bands become visible at 1906 and 1832 cm^{-1}; they have been assigned to a 1:2 complex in which two alcohol molecules interact with both CO groups.

Low temperatures make it possible to study also the intermolecular interaction of simple molecules, for example, those of NO and NO_2, in LXe.[13,61] In addition to the band due to the free molecule, a band at 1762 cm^{-1}, due to $(NO)_2$, appears in the spectrum of the NO solution and a band at 3594 cm^{-1} has been assigned to a combination band of the dimer. The authors were unable to conclude which form, *cis*- or *trans*-, of ON−NO exists in LXe. When NO_2 was dissolved in LXe, N_2O_4 bands were clearly manifested: at 375, 422, 743, 1251, and 1742 cm^{-1}; a large number of bands due to the combination vibrations of N_2O_4 were also observed. The authors suggest that only a planar conformation of N_2O_4 with D_{2h} symmetry exists in LXe between 163 and 233 K. One of the bands, at 1813 cm^{-1}, may be due to the asymmetric form $ONONO_2$, which has been identified in the IR spectrum of solid N_2O_4. According to spectroscopic and photolytic data, N_2O_3 exists in the form of two isomers: $ONNO_2$ and ONONO. In the spectrum of the solution of NO and NO_2 in LXe, the IR bands of the asymmetric N_2O_3 form can be clearly identified: at 244, 411.5, 768.6, 1294, 1625, and 1829 cm^{-1}. The situation with *sym*-N_2O_3 is less clear. The 375 and 1687 cm^{-1} bands clearly refer to this species and possibly also the weak 965 cm^{-1} band. The fractions of the isomers were determined from the temperature dependence of the bands. The difference between the energies of *symm*- and *asymm*-N_2O_3 was calculated: $\Delta H = 1.8 \pm 0.2$ kcal mol^{-1}.

The formation of HBC between benzene and CHF_3 in LKr has also been studied by UV spectroscopy.[62] The measurements were based on the longest-wavelength, the so called ^1L_b band due to the ππ* transition of benzene located in the region of 255 nm. In cryosolutions, the ^1L_b band has fairly pronounced vibronic structure, which makes it possible to study individual vibronic components. For the HBC with benzene, quantitative data have been obtained in the region of the σ_0^1 transition, the band undergoing a hypsochromic shift relative to the band of monomeric benzene on formation of the complex. Heating of the HBC solution in LKr from 120 to 180 K increases the band half-width from 140 to 240 cm^{-1} and decreases the distance between the maxima of the bands of the monomer and the HBC from 240 to 120 cm^{-1}. The enthalpy of complex formation has been determined as 2.0 kcal mol^{-1} from the temperature variation of the equilibrium constant.

VII. NON-LINEAR ABSORPTION OF INFRARED RADIATION AND STIMULATION OF CHEMICAL REACTIONS IN CRYOSOLUTIONS

The influence of vibrational excitation on the reactivity of molecules is nowadays being vigorously investigated. As mentioned in the previous Sections, the use of cryosystems greatly simplifies the form of the spectrum by virtue of the suppression of the hot transitions and the temperature changes are also reduced to a minimum on vibrational excitation as a consequence of the high specific heat of the condensate. The measurement of the populations of various vibrational states is thereby facilitated.

The possibility of carrying out chemical reactions, stimulated by laser radiation, in solutions is of independent interest, since it is possible to establish a higher density of molecules in solution than in the gas phase at the same temperature.

Burtsev and Bulanin[63] investigated the characteristic features of the non-linear absorption of the IR radiation from a CO_2 laser ($\nu = 936.8$ cm^{-1}) in a solution of SF_6 in LKr (at 140 K) in order to estimate the time τ of the V−T relaxation of $\nu_3(SF_6)$ in the cryosystem. Within the framework of the approximations adopted, $\tau = 9$ ns was obtained. In a subsequent study,[64] the same workers used much higher intensities of the laser radiation. An extremely strong saturation of the test solution was observed; for example, at $I_0 = 1.5$ MW cm^{-2}, the transmittance of the specimen increases by a factor of 2×10^3 compared with the transmittance in a weak field. The formalism of the two-level model now no longer ensured a complete agreement with experiment and a model based on a three-level scheme was used to interpret the experimental data. A somewhat shorter vibrational relaxation time of SF_6 was obtained: $\tau \simeq 3$ ns. In the same study, the influence of extraneous substances on the relaxation of SF_6 was investigated. The introduction into the cryosystem of several mole per cent of a molecular admixture has an appreciable influence on the saturation of the absorption, although it does not affect either the position or the width of the SF_6 absorption band. The following relaxation times have been obtained in the presence of additives: 0.15 ns for O_2, 0.06 ns for CH_4, and 0.01 ns for NO. The fast relaxation in the case of NO has been explained by the appearance of low-lying acceptor levels as a result of the dimerisation of NO in the cryosystem.

The SF_6 molecule has also been investigated in liquid O_2 and Ar.[65,66] The V−T relaxation time of SF_6 is ~37 ps in LO_2 and ~160 ps in LAr.

Bertsev and Burtsev[67] chose the ozone molecule as the object of investigation, which is a suitable candidate for carrying out vibrationally-activated reactions in low-temperature condensed

systems. Solutions of O_3 in LAr and LO_2 were investigated at temperatures in the range 90–100 K: τ is ~100 ns in LAr and ~40 ns in LO_2. The result obtained was compared with vibrational relaxation data for O_3 in the gas phase, where the ratio of the efficiencies of Ar and O_2 as deactivators of the (001) state of ozone is known to be ~1:3. The populations of the vibrational states of O_3 were estimated for a specified level of pumping on the assumption that direct V–T relaxation of the (001) level is unlikely and that this state is deactivated stepwise:

$$(001) \xrightarrow{\tau_1} (010);\ (010) \xrightarrow{\tau_2} (000)\ .$$

As a result, it is possible to attain an appreciable population of the excited vibrational level of the O_3 molecules (up to 0.4) and the systems investigated are thus found to be potentially suitable for carrying out reactions involving vibrationally excited molecules in the condensed phase.

In one of the first investigations,[68] a study was made of the relaxation of the vibration of CH_3F in LAr and LO_2 from the saturation of the IR absorption and also experiments were performed on double IR–IR resonance, yielding directly the V–T relaxation time. Thus induced absorption at 1021.2 cm^{-1}, due to the $\nu_3 \rightarrow 2\nu_3$ transition, is observed in the experiment by the double IR resonance method with pumping by radiation at a frequency of 1037.4 cm^{-1}. As for O_3, the CH_3F relaxation time in LAr (1.30 μs) is several times greater than in LO_2 (375 ns) and probability of the V–T transition in the cryosystem is only an order of magnitude higher than in the gas phase for systems of the same type.

Thus the hot transition in the SF_6 spectrum in LKr at 140 K has also been observed by the double IR resonance method.[69] The maximum of this "hot" absorption is displaced by –4.5 cm^{-1} relative to ν_0, the V–T relaxation time of the $\nu_3 = 1$ level is ~3 ns, and the population of this level reaches 0.7. The absorption observed from the excited vibrational level[69] is more suitable for the study of the anharmonic structure of the $\nu_3 \geqslant 2$ states than the diffuse pattern characteristic of the gas phase. The calculation for the transition

$$v_3 = 1\,(F_{1u}) \rightarrow v_3 = 2\,(A_{1g},\ E_g)$$

shows that the anharmonic constants are $X_{33} = -1.2$ cm^{-1}, $G_{33} = 0.53$ cm^{-1}, and $T_{33} = -0.27$ cm^{-1}. According to the authors, the results show that the inversion of the populations does really occur in the optical pumping of cryosystems.

Experiments of another type have been performed with excitation of the N_2 vibrational mode with the aid of an HBr laser. The relaxation of the vibrational energy was followed from the fluorescence of the CO impurity molecule.[65] In the limit reached on decreasing the CO concentration, the relaxation time constant characteristic of pure LN_2 was obtained: ~0.018 s^{-1}. Overall, the rates of collision-induced vibrational deactivation in liquid CO–N_2 mixtures are low and the radiation-induced decomposition processes predominate as vibrational energy is lost in solution. The principal result of these measurements is that, at least for the system investigated, the kinetics of the vibrational exchange in simple cryogenic liquids do not differ greatly from those in a dilute gas; the rate constants measured in the gas phase can be simply extrapolated to the density of the liquid phase without any significant correction. Lupo et al.[70] reached an analogous conclusion having measured the rate constant for energy transfer from CO to O_2 in LAr in the temperature range 86–145 K:

$$CO(v=1) + O_2 \rightarrow CO + O_2(v=1) + \Delta E,$$

where $\Delta E = 589$ cm^{-1}. The rate constant for the quenching of the CO fluorescence in the above temperature range is higher by a factor of ~3 but remains equal to values for the gas phase within the limits of experimental error. The vibrational relaxation of CO in the presence of CH_4, CD_4, and CF_4 is several times faster than both for the solution in LAr and for the gas phase.[71] In the absence of impurities, the V–T relaxation in the CO solution in LAr is not the dominant process, the purely radiation-induced relaxation with a lifetime of 18 ns predominating.[72] With increase in CO concentration, the radiation was reabsorbed and the lifetime increased to 1 s. Isotope-enriched carbon monoxide (88% $^{13}C^{16}O$, 12% $^{13}C^{18}O$) in LAr has been optically pumped to the $v = 1$ level by means of a continuous CO laser.[73] As a result of the collision-induced redistribution of energy, some of the molecules were excited to higher vibrational states; fluorescence was recorded from vibrational levels up to $v = 20$ and the inversion of the populations of the level was noted.

A transition from an excited vibrational state to an excited electronic state is not ruled out either. When matrix-isolated $^{13}C^{18}O$ in Ar was irradiated by a colour-centre laser, the frequency of the radiation of which coincided with the first overtone of the CO band, fluorescence was observed in the visible and UV part of the spectrum.[74]

Overall, by virtue of the relatively slow V–T relaxation in solutions in liquefied monatomic gases, a high population (tens %) of the excited vibrational states of the impurity diatomic molecules in cryosolutions is readily attained. However, it seems unlikely that multiphoton IR excitation should occur in polyatomic molecules dissolved in cryogenic liquids. SF_6 dissolved in LAr, LO_2, and LN_2 has been irradiated[66] by a CO laser using a power much greater than that employed in multiphoton experiments in the gas phase, but no traces of dissociation were observed.

Processes in which single-photon IR excitation can increase the rate of reaction between an excited molecule and other molecules in the cryogenic solution are of interest. Such a process has apparently been discovered. The reactions of ozone with NO in the cryosystem stimulated by IR radiation have been investigated.[75] Preliminary experiments showed that the solutions of O_3 in NO at temperatures in the range 130–160 K are fairly stable. The character of the spectrum shows that the formation of a complex between NO and O_2 cannot be ruled out.

When the solution is irradiated by a CO_2 laser ($\lambda = 9.5$ μm), the concentration of excited O_3 molecules is about 10%. It was established that the irradiation leads to a rapid loss of O_3 from the solution: after 20 pulses, the O_3 concentration decreased by 30–50%, which corresponds to a quantum yield of the order of 3×10^{-2} molecules per photon under the experimental conditions. This result demonstrates the real occurrence of the stimulation of a reaction in cryosystems by IR radiation.

In a two-step IR–UV isotope separation process, an IR photon can be used to excite selectively the vibrational state of one of the isotope-substituted derivatives, while a UV photon can lead to the dissociation of vibrationally excited molecules. The possibility of marking molecules with the aid of an IR photon and then of the excitation of only the marked molecules by another photon has been demonstrated in measurements of double IR–IR resonance (see above).[65,69]

VIII. PHOTOCHEMICAL REACTIONS IN CRYOSOLUTIONS

The transparency of cryosolvents in the UV region facilitates photophysical studies and the weak interaction of the molecules with the solvent makes it possible to investigate molecules virtually in a free state. On exposure to a picosecond pulse (λ = 505 nm), predissociation of I_2 in LXe ($\tau \simeq 14$ ps) and the subsequent primary recombination ($\tau \simeq 40$ ps) were observed.[22] As a result of the photoexcitation of HCl in LXe (λ = 193 nm), IR fluorescence of HCl from the $v = 1$ state was noted.[76] The formation of vibrationally excited HCl molecules as a result of triple collisions of H and Cl atoms with Xe is the most probable. Emission by HCl from the $v = 2$ level appears[77] in SXe and the rate of relaxation from the $v = 1$ level diminishes. Both these effects have been attributed to the loss of mobility by HCl in the solid phase and the consequent decrease in the intensity of the interactions between the HCl molecules. It has also been shown[78] that the rate constant for the deactivation of DCl is smaller than that for HCl. It has been suggested that the rotational degrees of freedom also play a role in the vibrational relaxation of molecules in the liquid phase.

Photochemical reactions have been studied systematically by Turner and Poliakoff[2] using cryostats described previously.[9,13] Oskam's group[79,80] has been working on the same lines. The interaction of the environment in a solid matrix with the complex $Cr(CO)_5$ obtained on UV photolysis of $Cr(CO)_6$ had been investigated earlier from the position of the absorption band of the pentacarbonyl complex in the visible part of the spectrum.[81] For a series of matrices (CH_4, Xe, Kr, Ar, CF_4, SF_6, and Ne), the absorption band shifts from 480 to 640 nm. The magnitude of the shift shows that no solvent is completely inert towards $Cr(CO)_5$ and that the influence of trace impurities may be important in photochemistry.[82]

The first experiments in cryogenic solutions were performed in order to obtain complexes of metal carbonyls with N_2.[83] A band at 2236 cm^{-1}, associated with the $\nu(N-N)$ vibration, has been clearly observed in the IR spectrum of $Cr(CO)_5N_2$. A careful study[84] demonstrated that more prolonged photolysis of $Cr(CO)_6$ in LXe at a higher N_2 concentration makes it possible to obtain species with a higher N_2 content. Narrow-band photolysis at 367 nm in a solution in LXe containing N_2-substituted $Cr(CO)_{6-x}(N_2)_x$ complexes decomposes certain compounds while leaving others comparatively unaltered. At the same wavelength (corresponding to $d-d$ transitions), different isomers have markedly different absorption intensities and respond differently to irradiation. Thus the *cis*- and *trans*-isomers of $Cr(CO)_4N_2$ and the *mer*- and *fac*-isomers of $Cr(CO)_3(N_2)_3$ have been clearly separated. The introduction of additional N_2 molecules reduces the thermal stability of the complexes; it has not been possible to identify the $Cr(N_2)_6$ complex at −79 °C in solution in LXe.

Using a cell with four windows, Maier et al.[85] were able to obtain the IR spectra of the very unstable compound $Ni(CO)_3N_2$ as a result of the photolysis (λ = 286 nm) of $Ni(CO)_4$ in LKr with added N_2 at −170 °C. On switching off the UV lamp, the IR spectrum of Ni.$(CO)_3N_2$ (2267.5, 2101.0, and 2030.0 cm^{-1}) disappears fairly slowly and the kinetic parameters of the reaction

$$Ni(CO)_3N_2 + CO \rightarrow Ni(CO)_4 + N_2$$

were measured. The disappearance of the $Ni(CO)_3N_2$ bands follows first order kinetics. However, the kinetics are complicated by the dependence of the reaction rate constant both on the CO concentration and on the N_2/CO ratio. This agrees with the hypothesis of the occurrence of two competing processes in the reaction. One is dissociative in character, while the other results in CO participating in the transition state.[86]

The possibilities in the study of the kinetics of ligand substitution in liquefied gases can be seen particularly clearly in relation to the reaction of the complex $Fe(CO)_2(NO)_2$ with N_2 in LKr.[87] After UV photolysis for 4 min, the intensity of the bands due to $Fe(CO)_2(NO)_2$ fell and bands appeared at 2257.5 cm^{-1} [$\nu(N-N)$], 2046.0 cm^{-1} [$\nu(CO)$], and 1805.1 and 1761.5 cm^{-1} [$\nu(NO)$]. After further photolysis, additional bands appear at 2250.5 and 2228.0 cm^{-1} [$\nu(N-N)$] and 1796.3 and 1749.4 cm^{-1} [$\nu(N-O)$]. The experiments described indicate the stepwise substitution of CO by N_2. The primary photoproduct $Fe(N_2)(CO)(NO)_2$ is stable at −155 °C and begins to vanish only after the solution has been heated to −107 °C. Thus, in addition to the information obtained in matrix isolation experiments about the existence of complexes, in cryosolutions it is possible to obtain data concerning their stability and hence also their thermodynamic parameters.

The photolysis of $Cr(CO)_6$ in pure LXe or LKr with 5% of added LXe gives rise to the IR bands of an intermediate compound ($\tau_{1/2} \simeq 2$ s at −98 °C), which may be due to the unstable complex $Cr(CO)_5$...Xe.[88] In the absence of Xe, these bands were not observed in the spectrum.

The simplest complex of H_2 with a d^6 metal is $Cr(CO)_5H_2$. Its existence as a reaction intermediate has been postulated and it has been the object of several theoretical studies. UV photolysis of $Cr(CO)_6$ dissolved in LXe with added H_2 [89] leads to the formation of a new carbonyl-containing compound, which was not observed in the absence of H_2. The spectrum of the compound has a broad absorption in the near UV region at 370 nm and the compound is decomposed by the UV light at this wavelength:

$$Cr(CO)_6 + H_2 \underset{367\ nm}{\overset{228\ nm}{\rightleftarrows}} Cr(CO)_5(H_2) + CO\,.$$

The IR spectrum of the compound in the region of the CO vibrations has three bands: at 2094, 1974.3, and 1971.9 cm^{-1}. When D_2 is introduced into the complex, the low-frequency band undergoes a distinct downward shift by ~ 1 cm^{-1}. The shift is not caused by a solvent effect, which led the authors to the conclusion that they had obtained a hydrogen-containing compound. The three $\nu(VO)$ bands agree with the C_{4v} symmetry of the $Cr(CO)_5$ ($2a_1 + e$) fragment. This structure was confirmed by the preparation of a hydrogen-containing complex from $Cr(^{12}CO)_5(^{13}CO)$; as expected, the decrease in symmetry leads to the appearance of additional CO bands. A comparatively broad band with a maximum of 3030 cm^{-1}, which shifts to 2241 cm^{-1} for the deuterio-derivative, was also observed in the spectrum. The shift is somewhat smaller than for the isolated H_2 molecule, but the authors believe that an interaction with the CO vibrations must be considered. These bands have been assigned unambiguously[89] to the H−H and D−D stretching vibrations of the molecular hydrogen in the complex, which proved to be entirely stable up to −35 °C even after the evacuation of a large part of the excess H_2.

A comparative study has been made[90] of the interaction of the complexes $M(CO)_6$ (M = Cr, Mo, or W) with H_2 in LXe: $M(CO)_5$.(H_2) is always formed and in the case of Cr and W *cis*-$M(CO)_4(H_2)_2$ is also produced. The complex $W(CO)_5(H_2)$ has likewise been obtained in solution in LXe.[91] The $\nu(H-H)$ frequency for the Cr complex quoted above (3030 cm^{-1}) proved to be intermediate between the values for the molybdenum (3080 cm^{-1}) and tungsten (2711 cm^{-1}) complexes. The stability of the chromium complex in

LXe is greater than that of the molybdenum complex and smaller than that of the tungsten complex. Under D_2 pressure, the exchange reaction

$$Cr(CO)_5(H_2) \rightarrow Cr(CO)_5(D_2)$$

takes place. HD is probably formed as a result of the intramolecular exchange

$$Cr(CO)_5(H_2)(D_2) \rightarrow Cr(CO)_4(HD)_2 .$$

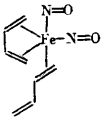
Metals with the d^8 configuration form dihydrides and not complexes with H_2. UV photolysis of $Ru(CO)_4PPh_3$ and H_2 dissolved in supercritical Xe at room temperature leads to the formation of $Ru(CO)_3(H_2).PPh_3$—an unstable dihydride, the existence of which in heptane at higher temperatures and an H_2 pressure of 550 atm had been reported earlier. The 1892.3 and 1810 cm^{-1} bands, which are more distinct in LXe than in heptane, were assigned to Ru—H bond vibrations.

The interaction, on photolysis, of H_2 with the most active catalysts for homogeneous catalysis, namely $Fe(CO)_2(NO)_2$ and $Co(CO)_3NO$ in LXe at −104 °C and under a 10—20 atm H_2 or D_2 pressure, had also been investigated.[92] The coordinated H_2 or D_2 molecules in $Fe(CO)(NO)_2(H_2)$ and $Co(CO)_2(NO)(H_2)$ were identified from the IR bands at 2973 and 2195 cm^{-1} and 3000 and 2228 cm^{-1} respectively. The symmetrical and antisymmetric stretching vibrations of the $M-H_2(D_2)$ were also assigned. Experiments in LXe showed that the reaction proceeds via the same pathways as in the usual solvent but at the same time it is possible to follow them in greater detail. It was found that the complexes of molecular H_2 are more abundant than had been supposed and that hydrogenation reactions, especially photocatalytic reactions with metal carbonyls, can proceed via the coordinated H_2 and not via metal hydrides.

Previously unknown complexes of ethylene with $Cr(CO)_6$ derivatives, namely $Cr(CO)_5(C_2H_4)(m)$, $Cr(CO)_4(trans\text{-}C_2H_4)_2(t)$, and $Cr(CO)_4(cis\text{-}C_4H_4)_2(c)$, have also been obtained on LXe at −78 °C.[93]

Brief photolysis at very low C_2H_4 concentrations yielded the complex (*m*) (with the IR bands of the CO groups at 2078.9, 1967.4, and 1960 cm^{-1}). At a higher C_2H_4 concentration, the complexes (*c*) (2036.8, 1949.3, and 1913 cm^{-1}) and (*t*) (1953.1 cm^{-1}) were formed. Bands referring to the C_2H_4 vibrations also appear in the IR spectrum in the range 1000—1600 cm^{-1}. The structures of the complexes were established spectroscopically: C_{2v} for (*m*), C_{2v} for (*c*), and pseudo-D_{4h} for (*t*).

Similar experiments with $Mo(CO)_6$ and $W(CO)_6$ lead to the formation of not only the previously known complexes (*m*) and (*c*) but also of the unknown analogues (*t*) for Mo and W. In contrast to the unstable chromium complexes, the molybdenum and tungsten complexes are stable under the experimental conditions.



When the photolysis of $Co(CO)_3$ was carried out in LXe with added but-1-ene, it was clear from the spectrum that the photoproduct contains two CO groups and one NO group. The fourth coordination site is apparently occupied by the π-linked olefin.[2]

The photolysis of the $Fe(CO)_2(NO)_2$—but-1-ene system in LXe proceeds with formation of two photoproducts:[94]

$$Fe(CO)_2(NO)_2 \xrightarrow{h\nu} Fe(CO)(NO)_2(\eta^2\text{-}1\text{-}C_4H_8) \xrightarrow{h\nu} Fe(NO)_2(\eta^2\text{-}1\text{-}C_4H_8)_2 .$$

No signs of the decomposition of either complex in LXe were observed for 1 h at −104 °C.

A greater variety of products is attained in the reactions of the same complexes $Co(CO)_3NO$ and $Fe(CO)_2(NO)_2$ with buta-1,3-diene in LXe, since the η^2-C_4H_6 and η^4-C_4H_6 derivatives are obtained.[95] Under similar photolytic conditions in LKr, $Ni(CO)_4$ affords only $Ni(CO)_3(\eta^2\text{-}C_4H_6)$, which is thermally less stable than the above iron and cobalt complexes. The compound $Fe(CO)_2(NO)_2$ forms a bis-η^2-butadiene complex, which can be regarded as an active intermediate in dimerisation reactions. The catalytic process apparently proceeds via a pentacoordinate intermediate with a bent NO group:

This intermediate, which has three coordinated C=C bonds, leads to the formation of mainly 4-vinylcyclohexene and not other possible dimers such as cyclo-octadiene. The stabilising role of the hydrocarbon ligand has been discovered in the photochemical synthesis of $(\eta^4\text{-}C_4H_6)Fe(CO)_2(N_2)$ in solution in LXe with added 1.7% N_2 at −110 °C.[96] No decomposition of the complex was observed on heating the solution to −80 °C.

The photolysis of $CpRh(C_2H_4)_2$ dissolved in LXe with added N_2 at 173 K leads to the splitting off of C_2H_4 and the formation of $CPRh(C_2H_4)(N_2)$.[97]

The experiments described here show that LXe is a solvent which yields additional information compared with low-temperature solid matrices and solutions at room temperature.

Naturally, the photochemical processes in the cryosolutions are not restricted to organoelemental compounds. It has been demonstrated for formaldehyde[23] that it is possible to carry out even isotopically selective processes (see Section V). When a mixed solution of CD_2O and CH_2O in LXe is irradiated, the concentration of each component decreases linearly with time, which indicates cross-order kinetics. the CD_2O concentration then falls somewhat faster than that of CH_2O; this is clearly indicated by the relative intensities of the IR bands of CD_2O and CH_2O. At −94 °C and −106 °C and at irradiation wavelengths of 325 and 318.7 nm, the preferential decomposition of CD_2O (by a factor up to two) was attained. The quantum efficiency of the photo-decomposition of CH_2O at 325 nm is ~0.001. The ratio of the rates of decomposition of the CD_2O and CH_2O molecules is approximately proportional to the ratio of the optical densities in their spectra at the excitation wavelength.

The dissociation of molecules in solution in simple gases has also been achieved using the UV radiation generated by the electrical breakdown of the liquid medium effected by an intense CO_2 laser:[65]

$$OCS + h\nu \rightarrow CO + S;\ C_2H_4 + h\nu \rightarrow C_2H_2 + H_2;\ O_2 + h\nu \rightarrow 2O(^3P) .$$

The construction of lasers with a tunable frequency combined with the characteristics of the cryosolutions should lead to further development of photocheistry in the condensed phase. On the other hand, in order to investigate the reaction mechanism, it is useful to apply the methods of the high-speed IR spectroscopy developing at the present time.[2,98-100] With the aid of multichannel Raman spectrometers, it is possible to record rapid processes up to the picosecond range. In experiments with solvents such as N_2, O_2, and Ar,[101] it was found that the low solubilities make the Raman method rather unpromising. However, the comparatively high solubilities of the molecules in LXe give rise to the hope that Raman

spectroscopy will find extensive application in the study of the mechanisms of photochemical reactions.

- - - o 0 o - - -

Thus reactivity and chemical reaction mechanisms can be studied spectroscopically in solutions in liquefied elemental gases. The low temperatures and the weak interaction of the molecules with the solvents make it possible to obtain the spectra of reactive and unstable compounds with standard instruments. The absence of absorption by the solvents at wavelengths ranging from UV to far infrared ensures the possibility of investigating the effect of laser radiation on the course of reactions. The measurement of the spectra of very thick layers of solution (up to several metres) compensates for the relatively low solubility of molecules and renders the method general.

Photoelectron Spectroscopy of Organofluorine Compounds

N.E.Akopyan, A.V.Golovin, A.A.Rodin, and Yu.L.Sergeev

The analysis of the photoelectron spectra of organofluorine compounds is described. The influence of substitution by fluorine on the electronic structure of the molecules is examined on the basis of experimental data and quantum-chemical calculations. A table of the ionisation energies of organofluorine compounds is presented.
The bibliography includes 170 references.

I. INTRODUCTION

The wide-scale application of organofluorine compounds in various branches of science and engineering is responsible for the great interest by chemists in the study of their electronic structure and reactivity. The commonest method of securing information about electronic structure is nowadays the photoelectron spectroscopy of molecules (PES),[1-4] which permits a direct comparison with experiment of various quantum-chemical models used for the calculation of the physicochemical characteristics of molecules.

The aim of the present review is the analysis of data obtained for organofluorine compounds by the PES method. Although there are several reviews of a general character (see, for example, Vovna and Vilesov[2] and Rao et al.[5]) as well as reviews for individual classes of compounds,[6,7] data on organofluorine compounds have not been described systematically or discussed. One may mention only two communications[8,9] in which photoelectron spectra (PE spectra) are presented without discussion for a series of fluorine-containing compounds together with tables of experimental and calculated ionisation energies. This review discusses the results of the most detailed investigations, which are naturally available only for not unduly complex molecules. Examples of the application of PES to the study of the correlation between the electronic structure of fluorine-containing molecules and their reactivity are examined. In order to cover fully the studies on the PES of organofluorine molecules, the review presents a table of the first ionisation energies of the molecules of compounds in all the classes considered.

The information which can be extracted from the PES refers strictly speaking not to the neutral molecule but to the corresponding molecular radical-cation, PES yielding the spectrum of the energy states of the molecular ion. However, the PE spectra are frequently interpreted using the Koopmans theorem by comparing the PE spectral bands with a definite molecular orbital (MO) of the ground electronic state of the neutral molecule. In this approximation, PES yields the binding energies of the electrons in different MO (ionisation energies) and the band shape is determined by the character of the localisation of the electron in the corresponding MO (distribution of electron density).

The relation between the ionisation energy (EI) and the orbital energy (ε_ρ) is expressed by the equation

$$IE - (-\epsilon_\rho) = \Delta E_{cor} + \Delta E_{reorg},$$

where ΔE_{cor} is the difference between the correlation energy of the ion and the molecule ($\Delta E_{cor} > 0$) and ΔE_{reorg} is the reorganisation energy ($\Delta E_{reorg} < 0$).[2] For the Koopmans theorem to be valid, the equality $\Delta E_{cor} = -\Delta E_{reorg}$ must hold. A detailed analysis of the Koopmans theorem may be found in two monographs.[2,4] Both non-empirical and semiempirical quantum-chemical calculations, carried out using the Koopmans theorem, sometimes fail to yield a satisfactory agreement with experimental EI. Despite this, the MO concept remains fairly fruitful both in the analysis of the PE spectra and in the study of the reaction mechanisms and of the structure of organic compounds.[10]

The concept of the weighted mean (with respect to the degree of degeneracy of the MO) ionisation energy of the unshared (lone) electron pair of the halogen atoms has been introduced[1] and linear correlations have been established between the ionisation energies and the valence and inner electrons of the halogens, which it has been suggested can be used for the identification of the lone electron pair bands in the PE spectra. The authors of the above study note that, in establishing correlations for fluorine-containing compounds, definite difficulties arise associated with the necessity to re-examine the existing interpretation of a number of spectra in the literature. Apparently, as a result of the marked delocalisation of the unshared (lone) electron pairs (LEP) of the fluorine atom, the proposed correlations must be used with much caution.

II. FLUORINE-CONTAINING ALKANES AND HALOGENOALKANES

Fluorinated halogenomethanes are the most thoroughly investigated compounds of this class.[12-17] The most thorough experimental study of CH_nF_{4-n} is one[17] in which the PE spectra were obtained by excitation with the HeI and HeII lines, the vibrational structure was analysed, a comparison was made with the absorption spectra and photoionisation mass-spectrometric data, and calculations of the

electronic structure were carried out in terms of the Hartree–Fock approximation. The above investigation included also the analysis of the theoretical and experimental data obtained previously.

The substitution of a hydrogen atom by a fluorine atom greatly complicates the PE spectra both as a result of the increase in the number of valence electrons and owing to the decrease in symmetry. Even in the PE spectrum of CH_3F the second band consists of a superposition of two unresolved bands. X-Ray electronic spectra have been obtained[18] in the valence region and the complex bands with Lorentzian profile were resolved using the calculated intensities of the individual bands. The vertical ionisation energies (EI) obtained are used in comparing theory and experiment. Here it is necessary to bear in mind that, owing to the large step (0.16 eV) in the measurement of the PE spectra and the low resolution, the accuracy of the determination of the EI is low and probably does not exceed a level to within 0.2 eV.

Despite the difficulties mentioned, the interpretation of the PE spectra of fluoromethanes can be regarded as fairly reliable. The sequence of the MO for these molecules in order of increasing ionisation energy is presented in Fig.1. Some uncertainty remains in the sequences of the close MO $1b_1$, $3a_1$, and $2b_2$ for CH_2F_2 (in the EI range 18.5–19.8 eV). We present the sequence proposed[19] on the basis of calculations in terms of the $X\alpha$ approximation with overlapping spheres. Another sequence has been obtained for this energy range in other studies.[9,17,18]

The nature of the majority of the MO in CH_nF_{4-n} is complex because of the pronounced mixing of the atomic orbitals of fluorine with the σ orbitals of carbon. On the basis of the results of Du Li et al.,[19] only the MO $3b_2$ and $1a_2$ (EI = 15.2 and 15.6 eV) in CH_2F_2 can be regarded as localised on the fluorine atoms. According to Brundle et al.,[17] the MO $4e$ with EI = 17.2 eV in CF_3H and $1e$ with EI = 18.5 eV in CF_4 are closest to the unshared electron pair of fluorine, while in CH_3F the unshared electron pairs of fluorine do not exist in a pure form. One should note that different methods of calculation yield appreciably different results for the MO populations.[17,19–21] However, the band widths in the PE spectra agree with an appreciable delocalisation of the unshared electron pairs of fluorine.

The character of the highest occupied MO (HOMO) is especially important in the study of reactivity. For all the fluorine-substituted methanes except CF_4, the HOMO is bonding in relation to the C–H bond and antibonding in relation to the C–F bond.[17] In CF_4, the HOMO of the C–F bond must be bonding, since the removal of an electron from this MO is accompanied by the dissociation of the molecular ion.[22]

The PE spectra of C_2H_5F and n-C_3H_7F have been published.[9,23–25] It is seen from these data that the HOMO of the C–C bond in the alkyl fluoride is bonding. The first vertical EI decrease with increase in the length of the alkyl chain but remain approximately 0.4 eV higher than the EI of the corresponding alkanes owing to the high electronegativity of the F atom. The same effect leads to a further increase in EI with increase in the number of F atoms in $C_2H_nF_{6-n}$.[25] However, the spectra become so much more complex that even for $n = 2$ it is possible to distinguish only three bands.

The introduction of a single halogen atom X (X = Cl, Br, or I) into perfluoromethane lowers the molecular symmetry to C_{3v} and leads to the partial removal of the degeneracy of the MO (Fig.2). In the low-energy part of the PE spectrum, the bands of the unshared electron pairs of the X atom, corresponding to the removal of the electron from the HOMO, can be readily differentiated both as regards shape and the characteristic spin–orbital splitting. The first vertical EI decrease appreciably in the sequence Cl, Br, I (13.08, 12.12, and 10.45 eV). The bands of the n_X electrons are followed by the band of the C–X bonding MO with vertical EI of 15.20,

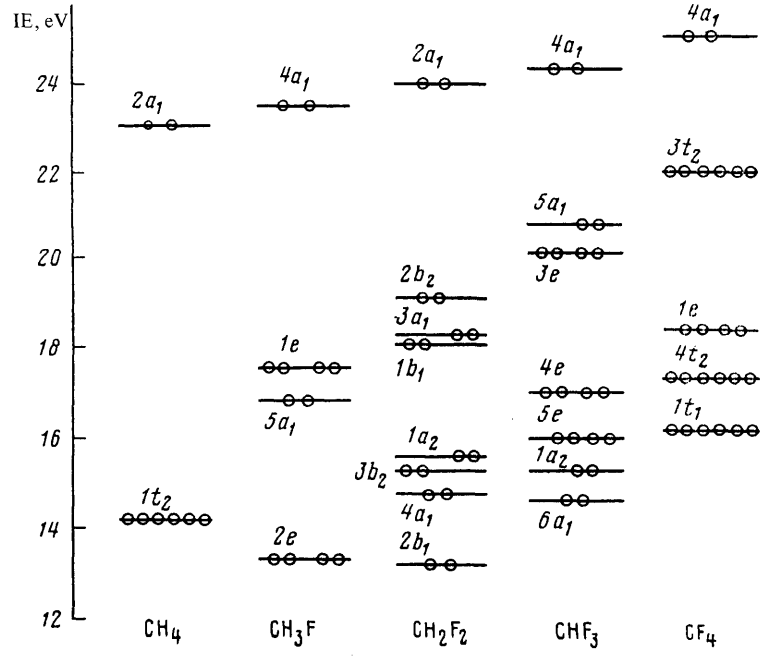

Figure 1. Schematic arrangement of the molecular orbitals of CH_nF_{4-n}.

14.28, and 11.18 eV for Cl, Br, and I respectively. In the region of higher energies, the PE spectra of all three halogenotrifluoromethanes are similar,[14,15,26-29] Despite the large number of bands, one can resolve all the bands whose appearance is possible up to an energy of 24 eV. Analysis of the vibrational structure, the change in band intensity on passing from excitation by the HeI line to excitation by the HeII lines, and comparison with the CF_4 and CF_3H spectra made it possible to interpret all the bands unambiguously.[15,16] The following sequence of MO was obtained: $1a_1$(C2*s*); $1e$(CF_3); mixed orbitals of the unshared electron pairs of the F atom and the C–F bond; $2a_1$, $2e$, and $3e$; $1a_2$(F); $3a_1$(C–X); $4e$(X). Calculations by the extended Hückel (EHM) and CNDO/2 methods for CF_3Cl and CF_3Br yield the reverse sequence of the MO $1a_2$ and $3e$.[20]

An increase in the number of isotypical X atoms in $CF_{4-n}X_n$ leads to a further decrease in EI and to a redistribution of the band intensity in the PE spectra between the high-energy and low-energy parts, since the EI of other halogens are lower than the EI of fluorine. For X = Cl or Br and n = 1–3, it has been possible to differentiate and identify virtually all the stretching vibration bands of the electrons.[13-16,27,28] The following sequence of MO was obtained: $3b_2$, $3b_1$, $2a_2$, $4a_1$, $2b_2$, $2b_1$, $1a_2$, $3a_1$, $1b_1$, $2a_1$, $1b_2$, and $1a_1$ for CF_2X_2 and $1a_1$, $4e$, $3e$, $3a_1$, $2e$, $1e$, $2a_1$, and $1a_1$ for CFX_3. The four highest MO are those of the unshared electron pairs of the atom X. The $(4e)^{-1}$ and $(3e)^{-1}$ bands in PE spectrum of $CFBr_3$ exhibit spin–orbital splitting. The sequence of the MO of the unshared electron pairs of the atoms X in CF_2X_2 and CFX_3 differs from the sequence of the MO of the corresponding X-substituted derivatives of methane not containing fluorine.[12,19,30,31] If the increase in EI on passing from perfluorinated halogenomethanes to the fluorinated derivatives is attributed to the inductive influence of the fluorine atom, then the inductive effect is found to be different for different MO.

The PE spectra of a series of less symmetrical fluorine-containing halogenomethanes have been obtained and interpreted in fair detail: $CHFCl_2$, CHF_2Cl, CH_2FCl, and CF_2BrCl.[12-14,26,28] The HOMO are described satisfactorily by the AO of the unshared electron pair of the Cl atom for the first three molecules and the AO of the Br atom for the last. The most thorough studies of both fluorinated and fluorine-free halogenomethanes have been carried out by a group of Yugoslav spectroscopists,[12-16] who paid special attention to the influence of the changes in the energy of ionising radiation (the HeI and HeII lines) on the spectra. They established that the sensitivity of the bands with an appreciable contribution by the unshared electron pairs of the halogens decreases in the sequence F ≫ Br ≅ I > Cl. This regularity can be usefully borne in mind in differentiating the bands corresponding to the removal of electrons from different halogen atoms.

Successive fluorination of ethane leads to the stabilisation of the HOMO, which is C–C bonding in character.[9,23,25] A fairly complete analysis of the PE spectrum has been carried out only for C_2H_5F.[9] Semiempirical calculations of the electronic structure yielded the following MO sequence: $3a''$(CH), $10a'$(Cl), $9a'$(C–H), $2a''$(F), $8a'$(C–F), $1a''$(F, C–H), $7a'$(F), $6a'$, and $5a'$.[41] However,

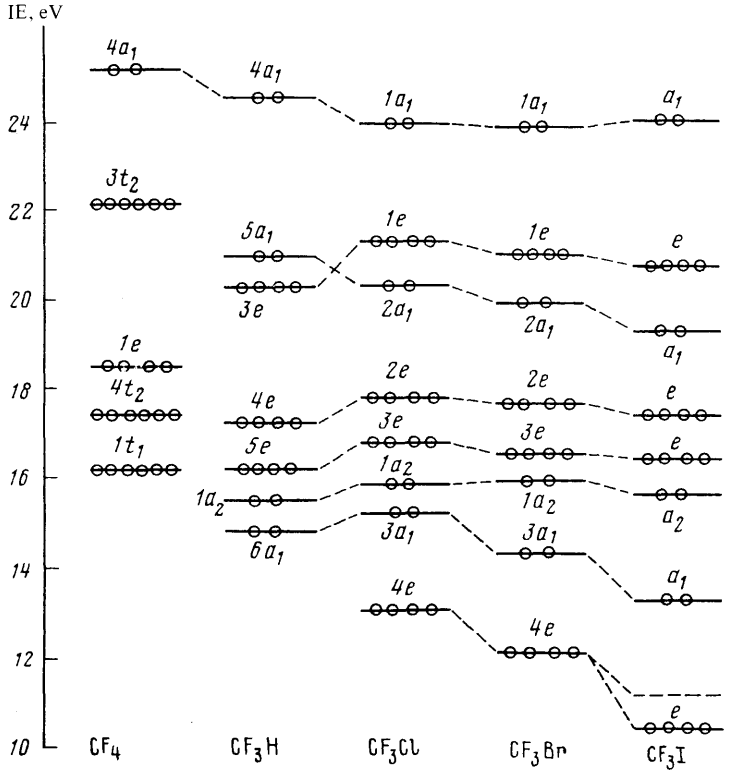

Figure 2. Schematic arrangement of the molecular orbitals of trifluoromethanes CF_3X, where X = H, F, Cl, Br, or I.

the observed regularities in the variation of the first EI in the successive fluorination of methane and ethane agree better if the highest two occupied MO are interchanged.

The introduction of Cl, Br, and I atoms into fully or partly fluorinated ethane entails the same changes in the PE spectrum[26,32-34] as those examined above for methane. The spectra of $(CF_2X)_2$, where X = Cl, Br, or I, have been analysed in greatest detail,[32] but in this case too the number of bands identified is appreciably smaller than expected even when account is taken of only the valence *p* electrons of the atoms.

Analysis of the spectra of halogenoethanes is complicated by the fact that the specimens consist of mixtures of *gauche*- and *trans*-isomers. A structure attributed to the ionisation of individual isomers was discovered only for $(CF_2I)_2$ [32] and CH_2FCH_2Br [33] in the region of the spectra corresponding to the removal of one of the electrons of the unshared electron pairs of I and Br. For $(CF_2I)_2$, EI proved to be higher by 0.1 eV for the *gauche*-isomer, while for CH_2FCH_2Br it proved to be higher by 0.2 eV for the *trans*-isomer. Higher values of the EI for the *anti*-isomers have been obtained also for a series of monofluoro- and monobromo-derivatives of propane and butane and also for *trans*-1-bromo-2-fluorocyclohexane.[33] The bands have been assigned to different conformers[32,33] on the basis of semiempirical calculation. Gounelle et al.[33] took into account only the interaction through space, while Chan and McDowell took into account[32] also the interaction through σ bonds. Possibly the different sequences of the EI of the conformers of derivatives of ethane obtained in these two studies may be associated with this factor.

III. FLUORINE-CONTAINING ALKENES AND HALOGENOALKENES

All the studies on fluorine-containing molecules with an isolated double bond carried out by the PES method concern ethylene derivatives $R^1R^2CCR^3R^4$ (R^1, R^2, R^3, R^4 = H, F, or CF_3). The first EI correspond to the removal of the π electrons of the double bond.

For all the six fluorinated ethylenes,[35-38] the PE spectra were obtained with excitation by the HeI and HeII lines, the variation of the parameter of the angular anisotropy of the scatter of the photoelectrons has been studied for all the spectral bands in the region up to 20 eV, the vibrational band structure has been analysed,[36,38] and empirical and non-empirical calculations, including many-particle calculations, of the electronic structure have been performed.[35,39] This made it possible to interpret fairly reliably the spectra in the region up to 25 eV taking into account all the valence electrons, although some of the ionisation transitions then proved to be somewhat degenerate with respect to energy.

Successive fluorination of ethylene hardly alters the HOMO energies (the vertical EI are in the range 10.38 – 10.69 eV). Such behaviour can be explained by the compensation of the inductive influence of the F atoms and by the interaction through space between the π MO of the C=C bond and the AO of the unshared electron pairs of fluorine ($n-\pi$ conjugation). Indeed, both quantum-chemical calculations[35] and the observed variation of the parameter of angular anisotropy[36] for the series of fluorethylenes indicate an appreciable contribution by the AO of fluorine to the HOMO. The second EI, corresponding to the removal of σ electrons, increase appreciably with increase in the number of F atoms in the substituted ethylene; for example, the second EI of perfluoroethylene is higher by 3 eV than that of the unsubstituted ethylene. The different influences of the substitution of hydrogen by fluorine on the energies of the π and σ MO have been called the perfluoro-effect, the fluorination of ethylene being regarded as the classical example of the manifestation of the perfluoro-effect in planar molecules.[3,4,38] However, more thorough experimental theoretical study[35,39] showed that the shifts of both σ and π MO depend greatly on the nature of the MO and can vary within wide limits (see below). The almost complete agreement between the PE spectra of *cis*- and *trans*-1,2-difluoroethylenes, which agrees well with the many-particle calculations for these molecules, is noteworthy.[35] Semiempirical calculations in terms of the CNDO approximation yield appreciably different MO schemes for the isomers.

Complete fluorination of propene, *cis*- and *trans*-but-2-enes, and 2,3-dimethylbut-2-ene increases the first vertical EI by 1.3 – 4.0 eV.[40-43] However, the variation of the EI with *n* in $C_2H_{4-n}(CF_3)_n$ is irregular and its explanation requires further experimental and especially theoretical studies of the electronic structure. Among other fluoropropene derivatives, only 3-fluoropropene has been studied in fair detail, although a complete interpretation of the spectrum has not been carried out.[44-46] The regularities in the variation of the first ionisation potential in the C_3H_5X series, where X = F, Cl, Br, or I, have been considered as the first semiquantitative demonstration of the existence of "hyperconjugation".[46]

Scott and Russell[47] carried out a joint empirical analysis of the PE spectra and UV absorption spectra of chlorofluoroethylenes. With the aid of the experimental quantities obtained, characterising the successive substitution of hydrogen atoms by fluorine or chlorine atoms, they were able to reproduce the experimental energies of the highest occupied and lowest unoccupied MO of nine chlorofluoroethylenes.[48,49] The introduction of chlorine or bromine atoms into fluorinated ethylenes (the spectra of fluoroiodoethylenes were not obtained) leads to an appreciable (by 0.3 – 1.0 eV) decrease in the first EI corresponding to the removal of π electrons[43,47,49] owing to the effect of $n-\pi$ conjugation. Detailed quantitative studies of this effect for the compounds considered are not described.

A second characteristic feature of fluorohalogenoethylenes is the presence in the PE spectra of the bands due to the LEP of the chlorine and bromine atoms and the bands associated with the C – X bonds. They appear in the energy range (11 – 15 eV) which in the spectra of fluoroethylenes is free from bands and can be readily identified from their characteristic features (see above).

The electronic structure of allene is characterised by the presence of two systems with mutually perpendicular nodal planes. The corresponding MO are degenerate in both allene and perfluoroallene and are HOMO.[50,51] In contrast to fluorinated ethylenes, an appreciable increase (by 1.3 eV) in the first EI is observed, which the authors[51] explained by the predominance of the effect due to negative hyperconjugation and of the inductive effect over $n-\pi$ conjugation.

In 1,1-difluoroallene, the degeneracy of the π MO is removed, since $n-\pi$ conjugation is ruled out for symmetry reasons in the case of the π MO localised on the C(2)=C(3) bond and hyperconjugation is ruled out for the π MO of the C(1)=C(2) bond.[51] As a result, the HOMO is the bonding π MO of the C(1)=C(2) bond. The second π MO of the C(2)=C(3) bond lies 1.5 eV lower. The nonequivalence of the two π bonds in 1,1-difluoroallene [the C(1)=C(2) bond is characterised by an excess electron density, while the C(2)=C(3) bond is characterised by its electron deficiency compared with the bonds in allene and perfluoroallene] is manifested in the chemical reactions of 1,1-difluoroallene.

In tetraflurobutatriene, all the fluorine atoms are located in the nodal plane of the highest occupied π MO of the C(2)=C(3) bond, whose energy (9.3 eV) has not changed compared with butatriene

(the perfluoro-effect).[52] The terminal localised π MO, whose nodal plane is perpendicular to the plane passing through the F atoms, interact effectively with these atoms via the conjugation mechanism. When account is taken of the π−π conjugation, the delocalised b_{3u} and b_{2u} MO with 12 and 12.5 eV binding energies are obtained. Such interpretation of the spectrum agrees with the quantum-chemical calculations (see Basch et al.[52] and the references quoted therein).

The PE spectra of 1,1,4,4-tetrafluoro- and perfluoro-butadienes were used to identify the sequence of the occupied MO in buta-1,3-diene.[53] The sequence $(\ldots 1a_u\pi 7a_g\sigma 1b_g\pi)$, proposed on the basis of the analysis of the spectra, agrees with semiempirical calculations. Non-empirical calculations as well as later calculations by the modified complete neglect of the differential overlap method yields the $7a_g\sigma$ and $1b_g\pi$ order of MO.[54] Analysis of the PE spectra as well as absorption spectra enabled Brundle and Robin[53] to conclude that the carbon skeleton of tetrafluorobutadiene is planar, while perfluorobutadiene is characterised by the rotation of two π-bonds by an angle of 42° about the C−C bond.

Among cyclic compounds with double bonds, we shall mention the fully fluorinated Dewar benzene—hexafluoro[2.2.0]hexa-2,5-diene. In this case, the PE spectra of the fluorinated compound[55,56] were used to demonstrate the absence of interaction between the isolated π-electron systems.

IV. FLUORINE-CONTAINING ALKYNES AND HALOGENO-ALKYNES

The small number of valence electrons in fluorinated acetylenes leads to fairly simple spectra, which have been interpreted reliably by comparison with quantum-chemical calculations.[57–59] It has been

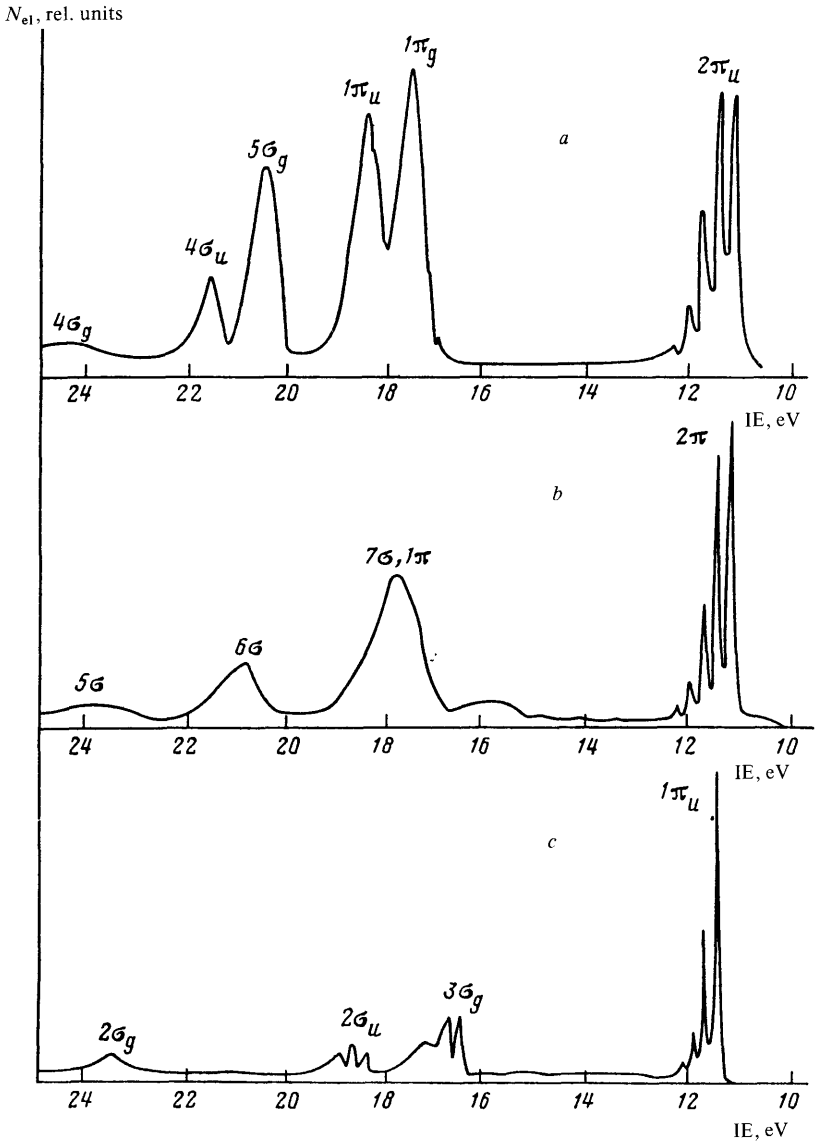

Figure 3. Photoelectron spectra of C_2F_2 (*a*), C_2FH (*b*), and C_2H_2 (*c*).

shown that the HOMO is a C–C bonding MO of the π type with a considerable contribution by the antibonding combination of the $2p\pi$ AO of fluorine (Fig.3). As a result of the cancelling out of the inductive effect and the $n-\pi$ conjugation effect, the first EI of acetylene changes on fluorination by not more than 0.2 eV (the perfluoro-effect). However, approximately the same shift is observed also for the σ(C–H) MO of fluoroacetylene relative to the centre of gravity of two analogous MO of acetylene, which does not agree with a simple treatment of the perfluro-effect. The spectra of other fluorinated alkynes are much more complex and their complete analysis has not been carried out.[9,60–63] In this case, the HOMO are MO of the π type. Fluorination of the methyl groups in propyne and but-2-yne leads to an appreciable (by up to 2.8 eV in perfluorobut-2-yne) increase in the first EI as a result of the inductive influence and negative hyperconjugation.[51]

Similar regularities have been observed also in the spectra of fluorinated dialkynes with conjugated π systems:[9,57,58,60] the fluorination of diacetylene does not change the energy of the HOMO of the π(C≡C) type, but substitution of the hydrogen atoms in the methyl groups of penta-1,3-diyne and hexa-2,4-diyne by fluorine atoms increases appreciably the first EI of their molecules. As an example of the sharp deviation from the usual behaviour of the σ MO on fluorination, we may mention the increase in the EI for the σ(C–C) electron in fluoro- and difluoro-diacetylenes compared with the unsubstituted molecule. This is explained by the interaction of the σ(C–C) MO with the σ(C–H) and σ(C–F) orbitals, the first of which is charactersied by a lower binding energy than the σ(C–C) orbital, while the second is characterised by a higher binding energy.[58]

PES data have been published[61] for the compounds CF_3CCX, where X = Cl, Br, or I. Spin–orbital splitting has been observed in the first bands of bromo- and iodotrifluoropropynes, whose magnitude agrees with the splitting for bromo- and iodoacetylenes[59] and is somewhat smaller than the splitting in the spectra of alkyl halides. This indicates an appreciable $n-\pi$ conjugation in CF_3CCI and CF_3CCBr. Although quantum-chemical calculations have not been made, the HOMO in these two molecules are apparently predominantly np_X AO. For X = Cl, the interaction of the π(C≡C) MO with the p_C AO is weak and the HOMO is in this case an almost pure π(C≡C) MO. The different character of the HOMO for X = Cl and X = Br or I can affect the reactivity of the molecules considered.

V. FLUORINATED AROMATIC COMPOUNDS

Fluorobenzenes have been investigated in greatest detail: the PE spectra have been obtained for different energies of ionising radiation,[9,39,64–66] a thorough analysis of the vibrational structure of the spectra[39] and of the angular distribution of the scattering of photoelectrons removed from different MO [37] has been carried out, and numerous quantum-chemical calculations of the electronic structure have been made.[9,39,54,65,67,68] The PE spectra with excitation by the HeII line have been published[9] for all the fluorobenzenes as well as the results of quantum-chemical calculations taking into account all the valence electrons. In the range of energies less than 25 eV, fluorobenzene has 16 MO according to calculations, but only 11 bands could be resolved in the PE spectra. The situation is still more complex for substituted benzenes with a larger number of fluorine atoms. Despite this, the sequences of the MO quoted[9] are fairly reliable. As an example, we shall quote recommended sequences of MO for fluorobenzene:

$3b_1\pi_{CC}$, $1a_2\pi_{CC}$, $8b_2$, $2b_1\pi_{CC}$, $13a_1$, $7b_2$, $6b_2$, $12a_1$, $5b_2$, $1b_1\pi_F$, $11a_1$, $10a_1$, $4b_2$, $9a_1$, $8a_1$, $3b_2$, $7a_1$, and $6a_1$

and similarly for perfluorobenzene:

$2e_{1g}\pi_{CC}$, $2a_{2u}\pi_{CC}$, $2b_{2u}$, $6e_{2g}$, $1a_{2g}$, $6e_{1u}$, $1b_{2g}\pi_F$, $1e_{2u}\pi_F$, $1e_{1g}\pi_F$, $5e_{2g}$, $1a_{2u}\pi_F$, $5e_{1u}$, $5a_{1g}$, $1b_{2u}$, $4b_{1u}$, $4e_{2g}$, $4e_{1u}$, $4a_{1g}$, $3b_{1u}$, $3e_{2g}$, $3e_{1u}$, and $3a_{1g}$.

In all the fluorobenzenes, the HOMO is the π MO of benzene whose binding energy increases somewhat on fluorination to the maximum value of 9.90 eV in hexafluorobenzene. However, the changes in the first EI on fluorination cannot be accounted for on the basis of the consideration of the conjugation and inductive effects and many-particle calculations are required.[65] Fluoroderivatives of toluene and xylenes have been investigated to a much lesser extent.[65,66,69,70] Detailed analysis of the PE spectra using non-empirical calculations have been carried out and the changes in band intensities in the spectra with excitation by the HeI and HeII lines have been studied only for three $CH_3C_6H_4F$ isomers.[65]

The PE spectra have been obtained and partly identified for a series of fully fluorinated condensed aromatic hydrocarbons[71] as well as 9-fluoroanthracene.[72] For nine substituted anthracenes (apart from fluorine, other halogen atoms as well as CH_3, OCH_3, CHO, etc. were used as substituents), a linear relation has been obtained between the first EI and the Hammett constants.

The comparative analysis of the PE spectra of the *ortho*- and *meta*-substituted benzonorbornadienes carried out by Santiago et al.[73] indicates a different nature of the HOMO in *o*- and *m*-fluorobenzonorbornadienes. The authors attribute the difference between their photochemical activities to this factor.[73]

One of the first studies involving the use of PES to obtain information about the geometrical structure of molecules, is that of Maier and Turner[74] who analysed the spectra of substituted (including seven fluoro-substituted) biphenyls. The difference between the first and fourth EI was used to determine the dihedral angle between the planes of the two benzene groups on the basis of the linear relation $\Delta E = A\cos\theta + B$, where θ is the dihedral angle and A and B are constants. In connection with the hypothesis that the physiological activity of certain biphenyl derivatives (namely chloro-derivatives) is determined by the degree of coplanarity of the molecules, this question has been recently re-examined[75] using new electron diffraction and PES data.

The introduction of chlorine, bromine, and iodine atoms into perfluorobenzene leads to the changes in the PE spectra already examined: the splitting of the first band as a result of the removal of the degeneracy of the HOMO e_{1g} with some decrease (to 0.5 eV for the iodine atom) in the first EI and the appearance of the bands due to the unshared electron pairs of the halogen in the range 11 to 12.5 eV, which is free from bands in the PE spectra of perfluorobenzene.[8,68,76] The sequence of the first five MO in C_6F_5X, namely $a_2\pi$, $b_1\pi$, b_2h_x, $b_1\pi$ (for X = Cl, we have $b_1\pi$, b_2h_{Cl}), π, has been fairly reliably established and confirmed by quantum-chemical calculations.[8,68] The PE spectra of 52 fluorinated compounds containing more than one chlorine or bromine atom, excited by the HeI and HeII lines, as well as the symmetry types of the highest (up to 6) MO, obtained from non-empirical calculations, have been published;[8] they have not so far been analysed. The PE spectra of the *m*-, *p*-, and *o*-isomers of the chloro- and bromo-derivatives of ααα-trifluorotoluene are similar and the first four EI of the different isomers differ by not more than 0.15 eV.[7,66] The first two bands in the spectra correspond to the removal of π electrons and the next two to the removal of the electrons of the unshared pairs of chlorine and bromine.

VI. FLUORINATED ORGANIC COMPOUNDS CONTAINING NITROGEN, OXYGEN, AND SULPHUR HETEROATOMS

Among nitrogen-containing compounds, fluoro-derivatives with the CN group have been investigated in fair detail. The PE spectra of FCN excited by the HeI and HeII lines and the correlation diagram for the first four EI of XCN, where X = I, Br, Cl, or F, have been published.[77] Comparison of the PE spectra of the more complex $CH_2F-C\equiv N$ and $CH_2F-C\equiv CH$ molecules made it possible to assign the bands in the $CH_2F-C\equiv N$ spectrum,[62] although the assignment cannot be regarded as unambiguous because the PE spectrum of $CH_2F-C\equiv N$ is fairly complex owing to the superposition of the bands of the triple bond and the unshared electron pair of the nitrogen atom. For a more accurate interpretation of the spectrum, non-empirical calculations were carried out. The PE spectra, excited by the HeI and HeII lines, of a series of compounds of the type $X-C\equiv C-C\equiv N$, where X = CF_3, F, Cl, Br, or I, have been published.[61] Fig.4 presents the correlation diagram for the EI of cyanoacetylenes on the basis of which the bands in the PE spectra of these substances were assigned. For the bromo-, chloro-, and iodoacetylenes, a strong interaction of the $1\pi_\lambda$ and $2\pi_\lambda$ orbitals is observed. It has been shown that calculations using Green functions predict much better the band sequence and the trend in the variation of EI of cyanoacetylenes than the calculations in terms of the Koopmans approximation.[61]

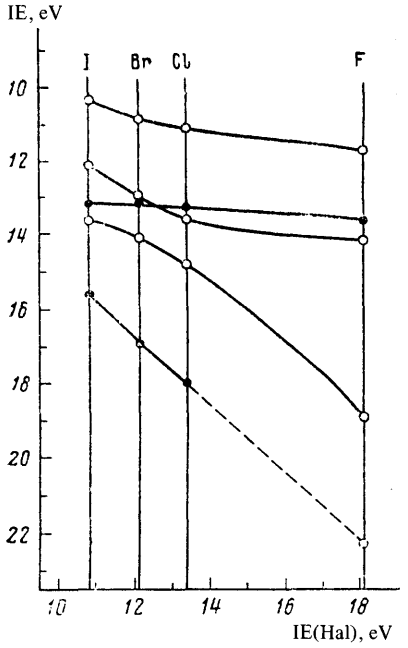

Figure 4. Correlation diagram for the ionisation energies of cyanoacetylenes $X-C\equiv C-C\equiv N$ as a function of the ionisation energy of the halogen atom X = I, Br, Cl, or F.

Comparison of the angular distributions of the photoelectrons, formed on photoionisation of pyridine, pentafluoropyridine, and 2,6-lutidine by the HeI line, made it possible to refine the assignment of the bands in the PE spectrum of pyridine.[78] Thus the first pyridine band was assigned to the a_1n MO, while the fifth band corresponds to the lowest occupied $b_1\pi$ Mo. The asymmetry parameter β of the angular distribution of photoelectrons for pentafluoropyridine hardly changes (in contrast to pyridine and 2,6-lutidine) within the limits of the first band and differs only slightly for different bands: for bands 1–5, β = 0.60, 0.68, 0.65, 0.55, and 0.34 respectively.

The UV absorption spectra and the PE spectra of $(CF_3)_2C=NH$ and other hydrocarbons with the azomethine group have been compared[79] and it has been observed that fluoro-substitution leads to a significant shift, by more than 2 eV, of the n, π, and the first σ ionisation energies for $(CF_3)_2C=NH$ compared with the analogous hydrocarbons. On the other hand, the $\pi^* \leftarrow n$ band shift of the absorption spectra of the corresponding compounds is hardly observed.

Staley et al.[80] used the EI of fluoramines, measured by the PES method, to determine the homolytic dissociation energies of protonated molecules (B), while the difference between the influences of alkyl and fluoroalkyl substitutents on the electronic structure of amines was used to account for the irregularities in the variation of the proton affinities and the values of $D(B^+-H)$ for the test compounds.

The PE spectra of benzonitrile, 1,2- and 1,4-dicyanobenzenes, and their perfluoro-analogues have been studied in detail.[81] The CNDO, INDO, and the linear combination of bond orbital methods were used to assign the bands. It was observed that the difference between the changes in the energies of the σ and π orbitals of benzonitrile on perfluorination is significantly greater than for 1,2- and 1,4-dicyanobenzenes. The fluorescence of perfluorobenzonitrile ions has been observed and investigated;[69] fluorescence has not been observed for benzonitrile itself. The difference is explained by the fact that perfluorination of benzonitrile alters the sequence of the close lying γ^{-1} and π^{-1} ($\tilde{B}$ and $\tilde{C}$) states of the cations.

The study of the influence of the position of fluorine on the PE spectra of fluoroanilines[65] showed that the position of the band corresponding to the removal of an electron from the b_1 MO, in which the contribution by the n_N AO predominates, hardly changes on fluorination in the *ortho*-, *meta*-, and *para*-positions. On the other hand, the HOMO, which is predominantly of the π type, shifts on fluorination towards higher energies, the shift being particularly marked for *meta*-fluoroaniline.

An increase in the number of atoms in a compound usually entails a sharp increase in the complexity of the PE spectrum. However, for molecules with multiple bonds and heteroatoms, the first bands in the PE spectrum are frequently well differentiated. Fig.5 presents the PE spectra of indole and 4,5,6,7-tetrafluoroindole.[82] Fluorination shifts the first four bands by 0.72, 0.60, 0.56, and 0.44 eV respectively and leads to the separation of the fourth band from the remaining group of strongly overlapping bands. The PE spectra of diazanaphthalenes and their fluoro-derivatives have been published.[83] The results of quantum-chemical calculations by the extended Hückel method were used for analysis. Attempts to apply the methods of perturbation theory within the framework of the model involving interactions through the bonds between localised orbitals of the unshared pairs of nitrogen for the description of the splitting of the MO with a considerable contribution by the h_N AO proved unsuccessful for compounds of this class.

Among oxygen- and fluorine-containing hydrocarbons, carbonyl compounds have been studied in greatest detail. The first and second bands in the PE spectra of substituted aldehydes and ketones

usually correspond to the unshared pair of oxygen and the π orbital of the C=O bond. A correlation analysis of the PE spectra of H_2CO, HFCO, and F_2CO has been carried out.[84] The bands in the HFCO spectrum are located in the centre between the corresponding bands of H_2CO and F_2CO. For the carbonyl halides $X_2C=O$, the band of the unshared electron pair of oxygen shifts upwards in the sequence X = H, Br, Cl, F. The first EI of oxalyl halides $(COX)_2$ corresponds to the LEP of the oxygen atom and increases in the sequence X = Br, Cl, F.[85] For $(COBr)_2$ and $(COCl)_2$, groups of four sharp peaks, corresponding to the unshared electron pairs of Br and Cl, are observed at 11.7 and 12.7 eV. A similar sharp structural group is not observed for $(COF)_2$. Comparison of the PES data, the results of the CNDO semiempirical calculation, and the temperature variation of the PE spectra led to the conclusion that these compounds have two isomers. Comparison of the PE spectra of ten chlorofluoroacetones with semiempirical CNDO/2 calculations[86] permitted the assignment of the bands in the PE spectra. The first EI of all the compounds correspond to the removal of one electron of the LEP of oxygen. The second EI for fluoroacetones corresponds to the removal of electrons from the π orbital of the C=O bond, while for chlorofluoroacetones there are several orbitals corresponding to the LEP of chlorine between the above two orbitals.

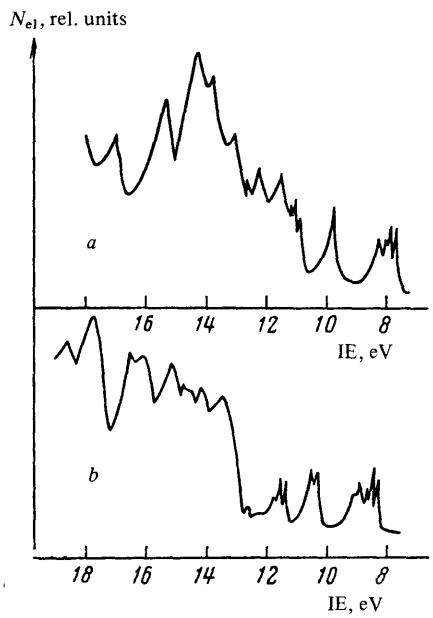

Figure 5. Photoelectron spectra of indole (*a*) and tetrafluoroindole (*b*).

Studies on the PE spectra, excited by the HeI line, of a series of fluoroethers[87] or the type $F[CF(CF_3)CF_2O]_nCHFCF_3$, where $n = -4$ (the E-1, E-2, E-3, and E-4 Freons) showed that they have EI higher by 3.5 eV than the corresponding ordinary ethers. Their vacuum UV absorption spectra begin at energies greater than 10 eV. Both photoelectron and UV spectra are complex, which indicates the existence of several close orbitals of the LEP of oxygen. The EI corresponding to the unshared electron pairs of oxygen and the C–C orbitals must lie close to one another in the region of low EI. The remaining orbitals are difficult to identify from the spectra, since the PE spectra of these compounds are continuous without very distinct bands.

A correlation analysis has been carried out[88,89] and the PES data for *p*-benzophenone and its fluoro-analogues have been compared with the semiempirical calculations by the CNDO/2 and CNDO/S methods. The MO energies have been determined for *p*-benzophenone and have been found to decrease in the sequence $n > n_+ > \pi_+ > \pi_-$, the sequence for *p*-perfluorobenzophenone being $n_+ > n_- > \pi_- > \pi_+$. The perfluoro-effect for these compounds leads to a shift of the *n* orbitals by ~1 eV; the shift of the π orbitals is significantly smaller than that of the *n* orbitals.

The first bands in the PE spectra of fluorine-containing thiocarbonyl compounds correspond, like those for carbonyl compounds, to the LEP of the sulphur atom with a lower EI than for oxygen, while the second band corresponds to the π orbitals of the C=S bond. The bands in the PE spectra of $F_3CS-C(S)-X$, where X = F, Cl, or CF_3, have been assigned on the basis of correlation analysis relative to the PE spectra of halogen-containing carbonyl compounds.[90] Among all the compounds examined, only $F_2C=S$ undergoes $\sigma-\pi$ polarisation. It has been observed that the use of a chlorine atom or the CF_3 group as the substituent results in identical shifts of the PE spectral bands.

The formula relating the first EI of the unshared electron pair of sulphur to the sum of the electronegativities X_α of the substituents has been found from the analysis of the PE spectra of the sulphuranes CF_3SF_3, $(CF_3)_2SF_2$, $(CF_3)_2S$, and others:[91]

$$EI(n_S) = 0.73(\Sigma X_\alpha + 7.10)\ \text{eV}.$$

The outer valence levels in the phenyl and pentafluorophenyl derivatives of bivalent sulphur have been investigated by PES.[92] It has been established earlier for these compounds by X-ray fluorescence spectroscopy that, on passing from phenyl to pentafluorophenyl derivatives of bivalent sulphur, the 3*p* electrons are displaced from conjugation with the aromatic π system, forming a virtually nonbonding level. At first sight, this should promote reactions in which the sulphur atom behaves as a π-electron donor. However, in reality the reactivity of the compounds C_6F_5SX in such reactions is significantly lower than that of their hydrocarbon analogues. The absence of this effect is explained by the increase in EI as a result of the perfluoro-effect.

The influence of the substituents on the EI of the outer occupied molecular orbitals has been investigated for certain groups of compounds containing oxygen and sulphur of the type $X-C_6H_4-Y$, where X is a halogen or another group and Y is a group containing sulphur or oxygen.[93–95] For all the series of compounds, the stabilisation of the HOMO was greatest on substitution of X by fluorine.

With increase in the size of the molecule, the interpretation of the spectrum usually becomes much more complicated owing to the diffuseness of the spectrum and the difficulties in calculations for many-electron systems. However, in many instances the high symmetry of the molecules makes it possible to diminish these difficulties. An example is provided by a comparative study of the PE and vacuum UV absorption spectra of tetrathiofulvalene and related compounds, including tetrakis(trifluoromethyl)tetrathiofulvalene,[96]

where the use of a simple theoretical model and semiempirical calculations made it possible to determine fairly satisfactorily the sequence of orbitals in these compounds.

Ionisation potentials (IP) of fluorine-containing hydrocarbons determined by the EPS method.

Notation. Ionisation potentials: a = adiabatic, v = vertical.

*Photoionisation mass spectrometry.

**Spectroscopic ionisation method.

***Multiphoton ionisation.

The first adiabatic and vertical ionisation energies of all the fluorine-compounds in the classes dealt with in the review which have been investigated up to 1985 are presented in the Table. As a rule, one most reliable value of the ionisation energy is included for each

molecule. The error in the ionisation energy is quoted only when it is given in the original communication. In the remaining cases, it can be estimated as 0.1 eV for values quoted with a single figure after the decimal point and 0.05 eV for those quoted with two figures after the decimal point. The compounds are listed in the Table in order of increasing numbers of the S, O, N, I, Br, Cl, F, H and C atoms (starting with their absence).

---o0o---

Thus chlorination of organic compounds increases the ionisation energies of almost all the orbitals. This effect is particularly large for perfluorohydrocarbons and can be used for the specific synthesis of compounds with high ionisation potentials.

The observed regularities in the variation of the ionisation energies of the compounds on replacement of all the hydrogen atoms by fluorine (the perfluoro-effect) provide an effective method for the recognition of the character of the MO in certain classes of compounds, despite its limited applicability. Thus the replacement of hydrogen by fluorine in a planar molecule has a much greater stabilising effect on σ MO than on π MO. This effect is most pronounced for non-aromatic hydrocarbons whose fluorination shifts the π MO by 0–0.5 eV and the σ MO by 2–3 eV. For aromatic compounds, the shift of the π orbitals can be somewhat greater. Analysis of a large number of PE spectra demonstrated that detailed analysis of the electronic mechanism which leads ultimately to the perfluoro-effect is fairly complex. This is because, when hydrogen is replaced by fluorine, two competing influences are observed: the greater electronegativity of the fluorine atoms, leading mainly to the polarisation of the σ-skeleton of the molecule, and the repulsive interaction of the unshared electron pairs of fluorine with the π-system to which they are linked. In studying the influence of the perfluoro-effect, it is essential to take into account the molecular symmetry.

The PE spectra of organofluorine compounds differ greatly from the spectra of other halogen-substituted compounds. This is associated with the following properties of the fluorine atom, which distinguish it among the halogens. Firstly, the C–F bonds are appreciably shorter than the C–X bonds, where X = Cl, Br, or I. If the sum of the covalent atomic radii is used to estimate the length of these bonds, then 1.4, 1.7, 1.9, and 2.1 Å are obtained for F, Cl, Br, and I respectively. Secondly, the 2*p* AO of fluorine is smaller (less diffuse) than the AO of the valence *p* electrons of the remaining halogens. Such properties lead to an effective interaction of the AO of fluorine with the MO of the C–C and C–X bonds which have the correct symmetry and hence to an appreciable delocalisation of the unshared electron pairs of fluorine. Therefore the PE spectra of organofluorine compounds do not contain the narrow bands characteristic of the unshared electron pairs of the other halogens. In many instances, there is probably no point at all in considering the unshared electron pairs of fluorine. The differentiation of the corresponding bands in the PE spectrum is a very complex task, especially if account is taken also of the small spin–orbital splitting of these bands. For the other halogens, the spin–orbital splitting is manifested reliably in the spectra and is a satisfactory diagnostic feature for the identification of the bands corresponding to the removal of the electrons of the unshared pairs.

Yet another important difference between the PE spectra of organofluorine compounds and those of other organic substances is the lower frequencies of the corresponding vibrations of the ions when hydrogen atoms are replaced by fluorine. Thus the energies of the vibrational quanta for the stretching vibrations of the C–H and C–F bonds are approximately 3000 and 1300 cm^{-1} respectively. Such a marked change in frequency can alter significantly the shape of the individual bands in the PE spectra, especially when the vibrational structure is resolved.

In comparing the ionisation energies obtained from the PE spectra with theoretical calculations, preference should be given to many-body calculations of ionisation energies. Semiempirical calculations can in certain cases yield appreciably different arrangement of orbitals, especially for different isomers.

Oxidative Substitution of Halogen Atoms in Organic Halogeno-derivatives—a New Type of Nucleophilic Substitution Reactions at a Saturated Carbon Atom

L.S.Boguslavskaya, N.N.Chuvatkin, and A.V.Kartashov

The review surveys and gives a systematic account of data on the oxidative substitution of halogen atoms in organic halogeno-derivatives. The stereochemistry of the reactions as well as numerous rearrangements occurring on oxidative substitution are considered. The influence of the substituted halogen (Cl, Br, or I), the substituents at the reaction centre, and the oxidant on the character of the products and the reaction mechanism is demonstrated.
The bibliography includes 97 references.

I. INTRODUCTION

During the last decade, numerous reactions of alkyl halides with oxidising agents under mild conditions, leading to the exchange of a halogen for another nucleophilic residue and to the oxidation of the halogen eliminated to the molecular form Hal_2 or heteroatomic molecules containing the oxidised halogen, have attracted the attention of investigators:

$$RI + HNO_3 \rightarrow RONO_2 + I_2 , \quad (1)$$

$$RBr + HNO_3 \xrightarrow{HF} RF + Br_2 , \quad (2)$$

$$RI + ArCO_3H \xrightarrow{H_2O} ROH + I_2 + I_2O_5 , \quad (3)$$

$$RCl + ClOSO_2F \rightarrow ROSO_2F + Cl_2 , \quad (4)$$

$$RBr + ClF \rightarrow RF + BrCl . \quad (5)$$

Sverlakov and co-workers, who discovered such reactions in a study of the nitrolysis of halogenoalkanes with nitric acid [Eqns.(1) and (2)], who proposed an apt name, from our point of view, for reactions of this type—oxidative substitution.

Interest in these reactions has been aroused for several reasons. Thus it has been suggested that reactions of an analogous type occur in the metabolism of alkyl halides in the living organism [Eqn.3], which is the reason for the carcinogenic properties of certain halogenoalkanes. On the other hand, the introduction by this procedure into highly halogenated substrates of an oxygen-containing functional group [Eqn.(4)] or the fluorine atom [Eqn.(5)] by treatment with powerful oxidants such as chlorine fluorosulphonate, chlorine monofluoride, and related reagents is of preparative value. The third and most important stimulus which led to the investigation of these reactions has been the endeavour to understand their mechanism.

This review surveys and gives a systematic account of the available data and puts forward considerations concerning certain details of the mechanism of the oxidative substitution of the halogens at a saturated carbon atom.

II. REACTIONS OF ALKYLIODIDES AND BROMIDES WITH Cl_2, Br_2, AND ICl

In the last century, it was already known that alkyl iodides and t-alkyl bromides interact under mild conditions (at a low temperature in inert solvents) with molecular chlorine to form alkyl chlorides and I_2 or Br_2.[1-3] In the 1950's, this unusual substitution reaction at a saturated carbon atom attracted the attention of theoretical chemists.

Like aryl iodides, on chlorination alkyl iodides afford organic compounds of tervalent iodine, which, however, are unstable and readily decompose to alkyl chlorides and molecular iodine:[4,5]

$$CH_3I + Cl_2 \xrightarrow{-196^\circ C} CH_3ICl_2 \xrightarrow{-30^\circ C} CH_3Cl + ICl .$$

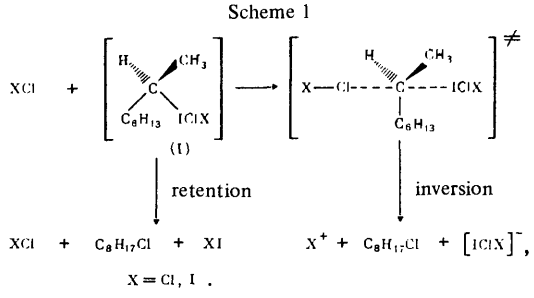
The first data on the mechanism of these reactions were obtained as a result of the study of the kinetics of the reactions of ICl with alkyl iodides and bromides in CCl_4 at 25 °C.[6,7] For the reaction of benzyl bromide and iodide with ICl in the presence of a large excess of the benzyl halide, the rate equation was obtained:

$$\frac{d(IX)}{dt} = k[C_6H_5CH_2X][ICl]^2 .$$

The reaction of isopropyl iodide is also of second order with respect to ICl but the rate is not directly proportional to the concentration of isopropyl iodide; analogous data have been obtained also for t-butyl bromide. The reaction of t-butyl iodide with ICl is so fast that its rate cannot be investigated even in very dilute solutions.

Under the given conditions, benzyl halides give rise to the corresponding chlorides, while in the case of isopropyl iodides mainly chloroiodopropane is formed. In the reaction with t-butyl bromide, a complex mixture of dihalogenoisobutanes is formed together with t-butyl chloride:

$$(CH_3)_3CBr \xrightarrow{ICl} (CH_3)_3CCl + C_4H_8ICl + C_4H_8Cl_2 + C_4H_8BrCl\ .$$



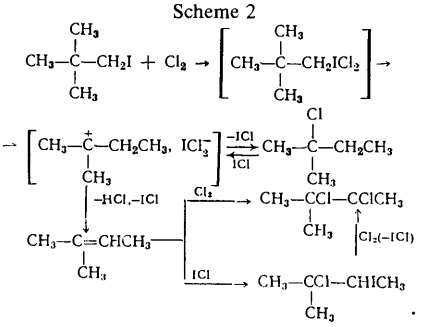
Kinetic data led to the conclusion that the rate-determining stage in the given reaction consists in the attack by the ICl molecule on the alkyl halide–iodine monochloride complex:

$$R{-}I \rightarrow I{-}Cl + ICl \rightarrow \text{products}.$$

The stereochemistry of the substitution of iodine by chlorine and bromine has been investigated in relation to the optically active 2-iodo-octane.[8,9] The reaction of 2-iodo-octane with Cl_2, ICl, and Br_2 proceeds smoothly at −78–0 °C in inert solvents (CH_2Cl_2, $CHCl_3$, CCl_4) and also in a mixture of CH_2Cl_2 with CH_3OH or pyridine, in the absence or presence of HCl, with formation of 2-chloro- and 2-bromo-octanes, preferentially with inversion of the configuration. The higher the polarity of the medium, the greater the amount of the product with inverted configuration formed. Thus the ratios c_i/c_r (c_i and c_r are the amount of products with the inverted and retained configurations respectively) in the reaction of optically active 2-iodo-octanes with an excess of Cl_2 in CH_2Cl_2 and 3:1 CH_2Cl_2–CH_3OH and [CH_2Cl_2–CH_3OH (3:1)]–HCl (4 M) mixtures are respectively 1.5, 5.8, and 10.2.[8] An analogous dependence of c_i/c_r on the polarity of the medium has been observed for the reaction of 2-iodo-octanes with ICl.

According to Corey and Wichter,[8] the results agree with a mechanism involving bimolecular nucleophilic substitution of the complex of alkyl iodide with the halogen (I) by a halogen molecule in accordance with Scheme 1:

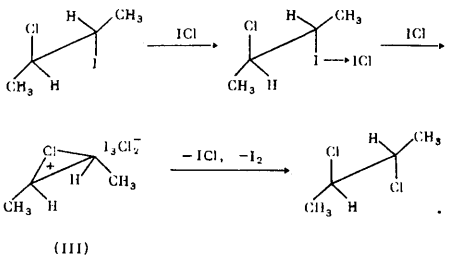
Scheme 1



Attack on the complex (I) by the external nucleophile XCl leads to inversion of configuration, while intramolecular capture of chlorine in the complex (I) leads to the retention of configuration of the alkyl chloride. The complex (I) is in essence an intermediate—an organic compound of tervalent iodine. The mechanism presupposing the heterolysis of the complex (I) to the 2-octylcarbonium ion (II) is unlikely:

$$\underset{(I)}{[C_8H_{17}ICIX]} \rightarrow \underset{(II)}{[C_8H_{17}]^+} + [ICIX]^- \rightarrow C_8H_{17}Cl + IX\ .$$

In this mechanism, one would have to expect a higher degree of racemisation of 2-octyl chloride on increase in the polarity of the reaction medium.



The reaction of neopentyl iodide with molecular iodine yielded t-pentyl chloride and 2,3-dichloro-2-methylbutane.[9] Special experiments showed that t-pentyl chloride also gives rise to 2,3-dichloro-2-methylbutane on treatment with a mixture of ICl and Cl_2, while the reaction with pure Cl_2 does not occur. A mechanism of the reaction of neopentyl chloride with Cl_2 has been proposed on the basis of the data obtained:[9]

Scheme 2

The kinetics and stereochemistry of the reactions of vicinal chloroiodoalkanes with ICl in CCl_4, leading to vicinal dichlorides, have been investigated in a recent study.[10] The reaction of 3-chloro-2-iodo-2,3-dimethylbutane with ICl has overall third order—first with respect to the substrate and second with respect to ICl. The substitution of iodine in *erythro*- and *threo*-3-chloro-2-iodobutanes takes place stereospecifically with retention of configuration, which can be explained by the involvement of the vicinal chlorine in retention of the configuration of the carbonium ion intermediate (III).

Scheme 3

The reactions of *erythro*- and *threo*-2-chloro-1-iodo-1-phenylpropanes with ICl proceed non-stereospecifically and in each case lead to a mixture of *erythro*- and *threo*-1,2-dichloro-1-phenylpropanes. This result can be explained by the fact that the geminal phenyl substituent delocalises the positive charge on the carbonium ion intermediate and thereby prevents the involvement of the neighbouring chlorine in the formation of the bridged cation of type (III).

A single example of the use of iodine trichloride in oxidative substitution reactions has been described in the literature.[11] When n-pentyl iodide reactions with ICl_3 in CH_2Cl_2, n-pentyl chloride is formed in a high yield.

III. REACTIONS OF ALKYL HALIDES WITH NITRIC ACID AND OTHER INORGANIC OXIDANTS

It was observed in 1968 that, when αβ-dibromo-α-nitroalkanes (IV) are treated with concentrated nitric acid at 40–50 °C, the bromide atom in the β-position is replaced by the nitrate group with liberation of elemental bromine in accordance with the scheme[12]

$$2O_2NCBrCBr + 4HNO_3 \rightarrow 2O_2NCBrCONO_2 + Br_2 + N_2O_4 + 2H_2O .$$

(IV) (V)

The bromine atom in the α-position is not substituted by the nitrate group. The corresponding nitric acid esters (V) have been isolated in 35–75% yields. The authors investigated this unusual reaction in detail.[13,14] It was established that alkyl iodies interact most readily (at temperature below 0 °C) with nitric acid. The reactivity of alkyl iodides varies in the sequence tertiary > secondary > primary. Under these conditions, the chlorine and bromine atoms in the molecule are not substituted, for example:

$$CH_3CHICH_2Br \xrightarrow[-5-0°C]{98\%HNO_3} CH_3CHCH_2Br \quad 46\%$$
$$\qquad\qquad\qquad\qquad\qquad\quad ONO_2 ,$$
$$CH_2ClCHICH_2Cl \xrightarrow[-3-0°C]{98\%HNO_3} CH_2ClCHCH_2Cl \quad 53\%$$
$$\qquad\qquad\qquad\qquad\qquad\quad ONO_2 .$$

Alkyl bromides react with nitric acid with greater difficulty than alkyl iodides. The corresponding nitrates are obtained from secondary alkyl bromides at 10–15 °C in yields up to 80%. Primary alkyl bromides react with still greater difficulty and at higher temperatures. The reaction is accompanied by the oxidative decomposition of the nitrate and the yield of the nitrolysis product is therefore reduced:

$$CH_2ClCH_2Br \xrightarrow[0-20°C]{HNO_3-H_2SO_4} CH_2ClCH_2ONO_2 \quad 31\% .$$

Iodocarboxylic acids and their esters also react with nitric acid to form the corresponding nitrates:[14]

$$ICH_2CO_2H \xrightarrow[0-4°C]{HNO_3-(CH_3CO)_2O} O_2NOCH_2CO_2H \quad 46\% ,$$
$$CH_3CHICO_2CH(CH_3)_2 \xrightarrow[12-16°C]{HNO_3} CH_3CHCO_2CH(CH_3)_2 \quad 70\% .$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\quad ONO_2$$

The nitrolysis of the optically active 2-iodo-, 2-bromo-, and 2-chloro-octanes with nitric acid or a mixture of nitric acid and acetic anhydride affords the optically inactive 2-octyl nitrate. On this basis, it has been concluded[13] that the reaction proceeds with formation of carbonium ion intermediates. This is confirmed by the finding that elimination products (alkenes) are formed in the nitrolysis of t-butyl chloride and 2-bromo-octane, which subsequently give rise to addition products:

$$CH_3-\overset{CH_3}{\underset{CH_3}{C}}-Cl \xrightarrow[-Cl_2]{HNO_3} \left[CH_3-\overset{CH_3}{\underset{+}{C}}-CH_3\right] \xrightarrow[-H^+]{} \left[CH_2=\overset{CH_3}{C}-CH_3\right] \xrightarrow{HNO_3} CH_2(NO_2)-\overset{CH_3}{\underset{ONO_2}{C}}(CH_3) ,$$

$$C_6H_{13}CHBrCH_3 \xrightarrow[-Br_2]{HNO_3} [C_5H_{11}\overset{+}{C}HCH_3] \xrightarrow[-H^+]{HNO_3} C_6H_{13}CHCH_3 ,$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad ONO_2$$
$$[C_5H_{11}CH=CHCH_3] \xrightarrow{Br_2} C_5H_{11}CHBrCHBrCH_3 .$$

Further study of the interaction of iodo- and bromo-alkanes with nitric acid, nitrogen pentoxide, acetyl nitrate, and nitryl chloride shows that the active species inducing the heterolytic dissociation of the covalent carbon–halogen bond in the organic halogeno-derivative is the nitronium cation:[15]

Scheme 4

$$NO_2X \rightleftarrows NO_2^+ + X^- , \qquad (6)$$

$$RHal + NO_2^+ \rightleftarrows R^+ + NO_2Hal \rightarrow NO_2 + {}^1/_2Hal_2 , \qquad (7)$$

$$R^+ + X^- \mapsto RX \qquad (8)$$

X=ONO_2, CH_3COO, Cl; Hal=I, Br.

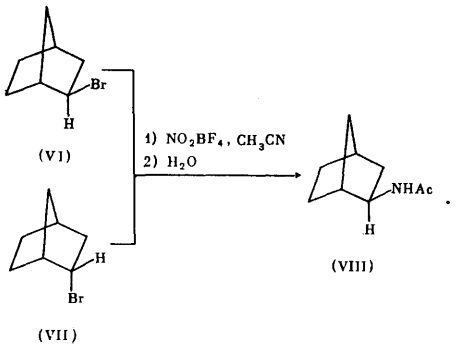
The necessary condition in the oxidative substitution of halogeno-alkanes is the oxidation of the eliminated halogen to Hal_2 [reaction (7)], which shifts the reaction equilibrium towards the formation of the carbonium ion. The primary carbonium ions formed undergo a rearrangement which results in the formation of a mixture of isomeric substitution products. Thus the interaction of 1-iodopropane with 98% HNO_3 in CH_2Cl_2 at −18 – −20 °C results in the formation of a a 48.6 : 51.4 mixture of 1-propyl and 2-propyl nitrates, while several products were obtained from 1-iodo-octane under these conditions: 1-octyl nitrate, 2-octyl nitrate, and 3(4)-octyl nitrate in proportions of 23.2 : 29.2 : 47.6. The authors note that the isomeric composition of the reaction products depends on many factors: the order in which the reactants are mixed, the concentration of nitric acid, the reaction temperature, etc. For example, when a solution of 1-iodo-butane in methylene chloride is added to nitric acid (in molar proportions of 1 : 10), the ratio of 1- and 2-butyl nitrates is 18 : 82, while for the reverse order of the addition the ratio is 96 : 4.

Treatment of 1-bromobutane with a mixture of concentrated nitric acid and acetic anhydride at 15–20 °C leads to the formation of 1-butyl nitrate (15.7%), 2-butyl nitrate (63.0%), 1-butyl acetate (8.1%), and 2-butyl acetate (13.2%).

Not only nitric acid but also HCl, HBr, or HF can act as nucleophiles in the oxidative substitution of the halogens in organic halogeno-derivatives.[16-18] H_2O_2, $KMnO_4$, $K_2Cr_2O_7$, $KClO_3$, $NaNO_2$, and chlorinated lime can also act as oxidants together with HNO_3:[17]

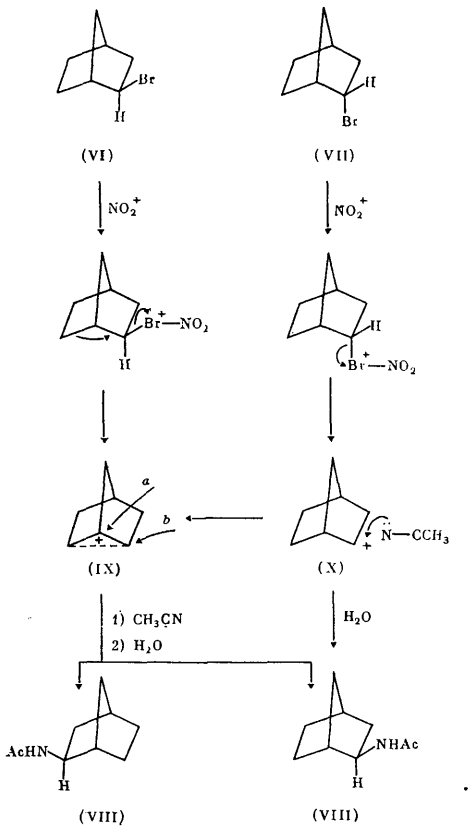
$$RI \xrightarrow{\text{oxidant}} [R^+] \xrightarrow{HCl} RCl ,$$
$$\qquad\qquad\qquad\quad \xrightarrow{HBr} RBr ,$$
$$RI\,(Br) \xrightarrow{HNO_3} [R^+] \xrightarrow{HF} RF .$$

When HCl is passed into a mixture of iodoalkanes with hydrogen peroxide, the yield of the corresponding chloroalkanes reaches 88%. $KMnO_4$ and $K_2Cr_2O_7$ are active oxidants: the reactions in their presence are carried out with slight heating and the yield of chloro-alkanes exceeds 90%. When 2-iodo- or 2-bromo-alkanes are treated with a mixture of concentrated nitric acid and anhydrous hydrogen fluoride, the yield of 2-fluoroalkanes exceeds 70%.



The reactions of alkyl halides with nitronium and nitrosonium fluoroborates in acetonitrile, leading to substituted acetamides, are also a type of oxidative substitution:[19-22]

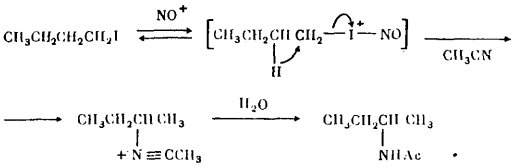
$$R_3CX + NO_2BF_4 \xrightarrow{-NO_2X} [R_3C^+] \xrightarrow{CH_3CN} [R_3C\overset{+}{N}\equiv CCH_3] \xrightarrow{H_2O} R_3CNHAc .$$



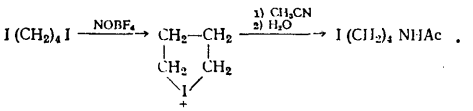
X=I, Br, Cl, F

The reactivity of alkyl derivatives varies in the sequence RI > RBr ≫ RCl > RF. In the general case, the ease of elimination of X corresponds to the stability of the carbenium ions: tertiary > secondary > primary. The relative reactivities of adamantane derivatives are AdF : AdCl : AdBr : AdI = 1 : 6.6 : 67 : 240.[21]

The oxidation of the optically active *exo*-2-norbornyl bromide (VI) under these conditions affords the optically inactive *N*-(exo-2-norbornyl)acetamide (VIII) whilst the optically active *endo*-isomer (VII) gives rise to the *exo*-acetamide (VIII) having a low optical activity (1.2–1.6%):[19]



The heterolysis of the C—Br bond in *exo*-2-norbornyl bromide (VI) by the nitronium cation is accompanied by the nucleophilic attack on the C(2) atom by the electrons of the C(6)—C(1) bond, which results in the formation of the symmetrical non-classical bridged cation (IX). The capture of this cation by the solvent and the hydrolysis of the nitrylium ion afford the racemic *exo*-acetamide (VIII). In the case of the *endo*-isomer (VII), the involvement of the C(6)—C(1) bond in the heterolytic process is ruled out for geometrical reasons. The 2-norbornyl cation (X) formed is either captured by the solvent on the side opposite to that of the leaving group, or leads to the optically active *exo*-acetamide, or, to a much greater extent, rearranges to the bridge ion (IX), which gives rise to the *exo*-racemate (VIII).



An analogous result has been obtained in the solvolysis of the optically active *exo*- and *endo*-2-norbornyl *p*-bromotoluenesulphonates.[23] In the case of the optically active *endo*-*p*-bromotoluenesulphonate, 7—8% of the optical activity was retained, while the *exo*-isomer yielded only the *exo*-racemate.

The substitution of bromine in the optically active 2-bromooctane on treatment with nitronium fluoroborate in acetonitrile takes place preferentially with inversion of configuration.[19]

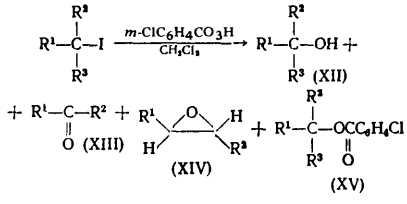
Nitrosonium fluoroborate is somewhat less reactive in the oxidative substitution reaction than nitronium fluoroborate.[22] Tertiary and secondary alkyl iodides react smoothly with $NOBF_4$ in acetonitrile at 0 °C with formation of the corresponding amides. The primary iodides react more smoothly and afford a mixture of 1-alkyl- and 2-alkyl-amides:

A rearrangement is not observed for 1,4-diiodobutane owing to the involvement of iodine in the formation of a five-membered iodonium intermediate:

IV. REACTIONS OF ALKYL IODIDES WITH ORGANIC PEROXY-ACIDS

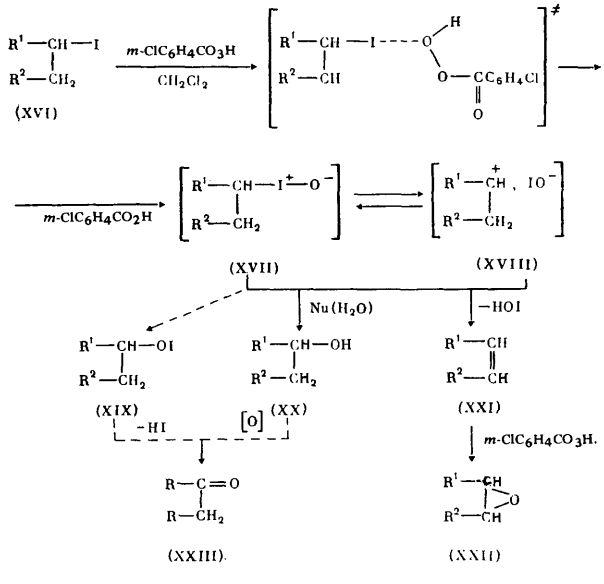
The oxidative substitution of iodine in alkyl iodides when the latter are treated with organic peroxy-acids has been thoroughly investigated[24–30] and it has been established[25] that the complete oxidation of one mole of n-heptyl iodide in methylene chloride requires about two moles of *m*-chloroperoxybenzoic acid. The products of the initial state of this reaction are O_2, I_2, and I_2O_5. The overall stoichiometry of the reaction is described by the set of equations

$$6ArCO_3H + 6RI \rightarrow 6[R\overset{+}{I}\overline{O}] + 6ArCO_2H,$$
$$6[R\overset{+}{I}\overline{O}] + 6H_2O \rightarrow 6ROH + 6HOI,$$
$$6HOI \rightarrow 4HI + 2HIO_3,$$
$$4HI + 2ArCO_3H \rightarrow 2ArCO_2H + 2I_2 + 2H_2O,$$
$$2HIO_3 \rightarrow I_2O_5 + H_2O,$$
$$n\,ArCO_3H \xrightarrow{[cat.]} n\,ArCO_2H + (n/2)\,O_2;$$
$$(8+n)\,ArCO_3H + 6RI + 3H_2O \rightarrow (8+n)\,ArCO_2H + 6ROH + 2I_2 + I_2O_5 + (n/2)\,O_2.$$



$R = n\text{-}C_7H_{15}$, $Ar = m\text{-}ClC_6H_4$, $n = 4\text{-}16$.

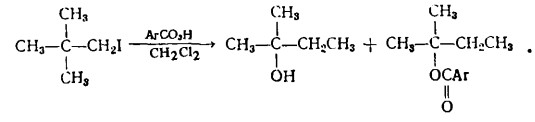
The iodoso-group in the intermediate iodo-compound $R\overset{+}{I}\overline{O}$ is substituted in this case by water, which is present in the peroxy-acid as an impurity. Careful drying of *m*-chloroperoxybenzoic acid and of the solvent reduces the amount of alcohol (60%) and increases that of n-heptyl *m*-chlorobenzoate (40%). This ratio is close to the maximum possible, because 0.5 mole of water is formed on oxidation of one mole of alkyl iodide. When the water-saturated solvent is used, the alcohol is formed exclusively.



The reactivity of alkyl iodides in relation to organic peroxy-acids varies in the sequence tertiary > secondary > primary. The character of the products formed on oxidation of alkyl iodides is determined by the type of substrate and solvent. When a non-nucleophilic solvent (CH_2Cl_2, C_6H_6) or a solvent with a low nucleophilic activity [tetrahydrofuran (THF), $(C_2H_5)_2O$, C_2H_5OAc] is used, the primary alkyl iodides give rise to the corresponding alcohols and *m*-chlorobenzoates. Secondary and tertiary alkyl iodides, afford, together with substitution products, also carbonyl compounds and epoxides. By carrying out this reaction over a wide temperature range (from -80 to 80 °C), it has been shown that it leads to the same products and only their ratio depends on the temperature.

The dependence of the composition of the products on the type of substrate (in accordance with Scheme 5) is indicated in the Table.

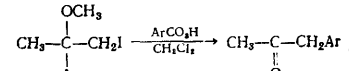
Scheme 5



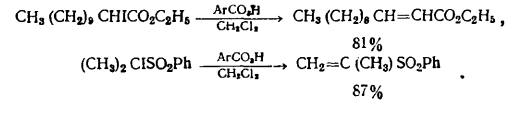
The authors explain the formation of the observed products in the following way:

The alkyl iodide (XVI) is oxidised by *m*-chloroperoxybenzoic acid to the iodoso-compound (XVII), which can dissociate to the ion pair (XVIII). The rearrangement of the iodoso-compound (XVII) to the hypoiodite (XIX) probably proceeds via the ion pair (XVIII). Nucleophilic attack on the iodoso-compound or the ion pair leads to the formation of the substitution products (XX). The elimination of HOI from the iodoso-compound (XVII) results in the formation of the alkene (XXI), which is oxidised under the reaction conditions to the epoxide (XXII). The ketone (XXIII) is formed as a result of the oxidation of the alcohol (XX) and also probably on elimination of HI from the intermediate alkyl hypoiodite (XIX).

Carbonium ion rearrangements on interaction of alkyl iodides with peroxy-acids are observed only when the substitution of iodine is sterically hindered. Thus t-pentyl alcohol and the corresponding *m*-chlorobenzoate have been obtained in the reactions involving neopentyl iodide:

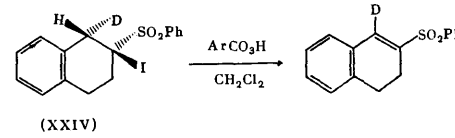


The results of the reactions of alkyl iodides $R^1R^2R^3CI$ with *m*-chloroperoxybenzoic acid.[25]



R^1	R^2	R^3	Solvent	*t*° C	Product ratios			
					(XII)	(XIII)	(XIV)	(XV)
n-C_6H_{13}	H	H	CH_2Cl_2	27	90	0	0	10
n-C_5H_{11}	CH_3	H	CH_2Cl_2	27	48	23	20	9
n-C_5H_{11}	CH_3	H	CH_2Cl_2	−80	55	18	23	4
n-C_5H_{11}	CH_3	H	C_6H_6	80	28	22	28	22
n-C_5H_{11}	CH_3	H	C_2H_5OAc	0	65	7	26	2
CH_3	CH_3	CH_3	CH_2Cl_2	27	85*	0	0	15*

*In all the experiments with the exception of the reaction with t-butyl iodide, the overall yield of the products was 80–100% for the total conversion of the initial compound: in the case of t-butyl iodide, the yield of the substitution product was 60%, the remaining 40% comprising low-boiling olefins and epoxides.



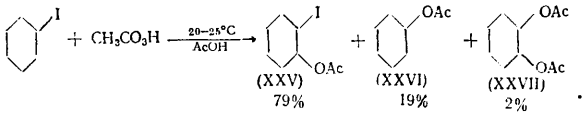
An analogous rearrangement has been observed[26] in the reaction of 2-aryl-1-iodo-2-methoxypropanes with *m*-chloroperoxybenzoic acid:

The elimination of HI can become the main reaction pathway in the presence of electronegative substituents at the α-carbon atom.[27] For example, the oxidation of ethyl 2-iododecanoate and 2-iodo-2-benzenesulphonylpropane with *m*-chloroperoxybenzoic acid leads to unsaturated compounds in a high yield:

It has been shown in relation to the bicyclic iodide (XXIV) that alkenes are formed as a result of *syn*-elimination:

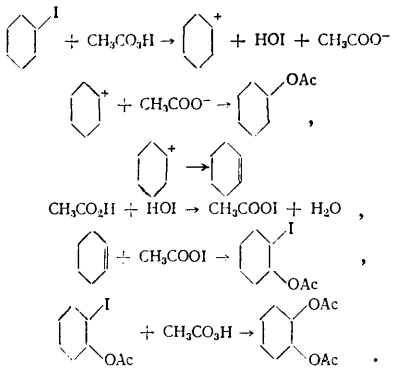
(XXIV)

The quantitative formation of 1,2-epoxycyclohexane in the oxidation of cyclohexyl iodide by *m*-$ClC_6H_4CO_3H$ in methylene chloride has been noted.[28]



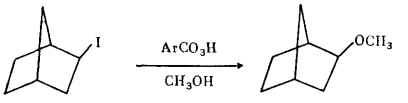
The oxidation of alkyl iodides in nucleophilic solvents (CH_3OH, CH_3COOH) gives rise mainly to products involving the solvent:[28-30]

$$CH_3(CH_2)_6CH_2I \xrightarrow[CH_3OH]{ArCO_3H} CH_3(CH_2)_6CH_2OCH_3\ ,\quad 91\%$$

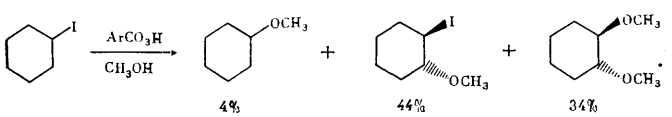


$$CH_3(CH_2)_6CHICH_3 \xrightarrow[AcOH]{ArCO_3H} CH_3(CH_2)_5\underset{\displaystyle OAc}{\underset{|}{C}}HCH_3 + CH_3(CH_2)_6\overset{\displaystyle O}{\overset{\|}{C}}CH_3\ .$$

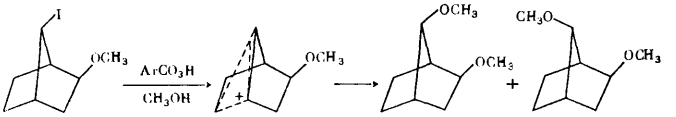
84% 15%



The oxidation of cyclohexyl iodide by peroxyacetic acid in acetic acid produces, in contrast to the reaction with *m*-$ClC_6H_4CO_3H$ in CH_2Cl_2, the vicinal iodoacetate (XXV) together with cyclohexyl acetate (XXVI) and diacetate (XXVII).[29] For a reactant : substrate ratio of 0.7, the following proportions of the products have been obtained:



With increase in the peroxyacetic : cyclohexyl iodide ratio, the amount of iodoacetate (XXV) diminishes and that of the diacetate (XXVII) increases. The authors proposed the following reaction scheme:



The reactions of alkyl iodides with *m*-chloroperoxybenzoic acid in methanol,[6] in which the corresponding methyl ethers have been obtained in high yield in most cases, have been studied in detail:[30]

The interaction of cyclohexyl iodide with two equivalents of *m*-chloroperoxybenzoic acid led to the isolation of products analogous to those obtained in the reaction with peroxyacetic acid in acetic acid:

Under the given conditions, it has been possible to substitute iodine in highly inert systems such as 1- and 7-bicyclo[2.2.1]heptyl iodides, but, compared with other substrates, under these conditions a (7 – 10)-fold excess of oxidant is necessary. The formation of products with the preferential retention of configuration in the oxidative substitution of iodine in the 7-*syn*-iodide (XXVIII) is explained by the fact that the intermediate species is the σ-delocalised 7-bicyclo-[2.2.1]heptyl cation (XXIX):

(XXVIII) (XXIX) 66% 15%

The influence of various lithium salts on the character of the oxidative substitution product has been investigated in relation to the reaction of n-octyl iodide with *m*-chloroperoxybenzoic acid. It was found that, in the presence of a five-fold excess of lithium chloride or bromide, the main reaction products become the corresponding chlorides and bromides, but the addition of lithium fluoride and perchlorate does not result in the formation of "participation products":

$$CH_3(CH_2)_6CH_2I \xrightarrow[CH_3OH,LiX]{ArCO_3H} CH_3(CH_2)_6CH_2X + CH_3(CH_2)_6CH_2OCH_3\ ;$$

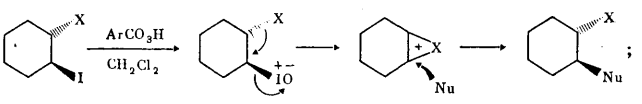
70–80% 10–15%

X = Cl, Br .

The stereochemistry of the oxidative substitution of iodine by peroxy-acids has been investigated in relation to the optically active 2-iodo-octane.[28,30] The substitution of iodine in (*S*)(+)-2-iodo-octane in methylene chloride affords a mixture of products containing (*R*)(–)-octan-2-ol 56%, the corresponding *m*-chlorobenzoate (29%), octan-2-one (9%), as well as traces of octan-3-ol. Thus the chiral reaction products are formed with complete inversion of configuration, which indicates the operation of the S_N2 mechanism. However, when the reaction is carried out in methanol,[30] the corresponding methyl 2-octyl ether is formed only with the preferential inversion of configuration (c_i/c_r = 2), which indicates the partial heterolysis of the intermediate iodoso-compound on passing to a more polar solvent.

The iodoso-group is an excellent leaving group, comparable in its ability to be substituted to the diazo-group in alkanediazonium ions. It is well known that the solvolysis of the aryl ethers of β-phenylethanol in aqueous and alcoholic media proceeds without a rearrangement,[31] but the oxidation of the deuterium-labelled 1-iodo-2-phenylethane in methylene chloride results in the formation of 35% of the alcohol with migration of the phenyl group. Similarly the deamination of labelled β-phenylethylamine in aqueous solution yields 27% of the alcohol with a displaced phenyl group:[32]

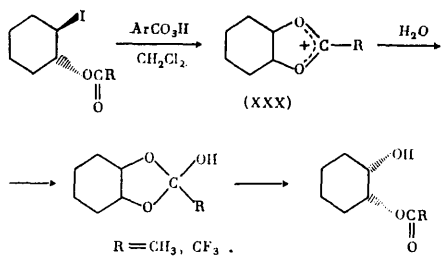
$$PhCH_2CD_2I \xrightarrow[CH_2Cl_2]{ArCO_3H} PhCH_2CD_2OH + PhCD_2CH_2OH\ ,$$



65% 35%

$$Ph^{14}CH_2CH_2NH_2 \xrightarrow[H_2O]{HNO_2} Ph^{14}CH_2CH_2N_2^+OH^- \rightarrow$$

$$\rightarrow Ph^{14}CH_2CH_2OH + PhCH_2^{14}CH_2OH\ .$$



73% 27%

The substitution of iodine in *trans*-vicinally substituted iodocyclohexanes affords alcohols and the corresponding *m*-chlorobenzoates with retention of configuration also as a result of the involvement of the neighbouring group:

X = Cl, Br, OH, OCH_3, N_3 .

The formation of *cis*-hydroxyethers from *trans*-2-iodocyclohexyl acetate or trifluoroacetate is explained by the attack of water on the C(2) atom in the 2-alkyl-1,3-dioxolanolium ion (XXX).

(XXX)

Analogous results have been obtained in the oxidation of *trans*-vicinally substituted iodocyclohexanes by iodine trifluoroacetate (III).[33,34] The reaction with *trans*-2-bromo-1-iodocyclohexane yielded a product with retention of configuration, while in the reaction with 2-iodocyclohexyl trifluoroacetate the configuration is inverted.

V. INTERACTION OF ALKYL HALIDES WITH HYPOHALITE DERIVATIVES OF STRONG ACIDS

Hypohalite derivatives of strong acids (fluorosulphonic, trifluoromethanesulphonic, perchloric, and nitric) have been synthesised and investigated comparatively recently.[35] These compounds are very strong electrophiles capable of substituting the halogen atoms in polyhalogenoalkanes by the strong acid residue.

The hypohalite derivatives of fluorosulphonic acid, usually referred to as halogen fluorosulphates, have been most thoroughly investigated among compounds of this class.[36–48] Chlorine and bromide fluorosulphates readily interact even at temperatures below 0 °C with usually inert solvents such as CH_2Cl_2, CCl_4, and $CHCl_2CHCl_2$:[38–38]

$$CH_2Cl_2 + ClOSO_2F \xrightarrow{<0^\circ C} CH_2ClOSO_2F + Cl_2 ;$$
$$CCl_4 + n\,BrOSO_2F \xrightarrow{-22^\circ C} CCl_{4-n}(OSO_2F)_n + n\,BrCl ;$$
$$n = 1-4 .$$

Owing to the high reactivity of halogen fluorosulphates and also the low stability of the non-halogenated alkyl fluorosulphates,[38,47] these reagents have been investigated in reactions with polyfluoroalkyl halides. The reactivity of perfluoroalkyl halides in relation to chlorine fluorosulphate varies in the sequence $R_FI > R_FBr > R_FCl$.[35,39] Thus, perfluoroalkyl iodides are converted into solid white or cream coloured compounds, probably having the structure $R_FI(OSO_2F)_2$, already at tempereatures between −50° and −40 °C. With increase in temperature, these compounds decompose into perfluoroalkyl fluorosulphates and iodine fluorosulphates:[40]

$$R_FI + ClOSO_2F \xrightarrow{-50^\circ C} [R_FICIOSO_2F] \xrightarrow{ClOSO_2F} \rightarrow R_FI(OSO_2F)_2 \xrightarrow{-20^\circ C} R_FOSO_2F + IOSO_2F$$
$$R_F = CF_3,\ n\text{-}C_3F_7,\ n\text{-}C_7F_{15}.$$

Perfluoroalkyl bromides react with chlorine fluorosulphate under more severe conditions. Both primary bromine atoms in 1,2-dibromoperfluoroethane and 1,3-dibromoperfluoropropane can be substituted only at 50–60 °C:[40]

$$Br(CF_2)_3Br + ClOSO_2F \xrightarrow[48\ h]{65^\circ C} \underset{64\%}{FSO_2O(CF_2)_3OSO_2F} + \underset{31\%}{Cl(CF_2)_2OSO_2F} .$$

The secondary bromine atoms are not involved under these conditions. The chlorine atoms in chlorofluoroalkanes are substituted with even greater difficulty. The reaction is catalysed by fluorosulphonic acid.[41–43] Thus Freon 112 ($CFCl_2CFCl_2$) does not react with chlorine fluorosulphate even after prolonged heating (at 70–80 °C), but, after the addition of catalytic amounts of FSO_3H (5 mole %) an exothermic reaction begins at room temperature and is completed after 5 h at 35–45 °C:[41]

$$CFCl_2CFCl_2 + ClOSO_2F \xrightarrow{35-45^\circ C} CFCl_2CFClOSO_2F .$$

Freon 112 (CF_2Cl_2) reacts similarly but 1,2-dichlorohexafluoropropane does not react even at 100 °C.

In the presence of catalytic amounts of FSO_3H, chlorine fluorosulphate interacts with Freon 113 ($CF_2ClCFCl_2$) at 40–50 °C, but the completion of the reaction requires 8 h. The catalytic action of fluorosulphonic acid probably consists in protonating the $ClOSO_2F$ molecule, as a result of which the partial positive charge on the chlorine atom increases:[36,42]

$$ClOSO_2F + HOSO_2F \rightleftarrows \overset{+}{Cl}(H)-O-SO_2F + OSO_2F^- .$$

In fluorosulphonic acid at room temperature, chlorine fluorosulphate substitutes one chlorine atom and at 85 °C a second chlorine atom in Freon 113; all three chlorine atoms are substituted in a superacid medium (HSO_3F/SbF_5):

$$CF_2ClCFCl_2 + ClOSO_2F \xrightarrow[40-50^\circ C]{cat.\ HSO_3F} \underset{84\%}{CF_2ClCFClOSO_2F} ,$$
$$CF_2ClCFCl_2 + ClOSO_2F \xrightarrow[\sim 20^\circ C]{HSO_3F} CF_2ClCFClOSO_2F \xrightarrow{65^\circ C} \underset{65\%}{CF_2ClCF(OSO_2F)_2}$$
$$CF_2ClCFCl_2 + ClOSO_2F \xrightarrow[30^\circ C]{HSO_3F/SbF_5} FSO_2OCF_2CF(OSO_2F)_2 \rightarrow$$
$$\xrightarrow{HSO_3F/SbF_5} FSO_2OCF_2C(=O)F + S_2O_6F_2$$
$$\sim 50\% \qquad \sim 50\% .$$

With the aid of chlorine fluorosulphate in the superacid medium, it has been possible to substitute the secondary bromine atom in 2-bromohexafluoropropyl fluorosulphate (XXXI):

$$\underset{(XXXI)}{CF_3CFBrCF_2OSO_2F} + ClOSO_2F \xrightarrow[80-100^\circ C]{HSO_3F/SbF_5} CF_3\underset{\displaystyle OSO_2F}{\underset{|}{C}}FCF_2OSO_2F .$$

However, even under these conditions the secondary chlorine and tertiary bromine atom in polyfluoroalkanes cannot be substituted.[43] The reactivity of chlorine fluorosulphate increases also after the addition of bromine, which has been explained by the formation of $BrOSO_2F$ *in situ*.[40] However, in a later study[43] it was shown that bromine fluorosulphate is less reactive than chlorine fluorosulphate; in particular, it reacts with compound (XXXI) in the superacid medium even at 120–130 °C. The catalytic action of bromine in reactions involving substitution by chlorine fluorosulphate has been explained[43,44] by the formation of the compound $BrCl(OSO_2F)_2$ as a possible intermediate, whose molecule contains a tervalent bromine atom. The same workers showed that bromine tris(fluorosulphate), which readily interacts with Freon 113, is even more reactive than chlorine fluorosulphate:[45]

$$CF_2ClCFCl_2 + Br(OSO_2F)_3 \xrightarrow[2\ h]{30^\circ C} \underset{51\%}{CF_2ClCFClOSO_2F} + \underset{39\%}{CF_2ClCF(OSO_2F)_2} .$$

In the superacid medium, $Br(OSO_2F)_3$ substitutes the chlorine atom in 2,3-dichloro-2-trichloromethyl pentafluoropropane.[44]

Iodine tris(fluorosulphate)† and iodine fluorosulphate do not substitute chlorine atoms in Freons in the presence of fluorosulphonic acid even on prolonged heating.[46] $I(OSO_2F)_3$ is capable of substituting only iodine by the fluorosulphate group in perfluoroalkyl iodides:[46]

$$n\text{-}C_3F_7I + I(OSO_2F)_3 \xrightarrow[120\ h]{20^\circ C} n\text{-}C_3F_7OSO_2F + I_3SO_2F + IOSO_2F\ .$$

Nevertheless iodine tris(fluorosulphate) and iodine fluorosulphate readily interact with ethyl chloride at room temperature:[46]

$$CH_3CH_2Cl \xrightarrow[-\frac{1}{3}ICl_3,\ -ICl]{\frac{1}{3}I(OSO_2F)_3,\ IOSO_2F} CH_3CH_2OSO_2F\ (50\%)\ .$$

As regards the mechanism of the interaction of halogen fluorosulphates with alkyl halides, it has been recently suggested[48] that, in the substitution of a halogen by the fluorosulphate group, the substituted halogen is initially oxidised to the tervalent state and the resulting intermediate (XXXII) decomposes under these conditions in accordance with the scheme

$$RHal + XOSO_2F \longrightarrow \underset{\text{(XXXII)}}{R(Hal)(X)(OSO_2F)} \longrightarrow ROSO_2F + HalX\ ;$$

$Hal = Cl, Br, I$; $X = Cl, Br, I, Br(OSO_2F)_2, I(OSO_2F)_2$.

The proposed scheme is hardly applicable to the substitution of chlorine atoms in alkyl halides by bromine and iodine fluorosulphates. In particular, it is unlikely that the electropositive iodine should oxidise the chlorine atom in C_2H_5Cl to the tervalent state in the above reaction of ethyl chloride with $I(OSO_2F)_3$ or $IOSO_2F$.

Chlorine and bromine trifluoromethanesulphonates are also capable of substituting the Cl and Br atoms in perfluorohalogenoalkanes by the trifluoromethanesulphonate group. In contrast to the analogous fluorosulphates, chlorine and bromine trifluoromethanesulphonates are unstable at temperatures above 0 °C and the reactions with them have therefore been carried at low temperatures (down to −160 °C).[49] Comparison of the reactivities of chlorine and bromine trifluoromethanesulphonates and fluorosulphates shows readily that the corresponding trifluoromethanesulphonates are significantly more vigorous reagents. For example, the reaction of $ClOSO_2CF_3$ with Freon 12 takes place readily at −60 °C,[50,51] while in the case of chlorine fluorosulphate heating to 80 °C is necessary:[41]

$$CF_2Cl_2 + ClOSO_2CF_3 \xrightarrow{-60^\circ C} CF_2ClOSO_2CF_3\ ,$$
$$CF_2Cl_2 + ClOSO_2F \xrightarrow{80^\circ C} CF_2ClOSO_2F\ .$$

As for chlorine and bromine fluorosulphates, the reactivity of $ClOSO_2CF_3$ is higher than that of $BrOSO_2CF_3$, which can be seen especially well in the reactions with perfluoroalkyl bromides:[50]

† Bromine tris(fluorosulphate) and iodine tris(fluorosulphate) are considered in this Section as compounds related to the hydrophalite derivatives of fluorosulphonic acid.

$$CF_3Br + ClOSO_2CF_3 \xrightarrow[1\ h]{-111^\circ C} \underset{95\%}{CF_3OSOCF_3}\ ,$$
$$CF_3Br + BrOSO_2CF_3 \xrightarrow[15\ h]{-111\div-10^\circ C} \underset{58\%}{CF_3OSO_2CF_3}\ .$$

In relation to $ClOSO_2CF_3$, the reactivity of alkyl chlorides decreases in the sequence

$$CCl_4 > CCl_3F > CCl_2F_2 > CF_3Cl\ .$$

Chlorotrifluoromethane does not react with $ClOSO_2CF_3$ in the course of 24 h at temperatures in the range −111 − 22 °C. The reactivity series obtained can be accounted for by the decrease in the negative charge on the chlorine atom with increase in the number of fluorine atoms, which should hinder the interaction with the electropositive halogen in $ClOSO_2CF_3$. Under the conditions indicated, the secondary bromine atoms in perfluoroalkanes are not substituted, which the authors explain by the increasing steric hindrance.[50]

The stereochemistry of the substitution of the chlorine atom in *erythro*- and *threo*-$CF_3CO_2CHFCHFCl$ has been investigated.[50] For each diastereoisomer, one diastereoisomer of trifluoromethanesulphonate (XXXIII) was obtained:

$$CF_3CO_2CHFCHFCl + ClOSO_2CF_3 \xrightarrow{-111\div22^\circ C} \underset{\text{(XXXIII)}}{CF_3CO_2CHFCHFOSO_2CF_3}\ .$$

Careful examination of the ^{19}F NMR spectra of the diastereoisomers obtained enabled the authors to conclude that the substitution takes place with retention of configuration. On the basis of the data obtained, a synchronous cyclic mechanism of the type S_Ei was proposed:

Scheme 6

$$\equiv C{-}Cl + ClOSO_2CF_3 \longrightarrow \equiv C{-}Cl{\cdots}OSO_2CF_3 \longrightarrow \equiv C{-}OSO_2CF_3 + Cl_2\ .$$

The hypochlorite derivative of perchloric acid (chlorine perchlorate) and virtually all covalent perchlorates are explosive substances sensitive to impact. Chlorine perchlorate is itself stable at room temperature.[52] Perfluoroalkyl and perfluoroaryl iodides interact vigorously with chlorine perchlorate. As for the majority of the reactions of alkyl iodides with oxidants described above, here organic compounds of tervalent iodine (XXXIV) are formed initially and are then converted into the corresponding alkyl perchlorates (XXXV):[53]

$$2R_FI + 4ClOClO_3 \rightarrow \underset{\text{(XXXIV)}}{(R_F)_2I^+I(OClO_3)_4^-} \rightarrow \underset{\text{(XXXV)}}{2R_FOClO_3} + 2[IOClO_3]\ .$$

The intermediates (XXXIV) have been isolated and characterised for R_F = n-C_7F_{15}, iso-C_3F_7, or C_6F_5. The covalent perchlorates (XXXV) cannot always be obtained on heating the intermediates (XXXIV). Thus explosions occurred in the cases of the perfluorophenyl and perfluoroisopropyl derivatives.

Perfluoroalkyl bromides interact just as readily with chlorine perchlorate and afford covalent perchlorates in satisfactory yields. Molecular chlorine and bromine perchlorates are then produced:

$$R_FCFBrCF_2Br + ClOClO_3 \xrightarrow{-25\div0^\circ C} \underset{40-90\%}{R_FCFBrCF_2OClO_3} + BrOClO_3 + Cl_2\ .$$

Primary and secondary perfluoroalkyl chlorides do not enter into this reaction. In the less fluorinated chlorofluorohydrocarbons, the chlorine atoms can also be substituted:[53]

$$\begin{array}{l}CF_2{-}CCl_2\\ |\quad\ |\\ CF_2{-}CCl_2\end{array} + 2ClOClO_3 \rightarrow \begin{array}{l}CF_2{-}CClOClO_3\\ |\quad\ \ |\\ CF_2{-}CClOClO_3\end{array}.$$

Bromine perchlorate is formed in the reactions of $ClOClO_3$ with perfluoroalkyl bromides probably as a result of the oxidation of the elemental bromine formed as an intermediate; owing to the lower reactivity, $BrOClO_3$ accumulates in the reaction products:

$$R_FBr + ClOClO_3 \xrightarrow{k_1} R_FOClO_3 + BrCl,$$
$$BrCl \rightleftarrows {}^1/_2Br_2 + {}^1/_2Cl_2,$$
$${}^1/_2Br_2 + ClOClO_3 \xrightarrow{k_2} BrOClO_3 + {}^1/_2Cl_2.$$

The absence of appreciable amounts of elemental bromine may be evidence that Br_2 is oxidised more readily than the bromine atom in the perfluoroalkyl bromide, i.e. in the reaction schemes presented we have $k_2 > k_1$. Bearing in mind that chlorine trifluoromethanesulphonate[51] and chlorine fluorosulphate[54] readily oxidise Br_2 to the corresponding hypobromites, presumably an analogous picture obtains also in the substitution by these reagents of the bromine atoms in the relatively unreactive perfluoroalkyl bromides.

Yet another representative of reagents of this type, namely chlorine nitrate, is stable at low temperatures (–40 °C), decomposing gradually at 20–25 °C.[55] Trifluoromethyl iodide is readily oxidised at low temperatures by chlorine nitrate, but covalent alkyl nitrates have not been isolated, in contrast to the perchlorates:[56,57]

$$CF_3I + ClONO_2 \xrightarrow{-45^\circ C} [CF_3IClONO_2] \xrightarrow{-20^\circ C} CF_3I(ONO_2)_2 + Cl_2.$$

Trifluoromethyl iodosodinitrate decomposes at room temperature in accordance with the scheme[57]

$$10CF_3I(ONO_2)_2 \xrightarrow{20^\circ C} 5CF_3I + 5COF_2 + 10N_2O_4 + I_2 + IF_5 + I_2O_5.$$

VI. THE INTERACTION OF ALKYL HALIDES WITH HALOGEN FLUORIDES

The most readily available halogen fluorides, namely IF_5, BrF_3, ClF, and ClF_3, were tested as early as the 1930's–1950's as fluorinating agents in the substitutional fluorination reactions of polyhalogenohydrocarbons, mainly halogenomethanes:[58–61]

$$CHI_3 + IF_5 \rightarrow CHF_3 + I_2,$$
$$CBr_4 + BrF_3 \rightarrow CBrF_3 + Br_2,$$
$$CCl_4 + BrF_3 \rightarrow CCl_2F_2 + BrCl.$$

It was then already noted that, as the geminal halogen atoms (I, Br, Cl) are substituted by fluorine, further fluorination is hindered.

Bromine and chlorine trifluorides effectively substitute the iodine atoms by fluorine in perfluoroalkyl iodides, the corresponding perfluoroalkanes being then formed in high yields.[62] Later it was shown that at low temperatures the interaction of ClF_3 and BrF_3 with perfluoroalkyl iodides leads to the formation of the corresponding derivatives of tervalent and quinquevalent iodine:[63]

$$R_FI + 2ClF_3(BrF_3) \rightarrow R_FIF_2,$$
$$R_FI + 4ClF_3 \rightarrow R_FIF_4,$$
$$R_F = C_2F_5,\ C_4F_9,\ \text{etc.}$$

Overall, the early data surveyed in a number of reviews[59–61] led to the conclusion that halogen fluorides are relatively unselective reagents and that their application in organic chemistry would be restricted to reactions with highly halogenated substrates. Nevertheless, subsequent investigations demonstrated that highly reactive compounds such as ClF and BrF_3 can be used successfully for the selective substitution of bromine and chlorine atoms by fluorine in hydrogen-containing halogenoalkanes.[64–70] Thus the use of a solution of bromine trifluoride in bromine for the selective fluorination of bromofluoroethanes has been described:[64]

$$CF_3CHBr_2 \xrightarrow[25-35^\circ C]{BrF_3/Br_2} \underset{92\%}{CF_3CHBrF} + \underset{5\%}{CF_3CHF_2},$$
$$CF_2BrCH_2Br \xrightarrow{BrF_3/Br_2} \underset{77\%}{CF_3CH_2Br}.$$

A possible reaction mechanism taking into account the tendency of BrF_3 to undergo self-ionisation has been proposed:

$$2BrF_3 \rightleftarrows BrF_2BrF_4 \rightleftarrows BrF_2^+ + BrF_4^-,$$
$$-\overset{|}{C}-Br + BrF_2^+ \rightarrow [-\overset{|}{C}^{\delta+}\cdots Br\cdots Br^{\delta-}F_2] \rightarrow [-\overset{|}{C}^+] + [Br_2F_2],$$
$$[-\overset{|}{C}^+] + BrF_4^- \rightarrow -\overset{|}{C}-F + BrF_3,$$
$$[Br_2F_2] \rightarrow 2BrF \rightleftarrows {}^2/_3Br_2 + {}^2/_3BrF_3.$$

The BrF formed in the above scheme is extremely unstable and readily disproportionates to Br_2 and BrF_3.[58] Ultimately 1/3 of a mole of BrF_3 is consumed in the substitution of a single bromine atom in the bromoalkane:

$$RBr + {}^1/_3BrF_3 \xrightarrow{Br_2} RF + {}^2/_3Br_2.$$

In a recently published series of studies, it has been shown that ClF and BrF_3 smoothly substitute a bromine atom by fluorine in bromine-containing alkanes and esters.[66–70] The process is carried out at room temperature by the gradual addition of pure BrF_3 to a solution of the bromo-derivative in Freon (5–30 vol.%).[69] In the case of chlorine monofluoride, the gaseous reagent is passed through the liquid bromoalkane or its solution in an inert solvent ($CHCl_3$, CCl_4, $CF_2ClCFCl_2$) at temperatures between –50° and 50 °C.[66]

Fluorination with chlorine monofluoride and bromine trifluoride produces virtually identical results both as regards the yield and the character of the reaction products, for example:

$$CH_2ClCHBrCH_2Br \xrightarrow{ClF\ or\ 1/3BrF_3} \underset{60\%}{CH_2ClCHFCH_2Br} + \underset{20\%}{CH_2ClCHBrCH_2F}.$$

Bearing in mind that the reactions of ClF with bromo-derivatives result in the formation of elemental bromine, which is capable of reacting with ClF to form BrF_3,[58] one may assume that ClF reacts only initially with the bromoalkanes and that subsequently the fluorination is effected by BrF_3:

$$RBr + ClF \rightarrow RF + BrCl,$$
$$2BrCl \rightleftarrows Br_2 + Cl_2,$$
$$Br_2 + 6ClF \rightarrow 2BrF_3 + 3Cl_2,$$
$$RBr + 1/3BrF_3 \rightarrow RF + 2/3Br_2.$$

However, special experiments have shown that chlorine monofluoride reacts with hydrogen-containing bromoalkanes as a rule much faster than with bromine.[69]

As already mentioned previously, the opposite ratio of the rates of reaction with the organic substrate and elemental bromine (see Section V) is observed in the reactions of chlorine perchlorate with perfluoroalkyl bromides. This difference is apparently associated

with the fact that the electron density of the bromine atom of the perfluoroalkyl bromide is greatly reduced under the influence of the powerful $-I$ effect of the perfluoroalkyl group and not with the character of the oxidant (ClF and $ClOClO_3$). For this reason, substitution of bromine in perfluoroalkyl bromides is slower than the oxidation of the elemental bromine (formed as a result of the reaction) to $BrOClO_3$. On the other hand, the organic bromides used in the reactions with ClF do not as a rule have such poweful electron-accepting substituents at their reaction centre.[66,69] For this reason, in the interaction of ClF with hydrogen-containing alkyl bromides, Br_2 does not enter into a competing reaction and BrF_3 is not formed as an intermediate.[69] Virtually identical results of the substitutional fluorination with chlorine monofluoride and bromine trifluoride indicate a common mechanism of fluorination by these reagents.

The interaction of alkyl bromides with chlorine monofluoride and bromine trifluoride probably proceeds with formation of linear bromonium ions in the first stage of the reaction, which is followed by the substitution of the Br—X group by the fluoride anion or an internal nucleophile:

$$R{-}Br + ClF \rightarrow R{-}\overset{+}{Br}{-}Cl, F^- \rightarrow RF + BrCl\ ,$$

$$R{-}Br + BrF_3 \rightarrow R{-}\overset{+}{Br}{-}BrF_2, F^- \rightarrow RF + Br_2F_2\ ,$$

$$Br_2F_2 \rightarrow 2BrF \rightleftarrows {}^2/_3Br_2 + {}^2/_3BrF_3\ .$$

A characteristic feature of the reactions involving the oxidative substitution of bromine by ClF and BrF_3 is that rearrangement products are formed exclusively from primary alkyl bromides in a non-polar medium:[66,68,69]

$$CH_3(CH_2)_3CH_2Br \xrightarrow{ClF \text{ or } 1/3BrF_3} CH_3(CH_2)_2CHFCH_3\ ,$$

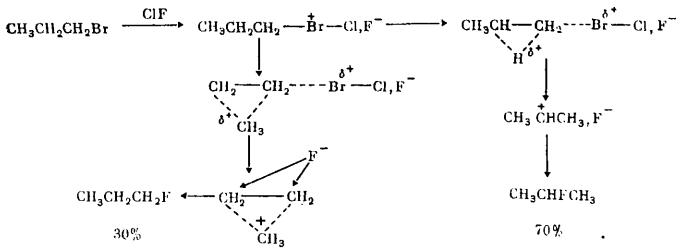
$$CH_3\underset{CH_3}{CH}CH_2Br \xrightarrow{ClF} CH_3\underset{CH_3}{CF}CH_3 + CH_3CHFCH_2CH_3\ ,$$

$$\underset{CH_3}{CH_2ClCFCH_2Br} \xrightarrow{{}^1/_3BrF_3} \underset{90\%}{CH_2ClCF_2CH_2CH_3} + \underset{10\%}{CH_2ClCFCH_2F}\ .$$

$$\underset{CH_3}{\quad} \qquad\qquad \underset{CH_3}{\quad}$$

$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad > 90\% \qquad < 10\%$$

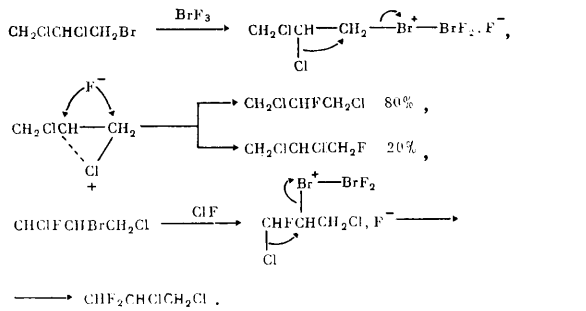
Br—Cl and Br—BrF_2 are probably groups which are so readily removed that any neighbouring group, including the methyl group and the hydrogen atom, is capable of participating in the stabilisation of the resulting carbonium ion:



$$\underset{R}{\overset{|}{-C}}{-}CH_2Br + XF \rightarrow \underset{R}{\overset{|}{-C}}{-}CH_2{-}\overset{+}{Br}{-}X, F^- \rightarrow \underset{R^{\delta+}}{\overset{|}{-C}}{-}CH_2{-}Br^{\delta+}{-}X, F^- \rightarrow$$

$$\xrightarrow{BrX} \underset{+}{\overset{|}{-C}}{-}CH_2R, F^- \rightarrow \underset{F}{\overset{|}{-C}}{-}CH_2R\ ;$$

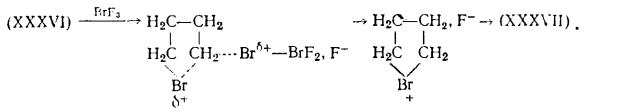
$$X = Cl, BrF_2 \qquad R = H, CH_3\ .$$



Thus it has been noted in a study of the solvolysis reactions that the degree of involvement of the neighbouring group in the stabilisation of the carbonium ion centre formed increases in the presence of neutral readily removable groups incapable of forming ion pairs.[71]

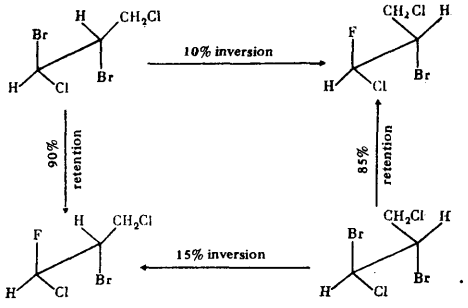
In contrast to the majority of the reactions of primary alkyl bromides, the interaction of 1-bromopropane with ClF leads to the formation of an appreciable amount of the primary fluoride, which can be explained by the involvement of the methyl group with formation of protonated cyclopropane:

The deamination of n-propylamine by nitrous acid also proceeds via the protonated cyclopropane stage.[72]



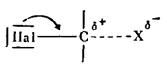
In the presence of a vicinal halogen (Br, Cl) in the substrate molecule, the halogen behaves as an internal nucleophile:

Interesting results have been obtained in a study of the interaction of 1,4-dibromobutane (XXXVI) with bromine trifluorides.[69] For the complete conversion of the initial substrate, a 50% excess of the reagent is necessary, whereupon a mixture of approximately equal amounts of the mono- and di-fluorides is formed:



$$\underset{(XXXVI)}{Br(CH_2)_4Br} \xrightarrow{{}^1/_2BrF_3} \underset{24\%}{\underset{(XXXVII)}{Br(CH_2)_4F}} + \underset{6\%}{\underset{(XXXVIII)}{Br(CH_2)_2CHFCH_3}} + \underset{28\%}{F(CH_2)_2CHFCH_3}\ .$$

The preferential formation of 1-bromo-4-fluorobutane (XXXVII), in contrast to the reactions with primary monobromo-derivatives, indicates the involvement of bromine in the stabilisation of the carbonium ion formed

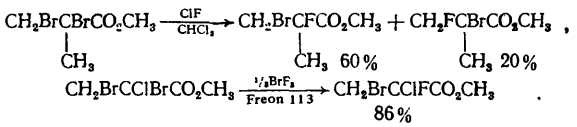


The fluorine atom is incapable of such stabilisation, as a result of which the substitution of bromine in 1-bromo-4-fluorobutane (XXXVI) takes place exclusively with a hydride shift. The presence of 1-bromo-3-fluorobutane (XXXVIII) in the reaction products confirms yet again that Br—BrF_2 is an excellent leaving group; the degree of involvement of a neighbouring group in the oxidative substitution by halogen fluorides is more likely to be controlled by a kinetic factor than by a thermodynamic factor, in contrast to the solvolysis of primary halogen-containing tosylates.[73]

The substitution of bromine by fluorine in *erythro*- and *threo*-1,2-dibromo-1,3-dichloropropanes by chlorine monofluoride takes place regiospecifically with respect to the terminal bromine atom and preferentially (85—90%) with retention of the configuration as a result of the involvement of the vicinal bromine atom:[66]

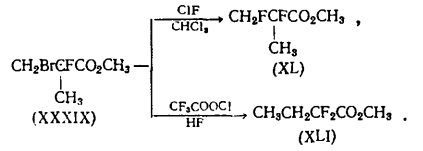
The fluorination of *erythro*- and *threo*-1-bromo-1,2-dichloro-2-fluoroethanes by chlorine monofluoride or bromine trifluoride proceeds non-stereospecifically.[66,69]

The influence of geminal and vicinal halogen atoms on the rate of the oxidative substitution of bromine by chlorine monofluoride in a non-polar medium has been investigated recently[68] by the method of competing reactions. It has been shown that the vicinal halogens greatly retard the rate of fluorination ($CH_3CHBrCH_3 \gg CH_3CH.BrCH_2Cl \gg CH_2ClCHBrCH_2Cl$). The geminal halogen atoms (Br, Cl) have only a weak influence on the rate of substitution. Thus the halogenoethanes CH_3CH_2Br and $CH_3CHClBr$ react with the monofluoride at approximately the same rates, while the accumulation of the halogens at the substituted bromine atom only slightly reduces the rate of the oxidative substitution ($CH_2BrCH_2Br : CH_2BrCHClBr : CH_2BrCCl_2Br = 10:3:1$). It is of interest to compare the results with data for the influence of the geminal and vicinal halogen atoms on the rates of solvolytic reactions proceeding via carbonium ion transition states. According to the results of Winstein and Grunwald,[74] the vicinal chlorine atom decreases the rate of solvolysis by a factor of 1000 compared with the hydrogen atom. On the other hand, geminal halogens increase the rate of reaction by stabilising the transition state:

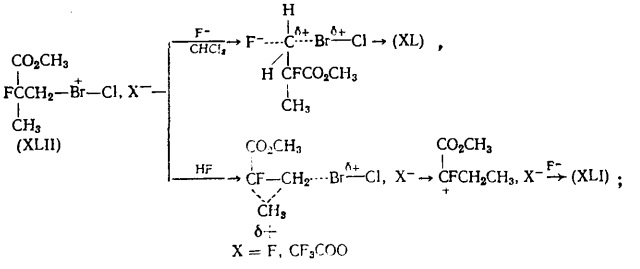


In particular, the ratios of the rate constants for the hydrolysis of benzyl bromide, 1-bromo-1-chloromethylbenzene, and 1-bromo-1,1-dichloromethylbenzene in 50% aqueous acetone are 1:6:70.[75] The geminal chlorine atom increases the rate of reaction more than does the bromine atom as a result of the powerful "back donation" effect ($C_6H_5CBr_3$‡ : $C_6H_5CClBr_2 : C_6H_5CCl_2Br = 1.0:2.4:5.6$). Analogous results have been obtained also for the hydrolysis of 2,2-dihalogenopropanes[76] ($CH_3CHBrCH_3 : CH_3CBr_2$‡$CH_3 : CH_3CClBrCH_3 = 1:6:47$). Thus vicinal halogen atoms significantly reduce the rate of both solvolysis and oxidative substitution. By increasing the rate of solvolysis, geminal halogens lower the rate of oxidative substitution. The observed difference is probably associated with the fact that the geminal halogens exert a dual influence on the rate of reaction in substitutional fluorination reactions. As a consequence of the significant inductive effect, they diminish the electron density on the substituted bromine atoms, as a result of which the rate of reaction should decrease as the geminal halogen atoms accumulate. However, the significant decrease in the rate of reaction compared with the influence of the vicinal halogens shows that the geminal halogens stabilise the transition state by diminishing the positive charge on the α-carbon atom:

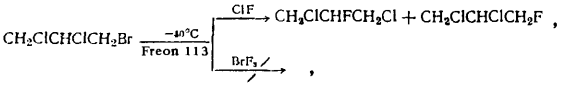
‡ The rate of hydrolysis calculated per bromine atom.



Nevertheless, the deactivating inductive effect proves stronger than the activating mesomeric effect.



Compounds containing a functional group—esters of halogenated carboxylic acids—can be used as substrates in reactions involving substitutional fluorination by chlorine monofluoride or bromine trifluoride:[66,69]



Interesting data have been obtained for the interaction of methyl 3-bromo-2-fluoro-2-methylpropanoate (XXXIX) with ClF in chloroform[66] and for the oxidative substitution of the ester (XXXIX) by the trifluoroacetyl hypochlorite–anhydrous HF system (the stoichiometric equivalent of ClF).[77] The vicinal difluoride, namely methyl 2,3-difluoro-2-methylpropanoate (XL), was obtained in a high yield in a non-polar medium, while in HF the product was methyl 2,2-difluorobutyrate (XLI), formed as a result of the 1,2-migration of the methyl group:

The result obtained can be explained by the fact that the Br–Cl group in the ion pair (XLII) formed is substituted in a non-polar medium by the fluoride ion, while hydrogen fluoride, which is a highly polar weakly nucleophilic solvent, promotes the splitting off of Br–Cl with the simultaneous migration of the methyl group:

Chlorine monofluoride is a more vigorous reagent than BrF_3. For example, whereas ClF readily substitutes the bromine atom in 1-bromo-2,3-dichloropropane at –40 °C, BrF_3 does not react under the conditions indicated:[69]

The chlorine atoms present in the substrate molecule are not as a rule involved in the reactions of ClF and BrF_3 with organic bromo-derivatives. Nevertheless, depending on the electronic properties of the substitutents in the α- and β-positions with respect to the chlorine atom to be substituted, the substitution of the latter by fluorine can

take place in a non-polar medium or in anhydrous HF.[67] In order to predict the influence of substituents on the ease of substitution of chlorine atoms in alkyl chlorides, one can undoubtedly use the result obtained in a study of the relative rates of reaction of ClF with alkyl bromides.[68] Chlorine atoms are most readily substituted when electron-donating substituents are present at the reaction centre. For this reason, the interaction of t-butyl chloride and 1,2-dichloropropane in an inert solvent (Freon 113, CCl_4) at temperatures between -30° and -50°C with an equimolar amount of ClF affords the corresponding fluorides. In the case of 1,2,3-trichloropropane and chloroform, the completion of the reaction requires an excess of the reagent:

$$(CH_3)_3CCl \xrightarrow[CCl_4,\ -60\text{—}-30^\circ C]{ClF} (CH_3)_3CF\ ,$$
$$CH_3CHClCH_2Cl \xrightarrow[-30^\circ C]{ClF} CH_3CHFCH_2Cl\ ,$$
$$CHCl_3 \xrightarrow[-50\text{—}-40^\circ C]{ClF} CHCl_2F\ .$$

Low temperatures promote the reactions by increasing the solubility and hence the concentration of chlorine monofluoride in the substrate.

The synthetic possibilities of the substitutional fluorination of organochlorine compounds increase significantly when anhydrous HF is used as the solvent.[67] Hydrogen fluoride does not then play solely the role of a highly polar solvent but also increases the reactivity of ClF as a result of the formation of the complex $Cl^{\delta+}-F-H-F^{\delta-}$.[78] The esters of chlorine-containing carboxylic acids, forming homogeneous mixtures with HF, are convenient substrates in this case:

$$CH_3CClFCHClCO_2C_2H_5 \xrightarrow[HF]{ClF} \underset{90\%}{CH_3CF_2CHClCO_2C_2H_5}\ .$$

The reactions of chloroalkanes are performed by passing ClF through a cooled stirred emulsion of the corresponding chloroalkane in anhydrous HF. Under these conditions, the oxidative substitution of the primary chlorine atom in 1,3-dichloro-2-fluoropropane is accompanied by the 1,2-hydride shift and the formation of a geminal difluoride:

$$CH_2ClCHFCH_2Cl \xrightarrow[HF]{ClF} CH_2ClCF_2CH_3\ .$$

An even greater increase in the fluorinating capacity of chlorine monofluoride is observed as a result of the use of catalytic amounts (1—5%) of antimony halides in a non-polar medium.[67] ClF then becomes so reactive that at -40 °C it substitutes the chlorine atoms in Freon 113:

$$CF_2ClCFCl_2 + ClF \xrightarrow[-10^\circ C]{SbF_5} CF_2ClCF_2Cl\ .$$

Antimony pentafluoride does not react under these conditions with Freon 113. Probably in the presence of antimony halides the fluorinating agent is the intermediate fluorodichloronium hexafluoroantimonate $Cl_2F^+SbF_6^-$—a compound analogous to $Cl_2F^+AsF_6^-$ and $Cl_2F^+BF_4^-$ described in the literature.[79]

The fluorinating capacity of BrF_3 also increases sharply in the presence of antimony halides. Tin halides can be used as effective catalysts of the fluorination of alkyl halides by bromine trifluorides.[80] Evidently, other Lewis acids, capable of producing salt-like compounds containing the BrF_2^+ cation on reaction with BrF_3, are also suitable for this purpose. The fact that the oxidising capacity of such compounds is much higher than that of the initial halogen fluorides has been demonstrated for the reactions of $BrF_2^+SbF_6^-$, $ClF_2^+BF_4^-$, $BrF_4^+SbF_6^-$, $IF_4^+SbF_6^-$, and $BrF_4^+Sb_2F_{11}^-$ with aromatic perfluoro-compounds.[81,82] The reactions proceed via a mechanism involving the one-electron oxidation of the aromatic perfluoro-substituted nucleus.[82] There is every reason to believe that such compounds should be the most powerful reagents for the substitutional fluorination of relatively unreactive alkyl halides.

Alkyl iodides react very vigorously with ClF and BrF_3 but they are not suitable substrates for fluorination by these reagents—the reactions result in complex mixtures of products, among which alkyl fluoride as well as alkyl chlorides or alkyl bromides respectively have been found.

When the *N*-bromosuccinimide—anhydrous HF system (the stoichiometric equivalent of BrF) is used as the reagent,[65] it is possible to achieve successfully the oxidative substitution of the iodine atom by fluorine in primary alkyl halides, for example, in 2,3-dichloro-1-iodopropane:

$$CH_2ClCHClCH_2I \xrightarrow[HF]{>N-Br} \underset{56\%}{CH_2ClCHFCH_2Cl} + \underset{14\%}{CH_2ClCHClCH_2F}\ .$$

The oxidative substitution of bromine atoms in tertiary and secondary alkyl bromides takes place on treatment with stoichiometrically equivalent amounts of ClF (the *N*-chloramine—HF system):[77]

$$CH_2BrCBrCH_2Cl \xrightarrow[HF]{>N-Cl} \underset{CH_3}{\overset{|}{CH_2BrCFCH_2Cl}}\ .$$

In the reactions presented, *N*-chloramine (*N*-bromamine) acts as the oxidant and HF acts as a highly polar ionising solvent and a source of fluoride anions.

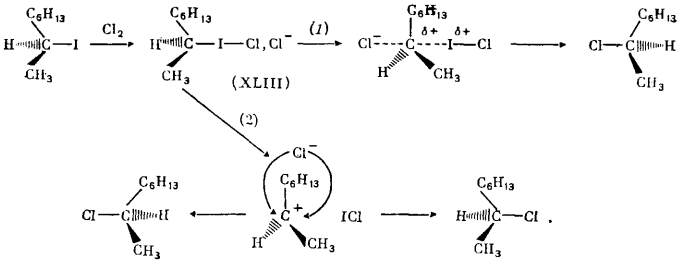
VII. THE MECHANISM OF THE OXIDATIVE SUBSTITUTION

Critical examination of the original communications devoted to the reactions of alkyl halides with oxidants makes it possible to propose, in our view, the following general reaction mechanism:

$$R—Hal + X^{\delta+}—Y^{\delta-} \rightarrow \underset{(XLII)}{R—\overset{+}{Hal}—X,\ Y^-}\ ,$$
$$R—\overset{+}{Hal}—X,\ Y^- \rightarrow \text{products}.$$

The first rate-determining reaction state consists in the electrophilic attack by the reagent on the unshared electron pairs of the halogen atom with formation of the ion pair (XLII). The subsequent reaction of the ion pair can take place via several competing pathways: the first involves the substitution of the Hal—X group by the internal or external nucleophile, the second involves the addition of the anion Y^- with formation of compounds of the tervalent halogen $R-Hal\begin{matrix}X\\ \diagdown\\ \diagup\\ Y\end{matrix}$, the third involves elimination with formation of an olefin, and in the fourth Hal—X is split off with formation of a carbonium ion. The preferential occurrence of one of these reactions depends both on the halogen substituted itself and on the oxidant, the structure of the hydrocarbon group, and the reaction conditions.

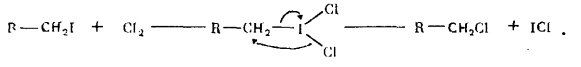
The possibility of the formation of a linear halogenonium ion ($R-\overset{+}{Hal}-X$) as an intermediate species follows from the fact that halogenonium ions of analogous structure are well known.[83—85] Thus, as early as the middle of the 1950's, diarylhalogenonium salts having the general formula $Ar-\overset{+}{Hal}-ArX^-$ (Hal = I, Br, or Cl X = BF_4



etc.) were obtained.[83] Olah and Demember[85] detected spectroscopically the formation of dialkylhalogenonium ions following the addition of a solution of antimony pentafluoride in SO_2 to an excess of the corresponding alkyl halide:

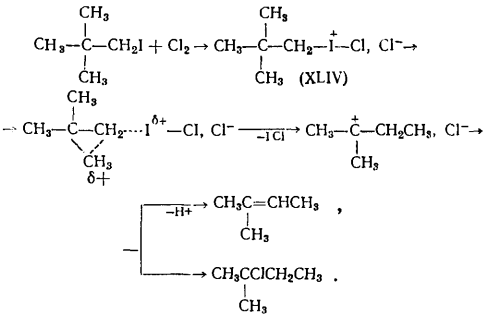
$$2R{-}Hal \xrightarrow[-60°C]{SbF_5,SO_2} R{-}\overset{+}{Hal}{-}R,\ SbF_5Hal^- ;$$
$$Hal = I,\ Br,\ Cl,\quad R = CH_3,\ C_2H_5,\ iso\text{-}C_3H_7.$$

Alkylmethylhalogenonium ions are formed when an alkyl halide is treated with the complex of antimony pentafluoride and methyl fluoride:

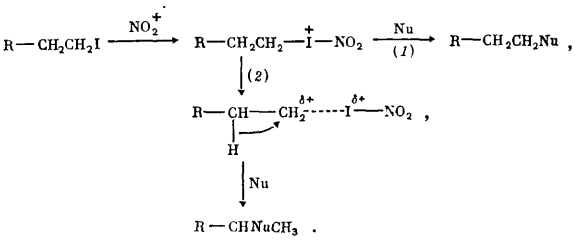


$$R{-}Hal + (CH_3F + SbF_5) \rightarrow R{-}\overset{+}{Hal}{-}CH_3\,SbF_6^- .$$

The general mechanism of the reactions of alkyl halides with oxidants discussed above makes it possible to explain satisfactorily also the majority of experimental data. Thus the formation of products with the preferential inversion of configuration on interaction of the optically active 2-iodo-octane with Cl_2, ICl, and Br_2 in methylene chloride probably takes place as follows:



When 2-iodo-octane interacts with molecular chlorine, the ion pair (XLIII) is formed and is converted into the reaction product via two competing pathways. The main pathway (1)—the substitution of I—Cl by the chloride anion—is a usual S_N2 process which takes place with inversion of configuration. However, the I—Cl elimination reaction with formation of a carbonium ion takes place simultaneously. This is pathway (2), which in fact affords a racemic product. The increase in the yield of the products having inverted configuration following an increase in the nucleophilicity of the medium (as a result of the addition of pyridine, methanol, or diethyl ether) can be explained by the solvation of the halogenonium ion, as a result of which attack from the front becomes increasingly difficult.

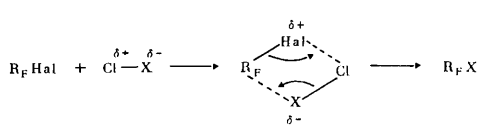


The absence of rearranged products in the interaction of chlorine and bromine with primary alkyl iodides shows that the reaction takes place exclusively via the S_N2 pathway. On the other hand, bearing in mind the fact that the interaction of alkyl iodides with Cl_2 at a low temperature leads to the formation of alkyliodine(III) dichlorides, the following alternative mechanism can be put forward:

The non-rearranged products are formed as a result of intramolecular substitution. However, the reaction of neopentyl iodide with Cl_2, which results in the formation of only a tertiary chloride and of the products of the further reaction of trimethylethylene, shows that the intramolecular substitution in alkyliodine(III) dichloride is unlikely. The interaction of neopentyl iodide with Cl_2 is consistent with the following mechanism:

For the halogenonium ion (XLIV) formed, the presence of the bulky t-butyl group in the α-position relative to the reaction centre precludes the nucleophilic attack from the rear and this is why the methyl group behaves as the internal nucleophile, i.e. the splitting off of I—Cl and the migration of the methyl group take place simultaneously. The tertiary carbonium ion formed actually affords the reaction products. An analogous picture has been observed also in the solvolysis of neopentyl derivatives[86] and it has been shown with the aid of kinetic isotope effects that the methyl group migrates in the rate-determining stage and that the successive conversion of the primary carbonium ion into the more stable tertiary carbonium ion does not occur. The reactions of primary alkyl iodides with nitrous acid and other nitrogen-containing oxidants are always accompanied by hydride shifts. This can probably be explained by the occurrence of the reaction via two competing pathways:

Depending on the reaction conditions, one of the two possible pathways can operate. Thus in the reaction in the weakly polar methylene chloride, the iodonium ion is more stable than the secondary carbonium ion formed as a result of the rearrangement and the reaction therefore takes place fully via pathway (1) (see Section III). In nitric acid, which is highly ionising weakly nucleophilic solvent, pathway (2), leading to a secondary carbonium ion, begins to predominate.

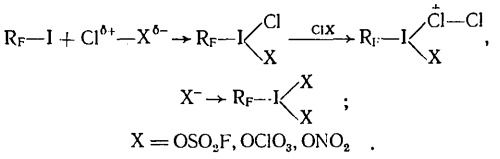


In the light of the mechanism which we propose, the general features of the oxidative substitution reactions can also be explained. Since the halogenonium ion formation stage is rate determining, it follows that the more readily is the electron pair of the halogen atom oxidised and the higher the electron density on it, the higher should be the rate of the reaction. Indeed, the reactivity of alkyl halides in reactions with any oxidant decreases in the sequence

$$-\overset{|}{\underset{|}{C}}I > -\overset{|}{\underset{|}{C}}Br > -\overset{|}{\underset{|}{C}}Cl.$$

The dependence of the reactivity on the structure of the hydrocarbon group, namely tertiary > secondary > primary, is also general. This sequence is inverted for perfluoroalkyl halides: primary > secondary > tertiary, because perfluoroalkyl substituents reduce the electron density

on the halogen atom. A characteristic feature of the reaction considered is that the structures of the products of the oxidative substitution of alkyl iodides, on the one hand, and alkyl bromides and chlorides, on the other, differ significantly. Thus the reactions of primary alkyl iodides with various oxidants (Cl_2, ICl, ICl_3, RCO_3H, HNO_3) in a non-polar medium result in the preferential formation of non-rearranged products, in contrast to the reactions of alkyl bromides with ClF and BrF_3. This is probably associated with the fact that the iodonium ion $R-\overset{+}{I}-X$, formed on oxidation of alkyl ioides, is fairly stable and that substitution takes place only on treatment with a nucleophile. It is noteworthy that the I—X group is an excellent leaving group, which is indicated by the significant involvement of the aryl substituent in the reaction of β-phenylethyl iodide with *m*-chloroperoxybenzoic acid and also by the fact that, together with the usual products, the corresponding covalent tosylates, perchlorates, triflates, etc. were isolated in the oxidative iodine substitution reactions on treatment with Cl_2, $ArCO_3H$, and NO_2BF_4 in the presence of nucleofugitive anions (TsO^-, ClO_4^-, $CF_3SO_3^-$, etc.).[87,88] However, we have observed that iodine pentafluoride in Freon 113 readily substitutes the iodine atom in 1-iodohexane with formation of 2-fluorohexane. An analogous result was obtained in the reactions of 1-bromopentane with ClF and BrF_3. Therefore the nature of the oxidant and hence the structure of the cationic intermediate probably has a decisive influence on the structure of the oxidative substitution products.

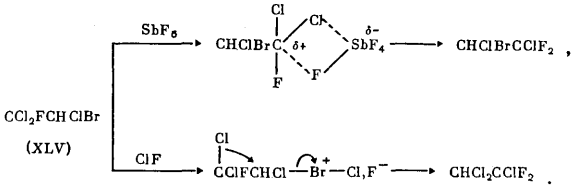


The oxidative substitution of bromine and chlorine atoms is possible only on treatment with vigorous reagents such as the hypohalite derivatives of strong acids and halogen fluorides. As a consequence of the high electronegativity of bromine and chlorine, it is inconvenient for the latter to acquire a positive charge and for this reason the halogenonium ion $R-\overset{+}{Hal}-X$, formed in the oxidation of alkyl chlorides and bromides, is extrememly unstable. The Hal—X group is readily eliminated, generating a considerable positive charge on the carbon atom, which in fact accounts for all the wide variety of rearrangements observed in the reactions with halogen fluorides. Analogous rearrangements are probably to be expected in the reactions of alkyl bromides and chlorides with the hypohalite derivatives of strong acids. However, in the substitution of chlorine and bromine atoms in perfluoroalkyl halides the accumulation of a significant positive charge on the halogen or carbon atom on oxidation is unlikely and the reaction mechanism probably therefore acquires the features of the synchronous mechanism proposed by Katsahara and Des Marteau:[50]

Hal = Br, Cl X = OSO_2F, OSO_2CF_3, $OClO_3$.

It is noteworthy that *erythro*- and *threo*-2-chloro-1,2-difluoroethyltrifluoroacetates, selected to demonstrate this mechanism, are not very suitable for this purpose, because the molecule contains the trifluoroacetate group, which can act as an internal nucleophile (see Section III). For this reason, the retention of configuration may be due to the involvement of the trifluoroacetate group and not the operation of a cyclic mechanism.

The formation of organic derivatives of tervalent iodine in reactions of perfluoroalkyl iodide with the hypohalite derivatives of strong acids can be described by the scheme



It is of interest to compare the reactions of alkyl halides with oxidants and Lewis acids such as mercury and antimony halides, silver salts, etc. The action of these reagents reduces to the conversion of the substituted halogen into a more readily eliminated group:

$$R—Hal + X^{\delta+}—Y^{\delta-} \rightarrow R—\overset{+}{Hal}—X,\ Y^- \rightarrow R—Y + HalX\ ,$$
$$R—Hal + MHal_n' \rightarrow R^{\delta+}\text{--}Hal\text{--}MHal_n'^{\delta-} \rightarrow R—Hal' + MHal_{n-1}'Hal\ .$$

In the classical solvolytic reactions, the protic solvent plays an analogous role.

However, whereas the substituted halogen atom is split off in the form of a negatively charged species in the interaction of alkyl halides with Lewis acids, on treatment with oxidants it is split off in an oxidised form. Therefore, in the interaction of polyhalogenoalkanes, the Lewis acid attacks the halogen atom whose elimination gives rise to the more stable carbonium ion, whereas the attack by the oxidant is always directed to the more readily oxidised halogen atom. Thus the interaction of 1,2-dibromo-2-chloropropane with mercury fluoride leads to the formation of 1-bromo-2,2-difluoropropane.[89] In the Swarts fluorination of 1-bromo-1,2,2,-trichloro-2-fluoroethane (XLV), only the chlorine atoms of the CCl_2F group are substituted by fluorine,[90] while on treatment of compound (XLV) with chlorine monofluoride the bromine atom is substituted with accompanying 1,2-migration of the chlorine atom:

Yet another feature of the oxidative substitution reaction consists in the fact that the halogen atom is as a rule substituted by a more electronegative atom or group. Bearing this in mind, one may say that ultimately not only the halogen atom but also the carbon atom at the reaction centre is oxidised.

The term "halogenophilic reaction" has been recently applied[91] to reactions involving the substitution of halogens on treatment with chlorine and bromine fluorosulphates. In our view, this term is inapplicable to the reactions discussed, since halogenophilic reactions are usually understood as reactions in which a halogen atom in an organic substrate is attacked by nucleophiles and the intermediate is a carbanion.[92] In oxidative substitution reactions, the halogen atom is attacked by an electrophilic species, which is followed by the nucleophilic substitution of the oxidised halogen.

Thus the reactions discussed are nucleophilic substitution reactions at a saturated carbon atom. The principal role of the oxidant consists in converting the substituted halogen into a readily eliminated group.

During the preparation of the manuscript for the press, a study was published[93] in which the authors estimated quantitatively the oxidising capacity of a series of halogeno fluorosulphates as well as

peroxysulphuryl difluorides [$(FSO_2O)_2$] and showed that the reactivity of these compounds changes on the whole in parallel with their oxidising capacity. It was also shown that the increase in the reactivity of these compounds in a mixture with HSO_3F and HSO_3F-SbF_5 is consistent with the increasing strength of oxidants in strongly acid media.[93,94] The results obtained[93] and the proposed reaction schemes are of undoubted interest for the understanding of the mechanism of the oxidative substitution of the halogens in alkyl halides. Nevertheless, one cannot agree with the treatment of these reactions as oxidative electrophilic substitution at a carbon atom, since in electrophilic substitution at an sp^3-carbon atom the attack by the electrophile is directed to the carbon atom with which the entering electrophile subsequently forms a σ-bond. Taking this into account, the term "electrophilic substitution at a halogen atom" proposed by Katsahara and Des Marteau[50] (see Scheme 6) may be regarded as more apt. However, this definition can also be hardly regarded as acceptable for organic reactions where the carbon-containing fragment of the substrate is considered in the first place. Furthermore, in such a case the numerous nucleophilic substitution reactions occurring in electrophilic catalysis by Brønsted or Lewis acids would have to be classified as electrophilic substitutents at a heteroatom.

According to Fokin and co-workers,[93,95] the substitution of the nitroso-group in CF_3NO by chlorine fluorosulphate takes place analogously to the substitution of the halogens. One cannot rule out the possibility that the heterolytic substitution of the hydrogen atom in the C–H bond by oxidants[45,46,97] can also be interpreted as oxidative nucleophilic substitution. However, thse reactions are not numerous and are not as important as the substitution of the halogens.

In conclusion of this review, we should like to note that the reactions involving the oxidative substitution of the halogens in alkyl halides, which initially appeared to be unusual to chemists working with various oxidants and substrates, have been explained within the framework of the classical ideas of theoretical organic chemistry and have been defined as a new type of nucleophilic substitution at an sp^3-carbon atom. Many reactions of this type can be regarded as constituting yet another method for the generation of various cationoid species in polar and, what is particularly important, in non-polar media. Interesting results can apparently be obtained by using as reagents compounds such as PtF_6, $O_2^+SbF_6^-$, $XeF^+SbF_6^-$, and other "superoxidants", with an extremely high electron affinity. One may expect that further studies will make it possible to extend the synthetic possibilities of these interesting reactions and also to achieve a deeper understanding of their mechanism.

The Synthesis and Complex Forming Capacity of Phosphorus-containing Macrocycles

E.N.Tsvetkov, A.N.Bovin, and V.Kh.Syundyukova

The review considers questions concerning the synthesis and complex-forming capacity of macrocyclic compounds containing in the ring phosphorus atoms with different degrees of coordination (from three to five) as well as macroheterocycles with phosphorus-containing side chains (lariat compounds). The introduction of the phosphoryl group into the macrocycle lowers the stability of the complexes of the macrocyclic compounds with alkali metals and reduces the selectivity compared with the analogous crown-ethers. Only the lithium cation in the case of macrocyclic phosphine oxides is an exception. Lariat macrocycles are promising: the phosphorus fragment ensures the effective additional binding of the cation imparting a high stability to the complex.
The bibliography includes 191 references.

I. INTRODUCTION

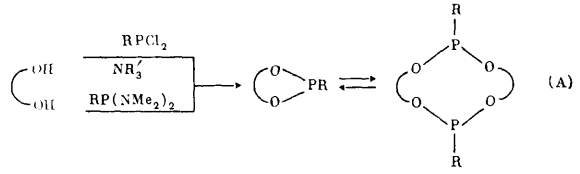
The discovery by Pedersen[1] in 1967 of the complex forming properties of macrocyclic polyethers (crown-ethers) in relation to alkali and alkaline earth metal cations has had a revolutionary influence on organic synthesis, which may be compared only with the influence by another major event in organic chemistry—the discovery of the method of synthesis in two-phase systems using phase transfer catalysts.[2] The discovery of crown-ethers gave rise to a powerful wave of studies not only on the use of the complex forming phenomenon in various branches of chemistry but also on the synthesis of new macrocyclic complex forming agents. Despite the fact that the principle of the macrocyclic binding of a metal was known before the discovery of crown-ethers both in the field of natural products (porphyrin and corrin complexes,[3-7] cyclic peptides, cyclic depsipeptides[8]) and among synthetic complex forming agents (phthalocyanine dyes,[9,10] certain other nitrogen-containing macrocycles[11]), only the discovery of crown-ethers has made this principle a guiding light in the search for new complex forming compounds. The "chelation" principle, which until recently predominated in the construction of new complex forming agents, became of secondary importance.

A large field of the synthesis of macrocyclic complex forming substances, which embraces increasing numbers of new elements, including phosphorus, has arisen on the basis of the new approach. The first studies on the specific synthesis of phosphorus-containing macrocyclic compounds were published in 1974 in France and in the USA. Soviet investigations on this problem began to be published since 1976. From the very beginning, two almost independent aspects arose in studies on the synthesis and properties of phosphorus containing macrocycles: (1) the preparation of macrocyclic compounds of tervalent phosphorus, mainly phosphines, and (2) the synthesis of phosphoryl macrocycles. The first aspect is related genetically to the chemistry of ligands for transition metals (phosphines and polyphosphines) and the second to the chemistry of phosphoryl extractants.

The data in the review are described in accordance with this subdivision into two aspects: the macrocyclic compounds with a tervalent phosphorus atom are described initially and this is followed by a description of the phosphoryl and thiophosphoryl macrocycles—compounds of pentacoordinate phosphorus: in conclusion, data are presented on the complex forming capacity of phosphorus-containing macrocycles.

In contrast to the reviews already published, devoted to the synthesis of phosphorus-containing macrocycles[12] and the complex forming compounds of some of them,[13] the aim of the present communication is an exhaustive description of the literature and analysis of the likely usefulness of individual aspects of the field of phosphorus-containing macrocyclic compounds.

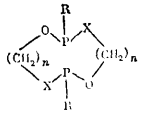
II. MACROCYCLIC COMPOUNDS OF TRICOORDINATE PHOSPHORUS

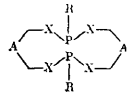


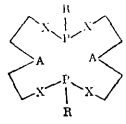
Despite the fact that the first ten-membered phosphorus-containing macrocycles of the phosphite type (acid and neutral) were obtained as early as the end of the 1940's,[14] i.e. long before the discovery of crown-ethers, specific research in this field was not begun until the 1970's. The majority of the macrocyclic tervalent phosphorus acid esters are phosphonites. These compounds have not acquired independent importance because of their instability, although they have come to be used as the starting materials for the synthesis of macrocyclic phosphonates and especially phosphonothioates, which are stable.

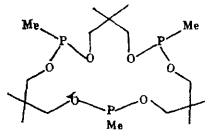
1. Macrocyclic Phosphonites

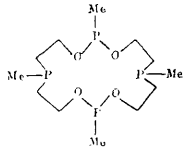
The principal method of synthesis of macrocyclic phosphonites [method (A)] is the dimerisation or oligomerisation of cyclic phosphonites (ring size ranging from five to eight atoms). The capacity of such compounds for oligomerisation has been frequently











noted in the literature,[15-18] but a detailed investigation of the oligomerisation of cyclic phosphonites and their derivatives as a method of synthesis of phosphorus-containing macrocycles has been undertaken only recently.[19-29]

The cyclic phosphonites, obtained by the interaction of a diol with alkyldichlorophosphine or an alkyl phosphonodiamidite in ether, dimerise spontaneously and oligomerise:

The oligomerisation is reversible. The equilibrium shifts towards the initial compound on heating (distillation) or dilution of the solution. The macrocyclic phosphonites (I), (IIa–c), (IIIa–g), (IV), and (V), listed in Table 1, were therefore investigated mainly by NMR. The products of the addition of sulphur—the corresponding phosphonothionates—are stable compounds (they will be examined in Section III).

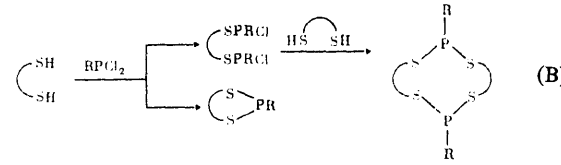


Table 1. Macrocyclic phosphonites.

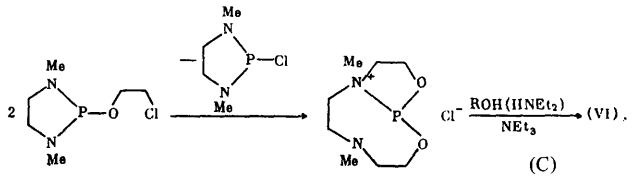
(V)		—	[28]

The rate of dimerisation depends on the structure of the phosphonite. Dioxaphospholans dimerise fastest and are followed in this respect by dioxaphosphorinanes and dioxaphosphepans.[25] It has been shown that the oligomerisation of dioxaphosphorinanes is accelerated in the presence of the following series of substituents at the phosphorus atom:[25]

$$Ph \ll Me < Et < iso\text{-}Pr < t\text{-}Bu.$$

Dimerisation does not occur in those cases[23] where the substituent of this kind is an electronegative atom or a group of atoms with unshared electron pairs (F, Cl, OMe, OPh, NMe_2). Dithia- and diaza-phospholans and dithia- and diazaphosphorinanes do not oligomerise either.[21,23,24]† Oxazaphospholans do oligomerise;[21] the process evidently proceeds via the dissociation of the P–O bond. Despite the fact that dithiaphospholans do not dimerise, the interaction of alkyldichlorophosphine with dithiole leads not only to cyclic phosphonodithioites but also to their dimers.[23,24,27] It has been shown that the latter are formed via intermediate metastable bischlorides:

The macrocycles (IId, e) and (IIIh, i) have been obtained in this way [method (B)]. The replacement of the endocyclic oxygen atoms by sulphur stabilises the dimers so much that it is possible to isolate their *cis*- and *trans*-isomers by column chromatography [compounds (IIe) and (IIIh, i)]. Heating and/or dilution of a solution of one of the isomers of the dimer leads to the formation of the second isomer and the monomer.

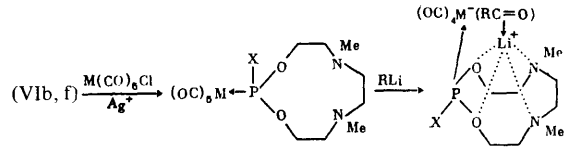


The ratio of the diastereoisomers of the 10- and 12-membered macrocycles is determined by the size of the substituent at the phosphorus atom: the macrocycle (Id), for example, is formed only as the *trans*-isomer. For the 16-membered macrocycles (IIIh, i), the ratio of the isomers becomes statistical. In the oligomerisation of 2,5,5-trimethyl-1,3,2-dioxaphosphorinane in concentrated solutions (~50%),[22] the corresponding *cis*- and *trans*-trimers (IV) were isolated together with the dimers (IIa). One should note that in all cases of oligomerisation polymeric compounds of a known structure (cyclic or linear) are also formed. Their molecular weight varies from 2000 to 15000 (established after the addition of sulphur).

2. Macrocyclic Phosphites

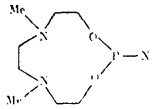
A sufficiently general method of synthesis of macrocyclic phosphites has not been devised. There exist only individual examples of the preparation of particular macrocycles. Thus diazaphospholans, which are incapable of oligomerising as already mentioned above, can nevertheless be used[32] for the preparation of macrocyclic phosphites in the presence of the β-chloroethoxy-group in the molecule [method (C)]. Such a diazaphospholan is converted quantitatively and spontaneously into an ammonium salt, the exchange of the chlorine atom in which by an alkoxy-group[32,33] or amino-group[34]

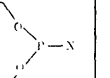
†The effect of the structure of cyclic compounds on their tendency to dimerise has been examined[31] from the standpoint of the concept of antibonding orbitals.

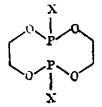


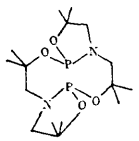
leads to the formation of 11-membered macrocycles (VI) (Table 2):

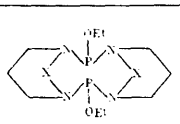
(C)









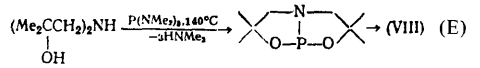


The quaternisation is accelerated in polar solvents (acetonitrile).

The complexes of the macrocycle (VI) with molybdenum or tungsten pentacarbonyls readily interact with aryl- or alkyl-lithium reagents,[34] forming lithium benzoylate or acylate complexes, which are stable by virtue of their macrocyclic nature:

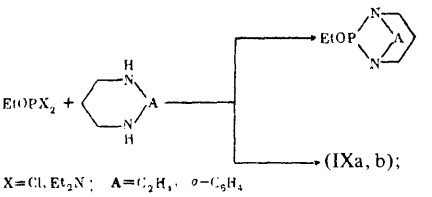
The rhodium complexes obtained from the macrocyclces (VIa–e), having the composition RhCl(CO).L and $RhCl(C_2H_4).L$, are promising catalysts of the hydroformylation of olefins.[33]

Table 2. Macrocyclic phosphites.



Compound	Formula	X	Refs.
(VIa–f)		OMe (a), OEt (b), OCH(Me)Et (c)	[32,33]
		OCH(Me)Pr (d), O–  (e)	[33]
		NEt_2 (f)	[34]
(VII)		OCH_2CH_2Cl	[35]
(VIII)		—	[36]
(IXa, b)		CH_2CH_2 (a), o-C_6H_4 (b)	[37]

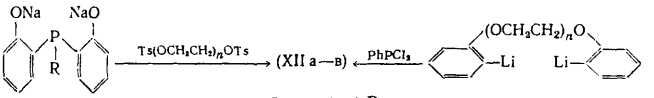
Another method of synthesis [method (D)] of macrocyclic phosphites involves the condensation of two molecules of tri(β-chloroethyl) phosphite with liberation of dichlorethane and the formation of the dimeric phosphite (VII) (Table 2), which is entirely stable.[35]



$$2\,(ClCH_2CH_2O)_3P \xrightarrow[-2ClCH_2CH_2Cl]{\Delta} \text{(VII)} \quad \text{(D)}$$

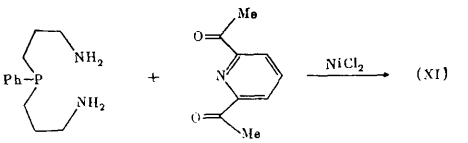
20%

In contrast to the monocyclic phosphoromonoamidites, which do not dimerise,[23] the bicyclic dialkyl phosphoramidite, obtained[36] from di(β-hydroxyalkyl)-amine and phosphorous tris(*NN*-dimethyl)triamide, is converted irreversibly and stereoselectively on heating into the dimer (VIII) [method (E)] (Table 2), whose structure has been established by X-ray diffraction:



The interaction of ethyl phosphordichloridite or ethyl phosphorodi-imidite with cyclic diamines probably leads not to the expected product but to the dimer (IX) for the same reason:[37]

3. Macrocyclic Phosphines



The field of macrocyclic phosphines and polyphosphines is probably the most thoroughly developed branch of the chemistry of phosphorus-containing macrocycles. More than 40 free macrocyclic ligands of the phosphine type, containing between one and four phosphorus atoms, frequently together with other heteroatoms (nitrogen, oxygen, sulphur, and arsenic), are now known. A series of macrocyclic phosphines have been obtained only in the form of transition metal complexes. Unusual catalytic properties are to be expected from complexes of this type. The stabilising capacity of macrocyclic phosphines in relation to the lowest valence states of transition metals is of interest.

The crown-ethers (Xa–c) (Table 3) containing one phosphorus atom have been obtained both by alkylating the diphenoxides of phosphorus-containing bisphenols with ditosylates of oligo(ethylene glycols) and by the interaction of dichlorophenylphosphine with organic dilithio-derivatives of polyethers:[38]

$n = 4, 5$; R=Ph, t-Bu.

A whole series of macrocycles in the form of metal complexes have been synthesised by the interaction of diketones with phosphine-containing diamines. Thus compound (XI) (Table 3) has been obtained from diacetylpyridine in the presence of $NiCl_2$:[39]

Its reduction with sodium tetrahydroborate yielded the macrocycle (XII) (Table 3). The complexes of the pentadentate macrocycle (XIII) have been synthesised analogously from diaminodiphosphines and diacetylpyridine in the presence of $Cd(ClO_4)_2$ or $AgClO_4$,[40] while the tetradentate complexes (XIVa, b) have been obtained[41,42]

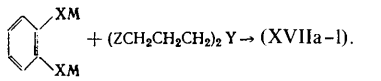
from acetylacetone in the presence of $NiCl_2$ (Table 3). The macrocycle (XIVb) has been shown to have a *meso*-structure by X-ray diffraction.

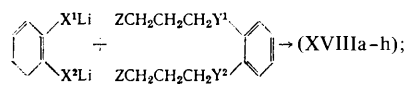
Macrocyclic bisoxides of bisphosphines have been synthesised by reducing polymethylenebisphosphinates with sodium bis(2-methoxyethoxy)aluminium hydride followed by their alkylation (without isolation) by dibromoalkanes under the conditions of high dilution (10^{-3} M).[43] Their reduction gave rise to the corresponding bisphosphines (XIVa–c), isolated in the form of *cis*- and *trans*-isomers (Table 3):



The phosphinocrown-ethers (XVIa–c) have been obtained by alkylating, under the conditions of high dilution, lithium 1,2-ethylene- and 1,3-propylenediphosphides, generated in solution, with αω-dichloro-derivatives of polyaminoethers and the ditosylates of polyether diols (Table 3):[44]

The *syn*- and *anti*-isomers of the macrocycle (XVIa) have been isolated via their complexes with $NiCl_2$. Their detosylation with sodionaphthalene takes place without isomerisation. The complex $PdCl_2.L$ has been obtained from the *anti*-isomer (XVIb), while the macrocycle (XVIc) gave rise to the complexes $NiCl_2(BF_4)_2.L$ and $Ni(NCS)_2(NCS)_2.L$.[44]

A series of 11-membered macrocyclic phosphines (XVIIa–l) (Table 3), containing between one and three phosphorus atoms in the ring together with other heteroatoms, have also been synthesised under the conditions of high dilution:[45–53]

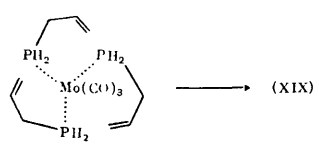


$$+ (ZCH_2CH_2CH_2)_2Y \rightarrow (XVIIa\text{–}l).$$

M = H, Li; X, Y = PH, PPh, AsPh, AsMe, NPh, NMe, S, O, CH_2; Z = Cl, Br, OSO_2Me

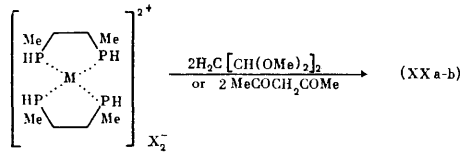
The study of the steric structures of compounds (XVIIa, d, e, g) established the *cis*-orientation of the phenyl substituents at the phosphorus atoms. The isomers with the *trans*-configuration were not detected even after heating under conditions promoting the inversion of the tertiary phosphines (xylene, 135 °C, 1 h). Carbonyl-containing complexes with a series of transition metals (Cr, Mo, and W)[49,50,54] and complexes with $NiCl_2$ and CuCl [50,54] have been obtained from the macrocycles (XVIIa, d, e) and the structures of some of them have been determined.[50,54] The electrochemical properties of the carbonyl complexes of the macrocycles (XVIIa, e) have been investigated.[55] Three geometrical isomers are possible for the macrocycles (XVIIh, i), but compound (XVIIh) exists only in two isomeric *meso*-forms and only one isomer has been isolated for the macrocycle (XVIIi).

The tetradentate macrocycles (XVIIIa–h) (Table 3), containing phosphorus, nitrogen, arsenic, oxygen, and sulphur atoms in the ring, have also been synthesised under the conditions of high dilution:[46,51,56]



$$\rightarrow (XVIIIa\text{–}h);$$

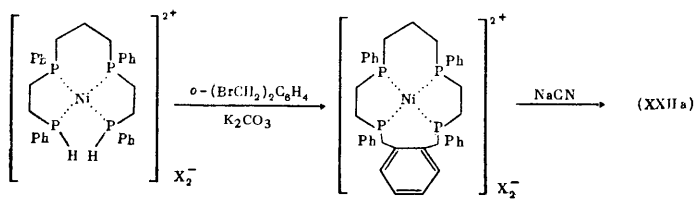
X = PPh, S; Y = PPh, S, NMe, O, AsMe; Z = Cl, OH, OSO_2Me



The starting compound in the synthesis of compounds (XVIIIf–h) (Table 3) was 2-(phenylphosphino)thiophenol.[56] The *cis*- and *trans*-isomers of the macrocycles (XVIIIa, f–h) have been isolated and for compounds (XVIIIf–h) the structures have also been established.[56] Four different types of complexes are formed by 11- and 14-membered ligands with cobalt halides depending on the reaction conditions and the structure of the macrocycle.[57]

A series of polyphosphine macrocycles have been obtained in the form of complexes or as free ligands by the matrix cyclisation method, i.e. by the cyclisation of phosphine ligands already bound in complexes. Thus a molybdenum tricarbonyl complex, containing three allylphosphine molecules, gives rise to a high yield of the complex (XIX) with a triphosphine macrocycle (Table 3) as a result of the intermolecular interligand free-radical addition of phosphino-groups to the double bonds:[58]

(XIX)



The tetradentate 14-membered cyclic adducts (XXa–c) (Table 3) have been obtained analogously by the interaction of diphosphine complexes of nickel(II) and palladium(II) with malonic dialdehyde or with acetylacetone:[59,60]

(XXa-b)

The macrocyclic complexes (XXb, c) were then obtained in the form of two isomers. The complexes (XXd, e) [59,60] and (XXIa–f) (Table 3)[61] have also been synthesised by a similar method.

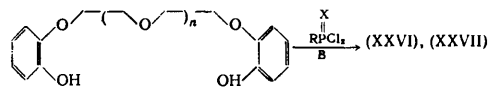
Alkylation of the nickel complex of a tetraphosphine ligand with *o*-xylylene dibromide in the presence of K_2CO_3 led to the synthesis of a macrocyclic complex, from which the macrocyclic tetraphosphine (XXIIa) (Table 3) was isolated by treatment with NaCN:[62,63]

(XXIIa)

The macrocycle (XXIIb) was obtained analogously from 1,4-di-(methylphosphino)-ethane and *o*-xylylene dichloride using K_2PdCl_4 as the matrix.[64] Complexes having the compositions $PdCl_2.L$ and $NiBr_2.L$ were synthesised from this compound.[64] Alkylation of the amino-group of the nickel *meso*-complex of 1,3-di[(*o*-aminophenyl)-phenylphosphino]propane[65] made it possible to obtain the tetradentate ligand (XXIII) (Table 3).[66] The cyclic nature and *meso*-configuration of the ligand have been demonstrated by X-ray diffraction.

The 18-membered macrocyclic phosphines (XXIVa–g) (Table 3) have been synthesised by alkylating the dilithio-derivative of 1,2-di-(phenylphosphino)ethane with the corresponding dihalides containing the oxygen or sulphur atoms or the propylimino-group as the heterofragment Y:[67–75]

$$2LiPCH_2CH_2PLi + 2ClCH_2CH_2YCH_2CH_2Cl \rightarrow (XXIVa\text{–}d),$$



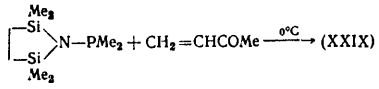
All five possible isomers have been isolated by the ion-exchange chromatography and fractional crystallisation of the metal complexes of the macrocycles. The diastereoisomers obtained show different numbers of binding sites (from 4 to 6). Their structure has been established by the X-ray diffraction analysis of the complexes of the tetraphosphines (XXIV) with the Co^{2+}, Ni^{2+}, and Fe^{2+} cations.[69–78]

A method of synthesis of the oligophosphacycloalkanes (XVd–h) and (XXVa–c) (Table 3), containing two or four phosphorus atoms, based on the reduction of the macrocyclic benzylphosphonium salts of lithium tetrahydroaluminate, has been proposed in Horner's studies.[79,80] The synthesis of the phosphonium salts themselves is examined in Section IV.

III. MACROCYCLIC COMPOUNDS OF TETRACOORDINATE PHOSPHORUS

1. Macrocyclic Phosphonates, Phosphonothioates, Phosphonimidates, and Phosphates

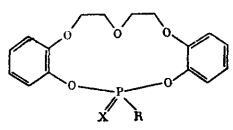
(a) *Macrocycles with a single phosphorus atom.* Studies on the specific synthesis and the physicochemical properties of macrocycles containing one phosphorus atom were first initiated in the USSR. The results of these investigations have been published since 1976. Macrocyclic compounds (Table 4) have been obtained by the reaction of phosphorus acid dichlorides with polyether-bisphenols:[81-90]

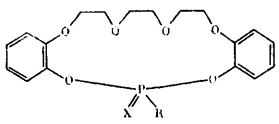


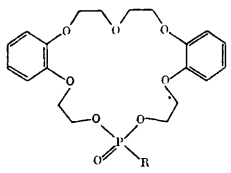
X=O, S, NSO_2Ph; $n = 1, 2$

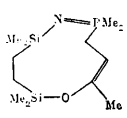
Methyl di(β-chloroethyl)phosphonate was used as the phosphorus component in the synthesis of single phosphorus atom (Table 4), the corresponding dimers were also isolated in a number of instances (3–18%) [Table 5, compounds (XXVIIa–e)], their formation being promoted by the use of an aprotic solvent (acetonitrile).[82] The employment of the corresponding bisphenoxides instead of triethylamine increases the yield by ~10%.[83] The macrocycles (XXVIg) and (XXVIII) can be obtained only by the latter method because of the low reactivity of the phosphorus-containing fragment.[91,92] $LiClO_4$ was added as the matrix in the synthesis of compounds (XXVIc, d). The use of potassium bisphenoxide ($n = 1$) rather than sodium bisphenoxide ($n = 2$) in the reaction with methyl phosphonodichloridothioate alters the direction of the process—a mixture of the isomeric dimers (XXXVIIe) is obtained instead of the monomeric product (XXVIf) (Table 5).[83] The macrocycles (XXVIIa, b, e) have been synthesised by the high dilution method. It is of interest to note that, when lithium and potassium bisphenoxides are used in the synthesis of compound (XXVIII) instead of sodium bisphenoxide, the yield is reduced from 40 to 3–5%, which the authors believe to be associated with the matrix effect of the Na^+ cation.

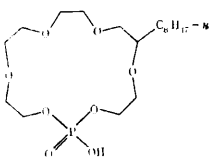
The macrocycle (XXVIe) is a mixture of three polymorphic modifications, having different melting points. Their structure was investigated by IR spectroscopy.[87] The macrocycles (XXVIa, c) have been investigated by field desorption method mass spectrometry.[93]





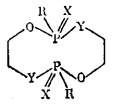


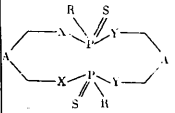


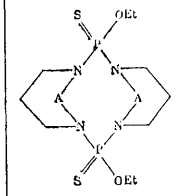


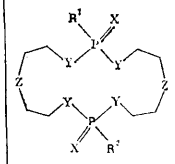
The 10-membered macrocycle (XXIX) (Table 4) has been obtained by adding methyl vinyl ketone to the cyclic phosphinic *NN*-disilylamide:[94]

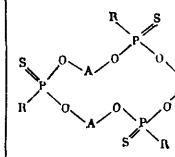
The slow addition of methyl vinyl ketone to the reaction medium leads mainly to the formation of the (*Z*)-isomer, which is in its turn slowly converted into the (*E*)-isomer.

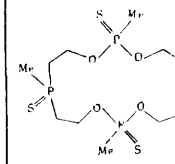


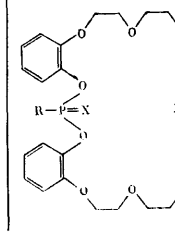












(b) *Macrocycles with two and more phosphorus atoms.* The 10-membered cyclic acid bisphosphite and the dihydrobisphosphonate (XXXIa) (Table 5) were obtained long before interest was aroused in macrocyclic complex-forming agents and an attempt was made to synthesise the acid ethylene phosphite. Later it was shown[95] that, like the cyclic phosphonites, the acid cyclic phosphites oligomerise, the process slowing down on passing from the unsubstituted acid ethylene phosphite to a substituted derivative and further to acid trimethyl phosphite. The reaction is accelerated in the presence of acids and bases. This is evidently why the interaction of phosphorus trichloride with ethylene glycol leads[14] not to the expected ethylene phosphite but to its dimer (XXXIa), which has also been obtained[35] by the condensation of two molecules of di(β-hydroxyethyl) phosphite [analogously to the method (D) for the synthesis of the macrocyclic phosphite (XII) (Table 2)]. The interaction of the diphosphite (XXXIa) with αβ-unsaturated compounds made it possible to obtain the macrocycles (XXXIb) with different side chains (Table 5), which have found applications as antipyrenes for synthetic resins:[96]

Table 4. Macrocycles with a single tetracoordinate phosphorus atom.

The principal method of synthesis of macrocyclic phosphonates and phosphonothioates with two and more phosphorus atoms in the ring is the oxidation of the corresponding phosphonites or the addition of sulphur to the latter. As already mentioned in the previous Section, macrocycles with tervalent phosphorus are unstable and are

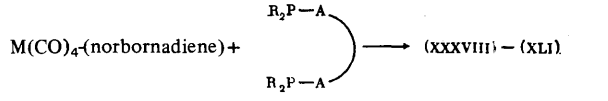
almost always isolated as phosphonates or phosphonothioates. The macrocycles (XXXIc–g), (XXXII)–(XXXIV), (XXXVa), and (XXXVI) (Table 5) have been synthesised in this way.

The stability of the bischloride, formed in the course of the synthesis of macrocyclic phosphonites [method (B)] made it possible to introduce it into the reaction with a diol and to obtain after oxidation the mixed type dimer (XXXIIf):[24]

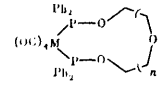


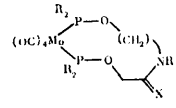
The ease of the opening of the phosphonite ring already mentioned has been used for the synthesis of the macrocyclic phosphonothioates (XXXIVc, d, k) and (XXXVb). The interaction of

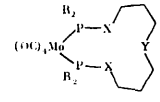
diethylene glycol with an eight-membered cyclic phosphonite leads to the intermediate diol, which is capable of reacting with the next phosphonite molecule. The oxidation of phosphorus-containing polyglycols with sulphur, the subsequent interaction with alkyl- or aryl-dichlorophosphine, and the repeated addition of sulphur made it possible to obtain macrocycles containing 2–3 phosphorus atoms:[23,29]

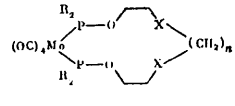
Compounds (XXXIId, e) and (XXXIVe–h) have been studied in detail by NMR.[97] The structure of the *cis*-isomers of the macrocycles (XXXIIa) and (XXXIVh) has been confirmed by X-ray diffraction.[98,99] The complex forming properties of compounds (XXXIVe, f) in relation to uranyl nitrate and $SnCl_4$ have been investigated.[27] Among the macrocyclic dimers (XXXVIIa–e) (Table 5), compound (XXXVIIa) has been studied in greatest detail. Three isomers of this macrocycle have been isolated. The authors believe that one of the factors determining the isomerism is the steric directionality of the phosphoryl groups in relation to the polyether ring. Compound (XXVIIa) has been studied by mass spectrometry[93] and ^1H NMR using lanthanide shift reagents.[100]

The heteronuclear macrocycles (XXXVIII)–(XLI), containing a transition metal atom in the ring (Table 6), have been obtained from the polyether bisphosphites, bisphosphinates, and bisphosphinamidites by reaction with the norbornadiene complexes of molybdenum, chromium, and tungsten tetracarbonyls under high dilution conditions (in 5–70% yields):[101-103]



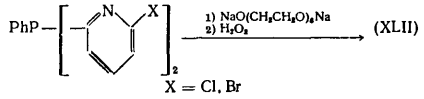






M = Mo, Cr, W; A = O, NH, NMe; R = Alk, Ar; O–Alk, OAr, NR_2

The macrocycles obtained interact effectively with alkali metal cations and form stable products of the reaction with organolithium compounds via the intermolecular coordination of lithium to the polyether ring. On hydrolysis, the latter are capable of giving rise to stable hydroxycarbenes.[104]



2. Macrocyclic Phosphine Oxides and Their Analogues

Among phosphoryl-containing complex forming agents, phosphine oxides are some of the most effective.[105] This is precisely why macrocyclic phosphine oxides containing, together with phosphorus,

other heteroatoms (O, N) have attracted special attention. Thus the phosphine oxide (XLII) (Table 7) has been synthesised by the reaction of di(halogenopyridyl)phosphine with sodium polyglycolate and subsequent oxidation of the resulting macrocyclic phosphine:[106]

Under conditions analogous to those in the synthesis of the phosphonate macrocycle (XXVIII) (Table 4), the macrocycle (XLIII) (Table 7) was obtained from sodium bisphenoxide di(chloromethyl)-methylphosphine:[107]

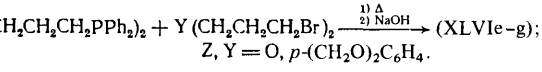
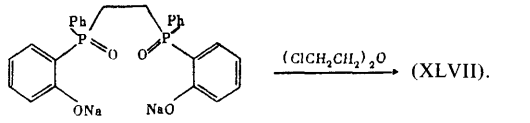
The phosphine oxides (XLIVa–c) (Table 7) have been synthesised by oxidising the corresponding macrocyclic phosphines (XIIa–c) (Table 3).

The interaction of di(*o*-bromomethylphenyl)-substituted phosphine oxides and phosphinic acids with sodium polyglycolates under high dilution conditions led to the formation of the macrocycles (XLIVd–h) (Table 7):[108]



$n = 4, 5$; R=Ph, $C_6H_4CO_2H$-*o*, $C_6H_4CO_2Me$-*o*, OMe

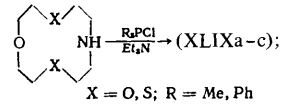
Using ethylene glycol, the bisphosphine bisoxide (XLV) (Table 7) has been synthesised under the same conditions in the form of two isomers (apparently *syn*- and *anti*-). The above study[108] has played a major role in the elucidation of the effect of the phosphoryl group on the complex forming capacity of the macrocycles compared with other coordination centres.



The synthesis of the bisphosphine bisoxides (XLVIb–d) (Table 7),[43] the reduction of which yielded the bisphosphines (XVa–c) (Table 3), was described in the same Section. The pairs of isomers of each macrocycle isolated after the reaction have apparently the *cis*- and *trans*-configurations.

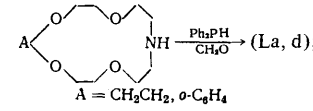
The *trans*-isomer (XLVIa) proved to be the first phosphorus-containing macrocycle whose X-ray diffraction analysis has been carried out.[109] The macrocycles (XLVIe–g) with a more complex structure have been synthesised from an acyclic bisphosphine and the corresponding dibromide via cyclic bis-phosphonium salts (see Section IV) with the aid of the alkaline cleavage of the latter:[110,111]

Z, Y = O, *p*-$(CH_2O)_2C_6H_4$.



The macrocyclic bisphosphine bisoxide (XLVII) (Table 7) has been synthesised by alkylating the disodium salt of di[phenyl(*o*-hydroxyphenyl)phosphinyl]ethane with chlorex:[112]

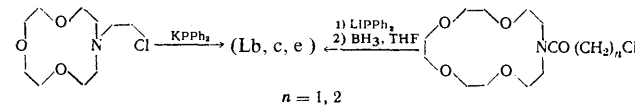
The macrocycle (XLVIII) (Table 7) has been obtained by adding sulphur to the tetraphosphine (XXIIb) (Table 3).[64]



3. Macrocycles with Exocyclic Phosphorus-Containing Groups

Much attention has been devoted recently to the study of crown-ethers modified with various complex forming side groups. Macrocycles containing additional polyether groups have been called lariat (or lasso-like) ethers.[113] Similar phosphorus-containing compounds (Table 8) are obtained by modifying the usual crown-ethers. Thus the macrocyclic phosphinamidites (XLIXa–c) have been synthesised by the reaction of azacrown-ethers with dialkyl- and diaryl-chlorophosphines:[114,115]

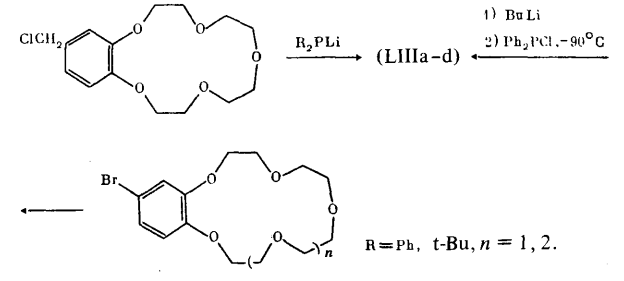
X = O, S; R = Me, Ph



The macrocycles (La, d) (Table 8)[115,116] with phosphinomethyl side groups have been obtained in high yields by a modified Mannich reaction:

A = CH_2CH_2, *o*-C_6H_4

The macrocycle (LI) (Table 8) with four lariat phosphine groups has been obtained analogously from 1,4,8,11-tetra-azacyclotetra-decane.[117] Lariat phosphine ligands form complexes with both transition and alkali metals: complexes of the macrocycles (XLIXa, b) and (La) with Pd, Rh, Ir, Fe(0), and Cu(I) compounds and those of the ligands (XLIXc) and (Ia) with $LiPF_6$ and $NaPF_6$ respectively have been obtained.



The macrocycles (Lb, c, e), in which the phosphine groups are separated from the polyether ring by 2–3 methylene units, have been synthesised by alkylating lithium (potassium) diphenylphosphite with ω-chloroalkyl derivatives of azacrown-ethers:[115,118]

$n = 1, 2$

The macrocycles (LIIa–e) (Table 8) have been synthesised similarly by the reaction of *NN'*-di(ω-chloroalkyl) derivatives of diaza-crown-ethers and diazathiacrown-ethers with potassium diphenylphosphide generated in solution from PPh_3 and potassium.[118,119] Compounds (LIIa–d) are capable of interacting with both "hard" cations of alkali and alkaline earth metals and with "soft" cations of transition metals via the phosphine. The primary coordination of the cation to the polyether ring and the oxygen atoms in the lariat groups then ensures the *cis*-configuration of the bisphosphine section in the secondary coordination to the transition metal cation. Thus a heteronuclear complex of the macrocycle (LIId) with $CaCl_2$ and $PdCl_2(PhCN)_2$ and the complex of the macrocycle (LIIb) with $Zn(ClO_4)_2$ and $Rh(nbd)_2^+ ClO_4^-$, where nbd = bicyclo[2.2.1]hepta-2,5-diene, have been obtained.[119]

The macrocycles (LIIIa–d) (Table 8)—benzocrown-ethers containing a phosphino-group in the benzene ring—have been synthesised from the corresponding chloromethyl and bromo-derivatives:[120,121]

R=Ph, t-Bu, $n = 1, 2$.

The complexes of these macrocycles with a series of rhodium, iridium, palladium, and tungsten salts have been obtained. The complexes *trans*-$PdCl_2.L_2$ and *trans*-$PdBr_2.L_2$ of the ligands (LIIIc, d) have been shown[121] to be not only reaction catalysts but also to

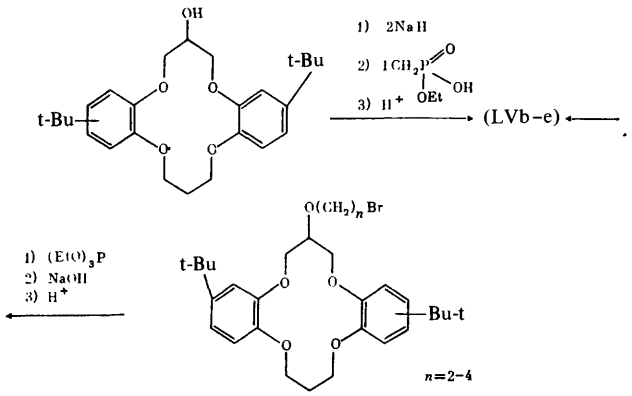
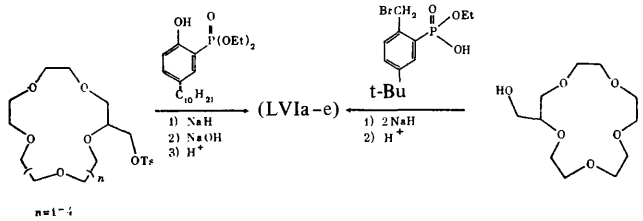
fulfill the role of phase transfer catalysts in the two-phase reduction of chloromethylnaphthalene by formic acid salts. In this case the HCO_2K complex of the ligand (LIIId) (an analogue of 18-crown-6-ether) is more active.

The macrocyclic triamides of phosphoric and phosphorithoic acids (LIVa–d) (Table 8), which exhibit antitumour activity, have been synthesised by phosphorylating monoazacrown-ethers with $POCl_3$ (or $PSCl_3$), this being followed by treatment with aziridine:[122]



Crystalline complexes with $NaBPh_4$ have been isolated for all the complexes (LIVa–d) and have been investigated by ^{23}Na NMR.

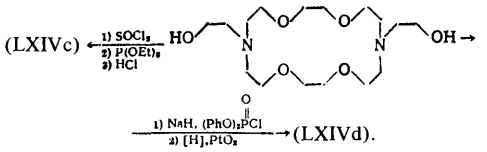
In order to increase the lithium selectivity of 14-crown-4-ethers, its various lariat derivatives have been obtained,[123] including the macrocycle (LVa) (Table 8):



The monoethyl esters of crown-ether-substituted phosphonic acids (LVb–e) have been synthesised[124] as extractants for alkali metals from di(t-butylbenzo)-14-crown-4-ether by alkylating its hydroxy-derivative with $ICH_2PO(OEt)ONa$ [compound (LVb)] or by the reaction of the ω-bromoalkoxy-derivative of the crown-ether with triethyl phosphite [compound (LVc–e)]:

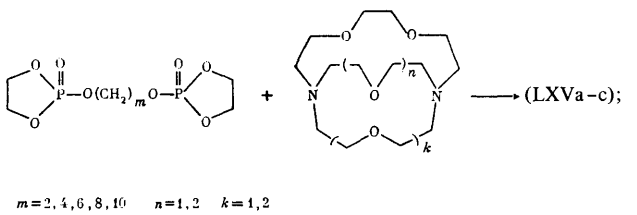
Compound (LVc) could not be obtained by alkylation [by analogy with compound (LVb)] with the aid of $BrCH_2CH_2PO(OEt)_2$ or by the addition of diethyl vinyl phosphonate.

The macrocyclic extractants (LVIa–e) (Table 8), containing the lipophilic phosphite groups, have been synthesised from the hydroxymethyl derivative of the corresponding crown-ether and the esters of *o*-bromomethyl- and *o*-hydroxyarylphophonic acids:[125,126]



The macrocycles (LVIIa–c) (Table 8) have been synthesised by the reactions of the di(chloromethyl) derivatives of octahydrobinaphthyl-17-crown-5-ether, binaphthyl-20-crown-6-ether, and binaphthyl-23-crown-7-ether with triethyl phosphite.[127] The macrocycle (LVIII) (Table 8) has been synthesised analogously from bis-[4,5-di(bromoethyl)benzo]-18-crown-6-ether,[128] while the bisphosphonates (LIXa–c) (Table 8) have been obtained from dibromobenzo-18-crown-6-ether in the presence of nickel halides.[129]

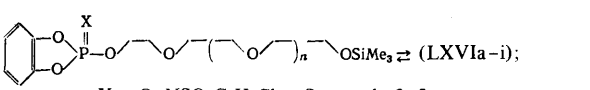
The macrocyclic bisamides (LXa–e) (Table 8) have been obtained by phosphorylating the 4,4′-diaminodibenzo-18-crown-6-ether[130] and two polymorphic modifications of compound (LXb, c) have been isolated.



A whole series of azacrown-ethers and cyclans have been converted by reaction with paraformaldehyde (formaldehyde) and phosphorous acid or its analogues into lariat derivatives with neutral and acid phosphinylmethyl groups—the macrocycles (LXIa, b),[131–133] (LXIIb, c),[134,135] (LXa, b),[136] and (LXIVa, b).[136,137]

The octadentate ligand (LXIIa) has been synthesised by the addition of diphenylvinylphosphine oxide to 1,4,7,10-tetra-azacyclododecane.[138]

Macrocycles with acid phosphonate [compound (LXIVc)] and phosphate [compound (LXIVd)] groups have been obtained from the *NN′*-di(β-hydroxyethyl) derivative of diaza-18-crown-6-ether:[137]

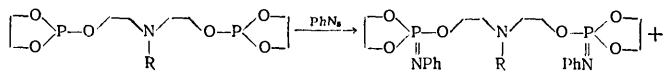


The oligomers (LXVa–c) (Table 8), capable of extracting alkali metal cations into the organic phase, have been obtained by the reaction of cyclic bisethylene phosphates with various cryptands:[139]

Their selectivity is determined by the size of the cryptand and their efficiency increases with increase in the length of the alkylene unit (*m*).

IV. MACROCYCLIC COMPOUNDS OF PENTACOORDINATE PHOSPHORUS

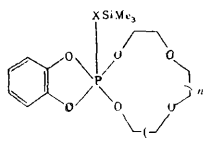
A series of macrocyclic pentacoordinate phosphorus compounds have been synthesised (Table 9). Here the phosphorus atom plays merely the role of a structural unit, determining in many instances the conformation of the polyether ring. Compounds of this kind have been obtained with the aid of reversible intermolecular cyclisation of *o*-phenylene phosphates or their analogues containing a poly(ethylene glycol) chain with the trimethylsilyl group in the ring:[140,141]

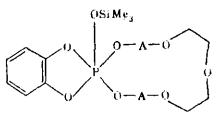


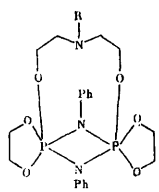
X = O, $NSO_2C_6H_4Cl$-*p*, S; *n* = 1–3, 5

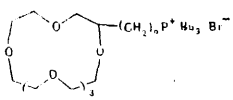
The macrocycles (LXVIIa–c) (Table 9) have been obtained in an analogous way.

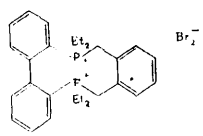
The cyclisation equilibrium, investigated by NMR, shifts towards the macrocyclic spirophosphorane with increase in temperature or with increase in solvent polarity. In particular the addition of pyridine stabilises the macrocyclic molecule, which the authors believe to be the result of the coordination to the phosphorus atom. However, such coordination does not cause an appreciable upfield shift of the signal in the ^{31}P NMR spectrum.[141] The tendency towards cycli-sation diminishes with increase in the length of the polyether chain and also on decrease of its conformational flexibility (after the intro-duction of the cyclohexane or benzene ring). As a

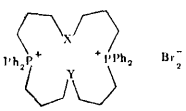


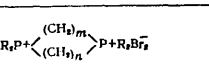


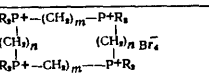


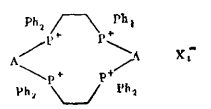












consequence of the lower affinity of silicon for nitrogen compared with oxygen, the equilibrium involving the *N*-trimethylsilyl derivatives (LXVIc, f, i) is greatly displaced towards the linear form. In the case of the thio-phosphoranes (LXVIb, e, h), the slow cyclisation is followed by the reversible dissociation of the P–OC bond in the macrocycle. The equilibrium in this process is displaced towards the quasi-phospho-nium structure. The authors believe that, according to ^{31}P NMR data, the equilibrium mixture contains also dimeric linear and cyclic phosphoranes in an amount of 1–5%.

The addition of phenyl azide to the bisdioxaphospholan phosphite entails not only the formation of a bisiminophosphoryl compound but also of its cyclisation product (LXVIIIa, b) (Table 9) as a result of the formation of the diazadiphosphetidine fragment:[142,143]

This Section presents data not only on pentacoordinate phosphorus compounds but also on phosphonium salt. Some of them have already been discussed in Sections II and III.

The macrocycle (LXIX) (Table 9), which has an exocyclic phosphonium group, has been obtained by the reaction of ω-bromononyl-18-crown-6-ether with tributylphosphine:[144]

Compound (LXIX) can effect phase transfer catalysis both in a liquid–liquid system via the phosphonium fragment and also solid–liquid phase transfer catalysis by virtue of the crown-ether fragment. However, both catalytic centres (in the reaction involving the exchange of a halogen or the cyano-group) act indpendently without synergism.[144]

The macrocyclic bisphosphonium salts (LXX) [145] and (LXXIa–c) [110,111] (Table 9) have been obtained by alkylating bisphosphine by the corresponding dibromide under the conditions of high dilution.

The bis- and tetrakis-phosphonium salts (LXXIIa–e) and (LXXIIIa–d) (Table 9) have been synthesised by the reactions of αω-alkylenebisphosphines with αω-dihalogenoalkanes and by the reactions of di(ωω′-halogenoalkyl)bisphosphonium salts with alkylenediphosphines respectively.[79,80] The use of high dilution does not increase the yield of macrocycles.

The macrycyclic phosphonium salts (LXXIVa, c, d) (Table 9) have been synthesised in an unusually high yield (80–98%) from bis(diphenylphosphino)ethane and *p*-di(chloromethyl)arenes[146] or 1,4-dichlorobut-2-ene[147] under the conditions of high dilution (10^{-2} M) on prolonged refluxing in toluene (96 h):

$$Ph_2PCH_2CH_2PPh_2 + ClCH_2{-}A{-}CH_2Cl \rightarrow (LXXIVa, c, d);$$
$$A = CH{=}CH,\ p\text{-}C_6H_4,\ p\text{-}C_6Cl_4.$$

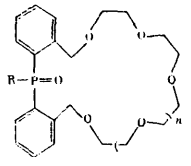
Compound (LXXIVa) apparently the (*E*)-isomer, is formed regardless of whether the *cis*- or the *trans*-isomer of the dichlorobutene is used in the reaction. Its catalytic hydrogenation yielded the macrocycle (LXXIVb).

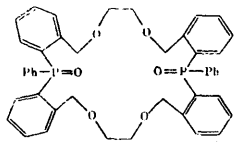
V. COMPLEX FORMING PROPERTIES OF PHOSPHORUS-CONTAINING MACROCYCLES

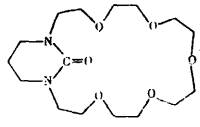
Mainly the complex-forming properties in relation to alkali and alkaline earth metal cations are considered in this Section. Data on the formation of complexes by phosphine macrocycles with transition metals are described above together with studies on their synthesis.

1. The Complex Forming Properties of Macrocycles Containing a Tervalent Phosphorus Atom

The polyether macrocycles containing a tervalent phosphorus atom, which is incapable of interacting effectively with alkali metal cations, resemble in their complex forming properties the crown-ethers having a macrocyclic ring of the same size. The stability constant and the selectivities of substances of these types are similar. For example, compounds (VIa, b) (Table 2) interact effectively with Li^+: K_s > 300 litre mol^{-1} (acetonitrile), whereas in the case of Na^+ and K^+ the stability constants fall to 8 and 5 litre mol^{-1} respectively.[148] Similarly unstable complexes with Na^+ and K^+ are formed by the macrocycles (Xa) (Table 3) and (XLIa) (Table 6). However, compound (Xc) (Table 3), differing from compound (Xa) by the substituent at the phosphorus atom (t-butyl instead of phenyl), is capable of interacting with $NaPF_6$.







2. The Complex Forming Properties of Macrocycles Containing a Tetracoordinate Phosphorus Atom

The synthesis of phosphoryl-containing macrocycles was dictated by the endeavour to increase the efficiency of macrocyclic ligands by introducing into the ring the phosphoryl group, which possesses a high complex forming capacity. The effect of the introduction of phosphorus-containing fragments has been studied in greatest detail by Cram and co-workers.[108] Their data (Table 10) show that the introduction of the phosphoryl fragment lowers the stability of the complexes of macrocycles with Na^+, K^+, Rb^+, and Cs^+ and also the selectivity relative to the analogous crown-ethers. Only lithium is an exception in the case of the phosphine oxides (XLIVd–g) and (XLV). A decrease in the efficiency of the ligand after the introduction of the phosphorus-containing fragment into the ring can apparently be explained by the characteristics of the conformational structure of the macrocycle which prevents the cooperative interaction of all the oxygen atoms with a metal cation—the phosphoryl group is oriented away from the polyether fragment. On the other hand, the introduction of lariat carboxy-groups in the *o*-position relative to the phosphoryl group [compounds (XLIVf, g)] stabilises the complex formed. It is of interest to note that the use of the urea residue in the polyether ring [the macrocycle (LXXV), (Table 10)] leads, as in the case of the phosphoryl group, to a decrease in selectivity and in the stability constants.

The results of the study of the formation of complexes by the macrocycles (XXVI), (XXVIII), (XLVII), and (XXXVIIa) (Table 11), obtained by Yatsimirskii and Kabachnik and co-workers,[149,152] agree with the features demonstrated by Cram.[108] The compounds enumerated as well as the macrocyclic phosphine oxide (XLIII) (Table 11) [107] are inferior to crown-ethers as regards the efficiency and selectivity of their interaction with alkali metals. The "macrocyclic effect" for Li^+ is in this case insignificant, in contrast to the other cations, as can be seen from the comparison of the ligand (XLVII) with its acyclic analogue (LXXVII). The low efficiency of the phosphorus-containing crown-ethers is due to the unfavourable orientation of the phosphoryl (or thiophosphoryl) group away from the polyether ring. This conformation is energetically most favourable for the macrocycles (XXVIa),[153,154] (XXVIII),[155] and (XXVIf) (Table 4).[156]

The phosphoryl groups make the main contribution to the stability of the complex. Their decisive role in complex formation has been demonstrated by NMR for compounds (XXVIII) [152,153] and (XLIII) [157] and by IR and Raman spectroscopy for the ligands (XXVIa) [89,158] and (XXVIIe) (Table 4).[89,159] Together with the phosphoryl group, in compounds (XLIII) and (XXVIII) the oxygen atom on the opposite side of the macrocycle participates in the coordination of the cation. This conclusion is based on the chemical shift differences in the ^1H NMR spectra in the presence of lithium dinitrophenoxide for compound (XLIII) [157] and $NaClO_4$ for compound (XXVIII) [152] and also on interaction with shift reagents.

Table 10. Stability constants (10^3 K_s, M) of complexes of phosphorus-containing crown-ethers of the neutral type and their analogues with alkali metal picrates in $CDCl_3$ (24–26 °C).[108]11.

(LXXVI)	2,3-naphtho-18-crown-6-ether	—	22.5	1220	85 990	11 300	1250

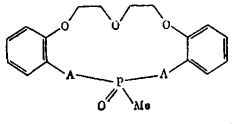
The increase by approximately an order of magnitude in lg β for Na^+ (Table 11) corresponds to the increase in the size of the cavity in the macrocycle on passing from the ligand (XLIII) to (XXVIII) for the same number of active donor centres. Compounds (XXVIIa–g) (Table 4) also interact more effectively with Na^+ than with Li^+ and K^+.[90] On the other hand, the study of the ionophoric properties of the ligand (XXVIIe) on double layer lipid membranes[89] revealed its high K^+/Na^+ selectivity. It has been suggested that a stable complex of the sandwich type analogous to the 2:1 calcium complex, in which the two phosphoryl and four (anisole) oxygen atoms are coordinated to the cation, is formed in this case.[159,160] The calculated radius of the cavity formed then corresponds to the crystallographic radius of the K^+ ion.[89] In contrast to the ligand (XXVIIe), compounds (XXVIa) and (XXVIII) form 1:1 and 1:2 calcium complexes respectively,[160] in which the cation is not shielded, as a consequence of which they do not possess an ionophoric activity.[89,161]

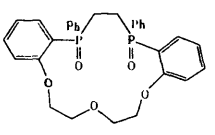
The stability constants of the complexes of the ligands (XLVII) [162] and (XXVIIa–g) [90] with calcium and magnesium salts have been determined by the solubility method. The thiophosphoryl macrocycles (XXVIIf, g) are weaker complex forming agents in relation to alkali and alkaline earth metals than their phosphoryl analogues (XXVIIa, c) but, like compounds (XXVIf, g), they form stable complexes with Ag^+ [85] and are effective agents for the transfer of silver picrate through a liquid dichloroethane membrane.[163]

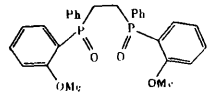
The macrocycles (XXVIa, f),[158] (XXXVIIa),[164] and (XLVII) [165] are capable of interacting effectively with transition metal (Fe^{3+}, Cu^{2+}, Ni^{2+}, and Co^{2+}) salts and also of transporting them through a liquid membrane, which is done, for example, by the macrocycle (XXVIa) (transport of $FeCl^3$ through dichloroethane).[166]

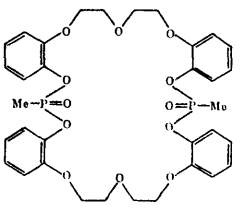
The macrocycle (XXX) (Table 4) is an ionophore of the acid type which at pH 1.5 effectively transfers K^+ and (in the opposite direction) H^+.[167]

3. The Complex Forming Properties of Macrocycles Containing Lariat Phosphoryl Groups.









The most promising of the phosphorus-containing macrocycles at the present time are apparently crown-ethers or their analogues with phosphoryl groups in the side chain (lariat compounds). The phosphorus-containing fragment does not significantly distort the conformation of the macrocycle in this instance and hence does not disturb the effect of the cooperative interaction of the donor ring atoms with the cation. At the same time, the phosphoryl group is capable of ensuring additional binding of the cation, imparting a high stability to the complex. Thus the introduction of two phosphonate groups into the dinaphthyl residue of the crown-ether significantly increases the binding constants, as can be seen from the comparison of compounds (LVIIb, c) with compound (LXXIX) (Table 12). The values $\Delta G = -12.4$ kcal mol^{-1} for the binding of the ligand (LVIIb) to Na^+ and $\Delta G = -12.2$ kcal mol^{-1} for the formation of the complex between compound (LVIIc) and Rb^+ correspond to this kind of jump in K_s.[127] It must be emphasised that the macrocycle (LVIIb) forms the most stable complex with K^+ among the crown-ethers containing the 1,1′-binaphthyl residue.[168] X-Ray diffraction analysis has shown[169] that, in the potassium complex of the macrocycle (LVIIb) having the composition L.KSCN.$CHCl_3$, the cation is located at the centre of the polyether ring and the two oxygen atoms of the P=O groups are coordinated to it, being located on the axis

perpendicular to the plane of the polyether ring and passing through its centre. The $O_{eth}...K^+$ and $O_{P=O}...K^+$ distances are respectively 2.76 and 2.70 Å, while in most crown-ether complexes the distance exceeds somewhat 2.8 Å.[169]

In contrast to compounds (LVIIb, c), the macrocycle (LVIIa), which should be an ideal complex forming agent for Na^+ according to theoretical calculations, interacts only weakly with alkali metal cations (Table 12), although it does exhibit a very pronounced selectivity. The introduction of four diphenylphosphinylmethyl groups in the *meta*-position relative to the polyether ring in dibenzo-18-crown-6-ether [compound (LVIII, Table 13)] lowers the selectivity in relation to K^+ (cf. Table 11). However, the four additional centres, which differ from the ether oxygen atoms in the macrocycle, make it possible to obtain dimetallic complexes, such as, for example, $(CoCl_2)_2.KCl.L$,[170] in which the potassium cation is in the plane of the macrocycle and the phosphoryl groups are coordinated to the cobalt atoms.

For the lariat compound (LXIa), constructed from triazacyclononane and carrying phosphine oxide side chains (Table 13), highly stable complexes have been obtained with magnesium and calcium iodides, namely $(MgI_2)_3L_2.3H_2O$ and $CaLI_2.3H_2O$,[171] which do not decompose on heating at 100°C. Analysis of the ^1H NMR spectra of the complexes led to the conclusion that all the nitrogen atoms of the ligand in the Mg^{2+} complex are involved in coordination to the metal, whereas in the Ca^{2+} complex only one nitrogen atom interacts with the cation. The different stabilities of the complexes are indicated also by the values of $\lg K$ for MgI_2 and CaI_2—2.8 and 2.4 respectively (1:1 acetonitrile–$CHCl_3$ mixture).[171] The study of complex formation with alkali metals showed that the macrocycle (LXIa) forms a highly stable complex with Li^+: $\lg\beta = 5.6$ (4:1 THF–$CHCl_3$ mixture).[131] The higher selectivity of the compound with respect to lithium compared with the simplest analogues, for example, compound (LXXX) (Table 13) is caused, according to the authors, by the flexibility of the lariat molecule, which enables it to

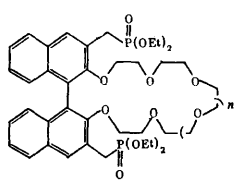
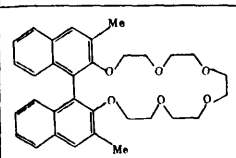
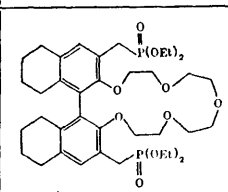
assume the energetically most favourable conformation. The linearity of the relation between $\lg\beta$ and $1/r$ (where r is the ionic radius of the cation) indicates the ion–dipole character of the interaction, i.e. the electrostatic interaction of the cation with the polar groups of the ligand makes the main contribution to the free energy change.[131]



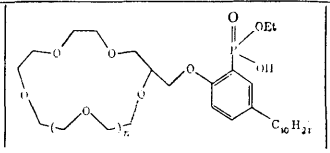




In contrast to the macrocycle (LXIa), the phosphinylethylated tetra-azacyclododecane (LXIIa) (Table 13) interacts preferentially with Na^+ and is significantly superior to dibenzo-18-crown-6-ether (Table 11) as regards efficiency and Na^+/K^+ selectivity.[138] Complexes with cobalt salts have been obtained for both compound (LXIa) [172,173] and the macrocycle (LXIIa).[173]

The acid analogue of compound (LXIa) [the macrocycle (LXIb), Table 8)] does not form stable complexes with alkali metal cations in water but it does interact effectively and selectively with doubly charged cations having a small radius.[132,133] Thus the difference between the stability constants of the complexes with Mg^{2+} and Ca^{2+} is by about 5 orders of magnitude (the $\lg K$ for the complexes ML are respectively 11.01 and 6.38). A high selectivity is observed also in the series of Group II B transition metals: the complex with Zn^{2+} (r = 0.74 Å) formed by the ligand is the most stable among all those known for zinc ($\lg K$ = 24.9 for the complex ML). The stability constant for Cd^{2+} (r = 0.97 Å) is lower by five orders of magnitude. A very stable complex is also formed with the Fe^{3+} ion (r = 0.64 Å): $\lg K$ = 29.6 for the complex ML. According to X-ray diffraction data,[174] the Fe^{3+} cation in the complex is located in the inner cavity of the ligand, formed by the side groups, and interacts with all its donor centres. The "twisted basket" conformation produced under these conditions differs in energy from the conformation in the free state by only ~5 kJ mol^{-1}.[175]

The tetraphosphinic acid (LXIIb) (Table 8), whose ring has been increased by one aminoethyl unit, has a completely different spectrum of interaction with cations:[134] whereas complexes of the ligand (LXIb) are more stable for cations with an ionic radius $\leqslant$0.7 Å, cations with a radius >0.8 Å form more stable complexes with the ligand (LXIIb). For example, the macrocycle (LXIIb) forms a more stable complex with Ca^{2+} than with Mg^{2+} (the $\lg K$ for the complexes ML are 10.3 and 7.3 respectively). The ligand (LXIIb) is a selective complex forming agent for Cd^{2+} and Pb^{2+}, but, in relation to a whole series of cations, including alkaline earth metals, it is greatly inferior to the carboxyl-containing analogue 1,4,7,10-tetrakis-(carboxymethyl)-1,4,7,10-tetra-azacyclododecane, and also to the macrocycle (LXIb), and is close to the relatively weakly selective complexone EDTA. Atom–atom potential function calculations have shown[175,176] that the low selectivity of compound (LXIIb) can be explained by the adequate conformational possibilities for the formation of six- and five-coordinated complexes with various cations. The maximum number of binding sites (eight) is not utilised owing to the mutual repulsion of the phosphenyl group. Like compound (LXIb), the macrocycle (LXIIb) forms relatively unstable complexes with the alkali metal cations, the stability decreasing in the sequence $Li^+ > Na^+ > K^+$. For the K^+ cation, $\lg K < 1$.[134]



The "expansion" of the ring in the ligand (LXIIb) by two methylene units [to give compound (LXIIc), Table 8] and hence the increase in its conformational mobility lead to a sharp decrease (by 6–8 orders of magnitude) of the stability of the complexes with all cations.[135] For example, $\lg K < 2$ for alkaline earth metal cations (for the ML complexes). The carbonyl-containing analogue of compound (LXIIc)—1,5,8,12-tetrakis(carboxymethyl)-1,5,8,12-tetra-azacyclotetradecane—is only slightly inferior to it as regards efficiency, but the difference between the values of $\lg K$ for the two ligands in the case of Cu^{2+} reaches 8 orders of magnitude. The high selectivity of compound (LXIIc) with respect to the Cu^{2+} ion ($\lg K$ = 26.6 Cu^{2+} and $\lg K$ = 15.6 for Ni^{2+}) is probably favoured by the

Table 12. Stability constants (10^{-3} K_s, M) of complexes of phosphonate lariats of the neutral type with alkali metal picrates in $CDCl_3$.[127]

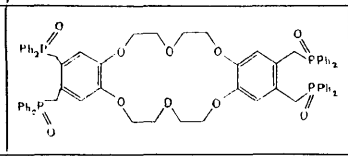
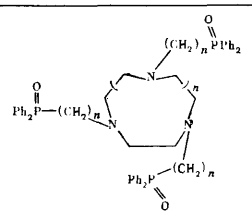
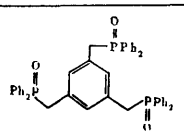
(LVIe)		4	11	22	23	18	20



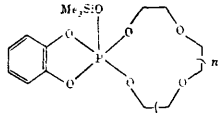




In contrast to the ligands (LXIb) and (LXIIb, c), the *N*-dihydroxyphosphinylmethylated azacrown-ethers (LXIIIa, b) and (LXIVa) (Table 8) form more stable complexes with Na^+: $K_{NaL} = 20-40$.[136] The presence of at least one phosphonate group is essential for the formation of stable complexes, since unsubstituted monoaza- and diaza-crown-ethers do not interact with Na^+. Macrocycles with five heteroatoms in the ring [compound (LXIIIa)] are the most effective, which is particularly characteristic of the carboxy-analogues of compound (LXIVa).

The macrocycle (LXIVa) and its analogues with carboxy- and phosphonite groups [compound (LXIVb), Table 8] proved to be promising solubilising agents for barium sulphate.[137] Their efficiency in relation to the [2.2.2]cryptand is 65, 65, and 19% respectively. The use of longer phosphonoalkyl and carboxyalkyl chains or other polar groups (SO_3H, OPO_3H_2, OSO_3H) lowers sharply the solubility of the Ba^{2+} complexes.

The introduction of a lariat phosphoryl-containing group [the macrocycle (LVa), Table 8] or of the amino-group into 14-crown-4-ether increases its selectivity with respect to lithium.[123] The selectivity coefficients in a polymer membrane then reach 182 (Li^+/Na^+) and 288 (Li^+/K^+). On the other hand, ester and 8-hydroxyquinoline groups impair the selective properties of the crown-ether.



A whole series of crown-ether-substituted phosphonic acids have been investigated as extractants of alkali metal cations.[124–126] Thus, among phosphinylalkoxy-derivatives of di(t-butylbenzo)-14-crown-4-ether (LVb–e) (Table 8), a highly selective extractant for Na^+ has been found, namely the ligand (LVc).[124] A further increase in the length of the alkyl chain between the polyether ring and the charged phosphonate group leads to the loss of selectivity and to a decrease in the efficiency of the extractant [compounds (LVd, e)]. As shown on models, the length of the lariat group in compounds (LVc) is optimum from the additional stabilisation of the sodium complex. The macrocycles (LVIb–e) (Table 14),[125] containing the lipophilic

phosphonate group, extract cations in conformity with the size of their polyether ring. For example, the macrocycle (LVIb), constructed from 15-crown-5-ether, extracts Na^+ preferentially. Compound (LVIa) (Table 8) behaves analogously. The formation of its highly stable sodium complex has been demonstrated by ^1H NMR.[126] The principal advantage of the phosphorus-containing extractants investigated compared with their carboxy-analogues is their higher efficiency and also their ability to extract cations at low pH (down to pH 2).

4. The Complex Forming Properties of Macrocycles Containing a Pentacoordinate Phosphorus Atom

The formation of complexes by the macrocycles (LXVIa, d, g) and (LXVIIa) (Table 15), containing the phosphoranyl group, with alkali metal chloride has been investigated by the solubility method.[141] In contrast to compound (LXVI) (n = 0), which does not possess complex forming properties because of its small ring size, the macrocycles (LXVIa, d, g) and (LXVIIa) interact selectively and effectively with Li^+, being greatly superior in this respect to 18-crown-6-ether. With increase in ring size and in the number of ether oxygen atoms on passing from compound (LXVIa) to (LXVIg), the efficiency of the complex formation with LiCl also increases. On the other hand, the interaction with cations having larger radii (Na^+, K^+, Rb^+, Cs^+) is weaker, even for the 23-membered macrocycle. The authors explain the selectivity with respect to Li^+, especially for compounds (LXVIa, d) and (LXVIIa), by the fact that the trigonal-bipyrimidal configuration of the phosphorus atom imparts to the conformationally labile ring a geometry in which the donor oxygen atoms are not in a single plane and the size of the cavity formed by them corresponds only to the lithium cation. The disadvantage of the phosphorane macrocycles is their hydrolytic instability.

---o0o---

During the preparation of the manuscript for the press, new studies on the synthesis and complex-forming properties of phosphorus-containing macrocycles were published. Thus macrocycles with phosphorus(III) have been obtained by the transamidation of the amide $PhP(NMe_2)_2$ or $P(NMe_2)_3$ with polyetherbisamines containing *o*-aminophenol or 3-amino-2-methoxybenzyl alcohol fragments as the end group. They were converted by oxidation or the addition of sulphur into the corresponding macrocycles with phosphorus(IV).[177] A tetraphosphorus(III) macrocycle has been synthsised in a high yield in the form of the nickle complex by the matrix cyclisation method from the phosphine complex $PhP[(CH_2)_3PhMe]_2.NiBr_2$ and the amide $Et_2NP(CH=CH_2)_2$ [cf. the ligand (XIX) (Table 3)] in a high yield. The nickel complex was then oxidised to the phosphorus(IV) derivative.[178] A 22-membered bisphosphonate macrocycle has been obtaind[179] in 6–8% yield from *OO'*-di(β-hydroxyethyl)-catechol and $MeP(O)Cl_2$ by the same method as compound (XXXVIIa–e) (Table 5). The stability of its complexes with alkali metals varies in the sequence Na > Li ≫ K. The complex-forming properties of the macrocycles (XXVIa, c), (XXVIIa, c), (XXVIII), and (XXXVIIa) in relation to the lithium, sodium, potassium, magnesium, and calcium cations have been investigated by a modified solubility method in the CH_2Cl_2 + 2% MeCN mixture.[180] The extraction of sodium, potassium, magnesium, calcium, strontium, barium, and other metals by chloroform solutions of the macrocycles (XXVIa, f), (XXVIIIa, e, f), and (XXXVIIe) has been studied.[181] In contrast to the phosphonate crown-ethers, which possess no extracting properties, the phosphonothionates (XXVIf), (XXVIIf), and (XXXVIIe) extract to a slight extent silver, mercury, and palladium at pH 1–5 and extract them quantitatively from concentrated acid solutions. Phosphate ionophores of the acid type—compound (XXX) (Table 4) and five of its analogues—have been obtained by the interaction of oligo(ethylene glycols) with $POCl_3$ under high dilution conditions (5×10^{-2} M) with subsequent hydrolysis of the resulting cyclic phosphoromonochloridate[182] [demonstrated in relation to compound (XXX)]:

$$HOCH_2CH_2OCH(CH_2OCH_2)_3CH_2OH \xrightarrow[2)\ H_2O,15^\circ C]{1)\ POCl_3,\ -70^\circ C} (XXX)$$
$$\quad\quad\quad

Methods of synthesis have been developed for phosphorane macrocycles. Such compounds with two and more phosphorus atoms can be obtained by the reaction of the disilyl ethers of alkane-αω-diols with $PhPF_4$ [189] or of the diols themselves with Ph_3P in the presence of di-isopropyl azodicarboxylate.[190,191]

Dissociation of Water Molecules in Systems with Ion-exchange Membranes

V.I.Zabolotskii, N.V.Shel'deshov, and N.P.Gnusin

The principles of the dissociation of water molecules in membrane systems containing cation-exchange, anion-exchange, and dipolar membranes are examined. The characteristics of the attainment of the limiting state at the membrane-solution boundary and the differences in the behaviour of cation-exchange and anion-exchange membranes are discussed from the standpoint of the possibility of the dissociation of water at the interfaces. The mechanisms and the kinetics of the dissociation of water in membrane systems involving catalytically active centres† are considered.
The bibliography includes 87 references.

III. Dissociation of water molecules in dipolar membranes 804

I. INTRODUCTION

The problem of the dissociation of water molecules in a membrane system when an electric current flows through the latter is one of the central problems in the electrochemistry of membranes. This is associated with the complications arising from the dissociation of water in membrane systems and with the new possibilities for electrochemical technology opened up by its use. In the demineralisation of solutions by electrodialysis, the dissociation of water in the region of the membrane–solution boundary leads to the participation of the H^+ and OH^- ions in transport across cation-exchange and anion-exchange membranes. As a consequence of this, the limiting current decreases,[1] there is an additional consumption of electrical energy on demineralisation, the pH changes in the electrodialyser chambers, and chemical reactions sensitive to changes in the acidity of the medium occur, including the crystallisation of calcium carbonate and magnesium hydroxide in the concentration chambers, where the pH is in excess of 7, or reactions sensitive to the precipitation of silicic acid in the desalination chambers, in which the medium is acid.

Since the transport of the water dissociation products across the membrane begins after the attainment of the limiting state when the concentration of the H^+ and OH^- ions in the region of solution near the membrane becomes comparable to the electrolyte concentration,[2–4] attention has been concentrated on the search for signs preceding the onset of limiting state in order to have reliable ways of maintaining the membrane system in the pre-limiting state, where water does not decompose.

Recently there has been a growth of interest in the decomposition of water in membrane systems for several reasons. Firstly, this is associated with the appearance of dipolar membranes and their use in electrodialysers for the preparation of acids and alkalis or for other chemical reactions with participation of hydrogen and hydroxide ions. The decomposition of water in such systems is the "working" process and the efficiency of the entire electromembrane technology depends on the overpotential and current yield with which the H^+ and OH^- ions are generated.[5,6] The joint demineralisation and preparation of acid and alkali can be achieved in the so-called "semidipolar" membranes,[7–9] which are obtained by depositing a unipolar cation or anion exchanger on the membrane and also by the coprecipitation of the ion exchanger and polyelectrolyte.

Secondly, the problem of the intensification of the mass transfer in membrane systems has come to the fore and the applications of electrodialysis have been extended to the preparation of deionised or ultrapure water. The electrodiffusion process is then carried out under postlimiting conditions (the current is greater than the limiting diffusion current), where water decomposes very quickly and this process itself can intensity the mass transfer of electrolyte across membranes[10,11] by increasing the electrolyte concentration in the region of the diffusion layer near the membrane and by increasing thereby the migration current (the so called "current exaltation effect"). Finally, there has been a growth of interest in the role which the transport of H^+ ions across biological membranes plays, especially in photosynthetic processes,[12,13] where local electric fields in membranes initiate the heterolytic cleavage of water molecules and the injection of H^+ into the membrane.

II. DISSOCIATION OF WATER MOLECULES AT THE MEMBRANE–SOLUTION BOUNDARY

The possibility of the dissociation of water when an electric current is passed through ion-exchange membranes was established a long time ago. As early as 1914, Bete and Toropoff[14] observed the transport of water dissociation products through certain membranes (gelatin, parchment, and collodion membranes). The involvement of H^+ and OH^- ions in transport across ion-exchange membranes was observed in 1946 by Frilette[15] and independently by Kressman and Tye[16] and was later confirmed by many workers.[17–27]

It has now been established reliably that the rate of decomposition of water and the fluxes of H^+ and OH^- ions in the membrane system depend greatly on the nature of the ionogenic groups.[11,19–24,28–30]

† This article was planned for publication in issue No.6 (1988) of this journal, which was devoted to the problem of polymer membranes.

For cation-exchange membranes at currents exceeding the limiting current by a factor of 1.5–2, the change in the pH of the solutions near the membrane is insignificant[31] and the transport numbers of the H^+ ions are in the range from 4×10^{-5} to 0.11.[4,18,26,29,32,33] On the other hand, the transport of OH^- ions across anion-exchange membranes takes place at a much higher rate and the transport numbers reach 0.03–0.6.[4,17-19,26,29,32-36]

Since the concentrations of H^+ and OH^- ions in the spontaneous decomposition of water molecules in water are identical, while the mobility of H^+ ions in ion-exchange resins is greater than that of OH^-, this finding is in conflict with the usual ideas about the electrodiffusion character of the transport of ions across membranes. Many workers therefore assumed that the transport of H^+ ions across a cation-exchange membrane is suppressed by some factor and they introduced the additional hypothesis that the states of the interfaces at the cation-exchange and anion-exchange membranes are different. Thus it has been postulated[37,38] that, at high current densities, an intense flux of electrolyte ions induces the partial disruption of the diffusion layer. The effect of the disruption of this layer is greater on the side of the cations, since they are more hydrated. This results in the appearance of additional possibilities for increasing the electrolyte flux, while the transport of H^+ ions across the cation-exchange membrane is suppressed.

Similar ideas were developed in other studies.[15,33,34,39] The decomposition of the diffusion layer has been attributed[15] to the establishment of electro-osmotic fluxes on the surface of the membrane owing to its inhomogeneity, while other workers[33,34,39] attributed it to the appearance of local convective currents near the interface as a consequence of the evolution of joule heat in the desalinated layer of solution. By applying the schlieren method and photography with the aid of Toepler's apparatus, Varentsov and Pevnitskaya[34] confirmed experimentally that the local thermoconvection arises at a cation-exchange membrane for electric currents exceeding the limiting diffusion current, while at an anion-exchange membrane this effect is very weak. The results obtained were explained by the different degrees of hydration of anions and cations (Mandersloot's mechanism[37,38]) and also by the existence on the surface of anion-exchange membranes of films with a low concentration of fixed groups.[33,34,39] Kononov and Vrevskii[4] explain the preferential transport of OH^- ions across anion-exchange membranes by their high selectivity with respect to hydroxide ions. After converting the membranes from the salt to the hydroxide-forms, they observed an increase in the rate of dissociation of water. Measurement of the electrolyte concentration at the interface using the commutator method (the current interruption method) made it possible to establish[18] that, at currents close to the limiting diffusion current, the limiting electrolyte concentration near the cation-exchange membrane does not attain low values comparable to the concentrations of the H^+ and OH^- ions in water, while at an anion-exchange membrane they are attained readily. Subsequently these results were confirmed in a study[40] using analogous methods and in other investigations[41–44] in which modern direct methods for recording electrolyte concentrations with the aid of laser holography were employed.

The earlier conclusions[34,39] that local convection arises in the solution at the surface of a cation-exchange membrane were confirmed and specified in greater detail by the methods of laser holographic interferometry[41,43,45] and also by measuring the electrochemical noise in membrane systems.[46–50] At currents only slightly exceeding the limiting current, the convective streams are laminar in character and do not influence the electrical resistance of membrane systems.[48] When the limiting current is exceeded by a factor of three, laminar convection is converted into turbulent convection, causing random oscillations in the resistance of the desalinated layer of solution, which is manifested by the appearance of flicker noise.[48] After the attainment of the turbulent thermoconvection regime, the electrical resistance of the membrane system falls.[48] By an additional series of elegant experiments, the authors[48] demonstrated that the convective currents generated obey known laws: with increase in the viscosity of the system by the addition of a non-ionisable water-soluble polymer, with decrease in the temperature of the solution, or for the horizontal disposition of the cation-exchange membrane (the desalinated layer of the solutions lies below), the noise induced by convection weakens. The frequency-independent "white" noise, associated with the water dissociation reaction, is not observed in a system with a cation-exchange membrane.[47]

On the other hand, convective currents in the desalinated layer of solution have not been observed at an anion-exchange membrane for currents close to the limiting value either from the form of the interferograms[45] or by analysing the frequency spectrum of the noise[47,49] but the "white" noise has been distinctly observed, indicating the decomposition of water. With increase in the current, the intensity of the "white" noise increased linearly and, after the attainment of the limiting current, it began to grow faster than predicted by a linear law.[49] Only at very low current densities, exceeding the limiting current by a factor greater than three, does a weak flicker noise appear for an anion-exchange membrane, indicating the occurrence of thermoconvection.

Quantitative allowance for thermoconvection in a rigorous description of electrodiffusion is a complex task and involves many difficulties already in the stage of its formulation. Theoretically, thermoconvection can be taken into account indirectly by assuming that the electrolyte concentration at the interface does not diminish below a certain value as a result of thermoconvection. Here it has been shown[51] that, instead of a horizontal plateau on the voltage–current plot, a section corresponding to a retarded growth of current with increasing potential appears.

The reason for the different behaviour of cation-exchange and anion-exchange membranes has not been elucidated.[44–50] It also remains obscure why thermoconvection is observed near a cation-exchange membrane but not near an anion-exchange membrane, although, it follows from results of these workers and those of other investigators[18,40,43] that the boundary electrolyte concentration near an anion-exchange membrane in the limiting state is lower than near a cation-exchange membrane and that the liberation of joule heat because of this should be more intense near an anion-exchange membrane.

In our view, the appearance of thermoconvection and the consequent growth of the concentration of the counterions at the cation exchanger–solution interface are a consequence and not the cause of the low rate of decomposition of water. In fact, the dissociation of water, which occurs with a large negative heat change (the enthalpy of dissociation of water is 56.6 kJ mol^{-1} [52]), compensates for the liberation of joule heat on passage of the current through the highly desalinated layer of solution at the interface, so that thermoconvection is very significant near an anion-exchange membrane, while the concentration of counterions diminishes to values comparable to the concentrations of H^+ and OH^- ions.[18,40,43,44,53] Around a cation-exchange membrane, the endothermic water dissociation process takes place at a very low rate and the passage of current therefore causes local heating of the solution at the interface and intense thermoconvection with all the consequences arising from it.

This approach explains the differences in the hydrodynamic state of the interfaces of cation-exchange and anion-exchange membranes observed in practice but leaves open the question of the causes of the different rates of decomposition of water at these membranes. The solution of this problem requires primarily the elucidation of the characteristic features of the mechanism of the dissociation of water in membrane systems.

If it is assumed that in a membrane system water decomposes at the same rate as in the usual aqueous solutions (the dissociation rate constant is $k_d = 2.5 \times 10^{-5}$ s^{-1} [54]) and the concept of the reaction layer is used,[55] the current transported by the H^+ and OH^- ions across the membrane (i_w) can be expressed in terms of the rate constants for the forward (k_d) and reverse (k_r) reactions, the concentrations of water (c_{H_2O}) and H^+ and OH^- ions (c_H and c_{OH} respectively), and the thickness of the reaction layer (λ):

$$i_w = F\int_0^{\lambda}(k_d c_{H_2O} - k_r c_H c_{OH})\,dx \leqslant F k_d c_{H_2O}\lambda. \qquad (1)$$

As can be seen from Eqn.(1), the partial electric current involving hydrogen or hydroxide ions (i_w) has an upper limit: under stationary conditions, the fluxes of H^+ and OH^- ions across membranes cannot be greater than the rate of formation of these ions in the reaction layer and the latter quantity is limited by the values of k_d and λ. The upper limit to i_w has been estimated[35,36] as 2×10^{-4} A m^{-2} at 25 °C, i.e. it is 10^7 times smaller than the current due to H^+ and OH^- ions actually observed in membrane systems.

Despite the approximate character of these estimates (the approach adopted by Simons and co-workers[35,56] is strictly applicable only in the presence of a supporting electrolyte when the electromigration transport of the ions formed in the reaction can be neglected[55]), a marked inconsistency is observed between the results of the calculation and the real rates. Even allowance for the electromigration ion transport[57] does not greatly improve the estimate.[36] The high rates of dissociation of water in the membrane–solution system cannot be explained from the standpoint of the Wien effect for weak electrolytes. The strength of the electric field arising in the region of the membrane–solution boundary is too low and the rate constant for the dissociation of water hardly differs from its value in the absence of the field.[58] The very fact of the decomposition of water and of the transport of H^+ and OH^- ions at the experimentally observed rates is therefore surprising and requires explanation, and not the ability of cation-exchange membranes to "suppress" the dissociation of water.[15,34,37–39]

The low limiting kinetic current for the water dissociation reaction in solution and marked dependence of the transport numbers of the H^+ and OH^- ions on the nature of the ion-exchange membranes lead to the conclusion that the cause of the high rate of this process should be sought not in the properties of the solution but in the characteristic features of the ion-exchange membranes.

As already mentioned, the rate of dissociation of water at cation-exchange (sulphonic acid) membranes in solutions of alkali metal salts is very low even when the actual current exceeds the limiting diffusion current by a large factor. However, as shown for the first time by Oda and Yawataya,[20] the dissociation of water increases sharply in this system when alkali metal cations are replaced by the Ca^{2+}, Mg^{2+}, and NH_4^+ cations. This effect was observed in the electrodialysis of sea water.[50] Subsequently it was established[60] that also certain other cations of weakly dissociating bases (Ni^{2+}, Co^{2+}, Mn^{2+}) are able to accelerate the decomposition of water, the reaction being accelerated not by the above ions themselves but by their hydroxides which are deposited on the surfaces of the membranes in electrodialysis and under postlimiting conditions are deposited especially on the surface of the cation-exchange membrane. The compounds $Cu(OH)_2$, $Fe(OH)_3$, $Al(OH)_3$, and $MnCO_3$ also exhibit a catalytic activity. On the other hand, deposits of the compounds $Zn(OH)_2$, $CaSO_4$, $BaSO_4$, and $CaCO_3$ on the surface of the cation-exchange membrane do not influence the rate of decomposition of water.[60] This shows that the diffusion-dependent obstacles to the transport of electrolyte across the solid phase of the deposit on the membrane surface and the associated additional concentration polarisation are not the causes of the intensification of the dissociation of water.

The observed acceleration can be explained (at least qualitatively) by assuming that certain weakly dissociating substances are involved directly in the dissociation of water, for example, in accordance with the scheme

$$Mg(OH)_2 \rightleftarrows MgOH^+ + OH^-\,,$$
$$MgOH^+ + 2H_2O \rightleftarrows (MgOH)_2 + H_3O^+\,.$$

The rate constant for the heterolytic decomposition of water on groups of the type of $MgOH^+$ can be higher by several orders of magnitude than the rate constant for the non-catalytic reaction; the reaction can also be accelerated by the electric field at the deposit–membrane interface, where the space charge is localised. According to the data of Tanaka and Seno,[60] the formation of the deposits on the boundary between the membrane and the diffusion layer, which serves as the recipient of the counter ions, fails to influence the rate of decomposition of water in all cases.

In principle, the simple cations of weakly dissociating bases can also possess catalytic activity, for example, as a result of their participation in the reactions[36]

$$Mg^{2+} + 4H_2O \rightleftarrows Mg(OH)_2 + 2H_3O^+\,. \qquad (2)$$

$$Mg(OH)_2 \rightleftarrows Mg^{2+} + 2OH^-\,. \qquad (3)$$

The detailed mechanism of the dissociation of water in solutions with catalytically active inorganic ions is obscure as yet; the studies carried out hitherto on this question[20,59,60] have been qualitative. In particular, the claim by Tanaka and Seno[60] that the acceleration of the water dissociation reaction takes place in all cases only after the formation of the solid phase of the deposit, is incomprehensible and requires additional experimental confirmation. From the standpoint of Simon's scheme[36] [Eqns.(2) and (3)], the acceleration can be promoted by catalytically active cations of the type of Mg^{2+} present in the double layer at the membrane–solution interface, while the presence of the solid phase of the insoluble compound is not obligatory.

It has been shown[25,35,36] that the dissociation of water can be accelerated by certain organic bases B and acids AH, in particular compounds with tertiary amino-groups:

$$B + H_2O \rightleftarrows BH^+ + OH^-\,, \qquad (4)$$

$$BH^+ + H_2O \rightleftarrows B + H_3O^+\,, \qquad (5)$$

$$A^- + H_2O \rightleftarrows AH + OH^-\,, \qquad (6)$$

$$AH + H_2O \rightleftarrows A^- + H_3O^+\,, \qquad (7)$$

and that the dissociation can be accelerated both by the groups contained in the membrane[25] and introduced into the solution.[36] Having compared, in terms of the reaction layer approximation, the rates of decomposition of water in the catalytic reaction [Eqns.(4) to (7)] and the usual reaction

$$H_2O \rightleftarrows H^+ + OH^- \qquad (8)$$

Simons[36] showed that the acceleration of the reaction as a result of catalysis by organic substances can be very great.

In a number of studies, the description of the voltage–current plots for membrane systems by the authors assumes a local equilibrium in the water dissociation reaction at all points within the system,[61,62] which is equivalent to considering the reaction as "rapid". Despite the controversial nature of this assumption, Zholkovskii and co-workers[61,62] were able to describe qualitatively the shape of the voltage–current plots.

III. DISSOCIATION OF WATER MOLECULES IN DIPOLAR MEMBRANES

The term dipolar ion-exchange membranes is applied to layered membranes consisting of at least one cation-exchange and one anion-exchange layer which are in contact. In an electric field, dipolar membranes are arranged in such a way that the layers represent series-connected resistances in relation to the electric current passing through the system. If the cation-exchange layer is directed towards the cathode and the anion-exchange layer towards the anode, then, on passing of the electric current, the electrolyte concentration in the region of contact between the layers diminishes and, from a certain instant, the H^+ and OH^- ions formed in this region on dissociation of water are included in the transport process.

The dipolar membranes operating under conditions involving the generation of H^+ and OH^- ions have undoubted advantages over the membrane–solution system from the standpoint of the possibility of investigating the dissociation of water. Instead of the diffusion layer, which arises, for example, near a cation-exchange membrane, in a dipolar membrane there exists an anion-exchange layer which suppresses the influence of convection in solution, is selective with respect to anions, and thereby diminishes the transport of cations. This results in a high current yield of the H^+ and OH^- ions, reaching 0.9–0.96.[63] Furthermore, more reproducible data have been obtained at dipolar membranes than in a membrane–solution system.

The high current densities with respect to H^+ and OH^- ions, reaching 10^3 A m^{-2}, are a unique feature of dipolar membranes.[64] This exceeds by many orders of magnitude the limiting kinetic current for the water dissociation reaction [Eqn.(1)]. For a long time no attention was paid to this paradox and the water dissociation reaction was regarded as rapid[65] without any explanation.

Greben' et al.[66] were the first to point out the important role of the ionogenic groups in the dissociation of water, having assumed that the ionogenic group can participate directly in the reaction, accelerating it. They investigated by the voltammetric method dipolar membranes containing sulphonic, carboxylic, and phosphonic acid groups and concluded that the decrease in the potential differences in the membranes in the sequence

$$-SO_3H > -COOH > -PO(OH)_2$$

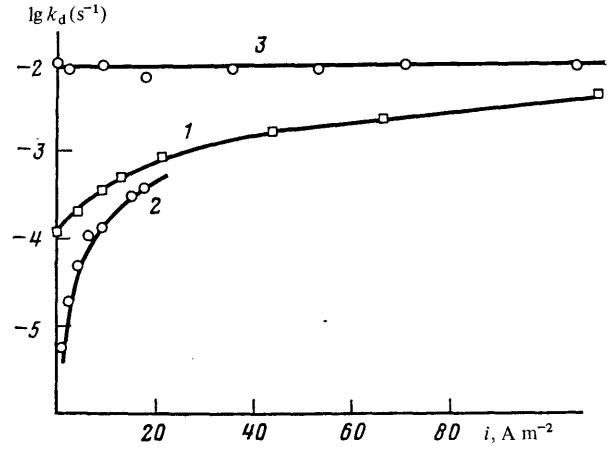
can be explained by the decrease of the energy barrier to the interaction of the ionogenic groups with water molecules as the pK of the cation-exchange groups increase in the same sequence.

The available quantitative information about the dissociation of water in dipolar membranes[67–74] includes voltage–current plots for the dipolar region, which are inaccessible to direct d.c. measurements, the effective dissociation and recombination rate constants, and equilibrium constants. The authors of the above studies used for the investigation of dipolar membranes the method of the frequency spectrum of the electrochemical impedance[67] with simultaneous polarisation of the membranes with a direct current. Analysis of the frequency spectrum made it possible to isolate from the overall impedance its component which refers to the dipolar region[69] and to calculate the effective reaction constants.[68] The mechanism of the dissociation, postulated in the calculations, does not take into account the role of the ionogenic groups in the reaction; as a result of this, the calculated constants are merely effective quantities. Nevertheless, this approach made it possible to compare the properties of dipolar membranes differing from one another by the nature of the ionogenic groups.[74]

The brands of the dipolar membranes and of the cation- and anion-exchange resins used for this preparation.[75]

No.	Brand			No.	Brand		
	of dipolar membrane	of cation-exchange resin	of anion-exchange resin		of dipolar membrane	of cation-exchange resin	of anion-exchange resin
1	MB-4	KF-1	AV-23M	6	MB-51	SG-1	AV-17
2	MB-31	KF-1	EDE-10P	7	MB-6	KU-2	AN-22
3	MB-3	KF-1	AV-17	8	MB-1	KU-2	EDE-10P
4	MB-42	SG-1	AV-23M	9	MB-2	KU-2	AV-17
5	MB-13	SG-1	EDE-10P				

Note. The brand names of the industrial MB-1, MB-2, MB-3, and MB-4 membranes are as given in a catalogue (Ref.75, p.15). The MB-2 membrane has been alkylated with methyl iodide.[70] The remaining membranes are experimental (conventional brand names) and have been prepared at the "Plastmassy" [Plastics] NPO.



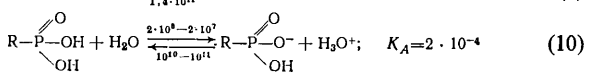


Figure 1. Dependence of the rate constants for the dissociation of water in the dipolar region of MB-1 (curve *1*) and MB-2 (curve *2*) membranes at 25 °C and the MB-3 membrane (curve *3*) at 4 °C on the current density. The logarithm of the rate constant for the dissociation of water is -4.6 at 25 °C and -5.5 at 4 °C.[72]

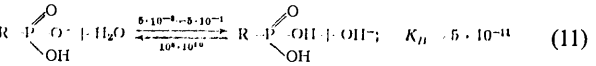
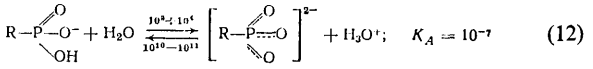
The rate constants for the dissociation of water in dipolar membranes (the bands of the membranes are indicated in the Table) differ sharply from the corresponding constants for the same reaction in pure water (Fig.1); they depend on the nature of the ionogenic group and the current density. Phosphonic acid groups have

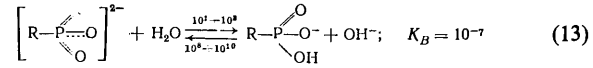


such a marked catalytic effect that the increase in the reaction rate constant due to the electric field applied to the membrane from outside cannot be seen against this background (Fig.1, curve *3*). At low current densities, sulphonic acid groups hardly accelerate the dissociation (Fig.1, curve *2*) and the rate constant is in this case almost the same as in pure water. At high current densities, the constant increases, the field effect predominating under these conditions. The involvement of the tertiary amino-groups in the dissociation of water in dipolar membranes has been confirmed:[70] the alkylation of tertiary amino-groups of the dipole membrane sharply increases the overpotential and decreases the rate constant for the dissociation of water. This effect also shows that sulphonic acid groups have a significantly weaker catalytic activity than the tertiary amino-groups.

The extremely low overpotential in the dipolar region of the membranes containing phosphonic acid groups can be explained from the standpoint of the catalytic mechanism.[71] Calculation showed[72] that, among all the possible water dissociation reactions in these membranes



$$H_2O + H_2O \underset{1,4\cdot10^{11}}{\overset{2,5\cdot10^{-5}}{\rightleftharpoons}} H_3O^+ + OH^-; \quad K = 1,8\cdot10^{-16} \qquad (9)$$



(10)

(11)

(12)

(13)

(the rate constants, in s^{-1} expressed for the forward reaction and in litre $mole^{-1}$ s^{-1} for the reverse reaction, are indicated above and below the arrows; the equilibrium constants, in mole $litre^{-1}$, are indicated after the reactions), the last two make the main contribution. In order to ensure the dissociation of water, reactions (10) and (11) or (12) and (13) (or both pairs simultaneously) must take place consecutively in the forward direction. In each pair of reactions, the rate of dissociation is limited by the stage with the lowest rate constant [stages (11) and (13)]. Since both pairs of reactions can take place simultaneously, and the rate constant for stage (13) in the forward direction is greater by a factor of 2×10^3 than the rate constant for stage (11), reactions (12) and (13) make the greatest contribution to the dissociation.

The catalytic mechanism of the dissociation of water in dipolar membranes is confirmed by the dependence of the rate constant for the rate-limiting stage of the dissociation of water, found for reactions (9)–(13), on the effective equilibrium constant for the dissociation calculated from the impedance frequency spectra (Fig.2). In terms of the catalytic effectiveness, the ionogenic groups of dipolar membranes can be arranged in a sequence in order of increasing rate constants for the dissociation of water involving their participation:[74]

	$-N(CH_3)_3$	$<$	$-SO_3H$	$<$	$-PO_3H^-$	$<$	$=NH$,	$-NH_2$	$<$	$\equiv N$	$<$	$-COO^-$	$<$	$-PO_3^{2-}$
k (s^{-1})	0		$3\cdot10^{-3}$		$3\cdot10^{-2}$		10^{-1}			1		10		10^3

The dependence of the activation energy for the dissociation of water on the nature of the ionogenic groups (Fig.3) is important evidence in support of the catalytic mechanism for the dissociation of water in dipolar membranes. The activation energy for membranes with a weak catalytic effect (MB-1 membrane, 45 kJ mol^{-1}) is close to the activation energy in pure water (56 kJ mol^{-1}), while phosphonic acid groups reduce sharply this quantity (MB-3 membrane, 26 kJ mol^{-1}). The low activation energies for the MB-2 membrane (32.5 kJ mol^{-1}) are associated with the pronounced heating of its dipolar region.[77]

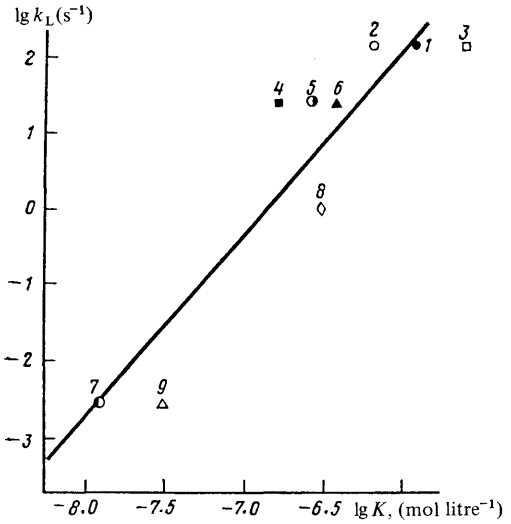


Figure 2. Dependence of the rate constant for the rate-limiting stage (k_L) of the dissociation of water on the effective equilibrium constant of the water dissociation reaction calculated from the impedance frequence spectra.[74] The numerals opposite the symbols correspond to the numbers of the membranes in the Table.

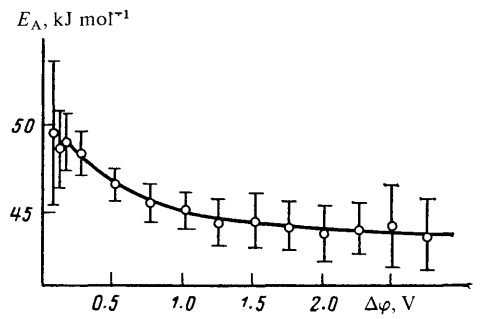

Figure 3. Dependence of the activation energy for the dissociation of water in the MB-1 membrane[69] on the overpotential of the dipolar region. The activation energy for the dissociation reaction is 56 kJ mol^{-1} in pure water,[76] 32.5 kJ mol^{-1} in the MB-2 dipolar membrane,[66] and 26 kJ mol^{-1} in the MB-3 membrane.[66]

The dissociation of water in the dipolar region takes place under conditions different from those in pure water or in aqueous solutions. This is associated not only with the presence of the polymer

matrix, the fixed ionogenic groups, and counterions but also with the presence of electrical double layer at the site of contact between the cation exchanger and the anion exchanger.[78] Within the limits of this layer, the concentration of both the counterions and co-ions is low compared with the concentration of the fixed ions and this region has come to be called the "exhausted" layer.

There are at least three causes of the increase in the rate of dissociation of water in the exhausted layer. Firstly, the decrease in the concentration of the H^+ and OH^- ions in the exhausted layer increases the degree of dissociation of the ionogenic groups, and hence also the concentrations of the charged forms, and increases the rates of the proton transport reactions in which they participate.[79] The second cause is associated with the polarisation of the H—OH bond by the electric field of the ionogenic group and also by the external electric field applied to the exhausted layer:[80–84]

$$k_d = k_d(0)\exp\left(\beta E + \frac{\alpha FE}{RT}\right) ,$$

where k_d is the rate constant for the heterolytic dissociation of water molecules in an electric field with a strength E, $k_d(0)$ is the corresponding constant in the absence of the field, and α and β are parameters taking into account respectively the decrease in the activation energy for the dissociation of water in the electric field and the entropy effect accompanying the orientation of water molecules in the vicinity of the ionogenic group and its dissociation. Thirdly, the dependence of the rate of dissociation of water molecules on the potential applied to the membrane is due to the expansion of the region of the space charge where dissociation actually occurs.

The dependence of the rate constant for the dissociation of water on the electric field strength, predicted by the Onsager theory for the second Wien effect, has been used in a number of studies for the description of processes in dipolar membranes.[85–87] Despite the qualitative agreement with experiment, from the standpoint of these ideas, it is difficult to explain the marked dependence of the properties of the membranes on the nature of the ionogenic groups. The same difficulty arises when one uses the model of the "neutral" layer, which is assumed to exist btween the cation exchanger and the anion exchanger in the dipolar region.[56] For certain membranes with an increased electrical resistance, it is essential to take into account the increase in the rate constants for the dissociation of water owing to the heating of those membranes at high current densities.[77]

It is noteworthy that all the approaches used to describe the dissociation of water in dipolar membranes and the models of such membranes[56,81,85] are mutually exclusive, although each investigator has found good agreement when comparing his model with experiment.

Comparison of the known models for the dissociation of water in dipolar membranes with experiment has demonstrated that the model of Timashev and Kirganova[81] agrees with the experimental data in terms of the largest number of criteria. Unfortunately, the accuracy of the experimental data (the voltage—current plots, the impedance frequency spectra) does not at present make it possible to determine all the constants for the space charge region and the water dissociation reaction.

Thus the best model of the dipolar membrane under the conditions corresponding to the generation of H^+ and OH^- ions, which takes into account the non-equilibrium nature of the processes occurring in the space charge region, is that proposed by Timashev and co-workers.[81–83] The ideas developed in these studies agree fully with the catalytic mechanism of the water dissociation reaction at the ionic groups of the membranes.

---o0o---

One can now regard it as a reliably established fact that the dissociation of water molecules in membrane systems takes place preferentially in the regions of the localisation of the space charge in the membrane phase with active participation of the ionogenic groups. In membrane systems lacking catalytically active groups, the dissociation of water takes place via the usual mechanism as a non-catalytic homogeneous reaction. In order to intensify the dissociation of water in membrane systems, catalytically active groups can be introduced both into the polymer matrix of the membrane and into the solution around the membrane.

Further progress in the study of the water dissociation reaction in membrane systems is related to the need to examine the elementary processes occurring with participation of catalytic centres in the space charge regions and the interfaces. The knowledge of the characteristic features of the water dissociation reaction in such systems will make it possible to alter specifically the surface properties of the membranes in order to facilitate or suppress this reaction. The dissociation of water must be taken into account in a theoretical description of membrane systems and in the planning and operation of electromembrane apparatus.

Interaction of Refractory Metal Oxides with Carbon

A.G.Vodop'yanov, G.N.Kozhevnikov, and S.V.Baranov

Certain characteristics of carbothermal processes involving the reduction of refractory oxides to the metal are surveyed with allowance for the structure of the outer and penultimate electron shells. The similarity and difference between the kinetics and mechanisms of reactions on the surfaces of the metal oxides and the carbon reductant are analysed.
The bibliography includes 147 references.

I. INTRODUCTION

The interaction of refractory metal oxides with carbon constitutes the basis of many metallurgical processes and of the technology for the preparation of materials for high-temperature engineering. The complexity of the mechanisms of these processes is due to the wide variety of the physicochemical properties of the elements formed in the reduction process and of their compounds. For this reason, carbothermal processes involving reduction to the metals have been the subject of continuous investigations and attempts to create a unique theory[1-10] from the standpoint of which it will be possible to predict and explain the role of the individual components of the reduction reactions.

The various views which have arisen hitherto concerning the mechanism of carbothermal reduction to the metals are related to the appearance of new promising trends in chemistry and to the employment of the advances achieved in them. Thus the application of the thermodynamic analysis to the study of metallurgical process has served as a basis for the development of ideas concerning the leading role of oxide dissociation reactions,[11] the development of catalysis led to the adsorption-autocatalytic theory,[1] studies on the evaporation and dissociation of substances led to the discovery of the oxide-sublimation mechanism of the reduction process,[4] mass-spectrometric detection of short-lived oxygen–carbon compounds demonstrated the active role of C_2O_5 as a reductant,[9,12] and the use of atomic-absorption analysis led to the discovery of the gas-carbide reduction mechanism.[13,14]

All these ideas reflect to different extents the phenomena observed in the study of reduction processes. As a result, many investigators have now adopted the view[4,5,9,12,15] that the mechanism of carbothermal reduction to the metals cannot be described from the standpoint of any single universal theory. This view is correct. However, it does not rule out the possibility of establishing general characteristics of the reduction of different groups of oxides having similar physicochemical properties (Ref.4, p.269).

The present review surveys data which have accumulated during the last decade on the high-temperature chemisorption of gases and the thermodynamics, kinetics, and mechanisms of the interactions of solid oxides of refractory metals with carbon. These processes take place simultaneously on the surfaces of both reactants and for this reason in the systematic treatment of the results the reduction process has been divided into two classes of reactions occurring on the surfaces of metal oxides and carbon reductants.

The characteristics of the variation of the properties of chemical compounds (including metal oxides) on passing from one compound to another are associated with the properties of the individual atoms. In order to elucidate the features of the kinetics and mechanisms of carbothermal reduction processes, it is therefore useful to examine the accumulated data with allowance for studies in the field of the systematic treatment of the elements.[16-19] The new version of the Periodic System of the elements[19] takes into account not only the limiting number of valence electrons but also the force characteristics of the latter, which are determined by the structure of the outer and penultimate electron shells. Together with group and type analogues of the elements, two new types of analogues have been differentiated in addition:[19] the shell analogues, i.e. those which not only refer to one subgroup but also have isotypical non-kinosymmetrical electron shells (for example, Ca–Sr–Ba, Zr–Hf, Y–Lu, etc.) and the shrink analogues—pairs of elements one of which (with the larger atomic number) has an orbital radius similar to or smaller than that of the preceding type analogue in the given group as a consequence of the *p*, *d*, or *f* contraction (for example, Ba–Ra, Si–Ge, etc.). The maximum similarity between the properties of certain elements has in fact been explained by their belonging to shell and shrink analogues.[19]

II. THERMODYNAMICS OF CARBOTHERMAL REDUCTION PROCESSES

Until recently, the method for the estimation of the probabilities of particular isolated reactions based on a comparison of their Gibbs free energies at the corresponding temperatures was widely used in the theoretical study of reduction processes. However, real reduction processes represent a set of interlinked reactions, which must be taken into account as an assembly of reactions.

Methods for the construction of phase and chemical equilibrium diagrams[20,21] and thermodynamic balances,[22] involving the solution of a system of equations for the equilibrium constants of the corresponding reactions under the conditions of a congruent transition

of the chemical compound from the condensed to the gaseous state, are used for this purpose.[8,23-25] On the basis of this approach, the carbothermal reduction process is represented by a set of reactions involving the dissociation of metal oxides and molecular oxygen to the constituent gaseous elements, the oxidation of CO to CO_2 by oxygen, and the regeneration of CO by solid by solid carbon.[26] The solution of the system of equations for the equilibrium constants of these reactions at a fixed CO pressure makes it possible to estimate the composition of the gas phase under conditions where the metal oxide is in equilibrium with the $O-O_2-CO-CO_2$ gas phase, which is in its turn in equilibrium with solid carbon. The equilibrium compositions of the gas phase in the interaction of SiO_2,[27] Al_2O_3,[28] Group IIA metal oxides,[29,30] and MnO [31] with carbon have been calculated by a similar method.

In the study of reduction processes in multicomponent systems, computer programs for thermodynamic calculations have been used in recent years.[32-36] Theoretical studies of the equilibrium compositions of condensed and gaseous phases in the interaction in the Si–O–C,[37,40] Al–Si–O–C,[41] Al–O–C,[10,42] Ti–O–C,[43,44] Nb–O–C,[45-48] Zr–O–C,[43] Ce–O–C,[49] and Nd–O–C [10] systems have been carried out by these methods.

A decrease in pressure in these systems promotes the development of reduction processes with lower temperatures and intensifies the tendency towards decomposition of the condensed reduction products—towards the transfer of the substance to the gas phase.

The accumulated results of thermodynamic studies have shown that, under equilibrium conditions, the main gaseous reduction product is CO. The pressure of the remaining carbon oxides C_2O, CO_2, and C_3O_2 as well as the C, C_2, C_3, O, O_2, and O_3 components is more than 5 orders of magnitude smaller than the CO pressure. At pressures close to 0.1 MPa, the reduction of oxides to *s* and *sp* elements (BeO, MgO, CaO, SrO, BaO, SiO_2, and Al_2O_3) and MnO is accompanied by the formation in the gas phase of the vapours of the metals and their lower oxides as the reduction products. On the other hand, the reduction of oxides to the *d* and *f* elements (TiO_2, Nb_2O_5, ZrO_2, Ce_2O_3, and Nd_2O_3) is characterised by very low concentrations of the metal-containing reduction products in the gas phase. An increase in their concentration in these systems is observed only at high temperatures or as a consequence of the thermal decomposition of the intermediate compounds, in particular metal carbides.

The low equilibrium concentration of CO_2 in systems with metal oxides which are difficult to reduce does not provide grounds for the conclusion that it plays an insignificant role in reduction processes. However small the equilibrium CO_2 pressure, the probability of the interaction of metal oxides with CO in the presence of solid carbon increases at the temperatures where the carbon gasification reaction ensures an equilibrium CO_2 pressure lower than in an isolated reaction involving reduction with carbon monoxide.

Thus, in terms of the composition of the components of the equilibrium gas phase, the interactions of refractory metal oxides with carbon at pressures close to 0.1 MPa can be divided into two groups differing in the content of the vapours of metals and their lower oxides. The difference between them is correlated with the structure of the outer and pre-outer electron shells of the elements produced by the reduction process. The first group includes processes involving reduction to the *d* and *f* elements with the preferential formation of CO and the second involves the reduction of oxides to *s* and *sp* elements and manganese (from MnO) with the additional formation of the vapours of metals and their lower oxides.

III. CHEMICAL ADSORPTION OF CARBON MONOXIDE ON METAL OXIDES

The chemical adsorption of CO on the surfaces of metal oxides is not only one of the intermediate stages in the carbothermal reduction process but it also has independent importance in processes involving the catalytic oxidation of CO and the purification of exhaust gases. The results[50-53] which have accumulated in the field of heterogeneous catalysis and oxygen exchange involving metal oxides therefore make it possible to elucidate the mechanism of the chemical adsorption of CO and its role in high-temperature reduction processes.

The adsorption properties of metals and their oxides are determined to a large extent by their electrical properties and the participation of conduction electrons in the formation of complexes between the adsorbent and adsorbate. The higher their electrical conductivity, the greater their adsorption-catalytic capacity. In non-transition metal oxides, cations with outer s^2 and s^2p^6 electron shells are stable, because their electronic levels are not split by the atoms or molecules in the first coordination sphere. For this reason, the conductivity of the oxides of *s* and *sp* elements is very low. A similar stability of the electron shells of the cations has been observed also for transition metal oxides with ions having the configurations $d^0(Sc^{3+}, Ti^{4+}, V^{5+})$, $d^5(Mn^{2+}, Fe^{3+})$, and $d^{10}(Cu^+, Zn^{2+})$, which makes their catalytic properties similar to those of non-transition metal oxides.[54] The oxides of *d* transition metals, on the surfaces of which coordination-unsaturated cations with incomplete *d* orbitals (in which the number of electrons is not 5 or 10) are present, have the maximum catalytic activity. Such oxides are characterised by a higher crystal lattice energy than oxides with analogus ions having the s^2, s^2p^6, d^5, and d^{10} outer electrons. Lanthanide oxides with incomplete *f* orbitals (in which the number of electrons is not 7 or 14) also possess a considerable catalytic activity, for example, Nd_2O_3 [55] and ThO_2.[56] CO is adsorbed reversibly on zinc oxide at temperatures below 373 K.[53] At higher temperatures the adsorption is irreversible with formation of CO_2 molecules. Irreversible adsorption of CO has been recorded on the surfaces of Cr_2O_3, ZnO, CoO, and Mn_2O_3.[53] Under these conditions, the irreversibly adsorbed CO is bound to the surface of the metal oxide in the form of the "carbonate ion" CO_3^{2-}, which arises when CO interacts with the oxygen ions of the oxide lattice. On copper, cobalt, and nickel oxides, the adsorbed CO is capable of reacting not only with the oxygen of the oxide lattice but also with oxygen adsorbed on the oxide surface.

Depending on the temperature, the catalytic oxidation of CO on the surfaces of transition metal oxides proceeds via two mechanisms. At low temperatures it proceeds via an associative mechanism with formation of intermediate carbonate CO_3^{2-} structures,[57-59] which are decomposed by gaseous oxygen with formation of CO_2 molecules. With increase in temperature, the associative mechanism of the oxidation of CO passes to a multistage mechanism,[57-61] which is induced by the sharp decrease in the coverage of the metal oxide by surface carbonate ions and their rapid thermal decomposition with formation of CO_2 by reaction with the oxygen in the oxide lattice. The subsequent adsorption of oxygen from the gas phase leads to the disappearance of metal ions as the reduction products and to the formation of the radical-ions O_2^- on the surface of the metal oxide. As a result, the multistage mechanism represents alternate oxidation-reduction of the surface of the oxide catalyst. The temperature range corresponding to the change in the mechanism of the catalytic

oxidation of CO on oxides of metals in the Fourth Period (V_2O_5–ZnO) is 518–863 K,[60] while on TiO_2 this happens at 1173 K,[57] which is close to the temperatures of the onset of the surface diffusion of the metal oxide cations and anions.[62] In essence, the change of the mechanism of the catalytic oxidation of CO at high temperatures is induced by the involvement of reactions leading to reduction to the metal by the gaseous reductant.

The oxides of *s* and *sp* elements, which are dielectrics under normal conditions, exhibit the properties of semiconductors at high temperatures and low pressures.[63] As a result, conduction electrons, capable of participating in gas–adsorbent reactions, appear on their surfaces. Thus Group IIA metal oxides (BeO–BaO) and aluminium oxide (Al_2O_3) exhibit electronic conductivity at temperatures[63] close to the temperatures of the onset of appreciable interaction with carbon. A similar relation between the semiconducting nature of metal oxides and the temperature of the onset of interaction with carbon has been established in relation to the oxides V_2O_5, WO_3, and TiO_2.[4]

The isotope exchange observed in the study of the self-diffusion of oxygen in metal oxides[53] also indicates the occurrence of the high-temperature chemical adsorption of gases on the surfaces of metal oxides. The character of the adsorption of oxygen depends on temperature. At room temperature, oxygen is adsorbed in the molecular form, while at elevated temperatures it is adsorbed in various dissociatively adsorbed forms.[53]

The high-temperature isotope exchange of oxygen has been studied in the oxides SiO_2 [64] and Y_2O_3 [65] at 1123–1523 K and 1273–1773 K respectively. According to Finikov,[66] it is observed from 673 K to the melting point and in melts of oxygen-containing compounds. The mechanism of such reactions is based on the isotope exchange within a chemisorption complex of the type $M_x[O_nA-O_2]_y$, where M is the metal and A the element forming the anion in which O_2 combines with A via a chemisorption bond, and ^{18}O is redistributed in the exchange process between AO and O_2.

Thus, results accumulated in the field of the catalytic oxidation of CO indicate an important role for chemical adsorption of CO in processes involving the high-temperature reduction of refractory oxides. In contrast to the oxides of *d* and *f* transition metals, the CO chemisorption processes on non-transition metal oxides take place at very high temperatures, corresponding to the appearance of semiconducting properties in the oxides. It has been established[10] for the non-contact reaction of ZrO_2 with graphite at 2223–2323 K that, with increase in temperature, the intensity of the processes associated with the chemisorption of CO increases as a consequence of the increase in the number of active chemisorption centres formed owing to the increase in the concentration and mobility of the defects in the crystal lattices of the oxides.

IV. REACTIONS INVOLVING THE REDUCTION OF REFRACTORY OXIDES TO THE METALS

The interactions of metal oxides with carbon represent a definite class of chemical reactions whose common character and the differences between their properties are determined by the similarities and differences between the properties of the elements produced by the reduction process—the characteristic features of their variation as a function of the fundamental properties of atoms. Therefore the most common features of the kinetics and mechanisms of the high-temperature reduction processes in general and for individual groups of refractory metal oxides can be manifested in the analysis of the experimental data taking into account the distribution of the elements generated by reduction within the framework of the Periodic System.[18,19]

1. Reactions Involving Reduction to Group IIA Elements

The oxides of Group IIA metals interact with carbon to form a gas phase containing the vapours of the oxides and of the metals produced by reduction.[29,30,67–72] At p_{CO} = 0.1 MPa, the principal metal-containing component of the gas phase is the metal as the reduction product, whose partial pressure is higher by several orders of magnitude than that of the vapour of the corresponding metal oxide.[30] In the gaseous products of the reduction of barium oxide, the relative concentration of the oxide is somewhat higher than for the remaining group IIA metal oxides. With increase in temperature from 1773 to 2073 K, the fraction of BaO in the mixture of the metal-containing components of the gas phase diminishes from 26.09 to 5.73 vol.%.

The reduction on the surfaces of metal oxides without contact with the carbon reductant is accompanied by the formation of only gaseous products.[29,30] The highest average rate of reduction, referred to unit geometrical surface of the metal oxide, is observed at p_{CO} = 0.1 MPa. The decrease in the rate of reduction when CO is replaced by an inert gas indicates the leading role of CO as the reductant. The interaction of MgO, CaO, SrO, and BaO with carbon at p_{CO} = 0.1 MPa begins at an appreciable rate at ~1773 K and that of BeO begins at 2173 K. However, the carbides CaC_2, SrC_2, and BaC_2 are formed on carbon only at temperatures close to 2073, 1973, and 1923 K respectively when the partial pressure of the reduction-product metals, transferred from the surfaces of the oxides to solid carbon, exceeds the dissociation pressure of the corresponding carbide. The appearance of BeC_2 on solid carbon is possible only above 2560 K.[29,30]

Thus the metal formed on reduction in the presence of solid carbon can be either removed with the effluent gases or can react with the carbon to form the carbide depending on the conditions.

When the CO pressure is reduced from 0.1 to 3.4×10^{-6} MPa, the degree of conversion of the oxides BeO, MgO, and CaO increases (Fig.1), passing through a maximum close to $p_{CO} \simeq 4 \times 10^{-3}$ MPa.[10,29] The decrease in the CO pressure in the system favours an increase in the rate of diffusion and mass transfer between the reactants, which compensates for the decrease in the CO concentration in the range $p_{CO} = 4 \times 10^{-3}$–0.1 MPa. At p_{CO} less than 4×10^{-3} MPa, the contribution of the reactions involving reduction by carbon monoxide diminishes and the role of the oxide dissociation reactions, forming a vapour–gas phase consisting of the atomic metal, its monoxide, and molecular and atomic oxygen, is enhanced.[73] The rate of reduction on the surfaces of metal oxides *v* is correlated with the partial pressure of the metal produced by reduction[30,74] and with the Gibbs free energy ΔG_T^0 of the overall reduction reaction:[72]

$$MO(solid) + C(solid) = M(gas) + CO(gas),$$

which is expressed by the equation

$$\lg v = a - b\Delta G_T^0 \qquad (1)$$

where *a* and *b* are coefficients.

In contrast to BeO and MgO, whose rates of reaction with carbon obey individual relations, the rate of reduction of CaO, SrO, and BaO obeys a common numerical relation of type (1) determined by

the great similarity of the physicochemical properties of the corresponding metals as shell analogue Group IIA elements.[19]

Under conditions where CaO is in contact with CaC_2, a eutectic is formed, its fusion at a temperature above 2100 K leading to intense dissolution of CaO in the $CaO-CaC_2$ melt, a diminution of the role of the reduction reactions via the gas phase, and the preferential development of reduction reactions between the $CaO-CaC_2$ melt and solid carbon.[68] A similar change of mechanism is observed when barium is obtained by reduction at temperatures above 1923 K,[30] ensuring the formation of BaC_2 on carbon in the initial stage.

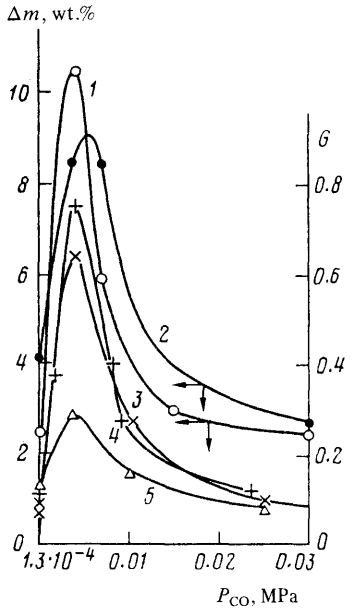

Figure 1. Decrease in the mass of metal oxides (Δm, wt.%) at a distance of 0.5 mm from graphite and in the degree of conversion of the oxides (G) in particulate mixtures with graphite as a function of the CO pressure: 1) Cr_2O_3 (1673 K); 2) CaO (2073 K); 3) SiO_2 (1773 K); 4) BeO (2223 K); 5) MgO (1873 K).[10]

2. Reduction to Aluminium

Among the oxides of Group IIIA elements, the most stable and refractory oxide is Al_2O_3. Its interaction with carbon takes place with formation of condensed (Al_3O_4, Al_4O_4C, Al_2OC, and Al_4C_3) and gaseous (Al, AlO, and Al_2O) products.[4,26,75] When Al_2O_3 was atomised in a graphite furnace, the presence of the carbide Al_2C_3 was detected together with aluminium in the gas phase by atomic-absorption analysis.[76-80] The ratios of the components of the gas phase ($c_{Al_2C_2}:c_{Al} = 10^2-10^3$) [77] calculated from the absorption spectrum of Al_2C_2 [13] conflict with the equilibrium concentrations of the components ($Al_2O_3:C:CO = 1:3:1$) [10] in the initial Al_2O_3-C systems[81] and with the results of the mass-spectrometric analysis of the evaporation products in the Al–C system.[82] According to the latter, $c_{Al}:c_{Al_2C_2} = 1050:1$. An analogous composition of the gas phase, mainly containing the metal vapour, has been observed in the mass-spectrometric analysis of the evaporation products of the carbides of *f* elements.[83] The results of the above studies[13,76-80] have been criticised[84] in a study where it was noted that the molecular spectrum obtained by L'vov and Ryabchuk[76] was arbitrarily attributed to the Al_2C_2 molecule (and not the AlC_2 molecule), while the estimate of the relative Al and Al_2C_2 concentrations, made on the assumption that the integral absorption coefficients of the corresponding atomic and molecular lines are similar,[13,79] is extremely inaccurate because the difference between the oscillator strengths even for atomic absorption lines can exceed 2–3 orders of magnitude. Therefore the concept of the gas-carbide reduction mechanism, which presupposes the transfer of carbon from the oxide surface by gaseous carbides of the type of MC_2 and its universal character regardless of the individual features of the oxide, experimental conditions, and the form of the products formed ultimately,[14] cannot be regarded as sufficiently well founded. Without contact between aluminium oxide and solid carbon at $p_{Ar} = 0.1$ MPa [85] and $p_{CO} = 0.1$ MPa,[28] condensed products (Al_4C_3) are formed on the surface of the reductant as a result of its interaction with the vapours of aluminium and its lower oxides.[86] The temperature of the onset of interaction at an appreciable rate is close to 2030 K at $p_{CO} = 0.1$ MPa,[28] at 1873 K at $p_{Ar} = 0.1$ MPa,[85] and at 1623 K in a high vacuum.[87] A decrease in the CO pressure from 0.1 to 3×10^{-6} MPa [10] promotes the acceleration of the reaction, which is particularly sharp at $p_{CO} < 4 \times 10^{-3}$ MPa (Fig.2).

When Al_2O_3 and the carbon reductant are in contact under conditions where $p_{Ar} = 0.1$ MPa,[85] reduction reactions through the gas phase proceed on the sections of the oxide surface free from contact with graphite, while at the sites of contact diffusional interaction occurs with formation of a $Al_2O_3-Al_4C_3$ solution. Ultimately the reaction of Al_2O_3 at the sites of contact with the reductant terminates with formation of aluminium oxide carbides and carbide.[20,75] In mixtures with graphite at $p_{CO} = 0.1$ MPa in the temperature range 2073–2173 K, condensed products are not formed. Aluminium carbide is formed above 2173 K when the partial pressure of the reduction-product aluminium in the briquet exceeds the dissociation pressure of Al_4C_3. The formation of the $Al_2O_3-Al_4C_3$ melt on metallic aluminium intensifies sharply the reduction process as a result of the appearance of liquid "bridges" between aluminium oxide and graphite, which, by dissolving carbon, promotes the preferential development of reduction reactions with participation of the liquid $Al_2O_3-Al_4C_3-Al$ melt.[28]

The absence of carbon-containing phases on the surface of the specimen[28,85] precludes an unambiguous conclusion about the reduction mechanism. These ideas can be refined by employing experimental data for the reduction to the elements of the oxides of group analogues of aluminium.

3. Reduction to Group IIIB and IIIC Elements

The oxides of Group IIIB and IIIC elements possess high thermodynamic stability[83] and are very refractory.[88] At $p_{CO} = 0.1$ MPa, the temperature of the onset of their appreciable interaction with graphite lies above 2170 K. An increase in the content of carbon without an appreciable change of the parameters of the crystal lattices of the oxides has been observed in the products formed on the surfaces of the oxides during their interaction with

graphite through space in CO.[89,90] This justified the assumption[10] that reactions involving the chemisorption of CO and its disproportionation to CO_2 and C with subsequent substitution of part of the oxide oxygen by carbon and the formation of oxide carbide and carbide phases develop on the surfaces of metal oxides. The oxide carbide and carbide phases form a solution of the type of $M_2O_3-MC_2$, which has been observed on the surfaces of scandium,[89] yttrium, lanthanum, gadolinium, and lutetium[90] oxides at 2470, 2223, 2123, 2323, and 2373 K respectively, which are lower than the melting points of the metal oxides and carbides. As a result of this, the contribution of the reactions involving reduction through the gas phase diminishes and reduction reactions with participation of the $M_2O_3-MC_2$ melt, which take place under diffusion conditions without the formation of gaseous metal-containing products, become dominant. Such change of mechanism has been reflected, in our view, by the two maxima on the kinetic curves for the reduction of bricketted mixtures (Y_2O_3 + 7C).[91]

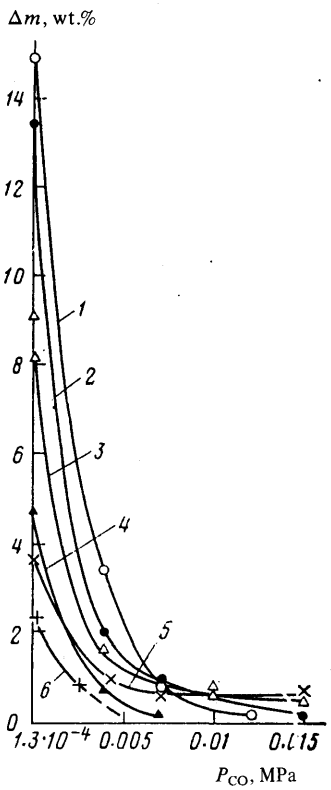

Figure 2. Decrease in the mass of metal oxides at a distance of 0.5 mm from graphite as a function of the CO pressure: 1) Al_2O_3 (2073 K); 2) La_2O_3 (1973 K); 3) Sc_2O_3 (2323 K); 4) Nd_2O_3 (1973 K); 5) Lu_2O_3 (2373 K); 6) Y_2O_3 (2223 K).[10]

At CO pressures in the space between the reactants less than 5×10^{-3} MPa, the rate of their interaction increases sharply (Fig.2). Under these conditions, the dissociation reactions of the oxides predominate with formation of the vapours of the atomic metals, their lower oxides, and atomic oxygen,[73] which react with solid carbon to give CO and the corresponding metal carbides. A similar character of the change in the degree of reduction of the oxide with decrease in pressure is observed in the reduction of aluminium,[10] which is a group analogue of the above metals.

When the reactants come into contact *in vacuo*, the interaction proceeds the gas phase up to a certain temperature with formation of the corresponding metal carbides on the carbon reductant and then, at temperatures significantly below the melting points of the metal oxides and carbides, reduction reactions with participation of the $M_2O_3-MC_2$ melt develop.

The rate of interaction of mixtures of lanthanum and gadolinium oxides with carbon *in vacuo* obeys a general correlation with the Gibbs free energy of the reduction reaction at the corresponding temperatures:[90]

$$M_2O_3+7C=2MC_2+3CO$$

This is associated with the similar chemical properties of the elements, determined by the identical numbers of valence electrons and the presence of the unfilled f^0 configuration and the stable f^7 configuration of the electrons. For the oxides of elements which are shell analogues of yttrium and lutetium, there is no similar relation in the temperature range 1900–2070 K owing to the difference between the mechanisms of the interactions with carbon which take place through the liquid and vapour–gas phases respectively. This is due to the difference between the appearance temperatures of the carbide oxide melts and the onset of the reduction through the liquid phase. Thus, when the reactants are in contact, the welding of Y_2O_3 to graphite, indicating the formation of the liquid phase, is appreciable already at 1923 K, while that of Lu_2O_3 is appreciable at 2373 K.[90]

4. Reduction to Group IVA Elements

Among the oxides of Group IVA elements, SiO_2 is the most stable and refractory. In the non-contact interaction with graphite in the presence of CO or argon or *in vacuo*, the maximum rate of reduction on the SiO_2 surface is observed at p_{CO} = 0.1 MPa.[27] A phase with a melting point close to 1823 K is then formed on the SiO_2 surface,[92] consisting of the $SiO-SiO_2$ solution.[93,94] As for the Group IIA oxides, a decrease in CO pressure[10,29] (Fig.1) promotes an increase in the rate of diffusion and mass transfer between the reactants, which compensates for the decrease in the CO concentration. At $p_{CO} < 4 \times 10^{-3}$ MPa, the contribution of reactions involving reduction by carbon monoxide diminishes and the role of SiO_2 dissociation reactions with formation of SiO and atomic oxygen,[73] which react with the carbon reductant affording CO and SiC, increases. The dominant role of the SiO_2 dissociation reactions persists in an inert gas in the presence of carbonaceous and non-carbonaceous reductants which are not in contact with the gas.[21,93]

The interaction of both liquid and solid SiO_2 with solid carbon at p_{CO} = 0.1 MPa takes place through the gas phase with participation of CO as the reductant without the formation of oxide carbide melts.[39]

The reduction of germanium, like that of its group analogue silicon, takes place through the gas phase with formation of the intermediate gaseous monoxide GeO. In the presence of solid carbon in the reducing medium, the reaction involving reduction by

carbon monoxide to gaseous GeO takes place on the GeO_2 surface, the monoxide being adsorbed on the surface of the carbon reductant and being converted into metallic germanium.[95-97]

5. Reduction to Group IVB Elements

Group IVB includes titanium and its shell analogues—zirconium and hafnium, which is the reason for the significant difference between the properties of titanium oxides and the oxides of the remaining elements in this group. In particular, it is manifested by the presence of a whole series of lower valence oxides[63] and a wider range of homogeneity of the oxide carbides than for zirconium and hafnium.[98]

The interaction of TiO_2 with CO is characterised by a very low equilibrium CO_2 pressure and has been achieved at 1373 K up to a degree of reduction of 0.08 in a circulation apparatus in which CO_2 is frozen out with liquid nitrogen.[99] On the other hand, in the presence of solid carbon,[100,101] the process proceeds vigorously. The adsorption of CO on TiO_2 surface results in the formation of Ti_3O_5 and CO_2, which react with carbon to form CO. The dissolution of CO in the defective anionic oxide sublattice and the disproportionation of CO to CO_2 and C with the subsequent substitution of part of the oxide oxygen by carbon begins after the attainment of compositions close to Ti_2O_3. The contribution of the last reaction in TiO specimens increases with increase in temperature.[100] The mass of the specimens increases and the molar ratio of the inserted elements C:O increases from 0.975 at 1773 K to 1.285 and 1.975 at 1873 and 1973 K respectively.

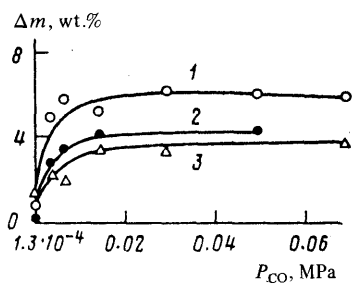

Figure 3. Decrease in the mass of metal oxides at a distance of 0.5 mm from graphite as a function of the CO pressure: 1) Nb_2O_5 (1623 K); 2) TiO_2 (1523 K); 3) Ta_2O_5 (1873 K).[10]

A decrease in the pressure of CO (Fig.3) and its replacement by an inert gas or a vacuum diminish the rate of reduction of TiO_2. In an inert gas, the dissociation of TiO_2 with formation of condensed products close in composition to $TiO_{1.9}$ predominates, whilst *in vacuo* the products have the composition $TiO_{1.87}$ [100]—the latter evaporate congruently, predominantly in the form of TiO and TiO_2,[73] and are converted into titanium carbide by reaction with solid carbon.

According to mass-spectrometric data,[12] the gas phase in the reduction of oxides of Group IVB and VB elements at $p_{Ar} = 1.33 \times 10^{-2} - 2.0 \times 10^{-3}$ MPa consists predominantly of CO and an insignificant amount of CO_2 in the range 573–1573 K. According to material balance, the overall composition of the gas phase formed is close to C_3O_2. A number of workers have therefore suggested[9,12,44,101,102] that the main reductant of titanium and other group IVB and VB elements is not CO but gaseous (or amorphous) carbon—one of the products of the decomposition of C_3O_2, whose condensate is observed on the cold parts of the furnaces. However, in the mass-spectrometric analysis of the gaseous products of the reduction to molybdenum C_3O_2 molecules have been detected experimentally at temperatures not exceeding 773 K.[103] The compound C_3O_2 is unstable and the possibility of its formation at the real reaction temperature is low.

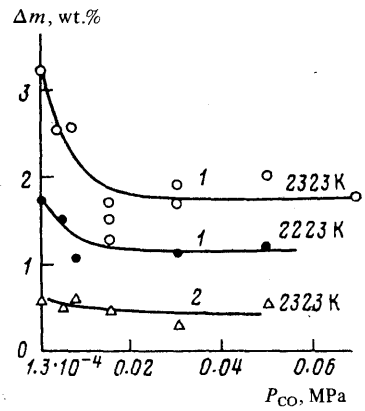

Figure 4. Decrease in the mass of metal oxides at a distance of 0.5 mm from graphite as a function of the CO pressure: 1) ZrO_2; 2) HfO_2.[10]

Zirconium and hafnium dioxides are the only thermodynamically stable solid oxides of these metals. At high temperatures (2223 to 2323 K) in the presence of carbon, they react with CO [10] to form carbides on the surfaces of the oxides. The decrease in the CO pressure to 0.01 MPa (Fig.4) influences only slightly the degree of reaction of the oxides as a consequence of diffusion-dependent obstacles arising as a result of the formation of the carbide phase. The acceleration of the interaction is observed at $p_{CO} < 0.01$ MPa in connection with the development of the dissociation reactions of the dioxides uncomplicated by the formation of any products on their surfaces and occurring via congruent evaporation from dioxides having a composition MO_{2-x} [100] predominantly in gaseous ZrO and HfO and oxygen.[73] The presence of the carbon reductant promotes a vigorous removal of the dissociation products from the surface of the oxide and the formation of ZrC, HfC, and CO on the carbon surface. At $p_{CO} = 0.1$ MPa, the amount of ZrC formed on the ZrO_2 surface increases with increase in temperature,[10] which is associated with the increase in the concentration of the active centres for

the chemisorption of CO as a result of the increase in the mobility of the crystal lattice defects in the oxides at temperatures above $0.5\,T_m$.† [62]

In vacuo, at relatively low temperatures (1523–1823 K) the reduction of particulate mixtures of the reactants also proceeds with participation of the CO adsorbed on the ZrO_2 and HfO_2 surfaces.[105-107] In the initial stage of the interaction, part of the oxygen in the anionic sublattice is removed and the oxides $ZrO_{1.98}$ and $HfO_{1.941}$ with a deficiency of oxygen are formed. In the last stage, the anionic vacancies in the lattices of the dioxides are filled with carbon, ensuring their conversion into the oxide carbide and carbide.[105,106] The formation of zirconium and hafnium oxide carbide melts is observed at 2373 and 2423 K respectively.[10]

6. Reduction to Group VB Elements

Group VB includes vanadium and its shell analogues – niobium and tantalum.[19] In contrast to the latter, vanadium forms a large number of oxides with a lower degree of oxidation and a β-phase with 15–25 at.% of oxygen.[63] In the reduction of the highest oxide to vanadium, oxides with lower degrees of oxidation are formed in succession as far as V_2O_3. In individual stages, the rate of reduction of V_2O_5 is limited by various elementary stages—in the reduction to V_2O_3 by the adsorption of CO with the subsequent diffusion of carbon and oxygen into the lattices of the oxides with formation of oxide carbide phases.[98,108]

The reduction to niobium is complicated by the formation in the condensed state of the intermediate lower oxide NbO_2 and variable-composition niobium oxide carbides.[98] For this reason, at a CO pressure above 2×10^{-3} MPa (Fig.3), the degree of conversion of Nb_2O_5 increases insignificantly owing to diffusion-dependent obstacles arising in the condensed phase.

As a result of the reduction by carbon monoxide, oxygen vacancies accumulate in the highest Group IVB and VB metal oxides and are partly filled with carbon atoms. Oxides with a lower degree of oxidation are then formed with a small amount of incorporated carbon. The CO adsorbed on the surfaces of vanadium and niobium monoxides can be absorbed, as in the case involving titanium monoxides,[100] by the defective lattices of the monoxides[102] and can also disproportionate to CO_2 and carbon atoms which fill the oxygen vacancies. This infringes the stoichiometry and causes a shift of the overall composition of the monoxide to the heterophase region of the M–O phase diagram and its decomposition with formation of an oxide with a higher degree of oxidation and the metallic phase. The metal reacts with CO and is converted into oxide carbides.[101,102,109] The absence of vanadium and niobium monoxides from the reduction products is associated with the fact, according to Shvikin,[5] that the rate of their conversion into oxide carbides having crystal lattices isostructural with those of the monoxides greatly exceeds the rates of the preceding reduction stages.

The reduction of Ta_2O_5 to tantalum is in many respects analogous to the reduction to hafnium,[10] which is due to the similarity of their properties since they are neighbours along the Period.[19] Like zirconium and hafnium dioxides, Ta_2O_5 reacts with carbon and is converted into oxide carbides with a cubic structure in accordance with the scheme described above for ZrO_2 and HfO_2, by-passing the monoxide formation stage.[98,107] The stability and composition of the oxide carbides depend on the temperature and the CO pressure in the system. An increase in the CO pressure at a specified temperature promotes not only their stability but also the expansion of the region of homogeneity, while a decrease in the CO pressure and an increase in temperature tend to increase the carbon content in the oxide carbides and bring the composition closer to that of the corresponding tantalum carbide. In the absence of contact with the solid carbon, the degree of conversion of Ta_2O_5 into the product increases with increasing CO pressure (Fig.3). However, at $p_{CO} = 2 \times 10^{-2}$ MPa, this process slows down as a consequence of the diffusion-dependent obstacles arising in the layer of products. Thus at 1873 K in the absence of contact with graphite in CO,[10] the carbide $TaC_{0.6}$ is formed on the Ta_2O_5 surface and then reacts further with the highest oxide, forming gaseous TaO and TaO_2. These oxides are adsorbed on the surface of solid carbon and are reduced to TaC. At temperatures close to 1973 K, under conditions where Ta_2O_5 is in contact with solid carbon, the interaction takes place with participation of the oxide carbide melt.[10]

7. Reduction to Group VIB Elements

Among the oxides of Group VIB elements, Cr_2O_3 is the most stable.[19,88] Its interaction with solid carbon proceeds in the initial stage with participation of CO as the reductant.[2,10,110,115] This is confirmed by the acceleration of the reduction when graphite is replaced by more active forms of carbon reductants, accelerating the gasification of carbon,[110,111] and also by the formation of reduction products on the surface of the oxide in the absence of contact with solid carbon at $p_{CO} = 0.1$ MPa.[110,112] A decrease in CO pressure in the space between the solid reactants which are not in contact with one another intensifies the reduction of Cr_2O_3 (Fig.1) [10] owing to the increase in the rate of diffusion and mass transfer which compensates for the decrease in the CO concentration. However, at $p_{CO} < 4 \times 10^{-3}$ MPa the degree of conversion of Cr_2O_3 diminishes sharply due to the decrease in the CO concentration and the oxide dissociation reactions develop preferentially, occurring at rates lower than in the reduction with carbon monoxide. The oxide Cr_2O_{3-x}, in which the concentration of oxygen corresponds to the lower limit of the region of homogeneity,[116] is formed under these conditions in the initial stage. This is followed by congruent evaporation with formation of atomic chromium and the vapours of the lower oxides CrO and CrO_2 and oxygen,[73] which react with solid carbon to give the carbide Cr_3C_2 and CO. At $p_{Ar} = 0.1$ MPa [116] and *in vacuo* ($\sim 4.6 \times 10^{-8}$ MPa), the interaction of the Cr_2O_3 specimens and solid carbon, which are not in contact, in the range 1373–2073 K [117] also includes the oxide dissociation stage.

When the solid reactants are involved in contact interaction *in vacuo* at 1773 K,[117,118] the carbide phase grows into the oxide specimen at the sites of contact between them. However, the role of this process is small owing to the extremely small area of contact in mixtures of reactants compared with their overall surface area.[2]

The interaction of Cr_2O_3 with carbon intensifies sharply at temperatures above 1773 K [116] where the reduction on the surface of chromium oxide results in the formation of the metallic Cr–C melt, which, creating a liquid contact between the reactants, ensures the preferential development of the reactions involving the reduction by the carbon dissolved in the metallic phase.

† T_m is the melting point (Ed.of Translation).

8. Reduction to Group VIIB Elements

Among the Group VIIB elements, manganese and its alloys have been obtained by the carbothermal reduction. The most stable manganese oxide is MnO, which has been detected as part of the composition of complex intermediate compounds in the reduction of concentrates and ores.[2,119,120] In a free state, without contact with solid carbon at p_{CO} = 0.1 MPa,[31] MnO reacts in the temperature range 1473–1623 K with the CO adsorbed on its surface, forming gaseous metallic manganese and CO_2. At temperatures in excess of 1623 K, the carbide Mn_7C_3 is formed on the surface of the carbon reductant. The replacement of CO by an inert gas greatly diminishes the rate of the reduction reactions on the MnO surface as a consequence of the sharp decrease in the contribution of reactions with participation of CO and the development of MnO dissociation reactions with the preferential formation of atomic manganese and molecular oxygen.[73] At temperatures close to the fusion of Mn_7C_3 (~1623 K), the contribution of the reactions of MnO with CO diminishes[31,121] owing to the formation of liquid Mn_7C_3 carbide bridges between the solid reactants and the development of reactions involving reduction by the carbon dissolved in the liquid metallic phase.

9. Reduction to Metals with Participation of Metals

Analysis of the accumulated experimental data shows that at certain temperatures reactions with participation of melts play a leading role in carbothermal reduction processes. The intensification of the reduction processes observed under these conditions is due to a number of factors; the closer contact between the fused metal oxide with the solid carbon (SiO_2 [39]); contact between the solid metal oxide and the carbon dissolved in a metallic melt (Cr_2O_3, MnO [2,31,116]); the dissolution of the initial reactants in the melt with subsequent interaction in the liquid phase (CaO,[68] Al_2O_3,[28] Group IIIB elements[89,90]), and also the stirring of the melt by the evolved gas. Under these conditions, when ionic activity is appreciable, the interaction becomes electrochemical in character. These processes have been studied in detail in the reduction of slag melts to iron, manganese, and chromium. The mechanism of the reduction of melts of this type is represented as the sum of the cathodic and anodic half-reactions, which takes place on different sections of the surface[122]

$$M^{n+1}+e=M^{(n-1)+}$$
$$M^{n+}+ne=M$$
$$C(Solid)+O^{2-}=CO+2e$$

The electron exchange necessary to maintain the electroneutrality of the phases takes place through solid carbon.

The Table presents the appearance temperatures of the melt menisci around the metal oxide specimens in their contact interaction with graphite at different CO pressures. Under these conditions and also at higher temperatures, the reduction reactions in the liquid phase assume the leading role.

10. Reduction of Complex Refractory Metal Oxides

The reduction of complex refractory oxides to the metal takes place consecutively in conformity with the thermodynamic stabilities of simple metal oxides forming part of the composition of the complex compound. Thus in the reduction of chromium ores containing chromium spinelides and chromites, the spinelides are initially reduced to iron and chromium, while at higher temperatures chromites are reduced to the metals with formation of MgO and $MgAl_2O_4$ spinel.[123] The reduction of $MgAl_2O_4$ spinel to magnesium at 2020 and 2170 K without contact with graphite at p_{CO} = 0.1 MPa takes place with participation of CO as the reductant.[124] A solid solution of Al_2O_3 in the spinel is formed as a result on the surface of the complex oxide. After the attainment of the limit of the region of its homogeneous composition, Al_2O_3 is segregated in an independent phase. The reduction reaction at the spinel–reducing gas (CO) interface take place under diffusion conditions and its rate depends on the ratio of the specific surfaces of the initial reactants.

Temperatures of the appearance of melt menisci in the contact interaction of metal oxides with graphite.[10]

Oxide	T, K	p_{CO}, MPa	Oxide	T, K	p_{CO}, MPa
Al_2O_3	2223	0.1	ZrO_2	2373	$3\cdot10^{-2}$
Sc_2O_3	2273	$1.3\cdot10^{-4}$	HfO_2	2423	0.1

*According to data in Ref.30.
**According to data in Ref.31.

The interaction of the aluminosilicates with carbon also takes place in stages. In the initial stage of the reduction, gaseous SiO is formed and reacts with the carbon reductant to give silicon carbide.[125] This process is controlled by diffusion through the layer of the microporous product—α-Al_2O_3.[126] The contribution of the mullite dissociation reactions to the reduction process increases with decrease in pressure in the system. Under these conditions, the dissociation of Al_2O_3 at a lower rate than that of the formation of gaseous SiO is observed together with the thermal decomposition to gaseous SiO and solid Al_2O_3. Thus CO retains the role of the reductant in the reduction of complex oxides to the metals. When CO is diluted with an inert gas and *in vacuo*, the contribution of the reduction by carbon monoxide diminishes and the role of the metal oxide dissociation reaction increases. The reduction processes on the surfaces of solid oxides are associated with diffusion-dependent obstacles as a consequence of the segregation in an independent phase of the oxides which are more difficult to reduce to the metals.

Analysis of the accumulated experimental data shows that, in the absence of liquid phases, the interaction of solid metal oxides with carbon proceeds through the gas phase via a mechanism including reactions involving reduction by carbon monoxide and the dissociation of metal oxides. The contributions of these reactions to the overall reduction process depend on the composition of the gas phase between the reactants. At p_{CO} in excess of 4×10^{-3} MPa, the

reactions involving the reduction by carbon monoxide play a leading role, while at p_{CO} less than 4×10^{-3} MPa, the dissociation of the metal oxide predominates in an inert gas and *in vacuo*.

The character of the variation of the mass of specimens of the oxides of Group IIA elements, SiO_2, and Cr_2O_3 out of contact with graphite as a function of the CO pressure (Fig.1) indicates the presence of common features in the change of the reduction mechanism. An analogous similarity (Fig.2) has been observed for the oxides of aluminium and its group analogues (in Groups IIIB and IIIC). The formation of carbon-containing phases in chromium oxides and the oxides of Group IIIB and IIIC elements justifies the assumption that carbon monoxide is also a reductant in relation to SiO_2 and Al_2O_3. The absence of carbon-containing phases on the surfaces of oxides of Group IIA elements, Al_2O_3, and SiO_2 at p_{CO} = 0.1 MPa, interpreted by some investigators as an argument in support of the oxide-sublimation mechanism of the reduction process, is associated with the fact that, in contrast to the refractory oxides of *d* and *f* elements, the oxides of *s* and *sp* elements under the conditions of real processes are incapable of substituting part of the oxygen in the anionic sublattice by carbon atoms and of creating conditions for the appearance of carbide and oxide carbide phases.

At temperatures in excess of $0.5\,T_m$ of the metal oxides, the contribution of the reactions involving reduction by carbon monoxide on the surfaces of the solid metal oxide increases as a consequence of the increase in the concentration and mobility of the crystal lattice defects responsible for the increase in the number of centres for the chemisorption of CO.[10] The dissociation reactions become the mains ones under the conditions of a low-temperature plasma.[127]

The composition of the products of the reduction by carbon monoxide depends on the nature of the elements produced by the reduction process. The reduction of the oxides of *s* and *sp* elements and manganese with a stable $3d^5$ electron shell of the metal atom takes place via the chemisorption of CO and its subsequent oxidation by the oxide oxygen to CO_2 with formation of the vapours of the metals and the lower oxides. On the oxides of *d* and *f* elements, the chemisorbed CO disproportionates predominantly to CO_2 and carbon, which is oxidised by the oxide oxygen and also partly fills the oxygen vacancies. The kinetics of the reduction reactions on the surfaces of solid oxides of the shell analogue elements under different initial conditions obey the general correlation with the Gibbs free energy of the reduction reaction. At the corresponding temperatures, the interaction through the gas phase is limited as a consequence of the appearance of carbide oxide or carbon-saturated metallic melts.

V. OXIDATION REACTIONS OF SOLID CARBON

Reactions of two types take place on the surfaces of carbon reductants: the gasification of carbon and the formation of metal carbides in the interaction with the vapours of metals and their lower oxides. The high-temperature carbon gasification processes have been described in detail by Golovina.[128] The gasification of carbon has a multistage mechanism, which includes the chemisorption of CO_2 and the formation of intermediate complexes on active sites of the surface:

$$C + CO_2 \rightleftharpoons C(O) + CO(gas), \quad (2)$$

$$C(O) \rightleftharpoons CO(gas). \quad (3)$$

where C(O) is an intermediate complex.

At p_{CO_2} close to 0.1 MPa, the gasification reaction in the temperature range 1300–1650 K takes place not only on the surface of the carbon material but also throughout its volume. In the range 1700–2400 K, the reaction shifts to a narrow zone at the reductant surface. In this temperature range, the specific rate of the reaction is seen to diminish, passing through a minimum at 2000–2300 K as a consequence of the diffusion-dependent inhibition in the gas phase, which arises with increase in the absolute rate of oxidation of carbon. The rate of reaction depends on the number of active centres adsorbing CO_2 molecules. The decrease in the rate of reaction at 2000–2300 K, when the desorption of CO is rapid and the role of the reverse reaction (2) is small, has been attributed to the thermal deactivation of the reductant surface. At temperatures in excess of 2400 K, the depth of the reaction zone and the specific rate of the reaction again increase as a consequence of the development of the self-diffusion of carbon from the bulk phase to the reaction centre and the increase in the concentration of defects, whose number reaches a maximum at temperatures close to those corresponding to a change in the state of aggregation of the substance. This stimulates an increase in the degree of chemisorption of CO_2 and in the rate of reaction as a whole. The sublimation of graphite begins to play an appreciable role under these conditions. The disordered "amorphous" part of the reductant is then sublimed in the first place.

Carbon reductants differ significantly in their crystal structure, the type and size of pores, and the character of their distribution. The rate constants obtained for the oxidation reactions of reductants[129,130] as well as the estimation of the reactivity with respect to CO_2 [131] are valid only for specific reduction conditions. A general treatment of the results accumulated in this field established[129] that one of the main parameters determining the rate of reaction with the gas is not only the activation energy *E* but also the pre-exponential factor *A* in the Arrhenius equation, which changes on passing from one kind of material to another and obeys the relation

$$\lg A = \lg A_0 + \alpha E$$

where A_0 and α are coefficients. The relation obtained for porous (cokes, semicokes, different types of coal, anthracites) and nonporous (carbon black, carbon fibres, pyrographite) materials is universal and applicable to different textures of the material. It can be used to estimate the reactivities of reductants in relation to CO_2 in the absence of data on the size of the reaction surface. It is sufficient to know what the gas medium is and to determine the apparent activation energy for the oxidation of the reductant.

In the reduction of *s* and *sp* elements on the reductant surface, reactions with participation of the vapours of metals and the lower oxides and leading to the formation of carbides take place in addition. Therefore, if the reductant surface is blocked by the reaction products, the oxidation of carbon passes from the kinetic to diffusion conditions[90,131] with a change in the size of the specific surface.[132] Under these conditions, the growth of the layer of products, especially SiC,[132] is caused by the counterdiffusion of the metal ions and carbon along the grain boundaries and microstructural defects. The rate of diffusion of the metal ions, for example of the silicon ions in SiC, is then higher by several orders of magnitude than that of carbon ions, which promotes the preferential growth of the reaction front into the bulk of the reductant and the formation of a pseudomorphic analogue of the carbide from the carbon.

Silicon[132] is formed on the surface of the particles of the carbon reductant only after the complete conversion into silicon carbide. The partial pressure of SiO in the system should then be significantly greater than in its formation from SiO_2 and carbon.

The chemical reactivity of the reductant in relation to the metal oxide is a complex function of factors acting simultaneously (the porous structure, the specific surface, and the degree of order in the crystal structure of carbon), whose influence cannot be taken into account separately.[131] Two principal forms are present in the macrostructure of cokes—finely dispersed crystalline regions with a well developed system of pores and non-porous amorphous regions. The greater the number of crystallite intermediate forms in the microstructure and the greater their defectiveness, the larger the surface area of the reductant and correspondingly the higher its chemical reactivity.[133,134] A clear dependence of the reactivity of the reductant in relation to SiO_2 on the specific surface is observed only for petroleum cokes.[135] In other types of reductants, it depends little on the specific surface. The reactivity of different types of carbon blacks in relation to SiO_2 [135,136] depends on the degree of order in the structure. Many carbon blacks having a high specific surface are extremely compact and there is a film of high-molecular-weight products preventing the diffusion of silicide forming agents into the bulk of the particles.

In practice, the reactivity of the reductant is estimated from the intensity of its interaction with CO_2.[131] However, this method does not take into account the specific features of certain metals, whose reduction is accompanied by the formation of carbides blocking the surface of the reductant. The methods proposed for the estimation of the reactivity of the reductant from the change in the mass reacting with gaseous SiO,[137–140] with SiO_2,[131] and with CaO [141] reflect the overall result of the interaction and do not allow the determination of the influence of the surface area on the intrinsic reactivity of the reductant, which is estimated quantitatively from the ratio of the rate constants for isotypical reactions (k/k_0) carried out under identical conditions, where k_0 is the rate constant for the reaction of one of the substances in the reaction series.[142] Overall, the influence of the surface of the reductant and of its reactivity on its chemical activity in relation to the metal oxide being reduced (for example, SiO_2) has been estimated[39] from the quantity

$$A = S k$$

where S is the initial surface of the reductant ($m^2\ kg^{-1}$) and k the rate constant for the reaction of carbon ($kg\ m^{-2}\ s^{-1}$).

Thus the chemical activity of the reductant depends on two factors acting simultaneously, its specific surface and its reactivity. The activity of the reductant can therefore be increased not only by selecting the necessary degree of dispersion and hence the specific surface of the reductant[139,143,144] but also by increasing its reactivity. The latter is achieved by introducing mineral admixtures,[131,133,135,145] by mechanochemical treatment together with the metal oxides to be reduced,[12,146] and by γ-irradiation,[147] which ensures the appearance of oxide–carbon–oxygen complexes at additional defects in the carbon structure.

- - - o 0 o - - -

It follows from the analysis of the data described that the observed difference in the interaction of refractory metal oxides with carbon are correlated with the differences in the fundamental properties of the metal atoms generated in the reduction process, which are reflected in the Periodic System of the elements. This made it possible to deduce a general basis for the description of the interactions of solid metal oxides with carbon, according to which they proceed via an adsorption-dissociative mechanism including reactions involving reduction by carbon monoxide in combination with reactions involving the gasification of solid carbon by its dioxide and the dissociation of the metal oxide. At CO pressures in the space between the reactants in excess of 4×10^{-3} MPa, the reactions involving reduction by carbon monoxide develop preferentially. The contribution of the metal oxide dissociation reactions to the overall reduction process is insignificant under these conditions. On decrease in the CO pressure to less than 4×10^{-3} MPa, *in vacuo*, and in an inert gas, the metal oxide dissociation reactions make the main contribution to the reduction process.

The differences in the interaction of certain metal oxides with carbon at p_{CO} close to 0.1 MPa depend on the properties of the oxides, which are determined by the electronic structure of the reduction product metal atoms. Thus the reduction of the oxides of *d* and *f* elements by carbon monoxide in the presence of solid carbon is accompanied by the liberation of CO_2 to the gas phase, while the reduction of the oxides of *s* and *sp* elements results in addition in the evolution of the vapours of the metals and their lower oxides, which block the surfaces of the carbon reductants by the corresponding carbides. The CO adsorbed on the surfaces of the oxides of *s* and *sp* elements is oxidised by the oxygen of the oxides to CO_2, while on the surfaces of the oxides of *d* and *f* elements it disproportionates to CO_2 and carbon, which is oxidised by the oxide oxygen and partly fills the oxygen vacancies, forming solutions of carbon in the oxides and carbon-containing phases. The existence of groups of oxides for which there are general correlations between the rate of reduction and the Gibbs free energy of the reduction reaction has been established in relation to the oxides of elements, which are shell analogues of calcium, strontium, and barium, and also lanthanum and gadolinium oxides.

The chemical activity of the reductant depends on the two factors acting simultaneously: its specific surface and its reactivity. The latter can be increased by introducing mineral admixtures, by mechanochemical treatment, and by γ-irradiation.

It is noteworthy that many ideas about the interaction of CO with the surfaces of solid metal oxides require confirmation by refined experimental methods. It is essential to accumulate qualitatively new information about the elementary steps in the reduction process by employing research methods from adjacent fields of science. Overall, the views formulated on the mechanism of the reduction process make it possible to estimate the interrelation between the individual stages of the processes, to select the optimum compositions of the gas phase, the carbon reductants, etc., and to influence the intensity of technological processes.

Photon Transfer Reactions in Free Radicals. Spin pH Probes

V.V.Khramtsov and L.M.Vainer

The kinetics and thermodynamics of proton transfer processes with participation of short-lived and stable radicals are surveyed. The extensive possibilities for the use of pH-sensitive nitroxy-radicals for the measurement of acidity in microheterogeneous chemical and biological systems, including cells, are demonstrated.
The bibliography includes 102 references.

I. INTRODUCTION

Proton transfer is one of the commonest reactions in organic chemistry.[1,2] The study of the proton transfer reaction is timely because of its important role in acid and alkaline catalysis[2,3] and in technological and biological processes.[4] The simplicity of these reactions, which proceed without the interaction of the electron shells of the reactants, making it possible to model the given reactions by methods of theoretical chemistry and promoting a deeper understanding of the nature and kinetics of the elementary step in condensed media, has also attracted physical chemists.[1,2,5] The large hydrogen isotope effect has stimulated numerous investigations of such effects in proton transfer reactions. They serve as an important test of the theory of isotope effects and yield significant information about the mechanisms of the processes considered.[5,6] As a consequence of the unique properties of the proton (the absence of an electron shell, anomalous mobility), proton transfer reactions are the fastest reactions occurring in solution; this gives rise to methodological complexities in the study of the kinetic parameters of such reactions. Relaxation methods (methods based on the abrupt change in temperature, pressure, the electric field pulse, etc.) as well as the NMR method (the study of the broadening of the ^{1}H and ^{17}O lines in the NMR spectra) are most often used to study the kinetics of proton transfer.[1] The relaxation methods are based on the observation of the kinetics of the return of the system to the equilibrium position (by optical or electrical procedures) after a rapid change in external parameters; their application is restricted to reversible proton transfer reactions. The NMR method is free from this limitation, since its application is based on the analysis of the form of the spectrum of the molecule participating in the reaction. However, when it is used, it is essential to have large concentrations of the reactants and, in the case of complex unresolved NMR spectra, the problem of the interpretation of the experimental data arises. Methods which make it possible to follow directly the state of the reacting species in the course of the proton exchange process (among the procedures indicated, the NMR method is of this kind) are of greatest interest. Evidently, the development of new methodological approaches which yield quantitative information about the kinetic and thermodynamic characteristics of proton exchange is a problem of extremely urgent current interest. The use of the EPR method, which is highly sensitive and makes it possible to observe directly the paramagnetic reactant and to obtain quantitative information about the kinetics of proton transfer, is promising. It may be expected that the application of the EPR method to proton transfer reactions in stable radicals will make it possible to employ such reactions as model processes for securing quantitative information about the influence of the steric factor, the solvent, and the electron-donating and electron-accepting substituents on the kinetics and equilibrium parameters of proton transfer. When a reversible proton transfer reaction takes place in radicals, the pH may influence the EPR spectra of the radicals. The possibility of measuring pH by the EPR method thus arises.

The measurement of pH is one of the most important problems in chemistry and biology, since the occurrence of an enormous number of chemical reactions and many processes involved in the vital activity of cells and cell organelles depends on this quantity. The electrometric method using glass electrodes is traditionally employed for this purpose.[7] Its main disadvantage is the large size of the glass electrodes and the impossibility of introducing them into closed structures (cell organelles, model membrane vesicles, etc.). Despite the recent development of microelectrode pH measurements,[8] this limitation in most cases precludes the use of glass electrodes for the measurement of local changes in pH (within the structures indicated, at interfaces, etc.). Fluorescent probes and the NMR method are therefore widely used nowadays in biological systems on the basis of the influence of the pH of the medium on specific characteristics of the spectra of these probles (fluorescence intensity, the chemical shift).[9-16] The application of fluorescent probes is restricted by the complexities in the interpretation of the fluoresecence intensity, which is sensitive to the interaction of the probe with the lipid membrane, to the type of buffer employed, to the ionic strength of the solution, etc. A significant limitation of the NMR method is its low sensitivity. The employment of stable nitroxy-radicals (NR) as pH probes is therefore promising, in view of the high sensitivity of the EPR method and the major advances in the organic chemistry of NR.[17,18] The considerable influence of pH on the EPR spectra of stable NR observed recently[19-21] makes it possible to take a fresh look at the prospects for their employment in the study of the mechanisms of proton transfer reactions and as pH probes.

The present review examines the results of studies of the influence of pH on the EPR spectra of short-lived and stable radicals of different types. The proton transfer in imidazoline and

imidazolidine radicals has been considered in especially great detail, because these radicals actually make it possible to obtain information about the mechanism of the proton transfer and are most promising for use as pH probes in various systems, including biological systems.[22]

II. THEORETICAL EXAMINATION OF PROTON TRANSFER REACTIONS IN RADICALS

The reversible proton transfer reaction (proton exchange) between the conjugate base (the $\dot{R}$ radical) and acid (BH^+) is described by the equation

$$\dot{R} + BH^+ \underset{k_r}{\overset{k_f}{\rightleftarrows}} \dot{R}H^+ + B \ . \qquad (1)$$

A necessary condition for the application of the EPR method in following the course of reaction (1) is a difference between the magnetic-resonance parameters of the radical in the $\dot{R}$ and $\dot{R}H^+$ forms. In this case, reaction (1) should lead to rapid exchange between the corresponding components of the EPR spectra of the radicals in the $\dot{R}$ and $\dot{R}H^+$ forms. The line shape of the EPR signal $G(X)$ in the case of rapid exchange involving two positions, corresponding to the $\dot{R}$ and $\dot{R}H^+$ forms of the radical, is described by the equation[23]

$$G(X) = I_m \left\{ iG_0 \frac{\tau_{RH^+} + \tau_R + \tau_{RH^+}\tau_R (p_{RH^+}\alpha_R + p_R\alpha_{RH^+})}{(1 + \alpha_R\tau_R)(1 + \alpha_{RH^+}\tau_{RH^+}) - 1} \right\} \ , \qquad (2)$$

where G_0 is a constant coefficient, τ_R and τ_{RH^+} are the lifetimes of the radical in the $\dot{R}$ and $\dot{R}H^+$ forms respectively, $p_R = \tau_R/(\tau_R + \tau_{RH^+})$, $p_{RH^+} = \tau_{RH^+}/(\tau_R + \tau_{RH^+})$, $\alpha_R = (1/T_2)_R - i\gamma X$, $\alpha_{RH^+} = (1/T_2)_{RH^+} - i\gamma(X + \Delta\omega/\gamma)$, $\Delta\omega$ is the difference between the frequencies of the corresponding lines in the EPR spectra of the radical in the $\dot{R}$ and $\dot{R}H^+$ forms, $(T_2)_R$ and $(T_2)_{RH^+}$ are the transverse relaxation times of the radicals $\dot{R}$ and $\dot{R}H^+$ respectively, and γ is the gyromagnetic ratio of the electron. The variable X is linked to the "permanent" magnetic field H_0 by the relation $X = H_0 - H_0^R$, where H_0^R is the field strength corresponding to the centre of the EPR signal of the radical in the form $\dot{R}$.

In conformity with Eqn.(2), different cases of exchange are realised experimentally: rapid ($1/\tau_R$, $1/\tau_{RH^+} \gg \Delta\omega$), slow ($1/\tau_R$, $1/\tau_{RH^+} \ll \Delta\omega$), or intermediate ($1/\tau_R$, $1/\tau_{RH^+} \simeq \Delta\omega$) in terms of the EPR time scale. Regardless of the frequency of the $\dot{R} \rightleftarrows \dot{R}H^+$ exchange, the ratio τ_R/τ_{RH^+} can be determined from the EPR spectra using Eqn.(2). On the other hand, analysis of Eqn.(2) shows that the determination of the lifetimes τ_R and τ_{RH^+} is possible only in the case of the intermediate exchange.[23] In the presence of well resolved lines in the EPR spectra, Eqn.(2) simplifies greatly and it is sufficient to know the positions and widths of the lines in order to find τ_R and τ_{RH^+}.[23] Knowing the ratio τ_R/τ_{RH^+}, it is possible to determine the equilibrium constant K:

$$K = k_r/k_f = \frac{[BH^+][\dot{R}]}{[B][\dot{R}H^+]} = \frac{\tau_R}{\tau_{RH^+}} \frac{[BH^+]}{[B]} \ . \qquad (3)$$

When reaction (1) describes the exchange with a solvent proton ($BH^+ \equiv H^+_{solv}$, i.e. a solvated proton), Eqn.(3) relates the equilibrium constant K to the concentration of protons $[H^+]$, i.e.

$$\left(K = \frac{\tau_R}{\tau_{RH^+}} [H^+]\right),$$

which leads to the possibility, in principle, of using radicals as pH probes.

The quantities τ_R and τ_{RH^+} determine the kinetic parameters of reaction (1), namely the rate constants k_f and k_r:

$$k_f = \frac{1}{\tau_R}[BH^+], \quad k_r = \frac{1}{\tau_{RH^+}}[B] \ . \qquad (4)$$

Thus in the cases indicated analysis of the form of the EPR signal makes it possible to obtain quantitative information about the thermodynamics and kinetics of the proton exchange in radicals.

In the case of irreversible proton transfer reactions in radicals, the difference between the magnetic-resonance parameters of the $\dot{R}$ and $\dot{R}H^+$ forms permits the direct recording by the EPR method of the accumulation (disappearance) of one of the forms of the radical. The characteristic times accessible to investigation by the EPR method are limited by the time required to "start" the reactions (for example, in the stopped flow method, the time taken to mix the reactants is $\gtrsim 10^{-3}$ s).

III. PROTON EXCHANGE IN SHORT-LIVED RADICALS

Changes in the EPR spectra of a series of alcohol radicals $\dot{R}OH$ in an acid medium have been observed.[24–26] These changes are manifested by the reversible merging of the lines of the doublet, which arises from the hyperfine interaction (HFI) with the hydroxyl proton, to a singlet as a consequence of the proton exchange:

$$\dot{R}OH + H^+ \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} \dot{R}OH_2^+ \ . \qquad (5)$$

Reaction (5) alters the projection of the nuclear spin of the hydroxyl proton of the ROH radical and thus leads to frequency exchange between the lines of the doublet due to the HFI with the given proton. Analysis of the positions and widths of the lines in the EPR spectra of the $\dot{R}OH$ radicals made it possible to determine the proton exchange rate constant k_1, which is in the range 6.5×10^6 to 1.8×10^8 litre mol^{-1} s^{-1}. The temperature variation of the rate constant for the protonation of the hydroxymethyl radical k_1, characterised by the activation energy $\Delta E = 2.8$ kcal mol^{-1}, has also been found.[26]

Whereas the influence of pH on the EPR spectra is a consequence of the protonation of the OH group in hydroxyalkyl radicals in an acid medium in the studies[24–26] mentioned above, in other investigations[27–29] such influence was caused by the deprotonation of the OH group in accordance with the reaction

$$\dot{R}OH + OH^- \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} \dot{R}O^- + H_2O \ . \qquad (6)$$

The difference between the EPR spectra of the $\dot{R}OH$ and $\dot{R}O^-$ forms made it possible to determine the pK of the radicals investigated and, in the two cases where intermediate exchange was observed, also the rate constants: pK = 11.51 and $k_1 = 7 \times 10^9$ litre mol^{-1} s^{-1} for the radical $CH_3\dot{C}HOH$ and pK = 1203 and $k_1 = 9 \times 10^9$ litre mol^{-1} s^{-1} for the radical $(CH_3)_2\dot{C}HOH$.[27–29] It is noteworthy that, in the case of slow and intermediate exchange, the EPR spectra of the test radicals[28] had a very complex form at pH $\simeq$ pK. Therefore 1 M orthophosphoric acid with pK = 12.32 was added to the solution of the radical. The rate of proton exchange then increases,[30,31] which simplifies the EPR spectrum. The essential feature of the proposed approach can be readily understood by considering all the proton exchange reactions with participation of the radical and the added buffer B:[30]

$$\begin{aligned} &\text{(a)}\ \dot{R} + H^+ \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} \dot{R}H^+ \ , \\ &\text{(b)}\ B + H^+ \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} BH^+ \ , \\ &\text{(c)}\ \dot{R} + BH^+ \underset{k_{-3}}{\overset{k_3}{\rightleftarrows}} \dot{R}H^+ + B \ . \end{aligned} \qquad (7)$$

The quantities pK_1, pK_2, and pK_3 are linked by the relation[31]

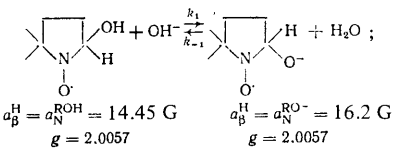
$$pK_3 = pK_1 - pK_2 . \quad (8)$$

The addition of a buffer to the system alters only the kinetic parameters of the $\dot{R} \rightleftarrows \dot{R}H^+$ exchange (τ_R, τ_{RH^+}), while the equilibrium in this reaction (τ_R/τ_{RH^+}) is undisturbed:

$$\begin{aligned} &(a)\ 1/\tau_R = k_3[BH^+] = k_3B_0/(1 + 10^{pH-pK_3}) , \\ &(b)\ 1/\tau_{RH^+} = k_{-3}[B] = k_{-3}B_0/(1 + 10^{pK_3-pH}) , \\ &(c)\ \tau_{RH^+}/\tau_R = [RH^+]/[R] = 10^{pK_1-pH} , \end{aligned} \quad (9)$$

where $B_0 = [B] + [BH^+]$ is the buffer concentration; here it is understood that $k_3[BH^+] \gg k_1[H^+]$, and $k_{-3}[B] \gg k_{-1}$. According to Eqns.(9), the most effective acceleration of the exchange (decrease in τ_{RH^+} and τ_R) is observed under conditions where $pK_1 \simeq pK_2$.

The proton exchange reaction between two forms of the glycine radical has been investigated:

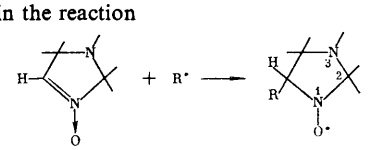


$$NH_2{-}\dot{C}H{-}COO^- + H_2PO_4^- \underset{k_{-3}}{\overset{k_3}{\rightleftarrows}} NH_2{-}\dot{C}H{-}COOH + HPO_4^{2-} . \quad (10)$$

In the absence of a buffer, the proton exchange via reaction (7a) leads to slow exchange between the corresponding lines of the EPR spectrum of the glycine radical. The addition of the phosphate buffer ($pK_2 = 6.4$) made it possible to pass to the region of the intermediate exchange and to calculate the rate constants for the proton exchange reaction (10): $k_3 = (2.5 \pm 0.5) \times 10^9$ litre mole^{-1} s^{-1} and $k_{-3} = (1.4 \pm 0.5) \times 10^9$ litre mol^{-1} s^{-1}. Rapid $\dot{R} \rightleftarrows \dot{R}H^+$ exchange occurs in 0.5 M phosphate buffer and $pK_1 = 6.65$ for the carboxy-group in the glycine radical was calculated from the pH dependence of the HFI constants: a_H^{CH}(pH) and a_N(pH). In the analysis of the a(pH) dependences use was made of Eqn.(11), which can be readily obtained for the case of rapid exchange from Eqns.(2) and (9c):

$$a(pH) = a_R \cdot p_R + a_{RH^+} \cdot p_{RH^+} = (a_R + a_{RH^+} \cdot 10^{pK_1-pH})/(1 + 10^{pK_1-pH}) , \quad (11)$$

where a_R and a_{RH^+} are the HFI constants of the radicals in the $\dot{R}$ and $\dot{R}H^+$ forms respectively.



An interesting case of the manifestation of the deprotonation of the OH group has been observed[32] in a hydroxynitroxy-radical:

(12)

The protonated ($\dot{R}OH$) and deprotonated ($\dot{R}O^-$) forms of the radical differed in their HFI constants. In the region where pH $\simeq$ pK, the rapid $\dot{R}OH \rightleftarrows \dot{R}O^-$ exchange was observed and the $a_N = a_\beta^H$(pH) dependence was described by Eqn.(11).

The influence of pH on the EPR spectra of a series of spin adducts formed in the reaction

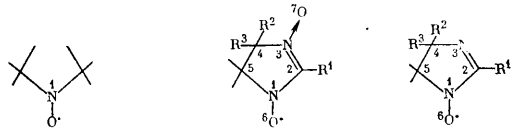
(13)

R=OH, O_2^-(HO$_2$), CH_2OH, O_4^- .

has been observed.[33] The change in the EPR spectra of the short-lived NR formed via reaction (13) in the pH range 2–5 was explained by the authors of the above study by the protonation of the N(3) atom. A number of studies[34–38] have been devoted to the investigation by the EPR method of the proton exchange reactions in semiquinone, semidione, and other short-lived radicals.

Thus the manifestations of the proton exchange in the EPR spectra of short-lived radicals have been fairly thoroughly investigated. Analysis of these spectra makes it possible to measure both the equilibrium constants of the proton exchange reactions and the bimolecular protonation constants. It has been noted in a number of studies that the pK of the radicals are appreciably lower than those of the corresponding diamagnetic molecules,[27–31] which has been attributed to the electron-accepting influence of the radical centre. The protonation constants are in the range $5 \times 10^6 - 10^{10}$ litre mol^{-1} s^{-1}.[24–26,28,30,31,35–37]

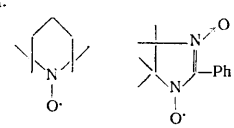
The use of the radicals considered as pH probes is in general impossible as a consequence of their instability.



IV. PROTON EXCHANGE IN STABLE NITROXY-RADICALS

As can be seen from the previous Section, the presence of groups capable of being protonated (deprotonated) in the structure of the radical in the immediate vicinity of the radical centre leads to a difference between the EPR spectra of the protonated ($\dot{R}H^+$) and deprotonated ($\dot{R}$) forms of the radical. However, the simultaneous fulfillment of two requirements—the presence of a functional group near the radical centre and the stability of the radical—is not easy. The manifestation of proton exchange in the EPR spectra of stable radicals has therefore been recorded only in rare instances.

The greatest changes in the parameters of the EPR spectra of NR are to be expected when the latter are protonated at a radical centre where the main bulk of the spin density is localised.

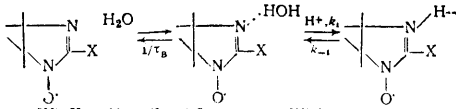


1. Protonation of Nitroxy-radicals at the Radical Centre

The spin density in di-t-alkylnitroxy-radicals is localised mainly on the nitroxy-fragmnent [$\rho_O^\pi \simeq 0.6$; $\rho_{N(1)}^\pi \simeq 0.4$ [39]], in nitronylnitroxy-radicals (NNR) it is localised on the two nitroxy-groups [$\rho_{N(1)}^\pi \simeq \rho_{N(3)}^\pi \simeq 0.22$; $\rho_{O(6)}^\pi \simeq \rho_{O(7)}^\pi \simeq 0.21$ [39]], while in iminonitroxy-radicals (INR) it is localised on the nitroxy-fragment and nitrogen of the imino-group [$\rho_{N(1)}^\pi \simeq 0.38$; $\rho_{O(6)}^\pi \simeq 0.4$; $\rho_{N(3)}^\pi \simeq 0.16$ [40]]:

di-t-alkyl nitroxide nitronyl nitroxide iminonitroxide

The N–O fragment in NR is protonated only in acid media.[41–43] Such protonation of the radical (I) in aqueous 80% sulphuric acid solution increases the constant $a_N(\Delta a_N = 5.7$ G) and decreases the g-factor ($\Delta g = 0.0013$) of the radical and also leads to the appearance of additional doublet splitting ($a_H = 3.12$ G) due to the HFI with the added proton:[43]



(I) (II)

$a_N = 15.87$G $a_{N(1)} = 7.5$G

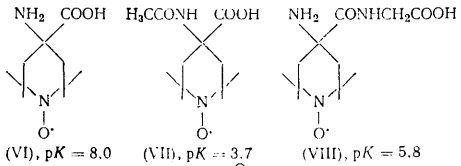
$g = 2.0059$ $a_{N(3)} = 7.5$G

For the majority of NR, protonation at the oxygen atom of the N—O fragment cannot be observed, since in aqueous solutions this process is accompanied by the disproportionation of the NR to the corresponding oxoammonium and hydroxyammonium cations.[44] The protonation of the oxygen atom in the same fragment of NNR in aqueous solutions has not been observed as a consequence of the disproportionation of these radicals in an acid medium.[45] However, in benzene, in the presence of trifluoroacetic acid, it has been possible to observe the EPR spectrum of the radical (II) protonated at the oxygen atom of the nitroxy-group; the constants of the HFI with both nitrogen atoms then decreased (Δa_N = 1.8 G; $\Delta a'_N$ = 2.8 G) and an additional doublet splitting appeared due to the HFI with the added proton (a_H = 4.7 G).[45]

In contrast to the di-t-alkylnitroxy-radicals[41–43] and the nitronyl-nitroxy-radicals,[45] protonated at the nitrogen atom of the imino-group N(3), which is more basic than the nitroxy-group, has been observed for INR:[40,46]

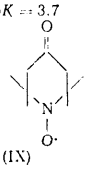
(14)

(III) X = Ph; pK = 1.9; $a_{N(1)}$ = 9.9G; $a_{N(3)}$ = 4.5G
(IV) X = NH_2; pK = 6.4;
(V) X = N $(CH_3)_2$; pK = 6.8
(III)·H^+ $a_{N(1)}$ = 6.2G; $a_{N(3)}$ = 4.9G; a_H = 4.6 G



The large spin density in INR at the N(3) atom is responsible for the greater changes in the constants of the HFI with the nitrogen atom when the latter is protonated [Eqn.(14)]. The constant for the HFI with the added proton a_H in the protonated form of the radical (III) at pH > 1 is not observed as a consequence of the rapid (in terms of the EPR time scale) exchange [via reaction (14)]. The determination of the H^+ concentration at which additional doublet splitting due to the HFI with the added proton appears in the EPR spectrum of the radical form (III)-H^+ made it possible to estimate the lifetime of the $=N\cdots HOH$ hydrogen bond in the radical (III): $\tau_H \simeq 2 \times 10^{-10}$ s.[46] The condition for the rapid $\dot{R} \rightleftarrows \dot{R}H^+$ exchange in the radical (III) makes it possible to determine the lower limit to the bimolecular protonation constant: $k_1 \gg 5 \times 10^7$ litre mol^{-1} s^{-1}. According to other data,[40] the averaging of the signals of the $\dot{R}$ and $\dot{R}H^+$ forms of the radical (III) is incomplete and the exchange has a measureable effect on the position and width of the lines of the EPR signal; this made it possible to calculate the rate constant for the protonation of the radical (III): $k_1 \simeq 10^9$ litre mol^{-1} s^{-1}. The values of k_1 have also been obtained for three other INR and were found to lie in the range $3 \times 10^6 - 10^9$ litre mol^{-1} s^{-1}.[40]

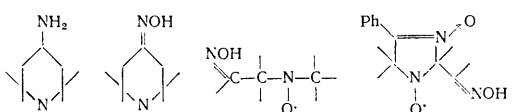
Iminonitroxy-radicals can also form equilibrium complexes in aqueous solutions not only with the proton but also with a series of diamagnetic metals [Hg(II), Zn(II), Cd(II); Ag(I), etc.[40,47]]. Complex formation with participation of the N(3) atom in the INR and of the metal leads to a change in the HFI constants $a_{N(1)}$ and $a_{N(3)}$, which can be recorded by EPR, and to the appearance of HFI with the nucleus of the metal [the HFI constant $a_{Hg} \simeq 40$ G for Hg(II) [40]].



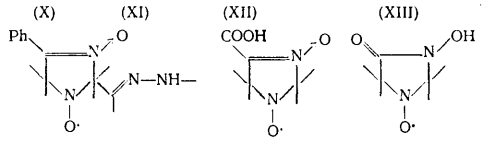
Among the radicals investigated in a series of studies,[40–43,45,46] only two [(IV) and (V)] can be used as pH probes in aqueous solutions in the pH range of practical interest. However, the interpretation of the EPR spectra of the radicals (IV) and (V) at pH $\simeq$ pK is extremely complex, since these spectra are formed as a result of the superposition of the signals of the $\dot{R}$ and $\dot{R}H^+$ forms, in each of which HFI with three non-equivalent nitrogen atoms and protons of the substituent X is manifested.[40]

2. Protonation of the Functional Groups of Nitroxy-radicals

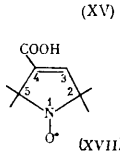
The influence of pH on the EPR spectra of radicals of the piperidine type [(VI)—(VIII)] containing functional groups capable of being protonated (deprotonated) at C(4) has been observed:[48]



(VI), pK = 8.0 (VII), pK = 3.7 (VIII), pK = 5.8

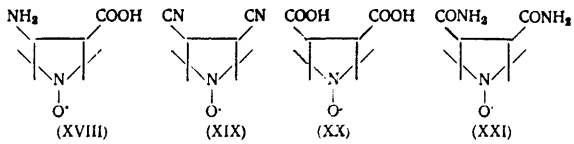


(IX)



A decrease in the HFI constant a_N(Δa_N = 0.15—0.3 G) and an increase in the g-factor ($\Delta g \simeq 0.0001$) have been observed for these radicals with decrease in pH. On the other hand, the EPR spectrum of the radical (IX), which has no group capable of protonation at C(4), did not change over the pH range 2—12. The authors[48] therefore explained the observed changes in the EPR spectra by the reversible protonation of the amino-group in the radicals (VI) and (VIII) and the deprotonation of the carboxy-group in the radical (VII). The slow exchange between the $\dot{R}$ and $\dot{R}H^+$ forms of the radicals (VI)—(VIII) leads to the asymmetry of the EPR spectra, which is manifested most markedly by the decreased intensity of the high-field component. It has been suggested that the pH dependence of the consant a_N and also of the parameters characterising the asymmetry of the signal (the ratio of the intensities of the central high-field components, etc.) be used to determine the pK of the radical by the EPR method. The pH dependence of a_N can be employed to determine the pK also in the absence of the asymmetry of the signal, as in the case of the rapid $\dot{R} \rightleftarrows \dot{R}H^+$ exchange. The sensitivity of the EPR spectrum of the radical (X) of the piperidine type, with the NH_2 group at C(4), to the pH has been reported.[49] However, the authors[49] did not interpret the observed slight increase in the HFI constant ($\Delta a_N \simeq 0.13$ G) in the alkaline pH range 8 to 10.5, which in our view is due to the deprotonation of the NH_2 group (pK = 9.5 [50]):

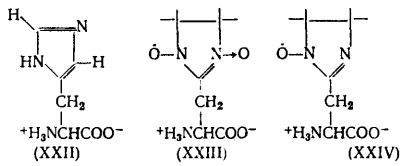
(X) (XI) (XII) (XIII)



(XIV) (XV) (XVI)

(XVII)

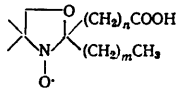
For another radical of the piperidine type with the =NOH group at C(4) [the radical (XI)], an increase in a_N in an alkaline medium has also been observed (Δa_N = 0.16 G).[51] The observed reversible



change in a_N over the pH range 10–12.8 was explained by the reversible deprotonation of the =NOH group. This is confirmed by the similar pK values found by the EPR method from the dependence of a_N on pH for three radicals of different types containing the =NOH group:[51] the piperidine type radical (XI) (pK = 11.35; Δa_N = 0.16 G), the acyclic di-t-alkylnitroxy-radical (XII) (pK = 11.55; Δa_N = 0.34 G), and the radical (XIII), which is of the 3-imidazoline 3-oxide type (pK = 10.7; Δa_N = 0.22 G). Much lower pK values have been found for the 3-imidazoline 3-oxide type radicals (XIV) and (XV) with other functional groups, amounting to 1.6 and 1.9 for the =N–NH group in the radical (XIV) (Δa_N = 0.47 G) and the COOH group in the radical (XV) (Δa_N = 0.15 G) respectively. A difference between the EPR spectra of the $\dot{R}$ and $\dot{R}H^+$ forms of the imidazolidine type radicals (XVI), which are analogues of hydroxamic acid (pK = 7.0; Δa_N = 0.24 G), and the pyrrolidine type radicals (XVII) with the carboxy-group at C(4) (pK = 3.5; Δa_N = 0.31 G) [51] has also been observed. The influence of pH on the EPR spectra of the pyrrolidine type radicals (XVIII)–(XXI) has been reported recently:[52]

(XVIII) (XIX) (XX) (XXI)

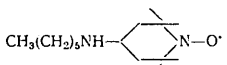
The spectra of these radicals at pH 2 and pH 12 differed in the values of the HFI constant (Δa_N = 0.3–0.5 G). However, in contrast to Nakie et al.[48] and Khramtsov et al.,[51] Matthew and Dodd[52] presented no data concerning the pH dependence of the parameters of the EPR spectra (a_N, g-factor), so that the question of the pK of the groups protonated in the radicals (XVIII)–(XXI) remains open. The prospects for the use of these radicals as pH probes are also obscure. We may likewise note that the difference between the EPR spectra of the $\dot{R}$ and $\dot{R}H^+$ forms can be determined by the influence of the protonation of the functional groups of the radical on its intermolecular or intramolecular interactions.



Changes in the EPR spectra of a series of radical analogues of histidine (XXII) have been observed as a function of pH:[53]

(XXII) (XXIII) (XXIV)

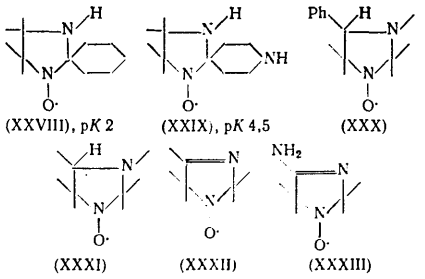
The protonation of the carboxy-group in the radicals (XXIII) and (XXIV) altered the constants for HFI with the non-equivalent β-protons of the methylene group. This was explained by the ion–dipole interaction between the electron-deficient nitronylnitroxy-ring [for the radical (XXIII)] or the iminonitroxy-ring [for the radical (XXIV)] and the carboxylate anion. The protonation of the carboxy-group disturbs such interaction and shifts the equilibrium between the conformations responsible for the non-equivalence of the constants for the HFI with the methylene protons. An analogous ion–dipole interaction between the imidazole ring and the carboxylate ion in histidine has been observed by NMR.[53]



The pH influences the EPR spectra of the spin-labelled aliphatic acids (XXV) and (XXVI) in an aqueous lecithin suspension:[54]

(XXV) $m = 12$, $n = 3$
(XXVI) $m = 5$, $n = 10$

The spectra of the radicals (XXV) and (XXVI) have the form characteristic of immobilised radicals and the order parameter S, characterising the degree of hindrance of the rotation of the NR,[55] depended on the pH of the medium in the pH range 4–7. Since no influence of the pH on the EPR spectra of the methyl ester of the radical (XXVI) was observed under these conditions, the pH-dependent changes in the spectra of the radicals (XXV) and (XXVI) were explained[54] by the deprotonation of the carboxy-group. Since the carboxy-group is very remote from the N–O· radical fragment in the radicals (XXV) and (XXVI) [in the radical (XXVI) they are separated by a chain of 10 CH_2 groups], the observed differences between the EPR spectra of the protonated and deprotonated forms of the radicals are apparently entirely due to the interaction of both forms with the lipid phase, which leads to a difference between their rotational characteristics manifested in the EPR spectra.

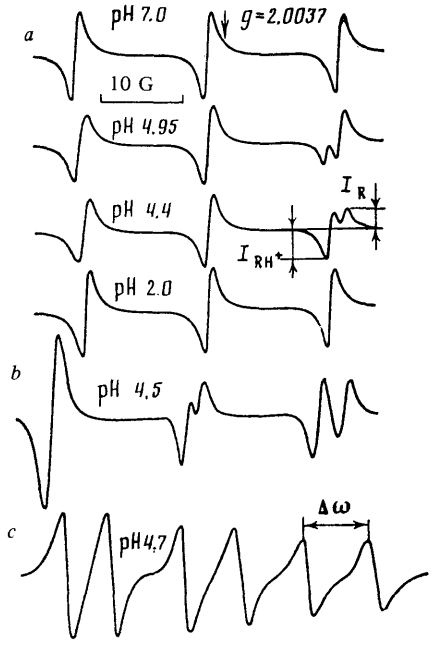


The influence of pH on the EPR spectrum of the NR (XXVII) in an aqueous suspension of lipid vesicles (liposomes) has been investigated:[56]

(XXVII)

In this medium, the radical (XXVII) is distributed between the aqueous and lipid phases, the EPR signal in the lipid phase being greatly broadened as a consequence of immobilisation. The partition coefficient of the radical (XXVII) between the aqueous and lipid phases varies by a factor of ~10 in the pH range 3.5–11.5, which has been explained by the difference between the partition coefficients of the form of the radical (XXVII) protonated at the third nitrogen atom linked to the C(4) atom and of its non-protonated form. The radicals (XXV) and (XXVII) have been used[57,58] to investigate the transmembrane proton transport through a model phospholipid membrane. The different permeabilities of the membranes to the $\dot{R}$ and $\dot{R}H^+$ forms of the radical (X) have been used to determined ΔpH on natural membranes.[50,59,60] Since the sensitivity of the EPR spectra of the radicals (XXV)–(XXVII) to pH is observed only when the solution contains the lipid phase, their use for the direct measurement of pH in general is not possible.

In 1982, the influence of pH on the EPR spectra of NR of the imidazoline and imidazolidine types was observed independently in a number of studies.[19–21] Rapid proton exchange between the $\dot{R}$ and $\dot{R}H^+$ forms of the radicals (XXVIII) and (XXIX), differing in the HFI constants ($\Delta a_N \simeq$ 1.2 G) was noted by Keana et al.[19] Khramtsov et al.[21] observed different cases of proton exchange (rapid or slow) for the radicals (XXX)–(XXXIII), whose $\dot{R}$ and $\dot{R}H^+$ forms differed both as regards the HFI constants (Δa_N = 0.8–1.2 G) and the g-factors (Δg = 0.0002–0.0003). As a consequence of such appreciable differences, the radicals of the imidazoline and imidazolidine types are most promising for the study of the mechanisms of the proton exchange reactions by EPR and also for use as pH probes:



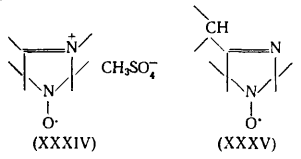


Figure 1. EPR spectra of an aqueous solution (at a concentration of 5×10^{-4} M) of the radical (XXXI) at different pH in the *X*-band (*a*), *Q*-band (*b*), and the 2-mm band (*c*) at 23 °C.[21]

observe the doublet splitting of two (in the *Q*-band) or all three (in the 2 mm range) components of the triplet (Fig.1) the EPR spectrum of the radical (XXXI). It has been shown[21] that the observed effect is associated with the protonation of the N(3) atom in the radical (XXXI) and with the difference between the HFI constants a_N and the *g*-factors of the Ṙ and $\dot{R}H^+$ forms.

This conclusion has been confirmed, firstly, by the similarity of the p*K* values for this radical measured potentiometrically and by EPR.[61] The dependence of the function $f = I_{RH^+}/(I_R + I_{RH^+})$ (I_{RH^+} and I_R are the intensities of the EPR signals of the $\dot{R}H^+$ and Ṙ forms respectively) on the pH was used to determine the p*K* by the EPR method (Fig.2). Previously this function had been employed[62] to describe the distribution of the radical (I) between the aqueous and lipid phases:

Secondly, the HFI constants and the *g*-factor of the radical (XXXI) in the $\dot{R}H^+$ form are close to the corresponding values for the imidazolinium salt (XXXIV) (Table 1). Thirdly, the effect of pH on the EPR spectra of the radicals (I) and (XXXIV), in which the N(3) atom capable of being protonated is absent, has not been observed.

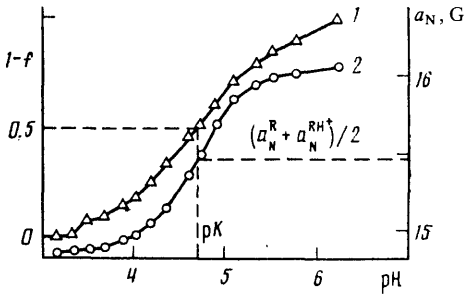

Figure 2. The pH dependence of the function $I-f = I_R/(I_R + I_{RH^+})$ (curve *1*) and of the HFI constant a_N (curve *2*) for the radical (XXXI).[61]

3. Proton Exchange in Nitroxy-radicals of the Imidazoline and Imidazolidine Types

(a) Manifestation of the protonation of the N(3) atom in radicals of the imidazoline and imidazolidine types in EPR spectra. The influence of pH on the EPR spectra of one of the radicals—an imidazolidine derivative (XXXI)—is illustrated in Fig.1.[21] In the pH range 3.5–6, the high-field component of the EPR spectrum in the *X*-range (Fig.1*a*) is split into two resolved components, whose relative intensities vary reversibly with pH. This form of the spectrum has been explained by the superposition of two triplet EPR spectra differing in the HFI constants and *g*-factors. Indeed, the use of spectrometers with a higher working frequency made it possible to

The p*K* found by the EPR method, the HFI constants, and the *g*-factors are listed in Table 1 for a series of radicals of the imidazoline and imidazolidine types.

The EPR spectrum of the radicals (XXXI) and (XXXIII) with $pK > 3$ in the region where $pH \simeq pK$ represents a superposition of the spectra of the Ṙ and $\dot{R}H^+$ forms of the radical, which is due to the slow $\dot{R} \rightleftarrows \dot{R}H^+$ exchange.[61] In this case, the p*K* of the radicals were determined using the pH dependence of *f* (Fig.2). It is noteworthy that the p*K* of the radicals determined in this way can differ in general from the true values as a consequence of the different widths of the high-field components of the spectra of the Ṙ and $\dot{R}H^+$ forms. However, for the radicals investigated (Table 1), these differences are small ($\lesssim 5\%$) and can lead to an error not greater than 0.1 in the measurement of the p*K*. In the *X*-range, the pH

dependence of the quantity a_N (Fig.2), measured as the distance between the first and second components of the triplet, can be used together with the functions f for the determination of the pK of the radical; here $a_N(pK) = (a_N^{\dot{R}H^+} + a_N^{\dot{R}})/2$ ($a_N^{\dot{R}H^+}$ and $a_N^{\dot{R}}$ are the HFI constants for the $\dot{R}H^+$ and $\dot{R}$ forms respectively). Two resolved signals in the third component of the EPR spectrum were not observed for the radicals (XXXII) and (XXXV) in the pH $\simeq$ pK region. The change in pH led to a reversible change in the parameters of the triplet EPR spectra of these radicals, namely the HFI constant and the g-factor, which can be explained by the rapid proton exchange $\dot{R} \rightleftarrows \dot{R}H^+$. In this case, the p$K$ of the radical can be calculated from the conditions leading to agreement between the experimental curve and the curve calculated by Eqn.(11) and also from the condition

$$a_N(pK) = (a_N^{\dot{R}H^+} + a_N^{\dot{R}})/2.$$

Table 1. The pK values, found by EPR, the calculated and experimental HFI constants a_N, and the g-factors for the $\dot{R}$ and $\dot{R}H^+$ forms of certain radicals of the immidazoline and imidazolidine types.[21,61,63]

* The experimental g-factors, determined by Khramtsov and coworkers,[21,61] are displaced relative to the tabulated values by the constant amount $\Delta g = 6 \times 10^{-4}$ as a consequence of a systematic apparatus error.

** Calculated values (without allowance for solvation effects).[61]

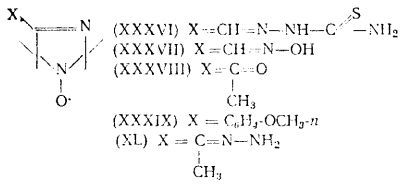
*** Calculated values (with allowance for solvation effects).[64]

As can be seen from Table 1, when the N(3) atom is protonated, the changes in the g-factor are $(2-3) \times 10^{-4}$ and those in the HFI constant are 0.8 – 1.2 G. Additional evidence for the possibility of such large changes in the parameters of the EPR spectra of NR of the imidazoline and imidazolidine types on protonation of the N(3) atom has been obtained by quantum-chemical methods.[61]

(b) Quantum-chemical calculations of the HFI constants and g-factors of radicals of the imidazoline and imidazolidine types in the protonated and non-protonated forms. Quantum-chemical calculations of the electronic structures of the radicals have been carried out[61] by the restricted and unrestricted Hartree – Fock methods in terms of the INDO approximation.[65] In the calculation of the g-factor by the restricted Hartree – Fock method, the molecular orbitals were calculated by Stone's method.[66] The available experimental data for the geometries of the analogous imidazoline radicals with the N-oxide linkage were used for the radicals (XXXII) – (XXXV).[67] In the calculation of the electronic structure of the radical (XXXI), the geometry of the corresponding hydroxypyrrolidine was attributed to the latter.[68]

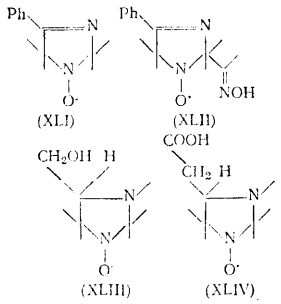
The constants for the HFI with the N(1) atom (a_N) and the g-factors for the above radicals, calculated theoretically and found experimentally,[61] are compared in Table 1. The calculated constants a_N differ appreciably from the experimental values owing to the approximate nature of the INDO method used in the calculation.[65] However, the characteristics of the changes in the HFI constants on passing from uncharged to charged forms are reproduced quite satisfactorily. In these radicals, the spin density is localised mainly on the N – O· π orbital ($\rho_N^\pi \simeq 0.31$; $\rho_O^\pi \simeq 0.67$). When the N(3) atom is protonated, the splitting of the levels of the π orbitals of the N and O atoms increases under the influence of the field of the positive charge and the relative electronegativity of the oxygen atom diminishes: as a result of this, the antibonding orbital of the unpaired electron is localised to a greater extent on the oxygen atom and to a lesser extent on the nitrogen atom ($\rho_N^\pi = 0.26$; $\rho_O^\pi = 0.72$). The sum $\rho_N^\pi + \rho_O^\pi$ then remains almost constant. Since the constant a_N is linked to the π-electron spin populations by relations of the type[65] $a_N = Q_N^N \rho_N^\pi + Q_O^N \rho_O^\pi$, where $Q_N^N > 0$ and $Q_O^N < 0$, the above redistribution of spin density on protonation of the N(3) atom does in fact diminish the constants a_N.

The values of a_N for the $\dot{R}$ and $\dot{R}H^+$ forms of the radical (XXXII) have been calculated recently[64] taking into account solvation within the framework of a solvate model.[69] As can be seen from Table 1, allowance for solvation ensures the best agreement between the calculated and experimental values of a_N with retention at the same time of the difference between the a_N for the two forms of the radical, amounting to 1 G.



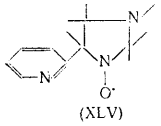
It follows from Table 1 that, in agreement with experiment, the g-factors of the protonated radicals are close to one another and do not differ from the g-factor of the imidazolinium salt (XXXIV). The non-protonated radicals are also characterised by a similar g-factor [with the exception of the radical (XXXI), whose geometry has been estimated tentatively by Khramtsov et al.[61]]. The g-factors of the protonated radicals are appreciably greater than those of the non-protonated radicals.

Analysis of the calculated data has shown that this increase in the g-factors is caused mainly by the increase in the component of the g-tensor $\Delta g_{zz} = 0.0034$ corresponding to the direction of the N – O· bond. The main contribution to this component ($\Delta g_{zz} = 0.0042$) comes from the transition from the molecular orbital corresponding approximately to the orbital of the unshared electron pair of oxygen n to the orbital of the unpaired electron $\pi\uparrow$, whose admixture in the ground state is determined mainly by the spin – orbital interaction at the oxygen atom.

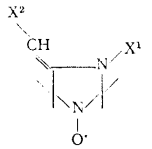


The above analysis has confirmed that the effects associated with the protonation of the N(3) atom can induce changes in the constants a_N and in the g-factor, which have been observed experimentally, and thus serves as yet another confirmation of the validity of the assignment of the EPR spectra by Khramtsov et al.[61]

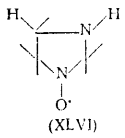
(c) The equilibrium constants of the proton exchange in radicals and their relation with the character of the frequency exchange in the EPR spectra. The influence of the protonation of the N(3) atom on the EPR spectra of a large series of radicals of the imidazoline and imidazolidine types has been investigated.[51] Table 2 presents the pK,



the HFI constants, and the *g*-factors for the radicals (XXXVI)–(LI) in the protonated and deprotonated forms found by EPR and also indicates the character of the $\dot{R} \rightleftarrows \dot{R}H^+$ exchange.

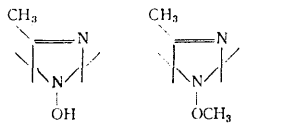


(XXXVI) X = CH=N–NH–C(=S)–NH$_2$
(XXXVII) X = CH=N–OH
(XXXVIII) X = C(=O)–CH$_3$
(XXXIX) X = C$_n$H$_{2n}$–OCH$_3$-*n*
(XL) X = C(CH$_3$)=N–NH$_2$

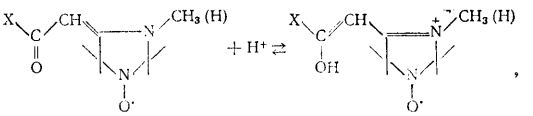


(XLI) (XLII) (XLIII) (XLIV)

(XLV)



(XLVII) X^1 = H X^2 = NO$_2$
(XLVIII) X$_1$ = H X^2 = C(=O)–CH$_3$
(XLIX) X^1 = H X^2 = C(=O)–(CH$_2$)$_4$–COOH
(L) X^1 = CH$_3$ X^2 = C(=O)–CH$_2$–N
(LI) X^1 = CH$_3$ X^2 = C(=O)–CH$_2$I



(XLVI)

The protonation of the N(3) atom in the given radicals is accompanied by appreciable changes in the HFI constants a_N (Δa_N = 0.8 to 1.3 G) and in the *g*-factor [$\Delta g = (2-3) \times 10^{-4}$]. The values of p$K$ for the imidazoline radicals correspond to the region of low pH values [pK < 3, with the exception of the radical (XXXIII), which has pK = 6.1]; they are smaller than the pK of the imidazolidine radicals [pK = 3.0–4.7 for the radicals (XXX), (XXXI), and (XLIII)–(XLVI)]. The smaller pK of the radicals compared with the pK of the corresponding diamagnetic molecules of imidazolines and imidazolidines[19,51] have been explained by the electron-accepting influence of the nitroxy-group. Indeed, pK = 1.9 for the radical (XXXII), which is appreciably less than the pK of the corresponding diamagnetic analogues (LII) and (LIII):[61]

(LII), pK = 3.85 (LIII), pK = 3.85

We may also note that pK = 11.15 for the =NOH group in the radical (XLII) [cf. the radical (XIII)] and pK = 2.0 for the COOH group in the radical (XLIV) [cf. the radical (XV)] [51] have been found by EPR. The high pK = 7.8, found by EPR for the imidazolidine radical (XLVII), is associated with its deprotonation in the 3-position. The deprotonation of this radical has been demonstrated chemically.[70] The deprotonation in the 3-position is also responsible for the change in the EPR spectra of the imidazolidine radicals (XLVIII) and (XLIX) in an alkaline medium (Table 2).[51] For the radicals (XLVIII) and (XLIX), yet another pK has been observed (Table 2) in the region of low pH values, which, as for the radicals (L) and (LI), has been explained by the protonation of the enamino-keto-group. It is known that the vast majority of enaminoketones are protonated at the oxygen atom.[71,72] The protonation of the radicals (XLVIII)–(LI) at the oxygen atom is described by the equation

(15)

where X are substituents. The positive charge on the $\dot{R}H^+$ form is then mainly localised at the N(3) atom, which explains the similarity of the values of Δa_N and Δg for the protonation of the radicals (XLVIII)–(LI) and of the N(3) atom in radicals of the imidazolidine type (Table 2).

Table 2. The values of pK, a_N, and *g*-factors for the $\dot{R}$ and $\dot{R}H^+$ forms of certain radicals of the imidazoline and imidazolidine types as well as the character of the $\dot{R} \rightleftarrows \dot{R}H^+$ frequency exchange.[51,63]

*r = rapid, i = intermediate, and s = slow (in terms of the EPR time scale).
**See first footnote to Table 1.

The relation between the character of the $\dot{R} \rightleftarrows \dot{R}H^+$ exchange and the pK of the radical has attracted attention: for radicals with pK > 3 and also for the radicals (XLVIII) and (XLIX) with pK = 13.25 and 13.5 respectively, a rapid exchange has been observed, while in the case of the radicals with pK = 3–8 a slow exchange has been observed (Table 2). This has been explained in two investigations.[51,61] In aqueous solutions, the proton exchange between the $\dot{R}$ and $\dot{R}H^+$ forms is described by two mechanisms:

$$\dot{R} + H^+ \underset{k_{-1}^{H^+}}{\overset{k_1^{H^+}}{\rightleftarrows}} \dot{R}H^+; \qquad (16)$$

$$\dot{R}H^+ + OH^- \underset{k_{-1}^{OH^-}}{\overset{k_1^{OH^-}}{\rightleftarrows}} \dot{R} + H_2O\,. \qquad (17)$$

The condition for slow exchange requires that the reciprocals of the lifetimes of the radicals in the $\dot{R}$ and $\dot{R}H^+$ forms ($1/\tau_R$ and $1/\tau_{RH^+}$ respectively) should be appreciably smaller than the difference between the frequencies of the EPR signals of these forms $\Delta\omega$:

$$1/\tau_R,\ 1/\tau_{RH^+} \ll \Delta\omega \qquad (18)$$

For the mechanism (16), which is the main one in an acid medium, we have

$$1/\tau_{RH^+} = k_{-1}^{H^+} = k_1^{H^+}K_a = k_1^{H^+} \times 10^{-pK},$$
$$1/\tau_R = k_1^{H^+}[H^+] = k_1^{H^+} \times 10^{-pH}, \qquad (19)$$

where $K_a = k_{-1}^{H^+}/k_1^{H^+}$ is the equilibrium constant of reaction (16) (by definition $K_a = 10^{-pK}$). For the mechanism (17), which is the main one in an alkaline medium, we have

$$1/\tau_{RH^+} = k_1^{OH^-}[OH^-] = k_1^{OH^-} \times 10^{pH-14}, \qquad (20)$$
$$1/\tau_R = k_1^{OH^-} \times 10^{pK-14}.$$

On substituting Eqns.(19) and (20) in Eqn.(18), we obtain the condition for slow exchange:

$$\lg(k_1^{H^+}/\Delta\omega) < pK,\ pH < 14 - \lg(k_1^{OH^-}/\Delta\omega)\,. \qquad (21)$$

For diffusion-controlled proton exchange reactions, $k_1^{H^+} \simeq k_1^{OH^-} \simeq 10^{10}$ litre mol^{-1} s^{-1} [1] and $\Delta\omega \simeq 10^7$ s^{-1} for the protonation of the N(3) atom (Fig.2). On substituting the values of $k_1^{H^+}$, $k_1^{OH^-}$, and $\Delta\omega$ in Eqn.(21), we obtain the condition for the slow frequency exchange in the EPR spectra for diffusion-controlled proton exchange reactions:[61]

$$3 < pK < 11\,. \qquad (22)$$

This condition is satisfactorily consistent with the available experimental literature data. Indeed, for the radicals (III),[46] (XXVIII),[19] (XXXII), (XXXV)–(XXXIX), (XLI), and (XLII) [51] with $pK < 3$, the hydroxynitroxy-radical ($pK = 12.96$),[32] a series of alcohol radicals,[28] and the radicals (XLVIII) and (XLIX) [51] with $pK > 11$, a rapid $\dot{R} \rightleftarrows \dot{R}H^+$ proton exchange was observed. For the radicals (VI)–(VIII),[48] (XXX), (XXXI), (XXXIII),[62] (XLIII), (XLIV), (XLV), and (XLVII) [51] with pK in the range $3 < pK < 11$, a slow exchange was observed. Finally, for the radical (XL) [51] ($pK = 2.5$) and the radicals $CH_3\dot{C}HOH$ ($pK = 11.51$) and $(CH_3)_2\dot{C}OH$ ($pK = 12.03$),[28] the character of the exchange is intermediate. On the other hand, the rapid $\dot{R} \rightleftarrows \dot{R}H^+$ frequency exchange in the EPR spectra of the radical (XXIX) ($pK = 4.5$) [19] and the slow exchange in the EPR spectra of the radicals (L) ($pK = -0.7$) and (LI) ($pK = 0.2$),[51] conflict with condition (22). In order to account for these findings in conformity with condition (21), it is essential to postulate that $k_1^{H^+} \gg 10^{10}$ litre mol^{-1} s^{-1} for the radical (XXIX) (i.e. $k_1^{H^+} \simeq 10^{11}$ litre mol^{-1} s^{-1}) and $k_1^{H^+} \ll 10^{10}$ litre mol^{-1} s^{-1} (smaller by 3–4 orders of magnitude or more) for the radicals (L) and (LI). Appreciably lower bimolecular protonation constants $k_1^{H^+}$ compared with the corresponding value for diffusion-controlled reactions have been noted in the literature, for example for CH acids.[1] As mentioned above, the enaminoketo-group in the radicals (L) and (LI) is apparently protonated at the oxygen atom in accordance with Eqn.(15). The redistribution of electron density occurring under these conditions can lead to an appreciable increase in the activation energy for the chemical reaction and hence to a decrease in $k_1^{H^+}$. It is also possible that a decrease in the constants $k_1^{H^+}$ for the radicals (L) and (LI) can be explained by steric hindrance.[51]

(d) Kinetic characteristics of the reactions. The appreciable difference between the parameters of the EPR spectra of the $\dot{R}$ and $\dot{R}H^+$ forms of the imidazoline and imidazolidine radicals (Tables 1 and 2) enabled us[73,74] to propose a new approach to the study of the kinetics of proton exchange reactions by EPR. For the intermediate $\dot{R} \rightleftarrows \dot{R}H^+$ frequency exchange, all the parameters characterising the kinetics of the proton exchange reaction are susceptible to determination by EPR: the rate constants, the activation energies, and the kinetic isotope effects.[61,73,74]

According to Eqn.(22), the intermediate exchange should be observed for radicals with $pK \simeq 3$ and $pK \simeq 11$; among the radicals investigated (Tables 1 and 2), this condition is satisfied by the radicals (XXX) with $pK = 3.0$ and (XL) with $pK = 2.5$. Indeed, for $pH \simeq pK$, the high-field component of the radical (XL) is broadened as a result of the $\dot{R} \rightleftarrows \dot{R}H^+$ exchange.[72] In the case of tha radical (XXX), for increased temperatures spectral changes characteristic of the transition from slow to intermediate exchange are also observed.[61] In conformity with Eqn.(22), such spectral changes with increase in temperature have not been noted for the radical (XXXI) with $pK = 4.7$.

In order to determine the lifetimes τ_R and τ_{RH^+} and the corresponding proton exchange rate constants $k_1^{H^+}$ and $k_{-1}^{H^+}$, the high-field component in the EPR spectra of the radicals (XXX) and (XL) was modelled on a computer.[61,74] In calculating the spectra, use was made of Eqn.(22), describing the line shape of the EPR signal for rapid exchange involving two positions; the unresolved superhyperfine structure was taken into account in two ways: (a) by the direct allowance for the HFI with the methyl protons, whose contribution to the non-uniform broadening of the EPR signal is decisive,[61] and (b) by representing the form of the spectral line by a composite function comprising one calculated by Eqn.(2) and the Gaussian distribution function[73,74] [this is based on the insignificant difference ($\lesssim 5\%$) between the width of the Gaussian distributions in the $\dot{R}$ and $\dot{R}H^+$ forms of the radicals investigated (see also Lebedev and Muromtsev[75])].

The bimolecular protonation constants $k_1^{H^+}$ for the radical (XL), amounting to $3 \times 10^9 - 10^{10}$ litre mol^{-1} s^{-1} (Fig.3) in the experimental temperature range (274–300 K), are appreciably greater than for the radical (XXX) ($k_1^{H^+} \simeq 5 \times 10^8$ litre mole^{-1} s^{-1} at 20 °C); under these conditions, the temperature dependence of τ_R and τ_{RH^+} can be described by a linear function in terms of the Arrhenius parameters and, according to Eqn.(19), we have

$$k_1^{H^+} = 1{,}6 \cdot 10^{14} \exp(-5800/RT),\ \text{litre mol}^{-1}\,\text{s}^{-1};$$
$$k_{-1}^{H^+} = 1{,}0 \cdot 10^{14} \exp(-8900/RT),\ \text{s}^{-1}. \qquad (23)$$

The high activation energy for the protonation of the radical ($\Delta E = 5.8 \pm 0.4$ kcal mol^{-1}) may indicate non-diffusional control of the reaction.

The possibility of obtaining quantitative information about the isotope effects in proton exchange reactions using pH-sensitive NR is of interest. A difference has been observed[74] between the EPR spectra of the radical (XL) in H_2O and D_2O (Fig.3). Therefore, in D_2O the temperature dependence of the lifetimes of the radical in the $\dot{R}$ and $\dot{R}D^+$ forms can also be described by a linear function in terms

of the Arrhenius parameters and the rates of the forward and reverse exchange reactions can be formulated as follows:

$$k_1^{D^+} = 9{,}9 \cdot 10^{13} \exp(-6100/RT), \text{ litre mol}^{-1}\text{ s}^{-1};$$
$$k_{-1}^{D^+} = 9{,}7 \cdot 10^{13} \exp(-10\,000/RT), \text{ s}^{-1}. \quad (24)$$

Comparison of Eqns.(23) and (24) shows that, for the given reaction, both thermodynamic (different equilibrium constants) and kinetic (different rate constants) isotope effects are observed. The thermodynamic isotope effect $\Delta pK = pK^{D_2O}/pK^{H_2O} = 0.4$ (at $T = 294$ K). This agrees with the fact that, for the majority of ionising groups, the pK corresponding to ionisation via the loss of a deuteron in D_2O are higher by $\sim 0.4-0.6$ of a unit than the pK for the ionisation of the same groups via the loss of a proton in H_2O.[76] The kinetic isotope effect has the usual value for reactions of this type ($k_1^{H^+}/k_1^{D^+} = 2.7 \pm 0.2$ and $k_{-1}^{H^+}/k_{-1}^{D^+} = 6.9 \pm 0.4$ at $T = 294$ K) and in order to account for it there is no need to resort to tunnelling effects.[5,6] This conclusion is confirmed by the satisfactory validity of the Arrhenius relation for k_1 (Fig.3). We may note that, in the case of the radical (XXX), where the interaction between the N(3) atom and the proton is additionally hindered by the presence of the bulky CH_3 group, the Arrhenius relation does not hold for k_1,[61] the rate constant k_1 being an order of magnitude smaller than for the radical (XL) (Table 3). Naturally the determination of the contribution of tunnelling on the basis of the temperature variation of the constant k_1 requires the measurement of the latter over a wider temperature range. Unfortunately, the proton exchange frequencies can be measured by EPR only when they are close to the difference between the Zeeman frequencies of the protonated and non-protonated forms of the radical, which limits the temperature range for the measurement of k_1 for the radicals (XXX) and (XL) to $\Delta T \simeq 40$ K.[61,74] We may point to the possibility, in principle, of extending the range of measurement of the proton exchange frequencies by EPR involving the use of spectrometers with different working frequencies. As can be seen from the EPR spectra of the radical (XXXI) presented in Fig.1, the difference between the frequencies of the $\dot{R}$ and $\dot{R}H^+$ forms in the X, Q, and 2 mm bands is significantly different (by a factor of ~ 4).

Table 3. The rate constants for the forward (k_f) and reverse (k_r) proton exchange reactions of certain radicals with the compounds BH^+ at 21 °C.[74]

Radical	BH+	$10^{-7}\,k_f$, litre mol^{-1} s^{-1}	$10^{-7}\,k_r$, litre mol^{-1} s^{-1}
(XL)	H_3O^+	850±90	2.7±0.3*
(XXX)	H_3O^+	50	0.05*
(XLVI)	CH_3COOH	20±1.5	53±3
(XXXI)	CH_3COOH	9.3±0.6	9.3±0.6
(XXXIII)	$H_2PO_4^-$	20±2	200±20

* The constant is expressed in s^{-1}.

Thus the EPR method makes it possible to determine all the kinetic parameters of the proton exchange reactions in nitroxy-radicals. However, this method is significantly limited, since it is applicable only to reactions in radicals with $pK \simeq 3$ and $pK \simeq 11$.

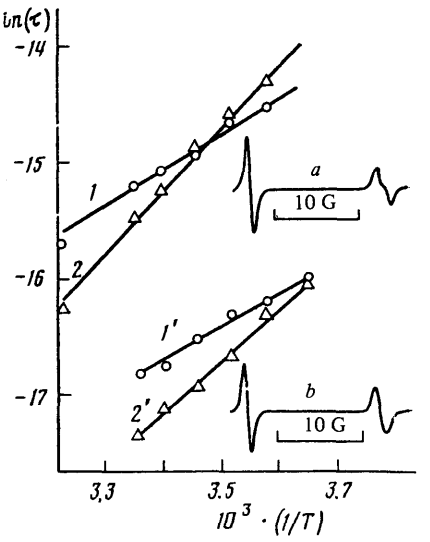

Figure 3. EPR spectra of 5×10^{-5} M solutions of the radical (XL) (the central and high-field components) at 278 K in D_2O (*a*) and H_2O (*b*); temperature variation of the lifetimes τ_R (line *1*) and τ_{RD^+} (line *2*) in D_2O and τ_R (line *1'*) and τ_{RH^+} (line *2'*) in H_2O.[74]

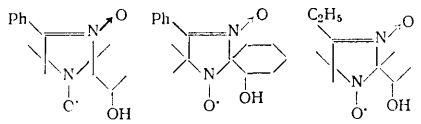
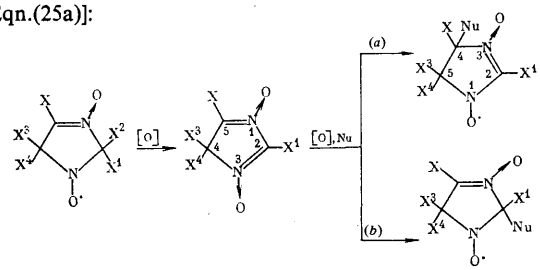


The methodological approach permitting an increase in the rate of the $\dot{R} \rightleftarrows \dot{R}H^+$ exchange without raising the temperature is therefore very useful for stable nitroxy-radicals.[73,74] Previously[30,31] this approach was realised for short-lived radicals by adding to the aqueous solution a buffer with pK_{buf} close to the pK of the radical, as a result of which reaction (7b) becomes the principal exchange mechanism. The influence of the buffer concentration on the rate of exchange has been investigated[73,74] for a series of pH-sensitive stable NR with $3 < pK < 11$, where a slow exchange is observed in the absence of a buffer. An increase in the buffer concentration led to spectral changes characteristic of the transition from the slow to the intermediate exchange and then to rapid exchange (Fig.4). In the region of the intermediate exchange, the lifetimes of the radicals τ_R and τ_{RH^+} and the corresponding rate constants k_f and k_r were calculated by modelling the EPR spectra (Table 3). Table 3 presents the rate constants for the forward and reverse proton exchange reactions of certain radicals with different partners. A correlation has been observed between the bimolecular protonation constant and the steric accessibility of the N(3) atom: in the exchange with a solvated proton in the radicals (XL) and (XXX), which have similar pK, the protonation constant is more than an order of magnitude smaller for the radical (XXX), which has the bulky CH_3 group at the N(3) atom; the replacement of the hydrogen atom at the N(3) atom in the radical (XLVI) by the CH_3 group [in the radical (XXXI)] also leads to a significant decrease in the bimolecular protonation constant in the proton exchange reaction with an acetic acid molecule.

Thus the EPR method is extremely effective in the study of the kinetics and thermodynamics of proton exchange reactions in solutions. The presence of an unpaired electron in the radical does not influence the rate of the chemical proton transfer reaction and makes it possible to follow it by EPR, which creates the possibility of using the proton exchange reactions in NR as model processes in

the study of various factors (the structure of the radical and the properties of the solvent) influencing the proton transfer. It is important to note that the organic chemistry of NR has been well developed and ensures the availability of different NR.[18,22]

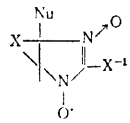


4. Proton Exchange in Nitronylnitroxy- and Iminonitroxy-radicals

(a) The transformations of 3-imidazoline 3-oxide nitroxy-radicals into nitronylnitroxy-radicals as a consequence of a change in pH. In the study of the influence of pH on the EPR spectra of stable 3-imidazoline 3-oxide radicals (LIV)–(LVI) with a hydroxyalkyl group in the 2-position in the heterocycle, it was observed unexpectedly[77,78] that at pH > 12 the spectra of aqueous solutions of these radicals are transformed irreversibly into more complex multiplet spectra typical of NNR:[46,79]

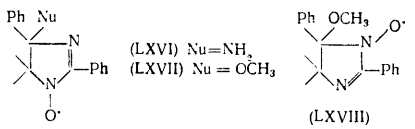
(LIV) (LV) (LVI)

It has been shown[77,78] that in this case the 3-imidazoline 3-oxide NR are indeed converted into NNR in accordance with a general scheme involving the intermediate formation of 4*H*-imidazole *N*-oxides [Eqn.(25a)]:



(25)

This reaction leads to extensive possibilities for the synthesis of new NNR; here it is possible to vary both the substituents X–X[4] and the nucleophile Nu (Nu = OH^-, OCH_3^-, NH_3, etc.) as a function of the reaction medium.



According to Eqn.(25b), nucleophilic attack can be directed not only to the 5-position in 4*H*-imidazole di-*N*-oxide, with formation of a NNR, but also to the 2-position, with formation of new 3-imidazoline 3-oxide NR.

By reducing with triphenylphosphine the NNR obtained by reaction (25a),[46] a series of new 3-imidazoline 3-oxide NR with a substituent (Nu) other than an alkyl substituent at C(2) (Nu = OCH_3 or NH_2) as well as INR have been obtained.[78,80]

Table 4 presents the parameters of the EPR spectra of a series of NNR and INR obtained in accordance with Scheme (25).

	(LXVII)	(LXVIII)	(LIX)	(LX)	(LXI)	(LXII)	(LXIII)	(LXIV)	(LXV)
Nu	OH	OH	OH	OH	NH_2	NH_2	OCH_3	OCH_3	OCH_3
X	Ph	Ph	Ph	C_2H_5	Ph	Ph	Ph	Ph	Ph
X^1	CH_3	$(CH_2)_4CHO$	Ph	CH_3	$(CH_2)_4CONH_2$	Ph	CH_3	$(CH_2)_4COOCH_3$	Ph

(LXVI) Nu=NH_2
(LXVII) Nu = OCH_3

(LXVIII)

Comparison of the HFI constants for the NNR (LVII) and (LVIII) with the corresponding values for radicals enriched in the ^{15}N isotope at N(3) made it possible to assign unambiguously the "nitrogen" HFI constants to the nuclei of the N(1) and N(3) atoms (Table 4).

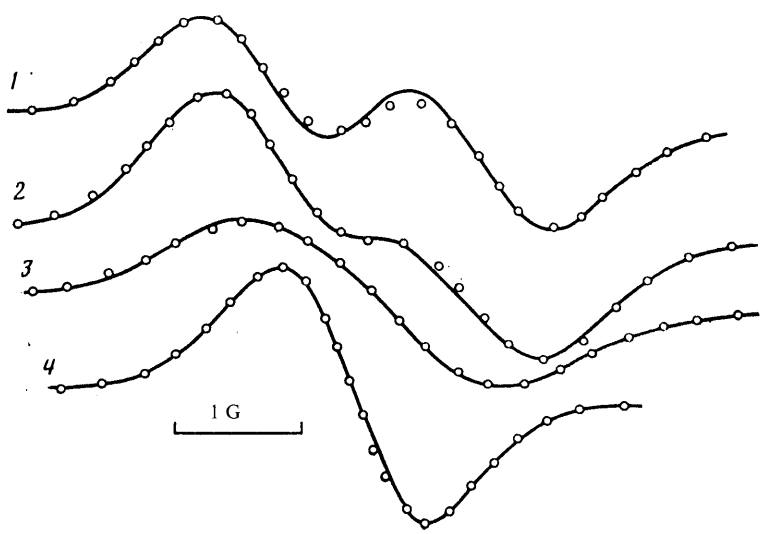


Figure 4. The high-field component of the calculated (circles) and observed (continuous lines) EPR spectra of a 5×10^{-5} M solution of the radical (XLVI) in the potassium acetate buffer (pH 4.35) at 294 K and different buffer concentrations (M): 1) 0; 2) 2.27×10^{-2}; 3) 5.76×10^{-2}; 4) 0.28.[74]

(b) The influence of pH on the EPR spectra of NNR and INR. Table 4 shows that the parameters of the EPR spectra of a series of NNR and INR change as the pH is varied, which has been explained by the protonation of NH_2 or the deprotonation of the OH group at the C(4) atom.[77,78] On the other hand, the EPR spectra of the NNR (LVIII)–(LXV) and the INR (LXVII) and (LXVIII), in the structure of which there are no such groups at C(4) capable of being protonated, did not change in the pH range 1–13.

The EPR spectra of the NNR (LVII)–(LX) in the pH range close to the pK represent a superposition of the spectra of the radicals and the deprotonated form; here p$K \simeq 9.2$ for the OH group in the radicals (LVII)–(LX).[78]

Table 4. The HFI* constants for a series of NNR and INR in H_2O (in gauss).[77,78]

*The accuracy of the determination of the constants is to within 0.05 G.

The radicals (LXVII)* and (LXVIII) are the radicals (LXVII) and (LXVIII) respectively enriched in the ^{15}N isotope at N(3).

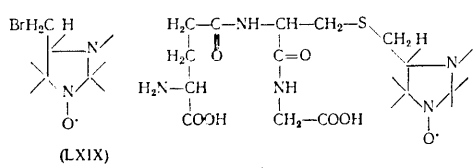
The lines in the EPR spectra of the NNR (LXI)–(LXII) initially broaden as the acidity of the medium increases to pH < 3 and beyond and are then split into three components with the intensity ratios 1 : 1 : 1.[78] The observed spectral changes have been explained by the rapid proton exchange in the given radicals and also by the significant increase in the constant for the HFI with the nitrogen nucleus of the NH_2 group when the latter is protonated. Since the relaxation time of the nuclear spin of nitrogen is high compared with the EPR time scale, in describing the experimental spectrum one may assume that proton exchange takes place between the $\dot{R}$ and $\dot{R}H^+$ forms of the radical with the same projection of the nuclear spin of nitrogen S_z^N. Thus, if the resonance frequencies of the $\dot{R}$ and $\dot{R}H^+$ forms of the radical are the same and equal to ω_0, then three lines for the following frequencies are observed in the EPR spectrum:

$$\bar{\omega}(S_z^N = 0, \pm 1) = (\omega_0 + S_z^N\delta_0)(1-f) + (\omega_0 + S_z^N\delta_+)f,$$

where f is the fraction of the $\dot{R}H^+$ form of the radical, δ_0 the HFI constant for the nitrogen of the NH_2 group, and δ_+ the HFI constant for the nitrogen of the NH_3^+ group. By modelling the central component of the EPR spectra of the radicals (LXI) and (LXII), the values of f at different pH were determined[78] and pK = 1.75 for the NH_2 group in these radicals was found.

The values p$K \simeq 9.2$ for the OH group in the radicals (LVII) to (LX) and p$K \simeq 1.75$ for the NH_2 group in the radicals (LXI) and (LXII) are smaller by approximately seven units than the pK of the corresponding aliphatic alcohols and amines,[81] which indicates a strong electron-accepting influence of the nitronylnitroxy-group. In conformity with this finding, deuterium exchange involving the methyl or methylene groups in the radicals (LVII) and (LVIII) is observed at pD $\gtrsim$ 12 in D_2O.[78]

It is essential to note that the character of the $\dot{R} \rightleftarrows \dot{R}H^+$ exchange in the NNR and INR investigated[77,78] is described by condition (22): in the radicals (LXI) and (LXII) with p$K \simeq 1.75$, the exchange is rapid, while in the radical (LXVI) with pK = 4.5 and in the radicals (LVII)–(LX) with p$K \simeq 9.2$ it is slow.



V. THE USE OF NITROXY-RADICALS AS pH PROBES

It follows from the preceding Sections that there are at present pH-sensitive NR which can be used as pH probes in the pH range 0–14. The measurement is then accurate to within 0.05 of a pH unit. This is especially important for biological systems including cell systems.[82,83]

1. Spin-labelled pH-Sensitive Proteins and Peptides

The spin-labelled pH-sensitive derivatives of the peptide hormone angiotension have been used[84,85] to study the conformational transitions and intramolecular interactions in the given octapeptide as a function of pH. The pH dependence of the EPR spectra of radical analogues of angiotensin containing NNR instead of the imidazole ring of histidine [similarly to the radical analogues of histidine (XXIII) and (XXIV)] has been investigated.[84] The observed spectral changes permitted the conclusion that an ion–dipole interaction takes place between the carboxylate ion and the C-end of the octapeptide and the nitronylnitroxy-ring. Such ion–dipole interaction promotes the stabilisation of the "loosened" structure of the hormone at neutral pH and its absence on protonation of the carboxy-group in an acid medium leads to a more compact "random" structure of angiotensin.[84] The above conformational transition has been recorded[85] from the change in the EPR spectra of the spin-labelled analogues of angiotensin, which the pH-sensitive radical (VI) was attached to the N-end, as a function of pH. It was concluded that the conformational transition is accompanied by the protonation of the amino-group at the N-end of the octapeptide.

When glutathione was modified by the radical (LXIX), a pH-sensitive spin analogue of the given tripeptide R-Glut was obtained:[63]

(LXIX) (*R*-Glut)

The parameters of the EPR spectrum of R-Glut in the pH range 1.5–4.5 varied to a much greater extent (Δa_N = 1.2 G, $\Delta g \simeq 0.0002$) than for the radical analogues of angiotensin ($\Delta a_N \lesssim 0.3$ G, $\Delta g \lesssim 0.0001$). This made it possible to use R-Glut as the pH-probe in the

study of the mechanism of proton transport through model biomembranes.[86,87]

We may note that the alkylating radical (LXIX) is capable of binding covalently to different functional groups of the aminoacid residues of proteins (SH, NH_2, NH [88]) with formation of macromolecular pH probes. In the solution of many biological problems, the possibilities involving the application of macromolecular spin pH probes are much greater than for the low-molecular-weight probes. A macromolecular probe of this kind has been obtained by modifying protein—human serum albumin—by the radical (LXIX).[61] The changes in the spectral parameters of the spin-labelled albumin in the pH range 1.7—4.7 (Δa_N = 1.15 G, $\Delta g \simeq 0.0002$) are due to the protonation of the N(3) atom of the radical ring and are not associated with the possible conformational transformations of the protein.

2. Proton Transport Through Model Phospholipid Membranes

Proton transport plays an important role in the regulation of a number of cell functions,[82,89] which has stimulated numerous investigations of the mechanisms of the transmembrane proton transfer.[90–100] In the study of proton transfer, through phospholipid vesicles, molecular pH probes are widely used; in most cases this is based on the possibility of inserting them into the inner volume within the vesicles (liposomes) and of recording with their aid the pH within the liposome (pH_{in}).[99,100] The change in the characteristics of the pH probe (fluorescence intensity,[99] the chemical shift of the ^{31}P NMR signal[100]) after a transmembrane pH gradient has been established makes it possible to measure the kinetics of the variation of pH_{in} and thus the proton fluxes across the membrane.

A spin pH probe (R-Glut) has been used to record the kinetics of the variation of the intraliposomal pH.[63,86,87] It was shown that R-Glut does not flow out of the inner volume within phosphatidylcholine (PC) monolamellar liposomes. When the pH in 0.1 M potassium citrate buffer is altered, a shift in the lines of the triplet EPR spectra of the R-Glut radical is observed without change in the line shape (rapid $\dot{R} \rightleftarrows \dot{R}H^+$ exchange); the high-field component then shifts to the greatest extent. For this reason, the intensity of the R-Glut spectrum at the frequency $\omega(pK)$ corresponding to the centre of the high-field component at pH = pK = 3.0 is a convenient parameter for the investigation of the kinetics of the variation of pH_{in}.

When a transmembrane pH gradient was created by altering the HCl concentration in the external volume relative to the PC liposomes, a change in the intensity $I(t)$ of the EPR spectrum of R-Glut was observed at a frequency $\omega(pK)$; when the sign of the HCl gradient was changed and its magnitude was reduced, the sign of the change in $I(t)$ was altered and its rate was diminished[63] (Fig.5). By analysing the initial section of the $I(t)$ kinetic curve, the derivative $(dI/dt)_{t=0}$ was determined, its value permitting the calculation of the proton flux j_{H^+} through a unit surface of the membrane in the initial instant after the pH gradient has been established. Table 5 presents the values of j_{H^+} following the creation of the same transmembrane pH gradient by varying the concentrations of different acids in the external volume relative to PC liposomes. The constancy of the EPR signal (over a period of ~2 h) in the case of the H_2SO_4 gradient in 0.1 M potassium citrate buffer shows that the electrically non-compensated proton transport, the K^+-dependent proton transport, and the transport of H^+ in the form of an undissociated citric acid molecule are slow processes and that their contribution to the observed $I(t)$ relations in the presence of HCl, $HClO_4$, and HNO_3 concentration gradients may be disregarded. The changes in $I(t)$ in the cases indicated are therefore determined by the anion- or X^--dependent transport of H^+ (X^- = Cl^-, ClO_4^-, or NO_3^-) or(and) the transport of protons in the form of the undissociated acid HX. Table 5 shows that the proton flux, calculated from the $I(t)$ relation, increases after an H^+ gradient has been established with the aid of acids having a high pK value (in the series $HClO_4$, HCl, and HNO_3, the pK are respectively –8, –7, and –1.62 [81]). This fact permits the conclusion that protons are transported in an acid medium in the form of the undissociated acid HX; this has been confirmed by the absence of an effect on j_{H^+} of the surface charge of the membrane, varied by adding the negatively charged phosphatidic acid or the positively charged 3-cetyl(methyl)ammonium bromide, while the addition of cholesterol diminishes j_{H^+} significantly. It is noteworthy that, according to the data of Nichols and Deamer,[90] approximately the same changes in the surface charge of the PC membrane of liposomes led to a significant alteration of the overall permeability coefficient of the membrane for protons and hydroxide ions (by a factor of 3—4). The conclusion that protons are transported through PC membranes of liposomes in the region of pH ~ 3 in the form of the undissociated acid did in fact make it possible to calculate the permeability coefficients P_{HX} for HCl, $HClO_4$, and HNO_3 (only the upper limit was estimated for H_2SO_4) (Table 5). The values of P_{HCl} and P_{HNO_3} obtained by the EPR method are close to those measured[92] on planar lipid membranes ($P_{HCl} \simeq$ 3 cm s^{-1}, $P_{HNO_3} \simeq 10^{-3}$ cm s^{-1}); proton transport through the membrane was also not recorded[92] for H_2SO_4.

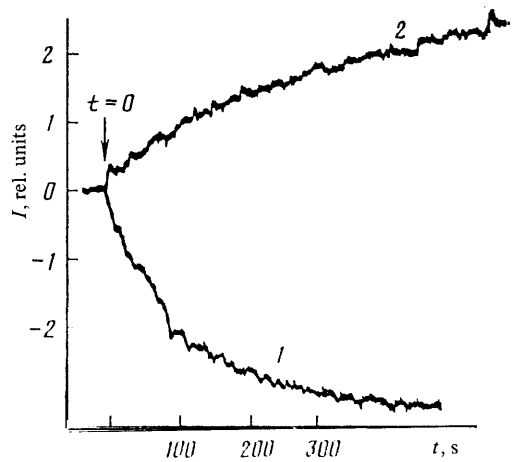


Figure 5. Time variation of the amplitude of the EPR spectrum of the R-Glut radical at the frequency $\omega(pK)$ after the establishment of a transmembrane HCl gradient:[63] 1) pH outside liposomes pH_{out} = 1.63, pH_{in} = 3.13; 2) pH_{out} = 4.63, pH_{in} = 3.13.

A new method for the investigation of the kinetics of proton transport through biomembranes, proposed in a number of studies,[63,86,87] can be extended to the region of neutral and alkaline

pH, since spin probes pH-sensitive in the given regions are now known.

Table 5. Proton fluxes j_{H^+} through the membrane of PC liposomes immediately after the establishment of a transmembrane pH gradient (pH_{out} = 1.63; pH_{in} = 3.13) using various acids and the permeability coefficients P_{HX} of the membrane for these acids.[63,86,87]

Acid	$HClO_4$	HCl	HNO_3	H_2SO_4
j_{H^+}, mol cm litre^{-1} s^{-1}	$2\cdot10^{-10}$	$1.8\cdot10^{-9}$	$3\cdot10^{-8}$	$\lesssim10^{-12}$
P_{HX}, cm s^{-1}	2.2 ± 1	2 ± 1	$(1.4\pm0.7)\cdot10^{-4}$	$\lesssim10^{-7}$

As can be seen from the above discussion, the use of stable NR sensitive to pH makes it possible to obtain quantitative information about the thermodynamic and kinetic characteristics of the very simple proton transfer reaction. Major advances in the organic chemistry of stable radicals[18,101,102] have led to the possibility of a detailed investigation of the influence of steric factors, electron-donating and electron-accepting substituents, and the solvents on the characteristics of the proton transport. Unique experimental possibilities for the study of isotope effects have been created by the application of the EPR method in such systems, including systems in non-aqueous solvents in the absence of solvation effects.

The use of pH-sensitive NR as pH probes in chemical and biological systems is extremely promising. The possibility of introducing hydrophobic and hydrophilic groups into the NR permits their use for the determination of pH within microheterogeneous regions. The determination of pH within cells and certain cell structures, for example, liposomes, is of special interest. Measurement of the rate of proton transport through natural membranes by EPR may prove useful in the solution of many problems in bioenergetics.

NMR Spectroscopy of Polyfluorinated Allyl Cations

V.I.Bakhmutov and M.V.Galakhov

The results of the NMR study of the hydrocarbon allyl cations are briefly surveyed. The ^{13}C and ^{19}F NMR spectra of polyfluorinated cyclic and acyclic allyl cations are considered and the spectral features of their formation in solutions are discussed. The influence of substituents and of the positive charge on the chemical shifts and the spin-spin coupling constants $^1J(^{13}C-^{19}F)$ and $^4J(^{19}F-^{19}F)$ of polyfluorinated allyl cations are considered. NMR data are presented on the relative stabilities of polyfluorinated allyl cations.
The bibliography includes 85 references.

I. INTRODUCTION

The study of the structures, thermodynamic stabilities, and reactivities of carbenium ions remains one of the most rapidly developing fields in modern organic chemistry of current interest. Since the publication of the first studies by Olah (see, for example, Ref.1), already regarded as classical, which have laid the foundations of this field and have made an appreciable contribution to its development, an enormous amount of data has accumulated in the world literature on carbonium ions with the most varied structures and on their properties, spectroscopic characteristics, and reactivities.[2] The ^1H and ^{13}C NMR spectroscopy has played a decisive role in the establishment and development of the chemistry of carbenium ions. The results obtained by this method have in essence led to the formulation of new fundamental concepts in the theory of the chemical bond. On the other hand, the experimental difficulties in the detection and investigation of charged organic species have exerted a certain influence on the improvement of the NMR experimental technique and on the search for increasingly new features relating the spectroscopic and structural characteristics of organic molecules.[3,4]

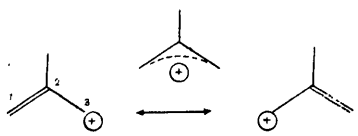
Studies on cations of the allyl type have made a major contribution to the formulation of the fundamental ideas in the chemistry of carbenium ions. The ^1H NMR spectra of allyl and 2-methylallyl cations, published in 1964,[5] induced an avalanche-like development of this field, which is indicated by hundreds of publications devoted to the investigation of the structures of positively charged allyl system (see, for example, Refs.6-11). However, until very recently there was virtually no information in the world literature about the polyfluorinated allyl cations, which have been merely postulated as intermediate species in electrophilic alkenylation reactions of fluoroolefins in the presence of Lewis acids.[12-14]

The theoretical interest in polyfluorinated allyl cations can be accounted for also by the following factors. The direct observation of α-fluoro-αα-diphenyl- and αα-difluoro-α-phenyl-methyl cations by ^{19}F NMR[8,11] has made it possible to put forward the concept of the ability of the fluorene atom to stabilise the positive charge localised on a neighbouring carbon atom. However, this concept, which has been convincingly justified experimentally in relation to cations of the alkyl type, for a long time clearly conflicted with the unsuccessful attempts to obtain perfluorinated allyl cations by treating perfluoropropene[8,14] and perfluorocyclobutene[14,15] with antimony pentafluoride. The perchlorinated allyl cation has been isolated in the form of the solid salt $C_3Cl_5AlCl_4$,[16] which in fact suggested that fluorine exerts an influence which is the opposite of that of chlorine, namely a destabilising influence in the case of allyl systems.[17] At the same time, the introduction of markedly electron-donating groups in the 1-position in perfluoroisobutene and perfluoropropene makes it possible to obtain smoothly the corresponding cations:[14,18]

Scheme 1

(Ib) (IIb)

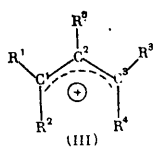
The present review, which is based on the literature of the last five years, is in fact devoted to the resolution of the uncertainties which have thus arisen.



The main method for the investigation of carbonium ions and carbanions is known to be NMR spectroscopy, which makes it possible not only to detect the appearance of a charged centre in the molecule but also to investigate in detail the structural features of the species formed. This is based on the comparatively simple relations found at the present time between the spectroscopic and structural parameters of organic molecules.[3,4] On the other hand, in the case of the ^{19}F and ^{13}C NMR of organofluorine compounds,[19,20] the problem of spectroscopic-structural relations is still far from being resolved. The present review therefore also has a methodological purpose—to survey the characteristic features of the NMR spectra of polyfluorinated allyl cations.

II. NMR SPECTRA AND CHARGE DISTRIBUTION IN HYDROCARBON ALLYL CATIONS

Before discussing polyfluorinated allyl cations, it is useful to consider briefly data on the hydrocarbon allyl cations, demonstrating the possibilities of NMR spectroscopy in the study of the structures of such species in solutions.



According to the current classification,[11] allyl cations can be regarded as cations of the classical type with the localisation of the positive charge on the terminal carbon atoms,[21,22] as shown in Scheme 2, from which the difference between the terminal and central atoms evidently follows:

Scheme 2

Accordingly, the analysis of the ^{13}C NMR spectra of a large number of acyclic cations having the general formula (III), presented in Scheme 3,[23,24,26–28] shows that the transition from the precursors (olefins) to cations is accompanied by appreciable downfield shifts (up to 100 p.p.m.) of the ^{13}C signals in the 1- and 3- positions so that the C(1, 3) chemical shifts δ are always significantly greater than the shifts δ for the C(2) nuclei in the same cation:

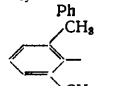
Scheme 3

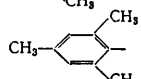
(III)

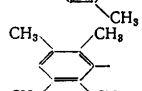
R^{1-5}=H [5]; R^{1-4}=H, R^5=CH_3 [5];
$R^{1,3,5}$ = H, $R^{2,4}$ = CH_3 [23, 24]; $R^{1,3,5}$ = CH_3, $R^{2,4}$ = H [24]
$R^{1,3,5}$ = H, $R^{2,4}$ = cyclopropyl [23]
$R^{1,2}$ = CH_3, R^{3-5} = H [23]; R^{1-3} = CH_3, $R^{4,5}$ = H [27]
$R^{1,3}$ = Ph, $R^{2,4,5}$ = H [23]
R^{1-4} = CH_3, R^5 = H [24]; R^{1-5} = CH_3 [24]
R^{1-3} = CH_3, $R^{2,4}$ = H, R^5 = Ph [24]
$R^{1,2}$ = CH_3, $R^{4,5}$ = H, R^3 = CH=C $(CH_3)_2$ [25]
R^1 = CH_3, R^{2-5} = H [26]; $R^{1,2,5}$ = CH_3, $R^{3,4}$ = H [27]
$R^{1-3,5}$ = CH_3, R^4 = H [27]

[Here and henceforth the numerals in square brackets denote references (Translator)].

Thus the relative positions of the C(1 – 3) signals in the ^{13}C NMR spectra correspond satisfactorily to the structure of the allyl cation, agree with the *ab initio* calculations of the π-electron density on the atoms of the allyl triad, and hence can be used successfully for the identification of systems of this kind in solutions. As regards the ^1H NMR spectra, in this case there is no unambiguous correspondence with the charge distribution scheme (Scheme 2).[5,25] Indeed, despite the fact that, on passing from the precursors to the cations downfield shifts of the signals are indeed observed in the ^1H NMR spectrum, there are nevertheless by no means infrequent cases where $\delta(^1H)$ for C(2) is greater than for the C(1, 3) atoms bearing a positive charge. This effect has been observed for example, for the simplest allyl cation (II) with R^{1-5} = H where $\delta(^1H)$ for C(2) is 9.64 p.p.m., whereas $\delta(^1H)$ for the terminal carbon atoms are smaller (δ = 9.0 p.p.m.).[5] Fig.1 indicates the ranges of the $\delta(^1H)$ and $\delta(^{13}C)$ for allyl cations (Scheme 3) which partly illustrates what has been said above.







The change in the nature of the substituents in allyl cations naturally leads to a redistribution of their charge density, which is also reflected in the ^{13}C NMR spectra. Thus the successive introduction of methyl groups into the allyl cation (III) has a significant influence on the positions of the signals in the ^{13}C NMR spectra in such a way that a linear relation is observed between the observed values of $\delta(^{13}C)$ and the π-charge density calculated by the *ab initio* method:[22]

$$\delta^{13}C = (433 \pm 11) - (449.5 \pm 22.2)\, q^{\pi},\ r = 0.97 \qquad (1)$$

Relations of this kind make it possible to investigate the distribution of charge density in the allyl cations[23] presented in Table 1. Evidently the shifts δ for the terminal carbon atoms are comparatively close in the case of the 1,3-disubstituted cations. On the other hand, for the 1,1-disubstituted allyl cations the difference δ[C(1)] – δ[C(3)] is large and can reach 120 p.p.m., which in fact permits the conclusion that there is a non-uniform charge distribution between the 1- and 3-atoms, namely that the charge is localised predominantly at C(1). The degree of charge localisation is then determined by the nature of the substituent and, on the basis of the values of $\delta[^{13}C(3)]$, decreases in the following sequence: cyclopropyl ≳ Ph > CH_3.[23] Indeed, in this series $\delta[^{13}C(3)]$ increases by 25 p.p.m. [we may note that in situations of this kind it is correct to compare the values of δ not for C(1) but for C(3) to which the substituent being varied is linked directly].

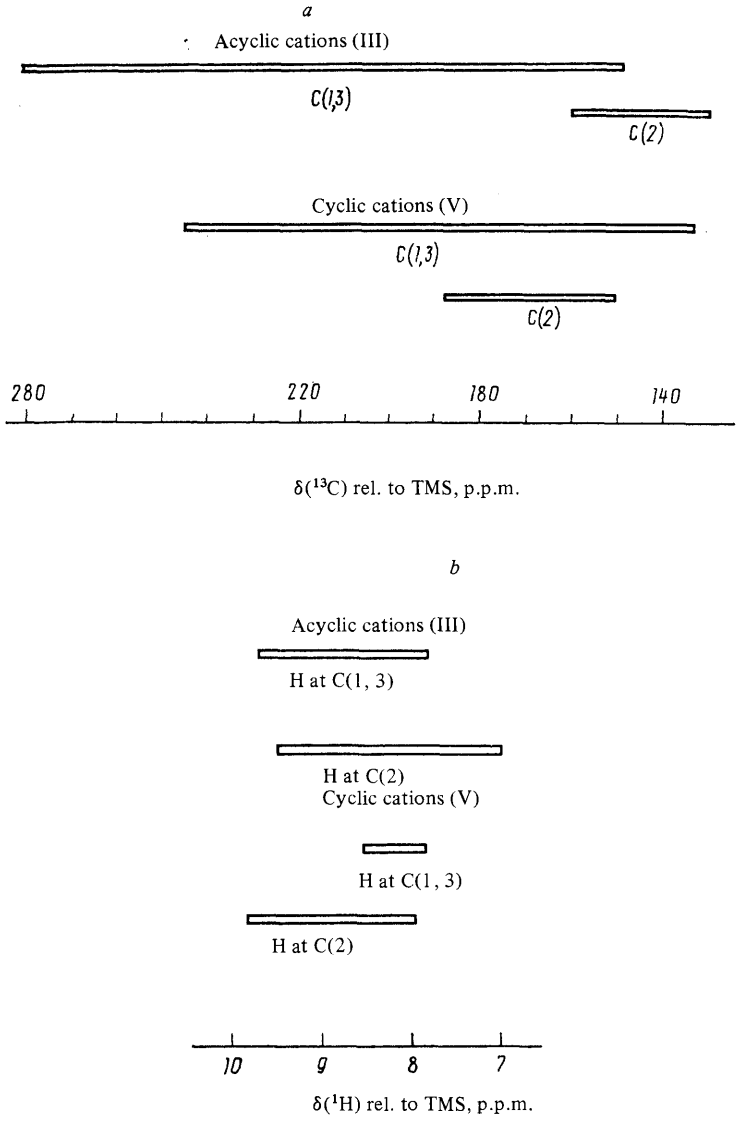
The principal mechanism of the stabilisation of the positive charge in acyclic allyl cation is *p*, π conjugation, which leads to the localisation of the charge on the ends of the allyl triad. However, when the distance between the terminal carbon atoms is shortened, direct overlap of their orbitals with increase in the resonance contribution of the structure (IV), ensuring the appearance of a positive charge on the central carbon atom (the so called 1,3-interaction[29]), becomes

possible in principle.

(IV)

From the standpoint of NMR, this method of charge stabilisation, together with the classical method, should correspond to the equalisation of the values of δ[C(1−3)] and δ(H) for the given atoms.

For this reason, 1,3-interaction as a method of charge stabilisation was initially invoked to account for the similarity of the values of $\delta(^1H)$ and δ[C(1−3)] for the simplest allyl cation,[5] which, however, was not confirmed by quantum-chemical calculations.[30] On the basis of purely geometrical considerations, 1,3-interaction may be expected for the four-membered cyclic cations (V) (Scheme 4), exhaustive information about which has been published.[31,32] Some of these data are presented in Table 2, from which it follows that a shift of the ^{13}C and ^1H signals of the C(2)−H fragment an even weaker field, compared with the signals of the C(1, 3)−H fragment,



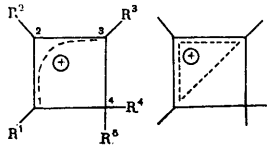


Figure 1. The scales of the ^{13}C (a) and ^1H (b) chemical shifts of hydrocarbon allyl cations.

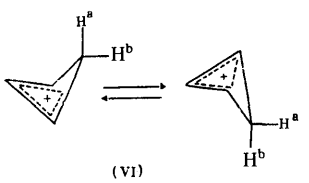
is characteristic of the compounds considered, with the exception of the last.

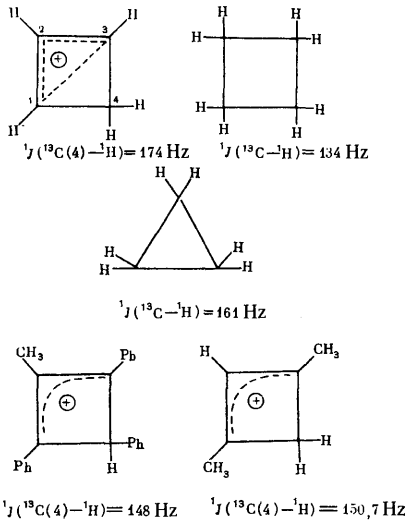


Scheme 4

(V)

$R^{1-5} = H$; $R^{1-4} = H$, $R^5 = Cl$; $R^{1-4} = H$, $R^5 = F$; $R^{2,4,5} = H$, $R^{1,3} = CH_3$;
$R^{1-4} = CH_3$, $R^5 = H$; $R^{1-4} = CH_3$, $R^5 = Cl$; $R^{1-4} = CH_3$, $R^5 = F$;
$R^{1,4} = H$, $R^{2,3} = CH_3$, $R^5 = Cl$; $R^{1,4} = H$, $R^{2,3} = CH_3$, $R^5 = F$;
$R^{1,3} = Ph$, $R^{2,4,5} = H$; $R^{1,3} = Ph$, $R^{2,4} = CH_3$, $R^5 = H$;
$R^{1-4} = Ph$, $R^5 = H$; $R^{1-4} = Ph$, $R^5 = Br$; $R^{1,4,5} = F$, $R^{2,3} = Ph$.

Thus NMR data for the first three cations suggest a distribution of their positive charge throughout the allyl system, as shown in Scheme 4. On the other hand, the introduction of methyl groups into the 1- and 3-positions in the cyclobutenyl cations alters the situation and, as can be seen from Table 2, shifts the C(1, 3) and C(2) resonance downfield and upfield respectively, thus making their spectral parameters closer to the parameters of acyclic allyl cations (Table 1). Consequently, according to NMR data, the probability of the 1,3-overlap depends on the nature of the substituents in the 1- and 3-positions and diminishes with increase in their ability to stabilise the positive charge on the α-carbon atom. Indeed, substituents such as Ph and F exhibit an analogous "spectral" activity.[31,32] Here it is essential to note that all the considerations put forward by the above workers[31,32] and described above are based on a "chemical shift–atomic charge" relation of type (I), which holds in the series of cations considered. However, the chemical shifts of the ^{13}C nucleus occupying the α-position relative to the carbon atom with sp^2 hybridisation in four-membered rings are known to be anomalously high;[33] this is due to the unique nature of the structural and orbital properties of the four-membered ring, which leads to an additional increase in the paramagnetic component of the ^{13}C shielding constant. In other words, the similarity of the values of δ for the C(1, 2, 3) nuclei or the observation of the C(2) signal in an even weaker field than for the C(1, 3) signals may be induced also by this cause and not by the uniqueness of the distribution of charge density. However, the magnetic non-equivalence of the H^a and H^b protons of the cyclobutenyl cation (VI), which is manifested in the NMR spectrum at a low temperature[31] and indicates a non-planar structure of the ring, suggests that the above conclusions[31,32] are correct.



(VI)

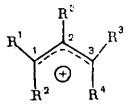
This is also indicated by the study of the dependence of $\delta(^{13}C)$ for the allyl triad in cyclic cations on the ring size,[35] which has shown that the 1,3-interaction is pronounced only in the cyclobutenyl cation and is not manifested in the ^{13}C NMR spectra of five- and six-membered structures.

In discussing the question of the 1,3-interaction, it is of interest to consider how such overlap is reflected in the spin–spin coupling constants $J(^{13}C-{}^{1}H)$, which in the case of cycloalkanes are extremely sensitive to angular deformations and increase with decrease in the ring size.[34] It is known that the constants $^{1}J(^{13}C-{}^{1}H)$ increase when a positive charge appears on the carbon atom, the increase being mainly due to the Fermi-contact contribution.[4] We shall therefore consider the values of the direct constants $J(^{13}C-{}^{1}H)$ characterising the unchanged carbon atom in the 4-position in cyclobutenyl cations and carrying information about the geometrical structure of the ring. As can be seen from Scheme 5, $^{1}J[^{13}C(4)-{}^{1}H]$ = 174 Hz for the cyclobutenyl cation and exceeds greatly the analogous constant for cyclobutane and only slightly that for cyclopropane (Scheme 5).

Scheme 5

On the other hand, the substitution of the hydrogen atoms in the 1- and 3-positions by methyl and phenyl groups increases the direct constants $J[^{13}C(4)-{}^{1}H]$, which corresponds to a decrease in the degree of 1,3-interaction.

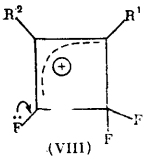
Table 2. The ^{1}H and ^{13}C chemical shifts of substituted cyclobuteyl cations (V).[31,32]



R^1	R^2	R^3	R^4	R^5	δ(^{1}H), p.p.m.				δ(^{13}C), p.p.m.			
					H (1)	H (2)	H (3)	H (4)	C (1)	C (2)	C (3)	C (4)
H	H	H	H	H	7.95	9.72	7.95	4.53	133.5	187.6	133.5	54.0
H	H	H	Cl	H	8.38	9.80	8.38	6.62	141.6	176.7	141.6	63.7
H	H	H	F	H	8.58	9.90	8.58	6.92	136.7	173.8	136.7	86.8
CH_3	H	CH_3	H	H	2.93	8.03	2.93	3.90	197.6	163.1	197.6	51.4

Thus, in conclusion of this Section of the review, one may state that NMR spectroscopy (and in the first place ^{13}C NMR) makes it possible to obtain unique and reliable information about the structure of allyl cations in solutions.

III. ^{13}C AND ^{19}F NMR SPECTROSCOPY OF POLYFLUORINATED ALLYL CATIONS



As stated above, the first attempts to obtain polyfluorinated allyl cations by treating perfluoropropene and perfluorocyclobutene with SbF_5 in SO_2 and SO_2FCl were unsuccessful[8,14,15] despite the fact that certain fluorinated cyclic and acyclic allyl cations containing electron-donating groups in the 1-position had been obtained under similar conditions and characterised by ^{19}F NMR.[13,15,18,36] However, in recent years the appliation of this methodological procedure (treatment of fluoro-olefins with SbF_5 in SO_2FCl or in the SbF_5 bulk phase) permitted the synthesis of a whole series of polyfluorinated allyl cations, including the perfluoroallyl and perfluoromethylallyl cations (the references are given in Scheme 6). Some of them proved to be stable and long-lived species even at room temperature. The negative results of the studies quoted above[8,14,15] are therefore incomprehensible. This is presumably due to the inadequate degree of purification of SbF_5 and SO_2FCl.

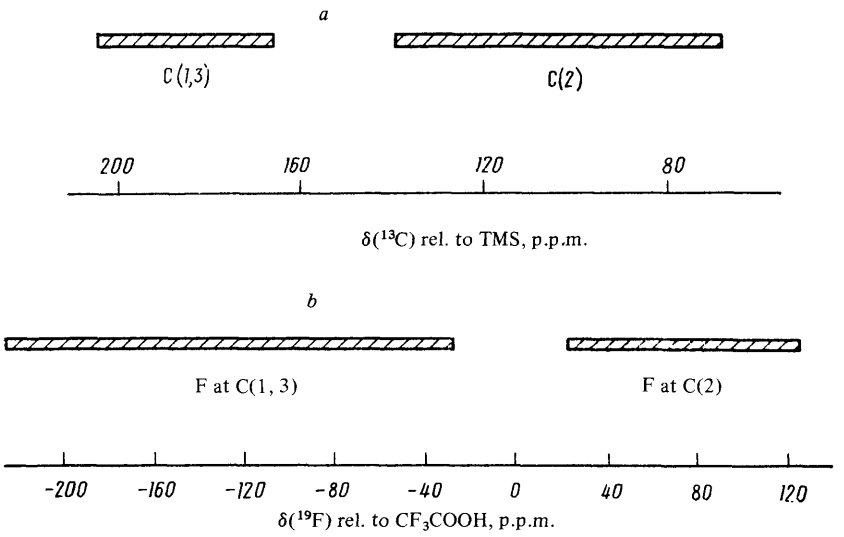
Scheme 6 presents the polyfluorinated allyl cations known at the present time and Fig.2 indicates the $\delta(^{13}C)$ and $\delta(^{19}F)$ scales characterising these species. Analysis of the spectral chraracteristics of the acyclic cations (VII) permits the following generalisations. On passing from the precursor fluoro-olefin to allyl cations, downfield shifts of the C(1) signals ($\Delta\delta$ = 20–80 p.p.m.) and C(3) signals ($\Delta\delta$ = 50–65 p.p.m.) are recorded in the ^{13}C NMR spectra with the virtual retention of the position of the C(2) signal (small changes in δ for this signal, both downfield and upfield, are observed as a function of the nature of the olefin and the cation), which indicates the localisation of the charge on the terminal fragments of the allyl system. This is also demonstrated by the very fact of the observation of the C(1, 3) signals in a weaker field than the C(2) signal (Fig.2). Analogous effects are characteristic also of the ^{19}F NMR spectra. The ^{19}F NMR spectra of the cations illustrated in Scheme 1 are an exception. For example, on passing from the olefins (IIa) to the corresponding cations (IIb), extremely small downfield shifts



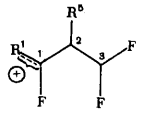


Figure 2. The scales of the ^{13}C (a) and ^{19}F (b) chemical shifts of polyfluorinated allyl cations.

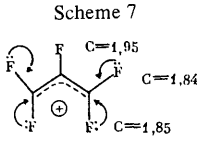
are characteristic of the ^{19}F nuclei in the 3-position, while the downfield shift of the signal of the ^{19}F nuclei at C(1) is by more than 90 p.p.m., which corresponds to the localisation of the charge on the C(1) atom in the structure (XI).[14]

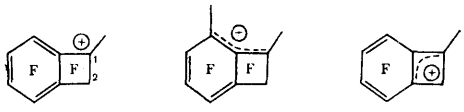


(XI)

$R^1 = p\text{-}CH_3OC_6H_4$
$R^5 = F$,
$R^1 = CH_3O$, $R^5 = CF_3$

An analogous conclusion that the positive charge is localised preferentially in the 1-position has been reached for the cation (VII), with $R^{1,3,4} = F$, $R^5 = CF_3$, and $R^1 = OCH_3$, on the basis of ^{19}F and ^{13}C NMR data.[40] In this case, on passing from the precursor to the cation, a downfield shift of the signal due to the OCH_3 group ($\Delta\delta$ = 15 p.p.m.) is observed in the ^{13}C NMR spectrum. Furthermore, this cation is characterised by a rapid rotation about the C(1)=C(2) bond, which can be retarded only at -70 °C on the ^{19}F NMR time scale (188.3 MHz).

Examination of the generalised spectral parameters presented in Figs.1 and 2 permits the conclusion that in the case of polyfluorinated allyl cations the signals of the C(1) and C(3) atoms, carrying a positive charge, are recorded in a weaker field compared with their hydrocarbon and chlorine-containing analogues.[37,39] On the other hand, the signals of the ^{19}F nuclei at the C(1, 3) atoms in fluorinated allyl cations are observed in extremely weak fields and their chemical shifts reach values down to -200 p.p.m. relative to CF_3COOH. These features of the NMR spectra of the cations (VII) have been explained by the involvement of the fluorine atoms in the delocalisation of the positive charge via the reverse suply of the *p*-electron density (Scheme 7) which has been confirmed by calculations of the charge distribution by the INDO[43] and MNDO[41,44] methods.

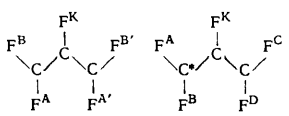


Scheme 7

We may note that, according to the *ab initio* calculation, the introduction of a fluorine atom in the 1-position in the simplest allyl cation increases its stability by 2.8 kcal mol^{-1}.[45]

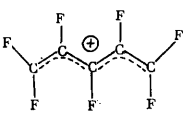
Virtually analogous changes in the ^{19}F and ^{13}C NMR spectra have been observed on passing from the initial cyclic olefins to the corresponding cations (VIII)–(X).[15,36,42] In describing the delocalisation of the positive charge in the cyclobutenyl cation (VIII) with $R^1 = OCH_3$ and $R^2 = F$,[15] 1,3-interaction was postulated on the basis of the downfield shift of the signal of the ^{19}F nucleus in the 2-position, observed on passing from the precursor to the cation. However, the study of the ^{13}C NMR spectra of the series of cyclic allyl cations (VIII)–(X), containing four-, five-, and six-membered fragments, did not confirm this hypothesis. It was shown that the C(2) signal for such cations is located at stronger fields compared with the C(1, 3) signals and that the difference between their chemical shifts $\delta[C(1, 3)] - \delta[C(2)]$ is 36–63 p.p.m.[42]

Thus experimental and theoretical data have accumulated in recent years which has made it possible not only to provide a firm answer to the previously controversial question of the existence of polyfluorinated allyl cations as kinetically independent species but also to represent the distribution of their positive charge. Unfortunately, there is as yet no information in the literature about the perfluorocyclobutenyl cation.[14,15] Its only and purely speculative analogue is the perfluorobenzocyclobutenyl cation (XII), which has been detected by ^{19}F NMR[46] and to which the authors have attributed the structure of the carbenium ion (XIIa) on the basis of the large shift of the ^{19}F resonance at C(1), observed on passing from the precursor to the cation ($\Delta\delta$ = 145 p.p.m.).



(a) (b)

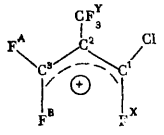
(XIII)



1. Characteristic Features of the ^{19}F and ^{13}C NMR Spectra of Polyfluorinated Acyclic Allyl Cations

The ^{19}F NMR spectra of organofluorine compounds are characterised by high values of *J*, which reach hundreds of Hz units.[19,47] Precisely for this reason, situations frequently arise where the differences between the chemical shifts $\Delta\nu$ become comparable to the spin–spin coupling constants ($J/\Delta\nu \geqslant 0.1$), which leads to the appearance of the NMR spectra of strongly bound spin systems,[48] in which the differences of the absorption frequencies of the spectral lines do not correspond to the real values of *J*. Hence it follows that, in order to obtain the true values of δ and *J* and hence in order to identify the structure, the complete quantum-mechanical calculation of such structures is necessary.[49] We shall explain this in relation to several examples. It has been noted[37] that, after the addition of SbF_5 to perfluoropropene, complex multiplets appear in the ^{19}F NMR spectrum in the -89 – -100 and +117 p.p.m. regions (relative to CF_3COOH), which were later identified[39] as the spectrum of a five-spin system of the type AA'BB'K (Scheme 8), which in fact makes it now possible to make the unambiguous claim that the perfluoroallyl cation is formed in the given mixture.

Scheme 8



Similarly the agreement between the theoretical spectrum of the seven-spin system, containing more than 140 bands, with the experimental spectrum demonstrates the formation of the perfluoropentadienyl cation which exists in solution in the form of the *s-trans*, *s-trans*-isomer (XIII):

(XII)

This is also confirmed by quantum-chemical calculations by the MNDO method,[41] according to which the *s-trans*, *s-trans*-structure is

energetically more favourable. The ^{19}F NMR spectrum of the *cis-isomer* of the 1-chloro-2-trifluoromethylallyl cation (XIV) is of interest as regards the complexity of the interpretation.

(XIV)

Thus, in the −144 p.p.m. region, it is possible to observe six signals in the above spectrum (Fig.3), each of which is split into a quartet with a non-equidistant disposition of lines. Calculation of the spectrum[40] permitted the classification of the given multiplet as the X-component of the $ABXY_3$ system and made it possible to obtain the true spin−spin coupling constants and hence to identify the cation investigated. Thus the principal feature of the ^{19}F NMR spectra of acyclic fluorinated allyl cations is their complex character. The ^{13}C NMR spectra of these cations are also complex, especially in the case of the symmetrical 2-substituted structures (VII) with R^{1-4} = F.[38,39] We shall illustrate this in relation to the perfluoroallyl cation as an example (Scheme 8). It was stated above that the ^{19}F NMR spectrum of this cation corresponds to the AA'BB'K spin system and is therefore rigorously symmetrical. On the other hand, on passing to ^{13}C NMR, the spectrum loses symmetry and is calculated as the X-component of another spin system, namely ABCDKX (Scheme 8).[39] Such a change in the type of spin system formed by the ^{19}F nuclei, is due to the specific features of the recording of the ^{13}C spectra, namely the isotopic shift on passing from ^{12}C to ^{13}C [50-52] and the associated loss of symmetry by the molecule. The isotopic shift of the signals due to the fluorine nuclei in all the 2-substituted analogues of the perfluoroallyl cation is 0.11 p.p.m.[39] In conclusion, we may note yet again that, despite the by no means simple procedure used to calculate the ^{13}C and ^{19}F NMR spectra of fluorinated allyl cations, requiring a certain amount of time, this approach is absolutely essential both for the establishment of the fact of their formation in solutions and in order to obtain accurate values of their spectral characteristics, including the signs of the constants J, whose knowledge permits the investigation of the relations between the spectral and structural parameters. Some of these relations are described below.

2. The "^{13}C Chemical Shift−Atomic Charge" Relation for Polyfluorinated Allyl Cations and Olefins as an Example

One of the central questions in NMR spectroscopy is the relation between the values of δ and the electron distribution in the molecules. According to Saika and Sliehter,[53] the shielding constants of the magnetically active nucleus can be represented by the sum of three terms [Eqn.(2)]:

$$\sigma=\sigma_d+\sigma_p+\sigma_a \ , \qquad (2)$$

where σ_d is the diamagnetic contribution, σ_p the paramagnetic contribution, and σ_a represeents the sum of the shielding constants due to the magnetic anisotropy of the bond, the influence of the solvent, etc. The ideas concerning the shielding constant of the ^{13}C nuclei[54-56] permit the assumption that in this case the paramagnetic contribution plays a decisive role. It is expressed by the simplified equation[56]

$$\sigma_p=(-e^2h/2m^2c^2\Delta E)\langle r^{-3}\rangle(Q_{AA}+\Sigma Q_{AB}) \ , \qquad (3)$$

where e, h, m, and c are known constants, ΔE is the average excitation energy, r is the distance between the nucleus and the $2p$ electrons, and Q_{AA} and Q_{AB} are elements of the "charge density/bond order" matrix. The first report of the observation of a correlation between the experimental values of $\delta(^{13}C)$ and the charge q' [Eqn.(4)] appeared after the comparison of the ^{13}C NMR spectra of aromatic molecules with the π-charge density calculated by the Hückel

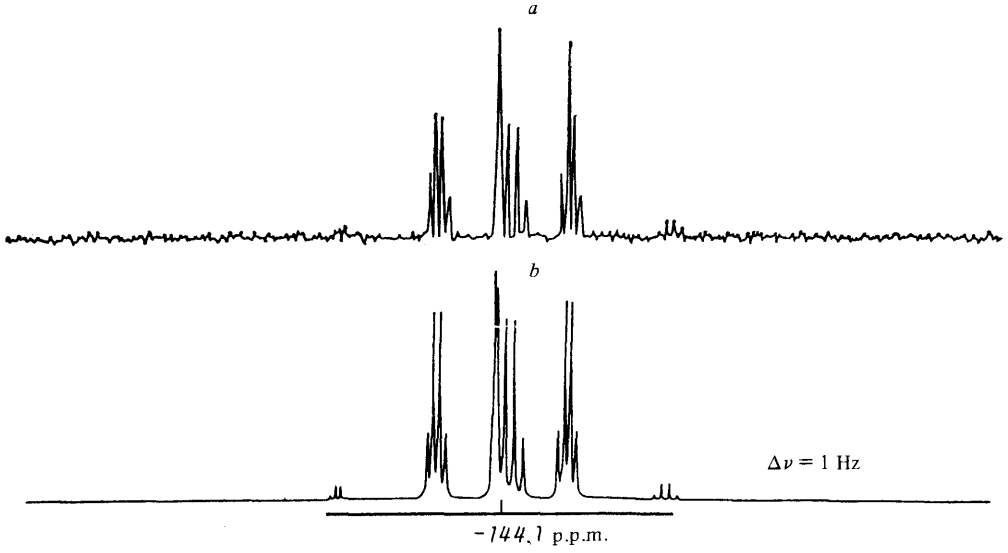


Figure 3. The experimental (a) and theoretical (b) spectra of the X-component of the type $ABXY_3$ spin system of the cation (XIV).[40]

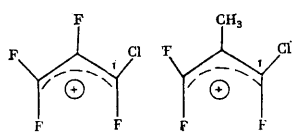
method:[57]



$$\delta^{13}C = A q^t + B$$
$$A = 160 \text{ p.p.m./electron.} \quad (4)$$

The above linear relation can be explained by the fact that the main charge-dependent term in Eqn.(3) is $<r^{-3}>$ (ΔE and Q remain constant on passing from one compound to another); this is confirmed by calculations of the atomic charges and the parameter r for a large number of organic compounds.[58,59] Among studies published later, devoted to the investigation of the "^{13}C chemical shifts – atomic charge" relation (see, for example, Refs.59–63), the study of Baumann and Olsen[59] in which this relation was analysed for 20 organic compounds (50 values of δ), including aromatic cations and anions, is of special interest in our view. The results obtained showed that (1) the coefficient A in Eqn.(4) depends on the LCAO-MO method used for the calculation, (2) that the change in the character of the chemical bond and in geomtetry on passing from one compound to another precludes the description of the "δ(^{13}C) – charge" relation by simple linear equations of the type of Eqn.(4) as a consequence of the change in Eqn.(3) of not only r but also of other parameters, and (3) in the analysis of the relation of the "δ(^{13}C) – charge" type it is essential to take into account also the diamagnetic component of the shielding constant. Summarising the foregoing, one may conclude that it is completely obscure in what way the simplified but nevertheless still complex Eqn.(3) frequently reduces in practice to simple equations of type (4). Nevertheless, this has been established for many classes of organic compounds and it has even been suggested that relations of this type be used for the computer analysis of ^{13}C NMR spectra.[64]

In the study quoted above,[59] a deviation of fluorine-containing compounds from the so called "δ(^{13}C) – charge" correlations was reported. This concerns, for example, δ[C(1)] for the 1-fluorobenzocyclopropyl cation. On the other hand, it has been shown that, on passing from fluorinated olefins to the corresponding allyl cations (VII), downfield shifts of the C(1, 3) resonance are observed in the ^{13}C NMR spectra[38,39] and, conversely, on formation of carbanions from fluorinated cycloalkenes, upfield shifts, reaching 70 p.p.m., are characteristic of the carbon atom carrying the negative charge.[65] Thus there are grounds for seeking correlations of type (IV) also in the case of organofluorine compounds. The geometries and charge density distributions in polyfluorinated olefins and acyclic allyl cations have been calculated[41,44,66] by the LCAO-MO MNDO method. This made it possible to analyse[67] 27 values of δ(^{13}C) as a function of the overall atomic charge of the sp^2-hybridised carbon atom q^t and to observe the linear relation

$$\delta_{^{13}C} = (84.2 \pm 7.5) q^t + (124.4 \pm 3.8), \; r = 0.93 \; , \quad (5)$$

which can be used to estimate the atomic charges from ^{13}C NMR spectra. The values of δ for the ^{13}C(1) nuclei in the cations (XV), i.e. for the atoms which are linked directly to the substituent, in the given instance to the Cl atom, deviate from the given correlation to the greatest extent.

cis-, trans- *cis-, trans-*

(XV)

Indeed, on passing from perfluorinated analogues to the cations (XV), the positive charge on the G(1) atom fails as a consequence of the polarisation of the C–Cl bond along the σ-skeleton,[44] while δ(^{13}C) increases significantly (by 20 p.p.m.). Such increase in δ[C(1)] on substitution of fluorine by a "heavy" halogen is in general characteristic of 1-halogeno-derivatives of the perfluoroallyl and perfluoromethylallyl cations (Table 3), the effect being thus opposite in sign to the "heavy" atom effect usually observed in ^{13}C NMR spectroscopy (see, for example, Levy and Nelson[4]), which is illustrated here in relation to fluoro-olefins in Table 3. In order to elucidate the cause of the deviation of the δ(^{13}C) for the C(1) atoms in compound (XV) from the relation (5), the diamagnetic contributions to the shielding constant were estimated[67] by the method of Flygar and Goodisman[69] and then, after introducing the diamagnetic correction ($\delta^{exp} - \delta^d = \delta^p$), the values obtained were again compared with the overall charge q^t. It was found that the application of this correction improves the situation, but again with the exception of the δ[C(1)] points for the cation (XV). Thus one can only assume that, on passing to 1-halogeno-substituted polyfluorinated allyl cations, δ[C(1)] is determined not so much by the change in the charge (or in other words in the parameter $<r^{-3}>$) as by the change in the orbital properties of the C(1) atom replaced by the halogen atom.[67]

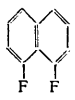
3. The ^{19}F – ^{19}F Spin – Spin Coupling Constants of Polyfluorinated Allyl Cations



The spin – spin coupling constants play a major role in the determination of the structures of organic compounds and in the study of their electronic structures by NMR.[3] For this reason, it is legitimate to analyse the constants $J(^{19}F - ^{19}F)$ for polyfluorinated allyl cations in order to discover to what extent they are characteristic of the given class of compounds. It follows from the analysis of the ^{19}F NMR spectra[14,18,37–41,68] that the geminal $J(^{19}F - ^{19}F)$ constant (J^{gem}) increases sharply on passing from fluorinated olefins (10–60 Hz) to the corresponding cations (VII) (160–245 Hz), which can be used as the spectroscopic sign of the formation of the given cations. We may note that the constants J^{gem} for allyl cations and fluoroalkanes have similar values. This may be caused by the fact that the F–C(1, 3)–F angle in acyclic fluoroallyl cations is close to the tetrahedral angle and, according to a MNDO calculation carried out with complete optimisation of the geometry, amounts to

110–112°.[41,44] In contrast to the constants J^{gem}, the vicinal (spanning three bonds) $J(^{19}F-^{19}F)$ constants of polyfluorinated allyl cations are not characteristic. Indeed, they are approximately equal for the initial olefins ($^3J^{cis}$ = 6–40 Hz, $^3J^{trans}$ = 117–143 Hz) and for the acyclic cations (VII) ($^3J^{cis}$ = 8–30 Hz, $^3J^{trans}$ = 90 to 124 Hz).

Table 4. The constants $^4J(^{19}F-^{19}F)$ for the allyl cations (VII) (Scheme 6) ($R^1 = R^2 = R^4 = F$[73]).

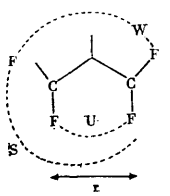
CF_3	Br	−173.4	—	−36.9	−136.5	2.634



The appearance in the ^{19}F NMR spectra of large long-range (spanning four bonds) spin–spin $^{19}F-^{19}F$ coupling constants (Table 4), which, for the *cis–cis* disposition of the interacting nuclei, exceed by a factor greater than two the ^4J ($^{19}F-^{19}F$) constant for the isostructural but uncharged 1,8-difluoronaphthalene (XVI) fragment, must be regarded as an invariable sign of the formation of fluorinated acyclic allyl cations.[70]

(XVI)

We may note that $J(^{19}F-^{19}F)$ constants spanning six bonds and amounting to 10–12 Hz have been observed for the perfluoropentadienyl cation (XIII).[71] The constants J spanning three and more bonds are known to depend markedly on the mutual orientation of the chemical bonds along the interaction pathway.[19,49,72] Table 4 illustrates this situation for polyfluorinated allyl cations. It follows from the data presented that the constants $^4J(^{10}F-^{19}F)$ decrease in absolute magnitude in the sequence "U" > "W" > "S" (Scheme 9) without change in their sign.[73]

Scheme 9

The deviation from the W-rule, well known for the proton–proton spin–spin coupling constants,[49] can be explained by the spin–spin coupling "through space" in the case of the *cis–cis* orientation. (Examples, mechanisms, and semiempirical theories of the transfer of spin information by-passing chemical bonds can be found in several communications[72,74–80]). Indeed, it has been shown that [73] the "spatial" contribution ($J^{sp} = J^U - J^s$) to $^4J(^{19}F-^{19}F)$ constants for the *cis–cis* orientation (Table 4), which has been differentiated by Bakhmutov et al.,[71] diminishes with increase in the internuclear distant r (Scheme 9) determined by the LCAO-MO MNDO method.[44,73] The experimental dependence is then best fitted, taking into account the sign, by Eqn.(6), whose physical significance can be interpreted in terms of direct overlap of the *p*-electron clouds of the fluorine atoms in close proximity in space:

$$J^{sp} = -431(\pm 50)\exp(-0.16\cdot r^2) + 1.2 \qquad (6)$$

It is noteworthy that the variation of the overlap integral for the fluorine molecule for distances between the atoms exceeding the sum of the van der Waals radii is a function of an analogous type.[73] In the calculation of the constant $J(^1H - ^1H)$ spanning five chemical bonds on the basis of the Fermi-contact mechanism for the *s-cis*-conformation of butadiene, a dependence of $^5J(H-C)$ on the internuclear distance of the Gaussian type was also obtained.[81] Thus, there are grounds for the assumption that the nuclei interacting through space can be regarded as "magnetic probes" for "sensing" the form of the overlapping part of the electron clouds.

4. The $^{13}C-^{19}F$ Spin–Spin Coupling Constants of Polyfluorinated Allyl Cations

The accumulation of extensive data concerning the influence of various factors on the constants for the direct spin–spin coupling (via one chemical bond) with participation of ^{13}C nuclei constitutes the basis of their use for the determination of the structures of organic compounds by NMR.[3] The spectroscopic data on polyfluorinated olefins and allyl cations (VII) permit certain generalisations also for the $^1J(^{13}C-^{19}F)$ constants characterising the sp^2-hybridised carbon atoms and atoms with a hybridisation close to sp^2. A significant (up to 100 Hz) increase in $^1J(^{13}C-^{19}F)$ on passing from fluoro-olefins to the corresponding allyl cations has been noted[37–40,42] (this concerns carbon atoms carrying a positive charge). The constants of the acyclic and cyclic cations (VII)–(X) are themselves in the range from 310 to 410 Hz. We may note that these values greatly exceed the direct $J(^{13}C-^{19}F)$ constants observed in the NMR spectra of related polyfluorinated arenonium ions.[82,83] The foregoing refers to the increase in the spin–spin coupling constants in absolute magnitude, since $^1J(^{13}C-^{19}F)$ is negative.[3,83] More than 30 values of the direct constants $J(^{13}C-^{19}F)$ of fluorinated olefins and allyl cations have been analysed and on this basis it has been established that there is a tendency towards their increase with increase in the positive charge on the sp^2-hybridised carbon atom and with decrease in the negative charge on the neighbouring fluorine atom, which is expressed in the two-parameter correlation[7]

$$^1J(^{13}C-^{19}F) = 92q^C + 501q^F + 325,\ r = 0.89 \qquad (7)$$

However, the one-parameter Eqn.(8), which makes it possible to estimate the atomic charge on the carbon atom using available spectroscopic data, is apparently of greater practical value:

$$^1J(^{13}C-^{19}F) = 122q^C + 277;\quad r = 0.84. \qquad (8)$$

The increase in $^1J(^{13}C-^{19}F)$ following the appearance of a positive charge on C(1, 3) corresponds, in principle, to the increase in the amount of *s* character of the given atom as a result of the splitting off of the fluorine atom from the initial olefin and the subsequent

delocalisation of the *p*-electron density, i.e. is treated within the framework of the Fermi-contact mechanism.[19] However, within the framework of this mechanism, it is difficult to explain the fact that $^1J(^{13}C^1-^{19}F)$ for the cation (XV) is greater than $^1J(^{13}C^3-^{19}F)$ despite the smaller positive charge localised on the C(1) atom (Table 5). Moreover, an increase in the direct constant J with decrease in the electronegativity of the heteroatom of the substituent is characteristic of 1-substituted fluorinated olefins and allyl cations (Table 6). However, in each specific case, the direct $J(^{13}C-^{19}F)$ constant for the cation is significantly greater compared with the olefin. Such complex character of the variation of J under the influence of the substituent and on passing from olefins to cations can apparently be explained by non-concerted changes in the Fermi-contact and spin–orbital contributions,[68] which have been shown by quantum-chemical calculations[83] to be virtually equal for interaction through one chemical bond. Despite this, the constants J discussed should be recognised as characteristic in relation to polyfluorinated allyl cations.

Information about the values and signs of the constants $^2J(^{13}C-^{19}F)$ and $^3J(^{13}C-^{19}F)$ of polyfluorinated olefins and cations can be found in a number of communications.[37–41] Here we shall note that the values of J spanning three bonds for the *trans*-disposition of the interacting nuclei vary from −9 to −34 Hz. On the other hand, in the case of the *cis*-disposition they change sign and do not exceed 4 Hz in absolute magnitude.

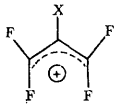
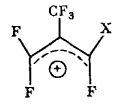
5. ^{19}F NMR Spectra and Relative Stabilities of Polyfluorinated Allyl Cations



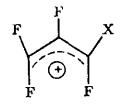
The spectral characteristics of polyfluorinated allyl cations described in the preceding Sections and their characteristic features permit a reliable solution of the problem of the identification of such species in solutions by NMR. Another important problem, namely the problem of the influence of the substituents on the relative stabilities of polyfluorinated allyl cations, can also be solved successfully by NMR. For this purpose, one can use three approaches: (1) the study of the thermodynamics of the equilibrium (9) on the basis of the measurement of the relative integral intensities of the signals of the olefins and cations in ^{19}F NMR spectra at different temperatures:[68,84]

$$CF_3-\underset{R^1}{C}=CFR^2 + SbF_5 \overset{Kp}{\rightleftharpoons} F_2C=\underset{R^1}{C}-CFR^2 \quad (\oplus) + SbF_6^- ; \qquad (9)$$

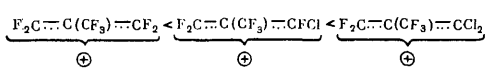


(2) analysis of the ^{19}F NMR spectra of a mixture of two polyfluoro-olefins in the presence of a deficiency of a Lewis acid, i.e. under the conditions of a competing reaction;[85] (3) the study of the kinetic characteristics of the reaction involving the addition of counterions to the corresponding allyl cation[84] on the basis of the analysis of the temperature dependent evolution of the line form in the ^{19}F NMR spectrum containing the olefin and cation signals. The qualitative and quantitative data obtained in this way are compiled in Tables 7

and 8 and in Scheme 10.



Scheme 10



$CF_3 < F < Br < Cl < H$ (a)

$F < Cl < Br < I < OCH_3$ (b)

$H < F < Cl < Br$ (c)

As can be seen, the formation of polyfluorinated allyl cations from the corresponding fluoro-olefins in solutions is an energetically favourable process, since the enthalpy of formation ($\Delta H = H^{cat} - H^{ol}$) is always negative. On the other hand, the negative values of ΔS, which are almost identical in all cases, correspond satisfactorily to an increase in order in the system following the appearance of a charge centre in the latter. Comparison of the data in Tables 7 and 8 shows that the kinetically less favourable addition of the counter-ion to the cation corresponds to its high thermodynamic stability.

Table 8. Kinetic parameters of the addition of the fluoride ion to the polyfluorinated allyl cations [84,85]

X	Y	E_a, kcal mol^{-1}	$\Delta H^{\neq}$, kcal mol^{-1}	$\Delta S^{\neq}$, e.u.	$\Delta G^{298\neq}$, kcal mol^{-1}
F	F	6.2±0.3	6.9±0.3	−8.4±0.4	9.4
Cl	F	21.6±1.3	22.2±1.3	−12.1±1.5	25 5
Br	F	13.7±0.9	14.2±0.9	−15.0±1.0	18.7

Cl	Cl**	11.8±1.1	12.4±1.1	−12.1±2.5	16.0

*The 1,1-dichloroperfluoromethylallyl cation.
**The 1,1,2-trichloroperfluoroallyl cation.

The influence of substituents on the relative stabilities of polyfluorinated allyl cations is expressed by the series presented in Scheme 10. As can be seen, in the case of 2-substituted perfluoroallyl cations (10a) this influence cannot be treated in terms of a change in only the electronic properties of the substituents. It is apparently necessary to invoke also steric factors. The increase in the stability of 1-substituted analogues of the perfluoromethylallyl cation (10b) corresponds to a decrease in the $-I$ effect of the substituent and to an increase in its polarisability. An increase in the number of "heavy" halogens at one of the ends of the allyl system also increases the stability of the given species (10d). The decrease in stability on passing from the perfluoroallyl cation to its 1-hydro-derivative (10c) must be specially emphasised. The observed effect then amounts to 1.5 kcal mol^{-1} (Table 7)[68] and agrees well with the results of a theoretical calculation by the *ab initio* method.[45] It follows from the NMR spectra that the F atom participates in the stabilisation of the positive charge localised on a neighbouring carbon atom via the reverse supply of *p*-electron density. Apparently this ability of the fluorine atom is in fact the cause of the result obtained. Indeed, in the case of the perfluoroallyl cation and its 2-hydro-derivative, i.e. on substitution of the fluorine atom by hydrogen in the 2-position which does not carry a positive charge, the opposite picture (10a) is observed.

---o0o---

The main aim of the present review was to survey the results of the study of polyfluorinated allyl cations which had been regarded for a long time as hypothetical species and had been assumed to exist only as intermediates in electrophilic alkenylation reactions of fluoro-olefins. This uncertainty in the theroretical ideas about the mechanisms of the above reactions and in the chemistry of carbenium ions has now been eliminated as a result of the direct observation by ^{19}F and ^{13}C NMR of a series of polyfluorinated allyl cations (cyclic and acyclic) as both long-lived and kinetically independent species. Presumably data on the stability of allyl cations in solutions and on the distribution of their positive charge will extend the scope of the synthetic use of the reactions in which they are formed as intermediate species.

It may be hoped that the spectral signs of the formation of polyfluorinated allyl cations examined and surveyed in the present review will be of practical use to specialists working in the field of the NMR of organofluorine compounds which is nowadays developing rapidly. Analysis of the literature data devoted to the NMR spectra of fluorine-containing olefins and allyl cations has shown that such compounds can be used successfully as model molecules to establish new relations between spectra and structure.

Fluoroalkenylphosphonates

A.A.Kadyrov and E.M.Rokhlin

In this review we survey the methods for the preparation of derivatives of fluoroalkenylphosphonic acid and their reactions. The main methods for obtaining these compounds are based on the reactions of fluoroolefins with phosphites and also on the elimination of halogens, hydrogen halides and alkyl halides from fluoroalkylphosphonates or fluorine-containing phosphorus ylides. The chemical properties of fluoroalkenylphosphonates are due to the combined effect of the fluorine atoms and the phosphonate group. Their reactions with different reagents leads to modifications of the phosphonate group, addition to the C=C bond, replacement of the vinyl halogen atom, and cleavage of the C-P bond.
The bibliography includes 96 references.

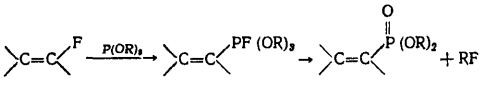
I. INTRODUCTION

Unsaturated phosphonic acids and their derivatives make up an important class of organophosphorus compounds that are of interest because of the variety of their chemical reactions and their possible practical applications.[1-4] The attention of research workers has in recent years been drawn increasingly towards fluorine-containing alkenylphosphonates. The presence in the same molecule of fluorine atoms, a C=C double bond, and $PO(OR)_2$ groups gives these compounds a unique reactivity, combining the properties of fluoroolefins and unsaturated phosphonates. There are also some examples which confirm the practical value of products derived from them. Some compounds of this type have been proposed as monomers for making cation exchange resins,[5-7] impregnating agents for textiles and paper,[8] intermediates in the synthesis of insecticides and incombustible polymers,[9] extraction agents for heavy metal ions,[10] components of toothpaste[11] and even antibiotics.[12]

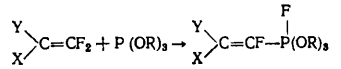
The present review attempts to correlate and systematise the information on the methods of obtaining and the chemical properties of fluoroalkenylphosphonic acids and their derivatives, in particular for those compounds in which the phosphonate group is bonded directly to the α-carbon atom of the fluoroalkenyl fragment

In selecting literature data we used the automated formation search system AIPS-FTOR [AISS-FLUORINE] (VINITI) [All Union Institute of Scientific and Technical Information].



II. METHODS OF SYNTHESIS

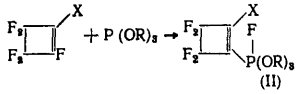
Some methods used for obtaining fluoroalkenylphosphonates are essentially no different from those used for their nonfluorinated analogues, in this case being mainly reactions such as dehalogenation and dehydrohalogenation of haloalkylphosphonates. However, specific methods based on the unique reactions of fluoroolefins and other fluorine-containing unsaturated compounds are often used for the synthesis of fluoroalkenylphosphonates.



1. Substitution of Vinyl Halogen Atoms in Fluoroolefins

A reaction for "vinyl" substitution of a halogen atom that is typical for fluoroolefins and related compounds is widely used for the synthesis of fluoroalkenylphosphonates containing a C=C bond conjugated with the phosphonate group.

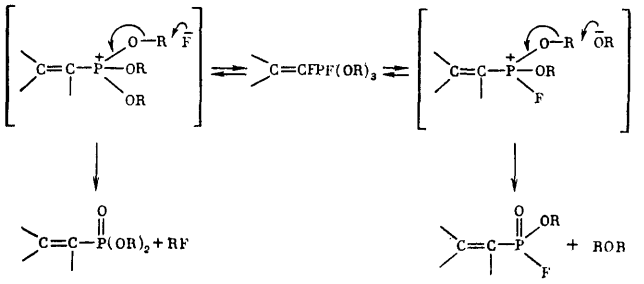
Trialkyl phosphites react fairly readily with polyfluoroolefins to form fluoroalkenylphosphonates:



In this case trialkoxyfluorophosphoranes are likely to be formed as intermediates. Phosphoranes such as (I) and (II) are isolated from reactions of trialkyl phosphites with perfluoroisobutylene,[13] polyfluorocyclobutenes,[13,14] perfluoromethacrylates,[15-17] and difluoromethylenemalonates[17,18]†

(I)

R = Et, X = Y = CF_3 (a); R = Me, X = CF_3, Y = COOMe (b), COOEt (c); R = Et, X = CF_3, Y = COOMe (d), COOEt (e); R = Me, X = Y = COOME (f); R = Et, X = Y = COOEt (g)

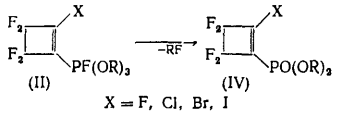


(II)

X = F, R = Me (a), Et (b); R = Me, X = Cl (c), Br (d), I (g)

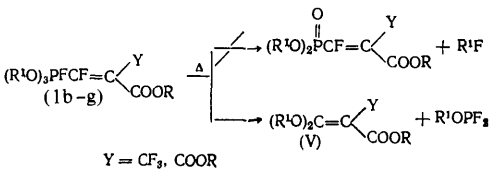
Thermal decomposition of polyfluoroalkenyltrialkoxyfluorophosphoranes, which may be regarded as intermediates of an Arbuzov rearrangement, usually leads to the formation of alkyl fluorides and dialkyl polyfluoroalkenylphosphonates.[13-15] In some cases there is a different decomposition route—dialkyl ether and monoalkyl polyfluoroalkenylphosphonofluoridate are formed.[13-15] Elimination of the fluoride anion from trialkoxyfluorophosphonate is evidently

† A similar reaction of pentafluoroazapropene $CF_3N=CF_2$ leads to the formation of stable pentafluoroazapropenyltrialkoxyfluorophosphoranes $CF_3N=CFPF(OR)_3$.[19]



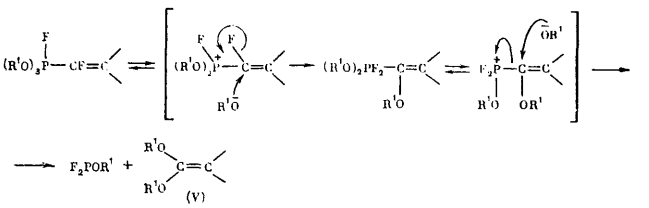
inhibited as a result of the strength of the P–F bond and the elimination of alkoxide anion starts to complete successfully with this reaction. The latter is alkylated by a quasiphosphonium cation and as a result there is a second route for formation of decomposition products—phosphonofluoridate and ether:

For example, when perfluoroisobutenyltriethoxyfluorophosphorane (Ia) is heated to 120–150 °C, ethyl fluoride, diethyl ether, and the perfluoroisobutenylphosphonic acid derivatives—the ester $(CF_3)_2C=CFPO(OEt)_2$ (III) and phosphonofluoridate $(CF_3)_2=CFPF(O)OEt$—are formed.[13]



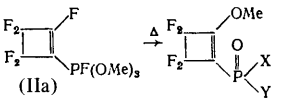
Fluorophosphorane (Ia) is converted to perfluoroisobutenyl phosphonic acid derivatives not only by thermal decomposition but also by hydrolysis. Prolonged reaction with an aqueous solution of sodium bicarbonate gives a mixture of the phosphonic acid $(CF_3)C=CFPO(OH)_2$ and its acid ester $(CF_3)_2C=CFPO(OEt)OH$.[20]

The corresponding phosphonates (IV) are obtained from polyfluorocyclobutenylphosphoranes (II) by heating:[13,14]



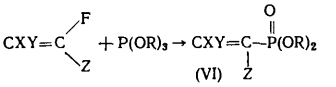
X = F, Cl, Br, I

The alkoxide anion that is formed as an intermediate on decomposition of trialkoxyfluorophosphoranes can, in addition to attacking the alkyl group, react with other electrophilic sites of the molecules, which leads to unusual decomposition of fluorophosphoranes. Thus, pyrolysis of fluorophosphoranes (Ib–g) containing carbalkoxyl groups results in the formation not of fluoroalkenylphosphonates but of acetals of substituted ketones (V) and the trivalent phosphorus compounds—alkyl phosphorodifluoridites:[15,17,18,21]

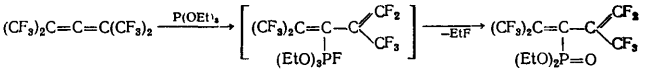


Y = CF_3, COOR

Such a marked difference is probably due to the much greater electrophilicity of the carbon atom in the CF= group in phosphoranes (Ib–g), obtained from perfluoromethacrylates or difluoromethylenemalonates compared to phosphorane (Ia) obtained from perfluoroisobutylene (cf. Ref.22). During pyrolysis it is not the alkyl group but the β-carbon atom of the "acrylic" system that is attacked by the alkoxide anion. As a result of "vinyl" substitution of the geminal fluorine atom a new phosphorane is formed, in which the fluorine atom and alkoxy group have exchanged places. This phosphorane dissociates again into an R^1O^- anion and quasiphosphonium cation; repeated attack by R^1O^- on the β-carbon atom leads to the splitting of the molecule into acetal (V) and alkyl phosphorodifluoridite



Attack by alkoxide anion on the sp^2-hybridised carbon atom leading to an exchange of substituents between these atoms and the phosphorus atoms has also been detected in the thermal decomposition of perfluorocyclobutenyltrimethoxyfluorophosphorane (IIa).[13,14] However, in this case a vinyl fluorine atom is replaced, the C–P bond does not break, and as a result 2-alkoxytetrafluorocyclobutenyl phosphonic acid derivatives are formed:



X, Y = F, OMe

In the reactions of fluoroolefins with trialkyl phosphites the fluorophosphoranes formed as intermediates have in a majority of cases not been isolated; heating of the initial compounds gives esters of polyfluoroalkenylphosphonates. Thus, the syntheses of the respective α,β-unsaturated phosphonates (VI) have been reported from tetrafluoroethylene,[20,23,24] trifluorovinyl chloride,[24] trifluorovinyl iodide,[25] perfluoropropylene,‡[23,24,26] perfluoroisobutylene,[23,24] monohydroperfluorobutylene,[27] and ethoxyperfluoroisobutylene:§[27]

	(a)	(b)		(c)	(d)				(e)	
X=F	F	Cl	I	CF_3	CF_3	CF_3	CF_3	CF_3	CF_3
Y=F	F	F	F	F	F	CF_3	CF_3	F	H	OEt
Z=F	F	F	F	F	F	F	F	F	OEt	OEt
R=Et	iso-Pr	Et	iso-Pr	Et	iso-Pr	iso-Pr	Bu	Et	Et

Reaction of *tetrakis*(trifluoromethyl)allene gives the corresponding 1,3-dienyl-2-phosphonate probably by an S_N2' reaction:[28]

Nonafluorohexene[29] and perfluoroallyl chloride[30] undergo similar reactions:

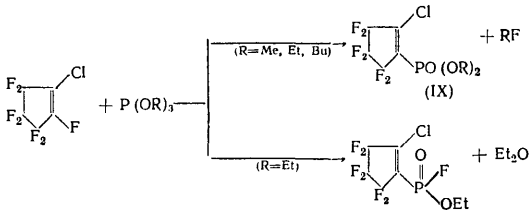
Trifluorovinyl iodide reacts with $(iso\text{-}PrO)_3P$ or $(EtO)_2POSiMe_3$ to form phosphonate (VIc) or $ICF=CFPO(OEt)_2$. When phosphite is in excess, products derived from substitution of the

‡ In the reaction of perfluoropropylene with triethyl phosphite (130–140 °C), phosphonofluoridate $CF_3CF=CFPF(O)OEt$ is formed in addition to ester (VId).[13]

§ Ethoxyperfluoroisobutylene also shows alkylating properties towards triethyl phosphite.[32]

fluorine and iodide atoms are obtained—*bis*-phosphonates (VII).[25,31] *bis*-Phosphonate (VIIa) is also formed by the action of $(EtO)_2POSi.Me_3$ on tetrafluoroethylene[31]

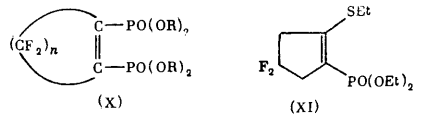
$$(RO)_2\overset{O}{\overset{\|}{P}}CF=CF\overset{O}{\overset{\|}{P}}(OR)_2,\ R = Et\,(a),\ iso\text{-}Pr\ (b)$$
(VII)



Halogen-substituted polyfluoroalkanes are sometimes used as starting materials for the preparation of polyfluoroalkenylphosphonates:[33,34]

$$RCF(X)-CY_2(Cl) \xrightarrow[-XCl]{P(OEt)_3} [RCF=CY_2] \xrightarrow[-EtY]{P(OEt)_3} RCF=CYPO(OEt)_2$$
(VIII)

$X = F,\ Y = Cl,\ R = CFCl_2;\ X = Cl,\ Y = F,\ R = I(CF_2)_2\,(a),\ I(CF_2)_4\,(b),\ I(CF_2)_6\,(c)$

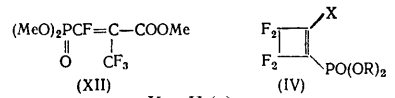


In this case fluoroolefins are evidently formed as intermediates. The formation of the fluoroolefin $CFCl_2CF_2CF=CF_2$ has been demonstrated, for example, in the reaction of 1,2,4,4-tetrachloroperfluorobutane with triethyl phosphite.[3]

1-Chloroperfluorocyclopentene reacts with trialkyl phosphites to give 2-chloroperfluorocyclopenteneylphosphonates (IX). When triethyl phosphite is used, Et_2O and phosphonofluoridate are also formed:[36]

Products from the substitution of both chlorine atoms (X) are obtained from 1,2-dichloroperfluorocycloalkenes.[10] However, reaction of dichloroperfluorocyclopentene with triisopropyl phosphite gives exclusively the monosubstitution product (IX), where R = iso-Pr. Evidently steric hindrance plays an important role in substitution of the second halogen atom.

In the reaction of 1-ethylthio-2-chloroperfluorocyclopentene with triethyl phosphite the corresponding phosphonate (XI) is obtained.



$n = 2-4;\ R = Me, Et, Bu,\ CH_2=CHCH_2$

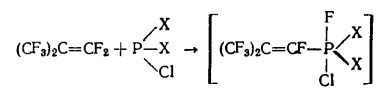
Neutral phosphonites and phosphinites react with flouroolefins in a similar manner to trialkyl phosphites, giving perfluoroalkenylphosphinates and perfluoroalkenylphosphine oxides.[24,38]

Dialkyl phosphites usually react with fluoroolefins to form addition products.[39] However, in some cases "vinyl" substitution products are also formed. Thus, when perfluoromethacrylate reacts with dimethyl phosphite the unsaturated phosphonate (XII) is obtained.[15] The mechanism of this reaction is not clear. The possibility cannot be excluded that here, as in certain other cases, an addition product is initially formed, then undergoes dehydrofluorination by the action of dialkyl phosphite.

Polyfluorocyclobutenylphosphonates (IV) are formed from polyfluorocyclobutenes and dialkyl phosphites by irradiation.[39]

$X = H\,(a), F, Cl, OR$

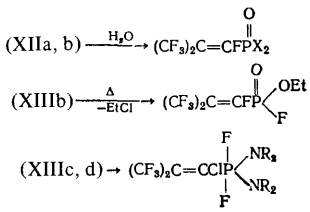
Sodium dialkyl phosphite reacts with terminal perfluoroolefins by replacing one of the fluorine atoms in the difluoromethylene group:[8]



$$R_FCF=CF_2 + NaOP(OEt)_2 \rightarrow R_FCF=CFPO(OEt)_3$$
$$R_F = n\text{-}C_6F_{13},\ n\text{-}C_7F_{15}$$

The substitution of both vinyl fluorine atoms on treatment with salts of acid esters of phosphorus or methylphosphorous acids has been reported for perfluorosiobutylene,[40] in a similar manner to reactions of this fluoroolefin with certain other nucleophiles:[41]

$$(CF_3)_2C=CF_2 + NaOP(X)OR \rightarrow (CF_3)_2C=C[P(O)(X)OR]_2$$
$X = RO, Me$



However, there is some doubt about this result since the IR spectra ($\nu_{C=C}$ at 1745 cm^{-1}) are apparently not consistent with the proposed *bis*-phosphonate and *bis*-phosphinate structures.

The vinyl fluorine atom in perfluoroisobutylene is replaced by the action of certain acid chlorides of trivalent phosphorus.[42] The intermediate formation of fluorophosphoranes (XIII) is suggested here:

$X = Et\,(a), OEt\,(b), NMe_2\,(c), NEt_2\,(d)$

Dialkyl- and dialkoxy-fluorochlorophosphoranes (XIIIa, b) are hydrolysed with very great ease to the phosphine oxide or phosphonate respectively. For dialkoxy derivative (XIIIb) in the complete absence of moisture the reaction is accompanied by the liberation of alkyl chloride and the formation of phosphonofluoridate. Diamino derivatives (XIIIc, d) are isomerised to α-chloro-substituted difluorophosphoranes:

In this case the fluorine and chlorine atoms exchange places [the mechanism of this reaction is possibly similar to the mechanism for exchange of fluorine atoms and alkoxy groups in the thermal decomposition of trialkoxyfluorophosphoranes (Ib–g), see above].

Thus, reaction of fluoroolefins with phosphites is a general method for the synthesis of fluoroalkenylphosphonates with the olefin double bond in the α,β-position. However, in this case compounds with an internal double bond are formed since the mechanism for "vinyl" substitution in fluoroolefins usually makes these reactions unsuitable for the preparation of "terminal" fluoroalkenylphosphonates containing the $CF_2=\overset{|}{C}-P$ fragment:

An exception to this could be the reaction of trialkyl phosphites with tetrafluoroethylene, which, according to Ref.24, gives trifluorovinylphosphonates (VIa, b). However, these compounds apparently cannot be obtained from tetrafluoroethylene in satisfactory yield, since they readily react further with neutral phosphites[31] (see section III, 2e). The method used for preparing trifluorovinylphosphonates is given in section II, 3.

2. Formation of C=C Double Bond by Elimination

Like their nonfluorinated analogues[1] many fluorine-containing alkenylphosphonates are obtained by dehalogenation or dehydrohalogenation of the appropriate unsaturated halogenated derivatives. Thus, when products of the radical addition of dialkyl phosphites to dichlorodifluoroethylene or trichlorofluoroethylene are treated with zinc in alcohol, fluorine-containing vinylphosphonates are formed:[43,44]

$$CFCl{=}CX_2 + HPO(OR)_2 \rightarrow CHX_2CFClPO(OR)_2 \xrightarrow{Zn} CHX{=}CFPO(OR)_2$$
$$X = F,\ Cl;\ R = Me,\ Et,\ n\text{-}Pr$$

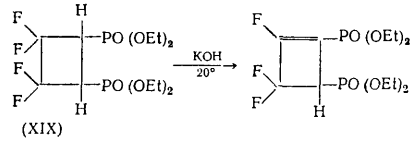
Dechlorination of the dichloro-substituted ester (XIV) with metallic zinc in ether gives an adduct of zinc chloride with unsaturated ester:[45]

$$ClCF_2{-}CCl{-}PO(OMe)_2 \xrightarrow{Zn} CF_2{=}C{-}PO(OMe)_2 \cdot ZnCl_2$$
$$\quad\ CF_3 \qquad\qquad\qquad\quad CF_3$$
$$\quad (XIV)$$

Trihaloethylphosphonates (XV)¶ are fairly readily dehydrochlorinated with triethylamine or potassium *tert*-butoxide to form dihalovinylphosphonates (XVI):[46–48]

$$YCH_2CXPO(OEt)_2 \xrightarrow[-HCl]{} YCH{=}CXPO(OEt)_2$$
$$\quad\ Cl$$
$$\quad (XV) \qquad\qquad\qquad (XVI)$$
$$X,\ Y = F,\ Cl$$

Dehydrofluorination of 2,2-difluoroethylphosphonates using sodium alkoxides gives various 2-fluorovinylphosphonates:[9]



$$HCF_2CH_2PO(OR)_2 \xrightarrow[-HF]{} HCF{=}CHPO(OR)_2$$
$$R = Me,\ Et,\ C_5H_{11}$$

2-Fluorovinylmethylphosphonate is synthesised in the same manner.[9]

Unsaturated α-phosphoryloxyphosphonates (XVIII) are obtained from α-*H*-α-phosphoryloxyphosphonates (XVII):[49]

$$R_FCF_2CH\begin{matrix}OPO(OR)_2\\PO(OR)_2\end{matrix} \xrightarrow{(iso\text{-}Pr)_2NLi} R_FCF{=}C\begin{matrix}OPO(OR)_2\\PO(OR)_2\end{matrix}$$
$$\quad (XVII) \qquad\qquad\qquad\qquad (XVIII)$$

The product (XIX) of the radical addition of diethyl phosphite to 2-monohydroperfluorocyclobutenylphosphonate is dehydrofluorinated with alkali under mild conditions:[39]

(XIX)

For the dehydrofluorination of 2,2,3,3-tetrafluorocyclobutyl phosphonate see section III, 2e.

The reaction of hexafluoroisopropylphosphonates (XX) with $Et_3N.BF_3$ adducts under mild conditions gives pentafluoroisopropenylphosphonates (XXI):[50,51]

$$(CF_3)_2C\begin{matrix}S\\S\end{matrix}C(CF_3)_2 \xrightarrow{P(OR)_3} (CF_3)_2C{=}P(OR)_3 \xrightarrow{HCl} (CF_3)_2CHPO(OR)_2 \rightarrow$$
$$\quad (XXII) \qquad\qquad\qquad\quad (XX)$$
$$\xrightarrow[-Et_3\overset{+}{N}H\ \bar{B}F_4]{Et_3N\cdot BF_3} CF_2{=}C{-}PO(OR)_2$$
$$\qquad\qquad\qquad\qquad\quad CF_3$$
$$\qquad\qquad\qquad\quad (XXI)$$
$$R = Me\ (a),\ Et\ (b)$$

Apart from 1,2-elimination of halogens or hydrogen halides, fluoroalkenylphosphonates can be obtained by 1,4-elimination of alkyl fluorides from P-alkoxy-substituted fluorine-containing phosphorus ylides. When hexafluoroisopropylidenetriethyoxyphosphorane (XXIIb) is heated with a catalytic quantity of boron trifluoride etherate, ethyl fluoride, and pentafluoroisopropenylphosphonate (XXIb)† are formed:[51]

$$(CF_3)_2C{=}P(OEt)_3 \xrightarrow{Et_2O\cdot BF_3} CF_2{=}C{-}PO(OEt)_2 + EtF$$
$$\qquad\qquad\qquad\qquad\qquad\quad CF_3$$
$$\quad (XXIIb) \qquad\qquad\qquad (XXIb)$$

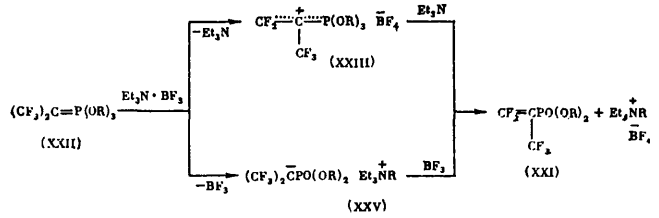
This reaction is similar to the conversion of alkoxypolyfluoroisobutylenes $(CF_3)_2C{=}CXOR$ to perfluoromethacrylic acid derivatives

$$CF_2{=}CCOX$$
$$\quad CF_3 \qquad [21].$$

1,4-Elimination of alkyl fluoride evidently occurs in stages. Initially the Lewis acid (BF_3) removes a fluoride anion from the phosphorus ylide to form an unstable adduct (XXIII) containing a mesomeric cation. This adduct readily decomposes to ethyl fluoride and an adduct (XXIV) of unsaturated phosphonate with boron trifluoride. The latter is converted to the final product—free phosphonate (XXIb) by the action of another molecule of phosphorus ylide (XXIIb), which in the process again gives adduct (XXIII), and so on:[51]

$$(XXIIb) \xrightarrow{BF_3} CF_2{\cdots}\overset{+}{C}{\cdots}P(OEt)_3\ \bar{B}F_4 \xrightarrow[-EtF]{} CF_2{=}C{-}PO(OEt)_2\cdot BF_3 \rightarrow$$
$$\qquad\qquad\quad CF_3 \qquad\qquad\qquad\qquad\quad CF_3$$
$$\qquad\qquad (XXIII) \qquad\qquad\qquad (XXIV)$$
$$\xrightarrow{(XXIIb)} CF_2{=}C{-}PO(OEt)_2 + (XXIII)$$
$$\qquad\qquad\quad CF_3$$
$$\qquad\qquad (XXIb)$$

Each stage of this scheme has been confirmed experimentally.

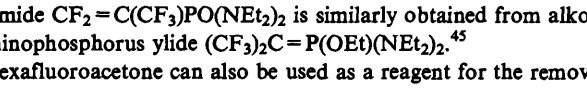


The *bis*-trimethylsilyl ester of pentafluoroisopropenylphosphonic acid (XXIc) is obtained by the direct reaction of *tris*(trimethylsilyl) phosphite with hexafluorothioacetone dimer, and also from phosphorus ylide (XXIIa) and trimethylsilyl iodide:[52]

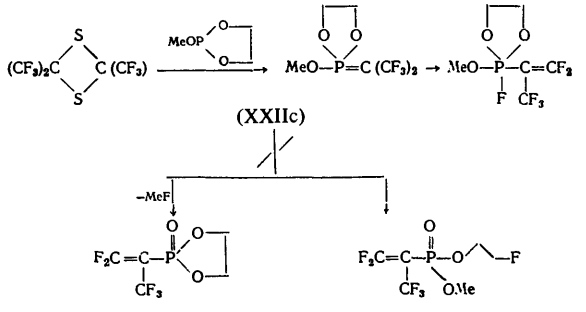
$$(CF_3)_2C\begin{matrix}S\\S\end{matrix}C(CF_3)_2 \xrightarrow[-(Me_3SiO)_4PS]{(Me_3SiO)_3P} [(CF_3)_2C{=}P(OSiMe_3)_3] \xrightarrow{-Me_3SiF}$$
$$(CF_3)_2C{=}P(OMe)_3 \xrightarrow[-MeI\ -Me_3SiF]{Me_3SiI} CF_2{=}C{-}PO(OSiMe_3)_2$$
$$\qquad\quad (XXIIa) \qquad\qquad\qquad\qquad\quad CF_3$$
$$\qquad\qquad\qquad\qquad\qquad\quad (XXIb)$$

¶ Obtained as mixtures of stereoisomers by treatment of the olefins FCH=CHF and FCH=CHCl with phosphorus trichloride and oxygen and subsequent ethanolysis of the reaction mixture.[48]

† Under similar conditions trimethoxyphosphorane $(CF_3)_2C{=}P.(OMe)_3$ (XXIIa) rearranges to the saturated phosphonate $(CF_3)_2C.(Me)PO(OMe)_2$.[51]



It seems that the most convenient method for obtaining pentafluoroisopropenylphosphonic acid derivatives is removal of alkyl fluoride from phosphorus ylides (XXII) with an equimolar quantity of $Et_3N.BF_3$ adduct:[51]



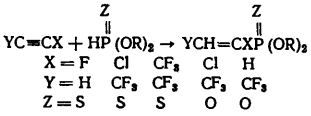
In the process tetraalkylammonium fluoroborates are formed together with phosphonates (XXI). The reaction may occur by one of two pathways. The first of them assumes an initial elimination of fluoride ion to give adduct (XXIII) followed by the transfer of alkyl to amine, the second assumes initial dealkylation followed by elimination of fluoride ion from the mesomeric carbanion of tetraalkylammonium salt (XXV).[51]

Amide $CF_2=C(CF_3)PO(NEt_2)_2$ is similarly obtained from alkoxydiaminophosphorus ylide $(CF_3)_2C=P(OEt)(NEt_2)_2$.[45]

Hexafluoroacetone can also be used as a reagent for the removal of alkyl fluoride. When it is heated with trialkoxyphosphoranes (XXIIa, b), alkyl perfluoroisopropyl ethers and unsaturated phosphonates (XXIa, b) are formed:[51]

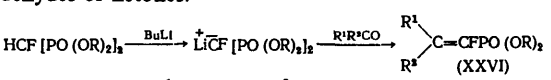
In contrast to trialkoxyphosphorus ylides (XXIIa, b), 2-(hexafluoroisopropylidene)-2-methoxy-1,3,2$\lambda^5\sigma^4$-dioxaphospholan (XXIIc) does not eliminate alkyl fluoride but rearranges under mild conditions to 2-(pentafluoroisopropenyl)-2-fluoro-2-methoxy-1,3,2$\lambda^5\sigma^4$- dioxaphospholan:[53]

The methods based on elimination of halogens, hydrogen halides, or alkyl halides from saturated phosphonates or alkoxyphosphorus ylides have considerable potential for the preparation of fluoroalkenyl phosphonates, although they have not so far been developed to a sufficient extent. It should be emphasised that when these methods are used both "internal" and "terminal" fluoroalkenylphosphonates can be obtained.



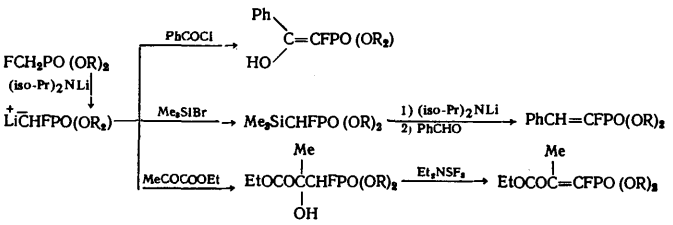
3. Other Methods

Apart from the two main synthetic methods described above, fluoroalkenylphosphonates can also be obtained by a variety of methods, which are based on the introduction of a fluorine atom, formation of a C–P bond, formation of a C=C bond by means of Wittig–Horner reactions, various rearrangements, etc.

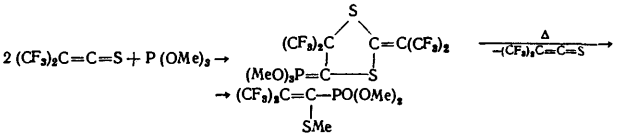


2-Chlorotetrafluoropropenylphosphonate is obtained by rearrangement of 2-chlorotetrafluoroallylphosphonate:[54]

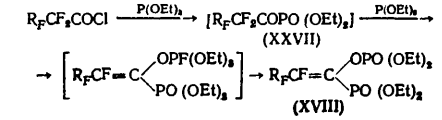
Treatment of fluorine-containing acetylenes with acid phosphites and phosphorothioites gives the corresponding fluoroalkenylphosphonates and fluoroalkenylthiophosphonates:[55]



The Wittig–Horner reaction is used to obtain α-fluorovinylphosphonates (XXVI) from tetraalkyl fluoromethylene-*bis*-phosphonates and aldehydes or ketones:[56]

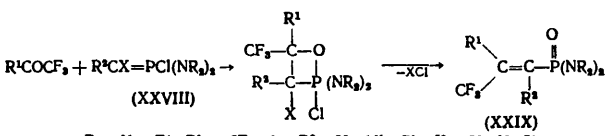


R = iso-Pr; R^1 = H, Me; R^2 = H, Me, iso-Pr, Ph, etc.



The lithium derivative obtained from dialkyl fluoromethylphosphonate is also used for the synthesis of unsaturated α-fluorophosphonates:[57]

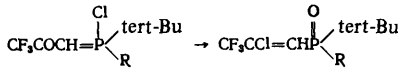
Reaction of *bis*(trifluoromethyl)thioketen with trimethyl phosphite gives α-methylthioperfluoroisobutenylphosphonate:[58]



An interesting method for obtaining α-substituted fluorine-containing alkenylphosphonates (XVIII) is that based on the reaction of perfluorocarboxylic acid chlorides with triethyl phosphite:[49,59–62]

Acylphosphonate (XXVII) formed as an intermediate cannot be isolated from the reaction as it immediately undergoes a rapid reaction with another molecule of phosphite. The mobility of the phosphate group in compounds (XVIII) opens up extensive possibilities of synthesising various organofluorine compounds either containing or not containing a phosphorus atom (see below).

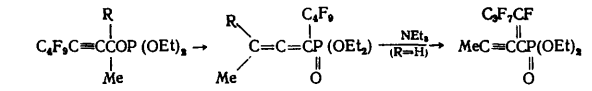
The reaction of chlorophosphonium ylides (XXVIII) with fluoroketones gives fluoroalkenylphosphonic acid amides (XXIX):[63–64]



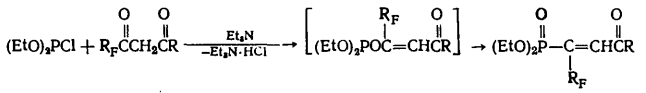
R = Me, Et; R^1 = CF_3, Ar; R^2 = H, Alk, Ph; X = H, Me_3Si

P-Chloro-substituted oxaphosphetans are formed in the process as intermediates.

Phosphinic acid amides and phosphine oxides are obtained in a similar manner.[63–66]



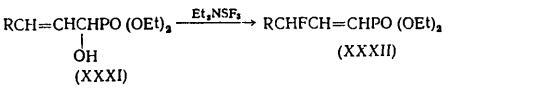
Chlorophosphonium acylmethylides undergo an interesting rearrangement:[67]



R = tert-Bu, NEt_2

The oxygen and chlorine atoms exchange places as a result of reaction.

Rearrangement of diethyl alkynyl phosphites (XXX) gives fluorine-containing allenylphosphonates; when R = H a further dehydrofluorination is possible:[68]



Reaction of fluorine-containing β-diketones with diethyl phosphorochloridite leads to the synthesis of α-perfluoroalkyl-γ-keto-vinylphosphonates, which are probably formed by rearrangement of the corresponding phosphites:[69]

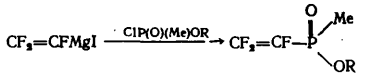
$R_F = CF_3$, C_3F_7; R = Me, tert-Bu

Monofluoroalkenylphosphonate derivatives can be obtained from unsaturated phosphonate compounds by standard reactions for the introduction of fluorine atoms. Thus, fluoroalkenylphosphonates (XXXII) are synthesised by treatment of hydroxyphosphonates (XXXI) with (N-ethylethanaminato)trifluorosulphur (DAST).[70]

The salt of 3-fluoropropenylphosphonic acid is obtained by the replacement of a bromine atom with a fluorine atom:[71]

When $C_2F_5SiF_3$ is pyrolysed in the presence of PF_3, trifluorovinyltetrafluorophosphorane is formed, hydrolysis of which gives trifluorovinylphosphonic difluoride:[72]

Reaction of trifluorovinylmagnesium iodide with dialkyl phosphorochloridates followed by oxidation of the phosphonites formed gives trifluorovinylphosphonates (VIa, f):[31]

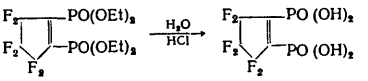


R = Et (a), Bu (f)

A similar sequence of reactions has been used previously to synthesise vinylphosphonates.[73]

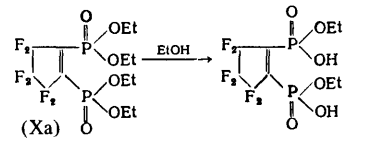
The direct formation of phosphonates $RPO(OR^1)_2$ from organometallic compounds RM and dialkyl phosphorochloridates $ClPO.(OR^1)_2$ is usually complicated by side reactions.[3] It was not possible to obtain trifluorovinylphosphonate (VIa) by reaction of trifluoromagnesium iodide with diethyl phosphorochloridate.[45]

However, the preparation of trifluorovinylmethylphosphinates by reaction of trifluorovinylmagnesium iodide with alkyl methylphosphonochloridates has been reported:[40]



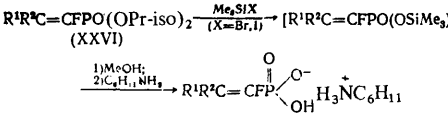
Among the methods for obtaining fluoroalkenylphosphonic acid derivatives it is also possible to include many reactions of those compounds which lead to products in which the C=C bond and $P(O)X_2$ group are retained. These reactions together with other conversions of fluoroalkenylphosphonates are examined in the next chapter.

III. CHEMICAL PROPERTIES



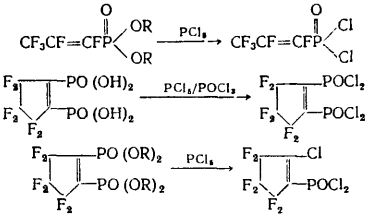
1. Modification of Phosphonate Groups

Fluorine-containing unsaturated phosphonate esters and also phosphinate esters are converted in the usual way to free acids by acid hydrolysis,[36,74–77] for example:



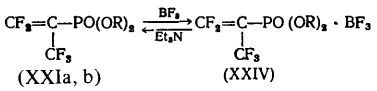
(Xa)

When *bis*-phosphonate (Xa) is boiled with ethanol, *bis*-phosphonic acid ester is formed:[74, 75]



(Xa)

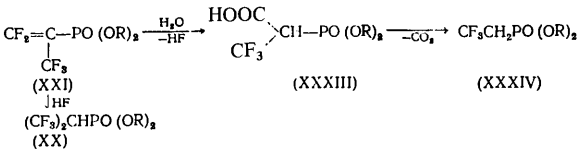
For the conversion of α-fluoroalkenylphosphonates (XXVI) to the corresponding acids, a reaction with trimethylsilyl halides is used followed by alcoholysis (the acids are isolated as their cyclohexylammonium salts):[56]



Reaction of fluoroalkenylphosphonic acids or their esters with phosphorus pentachloride gives the corresponding acid chlorides.[13,36,38,74,75] In the case of *bis*-phosphonates replacement of one of the phosphonate groups by a chlorine atom also sometimes occurs:[36,74]

The chlorine atoms in fluoroalkenylphosphonic acid chlorides can be replaced with fluorine atoms in the usual way by treatment with SbF_3 [13] and replaced with hydroxy or alkoxy groups by treatment with water or alcohol.[36,74–76]

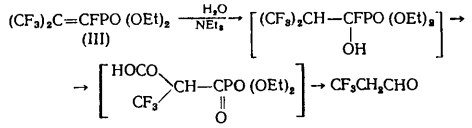
Despite the high electrophilicity of the pentafluoroisopropenyl residue, the phosphoryl group in pentafluoroisopropenylphosphonates displays its own basic properties. Esters (XXI) readily form adducts with the Lewis acids $ZnCl_2$ (see section II,2) and BF_3. When treated with triethylamine, the BF_3 adduct (XXIV) is converted to free phosphonate (XXI):[51]



(XXIa, b) (XXIV)

2. Reactions Involving the Fluoroalkenyl Group

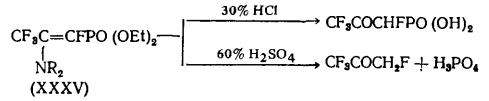
The electron-withdrawing effect of the phosphonate groups and fluorine atoms causes the C=C bond in fluoroalkenylphosphonates to have considerable electrophilicity. Hence they react quite readily with various nucleophiles, giving products from the substitution of the halogen atoms on the sp^2-hybridised carbon atom or addition products on the C=C bond.‡ There is considerable interest in the conversions that lead to cleavage of the C–P bond; these sometimes prove to be convenient methods for the synthesis of organofluorine compounds. Reactions with electrophiles are generally less typical for fluoroalkenylphosphonates, although there are examples of addition of halogens and hydrogen halides to the C=C bond.



(a) Reactions with Water, Alcohols, and Amines

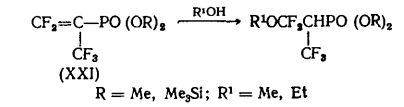
The highly electrophilic pentafluoroisopropenylphosphonates (XXI), the "phosphoric analogues of perfluoromethacrylates"§ readily react with water, and as a result of hydrolysis of the difluoromethylene group form unstable carboxyphosphonates (XXXIII), decarboxylation of which give trifluoroethylphosphonates (XXXIV):[80]

The reaction is complicated by the fact that the initial unsaturated phosphonate adds on liberated hydrogen fluoride to give dialkyl hexafluoroisopropylphosphonate (XX).



The less electrophilic perfluoroisobutenylphosphonate (III) reacts with water in the presence of triethylamine and is converted to trifluoropropionaldehyde, with the addition product of water to the multiple bond probably being formed as an intermediate:[27]

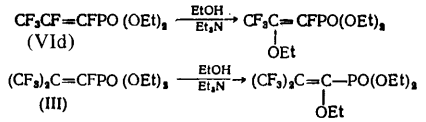
In this case the orientation for addition of water is determined by the strong electron-withdrawing action of the two trifluoromethyl groups (see below).



When perfluoroalkenylphosphonates are treated with aqueous alkalis, the fluorine atoms are removed as anions. By determining the quantity of fluoride anions eliminated, Knunyants, Sterlin, et al.[24] conclude that in the reaction of trifluorovinylphosphonate the C–P bond is preserved, while for pentafluoropropenyl- and perfluoroisobutenyl-phosphonates a "haloform" decomposition occurs.

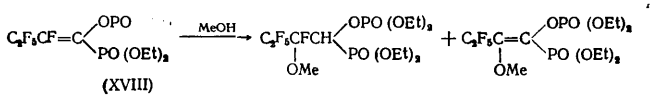
In contrast to perfluoroalkenylphosphonates, enaminophosphonate (XXXV) is readily hydrolysed in acidic medium, with either ketophosphonic acid or tetrafluoroacetone being formed depending on the conditions:[27]

(XXXV)



Pentafluoroisopropenylphosphonates (XXIa, c) react with alcohols under mild conditions to form addition products—α-*H*-β-alkoxypentafluoroisopropylphosphonates:[45,52,80]

On the other hand, trifluorovinylphosphonate (VIa) does not react with alcohol even after prolonged heating (~100 °C).[31]



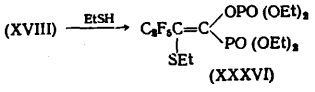
The completing reaction of pentafluoroisopropenylphosphonate (XXIa) and methyl perfluoromethacrylate has been used to demonstrate that these compounds have similar reactivity.[80]

Pentafluoropropenylphosphonate (VIa) and pentafluoroisobutenylphosphonate (III) react with ethanol in the presence of triethylamine.¶ In the first case a vinyl fluorine atom at the β-position is replaced by an alkoxy group, in the second case a fluorine atom at the α-position is replaced:[27]

Here, as in the reactions with water and secondary amines (see below) the direction of nucleophilic attack depends on the competition between the trifluoromethyl and phosphonate groups for conjunction with the C=C double bond; one CF_3 group cannot compete effectively with the $PO(OR)_2$ group, but the electron-withdrawing effect of two trifluoromethyl groups can "overcome" the effect from the $PO(OR)_2$ group.†[27]

α-Phosphoryloxy-substituted perfluoroalkenylphosphonate (XVIII) reacts with methanol to form a mixture of addition and substitution products:[59]

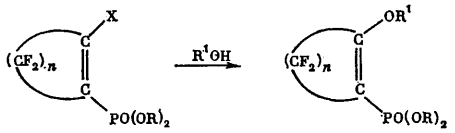
(XVIII)



‡ Nucleophilic additions to nonfluorinated alkenylphosphonates have become widely known.[1] However, vinylphosphonates are somewhat less reactive than the analogous acrylates.[78,79]

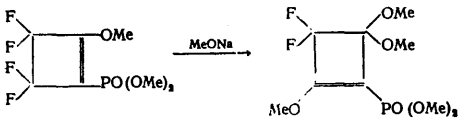
§ See Ref.21 concerning the electrophilicity of perfluoromethacrylates.

¶ In the reaction of (III) with ethanol in the presence of EtOK, the fluorine atoms are completely eliminated as anions.[27]

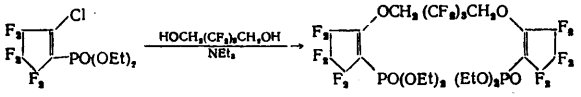


† For a similar competition between trifluoromethyl groups and carbalkoxyl groups, see Ref.81.

However, in the reaction with mercaptan only the product (XXXVI) from substitution of the vinyl fluorine atom is obtained.[59]

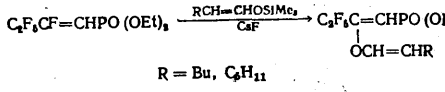


(XXXVI)



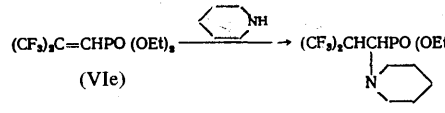
Reaction of unsaturated cyclic fluorine-containing phosphonates with alcohols leads to replacement of the vinyl halogen atoms.[14,39,82] Further substitution of the allyl fluorine atoms by alkoxy groups is also possible:[14]

$n = 2,3$; X = F, Cl, Br



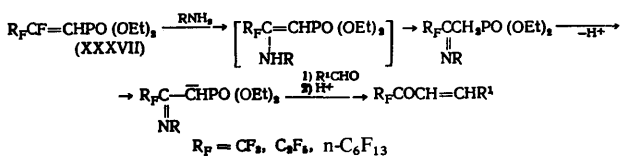
2-Chloroperfluorocyclopentenylphosphonate reacts with hexafluoropentanediol in the presence of triethylamine to form *bis*-phosphonate:[82]

In free 2-chloroperfluorocyclopentenylphosphonic acid the chlorine atom is stable towards the action of bases.[82]



Replacement of a vinyl fluorine atom by a vinyloxy group occurs when α-*H*-perfluorobutenylphosphonate reacts with trimethylsilyl enol ethers:[83]

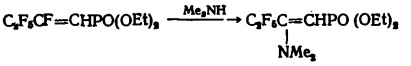
R = Bu, C_6H_{11}



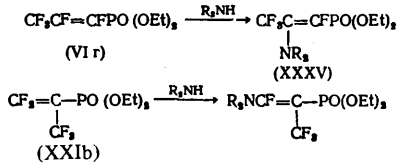
In the reactions of fluoroalkenylphosphonates with amines, depending on the structure of the initial compounds addition products are formed or substitution of the vinyl halogen atom or further conversions occur.

α-*H*-perfluoroisobutenylphosphonate (VIe) adds on a piperidine molecule to the double bond, with the nucleophile attacking the α-position:[27]

(VIe)

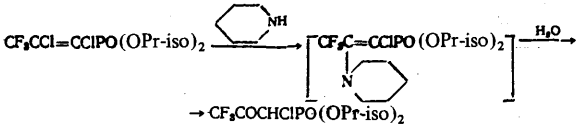


α-*H*-Perfluoroalkenylphosphonates (XXXVII) react with primary amines to form the corresponding imino derivatives evidently by substitution of the vinyl fluorine atom and subsequent rearrangement of the enaminophosphonates:[59]

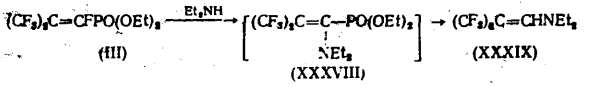


$R_F = CF_3$, C_2F_5, n-C_6F_{13}

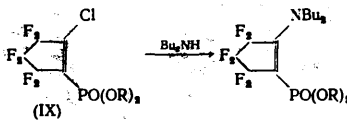
Reaction of iminophosphonates with bases gives carbanions that can undergo the Wittig–Horner reaction with aldehydes.[59]



A β-Enaminophosphonate is obtained by the reaction of α-*H*-perfluorobutenylphosphonate with dimethylamine:[59,84]

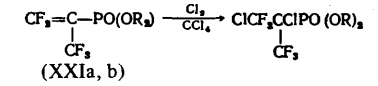


Products from the substitution of the vinyl β-halogen atoms are obtained from pentafluoropropenylphosphonate (VId)‡[38] and pentafluoroisopropenylphosphonate (XXIb):[80]



It is reported in one patent[71] that substitution of a vinyl chlorine atom occurred when 1,2-dichloro-3,3,3-trifluoropropenylphosphonate was treated with piperidine; subsequent hydrolysis gave a ketophosphonate:

Reaction of perfluoroisobutenylphosphonate (III) with diethylamine apparently leads to substitution of a vinyl fluorine atom in the α-position, but the unstable enaminophosphonate (XXXVIII) decomposes when treated with excess amine to form enamine (XXXIX):[27]



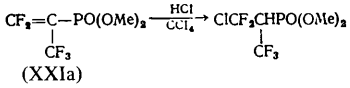
Reaction of unsaturated cyclic phosphonates (IX) with secondary amines gives the corresponding enaminophosphonates:[82]

(IX)

(b) Halogenation and Hydrohalogenation

The electrophilic addition of halogens and hydrogen halides to the C=C double bond is usually hindered when electron-withdrawing groups are introduced into an unsaturated compounds.[85,86] However, despite their high electrophilicity pentafluoroisopropenylphosphonates (XXIa, b) very readily add on chlorine in an inert solvent, and the reaction does not require base catalysis:[87]

(XXIa, b)



The less electrophilic trifluorovinylphosphonate (VIa) is chlorinated under these conditions much more slowly, which is demonstrated by means of a competing reaction.[31]

---

‡ Methyl(pentafluoropropenyl)phosphinate reacts in a similar way.[38]

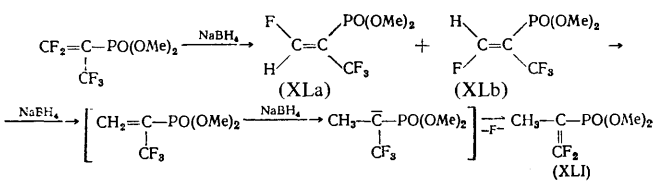
It is suggested that the phosphonate group acts as an "internal base" which activates the halogen molecule and transfers the halogenation of the highly electrophilic unsaturated compound to a "nucleophilic pathway".[87]

For a similar reason pentafluoroisopropenylphosphonate (XXIa) readily forms an addition product with hydrogen chloride:§[87]

(XXIa)

In these reactions pentafluoroisopropenylphosphonates behave similarly to perfluoromethacrylic acid dialkylamides (cf. Ref.21).

2-Chloroperfluorocyclopentenylphosphonate (IX), when R = Et, decolorises a solution of bromine, while *bis*-phosphonate (X), n = 3, R = Et, does not react with bromine.[77] When tetraallyl perfluorocyclopentenylene-*bis*-phosphonate is brominated, only the C=C bonds in the nonfluorinated allyl fragments react.[10,75]



(c) Reduction and Oxidation

The C=C double bond in fluoroalkenylphosphonate derivatives can be saturated by hydrogenation and oxidation. α-Fluorovinylphosphonates (XXVI) undergo catalytic hydrogenation to give the corresponding phosphonates:[56]

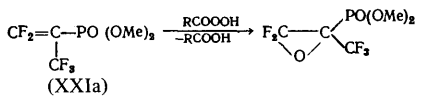
(XXVI)

Reaction of pentafluoroisopropenylphosphonate (XXIa) with sodium borohydride leads to replacement of fluorine atoms by hydrogen. The monohydro derivatives (XLa, b) and trihydro derivatives (XLI) have been identified among the reaction products:[45]

(XLa) (XLb)

(XLI)

The formation of the α-oxide from 3-fluoropropenylphosphonate salt has been reported:¶[71]



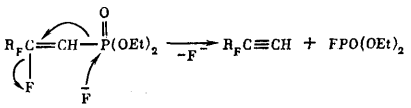
---

§ Chlorine-containing alkynylphosphonates react in a similar manner with hydrogen chloride.[88]

¶ Oxides of nonfluorinated unsaturated phosphonates can be obtained by various methods including epoxidation. Propenylphosphonic acid oxide $CH_3CH\!-\!CHPO(OH)_2$ (phosphonomycin) is an antibiotic.[91]

Pentafluoroisopropenylphosphonate (XXIa) is readily epoxidised when treated with an aromatic peroxyacid in ether:[89,90]

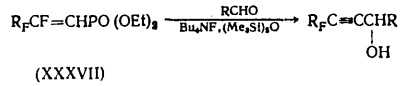
(XXIa)



Perfluoromethacrylic acid derivatives behave in a similar manner.[21,89]

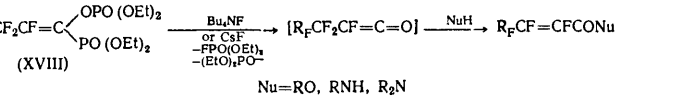
2-Chloroperfluorocyclopentenylphosphonate (IX), where R = Et, decolorises a solution of permanganate.[77]

(d) Reactions with Fluoride Ion



Attack by a fluoride ion can be directed on to either the phosphorus atom or an electrophilic carbon atom of a fluoroalkenylphosphonate depending on its structure.

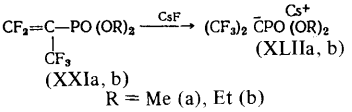
Thus, α-*H*-perfluoroalkenylphosphonates (XXXVII) when treated with a catalytic quantity of tetrabutylammonium fluoride or caesium fluoride are converted to perfluoroalkylacetylenes:[60,83]



(XXXVII)

In the presence of aldehydes, ethynylcarbinols are formed:[92]

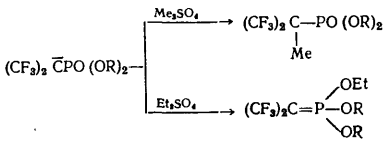
(XXXVII)



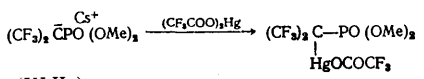
For phosphoryloxyphosphonates (XVIII) cleavage of the C–P bond is also possible. Combined treatment with fluoride anion and alcohol or amine gives α,β-unsaturated carboxylic acid derivatives, with fluorine-containing ketenes probably formed as intermediates:[93]

(XVIII)

Nu=RO, RNH, R_2N



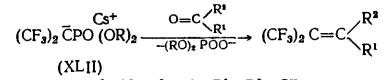
The highly electrophilic pentafluoroisopropenylphosphonates (XXI) add on an F^- anion to the C=C double bond under mild conditions. Treatment with CsF in polar aprotic solvents at low temperatures gives relatively stable solutions of salts (XLII), which contain an α-phosphonate-substituted carbanion:[80]



(XXIa, b) (XLIIa, b)

R = Me (a), Et (b)

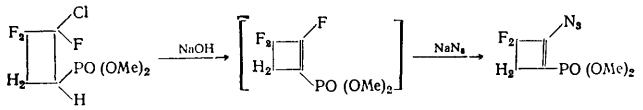
This mesomeric carbanion can be alkylated on either the carbon atom or oxygen atom:[80]



The mercuration of salt (XLIIa) has also been reported:[45]

(XLIIa)

There is considerable interest in the use of salts (XLII) in the Wittig–Horner reaction. On treatment with carbonyl compounds, fluorine-containing olefins are formed:[80]



(XLII)

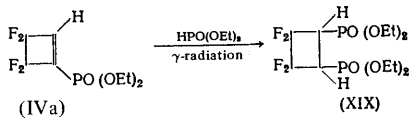
R^1=H, R^2=Ph; R^1=R^2=CF_3

In the Wittig–Horner reaction here a nonstandard method is used to obtain the initial α-phosphonate-substituted carbanion. Instead of the usual deprotonation of α-*H*-phosphonate,[94] use is made of the addition of a nucleophile (F^-) to an α,β-unsaturated phosphonate.†

(e) Other Reactions

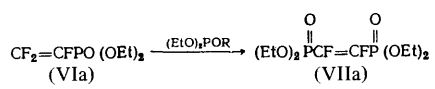
The action of sodium azide in the presence of alkali on cyclic phosphonate (XLIII) gives an unsaturated azidophosphonate, probably as a result of substitution of the vinyl fluorine atom in the cyclobutenylphosphonate (XLIV) formed as an intermediate:[96]

(XLIII) (XLIV)



In a similar manner to perfluoromethacrylates,[21,89] pentafluoroisopropenylphosphonate (XXIa) readily adds on carboxylic acids:[80]

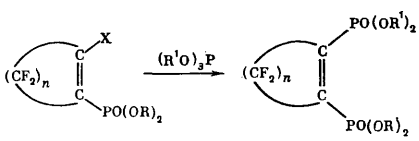
(XXIa)



X=H, *m*-Cl

The reaction of 2-*H*-perfluorocyclobutenylphosphonate (IVa) with diethyl phosphite occurs under conditions for radical formation and gives addition product (XIX):[39]

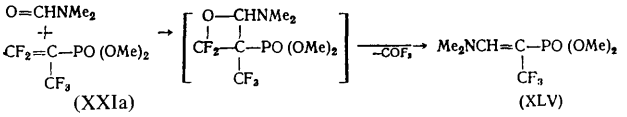
(IVa) (XIX)



When trifluorovinylphosphonate (VIa) is reacted with neutral phosphites, a vinyl fluorine atom is replaced and *bis*-phosphonate (VIIa) is formed:[31]

(VIa) (VIIa)

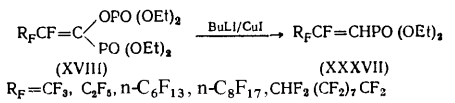
R=Et, Me_3Si



A similar substitution of the vinyl halogen atom also occurs for cyclic unsaturated phosphonates:[14,74]

n=2,3; X=Cl, Br, I

ω-Iodoperfluoroalkenylphosphonates (VIIIa–c) do not react with triethyl phosphite even on heating.[34]



Pentafluoroisopropenylphosphonate (XXIa) reacts with dimethylformamide to give enaminophosphonate (XLV), probably through the intermediate formation of a cycloadduct:[80]

(XXIa) (XLV)

The analogous reactions of perfluoromethacrylic acid derivatives have been widely reported.[21]

α-Phosphoryloxy-substituted phosphonates (XVIII) when treated with butylcopper are converted to α-*H*-perfluoroalkenylphosphonates (XXXVII):[61]

(XVIII) (XXXVII)

R_F=CF_3, C_2F_5, n-C_6F_{13}, n-C_8F_{17}, $CHF_2(CF_2)_7CF_2$

* * *

In the summary presented above the variety of reactions of fluoroalkenylphosphonates, which combine the properties of fluorine-containing olefins and phosphonic acid derivatives, should be noted. There is definite interest in a systematic study of this class of compounds especially since some of them may have practical application.

The Use of Electrochemical Methods for Studying the Structure and Reactivity of Organometallic Compounds

T.V.Magdesieva, K.P.Butin, and O.A.Reutov

The different aspects of using electrochemical methods for studying the structure and reactivity of organometallic compounds as well as for investigating certain details of their reaction mechanisms such as regioselectivity, process compatibility, the role of nucleophilic assistance, and so forth are examined.
The bibliography includes 95 references.

I. INTRODUCTION

In recent years electrochemical methods have become more widely used not only for the purposes of analysis but also for studying the structure and reactivity of organic molecules.[1,2] Electrode reactions can be regarded as models of the fundamental stages of a large number of organic reactions, above all redox reactions.[3]

However, electrochemical methods, apart from classical polarography and cyclic voltammetry, are still not sufficiently popular among organic chemists and organometallic chemists although their relative simplicity to use in terms of equipment could be very useful for solving such theoretical and practical questions as: 1) quantification of redox properties of compounds; 2) determination of the electronic effects of substituents 3) the use of half-wave potentials ($E_{1/2}$) for oxidation and reduction in quantum chemical calculations, including those for determining the site of localisation of electron changes in the molecule during redox reactions; 4) the study of processes leading to the formation of unstable products such as radicals and radical ions; 5) studying the mechanism (kinetics, stoichiometry) of the electrochemical process as a model of the fundamental event of a chemical reaction; 6) establishing a correlation between $E_{1/2}$ for reduction of the M−R σ-bond and the properties of the carbanion R^- or radical R, such as the acidity of RH, nucleophilicity of R^-, electron affinity of R, and so on; 7) the choice of conditions for electrosynthesis of organic and organometallic compounds.

Half-wave potentials are not standard redox potentials in the strict thermodynamic sense. They also include kinetic, adsorption, solvation, and other effects. Nevertheless, they characterise sufficiently precisely the redox properties of a vast number of organic molecules in solution and are often the only available numerical indicators of these properties. Values of $E_{1/2}$, to a greater degree than many other physicochemical quantities, are sensitive to electronic effects in molecules but reflect the spatial configuration and conformation of organic molecules less precisely.

Electrochemical methods can be successfully used to study heterolytic reactions in which the key stage is transfer of an electron from donor to acceptor. Specific criteria have been developed[4] for electrochemical modelling of the fundamental event of a chemical reaction.

1. In drawing an analogy between chemical and electrochemical reactions it is necessary that the same products are obtained as a result of their taking place.
2. After the electron transfer has been defined in a chemical reaction, it is necessary to introduce products formed from electron donors or acceptors into the solutions intended for electrochemical studies and to model their action using electrochemical methods.
3. If the reversibility of the events of electron transfer for the reagents studied can be demonstrated using electrochemical methods and EPR can be used to identify radical ions that are formed in electrochemical and chemical reactions, it may be assumed that the radical ions are sufficiently stable and that the rate of reaction is determined by the slow stage of their decomposition, after which σ-radicals are formed.
4. It should be taken into account that a change in the type of medium can produce a marked change in reaction mechanism and this is clearly defined using electrochemical methods.

It is necessary to take great care when considering the possibilities of using polarography for quantitative determination of the structure and reactivity of organic molecules. It is usually recommended that irreversible waves are immediately excluded from consideration, since the subsequent reactions of radical ions also contribute to their potentials. Two-electron waves are also unsuitable because in the majority of cases transfer of two electrons is due to rapid chemical reactions in the vicinity of the electrode. Consequently, consideration can only be given to reversible one-electron waves for oxidation or reduction, but in this case the heterogeneous nature of the electrode reaction and the specific interaction of substrate with reagent that precedes the transfer of an electron, etc, should be borne in mind. Therefore $E_{1/2}$ values may only reflect a general trend in the change of properties and are relative values. In this connection Okhlobystrin[5] has criticised Pozharskii,[6] who had proposed the use of polarography "as a guiding principle in quantitative studies on reactivity." Nevertheless, even a purely qualitative approximate assessment of the properties of compounds based on electrochemical data can often be very useful.

There have recently been a number of reviews and monographs published on the electrochemistry of heteroorganic compounds such as derivatives of nontransition elements,[7,63] Group I-III elements and transition metals,[8,9] and also metal chelates.[10,11] Aspects of electrochemical synthesis have been examined in reviews.[12,13] Works

devoted to studying π-complexes of transition metals have been correlated in reviews.[14,15] The increased interest in these compounds is due to the fact that the majority of them readily undergo redox conversions that occur with a change in formal oxidation state of the metal while retaining the structure of the organometallic compound and also because the values of the half-wave potentials lie in a convenient region to study. Moreover, processes in which cleavage of C−M or M−X σ−bonds does not occur, are, as a rule, reversible, which increases the strictness of the correlations obtained.

In the present review we examine the works of those authors who do not confine themselves to measuring redox potentials of a given compound and determining the products of their electrochemical conversions but use electrochemical data to study the electronic structure of molecules and predict their chemical properties. The subject matter is arranged in accordance with the site of localisation of electron changes during chemical and electrochemical redox reactions of π- and σ-organometallic compounds, the method for determination of this being proposed in [16].

II. REDOX PROCESSES IN WHICH ELECTRON CHANGES ARE LOCALISED ON THE METAL ATOM

If the metal atom in a complex is bonded by a delocalised π-bond only to carbocyclic ligands and has an electron shell similar to the atoms of an inert gas, when redox processes occur the electron changes are localised on the metal atom. Reactions such as this have the following characteristics: 1) the electron configurations of the oxidised and reduced forms are similar and the electrode reaction is reversible; 2) potentials are virtually independent of the solvent; 3) the polarographic properties do not depend on the addition of a proton donor:

The system ferrocene−ferrocenium ion is very convenient for study, as it is firstly, reversible and, secondly, the rate of its electron exchange is high. The electrochemical behaviour of this system and also π-complexes of other metals has been examined in reviews,[14,15] so we will not go into this subject in detail. The first attempts to establish correlations between the reactivity of organic compounds and the half-wave potentials for their oxidation or reduction date back to the beginning of the 1950s, when the linear free energy principle (equations of Hammett, Taft, Yukawa−Tsuno, and others) started to be applied to polarography. Leaders of this trend were Jaffé [17] and Zuman;[18] the latter applied the Hammett equation to half-wave potentials:

$$\Delta E_{1/2} = E^{X}_{1/2} - E^{H}_{1/2} = \rho\sigma_X,$$

where $E^{x}_{1/2}$ and $E^{H}_{1/2}$ are the half-wave potentials for oxidation or reduction of a compound with a substituent X and an unsubstituted compound, ρ is the reaction constant (measured in volts), σ is the substituent constant. This relationship is valid for both irreversible and reversible electrochemical processes. In the first instance it represents the perturbation introduced by the electronic effect of substituent X to the change in free energy when going from the oxidised (reduced) to the reduced (oxidised) form of the molecule, and in the second instance it represents the perturbation introduced by the substituent to the change in free energy of activation when going from the oxidised (reduced) form to the transitional electrode complex.

It was possible to make use of this concept in order to arrange systematically the material obtained from the polarography of organic compounds and to study the nature of the electronic effect of substituents on the reaction centre (metal atom) in redox reactions.

Comparison of different σ constants of substituents and also from a number of their combinations showed that the best correlation occurs between $E^{o}_{1/2}$ and σ^{0}_{n} derived by Taft.[22] The correlation dependences obtained were successfully used to determine the σ constants of metallocenyl groups and other polyatomic groups.[14,19,27] The electronic effects in ferrocenes,[20,21,23,24,28] and in arenecyclopentadienyliron cations,[29] ruthenocenes and osmocenes[25,30] are such that σ^{0}_{n} constants correlate better with $E_{1/2}$. This indicates that there is conjugation between the aromatic ring and the substituent. However, in *bis*-arenechromium compounds it is very weak, so $E_{1/2}$ for oxidation of *bis*-arene complexes of chromium correlates better with σ_m constants.[26,31,32] The difference between complexes of chromium and other metals is probably due to differences in the nature of the metal−ligand bond,[31] although it should be stressed that in both cases an inductive mechansim for transmission of the electronic effect of substituent to metal atom is the decisive factor.

The half-wave potentials of irreversible processes also correlate with σ constants of substituents. For example, $E_{1/2}$ for the irreversible two-electron oxidation of platinum complexes

$$[P(C_2H_5)_3]_2\,Pt(X{-}C_6H_4)_2 \xrightarrow[-2e]{} [P(C_2H_5)]_2\,Pt(X{-}C_6H_4)_2]^{2+}$$

correlates well with Hammett σ constants,[34] while $E_{1/2}$ for the reduction of chelate complexes of nickel with dithiocations [sic] of general formula $Ni(S_2C_2R_2)_2$ show a linear dependence on the inductive constants of substituents.[35]

It has been shown[36–38] that standard redox potentials E^0 for different one-electron redox transfers in sandwich-type π-complexes of transition metals, such as $Cp_2M^- \rightleftharpoons Cp_2M \rightleftharpoons Cp_2M^+ \rightleftharpoons Cp_2M^{2+}$ give a linear correlation with the corresponding ionisation potentials *IP* of metals and their ions, and this correlation should be common for all metals and all possible redox changes in a series of complexes with the same ligand environment. The existence of such a correlation is due to the fact that the main contribution to the highest occupied and lowest unoccupied molecular orbitals (HOMO and LUMO) of metallocenes is made by the atomic orbital (AO) of the metal. Therefore, the potentials for the reactions of metallocenes, including the electron-transfer stage involving the HOMO and LUMO, must be determined by the properties of the metal itself in the given oxidation stage. Although this correlation is approximate and holds for complexes with 12-17 and 19-21 electron configurations (the number of electrons in the valence shell of the metal is given), it is very useful and can be used to predict redox properties from known *IP* values of the metal, and hence also ranges of potential in which different classes of sandwich π-complexes are stable.

In one study[37] a diagram of zones of thermodynamic stability for metallocenes Cp_2M and their cations is given (Fig.1). As can be seen from the diagram, as the atomic weight of M increases the zone of stability for Cp_2M shrinks, in other words, metallocenes of 4d- and 5d-metals are oxidised more readily than their 3d-analogues. This makes it difficult to synthesize heavy metallocenes. The synthesis of doubly charged cations of type $(C_7H_7)M^{2+}$ is also very difficult as they are incompatible with most known solvents as a result of their very strong oxidising capacity ($E^0 > 3.0$ V). Thus, it is very useful to know the values of E^0 when choosing the most convenient method of synthesizing metallocenes and also to understand the nature of the active particles that are formed in reactions catalysed by metallocenes (for example, the products from the

reduction of Cp_2MCl_2, where M = V, Nb, catalyse the low-temperature reduction of carbon monoxide to hydrocarbons in the presence of added quantities of proton-donor compounds[39–41]).

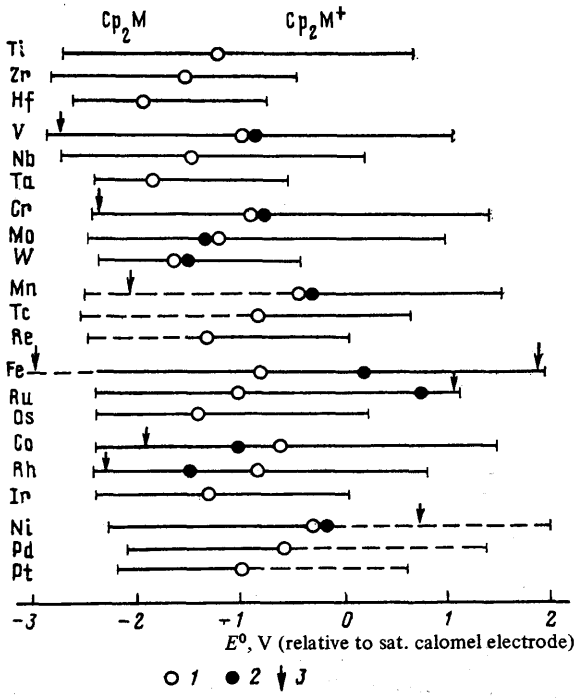

Figure 1. The zones of thermodynamic stability for Cp_2M complexes and their cations; (1) calculated values of E^0 for $Cp_2M^{0/+}$ redox pairs; (2) experimental values of E^0 for $Cp_2M^{0/+}$ redox pairs; (3) experimental values of E^0 for $Cp_2M^{0/-}$ and $Cp_2M^{2+/+}$ redox pairs; the dotted lines denote the zones of stability for Cp_2M^+ cations and Cp_2M complexes for $d^{5/6}$ and $d^{6/7}$ electron transitions for which there is a deviation from the linear dependence of E^0 on *IP*.[37]

Study of π-complexes of Fe, Co, Ni, Cr, Mo, W, Mn, Ru, Re, Au, and Cu,[37,38] has shown that the tangent of the gradient angle of the dependence of E^0 on *IP* for different types of sandwich complexes does not depend on the nature of the ligand and is equal to ~0.11:†

$$E^0 = a + 0.11 \cdot IP,$$

†The tangent of the gradient angle of the correlation dependence must theoretically be close to unity. (Thus, for example in some studies,[42–44] where the correlation between $E_{1/2}$ and *IP* is given for a number of organometallic compounds, it is equal to 0.89, 0.92, 0.98, and 0.87). The experimental value of 0.11 in the relationship obtained in these studies[37,38] is particularly interesting and needs to be explained.

where *a* is a constant dependent only on the nature of the ligand (E_0 in V, *IP* in eV). It has been calculated for the main types of π-ligands: Cp (–2.08 V), C_6H_6 (–0.73 V), $C_7H_7^+$ (+1.52 V), etc.[37]

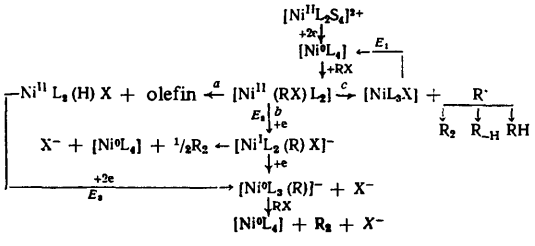
Studies[42–48] are devoted to linear relationships between $E_{1/2}$ and *IP*. In particular, a correlation has been found between $E_{1/2}$ for the reduction $M^{II} \rightarrow M^{I}$ and the second ionisation potential of Cp_2M metallocenes, where M = V, Cr, Co, Ni.[45] The value of $E_{1/2}$ for the process $Cp_2M^{III} \rightleftharpoons Cp_2M^{II}$ correlates with *IP* for the complexes Cp_2V, Cp_2Cr, Cp_2VCl_2, $CpNi(\eta^3\text{-}C_5H_7)$.[46] The oxidation potentials of bimetallic compounds:

$$R_3M{-}M'R_3 \xrightarrow{-e} R_3M{-}M'R_3^{+\cdot} \rightarrow R_3M^{\cdot} + M'R_3^{+}$$
M, M'=Si, Sn, Ge

correlate with vertical *IP* values.[44]

There is also a linear relationship between the electrochemical potentials for one-electron oxidation and the vertical ionisation potentials for compounds of type R_4Pb.[48]

Thus, it may be concluded from the data examined that in a number of cases the values of $E_{1/2}$, readily measured in solution, can be used to determine ionisation potentials in the gas phase.



Electrochemical methods can be used to study the disproportionation reactions of unstable complexes of various metals in which the metal is in an intermediate oxidation state and also to determine their HOMO and LUMO energies and spin state.[49] For example, in a study of the two redox systems:

$$Fe^{IV}L_3^+/Fe^{III}L_3 \text{ and } Fe^{III}L_3/Fe^{II}L_3^-$$

it was shown[50] that electrochemical electron-transfer reactions which are accompanied by a change in spin state are slower than reactions in which such a change does not occur. Values of E^0 have also been determined[51] for redox changes of $MF_6^{z/z-1}$ (z = 0, –1, –2; M = Ta, W, Re, Os, Nb, Mo, Ru) and it was shown that for the same metal E^0 increases for the different transitions according to the following series: $d^2/d^3 < d^1/d^2 < d^0/d^1$. The existence of a stepwise relationship between the standard redox potentials and the d^n-configuration of the metal for high-spin and low-spin octahedral complexes has been demonstrated.[52]

Electrochemical methods can be very useful in studying reaction mechanisms. For example, the dimerisation of alkyl and aryl halides catalysed by a Ni(0) complex has been studied.[49] Electrochemical methods were used to show the possibility of regenerating the catalyst, the reaction mechanism was studied and it was established that the Ni(II) complex containing a Ni–R σ-bond that is formed by oxidative addition can decompose by different routes depending on the nature of R (see Scheme 1). Thus, if R = Ar, the complex is thermally stable and can only be broken down by further reduction (route *b*). If R = Alk, the complex is thermally unstable and immediately decomposes according to route *a* (when β-H is present) or route *c*:

Scheme 1

Kochi et al.[48] studied alkyl transfer reactions using lead derivatives as a model and showed that Alk_4Pb reacts with $IrCl_5^{2-}$ according to the scheme:

$$R_4Pb + Ir^{IV}Cl_6^{2-} \xrightarrow{k} R_4Pb^{+} + Ir^{III}Cl_6^{3-}$$
$$R_4Pb^{+} \rightarrow R^{\cdot} + R_3Pb^{+}$$
$$R^{\cdot} + IrCl_6^{2-} \rightarrow RCl + IrCl_5^{2-} \text{ etc.}$$

The linear correlation found between $\log k$ for oxidation of $(C_2H_5)_{4-n}Pb(CH_3)_n$ with hexachloroiridate in acetonitrile and the electrochemical oxidation potentials indicates that the rate-determining stage of the overall process is formation of a radical cation. A similar type of correlation also occurred between $\log k$ in the reaction of Grignard reagents with di-tert-butyl peroxide and $E^{\circ x}_{1/2}$ values of Grignard reagents.[53]

III. REDOX PROCESSES IN WHICH ELECTRON CHANGES ARE LOCALISED ON THE π-BOND ORBITALS

Identification of the general rules governing the change in properties of arenes when coordinated with a metal atom is one of the most important aspects of the chemistry of organometallic compounds. In order to determine this it is possible to make use of an approach based on the comparison of redox properties of free arenes and those coordinated with a metal. Reduction of most complexes and the corresponding uncoordinated ligands in aprotic solvents is a reversible process, which makes it possible to study quantitatively the effect of coordination on the reactivity of π-bonded carbocyclic ligands in redox reactions. A quantitative determination is possible because: 1) these are equilibrium processes, so the difference in reactivity is not due to the nature of the transition state for coordinated and uncoordinated ligands; 2) one-electron reduction processes usually have a low activation energy and proceed rapidly, it may therefore be assumed that the difference between the reduction potentials of coordinated and uncoordinated ligands is caused only by electronic interactions and the changes in steric, solvation, and other effects are minimal; 3) the difference in potentials for reversible reduction of coordinated and uncoordinated ligands determined under the same conditions corresponds to the change in LUMO energies on coordination.

Among the large number of publications devoted to the electrochemical reactions of functional groups of a π-bonded ligand[15] it is possible to select some studies in which attempts have been made to relate the electrochemical behaviour of the compounds with their reactivity and electron properties. For example, a polarographic method was used to determine the electron affinity and σ constants for a number of metallocenyl groups,[54,55] the change in LUMO energy was calculated for acetophenone and benzoquinone when coordinated with $Cr(CO)_3$ [56] and π-$C_5H_5Rh(Ir)$[57] groups respectively. The values of $E_{1/2}$ for oxidation of nitrosyl cation complexes [π-$C_5H_5Mn(NO)LL'$], where L is a Lewis base, can serve as a measure of the π-acceptor properties of Lewis bases as ligands.[58]

The relationship between $E_{1/2}$ and the structure of complexes of Mg, Zn, Cu, Pb, Ni, Co, and V with ethylporphin and other porphyrins has been followed.[59] It was shown that introduction of a metal atom into the porphyrin molecule leads, as a rule, to $E_{1/2}$ changing to a more negative potential, while in a number of complexes of similar structure the change in reduction (oxidation) potentials depending on the nature of the metal is consistent with the change in LUMO (HOMO) energy of the complex.

Coordination affects the reactivity of arenes in different ways depending on the nature and donor-acceptor properties of substituents in the arene.[60,62] Not only the absolute magnitude of the effect can vary here but also its sign. Since the half-wave potential for oxidation of complex to radical cation ($E^{x}_{1/2}$) can serve as a measure of donor-acceptor properties of substituents

$$Arene_2Cr \underset{-e}{\rightleftharpoons} (Arene_aCr)^{+}$$

there must be a connection between the change in $E_{1/2}$ for reduction of arene due to complex-formation ($\Delta E^{ca}_{1/2}$) and $E^{x}_{1/2}$ values. Such a correlation was actually found:[60]

$$\Delta E^{ca}_{1/2} = a + \alpha E^{x}_{1/2},$$
$$a = (0.072 \pm 0.007)\,B;\ \alpha = (0.25 \pm 0.015);$$
$$r = 0.991.$$

Here $\Delta E^{ca}_{1/2}$ is the difference in half-wave potentials between a π-complex with chromium and free arene for a one-electron reversible reduction ($\Delta E^{ca}_{1/2} = E^{c}_{1/2} - E^{a}_{1/2}$).

Thus, the electrochemical cathode reduction reaction is an indicator that can be used to determine the change in free energy on going from arene to π-complex.

The electrochemical reduction of benzalacetophenone and its symmetrical chromium π-complex in DMSO has been studied,[61] and it was shown that the difference in half-wave potential for reduction of π-complex and free arene ($\Delta E^{ca}_{1/2}$) can be regarded as a measure of the effect of coordination on the ability of arene to be reduced to radical anion:

$$\Delta E^{ca}_{1/2} \approx \frac{RT}{nF} \ln \frac{k_c}{k_a}$$

where k_c and k_a are rate constants of reduction for π-complex and free arene respectively.

The dependence of the reactivity of coordinated arene on the nature of the second ligand is a unique feature of *bis*-arenechromium compounds. The high sensitivity of the cathode reaction to substituents in the second ligands is caused by the presence of the chromium atom, which transfers electron density to the ligand, and itself is positively charged.[62] Introduction of a substituent into the ligand has a strong effect on the electron density at the chromium atom and on the dative component of the metal–ligand bond, therefore for these components $\rho = 0.51$ V [62] (we should mention for comparison that $\rho = 0.33$ V [18] for the cathode reduction of substituted benzaldehydes in aqueous alkaline solution).

Thus, the electronic effects of substituents are transmitted from one ligand to another, and the chromium atom considerably intensifies the substituent effect on the second ligand, in other words, the systems in their way resemble an "amplifier" in radioelectronics. The half-wave potential for oxidation of *bis*-arenechromium ($E^{x}_{1/2}$) can be used as an indicator of the capacity of the chromium atom to transmit electron density to ligands. As was also demonstrated,[60] there is a linear correlation between $E^{x}_{1/2}$ and the change in reactivity in the cathode reaction when going from free arene to chromium π-complex ($\Delta E^{ca}_{1/2}$). The correlation equation obtained can be reduced to the general form:[62]

$$\Delta E^{ca}_{1/2} = b + \beta \sum \sigma,$$

where $b \approx 0.125$ V, $\beta = 0.13$ V. It follows from this that the first term in the equation is constant and is independent of the nature of substituent, while the second term expresses the effect of substituent

on the change in free energy when going from free arene to π-complex. The larger the electron-withdrawing effect of the substituent the greater is the decrease in absolute value of $\Delta E^{ca}_{1/2}$.

IV. REDOX PROCESSES IN WHICH ELECTRONIC CHANGES ARE LOCALISED ON THE σ-BOND ORBITALS

The reduction or oxidation of compounds with an M—M, M—C, or M—Hal σ-bond is known to be an irreversible process in most cases. In order to achieve a correlation between $E_{1/2}$ and the structural features, an essential condition is that there exists a constant electron-transfer coefficient for a series of compounds of similar structure. Experimental data indicates that when π-complexes contain localised σ-bonds, reduction in most cases affects only that bond which has the LUMO as an antibonding orbital. Capture of an electron in this orbital leads to cleavage of the σ-bond. When homo- and hetero-polymetallic compounds containing an M—M σ-bond are reduced, metal carbonyl anions $[L_nM]^-$ are usually formed, and readily undergo electrochemical oxidation.[64,65] There is a linear correlation between $E_{1/2}$ for oxidation of anion to radical and $\log k_2$, where k_2 is the rate constant for the nucleophilic substitution reaction:

$$[L_nM]^- + RHal \xrightarrow{k_2} L_nMR + Hal^-.$$

By comparing the values of k_2 for different anions it is possible to determine their relative nucleophilicity, and on the basis of the correlation obtained the relative nucleophilicity of those anions for which direct measurements of k_2 are not possible can be predicted. Using the experimental data obtained for various metal-containing anions (M = Bi, Sb, As, Ge, Sn, Pb, Fe, Ru, Co, Ni, Mn, Re, Cr, Mo, W) as a basis, the following conclusions have been made: in Groups Va, VI, and VII the nucleophilicity of the anions increases on moving down the Group, while in Groups VIII and IVa the nucleophilicity increases going up the Group.[65]

Extension of this approach showed that after measuring the oxidation and reduction potentials of two organometallic compounds it is possible to predict whether a one-electron exchange reaction will take place between them.[66] Thus, for example, for the reaction

$$m^- + S \rightarrow m^{\cdot} + S^- \qquad (1)$$

(where m^- is a metal-containing anion and S is a neutral or charged electron-acceptor molecule) a table has been compiled,[66] in which metal-containing anions arranged in order of increasing nucleophilicity (decrease in $E^{ox}_{1/2}$) are aligned vertically, while acceptor molecules, namely, different organometallic compounds which have $E^{Red}_{1/2}$ values that decrease in absolute value from left to right, are aligned horizontally. So in the top right-hand corner of the table are entered rapid reactions, while in the bottom left-hand corner are reactions which do not go at all or occur extremely slowly. And although the oxidation of anions to radicals on mercury or platinum electrodes is irreversible and $E_{1/2}$ is a kinetic rather than a thermodynamic parameter, the predictions based on these data are in good agreement with experiment (see Table.1).

Polarographic reduction of compounds of type $[\pi\text{-}C_5H_5M(CO)_3]_2$ and $\pi\text{-}C_5H_5M(CO)_3X$ (where M = Cr, Mo, W; X = Hal, CN, Ar, Alk) has been studied[67] and it has been shown that the ease of reduction of the M—M σ-bond decreases on changing from Cr to W.

Studies on the reduction of metal complexes that contain metal-halogen σ-bonds have shown[15,67] that the order of decrease in ease of reduction of this σ-bond for both one-electron and two-electron reduction is opposite to the series of increasing electronegativity of the halogens Cl > Br > I that determines the polarity of this bond. The observed order for decrease in ease of reduction of the M—Hal bond agrees with that of the change in $E_{1/2}$ values for reduction of the C—Hal bond in alkyl halides, which is accounted for by a radical mechanism for reduction. It may be concluded from this that the M—Hal bond in carbonyl complexes of transition metals has a strongly covalent character and has a tendency mainly to homolytic cleavage and not heterolytic cleavage.

Table 1. The dependence of the rate of reaction of (1) on $E^{ox}_{1/2}$ and $E^{Red}_{1/2}$ of reagents (DME, Ag/AgCl).[66]

*Time for half-conversion was 4 sec.

Transition metal compounds with a metal—carbon σ-bond are reduced, as a rule, at more negative potentials than complexes with M—Hal and M—M σ-bonds, and this occurs in a single irreversible stage that involves addition of one or two electrons. The irreversibility of the waves is due to the high reactivity of the particles formed. Three possible types of transition state in the reduction of the Fe—R bond for a series of $\pi\text{-}C_5H_5(CO)_2FeR$ compounds have been examined.[74] The route that leads to polarisation of the form $(Fe^{\delta+}\cdots R^{\delta-})$ can immediately be rejected as the least favourable, and the choice between radical $(Fe^{\cdot}\cdots R^{\cdot})$ and ionic $(Fe^{\delta-}\cdots R^{\delta+})$ routes can be made by studying the effect of substituents at the *para* position of the σ-phenyl ring on reduction. A linear correlation occurs between $E^{Red}_{1/2}$ and σ^0_n ($r = 0.973$, $\rho = 0.12$ V). If the contribution of the conjugation effect is greater than that allowed by σ^0_n, then large deviations from a linear relationship occur for such substituents. This fact and also the low value of ρ suggest that in the transition state of the electrochemical reaction studied the demands of the "reaction centre" for a polar substituent effect are not large, which corresponds well with a proposed homolytic type of activation of the Fe—C bond in the electrode field.

It has been shown[68] that replacement of a CO group in $\pi\text{-}C_5H_5.Re(CO)_3$ compounds by a phosphine ligand leads to a change in reduction mechanism (one-electron rather than two-electron). The values of $E_{1/2}$ of the first reduction wave were used to determine the

effect of substituents on the transition state of the electrode reaction. The best linear correlation occurred between $E_{1/2}^{Red}$ and the sum of the inductive constants from substituents at the phosphorus atom or with the basicity of the corresponding phosphines.

The polarographic reduction of compounds of type $XM(CO)_5$ (M = Mn, Re; X = Hal, Ar, acetyl, aroyl) occurs irreversibly according to a two-electron mechanism.[69] In all cases there is homolytic activation of the bond being reduced. In contrast to other types of σ-bond, the reduction of the M–C σ-bond (aromatic ring) is virtually independent of the nature of the metal.[69] The effect of substituents in the benzene ring of aryl derivatives on $E_{1/2}^{Red}$ is also small, which suggests that there is no conjugation between the aryl group and the metal atom in both the ground and transition states. However, the $E_{1/2}^{Red}$ values of acyl substituents vary considerably with the nature of the substituent. A good linear relationship is observed between $E_{1/2}^{Red}$ and Hammett σ constants (r = 0.985); ρ = +0.288 V and is the same for both Re and Mn derivatives.

An investigation using polarography and cyclic voltammetry showed[70] that reduction of planar cobalt chelate complexes occurs in the following way (chel is polydentate chelate ligand):

$$[RCo^{III}(Chel)L] \underset{-e}{\overset{+e}{\rightleftharpoons}} [RCo^{III}(Chel)L]^- \underset{-e}{\overset{+e}{\rightleftharpoons}} [RCo(Chel)L]^{2-}.$$

The $E_{1/2}$ values of the first reduction stage for the same type of complex depend on R, in other words, the electron affinity of the organometallic chelate depends on the stability of the R^- anion, and there is a correlation between $E_{1/2}^{Red}$ and pK_a (RH). This means that the orbital into which the electron goes on reduction is the antibonding orbital of the Co–C bond. Thus, the electrode process examined can serve as a model of a reductive cleavage reaction.

It was previously shown[71] that there is a clear correlation between the nucleophilicity of Co(I) complexes in oxidative addition reactions and $E_{1/2}$ for reduction of complexes Co(II) → Co(I). Special attention should be given to the fact that redox potentials of cobalt chelates can vary over a very wide range depending on the nature of the ligand. If the electron density on the Co atom varies to the same extent, the distribution of charge on the Co–C bond must vary accordingly. A change in electron density on the Co atom and a distribution of charge on the Co–C bond can mean that there are various mechanisms for cleavage of this bond, including the extreme cases – nucleophilic and electrophilic and electrophilic reactions on the carbon atom—and the intermediate homolytic cleavage. Such an approach can possibly be used to develop the chemistry of coenzymes that belong to the vitamin B_{12} group and which contain a Co–C bond.

Polarography can be a convenient method for determining the electron affinity of various radicals.[72,73] Organomercury compounds that are reduced on an Hg cathode in two one-electron stages can be used for this purpose:

$$RHgHal + e \rightarrow RHg^{\cdot} + Hal^-,$$
$$RHg^{\cdot} + e \xrightarrow{H^+} RH + Hg.$$

Since the C-Hg bond in $RHg^{\cdot}$ is weakened, it may be assumed that when this particle is reduced the changes in electron density are localised mainly in the half-filled orbital of R$^{\cdot}$, so that there is a good linear correlation between $E_{1/2}$ for the second reduction wave and the electron affinity of radical R$^{\cdot}$. The limited number of other methods for determining this value are less accurate. Study of the dependence of $E_{1/2}$ for the second wave on the substituent in the radical showed[73] that the best correlation occurs between $E_{1/2}^{Red}$ and σ_n^0, namely, the dependence of $E_{1/2}^{Red}$ on polar effects is small, as is typical for homolytic cleavage of a bond.

Electrochemical data can be used to predict the type of decomposition of radical cations formed as intermediates. Decomposition of the form $RH^{+\cdot} \rightarrow R^{\cdot} + H^+$. The scheme for decomposition of the triethylsilane radical cation predicted[74] on the basis of this principle

$$(C_2H_5)_3SiH \underset{-e}{\rightarrow} [(C_2H_5)_3SiH]^{+\cdot} \rightarrow (C_2H_5)_3Si^+ + H^{\cdot}$$

($E_{1/2}^{ox}$ = 0.230 V) is in good agreement with the experimental data.

Electrochemical methods can be successfully used to study the properties of organomagnesium compounds, in particular for determining their basicity.[75] Cathode-anode polarisation curves of solutions of RMgX and R_2Mg in THF on a hydrogen electrode probably correspond to the following process:

$$RMgX + {}^1/_2H_2 \underset{+e}{\overset{-e}{\rightleftharpoons}} RH + MgX^+.$$

The zero current potential $E_{i=0}$ of the polarisation curve is the equilibrium value for this redox system and depends on the basicity of RMgX. The pH value [sic] of solutions of organomagnesium compounds, calculated as a function of $E_{i=0}$, is a quantitative measure of their basicity. Polarography data can be used to determine the acidity of hydrocarbons. Determination of the acidity of weak CH acids such as hydrocarbons is not possible by a direct method because of the large pK_a value for most hydrocarbons and their slow dissociation. At the same time it is possible to measure the equilibrium constants of other reactions of carbanions and compare them with the pK_a values of hydrocarbons. The first attempt to use polarography for determination of the relative stability of carbanions was undertaken by Streitwieser and Perrin,[76] who tried to relate $E_{1/2}^{Red}$ for substituted benzyl chlorides and polycyclic arylmethyl chlorides in DMF with pK_a values of the corresponding arylmethanes. Then the $E_{1/2}$ value of the second reduction wave of organomercury salts was suggested[77] as a measure of the relative acidity of CH acids. However, the use of this parameter did not prove very successful because the value of $E_{1/2}^{Red}$ for the second wave depends on the rate of dimerisation of the initially formed radicals. A correlation was found successfully in two studies,[78,79] in which it was recorded that the acidity of CH acids over a wide range of pK_a values is related to the polarographic reduction parameters for symmetrical organomercury compounds R_2Hg, which undergo a two-electron reduction to form the corresponding carbanions R^-. There was found to be a linear relationship between values of $\alpha n_\alpha E_{1/2}$ (α is the electrochemical transfer coefficient, n_α is the number of electrons in the potential-determining stage) and pK_a values:

$$\Delta(\alpha n_\alpha E_{1/2}) = \rho \Delta pK_a,$$

where ρ is an empirical coefficient that is dependent on the experimental conditions. Using this equation a scale of CH acidity covering more than 50 hydrocarbons was compiled. Later the CH

acidity of some brominated toluenes was determined by the same method.[80]

Denisovich and Gubin[81] studied three series of compounds—RHgX, R_2Hg, and σ-derivatives of π-cyclopentadienyldicarbonyliron—in order to compare the reduction parameters and pK_a (RH). All these compounds are reduced by cleavage of the carbo–metal bond to give the carbanion R^-. The correlation between $E_{1/2}$ and structure is known to be good only for reversible processes. For irreversible processes the correlation holds only if the α coefficient is strictly constant. The reason for the scatter in α values for the different series of organomercury compounds is related to the unsaturated state of the coordinated mercury atom, which leads to complex-formation between molecules of organomercury compound and solvent and with each other. Iron π-complexes are free of these problems. The α coefficient for these series is virtually constant. It is therefore more suitable to use σ-derivatives of π-cyclopentadienyldicarbonyliron in the determination of unknown pK_a (RH) values. It is true that a significant shortcoming of these compounds is that it is difficult to synthesize them. The pK_a values of ferrocene have been determined[81] as well as those of cyclopentadienyltricarbonyls of manganese and rhenium.

Up to this point we have examined studies in which electrochemical methods have been used on processes that occur with cleavage of a carbon– metal σ-bond and on the properties of the particles formed by this. However, it is also possible to use electrochemical methods to determine the tendency of compounds to form such a bond. For example, it was shown[82] that preliminary polarographic analysis can be a useful test of whether benzyl bromide containing different substituents in the ring will readily undergo a reaction with metallic mercury to give the corresponding benzylmercury bromide. The C–Br bond in benzyl bromide is known to be reduced in a single two-electron stage (see [3], p.217). Such behaviour was observed[82] for unsubstituted benzyl bromide, the three isomeric monobromo derivatives, 3,5-dibromo- and pentafluoro-benzyl bromides. However, pentabromo-, pentachloro-, 2,3,4,6-tetrabromo-, 2,4,6-tribromo-, and 2,6-dibromo-benzyl bromides give polarograms that are identical with those of the corresponding benzylmercury bromides. This suggests that these benzyl bromides are reduced via organomercury compounds that are rapidly formed by contact of the benzyl bromides with the surface of the mercury electrode. Reduction by this route in fact occurs for those benzyl bromides which give organomercury compounds after a short time in good yield when the reactions are carried out preparatively.

Electrochemical methods in combination with different spectral methods can provide valuable information on the electronic structure of σ- and π-organometallic compounds, the charge transfer mechanism in reduction or oxidation products, the distribution of spin density in molecules, and skeletal rearrangements during reduction or oxidation. Answers to these questions are important for both theoretical and preparative chemistry. For example, there are a number of studies[83–89] on the mechanism for charge transfer to the metal atom and carbonyl groups in octahedral and bipyramidal complexes of Fe, Cr, Mo, and W and in their one-electron reduction products. It was shown that in the octahedral complexes transfer of charge to and from the metal atom occurs by a σ-mechanism, namely, one involving metal–ligand σ-bonds, while in the bipyramidal complexes there is a π-mechanism for charge transfer towards the metal atom, namely, one involving metal–ligand π- or δ-bonds, and a σ-mechanism in the opposite direction. The force constants calculated from IR spectra for octahedral complexes of the form $LM(CO)_5$ (M = Cr, Mo, W; L = Py, quinoline) and their reduction products are also discussed in terms of σ- and π-bonding; the electrochemical properties and EPR spectra of 27 different bimetallic compounds were also studied.

V. SIMULTANEOUS CALCULATION OF ELECTROCHEMICAL OXIDATION AND REDUCTION POTENTIALS OF ORGANOMETALLIC COMPOUNDS IN ORDER TO DETERMINE THEIR REACTIVITY

In the studies examined in the preceding chapters, the relation between the reactivity of a compound and only one of the redox potentials–oxidation potential or reduction potential—has been investigated. In our opinion a much more fundamental relation between the electrochemical potentials and electronic structure of molecules and their reactivity can be followed if both the oxidation potentials and reduction potentials measured under the same conditions are known. Then for reversible electrochemical processes it is possible to determine the relative energies of frontier HOMO and LUMO orbitals, their change of position in relation to molecular structure, and also the magnitude of the energy gap between these orbitals, on which the stability of a molecule is dependent during thermal or photoexcitation. In the case of irreversibly oxidised or reduced systems, which includes the majority of organic compounds, similar direct correlations are less good. Nevertheless, it may transpire that even for electrochemically irreversible processes the effect of substituents in a series of related substrates on $E_{1/2}^{ox}$ and $E_{1/2}^{Red}$ will have a corresponding effect on the HOMO and LUMO energies, and then readily available electrochemical potentials can be used to predict reactivity at a semi-quantitative level.

Such an approach was used for the first time[90] when oxidation and reduction potentials on a platinum electrode under absolutely identical conditions were measured for 35 alkyl-, aryl-, and benzylmercury halides. On the basis of the derived values of the half-wave potentials for oxidation and reduction, a new classification of organomercury halides was proposed, making it possible to predict their relative reactivity in reactions with different forms of cleavage of the C–Hg bond (Fig.2, Table 2). According to this classification organomercury compounds can be divided into four types—anionogenic, cationogenic, radicalogenic, and inert (labelled as A, C, R, and I respectively in Fig.2); this reflects the relative stability of carbanions (A), carbocations (C), and radicals (R) formed. This classification is very provisional and there is no sharp boundary between groups. For example, not only secondary benzyl but also primary benzyl and alkyl organomercury compounds can undergo radical decomposition. It should however be emphasised that on moving upwards along the diagonal *ir* the relative tendency to radical decomposition will increase, since as this occurs the magnitude of "the inherent polarographic gap" of the compound (i.e, the difference $E_{1/2}^{ox} - E_{1/2}^{Red}$) will decrease.

In one study,[91] of the stability of organometallic compounds (OMC) in their synthesis and decomposition processes, the values of the OMC ionisation potentials (or oxidation potentials in solution) are used to predict the stability of the compounds and their tendency to different types of cleavage of the C–M bond. For nontransition metals that have ionisation potentials IP_M of the order of 4–8 eV, there is typically formation of those OMC for which $IP_{OMC} > IP_M$ (when $IP_R > IP_M$) with organic radicals ($IP_R \sim 8-10$ eV). In this

case as a result of the electropositive nature of the metal the contribution of the orbital of the radical to the HOMO in the organometallic compound will be greater, which corresponds to the formation of a polar M–R bond with a negative charge on R. When $IP_M \approx IP_R$ the M–R bond will be covalent, even though $IP_{OMC} > IP_M \approx IP_R$. When $IP_M > IP_R$ the negative charge of the dipole will be localised on the metal atom and the HOMO will have a primary contribution from the metal orbital.

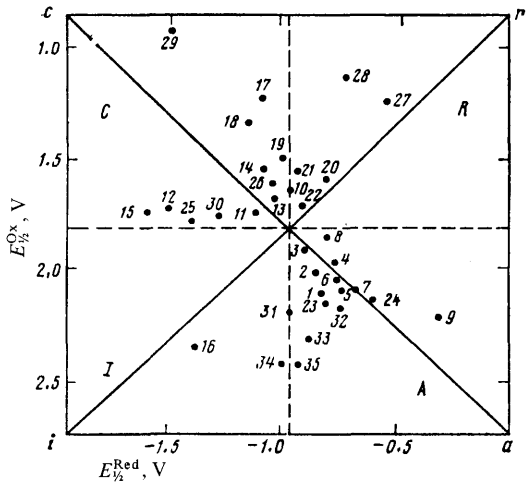

Figure 2. The classification of RHgHal compounds in accordance with their oxidation and reduction potentials measured on a Pt electrode in CH_3CN with 0.05 M Bu_4NBF_4 as supporting electrolyte at 20 °C relative to Ag/AgCl (sat. KCl), ω = 2700 revs/min.[90] Organomercury compounds of type 4-X–$C_6H_4CH(COOEt)HgHal$ (points 1–9) where X is: (1) tert-C_4H_9, (2) iso-C_3H_7, (3) C_2H_5, (4) H, (5) F, (6) Cl, (7) Br, (8) I, (9) NO_2; organomercury compounds of type AlkHgHal (points 10–16) where Alk is: (10) C_2H_5, (11) n-C_3H_7, (12) n-C_4H_9, (13) iso-C_3H_7, (14) tert-C_4H_9, (15) neo-C_5H_{11}, (16) CF_3; organomercury compounds of type Y–$C_6H_4CH_2HgHal$ (points 17–26) when Y is: (17) 4-OCH_3, (18) 4-CH_3, (19) 4-H, (20) 4-F, (21) 4-Cl, (22) 4-Br, (23) 4-CF_3, (24) 4-NO_2, (25) 3-OCH_3, (26) 3-Br; organomercury compounds of type $ArCH(CH_3)HgHal$ (points 27 and 28) where Ar is: (27) C_6H_5, (28) 8-quinoly; organomercury compounds of type 4-Z–C_6H_4HgHal (points 29–35) where Z is: (29) $N(CH_3)_2$, (30) OCH_3, (31) iso-C_3H_7, (32) CH_3, (33) H, (34) F, (35) Br.

However, calculation of only the ionisation potentials (or oxidation potentials in solution) is insufficient for an understanding of the nature of the R–M bond, since, as mentioned above, there is no one-to-one correspondence between the values for oxidation and reduction potentials. Simultaneous calculation of the tendency of OMC to both oxidation and reduction makes it possible in many cases to rule out a structure of type $R^+ - M^-$. These are probable only for compounds that are readily oxidised and are difficult to reduce, but if the compounds that are readily oxidised are comparatively easy to reduce, then a nonpolar structure R–M should be considered instead of structure $R^+ - M^-$. This is in accordance with the suggestion[90] that readily oxidised and reduced compounds must have a tendency to decompose into radicals.

Table 2. The classification of organomercury halides RHgHal on the basis of their electrochemical potentials.[90]

Area in Fig.2	RHgHal		R	Typical reactions
	oxidised	reduced		
C (cationogenic)	readily	with difficulty	ZC_6H_4, Alk, $ArCH_2$	$RHgHal \overset{+e}{\rightleftarrows} (RHgHal)^{\cdot-}$ $RHg^+ \rightarrow R^\cdot + Hg$
A (anionogenic)	with difficulty	readily	ArCH(COOEt), $4\text{-}NO_2C_6H_4CH_2$, YC_6H_4	$RHgHal \overset{+e}{\rightleftarrows} (RHgHal)^{\cdot-}$ $RHgHal + N^- \rightarrow R^- + HgHalN$
R (radicalogenic)	readily	readily	ArCH (Alk)	$RHgHal \rightarrow R^\cdot + HgHal^\cdot$ $RHgHal \overset{+e}{\rightleftarrows} (RHgNal)^{\cdot-} \rightarrow R^\cdot + Hg + Hal^-$ or $RHgHal \overset{+e}{\rightleftarrows} (RHgHal)^{\cdot-} \rightarrow R^\cdot + HgHal^-$
I (inert)	with difficulty	with difficulty	CF_3, R_F	—

Notation: Z—strong electron-donor; Y—strong electron-acceptor, N—mercurophile.

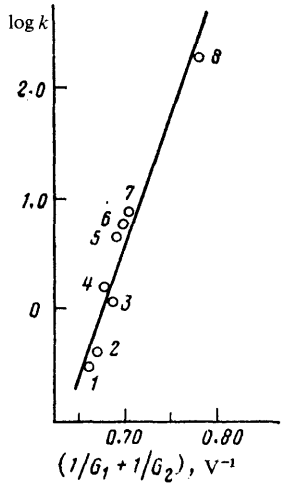
The approach suggested in this work[90] is also very fruitful for studying bimolecular reactions. It has been used[92] to study symmetrization reactions of substituted ethyl α-bromomercuryphenylacetates. Since the substituent effect conforms to the Hammett equation both in symmetrization[93] and (with a poorer correlation coefficient) electrochemical reduction of ethyl α-bromomercuryphenylacetates,[33] there must automatically be a correlation between $\log k_{symm}$ and $E^{Red}_{1/2}$. However, it does not follow from this that both reactions have an identical or similar mechanism (for example, symmetrization occurs via one-electron transfer) as the Hammett equation is obeyed by hundreds of reactions with a variety of mechanisms. The conclusion[33] that the rate of symmetrization tends to increase as the tendency of RHgHal to reduction grows but is not related in any way to its tendency to oxidation, is not at all consistent with a cyclic structure for the transition state in which one of the two RHgHal molecules is a donor and the other an acceptor. Therefore, in establishing correlations between redox potentials and rates of reaction it would be necessary to seek approaches in which both $E^{Red}_{1/2}$ and $E^{Ox}_{1/2}$ were taken into consideration.

An equation was obtained[92] for the symmetrization reaction, relating the rate of symmetrization to the electrochemical oxidation and reduction potentials of organomercury halides:

$$\log k = a(1/G_1 + 1/G_2) + b, \qquad (2)$$

where *a* and *b* are constants, $G_1 = E^{Ox}_{1/2} - E^{Red}_{1/2}$ is the polarographic gap for the given RHgX, $G_2 = E^{Ox}_{1/2}(Hg-Br) - E^{Red}_{1/2}$ is the difference between the oxidation potential of the Hg–X bond (when X = Br) and $E^{Red}_{1/2}$ (see Fig.3). It follows from this that organomercury salts that are readily oxidised and readily reduced must also readily undergo symmetrization, namely, an increase in electron-withdrawing properties of the substituents in the benzene ring must have an

accelerating effect, which was in fact observed experimentally.[93] This is due to the increased degree of nucleophilic assistance exerted by the bromine atom in the RHgBr molecule, but at the same time the ability of the R–Hg σ-bond in the other molecule to coordinate with the mercury atom of the first molecule must also increase. The second effect is stronger in all cases, namely, the decisive factor is dependence on the inherent polarographic gap. For a cross-symmetrization reaction the regioselectivity of reaction was shown[92] to be related to the electrochemical parameters of the reagents.



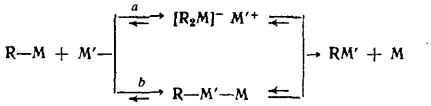


Figure 3. The dependence of the logarithm of rate constant for the symmetrization reaction of 4-X–$C_6H_4CH(COOC_2H_5)HgBr$ on the magnitude of the polarographic gap[92] where X is: (1) tert-C_4H_9, (2) iso-C_3H_7, (3) C_2H_5, (4) H, (5) F, (6) Cl, (7) Br, (8) I, (9) NO_2.

An electrochemical method has been used[94] to study the bromo- and iodo-mercuration of organomercury halides and an equation similar to (2) has been selected, only in this case $G_1 = E^{o}_{1/2}(\text{RHg}.\text{.Hal}) - E^{\text{Red}}_{1/2}(\text{Hal}_3^-)$; $G_2 = E^{o}_{1/2}(\text{Hal}_3^-) - E^{\text{Red}}_{1/2}(\text{RHgHal})$. The results obtained[94] can briefly be summarised as follows: 1) if RHgX is readily oxidised and readily reduced, the reaction must proceed rapidly since both electrochemical gaps G_1 and G_2 will be narrow; 2) if RHgX is readily oxidised but is reduced with difficulty, the rate of reaction is mainly determined by gap G_1 and will be higher the narrower this gap; 3) if RHgX is readily reduced but oxidised with difficulty, the rate of reaction is mainly determined by gap G_2 and will be higher the narrower this gap; 4) if RHgX is oxidised with difficulty and reduced with difficulty, the reaction must proceed slowly as both gaps will be wide. These conclusions are valid not only for bromomercuration but also apparently for other reactions of organomercury compounds that proceed via a cyclic transition state. The important factor is the relative position on the potential scale of the oxidation and reduction levels of the second ("electrophilic") agent, the width of gaps G_1 and G_2 being dependent on this.

An attempt was made[95] to predict the reaction pathway–ionic (a) or covalent (b)—for redox transmetallation reactions:

On the basis of the redox properties of the reacting metals (metal complexes or metalloids) expressed numerically as ionisation potential (*IP*) and electron affinity (*E*)‡ it was concluded that in reactions involving two metals M and M′, each of which has $IP + E < 8$ eV, ionic compounds are formed as intermediates. When $IP + E >$ 10 eV, covalent bonding occurs. Metals, metalloids, and complexes that have an average total value of $IP + E$ in the region 8–10 eV can evidently react by either an ionic or covalent pathway depending on the conditions. These findings make it possible to carry out a purposeful synthesis of polynuclear compounds and to choose metals–catalysts in thermodestruction processes of organometallic compounds.

---o0o---

From the material reviewed it may be concluded that electrochemical redox potentials can be used as energy characteristics of reagents in order to analyse the effect of structure on reactivity. A rational approach is to assign oxidation and reduction potentials to specific localised sites of electron change in the molecule being studied (bonds, individual atoms) during electrochemical oxidation and reduction and then to local regions of change in electron density in a nonelectrochemical reaction.

In order to establish a correlation between the rates of homogeneous reactions and electrochemical potentials it is necessary to measure both the oxidation potential and the reduction potential of both reagents. With such an approach it is possible to reveal the essential features of the reaction, which cannot be detected when a correlation with only $E^{o}_{1/2}$ or only $E^{\text{Red}}_{1/2}$ is considered; an example of this is the degree of reaction compatability on the terminal atoms of reacting molecular fragments (relative contribution of G_1 and G_2).

It cannot be concluded from the existence of a correlation between the rates of reaction and electrochemical potentials that these reactions must proceed according to a one-electron transfer mechanism (similarly for the existence of correlations with ionisation potentials or electron affinity) since both the rate of reaction and the redox potentials are related to the energies of the frontier orbitals. Interaction between the frontier orbitals does not necessarily lead to complete electron transfer and the formation of radical cation and radical anion particles.

Polymers Based on Unsaturated Derivatives of Carbaboranes

O.A.Mel'nik, A.A.Sakharova, and T.M.Frunze

The literature data on the polymerisation and copolymerisation of unsaturated derivatives of carbaboranes and silicon- and carbaborane-containing compounds as well as the physicochemical properties of the polymers obtained are surveyed. Special attention has been devoted to the synthesis of polymers with dicarbaundecaborate fragments and metallocarbaborane complexes based on them.
The bibliography includes 118 references.

CONTENTS

I. Introduction 875
II. Carbochain polymers based on unsaturated derivatives of carbaborane(12). 875
III. Silicon-carbaborane-containing polymers 879
IV. Polymers containing dicarbaundecaborate fragments 880

I. INTRODUCTION

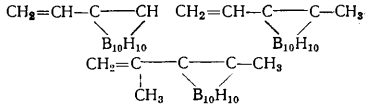
One of the interesting advances in the modern chemistry of organoelemental compounds is the discovery in 1962–1963 of carbaborane(12)† $C_2B_{10}H_{12}$ and its derivatives—a new class of electron-deficient polyhedral systems.[1-3] The great synthetic possibilities due to the high reactivity of the B–H and C–H bonds in the carbaborane nucleus and the unusual thermal behaviour of carbaboranes[4,5] have attracted the attention of investigators to these boron compounds for more than 20 years.

Carbaborane(12) has three isomeric forms which have come to be represented schematically in the following manner:[6]

1,2-dicarba-*closo*-dodecaborane(12) (*o*-carbaborane)

1,7-dicarba-*closo*-dodecaborane(12) (*m*-carbaborane)

1,12-dicarba-*closo*-dodecaborane(12) (*p*-carbaborane)



A large series of compounds have been synthesised on the basis of carbaboranes,[6-11] many of which are used to obtain various classes of polymers containing carbaborane units in the main or side chain. Carbaborane-containing polymers are obtained both by polymerisation and polycondensation methods. The advances in the synthesis of these polymers have been examined in a series of monograph and reviews,[12-18] but the latter have been devoted mainly to polymers of the polycondensation type. Hitherto there have been virtually no reviews on the polymerisation and copolymerisation of unsaturated carbaborane-containing monomers and to the study of the properties of carbochain polymers based on them. Nevertheless, appreciable progress has been noted in this field in recent years. The copolymerisation of carbaborane-containing compounds with vinyl monomers, which makes it possible to impart new valuable properties to known polymers by introducing carbaborane nuclei into their structure which as a rule increases the temperature of the onset of the decomposition of the polymers and the yield of the coke residue, has aroused special interest.

Since 1984, information has appeared in the literature on the polymerisation of new types of monomers—unsaturated derivatives of dicarbaundecaborates. A special section of the review has therefore been devoted to polymers with dicarbaundecaborate fragments and to polymeric metallocarbaborane complexes based on them.

II. CARBOCHAIN POLYMERS BASED ON UNSATURATED DERIVATIVES OF CARBABORANE(12)

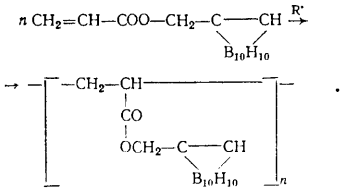
The problem of the synthesis of polymerisation carbaborane-containing polymers reduces to a study of the reactivity of the monomer, which is also usual for other compounds, and the allowance for specific properties of icosahedral carbaboranes such as the presence of steric hindrance due to bulky groups and the electron-accepting character of the carbaborane nucleus, which reduces the electron density in the double bonds of alkenylcarbaboranes.[13] In addition, one should note the sensitivity of the carbaborane groups to the action of the nucleophiles.[19] For this reason, the attempts to carry out the radical and ionic polymerisation of alkenylcarbaboranes were unsuccessful for a long time or led only to the formation of oligomers.

The first carbaborane-containing carbochain polymers were synthesised by polymerising monomers containing the vinyl group linked directly to the carbon atom of the *o*-carbaborane nucleus:

The polymerisation was carried out in solution or in bulk in the presence of phenyl-lithium at 33–200 °C. This yielded polymers with a molecular weight of $(1.4-7.1) \times 10^4$, which have been proposed as a component of the solid fuel for rocket engines.[20]

Subsequently, polyvinyl-*o*-carbaborane with a molecular weight (MW) ranging from 5×10^4 to 14×10^4 was obtained at room temperature in solution in ethyl ether in the presence of phenyl-lithium.[21] The polymers were white amorphous substances with a softening temperature of 250–280 °C (depending on the MW), soluble in benzene and ether, and insoluble in aliphatic hydrocarbons. The radiation-induced polymerisation of vinyl- and isopropenyl-*o*-carbaboranes in the melt at 100–140 °C [22] also leads to the formation of soluble polymers with MW up to 2.5×10^4.

† Dicarbadodecaborane(12) (Ed. of Translation)

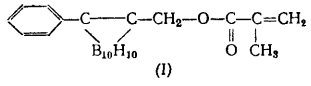


The polyvinyl-*o*-carbaborane synthesised by polymerising vinyl-*o*-carbaborane at 31 °C under the influence of γ-radiation[23–25] differs in its properties from those described above. It does not soften up to 430 °C, is readily soluble in alcohols, acetone, and dimethyl sulphoxide, and is less soluble in hexane and benzene. It has been found that the yield of the polymer increases linearly with increase in the radiation dose, reaching 50% for a dose of 3.5×10^{21} eV g^{-1} h^{-1}. The rate of polymerisation is proportional to the intensity of radiation raised to the power 0.76, the maximum degree of polymerisation being 11–12. The set of IR and ^1H and ^{11}B NMR spectroscopic data justified the hypothesis that the polymerisation of vinyl-*o*-carbaborane under the influence of γ-radiation is of the "head to tail" type.

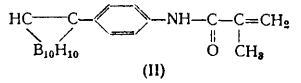
All the attempts to obtain a polymer from isopropenyl-*o*-carbaborane by radical polymerisation were unsuccessful.[21,26] The polymerisation of this monomer in the presence of t-butyl peroxide, the amount of which was 50 wt.%, yielded only a trimer, and a product with a MW of 1790, a softening temperature of 165 °C, and a melting point of 270 °C was obtained only when $AlCl_3$ (~5%) was used. Dimers and trimers with a main hydrocarbon chain, carbaborane side groups, and terminal vinyl groups have also been obtained by the radiation-induced polymerisation of isopropenyl-*o*-carbaborane.[23]

A solid vitreous substance with a molecular weight of (1.0 to 7.5) $\times 10^4$ is formed from 1-allyl-*o*-carbaborane in the presence of $AlCl_3$.[21] The products of the radiolysis of 1-allyl-*o*-carbaboranes by ^{60}Co γ-rays[27] were fractionated by gel chromatography and investigated by the IR, NMR, and chromatomass-spectrometric methods. It was found that the main products comprised seven dimers with the same molecular weight of 366, differing in the positions of two double bonds in the molecule, and saturated oligomers with a degree of polymerisation of 5, independent of the radiation dose and dose rate. According to the reaction mechanism proposed, the abstraction of a hydrogen atom from the allylcarbaborane results in the formation of radicals of the allyl type whose recombination yields unsaturated dimers. The addition of a hydrogen atom to the carbaborane monomer affords radicals of the propyl type, which propagate the radical chain process with chain transfer leading to the formation of unsaturated oligomers. The chain termination in the dimer and oligomer formation processes takes place via a bimolecular mechanism.

The influence of the physical state on the radiolysis of solid alkenyl-*o*-carbaboranes, for example, 1-allyl-*o*-carbaborane,[28] has been demonstrated. 1-Allyl-*o*-carbaborane can exist in three mesomeric phases: in the temperature range from −3° to −16 °C (phase 1), from 16° to −36 °C (phase 2), and below −36 °C (phase 3). The average degree of polymerisation of the oligomers obtained by the radiolysis of the allylcarbaborane is 5 and is independent of temperature in the range from −50° to +50 °C. The results obtained have been discussed from the standpoint of the influence of the structure of the crystal lattice and diffusion-controlled processes. The authors note that the nature of the solid state, i.e. the crystallinity, plays an important role in radiolytic reactions. The dipole moments of vinyl-, isopropenyl-, and allyl-*o*-carbaboranes have been measured.[29] The quantum-chemical calculation of the charge distribution in these compounds and of the dipole moments μ with the experimental (taken from the literature) bond lengths and valence angles have been carried out by the INDO (incomplete neglect of the differential overlap of atomic orbitals) method. The calculated absolute values of μ were found to be about twice as high as the experimental values taken from the literature. However, the orientation of μ and the charge distribution, indicating the transfer of negative charge to the substituent, confirmed qualitatively, in the authors' view, the hypothesis that the free-radical oligomerisation of 1-alkenyl-*o*-carbaboranes can result in the formation of radicals, leading to the incorporation of the carbaborane fragment in the main chain. However, the carbochain polymer with carbaborane groups in the main chain is formed preferentially, which has been demonstrated convincingly by the EPR method.



The polymerisation of monomers whose double bond is remote from the carbaborane nucleus, which promotes a decrease in the steric influence of the carbaborane group and the formation of polymers with large molecular weights, proceeds more readily. For example, 1-acryloyloxymethylene-*o*-carbaborane polymerises readily in bulk in the presence of 2% of benzoyl peroxide at 60 °C:[26]

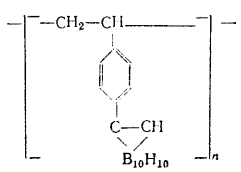


The polymer is a solid and brittle substance soluble solely in boiling terphenyl. It softens and becomes rubber-like at 165 °C. The poor solubility of this polymer is associated, according to the authors,[30] with the cross-links formed as a result of the interaction of the unsubstituted CH group of the *o*-carbaborane with the acrylic group of the growing chain. Under analogous conditions, 2-methacryloyloxymethyl-1-methyl-*o*-carbaborane affords a polymer which is readily soluble in chloroform.

A homopolymer of 1-methacryloyloxymethylene-*o*-carbaborane (MOC) with a MW of 5000 has been obtained by carrying out the reaction in benzene in the presence of 2% of azobisisobutyronitrile (ATBN).[22] Later, analysis of the structure of the MOC molecule, taking into account the remoteness of the carbaborane nucleus from the double bond, justified the assumption[31,32] that the radical polymerisation of this compound can yield products with higher molecular weights. A study of the kinetics of the radical polymerisation of MOC in benzene revealed the characteristic features of this reaction and demonstrated the influence of the concentration of the monomer in solution on the molecular weight characteristics as well as the possibility of obtaining polymers with molecular weights of (1.5–40) $\times 10^4$. The gel effect, which is so characteristic of the polymerisation of methacrylic acid esters, is absent. The orders of the polymerisation reaction with respect to the monomer and the initiator (1.28 and 0.44 respectively) and the process activation energy (17.5 kcal mol^{-1}) were determined. The polymer, with a MW of 40×10^4, begins to decompose vigorously in air at 270 °C without passing to a viscofluid state.

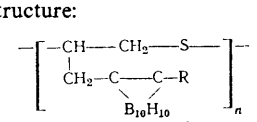
The synthesis and radical polymerisation in bulk of methacryloyl derivatives of *o*-carbaborane, not described previously, have been reported:[33] 1-methacryloyloxymethylene-2-phenyl-*o*-carbaborane (I) and 1-[4-(methacryloylimino)phenyl]-*o*-carbaborane (II):

(I)



(II)

The homopolymers obtained from these monomers are colourless transparent blocks insoluble in organic solvents and characterised by a gel fraction content of up to 70%. According to the results of dynamic thermogravimetric analysis (DTGA) in air, the temperatures of the onset of decomposition of the polymers of compounds (I) and (II) are 215° and 190 °C. The formation of structured polymers may be associated, in the authors' view, with the presence in the compound synthesised of mobile hydrogen atoms both in the C—H group of the carbaborane and in the *para*-position in the benzene ring, on the one hand, and in the methylene group $-CH_2-$, which is influenced by two electron-accepting groups in the monomer (I) and by the amide hydrogen in the monomer (II), on the other.

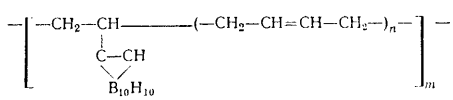


Communications explaining structure and formation in the course of the synthesis of carbaborane-containing polymers in the presence of peroxides by the involvement of free boron-centred radicals, leading to branching and to network structures have appeared recently.[34-36]

The capacity of 4-(1-*o*-carbaboranyl)styrene for polymerisation under various conditions has been investigatged.[37] Polymers with the highest molecular weight (up to 6×10^4) and a softening temperature of 280—240 °C have been obtained by thermal polymerisation at 160—200 °C. In the presence of radical initiators, polymers with a MW of $\sim 1.2 \times 10^4$ and a softening temperature of 320 to 340 °C are formed. Polymerisation via the anionic mechanism takes place slowly, while that involving the cationic mechanism does not occur at all. On the basis of the IR spectra of the polymers, the authors suggested that the polymerisation takes place in all cases via the vinyl group and that the polymer has the following structure:

The polymerisation of *p*-(*o*-carbaboranyl)phenylacetylene in solution in aromatic solvents in the presence of triphenylphosphine-nickel acetylacetonate has been investigated.[38] The use of this catalyst made it possible to obtain linear polyconjugated carbaborane-containing oligophenylacetylenes with MW of 1230—1320. A mechanism has been proposed for the formation of the active centre and the chain propagation. The oligomers synthesised are thermoplastics with a softening temperature of 80—115 °C.

The ionic polymerisation, with ring opening, of 3-[alkyl(aryl)-*o*-carbaboranyl]-1,2-epithiopropanes in bulk and in solution has been investigated[39] in order to obtain polymerisation polysulphides with enhanced solubility and thermal stability. Polymers with the highest molecular weight (2.5×10^5) were obtained via the anionic mechanism in solution using specially synthesised cyclic cadmium carbaboranylthiolates as initiators. Cationic polymerisation under the influence of BF_3 etherate takes place even at -20 °C, but it leads to polymers with a lower molecular weight (1.7×10^4). Polycarbaboranyl sulphides with the *o*-carbaborane group in the side chain are amorphous substances softening at 50—120 °C, which apparently have the following structure:



R=C_6H_5, $(CH_3)_2CH$;
n=60—970

According to DTGA data, the temperatures corresponding to a 5% weight loss by these polymers are 250—300 °C.

There are only a few literature data on the three-dimensional polymerisation of bifunctional unsaturated carbaborane-containing monomers. Carbochain cross-linked carbaborane polymers have been obtained by the radical polymerisation of unsaturated compounds with two allyl or acryloyl groups.[40,41] Thus the network polymer based on diallyl *m*-carbaboranedicarboxylate[40] with a glass point of 300 °C has been synthesised in bulk in the presence of a mixture of benzoyl peroxide and t-butyl peroxide as initiators. There is a good correspondence between the experimental and calculated glass points, which indicates the virtually complete conversion of the double bonds of the allyl groups. The polymerisation of di(acryloyloxymethylene)-*o*-carbaborane in the presence of peroxide initiators has been investigated by IR spectroscopy and differential thermal analysis.[41] It was shown tht the most effective initiator of the polymerisation leading to the formation of thermostable polymers is dicumenyl peroxide.

Thus, despite the difficulties encountered by investigators in the study of the homopolymerisation of carbaborane-containing compounds, definite advances have been achieved in this field in recent years and polymers with high molecular weight (MW up to 10^5) have been synthesised.

Unsaturated carbaborane-containing compounds are known to copolymerise readily with various vinyl polymers. Thus a rubber-like product having the following structure has been obtained by the copolymerisation of vinyl-*o*-carbaborane with butadiene:[21]

n = 5 or 7.

The copolymers of isopropenyl-*o*-carbaborane with butadiene have been synthesised by radical copolymerisation in bulk (the molecular weight did not exceed 1000)[42] and in emulsion.[43] The copolymer of acryloyloxymethylene-*o*-carbaborane with butadiene has been obtained in emulsion.[44] The radical copolymerisation of vinyl-*o*-carbaborane with allyl-*o*-carbaborane and 1-isopropenyl-*o*-carbaborane-2-carboxylic acid results in the formation of copolymers with MW of $(6-55) \times 10^3$.[21]

The synthesis of carbaborane-containing oligomers based on isoprene and vinyl- and isopropenyl-*o*-carbaboranes, with the copolymerisation initiated by hydrogen peroxide and cumenyl hydroperoxide in solution in alcohol, has been described.[45] The copolymerisation constants for the systems investigated were calculated by the integral Mayo—Lewis method and the low activity of alkenylcarbaboranes in copolymerisation with dienes was demonstrated. The oligomers obtained had molecular weights ranging from 2000 to 3340 and contained terminal hydroxy-groups. On the basis of the dependence of the degree of polymerisation on the concentration of monomers and the bifunctional nature of the oligomer, the authors suggested that chain termination takes place via a recombination reaction and that the reactions involving chain transfer from the alkenylcarbaborane group to the monomers and the solvent do not take place.

The copolymerisation of ispropenyl-*o*-carbaborane with methyl acrylate (MA) in the presence of AIBN produces a copolymer whose boron content depends on the concentration of isopropenyl-*o*-carbaborane in the initial mixture.[26,46] The copolymer, containing 22% of

boron, is a vitreous substance with a softening temperature of 45 to 80 °C, while the copolymer with 10% of boron softens at 45 – 50 °C. Copolymers with approximately the same boron content are formed in the copolymerisation of MA with vinyl-*o*-carbaborane.[46]

In contrast to MA, methyl methacrylate (MMA) hardly copolymerises with isopropenyl-*o*-carbaborane in solution in toluene in the presence of ATBN.[47] Vinyl-*o*-carbaborane does not copolymerise with MMA under these conditions either. The higher reactivity of vinyl- and isopropenyl-*o*-carbaboranes in copolymerisation with MA compared with MMA is due to the smaller steric hindrance and the higher activity of the macroradicals with terminal MA units.[46]

Both these carbaborane-containing monomers are relatively inactive in copolymeristion with styrene, which is indicated by the low boron content (not more than 4%) in the copolymers formed. Later it was possible to obtain[48] copolymers of the above monomers with *p*-chlorostyrene and *p*-methoxystyrene, in which the boron content reached 25 – 50% of the theoretical value.

Analogous results have been obtained in the copolymerisation 2-ferrocenyl-1-vinyl-*o*-carbaborane and 2-ferrocenyl-1-isopropenyl-*o*-carbaborane with styrene in MMA.[49] It was shown that both ferrocenyl-*o*-carbaboranes enter into the composition of the copolymers with MMA in an extremely limited amount and are much more active in copolymerisation with styrene. Furthermore, in all cases an increase in the content of the ferrocenyl-*o*-carbaboranes in the initial mixture reduces the molecular weight of the copolymers.

A copolymer of methacryloyloxymethylene-*o*-carbaborane with acryloylferrocene, having a MW of 3×10^4, and a copolymer of vinylferrocene, isopropenyl-*o*-carbaborane, and isoprene have also been synthesised.[50]

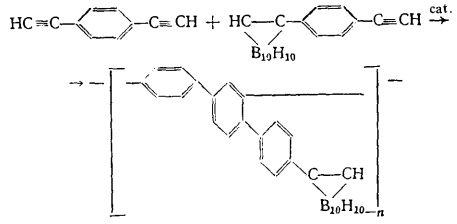
The radical copolymerisation of acryloyloxymethylene-*o*-carbaborane with fluorinated acrylates has been carried out in bulk and in emulsion.[26,51] Some of these copolymers are rubber-like substances with an MW of 2.3×10^3, soluble in acetone, ethyl methyl ketone, or diethyl ketone.

Copolymers with a boron content up to 24% have been obtained by the radical copolymerisation of 1-methacryloyloxymethylene-2-phenyl-*o*-carbaborane (I) and MMA in bulk in the presence of benzoyl peroxide.[52] It was found that the copolymers are enriched in MMA units for any initial monomer ratios. With increase in the fraction of the carbaborane compound (I), the softening temperature and the temperature of the onset of decomposition of the copolymers increase together with the yield of the coke residue. The copolymerisation under the same conditions of MMA with 1-[4-(methacryloylimino)phenyl]-*o*-carbaborane (II), the content of the latter in the reaction mixture not exceeding 5 mole % (limiting solubility),[52] results in the formation of copolymers with $\overline{M}_w$ = (9.1 to 10.8) $\times 10^4$ and polydispersity coefficients $\overline{M}_w/\overline{M}_n$ of 1.53 – 2.31.

In order to modify low-density polyethylene, the radical copolymerisation of ethylene with isopropenyl-*o*-carbaborane was carried out at a pressure of 1400 kg cm^{-1} and 160 °C in bulk and in solution.[53] It was shown that the rate of reaction and the molecular weight of the copolymers decrease with increase in the content of the carbaborane monomer in the reaction mixture. For a low overall degree of conversion of the monomers and a low content of isopropenyl-*o*-carbaborane in the initial mixture (up to 15 mole %), this relative activity proved to be higher than that of ethylene. The copolymers are plastic solids soluble in aromatic hydrocarbons and giving rise to elastic films on pressing at 130 – 170 °C. The influence of γ-radiation on copolymers containing 0.55 – 2.70 mole % of isopropenyl-*o*-carbaborane has been studied.[54] Measurements of the strength properties of the copolymers have shown that, for a low content of boron, their radiation stability is close to that of polyethylene. It has also been established that the resistance of the copolymers to thermo-oxidation diminishes after γ-irradiation.

The copolymerisation of vinyl-*o*-carbaborane with styrene in proportions of 1 : 3, initiated by γ-rays, has been investigated.[55] It was shown that the copolymer consists of 11 – 12 units and that there are approximately nine styrene units for two vinyl-*o*-carbaborane units. The structure of the copolymer was studied by NMR and flash pyrolysis; it softens up to 85 °C and melts at 105 °C.

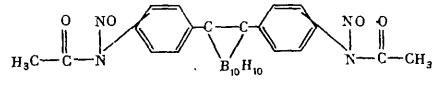
Copolymers containing terminal hydroxy- or carboxy-groups have been synthesised by the copolymerisation of vinyl-*o*-carbaborane, isopropenyl-*o*-carbaborane, and acryloyloxymethylene-*o*-carbaborane with isoprene, butadiene, and chloroprene in solution at 65 °C in the presence of 4,4′-azobis(4-cyano-1-pentanol) or 4,4′-azobis(4-cyanovaleric) acid.[56] It has been noted that the large difference between the polarities of the comonomers ensures the ease of copolymerisation. The M_n of the copolymers are 2200 – 7400 and M_w/M_n = 1.38 to 1.85. In all cases, the yield and the molecular weight of the copolymers decrease with increase in the content of the unsaturated derivatives of *o*-carbaborane in the reaction mixture from 5 to 50 wt.%.



A copolymer of MMA and 4-(1-*o*-carbaboranyl)styrene with a MW of 3.08×10^4 and a softening temperature of 172 – 220 °C has been obtained.[37] While according to DTGA data a weight loss of 2% by PMMA is observed at 100 °C, the above copolymer loses 2% of its weight at 250 °C. Subsequently the authors[57,58] carried out the radical and thermal copolymerisation of 4-(1-*o*-carbaboranyl)styrene with MMA, isoprene, and acryloylferrocene. The copolymers synthesised with MW up to 2.8×10^4 were tested by the thermomechanical method and the stress relaxation method under scanning conditions. It was shown that, owing to the heterounit nature of the copolymers, their thermal characteristics (the glass point and the temperature of the onset of weight loss) vary both additively (copolymers with MMA) and non-additively (copolymers with isoprene). For the copolymers with acryloylferrocene,[58] a smooth increase in the glass point and the non-additive variation of the thermal stability are observed with increase in their content of carbaborane units.

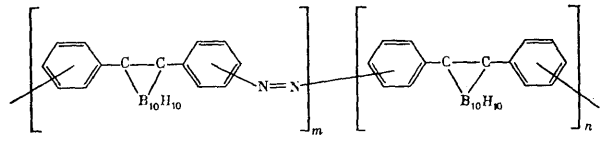
In order to increase the thermo-oxidative stability of PMMA, network copolymers of MMA with bifunctional unsaturated isomeric derivatives of carbaboranes—the diallyl esters of *m*- and *p*-carbaboranedicarboxylic acids[59,60] and 1,2-di(methacryloyloxymethylene)-*o*-carbaborane [61,62]—were synthesised in bulk via a radical mechanism. Investigation of the thermo-oxidative degradation of all the copolymers obtained showed that the introduction from 0.1 to 0.5 mole % of *m*- and *o*-carbaborane fragments into the PMMA chain increases sharply the thermo-oxidative stability of the polymer, while the presence of *p*-carbaborane nuclei in the copolymer structure reduces such stability. It has been suggested that small amounts of *m*- and *o*-carbaborane act as inhibitors of radical-chain processes.

The thermal and mechanical relaxation properties of network copolymers of MMA and the diallyl ester of *m*-carbaboranedicarboxylic acid of different composition have been investigated and the network structure has been determined from the comparison of the experimental and calculated glass points.[40] It has been found that, at a high concentration of the carbaborane comonomer, the network consists of two components, one of which is the product of the interaction of MMA with part of the diallyl *m*-carbaboranedicarboxylate used in the reaction, while the second is a network based on the homopolymer of the carbaborane monomer. This results in the formation of specimens having two main transition



temperatures and two regions of relaxation processes of different intensity.

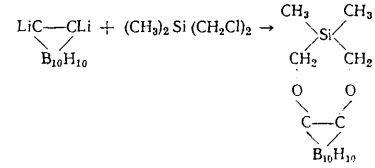
The joint polycyclotrimerisation of *p*-(*o*-carbaboranyl)phenylacetylene with *p*-diethynylbenzene in the presence of $NiCl_2.2PPh_3.2NaBH_4$ or $Al(iso\text{-}C_4H_9).TiCl_4$ in accordance with the scheme:[63]



has been achieved. The interaction of equimolar amounts of the starting materials yielded co-oligophenylenecarbaboranes soluble in toluene and having a high boron content. With increase in the amount of *p*-(*o*-carbaboranyl)phenylacetylene in the initial mixture, the yield of the oligomer and its molecular weight decrease (from 78 to 20% and from 3350 to 1020 respectively). *o*-Carbaborane-containing oligophenylenes are characterised by high thermal and thermo-oxidative stabilities. Furthermore, they are regarded[64] as ligands for the synthesis of π-arene complexes of chromium carbonyl. The use of the "triphenylphosphine–nickel acetylacetonate" catalytic system in the copolymerisation of *p*-(*o*-carbaboranyl)phenylacetylene and *p*-diethynylbenzene made it possible to obtain thermoreactive carbaborane-containing polyarylacetylenes in yields up to 93% and with a higher molecular weight.

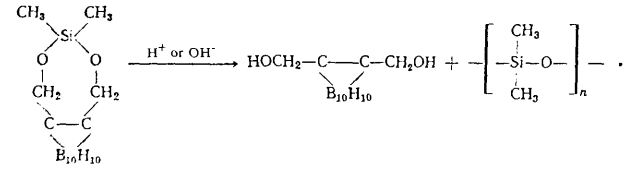
The recombination of the phenyl and azophenylene products of the decomposition of 1,2-di(*N*-nitrosoacetamidophenyl)-*o*-carbaborane (DC), i.e.

yielded *o*-carbaborane-containing polyazophenylene (PAPC) having the following structure:[65,66]



By combining the processes involving the recombination of the DC decomposition products with processes involving the radical polymerisation of various vinyl monomers, it is possible to obtain copolymers with carbaborane units. Thus copolymers containing between 4 and 38% of PAPC fragments have been synthesised by the emulsion copolymerisation of styrene with DC decomposition products. It was shown that the introduction of the carbaborane fragments into the macromolecules of polystyrene increases significantly the thermo-oxidative stability of the latter.

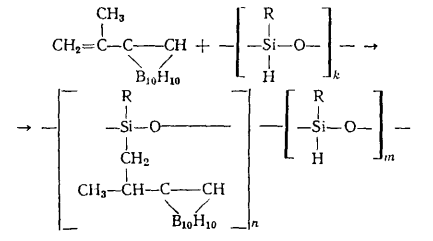
The influence of the nature of unsaturated *m*- and *p*-carbaborane-containing polyethers on their capacity for copolymerisation with vinyl compounds in bulk, solution, and emulsion in the presence of radical and ionic initiators under the influence of γ-radiation or high pressure has been examined.[67,68] The vinyl comonomers used were styrene, acrylonitrile, and 1,1,2-trichlorobuta-1,3-diene. It was found that the copolymers of carbaborane-containing unsaturated polyethers are characterised by a higher resistance to thermo-oxidation and by more effective adhesion parameters compared with the analogous copolymers in which there are no carbaborane groups.



Polymers and copolymers based on alkenylcarbaboranes can be used in various fields: as plasticisers and combustion catalysts,[44] as materials with enhanced thermo-oxidative stability,[59] in adhesives in order to increase their thermal stability,[69,70] for the preparation of anion-exchange resins,[71] and for the modification of rubbers.[72,73]

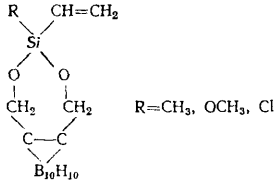
III. SILICON-CARBORANE-CONTAINING POLYMERS

It is known[15] that the polymers in which hydrolytic and chemical stability is combined with high thermal stability include silicon-carbaborane-containing polymers. The first attempts to synthesise such compounds by polymerisation and polycondensation methods were unsuccessful, since the initial *o*-carbaborane-siloxane derivatives exhibited a high tendency towards the formation of stable cyclic systems. This occurred apparently as a consequence of the adjacent location of the carbon atoms in the *o*-carbaborane nucleus involved in an ordinary covalent C–C bond whose length (1.64–1.67 Å) greatly exceeded the length of the ordinary covalent C–C bond in olefins (1.54 Å), which in fact favoured the formation of exocyclic derivatives.[74–76] For example, a stable cyclic product has been obtained by the interaction of dilithio-*o*-carbaborane with di(chloromethyl)dimethylsilane:[77]



The reaction of 1,2-di(hydroxymethylene)-*o*-carbaborane with dichlorodimethylsilane also results in the formation of a seven-membered cyclic compound.[78] When an attempt is made to open this ring in order to obtain a linear polymer, hydrolysis leads to the reformation of the initial carbaboranediol and polydimethylsiloxane:

For this reason studies were continued on the synthesis of monosilyl-*o*-carbaborane monomers from which various polymers containing *o*-carbaborane groups in the side chain were synthesised by polycondensation reactions.

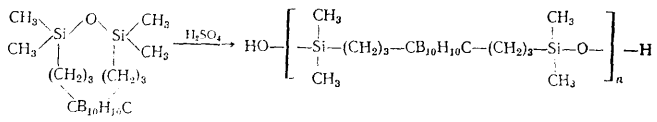


There are few available literature data on the synthesis of carbaborane-siloxane polymers. Polysiloxanes containing *o*-carbaborane nuclei in the side chain have been obtained by the migration copolymerisation of isopropenyl-*o*-carbaborane with the polyalkylhydrosiloxanes:[79,80]

R=CH_3, C_2H_5, C_6H_5; $k=n+m$.

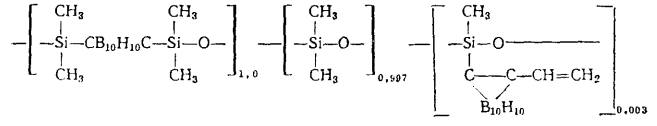
Studies have shown that, in the absence of the catalyst below 200 °C, the reaction hardly occurs and that even at high temperatures the rates of copolymerisation remain low, which can be accounted for by the electron deficiency of the carbaborane nucleus, deactivating the neighbouring unsaturated bond, and by steric hindrance. With increase in the boron content in the polymer, the solubility of the latter in aromatic hydrocarbons and alcohols diminishes. According to DTGA data, the above polymers are stable in air up to 400 to 500 °C.

Carbochain silicon-carbaborane-containing polymers have been synthesised by the radical polymerisation in bulk of carbaborane-containing exocyclic vinylsilanes with various substituents at the silicon atom:[81,82]



A mixture of benzoyl peroxide and t-butyl peroxide was used as the initiator. It was established that, in the polymerisation of the compounds with R = CH_3, only the dimer is formed, while in other cases insoluble homopolymers were obtained in yields up to 80%. The copolymerisation of the above vinylsilanes with MMA and styrene was achieved under the same conditions for different monomer ratios.[81-83] The copolymerisation with MMA yielded both linear soluble copolymers with a MW of $(4.0-6.9) \times 10^5$ and three-dimensional copolymers; linear copolymers with styrene have molecular weights up to 1.6×10^5. The formation of insoluble polymers and copolymers with MMA is determined by the fact that in certain cases homo- and co-polymerisation not only occurs via the vinyl group but is also accompanied by the partial ring opening and condensation of the resulting silanol groups SiOH.[82] The influence of the substituent at the silicon atom on the reactivity of the exocyclic compounds has been examined and it has been shown that the monomer with R = OCH_3 shows the greatest activity in the copolymerisation reaction. It has been noted that, with increase in the content of the silicon-carbaborane compound in the reaction mixture, its mole fraction in the copolymer also increases and the yield and the molecular weight of the copolymer diminish. Furthermore, the temperatures of the onset of weight loss by the copolymers and yield of the coke residue increase with increase in the mole fraction of the exocyclic derivative in the copolymer, while the softening temperatures decrease.

The migration copolymerisation reaction of epoxypropoxypropyltriethoxysilane with 1,2-di(hydroxymethylene)-*o*-carbaborane, which takes place with formation of a linear oligomer in the first stage, has been investigated.[80,84] In the second stage, the content of the epoxy-groups reaches a minimum, the ethoxy-groups undergo alcoholysis, and the product passes from the viscofluid state to the elastic state.



The study of the deformation thermal stability of siloxanecarbaborane oligoethers showed[84] that, in contrast to the majority of polymers, the product does not soften and does not melt with increase in temperature its volume increasing under these conditions at temperature above 360 °C. In view of the high thermal stability of the oligomers obtained, in which effective adhesion to glass and metal is combined with good dielectric properties, they can be used as thermoinsulating coatings.

The failure of the attempt to synthesise silyl-*o*-carbaborane compounds with a linear structure stimulated investigators to turn to *m*-carbaborane systems, in which the adjacent positions of the carbon atoms rule out the possibility of the formation of exocyclic structures. The stability at high temperatures is retained in these systems.

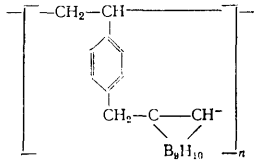
Thus an elastomeric *m*-carbaborane-containing polysiloxane with a molecular weight of 8500 has been obtained by the polymerisation of cyclic *m*-carboranylenesiloxane in the presence of acid catalysts:[85]

From the practical point of view, the synthesis of poly-*m*-carbaborane-siloxanes has been an important advance in the development of thermostable carbaborane elastomers.[6,86,87] These polymers (given the brand name "Decsil") consist of dialkyl- or diaryl-siloxane units linked by *m*-carbaborane groups and are obtained by the polycondensation of *m*-carbaborane-containing chlorosilanes and alkoxysilanes in the presence of $FeCl_3$ as catalyst. The high thermo-oxidative stability and the effective mechanical and elastic properties of the above polymers have served as a precondition for the development of a technology of the preparation of thermostable siloxane-carbaborane rubbers.[88-90] Polymers with the brand name "Decsil-201", in which some of the methyl groups have been substituted by vinyl derivatives of *o*-carbaborane, have been synthesised for this purpose:

This made it possible to carry out hardening via a free-radical mechanism.

There have been communications[91-93] about the synthesis by analogy with Decsils, of carbaborane-siloxane elastomers containing the carbaboranes $C_2B_5H_7$ and $C_2B_8H_{10}$ in the siloxane chain. In order to prevent their crystallisation and to improve their elasticity, these elastomers were modified by introducing 5–20% of vinyl-*o*-carbaborane into the main or side chain.[94,95] It was established that heating of such modified polymers in nitrogen to 350 °C and in air to 250 °C has no appreciable influence on the glass point and that even the solubility of the polymer in xylene is retained under these conditions. After heating in an atmosphere of nitrogen to 550 °C, the polymers are cross-linked.

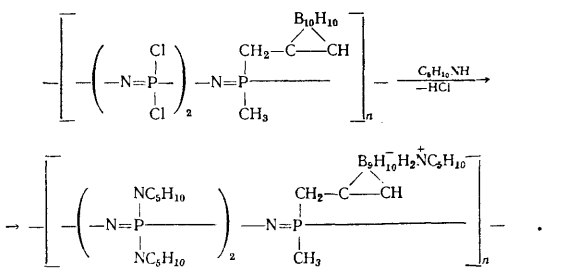
Summarising the analysis of the literature data on the polymerisation and copolymerisation of silicon-carbaborane-containing monomers, one may conclude that the polymerisation methods of synthesis of silicon-carbaborane-containing polymers have been little investigated hitherto. This is also indicated by the reviews published in recent years,[17,18,96-98] which have been mainly devoted to questions of the preparation of carbaborane-siloxane polymers by polycondensation methods.



IV. POLYMERS CONTAINING DICARBAUNDECABORATE FRAGMENTS

Apart from polyhedral carbaboranes, i.e. carbaboranes with a closed structure (*closo*-carbaboranes), open carbaborane structures of

nido-carbaboranes are known. On interaction with nucleophiles such as alkali metal alkoxides[19] or amines,[99] *o*- and *m*-carbaboranes(12), are cleaved selectively with abstraction of the boron atom from the third position in the *o*- and *m*-carbaborane nuclei with formation of dicarbaundecaborates(13) anions. Such anions are acids and on treatment with NaH they split off a proton and afford the dicarbollide ion (Fig.1).[100]



The negative charge on the dicarbaundecaborate anion leads to the appearance in the system of an electron-donating effect via inductive and resonance mechanisms, in contrast to the neutral *C*-carbaboranyl groups, which exhibit electron-accepting properties. Thus the electron-donating effect of the (3)-1,2-dicarbaundecaborate group is manifested in the pK_a values for the carboxylic acids of the (3)-1,2-dicarbaundecaborate group is manifested in the pK_a values for the carboxylic acids of the (3)-1,2-dicarbaundecaborate series (6.9–7.3 in 50% ethanol), which are very weak acids compared with carbaboranecarboxylic acids.[101]

Methods are known for the preparation of polymers with dicarbaundecaborate fragments[102–104] whose carbaborane nuclei are cleaved by alkalies or amines. However, these are multistage procedures and each stage takes 3–8 days. Thus, in studies by Hawthorne and co-workers,[102,103] polystyrene cross-linked with 1% of divinylbenzene was made to undergo successive reactions in accordance with the following scheme: (1) chloromethylation of polystyrene; (2) cleavage of *o*-carbaborane with alcoholic alkali to the dicarbaundecaborate anion; (3) preparation of the dicarbollide ion $(7,8\text{-}C_2B_9H_{11})^{2-}$; (4) reaction of the chloromethylated polystyrene with the dicarbollide ion leading to the formation of a polymer with dicarbaundecaborate groups:

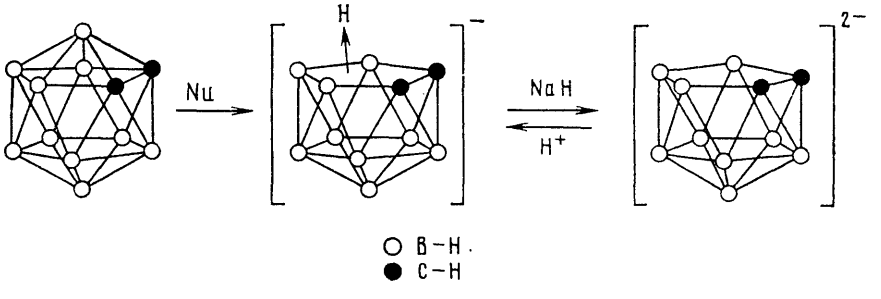
Rudolph and co-workers[104] also obtained the above polymers from cross-linked polystyrene in accordance with the following scheme: (1) chloromethylation of polystyrene; (2) preparation of *o*-carbaboranyl-lithium with chloromethylated polystyrene; (4) cleavage with piperidine of the carbaborane linked to polystyrene to give the dicarbaundecaborate anion.

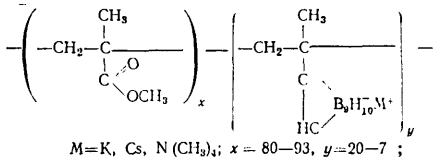
Later Allcock et al.[105] obtained *nido*-carbaboranylpolyphosphazenes by the interaction of carbaborane-containing polyphosphazenes with piperidine in solution in tetrahydrofuran:

Different reactions of *m*-carborane-containing polymers are very frequently accompanied by the cleavage of their *m*-carbaborane nucleus to the dicarbaundecaborate anion. This happens, for example, on heating *m*-carbaborane-containing polyamides in dimethylformamide and concentrated alkalies,[106] in their thermal and thermo-oxidative degradation,[107] in the cyclodehydration of *m*-carbaborane-containing polyaminoamides and polyhydroxamides,[108,109] and also in the formation of polyamides based on *m*-carbaboranyl-enediamine and the dichlorides of aromatic acids.[110] All these reactions result in the formation of heterounit polymers, whose properties depend on their content of dicarbaundecaborate groups.

Later Korshak, Bekasova, and co-workers[111–113] obtained heterounit *m*-carborane-containing polyamides by treatment with nucleophiles and demonstrated by ^1H NMR that the maximum attainable content of dicarbaundecaborate fragments, without degradation, in such polymers is about 50%. Polyamides differ from the starting materials in their solubility and chemical and therm-oxidative stability.

As already mentioned in the introduction, up to 1984 there was no information whatever in the literature about the preparation of polymers with dicarbaundecaborate fragments by the polymerisation or copolymerisation method. It is known that vinyl derivatives of *o*-carbaborane show a low reactivity in the radical polymerisation reaction. It was shown for the first time in a number of studies[114–117] in relation to 1-isopropenyl-*o*-carbaborane that the transition from neutral *closo*-carbaboranes to negatively charged *nido*-carbaborane structures facilitates the copolymerisation reaction of their unsaturated derivatives and it was established that the latter are capable of copolymerisation with vinyl monomers. The salts of 1-isopropenyl-(3)-1,2-dicarbaundecaborate (IDC) synthesised do not polymerise via radical and ionic mechanisms, but, in contrast to 1-isopropenyl-*o*-carbaborane,[47] enter into the copolymerisation reaction with MMA





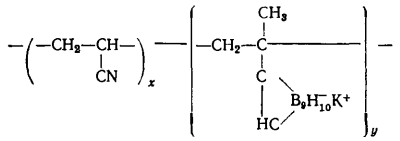


Figure 1. Scheme for the preparation of the dicarbaundecaborate(13) anion and the dicarbollide ion.[100]

and acrylonitrile, forming copolymers containing dicarbaundecaborate fragments:

M=K, Cs, $N(CH_3)_4$; $x = 80-93$, $y = 20-7$;

$x=50-99$, $y=50-1$.

The radical copolymerisation was carried out in solution at 60 to 80 °C in the presence of AIBN. The dependence of the yield, the intrinsic viscosity, and the composition of the copolymers on the reaction conditions was investigated[115,117] and the optimum parameters of the synthesis were determined. It was shown that the reactivity of the IDC salts in the copolymerisation with acrylonitrile is higher than in the copolymerisation with MMA: in the former case, it is possible to introduce up to 50 mole % of the dicarbaundecaborate units into the copolymer, while in the latter up to 20 mole % can be introduced. The molecular weights of the copolymers with acrylonitrile and MMA reach 5.0×10^4 and $(2.5-5.2) \times 10^4$ respectively. It was found that the yield and molecular weight of the copolymer diminish with increase in the mole fraction of the dicarbaundecaborate and also with increase in the ionic radius of the salt cation, which is caused in all probability by steric factors.

Copolymers of this kind are of interest also because they contain dicarbaundecaborate groups capable of behaving as ligands in transition metal complexes. For this reason, the copolymers of MMA with IDC salts have been used as polymer matrices in the synthesis of polymeric metallocarbaborane complexes (Fig.2).[114,116] A characteristic feature of the structure of these complexes is the fact that the dicarbollyl ligand of the metallocarbaborane is linked directly via a carbon atom to the main chain of the polymer matrix. The structure has been confirmed by elemental analysis, IR spectroscopy, and ^{31}P NMR. The catalytic activity of the synthesised phosphinocarbaborane complexes of rhodium in hydrogenation and isomerisation reactions of unsatuated hydrocarbons was investigated[114,118] and it was shown that these complexes are much more effective catalysts of the above reactions than the carbaboranerhodium complexes fixed on polystyrene which had been known previously.[102-104]

---o0o---

Thus, the literature data presented show that the use of homo- and co-polymerisation methods for the synthesis of carbaborane-containing polymers makes it possible both to obtain new high-molecular-weight compounds and to modify the known polymers and to impart to the latter properties of practical importance. The study of the polymerisation of unsaturted derivatives of dicarbaundecaborates and of the properties of the polymers formed is of great interest.

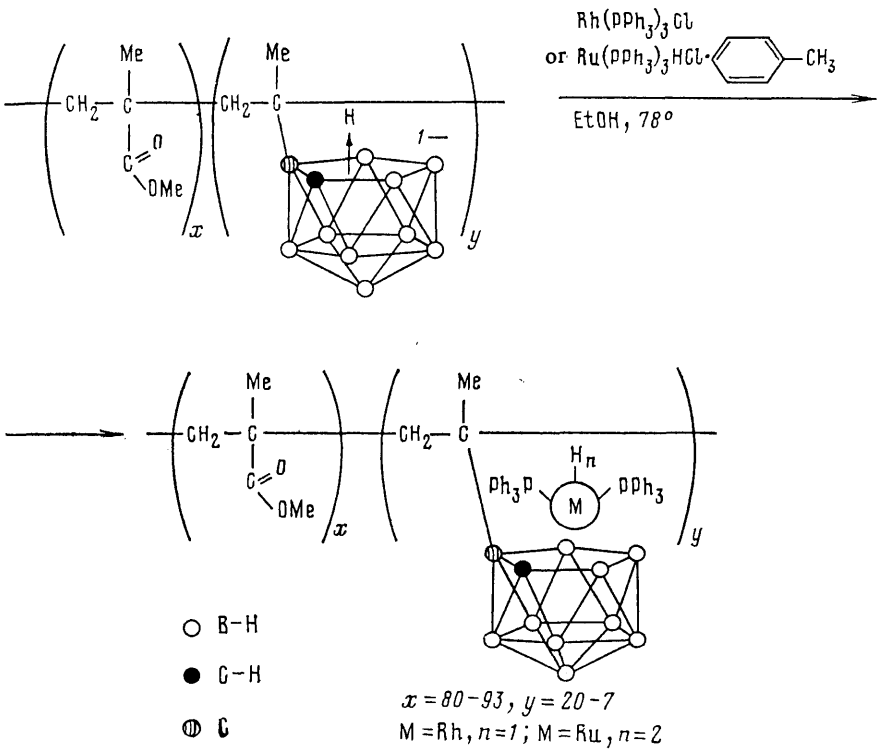

Figure 2. Scheme for the preparation of polymeric phosphinocarbaborane complexes of rhodium(I) and ruthenium(II).[114,116]

Phosphite Synthesis of Oligodeoxyribonucleotides

N.N.Karpyshev

Data in the literature published between 1983 and 1986 on the synthesis of oligodeoxyribonucleotides from nucleoside derivatives of phosphorous acid are reviewed. Attention is mainly focused on the techniques employed for preparing initial monomers for condensation. The individual stages in the solid-phase phosphite method are presented, and the potential of various approaches for achieving this type of synthesis is discussed. In addition, studies on the synthesis of oligonucleotides with the aid of monoesters of phosphorous acid (phosphonate synthesis) are assessed.
The bibliography includes 101 references.

I. INTRODUCTION

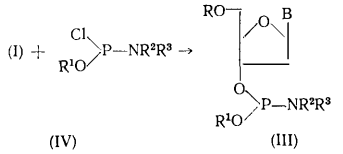
Chemical synthesis of DNA fragments is of key importance for the advancement of molecular biology and genetic engineering. Many commercial organisations in a number of Advanced Nations offer a range of reagents and efficient automatic synthesisers and also provide a service for synthesising oligodeoxyribonucleotides with the required sequence. Moreover many scientific centres are involved in the elaboration of synthetic methods and therefore one would anticipate further progress in this field.

Until recently advances in solid-phase synthesis of DNA had been mainly determined by developments in the chemistry of derivatives of tri-coordinated phosphorus, the nucleoside phosphites. The reviews present in the literature at the time when the present communication was submitted for publication did not consider aspects of phosphite synthesis in any detail.[1-5] The present review focuses on reports published between 1983 and 1986 in which nucleoside phosphites were used for oligonucleotide synthesis and which deal with various practical aspects of this type of synthesis.

II. SYNTHESIS OF NUCLEOSIDE PHOSPHORAMIDITES

It is generally accepted that the original monomeric units in solid-phase phosphite synthesis were the nucleoside chlorophosphites (II) obtained by the reaction between nucleosides‡ (I) and alkyl dichlorophosphites:[6-8]

(I) (II)



†The prefix *d* (deoxy) is omitted throughout for brevity.

‡The following arbitrary terms are used to describe the formulae: $(CH_3O)_2Tr$ – 4,4'-4,4'-dimethoxytrityl; throughout where not specially indicated R, triarylmethyl: R^1, alkyl or aryl; R^2 and R^3, alkyl; B, the protected heterocyclic base of the nucleoside.

Although this appears to be a straightforward process, the monomers (II) are relatively unstable during storage, and it is necessary to employ low temperatures (–78 °C), in order to reduce secondary reactions. Although until recently certain groups of research workers have adhered to the chlorophosphite approach[9] for this synthesis, the use of phosphoramidites (III) has gained universal acceptance, since the latter compounds may be converted into active intermediates by reaction with acidic reagents *in situ*.[10] A feature of this approach is the relative ease of use of these compounds, and they can be stored for months or even years under conditions which are easy to provide in practice. There are currently several techniques and modifications for preparing various phosphoramidites (III). Naturally not all of these modifications are used in practice but they all represent "progress steps" along the route towards a more efficient and cost effective method for the chemical synthesis of DNA.

1. Main Methods for Monomer Synthesis

The most extensively used method for preparing phosphoramidites (III) involves the reaction between the corresponding nucleoside (I) and the following type of phosphorylating agent (IV):[10-17]

(IV) (III)

This method is quite straightforward and well-defined provided that the phosphorylating agent (IV) is pure. In addition to synthesis of normal phosphoramidites (III) this method is also used for resolving certain non-routine problems, for example preparation of phosphoramidites of unusual nucleosides,[18] and also in a number of lipids.[19]

A considerable number of type (IV) agents have already been synthesised and characterised. Key information on certain of these compounds is presented in Table 1. Nevertheless, the preparation of compounds (IV) is labour-intensive and is not always a safe process (on account of their very high reactivity). Moreover, reagent (IV)

cannot be purified by distillation, when relatively high molecular weight substituents are present in positions R^1, R^2, or R^3. Hence, several alternative routes for the synthesis of nucleoside phosphoramidites (III) have been proposed which circumvent the phosphorylating agent (IV) preparation stage. In one of these methods,[20-24] a substituted dichlorophosphite is treated with excess of triazole or its trimethylsilyl derivative. The resultant bis-triazolide subsequently reacts sequentially with nucleoside (I) and the corresponding amine:

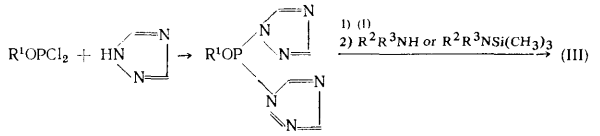


Table 1. Physicochemical properties of certain amidochlorophosphites (IV).

R^1—	—NR^2R^3	Boiling point, °C (mm Hg)	^{31}P NMR, p.p.m.	Refs.
CH_3—	—$N(CH_3)_2$	40—42 (13)	—179.5 (a)	[10]
CH_3—	—N O	52—54 (0.1)	—172.1 (a)	[11,17]

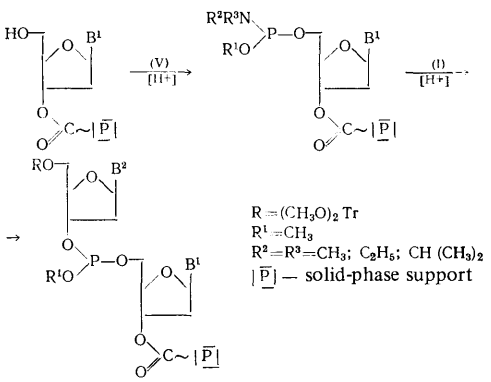
*Relative to H_3PO_4, solvent is indicated in the brackets: a) deuterochloroform; b) deuteroacetonitrile.

Conversion of the dichlorophosphite into the bis-triazolide leads to enhanced selectivity with respect to phosphorylation of nucleoside (I), i.e. a reduction in the proportion of by-products, 3',3'-dinucleoside phosphite. A similar result may also be obtained, when nucleoside (I) is treated with a large excess of dichlorophosphite R^1OPCl_2 with subsequent introduction of an adequate amount of amine:[25]

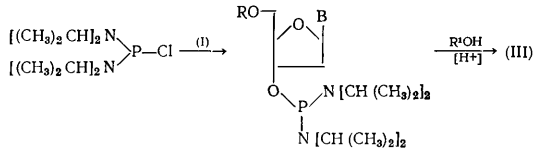
$$R^1OPCl_2 \xrightarrow{(I)} [(II)] \xrightarrow{R^2R^3NH} (III)$$

The latter method is of course only practicable, when a sufficiently effective technique (e.g. chromatography) is available for isolating the required phosphoramidite (III) from the multi-component reaction mixture.

The research workers who introduced the phosphoramidite method accept that this technique, used for activation of amides (III) with weak acids thereby creating an internucleotide linkage, is based on fundamental studies (mainly Soviet) on the protonation of amides of phosphorous acids (see communication[10] and the references in this article). Although specific questions in regard to the mechanism of protonation are still under debate,[26] this in no way imposes restrictions on the practical exploitation of the reaction in nucleic acid chemistry. For example, since bis(dialkylamino)alkoxyphosphines (V) are protonated by weaker acids than the phosphoramidites (III), the latter may be obtained by the reaction between nucleosides (I) and reagents (V) in the presence of specially selected proton donors:



A number of azoles, of which 4,5-dichloro-imidazole proved to be the most effective,[27,28] were selected as weak acids for activation of bis(pyrrolidino)methoxyphosphine (V), $R^1 = CH_3$, $R^2R^3 = (CH_2)_4$. Another group of workers[29] have proposed that tetrazolium salts of the corresponding dialkylamines should be used for the selective activation of phosphines (V), $R^1 = CH_3$.



The possiblity of obtaining phosphoramidites (III) of acceptable purity immediately prior to condensation is the main advantage of the selective activation method, since difficulties associated with the isolation and storage of the reactive monomers may be avoided (III). In contrast to the corresponding amidochlorophosphites (IV), it is also of importance that type (V) compounds are extremely stable and safe to use. From recent studies in this direction the use of bis(dialkylamino)phosphite containing a β-cyanoethyl substituent (V) [$R^1 = CNCH_2CH_2$; $R^2 = R^3 = CH(CH_3)_2$] is noteworthy.[30]

A somewhat different approach has been suggested by Korean workers[33] for the use of diamidophosphites (V). The method recommended resembles previously-described techniques for two-stage phosphite condensation.[31,32]

In this case (V) is initially activated with an equimolar quantity of tetrazole, and the nucleoside component attached to the solid phase reacts with the protected compound (I) in solution even in the presence of excess tetrazole. However the active component in the phosphite synthesis, the phosphoramidite, is irreversibly inactivated by traces of water. Therefore, like the early methods, the main defect of this method[33] is that this active component is associated with the polymer and it is impossible to maintain an excess of this component.

Recently yet another modification has been proposed for the synthesis of phosphoramidites (III) which is based on selective activation:[34]

The phosphorylating agent, bis(diisopropylamino)chlorophosphine, is quite stable and may be purified by vacuum distillation. The intermediate nucleoside bis(diisopropylamido)phosphite subsequently reacts with an alcohol R'OH to yield the required phosphoramidite (III). This variant has none of the limitations associated with the problems in obtaining dichlorophosphites or dialkylamidochlorophosphites.

A stage in which the preparation is obtained in the form of a dry powder by re-precipitation or directly from the reaction mixture or after chromatography in a silica gel column is quite typical for most above-mentioned modifications used for synthesis of nucleoside phosphoramidites (III). This is an extremely important stage in regard to the purity of the compounds (III) obtained and consequently their stability. The purity of phosphoramidites can be most conveniently monitored according to ^{31}P NMR spectra and in certain cases by thin-layer chromatography.[17] The use of fast atom bombardment mass spectrometry has been proposed for this purpose. This technique permits the detection of molecules of phosphorus-free impurities.[35] However the question arises of whether it is absolutely essential to obtain dry and extremely pure phosphoramidites (III) for satisfactory long-term storage and further use in the synthesis of oligonucleotides. In an earlier study[36] phosphoramidites (III) were prepared by a very conventional method, which involved the interaction between an equimolar ratio of nucleosides (I) and amidochlorophosphite (IV) [$R^1=R^2=R^3=CH_3$] in the presence of the base, ethyldiisopropylamine. After removal of the base as the hydrochloride and replacement of the solvent (tetrahydrofuran by actonitrile) the phosphoramidite (III) solutions were used for solid-phase synthesis of oligonucleotides. Preparations of morpholidophosphites (III) [$R^1=CH_3$, $R^2R^3=(CH_2CH_2)_2O$] obtained by a similar method were even more stable, and after storage for many months they were used for the synthesis of oligonucleotides of differing length up to 52 bases.[37]

2. The Effect of the Protecting Group at the Phosphorus Atom and the Nature of the Original Amine on the Properties of the Nucleoside Phosphoramidites (III)

Historically the first acid used in phosphoramidite synthesis was dimethylaniline hydrochloride, which on interaction with phosphite (III) [$R^1=R^2=R^3=CH_3$] quantitatively (according to ^{31}P NMR data) generated the corresponding nucleoside chlorophosphite (II).[10] Both the nature of the substituents R^1, R^2 and R^3 and also the acidity of the selected activator should naturally have an effect on the rate at which the reaction occurs. From the practical viewpoint phosphoramidites (III) with more electron-accepting substituents at the P atom are more stable during the isolation procedure and storage and they require stronger proton donors for activation. Compounds (III) with more lipophylic and bulky substituents at the N atom are also found to be more stable. When the R^1, R^2, and R^3 substituents are selected, any potential difficulties in the preparation of the respective phosphorylating agents (IV) should be taken into account or alternative routes for synthesis of the phosphoramidites (III) should be considered. The main criterion for selection of the R^1 substituent should be the ease with which it can be removed and the selectivity of the removal process following oligonucleotide synthesis.

Table 2. Certain phosphoramidites (III) used in the synthesis of oligonucelotides.

R^1	$-NR^2R^3$	Method of activation (solvent, activation period, min)	Refs.

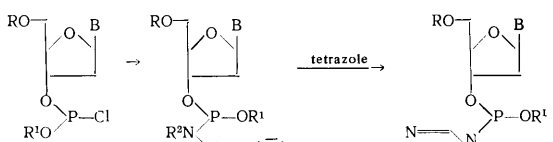
		N-methylaniline trifluoroacetate (acetonitrile, 5)	[21]

Certain known and currently used monomers (III) are presented in Table 2. It should be noted that one can only speculate on the possible advantages of certain specific phosphoramidites (III) over others. These assessments, which are based on yield comparisons at the condensation stages, final oligonucleotide yields, and certain other criteria, may not necessarily take into account the diversity of the condensation conditions, the properties of the solid-phase supports used, the apparatus, and the authors' individual interpretations. Nevertheless, as a result of the findings of many research groups the diisopropyl phosphoramidites (III) [$R^1=CH_3$, $R^2=R^3=CH(CH_3)_2$] [11,40] and morpholidophosphites (III) [$R^1=CH_3$, $R^2R^3=(CH_2CH_2)_2O$] [11,15,17] can be currently regarded as the most important agents practically. The former compounds are extremely stable and may be obtained in an appropriately pure form by direct precipitation in hexane without the use of chromatography, and they are therefore commercially most readily available. The latter compounds have even higher stability and may be carefully purified by means of silica gel chromatograpy. The methyl group in oligonucleotides, which have been obtained by using these phosphoramidites (III) [$R^1=CH_3$], may be easily removed by triethylammonium thiophenolate. However, a number of research groups use alternative protecting groups, which may be removed by the β-elimination mechanism under conditions in which the oligonucleotides are completely deblocked (concentrated aqueous ammonia, 50 °C): cyanoethyl [$R^1=NCCH_2CH_2$],[16] methylsulphonylethyl [$R^1=CH_2.CH_2SO_2CH_3$],[13] and phenylsulphonylethyl [$R^1=CH_2CH_2SO_2C_6.H_5$].[23] Monomers containing the cyanoethyl group are also commercially available. Apart from the absence of a separate stage for



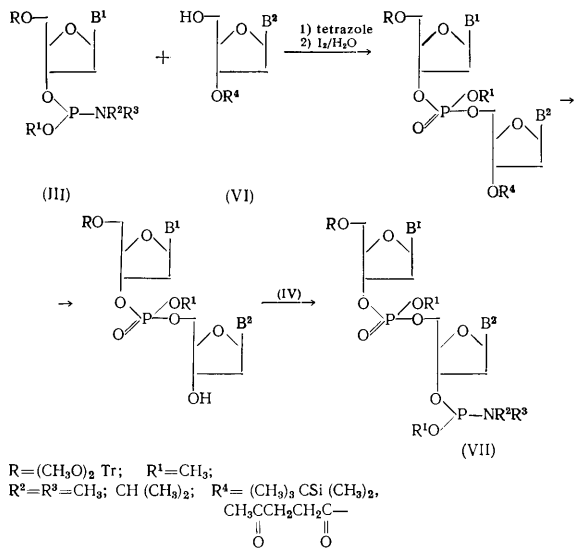
removal of the protecting group R after synthesis of the oligonucleotides, when these agents are used the obnoxious compound, thiophenol, may be omitted. Certain authors question the use of the cyanoethyl group and note that it is unstable in the presence of bases used when unreacted hydroxyl groups on the support are blocked.[5]

o-Chlorophenyl protection could be a possible alternative.[20,21] These phosphoramidites (III) [$R^1 = C_6H_4Cl$] are even more stable than their methyl analogues (III) [$R^1 = CH_3$, $R^2R^3 = (CH_2CH_2)_2O$] and may be readily purified in short columns of silica gel. In this case a five-fold excess of phosphoramidite over the nucleoside component in the polymer has been found adequate for oligonucleotide chain elongation in solid-phase synthesis, whereas in all other studies a 10–20-fold excess of phosphoramidites (III) with $R^1 = CH_3$ has been used.[21] The *o*-chlorophenyl protection can be quantitatively removed by tetramethylguanidinium *p*-nitrobenzaldoximate, but this procedure is much more time-consuming than treatment with thiophenolate and requires subsequent gel-filtration of the deblocked sample.

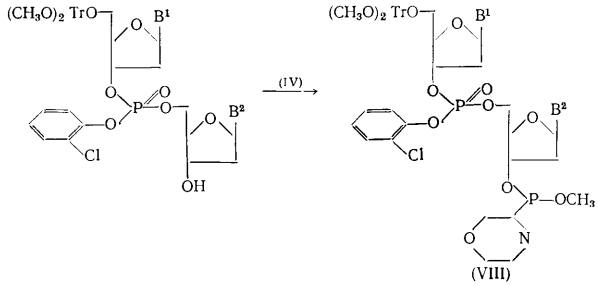
Phosphoramidites (III) containing a 1,1-dimethyl-2,2,2-trichlorethyl protecting group [$R^1 = C(CH_3)_2CCl_3$] have also been proposed, and the latter may be removed under reducing conditions, for example with tributyl phosphine or zinc dust.[41] This group has previously been used in the chlorophosphite approach.[9]

3. Amidophosphites (III) of Especial Interest

Immobilisation of the protected nucleoside chlorophosphite (II) on polystyrene containing NH-groups has effectively resolved the problem of isolating the required phosphoramidite (III).[42] After this type of polymer had been washed with tetrazole in acetonitrile, a solution of the nucleoside phosphite tetrazolide was obtained, and the latter may be effectively used in solid-phase synthesis.



This original scheme would probably be most useful in a study of the mechanisms of phosphite (III) activation rather than from a practical standpoint.



Even in the initial stages in the elaboration of the phosphite synthesis it was suggested that the synthesis should be performed by protecting the exocyclic amino groups in the heterocyclic rings.[43] The development of this concept as applied to the phosphoramidite variant led to the formation of phosphites (III) in which the bases had unprotected amino groups and also to the synthesis of certain dimers based on these phosphites.[22] Speed and cost efficiency are the attractions of this strategy. However it is inconsistent with the trend in solid-phase synthesis in accordance with which protection of amino and hydroxyl groups in the heterocyclic ring is becoming more reliable and perfected, and even in the distant future it is unlikely that this method could be used for preparing oligonucleotides of significant length. Some authors[22] consider that the principle of minimal protection could be useful in the synthesis of many short oligomers on cellulose discs.

4. Phosphoramidite Dimer Blocks

For some considerable time the use of pre-formed blocks in oligonucleotide synthesis monopolised conventional triester strategy. It appeared that during use of the monomers (III), on account of the speed and high yield of the phosphite condensation, any desired result could be achieved. However, a number of papers have now been published which describe the use of dimer blocks in phosphite synthesis.[9,44–49] There is normally a phosphate internucleotide linkage in such dimers which differs only in regard to the method employed for creating this bond (the latter may be both phosphotriester and phosphite and may be subsequently oxidised to phosphate). For example in a previous study[44] phosphoramidite blocks may be obtained as follows:

The levulinic protecting group R^4 was used which may be removed by mild hydrazinolysis. In the case of cytosine derivatives the use of (VI) containing the levulinic group is complicated by the poor solubility of this type of component in virtually any convenient solvent. This problem is resolved by substitution of levulinic by butyldimethylsilyl protecting groups. The resultant dimers are precipitated with cold hexane and may be stored until required. By using such dimers a number of oligonucleotides 29 bases in length have been synthesised. Other workers[45] have used pre-formed nucleoside blocks containing *o*-chlorophenyl protection of the internucleotide phosphate obtained by the normal triester method. By phosphorylation of these preparations it has been possible to construct 16 dimer blocks (VIII):

The blocks were purified by column chromatography and were characterised with the aid of ^{31}P NMR spectra.

The present authors consider that the above-mentioned methods for preparing phosphoramidite dimers require approximately the same number of man hours, and the choice of tactics has evidently depended on which method of synthesis in solution (phosphate or phosphite) the research worker has more effectively elaborated. However, since there were two different protective groups on the phosphorus in oligonucleotides synthesised with dimers (VIII), two different deblocking procedures should be carried out.

The use of phosphite blocks is undoubtedly accompanied by an increase in the yield of synthesised oligomers, since in this case there is a decrease in the number of essential condensations and secondary reactions are also reduced. The most outstanding example of the use of this method has been the synthesis of a 101-base polynucleotide.[48] However, construction of the blocks is a laborious process which demands very highly qualified personnel, and it is unlikely that phosphite dimers will be used extensively in practice for solid-phase synthesis. Increases in yield of oligonucleotides may apparently be achieved by less expensive methods, for example by scale-down of the process, by increasing the concentration of the monomeric phosphoramidites (III), and by optimising the solid-phase cycle with the aim of minimising secondary reactions.

III. REACTIONS AND REAGENTS FOR SOLID-PHASE PHOSPHITE TRIESTER SYNTHESIS

The main aspects of the solid-phase phosphite synthetic cycle are well conserved and comprise a sequence of stages including detritylation, condensation of nucleoside and nucleotide components, oxidation of phosphite to phosphate, and blocking of unreacted hydroxyl groups. However, the duration of the complete cycle has been reduced from 30–60 minutes to 10 minutes or less over a five-year period by the modern automatic synthesisers. This more rapid cycle time has resulted from the shortening of non-productive time in the automated devices, improvements in the mass-transfer processes as a consequence of solid-phase supports, and also the selection of the most appropriate reactions and reagents for rapid synthesis.

1. Detritylation and 5′-Protecting Groups in Phosphite Synthesis

The dimethoxytrityl group is often used for protection of the 5′-position of nucleotides in the phosphite synthesis. Similar types of groups may be removed in acid solution and in principle they may be accompanied by cleavage of purine bases. There is a large amount of data on the actual effect of depurination on the composition of the final reaction mixtures but these data are inconsistent.[6,50–55] It has been reported that removal of the dimethoxytrityl group under normal conditions (3% trichloracetic acid in dichlorethane) is not accompanied by any noticeable depurination throughout the treatment period (1.5 minutes per cycle).[54,55] Nevertheless certain authors as mentioned above prefer to use zinc bromide in nitromethane as a slowly acting but extremely selective detritylating agent.[45,46]

The monomethoxytrityl group is even more inconvenient for solid-phase synthesis if one considers the suggestion that secondary reactions may occur during detritylation. However there is an experiment cited in the literature in which this group has been effectively employed in phosphoramidite synthesis.[56] Various alternative detritylating solutions have been proposed by means of which the monomethoxytrityl group can be removed in the solid phase as rapidly as the dimethoxytrityl group: 0.1 M trifluoroacetic acid in dichloromethane, 1 minute;[56] 5% trichloroacetic acid in dichlorethane, 3.5 minutes,[57] 1 M $ZnBr_2$, 0.02 M 1,2,4-triazole in a dichloromethane-isopropanol mixture (85:15), 1.5–3 minutes.[58]

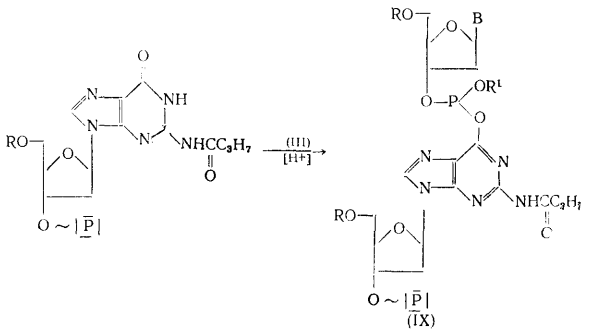
In a previous study[59] a number of triphenylcarbinol derivatives has been examined and different protecting groups have been proposed for each of the four nucleosides. Under normal detritylation conditions these groups give solutions of triarylmethyl cations in different colours (orange, blue, red, and black) and it is thus usually possible to monitor the sequence of bases in the oligomer under synthesis.

In principle weak acids used for promoting phosphoramidites may also have a detritylation action. Thus apparently the 9*H*-9-phenylxanthenyl (pixyl) protecting group, being more acid-labile than the dimethoxytrityl group[60] has not gained popularity among those who favour phosphite synthesis. The proposed protecting groups for the 5′-terminus in phosphite synthesis do not only consist of derivatives of triarylmethanes. The alkali-labile *p*-phenylazophenyloxycarbonyl group[61] has recently been reported, although at present difficulties would be encountered in the extensive use of this grouping.

2. Blocking of Unreacted Hydroxyl Groups on the Support (Capping)

As with detritylation, at this stage there are no major differences in any of the modifications of the solid-phase synthesis. In the early studies this stage was carried out by using phenyl isocyanate[7] or diethyl chlorophosphite.[8] The use of mixtures based on acetic anhydride in pyridine, lutidine, or collidine[46] is currently preferred, since they are more convenient in practice and quite effective, especially in the presence of the nucleophilic catalysts, dimethylaminopyridine[13,25,55] and N-methylimidazole.[56] This stage is essential for the synthesis of extended sequences, since it facilitates markedly subsequent isolation of the required oligonucleotides. It has already been mentioned in Section II that under certain conditions capping may lead to undesirable secondary reactions.[5]

3. Phosphoramidite Condensation and Factors Affecting the Efficiency of the Condensation



This stage is most important in regard to the efficiency of solid-phase synthesis. Acid activation of phosphoramidites has been briefly discussed by the present authors in Section II. In this Section weak acids normally used for this purpose are presented (Table 2). Tetrazole is most frequently used and may be obtained in a suitably pure and dry form by vacuum sublimation of commercially available preparations. However, tetrazole is not suitable when using the more stable type (III) compounds, for example the morpholidophosphites (III) [$R^2R^3=(CH_2CH_2)_2O$], and more effective proton donors are used in such cases. Selection of an acid should be made on the basis of the following properties: a) high stability in the medium; b) ability to protonate the selected phosphoramidite (III) at a rate compatible with the practical conditions; c) the absence of any detectable deblocking of the nucleotide component under the condensation conditions; d) chemical stability of the working acid solution for the entire duration of oligomer synthesis.

A distinctive feature of phosphite synthesis is the large (10–20-fold) excess of reagent (III) over the nucleoside component in the polymer. This excess is essential not only for ensuring an adequate rate of reaction for chain elongation but also for compensating the

consumption of phosphite (III) in secondary reactions, for example with the residual moisture in the solvents (in the phosphotriester condensation in the traditional variants an excess of condensing agent fulfils this function). However, in work involving micro-scale solid-phase synthesis even these excess quantities are found to be acceptable, and in certain instances authors have changed the method by repeating each condensation twice, and this modification guarantees that the process will proceed quantitatively.[28,48,62]

A significant excess of phosphite is undoubtedly an essential prerequisite for a highly efficient condensation. However, is this condition sufficient? A completely negative answer has been given to this question, viz. steric factors play a key role on solid-phase supports with a high degree of nucleoside modification.[62] It has been established empirically that an extremely high yield on silica supports is ensured, when the nucleoside loading does not exceed 0.4 $\mu mol/m^2$. The currently extensively used solid-phase supports based on glass modified with long-chain aminoalkyl "spacers" in particular satisfy this condition. It is relevant that the authors are aware of only one study in which phosphoramidites (III) have been used for the synthesis of cellulose discs.[65] The difficulties associated with mass-exchange on the cellulose matrix outweigh the main advantage of phosphite synthesis, viz. speed, and compound the problems associated with secondary reactions.

Secondary reactions can play an important role in reducing the yield at the condensation stage. For example, it has been shown that guanidine may be phosphorylated at position O(6) with the formation of "pseudo" chains, which are subsequently destroyed on treatment with aqueous ammonia:[54,55,66]

This process may to a marked extent complicate the synthesis and subsequent isolation of oligonucleotides with a high guanosine content. Difficulties may be avoided by the use of phosphoramidites (III) comprising O(6)-*p*-nitrophenylethyl-protected guanosine derivatives[54,55] or β-cyanoethyl group.[68] However, data are available which indicate that on introduction of a bulky diphenylcarbamoyl goup at this position there is a decrease in the rate of condensation due to steric hindrance.[67]

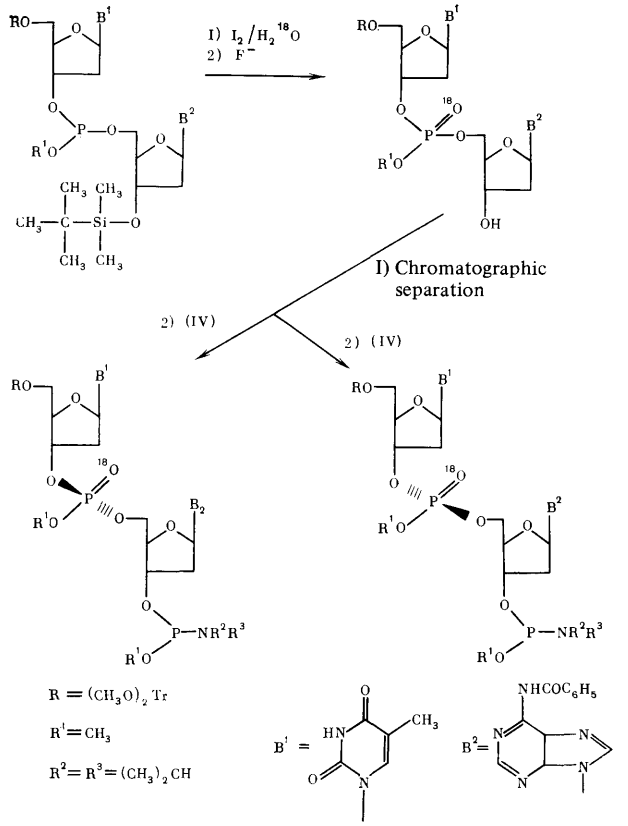
The product formed by phosphorylation at the heterocyclic ring (IX) is sufficiently reactive to be attacked rapidly by certain nucleophiles. This approach is the basis of a number of techniques for the decomposition of compound (IX) immediately after the condensation before oxidation to the phosphate, which markedly increases the possibility of synthesising oligonucleotides with a high guanosine content.

1) Regeneration of guanosine with water or the acetate ion before oxidation with iodine; the regeneration process also takes place, when a mixture of acetic anhydride and pyridine is used for capping prior to oxidation;[68]

2) the use of N-methylalanine as a phosphoramidite (III) activator;[68]

3) oxidation with an iodine solution in a pyridine-acetic acid mixture; in this case the product (IX) is attacked by the acetate ion more rapidly than oxidation of phosphite to phosphate.[56]

The instability of phosphoramidite derivatives of guanosine in solution during storage was the object of a thorough investigation in an earlier report.[69] This instability presents certain difficulties in the synthesis of mixed oligonucleotide probes, since the mixture becomes depleted of oligonucleotides with a high guanosine content. With the aid of ^{31}P NMR spectroscopy it was shown that a substance with a chemical shift corresponding to a secondary phosphate is predominant among the phosphoramidite (III) degradation products. The mechanism of this process has not been precisely determined, but there are grounds for suggesting that products from the type (IX) phosphorylation are formed as intermediates. These authors[69] also note that in the case of phosphoramidites containing a cyanoethyl group (III) [$R^1 = CH_2.CH_2CN$] the guanosine derivatives are not as unstable as the methyl analogues (III) [$R^1 = CH_3$].



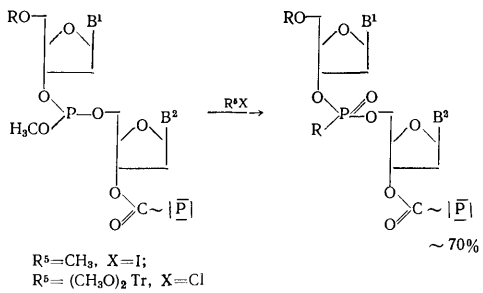
With phosphoramidites (III) [$R^1 = CH_3$] methylation of the thymine heterocycle may also occur,[70] although the practical importance of this type of secondary reaction under the actual conditions of solid-phase synthesis is questionable.[5] On the whole the effect of secondary reactions on oligonucleotide synthesis is clearly illustrated by the following example. When extended products from automatic phosphoramidite synthesis (60–90 bases) are cloned, on average there are base substitutions or deletions in 40% of the clones.[71]

4. Oxidation

This process is traditionally achieved with the aid of iodine in an aqueous-organic solution. The reaction is rapid and selective, although alternation of treatment of the support with water when the latter possesses a certain sorption capacity with subsequent condensation in "absolute" solution cannot be regarded as a satisfactory procedure. In an earlier study[6] *m*-chloroperbenzoic acid in pyridine was used as the oxidising agent, although this agent rapidly lost activity in the course of the synthesis. Currently bis-trimethylsilyl peroxide[72] is recommended for the conversion of phosphite to phosphate in the solid phase including the trimethylsilyl ester of pertrifluoromethane sulphonic acid as catalyst,[73] tetrabutylammonium periodate,[74] and iodosobenzene diacetate.[74] The latter compound is of interest, since it may be used directly in the capping solution. In regard to their application to solid-phase synthesis the new reagents are still under investigation although extensive testing of these compounds will be restricted by their lower availability in comparison with iodine. Nevertheless taking into account the modern-day arsenal of oxidising agents one would anticipate that new studies in this direction will be performed. The use of iodine in a pyridine-acetic acid mixture is also a promising method.[56]

The oxidation stage or generally the transition from tricoordinated phosphorus derivatives to tetracoordinated phosphorus derivatives is of great significance for the synthesis of oligomers modified at the internucleotide linkage. It has been shown that during condensation in the presence of phosphoramidites (III) phosphite triester

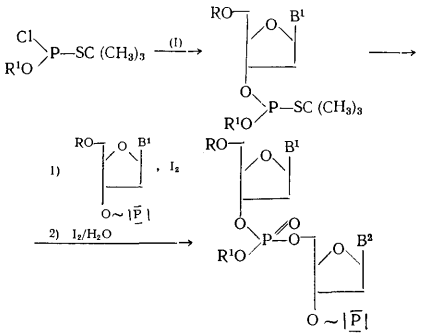
enantiomers are obtained, and that the ratio of the latter is dependent on the reaction conditions.[45,75,76] If $H_2{}^{18}O$ is used for the oxidation with iodine, the corresponding isotopically chiral phosphates are obtained and they may be used for the synthesis of chiral blocks.[47]



Both of these blocks are further used for the synthesis of oligonucleotides, which differ only in regard to the configuration of one of the internucleotide phosphates.

The phosphite synthesis is extremely convenient for the preparation of thiophosphate analogues of oligonucleotides, which are often used as model compounds in enzyme studies (see communication[77] and the references cited in this article for recent studies on the use of these analogues). In the automated solid-phase method of Stec et al.[78] the thiophosphate bond was introduced at the "oxidation" stage, aqueous iodine having been replaced by sulphur (0.4 M S_8 in lutidine; 60 °C; 15 minutes). The resultant chiral oligomers with respect to thiophosphate in most cases could be separated chromatographically into the individual enantiomers.

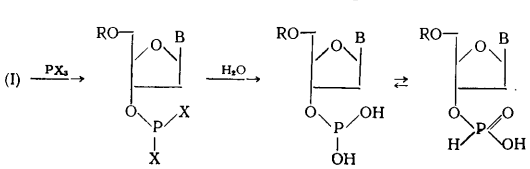
In a similar way to the thiophosphates, selenium phosphate analogues could in principle be obtained, the latter compounds being of interest in regard to X-ray structural studies on DNA and for studies on $^{31}P-{}^{77}Se$ spin–spin interactions. However, the authors[78,79] were only able to obtain a few di- and tri-nucleotide analogues (0.1 M KSeCN in acetonitrile; 60 °C; one hour), since selenium is lost by some mechanism unknown to the investigators during the repeating cycles at the stage involving oxidation with iodine.



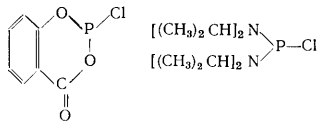
In the interaction between trialkylphosphite intermediates in solid phase and an iodine/alanine/lutidine mixture several phosphoramidite analogues of di- and trinucleotides were obtained, although the yield of the required products was low (less than 20%) and the methodology is in need of development.[79]

The internucleotide linkage may also be modifed by using the Arbuzov rearrangement.[80]

Oligomers obtained by means of this technique, in which one or several internucleotide groupings are phosphonate, may also be separated into the individual enantiomers with the aid of reversed-phase high performance liquid chromatography.



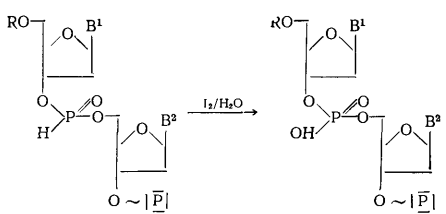
A new modification of the phosphite synthesis has been proposed in which the oxidation and condensation stages may essentially be integrated. Thiolphosphites[81] are used as the original monomers in this method:



The condensation is achieved in the presence of iodine in an anhydrous solvent, and oxidation may be subsequently carried out by simply adding water. However, it is unlikely that in the near future this method will provide a realistic alternative to the well developed phosphoramidite condensation.

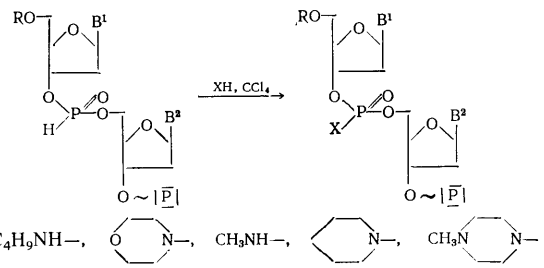
IV. NUCLEOSIDE PHOSPHITES IN THE SYNTHESIS OF OLIGONUCLEOTIDES (PHOSPHONATE SYNTHESIS)

It has recently been proposed that nucleoside phosphites (X) mainly in the H-phosphonate form should be used as monomers in solid-phase synthesis. The procedure used for synthesis of oligonucleotides is known as the "phosphonate" method.[82–85] The methods for preparing nucleoside phosphites (X) proposed by the pioneers of solid-phase phosphonate synthesis are based on the interaction between nucleosides (I) and tris(azolyl)phosphines:



Naturally, in order to prevent the formation of di- and tri-esters of phosphorus acid, a great excess of these phosphorylating agents was used. Later a report was published on the use of other phosphorylating agents:[86]

The use of these agents reduces the possibility that by-products are formed instead of tris(azolyl)phosphines. In all cases[82–86] monomers (X) obtained as a result of phosphorylation and subsequent hydrolysis were purified with the aid of adsorption or reversed-phase column chromatography. The nucleoside phosphites (X) are sufficiently stable in the form of tertiary amine salts and may be stored for considerable periods.



It has been shown that various anhydrides and acid chlorides of phosphorous acids and carboxylic and sulphonic acids may serve as monomer (X) activators during oligonucleotide synthesis, although the acid chloride of trimethyl acetic acid was found to be the best of the agents tested.[84,85] It has been suggested that the active phosphorylating compound in this case is a mixed anhydride of phosphorous and carboxylic acids. It is considered that pre-mixing of the nucleoside phosphite (X) and pivaloyl chloride leads to the formation of a bifunctional phosphorylating agent, diacyl nucleoside phosphite. It is therefore recommended that the reagents should be mixed directly during the condensation process in the reactor.[85]

A separate capping stage is evidently not required in the phosphonate synthesis, since non-phosphorylated hydroxyl groups on the support should be acylated in the condensation process. As there is a five-fold excess of condensing agent (pivaloyl chloride) over monomer (X), in the phosphonate method a lower amount of nucleotide component is consumed than in the phosphoramidite method. The internucleotide phosphite diester groups formed during the synthesis are chemically quite inert and do not require protection. They are oxidised with iodine in an aqueous-organic solution at the end of oligomer synthesis.

However the oxidation process is slower than with the trialkyl phosphites and in order to promote the oxidation, catalysis with stronger bases than pyridine is necessary.[84] Thus in the phosphonate synthesis the chain elongation cycle consists essentially of a condensation stage (1–2 minutes), detritylation (1–2 minutes), and a washing procedure, and therefore greatly extended oligonucleotides containing up to 100 bases may be synthesised rapidly.[84] At present there are certain unknown factors and reservations in regard to this synthesis. For example, partial detritylation in the condensation process[84] or incomplete capping is thought to occur. However, the phosphonate method is extremely straightforward and cost effective, and very shortly many research workers will undoubtedly favour this method.

This method also shows promise in regard to the synthesis of oligonucleotide analogues. Unfortunately the phosphite diester group itself is unstable in the presence of bases, and an unoxidised oligomer containing phosphite diester internucleotide groups cannot be removed from the support by conventional methods. However, this group may be susceptible to attack by a nucleophile, for example the Atherton–Todd reaction. This property has been exploited by Gryaznov et al.[87] for the synthesis of dinucleotides containing an internucleotide phosphamide linkage. By the application of this reaction to the oligomeric product from the solid-phase phosphonate synthesis it has been possible to obtain a number of amidophosphate analogues of oligonucleotides:[88]

This communication[88] describes the synthesis of nine undecathymidylate analogues which contained different numbers of morpholidophosphate internucleotide groups, and also mentions the possibility of preparing thiophosphate [0.1 M S_8 in a triethylamine–carbon disulphide (1:9) mixture 5 min] and triester [10% alcohol in an N-methylimidazole–triethylamine–carbon tetrachloride (5:5:90) mixture] analogues of oligonucleotides via the phosphite diesters on a support.

V. PHOSPHITE REAGENTS FOR THE INTRODUCTION OF DIFFERENT FUNCTIONAL GROUPS INTO OLIGONUCLEOTIDES

Oligonucleotides are nowadays increasingly used as carriers for various groupings, for example chemically active (complementarily addressed modification) and reporter (nonradioactive probes) groups. Research workers are focusing attention on the replacement of a number of enzyme processes in genetic engineering (for example kination and ligation) by purely chemical processes. There would be strong grounds to use for such purposes the same chemical arsenal as for the synthesis of the oligomers themselves.

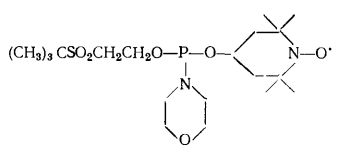
1. Introduction of the Phosphate Group at the 5′-Terminus of the Oligonucleotide

This operation represents a chemical alternative to the kinase reaction and has been thoroughly worked out in the phosphotriester synthesis. The main problem associated with the introduction of the 5′-terminal phosphate is the selection of a phosphorylating agent with easily removable protecting groups at the phosphorus atom, confirmation that the phosphorylation has taken place, and also the separation of the 5′-phosphorylated oligonucleotide from the normal oligonucleotide (when the chain is long enough, there is an insignificant difference between the chromatographic and electrophoretic mobility of both oligomers).

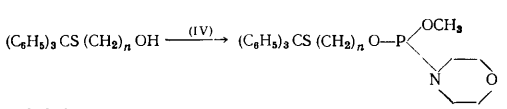
Several phosphorylating agents prepared by conventional methods of phosphite synthesis have been proposed.[89,90]

$R^1=R^2=CH_2CH_2C_6H_4NO_2$; $R^1=R^2=CH_2CH_2CN$;
$R^1=CH_3$, $R^2=CH_2CH_2C_6H_4NO_2$; $R^1=CH_3$, $R^2=CH_2CH_2CN$

Solid-phase phosphorylation of the oligomers by such agents with the aid of acid catalysis, oxidation, and subsequent deblocking yields the required oligonucleotide-5'-phosphates. Methyl and β-cyanoethyl groups are accordingly removed before the support is treated with ammonia and during this treatment. The *p*-nitrophenylethyl protection may be removed only by strong bases such as diazabicycloundecene. It may therefore be used as an hydrophobic probe during the removal of the 5'-phosphate of the oligomer by reversed-phase chromatography.



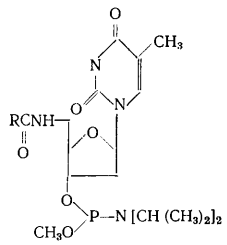
A phosphorylating agent containing the dimethoxytrityl group has also been described:[91]



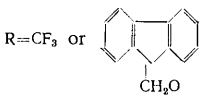
After oxidation of the phosphorylated oligomer and treatment with acid it is possible to determine whether phosphorylation is complete according to the concentration of the dimethoxytrityl cation. The remaining ethoxysulphonylethyl fragment is removed together with the β-cyanoethyl protection when the support is treated with ammonia.[91]

2. Introduction of the Reporter and Functional Groups

The synthesis of a phosphoramidite containing a nitroxyl fragment is an example of the direct introduction of a reporter group with the aid of a phosphorylating agent:[92]

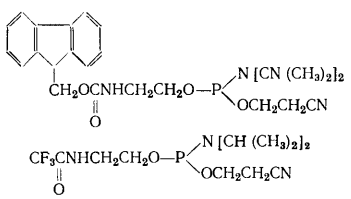


However, reporter groups such as coloured or fluorescent chromophores are often complex in structure. It is easier to introduce these groups under milder conditions into oligonucleotides, which have been preliminarily modified with certain functional groups. The authors of a study on 5'-phosphorylation with the aid of phosphoramidites[89-91] note that by using phosphite reagents it is possible to introduce a 5'-terminal thiophosphate, a potential acceptor group for different modifiers. A morpholidophosphite with trityl protection has been used to introduce the thiol group:[93]



$n=2, 3, 6$

After phosphorylation of the oligonucleotide and oxidation with iodine the trityl group was removed with silver nitrate.



The amino group was introduced by means of phosphoramidite derivatives of 5'-deoxy-5'-aminothymidine:[94]

Alkali-labile groups (fluorenylmethoxycarbonyl or trifluoracetyl) were removed while the support was being treated with ammonia. Oligomers containing amino groups obtained in this way have been used in the synthesis of primers for sequencing according to the method of Sanger which carried a fluorescent marker at the 5'-terminus.[94]

The fluorenylmethoxycarbonyl[95] and trifluoracetyl[96] groups have also been used in the construction of other phosphorylating agents, in order to introduce the amino group.

In the latter case in order to increase the yield of the required oligonucleotides, the protecting groups were removed not with ammonia but with diazabicycloundecane.[96]

---o0o---

As a result of the development of methods for nucleophilic catalysis it is now possible to achieve a phosphotriester condensation quite rapidly and efficiently.[67,97-101]. However, commercial manufacture of nucleoside phosphoramidites and automatic synthesisers, which operate according to the phosphoramidite cycle, has indeed become a mass-production venture. Phosphonate synthesis is also being rapidly commercialised. Operations in the synthetic cycle are constantly being improved and simplified with the result that the chemical synthesis of DNA is a rapidly-developing and refined procedure. The demand for modified oligonucleotides is also attracting increasing attention in regard to nucleoside phosphites and fundamental questions on the chemistry of organophosphorus compound, which should ensure further advances in phosphite synthesis.

Future Outlook for the Construction of Biologically Active Compounds

O.A.Raevskii and A.M.Sapegin

The state of the art in regard to studies on the relation between structure and properties expressed by chemical compounds, especially biological activity, has been assessed, the determination of structure-activity relationships being the only feasible alternative to costly empirical screening. It has been shown that in this area of research, which embraces the fields of chemistry, physics, mathematics, and biology, further advances will only be possible by means of a compatible language for the computer-aided description of structure, and methods for revealing structure-property relationships and quantitative criteria of properties.

I. INTRODUCTION

Progress in science and technology is concomitant with the growth in number of chemical compounds used in industry, agriculture, medicine, and domestic life. On account of the virtually limitless scope for synthesizing new compounds, chemistry ensures a constant improvement in the exploitable properties of available substances. At present there are approximately ten million known chemical compounds. However, together they represent a negligible portion of the inifinite number of total possible compounds. This is especially evident from the data presented in communication.[1] If merely fifty substituents well characterised in organic chemistry are used for substitution in various combinations into seven free positions of naphthalenecarboxylic acid alone, 7.8×10^{12} chemical compounds may be obtained. It clearly follows that there is a high probability that compounds may be synthesized which have markedly superior properties to those of existing chemicals. In this regard the question of what strategies to adopt in order to obtain highly effective compounds in the shortest possible time with minimal effort is of major importance. The use of comprehensive tests for properties (i.e. total screening) in order to find new preparations is a very expensive excercise (with this approach in order to introduce one new compound, 12 000 – 15 000 chemical compounds must be synthesized and thoroughly examined). For this reason it is necessary to elaborate sound principles for the construction of compounds with the desired properties.

According to references 2, 3 the development of concepts on chemical structure was closely linked to the identification of an interrelationship between structure and the properties expressed, initially at the qualitative level[3,4] but subsequently with the discovery of the periodicity of the elements there was a gradual transition to the quantitative determination of structure-activity relationships.[5]

The problem of establishing structure-activity relationships becomes of particular interest and significance in the search for biologically active compounds. Conventional approaches such as isolation of biologically active compounds from natural sources, synthesis of analogues of natural compounds, study of folk medicine, and extensive biological trials cannot keep pace with the rapidly increaseing demand for new preparations. For this reason from the middle of the nineteenth century a new approach to the search for biologically active compounds began to develop, i.e. determination of the relationship between the structure of a compound and the biological activity expressed by the compound (structure-activity relationship). Justification of this approach was demonstrated by the work of Richardson, who for the first time was able to demonstrate qualitatively the relationship between the structure of certain organic compounds and their physiological activity,[6] and also by the studies of Crum-Brown and Fraser, who made the first attempt to construct a mathematical model representing the relationship between structure and activity.[7] The basic principles for establishing quantitative structure-activity relationships have now been defined (see reference[3] for the historical aspects of the determination of structure-activity relationships). The following schematic illustrates current concepts on the mode of action of biologically active compounds based on quantitative structure-activity relationships:[8]

The interrelationship between the structure of a compound and its biological effect following the introduction of the compound into the body becomes specific and fully expressed only at the pharmacodynamic stage. As regards other processes associated with the transformation of compounds, enzyme inhibition, diffusion of compounds in different organs, etc., information (although steadily growing[9]) is sometimes extremely limited and therefore it is difficult

to determine quantitative structure-activity relationships. Thus the problem of the quantitative structure-acitivity relationship is a special case of the structure-property relationship. However, on account of the complexity of the application of the structure-activity relationship to biological specimens, it is necessary to go beyond the traditional framework of the structure-activity problem and to focus attention not only on methods for detecting relationships and on the development of experimental investigations into structure and the form of the description but also on the quantitative determination of biological activity and on the production of a detailed description of the biological processes themselves.

There are currently thousands of publications devoted to anlalyses of quantitative structure-activity relationships. In a specialised journal (Quantitative Structure-Activity relatinships) commenced publication in 1981 in addition to original articles a large number of abstracts of studies on quantitative structure-activity relationships published in other issues including monographs and reviews are cited.[10–20] However, in most cases these studies are either specialised and focus on a single approach or problem (i.e. regression analysis,[18] the use of computers,[19] application of quantitative structure-activity relationships to the analysis of pesticide activity[20]) or mainly concentrate on a description of mathematical methods for analysis of quantitative structure-activity relationships.[16,17]

In the present review emphasis is place on the basic principles of the construction of compounds with desired properties[21,22] which constitute the physicochemical foundation for the determination of quantitative structure-activity relationships. In this case the research worker should have reliable quantitative information on the level of biological activity that the chemicals possess.[18] When the objective is to establish the quantitative structure-activity relationship there is a tendancy to construct a model which describes the interaction between compound and receptor and to use a method for determining the relationship between the correct (within the limits of the method used) representation of the structure of the compound and the activity which it expresses.

II. MOLECULAR RECOGNITION, THE PLATFORM OF THE STRUCTURE-ACTIVITY RELATIONSHIP

It has now become evident that, when the wide range of properties possessed by chemical compounds is analysed, intermolecular interactions with potential partners should be examined. The so-called "problem of recognition in chemistry" is based on a large amount of information which indicates that a particular molecule A_0 (the recogniser) reacts or forms a complex in solution only with one particular moleculer effector B_0 in a mixture of sometimes a very large number of possible effectors B_i.[23–25]

Historically it was the analytical chemist who first encountered the qualitative aspect of recognition in the search for compounds which effectively bind specific ions in multi-component solutions. With advancements in chemistry the problem of recognition has extended into organic and physical chemistry. In this reagard it is relevant to mention the fundamental studies of van't Hoff concerning the development of the principles of the theory of solutions[26] which may be regarded as the transition to a study of the quantitative aspect of recognition. As mentioned in[25], when these processes are described quantitatively, the accuracy of the recognition of chemical compounds increases by an order of magnitude in sequence from the selective donor-acceptor interaction of H-bonding of molecules containing a single electron donor and acceptor centre, and subsequently to the selective complex-formation of metal ions with polydentate ligands, and to selective catalytic reactions and ultimately to enzyme reactions. In the same sequence there is an increase in the size and complexity of the structure of molecules which are involved in the recognition process.

The methods currently adopted to investigate recognition in chemistry usually involve systems of selective complex formation between macrocyclic polyethers and cryptands (see Refs.27, 28]. However, even for these relatively simple compounds complex stability is dependent on many factors, and it is therefore difficult to establish the principles of molecular recognition. It is therefore essential to establish a clear definition of the basic principles involved in the recognition process.

According to[23–25] recognizer A_0 should bind with a particular type of molecule B_0, i.e. with the correct effector from a solution containing N types of molecule: B_0, B_1, B_2 ..., B_{N-1} of random concentration. The number of possible false recognition events is defined as P_f. Then the degree of recognition may be expressed as the number of correct recognitions which is dependent on the total number of possible effects N and the proportion of false recognition P_f.

In the simplest case formation of complex A_0B_i may be represented by the equation:

$$A_0 + B_i \rightleftarrows A_0B_i$$

with a reaction constant of

$$\frac{[A_0B_i]}{[A_0]\,[B_i]} = K_{0i} = \exp(-\Delta G_{0i}/RT);\ i = 0, 1, \ldots, N-1$$

and the number of possible false recognitions P_f will be equal to

$$P_f = \frac{\sum_{i=1}^{N-1} [A_0B_i]}{[A_0B_0] + \sum_{i=1}^{N-1} [A_0B_i]} = \frac{\sum_{i=1}^{N-1} [B_i]\,K_{0i}}{[B_0]\,K_{00} + \sum_{i=1}^{N-1} [B_i]\,K_{0i}},$$

from which it follows that recognition becomes more accurate the greater is the value of the ratio of the correct recognition binding constant to the false recognition binding constant, or the greater the difference between the free energies ($\Delta\Delta G$) of formation of complexes A_0B_i (ΔG_{0i}) and A_0B_0 (ΔG_{00}) respectively:

$$\Delta\Delta G_i = \Delta G_{0i} - \Delta G_{00}.$$

Thus highly specific recognition demands a relatively large difference between the capacity of the recognizer A_0 to interact with the correct effector B_0 and with a false effector. When $\Delta\Delta G$ values are sufficiently high, recognizer A_0 is able to distinguish one effector B_0 from N other effectors B_i. Thus a targeted search for compounds with the desired properties could tend towards the construction of molecules the structure of which ensures maximum binding with the recognizer responsible for the property under investigation.

These aspects of the question of recognition with respect to biological specimens were further developed in studies by Fischer,[29] who by 1894 had already established that spatial compatibility affects the interaction between substrate and enzyme. This formed the basis of the so-called "lock and key" principle or "complementarity principle". This principle has now been changed to the generally-accepted concept that formation of enzyme-substrate complexes, which play an important role in enzyme catalysis, is determined by the fine

structure of active and effective centres and the unique structure of the overall enzyme molecule which ensure high catalytic activity and the specific action of the biocatalyst.[30]

Another important contribution to the development of the structure-activity concept is associated with Hansch, who in the sixties proposed an empirical model for biological activity based on the linear relationship between the free energy of the process under investigation and physicochemical parameters of the compounds. This model is the most widely used instrument in studies concerning optimization of the biological activity of chemical compounds.[1,31]

Development of the ideas of Fischer and Hansch has so far introduced two independent approaches to structure-activity relationship determinations associated with the selection of common structural elements in different compounds with one particular type of activity and with the optimization of biological activity in a homologous series of chemical compounds. It will later be demonstrated that, in order to make a transition to a qualitatively new level of interpretation of the problem of quantitative structure-activity relationships, these approaches should be unified within the same systemic study. Definition of the problem in this manner implies that the structure of the compounds has been adequately determined and correctly described, including the special features of the electron-topographic and conformational structure of the molecules.

III. CORRECT COMPUTER-AIDED DESCRIPTION OF STRUCTURE FOR ESTABLISHING A STRUCTURE-ACTIVITY RELATIONSHIP

Before commencing a study on the relationship between structure and activity, a method for presenting the original data should be selected.[14] A great deal of effort has been devoted to the selection of a system of parameters which may be either determined experimentally or by calculation and which would fully describe the structure. In the present review four main approaches for describing the structure of compounds are considered.

1. Fragment Code for Substructure Superimposition

A fragment code for substructure superimposition (FCSS) was proposed at the beginning of the seventies.[32] In the analysis of chemical structure based on this strategy potentially active centres named "descriptor centres" are identified and atoms containing mobile p- and π-electrons or a full electrostatic charge are related to these centres. They are all heteroatoms, nitrogen, oxygen, sulfur, phosphorus, halogens, and metals, and also rings and pairs of carbon atoms linked by multiple bonds. A detailed list of descriptor centres is presented in Ref.33. Initially for each compound a set of linear descriptors is produced on the basis of the structural formula, and each descriptor is represented by a seven-digit number (two of the numbers were designated to the descriptor code and the chain length. The property of conjugation was represented by one figure, which was unity in the presence of conjugation and zero when there was no conjugation). A calculation of the characteristics of the cyclic fragments when the compounds were coded for analysis of their similarity is presented in Ref.34. FCSS has been found to be useful in statistical studies on the large amount of information available on biologically active compounds. A method was subsequently proposed for coding the structure of a chemical compound by using the descriptor centre concept while retaining the topology of the molecular structure as a single entity in the form of a connection matrix for descriptor centres (CMDC).[33] In this matrix diagonal elements represent descriptor centre codes and non-diagonal elements may represent the distances between respective descriptor centres (in the case of a matrix for descriptor centre geometry) or the number of linkages between them. This approach has been used in a number of studies[16,17] for identifying the common elements in the structures of compounds possessing a specific type of biological activity.

2. Topological and Geometric Descriptor Systems

The advent of systems of topological and geometric descriptors is the natural development of a language for the description of chemical structures. The Wiswesser system has become the most widely used of the line-formula notation methods.[35] However, in view of the limitations inherent to linear coding systems, the main limitation having already been mentioned, nowadays the coding of structures with the aid of a connection matrix with a wide set of molecular descriptors is preferred. The latter include mainly topological descriptors, fragment descriptors, substructure descriptors, connection descriptors, and environment descriptors, etc. They are all designed to obtain a more accurate description of the vicinity of active centres in molecules.[14] As with FCSS, a deficiency of this coding method is that it is not the structure of the chemical compounds but their structural formula which is coded. This method for describing structure may be somewhat improved, if geometric descriptors are used in addition to topological descriptors. Geometric descriptors, which describe the general form and size of the molecules, imparts a three-dimensional structure to the compound diagram. Conformational calculations of equilibrium distances between the active centres by molecular mechanics techniques provide a more complete description of the structure of compounds.[36] However in this case also it is not possible to reveal the electronic properties of the active centres, which determine their ability to undergo intermolecular interaction. This circumstance significantly affects the identification of real interrelationships between the structure of chemical compounds and the activity which they express.

3. Quantum Chemical Methods Used for Describing Structure

Quantum chemical calculations of molecular structures have been used in structure-property relationship determinations since the time when they first appeared, and also at present as a result of progress in computer technology these methods are becoming more widely used in studies on the relationship between structural parameters of molecules and their properties, especially their biological properties.[19,21,37-39]

Currently-available computer programmes cover virtually the entire range of quantum chemical calculations from elementary schemes for the complete neglect of differential overlap (CNDO) to strict non-parametric approaches: CNDO/2, CNDO/BV, CNDO/S, INDO, INDO(S), MINDO/2, MINDO/3, MNDO, VRDDO, and the ab initio STO-39 calculation. However, the attraction of quantum chemical calculations for structure-activity relationship determinations is mainly that the most stable molecular conformations are determined in which the active centres are accessible for interaction with a receptor or that molecular physicochemical characteristics associated with the transport of the compound to the bio-target are evaluated. By transferring the "centre of gravity" of the

quantum chemical calculations to the electronic properties of the molecules, it has been possible to attempt identification (construction) of compounds with the desired properties within essentially new classes of compounds. The above-mentioned approaches do not offer such possibilities.

It is evident that the use of quantum chemical calculations for structure-activity determinations is a promising approach. Further development of computer technology and transition to non-empirical calculations[40] will undoubtedly lead to an increase in the role of quantum chemistry in the determination of structure-property relationships. Nowadays calculation of the electronic structure of large numbers of chemical compounds will be difficult to achieve even with the use of semi-empirical methods, on account of the huge demands on computer time. In this regard it will be necessary to devise a system of calculation which would be relatively simple and also which would effectively provide the correct description of the electronic structure within the limits of structure-activity relationship determinations. An attempt has been made[41] to fill the connection matrix of descriptor centres with a quantum chemical content, which takes into account the electronic structure of the molecules.

However, one should note that quantum chemistry is by no means a natural source of information on the electron-topographical structure of molecules. Moreover, in view of the above-mentioned difficulties, information obtained as a result of quantum chemical calculations is not always sufficiently reliable and accurate. Hence in the future development of methods for determining structure-property interrelationships, in addition to these calculations, physicochemical approaches to structure-activity relationship determinations will be elaborated and such approaches will be directly associated with experimental studies on the physicochemical properties of molecules or their fragments.

4. The Physicochemical Approach to Structure-Activity Relationship Determinations

Extensive use of physicochemical properties in structure-activity relationship determinations began with the studies of Hansch et al.[1,5,31] The complete set of diverse parameters used in calculations according to the Hansch equation have been described.[18,42] All of these parameters may be separated into three groups. The first group includes parameters associated primarily with hydrophobic properties, the logarithm of the partition coefficient ($\log P$), the lipophilicity parameter (π), thin-layer chromatography parameter ($\log K'$), parachor (Pr), molar volume (Vm), molecuar weight (M), logarithm of partition in water ($\log C_{aq}$), partial pressure (p), the Hildebrandt solubility parameter (σ_s^*), molar attraction constant (F_α), entropy constant (σ_s^{**}) and others. The second group includes various induction and resonance constants (σ^*, σ^0, σ^I, σ^R, etc), radical substitution constants (E_R), Swain and Lupton parameters (F, R), polarizability (α), molecular refraction (MR), dipole moment (μ), ionization potential (IP), spectral frequencies (ν), ionization constants (pK_a, pK_b), and other characteristics associated with electronic properties. Finally the third group consists of parameters characterising steric effects of intramolecular interactions, Taft's steric parameters (E_s and E_s^0), van der Waals radii (r_v), molecular binding potential (χ), etc. Although many of the above-mentioned parameters do not reflect in the pure state only hydrophobic, only electronic, or only steric properties, the separation of these parameters is extremely useful, for example in relation to the problem of multi-collinearity in the selection of parameters for a model in accordance with the scheme for the action of biologically active compounds.

Although the Hansch equation has been effectively used on many occasions, one should however emphasise that this approach and various modifications of this approach "operate" only within the narrow range of related compounds. Replacement of only one active centre in the molecule leads to a change in the nature of intermolecular interactions and consequently to the perturbation of previously-established correlations between physicochemical parameters describing the compound and the property expressed. In this regard the previously described approaches in which common structural elements may be selected would seem to be preferable, since a broad range of compounds could be studied. The question consequently arises, can the Hansch approach be extended for analysis of different orders and classes of compounds by combining this approach with other methods of differentiating common structural fragments. This concept described in Ref.43 was realised for the first time in structure-activity determinations in which the following cases were examined. In the traditional descriptor analysis of the similiarity of structures a set of descriptor centres with their classification in terms of the types of atoms and nature of the linkages is used. In an intramolecular environment the boundaries separating the electronic properties of the descriptor centres may become diffuse and this will complicate the separation of activities. It is therefore evident that descriptor centre classification should be based not on the type of atom but on its ability to participate in intramolecular interactions.

The enthalpy of complex formation (ΔH), which is proportional to the free energy (ΔG) of the interaction between molecules containing one electron-donor or acceptor centre, may provide a quantitative measurement of this interaction.[25] A wide range of experimental data on ΔH values has now been obtained by means of which it is possible to predict the thermodynamic properties of a whole variety of donor-acceptor pair combinations, and therefore one might suggest a new classification of the descriptor centres. For this purpose it is necessary either to have experimental data on ΔH values for all possible donor molecules with a given acceptor or to find a system of empirical parameters with the aid of which the ΔH value for the interaction between any donor–acceptor pair may be evaluated. In the first variant (see for example the donor numbers of Gutman[44]) there are significant limitations such as inadequate solubility of certain complexes or the possibility that an irreversible reaction may occur. The second variant has much more potential, and the two equations presented in[45,46] are extensively used for achieving this objective. In the latter modification of the equation[45] the enthalpy of complex formation is expressed as the sum of three paired products of six types of parameter. The formula based on the classification of donor–acceptor interactions and described in report[43] is much simpler.

According to report[46] the enthalpy of complex formation is proportional to the product of two dimensionless values, the i-acid (acceptor P_i) and j-base (donor E_j) factors.

$$\Delta H_{ij} = -\Delta H_{11} P_i E_j, \qquad (1)$$

where H_{11} is a coefficient determined according to a particular standard complex. In the development of this approach[43] a common scale of donor and acceptor factors has been proposed which is constructed on the basis of the following modification of equation (1):

$$\Delta H_{ij} = |\Delta H_{11}| E_i E_j,$$

where $E_i = P_i$. In later studies[21,22,47] not only neutral but also charged donors and acceptors were included in this approach. A descriptor centre classification based on this common scale has been proposed[48] for the analysis of structure-activity relationships. A list of E_i values for 70 extensively used acceptors and E_j values for 230 diverse electron-donor compounds is presented in communication.[22] Even with this relatively small group of data enthalpy values of complex formation may be calculated for more than 16 000 complexes.

From the analysis of a large group of experimental data on complex formation, the relationship may be established between $E_i(E_j)$ values and substitution constants characterising induction effects and the conjugation effect.[49,50] In this approach it was essential to calculate the values for these constants for complex functional groups. In this regard empirical equations have been derived[52,53] which describe the transfer of the induction effect via carbon, oxygen, and sulfur atoms. The creation of an automated system for evaluating $E_i(E_j)$ values should be regarded as the final stage in the introduction of donor–acceptor factors into the actual construction of biologically active compounds. Recently the authors of this review proposed and derived an algorithm on a NORD-10 minicomputer for calculating the value $E_i(E_j)$ with the automatic determination of the Taft constant of complex functional groups according to the structural formula programmed into the computer and the described types of atoms.† The mathematical software was thus created for providing a physicochemical approach to the description and classification of compounds in terms of electronic properties of descriptor centres used for selecting the structural elements responsible for a particular type of biological activity. Clarity and the high content of easily interpreted principles of the classification are features of this approach, and this classification is sufficiently straightforward for widespread use and it is already used at the qualitative level for constructing compounds with the desired properties.[54]

In addition to the correct evaluation of the electronic properties of descriptor centres, of no less importance is the accurate description of the spatial structure of the molecules, taking into account the dynamics of intramolecular motion, tautomeric and conformational transitions, and large- and small-amplitude oscillations. In this case it is evident that inclusion of descriptor centres in the previously-described connection matrix as non-diagonal elements in the values for the number of linkages between the respective descriptor centres is not consistent with current concepts on the spatial structure of molecules. Inclusion of equilibrium distances[17,33] in the connection matrix and the use of moments of inertia and molecular volumes[21] as descriptors is naturally more appropriate, but does not overcome the problem of correctly describing the spatial structure of the molecules. The use of the concept of the spatial structure of a molecule in the form of a radial distribution plot, as practised in gas chromatography, has been proposed[55] as a simple method for describing molecular structure which in general satisfies the requirements of the "ideal" method. An interesting attempt to use an analogous transformation of molecular structure in order to separate tranquilisers and sedatives[56] is noteworthy, and this method was found to be much more effective than the use of fragment descriptors with this material.[57]

The methods described for representing molecular structure reflect to a satisfactory extent the structure of the compounds, when a computer is used for determining structure-activity relationships.‡ Moreover, selection of the form of description of a molecular structure is closely linked with the particular objective of the study (classification of compounds in terms of the type of bio-activity expressed, an information search for related compounds, identification of common structural elements, a quantitative prediction of the order of bioactivity, etc.) and also with the method used for this purpose. From this point of view the question of optimal conformity between the form of description of a structure and the method selected for treatment of the structure information is very important.

IV. METHODS FOR DETERMINING STRUCTURE-ACTIVITY RELATIONSHIPS

The numerous methods available for determining structure-activity relationships can be divided into the following two major groups according to the type of problem in quesion:[21] methods directed towards the optimisation of properties in a series of related compounds and methods designed for the identification of common structural fragments in molecules of chemicals exhibiting a certain type of bio-activity.

1. Optimisation of Properties in a Series of Related Compounds

This group of methods involves the use of different multi-parameter regression models linking the structural parameters of the compounds with their bio-activity.[58–62] The main strategies for processing structural information used in structure-activity determinations for optimising the properties in a series of related compounds are presented in Table 1.

The successful use of the Hansch model described in the previous section has led to the appearance of many generalisations and modifications for "screening" of different sets of physicochemical and structural parameters and regression models. Even as early as the seventies more than 2000 regression dependences had been derived for more than 20 000 chemical compounds,[63] relating hydrophobic, electronic, steric and other properties of substituents to biological activity expressed by the compound. Certain of these relationships were used both for predicting efficacy[64–66] and also for determining the mode of action of biologically active compounds.[18,67] However, many of these, according toHansch,[68] were "astonishingly deformed". They included equations which were unrealistic in the physical sense or ineffective for predicting biological activity but which had high correlation coefficients.

The existence of these equations indicates that the high values of the correlation coefficient R, the square of which is numerically equal to the contribution of the bio-response function variance ($\sigma_y^2 - \sigma^2$) "explained" by the regression dependence

$$R^2 = (\sigma_y^2 - \sigma^2)/\sigma_y^2,$$

where σ_y is the bio-response function variance, and σ is the residual variance, is an essential condition but would not ensure a good

‡O.A.Raevsky, QSAR in Drug Des. Toxicology, D.Hadzi et al., (editors), Elsevier, Amsterdam, 1987, p.31.

regression model. This may be attributed to the fact that for a regression analysis there are certain limitations, and that infringement of the latter leads to "mishaps" with regression coefficients,[69] which characterise the contribution of each of the structure parameters of the compound to the bio-activity value.

Table 1. Main Methods for Optimising Properties in a Series of Related Compounds.

Form of analysis	Method of processing information	Field of use	Refs.
Multidimensional statistical	Calculation of the statistical characteristics of the distribution of random values, means, scatters, etc.	Omission of incorrect data and analysis of "rejections"	[72-76]
Multidimensional scaling	Reduction of the scale of multidimensional space with the object of omitting data and variables which do not provide sufficiently informative data	Selection of compounds which provide the greatest amount of information	[73-75]
Correlative	Identification of relationships between variables based on a correlation matrix	Testing the hypothesis concerning the independence of the parameters in the model	[78, 119]
Factorial	"Reduction" of information by introducing new variables representing linear combinations of the original data	Determination of the "structure" of the data, the extent to which the items and parameters in the model may be grouped	[79-82]
Regression and dispersion	Construction of a functional relationship between independent variables and the response (dependent variable)	Determination of the quantitative relationship between structural parameters and the bioactivity expressed by the compounds	[31, 61-68] [85-87]

For example in communication[70] attention is drawn to the irrational use of the Hansch model proposal concerning the normal rule for the distribution of the variables included in this model. Analysis of fourteen possible distribution rules for the variables in the Hansch model showed that, regardless of the hydrophobicity characteristics of the biologically-active compound, the best model for describing the transport of a compound to the bio-target is the exponent of a power rule for the size distribution of the hydrophobicity parameter with a clearly pronounced assymetry. The structure of this distribution indicates that the probability of the substrate reaching the site of action increases in proportion to its hydrophobicity in accordance with the power rule and decreases in accordance with the exponential rule. The presence of asymmetry indicates that random events in a given system are not always mutually-independent. The presence of a correlation between "independent" parameters is one of the most widespread reasons for the low predictive capacity of the derived relationships. The emergence of models, which do not effectively predict quantitative structure-activity relationships, in addition to "technical" features of the regression analysis, is associated with a number of fundamental difficulties: a) in establishing the uniformity of the mode of interaction between the group of compounds under investigation and the same receptors;[1] b) in selecting a regression model conforming to the mode of action of the compound; c) in selecting variables which adequately describe the property under analysis; d) in the use of bioactivity data obtained by different research workers (the problem of accuracy and reproducibility of a biological experiment); e) in establishing the relationship of the resultant biological activity of a compound, which affects many physiological processes occurring in the body.

On account of the above-mentioned difficulties and because there is currently no alternative to a regression analysis for obtaining a quantitative prediction of the magntitude of bioactivity, an alternative proposition would be to construct regression models after a preliminary qualitative analysis of the available data had been carried out. In this case an analysis of a quantitative structure-activity relationship could have the following sequence. In the first stage of the preliminary or, as otherwise termed, the "exploratory"§ analysis, the general structure of the data is established. For this purpose one may use graphic display of the multidimensional space of the data, and also automated methods of classification and statistical treatment of the information. At this stage within the limits of the structure-activity determination two problems may be resolved, i.e. to separate classes of related compounds, and to convert to a set of a significantly smaller number of informative parameters describing the structure of the compounds. In the following stage the hypothesis concerning the independence of parameters in the model may be checked with the aid of correlation analysis methods.[78] If necessary, by using factorial analysis methods, factors which represent a linear combination of the original parameters in the model may be introduced into the regression model.[79-82] It has been recommended[18] that the following rules should be obeyed, when the final regression model is being constructed: 1) at the preliminary analysis stage as many independent parameters as possible should be examined as model variables; 2) to select from the various combinations of variables those which contain parameters related to the different types of interaction (for example $\log P$ and σ [83]); 3) to disregard regression coefficient variables with a low level of significance; 4) to select a model with the lowest standard deviation, when the values of the correlation coefficients are similar; 5) in order to exclude random correlations, at least five–six results of the biological tests for each parameter tested in the model should be included;[84] 6) other conditions being equal to give preference to simpler models; 7) with the objective of reducing and simplifying the calculations and avoiding fundamental errors to take into account the reality of the proposed model from the point of view of the phenomenon under examination.

One should also take into account the potentialities of modern regression analysis in regard to the evaluation of the quality of the regression dependences obtained.[85-87] By correct construction of the regression dependence, a model describing the action of the biologically active compound may be obtained which has high predictive capacity and it is thereby possible to resolve the problem of optimising properties in a series of related compounds. However, it remains an open question whether it is possible to predict bioactivity of compounds which differ in structure. Resolution of this problem is dependent on the identification of common structural elements.

2. Identification of Common Structural Elements in Biologically Active Compounds

The suggestion that the biological activity of a compound results from the presence of certain molecular substructures (pharmacophores) patterns the basis for the search for common structural

§P.F.Velleman and D.C.Hoaglin, "Applications, Basics and Computing of Exploratory Data Analysis", Duxbury Press, Boston, 1981, p.354.

elements in compounds. A typical feature of this approach is the use of pattern recognition techniques (PRT)[87-89] for dividing compounds into active and inactive species according to a set of structural parameters. In these terms the Free-Wilson model,[90] based on the additive contribution of substructures in substituents to the bio-activity value, occupies an intermediate position between quantitative regression models and qualitative models of pattern recognition techniques. With this simple model it is possible to narrow down significantly the area in which searches are made for effective biologically active compounds. For example, when testing compounds in which substituents may occupy four positions or when the number of the substitutions is changed from three to five, use of the Free-Wilson method reduces the number of bio-tests required from 120 to eleven.[18] However, since information is used at the qualitative level concerning the presence or absence of certain types of pharmacophores in the structural formula of compounds, a quantitative prediction of the bio-activity value is often found to be unreliable. Thus attempts have been made to improve this model by linking the latter with the mode of action of compounds[91-94] or by including the mutual effect of the substituents in the examination.[95] However, in the latter case there is a sharp increase in the number of variables in the model and the model becomes difficult to operate.

In the case of items which may be described by a large number of parameters, pattern recognition techniques based on the automatic classification of items according to similarity or lack of similarity are found to be more effective.[96] Methods related to the three types of analysis (Table 2) are most frequently encountered in the literature concerning structure-activity determinations.

Table 2. Main Methods for Identifying Common Structural Elements and Classification of Compounds.

Form of analysis	Method of processing information	Field of use	Refs.
Discriminant	Construction of separating hyperplanes according to an instruction selection consisting of two classes of items	Selection of informative parameters of the model for describing the structure and classification of the compounds into active and inactive	[14, 77, 97-101]
Linear instruction machine	Non-parametric discriminant analysis, based on the correction of an incorrect classification by means of the inverse relationship in the iterational process	Ditto	[14, 88]
Logical-structural	A form of discriminant analysis based on the use of the laws of inductive logic	Ditto	[17]
Cluster	Classification of items according to similarity or differences with the aid of optimisation of the efficiency function	Classification of compounds according to types of activity	[102-107]
Modelling of spatial structure properties of the molecule	Calculation and construction of three-dimensional images of molecules by quantum chemistry and molecular mechanics methods with the aid of molecular graphics	Determination of the steric specificity of substrate-receptor interaction	[110-116, 119]

Discriminant analysis[97-101] is based on the division of compounds into active and inactive species by constructing a separating hyperplane or some other surface in the space of the parameters of the compounds which describe their structure. In the limits of this analysis a selection of the most informative parameters from the point of view of separating the compounds is presented, a separating surface is constructed, and the effectiveness of the resultant discriminant model is tested on instruction and examination selections of compounds. Certain data cited in the literature[99-101] serve as examples of the successful use of discriminant analysis.

Logical structural analysis[17] uses algorithms of discriminant analysis methods in which information is presented in a natural form for the research worker. Many procedures for processing information are directed towards the dialog mode of computer operation.

Cluster analysis[102] involves the grouping of items as concentrations of points in multidimensional space which describe these items of the parameters. This kind of analysis is clearly associated with multidimensional scaling techniques (mapping of the points of multidimensional space on a surface of smaller dimensions) and numerical taxonomy (separation of items into pre-determined classes). The absence of empty clusters is a distinctive feature of cluster analysis techniques. Cluster analysis methods may be used in structure-activity determinations either independently[104-106] or in combination with other methods.[77,107,108]

In all automatic classification methods the studied topological and topographic features of molecular structure are represented in the form of a set of indexed parameters, geometric descriptors which are coordinates of the compounds like points in the multidimensional space of the parameters. In recent years with the development of computer graphics it has become possible to produce a visual three-dimensional image of the molecular structure on the graphic display screen of a computer.[108-110] This has initiated yet another approach in structure-activity relationship studies, the molecular modelling of the spatial structure of compounds.

The most productive approach was found to be the use of methods for modelling the three-dimensional structure of molecules in order to study the spatial specificity of the substrate-receptor interaction by the "lock and key" principle,[110] especially when the electronic pattern of the molecule is represented as surfaces surrounding a nuclear skeleton of the molecular conformation[27] obtained with the aid of a quantum-chemical calculation[111] or the molecular mechanics method.[36] By using this approach it is possible to determine the similarity between the electron-topographical properties of the molecules which is not discernable with the other analytical methods. The quantitative aspect of the calculation of steric specificity of the substrate-receptor interaction has been developed in a regression analysis,[112-115] although a trend towards the combined use of molecular modelling techniques and regression analysis has recently become apparent[115-116] and this should ultimately lead to a system approach to the determination of structure-activity relationships.

3. The System Approach to the Analysis of Structure-Activity Relationships

The concept of the system approach to the analysis of structure-activity relationships involves the creation of a single model for the search for biologically active compounds covering both qualitative and quantitative and also a priori information on the class of compounds studied within the limits of the expert system, which includes a corresponding group of methods for determining structure-activity relationships. The usefulness of this approach is dictated by the need to take into account all information available to the research

worker and also by the selection of the optimal method for processing the information. In fact, if for example the problem of binding between receptor and substrate is defined as a problem of finding the distribution density function of the probability of complex formation according to a set of parameters characterising the structure of the substrate, it becomes apparent that there is a link between this problem and that of the reduction in the dependences under conditions of the inverse incorrect problem.[87] From the theory for the resolution of similar problems[117] one might conclude that the quality of the result obtained is to a marked extent dependent on the degree of detail in which a specific problem is investigated and the selection of the corresponding method for resolving the problem. Since at the various levels and stages of the analysis of structure-activity relationships the research worker presents information differing in quantity, quality and form in which it is presented and usefulness, there obviously is a need to use not one method for determining structure-activity relationships but a range of methods in a sequence which would ultimately lead to a quantitative prediction of the magnitude of the biological activity possessed by an unexamined compound on the basis of parameters characterising the structure of the compound.

The first stage towards combining qualitative and quantitative methods of analysis of structure-activity relationships within a single model was the elaboration of a physicochemical strategy similar to that described in Section III.

The potential of a system analysis of structure-acitivity relationships in this approach was linked with the formation of a unified description of the electron-topographical properties of molecules based on a single donor-acceptor model representing the substrate-receptor interaction, in which the model parameters could be extended as indicator variables at the automatic compound classification stage and as quantitative variables on reduction of the structure-activity regression dependences. This poses the problem of optimising the properties in the series of compounds with different structural formulae including those which belong to different classes but which have similar donor-acceptor and topographic properties of the descriptor centres.

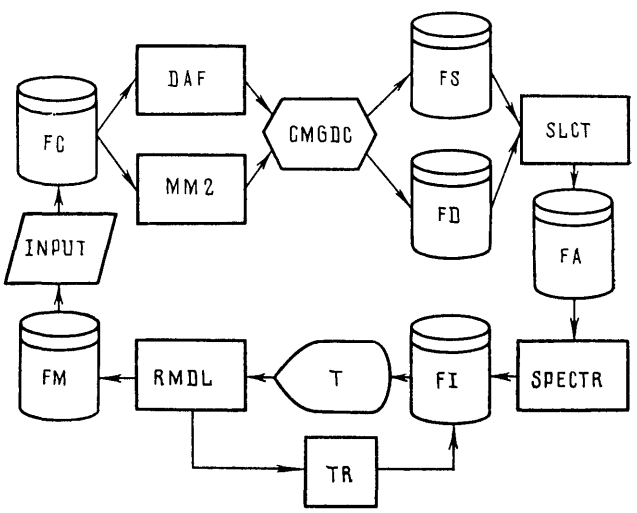
The present tendency to integrate the methods and approaches in the structure-activity relationship determination is also reflected in the packages of programmes currently being elaborated.

V. SOFTWARE PACKAGES FOR DETERMINING STRUCTURE-ACTIVITY RELATIONSHIPS

In order to perform the methods and approaches considered for the analysis of structure-activity relationships, relevant software packages must be produced. Currently-available software packages differ both in function and in the extent to which they cover the problem to be resolved, and also in the class of computer in which they may be used. Software packages designed according to the modular principle with a dialog operation regime are most convenient. Such packages are usually designed for use in mini-computers, and on account of the ease with which new programmes can be incorporated into the package, they undoubtedly have an advantage over other software packages in regard to the production of an expert system for determining structure-activity relationships based on a laboratory mini-computer.

By way of an example four of these packages will be examined in which previously-described approaches to the analysis of structure activity relationships are performed: automatic classification based on methods for recognition of samples (ADEPT), logical-structural method (TOPLOG), molecular modelling (MOLY), and physicochemical (RASTR) approaches.

The ADAPT software packages[14] based on processed information contains the structural formulae of the compounds. Any of them may be entered into the computer by building its image on a graphic display monitor with the aid of a special set of commands in the interactive mode. The structural formulae entered are stored in the form of a connection matrix on discs (disc drives). It is envisaged that there could be facilities for the addition, exclusion, alteration, and recalling of the stored structures of compounds. Structure-activity relationship analysis is based on the methods of parametric and non-parameteric statistics and recognition of the items: linear regression, discriminant analysis; a linear instruction machine, and classification according to the number of close neighbours. The ADEPT system operates on the basis of a 16-bit MODCOMP II/25 minicomputer and together with the data bank occupies approximately 2 Megabites of memory on magnetic discs.



The software package TOPLOG[17] offers the user a more advanced system of input, editing, and information conversion to a form which is acceptable to the research worker. This is reflected in the file system of the package which counts 14 types of files with different functions. The package includes a procedure for achieving a logical-structural approach like that described in reference 17. A distinctive feature of the TOPLOG package is the inclusion of an algorithm for selecting common structural fragments of molecules based on an analysis of graphic representations of structural formulae of the compounds under investigation. The package consists of 14 programmes with a total capacity of approximately 8000 fortran operators and it may be run in an HP-1000 minicomputer.

In contrast to the packages described in which the main type of information is the structural formula of compounds, in the MOLY package[10,118] in order to construct a biologically-active compound a stereoscopic three-dimensional image of the molecule is used in which its properties are represented (for example surfaces of electrostatic potential). With the aid of molecular modelling techniques it is possible to obtain parameters of the molecule structure which reflect the spatial specificity of the interaction between substrates and receptors and which may be used for constructing regression models of quantitative structure-activity relationships. The MOLY package contains approximately 15 000 fortran operators and occupies 1 Megabite of memory.

In the RASTR (recognition of active structures)¶ software packages procedures are included which provide a physicochemical approach for the detection of common fragments of biologically active compounds according to the electron-topographic properties in structure-activity determinations. A feature of this package is that a system approach to the analysis of structure-activity relationships may be achieved by using a set of previously-examined methods at different stages of the study (Tables 1 and 2). This is achieved by means of a unified description of the electron-topographic properties of the molecules from the position of a single donor-acceptor model of the substrate-receptor interaction. For example one possible operational variant with the RASTR package may be as follows. The structural formula of a compound and

¶O.A.Raevskii and A.M.Sapegin, Khim.-farmatsevt. zhurn., 1987, **21**, 1338; A.M.Sapegin, A.N.Razdol'skii, V.V.Chistyakov, and O.A.Raevskii, Khim.-farmatsevt. zhurn., 1987, **21**, 1341.

information on the type of atoms contained in the formula are introduced from the computer terminal. With the aid of an INPUT programme (Fig.1) these data are converted into a connection matrix and are entered into the compound file on a magnetic disc. Information from this file is used for calculating a descriptor centre geometry matrix, a physicochemical "portrait" of the molecule describing donor-acceptor and topo-graphic properties of the active centres in the substrates. Diagonal elements of the descriptor centre geometry matrix are coded on the basis of calculated values of donor-acceptor factors in the descriptor centres in accordance with a unified scale of a donor-acceptor interactions. An algorithm for calculating the donor-acceptor factor of the descriptor centre (DAF programme) is constructed in order to analyse the tree of a graphic representation of the compound's structural formula using a data bank of Taft constants for different types of atoms and correlation equations for calculating the Taft constant of complex substituents and the donor-acceptor factor of the descriptor centre.[50,52-53] Extra-diagonal elements of the descriptor centre geometry matrix contain information on the topography of the descriptor centres in the form of the distance between respective descriptor centres for equilibrium conformations calculated by the molecular mechanics method[36] (programme MM2). The descriptor centre geomtry matrix is formed by the CMGDC programme which operates in two modes: analysis of structure-activity relationships, and in a mode for logging the descriptor centre geometry matrix into the data bank.

Operating configuration for the main nucleus of the RASTR package Programmes: INPUT, Input; DAF, calculation of donor-acceptor factors; MM2, calculation of equilibrium conformations of molecules by the molecular mechanics method; CMGDC, formation of descriptor centre geometry matrix; SLCT, selection of common structural fragments; SPECTR, construction of the spectrum of interatomic distances; RMDL, construction of regression models; TR, transformation of regression models of the pharmacophores into the spectrum of interatomic distances; files: FC, compounds; FS, structures; FD, structures in data bank; FA, activities (of pharmacophores); FI, images (spectra of interatomic distances); FM, regression models.

With the aid of the SLCT programme common structural fragments are selected for the compound under investigation (FC file) and compounds stored in the data bank (FD file). The procedure for searching for common structural fragments is analogous to that used in the TOPLOG package.[24] It differs only in that in this instance the common structural fragment is considered to be not a strict identity of the elements in the structural formula of the compound but their closeness with respect to electron-topographic properties which may be regulated by the research worker. The isolated fragments are potential pharmacophores and are entered into the biologically active structure file (FA file).

The descriptor centre geometry matrix of common structural fragments in the biologically active compounds which are contained in the FA file may be represented (with the aid of a SPECTR programme) as a range of interatomic distances, which is convenient for a visual comparison of the structures of the compounds or as a set of structural parameters for constructing regression models of structure-activity relationships. Interatomic distance spectra are stored in the "Images" file (FI file).

Thus at the stage described above the problem of identification of potential pharmacophores is qualitatively resolved, i.e. on the basis of indicator parameters of the donor-acceptor model a concept can be formed concerning the electronic and spatial properties of the active centres in substrates responsible for a particular kind of biological activity.

The next important step is to determine the quantitative relationship between structural parameters of the compound and the magnitude of the biological response. In the RASTR package examined the original information for the construction of regression models (RMDL programme) is the information from the FI file. The search for the optimal regression dependence is based on the principle of the structural minimisation of mean empirical risk.[87] The predictive capacity of the model is assessed according to a test selection of data.

Results obtained at the regression analysis stage may be repeatedly used in the RASTR package for designing a more accurate model or for constructing a new model. These data are stored in the FM file. As a result of the file organisation for transfer of information between programmes in the package, the system is highly flexible as regards the inclusion of standard or original methods for processing information at any stage in the study, and may accept all kinds of quantitative structure-activity relationship analysis, the main condition for constructing an advanced expert system.

All programmes in the package have been written in FORTRAN-77 language and are used in a NORD-10 minicomputer (OZU capacity, 128 kilobites).

The programme packages examined indicate that nowadays the software covers a wide range of algorithms for processing structural information and thereby creates the basis for a system approach to the analysis of structure-activity relationships. This objective could be achieved in practice by elaborating a problem-orientated expert system for the construction of compounds with desired properties.

VI. CONCLUSION

In order to search for effective biologically active synthetic compounds in accordance with the basic principles of constructing compounds with desired properties, the following problems must be resolved: 1) identification of the compound interacting with the

receptor; 2) determination of the electron and spatial structure of the compound; 3) the correct description of the structure within the limits of the computer used; 4) derivation of statistically significant data on the biological activity of the compounds; 5) optimisation of a method or group of methods for resolving specific problems related to the determination of structure-activity relationships.

Table 3. Examples of correct predictions of structure-activity relationships.[119]

Type of compound	Form of bioactivity
Benzothiadiazines	Hypotensive action
Propinylamines	Monoamine oxidase inhibition
N-(Phenoxyethyl)-cyclopropyl-amines	Monoamine oxidase inhibition
β-Carbolines	Monoamine oxidase inhibition
Sulphonamides	Carboanhydrase inhibition
Carbanoylpiperidines	Choline esterase inhibition
Ketones	Chymotrypsin inhibition
Benzylpyridinium ions	Inhibition of complement
Steroids	Binding with progesterone receptor
Esters	Papain hydrolysis
Dopamine esters	Hydrolysis of arylamidases
Peptidyl-*p*-nitroanilines	Subtilisin hydrolysis
Polycyclic aromatic hydrocarbons	Hydroxylation of microsomal oxidase
Isatin-β-isothiosemicarbazones	Antiviral carcinogenicity
Pyrazoles	Ditto
Cytidine derivatives	Cytostatic, immunodepressive
Nitrosourethanes	Cytostatic
Mitomycins	Ditto
Hydantoin derivatives	Ditto
Rifamycin amides	Antibacterial
Sulphonamides	Ditto
Erythromycins	Ditto
Quinoxaline-1,4-dioxides	Ditto
Phenanthrenes	Antimycoplasma activity
Phenylamidinourethanes	Ditto
Naphthoquinones	Ditto
Tuberines	Ditto
Methoxychlorines	Insecticidal
N-Hydroxypyridones	Fungicidal
Pyridine derivatives	Ditto
Trifluoromethane sulphonamides	Herbicidal
Alkylarylcarboxylic compounds	Ditto
Aromatic esters	Ditto
Piperidinoacetanilides	Phytoactivity
Pyrimidones	Inhibition of the Hill reaction
Urethanes	Herbicidal
Phenylacetamides	Hypnotic
Pyridylmethanes	Spasmolytic
Pronazines	Neuroleptic
Aromatic and aliphatic acids	Anti-inflammatory
Benzothiopine derivatives	Neuroleptic
Carboxylated esters	Antithrombic
Acrylates	Toxicity
Copper chelates	Cytotoxicity
Pyramine amines	Immunodepressive
Azapurine-6-ones	Immunodepressive
Phenyloxazolidines	Radioprotectant
Carbonoylethylamines	Cholinolytic
Triazines	Dehydrofolate reductase inhibition
Benzdiazepines	Anti-pentylene tetrazolium activity
Cyanocyclohexylamines	Fungicidal
Piperidinoacetanilides	Anti-serotonin activity
Somatostatin analogues	Antidiabetic
Steroids	Progesterone activity
Azacycloalkanes	Analgetic
Organosilicon amines	Fungicidal
Inda-1,3-diones	Toxicity
Sulphones	Antibacterial
Alkobenzylalkylamines	Toxicity
Spirobarbituric acids	Sedative
Adenosine analogues	Hypotensive
Trimethoprim analogues	Antibacterial

An incorrect approach to the resolution of any of the above-mentioned problems could impede the determination of the "true" structure-activity relationship or even lead to the proposal of a false relationship. For example identification of the substrate with a substance introduced into the body (i.e. disregard of the possibility that chemical and biochemical transformations of the chemical may occur during transportation from the site of administration to the bio-target) sometimes causes complications in the detection of common structural fragments among compounds expressing a particular kind of biological activity. Approximation of a model describing the electronic and spatial structure of compounds automatically affects the predictive potential of the model. The efficiency of the latter may also be determined by selecting a method for processing the information, i.e. its compatibility with the form of the presentation and level of information on the structure and properties of the molecules.

There are now many examples in the literature concerning the correct prediction of the biological activity of compounds (Table 3).[19] However, most of these studies are concerned with the optimisation of properties within a series of related compounds. A qualitatively new level in quantitative structure-activity relationship determinations, which would lead to the identification of essentially new classes of effective compounds, would only be attainable by using methods for the selection of common structural fragments within a diverse range of compounds with subsequent optimisation of the useful properties which they express.

This leads to the need to develop a system approach to the determination of structure-activity relationships which should include, in addition to the previously-considered questions, an extended section of chemical data[120] and artificial intelligence.[121] The ultimate stage in a system investigation of a structure-activity relationship could include a plan for synthesis and technological schemes for producing the new compounds.[122,123] Development of this strategy should eventually transform an empirical approach for structure-activity relationship determinations into a fundamental scientific approach exploiting the advances in chemistry, physics, biology, and information technology. A powerful platform will thereby be created for the cost-effective construction of compounds with desired properties for the needs of industry, agriculture, and medicine.

---o0o---

While this review was being prepared for publication a significant number of papers appeared in the literature on studies dealing with virtually all aspects of the question of targeted screening and the construction of effective biologically-active compounds. Worthy of mention are a paper presented at the Sixth European Symposium on Quantitative Structure-Activity Relationships[124] and a monograph[125] in which the fundamentals of the construction of systems for determining the main kinds of bioactivity for large numbers of compounds are presented.

The approach concerned with the three-dimensional perspective of molecular structure by molecular graphics techniques[126–131] based on empirical[132,133] and quantum-chemical[134,135] calculations of molecular conformations or the corresponding X-ray data[136,137] is progressing in an interesting manner. Considerable attention is being focused on the elaboration of models for describing structure with the aid of sets of descriptors[138–149] and on the visual representation of results obtained from the statistical analysis of structural information.[150–153]

Closer examination of the physicochemical content of quantitative structure-activity relationship models[154–157] including the radical changes in programming technology in expert systems[165–171] together with the pharmacodynamic and pharmacokinetic stage[158–164] should be included in the new trends in structure-activity determinations.

The creation of an expert system for quantitative structure-activity relationships could become essential for the formation of a unique "programme" theory for the targeted search and construction of biologically active compounds.

Short-range Order and Local Displacements of the Atoms in Non-stoichiometric Compounds

A.I.Gusev

Published data on the local distribution of the atoms and their displacements in non-stoichiometric transition metal carbides and nitrides have been reviewed. The phenomena of short-range order in disordered and ordered non-stoichiometric compounds, and their solid solutions, have been discussed in detail. Data on the static displacements of the atoms in disordered carbides and nitrides have been analysed. The possibilities for the further study of the distribution of the atoms in non-stoichiometric compounds have been discussed.
The bibliography contains 79 references.

IV. Local displacements of the atoms 922

I. INTRODUCTION

In recent years there has been a continuous increase in interest in the study of the structures of transition metal carbides and nitrides. This is due chiefly to the use of highly sensitive experimental methods, which have established that the distribution of non-metal atoms in these compounds is not statistical, as previously assumed. Another reason for the interest in non-stoichiometric carbides and nitrides is related to their properties. These compounds are among the most refractory materials; the melting points T_f of most of them exceed 3500 K, and tantalum carbide has the highest known melting point, T_f = 4270 K; they are radiation-stable superconductors with transition temperatures to the superconducting state $\leqslant 17$ K. In addition, they are extremely hard, their hardness approaching that of diamond. Another characteristic of non-stoichiometric compounds is the possible formation of unrestricted reciprocal solid solutions, so that their physicochemical characteristics can be influenced considerably by replacing the metal and non-metal atoms. The properties of non-stoichiometric compounds are directly related to their structural state, that is to the presence or absence of correlations and short-range or long-range order in the relative positions of the atoms.

In the present work, an attempt has been made to systematise the comparatively few but nevertheless important data obtained in the last 10–15 years in the study of the local distribution of the atoms and their displacements in non-stoichiometric compounds and their solid solutions. Before discussing these results, however, it is appropriate to give a general description and examination of the principal characteristics of the crystal structure and the chemical bonding in non-stoichiometric compounds of the transition metals, necessary for the subsequent discussion.

Non-stoichiometric compounds are often called interstitial phases, indicating that a characteristic of their structure is the presence of a face-centred cubic (FCC) or hexagonal close-packed (HCP) metal lattice with interstitial non-metal atoms in the octahedral interstices. At the same time, the symmetry of the metal lattice in the carbides and nitrides differs from that of the crystal lattice of the corresponding transition metals, that is the crystal structure of the metal changes on formation of the carbides and nitrides (cobalt is an exception). The group IV transition metals (titanium, zirconium, hafnium), which have an HCP structure, form carbides and nitrides with an FCC metal sub-lattice. Transition metals with a body-centred structure (vanadium, niobium, tantalum, chromium, molybdenum, tungsten) form carbides and nitrides with FCC or HCP metal sub-lattices. The change in the crystal structure of the metal on formation of the carbide or nitride indicates fairly strong interactions between the metal and non-metal atoms, so that the application of the term "interstitial phase" to these substances is not completely justified. In the narrow sense of the word, only restricted interstitial solid solutions are true interstitial phases.

The concept of "interstitial phase" (or "interstitial alloy") has recently been used fairly widely. It is used to describe a wide range of phases with related structures, formed as a result of the insertion of hydrogen, nitrogen, carbon, oxygen, boron, or silicon atoms into the interstices in the crystal lattice of a transition metal. Both interstitial solid solutions and the transition metal hydrides, carbides, nitrides, oxides, and borides, and also the reciprocal substitutional solid solutions formed by these compounds, are interstitial phases. These compounds are also called compounds of variable composition, emphasising the existence of wide homogeneity ranges, within which the composition of the compound may deviate considerably from the stoichiometric composition with preservation of the crystal structure. Since the deviation from stoichiometry, that is non-stoichiometry, is a characteristic property of these compounds, it is more correct to call them non-stoichiometric compounds of the interstitial phase type. This term emphasises that these substances (carbides, nitrides, etc.) are compounds, and not interstitial solid solutions, and at the same time draws attention to the most important characteristics of their structure, namely the location of the non-metal atoms in the interstices of the metal sub-lattice and the possibility that the composition deviates considerably from the stoichiometric.

In the full sense of the term, only the carbides, nitrides, and lower oxides of the transition metals can be described as non-stoichiometric compounds of the interstitial phase type. Thus the stability of the hydrides and the limiting concentration of hydrogen in them may change with change in the external conditions. The difference between transition metal hydrides and solid solutions of hydrogen in transition metals therefore becomes indistinct. The borides and

more particularly the silicides have practically no homogeneity ranges; moreover, in these materials a fairly important role is played by direct B—B and Si—Si bonds (in the carbides, nitrides, and oxides, direct interactions between the non-metal atoms are negligible). The higher oxides also have practically no homogeneity ranges. In the present review, therefore, the carbides, nitrides, and lower oxides of the transition metals are regarded as non-stoichiometric compounds of the interstitial phase type.

A characteristic feature of non-stoichiometric compounds is the, as it were, independent existence of the sub-lattice of the pure metal, which acts as the matrix for the atoms which are introduced into its interstices and which form the non-metal sub-lattice. The pure metals can be regarded as a unique type of interstitial phase corresponding to unoccupied interstices, and the unoccupied interstices can be regarded as "holes", equivalent to interstitial atoms. When the non-metal sub-lattice is partly occupied, the unoccupied interstices (structural vacancies) can diffuse through the lattice and behave like real interstitial atoms. Thus the structural vacancies in non-stoichiometric compounds of the interstitial phase type can be regarded in a first approximation as analogues of interstitial atoms.[1-4] Thus deviation from stoichiometry can be (and is) examined using the theory of substitutional solutions, whose components are interstitial atoms and structural vacancies. The deviation from stoichiometry leads to a change in all the properties of non-stoichiometric compounds.[3-9] The defect character of the crystal structure, that is the presence of a high concentration of structural vacancies, is apparently one of the most important characteristics of non-stoichiometric compounds.

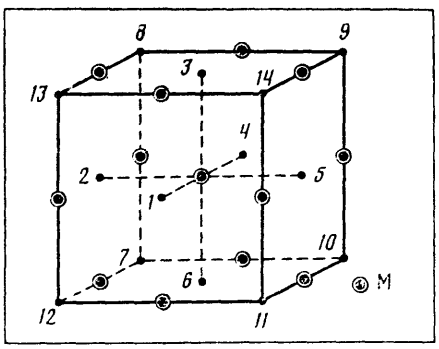

Figure 1. NaCl structure and the immediate environment of the metal atom: (1—6) first coordination sphere, formed by six sites of the non-metal sub-lattice; (7—14) second coordination sphere, formed by eight sites of the non-metal sub-lattice; twelve metal atoms form an independent coordination sphere (M represents a metal atom; the sites of the non-metal sub-lattice are numbered).

Non-stoichiometric transition metal monocarbides, mononitrides, and monoxides MX have the NaCl structure. In this structure (Fig.1), the non-metal atoms occupy statistically the octahedral interstices of the metal sub-lattice, so that each metal atom is in an octahedral environment of six sites of the non-metal sub-lattice, which form the first non-metal coordination sphere; the second non-metal coordination sphere is formed by eight sites of the non-metal sub-lattice; twelve metal atoms form an independent metal coordination sphere, situated between the first and second non-metal coordination spheres. The lower carbides and nitrides with the composition M_2X have the hexagonal $W_2C(L'3)$ structure, in which the non-metal atoms occupy statistically half of the octahedral interstices.

An analysis of theoretical considerations[10-15] and a large number of calculations by zone and cluster methods led to the formulation[8,16] of the principal regular features of the structure of the valence zone of non-stoichiometric compounds with the NaCl structure. According to Refs.8 and 16, the valence zone of these compounds includes a low-energy $2s$(X) band containing small contributions from the *s*-, *p*-, and *d*-states of the metal; the principal valence-bonding band, formed by strong mixing of the $2p$(X) and d(M) functions; and a high-energy partly occupied conductivity band, formed chiefly by nd(M) functions with a small contribution from $2p$(X), $(n+1)p$(M), and $(n+1)s$(M) functions. The redistribution of the individual atomic states on the formation of non-stoichiometric compounds leads to partial charge transfer between the metal and non-metal atoms, and this is responsible for the ionic component of the chemical bond.

Thus in non-stoichiometric compounds there is a combined covalent—metallic—ionic chemical bond.[8,16] With increase in the concentration of vacancies, the populations of the single bonds M—X increase, but the number of such bonds decreases with a simultaneous decrease in the charge localised on the atoms; this leads to a decrease in the ionic component of the bond. In addition, the deviation from stoichiometry is accompanied by an increase in the width and population of the *d*-band of the metal and a decrease in the width of the $2p$(X) band, and this can be regarded as an increase in the strength of the M—M interactions and a decrease in the covalent component of the M—X bond.

More detailed information on non-stoichiometric compounds can be found in a number of monographs.[1,3-8]

II. SHORT-RANGE ORDER IN NON-STOICHIOMETRIC COMPOUNDS

The presence of structural vacancies and the possibility of their redistribution within the lattice, together with the combined type of chemical bond, are responsible for the fairly wide occurrence in non-stoichiometric compounds of correlations and of short-range or long-range order in the relative arrangement of the atoms.

Any disorder destroys the crystal symmetry and leads to a decrease in the degree of long-range order. The simplest type of disorder occurs in ideal binary substitutional solid solutions. In an ideal solid solution, when an atom A is replaced by an atom B, the crystal lattice is not distorted, and the sites in which this replacement has taken place are distributed randomly, that is statistically, in space. In this case the probability of finding an atom of a given element in any site of the crystal lattice is equal to the atomic fraction of this element in the solid solution. Thus in an ideal solution, the occupancy of a given site by an atom of a given element is independent of the nature of the occupancy of the other sites, both neighbouring and distant. In a real crystal, the atoms of different elements have different masses and dimensions, so that the energies of interaction between atoms of the same kind and atoms of different kinds differ considerably. It is for this reason that statistical

disorder in a crystalline solid can arise only at sufficiently high temperatures, when the forces of interatomic interaction are small compared with the energy of the thermal vibrations. This state can be "frozen" by quenching, that is by cooling rapidly to low temperatures, at which the diffusion mobility of the atoms is negligible.

In non-stoichiometric compounds, statistical distribution of the interstitial atoms and structural vacancies is also obtained by rapid cooling. For a long time it was assumed that for non-stoichiometric compounds this disordered state was the only one possible, and it is only in recent decades that it has become clear that this is not the case. It has been found that on comparatively slow cooling of non-stoichiometric compounds, the statistical distribution gives way to correlations in the arrangement of the atoms and vacancies in neighbouring lattice sites, as a result of which the atoms of a given element may be surrounded preferentially by atoms of the same or another element (or vacancies), that is short-range order may be observed.

The arrangement of the atoms in the crystal lattice of non-stoichiometric compounds can be characterised by the long-range and short-range order. In the present review, particular attention is paid to recent studies of short-range order and the associated local displacements of the atoms in refractory non-stoichiometric compounds and their solid solutions.

The principal experimental methods for studying short-range order in non-stoichiometric compounds of the interstitial phase type are nuclear magnetic resonance (NMR) and the diffuse scattering of neutrons (to study the distribution of interstitial atoms) and X-rays (to study the distribution of metal atoms). None of these methods is universal (applicable to all non-stoichiometric compounds) in giving information on the nature of the distribution of the atoms of all elements. NMR has the most restricted range of applicability, since magnetic resonance signals are given only by nuclei with a non-zero spin I, which have a magnetic moment. Thus NMR studies are possible in principle for non-stoichiometric compounds of vanadium, niobium, and tantalum, since the most abundant isotopes of these metals have nuclei with $I \neq 0$. On the other hand, NMR cannot be used to study the non-stoichiometric compounds of the group IV transition metals (titanium, zirconium, hafnium), since the nuclei of the most abundant isotopes of these metals do not have a magnetic moment.

As far as the interstitial atoms (carbon, nitrogen, oxygen) are concerned, the nuclei of the abundant isotopes ^{12}C and ^{16}O have zero spin, and magnetic resonance cannot be observed. The most abundant nitrogen isotope ^{14}N has a magnetic moment ($I = 1$), but no ^{14}N NMR studies of non-stoichiometric compounds of the interstitial phase type have yet been carried out. The NMR study of the nuclei of the carbon isotope ^{13}C with spin 1/2, which would increase considerably the amount of information on the nature and structure of non-stoichiometric carbides, appears extremely promising.

In those cases where it is possible in principle, the use of NMR to study non-stoichiometric compounds is extremely effective, because of the high sensitivity of the method to slight changes in the symmetry of the environment of the resonating atoms.

1. NMR Studies of Short-range Order

NMR can be used to determine the relative positions of interstitial atoms and structural vacancies in the non-metal sub-lattice of non-stoichiometric compounds, that is to study the nature of the short-range order in them. In addition, NMR reveals various characteristics of the electronic structure of non-stoichiometric compounds.

A special notation will be used for convenience in the subsequent discussion. The immediate environment of a metal atom in a carbide MC_y or a nitride MN_y with the NaCl($B1$) structure includes two coordination spheres formed by sites of the non-metal sublattice, and one coordination sphere formed by metal atoms (see Fig.1). It is convenient to denote the position of a metal atom in this environment by means of subscripts and superscripts giving the numbers of vacancies in the first and second coordination spheres respectively, formed by the sites of the non-metal sub-lattice; for example, the metal atom position M_0^2 indicates that its first coordination sphere is complete (contains no vacancies), while the second coordination sphere contains two vacancies.

Among the non-stoichiometric compounds, the vanadium compounds have been studied in most detail. VC_y specimens with $y = 0.66$, 0.7, 0.8, 0.84, and up to $y = 0.87$, that is throughout the homogeneity range of vanadium carbide, have been studied.[17] The ^{51}V NMR spectra of the carbides $VC_{0.875}$, $VC_{0.84}$, and $VC_{0.70}$ showed several resonance lines, whose intensity changed with change in the composition of VC_y. Comparison of the total intensity of the resonance lines in metallic vanadium and its carbides showed that NMR makes it possible to detect practically all the vanadium nuclei in VC_y, irrespective of its composition. At the same time, the presence of vacancies in the carbon sub-lattice of VC_y had a significant influence on the relative intensity of the observed resonance lines. The lines and their satellites in the ^{51}V NMR spectra were associated with the positions of vanadium atoms in VC_y having definite configurations of the vacancies in the first coordination sphere.[17] This identification was possible since the electric field gradient of vanadium nuclei with no vacancies in the first coordination sphere should be much smaller than that for vanadium nuclei having one or several vacancies. Thus the observed lines were associated with the positions of vanadium atoms V_0 (without vacancies in the first coordination sphere), V_1, V_2, and V_3 (with one, two, and three vacancies respectively in the first coordination sphere).

A relationship was also established[17] between the number of vacancies n in the immediate environment of a vanadium atom and the sharp change in the Knight shift (K):

$$K_n - K_{n-1} \approx nK_0, \qquad (1)$$

where $K_0 \simeq 0.07-0.09\%$, that is the change in K is proportional to the number of vacancies in the first coordination sphere of a vanadium atom in VC_y.

In Ref.17, to investigate the nature of the distribution of the vacancies in vanadium carbide, the experimentally determined probability distribution $P(n)$ of the positions of the vanadium atoms n was compared with the random probability distribution, calculated from the equation:

$$P(n) = C_6^n (1-y)^n y^{6-n}. \qquad (2)$$

The experimental distribution differed from the random distribution for all VC_y specimens studied; for example, the probability of the position V_0 decreases much more rapidly than for the random distribution, and the V_3 positions are encountered much less frequently than in the statistical distribution. The small number of V_3

positions and the absence of vanadium atom positions with more than three vacancies in the first coordination sphere were attributed to repulsion between neighbouring vacancies. Thus the existence of short-range order in a non-stoichiometric compound, namely vanadium carbide, was established experimentally for the first time.[17]

In the same work,[17] NMR was used for the first time to study the ordered phase of a non-stoichiometric compound. The ^{51}V NMR spectrum of $VC_{0.875}$ differed considerably from the spectra of vanadium carbide specimens with other compositions. In particular, the ratio of the intensities of the lines corresponding to the positions V_0 and V_1 was 1/3. If the relative intensity of each line is proportional to the relative number of corresponding positions, this intensity ratio can be explained if in the carbide $VC_{0.875}$ three quarters of all the vanadium atoms have one vacancy in the first coordination sphere, and the others have a complete environment. This distribution of the vacancies indicates the existence of a superstructure of the V_8C_7 type with space group $P4_332$ or $P4_132$. It should be noted, however, that in the opinion of the authors cited,[17] this model of the distribution of the vacancies does not provide a completely accurate description of the real lattice. Thus this superstructure with helical arrangement of the vacancies contains only the positions V_0^1 and V_1^1, whereas study of the satellites indicates the existence of three types of position V_1, which could not be distinguished by the authors cited.[17] Moreover, the proposed distribution of the atoms in the ordered carbide V_8C_7 cannot be described by the space group $P4_332$.

Interesting results revealing another ordered structure were obtained in an NMR study of an annealed single crystal of vanadium carbide $VC_{0.84}$.[18,19] The ^{51}V NMR spectra obtained were broken down into lines corresponding to the positions V_0 and V_1. An analysis of the satellites made it possible to break down the intense line V_1 into lines corresponding to the positions V_1^0, V_1^1, and V_1^2 (without vacancies and with one and two vacancies in the second coordination sphere). The ratio of the intensities of the V_1^1 and V_1^2 lines in the spectra was 2:1, so that in the carbide studied, the number of V_1^1 positions is apparently twice the number of V_1^2 positions. The higher intensity of the lines corresponding to the V_1^1 and V_1^2 positions makes it possible to regard them as the positions of the ordered structure of vanadium carbide. In an electron diffraction study of $VC_{0.84}$,[18] the trigonal symmetry of the ordered vanadium carbide V_6C_5 was proposed; the use of the NMR data on the ratio of the numbers of the positions V_1^1 and V_1^2 made it possible to describe the distribution of the carbon atoms and the vacancies in the trigonal unit cell, that is to determine the structure of V_6C_5. The presence of weak lines corresponding to the positions V_0 and V_1^0 was attributed to the deviation of the composition of the carbide studied from the composition of the ordered phase $VC_{0.83}$ (that is V_6C_5). The presence of these lines in the spectrum may also be related to the deviation of the degree of long-range order in the specimens studied from the maximum possible.

These NMR studies [17–19] gave a qualitative picture of the distribution of the carbon atoms and vacancies in the non-metal sub-lattice of vanadium carbide. The next step was an attempt to obtain quantitative information on the short-range order in VC_y by minimising the ^{51}V NMR spectra.[20,21] The experimental ^{51}V NMR spectra obtained[20] for $VC_{0.75}$, $VC_{0.84}$, $VC_{0.85}$, $VC_{0.86}$, and $VC_{0.87}$ are analogous to the spectra previously described[17] and contain resonance lines corresponding to the positions V_0, V_1, and V_2. Assuming that the complex form of the line in the spectrum is due to the presence in the crystal of nuclei with different local environments, and that the intensity of a signal is proportional to the number of positions of a given type, the following relationship was obtained for calculating the intensity

$$I_p(\nu) = \sum_i \lambda_i P_i I_i(\nu), \qquad (3)$$

where P_i is the probability of the cluster with the i-th configuration of the immediate environment of non-metal atoms round the resonating nucleus (for non-stoichiometric compounds with the NaCl structure, an octahedron of six sites of the non-metal sub-lattice with a metal atom at its centre is taken as the basis cluster figure); λ_i the multiplicity of the i-th configuration of the octahedral cluster; and $I_i(\nu)$ a mathematical model of the ideal spectral line, corresponding to the i-th configuration of the immediate environment of the resonating nucleus (in Ref.20 the lines were described by a Gaussian distribution). The probabilities P_i were expressed by expansion with respect to paired and many-particle correlation parameters by the published method.[22]

The minimisation of the ^{51}V NMR spectra for VC_y with successive allowance for the correlation parameters, beginning with the paired parameters and ending with the sixth-order correlation parameters, showed[20,21] that the best description of the spectrum is achieved by taking account of paired and three-fold correlations. Allowance for correlations of higher orders did not lead to any significant change in the calculated spectrum. According to the results obtained, the paired correlations ε_{21} describing the nature of the distribution of the carbon atoms (or vacancies) in two neighbouring sites of the octahedron situated relative to one another in the first coordination sphere are negative throughout the homogeneity range of vanadium carbide. This means that throughout the homogeneity range of VC_y, the probability of detecting neighbouring vacancies is smaller than that for the statistical distribution. The short-range parameter for the first coordination sphere $a_1 = \varepsilon_{21}/y(1-y)$ is approximately –0.1, increases slowly with the increase in the deviation from stoichiometry, and shows a slight minimum close to the composition $VC_{0.83}$.

Thus the results of the calculation of the correlations and the short-range order parameter in vanadium carbide on the whole agree with the conclusions[17–19] that in VC_y there is short-range order due to the repulsion of vacancies. At the same time, it was incorrectly stated in Ref.21 that the production of the ordered phases of vanadium carbide is due to the existence of a definite type of short-range order. As shown in Refs.23–27, in non-stoichiometric compounds with the NaCl structure, long-range order may not be produced even when there is maximum short-range order in the first and second coordination spheres, so that the existence of short-range order in these compounds is only a necessary but not a sufficient condition for the production of long-range order.

The influence of composition on the ^{51}V NMR spectra of the compounds VN_y ($0.980 \leqslant y \leqslant 0.706$) has been studied.[28] The total intensity of the NMR signal, normalised for the quantity of vanadium, was found to be constant for all values of y. This means that, as in the case of VC_y, in the nitrides VN_y studied all the vanadium nuclei contribute to the resonance absorption line, so that quantitative analysis of the results is possible. The resonance peak observed in the spectra was broken down into two lines, corresponding to the complete position V_0 and the positions of vanadium atoms with one or more vacancies in the first coordination sphere. At a high concentration of vacancies, a systematic deviation of the experimentally observed intensity of the resonance lines from the intensity calculated in the approximation of a random distribution of the nitrogen atoms and vacancies was observed. This indicates that

the nitrogen atoms and vacancies are distributed with a certain degree of order in the non-metal sub-lattice of vanadium nitride.

A quantitative analysis of the short-range order in vanadium nitride was carried out[21] using the same scheme as for vanadium carbide. Minimisation of the NMR spectra established a regular change in the paired and three-fold correlation parameters with change in the composition of the nitride VN_y. According to the calculation, throughout the homogeneity range of VN_y, the parameter ε_{21} is negative and decreases, and the parameter ε_{22} is positive and increases, with increase in the number of vacancies. This means that in vanadium nitride there is short-range order with preferential arrangement of the vacancies at opposite vertices of the octahedron, whose six sites form the first coordination sphere of the vanadium atom.

Cubic vanadium monoxide VO_y has been studied by spin echo and broad-line NMR methods in the temperature range 1.4 to 300 K.[29,30] The ^{51}V NMR spectra showed only one line, whose width increased with increase in the oxygen concentration in VO_y. The measurements also showed that the magnitude of the Knight shift is independent of temperature and the composition of VO_y.

NMR has been used to study short-range order not only in non-stoichiometric compounds of vanadium, but also in solid solutions, chiefly vanadium oxide carbides and oxide nitrides.[21,31] The ^{51}V NMR spectra of the oxide carbides VC_xO_y consist of sets of four lines, whose widths and positions are practically independent of the composition of the oxide carbide. From a comparison of the integral intensity of the ^{51}V NMR spectra of the carbide $VC_{0.87}$ and the oxide carbide VC_xO_y ($x + y = 0.75-0.94$), it was concluded[21] that all the vanadium nuclei contribute to the spectrum of the oxide carbide; in the oxide carbides rich in oxygen ($y \geqslant 0.4$), vacancies are present not only in the non-metal sub-lattice but also in the metal sub-lattice, but no influence of the vacancies in the metal sub-lattice on the integral intensity of the NMR spectra could be detected.

In the analysis of the NMR spectra, the observed lines were associated with non-equivalent positions of the vanadium atoms; it was noted that the intensity of the lines is determined by the concentration of oxygen in the specimens studied. According to Ref.21, all the lines correspond to a complete environment of C and O atoms simultaneously round the vanadium atoms, but the ratio of the numbers of C and O atoms may be different, for example $[VC_5O_1]$, $[VC_4O_2]$, $[VC_1O_5]$, $[VC_3O_3]$. The intensities of the lines in the spectrum are determined by the probabilities of the corresponding positions. Comparison of the experimentally determined values of the probabilities with the values calculated assuming a statistical distribution of the C and O atoms showed that the distribution of the non-metal atoms is close to random for $V_{0.61}O_{0.14}$ and $VC_{0.67}O_{0.15}$, and differs considerably from the random distrubtion at high oxygen concentrations.

In the ^{51}V NMR spectra of the oxide nitrides VN_xO_y, the authors cited[21] observed three lines, two of which, by analogy with VC_xO_y, were associated with the positions $[VN_5O_1]$ and $[VN_3O_3]$.

An analysis of the ^{51}V NMR spectra of solid solutions VC_xO_y, VN_xO_y, and VC_xN_y [21] established that the replacement of one of the atoms forming the immediate environment of a vanadium atom by an atom of another element leads to an increase in the Knight shift compared with that for a uniform complete environment. The highest value of the Knight shift is observed for equal numbers of the atoms of the two elements in the first coordination sphere of the vanadium atom. It may be noted that in vanadium carbide, nitride, and oxide, the Knight shift also increases with increase in the number of vacancies in the immediate environment of the vanadium atom.

Taken together, these data indicate that the introduction of any impurity defect into the immediate environment of the metal atom in a non-stoichiometric compound should lead to an increase in the Knight shift compared with that for a uniform complete environment (the particles whose relative fraction in the first coordination sphere of the metal atom is smaller are regarded as the impurity defect).

Only a few papers have been devoted to the ^{93}Nb NMR study of non-stoichiometric compounds of niobium. Here, mention may be made of Ref.32, where NMR was used for the phase analysis of niobium nitride NbN_7. According to the results obtained, the phases correspond to definite lines in the NMR spectrum, and it is possible to establish from the spectrum which phases are present in the specimen being studied. It was also noted[32] that the quadrupole interactions in niobium nitride are stronger than those in vanadium nitride.

In the ^{93}Nb NMR spectra of NbC_y specimens,[17] only one line was detected, whose intensity decreased rapidly on going from $NbC_{0.94}$ to $NbC_{0.90}$; the intensity of this line decreased only slightly with further decrease in the carbon concentration. This line was assigned to the positions of niobium atoms having a complete environment as far as the third coordination sphere.

The short-range order in NbC_y has been studied in detail by highly sensitive pulse NMR spectroscopy.[23,33-36] Specimens of non-stoichiometric niobium carbide NbC_y ($0.995 \leqslant y \leqslant 0.75$) were obtained by sintering niobium and carbon powders. To obtain niobium carbide specimens in states with different degrees of order, the specimens synthesised were subjected to thermal treatment under different conditions of temperature, heating time, and rate of cooling. The conditions of the thermal treatment had a significant influence on the phase composition of the specimens; heating at temperatures above the temperature of the order–disorder transition (1304 K for $NbC_{0.83}$ [23]) with subsequent quenching (conditions *a*) gave niobium carbide specimens in the disordered state. Heating at 1300 K with subsequent slow cooling (conditions *c*) led to the formation of an ordered phase. Heating at 1300 K with rapid cooling (conditions *b*) gave specimens containing ordered and disordered phases simultaneously. The conditions of thermal treatment will subsequently be indicated after the niobium carbide composition, for example $NbC_{0.88}(c)$.

The ^{93}Nb NMR spectra of the carbides NbC_y, obtained[23,33,34] on a Bruker SXP4-100 pulse spectrometer at frequencies of 22.0, 21.5, and 14.01 MHz, are shown in Figs.2 and 3. Most of the spectra contain a line *O*, whose position coincides with that of the line observed[17] in the NMR spectra of niobium carbide. With increase in the defect character of the carbon sub-lattice, this line becomes less intense and then disappears; in spectrum IV, however, corresponding to $NbC_{0.75}(b)$, the line *O* appears again (Fig.2). The slower decrease in the intensity of the line *O*, compared with the data in Ref.17, on going from $NbC_{0.995}$ to $NbC_{0.845}$, and the increase in its width, do not make it possible to assign this line to positions of niobium atoms with a complete environment up to the third coordination sphere, as was done in Ref.17. It is logical to assume that the line *O* in spectra *I–IV* (Fig.2) corresponds both to complete positions Nb_0^0 (Fig.4*a*) and to niobium atom positions containing vacancies only in the third coordination sphere, for example Nb_0^1 (Fig.4*b*), Nb_0^2, etc.

Fig.3, which shows the change in the form of the spectra with change in the degree of order, gives the ^{93}Nb NMR spectra obtained at frequencies of 21.5 MHz and 14.01 MHz for specimens with the composition $NbC_{0.83}$, subjected to thermal treatment under the three

conditions. Spectrum *I* for the specimen $NbC_{0.83}(a)$ contains one broad peak on either side of the line *O*; spectra *II* and *III* for the specimens $NbC_{0.83}(b)$ and $NbC_{0.83}(c)$ contain five peaks in addition to the line *O*. Spectra *IV* and *V* were obtained for the same specimens as spectra *I* and *II*, but at a lower frequency (Fig.3). The low relative intensity (~4%) of the line *O* (spectrum *II* in Fig.3), assigned to the positions Nb_0, and the approximately equal numbers of positions Nb_0 and Nb_2 in $NbC_{0.83}$ indicate that the peaks observed in spectrum *II* are associated chiefly with the positions Nb_1 (the peaks corresponding to the positions Nb_2 are not observed, in accordance with the second-order quadrupole effect).

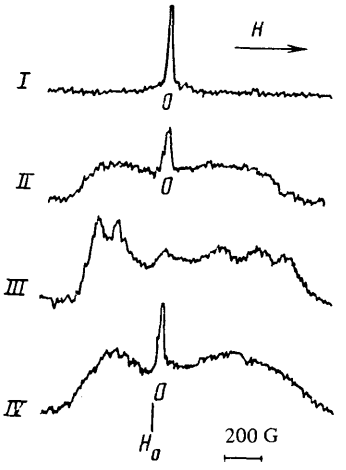

Figure 2. Change in the form of the ^{93}Nb NMR spectra with change in the composition of niobium carbide NbC_y (ν_0 = 21.5 MHz, H_0 = 20.69 kG); (*I*) $NbC_{0.995}$, (*II*) $NbC_{0.88}$ (*b*), (*III*) $NbC_{0.845}(b)$, (*IV*) $NbC_{0.75}(b)$.[34]

An analysis[33,34] of the frequency dependence of the positions of the peaks in the NMR spectra (spectra *II* and *V* in Fig.3) shows that the satellites can be only *O'* peaks, and the line of the central transition for them is the line *O*. The positions of the remaining peaks change with change in frequency, so that they are not satellites, but central transition lines. The broadening of the NMR spectra at low frequencies indicates that the contribution of quadrupole interactions is greater than that of the magnetic, so that the positions of the peaks *A*, *B*, *A'*, *B'* (spectrum *II*) and *A*, *B*, *A'*, *B'*, *C'*, *D'* (spectrum *V*) coincide with the positions of unique points of split central transition lines (the satellites of these lines are not observed, in accordance with the first-order quadrupole effect).

As a consequence of the asymmetry and high values of the electric field gradient, the positions of the peaks in the NMR spectra obtained at different frequencies change in a fairly complex fashion, so that in Refs.23, 33, and 34 a calculation was carried out making it possible to distinguish in spectra *II*, *III*, and *V* (Fig.3) the peaks assigned to different lines of the central transition. The calculation showed that in the NMR spectra of the carbide $NbC_{0.83}$ (Fig.3), in addition to the line *O*, it is possible to distinguish another four central transition lines. The positions of the unique points of the central transition lines and the corresponding parameters of the hyperfine interactions (the frequency of the quadrupole coupling ν_Q, the electric field gradient asymmetry parameter η_{as}, and the Knight shift *K*) are given in Table 1.

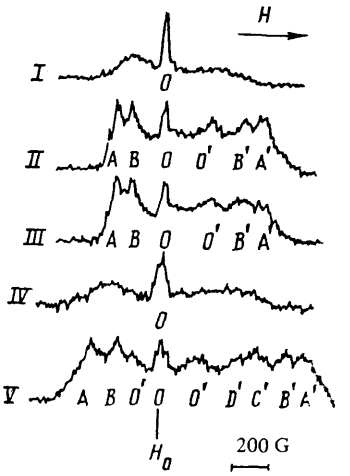

Figure 3. Influence of ordering on the ^{93}Nb NMR spectra of the carbide $NbC_{0.83}$; (*I*, *IV*) conditions *a*; (*II*, *V*) conditions *b*; (*III*) conditions *c* (*I*–*III*—ν_0 = 21.5 MHz, H_0 = 20.69 kG; (*IV*, *V*)—ν_0 = 14.01 MHz, H_0 13.46 kG).[33]

To assign the lines in spectra *II* and *V* (Fig.3) to various oppositions of the niobium atoms, a model calculation of the asymmetry parameter η_{as}, of the relative value of the frequency of the quadrupole coupling $\nu_Q/|q_C - q_\square|$ (where $|q_C - q_\square|$ is the absolute magnitude of the difference in the charges of the carbon atom and the vacancy, expressed in units of electron charge), and of the probabilities of the different positions of the niobium atoms $P_i^{disordered}$ and $P_i^{ordered}$ in the disordered and ordered states of $NbC_{0.83}$ respectively was carried out.[23,33,34] The results of the calculations[23,24] are given in Table 1. The large difference between $P_i^{disordered}$ and $P_i^{ordered}$ indicates that the NMR spectra of the disordered and ordered phases should differ considerably from one another. For example, for the disordered carbide $NbC_{0.83}$, the most probable positions are Nb_0^0 and Nb_0^1 (Fig.4) with a complete first coordination sphere, whereas for the ordered phase the most probable position is Nb_1^1 (Fig.4*b*), and there should be no niobium atom positions with a complete first coordination sphere.

In the comparison of the data on ν_Q and η_{as} obtained from the model calculation and from experiment, the authors cited[23] gave preference to the coincidence of the calculated and experimental values of the asymmetry parameters η_{as}^{calc} and η_{as}^{expt}. As a result of this comparison, they were able to find the experimental values of the hyperfine interaction parameters ν_Q, η_{as}, and *K* (Table 1) for different niobium atom positions.

By taking into account the environments of the niobium atoms with an accuracy up to three coordination spheres, the authors cited[23,33,34] were able to explain the presence of all the peaks in the ^{93}Nb NMR spectra of the carbide $NbC_{0.83}$. In the completely ordered $NbC_{0.83}$, only two types of position are possible, namely Nb_1^1 and Nb_1^2 (Figs.4*d* and 4*e*). The study of the carbides $NbC_{0.81}$ and $NbC_{0.88}$ showed that the nature of the short-range order in them is the same as in the monoclinic ordered phase Nb_6C_5 with space group $C2/m$.[37–40] Calculation of the Knight shifts showed that for niobium carbide, as for other non-stoichiometric compounds, the value of K increases with increase in the number of vacancies in the environment of the metal atom. The difference in the Knight shifts for different positions of the niobium atoms indicates a difference in the populations of their *d* orbitals for different immediate environments. Overall, the results obtained[23,33–36] indicate that the nature of the short-range order in niobium carbide, as in other non-stoichiometric compounds, is determined chiefly by the mutual repulsion of the vacancies in the non-metal sub-lattice.

2. The Study of Short-range Order by Diffuse Scattering

There are few published papers on the study of short-range order in non-stoichiometric compounds by diffuse scattering. Experimental data[45] on the intensity of the diffuse scattering of electrons by vanadium carbide $VC_{0.75}$ have been used[41–44] to calculate the parameters of the short-range order $\alpha(hkl)$ for the eight nearest coordination spheres of the non-metal sub-lattice; a vacancy was chosen as the centre of the coordination sphere. The results of the determination of the parameters α and the numbers of carbon atoms n_C and vacancies $n_\square$ in each coordination sphere are given in Table 2 (for comparison, the same quantities were calculated for the ordered phase V_6C_5 with a trigonal superstructure).

The data in Table 2 show that the nature of the distribution of the carbon atoms and vacancies in the non-metal sub-lattice of the carbide $VC_{0.75}$ differs considerably from the statistical distribution; for example, in the first two coordination spheres the number of vacancies is much smaller than that expected for the random distribution. With increase in the radius of the coordination sphere, the value of α oscillates, and its absolute magnitude gradually decreases. The results were attributed[43,44] to the mutual repulsion of the vacancies, and it was noted that analogous short-range order should be observed in niobium and tantalum carbides. The conclusion that there is similar short-range order in the non-stoichiometric monocarbides of the group V transition metals was also reached in Ref.46. According to Ref.46, it is impossible to obtain absolutely disordered (without short-range order) VC_y specimens with $y > 0.78$.

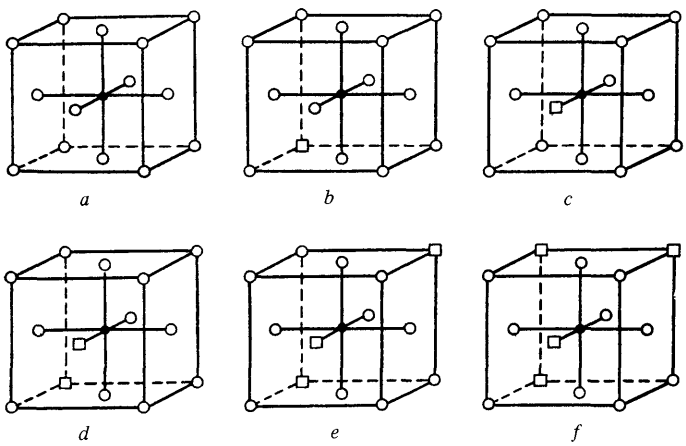

Figure 4. Most probable positions of the niobium atom in niobium carbide NbC*y*: (a) position Nb_0^0, (b) position Nb_0^1, (c) position Nb_1^0, (d) position Nb_1^1, (e) position Nb_1^2, (f) position Nb_1^3 (○—carbon atom, □—vacancy, ●—resonating niobium atom).

Short-range order has been studied by the diffuse scattering of neutrons by the carbides $TiC_{0.76}$ and $NbC_{0.73}$.[47] The distribution of the intensity of the diffuse scattering of neutrons by single crystals of carbides with the composition indicated was measured at room temperature in the $(1\bar{1}0)$ plane of the reciprocal lattice in the range of change in the modulus of the diffraction vector $0.2\ Å^{-1} < 2\pi q < 4\ Å^{-1}$. Before the measurements, the single crystals of $TiC_{0.76}$ and $NbC_{0.73}$ were annealed in a vacuum for several days. The values obtained for the intensity of the diffuse scattering indicate that the atoms are displaced from the positions of the ideal undistorted lattice. A Fourier transformation was used[47] to determine the short-range order parameter α for the eight nearest coordination spheres of the non-metal sub-lattice of these carbides (Table 2). The data given in Table 2 show that the nature of the distribution of the vacancies in $TiC_{0.76}$ and $NbC_{0.73}$ is fundamentally the same, and, as in VC_y, is due to the mutual repulsion of vacancies. It was also noted[47] that the correlations in niobium carbide extend to more than nine coordination spheres. The results[47] show qualitative agreement with data obtained[46] in a study of NbC_y powders by the diffuse scattering of neutrons.

Table 2. Parameters of the short-range order and the distribution of the carbon atoms and vacancies in the carbide $VC_{0.75}$, the ideal ordered phase V_6C_5, and the carbides $NbC_{0.73}$ and $TiC_{0.76}$.

Notation: N is the number of sites in the coordination sphere (hkl).

The study of polycrystalline specimens of $ZrC_{0.80}$ and $ThC_{0.75}$ by the diffuse scattering of neutrons[46] made it possible to determine the correlations in the distribution of the vacancies in three coordination spheres (with a vacancy at the centre). According to these data, the first coordination sphere contains a small number of vacancies (smaller than that for the statistical distribution), the second coordination sphere contains no vacancies, and the third coordination sphere contains many more vacancies than for the random distribution ($\alpha_1 = -0.05$, $\alpha_2 = -0.20$, $\alpha_3 = 0.075$).

The diffuse scattering of electrons has been used to study short-range order in the lower carbides of vanadium and niobium V_2C and Nb_2C.[48] The short-range and long-range order in these compounds was related to the distribution of the interstitial atoms in regular rows $C-\square-C-\square-\ldots$ parallel to the c axis. Comparison of the experimental and calculated values of the intensity of diffuse scattering established the possible types of order in Nb_2C and V_2C.[48]

Overall, the available published data on short-range order in the non-metal sub-lattice of non-stoichiometric compounds indicate that the correlations in the distribution of the interstitial atoms and vacancies have been studied comparatively effectively only in the compounds of vanadium and niobium; the carbides of these metals have been studied in most detail. The nature of the short-range order in the non-metal sub-lattice of non-stoichiometric carbides is due mainly to the repulsion of vacancies. In the carbides of the group V transition metals, the sites of the first two coordination spheres (with a vacancy at the centre) are occupied chiefly by carbon atoms, whereas the vacancies are present mainly in the third coordination sphere; this type of short-range order corresponds to the distribution of the atoms in ordered phases of the type M_6C_5. In the carbides of the group IV transition metals, the nature of the short-range order is related to the fact that the second coordination sphere contains practically no vacancies, while the third coordination sphere contains large numbers of vacancies. The short-range order in the lower hexagonal carbides and nitrides M_2X is due to the formation of rows $X-\square-X-\square-\ldots$ directed along the c axis.

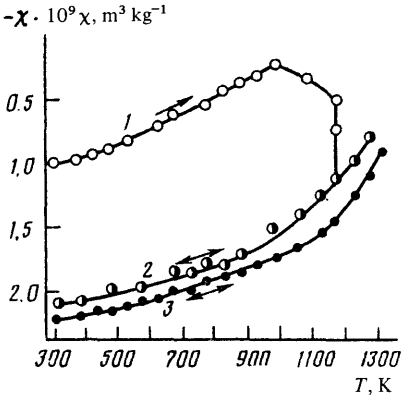

Figure 5. Influence of ordering on the magnetic susceptibility χ of niobium carbide $NbC_{0.83}$ (the arrows indicate the direction of the change in temperature): (1) quenched disordered carbide (2) carbide ordered during the measurement of the susceptibility, (3) annealed ordered carbide.[23,50]

3. The Study of Short-range Order by Magnetic Susceptibility

Magnetic susceptibility was first used to analyse the distribution of the atoms in a crystal and to determine short-range order in studies[23,49–51] of the non-stoichiometric niobium carbide NbC_y.

Measurements of the magnetic susceptibility χ of niobium carbide specimens with different compositions in the temperature range 300 – 1300 K showed that the value of χ depends on the nature of the thermal treatment of the carbide NbC_y ($0.81 \leqslant y \leqslant 0.88$). For specimens which were quenched from temperatures appreciably higher than the temperature of the disorder – order transition and which gave neutron diffraction patterns with no superstructural reflections, an abrupt decrease in χ was observed (Fig.5) to values characteristic of ordered specimens with the same composition, obtained by the methods of Refs.23 and 37. The neutron diffraction patterns recorded after the $\chi(T)$ measurements showed superstructural reflections, indicating that ordering of the structure takes place during the measurements. It was also found that the values of χ are the same for specimens containing the disordered and ordered phases simultaneously and for NbC_y specimens with the

same composition containing only the ordered phase, that is the susceptibility is independent of the concentration of the ordered phase. Since the production of long-range order is accompanied by the production of short-range order, the fact that χ is independent of the concentration of the ordered phase, and the change in χ on thermal treatment, indicate that the magnetic susceptibility is determined chiefly by the production of short-range and not long-range order.

The idea that short-range order has a definite influence on the magnitude of the magnetic susceptibility was confirmed by the calculation[23,49,50] of the short-range order parameters from experimental data.[23] The essential features of the calculation were as follows. Firstly, the $\chi(T)$ relationships for NbC_y specimens with different compositions in the disordered and ordered states were used to determine by the published method[49] the values of $P_i(y)$, the probabilities of existence in the NbC_y crystal of niobium atom positions with the i-th configuration of the carbon atoms, and the vacancies forming the immediate environment of the metal atom.

According to Refs.23, 49, and 50, for a correct description of the carbide MC_y in the composition range $1.0 \geqslant y \geqslant 0.80$ it is sufficient to consider only four positions: the position with a complete metal atom environment, having a probability P_0; the position with one vacancy in the octahedral environment of the metal atom, having a probability P_1; and positions with two non-adjacent and adjacent vacancies, having probabilities P_2 and P_3 respectively.

The short-range order parameter α_j in the j-th coordination sphere of the non-metal sub-lattice can be determined from the equation:[23]

$$\alpha_j = 1 - P^{(j)}_{C-\square}/P^{bin}_{C-\square}, \quad (4)$$

where $P^{(j)}_{(C-\square)}$ and $P^{bin}_{(C-\square)}$ are the probabilities of formation of the pair $C-\square$ in the compound being studied and in the completely disordered compound. For the carbide MC_y the binomial probability is $\lambda_{C-\square}P^{bin}_{C-\square} = 2y(1-y)$, and the actual probability of formation of the pair $C-\square$ in the j-th coordination sphere can be found from the known probability $P_i(y)$ using the equation:

$$\lambda_{C-\square}P^{(j)}_{C-\square} = \sum_i n_i^{(j)}\lambda_i P_i(y), \quad (5)$$

where $n_i^{(j)}$ is the relative fraction of $C-\square$ pairs in the j-th coordination sphere of the position of the metal atom with the i-th configuration; $\lambda_{C-\square} = 2$ is the multiplicity of the $C-\square$ pair; and λ_i is the multiplicity of the i-th configuration of the immediate environment of carbon atoms and vacancies round the metal atom (the multiplicity of a given group of atoms is the number of its equivalent configurations, which are brought into coincidence with one another by symmetry transformations). In the examination of the above four metal atom positions,

$$\lambda_{C-\square}P^{(1)}_{C-\square} = \lambda_1 P_1(y)/3 + 2\lambda_2 P_2(y)/3 + \lambda_3 P_3(y)/2$$

and

$$\lambda_{C-\square}P^{(2)}_{C-\square} = \lambda_1 P_1(y)/3 + 2\lambda_3 P_3(y)/3.$$

The calculation showed that for NbC_y specimens in the disordered state, the values of α_1 and α_2 are close to zero, whereas for the annealed specimens, the values of α_1 and α_2 are negative and differ considerably from zero; for example, for the annealed carbides $NbC_{0.88}$, $NbC_{0.83}$, and $NbC_{0.81}$, the parameters α_1 and α_2 have the values −0.064 and −0.040, −0.132 and −0.126, and −0.153 and −0.137 respectively. The negative values of α_1 and α_2 indicate the mutual repulsion of particles of the same kind, which also determines the nature of the short-range order in the non-metal sub-lattice of niobium carbide.

Magnetic susceptibility has also been used[52] to study the ordering in non-stoichiometric tantalum carbide TaC_y. The temperature dependence $\chi(T)$ for tantalum carbide specimens in the disordered and ordered states was similar to that observed[23,50] for niobium carbide. The experimentally measured magnetic susceptibility of tantalum carbide was used[52] to calculate the short-range order parameters. According to the calculation, the parameters in the first and second coordination spheres of the non-metal sub-lattice of ordered tantalum carbide are non-zero: $\alpha_1 = -0.086$ and $\alpha_2 = -0.054$ for $TaC_{0.83}$, and $\alpha_1 = -0.076$ and $\alpha_2 = -0.020$ for $TaC_{0.85}$.

For ideal ordered phases of the type $M_6C_5(MC_{0.83})$, $\alpha_1 = \alpha_2 = -0.20$,[49] in good agreement with the values obtained for $TaC_{0.83}$. The slight differences between the values of α_1 and α_2 calculated from the magnetic susceptibility and the limiting possible values of these parameters indicate that complete ordering was not achieved in the niobium and tantalum carbide specimens studied in Refs.49–52.

Overall, the results of the study of the short-range order in niobium and tantalum carbides by magnetic susceptibility[23,49–52] show good agreement with one another and with the results of NMR studies of the short-range order in non-stoichiometric carbides of the group V transition metals.

III. SHORT-RANGE ORDER IN CARBIDE SOLID SOLUTIONS

In the works discussed, the short-range order was studied in the non-metal sub-lattice of the non-stoichiometric compounds. The results of the study of the atom distribution in the metal sub-lattice of solid solutions of non-stoichiometric compounds of various transition metals are of considerable theoretical and practical interest.

The diffuse scattering of X-rays has been used repeatedly to study the short-range order in the metal sub-lattice of solid solutions formed by transition metal carbides with compositions close to the stoichiometric. In the opinion of Iveronova and Katsnel'son,[53] the most significant results of the study of short-range order in solid solutions M^1C-M^2C is the actual establishment of the fact that the distribution of the metal atoms in the sites of the metal sub-lattice is not random, and the detection of the influence of carbon on the nature of the correlations in the arrangement of the metal atoms.

The first studies of the local distribution of the atoms in the metal sub-lattice of the solid solutions NbC–TaC and ZrC–HfC with the equimolar composition were described in Refs.54–56. The absence of vacancies in the carbon sub-lattice and the similarity of the atomic radii of the metals replacing one another (Nb, Ta, Zr and Hf) made it possible to assume the absence of static distortions in the lattice of the solid solution. The short-range order parameters for the three nearest coordination spheres were calculated from the measured intensities of the diffuse scattering. For the first and second coordination spheres, the values of the short-range order parameters were found to be positive, and α_1 and α_2 increased with decrease in the temperature of quenching or annealing (Table 3). The positive values of α_1 and α_2 indicate that in the first and second coordination spheres of the metal atoms of a given kind, the concentration of metal atoms of the same kind is higher than that for the statistical distribution, that is there is short-range order involving short-range separation into layers. Short-range separation into layers has also been observed in Nb–Ta alloys.[57]

The short-range order parameter α_3 for the third coordination sphere is negative and close to zero, so that the correlations in the arrangement of the atoms in the metal sub-lattice apparently extend to only two coordination spheres. Additional annealing of the specimens of the solid solutions, and also the addition of 1 mole % WC, led to an increase in the correlations in the relative arrangements of the metal atoms.[54-56]

*Specimens subjected to thermal treatment by annealing; in the other cases by quenching.

Diffuse scattering has been studied[58,59] in the solid solutions with the equimolar composition TiC—NbC, TiC—TaC, TiC—WC, VC—NbC, and VC—WC, and in the alloys Ti—Ta with the equiatomic composition, V—Nb (36 at.% Nb), and V—W (35 at.% W). The short-range order parameter α_1 is positive for the Ti—Ta alloys, and negative for the V—Nb and V—W alloys. For all the carbide solid solutions studied except VC—WC, $\alpha_1 < 0$; for VC—WC, $\alpha_1 > 0$. Comparison of the values of α_1 in the carbide solid solutions and in the corresponding metal alloys shows that in the solid solutions TiC—NbC, VC—WC, and TiC—TaC, the sign of α_1 is the opposite of that for the alloys Ti—Nb,[60] V—W, and Ti—Ta (Table 3).

The short-range order in TiC—WC solid solutions was studied in Refs.61—63. The intensity of the diffuse scattering of X-rays was measured using specimens with different compositions subjected to thermal treatment under slightly different conditions (sintering at different temperatures, quenching, gradual cooling in the furnace, etc.). According to the results, in all the specimens of the TiC—WC solid solutions with a complete carbon sub-lattice, $\alpha_1 < 0$, and for the second and third coordination spheres the parameters α_2 and α_3 are close to zero (Table 3). This means that the correlations in the arrangements of the titanium and tungsten atoms are observed at short distances within 1—3 coordination spheres. In all cases, additional annealing of the specimens led to an increase in the absolute magnitude of the short-range order parameters. States with a metal atom distribution close to the statistical distribution were not detected.

Increase in the tungsten concentration in the TiC—WC solid solutions is accompanied by an increase in the degree of short-range order in the first coordination sphere. The nature of the distribution of the metal atoms is influenced considerably by the carbon concentration. When the carbon concentration deviates from the stoichiometric, the short-range order parameters for the three nearest coordination spheres become positive (Table 3). At the same time, the nature of the diffuse scattering of X-rays by non-stoichiometric solid solutions indicates that there are two types of short-range order in their structures: with $\alpha_1 < 0$ and with $\alpha_1 > 0$. The authors cited[61-63] therefore suggested that in the non-stoichiometric solid solution $Ti_xW_{1-x}C_y$, in addition to the formation of segregations of the atoms of one metallic element, regions of short-range order with the structure typical of the stoichiometric solid solution are preserved.

IV. LOCAL DISPLACEMENTS OF THE ATOMS

In the disordered state, non-stoichiometric compounds are characterised by a random distribution of the interstitial atoms and vacancies in the sites of the non-metal sub-lattice, and therefore do not have the translational symmetry of the crystal with the stoichiometric composition. As a consequence of this random distribution, however, the probabilities of occupancy of the sites of the non-metal sub-lattice are equal, so that all these sites are crystallographically equivalent. In other words, in disordered non-stoichiometric compounds there is translational symmetry of a lattice of site occupancy probabilities.

Most non-stoichiometric compounds with wide homogeneity ranges have a highly symmetrical structure of the NaCl type, which is preserved for the disordered distribution of the interstitial atoms and vacancies. A result of the disordered distribution is the loss of the symmetry of the local environment of each atom. The distortion of the local symmetry leads in turn to static displacements of both the metal atoms and the interstitial atoms. The static displacements are the deviations of the atoms from the positions corresponding to the ideal basic structure of the compound, that is they represent the quantity $\mathbf{u}_n = \mathbf{R}_n - \mathbf{r}_n$, where $\mathbf{R}_n$ and $\mathbf{r}_n$ are the radius-vectors defining the position of the atom n in the real and ideal lattices respectively. Unlike the dynamic displacements, due to the thermal vibrations of the atoms, the static displacements result from the difference in the energies of the bonds between neighbouring atoms.

The cubic symmetry of disordered non-stoichiometric compounds allows only a spherically symmetrical distribution of the static displacements of the atoms, since otherwise the crystallographic equivalence of different sites of the crystal would be destroyed. In disordered non-stoichiometric compounds, the symmetrical distribution of the static displacements is ensured by the random distribution of the vacancies. By taking account of the radial distribution of the

static displacements and making use of the analogy with dynamic displacements, it is possible to examine the mean-square static displacements.

During ordering, the symmetry of the crystal is lowered, and is accompanied by a change in the symmetry of the local environment of the atoms (for the stoichiometric composition of the ordered phase, the symmetry of the local environment coincides with the crystal symmetry). Since in the ordered state the symmetry of the local environment is not cubic, ordering must be accompanied by static displacements of the atoms. The magnitude of the static displacements is different for the disordered and ordered states of a crystal, since the local environments of the atoms are different in these states.

The determination of the magnitude and direction of the static displacements for each atom in non-stoichiometric compounds with different structural states makes it possible to find the equilibrium positions, that is to determine the crystal structure more accurately and completely. Comparison of the values of the static displacements corresponding to different structural states can also be used to investigate possible mechanisms of phase transformations of the order–disorder type and to analyse the nature of the change in the inter-particle interactions in a crystal during ordering.

The principal methods for determining the displacements of atoms are by the diffraction of X-rays and thermal neutrons. There is no fundamental difference between these methods, since the elastic scattering of neutrons at the nuclei of the atoms and the scattering of X-rays on the static imperfections of the crystal are described by essentially identical equations and can be examined using the same theory.[64,65] At the same time, the difference in the parameters of the theory may lead to extremely significant methodological advantages.

The amplitudes of the scattering of X-rays by individual atoms are determined by the number of electrons in them, and increase regularly with increase in the atomic number of the element in the periodic system, whereas the amplitudes of the scattering of neutrons by the nuclei of different atoms change in irregular fashion. For non-stoichiometric compounds such as the transition metal carbides and nitrides, this means that in the scattering of X-rays, the main contribution to the intensity of the diffraction peaks will be made by the transition metal atoms, so that when X-ray diffraction is used to determine displacements, the information on the non-metal sub-lattice is practically completely lost. In neutron diffraction, the amplitudes of the atomic scattering of the neutrons by different components of non-stoichiometric compounds are of comparable magnitude (for example, for zirconium, hafnium, niobium, tantalum, carbon, and nitrogen, the amplitudes of the scattering of neutrons are 0.71×10^{-12}, 0.78×10^{-12}, 0.71×10^{-12}, 0.70×10^{-12}, 0.665×10^{-12}, and 0.94×10^{-12} cm respectively[66]). Thus when the diffraction of thermal neutrons is used, contributions to the intensity of the observed reflections are made by both the metal atoms and the non-metal atoms. The determination of displacements by neutron diffraction is in general more accurate than that by X-ray diffraction, since the amplitude of the scattering of neutrons is independent of the angle of scattering, and it is not necessary to introduce a correction for extinction; moreover, the absorption of neutrons by a substance is much less than the absorption of X-rays. Thus neutron diffraction is preferred for determining displacements in non-stoichiometric compounds of transition metals.

The decrease in the intensity of the diffraction lines is due to both dynamic (thermal) and static displacements of the atoms from the sites of the ideal crystal lattice, and in the absence of ordering these two factors bring about a decrease in intensity according to the same law.[64,67] In fact, the presence of dynamic displacements means that the positions of the atoms are time-dependent, but since the frequency of the scattered radiation is several orders of magnitude greater than the frequency of the thermal vibrations of the atoms, it can be assumed that the scattering takes place on stationary atoms occupying certain instantaneous positions. From this it follows that for the diffraction experiment there is no fundamental difference between dynamic and static displacements; it is necessary only to consider their superposition, as a result of which the intensity of the spectrum will depend on the sum of their mean-square values:

$$\langle U_{\Sigma}^2 \rangle = \langle U_{st}^2 \rangle + \langle U_{dyn}^2 \rangle. \quad (6)$$

The dynamic displacements can be separated from the total displacements, for example, by using the temperature dependence of the intensities of the diffraction lines.

At present, static displacements have been determined only for several transition metal carbides and nitrides; almost all the studies have been carried out only with compounds in the disordered state.

X-Ray diffraction has been used[68] to determine the displacements $< U_{\Sigma}^2 >$ of the atomic complex MX_y in the homogeneity ranges of the carbides of titanium, zirconium, and hafnium. The recording was carried out at room temperature, at which, in the opinion of the authors cited, the thermal vibrations of the atoms are small and the dynamic displacements can be neglected. Thus it was assumed[68] that $< U_{\Sigma}^2 > \simeq < U_{st}^2 >$. Increase in the defect character of the carbon sub-lattice was accompanied by a marked increase in the static distortions of the lattice (Table 4). The greatest static displacements are observed for titanium carbide; the magnitude of the displacements decreases on going to zirconium and hafnium carbides. Comparison of the nature of the change in the crystal lattice constants and the displacements with change in the composition of the carbides indicated that a sharper change in the crystal lattice constant with change in composition is accompanied by larger static distortions.

Neutron diffraction has been used[69] to determine the static displacements in the carbides of titanium, zirconium, vanadium, niobium, and tantalum. The effective mean-square displacements were found from the experimentally determined intensities of the diffraction reflections. For carbides MC with compositions close to the stoichiometric, the static distortions should be small, since the lattice is practically complete; thus for the stoichiometric compositions, $< U_{\Sigma}^2 > = < U_{dyn}^2 >$. Evidence in support of this is provided by the good agreement between the values obtained for $< U_{\Sigma}^2 >$ and the values of $< U_{dyn}^2 >$ calculated[70] from the elastic constants in the Debye approximation ($< U_{dyn}^2 >^{1/2}$ has the values 0.081 Å for TiC, 0.069 Å for ZrC, and 0.072 Å for NbC). The authors cited[69] assumed that the Debye temperature depends little on the composition of the carbides, and hence that the dynamic distortions of the lattice change little with decrease in the carbon concentration and that in a first approximation their dependence on the composition of the carbide MC_y can be neglected. This makes it possible to calculate the static displacements from the equation:

$$\langle U_{st\,MC_y}^2 \rangle = \langle U_{\Sigma\,MC_y}^2 \rangle - \langle U_{dyn\,MC}^2 \rangle = \langle U_{\Sigma MC_y}^2 \rangle - \langle U_{\Sigma MC}^2 \rangle. \quad (7)$$

The values obtained[69] for the displacements for titanium carbide were much lower than those obtained[68] by X-ray diffraction; the data[68,69] for zirconium carbide show better agreement (Table 4).

Neutron diffraction has been used[71] to determine the mean-square displacements of the atomic complex MN and the metal and nitrogen atoms, $< U_{\Sigma MN}^2 >$, $< U_{\Sigma M}^2 >$, and $< U_{\Sigma N}^2 >$, in the nitrides

$TiN_{0.98}$, $ZrN_{1.00}$, and $HfN_{0.98}$ with compositions close to the stoichiometric (Table 4). The results for titanium and zirconium nitrides agree satisfactorily with calculated data[72] obtained from the elastic constants in the Debye approximation ($<U^2_{dyn}>^{1/2}$ has the values 0.083 Å for TiN and 0.080 Å for ZrN).

The magnitude and direction of the relative static displacements of the atoms in the carbides $ZrC_{0.64}$,[46] $TiC_{0.76}$, and $NbC_{0.73}$ [47] have been determined by the diffuse scattering of neutrons. In $ZrC_{0.64}$, the zirconium atoms are displaced from the vacancies by 0.04 Å. In titanium and niobium carbides, the metal atoms are also displaced from the vacancy towards the carbon atom by 0.030 Å and 0.033 Å respectively, whereas the carbon atoms move away from one another (in the first coordination sphere of the non-metal sub-lattice, the distance between neighbouring carbon atoms increased by 0.011 Å in $TiC_{0.76}$ and by 0.006 Å in $NbC_{0.73}$).

The local displacements of the atoms situated round the carbon vacancy in NbC_y ($0.05 \leqslant y \leqslant 0.12$) have been determined[73] by an X-ray diffraction study of single crystals. To distinguish the dynamic and static displacements, the X-ray spectra of $NbC_{0.88}$ and $NbC_{0.93}$ were recorded at 299 K and 479 K. This made it possible to find the average Debye–Waller thermal factor for the temperature range indicated, equal to $2M = \ln(I_{479}/I_{299})$. According to the data obtained,[73] the magnitude of the dynamic displacements $<U^2_{dyn}>$ decreases with increase in the number of vacancies in the carbon sub-lattice of NbC_y, and can be described by the linear relationship

$$\langle U^2_{dyn}\rangle = 0.0027 - 0.005\,(1-y),\ \text{Å}^2. \qquad (8)$$

Since X-ray diffraction makes it possible to obtain information only on the metal sub-lattice, the authors cited[73] suggested that the vacancy is surrounded by six niobium atoms in the first and eight niobium atoms in the second coordination spheres, and that the displacement of the metal atoms in the subsequent coordination spheres and the displacements of the carbon atoms do not lead to a change in the X-ray diffraction patterns. It was also assumed that the vacancies are situated at an appreciable distance from one another, so that the position of the niobium atoms is influenced by only one vacancy. This assumption is applicable only for niobium carbide compositions close to the stoichiometric, and is not applicable to the $NbC_{0.88}$ specimen studied in Ref.73.

The static displacements of the niobium atoms for the first and second coordination spheres of a vacancy are $<U^2_{st}>_1 = 0.125$ Å and $<U^2_{st}>_2 = 0.009$ Å^2 respectively.[73] The directions of the displacements were also found; the niobium atoms in the first coordination sphere are displaced away from the vacancy, and those in the second coordination sphere are displaced towards the vacancy. Although the displacements of the niobium atoms in the second coordination sphere are much smaller than those in the first coordination sphere, the authors cited[73] assume that the displacements $<U^2_{st}>_2$ compensate the displacements in the first coordination sphere and lead to a decrease in the lattice constant of niobium carbide with increase in the concentration of vacancies. This interpretation of the experimental data appears doubtful, since in the work cited the coordinates of the carbon atoms were not determined, and the information on the positions of the niobium atoms is incomplete, that is there is practically no information on the crystal lattice constant.

The displacements $<U^2_{\Sigma MX_y}>$, $<U^2_{\Sigma M}>$, and $<U^2_{\Sigma X}>$ in titanium carbide $TiC_{0.96}$, titanium nitride $TiN_{0.98}$, and titanium carbide nitride $TiC_{0.48}N_{0.51}$ have been determined by neutron diffraction.[74] The authors cited give the values of the quantity $B = 8\pi^2 <U^2>/3$, from which the present authors calculated the values of the mean-square displacements $<U^2>$ (Table 4). The values of the displacements for titanium carbide and nitride show good agreement with the data of Refs.69 and 71, which were also obtained by neutron diffraction. In the study of titanium carbide in Ref.74, no deviations of the intensities of the diffraction reflections from the values calculated using the model of random displacements of the atoms from the positions of the ideal lattice were detected.

The displacements of the atoms in the homogeneity range of the disordered carbide NbC_y ($0.75 \leqslant y \leqslant 1.00$) have been studied in detail by neutron diffraction.[23,75,76] The presence of structural vacancies in non-stoichiometric niobium carbide brings about distortion of the symmetry of the local environment of the sites of the crystal lattice, and leads unavoidably to static displacements of both the atoms of the metallic matrix and the carbon atoms. When a special thermal treatment[23] ensuring a statistical distribution of the structural vacancies in the crystal lattice of the carbide is used, the symmetry of the carbide remains the same as that of the lattice of the defect-free carbide $NbC_{1.00}$, that is the disordered non-stoichiometric carbide NbC_y has an "average" highly symmetrical lattice, whose parameters change with change in composition. In this case the static distortions can be represented by the mean-square static displacements of the atoms, measured from the sites of this "average" lattice.

X-Ray diffraction[23] established that the concentration dependence of the cubic unit cell parameter of the disordered carbide NbC_y ($0.75 \leqslant y \leqslant 1.00$) is appreciably non-linear, with a point of inflection in the region of the composition $NbC_{0.83}$ (curve *1* in Fig.6).

In Refs.75 and 76, the mean-square static and dynamic displacements of the atoms were determined by neutron diffraction. The amplitudes of the scattering of neutrons by niobium and carbon atoms are of similar magnitude, and in this case the influence of the disordered displacements of the atoms on the diffraction effects can be taken into account using a Debye–Waller factor averaged over the atoms of different elements.[64,65,77] In a first approximation, the quantity M in the Debye–Waller factor can be regarded as a linear function of the displacements $\langle U_\Sigma^2 \rangle$:[77]

$$M = 2\pi^2 q^2 \langle U_\Sigma^2 \rangle / 3, \qquad (9)$$

where

$$q = |\mathbf{q}| = 2 \sin[\theta(hkl)]/\lambda$$

is the length of the vector of the reciprocal lattice.

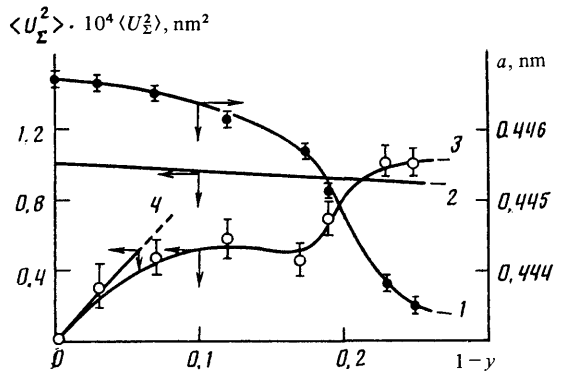

Figure 6. Changes in the crystal lattice parameter (1) and the dynamic (2) and static (3) mean-square displacements of the atoms in disordered niobium carbide NbC_y and the approximation of the static displacements (4) by Eqn.(11) in the range of low concentrations of vancancies.[76]

Measurement of the intensity of the diffraction peaks on the neutron diffraction patterns of the specimens of disordered NbC_y and construction of the $M = f(q^2)$ relationships, however, showed that they are non-linear at high values of q^2,[75,76] and the deviation from linearity takes place towards an increase in M for all niobium carbide specimens studied. Since a deviation of the $M = f(q^2)$ relationship from linearity is also characteristic of stoichiometric niobium carbide, the observed deviations were attributed[75,76] to the anharmonicity of the lattice vibrations of the atoms in niobium carbide. This conclusion agrees with the results of a study of the heat capacity of disordered niobium carbide,[78,79] where appreciable anharmonic effects were observed at $T \simeq 300$ K.

The contributions of the dynamic and static displacements of the atoms to $\langle U_\Sigma^2 \rangle$ were distinguished[75,76] using the concentration dependence of the dynamic displacements of the niobium and carbon atoms in NbC_y, found from data on the low-temperature heat capacity

$$\langle U_{dyn}^2 \rangle = [0.010 - 0.004(1-y)] \times 10^{-2} \text{ nm}^2, \qquad (10)$$

which indicates larger values of the dynamic displacements than in Ref.73. According to Eqn.(10), increase in the concentration of structural vacancies in niobium carbide is accompanied by a decrease in the magnitude of the dynamic displacements (curve *2* in Fig.6). This can be attributed to a change in the contribution of the displacements of the carbon atoms as a result of the decrease in the carbon concentration when the niobium carbide composition deviates from the stoichiometric.

Data on the total mean-square displacements of the atoms $\langle U_\Sigma^2 \rangle$ in NbC_y and the concentration dependence (10) of the dynamic displacements were used to determine the dependence of the mean-square static displacements $\langle U_{st}^2 \rangle$ on the niobium carbide composition (curve *3* in Fig.6). The magnitude of the static displacements increases when the niobium carbide composition deviates from the stoichiometric; a local minimum is observed for the specimen $NbC_{0.83}$. The appearance of this minimum is apparently due to the existence of short-range order in the arrangement of the carbon atoms and the vacancies; this could not be eliminated[75,76] even by quenching the specimens. The composition range in which the $\langle U_{st}^2 \rangle$ minimum is observed corresponds to the range in which, according to the data of Refs.23 and 37, the ordered monoclinic phase Nb_6C_5 is formed on prolonged annealing.

According to Ref.65, at low concentrations of defects and in the absence of correlations in the relative positions of the atoms, the dependence of the magnitude of the mean-square static displacements on the concentration of defects c bringing about static displacements has the form:

$$\langle U_{st}^2 \rangle = c(1-c)a^2 M_0 / 2\pi^2. \qquad (11)$$

Here,

$$M_0 = R^{-1}(dV/Vdc)^2,$$

where R^{-1} is the proportionality coefficient, a the unit cell parameter, and V the unit cell volume.

In NbC_y, the defects bringing about the static distortions are structural vacancies, so that $c = (1 - y)/2$. In Ref.76 it was shown that Eqn.(11) provides a good approximation to the experimentally observed static displacements only in the composition range $0.97 < y < 1.00$ (curve *4* in Fig.6). The value of R^{-1} determined for this composition range was found to be greater by approximately two orders of magnitude than that calculated[65] for interstitial alloys of non-transition metals. This indicates that in niobium carbide the static displacements of the atoms are greater than those in the alloys, and that strong localised interactions predominate. It also follows from Fig.6 that at high concentrations of defects, the theoretical values of the displacements become much larger than the experimental values. This is apparently related to the fact that in Ref.65, in the derivation of Eqn.(11), no account was taken of the overlap of

the perturbations created by the point defects. This overlap arises in NbC_y when the deviation from stoichiometry is large, and it unavoidably leads to a decrease in the rate of increase in the static displacements with increase in the concentration of vacancies.

---o0o---

The material presented shows that in the last 10–15 years the study of the local distribution of the atoms in non-stoichiometric compounds of the transition metals has developed intensively. The results of the study of the structure of non-stoichiometric compounds and their solid solutions by diffraction, resonance, and other experimental methods show that the existence of short-range order in the relative arrangement of the atoms is an extremely widespread phenomenon in these substances, whereas it was previously assumed that the distribution of the interstitial atoms in non-stoichiometric compounds was completely statistical. The study of short-range order has been particularly successful using NMR, which is highly sensitive to small changes in the symmetry of the local environment of the atoms at which resonance is observed. The study of short-range order in non-stoichiometric compounds by magnetic susceptibility, which has not previously been used for this purpose, is also noteworthy.

An analysis of the experimental data shows that the nature of the short-range order in non-stoichiometric compounds is determined chiefly by the mutual repulsion of the vacancies or atoms of the same kind. This is indicated by the negative value of the short-range order parameters for the nearest coordination spheres of the non-metal sub-lattice. Studies of short-range order in the metal sub-lattice of carbide solid solutions have detected the existence of correlations in the relative arrangement of the metal atoms, and also the influence of the carbon concentration on not only the magnitude but also the sign of the short-range order parameter for the first coordination sphere.

The breakdown of the symmetry of the local environment of the atoms in non-stoichiometric compounds leads to static displacements of both the metal atoms and the interstitial atoms. The magnitude and direction of the static displacements are different for compounds in the disordered and ordered states. Comparison of the displacements corresponding to different structural states of a compound makes it possible to analyse the nature of the inter-particle interactions. Up to the present, however, experimental work in this direction has been restricted to the study of only disordered non-stoichiometric compounds.

Thus in the last ten years, the experimental study of the local distribution of the atoms in non-stoichiometric compounds has begun, but the problem of studying short-range order in these compounds has not been resolved. This applies particularly to the ordered phases of non-stoichiometric compounds, and also to non-stoichiometric compounds synthesised under thermobaric conditions, that is with the simultaneous application of high pressures and temperatures. The preparation of ordered phases by a redistribution of the atoms in the lattice, and the thermobaric synthesis of non-stoichiometric compounds, involving the filling of structural vacancies by atoms, provide new and promising methods for the directed synthesis of substances with specified properties. Studies of short-range order and the displacements of atoms may reveal the mechanisms of the transformations taking place in non-stoichiometric compounds, the nature of the interatomic interactions, and the influence of short-range order on the properties of these compounds. The principal experimental methods which should be used as widely as possible in the study of the phenomena of short-range order in non-stoichiometric compounds are the highly sensitive pulse NMR spectroscopy, the diffuse scattering of X-rays, neutrons, and electrons, and structural neutron diffraction.

The Anisotropy of Molecular Magnetic Susceptibility and Its Structural-chemical Aspects

S.G.Vul'fson

Experimental data on the anisotropy of the magnetic susceptibilities of molecules and complexes have been summarised and systematised. A tensor additive scheme for the magnetic susceptibilities of the chemical bonds and groups of atoms in diamagnetic compounds has been developed. The application of the additive scheme to the analysis of the effects of the mutual influence of atoms, the problem of aromaticity, conformational structure, solvation, and complex formation has been examined.

I. INTRODUCTION

For a long time, molecular magnetochemistry, which studies the relationship between the magnetic properties and the structure of molecules, developed chiefly on the basis of a group of methods for determining average magnetic susceptibilities (MS). In the great majority of studies, with the exception of those devoted to the determination of the principal components of the molecular tensors of the MS in crystals, the anisotropies of the MS were not analysed. The intensive study of magnetic anisotropies has become possible as a result of the use in recent years of the molecular Zeeman effect in the gas phase,[1] the effects of linear magnetic birefringence in liquid media and the gas phase,[2-4] and NMR spectroscopy in strong fields.[5] The discussion of these methods in the literature is limited or non-existent, since the emphasis has been on the physics of the phenomena, and not on their application to chemical problems.

Unlike the average MS, the anisotropy is highly sensitive to the effects of intra- and intermolecular electronic interactions, and also to the relative orientation of functional groups. The experimental material which has now accumulated makes it possible to summarise published data on the determination of the anisotropic MS of molecules and the application of this fundamental electronic property to the solution of structural chemical problems.

II. METHODS FOR DETERMINING MAGNETIC SUSCEPTIBILITIES

The magnetic properties of an anisotropic molecule are described completely by nine quantities (k_{XX}, k_{XY}, k_{XZ}...k_{ij}), the set of which is called the MS tensor; from symmetry, $k_{ij} = k_{ji}$. The MS tensor can be represented in matrix form:

$$\begin{vmatrix} k_{XX} & k_{XY} & k_{XZ} \\ k_{YX} & k_{YY} & k_{YZ} \\ k_{ZX} & k_{ZY} & k_{ZZ} \end{vmatrix} \quad (1)$$

After reduction to the principal axes, the tensor becomes "diagonal":

$$\begin{vmatrix} k_{11} & 0 & 0 \\ 0 & k_{22} & 0 \\ 0 & 0 & k_{33} \end{vmatrix} \quad (2)$$

The invariants of a tensor are its trace and anisotropy. The trace is the sum of the diagonal elements, often characterised by the total (Σk_{ii}) or average ($\Sigma k_{ii}/3$) MS; their difference is the anisotropy (γ).[6-9] Methods for finding average MS have been described in detail in many reviews and monographs.[7,8,10-19] The data for approximately 800 compounds have been summarised in Ref.20.

Data on magnetic anisotropies have been analysed to a much smaller extent.

1. Microwave Spectroscopic Effects

The rotational Zeeman effect[1,21] in a gas consists of the splitting of the spectral lines into several components under the influence of a strong magnetic field. It has now become possible to measure and interpret the quadratic Zeeman effect, associated with the anisotropy of the MS. Measurement of the Zeeman effect is practically the only experimental method making it possible to separate the total MS into diamagnetic and polarisation paramagnetic components.[1,22] Since MS anisotropies are determined using the Zeeman effect in the gas phase, they can be regarded as standard. Unfortunately, a number of restrictions are imposed on the materials which can be studied by this method, and this reduces the range of substances which can be examined. These restrictions relate to the thermal stability of the specimens, the number of atoms other than hydrogen in the molecule (not more than 10), and the existence of a permanent electrical dipole moment in the molecule. The last restriction can be removed by studying the weak van der Waals complexes formed by the polar hydrogen halides with the centrosymmetric molecules

under investigation, for example acetylene[23] and cyclopropane.[24] Another approach involves partial deuteriation, used, for example, to determine the anisotropy of the MS of ethane (CH_3-CD_3).[25,26]

The anisotropies of the MS of the simplest molecules can also be determined by double electric resonance in molecular beams.[27,28]

2. The Molecular MS of Single Crystals

To find the principal MS of crystalline substances, it is sufficient to place a single crystal in a magnetic field in such a way that its lines of force coincide with one of the principal axes of the MS. Another approach is based on the tendency for a crystal of low symmetry suspended in a uniform magnetic field to orientate itself always in such a way that the axis corresponding to the MS of greatest absolute magnitude lies in the direction of the lines of force of the magnetic field.[7,8] The total MS tensor of a single crystal can be found by studying it in a non-uniform magnetic field.[8,12] A number of other methods can also be used to determine the principal MS of single crystals.[8]

At present, because of significant experimental difficulties, the tensors of only a limited number of molecules have been determined from data on the MS of crystals. Most of these data for diamagnetic materials have been tabulated;[7,29,30] values have also been obtained for a number of benzoic acids,[31-36] substituted nitrobenzenes,[37,38] and steroids,[39] and data on paramagnetic substances have been summarised;[40] data for lanthanide α,β-diketonates have also been published.[41]

It is assumed that the crystal packing has no influence on the molecular MS tensor, since the average MS of molecules in the liquid and solid phases are similar.[7] This assumption is not wholly correct, however. Rearrangement of the magnetic axes with preservation of their average value is always possible in principle. It would be strictly correct to compare the MS tensors of the same molecules in different states of aggregation. Special studies in this direction have not been carried out, and it has been reported only that these tensors are similar for various compounds, for example benzene and polynuclear hydrocarbons.[5] A correspondence between the results of measurements on crystals and measurements of the Cotton–Mouton effect in solutions has been reported for a number of aromatic compounds.[42,43] For compounds containing highly polar substituents, this question remains open. Thus for *p*-nitroaniline, satisfactory agreement is observed between the results of measurements of the Cotton–Mouton effect and measurements on crystals, whereas this agreement is not observed for *m*- and *p*-dinitrobenzenes.[44]

3. Magnetic Birefringence Effects

Data on magnetic birefringence in a transverse magnetic field can be used to determine the anisotropies of the MS in a gas, pure liquids, and solutions. Three types of magnetic birefringence are distiguished: in colloids[45] (the Majorana effect,[46] discovered in 1901), in diamagnetic molecules (the Cotton–Mouton effect, 1904),[2,3] and in paramagnetic substances, recently observed in solutions of lanthanide salts and complexes.[4,47]

Strange as it may seem, until recently, attempts to detect the paramagnetic effect were either unsuccessful[48] or declaratory in character;[49] in a number of cases the results contradicted one another,[49-51] and the superposition of other magneto-optical effects also took place.[50-57] Thus Elias[54] apparently observed in $Er(NO_3)_3$ the Voigt effect, that is birefringence in the characteristic absorption bands of the substance or in their direct proximity. In view of the tendency for Ce^{3+} salts to undergo hydrolysis,[58] the study of their aqueous solutions[52,53] apparently involved the Majorana effect in colloidal hydroxoaquo-complexes. An anomalously high magnetic birefringence effect was recorded in liquid oxygen.[55-57] Since however liquid oxygen is a liquid crystal[59] (and this state of matter is characterised by extremely large electro- and magneto-optical effects[60]), its high birefringence is due not to its paramagnetic character but to its liquid-crystal structure.

The molar constants of the diamagnetic ($_mC$) and paramagnetic ($_mP$) effects are described by expressions including the components of the tensors of the optical polarisability (b_{ij}), the diamagnetic susceptibility (k_{ij}), and the *g*-tensor:[47]

$$_mC = (2\pi N/45kT)\,[\Sigma(b_{ii}-b_{jj})(k_{ii}-k_{jj}) + 6\Sigma b_{ij}k_{ij}], \quad (3)$$

$$_mP = [(2\pi N/45kT(T-\delta)]\,(\mu^2/\Sigma g_{ii}^2)\,[(b_{ii}-b_{jj})(g_{ii}^2-g_{jj}^2) + 6\Sigma b_{ij}g_{ij}^2], \quad (4)$$

where N is Avogadro's number, k the Boltzmann constant, T the absolute temperature, δ the Weiss temperature correction to the Curie law in degrees absolute, and μ the magnetic moment in Bohr magnetons. Eqn. (4) clearly shows why the paramagnetic effect could not be observed in solutions of $FeCl_3$ and $Mn(NO_3)_3$ and in K and Na vapour;[48] the effect should be absent in purely spin systems. For systems with strong spin–orbit coupling, the paramagnetic effect is greater by 2–4 orders of magnitude than the Cotton–Mouton effect.[4,47] The latter can in principle be observed for any system both in the gas and in liquids and dilute solutions.[61-63] Unlike the constants of the electric analogue (the Kerr effect), the Cotton–Mouton constants are independent of the dielectric constant of the medium. This is indicated by $_mC$ data for aromatic compounds; the reliable determination of $_mC$ is possible not only for individual liquids ($_mC_l$) but also for solutions ($_mC_s$).[63,64] Further confirmation is provided by the identical values of the anisotropies of the MS of C_6H_6, alkyl halides, and CH_3CN, found by measuring the Zeeman effect in the gas phase and obtained from combined "solution" (Kerr effect) and "liquid" (Cotton–Mouton effect) data.[64] An exceptional place among other compounds is occupied by nitrobenzene, for which $_mC_l$ is almost twice $_mC_s$. This question is discussed in more detail in Section VI.

4. NMR Spectroscopy

Under the influence of strong magnetic fields (> 90 kG), the signals in high-resolution NMR spectra are split, the splitting being proportional to the magnitude of the anisotropy of the MS of the molecules and the square of the intensity of the applied field. This effect is due to the ordering of magnetically anisotropic molecules in liquids (solutions)[5] or gases,[65] which takes place as a result of the interaction of the quadrupole moment of the nuclei with the external field (the effect of dipole interaction is too small, and does not appear under these conditions). The most convenient object for the study of the NMR of partly oriented molecules is deuterium (^2H), since its quadrupole moment is sufficiently large for the splitting in real magnetic fields to be recorded, and at the same time is not so large that the broadening of the lines which it brings about makes it impossible to observe the splitting.[66] In very strong fields (~140 kG), the effect has also been studied at ^1H nuclei.[67,68]

The number of published studies using this approach is small, although it is undoubtedly promising. At present, this method is the only liquid-phase method which makes it possible to calculate all three components of the molecular MS tensor. Apart from halogenomethanes[69] and hydrogen cyanide,[70] this method has been used to find the anisotropies of the MS of only aromatic molecules[5,68,71-73] and anions.[73,74] It has also been applied to paramagnetic molecules.[67]

An alternative approach to the determination of the paramagnetic anisotropy of complexes is to solve the inverse problem, involving the analysis of the values of the pseudo-contact (dipole) contributions to the isotropic chemical shifts of ^{1}H and (or) ^{13}C due to the presence of the paramagnetic ions Co, Ni, and Ln.[75] Unfortunately, the application and accuracy of this method are restricted by a number of factors.[75,76] Nevertheless, it has been used successfully to determine the anisotropies of various complexes, in particular the bis-adducts of lanthanide dipivaloylmethanates with pyridine.[77] The components found in this way agree with the values previously obtained by direct magnetochemical measurements in single crystals.[41]

III. THE RELATIONSHIP BETWEEN MAGNETIC SUSCEPTIBILITY AND ELECTRIC POLARISABILITY

The electric polarisability and the magnetic susceptibility, which describe the deformability of the electron clouds of particles in magnetic and electric fields, are closely related to one another. This can be seen from the expressions

$$k = -(e^2/6mc^2)\Sigma\bar{r}^2, \quad b = (4/9na_0)\,|\Sigma\bar{r}^2|^2,$$

whose combination establishes the relationship between the MS (k) and the electric polarisability (b)[78]

$$k = -(e^2a_0^{1/2}/4mc^2)\,(nb)^{1/4}. \qquad (5)$$

Here, e is the charge of the electron, m its mass, n the total number of electrons in the system, $\Sigma\bar{r}^2$ the sum of the mean-square radii of the electron orbitals, and a_0 the Bohr radius. Eqn. (5) was obtained by Kirkwood, and is applicable for spherical atoms and monatomic ions. The main criticism of this equation is that the magnitude of the polarisability is determined chiefly by the electrons of the valence level, and not the inter levels, whereas all the electrons are equivalent with respect to precession in a magnetic field.[78] Nevertheless, for monatomic systems, good agreement is obtained between the results of experiment and calculation.[78] Kirkwood's model has also been developed for elliptical molecules and bonds. The magnetic susceptibility k_i oriented along the i axis is a function of the polarisability in two orthogonal directions, b_j and b_k:[79]

$$k_i = [-e^2(na_0)^{1/2}/8mc^2]\,[b_j^{1/2} + b_k^{1/2} - (b_j^{1/2} - b_k^{1/2})^2/(b_j^{1/2} + b_k^{1/2})]. \qquad (6)$$

For axially symmetrical systems, the anisotropy of the MS is described by the expression:[80]

$$\gamma = (-e^2/4mc^2)\,(na_0)^{1/4}\,[b_\perp\,(b_\perp^{1/2} - b_\parallel^{1/2})]/(b_\parallel^{1/2} + b_\perp^{1/2}), \qquad (7)$$

where $b_\parallel$ is the polarisability along the axis of cylindrical symmetry, and $b_\perp$ the perpendicular component. Eqn. (5) was subsequently applied to polyatomic molecules, and the difference between the calculated and experimentl MS was assigned *a priori* to the paramagnetic Van Vleck component.[78] Eqn. (6) has been used together with ^{1}H NMR spectroscopic data to estimate the MS and polarisability ellipsoids of the bonds C–C and C–H.[81] Verification of the practical applicability of Eqns. (5)–(7) for the case of the alkyl halides showed, however, that agreement with experiment is not observed at the level of the two invariants and the individual components of the tensor, including that for which the paramagnetic contribution should be small or non-existent.[80]

Analysis of the empirical $\Sigma k_i = f(\Sigma b_i)$ relationships shows that they are for the most part linear, although they are different for compounds of different classes.[82] Thus for a number of organophosphorus compounds containing saturated groups and P–O, P–S, P–Cl, P–H, P–C, P=O, and P=S bonds, the correlation has the form[64]

$$k_i = -0.180\cdot10^{-29} - 1.046(\pm0.037)\,\Sigma b_i\cdot10^{-5}.$$

Correlations with one another should probably be observed not only for the average characteristics of the bonds but also for their anisotropies. This is indicated by the fact that for chloro- and bromohydrocarbons the changes take place in the opposite sense.[80]

IV. THE TENSOR ADDITIVE SCHEME

The efficiency of magnetochemical studies of the structure of molecules depends significantly on the extent to which the additive principle relating molecular properties to the properties of individual atoms, bonds, and fragments is applicable to the anisotropic MS.

This principle is strictly observed for the average MS. This was first noted by Pascal, who pointed out that the difference in the MS of two neighbouring members of the homologue series of n-alkanes is constant. Having analysed the data for a large number of compounds, he concluded that the molar MS averaged over all directions and reduced to one molecule, $\chi_M = N\Sigma k_{ii}/3$, can be described by the relationship $\chi_M = \Sigma n_A\chi_A + \lambda$, where n_A is the number of atoms with MS χ_A in the molecule, and λ a constitutive correction which depends on the nature of the bonds between the atoms.[7,10,12,78] By analogy with the optical polarisabilities (refractions), this relationship can also be expressed in terms of bond characteristics.[78] The additive scheme of scalar MS was subsequently improved many times.[13,83-88] One of its most detailed versions is the system described in Ref.13. The values of the diamagnetic components for different ions are tabulated in Refs.7, 11, and 12. A theoretical validation of Pascal's empirical scheme was given in Ref.89.

In contrast to the scalar characteristics, the additivity of the MS tensor of molecules is not so obvious, except for aromatic hydrocarbons.[84,86,90] It has been shown that the diamagnetic component of the tensor retains additivity, but definite restrictions are imposed on the polarisation paramagnetic component, which changes with change in the symmetry of the orbitals on going from one molecular system to another.[1] It appears that in systems in which delocalised interactions (conjugation and hyperconjugation effects) predominate, so that the symmetry of a molecular orbital can be identified with the symmetry of the molecular framework, the paramagnetic part of the tensor may not be transferable. On the other hand, in molecules in which the interactions are localised (induction effects), that is in which the symmetry of the molecule is not related to the orbital symmetry, the MS tensor should remain additive, since in this case the molecular property is the sum of the properties of the individual bonds. This should be applicable for any electronic characteristic, including paramagnetism, which is independent of temperature.

Thus the MS tensor of 1,2-dibromoethane can be calculated sufficiently accurately from the MS of ethyl bromide (both compounds are characterised by only inductive interactions), in spite of the fact that these molecules have different symmetries and different positions of the centre of mass.[80] In contrast to this, the tensors of the molecules of benzyl bromide and 1,4-xylylene dibromide are not described by a single set of MS. In both compounds there is a strong interaction between a delocalised π-orbital of the aromatic ring and an antibonding orbital of the C−Br bond: $\pi_{ar}-\sigma^*(C-Br)$. In the case of benzyl bromide, the $\pi_{ar}-\sigma^*(C-Br)$ interaction as a result of the presence of the C−Br bond orientated unsymmetrically with respect to the ring leads to breakdown of the symmetry of the π-orbital as a whole, leading to the appearance of a super-additive contribution of the paramagnetic component in the direction perpendicular to the ring. In 1,4-xylylene dibromide, the CH_2Br groups in the *para*-positions increase the symmetry of the π-orbital of the aromatic ring delocalised over the unoccupied C−Br orbitals, and this "removes" the super-additive contribution of the Van Vleck component.[91]

It is convenient to examine the principles of the additivity of the MS tensors of the bonds and the solution of the inverse problem for a number of simple systems.

For a linear polyatomic molecule, the directions of the principal MS of the molecules and the bonds coincide. For non-linear molecules, the valence angles must be taken into account. For triatomic fragments AB_2 with an angle 2θ between the bonds in the system of principal axes, the following relationships apply:

$$k_1=2k_L\cos^2\theta+2k_T\sin^2\theta,$$
$$k_2=2k_L\sin^2\theta+2k_T\cos^2\theta,\quad k_3=2k_V. \tag{8}$$

Here and subsequently, k_1 is the MS directed along the axis of symmetry of the system, and k_2 and k_3 the MS in the other two orthogonal directions; k_L, k_T, and k_V are the longitudinal, transverse, and vertical MS of the bonds respectively. The solution of Eqn.(8) in the system of principal semi-axes of the MS ellipsoid of the bonds has the form:

$$k_V=k_3/2;\quad \gamma=k_L-k_T=(k_1-k_2)/(4\cos^2\theta-2). \tag{9}$$

similarly, for trigonal pyramidal molecules AB_3 (θ is the angle between A−B and the C_{3v} axis),

$$k_1=3(k_L\cos^2\theta+k_T\sin^2\theta),$$
$$k_2=k_3=1.5(k_L\sin^2\theta+k_T\cos^2\theta+k_V). \tag{10}$$

Assuming cylindrical symmetry of the bond ($k_T = k_V$), the solution of the system of equations (10) takes the form:

$$\gamma=k_L-k_T=(k_1-k_2)/1.5(3\cos^2\theta-1). \tag{11}$$

In the tensor additive scheme there is always a parameter whose value must be introduced arbitrarily or determined independently. This is related to the impossibility of separating the anisotropic molecular characteristics into components, even if the molecules contain bonds of only two types. Thus for example for ethane (and other alkanes), the irreducible combination of the anisotropies of the C−C and C−H bonds has the form:

$$\Gamma(C_2H_6)=\gamma(C-C)-2\gamma(C-H). \tag{12}$$

For mono-substituted methanes, the following relationship is applicable:

$$\Gamma(CH_3X)=\gamma(C-X)-\gamma(C-H)=\gamma(R-X). \tag{13}$$

For substituted benzenes which do not have axial symmetry but which contain a substituent with axial symmetry, the expression analogous to Eqn.(13) is converted into a system of equations including the anisotropy of benzene along the axis of symmetry $\Gamma(C_6H_6)$:

$$\Gamma_1(C_6H_5X)=\Gamma(C_6H_6)-1/2[\gamma(C-X)-\gamma(C-H)],$$
$$\Gamma_2(C_6H_5X)=-\Gamma(C_6H_6)/2+\gamma(C-X)-\gamma(C-H), \tag{14}$$

where Γ_1 and Γ_2 are the anisotropies of C_6H_5X perpendicular to and along the C−X bond respectively. In the more complex case of substituted ethylenes, the C=C bond is characterised by three different MS components, and the anisotropic part of the molecular tensor also includes combinations of the constant difference $\gamma(C-X)-\gamma(C-H)$.[92] This parameter in the calculation of the molecular tensor is reduced if the valence angles of the model systems and the systems being studied are close to one another. For clarity, this can be illustrated for the t-butyl derivative, whose molecular anisotropy is given by the expression

$$\Gamma(t\text{-}C_4H_9X)=\gamma(C-H)-\gamma(C-C)+\gamma(C-X). \tag{15}$$

On substitution of Eqns. (12) and (13) in Eqn.(15) and subsequent summation, γ(C−H) is eliminated:

$$\Gamma(t\text{-}C_4H_9X)=\Gamma(CH_3X)-\Gamma(CH_3X).$$

In contrast to methods involving the use of the Zeeman effect and NMR in strong fields, the method based on the measurement of the Cotton−Mouton effect makes it possible to determine the components of the MS only in the axially symmetrical approximation ($k_\parallel$ and $k_\perp$). The simultaneous examination of ${}_mC$ for several related compounds, for example homologues or molecules containing different numbers of identical functional groups, however, makes it possible to estimate the principal components of the MS for less symmetrical substituents. Thus in the determination of the three components of the MS tensor of the nitro-group it was assumed that γ(C−H) = 0, and a system of equations with three Cotton−Mouton constants for nitrobenzenes and *m*- and *p*-dinitrobenzenes was examined. After substituting the known numerical values of the fundamental constants and the tensors of the electric polarisability and the anisotropy of the MS of the benzene ring with allowance for the geometry of the molecules, expressions were obtained for ${}_mC$ as functions of the anisotropies $\gamma_1 = k_1-k_2$ and $\gamma_2 = k_1-k_3$ (k_1 is directed along the C−NO_2 symmetry axis, and k_3 is normal to the plane of the group):

$${}_mC(NB)=(-2.57\gamma_1+12.40\gamma_2+131.2\cdot10^{-29})/48.08\cdot10^{14},$$
$${}_mC(m\text{-}DNB)=(-15.75\gamma_1+37.8\gamma_2+199\cdot10^{-29})/48.08\cdot10^{14}. \tag{16}$$

Using the known experimental values of ${}_mC$ for NB, *m*-DNB, and *p*-DNB (3.83×10^{-15} emu, 6.00×10^{-15} emu, and 4.70×10^{-15} emu respectively), it can readily be shown that $\gamma_1 = 0.8\times10^{-29}$ cm^3 and $\gamma_2 = 2.7\times10^{-29}$ cm^3.[93] The values of γ_1 and γ_2, and also of k_l for the nitro-group, given in Ref.94, are incorrect, because of an error in writing the system of equations (16). Similarly, the triaxial MS tensor of the carbonyl group was calculated using the values of ${}_mC$ for acetone and cyclohexanone[95] and the tensors of the C=C bond (the corresponding values for *cis*- and *trans*-dichloroethylenes[92]) and the $C_{ar}-O$ bonds (the constants for different substituted anisoles[96]). The tensor characteristics of the bonds of a number of saturated and unsaturated molecules have been found from data on the Zeeman effect by averaging the MS of these bonds by the least-squares method.[1] The assumptions that the anisotropy of the MS of the C−H bond is independent of the hybridisation of the C atom and that k_T and k_V are equal, and also the differences in the valence

angles at the C_{sp^3}, C_{sp^2}, and C_{sp} atoms, made it possible to distinguish $\gamma(C-H)$. This quantity was found to be negative, as confirmed by the data in Ref.92, although it does not agree with Ref.97.

An approach based on the isotropic character of the C—H bonds is widely used in the analysis of tensor electric polarisabilities;[79] it facilitates considerably the calculation of the anisotropic molecular characteristics, since a knowledge of the spatial positions of the C—H bonds in the molecular structures and confirmations is not required. The relative values of the tensor additive MS of bonds, based on the assumption that the C—H bonds are isotropic, are given in Table 1. The values were calculated by the present authors from published data on the molecular ellipsoids or anisotropies of the MS obtained by the above methods. The Table does not include the data from Ref.98, which are erroneous.[43]

Table 1. Tensor additive magnetic susceptibilities of different bonds and groups, calculated assuming that the C—H bonds are isotropic ($k_t(\gamma) \times 10^{29}$, cm^3).

Table 1 (continued).

* Calculated from averaged data.[1]

Note: SC = method based on measurements of the MS of single crystals; CM = method based on the use of the Cotton—Mouton effect; Z = method based on the use of the Zeeman effect; NMR = NMR of partly orientated molecules; the state of aggregation of the substance is indicated in brackets: g = gas, l = liquid, s = solution.

The absolute values of the bond and group anisotropies are required in the analysis of intramolecular magnetic parameters such as the chemical shifts or the cones of the magnetic shielding in NMR spectroscopy.

NMR makes it possible to use the values of the chemical shifts (usually of ^{1}H and ^{13}C) to estimate the absolute anisotropies of individual bonds and groups of atoms. This estimation is based on the dependence of the shielding constants of the protons on a number of electronic properties, including the anisotropy of the MS of the fragments adjoining the proton. In existing models, the anisotropic fragment is represented as a point,[111] a one-dimensional dipole[97] or, which is most correct, as a closed contour of finite dimensions with electrons circulating in it.[112,113] It is convenient to carry out specific calculations for a known molecular geometry using the published magnetic iso-shielding map.[113] Here it is also necessary to take into account the contribution of the electrostatic component.[20] To eliminate effects transferred along the chain of atoms, the differences in the chemical shifts of geminal protons or protons in configurational (conformational) isomers are usually examined. It should be emphasised that the approach described is extremely approximate, and includes a number of assumptions, such as the localisation of the centre of the magnetic dipole or the maximum electron density of the substituent; in addition, there arise the questions of the applicability of the models of the dipole and non-dipole approximations used and allowance for intramolecular electronic interactions (induction, conjugation, hyperconjugation, and the field effect). Nevertheless, NMR spectroscopy is apparently the only method which makes it possible, particularly when combined with magneto-optical data, to separate the combinations of the anisotropies of the MS of bonds. This method was used, for example, to determine the anisotropy of the MS of the lone pair of electrons of the phosphorus atom.[110] The tensor additive characteristics of various chemical bonds and groups, found using the above models, are given in Table 2. It is emphasised that the data in Table 2 must be regarded as tentative, since they were obtained by different authors in different approximations. It is also obvious that the values of the anisotropic MS in Tables 1 and 2 cannot be compared without appropriate recalculation.

*LPE = lone pair of electrons of the phosphorus atom.

The paramagnetic susceptibility of complexes and ions is determined by the number of unpaired electrons and by the symmetry and strength of the ligand field.[9,136] Since the orientational paramagnetism is characteristic of a specific ion, the concept of additivity of the paramagnetic susceptibility tensor for mononuclear systems loses its meaning, and the primary problem becomes its transferability from one type of molecule to another. The transferability of the average characteristic of the tensor in the 4*f* lanthanide elements is well known (their magnetic moments are practically independent of the environment[12]), but it is greatly restricted for transition metal complexes. The individual components of the tensor, and the anisotropy, are more sensitive to the environment of the ion, although judging from paramagnetic birefringence data, satisfactory transferability of the tensor paramagnetic characteristics is also observed in various inner-complex compounds of the lanthanides with different degrees of coordination.[47,137,138] The dependence of the components of the paramagnetic susceptibility tensor on the symmetry of the crystal field has been clearly demonstrated.[139] The quantitative calculations are based on the fundamental theory of Van Vleck.[9] Examples of the calculation of the anisotropies of the lanthanides are given in Refs.76 and 136. One of the corresponding calculation programs is described in Ref.140.

V. EFFECTS OF THE MUTUAL INFLUENCE OF ATOMS AND THE MAGNETIC SUSCEPTIBILITY TENSOR

1. Magnetic Properties and the Nature of the Chemical Bond

The dependence of the anisotropy of the MS of a chemical bond on its nature (symmetry, multiplicity, and the hybridisation of the atoms forming it) and on the effect of neighbouring substituents has not been studied systematically. Sufficient experimental material (see Table 1) has now been accumulated, however, to make possible a number of simple generalisations.

1) Most bonds with cylindrical symmetry, whether single (C—C, C—F, C—Cl, C—Br, C—I, C—N, C—O, C—S, P—Cl, P—O, N—H) or multiple (C≡C, C≡N, C≡P, P=S), show maximum diamagnetism in the longitudinal direction, that is negative anisotropy.

2) For substituents which do not have axial symmetry, a decrease in the diamagnetism in the plane of the fragment and an increase in the vertical component along the axes of the *p* electrons (P=O, C=S, C=C, C—NO_2) are observed, as in aromatic systems.

3) The absolute magnitude of the anisotropies of the MS of bonds between atoms which have similar electronic structures (C—O and C—S; C=O and C=S; C=N and C=P; C—F, C—Cl, C—Br, and C—I) increases with increase in the atomic number of the element.

The influence of the nature of atoms in the same period of the periodic system does not show clearly defined regularities.

4) The magnetic anisotropy of a bond is not constant, and depends on the nature of the surrounding substituents. Thus its absolute magnitude increases with increase in the electronegativity (methyl and methylene halides and haloforms) and size of neighbouring groups of atoms (halogen derivatives).

The influence of the effects of the immediate environment, in particular the change in the double-bond character, can be clearly seen in the series of C–O bonds on going from aliphatic to aromatic ethers and carbonyl derivatives. In dioxan, as in 2,6-dimethylanisole, where as a consequence of the orthogonality of the methoxy-group there is no conjugation of the phenyl group with the p pair of electrons of the O atom, the MS tensor of the $C_{ar}-O$ bond retains axial symmetry, its components are diamagnetic, and $k_L < k_T$. In anisole, in which as a consequence of $\pi_{ar}-p_o$ conjugation the $C_{sp^2}-O$ bond acquires some multiplicity, the diamagnetism is preserved for k_L, decreases for k_T, and increases for k_V. The existence of paramagnetism in the plane of the C=O double bond is therefore quite regular.

2. Magnetic Susceptibility as a Criterion of Aromaticity

The problem of aromaticity has been examined in a large number of papers on magnetochemistry, dealing with the effects of the mutual influence of atoms. Among the various indices of aromaticity which have been used, the criterion based on the MS obviously has the strongest physical foundation, since the MS tensor is determined directly by the degree of delocalisation of the π-electrons in cyclic systems. Magnetochemical studies of aromaticity have been based on the assumption that any interaction can be described quantitatively by the deviation from additivity of those properties in which this interaction is revealed. For the electric polarisability, deviations from additivity are observed not only for aromatic molecules but also for other conjugated molecules, whereas for MS, super-additive contributions for both the average values ($\Lambda = \chi_{expt}-\chi_{add}$)[141–143] and the anisotropies,[144] and also the vertical components of the tensor,[145] are characteristic mainly of aromatic compounds.

The sharp increase in the diamagnetic properties in aromatic systems compared with all other compounds has been effectively explained using the ring current model.[7,78] From the ratios of the areas of the circulation of the π-electrons (S), expressed in terms of the anisotropy of the MS

$$\sum_p S = -\gamma\,(4\pi mc^2)/e^2$$

and in terms of the geometric dimensions of the ring $\Sigma S = \pi\Sigma\bar{r}_r^2$, it is possible to determine the effective radius of circulation ($\bar{r}^2$) (for a given number of circulating π-electrons p) or the effective number of electrons involved in the circulation.[146] This method has been used to estimate the parameters $\overline{S}$ and $\bar{r}$ for a series of aromatic hydrocarbons and simple heterocyclic compounds.[147] A study of the magneto-optical properties of a number of aromatic hydrocarbons and their corresponding quinone derivatives showed that the aromatic hydrocarbons have a higher MS anisotropy than their quinones, that is the production of the quinone structure leads to a decrease in the mobility of the π-electrons: Γ(benzene)/Γ(1,4-benzoquinone) = 1.37; Γ(naphthalene)/Γ(1,4-naphthoquinone) = 1.16; Γ(anthracene)/Γ(9,10-anthraquinone) = 1.19; and Γ(phenanthrene)/Γ(9-10-phenanthraquinone) = 1.23.[148] The Cotton–Mouton effect was used for a simple estimate of the aromaticity. Thus for 1,4-dithiin, the agreement between the experimental value of ${}_mC$ and the value calculated from the additivity principle indicates that there is no electron delocalisation.[149]

The ring current model has been heavily criticised. An extreme view is that because of the additivity of the MS of aromatic hydrocarbons, the agreement between the conclusions reached from this model and the real properties of molecules is accidental.[90,150,151] This conclusion cannot be fully accepted, however, since it has not been proved that "ring currents" should not obey the rule of additivity, particularly secondary additivity. In a calculation of molecular MS, Musher[150] was forced to introduce different tensor characteristics for the C atoms involved in the formation of C–H bonds on the one hand, and the C–C bonds shared by the two condensed rings on the other. It is not excluded that this differentiation of the magnetic anisotropies includes in implicit form the differences in the change in the number of π-electrons and the areas of their circulation on going from mono- to polynuclear systems. A more correct approach is that in which the MS of an aromatic fragment is represented by two terms: a localised term (k_l) which is due to the induced currents in the individual atoms and bonds and which is calculated using an additive scheme, and a delocalised term (k_d). The latter consists of two components with opposite signs: a diamagnetic component created by the ring currents of a single aromatic π-orbital, and a paramagnetic component produced as a result of a decrease in the delocalisation.[22] For example, it follows from Ref.145 (Table 3) that in benzene the localised component describes the MS completely in the plane of the ring and to the extent of 60% in the perpendicular direction. A similar picture is observed in heterocyclic and polynuclear systems.[152–154] Thus a quantitative measure of the aromaticity (A) of any substance relative to benzene should be provided by the ratios of the perpendicular components corresponding to the anisotropies of the delocalised MS or the exaltations of the average MS for benzene and the molecule being studied (M):

$$A = [k_{\perp d}(C_6H_6)/k_{\perp d}(M)] \approx [\gamma_d(C_6H_6)/\gamma_d(M)] \approx [\bar{\Lambda}(C_6H_6)/\bar{\Lambda}(M)]\,,$$

where $k_{\perp d} = k_{\perp expt}-k_{\perp add}$, $\gamma_d = \gamma_{expt}-\gamma_{add}$, $\Lambda = \Lambda_{expt}-\Lambda_{add}$.

The replacement of a CH group in benzene by N leads to a considerable decrease in the electron delocalisation and hence in the aromaticity in the series benzene > pyridine ≃ pyridazine ≃ pyrazine > pyrimidine > S-triazine.[153] The degrees of delocalisation in pyrrole, pyrazole, and imidazole, and also their N-methyl derivatives, are similar to one another.[154] These conclusions show qualitative agreement with results obtained in a study of the Zeeman effect in isoxazole and oxazole,[152] their thio-analogues,[155] and furan;[145] the degree of delocalisation of the electrons in furan is much less than that in benzene; in oxazole and isoxazole, a further decrease in the delocalisation is observed, and the level of aromaticity of thiophene is approximately the same as that of pyrrole. An interesting feature is that cyclopentadiene also shows excess delocalisation, although to a smaller extent than in furan; this arises as a result of the hyperconjugation of the methylene group with the π-electrons of the double bonds; in fulvene, the delocalisation of the electron cloud is even smaller[145] (Table 3).

In a study of the influence of dissociation on the magnetic anisotropy of aromatic molecules by ^2H NMR in a strong field, it was established that Γ for the fluorenyl anion is greater than Γ for fluorene,[73] whereas the values of Γ for anthracene[5] and its carbacation[74] are equal.

Magnetic birefringence has been used to study the influence of the nature of the nitrogen atoms in aniline, N,N-dimethylaniline, and the corresponding anilinium and N,N,N-trimethylanilinium derivatives on the anisotropy of the MS of the phenyl group.[44,156] The anisotropy of the MS of the aromatic ring in the anilines is depressed compared with the MS of benzene, whereas in N,N-dimethylaniline the additivity is preserved; this reflects the difference in the strength of the conjugation of the lone pair of electrons of nitrogen with the

phenyl ring.[44] Protonation of aniline "restores" the magnetic anisotropy to the value characteristic of benzene. Thus the positive charge of the NH_3 group has no influence on the magneto-optical properties of the ring. The anisotropy of the N,N,N-trimethylanilinium cation decreases sharply under the influence of the excess charge.[156] This difference is due chiefly to intermolecular and not intramolecular effects;[157] in the substituent $\dot{N}(CH_3)_3$, the charge is situated chiefly on the N atom and is shielded from the hydrate layer of the solvent by the methyl groups. In the $\dot{N}H_3$ group, the excess charge is delocalised over all the N–H bonds, so that it is compensated to a considerable extent by the surrounding water molecules.

Table 3. Anisotropic magnetic susceptibilities of molecules as a criterion of aromaticity.[145]

VI. MAGNETIC ANISOTROPY AND PROBLEMS OF STEREOCHEMISTRY

The systematic magnetochemical study of the spatial structure of molecules was begun comparatively recently. It is based chiefly on magneto-optical and resonance methods. Of particular interest are studies based on an analysis of the relationship between magnetic anisotropies and the chemical shifts of the ^1H and ^{13}C nuclei. The extensive information provided by this method, particularly for paramagnetic systems, the relative simplicity of the experimental procedure, and the possibility of theoretical interpretation of the results not only qualitatively but also quantitatively, led in the early nineteen-seventies to the publication of a large number of papers and to the development of an independent field, namely NMR using paramagnetic shift reagents. The method has been described in detail in many monographs, textbooks, and reviews (see for example Refs.75, 76, and 158–161), and therefore will not be discussed in the present work.

1. The Spatial Structure of Molecules and Complexes

Unlike its electric analogue, that is the Kerr effect, the Cotton–Mouton effect has been applied to conformational analysis to only a slight extent, although it should carry information on the spatial structure of molecules.[162] The molar Cotton–Mouton constants, and also the paramagnetic birefringence constants, are macroscopically additive. Moreover, the anisotropic components of ${}_mC$ and ${}_mP$ are also additive at the intramolecular level. The magnetic susceptibility of weakly magnetic substances is practically 1, so that the molecules of a solute are influenced by a magnetic field with practically the same intensity as the external field.[163] It is therefore possible to use magnetic birefringence to study the structure of molecules in the liquid condensed state. The accuracy of the results obtained using the Cotton–Mouton effect in conformation studies is such that the difference between the calculated magneto-optical constants of individual conformers is at least an order of magnitude greater than the uncertainty in their determination from the experimental data.[162]

The possibility of using the Cotton–Mouton effect in conformational analysis was first demonstrated for biphenyl (0°) and its structural analogues 2,2′-bipyridyl (25 °), 9,9′-dianthranyl (62°), 9-phenylanthracene (70°), 1-phenylnaphthalene (66°), and 1,3,5-triphenylbenzene (35°).[164] The dihedral angles φ characterising the deviations from planarity are given in brackets. In 1,3,5-triphenylbenzene and *sym*-triphenyltriazine, the angles φ are 30 ± 10° and 15 ± 15° respectively, and for tri(2-pyridinyl)-S-triazine in CCl_4, the existence of two conformers with different dihedral angles φ = 15 ± 5° has been established.[165] The measured magnetic birefringence in benzophenone and its *p*-chloro-, *p*-bromo-, *p*-methyl-, and *p*-methoxy-derivatives dissolved in CCl_4 was used to estimate the angles φ of the aromatic rings.[95] The angle of non-coplanarity of the nitrogroup in the *ortho*-position relative to the methyl group in trinitrotoluene is 50°,[93] and that in 4-nitrobiphenyl is 23°.[166] The study of individual liquid alkyl halides has confirmed that the *trans*-orientation of the C–Br bonds is preferred in methyl-substituted 1,2-dibromoethanes and cyclohexanes, and the *gauche* orientation of the C–C and C–Hal bonds is preferred in 1,3-dihalogenopropanes.[162] In the series of halogenopropanes and their methyl derivatives with the general formula $C(R^1R^2R^3)C(R^4R^5)Hal$, where Hal = Cl, Br, I, and R = H and (or) CH_3, the asymmetric *gauche* structures predominate in the pure liquids; the conformational energies of these structures are not additive, and are determined by hyperconjugative interactions $\pi[(CH_2)$ or $C(CH_3)_2] - \sigma^*(C-Hal)$.[167]

In the study of compounds containing functional groups with several axes of internal rotation, the simple application of one physical method (except diffraction methods) is insufficient. To solve a many-parameter structural problem, it is usual to employ either a combination of several methods or (and) data obtained by a single method but covering a group of compounds with the same conformation.[168] Studies of the spatial structure and conformational composition of halogen-substituted arylethanes were based on these principles.[169–172] In a complex graphical analysis of the structure of molecules,[168] new methods were proposed for determining conformations using the Cotton–Mouton effect. For this purpose, graphs of the "property–property" type are constructed: ${}_mC(C_6H_5) - {}_mC(p\text{-}X-C_6H_4)$ for a group of compounds with the same conformation,[169] and ${}_mC - {}_mK$ (${}_mK$ is the Kerr constant) for a given compound.[170] Dipole moment and ^1H NMR spectroscopic data show that 2-halogenoethylbenzenes in CCl_4 consist of equilibrium mixtures of the *trans*- and *gauche*-rotamers approximately

equally populated with respect to the ethane bond C—C. In the *gauche* form, according to data obtained using the Kerr effect, the aromatic ring shields the C—H bond. The angle of rotation of the aryl group in the *trans*-conformer was found by analysing the ${}_mC(C_6H_5CH_2CH_2Cl) - {}_mC(p\text{-}Cl-C_6H_4CH_2CH_2Cl)$ relationship.[169] The structures of 1,2-dihalogenoethylbenzenes,[171] 1,1-diphenyl-1,2-dihalogenoethanes,[172] and 1,2,2-tribromo-1-phenylethane[170] were studied similarly.

The mutual orientation of the chelate rings in molecular complexes of the lanthanides based on α,β-diketones has been studied by paramagnetic birefringence.[137,138] For the complexes of Pr and Dy with *tris*-3-trifluoroacetylcamphors, which are monomeric in $HCCl_3$ [Ln(Facam)$_3$] and dimeric in CCl_4 [Ln_2(Facam)$_6$], octahedral structures were found.[137] A structure close to octahedral was established for the adducts $Dy_2(Facam)_6.3DMF$ and $Dy(Facam)_3.2DMF$. Paramagnetic birefringence also gives information on the orientation of the molecular or ionic fragments of complexes relative to the direction of the paramagnetic anisotropy of the central ion.[47,173] In the mono-adducts of Er and Tb dipivaloylmethanates with pyridine [Ln(DPM)$_3$Py] in CCl_4, the plane of the aromatic heterocyclic ring is perpendicular to one of the principal axes of the paramagnetic susceptibility tensor.[47]

2. Orientational Effects of Solvation and Complex Formation

Magnetic birefringence and NMR spectroscopy are extremely sensitive to the effects of liquid-phase structure formation. Thus in ^1H NMR, the phenomenon of a chemical shift induced by aromatic solvents is observed; this is produced by the magnetically anisotropic continuum created by preferentially orientated aromatic molecules of the solvent arranged round the polar molecule of the solute.[174–176] New possibilities for studying intramolecular interactions influencing the alignment of molecules in liquids are being opened up by high-resolution NMR spectroscopy in strong magnetic fields.[5] In a study of the influence of the concentration of the substance and the nature of the solvent on the magnitude of the anisotropies of the MS of nitrobenzene and *m*-dinitrobenzene, a sharp decrease in the anisotropy of nitrobenzene was observed on going from the pure liquid ($\Gamma_1 = -34 \times 10^{-29}$ cm^3) to the solutions with extrapolation to infinite dilution ($_\infty\Gamma = -15 \times 10^{-29}$ cm^3).[72] In the case of benzene, a slightly different picture is observed; in $(CD_3)_2CO$, $_\infty\Gamma = -11.1 \times 10^{-29}$ cm^3, but with increase in concentration; $|\Gamma|$ begins to decrease, reaching a constant value of -9.3×10^{-29} cm^3 in a 60% solution of benzene in deuterioacetone. For naphthalene, a concentration dependence of Γ was not observed.[72] The data obtained agree with the results of magneto-optical studies;[43,62] the ratios $C_1/_\infty({}_mC)$ for benzene and nitrobenzene are of the same order of magnitude as the ratios $\Gamma_1/_\infty\Gamma$.

A quantitative approach to the estimation of the effects of liquid-phase ordering, estimated by the Cotton—Mouton method, has been proposed.[177] In the continuum model and the axially symmetrical approximation, the Cotton—Mouton constant of a solvated molecule has the form

$$ {}_mC = (2\pi N/45kT)\{2(b_\parallel - b_\perp)(k_\parallel - k_\perp) + [(b_\parallel - b_\perp)(k'_\parallel - k'_\perp) + (b'_\parallel - b'_\perp)(k_\parallel - k_\perp)]\langle(3\cos^2\theta - 1)\rangle\}, $$

where $\langle(3\cos^2\theta - 1)\rangle$ is the angular correlation factor, and b_i, k_i and b'_i, k'_i the electric and magnetic parameters of the molecules of the solute and the solvent respectively. For an individual liquid, the expression is simplified:

$$ {}_mC_l = (4\pi N/45kT)[(b_\parallel - b_\perp)(k_\parallel - k_\perp)]\{1 + (1/2)\langle\Sigma(3\cos^2\theta_j - 1)\rangle\}. $$

The corresponding solvation contribution obviously has the form:

$$ \Delta_mC = (2\pi N/45kT)(b_\parallel - b_\perp)(k_\parallel - k_\perp)\langle\Sigma(3\cos^2\theta_j - 1)\rangle. $$

Δ_mC is determined experimentally as the difference in the molar constants of the individual liquid and its dilute solutions in an inert solvent with subsequent extrapolation to infinite dilution: $-\Delta_mC = {}_mC_l - {}_\infty({}_mC_s)$. The angular correlation parameters can then be found from the relationship

$$ \Delta_mC_l/_\infty({}_mC_s) = (1/2)\langle\Sigma(3\cos^2\theta_j - 1)\rangle. $$

The numerical values of the ratios $\Delta_mC_l/_\infty({}_mC_s)$ are small, and their signs may be different; negative signs indicate the existence of chiefly ternary mutually perpendicular correlations, and positive signs indicate the existence of parallel correlations. They have been calculated for a large group of aromatic compounds.[63,64] The orientational effects of solvation are revealed most clearly in the magneto-optical anisotropy of nitrobenzene. The Cotton—Mouton constants have been obtained for nitrobenzene in 19 solvents of different character and polarity.[63] The ${}_mC$ values for this compound vary over a very wide range from $(3.3-3.4) \times 10^{-15}$ emu in dioxan, CCl_4, C_6H_6, and $HCCl_3$ to 7.5×10^{-15} emu in benzonitrile; for individual liquid nitrobenzene, ${}_mC = 6.4 \times 10^{-15}$ emu. In this case, the Cotton—Mouton constant is described by the relationship

$$ {}_mC = {}_mC_0 + A\mu\Delta k_\mu + B\mu\Delta b_\mu, $$

where Δk_μ and Δb_μ are the anisotropies of the MS and the polarisability in the direction of the molecular electric dipole moment μ. The theoretical analysis carried out indicated that a decisive role in determining the orientations round the solute molecules is played by interactions of the "solute dipole—solvent dipole" and "solute dipole—solvent quadrupole" type. A similar conclusion was reached in Refs.174—176.

In the study of the phenomena of complex formation and solvation in solutions of paramagnetic compounds, important information can be obtained by examining the effect of paramagnetic birefringence. This effect is extremely marked for complexes consisting of molecules or ions of two kinds, one of which is characterised by high anisotropy of the MS and low anisotropy of the electric polarisability, while the other has the opposite properties. For simple mixing of these species, that is in the absence of complex formation, the paramagnetic birefringence effect is small, and it is increased sharply only by the formation of associates accompanied by preferential mutual orientation of the central ion and the ligands.[173] Magneto-optical titration in CCl_4 has established the formation of an adduct of DMF with dysprosium *tris*-3-trifluoromethylacetylcamphorate with the 3:2 composition. The magnetic birefringence constant of this complex (-1300×10^{-15} emu) is approximately four orders of magnitude greater than the corresponding constant of DMF (0.17×10^{-15} emu). In an excess of DMF, the 1:2 complex is formed.[138] The formation of mono-adducts of Ln(DPM)$_3$ with pyridine in CCl_4 was confirmed similarly.[47]

- - - o 0 o - - -

Several new fields of study have developed in molecular magnetochemistry on the basis of the study of the rotational Zeeman effect, the Cotton—Mouton effect, linear birefringence in solutions of paramagnetic substances, and the high-resolution NMR of partly

oriented molecules in strong magnetic fields. The study of the anisotropic properties of molecules gives information of a qualitatively higher level than the study of their average properties. This makes it possible to include in the range of interests of magnetochemistry a number of fundamental problems of the stereochemistry of organic and complex compounds, and intramolecular and intermolecular interactions. Among the most promising fields of application of data on magnetic anisotropy, special mention must be made of the theory of the mutual influence of atoms, and in particular the problem of aromaticity. A second field is the study of the orientational effects of association and complex formation in liquid media, the effects of structure formation appearing in pure liquids, and the structural aspects of solvation, including that in electrolyte solutions. Finally, a third field is the conformational analysis of molecules in condensed liquid media and polar solvents, and also of complex ionised species and compounds of biological importance. The progress of molecular magnetochemistry in these fields obviously depends directly on the further development and improvement of the magnetic susceptibility tensor additive scheme.

NMR Spectroscopy of Azo Dyes

L.A.Fedorov

The known NMR spectroscopy data on different types of synthetic azo and polyazo dyes, including metal complexes, are correlated. The fundamentally new opportunities in the NMR spectroscopy of ^{1}H, ^{13}C, and ^{15}N nuclei in solving problems of structural chemistry in this field of industrial chemistry are demonstrated.
The bibliography includes 124 references.

I. INTRODUCTION

In relation to the practical application of synthetic dyes in chemistry and technology, azo compounds X−N=N−Y probably constitute the most important, diverse, and structurally ramified class of compounds.[1-5] Formazans −N=N−C(X)=N−NH− are also starting to be used actively in the chemistry of dyes.[5] While NMR spectroscopy as a powerful instrument for research into the molecular structure of compounds in solution and in the solid state is used for analysis of the structure and properties of azo dyes, the scale of its practical application falls short of the potentialities of this very same physical method and the number of unresolved problems in the chemistry of synthetic dyes. The first and until now only reviews on the NMR spectroscopy of synthetic dyes, primarily in its simplest form, appeared in the middle of the 1970's,[6,7] and they do not include the complete range of methods and wealth of opportunities which characterises the NMR spectroscopy of recent years. On the other hand, the chemistry of synthetic dyes is a forerunner of contemporary industrial chemistry and is frequently based on outdated concepts about the structure of some of its members, although many problems can be solved and have already been solved by means of NMR spectroscopy.

An attempt is made in the present work to correlate the existing NMR data on the structure and properties of azo dyes in solution and in the solid state and also on the methods of using NMR spectroscopy to resolve problems of structural chemistry in this area of chemistry.

Ideas about the actual structure of aromatic azo dyes in solution developed in spiral fashion, as so often happens, and NMR spectroscopy made a significant contribution to the solution of this problem and in a number of cases played a decisive role. By about 1970 the collection of NMR spectroscopy data obtained[8-20] (equally using other methods, see, for example one review[21]) contributed quite considerably to the understanding of the structure of these compounds in solution.[15] However, only in the last 15−17 years has the role of NMR spectroscopy in solving problems of azo dye chemistry become really significant.

The fact cannot be ignored that the structural problems of the chemistry of azo dyes and formazans are essentially inseparable from such fundamental chemical concepts as intramolecular hydrogen bonding, azo−quinone hydrazone tautomerism, internal rotation in molecules, complex formation of azo dyes with metal ions, and so forth. We have naturally taken this into account.

The aim of the present review is to show how the problems of the chemistry of synthetic azo dyes and formazans can be seen in the light of the existing information and potential applications of contemporary NMR spectroscopy. We believe that such a type of examination will be of some use to specialists working in this field of chemistry.

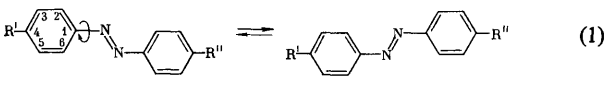
II. CHARACTERISTICS IN STUDYING AZO DYES BY NMR SPECTROSCOPY

(a) NMR Spectroscopy of Different Nuclei in Solution

^{1}H NMR spectroscopy has provided information about the structure of azo dyes in solution,[8-19, 22-49] including those containing a heterocyclic fragment.[34-39] In particular, information about the shielding of mobile protons in OH, NH, and SH groups, which are very frequently encountered in azo dyes, has proved productive. These and other findings provide definite information on intramolecular hydrogen bonding[8,11,18,27] and the tautomeric state[9,49] in azo dyes, on their protonation[12,13,16] and complex formation with metal ions,[28-33] and make it possible to build up initial ideas about their structure and transformations in solution.

In recent years, starting with one report,[50] a large amount of data has been obtained on the NMR spectroscopy of ^{13}C nuclei. These atoms constitute the skeleton of aromatic azo dyes and the information obtained is therefore especially useful. From the information available,[50-104] including that on compounds that do not contain functional hydroxy or amino groups,[50,81-93] it is possible to have

some idea about the electron distribution in the molecules,[50,88,89] to determine the barriers of internal rotation about the

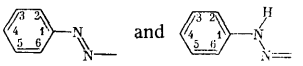


bond,[84,85] and to consider questions concerning the formation and cleavage of intramolecular hydrogen bonds in azo dyes,[59,62] the presence or absence of tautomerism in them,[70–74, 99, 101, 103, 104] and the spectral distinctions between *cis*- and *trans*-isomers.[90,91,93,100] All this information provides the necessary basis for an unequivocal interpretation of the ^{13}C NMR spectra of many types of azo dyes, including those containing heterocyclic groups.[66–69] It also provides the basis for making calculations to predict ^{13}C NMR spectra and computer knowledge of previously unstudied or newly synthesised dyes. There is also NMR information on dyes which has been obtained on ^{15}N,[93–109] ^{14}N,[20] and ^{17}O[19] nuclei; but the practical study of ^{15}N and ^{17}O nuclei at the present time is not yet as easy as it has become for ^{13}C and ^{1}H.

The NMR spectroscopy results on synthetic azo dyes are not limited to information on the shielding of their nuclei. In order to determine the structure and tautomeric state of the molecules, the results of studying various types of spin-spin coupling constant have been used, for example, mainly for ^{15}N-labelled molecules.[14,15,101, 103,106] Other techniques included in the arsenal of contemporary NMR spectroscopy have also been used—isotope effects,[94,96] temperature-dependent NMR spectra,[14,15,27] analysis of solvation effects,[62,72] two-dimensional spectroscopy,[104] and NMR titration.[57,58,64]

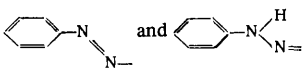
(b) NMR in the Solid State and Other Applications

The study of azo dyes in the solid state using high-resolution NMR spectroscopy started only in recent years.[77–80] Thus, in the first study of this type,[77] splitting of the signals from the *ortho*- and *meta*-carbon atoms was found in the solid state when the ^{13}C NMR spectra of *trans*-azobenzene and a large number of its *p,p'*-substituted derivatives (I) ($R' = R'' = H$, CH_3, OH, COOH, etc.) were studied. The overall range of differences ($\Delta\delta$) in the shielding of nuclei amounted to 13–18 p.p.m. for C(2,6) and 1.5–3 p.p.m. for C(3,5), and are thus virtually no different from what was observed in solution. The informative nature of high-resolution ^{13}C NMR spectroscopy in the solid state was demonstrated[77] when the first real example—the azo dye Disperse Orange—was studied. However, it should be emphasised that a more productive application of this branch of NMR spectroscopy is associated with solving the question concerning the unequivocal interpretation of NMR spectra, and the first steps in this direction have already been taken in the study[78] of the ^{13}C NMR spectra of Pigment Red 57:1 and for some other dyes that are azo derivatives of 2-naphthol (Pigments Red 1, 3, and 6).[80]



(1)

(I)



We can indicate other examples of using NMR spectroscopy that are important for the chemistry and technology of azo dyes such as analysis of the reaction of azo dyes with a substrate material,[45,46,52, 65,110] including those forming a mesomorphic phase[46] and investigation of their photo- and thermal isomerisation.[43,44,111] The aggregation of azo dye molecules in solution, and so on, has been examined.[48] All these reports undoubtedly constitute no more than the beginning of a wide range of research work which is expected to appear in the very near future, taking into account the progress in NMR spectroscopy in creating very new, extremely effective, and informative research methods.

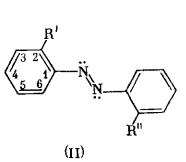
(c) Distinguishing Features of NMR Spectroscopy in Determining the Structure of Azo Dyes in Solution

One of these is directly related to the problem concerning the effect of the azo group on shielding of ^{13}C nuclei in the aromatic ring of the diazo component of azo dyes. Thus, fairly recently the basic possibility of differences in the ^{13}C NMR spectra of the phenylazo group in two fixed and structurally distinct positions was

demonstrated.[51] This fragment was subsequently used[66,69] as a convenient diagnostic instrument in the unequivocal determination of the structure of azo dyes using NMR (in azo derivatives of 5-pyrazoline,[63,99] chromotropic acid,[55] H-acid,[61] the simplest hydroxyazo compounds used to synthesise metal-complex dyes,[59] and so forth). Moreover, this method has been successfully used for a qualitative assessment of the position of the azo–quinone hydrazone tautomeric equilibrium in azo dyes (for example, azo derivatives of 2-naphthol,[72,99] violet acid,[63] etc.). It transpired that the

groups differ markedly and clearly with respect to their shielding of carbon nuclei. When changing from a phenylazo to a phenylhydrazone group there is an upfield shift in signals from C(1), C(2), and C(4) (by ~11, 7, and 5 p.p.m. respectively). Of course, in the chemistry of synthetic azo dyes the phenyl group itself is not used so much as mono- and poly-substituted aromatic groups with the most diverse forms of substitution (depending on the problem). An appropriate correlation[109] showed that other, more commonly used aryl groups of diazo components that contain a particular substituent in the benzene ring (SO_3Na, Cl, COOH, NO_2, etc.) or a combination of certain substituents can also be used successfully for identification of the structure and conversions of azo dyes using ^{13}C NMR.

Another distinguishing feature also relates to the problem of differentiating the azo and quinone hydrazone forms of azo dyes using NMR when some hydroxy derivative of benzene, naphthalene, or anthracene acts as the azo component during their synthesis. The ^{13}C NMR signal from the carbonyl group in different types of quinoid structures is known to occur at much lower field than the signal from the $^{13}C–OH$ group in corresponding aromatic hydroxy compounds.[109] This fact was used for unequivocal identification of azo dyes in the quinone hydrazone form (examples such as arylazo derivatives of 2-naphthol,[66,67,72] chromotropic acid,[55,56] H-acid,[61] etc.) or in the azo form (examples such as derivatives of phenol,[51,52,62,64] resorcinol,[62] and 2-naphthol,[59,72] etc.).



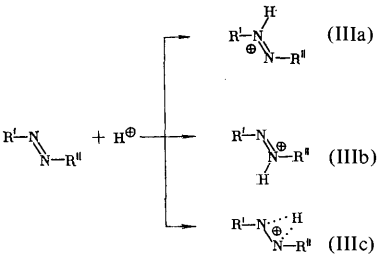
(d) Internal Rotation About the C—C Single Bond

The azophenyl fragment is known to be nonlinear in the gas phase and in the crystalline state a planar structure is the most favourable. The ^{13}C NMR spectra of *para*-substituted azobenzene (I), obtained under normal conditions, show, however, that in solution the pairs of nuclei of the *ortho*-carbon atoms C(2,6) as well as the pairs from the *meta*-carbon atoms C(3,5) are equivalent.[50,77] At low temperatures in inert solvents nonequivalence also does not occur either in the C(2,6) pair or the C(3,5) pair.[84] Thus, the available NMR data suggest a fairly rapid (relative to the time scale of NMR spectroscopy) internal rotation about the single C—N bond [reaction (1)]. This rotation is accompanied by averaging out of the shielding of these nonequivalent pairs of carbon nuclei (and, naturally, the hydrogen nuclei in ^1H NMR).

In recent years the conditions for slowing down process (1) were found when the ^{13}C NMR spectra of azobenzene derivatives in solution were studied.[84,85] The authors identified the conditions for structural modification of compounds (I) that would make it possible to increase the double-bond character of the C—N bond and slow down the internal rotation (1) accordingly. This can be achieved by the introduction of an $N(CH_2CH_3)_2$ substituent, which is often used in disperse azo dyes, at a position *para* to the azo group. As a result, in the ^{13}C NMR spectrum at a sufficiently low temperature in inert media it is possible to observe the signals from C(2) and C(6) separately ($\Delta\delta$ = 18 p.p.m.) as well as the signals from C(3) and C(5) ($\Delta\delta$ = 1.7 p.p.m.). The increase in rotation barrier about the C—N bond is determined, as the NMR data showed, not so much by steric factors as by electronic factors. In this case the electronic requirements necessary for slowing down the rotation about the C—N bond are different for the substituents acting from different sides of molecule (I). Process (1) is retarded by the introduction of an electron-donating group R′ = $N(CH_2.CH_3)_2$ on the aromatic ring side and also by the increase in electron-withdrawing capacity of the R″ group (in the series $N(CH_2.CH_3)_2$, H, NO_2) at the *para* position of the other benzene ring on the azo group side.

(e) Conformational Properties of Azophenyl Fragment

It is possible by means of NMR spectroscopy to determine unequivocally the structure of azo dyes of type (II) in solution, where groups R do not form intramolecular hydrogen bonds with a nitrogen atom.

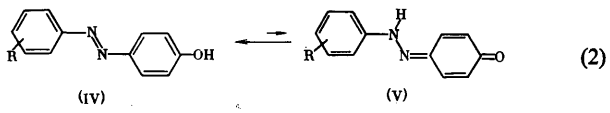


(II)

In fact, by introduction of *ortho* substituents and retardation of the internal rotation about the C—N bond, changes in shielding of the C(2) and C(6) nuclei in the ^{13}C NMR spectrum of compounds (II) take place in opposite directions. In the low-temperature splitting of the signal that corresponds to the C(2,6) nuclei in the high-temperature spectrum, the signal from the C(2) atom, which occupies the *cis* position relative to the unshared electron pair of nitrogen, is shifted downfield by about 8 p.p.m., while the signal from the C(6) atom, which occupies the *cis* position relative to the N=N bond, is shifted upfield by about 9 p.p.m.[84,85] This effect occurs in solution and at normal temperatures if the respective structural changes are made to azobenzene.[77] In particular, for 2,2′-dimethylazobenzene the C(6,6′) signal is shifted upfield by about 7.5 p.p.m. in comparison with unsubstituted azobenzene, which is clear evidence for the occurrence of only one out of three possible conformations, namely, conformation (II), R′ = R″ = CH_3. Similar results were also obtained for a wider range of compounds (II) (R′ = R″ = AlK[79]). Neither the interpretation nor the prediction of ^{13}C NMR spectra of new or previously unstudied azo dyes is possible without taking this fact into consideration.

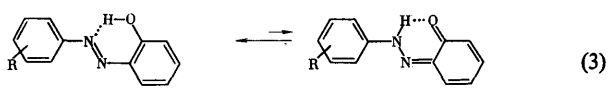
(f) Protonation and Deprotonation of Azo Dyes

The NMR data can resolve unequivocally questions about the structural changes in aromatic and aliphatic azo dyes that occur when they are protonated in strong acid media and also deprotonated in alkaline media.



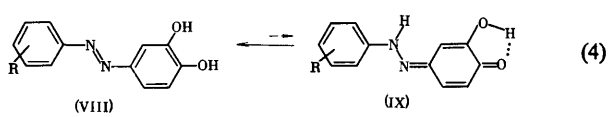
(IIIa) (IIIb) (IIIc)

In principle, the intermediates that are formed on protonation of azo dyes can have the form of (IIIa—c). NMR spectroscopy data[12,13] obtained using symmetrical model azo compounds with R′ = R″ = Ar as an example indicate that in the protonated form the aryl rings become nonequivalent (the NMR signals from indicative groups in both rings are nonequivalent). This suggests an asymmetric type of addition of the proton to the azo group. Similar results were obtained when R′ = R″ = tert-C_4H_9.[12] Thus with these results the concept of a symmetrically protonated azo structure (IIIc) can be rejected. The choice between the asymmetric structures (IIIa) and (IIIb) when R′ ≠ R″ is wholly related to the properties of the electronic effect of the R′ and R″ groups on the N=N fragment.

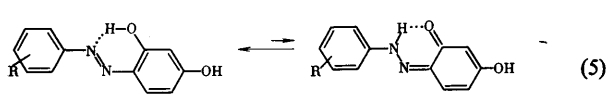


Results that are just as fundamental are given by NMR data, in particular for ^{13}C nuclei, when the consequences of deprotonation of molecules are studied (NMR titration).[64,109] The use of NMR titration to clarify the results of this chemically and industrially not infrequent situation, which occurs on alkali treatment of azo dyes, provided the answer to a number of questions concerning the structure in solution of azo derivatives of phenol,[62,64] resorcinol,[62,64] 1-naphthol,[64] and chromotropic acid.[57,58] Turning to the problem, for example, about the tautomeric form of azo dyes, ^{13}C NMR was successfully used to demonstrate, in particular, the possible occurrence of three conceivable situations during NMR titration—retention of the azo form (in phenol derivatives), its transformation from the azo to the quinone hydrazone form (in resorcinol derivatives), and its transformation from the quinone hydrazone to the azo form (in one of the 4-derivatives of 1-naphthol).[64] Even more complex situations were observed in the NMR studies of a series of azo derivatives of chromotropic acid.[57,58]

III. HYDROXYAZO DYES

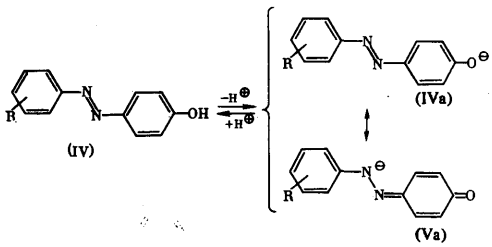


Hydroxyazo compounds constitute a considerable portion of the total number of azo dyes and include those acting as ligands in metal-complex dyes. The azo group in them is not only a chromophore but also a necessary component with an O-N type of coordination unit, because of the presence of a hydroxy substituent in the azo component.



(2)

(3)



(4)

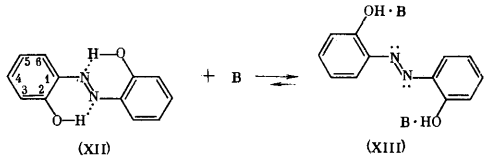
(5)

With regard to the question of the structure of hydroxyazo derivatives of benzene, which from a general hypothetical viewpoint can be represented as a mixture of products that make up tautomeric equilibria (2)–(5), there is extensive coverage on NMR in the literature. The ^{1}H,[8,14,15,17,25] ^{13}C,[59,77,99] and ^{15}N[105] NMR data suggest, however, that if diphenyl mono- and di-hydroxyazo compounds do not undergo special modification and the media conditions do not lead to complete removal of a hydroxyl proton, they only have the azo structure in solution. In other words, tautomeric equilibria (2)--(5) are shifted almost completely to the left. In fact, for each type of structure (IV), (VI), (VIII), and (X) the pattern of frequencies of ^{13}C NMR signals from the hydroxyphenyl fragment from compound to compound remains one and the same.[59] The ^{13}C NMR signal from the C–OH group, the most important in terms of identification, with allowance made for the electronic effect of the azo group in the spectra of compounds (IV), (VI), (VII), and (X) occurs in the same region as the C–OH signal of nonionised phenol: in (IV) $\delta_{C(4)}$ ~159–162.5 p.p.m.; in (VI) $\delta_{C(2)}$ ~150–154 p.p.m.; in (VIII) $\delta_{C(4)}$ ~146–147 p.p.m.; in (X) $\delta_{C(2)}$ ~153–160 p.p.m. and $\delta_{C(4)}$ ~163–166 p.p.m. These ^{13}C NMR findings can be used as a distinguishing feature in establishing the structure of the hydroxyphenylazo fragment in newly studied dyes.

In azo compounds (IV), by extrapolation from the conformational data, the proton signal from the *para*-hydroxy group in the ^{1}H NMR spectrum occurs at comparatively low field (δ_{OH} ~7.5–10 p.p.m.), and this suggests that it has a fairly acidic nature. Shielding of the hydroxy proton depends on both the properties of the substitutuent R and the properties of the medium.

In the anion form of compound (IV) the azo form (IVa) can be retained in principle, although on deprotonation it can be transformed at a given stage to the quinone hydrazone form (Va), as has been observed sometimes,[4] and these forms can be completely discrete rather than being two ways of writing the same intermediate structure. From the ^{13}C NMR data[62,64] obtained for the industrially important compounds (IV) with SO_3Na substituents at the ***meta*** position, however, it follows from the phenolate anions formed from them that in the spectra there are no fundamental differences from the corresponding anions not containing azo groups. Thus, there are no grounds for proposing the formation of the quinone hydrazone form (Va) during ionisation of azophenols.

However, the experimental data examined were obtained using the simplest examples of compounds (IV). Structural complexity of the molecules at times leads to unexpected results. An example of this is provided by the conditions identified[10,23,24,51] for shift of equilibrium (2) to the right and the existence of quinone hydrazone tautomer (V) in a series of 4-hydroxy derivatives of specifically substituted azobenzenes.



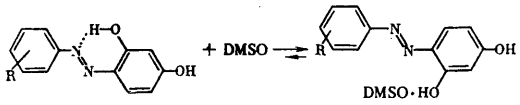
The authors[23,24] introduced electron-withdrawing substituents into the diazo component of 4-hydroxyazobenzene and electron-donating substituents into the azo component. In solutions of most of the compounds in aprotic solvents two tautomeric forms are observed separately in the ^{1}H NMR spectra—both the azo (IV) and quinone hydrazone (V) forms. Their identification was carried out by ^{1}H NMR and the ratio of tautomers was determined by integration. The ^{1}H NMR data obtained can be used to formulate the factors that determine the shift of the azo–quinone hydrazone tautomeric equilibrium (20) in either direction.

On changing from *para*- (IV) to *ortho*-hydroxy compounds (VI) the signal from the hydroxy proton is shifted downfield by 3 to 4 p.p.m. (when R = H, for example, depending on the properties of the medium and the concentration of the compound its chemical shift δ_{OH} = 12.0–12.9 p.p.m..[8,9,11,17] The magnitude of this shift is determined by the nature of the medium and the electronic and steric effects of substituents. This change in shielding of the hydroxy proton on going from (IV) to (VI) is due to the formation of a fairly strong intramolecular hydrogen bond C–O–H...N= in the respective azo structures.

Further changes in chemical shift of the hydroxy proton could be due to its intramolecular transition of NH/OH hydrogen bonding relating to the basic possibility of forming quinone hydrazone (VII). However, in reality, it hardly occurs at all in the compounds examined.

Interesting results have been obtained in studies of 2,2′-dihydroxyazobenzene (XII) using NMR. ^{1}H NMR data obtained at fairly low concentrations, which exclude the effect of aggregation, indicate that the compound has an azo structure in solution (δ_{OH} = 12.0 p.p.m. in inert media).[8,11] The same conclusion is reached when ^{13}C NMR spectroscopy is used.[59] However, when acetone-d_6

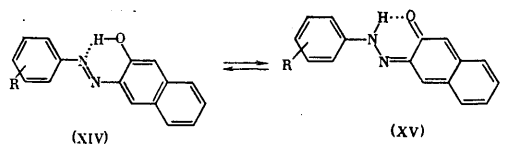
is used as the solvent instead of $CDCl_3$, in the ^{13}C NMR spectra of this compound there is a shift of the C(6) signal upfield by ~2.5 p.p.m. This fact is related to cleavage of the O—H...N intramolecular hydrogen bond in some of the molecules, in other words, there is a given shift of equilibrium (6) to the right. As a result, some of the molecules acquire a sterically more favourable conformation (XIII), in which the bulky *ortho*-substituent is aligned not in the direction of the N=N double bond but in the direction of the unshared electron pair of the nearest nitrogen atom. The average picture is recorded spectroscopically.



(XII) (XIII) (6)

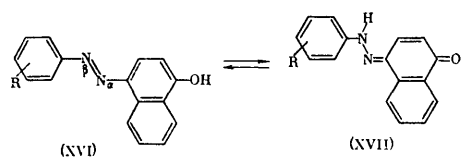
The maximum upfield shift of C(6) that occurs assuming conformation (XIII) is more than ~8 p.p.m., and this effect occurs only in DMSO when cleavage of the intramolecular hydrogen bond occurs for all the molecules of 2,2′-dihydroxyazobenzene.[109]

In the ^{13}C NMR spectrum of 2,4-dihydroxyazobenzene—the simplest of the azo compounds (X) with a resorcinol azo component (R = H)—the pattern of frequencies of the ^{13}C signals is that expected for the azo structure and is due to the electronic effect of two hydroxy and one azo group[5] taking into account some effect from the intramolecular hydrogen bond.

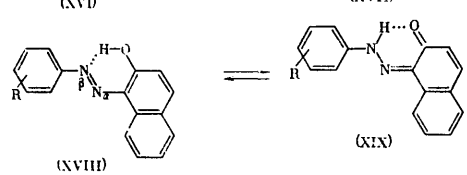


The same result is also shown by the introduction of an ^{15}N label into the compound at the N_β position.[15] The NMR signal of the proton at lower field (in this compound two hydroxy signals with δ_{OH} = 11.0 and 12.4 p.p.m. are observed), as also before introduction of the label, again proves to be a singlet over a wide temperature range although for equilibrium (5) it should have split into a doublet with the $^1J_{^{15}N-^1H}$ spin-spin coupling constant being greater the higher the content of quinone hydrazone tautomer (XI) in the mixture of (X) and (XI).

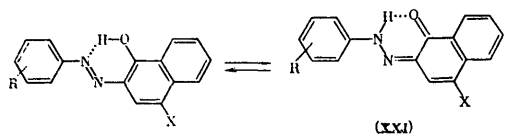
A feature of compounds of type (X) is that when acetone or alcohol is replaced by a powerful solvating medium such as DMSO, there is a marked upfield shift, which is almost the maximum possible, of the signal corresponding to C(6).[62] It is due to the replacement of an intramolecular by an intermolecular hydrogen bond with solvent, and, as a result, to the almost complete displacement of equilibrium (7) to the right and the adoption of a more favourable conformation by the compounds under these conditions:



(7)

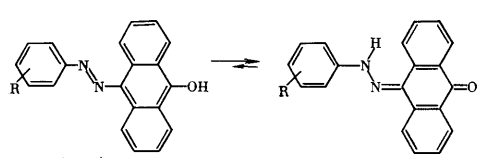


In phenyl-naphthol azo dyes, 1-naphthol or 2-naphthol act as the azo component. In principle they can participate in azo—quinone hydrazone equilibria (8)—(11). This class of compounds has been used and studied in the chemistry of azo dyes especially often.[1-5] However, in actual fact, when the equilibrium is significantly displaced in one or other direction, apparently only azo structures (XIV) and (XVI) can be identified as stable structures of this type—and then with reservations. The compounds that make up equilibrium (8) can in principle adopt both the azo form (XIV) and the quinone hydrazone form (XV). However, as it follows from the ^1H NMR data, in $CDCl_3$ they have the azo structure (XIV) (the value δ_{OH} = 12.1 p.p.m.[11] is consistent only with this type of structure). The question concerning the structure of these compounds in aqueous media remains open for the time being. Investigation of the ^1H NMR spectra of 1-benzeneazo-4-naphthol, in particular, analysis of the shape of the signal from the hydroxy proton when an ^{15}N label was introduced into the N_β position of the azo group showed[10,15] that in organic solvents this compound exists in the azo form (XVI) (R = H). ^{13}C NMR spectra obtained in nonaqueous media when R = *o*-OH are also consistent with the azo structure.[59] With regard to the possible shift of equilibrium (9) to the right in aqueous media, this question requires special consideration.



(XIV) (XV) (8)

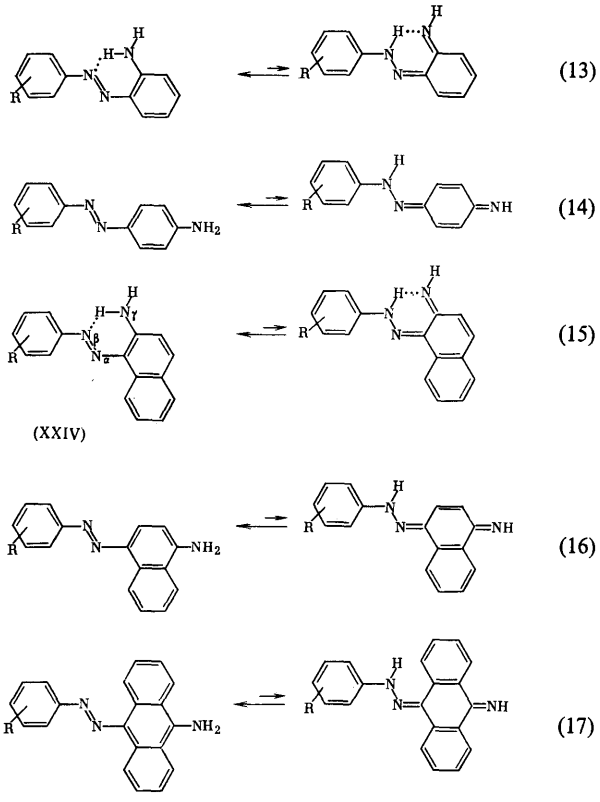
(XVI) (XVII) (9)



(XVIII) (XIX) (10)

(XX) (XXI) (11)

In one study[112] using ^1H NMR, the possibility of equilibrium (9) being displaced to the right (in acetone, where R = H) was discussed. However, this treatment was based on an analysis on the signal observed in solution with δ_{OH} = 3.59 p.p.m. (corresponding to an impurity, as has been revealed[70]) and consequently on an incorrect assignment of the main signal with δ_{OH} = 10.2 p.p.m. to the quinone hydrazone form (XVII), although in reality it belonged to the azo form of this compound (XVI).



(XXII) (XXIII) (12)

The last example from the number of basically distinct, stable aromatic hydroxyazo systems is 9,10-anthraquinone phenylhydrazone. According to ^1H [15] and ^{14}N [20] NMR data, this compound exists in the quinone hydrazone form (XXIII) (equilibrium (12) displaced to the right). Conformation of this is provided by the appearance of a $^{15}N-^1H$ spin-spin interaction in the ^1H NMR spectrum with a coupling constant that is independent of the temperature.

IV. AMINOAZO COMPOUNDS

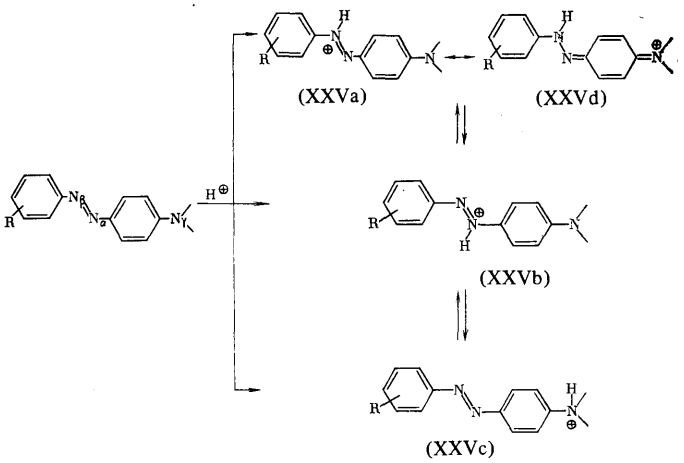
The conditions for formation of an iminoquinone hydrazone structure among aromatic aminoazo dyes is less favourable compared to hydroxyazo dyes as a result of the lower acidity of the NH proton compared to the OH proton and as a result of the differences in geometry for configuration of the proton in a hydrogen bond. Positive indications of the azo structure in aminoazo dyes are given by both ^1H [27,41] and ^{13}C [60,70,101] NMR spectroscopy data.

(13)

(14)

(15)

(XXIV)



(16)

(17)

According to ^1H NMR data,[27] in the dye Fat Yellow AB (XXIV) (R = H) and in azo dyes (XXIV) in general it is the shielding of the NH proton that participates in intramolecular hydrogen bonding that suggests an azo structure, namely a complete displacement of the hypothetical equilibrium (15) to the left. At fairly low temperatures the signals from the protons of the amino group in (XXIV) are split; the proton contained in the N–H...N hydrogen bond has a shift δ_{NH} = 10–10.2 p.p.m., while the free proton has δ_{NH} = 5–5.3 p.p.m. On the other hand, in iminoquinone hydrazone structures the NH proton is shifted to lower field (δ_{NH} = 14 to 16 p.p.m.). The fact that both NH protons in these compounds are located precisely on N_γ was confirmed[27] by the introduction of an isotopic label N_γ = ^{15}N. In this case both the NH_2 protons are split by the ^{15}N nucleus with approximately the same constant. Accordingly, introduction of a ^{15}N isotope to replace N_β did not lead to splitting of the NH proton.

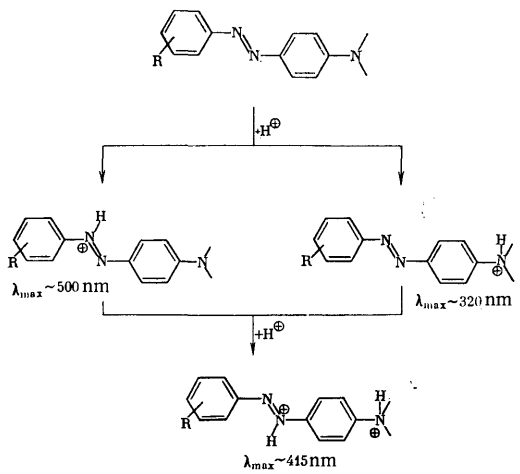
The ^{13}C NMR data[60,70,101] gave the same results. As was demonstrated in one study,[101] the azo structure actually occurs not only in substituted azobenzenes, where equilibria (13) and (14) could be assumed, but also in more complex compounds in which the amino group is joined to naphthalene or anthracene aromatic systems [hypothetical equilibria (15)–(17)]. In the ^{13}C NMR spectrum of the phenylazo derivative of aminoanthracene, for example, as in a number of related compounds, the chemical shifts of the different nuclei in the characteristic phenylazo group are clearly consistent with the azo structure of the $C_6H_5-N=N-$ fragment, namely, with the complete displacement of equilibrium (17) to the left. It is significant that the spectrum of the naphthylamine fragment of (XXIV) is the same regardless of the properties of the substituent R in the phenylazo group.[60,70,101] In this case the frequency pattern of the ^{13}C NMR signals from the naphthylamine fragment is consistent with its azo structure and is not satisfactorily interpreted on the basis of the iminoquinone hydrazone structure. The lack of dependence of the shielding of the NH proton participating in hydrogen bonding on the properties of substituent R was also observed in the ^1H NMR spectra of these compounds.[27]

Let us examine the NMR spectroscopy data on *para*-aminoazobenzene derivatives. Introduction of an amino group leads to a situation where in *para*-aminoazobenzene itself (Disperse Diazo Claret) and in dyes of this type in general (Fat Soluble Yellow 2G, Methyl Organe, etc.) that have three basic centres N_α, N_β, and N_γ, three monoprotonated structures (XXVa–c) that differ according to the site of proton attack, including two isomers (XXVa) and (XXVb) that are asymmetrically protonated on the azo group, can in principle occur:

(XXVa) (XXVd)

(XXVb)

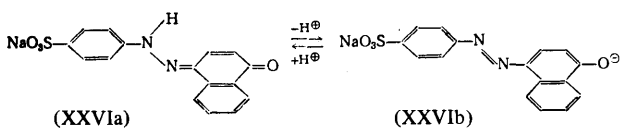
(XXVc)



There is an interesting debate[1,2,21] over the interpretation of the spectroscopic data on the protonation of aromatic aminoazo dyes. It is based on the suggestion of the possible occurrence in these compounds of tautomerism of the form:

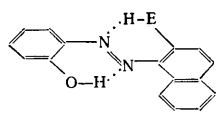
There has also been a discussion on the question concerning the addition site of a proton to the azonium cation—either to the α- or β-position.

These problems can be resolved almost completely using the NMR data. In weakly acid media these derivatives form one or both monocations—ammonium salt (XXVc) and one of the azonium salts. Making use of the arguments of NMR spectroscopy we can, in addition to ^1H NMR studies,[12,13,16] also indicate other works,[88,95]



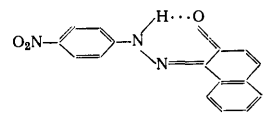
where a sample of Disperse Diazo Claret enriched with ^{15}N was analysed on its ^{13}C and ^{15}N nuclei. The authors showed that in a weakly acid medium the proton adds on either to N_γ or to N_β. The first isomer predominates in solution, while in the second isomer the distribution of electron density corresponds precisely to azonium structure (XXVa) and not to mesomeric structure (XXVd). Thus, on the basis of a direct NMR experiment, two questions are resolved—the site of addition of the proton to the azo group (N_α or N_β), namely, identification of cation (XXVa) or (XXVb), and the structure of the azonium cation formed. Addition of the proton to N_β is evidently due to the orienting effect of the *para*-amino group. In strong acid media there is a structural transformation in the dication formed, and the second proton is found to be added not to N_β but to N_α. Taking into account these results, protonation of Disperse Diazo Claret and related azo dyes can be represented as follows:

V. LABILE HYDROXYAZO COMPOUNDS. TAUTOMERISM.



From the four phenylnaphthol hydroxyazo systems (8)–(11), usually a given limiting tautomeric form does not occur in the two depicted in equilibria (10) and (11) but there is an azo–quinone hydrazone tautomeric equilibrium. Conditions can be selected when tautomeric system (9) also becomes labile; NMR data relating to the preferred formation of the azo form for this was given above.

When Orange I (structure (XVI)/(XVII), R = *p*-SO_3Na) was studied using ^{13}C NMR, it was found[65] that the chemical shift of the C(4) nucleus was 186.3 p.p.m. (probably in D_2O). Although the authors[65] interpreted the results in favour of the azo structure (XVI), the magnitude of the shielding of C(4) objectively indicates the quinone hydrazone structure (XVII), namely, the complete displacement of equilibrium (9) to the right. A subsequent study of this dye using NMR showed[64] that the change of colour it undergoes in an alkaline medium is due to conversion (18), which occurs by deprotonation, namely, transformation of neutral quinone hydrazone form (XXVIa) to the ionised azo form (XXVIb).

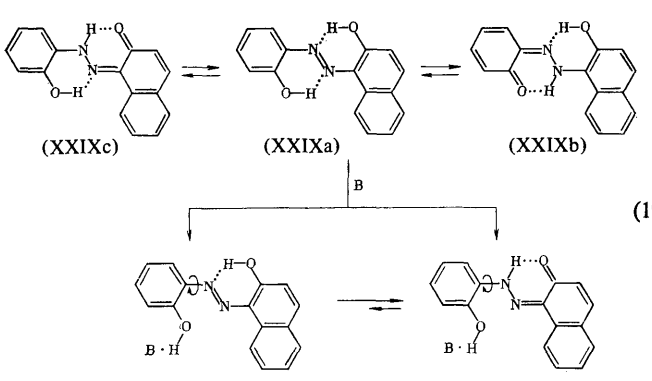


(XXVIa) yellow (XXVIb) red (18)

Arylazo derivatives of 2-naphthol constitute a large group of azo dyes (Fat Soluble Orange, Fat Soluble Orange 2K, Pigment Red G, Fat Soluble Dark Red, Chrome Violet K, Acid Orange G, Pigment Scarlet, etc.) that are not without significance in dye chemistry and are very interesting from the methodical viewpoint. It is not possible to assign a definite structure to these azo dyes but they should be regarded as forming azo–quinone hydrazone equilibrium (10). This equilibrium has been studied by NMR in relatively greater detail than the others—under different conditions and using various techniques of NMR spectroscopy.[8,10,14,15,19,20,49,59,70–74,80,99,106] Thus, when 1-benzeneazo-2-naphthol (Fat Soluble Orange dye; structure (XVIII), R = H) was studied, it was found[8] that the signal from the hydroxy proton was shifted downfield by ~3 p.p.m. relative to *ortho*-hydroxyazobenzene and 2,2′-dihydroxyazobenzene. Although an explanation for this effect was given in terms of azo structure (XVIII) (assuming that a stronger C–O–H...N hydrogen bond is formed in (XVIII) than in *ortho*-hydroxyazobenzenes), such an explanation could not be the only one since in the absence of any substantial structural changes in comparable hydroxyazo compounds that include the same type of intramolecular hydrogen bonding the magnitudes of the effect found[8] are too high. An alternative conclusion followed from ^{17}O NMR findings,[19] which indicated a certain double-bond character of the C–O bond, namely, some displacement of equilibrium (10) to the right. In other words, the downfield shift of the signal from the OH proton that occurs in compounds of type (XVIII) is due not so much to the increase in strength of the COH...N bond as to its change of form (C–O–H...N → C=O...H–N), namely to the development of azo–quinone hydrazone tautomerism (10). In subsequent NMR studies[10,14,15,20,49,59,70–74,80,99,106] the authors started precisely from this point and studied the dependence of the position of equilibrium in tautomeric system (10) on different factors such as the temperature of the solvent, type of medium, and changes in structure of the azo dye.

(XXVII) a) E = O, b) E = NH

(XXVIII)



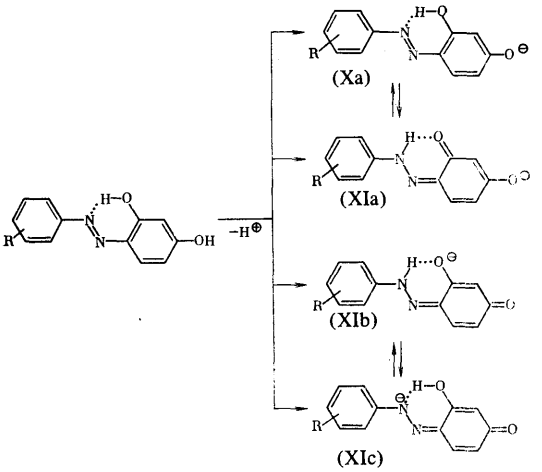
In particular, examples of the limiting tautomeric forms of these compounds—(XXVII) and (XXVIII)—were found, according to the ^{13}C NMR data.[59,70,109] In compounds (XXVII), studied in the polar but nonsolvating medium of chloroform, the experimental chemical shifts of the C(2) and C(4) nuclei ($\delta_{C(2)}$ ~153–155.8 p.p.m.; $\delta_{C(4)}$ ~133–136 p.p.m.) are similar to those calculated for a proposed azo structure. Here equilibrium (10) is displaced to the left and stabilisation of the azo form is achieved by two O–H...N hydrogen bonds that are similar in structure in (XXVIIa) or by the combination of different hydrogen bonds N–H...N and O–H...N in (XXVIIb). The dye Pigment Red G, on the other hand, has the quinone hydrazone structure (XXVIII), as is indicated by the value of the chemical shift $\delta_{C(2)}$ ~180 p.p.m., which is characteristic of the ketone group in the quinonoid ring, as well as by the significant change in chemical shift of C(4) ($\delta_{C(4)}$ = 143.5 p.p.m.). For this dye equilibrium (10) is displaced to the right.

Several NMR methods have been suggested for qualitative and quantitative determination of the position of the tautomeric equilibrium in system (10): a) from the change in proton chemical shift δ_{OH},[10,20] and also $\delta_{H(3)}$ and $\delta_{H(8)}$;[70] b) from the change in δ_{14_N}

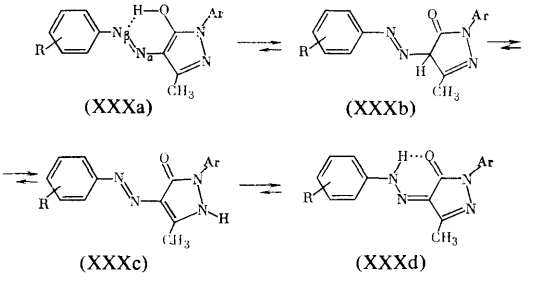
chemical shift of the N_β atom, which participates in the hydrogen bond (since the NMR signal in this case is measured under conditions of $^{14}N-\{^1H\}$ double resonance, these determinations are evidence for a six-membered ring of the hydrogen bond with N_β, as is depicted in (XIX), and not a five-membered ring with N_α;[20] c) from the changes in chemical shift of $^{15}N_\beta$ and $^{15}N_\alpha$ and also the direct spin-spin coupling constants $^1J_{^{15}N-^1H}$ and $^1J_{^{15}N-^{15}N}$ (due to the low content of natural ^{15}N isotope, a ^{15}N isotopic label was introduced for the measurements in these studies;[14,15,106] d) from the changes in chemical shifts of ^{13}C nuclei of specific atoms in the system, those most sensitive to its changes of state.[71,72,99] All these methods require a knowledge of the measured radiospectroscopic parameter for the limiting positions of the tautomeric system—for the pure azo form and for the definitely proved quinone hydrazone form—and assume a linear dependence of the measured parameter on the content of tautomers in the mixture.

Results[71,72,99] indicate that ^{13}C NMR spectroscopy is particularly successful in determining the ratio of the individual tautomers (XVIII) and (XIX) and the equilibrium constant of (10). One modification of this method is suitable for studying the temperature dependence of the position of tautomeric equilibrium [using the data on the change in chemical shifts of some types of ^{13}C nuclei of the unsubstituted benzene ring in 2-benzeneazo-2-naphthol (Fat Soluble Orange) or, generally, a substituted but fixed phenyl ring and a naphthol residue]. The effect of structural factors on the position of equilibrium (10) is more convenient to study from the shifts in the structurally invariable part of the molecule, namely, from the changes in shifts of the C(2), C(3), and C(4) nuclei of the naphthalene ring in relation to the substituents in the benzene ring, since the variation in shielding of ^{13}C nuclei in these positions is more sensitive to structural changes in the molecules.[71,72] Structures (XXVIIa) (studied in chloroform) and (XXVIII) can be used as reference compounds.

Dihydroxyazo compound (XXIX) (Eriochrome Violet C), which is one of a series of compounds for which equilibrium (10) is possible and one of the main types of dye,[1-5] deserves special consideration. According to the ^{13}C NMR data,[59] this compound in chloroform has only the azo structure (XXIXa) and there were no indications that the quinone hydrazone forms (XXIXc) and (XXIXb) existed under these conditions. Thus, equilibrium (19) does not actually occur in nonsolvating media.



(19)

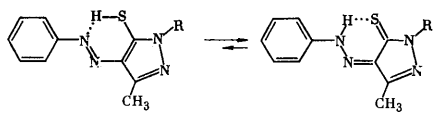


The displacement of the azo—quinone hydrazone equilibrium for compound (XXIX) towards azo structure (XXIXa) is apparently due to the formation of two O—H...N hydrogen bonds of similar structure. In one study[72] an attempt was made to find a solvation method (as opposed to a structural method) for conversion of the fixed tautomeric azo form to the corresponding tautomeric equilibrium.

It transpired that when chloroform was replaced by acetone and even more so by DMSO, the ^{13}C NMR spectrum of the compound changed considerably. Instead of the fixed tautomer (XXIXa), an equilibrium such as (19) occurs in solvating media. Strongly solvating media B that have basic properties promote the cleavage of one of the two hydrogen bonds (the weaker one), as a result of which in the compound with the remaining hydrogen bond the stabilisation conditions are virtually the same as those in other compounds with a substituent at the 2-position that does not form a hydrogen bond with the N=N group. Consequently, most of the molecules undergo a change in the type of hydrogen bond (N...H—O—C → N—H...O=C).

As has already been stated, resorcinol azo dyes in the neutral form have azo structure (X). However, a tautomeric conversion to the quinone hydrazone form was found in alkaline media by elimination of the primary, more acidic proton of the *para*-hydroxy group that does not participate in hydrogen bonding.[62,64]

The NMR spectroscopy data for azo dyes of type (X) (Sudan G, R = H; Azo Violet, R = *p*-NO_2; Resorcinol Yellow, R = SO_3Na) indicate that a quinonoid carbonyl group with chemical shift $\delta_{^{13}C-O}$ = 185—186 p.p.m. is formed in an alkaline medium. Thus, azo form (Xa) can be excluded as the monoanion state of resorcinol azo derivatives; in an alkaline medium they have one of the quinone hydrazone structures (XIa—c). From NMR titration curve graphs that were obtained[64] for compound (X), where R = *m*-SO_3Na, it was possible to make a more definite choice in favour of *para*-quinoid structure (XIb).



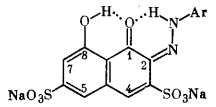
(20)

For dyes with a pyrazolone azo component, azo structure (XXXa) is to be expected from a traditional viewpoint.[5] An alternative approach with regard to possible tautomerism requires not just two

but four tautomeric forms (XXXa–d) to be considered for equilibrium (20). The "hybrid" forms (XXXb) and (XXXc), however, were ruled out many years ago by the first NMR studies (in the ^1H NMR spectrum of certain arylazo derivatives of 1-phenyl-3-methyl-5-pyrazolone, signals due to CH and NH protons not involved in hydrogen bonding were absent).[34-37] From the value of the chemical shift of the proton participating in NH/OH hydrogen bonding in nonsolvating media (δ_H = 13.5–13.8 p.p.m.[34,36]) and the changes in the ^1H NMR spectrum of the compound when it underwent N- and O-methylation it was possible to conclude further that out of the two more traditional tautomeric forms (XXXa) and (XXXd) keto form (XXXd) actually occurs in arylazo derivatives of 5-pyrazolone.[10,34,36] Confirmation of this was obtained[15,106] by introduction of a ^{15}N label into the β-position. In the ^1H and ^{15}N NMR spectra in chloroform there was a doublet which suggested the existence of a $^{15}N-^1H$ bond as part of the hydrazone form (XXXd).

The ^{13}C NMR data[54,63,99] are consistent with these results. Without dependence on the properties of the substituent in the aromatic diazo component and in the N-aryl azo component, the ^{13}C NMR spectra of the pyrazolone skeleton are only consistent with quinone hydrazone form (XXXd) for all the azo dyes based on 5-pyrazolone that have been studied, including the simplest, Fat Soluble Yellow 3 (R = H and Ar = C_6H_5) and more complex ones such as Acid Yellow Fast (R = H and Ar = p-$NaO_3SC_6H_4$), etc. These results can also be used to analyse the ^{13}C NMR spectra of other dyes of this class that have not previously been studied or have recently been synthesised.

(21)

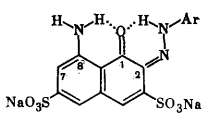


(XXXIa) (XXXIb)

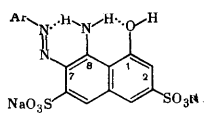
The results are similar for azo derivatives of 5-thiopyrazolone. It follows from the ^1H NMR data[47] that the hydrogen atom involved in NH/SH hydrogen bonding occurs at very low field (δ_H = 16.68 p.p.m. when R = C_6H_5 and 16.20 p.p.m. when R = CH_3). This result together with the ^{13}C NMR data[54] clearly suggest that these compounds have quinone hydrazone structure (XXXIb) (in other words, the hypothetical equilibrium (21) is displaced to the right), although the azo structure (XXXIa) was preferred by the authors of one study.[47]

VI. AZO DERIVATIVES OF NAPHTHOLSULPHONIC ACIDS

Azo derivatives of 1-naphthol- and 2-naphthol-sulphonic acids (Nevile and Winther's acid, Schaeffer's acid, G- and H-acids, etc.) and also 1-8-dihydroxynaphthalene-3,6-disulphonic acid (chromotropic acid) and 1-hydroxy-8-aminonaphthalene-3,6-disulphonic acid (H-acid)[1-5] occupy a position of important practical significance. Study of them by means of ^1H and ^{13}C NMR spectroscopy is essentially only beginning,[52,53,55-58,61,63-65,104] and the ^{13}C NMR data obtained for the initial naphtholsulphonic acids[113-115] is proving to be effective for this.



In the past it happened that in the studies devoted to dyes such as monoazo derivatives of chromotropic acid, the azo form of these compounds was usually a fundamentally accepted principle, and this transition has been preserved until recently. The structure and properties of both types of monoazo-substituted H-acid obtained under alkaline and acidic conditions and of monoazo-substituted Schaeffer's acid, G-acid, Violet acid, and others have also only been considered in terms of the azo structure.[5] The ^{13}C NMR spectroscopy data obtained for monoazo-substituted chromotropic and H-acids,[55-58,61,104] and equally for other compounds of this particular type,[52,53,63,104] necessitate a re-examination of these views.

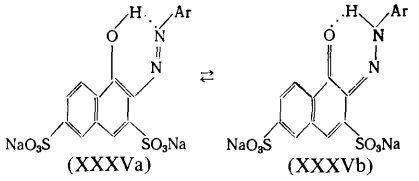


(XXXII)

Thus, it follows from the results obtained[55-58] that dyes of the form of monosubstituted derivatives of chromotropic acid have one and the same quinone hydrazone structure (XXXII). This applies not only to the simplest dye in the series—Chromotrope 2R (Ar = C_6H_5)—but also to any of the more complex structures—Victoria Violet BS, Acid Blue 3, Chromotrope 6B, etc. The main spectral feature of all the dyes is the presence of a signal with chemical shift 179–182 p.p.m. corresponding to C(1) in the naphthalene region of their ^{13}C NMR spectra. Signals from the carbonyl group of quinonoid compounds (in 1,2-naphthoquinone, for example, $\delta_{C(1)}$ = 180.9 p.p.m.[109]) are known to occur in this region of the spectrum.

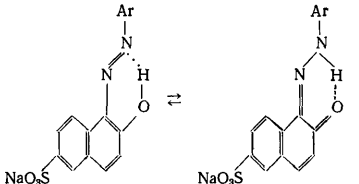
Thus, in none of the dyes does the corresponding tautomeric equilibrium actually occur since it is displaced towards the quinone hydrazone form (XXXII). In this case the keto group of the dyes participates in the formation of two intramolecular hydrogen bonds to give six-membered rings—a particularly strong keto–enol O–H...O=C bond and an additional keto–amine O...H–N bond. For the alternative azo structure, the intramolecular hydrogen bond in which the C(1)–OH naphthol group would be expected to participate is noticeably weaker.

(XXXIII)



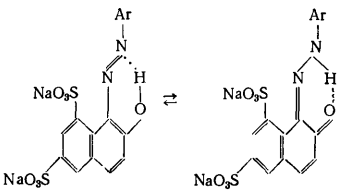
(XXXIV)

In monosubstituted derivatives of H-acid obtained in alkaline media (that is, synthesised under conditions where the site of addition of the arylazo group can only be the C(2) atom of the initial H-acid), for all the dyes investigated, either without (Acid Strong Fuchsin 2B) or containing a given substituent in the side chain, there is a ^{13}C NMR signal in the region 181–182 p.p.m.[61,104] This result is consistent only with the quinone hydrazone structure (XXXIII) and does not support the traditionally held view. For monosubstituted derivatives of H-acid that are synthesised under acid conditions where there is attack on the C(7) atom, it follows from the NMR data[61] that in this case the dyes formed exist in solution only in the azo form (XXXIV) similar to that observed in other azo derivatives of naphthylamine.



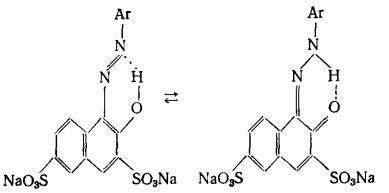
In one study[63] ^{13}C NMR data are reported on dyes of type (XXXV) (monosubstituted derivatives of violet acid), which do not contain a functional group at C(8) to participate in the formation of an intramolecular hydrogen bond. As a result, tautomers (XXXVa) and (XXXVb) exist at the same time in solution, although equilibrium (22) is displaced to the right to a considerable degree. Thus, while in monoazo derivatives of chromotropic and H-acids (XXXII) and (XXXIII)/(XXXIV) the respective tautomeric equilibria are only

theoretically possible, in derivatives of Violet acid (XXXV) the absence of additional six-membered rings involving keto–enol O–H...O=C or keto–amine N–H...O=C hydrogen bonding makes tautomeric equilibrium (22) quite real, observable, and it can be displaced by the effect of particular factors, structural or solvation.

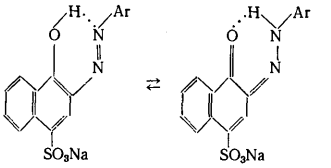


(XXXVa) (XXXVb) (22)

The ^{13}C NMR data which relates to several monoazo derivatives of Schaeffer's acid that are substituted in the aryl ring (Acid Brilliant Orange G) clearly suggest that azo–quinone hydrazone equilibrium (23) occurs in these dyes.[52,53] In this hypothesis the substantial differences in the experimental ^{13}C NMR chemical shifts from those calculated by the authors[52,53] for the traditional hypothesis of only the azo structure (XXXVIa) can readily be explained. The use of the method of calculation proposed in recent studies[63,72] in assessing the ^{13}C NMR data[52,53] leads to the conclusion that in system (23) when Ar = *m*-$NaO_3SC_6H_4$ the compound occurs to about 90% in the quinone hydrazone form (XXXVIb).



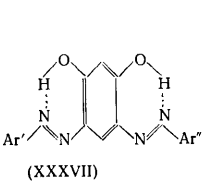
(XXXVIa) (XXXVIb) (23)



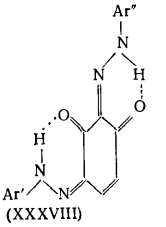
In some studies[52,53,104] ^{13}C NMR was used for the first time to study individual examples of dyes that actually (if the chemical shifts of the $\delta_{13_{CO}}$ nuclei obtained by the authors are analysed objectively) exist as equilibrium mixtures (23)–(26) as well as a number of other systems. Since the assessment of the ^{13}C NMR data in two studies[52,53] was made, in contrast to the other study,[104] from the traditional standpoint of the azo structure without including ideas about the possible occurrence of azo–quinone hydrazone tautomerism in these compounds, a reinterpretation of these findings and a possible reassignment of some signals is inevitable.

(24)

(25)



(26)

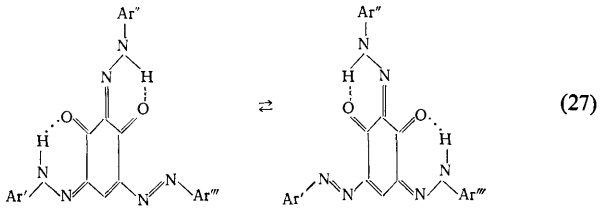


It is well known that azo-substituted derivatives of chromotropic acid as well as many other dyes are used over a very wide region of variation in the acidic and basic properties of the medium. In this connection, studies on the changes in the ^{13}C NMR spectra of azo dyes (XXXII) with the pH of the medium[57,58] are important. Although this aspect of the problem can include several different situations, there are two that are the most important. The first case occurs when there is a proton-donor group R (R = COOH, OH, AsO_3H_2, etc.) at the *ortho* position of Ar. In this case a corresponding structural complexity is possible in the compounds as a result of the formation of additional intramolecular hydrogen bonds. The second case occurs when the *o*-R group in Ar is a fairly "inert" group in relation to the formation of an additional hydrogen bond (R = Cl, CH_3, etc.). The first case has been examined[57] for R = AsO_3H_2. It transpired that in aqueous media the region for the compound existing in the azo form (more precisely, as the corresponding azo–quinone hydrazone equilibrium) is quite narrow—only in a weakly alkaline medium when the hydroxyl proton at C(8) still remains sufficiently strongly bonded to the oxygen atom. The second case was analysed[58] using a series of compounds with an "inert" *ortho*-group R. Here the changes in chemical shifts of the C(5)–C(9) nuclei, situated near the C(8)–OH hydroxy group, are in qualitative agreement with the successive change in pH observed in 1-naphthol and phenol up to complete removal of the hydroxy proton. In this case both tautomeric forms coexist in alkaline media to an approximately equal extent.

VII. POLYAZO DYES

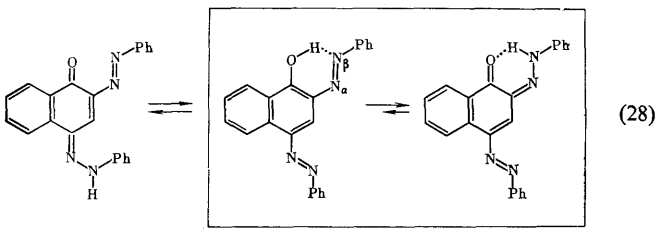
Bis- and poly-azo aromatic derivatives are among the most important compounds industrially, but their previous study by means of NMR spectroscopy has been particularly brief[9,15,18,53,56,61,109]

(XXXVII)



(XXXVIII)

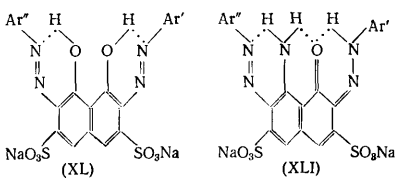
It follows from the respective ^1H NMR data[18] that both *bis*-azo compounds synthesised from the monofunctional azo component phenol, have the azo structure in solution, as do the monoazo compounds.



The NMR data on *bis*-azo derivatives of difunctional azo components such as resorcinol reveal a more complex picture. According to ^1H[9,18] and ^{13}C NMR[109] data, out of two structures the 4,6-isomer has the traditional *bis*-azo form (XXXVII). On the other hand, the 2,4-isomer occurs in a quite unexpected *bis*-quinone hydrazone form (XXXVIII). The shielding of the protons that participate in the two slightly nonequivalent NH...O hydrogen bonds does not leave open the possibility in the latter compound (δ_{NH} = 15.7 and

16.6 p.p.m. in $CDCl_3$ [9] and in DMSO;[18] $Ar' = Ar'' = C_6H_5$) of proposing any small amount of the corresponding mixed azo–quinone hydrazone forms. The ^{13}C NMR spectroscopic data is completely consistent with these results.[109] The conclusion about the structure of the 2,4- and 4,6-isomers as (XXXVIII) and (XXXVII) is consequently extremely important for understanding the structure in solution of dyes such as Acid Leather Brown 3K (XXXVIII), Acid Leather Light Brown (XXXVII), etc.

(27)

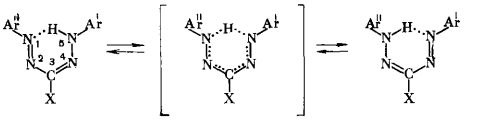


The *bis*-quinone hydrazone form of the *tris*-azo derivative of resorcinol ($Ar' = Ar'' = Ar''' = C_6H_5$) is sufficiently stable only at fairly low temperatures.[109] With an increase in temperature changes occur in the ^1H and ^{13}C NMR spectra that correspond to interconversion (27) of two *bis*-quinone hydrazone forms (when $Ar' = Ar'' = C_6H_5$ are equivalent). These findings are important for understanding the properties of the dye Acid Leather Brown K.

(28)

(XXXIXb) (XXXIXa) (XXXIXc)

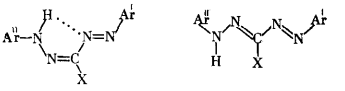
NMR data that relates to the *bis*-azo derivative of 1-naphthol [system (11), R = H, X = N=N–C_6H_5] have been reported.[15,103] In this dye, which traditionally could have been represented as (XXXIXa), there are two possibilities for formation of a quinone hydrazone form—(XXXIXb) and (XXXIXc). By introducing a $^{15}N_\beta$ isotope label the authors of one study[15] ruled out the 1,4-quinone hydrazone form (XXXIXb). A positive indication of the 1,2-quinone hydrazone form (XXXIXc) is given not only by the doublet splitting of the labile NH proton in the ^1H NMR spectrum of the labelled compound but also by the magnitude of shielding of this proton (δ_{NH} = 15–16 p.p.m.). From the change in the value of the $^1J_{^{15}N-^1H}$ constant as the temperature was decreased it was possible to establish that equilibrium (28) is displaced almost completely to the right under these conditions.



(XL) (XLI)

When we consider the 2,7-*bis*-azo derivatives of chromotropic acid and also H-acid, we can observe a basic difference in them. According to the ^{13}C NMR data,[56] the derivatives of chromotropic acid have the *bis*-azo structure (XL) in solution, which is quite distinct from quinone hydrazone structure (XXXII) that is typical for the corresponding monazo derivatives. On the other hand, the NMR spectroscopy data[61] for *bis*-azo derivatives of H-acid are consistent with structure (XLI), combining, as it were, both types of monoazo derivative obtained in alkaline and acid media [quinone hydrazone structure (XXXIII) and azo structure (XXXIV) respectively]. This applies, for example, to some well-known dyes such as Acid Blue Black ($Ar' = C_6H_5$, $Ar'' = p\text{-}O_2NC_6H_4$) and Acilan Dark Green B ($Ar' = C_6H_5$, $Ar'' = p\text{-}H_2NC_6H_4$).

VIII. FORMAZAN DYES



Formazan dyes have already been fairly widely accepted for solving practical problems.[5] They exist in two forms, "red" and "yellow", depending on the properties of the substituent X at the *meso*-carbon atom. There has until now been comparatively little NMR data[116–124] relating to formazans and their complexes with metal ions. In solution the "red" 3-X-1,5-diarylformazans (X = NO_2, Ar, and certain other groups that prevent the compounds being classified as dithizone derivatives, that is, when X ≠ SR) exist as equilibrium mixtures (29) of two cyclic *syn-s-cis* forms (XLIIa) and (XLIIc) with N(1)...H–N(5) and N(1)–H...N(5) intramolecular hydrogen bonds. When metal-complex dyes are formed the metal ion is introduced into the centre of the formazyl group with displacement of the hydrogen atom.

(29)

(XLIIa) (XLIIb) (XLIIc)

In 1,5-diarylformazans the N...H–N hydrogen bond is fairly strong (energetically favourable six-membered ring) but not so much as to exclude when there are certain forms of X (for example, when X = Cl, CH_3, etc.) the possibility of these compounds existing in solution in the "yellow" form, where the formazyl group acquires the *syn-s-trans* configuration (XLIII) with a weaker hydrogen bond as part of a five-membered ring or even the *anti-s-trans* structure (XLIV) completely without intramolecular hydrogen bonds (stabilised by intermolecular hydrogen bonding).

(XLIII) (XLIV)

It follows from ^1H [116–121] and ^{13}C [122–124] NMR data on compounds in which group X does not participate in the formation of strong hydrogen bonds that in relation to the NMR parameters these compounds can be separated into two groups that are chemically distinct. In the "red" formazans the signals from the NH protons occur in a region characteristic for compounds with strong intramolecular hydrogen bonds [δ_{NH} = 13.7–15.7 p.p.m. in $CDCl_3$);[117,119,121] structures (XLIIa) and (XLIIc)], and their chemical shift is only slightly dependent on the properties of the medium.[118] In the "yellow" formazans the chemical shift of the NH protons varies considerably (δ_{NH} = 8.7–8.8 p.p.m. in $CDCl_3$ for X = Cl,[12] and 10.2 p.p.m. in DMSO for X = CH_3 [119]), which

indicates the absence of strong hydrogen bonding [structures (XLIII) and (XLIV) with a weaker intramolecular hydrogen bond or with an intermolecular hydrogen bond].

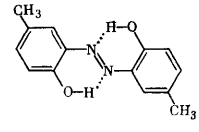
The participation of the NH proton in rapid intramolecular tautomeric conversions (29) in "red" formazans was demonstrated by means of ^{1}H NMR with isotopically enriched samples.[117,118,121] When N(1) = ^{15}N the NH proton appears as a double with $^1J_{^{15}N-^1H}$ = 46–47 Hz, and when N(1) = N(5) = ^{15}N it appears as a triplet with the same magnitude of spin-spin coupling constant. Since the coupling constant observed has half the magnitude of that typical for structures of a similar kind, the only reason for its decrease could be the participation of the NH proton in alternate formation of an N–H valence bond first with N(1) then with N(5) as part of the tautomeric intrachelation process (29) (a spin-spin interaction does not occur in an N...H hydrogen bond).

Our view has been expressed that the halving in value of $^1J_{^{15}N-^1H}$ can, in principle, be caused not only by process (29) but also by the formation of the mesomeric structure (XLIIb) instead of the limiting tautomeric forms (XLIIa) and (XLIIc).[118] This proposal can be rejected when taking into account the findings of one study,[117] in which the structural factors causing a displacement of equilibrium (29) in either direction were investigated on triarylformazans as a model. When X = C_6H_5 and N(1) = ^{15}N, introduction of a substituent into the *para* position of one of the aromatic rings (Ar′) (the other ring Ar″ = C_6H_5) has a marked effect on the constant $^1J_{^{15}N-^1H}$; when Ar′ = p-$CH_3OC_6H_4$, it amounts to 86.5 Hz, while when Ar′ = p-$O_2NC_6H_4$ it becomes equal to zero. Thus, electron-donor substituents at the *para* position of one of the aromatic rings promote such a displacement of equilibrium (29) that the azo group is stabilised next to this ring. Electron-withdrawing substituents have the opposite effect. In proposing mesomeric structure (XLIIb) these results would have no rational explanation. The tautomeric process (29) is a low-energy one since it is not possible to slow it down noticeably even on cooling the solutions.[118,119,121] This fact indicates the importance of establishing the position of this and similar equilibria by means of NMR spectroscopy. Apart from the one study,[117] related to this are two reports,[123,124] in which appropriate ^{13}C NMR data is presented.

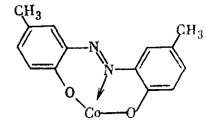
IX. COMPLEX COMPOUNDS OF AZO DYES WITH METAL IONS

Metallated and metal-containing hydroxyazo dyes constitute a fairly large and essentially important group of dyes. The NMR data relating to their complexes with metal ions[28–32,74–76,105,124] are still sparse, very incomplete, and provide only a few answers to certain structural problems.

In particular, data relating to the ^{1}H NMR spectra of complexes of 1-(2-hydroxybenzeneazo)-2-naphthol (XXIXa) with certain metal ions have been reported.[32] The absence of details in the interpretation of the spectra makes it difficult to discuss these data, but the conclusion of the authors[32] about the quinone hydrazone form of the ligand in the complex with Zr(IV) of composition 1 : 2 was not confirmed by the subsequent application of ^{13}C NMR spectroscopy.[75] It was established that the azo form of the ligand is preserved on complex formation with these ions.

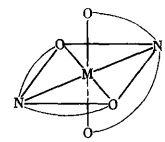


By means of ^{1}H,[28–31,76] ^{15}N,[105] and ^{13}C[76] NMR spectroscopy it was possible to study the isomerism for two types of complex based on 2,2′-dihydroxyazobenzene compounds with a wide variety of structure in which the dye is a tridentate O,N,O ligand—octahedral Co(III) complexes of the type (O N O)$_2$Co,[28–31,76] and square planar Pt(II) and Pd(II) complexes of the form (O N O)MB (B is pyridine or another additional ligand that has basic properties).[31,76,105]

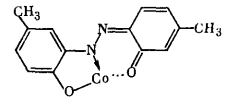


(XLVa)

(XLVb)



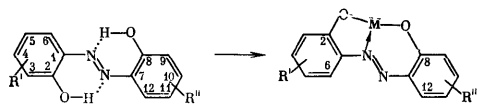
Some authors[31,76,105] used NMR spectroscopy methods to study, in particular, the differences between the isomers (XLVa) and (XLVb) of square planar Pt(II) and Pd(II) complexes when the left- and right-hand sides of the 2,2′-dihydroxyazobenzene dye molecule are nonequivalent.



A series of studies[28–31,76,105] constitutes the start of an extensive and technically important trend in NMR investigations that would be simply impossible without polynuclear NMR spectroscopy. Possibly because of the difficulties in interpreting ^{1}H and ^{13}C NMR spectra for complex structures, the authors limited themselves to discussion of only isolated NMR signals. The contemporary state of NMR spectroscopy permits the study of complex compounds—metal-containing dyes or compounds that are metallated in the dyeing process—with complete interpretation of the spectra.

(XLVI)

(XLVIIa)



To what extent this step is important can readily be seen from the studies[28,29,76] in which NMR spectroscopy was used to study octahedral Co(III) complexes with two ligands attached to one metal ion. The complex with substituted 2,2′-dihydroxyazobenzene (XLVI)[28] was studied by ^{1}H NMR. On replacement of two protons by metal the initial symmetrical dye (XLVI) becomes asymmetric in the coordination unit (XLVIIa), and in the spectrum of the complex instead of one there are two methyl signals ($\Delta\delta_{CH_3}$ = 0.1 p.p.m.) and two H(6) signals (Δd_H = 0.08 p.p.m.). Since only one set of ^{1}H NMR occurs in the spectrum of the complex, the solution to the problem concerning the configuration process of two coordination units of (XLVIIa) is considerably simplified—there are two planar (XLVIIa) fragments arranged perpendicular to each other in the octahedron [structure (XLVIII)].

(XLVIII)

(XLVIIb)

Thus the nonequivalence of the left- and right-hand sides of coordination unit (XLVIIa) for the symmetrical initial ligand (XLVI) follows from the very fact that coordinated and uncoordinated nitrogen atoms exist in it. In two studies,[28,29] where the discussion concerns complexes of Co(III) with an asymmetric 2,2′-dihydroxyazobenzene ligand, namely, with the possible formation of isomers and a more complex NMR pattern, the authors attribute the quinonoid structure (XLVIIb) to one of the sides of the ligand in the

coordination unit instead of the azoid structure (XLVIIa). Although this is not essential for the construction of the octahedral complex (XLVIII), this hypothesis in itself was not supported by the ^1H NMR spectra. The results of subsequent study of ^{13}C NMR spectra led the authors to the conclusion that coordination unit (XLVIIa) containing an azo structure was occurring.[76]

(XLIX)

A method for identifying the signal that corresponds to the C(6) carbon atom was proposed.[76] When coordination unit (XLIX) is formed, out of the two atoms C(6) and C(12) only atom C(6) changes its spatial position relative to the N=N bond, occupying a *cis* position relative to the N=N double bond after rotation about the C–N bond. Consequently, after rotation and subsequent complex formation (OH → OM), the signal corresponding to C(6) must be shifted upfield by an order of magnitude of 9 p.p.m. (plus or minus an addition shift due strictly to the effect of complex formation). The actual values of the upfield shift depending on the metal amount to: 13–14 p.p.m. for Pd(II) and Pt(II); 14–15 p.p.m. for Co(III). Thus, the upfield shift due to complex formation (as a result of replacing H^+ by M^{n+} and the change in angle values when going from a six-membered ring involving hydrogen bonding to a five-membered ring with M^{n+}) for C(6) amounts to 4–5 p.p.m. for Pd(II) and Pt(II) and 5–6 p.p.m. for Co(III). However, it may be assumed that this additional upfield shift is mainly due to transformation of the six-membered hydrogen bonded ring to the five-membered coordination ring since when complex formation occurs with preservation of a six-membered ring the C(6) signal is shifted downfield only by ~2.5 p.p.m.

Analytical Gas Chromatography of Volatile Metal Complexes

D.N.Sokolov

The recent advances in the gas chromatography of volatile metal complexes such as β-diketonates, adducts of β-diketonates with neutral donors, dialkyldithiocarbamates, β-ketoaminates, and other compounds are examined. Attention is mainly focused on methods for determining trace metals, capillary chromatography, chromatography in ligand vapour, and studies on the abnormal behaviour of metal chelates on a chromatography column.
The bibliography includes 138 references.

I. INTRODUCTION

The present review covers the period from the middle of 1975 to the end of 1986. During these 11 years there was a marked development of research into the gas chromatography of volatile metal complexes. About 120 original articles, a number of reviews,[1-17] and two monographs[18,19] which are completely or partly devoted to this topic have been published. Since in the preceding five-year period (1970–1975), which was covered in a previous review,[5] about 70 articles, including 7 reviews, were published, it is evident that the growth rate of research in this field has remained approximately the same. The main trends have also not changed significantly; these are either a comparative study of the properties of new volatile metal compounds that are united by some common feature (mostly these are complexes of a number of metals with one or more ligands or complexes of a single metal with a number of ligands) or better separation and improved sensitivity for determining those complexes already known.

Research into new volatile metal compounds has been conducted with considerable vigour. In addition to the traditional β-diketonates and β-ketoaminates, a large number of adducts of metal β-diketonates with neutral donors have been synthesised and studied as also have dialkyldithiocarbamates, dialkylthiophosphates, and analogues of β-diketonates that contain donor atoms of oxygen, sulphur, and nitrogen in different combinations. Several studies on the gas chromatography of metalloporphyrins have appeared.

As regards chromatographic experimental technique, mention can be made of the further development of gas chromatography using carrier gas into which the vapour of a ligand is introduced (GCLV) as well as the appearance of a promising new field—chromatography of metal chelates on glass and quartz capillary columns.

As before the most popular detectors are the flame ionisation detector and electron capture detector, although in some studies new ones such as microwave plasma, nitrogen-phosphorus, and flame photometric detectors are used. The heat-transfer detector is now rarely used. The use of chromatography–mass spectrometry has become quite common.

A considerable section of research is devoted to the practical application of gas chromatography in determining small traces of metals in a particular substance. Mention can be made here of the increase in the number of determinable metals and the improvement in sensitivity for determining many of them.

II. METAL β-DIKETONATES

β-Diketonates were the first volatile metal complexes to be used in gas chromatography. During the last two decades they have been thoroughly studied. However, even at the present time this class of compounds continues to attract the attention of research workers. Volatile β-diketonates of about forty metals have been synthesised. The most suitable for gas chromatography are metal complexes with β-diketones that contain *tert*-butyl and perfluoroalkyl substituents. The attraction in using β-diketonates for analysis lies in the fact that in most cases the ion being determined can readily and rapidly be converted quantitatively into a volatile chelate by extracting it from aqueous solution with a solution of the appropriate β-diketone in a non-polar organic solvent. However, the β-diketonates of many metals are kinetically labile and have insufficient thermal stability, which leads to their partial decomposition and irreversible adsorption on the chromatography column. As a result, abnormal effects occur during separation which prevent the widespread use of β-diketonates in quantitative analysis.[18]

Therefore, only the most stable β-diketonates of chromium(III), aluminium(III), beryllium(II), cobalt(III), and a few others are of practical use.

Numerous attempts using different methods to expand this list have not produced tangible results. An exception to this is the gas chromatography in ligand vapour (GCLV) proposed by Japanese authors, which will be examined below. However, this method is technically complex and excludes the use of the most common detectors (flame ionisation and electron capture), which considerably reduces its practical value.

1. Non-fluorinated β-Diketonates

Only a few studies in recent years have been devoted to non-fluorinated β-diketonates. The chromatographic behaviour of chromium and beryllium acetylacetonates and chromium propionylacetonates on different liquid phases has been investigated and it has been shown that beryllium acetylacetonate decomposes to a considerable extent on chromatography columns.[20] The satisfactory separation of chromium, aluminium, and cobalt(III) acetylacetonates on a column (1 m × 4 mm) with 5% Silicone OV-17 on Chromosorb W using a programmed increase in temperature from 190 to 250 °C (8 K/min) has been reported.[21,22] The gas chromatographic determination of aluminium as its acetylacetonate in soils has been reported[23] and a method has been developed[24] for determining copper in catalysts (also in the form of its acetylacetonate). The quantitative analysis of certain rare earth elements in the form of dipivaloylmethanates has been carried out.[25] One study,[26] in which for the first time gas chromatographic separation of rare earth acetylacetonates was achieved, is of interest. However, the gas chromatographic properties of these complexes are far from perfect and the separation of chelates of adjacent rare earth elements was not achieved. It was found that rare earth β-diketonates can react with vaporised β-diketonates, including acetylacetone (AA), in both the gas and condensed phases to give mixed ligand complexes.[27]

The use of non-fluorinated metal β-diketonates in gas chromatography is not likely to be of future interest. Only dipivaloylmethanes, which are of interest for the separation of rare earths and other metals, constitute an exception to this.

2. Fluorinated β-Diketonates

A considerably larger number of articles have been devoted to the volatile metal chelates with fluorine-containing β-diketonates. The chromatographic behaviour of vanadium(III) and vanadyl chelates with trifluoroacetylacetone (TFA), pivaloyltrifluoroacetone (PTA), and heptafluorodimethyloctanedione (HDO) has been studied.[28,29] It was shown that the chromatographic properties of vanadyl chelates were unsatisfactory. In addition to the usual abnormal effects (adsorption of the first samples of chelate on the column and a non-linear calibration curve at low concentrations), a partial reduction of vanadium(IV) to vanadium(III) also occurred on the column.

Vanadium(III) β-diketonates have better chromatographic properties. Particularly good results were obtained when studying a vanadium(III) chelate with HDO, which displayed virtually no abnormal effects. Volatile chelates of molybdenum(V) and (IV) with β-diketones that contain terminal CF_3, C_3F_7 or $C(CH_3)_3$, CH_3, thienyl, furyl, C_6H_5, and camphorate groups have been synthesised.[30] The authors claim that these chelates can be used in gas chromatography and also for improving the sensitivity of the atomic absorption method for analysing molybdenum. The thermal stability and chromatographic behaviour of chelates of copper and erbium with ten β-diketones that contain terminal CF_3, $C(CH_3)_3$, C_6H_5, and CH_3 groups have groups have been studied. As was to be expected almost all the copper complexes proved to be suitable for gas chromatography but the thermal stability of the erbium chelates was in most cases insufficiently high.

The chromatographic behaviour of complexes of aluminium, vanadium(III), chromium(III), iron(III), manganese(III), cobalt(III), and copper(II) with β-diketones containing terminal CF_3, C_2F_5, C_3F_7, CH_3, $CH(CH_3)_2$, and $C(CH_3)_3$ groups has been studied[32] on glass columns with Silicone SE-30 deposited on different solid supports.

Chelates of thallium(I) with PTA and HDO and thallium(III) with TFA, PTA, and HDO have been synthesised.[33] All these chelates can be satisfactorily chromatographed in microgram quantities on a glass column (75 × 0.4 cm) with 5% Silicone DC-550 on Chromatotone N AW DCMS at 170 °C, and thallium(I) compounds are retained to a considerably greater extent than thallium(III) compounds. Partial decomposition of the compounds studied on the column was recorded.

In a number of studies into the behaviour of volatile β-diketonates, compounds labelled with radioisotopes have been used. Thus, Buchtela et al.[34] chromatographed aluminium and chromium acetylacetonates and a number of rare earth complexes with HDO using ligands labelled with tritium. A flame ionisation detector and proportional counter were used for detection, and in the latter case it was possible to record a low detection limit for chromium ($\sim 10^{-15}$ g).

The gas chromatographic determination of chromium labelled with ^{51}Cr as a complex with hexafluoroacetylacetone (HFA) has been reported.[35] A gas-flow counter was used for detection. High accuracy in determining the isotope ratios for a number of alkaline-earth and transition metals (magnesium, calcium, chromium, iron, nickel, copper, cadmium, zinc) was achieved with the use of gas chromatography–mass spectrometry.[36] The metals were converted to complexes with TFA, PTA, or HDO or to diethyldithiocarbamates (DEDTC); separation was effected on a glass column with 1% or 6% Silicone SE-30 on Gas-Chrom Q. The authors maintain that the method is suitable for determining alkaline-earth and transition metals in natural materials using a mass spectrometric version of isotopic dilution.

The separation of geometric isomers of molybdenum(III) trifluoroacetylacetonates has been carried out.[37] The isolated preparatively pure complexes were identified from their electronic spectra, solubility, and melting points.

In one study[38] the suitability of a nitrogen-phosphorus detector for chelates with AA, TFA, and HFA was investigated. The sensitivity of the nitrogen-phosphorus detector proved to be comparable to that of the electron capture detector.

Volatile chelates of zirconium(IV) and hafnium(IV) with AA, TFA, and HFA have been synthesised, and their thermal stability and suitability for gas chromatography investigated.[39] Mikhailenko and Sereda[40] synthesised chromium(III) chelates with fifteen different β-diketones, carried out thermogravimetric analysis of these compounds, determined their dipole moments, and found that there was no correlation between the magnitude of the dipole moments and the retention times of the chelates studied. A number of thermodynamic values specific to the gas–liquid equilibrium for several stationary phases were also determined.

Several studies are devoted to the application of gas chromatography of β-diketonates for the practical analysis of metals in various substances. There have been reports on the determination of beryllium as a complex with TFA in natural and waste water[41] and also in tap water and uranium oxide[42] and in metal alloys.[43] The determination of aluminium and chromium (also as chelates with TFA) in aqueous solution at concentrations down to $10^{-6}-10^{-7}$ g/litre has been reported,[44] and the determination of vanadium in polymers, complex compounds, and petroleum has been described.[45,46] The determination of small quantities of chromium in various substances has also been the subject of studies.[47-51]

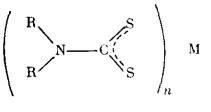
A method for determining traces of ruthenium in car exhaust gases in the form of a trifluoroacetylacetonate has been developed.[52] The detection limit for ruthenium reached 2.4×10^{-13} g. A method for determining aluminium and copper as complexes with PTA in glasses and alloys has been reported.[53]

III. ADDUCTS OF β-DIKETONATES WITH NEUTRAL DONORS

In recent years research workers have shown increased interest in adducts of metal β-diketonates with neutral donors. This applies particularly to complexes with HFA. As was indicated,[18] metal chelates with HFA were not of particular interest for a long time because of the tendency of HFA to react with water to give tetrahydroxy compounds incapable of forming complexes with metals. It transpired, however, that in the presence of neutral donors such as dibutyl sulphoxide (DBSO), tributyl phosphate (TBP), etc., adducts can be synthesised (usually containing one or two donor molecules) by normal extraction from aqueous solutions.[54,56,57]

In this connection a number of studies on the gas chromatography of compounds of this class have recently appeared. Thus, the gas chromatographic behaviour of adducts of manganese(II), iron(II), cobalt(II), and nickel(II) hexafluoroacetylacetonates with TBP and DBSO has been investigated.[54] Preliminary experiments showed that when TBP was used as a neutral donor the chromatographic peak from the donor was superimposed on the adduct peaks, so the studies were mainly conducted on adducts with DBSO. The metal ions were extracted from aqueous solutions at pH 5.0–5.5 with a solution of a mixture of HFA and DBSO in cyclohexane. All the adducts obtained by this method had the composition ML_2. .2DBSO (where M is metal ion, L is HFA anion). Separation was carried out on a glass column (25. × 0.3 cm) with 5% Dexsil-300 on Chromosorb W HP. The packing was silanised directly in the column. It was found that the concentration of DBSO in solution had little effect on the stability of the adducts. For all the adducts adsorption effects of the first samples of complex in the column, which are common for simple β-diketonates, and a column "memory" effect occurred. The presence of the respective metals in the adducts was confirmed by atomic absorption spectroscopy.

The behaviour of adducts of manganese(II), iron(II), cobalt(II), and copper(II) β-diketonates with neutral donors such as dimethylformamide (DMF) and tributylphosphine oxide (TBPO) has been studied.[55] A study of the thermal properties of anhydrous and hydrated manganese(II) β-diketonates and adducts of manganese(II) hexafluoroacetylacetonate with DMF and TBPO showed that introduction of a neutral donor into the molecule of complex considerably increased the thermal stability of the molecule and made it possible to sublime the complex almost without decomposition at 100–130 °C. Satisfactory chromatograms were obtained for adducts of hexafluoroacetylacetonates of the metals listed above for DMF and TBPO on a glass column (125 × 0.4 cm) with 5% Silicone SE-30 at 100 °C and their retention times were determined.



A radioactive indicator method was used to study the extraction of scandium, chromium(III), manganese(II), iron(III), cobalt(II), copper, zinc, yttrium, silver, cadmium, lanthanum, cerium(II). europium(III), ytterbium(III), mercury(II), thorium(IV), uranium(IV) and (VI), vanadium(IV), and americium(III) ions from aqueous solutions at pH 3.0–3.3 with cyclohexane solutions containing stoichiometric quantities of HFA and neutral donors such as *n*-butylamine, isobutylamine, *tert*-butylamine, TBP, TBPO, and trioctylphosphine oxide (TOPO).[56] The adducts obtained were studied thermogravimetrically. It transpired that the adducts with TBPO had the highest volatility. The chromatographic behaviour of these adducts was studied on different packings with programmed temperature change in the range 180–250 °C. The elution temperatures were found for a number of adducts of metal hexafluoroacetylacetonates with TBPO.

In a later study the same authors[57] studied adducts of rare earth hexafluoroacetylacetonates with TOPO, TBPO, TBP, tetrahydrofuran, *n*-butylamine, and dodecylamine. In this case adducts with TBPO also had the best properties as regards gas chromatography. Chromatographic separation was carried out on glass columns (60 × 0.4 cm or 90 × 0.4 cm) with 10% Silicone OV-101 or Dexsil-300 on Chromosorb W HP. The temperature was raised from 180 to 250 °C at a rate of 2 K/min, and a flame ionisation detector was used. Out of all the rare earth adducts the peaks from samarium, terbium, dysprosium, holmium, erbium complexes were effectively resolved on the chromatogram, the remaining peaks were only partially resolved.

IV. METAL COMPLEXES WITH NITROGEN- AND SULPHUR-CONTAINING LIGANDS

1. Dialkyldithiocarbamates

Recently chromatography researchers have shown increased interest in dialkyldithiocarbamates (DADTC) of metals with the general formula:

where M is a metal ion and *n* is its charge. The first report on the chromatographic separation of copper, nickel, and zinc DADTC appeared in 1969,[58] but a systematic study of the suitability of compounds of this class for gas chromatography has only started since 1975. Not long afterwards di(trifluoroethyl)dithiocarbamates (DTFEDTC), which have a higher volatility and better chromatographic properties, were synthesised.[59]

Non-fluorinated DADTC are less volatile than β-diketonates and are usually chromatographed at higher temperatures (in the region of 170–230 °C). Although there are not infrequent indications in the

literature that metal DADTC complexes partially decompose on columns or during thermogravimetric studies, there are virtually no reports about the type of abnormal effects that occur when using β-diketonates, such as adsorption of the first samples of chelate on a new column or the column "memory" effect. This is probably due to the greater kinetic stability of dialkyldithiocarbamates, which inhibits the rapid exchange of ligands between complexes. Satisfactory chromatographic properties are mainly displayed by DADTC chelates of bivalent ions (copper, nickel, zinc, and others), but some authors also managed to chromatograph complexes of chromium(III), iron(III), gold(III), thallium(I), antimony(III), bismuth(III), indium(III), and rhodium(III).[62,67-69,73,105,107]

DADTC complexes are even more convenient than β-diketonates as regards their practical application. A quantitative conversion of the ions being determined to the corresponding complexes is carried out by extracting them from aqueous solution as in the case of β-diketonates. But while the chromatographic determination of small quantities of metals as β-diketonates is only possible using expensive β-diketones with perfluoroalkyl substituents, in the case of DADTC perfectly satisfactory results are often obtained using readily available diethyldithiocarbamates (DEDTC).

In one study[60] the chromatographic behaviour of seven different nickel(II) DADTC that contained CH_3, C_2H_5, C_3H_7, H, *iso*-C_4H_9, and C_5H_{12} groups as terminal substituents was examined. The best results were obtained with diethyl derivatives. In the chromatogram of a mixture of diethyl, di-*n*-propyl, and di-*n*-butyl complexes of nickel shown in this study[60] there were no peaks from chelates with mixed ligands, which is confirmation of the kinetic stability of dialkyldithiocarbamate complexes.

The separation of nickel, copper, and zinc diethyldithiocarbamates on a glass column (60 × 0.3 cm) with 3% Silicone OV-25 at 260 °C has been reported.[61] The same authors[62] carried out the separation of lead(II), nickel, copper, cadmium, and zinc DEDTC under approximately the same conditions as well as di(trifluoroethyl)-dithiocarbamates (DTFEDTC) of nickel, copper, and zinc (in the same mixture) and bismuth(III), antimony(III), lead(II), cadmium, nickel, and zinc (in another mixture) at temperatures of 240 °C and 185 °C respectively on a column with 5% Silicone SE-30 on Chromosorb W. It was possible to determine a number of metal cations down to concentrations of 6×10^{-5}% using a flame ionisation detector.

The possibility of detecting small quantities of zinc, cadmium, nickel, mercury(II), and lead(II) DEDTC using an electron capture detector with ^{63}NI was examined, and it was found that the detection limit for lead complexes was 6 ng and 2–4 ng for the remaining complexes in a sample.[63] In some cases the peaks from the pure zinc and cadmium chelates were split. The explanation for this given by the authors is that the respective complexes are present in the system in both the monomer and dimer forms. However, this phenomenon was only observed in this study. The determination of zinc, copper, and nickel as their DEDTC complexes in marine residues and in other substances has been reported.[64,65]

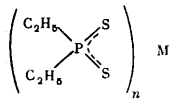
In one study[66] the chromatographic behaviour was examined and mass spectra obtained for copper, cadmium, cobalt, zinc, and nickel DEDTC and partial decomposition of the copper, cobalt, and cadmium complexes was detected on a column with Silicone SE-30 using different solid supports. For the quantitative determination of nickel and zinc DADTC the use of a column with 2% Silicone SE-30 on Chromosorb G AW DMCS or on Gas-Chrom Q was recommended. For the first time the separation of a number of DADTC complexes was also carried out on a glass capillary column of length 31.4 m with Silicone OV-101. Mass spectrometric analysis showed that with an increase in length of alkyl substituents in a DADTC molecule the degree of decomposition of the chelate on evaporation increased.

A method for determining chromium(III) and chromium(VI) in aqueous solution by their combined presence as DTFEDTC complexes has been developed.[67] The best results were obtained on packed columns with 3% Silicone OV-25 at 160–210 °C or Silicone OV-101 at 190–230 °C. The minimum concentration of chromium that could be detected was 5×10^{-5}%. Cobalt(II), nickel, zinc, cadmium, lead(II), copper, and iron(III) ions inferred with the determination. Similar methods have been reported in other studies.[68,69]

Meyer and Neeb[70] chromatographed nickel and cobalt DTFEDTC on packed columns with Silicone OV-101 (3%) deposited on different supports. When Chromosorb W HP was used on a glass column (90 × 0.25 cm) with programmed temperature change (2 K/min) in the range 135–200 °C, using a flame ionisation detector it was possible to detect down to 1×10^{-6}% nickel and cobalt in solution in the presence of tenfold quantities of copper, cadmium, and zinc and thousandfold quantities of iron.

The determination of rhenium(IV), (V), and (VII) in aqueous solution as DADTC complexes with ethyl and phenyl terminal groups has been reported.[71] The complexes were extracted with chloroform from hydrochloric acid solutions. Separation was carried out on a glass column of length 0.6 m with 5% Silicone SE-30 on Chromatone N AW DMCS.

A comparison of the suitability of different solid supports for the quantitative gas chromatographic determination of nickel and zinc DEDTC [72] showed that Chromosorb W HP and Chromatone N-Super had the best properties and that Chromosorb G was the least suitable.



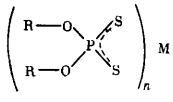
One study[73] is concerned with the determination of noble metal ions [gold(III), platinum(IV), palladium(II), rhodium(III), and iridium(IV)] as complexes with DTFEDTC. It should be noted that this is the first report on the quantitative gas chromatographic determination of gold. Separation was carried out on a glass column (80–100 × 0.2 cm) with 3% Silicone OV-3 on Chromosorb G AW DMCS at 210–220 °C using an electron capture detector with ^{63}Ni. The sensitivity for determination was comparable to the sensitivity of atomic absorption spectroscopy with electrothermal atomisation and in a number of cases even exceeded the latter.

In a study of the chromatographic behaviour of copper and nickel complexes with fifteen different DADTC on OV-101, NGA, and OV-225 liquid phases it was found that the shortest retention times were typical for chelates with short alkyl terminal groups if chromatography was carried out on a polar liquid phase.[74]

One study[75] is concerned with developing a method for determining trace metals as DEDTC complexes in aqueous solution. Analysis of small quantities of nickel, copper, zinc, cadmium, mercury, lead, and cobalt on columns of length 30–60 cm containing mixures of siloxane liquid phases—SE-30, QF-1, OV-101—on Gas-Chrom Q and Chromosorb W HP showed that lead, cadmium, and mercury DEDTC displayed signs of decomposition during the experiment. When a flame ionisation detector was used the limiting dilutions for the different metals ranged from 17 to 300 ng/ml. It is interesting to note that the authors carried out the experiments not only on glass columns but also on metal columns and found that in the latter case the detection limits increased by a factor of about one and a half.

2. Dialkyldithiophosphinates and Dialkyldithiophosphates

Kleinman and Neeb[76] synthesised diethyldithiophosphinates (DEDTP) of zinc, cadmium, cobalt, nickel, and lead with the general formula

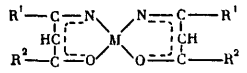


Thermogravimetric studies showed that all of the compounds obtained partially decomposed on sublimation (the non-volatile residue amounted to 2–11%). Nevertheless, the authors[76] prepared chromatograms of several mixtures of these compounds, including mixtures of zinc, cadmium, nickel, and lead DEDTP. Separation was carried out on a glass column (78 × 0.3 cm) with 3% Silicone OV-17 on Chromosorb N AW. Less satisfactory results were obtained when SE-30, OV-101, and Apiezon L were used as liquid phases. The cobalt complex was apparently not suitable for gas chromatography.

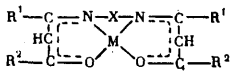
Somewhat later[77] the chromatographic behaviour of DEDTP complexes of the same metals was studied on columns with different silicone liquid phases on Chromosorb Q. The authors maintained that the lead chelate rapidly decomposed in solution on exposure to light. A method for determining traces of cadmium in aqueous solution at concentrations down to 3×10^{-6}% in the presence of a hundredfold excess of zinc is reported in the study.

The gas chromatographic behaviour of nickel, zinc, and cadmium di-isopropyldithiophosphinates under much the same conditions has also been reported[78] and the partial decomposition of the cadmium complexes was recorded. It was possible to detect these chelates in solution when their concentration was $\sim 2 \times 10^{-6}$ moles/litre.

Two studies[79,80] are devoted to the gas chromatography of



volatile dialkyldithiophosphates. From among the dimethyl- and diethyl-dithiophosphate complexes of nickel, palladium, and platinum, the di-*n*-propyldithiophosphate complexes of nickel and palladium, and the di-isopropyldithiophosphate chelates of zinc, nickel, palladium, platinum, copper, mercury(II), chromium(III), rhodium(III), cobalt(III), gold(III), ruthenium(III), and iridium(III) that were synthesised only the dimethyl- and di-isopropyl-dithiophosphates of nickel, palladium, platinum, chromium(III), and rhodium(III) proved to be suitable for gas chromatography.[79] The best chromatograms were obtained on columns with Silicone OV-101, SE-30, and PS-300 on Gas-Chrom Q or Chromosorb 750 at 150–180 °C.



The later study[80] described the chromatographic behaviour of diethyldithiophosphates of a number of metals on packed and capillary columns. When a flame ionisation detector was used the detection limits reached 10^{-11}–10^{-12} g of metal.

3. β-Ketoaminates and Metal Complexes with Ligands Containing S, O and S, N Donor Pairs

Bidentate and tetradentate β-ketoaminates (sometimes also called β-aminovinylketones, β-ketoimines, and Schiff bases) are formed by condensation of β-diketones with mono- or di-amines. They form chelate complexes with many metal ions. It is mainly β-ketoamine complexes with bivalent copper ions and metal ions of the nickel group that are suitable for gas chromatography:[18]

bidentate β-ketoamine complex

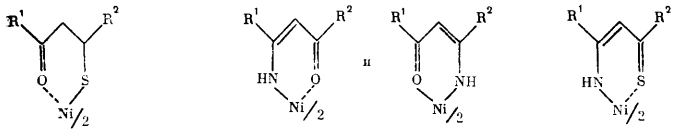
tetradentate β-ketoamine complex (X—hydrocarbon chain)

When considering bidentate β-ketoamines as ligands there is practical interest mainly in ketoamines obtained by condensation of diketones with ammonia, since metal complexes with N-alkyl-substituted β-ketoamines are thermally unstable and tend to hydrolyse. Unfortunately, even the most stable metal chelates with bidentate β-ketoamines fairly readily eliminate ligands on heating. As a result of this they usually decompose on the column during chromatography, which gives rise to abnormal effects.[18]

Complexes with tetradentate β-ketoamines are in most cases more stable and have better chromatographic properties despite their lower volatility. Under optimum conditions using an electron capture detector, such chelates can be detected using chromatography down to 10^{-12} g. Fluorinated complexes have particularly good properties. However, their practical application in analysis is made difficult by the extremely low solubility of fluorinated tetradentate β-ketoamines in water, which inhibits the use of the usual extraction methods for quantitative conversion of a metal being determined into the respective complex. The problems in the analytical use of β-ketoaminates have been examined in detail in a monograph.[18]

Attempts to use salicylaldiminate complexes of copper, nickel, and zinc for gas chromatography did not give favourable results.[18,81]

The thermal stability and chromatographic behaviour of 2-picolylalkylketonates [82] and 2-picolyltrifluoromethylketones [83] of beryllium, copper, zinc, nickel, and chromium were studied. It was found that the chelates of all the metals investigated apart from chromium were suitable for quantitative gas chromatographic analysis. However, the detection limits of these complexes were not stated.



The volatility and chromatographic behaviour of vanadyl,[84–87] copper, nickel,[84,86,87] and iron(III) [88] complexes with certain Schiff bases were studied. Satisfactory results were obtained when 1,1,1,1′,1′,1′-hexafluoro-4,4′-(1-methylethane-1,2-diyldi-imino)*bis*-(pent-3-en-2-one) [86] and 2,2,2′,2′-tetramethyl,5,′-(ethane-1,2-diyldi-imino)*bis*(hex-4-en-3-one) [85] were used as ligands for the determination of nanogram quantities of copper, nickel, and vanadium in petroleum and biological materials.

The simultaneous determination of copper and nickel as complexes with 1,1,1-trifluoro-1′,1′,1′-trimethyl-4,4′-ethane-1,2-diyldi-imino)*bis*(pent-3-en-2-one) in aqueous solution at concentrations of 0.02–0.12 mg/ml has been reported.[89]

For the gas chromatographic determination of iron(III), its complexes with hexadentate ligands—4,4′,4″-(neopentane-1,3,4-triyltri-imino)*tris*(pent-3-en-2-one) and 4,4′,4″-(cyclohexane-*cis*,*cis*-1,3,5-triyltri-imino)*tris*(pent-3-en-2-one)—were used.[88] It was possible to

detect down to 1×10^{-10} g of iron on a column (46 × 0.65 cm) with 3% Silicone OV-101 on Gas-Chrom Q at 200 °C using a flame ionisation detector.

Several studies have been published that are devoted to a comparison of the chromatographic properties of volatile nickel(II) complexes with ligands of analogous structure to β-diketones but containing S, O and O, N pairs as well as S, N [90-93] as donor atoms instead of two oxygen atoms. In these studies 25 compounds of four types were studied:

monothio-β-diketonates (MTBDK) β-aminovinylketonates (AVK) β-aminovinylthionates (AVT)

The terminal groups in the compounds investigated were CH_3, CF_3, $H(CF_2)_2$, $H(CF_2)_4$, C_3H_7, C_2F_5, $C(CH_3)_3$, $CH(CH_3)_2$, n-C_4H_9, and C_6H_5 in different combinations. The complexes obtained were chromatographed on glass columns (1 m × 3 mm) using a constant recombination rate detector. Tests on different packings showed that the best results were given by Chromatone N-Super with 3% Silicone SE-30. Retention of all the chelates studied increased with an increase in the length of alkyl terminal groups and also when CF_3 was replaced by $H(CF_2)_2$. Introduction of a *tert*-butyl group improved the chromatographic properties of all the complexes. Complexes with phenyl substituents were not eluted at all or were eluted with a very long retention time.

Nickel monothio-β-diketonates were eluted at 190–210 °C giving asymmetric peaks in all cases. Aminovinylketonates had greater volatility than the corresponding MTBDK complexes and were eluted from the same column at 140–160 °C. Under the experimental conditions, AVK complexes that contained a fluoroalkyl substituent on the carbon atom bonded to the amino group had better chromatographic properties than their structural analogues containing an amino group joined to a carboxyl carbon atom. In several cases the characteristic abnormal behaviour of chelates on a column occurred. Despite their lower elution temperature, in most cases the nickel AVK proved to be less stable during gas chromatography than the MTBDK complexes. Nickel AVT had the best chromatographic properties. Like MTBDK, they were eluted at high temperatures (in the region of 200 °C), but they displayed virtually no abnormal effects and gave symmetrical peaks. The detection limit for these chelates reached 2.5×10^{-10} g.

In one study[94] the thermal stability and chromatographic behaviour of complexes of copper, nickel, zinc, cadmium, platinum, and palladium with 4,4'-(ethane-1,2-diyldi-imino)*bis*(pent-3-ene-2-thione) and copper and nickel complexes of 4-[(3-oxo-1-methylbut-1-enyl)-aminoethylamino]-pent-3-ene-2-thione were studied and the possibility of simultaneous gas chromatographic determination of copper, nickel, and zinc as such complexes was demonstrated. Out of the compounds studied only the cadmium complex proved to be thermally unstable.

V. GAS CHROMATOGRAPHIC SEPARATION OF METAL CHELATES ON CAPILLARY COLUMNS

Although the gas chromatography of metal chelates has been in existence for over 30 years, the first studies on the separation of chelates on capillary columns were only published in 1979. This may have been due to the lack of success in the early attempts to use metal capillary columns for this purpose. There is nothing surprising in this as even when glass and quartz capillary columns, which are much more inert in the chemical sense, are used it is only possible to chromatograph some of the most stable β-diketonates—chelates of chromium, aluminium, beryllium, copper, and a few other metals. The range of metal dialkyldithiocarbamates that can be separated on capillary columns is more extensive, which is probably due to their kinetic stability. Recently, some dialkyldithiophosphates and metal complexes with Schiff bases and porphyrins have also been separated by this method.

The methods used to separate metal chelates on capillary columns are virtually the same as those used for other high-boiling compounds. The most successful results are obtained on columns of length 5–15 m with polysiloxane deposited or grafted stationary phases. Injection of the sample is carried out both directly into the column and with split flow. A flame ionisation detector is usually employed.

The separation of structural isomers of chromium trifluoroacetylacetonates and mixed ligand complexes of chromium with TFA and HFA as well as a number of copper β-ketoaminates and cyclopentadienyl compounds of manganese and chromium on capillary columns made of stainless steel with a porous layer has been described.[95] Dexsil-300 was used as the stationary phase. The separation of aluminium, beryllium, chromium, and copper trifluoroacetylacetonates has been carried out on glass and quartz capillary columns of length 5–15 m.[96] Sievers and Brooks[97] separated 25 isomeric chromium β-diketonates on a quartz capillary column (30 m × 0.32 mm) with Silicone SE-54.

The chromatographic behaviour of trifluoroacetylacetonates, pivaloyltrifluoroacetonates, and trifluoroacetylisovalerylmethanates of aluminium, beryllium, chromium, copper, cobalt, iron, and nickel has been studied on quartz capillary columns with OV-101, OV-17, and SE-54.[98] In particular, it was possible to separate isomeric aluminium and chromium pivaloyltrifluoroacetonates. The detection limits of the metals when using a flame ionisation detector reached 4×10^{-14}–2.2×10^{-12}g.

The first successful attempt to separate rare earth β-diketonates on the glass capillary column has been reported.[99] Rare earth chelates with PTA were separated on a column (9.5 m × 0.3 mm) with OV-17 stationary phase and a programmed temperature increase (15 K/min) in the range 175–250 °C. It was possible to separate mixtures of Sc–Lu–Er–La, Sc–Lu–Tm–Ho–La, and others. When longer columns were used and silicones SE-30, OV-101, and SE-52 were employed as liquid phases, separation was less good.

The separation of DADTC complexes of iridium, palladium, lead, cadmium, zinc, selenium, rhodium, cobalt, and arsenic was carried out on a glass capillary column (7 m × 0.3 mm) with Silicone OV-101 at 190–255 °C.[100] A flame ionisation detector was used. An attempt to use pyrrolidinedithiocarbamates proved unsuccessful. The use of dipropyl- and dibutyl-dithiocarbamates gave better results;[101] it was possible to separate selenium, zinc, lead, and palladium chelates with a programmed temperature increase (20 K/min) in the range 170–245 °C. Calibration curves remained linear over the range 5×10^{-8}–1×10^{-6} g of chelate. When the content of chelate in the sample was less than 5×10^{-8} g, partial irreversible adsorption on the column occurred.

In one study[102] the chromatographic behaviour of DTFEDTC and di-isobutyldithiocarbamates of nickel, copper, zinc, cadmium, mercury(II), lead(II), and cobalt(III) was investigated. Separation was carried out on short (1–7 m) quartz and glass capillary

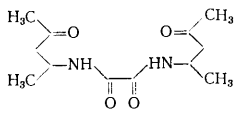
columns of internal diameter 0.30–0.32 mm with OV-101, SP-2100 and FFAP as liquid phases using different modes of programmed temperature increase. The best results were obtained when non-polar silicone liquid phases were used. Partial decomposition on the columns was only observed for the zinc chelates. The possibility of gas chromatographic detection of trace amounts of these metals was demonstrated.

More recently the determination of nickel, copper, and cobalt as their di-isobutyldithiocarbamates on capillary columns (3–4 m × 0.3 mm) with silicones SE-52 and SE-54 and a programmed temperature increase from 220–270 °C (30 K/min) has been reported.[103] The detection limits were $2-4 \times 10^{-11}$ g of metal. The method was used to determine metals in sea and tap water.

Sucre and Jennings[96] chromatographed different volatile metal complexes, including DEDTC and DTFEDTC complexes of zinc, copper, nickel, lead, and cobalt. Detection was carried out using flame ionisation, electron capture, flame photometric, and nitrogen phosphorus detectors. Separation was carried out on quartz and glass capillary columns of length 5–15 m with SE-30, SE-52, SE-54, SP-2100, Dexsil-300, and Carbowax 20 M as liquid phases. The best results were obtained on the silicone phases and on Dexsil. When an electron capture was used for the DTFEDTC complexes and a nitrogen phosphorus detector used to determine nitrogen, a sensitivity of $0.2-1.4 \times 10^{-12}$ g/sec was attained, when a flame photometry detector was used to determine sulphur the sensitivity was $0.7-1 \times 10^{-12}$ g/sec.

The determination of trace amounts of zinc, copper, cadmium, mercury, lead, and cobalt as DTFEDTC complexes using capillary glass chromatography at 90–250 °C on Silicone SE-30 with a flame ionisation detector has been reported.[104] The chromatographic behaviour of DTFEDTC complexes of thallium, mercury(II), cadmium, copper, cobalt, nickel, iron, lead, indium, bismuth, palladium, and zinc on glass and quartz capillary columns with Silicone SE-54 and on a capillary column with a chemically grafted phase of DB-5 has been investigated.[105] In one experiment the authors succeeded in separating complexes of thallium, zinc, copper, nickel, cadmium, palladium, cobalt, iron, indium, lead, and bismuth.

Chromatography of small quantities ($3-12 \times 10^{-8}$ g) of DEDTC and DTFEDTC complex of zinc, cobalt, lead, palladium, nickel, and copper on a short quartz capillary column (4.5 – 0.32 mm) with Silicone SE-54 has been carried out.[106] A flame ionisation detector was used. Dipropyl- and di-isobutyl-dithiocarbamates were also studied. Experiments were also carried out using a longer column (15 m), and the temperature was increased to 320 °C by programming. For the non-fluorinated chelates, in most cases it was only possible to obtain satisfactory chromatograms on the short column, and there was no advantage in using dipropyl and di-isobutyl derivatives. When separation was carried out on the long column, satisfactory peaks were obtained only for zinc and nickel DEDTC. The peak from bismuth DEDTC had a distorted shape in all cases.



Nanogram quantities of zinc, copper, nickel, palladium, cobalt, chromium, and iron as their DTFEDTC complexes were determined on capillary columns.[107] The metals were extracted from aqueous solution at pH 3.5 with a solution of the ligand in chloroform. The sample was injected into a quartz capillary (5 m × 0.32 mm) installed before the column (15 m × 0.32 mm) with polymethylsiloxane as liquid phase. The column temperature was increased in the range 64–260 °C using a complex program. C_{20} and C_{24} hydrocarbons or palladium chelate were used as internal standards. The calibration curve for the chromium chelate was linear over the range $0.2-20 \times 10^{-9}$ g.

The separation of nickel(II), palladium(II), and platinum(II) DEDTC on a glass capillary column was achieved.[80]

Scheller and Neeb[108] detected chromium, nickel, copper, zinc, cadmium, and cobalt as their DTFEDTC complexes down to 1×10^{-9} g/ml using a flame ionisation detector. When an electron capture detector was used it was possible to improve the sensitivity further by a factor of 100, but the detector used was not adapted to work with capillary columns and as a result the peaks were considerably broken.

A method for the determination of small quantities of copper and nickel DEDTC on a glass capillary column has been reported, and it was characterised by having a large sample (10 μl) injected into a deactivated glass capillary (6 m × 0.32 mm) installed before the column.[109] Normal C_{22} alkane was used as the internal standard. The calibration curves retained linearity over the range $0.25-10 \times 10^{-9}$ g of chelate.

The behaviour of copper, nickel, palladium(II), and vanadyl chelates with a number of tetradentate β-ketoamines including a new type of ligand (tetraketone):

was studied on quartz capillary columns of length 25 m and 6.3 m (internal diameter 0.32 mm) with OV-101, OV-17, PEG-20 M as liquid phases and BP-1, BP-10, and BP-20 chemically grafted phases at 150–240 °C, as well as on packed columns with Silicones SE-30, OV-3, OV-17, OV-25, OV-210, and Dexsil-300 at 200 °C.[110] The best results were obtained on the OV-3 and OV-25 phases. The most suitable carrier gas to use for the capillary columns was hydrogen, which made it possible to work with quite good efficiency at high flow rates. The detection limits for the packed columns using a flame ionisation detector reached $100-140 \times 10^{-9}$ g of chelate, while for the capillary columns the limits were $0.2-2 \times 10^{-9}$ g of chelate. When nitrogen was used as the carrier gas the detection limits were higher by about a factor of 10.

More recently the behaviour of 17 chelates of copper, nickel, zinc, cadmium, platinum, palladium, and vanadyl with a number of tetradentate β-ketoamines and β-aminovinylthiones [111] were studied on five different capillary columns. The rate constants for decomposition of the chelates on the columns were determined along with other parameters. Their values varied from 10^{-1} to 10^{-3} sec^{-1} for the relatively unstable aminovinylthionates and were as low as 10^{-5} sec^{-1} for the stable β-ketoaminates. Enthalpies of solution were also determined for a number of chelates on several different liquid phases.

The gas chromatographic separation of complexes of nickel, copper, vanadyl, and cobalt(II) with etioporphyrin I and octaethylporphyrin has been reported for the first time.[112] Separation was carried out on a quartz capillary column (6 m × 0.3 mm) with Silicone OV-1 and a programmed temperature increase from 60 to 300 °C followed by exposure to an isothermal system. It was also possible to chromatograph porphyrin complexes of zinc, palladium-(II), titanyl, and platinum(II) under similar conditions. Satisfactory results were obtained when a glass column (10 m × 0.3 mm) with CP Sil S as liquid phase was used. The separation of complexes of silicon, aluminium, gallium, rhodium(III), and nickel with octaethylporphyrin, etioporphyrin I, and etioporphyrin III under similar

conditions was subsequently reported.[113] Metalloporphyrin complexes are the least volatile of all those used up to now in the chromatography of metal complexes with organic ligands, their separation was only achieved because of their excellent thermal stability and by using short capillary columns. It is probably true that because of the difficult quantitative conversion of metal ions to porphyrin complexes, at the present time the use of the latter for practical analysis cannot be considered.

VI. GAS CHROMATOGRAPHY OF METAL β-DIKETONATES IN LIQUID VAPOUR

The studies initiated in 1971 by Fujinaga et al.[114] on the chromatography of metal β-diketonates using a carrier gas with vapour from the corresponding β-diketone added (this method is usually not quite correctly called gas chromatography in ligand vapour—GCLV) have undergone further development. Thus, the determination by GCLV of trace amounts of beryllium as its trifluoroacetylacetonate in aluminium and its alloys with magnesium has been reported.[43] Analysis was carried out on a glass column (90 × 0.3 cm) filled with 0.5% Silicone SE-30 on glass beads at 130 °C. The carrier gas was argon with 0.05% TFA added, and a plasma detector with electrodeless discharge was used. The detection limit reached 1×10^{-12} g of beryllium. A similar method[115] was used to determine traces of copper and aluminium in metallic zinc.

A short communication[116] reports for the first time the complete separation of trifluoroacetylacetonates of four neighbouring rare earth elements (gadolinium, terbium, dysprosium, and holmium) on a column with a mixture of 0.2% PEG-20 M and 1.8% Silicone OV-17 on Chromosorb W at 240 °C. The gas carrier was helium with an extremely high concentration (10%) of TFA vapour, and a katharometer detector was used. Unfortunately, the column length was not stated in the study.

The separation of hexafluoroacetylacetonate adducts of rare earth radionuclides with TBP and TOPO on a column (2 m × 2.4 mm) with 2% polyphenyl ether or 3% Dexsil-300 on Chromosorb W has also been reported.[117] The carrier gas was saturated with HFA vapour at 60 °C. The column temperature was programmed to increase from 150 to 215 °C (8 K/min). A chromatogram which indicates the satisfactory separation of ten rare earth adducts over a period of 8 minutes was shown in the study.

The chromatographic behaviour of nickel and a number of other metal chelates with TFA under GCLV conditions has been studied[118] and a method for determining nickel in steel has been reported. Lead, cadmium, tellurium, molybdenum, and tungsten interfered with the determination. The determination of palladium as its trifluoroacetonylacetonate in the other metals of the platinum group using GCLV has been reported.[119] Other studies[27,120–122] have also been devoted to the application of GCLV.

When a chelate of europium with PTA was chromatographed in carrier gas containing acetylacetone vapour, ligand exchange occurred and less volatile mixed chelates were formed, containing PTA and AA anions.[27] A similar phemenon was found when an adduct of europium β-diketonate with TBP was chromatographed. When ligand vapour (HFA) was introduced into the carrier gas (1.6×10^{-6} g/ml) it was possible to obtain symmetrical peaks of hexafluoroacetylacetonate adducts of americium, curium, europium, terbium, and lutetium with TBP on a column with 5% Silicone SE-30 on Chromatone N AW DMCS at 205 °C.[122] The detection limits reached 5×10^{-8} g for americium and 3×10^{-9} g for curium.

The separate determination of manganese(II) and (III) ions in aqueous solution as chelates with TFA using GCLV has been reported.[123] One study[124] examines trifluoroacetylacetonates of chromium, aluminium, and iron by means of GCLV. Addition of TFA vapour to the carrier gas without exception improved the calibration curves of all the chelates, even that of the most stable chromium chelate.

VII. BEHAVIOUR OF METAL CHELATES ON A CHROMATOGRAPHY COLUMN

The abnormal effects that occur when the β-diketonates of many metals are chromatographed have been of interest to reseach workers for a long time. Among these effects are the irreversible adsorption of the first samples of chelate on a new column, the "memory" effect of a column, the "disappearance" of small samples of chelate on a column, the abnormal broadening of peaks, and so on. These phenomena have been described in detail in, for example, one monograph.[18] Berezkin[125] showed that such effects are the partial manifestations of general characteristics of the chromatographic process complicated by an appreciable degree of irreversible or quasi-irreversible chemisorptive interaction beween the components being separated and the column packing. In the case of metal complexes such as β-diketonates this type of interaction is likely to occur mainly with elimination of one ligand from the complex to give a free β-diketone molecule and is accompanied by attachment of the residue of complex to the matrix (solid support or liquid phase):

$$ML_n + HA \rightarrow ML_{n-1}A + HL$$

where M is metal, L is ligand, H is mobile hydrogen, A is matrix, and HL is free β-diketone.

This hypothesis, which was proposed some time ago,[18] was supported experimentally for the first time in one study,[126] where it was shown that rare earth dipivaloylmethanates were adsorbed on the column as cation complexes containing two ligand molecules.

The abormal effects mentioned above have been investigated in detail on copper(II) trifluoroacetylacetonate as a model.[127,128] A study of the distribution of copper chelate adsorbed on the column using a ^{64}Cu radioisotope showed that the adsorption depended on the quantity of chelate introduced, the content of the liquid phase, the nature of the solid support and the liquid phase, and the temperature. Considerable adsorption of chelate by wads of glass wool and fluoroplastic fibre holding the packing in the column was observed. The adsorption of chelate in the column was partly reversible.

More recently a similar study was published, being devoted to the chromatographic behaviour of zinc di(trifluoroethyl)dithiocarbamate[129] on a column, and it was carried out using a ^{65}Zn radioisotope. The authors also observed considerable adsorption of chelate on glass, quartz, and Teflon wool and indicated that the best results were obtained using metal gauze as wadding. To reduce the adsorption effects it was recommended to use glass and quartz capillarly columns rather than packed columns.

The interaction processes between metal β-diketonates and packing and with each other that occur on a column when the chelates of two different metals are chromatographed was studied by computer simulation.[130] The abnormal effects due to adsorption of hexafluoroacetylacetonate adducts of americium, curium, and some rare earth elements have also been described.[122]

Similar abnormal effects occurred when copper and iron β-diketonates were chromatographed on quartz capillary columns with different liquid phases. The partial oxidation of vanadium(III) chelate on a column to form vanadyl chelate was also observed. It is interesting to note that when nitrogen carrier gas was replaced by hydrogen the decomposition of the chelates in the column increased. Another study[132] is also devoted to the abnormal behaviour of metal β-diketonates on chromatographic columns.

VIII. GAS CHROMATOGRAPHIC DETERMINATION OF TRACE METALS

It is evident from what has been stated that the previous period of 11 years has been marked by considerable progress in the use of gas chromatography for practical analysis of trace amounts of metals. It is true that the limiting sensitivity of the method has not improved very much—the detection limit of most metals lies in the region of $10^{-11}-10^{-13}$ g per sample—and this is due to the absence of any noticeable improvement in the sensitivity of chromatographic detection in general. However, the total number of elements that can be determined with high sensitivity has increased substantially as a result of using new volatile complexes and the application of capillary columns.

A general Table featuring the present potentialities of gas chromatography in this field is given below.

Detection limits (m) of metals as volatile complexes using gas chromatography.

Metal	$m.10^{10}$.g	Refs.	Metal	$m.10^{10}$.g	Refs.
Be	0.0004	[133]	Ru	0.0024	[52]
Al	0.009	[134]	Rh	0.01**	[73]
Sc	0.03*	[135]	Pd	0.005**	[73]

The η^5-Indenyl and η^5-Fluorenyl Complexes of Transition Metals and Their Comparison with the η^5-Cyclopentadienyl Compounds

I.A.Lobanova and V.I.Zdanovich

Data on the synthesis, structure, and reactivity of the η^5-indenyl and η^5-fluorenyl complexes of transition metals are examined and discussed. A comparison with the η^5-cyclopentadienyl analogues is made.
The bibliography includes 187 references.

CONTENTS

I. Introduction 967
II. Methods of synthesis and properties of the η^5-indenyl and η^5-fluorenyl complexes of transition metals 967
III. Conclusion 977

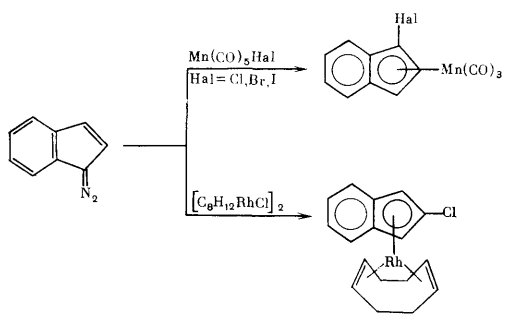
I. INTRODUCTION

The first η^5-indenyl complex (di-indenyliron)[1] was obtained almost simultaneously with ferrocene,[2] while difluorenylzirconium dichloride—the first compound with the η^5-fluorenyl ligand—was synthesised in 1965.[3] Nevertheless the chemistry of the indenyl and fluorenyl complexes of transitional metals has so far been little investigated, in contrast to the cyclopentadienyl complexes. However, the presence of a five-membered ring coordinated to the metal and of non-coordinated six-membered rings in the η^5-indenyl and η^5-fluorenyl complexes makes them of interest for the study of the influence of coordination to the metal on the distribution of π-electron density throughout the condensed system of the ligand. Indene and fluorene complexes are of interest also because different types of coordination to the transition metal (η^6, η^5, η^3, and η^1) are possible in such compounds and metallotropic rearrangments, widely investigated at the present time, are therefore characteristic of them. The η^5-indenyl and η^5-fluorenyl complexes of transition metals are more reactive than their cyclo-pentadienyl analogues in ligand exchange reactions because of their tendency to metallotropic rearrangements. The ease of ligand exchange in these complexes can be used in the synthesis of new organometallic compounds and also of catalysts of certain chemical processes.

II. METHODS OF SYNTHESIS AND PROPERTIES OF THE η^5-INDENYL AND η^5-FLUORENYL COMPLEXES OF TRANSITION METALS

1. Methods of Synthesis

The methods of synthesis of the η^5-indenyl and η^5-fluorenyl complexes of transition metals are usually analogous, with slight modifications, to those used in the synthesis of the η^5-cyclopentadienyl derivatives. The differences in the methods concern the reaction temperature and time, which is frequently associated with the lower stability of the η^5-indenyl and η^5-fluorenyl compounds.



The commonest method of synthesis of these compounds involves the interaction of indenyl and fluorenyl derivatives of alkali metals, more rarely organotin compounds or Grignard reagents, with transition metal salts, carbonyls, or halogen-containing complexes:[3-44]

$$3C_9H_7K + MCl_4 \rightarrow (C_9H_7)_3MCl + 3KCl,\ M = U,\ Th;$$
$$C_9H_7K + W(CO)_6 \rightarrow [C_9H_7W(CO)_3]^{\ominus}K^{\oplus} + 3CO;$$
$$C_{13}H_9Li + [CrCl(NO)(CO)_2] \rightarrow C_{13}H_9Cr(CO)_2NO + LiCl.$$

In order to obtain mixed indenyl sandwich compounds, the transition metal salt is acted upon by alkali metal derivatives of indene and a second ligand:[45-47]

$$TiCl_4 + C_9H_7Na + C_8H_8K_2 \rightarrow C_9H_7TiC_8H_8.$$

A novel method of synthesis of the η^5-indenyl complexes with a halogen substituent in the π-ligand is based on the interaction of diazoindene with halogen-containing transition metal derivatives:[48,49]

One of the most general methods of synthesis of new compounds in organo-metallic chemistry involves the exchange of the carbonyl or halogen groups in metal complexes for *n*- and π-donor ligands (phosphines, olefins, acetylenes, etc.). This method is used widely also for the synthesis of η^5-indenyl and η^5-fluorenyl complexes which have not been described hitherto:[35,38,50-76]:

$$C_9H_7W(CO)_3(CH_3) + C_2H_4 \rightarrow C_9H_7W(CO)_2(CH_3)(C_2H_4) + CO,$$
$$(C_{13}H_9)_2MCl_2 + Na(S_2CNR_2) \rightarrow (C_{13}H_9)_2M(S_2CNR_2)Cl + NaCl,$$
$$M = Ti,\ Zr;\ R = CH_3,\ C_2H_5,\ iso\text{-}C_3H_7.$$

Polymetallic heteronuclear clusters containing the η^5-indenyl ligand have been obtained from the highly reactive η^5-indenylrhodium complexes.[77–83]

2. The Nature of the Metal–π–ligand Bond in the η^5-Indenyl and η^5-Fluorenyl Complexes. The Stability of the Complexes

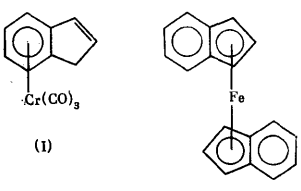
In the study of the properties of the η^5-indenyl and η^5-fluorenyl complexes of transition metals, it has been frequently noted that these complexes are less stable than their η-cyclopentadienyl analogues.[26,27,32,84–86] According to modern ideas, the π electrons of the ligand are mainly involved in the bond between the π-ligand and the metal.[87] Consequently, the strength of the metal–π-ligand bond should be influenced by substituents in the π-ligand which alter its π-electron density. Theoretical calculations[88] for the indenyl and fluorenyl anions (in alkali metal salts) have shown that the six-membered aromatic rings participate, together with the five-membered ring, in the distribution of π-electron density (including the negative charge) in these anions. Presumably, in the η^5-indenyl and η^5-fluorenyl complexes of transition metals, in which only the five-membered ring is linked directly to the metal, there is also interaction of the π-electron clouds of the six- and five-membered rings, which can weaken the donor–acceptor interaction between the five-membered ring and the transition metal. Indeed, the study of titanium and zirconium complexes has shown that the strength of the metal–π-ligand bond is sensitive to the donor and acceptor characteristics of the substituents in the π-ligand. Thus the resistance of compounds of the type L_2MCl_2 (M = Ti or Zr; L = $C_5H_4CH_3$, C_9H_7, or C_9H_{11}) to decomposition and hydrolysis is correlated with the nature of the substituents in the five-membered ring: the η^5-indenyl derivatives are less stable while the η^5-tetrahydroindenyl derivatives are more stable than the unsubstituted η^5-cyclopentadienyl analogue. This has been attributed[84] to the fact that the six-membered ring in the η^5-indenyl complexes behaves as an electron-accepting substituent in relation to the five-membered ring bound to the metal, which leads to a lower stability of these compounds in polar organic solvents. On the other hand, the saturated cyclohexane ring, which is an electron-donating substituent, increases the stability of the η^5-tetrahydroindenyl complexes of titanium and zirconium. A lower stability of the indenyl complexes compared with the cyclopentadienyl complexes has been established for compounds of Group VII metals. Thus the interaction of η^5-$C_9H_7Re(CO)_3$ with nitrogen-containing bases (pyridine or urotropine) entails the cleavage of the metal–π-ligand bond and the formation of dinuclear complexes with bridging hydroxy- or alkoxy-groups.[89] On the other hand, the reactions of η^5-$C_5H_5Re(CO)_3$ with these bases lead only to substitution of the CO group by the *n*-donor ligand.[90]

Further weakening of the bond between the π-ligand and the metal in the η^5-fluorenyl complexes compared with the indenyl complexes is due to the increase in the number of benzene rings condensed with the five-membered ring, such rings withdrawing the π-electron density from the cyclopentadienyl ring. Indeed, difluorenyl derivatives have not been obtained for metals of the iron triad, which form the most stable dicyclopentadienyl complexes.[32]

Calculations of the force constants for the C≡O bonds in the complexes $C_5H_5Mn(CO)_3$, $C_9H_7Mn(CO)_3$, and $C_{13}H_9Mn(CO)_3$ [26] failed to indicate appreciable changes in these quantities on passing from η^5-$C_5H_5Mn(CO)_3$ to η^5-$C_9H_7Mn(CO)_3$ and η^5-$C_{13}H_9Mn(CO)_3$, which indicates the retention of the same effective charge on the metal atom in all three complexes. The authors suggested that the decrease in the strength of the bond between the five-membered ring and the metal after its successive condensation with benzene rings is a consequence of the weakening of both donor–acceptor and dative metal–ring bonds.

A comparative quantitative estimate of the strength of the π-ligand–metal bond in the indenyl, fluorenyl, and cyclopentadienyl complexes was first made in relation to the carbonyl derivatives $LM(CO)_3$ (M = Mn or Re; L = η^5-C_5H_5, η^5-C_9H_7, or η^5-$C_{13}H_9$) or Group VII metals.[91] The authors used mass spectrometry for this purpose, which makes it possible to study the compounds with exclusion of the influence of the medium. The ratio of the sum of the intensities of the metal-containing ions (after subtracting the intensity of the metal ion) I_1 to the sum of the intensities of all the hydrocarbon ions and the metal ion I_2 was adopted as the measure of the strength of the metal–π-ligand bond. According to the results obtained by this method (see Table), the strength of the binding of the metal to the π-ligand diminishes greatly on passing from rhenium to manganese and diminishes appreciably in the sequence η^5-cyclopentadienyl > η^5-indenyl > η^5-fluorenyl complexes.

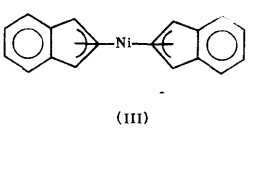
Mass-spectrometric data for the metal–π-ligand bond strengths.



Compound	I_1/I_2	Compound	I_1/I_2
$C_9H_5Re(CO)_3$	87	$C_5H_5Mn(CO)_3$	1.9
$C_9H_7Re(CO)_3$	64	$C_9H_7Mn(CO)_3$	0.51
		$C_{13}H_9Mn(CO)_3$	0.34

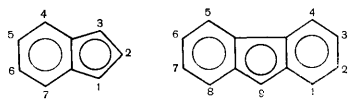
3. The Structure of the η^5-Indenyl and η^5-Fluorenyl Complexes of Transition Metals

Three types of coordination are known for the π-complexes of indene and fluorene with transition metals: η^6-coordination [as in the complex (I)], η^5-coordination [as in the complex (II)], and η^3-coordination [as in the complex (III)]. A compound of type (I) belongs to the class of π-arene complexes and the η^5- and η^3-indenyl derivatives are analogues of the cyclopentadienyl and allyl complexes respectively. However, for the indenyl and fluorenyl complexes there apparently exists also a transitional type of coordination between η^5- and η^3-coordinations, for example, in the π-complexes of the lanthanides and the actinides.



In the present review, we shall consider only η^5-coordination complexes and shall compare them with their cyclopentadienyl analogues.

The structure of the η^5-indenyl and η^5-fluorenyl complexes has been studied by IR spectroscopy,[68,92–94] mass spectrometry,[95] NMR spectroscopy,[96–100] and X-ray diffraction analysis (XDA).[27,57,59,101–102]



(I)

(II)

(III)

Important information about the type of coordination of the π-ligand in transition metal complexes can be obtained from study of the ^1H and ^{13}C NMR spectra. This is due to the fact that the proton and ^{13}C signals in the NMR spectra of the organic fragments π-coordinated to the metal undergo an appreciable upfield shift compared with the non-coordinated organic compound. Indeed, in the chromium(I) complex with η^6-coordinated indene, all the signals of the carbon atom nuclei in the six-membered ring undergo a 30 p.p.m. upfield shift, while the signals of the non-bridging carbon atoms in the five-membered ring hardly change compared with the non-coordinated indene.[97] On the other hand, in the case of the di-η^5-indenyl complex of iron(II), there is an appreciable upfield shift of the carbon atom signals of the five-membered rings, including bridging carbon atoms, while the signals of the other four carbon atoms in the six-membered rings remain in the same range as for the non-coordinated indene.[97] In the ^{13}C NMR spectrum of the nickel(III) complex in which the π-ligand is η^3-coordinated to the metal atom, only the signals due to the carbon atoms in the 1-, 2-, and 3-positions are appreciably displaced, the signal of the nucleus of the C(3) atom being displaced downfield and those of the nuclei of the C(1) and C(2) atoms being displaced upfield compared with free indene.[97] Here and henceforth the following numbering of the atoms is used:

It is believed[99] that the chemical shifts of the quaternary bridging carbon atoms of the indenyl ligand in the ^{13}C NMR spectra are a good indicator for the determination of the η^5- or η^3-coordination of the π-ligand. Thus the relatively small chemical shifts of the bridging carbon atoms in the dimer $[C_9H_7Mo(CO)_2]_2$ (111.5 p.p.m.) agree with the XDA data indicating the η^5-coordination of the indenyl ligands.

Valuable information about the distortion of the η^5-coordination of the indenyl and fluorenyl ligands has been obtained from ^1H and ^{13}C NMR spectra. Thus a slight distortion of the η^5-type of coordination towards η^3-binding was manifested in the ^1H NMR spectrum of the compound $C_9H_7Rh(C_2H_4)_2$.[19] Only the proton signal in the 2-position in the π-indenyl ligand was split as a result of the interaction with the ^{103}Rh nucleus of the kind observed for the η^3-allyl complexes of rhodium. However, signals of all the carbon atoms of the five-membered ring of this complex appear as doublets in the ^{13}C NMR spectrum as a consequence of the interaction of the ^{13}C nuclei with the ^{103}Rh atoms, which indicates the binding of the rhodium atom to all five carbon atoms.[19] An analogous distortion of the η^5-coordination was reflected in the ^1H and ^{13}C NMR spectra of the complex $C_9H_7Co[P(OR)_3]_2$.[17]

Judging from the NMR spectra, there is some contribution of η^1-type coordination in the fluorenyl complex η^5-$C_{13}H_9Co[P(OR)_3]_2$: the signal of the proton in the 9-position of the π-ligand is at stronger field than for the complexes η^5-$C_{13}H_9Mn(CO)_2L$ (L = CO or PPh_3) and $(\eta^5$-$C_{13}H_9)Zr(\eta^3$-$C_{13}H_9)Cl_2$. Furthermore, the spin–spin coupling constant (SSCC) of the carbon nucleus in the 9-position in the π-ligand to the phosphorus nucleus in phosphite is manifested in the ^{13}C NMR spectrum of the cobalt complex.[17]

The most complete idea about the structure of the η^5-indenyl and η^5-fluorenyl complexes of transition metals is provided by XDA. The first X-ray diffraction studies on η^5-indenyl complexes were performed at the end of the 1950's. The XDA data for di-indenyliron[101] indicated a great similarity between its structure and that of ferrocene. In the planar indenyl ligand, the C–C bond lengths are equalised (1.43 Å) and the C–C–C angles are 120 ° in the six-membered ring and 108° in the five-membered ring, which corresponds to a fully conjugated aromatic system. Di-indenylruthenium has an analogous structure.[102] Subsequently, in the study of the structure of the η^5-indenyl complexes, it was established that they have a number of characteristic features distinguishing them from their η^5-cyclopentadienyl analogues. A slight departure from planarity of the π-ligand as well as a difference in the metal–carbon bond lengths has been observed for the η^5-indenyl complexes: the length of the bonds between the metal and the bridging carbon atoms is somewhat greater than that of the bonds with the remaining three atoms. Thus there is a slight distortion of the η^5-coordination of the indenyl ligand to the metal in the direction of η^3-binding.[57,59,103–105] The mechanism of this distortion involves the movement of the metal atom parallel to the plane of the indenyl ligand. In recent years, the "slip parameter" Δ has been used to estimate this effect.[107–109] The parameter Δ represents the length of the vector between the centre of the five-membered ring and the projection of the metal atom onto the plane of the ring. For η^5-indenyl complexes, the "slip parameter" is usually $\Delta < 0.3$.[107] All the characteristic features of the indenyl complexes have been observed in a study of the structure of bis(1,3-dimethylindenyl)iron hexafluorophosphate: the distortion from planarity of the π-ligand was 0.049 Å and the difference between the Fe–C (five-membered ring) bond lengths was 0.08 Å.[103]

Comparison of the structures of the Group IVB metal complexes $(C_9H_7)_2M(CH_3)_2$ (M = Ti, Zr, or Hf) showed that the difference between the metal–carbon (five-membered ring) bond lengths depends on the nature of the metal: it is 0.19 Å for the titanium compound, 0.12 Å for the zirconium compound, and 0.13 Å for the hafnium compound.[111]

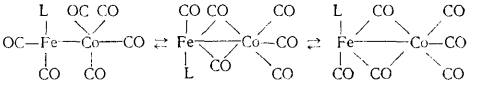
Undistorted η^5-coordination of the indenyl ligand has been observed only in exceptional cases. Such an example is provided by the complex $(CO)(\eta^5$-$C_9H_7)Mo \equiv Mo(C_9H_7$-$\eta^5)(CO)$.[112] The indenyl ligands in this complex are planar and their five-membered rings are linked almost symmetrically to the molybdenum atoms: the difference between the Mo–C(C_5H_3) bond lengths is only 0.06 Å.[112]

A rare example of structural comparison of analogous η^5-indenyl, η^5-fluorenyl, and η^5-cyclopentadienyl complexes has been described.[27,113] For $C_9H_7Cr(CO)_2NO$, $C_{13}H_9Cr(CO)_2NO$, and $C_5H_5Cr(CO)_2NO$, which have in the main similar structures, an increase has been observed in the distance between the chromium atom and the centre of the five-membered ring in the following series of complexes: η^5-cyclopentadienyl, η^5-indenyl, η^5-fluorenyl (1.845, 1.866, and 1.884 Å respectively), and also a decrease in the Cr–N bond lengths with the simultaneous increase in the Cr–CO distances for the indenyl and fluorenyl complexes.

Complexes where the fluorenyl and indenyl ligands are involved in different types of coordination to the same metal atom are of special interest: $(\eta^5$-$C_9H_7)W(\eta^3$-$C_9H_7)(CO)_2$,[114] $(\eta^5$-$C_9H_7)V(\eta^3$-$C_9H_7)$. $.(CO)_2$,[109] and $(\eta^5$-$C_{13}H_9)Zr(\eta^3$-$C_3H_9)Cl_2$.[115,116] In the tungsten complex, one of the indenyl ligands is linked to the metal atom almost symmetrically, the W–C (five-membered ring) bond lengths oscillating from 2.27 to 2.37 Å but remaining within the limits usual

for Group IVB metal complexes. This ligand is planar overall, the C–C bond lengths [1.41(3) Å] indicating the delocalisation of the π-electrons over the aromatic system. For the second indenyl ligand, the W–C (five-membered ring) bond lengths are 3.22(2) and 3.12(2) Å for the bridging carbon atoms and 2.26(2), 2.46(2), and 2.44(2) Å for the non-bridging atoms. This indenyl ligand has lost its planarity as a consequence of η^3-coordination: its five-membered ring is bent at an angle of 26°. For the vanadium complex, large differences between the η^5- and η^3-indenyl ligands have also been observed. For the η^5-coordinated ligand, the V–C (five-membered ring) bond length varies from 2.261(3) to 2.388(3) Å and the "slip parameter" Δ is 0.17. In the η^3-indenyl ligand, the dihedral angle between the planes of the η^3-allyl fragment and the six-membered ring is 12.0(3)°. The V–C (five-membered ring) bond lengths are 2.379, 2.184, and 2.359 Å for the carbon atoms of the allyl fragment and 2.857 and 2.876 Å for the bridging carbon atoms; Δ = 0.56.[109]

The zirconium complex $(\eta^5\text{-}C_{13}H_9)Zr(\eta^3\text{-}C_{13}H_9)Cl_2$ is one of the few compounds with fluorenyl ligands bound in different ways. The difference between the coordinations of the fluorenyl ligands in this complex follows from a comparison of the average Zr–C (five-membered ring) bond lengths. For one of these ligands, the bond length 2.56(7) Å is comparable to the bond length found for $(\pi\text{-}C_5H_5)_2Zr.Cl_2$, while for the other the average value of this distance is 2.52(8) Å for the three non-bridging carbon atoms and 2.80(1) Å (absence of a bond) for the two bridging atoms.[115,116] The authors believe that fundamental geometry of the molecule and the type of bond between zirconium and the π-ligands are determined by the steric requirements imposed by the bulky fluorenyl groups.

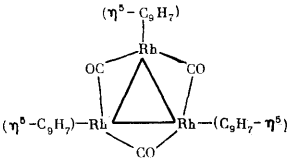


In the π-indenyl complexes of the lanthanides and actinides, distortion in η^5-coordination to the metal atom reaches a higher level than in the complexes of other transition metals. On the other hand, the changes in the bond length and in the planarity of the indenyl ligand in these complexes are smaller than for the η^3-coordinated indenyl ligand. As a result of this, some workers classify the indenyl complexes of the lanthanides and the actinides as η^5-derivatives, while others regard them as η^3-derivatives. XDA has been carried out for a series of samarium,[117] thorium,[118] and uranium[119–122] compounds. Having to choose betweeen the η^5- or the η^3-coordination of the indneyl ligand in $[1,4,7\text{-}(CH_3)_3C_9H_4]_3UCl$, Goffart et al.[120] decided on the η^5-type of binding on the basis of not only XDA data but also on the basis of a qualitative comparison of magnetic susceptibilities, vibrational spectra, and ^1H NMR spectra of this compound and its cyclopentadienyl analogue. The U–C (five-membered ring) bond lengths are 2.91 Å for the bridging carbon atoms and 2.72 Å for the non-bridging atoms. In the analogous thorium complex $[1,4,7\text{-}(CH_3)_3C_9H_4]_3.ThCl$, the Th–C (five-membered ring) bond lengths vary from 2.721(3) to 2.845(4) Å for the non-bridging carbon atoms and from 2.931(3) to 2.946(3) Å for the bridging carbon atoms. However, the authors[118] believe on the basis of these data that the indenyl ligands in the thorium complex are η^3-bound and that there is only a very weak interaction between the metal and the bridging carbon atoms in the five-membered rings.

Thus X-ray diffraction studies on the η^5-indenyl and η^5-fluorenyl complexes and the analogous η^5-cyclopentadienyl complexes have shown that the molecular structures of these compounds are in many respects similar: the η^5-coordinated ligand is planar with equalised C–C bonds, while in the carbonyl derivatives the metal–CO and C–O bond lengths are comparable. However, in contrast to the η^5-cyclopentadienyl complexes, in the η^5-indenyl and η^5-fluorenyl derivatives the bond lengths between the metal and the carbon atoms of the five-membered ring are different: for the three-non-bridging carbon atoms in the η^5-C_9H_7 ligand the metal–carbon bond lengths are smaller compared with the two bridge bonds. Some breakdown of the planarity of the η^5-indenyl and η^5-fluorenyl ligands is observed.

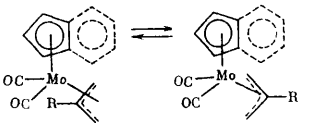
4. Stereochemical Non-Rigidity of the η^5-Indenyl Complexes

Comparison of analogous η^5-indenyl and η^5-cyclopentadienyl complexes of transition metals makes it possible to elucidate the influence of the η-ligand on the physicochemical properties and reactivity, in particular, on the properties of the other ligands. The nature of the π-ligand influences the dynamic equilibrium of isomers and conformers in solutions and barriers to the rotation of ethylene and acetylene ligands.



The IR spectra of the complexes $\pi\text{-}LFe(CO)_2Co(CO)_4$ (L = C_5H_5, $CH_3C_5H_4$, or C_9H_7), established that these compounds exist in solutions in the form of equilibrium mixtures of two isomers containing bridging CO groups [the isomers (B) and (C)] and one isomer having only terminal CO ligands [the isomer (A)]:

(A) (B) (C)



The fraction of the isomer (A) diminishes with decrease in temperature, with increase in solvent polarity, and in the sequence of ligands $\eta^5\text{-}C_9H_7 > \eta^5\text{-}CH_3C_5H_4 > \eta^5\text{-}C_5H_5$.[123] According to XDA data, in the solid state the complex $\eta^5\text{-}C_9H_7Fe(CO)_2Co(CO)_4$ has the structure (B).[124]

An analogous CO group migration process has been investigated for the η^5-indenyl cluster (IV). It was observed that the indenyl cluster exists in the form of only one isomer with bridging CO groups and that the ^{13}C NMR spectrum does not exhibit a temperature dependence in the carbonyl region, in contrast to its η^5-cyclopentadienyl analogue:[59]

(IV)

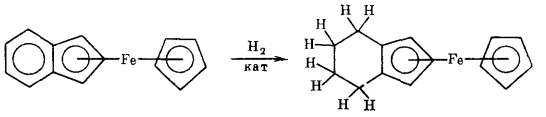
A series of studies have been devoted to the investigation of the stereochemistry of a number of η^5-indenyl and η^5-cyclopentadienyl complexes of molybdenum[125–127] and iron[128,129] by ^1H NMR. It was established in this way that in solution the compounds $\eta^5\text{-}LMo(CO)_2(\pi\text{-}C_3H_4R)$ (L = $\eta^5\text{-}C_5H_5$ or $\eta^5\text{-}C_9H_7$) exist as a mixture of two forms (D) and (E):[126]

(D) (E)

For the η^5-indenyl derivatives of molybdenum with R = CH_3, Cl, or Br, the equilibrium is displaced to the left, while in the case of the

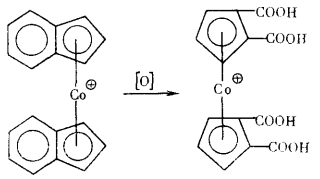
η^5-cyclopentadienyl complexes the substitution of the hydrogen atoms at the central carbon atom in the π-allyl group shifts the equilibrium to the right.[126] The analogous iron and ruthenium compounds η^5-LM(CO)(π-C_3H_4R) (M = Fe or Ru; L = C_5H_5 or C_9H_7) have been isolated in the form of only one isomer (E).[128]

In the study of the temperature variation of the ^1H NMR spectra of the rhodium complexes $LRh(C_2H_4)_2$ (L = η^5-C_5H_5 or η^5-C_9H_7), an appreciable influence of the π-ligand on the barrier to the rotation of ethylene was observed.[19,130] The barrier to the rotation of the ethylene ligand in the η^5-indenyl compound (10.5 ± 0.4 kcal mol^{-1}) is much lower than in the η^5-cyclopentadienyl compound (15.0 ± 0.2 kcal mol^{-1}). The coalescence temperature is −90° for the former complex and −19° for the latter.[19] The authors[19] draw a parallel between the lower barrier to the rotation of the olefin in the η^5-indenyl complex and the greater ease of the substitution of the C_2H_4 group in the same compound compared with η^5-$C_5H_5Rh.(C_2H_4)_2$.



In the cationic complexes of molybdenum with dimethylacetylene of the type $LMo[P(OCH_3)_3]_2(CH_3C{\equiv}CCH_3)^+BF_4^-$ (L = η^5-C_5H_5 or η^5-C_9H_7), the influence of the π-ligand on the barrier to the rotation of acetylene has also been observed: the coalescence temperature is −40° for the indenyl complex and below −90° for the cyclopentadienyl complex.[50]

However, the influence of the indenyl ligand is not always manifested. For example, although the ^1H NMR spectra of the ethylene and acetylene complexes of tungsten $LW(CO)_2(CH_3)(C_2H_4)$ and $LW(CO)(CH_3)(CH{\equiv}CR)$ (L = η^5-C_5H_5 or η^5-C_9H_7; R = H or CH_3) do in fact exhibit a temperature dependence, apparently associated with the hindrance of rotation of the π-olefin and π-acetylene ligands, about the metal−ligand bond, the barriers to rotation of the η^5-cyclopentadienyl and η^5-indenyl compounds are approximately equal.[35,52,53,131] In contrast to the tungsten compounds, in the cationic iron complexes $[LFe(CO)_2(C_2H_4)]^+BF_4^-$ (L = η^5-C_5H_5 or η^5-C_9H_7) there is free rotation of the ethylene group regardless of the nature of the π-ligand.[129]

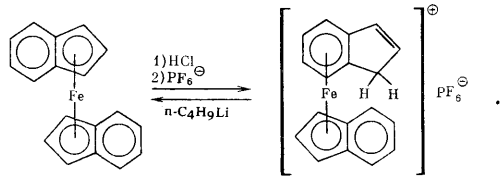


In certain studies, the barriers to rotation of the η^5-indenyl and η^5-cyclopentadienyl ligands have been compared qualitatively in analogous complexes. Thus in the π-allyl complexes of molybdenum η^5-$LMo(CO)_2$(π-C_3H_4R) (L = C_5H_5 or C_9H_7), the η^5-coordinated ligand rotates freely about the Mo−L bond, but the barrier to rotation of the indenyl ligand is higher than for the cyclopentadienyl ligand. As a result, there exists a preferred conformation of the indenyl complexes in which the six-membered ring is arranged above the π-allyl ligand.[126] The hindered rotation of the π-indenyl ligand has also been observed for the dinuclear complex η^5-$C_9H_7Rh.(CO)_3Cr(CO)[(CH_3)_2C_6H_3]$ in a study of the temperature variation of the ^{13}C NMR spectra.[132]

5. Chemical Shifts

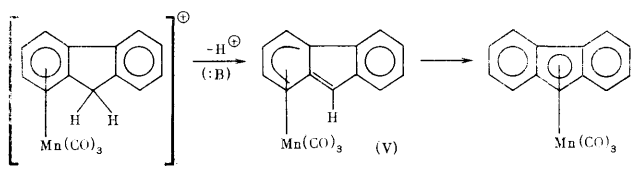
(a) *The reduction and oxidation of the η^5-indenyl complexes.* Hydrogenation with hydrogen in the presence of catalysts (Adams catalyst, platinum dioxide, etc.) has been investigated for a series of indenyl complexes such as di-indenyliron,[133] di-indenylruthenium,[16] cyclopentadienyl(indenyl)iron,[46] ethylenedi-indenyltitanium dichloride,[9,25] di-indenyltitanium dichloride,[32] di-indenylzirconium dichloride,[32] and the dimer of dicarbonylindenyliron.[134] It was found that in all cases only the double bonds of the six-membered rings of the π-ligand are hydrogenated, which apparently indicates the olefinic nature of these bonds:

In contrast to the indenyl complexes, the hydrogenation of the six-membered rings of the fluorenyl ligands in $(\eta^5$-$C_{13}H_9)(\eta^3$-$C_{13}H_9)Zr.Cl_2$ could not be achieved.[32] An example of the oxidation of a six-membered ring, not coordinated to the metal, on treatment of a cationic cobalt complex with potassium permanganate is also known:[135]



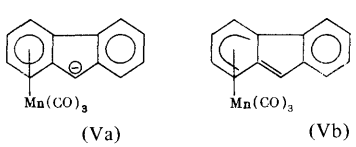
The oxidation-reduction processes in η^5-indenyl and η^5-fluorenyl complexes have also been investigated by electrochemical methods. The majority of these studies have shown that the condensed six-membered rings in the η^5-indenyl and η^5-fluorenyl ligands possess electron-accepting properties, diminishing the electron density on the metal. Thus the replacement of the η^5-cyclopentadienyl ligand by the η^5-indenyl ligand lowers appreciably the reduction potential of cobaltocenium salts: −1.16 V for $(\eta^5$-$C_5H_5)_2Co^+$ and −0.5 V for $(\eta^5$-$C_9H_7)_2Co^+$.[6] The same effect has been observed in the polarographic reduction of rhodium complexes with duroquinone: −1.76 and 2.03 V for $(\eta^5$-$C_5H_5)$Rh(duroquinone) and −1.43 and 1.76 V for $(\eta^5$-$C_9H_7)$Rh(duroquinone).[136] As a result of a study of the electrochemical oxidation of the 17-electron titanium complexes η^5-$LTi.(\eta^8$-$C_8H_8)$ (L = $CH_3C_5H_4$, C_5H_5, C_9H_7, or $C_{13}H_9$), the authors concluded that the influence of the six-membered condensed rings in these complexes is opposed to that of the CH_3 group.[137] However, data have been published on the electrochemical oxidation of iron compounds [0.49 V for $(\eta^5$-$C_5H_5)_2Fe$, 0.35 V for $(\eta^5$-$C_5H_5)$ $(\eta^5$-$C_9H_7)Fe$, and 0.21 V for $(\eta^5$-$C_9H_7)_2Fe$], from which it follows that the replacement of the η^5-cyclopentadienyl ligand by the η^5-indenyl ligand as well as the introduction of the electron-donating substituent into the π-ligand facilitates the oxidation of the central metal atom.[138]

(b) *Metallotropic rearrangements.* In the complexes of transition metals with polycyclic condensed aromatic ligands, the metal is capable of migrating from one ring to another under the influence of various reagents, altering thereby the character of the binding to the π-ligand. These metallotropic rearrangements are characteristic of the indenyl and fluorenyl complexes.



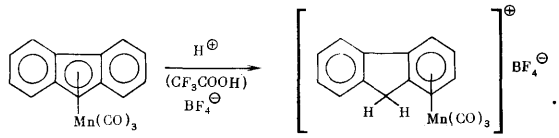
The first example of such inter-ring rearrangement was reported in 1971.[139] In a study of the interaction of di-indenyliron with boron trifluoride etherate, an analogous rearrangement was observed simultaneously.[140] In 1976, the protonation of di-indenyliron and cyclopentadienyl(indenyl)iron was investigated.[141] Under the influence of CF_3COOH and HCl, the iron atom migrated in the

η^5-indenyl complexes from the five-memberd ring to the six-membered ring and η^6-indene complexes of iron were obtained:



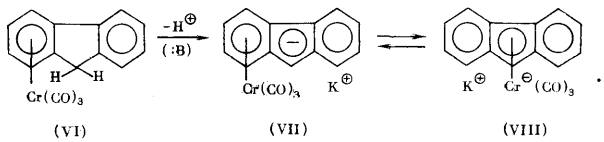
In order to elucidate the stereochemistry of the protonation reaction, the authors studied the interaction of $(\eta^5\text{-}C_9H_7)_2Fe$ with DCl and of $(\eta^5\text{-}1,1,3,3\text{-}C_9H_3D_4)_2Fe$ with HCl. Analysis of the ^1H NMR spectra of the products obtained in these reactions showed that the protonation is stereospecific. It has been suggested[141] that the iron atom is protonated initially and the hydrogen is then transferred to the five-membered ring so that *endo*-addition should result from such "ricochet reaction". Treatment of the η^6-indene complex with n-butyl-lithium regenerated $(\eta^5\text{-}C_9H_7)_2Fe$ in 23% yield. The study of the deprotonation of compounds partly labelled with deuterium and analysis of the mass spectra of the products obtained enabled the authors to conclude that the deprotonated reaction is non-stereospecific. Examples of metallotropic rearrangements of the π-complexes of other Group VIII metal atoms, for example rhodium and iridium, have also been described in the literature.[142-144]

The first metallotropic $\eta^6 \rightarrow \eta^5$-rearrangement of the π-complexes of Group VII metals was observed in a study of the deprotonation of tricarbonylfluorenemanganese:[145]



The complex $\eta^6\text{-}C_{13}H_9Mn(CO)_3$ (V) formed initially was converted on heating into the thermodynamically more stable $\eta^5\text{-}C_{13}H_9Mn.(CO)_3$. Two limiting structures were proposed initially for compound (V): the zwitter-ionic structure (Va) and the methylenecyclohexadienyl structure (Vb):[146]

(Va) (Vb)



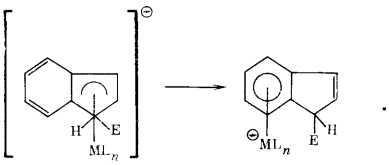
Subsequently XDA showed that the manganese complex (V) has the structure typical of cyclohexadienyl derivatives.[147] Theoretical calculations for the $\eta^6 \rightarrow \eta^5$ rearrangement of the fluorenyl complexes of manganese showed that the η^6-isomer is more stable than the η^5-isomer and that the activation energy for the rearrangement is 25 kcal mol^{-1}.[148] Subsequently kinetic studies on the $\eta^6 \rightarrow \eta^5$ rearrangements of three fluorenyl complexes of manganese, namely $\eta^6\text{-}C_{13}H_9Mn(CO)_3$, $\eta^6\text{-}C_{13}H_9Mn(CO)_2P(C_4H_9\text{-}n)_3$, and $\eta^6\text{-t-}C_4H_9.C_{13}H_8Mn(CO)_3$, confirmed these quantum-chemical calculations.[149] Since the activation energies for the $\eta^6 \rightarrow \eta^5$ rearrangements of $\eta^6\text{-}C_{13}H_9Mn(CO)_3$ and $\eta^6\text{-}C_{13}H_9Mn(CO)_2P(C_4H_9\text{-}n)_3$ proved to be similar and bearing in mind that the replacement of the CO group by the electron-donating phosphine ligand greatly increases the basicity of the central metal atom, the authors concluded that the basicity of the metal does not influence the rate of the rearrangement.

The reverse $\eta^5 \rightarrow \eta^6$ rearrangement was discovered in a study of the protonation of η^5-fluorenyltricarbonylmanganese with trifluoroacetic acid:[150]

In this case, the acid proton apparently adds directly to the fluorenyl ligand. In the η^5-indenyltricarbonylmanganese complexes of manganese and rhenium, the analogous $\eta^5 \rightarrow \eta^6$ rearrangement is observed only on treatment with stronger acids, namely $HFSO_3$ and $AlCl_3$.HCl, which is probably due to the lower basicity of the indenyl ligand compared with the fluorenyl ligand.[151] The increase in the basicity of the central metal atom in the complexes $\eta^5\text{-}C_9H_7.Mn(CO)_2PPh_3$, $\eta^5\text{-}C_9H_7Re(CO)_2PPh_3$, and $\eta^5\text{-}C_{13}H_9Mn(CO)_2PPh_3$ compared with the metal tricarbonyl leads to the protonation of the metal atom in the $CF_3COOH - CH_2Cl_2$ medium and there is no metallotropic rearrangement under these conditions.[151] On the other hand, it has been reported[149] that $\eta^5\text{-}C_{13}H_9Mn(CO)_2.P(C_4H_9\text{-}n)_3$ reacts rapidly with hydrogen chloride, affording the rearrangement product $[\eta^6\text{-}C_{13}H_{10}Mn(CO)_2P(C_4H_9\text{-}n)_3]^+X^-$ and the reaction is non-stereospecific. Hence the authors conclude that the acid proton adds directly to the carbon atom in a 9-position in the fluorenyl ligand.

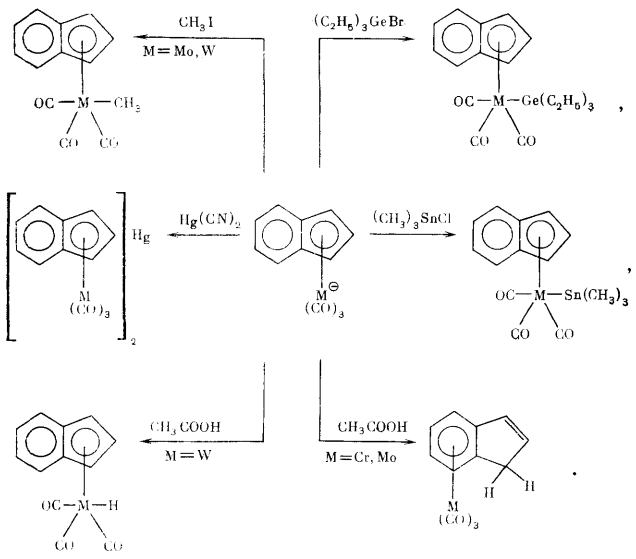
The inter-ring metallotropic rearrangements of the indenyl and fluorenyl complexes of Group VIB transition metals have been widely investigated by Nesmeyanov's school. In relation to the fluoride anion coordinated to the $Cr(CO)_3$ group, Nesmeyanov and co-workers[152,153] observed the first instance of metallotropic tautomerism where both the initial complex and the product of its metallotropic rearrangement are in equilibrium. Treatment of $\eta^6\text{-}C_{13}H_{10}.Cr(CO)_3$ (VI) with an excess of potassium t-butoxide in tetrahydrofuran (THF) at −70 °C led to its complete conversion into $\eta^6\text{-}C_{13}H_9Cr(CO)_3^-K^+$ (VII), whose isomerisation to $\eta^5\text{-}C_{13}H_9Cr.(CO)_3^-K^+$ (VIII) was observed even at 0 °C and equilibrium was attained after 1 h at 25 °C:

(VI) (VII) (VIII)



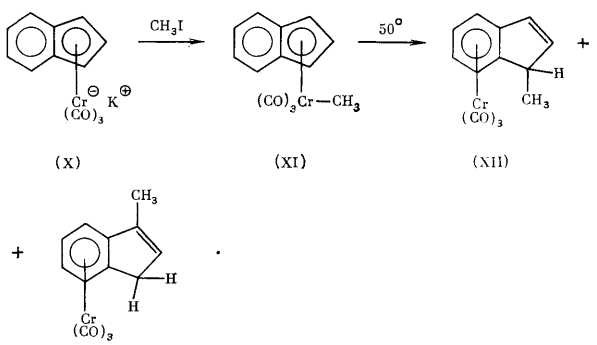
An equilibrium mixture of the same composition was obtained from the mercury derivative:

$$[\eta^5\text{-}C_{13}H_9Cr(CO)_3]_2Hg \xrightarrow{K/Na} (VIII) \rightleftarrows (VII).$$

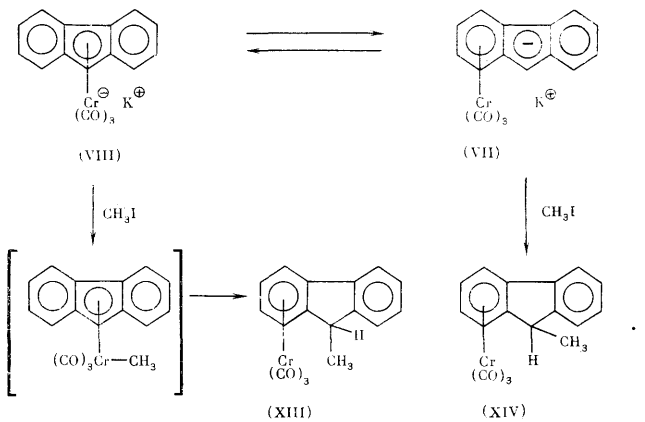


The kinetics of this equilibrium rearrangement have been studied by IR spectroscopy and also by ^1H and ^{13}C NMR.[152-156] The equilibrium constant was shown to depend on the nature of the cation, the solvent, and the concentration of the compound. It was also demonstrated that the rearrangement proceeds via an intramolecular mechanism.[157]

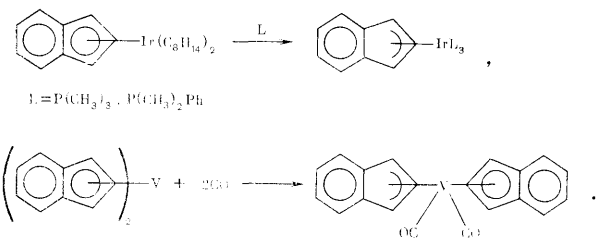
In contrast to η^6-fluorenechromium tricarbonyl, the deprotonation of η^6-fluorenemolybdenum tricarbonyl and η^6-indenechromium tricarbonyl leads to only one isomer of type VIII—$\eta^5\text{-}C_{13}H_9(CO)_3.Mo^-$ and $\eta^5\text{-}C_9H_7(CO)_3Cr^-$ respectively.[33,158]



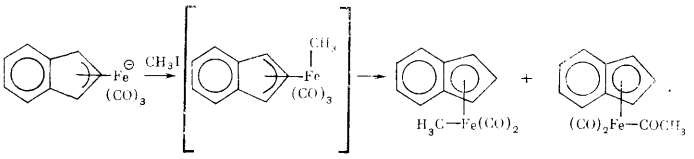
The study of the reactions of the η^5-indenyl and η^5-fluorenyl anionic complexes of Group VIB metals with electrophiles demonstrated a difference between these derivatives and their η^5-cyclopentadienyl analogues. This is associated primarily with the fact that, in contrast to the η^5-cyclopentadienyl systems, the polycyclic systems have an additional pathway leading to the stabilisation of the intermediate (IX)—as a result of the shift of the organometallic group to the six-membered ring of the π-ligand. This process may be thermodynamically preferable to the dissociation of the C—H and C—E bonds:[159]



The nature of the metal and the reagent influence appreciably the direction of the reactions of anionic η^5-indenyl complexes of Group VIB metals with electrophiles and determine the feasibility of the $\eta^5 \rightarrow \eta^6$ rearrangements:[33,160]

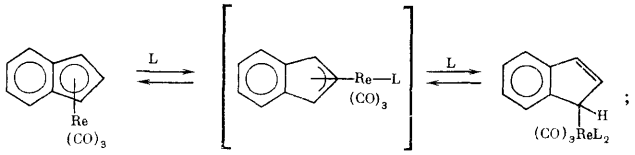


As a rule, the η^6-structures are thermodynamically preferable for chromium derivatives. The stability of the η^5-compounds increases in the sequence Cr < Mo < W.[33] The authors studied in detail the stereochemistry of the interaction of the anion η^6-$C_9H_7Cr(CO)_3^-$ (X) and the tautomeric mixture of compounds (VII) and (VIII) with alkyl halides. Investigations demonstrated the rigorous stereospecificity of these reactions: the "ricochet process" with the initial attack on the metal leads only to the *endo*-isomer, while direct attack on the carbon atom of the five-membered ring affords the *exo*-isomer. Thus the reaction of the complex (X) with CH_3I, which has been shown to proceed via the "ricochet mechanism" [compound (XI) has been isolated and characterised], leads to the *endo*-isomer (XII):[33,159]



The interaction of the tautomers (VII) and (VIII) with CH_3I proceeds stereoselectively via two different mechanisms with formation of the isomers (XIII) and (XIV):[153,160,161]

The first examples of the $\eta^5 \rightarrow \eta^3$ rearrangements of indenyl complexes in the course of ligand exchange reactions were published for the first time in 1986:[109,162]

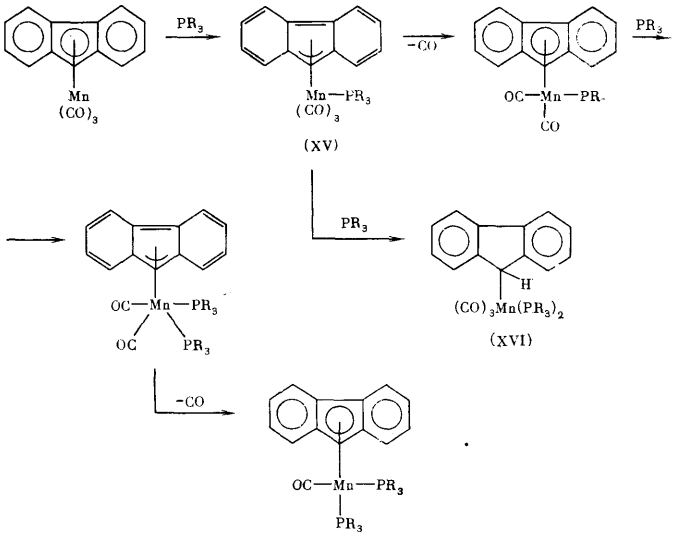


The $\eta^3 \rightarrow \eta^5$ rearrangement was described in 1987 for the reaction of an anionic iron complex with CH_3I:[163]

$\eta^5 \rightarrow \eta^1$ metallotropic rearrangements in which the type of binding of the ligand to the metal changes significantly are also known for the η^5-indenyl and η^5-fluorenyl complexes of transition metals. The ligand, previously coordinated to the metal via the π-electrons of the polycyclic system, forms a bond with the metal via the σ-electrons of one of the carbon atoms. Such rearrangements

have been described also for η^5-cyclopentadienyl compounds, but the presence of condensed benzene rings in the indenyl and fluorenyl ligands greatly facilitates these processes.

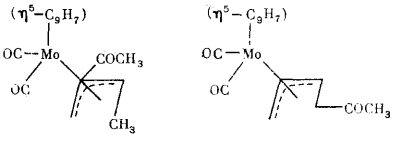
The $\eta^5 \rightarrow \eta^1$ rearrangements of carbonyl derivatives of rhenium have been reported recently.[164,165] The interaction of η^5-indenyltricarbonylrhenium with trimethylphosphine at room temperature results in the formation of a stable η^1-indenylbisphosphinerhenium complex:



$L = P(CH_3)_3$.

A structure with η^3-linked ligand has been proposed for the intermediate compound. An analogous rearrangement has been described for η^5-cyclopentadienyltricarbonylrhenium, but the rearrangement of the η^5-indenyl complex is 10^8 times faster than for the cyclopentadienyl complex. The $\eta^5 \rightarrow \eta^1$ rearrangement of the indenyl ligand also takes place on treatment of a η^5-indenyl complex of rhodium with an excess of t-butyl isocyanate.[130]

The reverse $\eta^1 \rightarrow \eta^5$ rearrangement of the indenyl ligand has been observed in a photochemical reaction of an iron complex:[166]

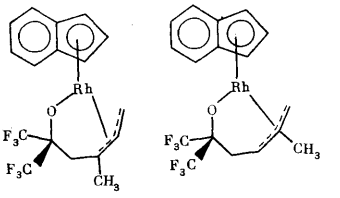


$$(\eta^5\text{-}C_9H_7)\,Fe\,(CO)_2\,(\eta^1\text{-}C_9H_7) \xrightarrow{h\nu} Fe\,(\eta^5\text{-}C_9H_7)_2 + 2CO.$$

The first instance of the $\eta^5 \rightarrow \eta^1$ rearrangement of the fluorenyl ligand has been noted in the reaction of η^5-fluorenyltricarbonylmanganese with an excess of tributyl phosphine:[167]

It has been suggested that the rearrangement proceeds as for the indenyl ligand—via the intermediate complex (XV) with the η^3-type of coordination. The structure of compound (XVI) with the η^1-fluorenyl ligand has been proposed on the basis of the ^{13}C NMR spectrum.

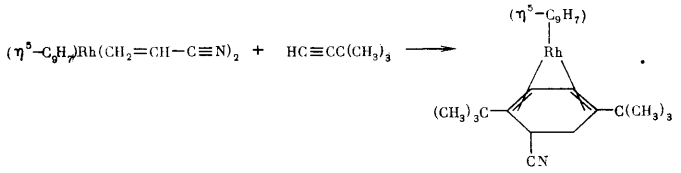
(c) *Ligand exchange reactions in η^5-indenyl and η^5-fluorenyl complexes of transition metals.* Extensive data have now accumulated in the literature concerning the influence of the η^5-indenyl ligand on the rate of exchange of carbonyl, olefinic, and acetylenic groups in the π-complexes of transition metals in thermal reactions. As early as 1965, it was noted that the decarbonylation of the η^5-indenyl complexes of molybdenum $RMo(CO)_3(\eta^5\text{-}C_9H_7)$ proceeds much more readily than that of the corresponding cyclopentadienyl complexes.[34] Subsequently, other studies were published in which the accelerating effect of the η^5-indenyl ligand had been observed. For example, it was noted that $[(\eta^5\text{-}C_9H_7)Mo(CO)_2(CH_3)_2C_2]^+BF_4^-$ reacts faster with PPh_3 [53] and $\eta^5\text{-}C_9H_7Mo(CO)_3CH_3$ reacts faster with but-2-yne[54] faster than their cyclopentadienyl analogues. It has also been established that methylenecyclopropane and buta-1,3-diene are inserted more readily in the $Mo-CH_3$ bond in $\eta^5\text{-}C_9H_7Mo(CO)_3CH_3$, which leads to the formation of the π-allyl complexes (XVII) and (XVIII) respectively with the simultaneous migration of a terminal CO group:[54]



(XVII) (XVIII)

The accelerating effect of the η^5-indenyl ligand compared with the cyclopentadienyl ligand is manifested in the π-complexes of not only Group VI but also of Group VII and VIII transition metals. Especially many examples are known for rhodium derivatives. For instance, $\eta^5\text{-}C_5H_5Rh(C_2H_4)_2$ does not react with carbon monoxide, while the η^5-indenyl analogue reacts rapidly with CO at room temperature, affording $\eta^5\text{-}C_9H_7Rh(CO)_2$ in a quantitative yield.[130] The high reactivity of $\eta^5\text{-}C_9H_7Rh(C_2H_4)_2$ is also manifested in the considerable ease of the exchange of ethylene for phosphines, cycloocta-1,5-diene, 2,3-dimethylbuta-1,3-diene,[19] methylcyclopropane, acrylonitrile, t-butyl isocyanate, isoprene, cyclohexadiene, and cyclohepta-1,3,5-triene.[20,130] Similar reactions are unknown for the analogous complex with the η^5-cyclopentadienyl ligand. The substitution of the Group L in the rhodium complexes $\eta^5\text{-}C_9H_7RhL_2$ (L = CO or PPh_3) for other ligands takes place very readily (20 °C, benzene).[19] The corresponding η^5-cyclopentadienyl compounds are difficult to obtain.

Whereas only prolonged photolysis of $\eta^5\text{-}C_5H_5Rh(CO)_2$ leads to two isomeric clusters $(\eta^5\text{-}C_5H_5)_3Rh_3(CO)_3$ and in a low yield, η^5-indenyl dicarbonylrhodium is converted selectively and with a high yield into the trimer (IV) on refluxing in heptane.[59,130]

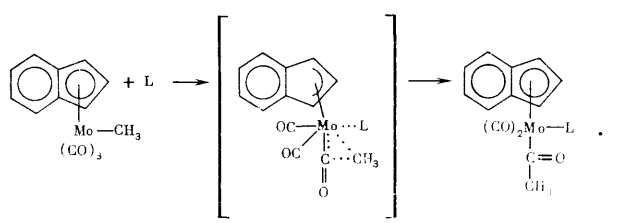


η^5-Indenyl complexes of rhodium with diene ligands exhibit an enhanced reactivity. Thus, in contrast to its η^5-cyclopentadienyl analogue, $\eta^5\text{-}C_9H_7Rh$(isoprene) reacts with $(CF_3)_2CO$ at room temperature with formation of the two isomeric products (XIX) and (XX):[168]

(XIX) (XX)

The reactions of the η^5-indenyl complexes of rhodium $\eta^5\text{-}C_9H_7RhL_2$ (L = isoprene, acrylonitrile, or 2,3-dimethylbuta-1,3-diene) with alkynes, which result in the cyclisation of acetylenes with the olefins

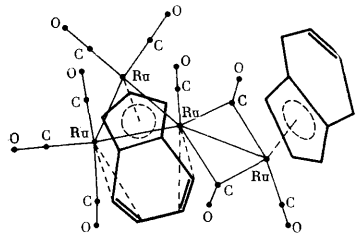
in the coordination sphere of the metal, are remarkable:[20,130]



The initial stage in this reaction is the coordination of the acetylene molecule to the metal, which is facilitated by the slip of the rhodium atom along the plane of the indenyl ligand.[20]

The ready carbonylation of the $Fe-CH_3$ bond in the complexes η^5-$C_9H_7Fe(CH_3)(CO)L$ (L = CO or PPh_3) has also been described.[169]

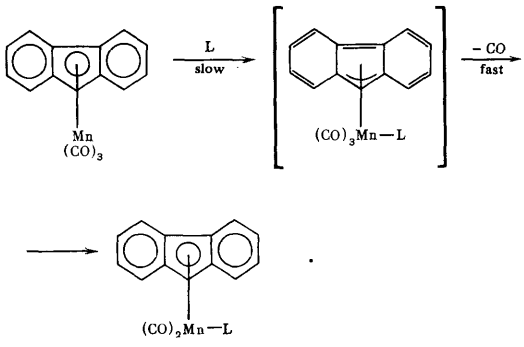
There are many fewer examples of the accelerating effect of the η^5-fluorenyl ligand compared with the η^5-indenyl ligand. For example, it has been noted that η^5-$C_{13}H_9Co[P(OR)_3]_2$ absorbs carbon monoxide more readily than η^5-$C_9H_7Co[P(OR)_3]_2$.[17]



All the examples described above concern the observation of the accelerating influence of the η^5-indenyl or η^5-fluorenyl ligands on the rates of ligand exchange reactions. The first studies designed to estimate quantitatively the comparative reactivities of the η^5-indenyl and η^5-cyclopentadienyl complexes of transition metals in thermal reactions were performed in the 1970's.[170,171] The authors first explained the accelerating influence of the η^5-indenyl ligand. They carried out a kinetic study on the thermal reactions involving the substitution of CO groups by phosphines and phosphites in the molybdenum complexes η^5-$C_9H_7Mo(CO)_3X$ and η^5-$C_5H_5Mo(CO)_3X$ (X = CH_3, Cl, Br, or I) and showed that the ligand exchange proceeds via two competing mechanisms: associative and dissociative. An appreciable accelerating influence of the η^5-indenyl ligand compared with the cyclopentadienyl ligand (at least by a factor of tens and at most by a factor of hundreds of thousands) was observed in both cases. In the associative mechanism, the accelerating effect of the indenyl ligand is caused, according to the authors, by the transition to a π-allyl system, which frees an orbital of the molybdenum atom for the interaction with the nucleophile and ensures thereby the easy occurrence of the reaction via the S_N2 mechanism:

The capacity of the cyclopentadienyl ligand for π-allyl type coordination to the metal is smaller, since in the change from the η^5-coordination to the η^3-coordination in the indenyl complex the six-membered ring retains its total resonance energy, while in the case of the cyclopentadienyl ligand an isolated double bond is formed.[170] The dissociative mechanism has been studied in detail for halogenoderivatives of η^5-indenyl and η^5-cyclopentadienyl complexes.[171] In this case, the reaction rate constants were found to undergo very pronounced changes on transition to the η^5-indenyl complexes and a dependence of the rate constants on the nature of the halogen was observed:

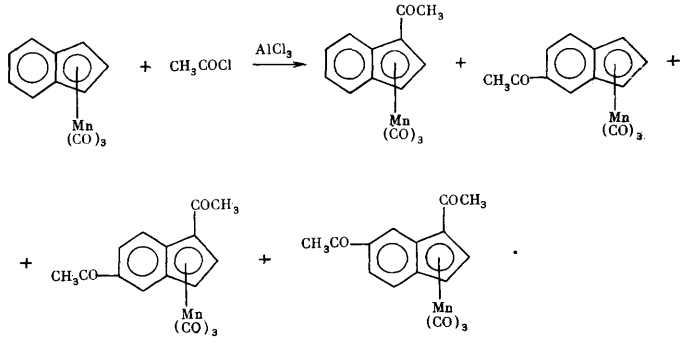
	$C_5H_5Mo(CO)_3Cl$	$C_5H_5Mo(CO)_3Br$	$C_5H_5Mo(CO)_3I$
$k_{rel}^{10°}$	1	23	614
	$C_9H_7Mo(CO)_3Cl$	$C_9H_7Mo(CO)_3Br$	$C_9H_7Mo(CO)_3I$
$k_{rel}^{10°}$	6600	211 000	3 580 000



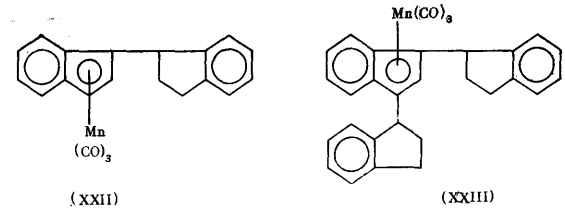
Since the absorption frequencies of the carbonyl groups in the IR spectra of the isostructural complexes η^5-$C_9H_7Mo(CO)_3X$ and η^5-$C_5H_5Mo(CO)_3X$ are almost identical, the differences between the rates of reaction are associated, according to the authors, with the appreciable change in the stability of the transition state. It has been suggested that the stabilisation of the transition state in the dissociative mechanism is achieved by the partial binding of the benzene ring of the π-ligand to the metal. In order to elucidate the role of the aromatic six-membered ring, the kinetic data for the η^5-cyclopentadienyl, η^5-indenyl, and η^5-tetrahydroindenyl complexes of molybdenum[172] and iron[173] were compared. It was found that the activation parameters and the rate constants for the tetrahydroindenyl complex η^5-$C_9H_{11}Mo(CO)_3Cl$ and η^5-$C_5H_5Mo(CO)_3Cl$ are very similar. On the other hand, the reaction rate constant for η^5-$C_9H_7Mo(CO)_3Cl$ is 6000 times greater than for the η^5-cyclopentadienyl analogue. Thus the hydrogenated six-membered ring of the tetrahydroindenyl ligand does not increase the rate of exchange of the CO groups, while the π-electron system of the condensed benzene ring participates in the stabilisation of the transition state. This is confirmed indirectly by the synthesis of the tetranuclear ruthenium cluster (XXI), since the metal atom is involved not only in η^5-type coordination to the five-membered ring but also in η^2,η^2-diene type coordination to the six-membered ring of the indenyl ligand:[174]

(XXI)

In the course of the further development of the kinetic studies on the thermal CO ligand substitution reactions in η^5-indenyl complexes of transition metals, it was shown that the rates of reaction of the indenyl complexes of rhodium η^5-$C_9H_7Rh(CO)_2$ and η^5-$(CH_3)_7C_9Rh(CO)_2$ with PPh_3 are respectively 3.8×10^8 and 6.1×10^5 times greater than for η^5-$C_5H_5Rh(CO)_2$.[175,176] The tendency of the rhodium atom to form π-allyl complexes facilitates the $\eta^5 \rightarrow \eta^3$ transitions in the associative reaction mechanism and leads to a very pronounced increase in rate, which is not observed for other metals. The quantitative effect of the η^5-fluorenyl ligand relative to the η^5-indenyl ligand in the thermal reactions of manganese carbonyl complexes with phosphines and phosphites was estimated in this connection.[167,176] It was shown that the rate of reaction with $P(OC_2H_5)_3$ in decalin is 388 times greater for η^5-$C_{13}H_9Mn(CO)_3$ than for η^5-$C_9H_7Mn(CO)_3$. The increase in the rate of substitution for the η^5-fluorenyl complex compared with the η^5-indenyl and η^5-cyclopentadienyl complexes has been explained[167] by the stabilisation of the η^3-intermediate as a result of the delocalisation of the π-electrons over all three rings, i.e. a high delocalisation energy



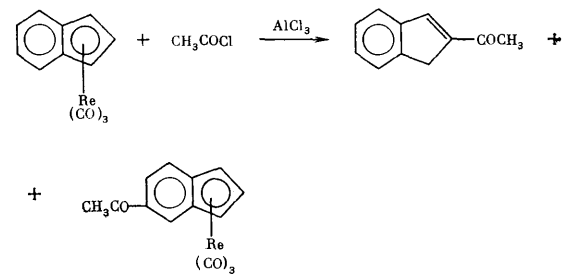
obtains in this instance.



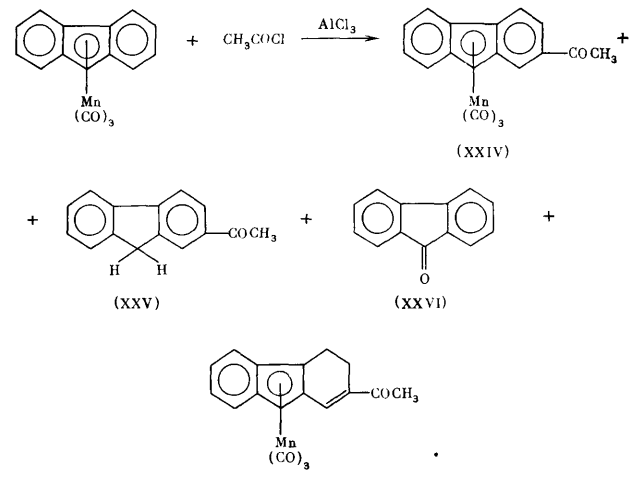
However, the accelerating effects of the η^5-indenyl and η^5-fluorenyl ligands is not always maintained. Thus the effect has not been observed in the photochemical substitution of the carbonyl groups in manganese complexes for triphenylphosphine.[177] The rate constants for the complexes $LMn(CO)_3$, where L = η^5-C_5H_5, η^5-C_9H_7, and η^5-$C_{13}H_9$ are 6.0×10^{-3}, 5.2×10^{-3}, and 3.8×10^{-3} min^{-1} respectively.

(d) *The hydrogen substitution reactions in η^5-indenyltricarbonyl and η^5-fluorenyltricarbonyl complexes of manganese and rhenium.* The hydrogen substitution reactions in the π-ligands of neutral η^5-indenyl and η^5-fluorenyl complexes of transition metals have been little investigated. Attempts to benzoylate η^5-cyclopentadienyl (η^5-indenyl)-iron with benzoyl chloride in the presence of $AlCl_3$ and also to metallate it by n-butyl-lithium were reported in 1964.[47] However, acylation led to the decomposition of the complex and treatment with n-C_4H_9Li and subsequently with D_2O led to the isolation of the non-deuteriated initial compound.

A series of studies[178–180] on the electrophilic and protophilic substitution η^5-indenyl and η^5-fluorenyl ligands of manganese and rhenium complexes were published in 1982–1985. It was shown that, in the interaction of η^5-$C_9H_7Mn(CO)_3$ with an excess of CH_3. .COCl in the presence of $AlCl_3$ in methylene chloride, hydrogen is substituted by $COCH_3$ in both the five-membered and six-membered rings of the η^5-indenyl ligand:[178]

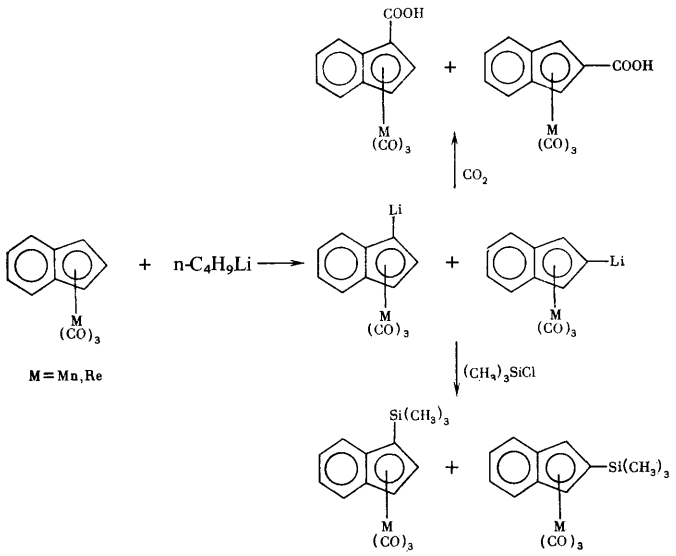


Similarly, in the isotope exchange of hydrogen involving η^5-C_9H_7. .$Mn(CO)_3$ on treatment with a mixture of the acids CF_3COOD and D_2SO_4 in CH_2Cl_2, hydrogen is replaced by deuterium in both rings of the π-ligand, although the substitution in the five-membered ring predominates. Apart from the deuteriated derivative, the deuterium-containing complexes (XXII) and (XXIII) were isolated in this reaction. These complexes are apparently formed as a result of the alkylation of the initial compound by the indene protonated in the acid medium, produced as a result of the cleavage of the metal–π-ligand bond.



(XXII) (XXIII)

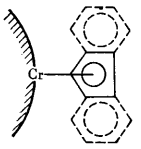
In order to compare the reactivities of the η^5-indenyl and η^5-cyclopentadienyl ligands, the competitive acetylation of η^5-$C_9H_7Mn(CO)_3$ and η^5-$C_5H_5Mn(CO)_3$ was carried out.[180] It was established as a result that the reactivity of the η^5-indenyl ligand is on the whole much higher than that of the η^5-cyclopentadienyl ligand. However, when the reactivity of only the five-membered ring of the η^5-indenyl ligand is compared with that of the η^5-cyclopentadienyl ligand, then the differences are insignificant.



In contrast to η^5-$C_9H_7Mn(CO)_3$ and η^5-$C_5H_5Re(CO)_3$, the acetylation of η^5-$C_9H_7Re(CO)_3$ [4] takes place mainly with abstraction of the π-ligand. Thus, after treatment with acetyl chloride in the presence of $AlCl_3$ in CH_2Cl_2, the complex (5-$CH_3COC_9H_6$)$Re(CO)_3$ (5%) and 2-acetylindene (17%) were isolated:[178]

The acetylation of η^5-$C_{13}H_9Mn(CO)_3$ takes place only in the six-membered ring of the π-ligand and is also accompanied by the dissociation of the metal–π-ligand bond. The acylated complex (XXIV) (40%), the products (XXV) and (XXVI) resulting from the elimination of the π-ligand, and the partly hydrogenated complex (XXVII) (6%) are formed:

Metallation of η^5-indenyl complexes of manganese and rhenium with n-butyl-lithium in THF involves only the five-membered ring of the indenyl ligand with formation of a mixture of the 1- and 2-isomers:[179]



For the quantitative estimation of the comparative reactivities of the η^5-indenyl and η^5-cyclopentadienyl complexes, Lobanova et al.[180] carried out the competitive metallation with n-butyl lithium of mixtures of the following pairs of compounds: η^5-$C_9H_7MnCO_3$ and η^5-$C_5H_5Mn(CO)_3$; η^5-$C_9H_7Re(CO)_3$ and η^5-$C_5H_5Re(CO)_3$; η^5-$C_9H_7Mn(CO)_3$ and η^5-$C_9H_7Re(CO)_3$; η^5-$C_5H_5Mn(CO)_3$ and η^5-$C_5H_5Re(CO)_3$. It was established that the η^5-indenyl complexes are somewhat more reactive than the corresponding η^5-cyclopentadienyl complexes, although the differences are slight. It was also discovered that the rhenium complexes are metallated much more readily than the manganese complexes, which has been explained by the greater tendency of the rhenium compounds to undergo protophilic substitution reactions.[180]

(e) *Catalytic properties of η^5-indenyl and η^5-fluorenyl complexes of transition metals.* The "coordination flexibility" of the η^5-indenyl and η^5-fluorenyl ligands, which accelerates the ligand exchange reactions in transition metal complexes, may be important when they are used as homogeneous catalysts of chemical processes where the lability of the ligands at the metal atom is significant.

The catalytic activity of η^5-indenyl complexes of transition metals has been reported in a number of studies. For example, the interaction of η^5-$C_9H_7Rh(C_2H_4)_2$ with an excess of acetylenes leads to the catalytic cyclotrimerisation of 3,3-dimethylbut-1-yne to 1,2,4-tri-t-butylbenzene, while but-2-yne is cyclotrimerised to hexamethylbenzene.[130] Furthermore, η^5-$C_9H_7Rh(C_2H_4)_2$ is a catalyst of the isomerisation of allyltrimethylsilanes to *trans*-propenyltrimethylsilanes.[181] Dinuclear rhodium complexes with indenyl ligands are also effective catalysts in the trimerisation of acetylenes.[182] The high catalytic activity of η^5-indenyl derivatives of Group IVB metals $(\eta^5\text{-}C_9H_7)_2M$ (M = Ti, Zr, or Hf) in the polymerisation of α-olefins has been noted.[183]

Studies have been made on the catalytic properties of di-indenyl- and difluorenyl-chromium complexes deposited on silica gel.[184] Like chromocene, these complexes exhibited a catalytic activity in the polymerisation of ethylene. It is believed that the polymerisation proceeds via an anionic mechanism and that the catalyst active centre is the chromium centre (XXVIII):

The increased thermal stability of the indenyl catalyst compared with the cyclopentadienyl catalyst has been noted. It has been indicated in patents[185,186] that η^5-$C_9H_7Mn(CO)_3$, η^5-$C_{13}H_9Mn(CO)_3$, as well as η^5-$C_5H_5Mn(CO)_3$ can be used as anti-knocking agents. It has been shown that the η^5-indenyl and η^5-fluorenyl derivatives of titanium L_2TiCl_2 (L = η^5-C_9H_7 or η^5-$C_{13}H_9$) as well as their η^5-cyclopentadienyl analogues exhibit an anticancer activity.[187]

III. CONCLUSION

Thus the data examined above show that η^5-indenyl and η^5-fluorenyl complexes of transition metals have a number of characteristic features apart from their great similarity to their cyclopentadienyl analogues. Thus the strength of the π-ligand–metal bond varies in the sequence η^5-cyclopentadienyl > η^5-indenyl > η^5-fluorenyl, which leads to a decrease in the stability of the indenyl and fluorenyl compounds. Furthermore, some distortion of the η^5-type coordination is observed for the η^5-indenyl and η^5-fluorenyl complexes, which is reflected in the difference between the lengths of the bonds linking the metal to the carbon atoms of the five-membered ring. On treatment of the η^5-indenyl and η^5-fluorenyl derivatives with certain reagents, a change in the type of coordination to the transition metal from η^5- to η^6-coordination and from η^3- to η^1-coordination has been observed, i.e. intramolecular metallotropic rearrangements are characteristic of such compounds. The fact that the rates of thermal ligand exchange reactions of the η^5-indenyl and η^5-fluorenyl complexes exceed by several orders of magnitude the rates of reaction of the η^5-cyclopentadienyl compounds may be of special interest from the practical point of view.

Microlayer and Glass Formation in Block Copolymers

Yu.D.Shibanov and Yu.K.Godovskii

The present state of the theoretical and experimental studies on one of the possible types of phase transformations in block copolymers, namely microlayer formation, as well as the influence on the latter of vitrification is surveyed. It is shown that microlayer formation leads to the appearance of supermolecular structures whose parameters depend on the composition, temperature, and the number and length of the blocks; microlayer formation also determines the vitrification parameters, which can in their turn inhibit the microlayer formation. The mutual influence of microlayer and glass formation processes is discussed.
The bibliography includes 165 references.

III. Mutual influence of microlayer and glass formation 991

I. INTRODUCTION

Block copolymers (BP) is the name usually given to substances whose linear macromolecules consist of fragments of homopolymers (blocks) linked covalently via their ends (Fig.1). Depending on the primary chain structure, the chemical structure of the monomer units, the length of the blocks, their number and distribution in the chain, and their flexibility, various phase transformations can take place in BP: separation into microphases in the melt, crystallisation (fusion), polymorphic transitions, liquid crystal ordering. Furthermore, the non-crystalline component is capable of vitrifying. The phase transformations in BP take place in many respects analogously to the phase transitions in mixtures, but the presence of a covalent bond between the components leads to a number of characteristic features, which differentiate BP as a separate class of multi-component systems.

This review is devoted to the consideration of one type of transformations in BP—microlayer formation—and its dependence on the primary structure of the macromolecule. The mutual influence of microlayer and glass formation processes is also discussed.

The study of phase transformations in BP is not only of purely theoretical interest but is also essential in connection with their possible application in the development of experimental techniques (neutron radiation monochromators, materials for microelectronics, and conductors several tens of angstroms in diameter), in medicine, and in industry (gas- and liquid-separating membranes, constructional materials). Since BP constitute the simplest models of a heteropolymer, the study of the phase transformations in them is also useful for the understanding of the processes occurring in biological structures (in particular, in cell membranes).

A BP constitutes a special case of a heteropolymer, i.e. a polymer made up of monomers having different chemical structures, and the description of the primary structure of an isolated heteropolymer macromolecule is analogous to the description of the structure of biopolymers.[1-7] We shall not dwell on the fundamental theoretical questions concerning the amount, complexity, and value of the information inherent in heteropolymers,[2,3,7] while questions relating to the selection and calculation of self-averaging quantities have already been discussed.[8,9] In the present review, we shall merely consider briefly the quantitative differences between the degrees of order in the intramolecular components,[10] such order influencing the parameters of the phase transformations. (The distribution of the intermolecular components characterises the feasibility of phase transformations at the intermolecular level and the difference between the structures of the macromolecules characterises their feasibility at the macroscopic level.)

The existing classification includes four types of linear synthetic heteropolymers: (1) periodic block copolymers; (2) statistical copolymers (SP), whose macromolecule is usually represented as one in which there is a non-ordered distribution of the monomers; (3) gradient (or conical) BP in which there is a SP block between two homopolymer blocks; (4) statistical BP in which the blocks are joined up statistically (a SP is a special case of such BP); the differences between the primary structures are specified by the methods and conditions of synthesis.

In the present review, the term block copolymer is understood (in contrast to the exact definition given previously) as a polymer whose linear chains are made up of blocks consisting of a continuous sequence of monomers of one kind, the average length of the blocks (with respect to the assembly of primary chain structures) being significantly greater than the standard deviation characterising the scatter of the blocks with respect to their lengths. We shall consider below only BP (type 1) and their blends, while blends of BP with homopolymers, statistical and gradient SP, as well as low-molecular-weight solvents are not included in the review.

II. SEPARATION INTO MICROPHASES IN THE MELT

A number of reviews have been devoted to the separation into different phases in BP melts.[11-19] However, in recent years much new information has been published, which permits a deeper understanding of the nature of this phenomenon. We shall therefore describe only briefly the information which has already become generally known and the main analysis will be devoted to studies carried out in recent years.

Like blends, BP are capable of separating into different phases. The fundamental difference between the phase separation in BP and the separation in blends consists in the fact that the characteristic size of the species and of the phase is of the order of several radii of inertia of the block and, depending on the length of the block, can

vary from several nanometers to several tens of nanometers. Separation into layers in BP occurs for dimensions of the phase species less than the length of the macromolecule and is an intramolecular process (Fig.1), so that it is referred to as microphase layer formation. Here one of the phases represents a monoconnected region (matrix) whilst the other constitutes a polyconnected region, i.e. one consisting of a large number of bounded domains, alternatively both phases can be polyconnected (alternating lamellae), or both phases can be monoconnected (interpenetrating phase networks).

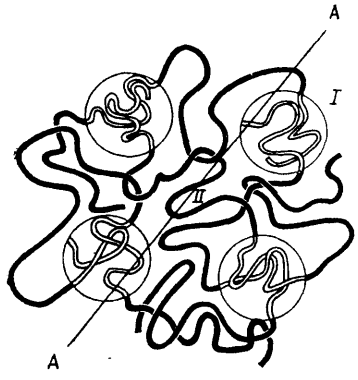

Figure 1. Schematic representation of the supermolecular structure of a periodic BP separated into pure microphases:[16] (I) phase consisting of spherical domains incorporating type 1 blocks; (II) phase constituting a monoconnected matrix consisting of type 2 blocks; $A-A$—straight line along which the concentration profile is determined.

Prolonged annealing leads to the improvement of the domain structure of the BP but does not entail the coalescence of the domains, as happens in blends. The improvement of the BP structure during annealing consists in the fact that in periodic BP the supermolecular structure (SMS), made up of domains having different relative positions, may become strictly regular, resembling the disposition of atoms at the crystal lattice sites of a crystal of a low-molecular-weight compound,[20,21] as a result of which such SMS is sometimes referred to as a supercrystal.[22] Thus one may say that microlayer formation in BP is analogous to separation into layers and supermolecular crystallisation.†

The phase state of BP is characterised by the spatial distribution of the concentrations of its components. The straight line passing through the BP ($A-A$ in Fig.1) determines the curve representing the distribution of concentration which is referred to as the concentration profile (Fig.2). The form of the profile, which can be characterised by its parameters, namely the amplitudes (phase compositions) Φ' and Φ'', the thicknesses of the domains T' and T'' and of the interfacial layer Δ, and the period D, depends in the general case on the temperature and the molecular weight distribution (MWD) of the blocks and also on the position of the straight line specified in space. We shall consider separately the influence of temperature and MWD on the parameters of the concentration profile and also on the symmetry of the SMS.

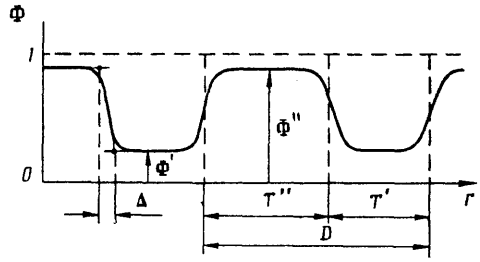

Figure 2. Second component concentration $\Phi = \Phi_2$ profile along a certain specified direction (r = distance); Φ' and Φ''—contents of the second component (concentration amplitudes) in phases I and II respectively; T' and T''—microphase thicknesses; D—SMS period; Δ—thickness of the interface.

1. Transition from the Non-ordered State to the State Separated into Microlayers

At sufficiently high temperatures or for sufficiently small lengths of the blocks r_1, the BP can exist in a single-phase (non-ordered) state. A decrease in temperature or an increase in r_1 should lead to a transition across the microphase separation boundary (MSB), provided, of course, that another phase transition or vitrification does not occur before that. In the general case, the MSB is represented by a curve in terms of the variables T, Φ_i, r_i or χ, Φ_i, r_i (χ is the Huggins interaction parameter, T the temperature, Φ_i the volume fraction of the ith component, and r_i the degree of polymerisation of the ith component block, and $i = 1-n_{ia}$, the number of intramolecular components).

Some of the qualitative features of the MSB are manifested when the method of geometrical thermodynamics is applied to the BP.[10,23-26] By analogy with blends, one can assume that, for a fixed composition of the BP, the compositions of the coexisting phases vary with temperature in conformity with the binodal curve in the temperature–composition plane. Since in binary periodic BP the intermolecular composition (the content of the second component) is defined by the formula

$$x \equiv x_2 = M_2/[a(n)M_1 + M_2] \qquad (1)$$

[M_1 and M_2 are the molecular weights of blocks 1 and 2 and $a(n)$ is a coefficient which depends on the number of blocks and, for branched BP, on the way in which unlike blocks are joined together], the construction of the temperature–composition diagram requires the variation of the molecular weight (MW), i.e. r_i, of the blocks, for example, by varying M_2 for a constant M_1. As for blends, a displacement and deformation of the binodal curve should then occur.

For a geometrical representation of the dependence of the position and form of the binodal curve on the MW, it is necessary to introduce a third coordinate (M_2) in addition to T and x, and M_1 should be regarded as a parameter (Fig.3). In the $T-x-M_2$ three-dimensional state, the binodal curve unfolds into the binodal surface

† BP separated into microphases are sometimes classified as lyophilic liquid crystals.[18]

and the composition defined by Eqn.(1) is represented geometrically by a curve in the $x-M_2$ plane. The MSB is then represented by a spatial curve defined by the intersection of the binodal surface with a curvilinear cylinder with the composition curve at its base. It is sometimes convenient to adopt as the MSB the projection of this curve onto the $T-x$ or $T-M_2$ plane. Such geometrical representation reveals that, firstly, the microlayer formation critical point for monodisperse BP is not displaced to the left of the maximum although it is located on the MSB; secondly, for certain relations governing the form of the binodal surface, which is determined by the nature of the components and the curvature of the composition curve, a second maximum can appear on the MSB, being located to the right of the maximum; thirdly, one cannot rule out the possibility of the existence of a single-phase state when M_2 increases very markedly.[23-26]

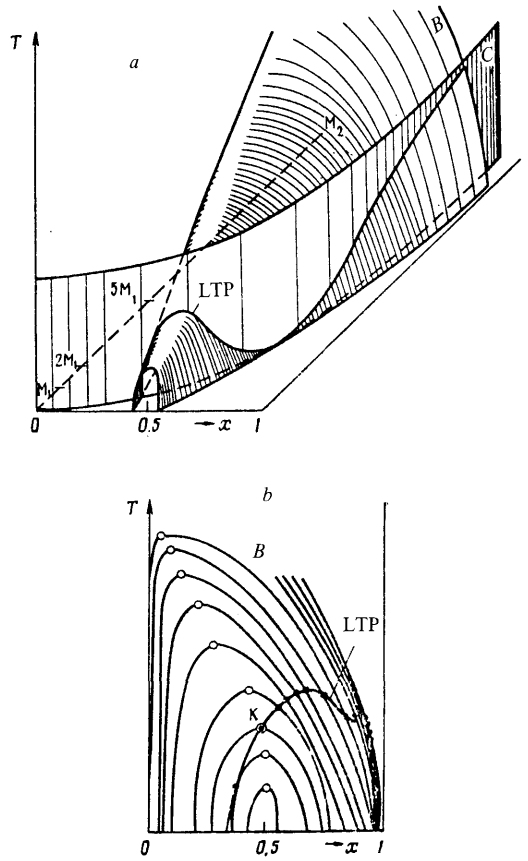

Figure 3. Construction of the locus of the turbidity points (LTP) for BP with M_1 = const. by the surface intersection method:[26] (a) three-dimensional representation in terms of the coordinates $T-x-M_2$ [B—binodal surface; C—curved cylinder, with generator parallel to the temperature axis, whose base is the overall composition curve $x = x(M_2)$]; (b) two-dimensional representation in the $T-x$ plane {B—family of binodal curves corresponding to different values of M_2 [with increase in M_2, the consolute point K (open circles) is displaced upwards]; LTP—projection of the three-dimensional LTP onto the $T-x$ plane}.

Microphase separation is possibly only in those heteropolymers in which the intermolecular components have been "mixed" along the chain to a sufficiently slight extent, i.e. the primary chain structure is closer to BP than to SP.[34] The conditions imposed on the primary BP structure to achieve microlayer formation have the form

$$\overline{R^2N^2}/\overline{N^2} > \overline{R_1^2N_1^2}/\overline{NN_1} + \overline{R_2^2N_2^2}/\overline{NN_2},$$
$$\overline{k_{12}}/\overline{N} < 2\,(\overline{N_1}/N)\,(\overline{N_2}/\overline{N}),$$

where $N_i(S)$ is the number of units of the ith kind in a macromolecule of type S, $N(S) = N_1(S) + N_2(S)$, $R_i^2(S)$ and $R^2(S)$ are the squares of the radii of inertia of the units of the ith kind of the macromolecule of S and of all the units respectively averaged with respect to the conformations, and $\overline{k}_{12}$ is the average number of bonds between unlike units (heterobonds) per macromolecule. The bars above the symbols denote averaging with respect to the molecular-structural distribution in the system: $\overline{A} = \sum_s n_s A(S)/\sum_s n_s$, where

n_s is the number of macromolecules of type S, which can be specified by their structural formula, per unit volume.

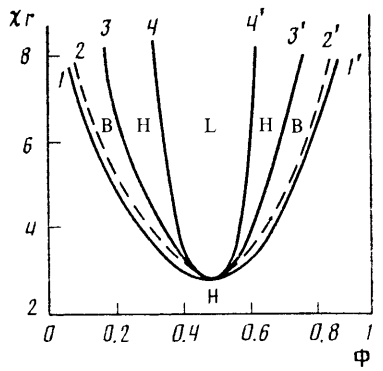

Figure 4. Phase diagram for a di-BP:[33,37] (1,1′) microphase separation boundary; (2) and (2′) spinodal curve; (3) and (3′) boundary corresponding to the transition from the body-centred cubic SMS (B) to the hexagonal SMS (H); (4) and (4′) boundary of the transition from the hexagonal SMS to the lamellar SMS (L); N—non-ordered phase.

For di-BP, the MSB has been calculated analytically both near the critical point[33] and at a distance from it.[37] These data supplement one another and make it possible to construct the complete phase diagram of the di-BP[37] (Fig.4). In a study,[33] based on Landau's theory of phase transitions, the free energy was defined by a series expansion in terms of powers of the order parameter $\psi(r)$:

$$\psi(\mathbf{r}) = \langle \delta\Phi_1(\mathbf{r}) \rangle \equiv \langle \Phi_1(\mathbf{r}) - \Phi_1 \rangle,$$

where $\Phi_1(\mathbf{r})$ is the ratio of the local density of type 1 monomers at the point $\mathbf{r}$ to the overall density of the monomers averaged with respect to the specimen (for a non-compressible system, Φ_1 corresponds to the concentration); the angular brackets denote averaging with respect to the Gibbs *ensemble*. The MSB was represented in the above study[33] by the dependence of χ' on composition. For $\Phi \neq 0.5$, the phase transition is a first-order transition, since the

order parameter varies abruptly.[33,37] For $\Phi = 0.5$, Landau's theory predicts a second-order transition, but at this point the concentration fluctuations with $|\mathbf{k}| \neq |\mathbf{k}^*|$, which can restore the first-order transition, should begin to play a role.[33] The above features of the thermodynamic behaviour of BP are associated with the fact that the spectrum of concentration fluctuations has a maximum at $k = k^*$, which is infinitely high on the spinodal curve. Several workers have noted simultaneously that fluctuations with $k^* \neq 0$ should grow in the vicinity of the spinodal curve.[33–36]

The range of temperatures and compositions where the BP is in the homogeneous state while blends of homopolymers with the same MW of the components have already separated into layers has been predicted theoretically.[33,38] This conclusion agrees with the results of experiments carried out on blends and polyblock BP.[39]

An important theoretical prediction is that the binodal and spinodal curves are close to one another,[33] which makes it possible to consider the influence of the primary structures of the macromolecules on the MSB as being the same as the influence on the spinodal curve, which is easier to calculate. The influence of the number of blocks and the way in which they are joined together and also of the polydispersity of the MW on the position of the spinodal curve has been examined.[34,40] The closeness of the spinodal curves for BP and homopolymers has been predicted and on the $T-x$ plane the spinodal curve for the BP lies below the spinodal curve for the blend, which agrees with conclusions reached in other studies.[33,38,39] An increase in the degree of asymmetry $s = r_1/(r_1 + r_2)$ of the tri-BP $A_{r_1}B_{r_2}A_{r_1}$ macromolecule and the increase in the number of blocks in periodic polyblock BP reduce the spinodal temperature T_{sp}.[34] A decrease in the fraction of long chains in a binary blend of monodisperse di-BP, differing in chain length, or in the polydispersity coefficient $P = r_w/r_n$ for a polydisperse BP also results in a smooth decrease in T_{sp} (increase in χ_{sp}).[40]

Hitherto, we have discussed the position and shape of the MSB itself, but BP have characteristic features also when the MSB is approached from the side of the single-phase region. It has been shown theoretically[41] and experimentally[42] that the "correlation hole" effect is observed in this region and leads to the appearance of a scattering maximum on the angular dependences of the intensities of X-rays and thermal neutrons. The value of k corresponding to the correlation hole has been predicted by the statistics of ideal chains. This effect is sensitive to the degree of polydispersity of the BP. The values of χ have been determined from the position of the scattering maximum by the method proposed by Leibler[33] and proved to depend on the composition in the region where they are low.

The prediction of the formation, as the MSB is approached from the side of the single-phase state, of a rarefied micelle gas, which becomes ordered only when its density increases, made[43] on the hypothesis of the mutual repulsion of the micelles, has been disproved[37] by demonstrating the existence of a region where the micelles attract one another. The formation of ordered structures made up of micelles should occur abruptly (first-order transition) without the formation of unified micelles. In order to reach a final conclusion, it is necessary to test experimentally the claims concerning the sign of the interaction of the micelles.

All the theoretical studies discussed in this review were performed on the assumption that there are no directed intermolecular interactions. However, the position and shape of the binodal surface for BP as well as for mixtures of low-molecular-weight liquids[27–30] must depend on the energy, direction, and degree of degeneracy of various intermolecular bonds, which may be formed both between the molecules of one component and between the molecules of different components. By analogy with mixtures, one can postulate that, when different types of intermolecular interactions are considered, the phase diagram for the BP may have a different lower consolute temperature and can contain loops, "compressed" loops, "compressed" domes, etc. On the other hand, covalent bonding can lead to additional changes in the phase diagram. The influence of directed intermolecular bonds on the shape of the MSB requires both theoretical and experimental study.

As a consequence of the complexity of the experimental investigation of the composition of the coexisting phases in microheterogeneous systems, no binodal curve for a real BP has been obtained hitherto. The optical methods and sample methods, employed to construct the binodal curves for these systems, are relatively ineffective or inapplicable. The low-angle X-ray and neutron scattering methods have been used so far only for the qualitative estimation of the segregation coefficient[31] but not for the quantitative measurement of the compositions of the coexisting phases. Apart from the diffraction methods, calibration relations between the glass point and the composition of the single-phase system[10,23–25] and also experimental $\chi(x,T)$ relations can be used to determine the phase composition.

2. The Symmetry and Repeat Period of the Supermolecular Structure

(a) The Influence of Temperature

It is known from early experimental data that the symmetry of the SMS varies as the intermolecular composition of the BP is varied.[18] The change in symmetry also as the temperature is altered has been predicted theoretically recently.[33,37] Semenov's theory[37] is valid in the region where $\chi_r \gg 1$, while Leibler's theory,[33] based on Landau's theory, is valid in the region where $(\chi_r)_{cr} = 2.62$. Thus the two theories supplement one another. With increase in χr (i.e. with decrease in temperature or with increase in the degree of polymerisation), a body-centred cubic SMS made up of spherical domains‡ should be formed immediately beyond the MSB and, under conditions such that $(\chi r)_1 > (\chi r)_{sp}$ [where $(\chi r)_{sp}$ represents the values of χr along the spinodal curve and $(\chi r)_1$ represents the values on the boundary corresponding to the transition from the body-centred to the hexagonal structure], is transformed into a hexagonal SMS made up of cylindrical domains; the latter is in its turn converted into a lamellar SMS for $\chi r = (\chi r)_2$ and then the structures are inverted, i.e. in the domains component 1 is replaced by component 2 and conversely (Fig.5). The transition from one type of SMS to another is a first-order phase transition. Although $(\chi r)_1 > (\chi r)_{sp}$, over a wide range of compositions ($0.2 < \Phi < 0.8$) these values are very close.

Since in the region of the diagram between the binodal and spinodal curves the formation of a microphase structure is very slow, the body-centred cubic SMS should be metastable. This may serve as an explanation of the absence of direct observations of the body-centred cubic SMS much below the microlayer formation temperature; we may note that the absence of such observations can be

‡ In contrast to Semenov's[33] and Leibler's[37] theories, the theory of Helfand and Wasserman[47] predicts a transition to an SMS with a face-centred cubic lattice made up of spherical domains.

accounted for also by the high stability of the face-centred cubic SMS (see the last footnote). These hypotheses require experimental confirmation. It may be expected that body-centred cubic SMS are easier to observe for low and high values of Φ (for $\Phi < 0.2$ or $\Phi > 0.8$), since in this case the difference $(\chi r)_1 - (\chi r)_{sp}$ is considerable and the temperature range corresponding to the stability of such SMS expands significantly. When the blocks are highly incompatible ($\chi r_1 \gg 1$), the transition from the spherical SMS to the cylindrical SMS occurs at $\Phi_1 = 0.12$ and that from the cylindrical to the lamellar SMS takes place whence $\Phi_2 = 0.28$.[37] The sequence of the changes in the SMS as Φ is varied from χr = const. agrees with thoroughly established empirical data.[11,13,18]

The formation of a SMS of the supercritical type depends on the preparation conditions. A structure of the paracrystalline type is frequently formed in which there is only short-range order in the arrangement of the domains and long-range order is absent;[45] such structures generate a single diffuse ring on low-angle X-ray diffraction patterns. The X-ray diffraction pattern of the supercrystal is characterised by a rigorously symmetrical distribution of localised reflections up to fairly high orders.[20,21,46] With increase in annealing time above the glass points of the components, the SMS is improved, which increases the number of reflections and their sharpness.[21]

The transitions between different types of symmetry of the supercrystal have been poorly investigated experimentally, but a series of studies have been published recently[48-58] on the disappearance of the SMS with increase in temperature. Their main results are presented in Table 1. Most of the experiments were performed on the polystyrene–polyisoprene and polystyrene–polybutadiene BP; precautions were taken to eliminate thermal degradation, which is known, from studies on blends of homopolymers,[59-61] to be capable of modifying greatly the phase diagram. The principal finding, which agrees with the theory, is the disappearance of the SMS with increase in temperature and also with decrease in the MW (even at room temperature[62]). The authors explain the disappearance of the SMS either as the breakdown of the ordered SMS or as the mixing of the components.

The disruption of the SMS was accompanied by characteristics which can be divided into two types: (1) a decrease in the number of small-angle Bragg reflections without change in the long period; (2) a decrease in the number of reflections with increase in the long period by a factor greater than 2 before the disappearance of the SMS. A decrease in the long period has been noted only for lamellar supercrystals (not in all the experiments), while for other types of SMS the periodicity vanishes without change in the period. Studies on the kinetics of the thickening of the lamellae have shown that the weight of the latter increases with increase in temperature and with decrease in MW.[55] One can therefore postulate that in certain cases the long period increases during a time shorter than the duration of the experiment. Qualitatively this hypothesis has been confirmed by the sudden disappearance of the long period from BP with a low MW (Table 1). Within the framework of the existing ideas, it is not altogether understood why the thickening in lamellar supercrystals begins at approximately the same temperature regardless of the MW. In order to elucidate the nature of the disappearance of the ordered SMS, further experimental studies are essential.

Certain hypotheses, which have not been discussed hitherto, can be put forward concerning the influence of temperature on the concentration profile and symmetry of SMS. With increase in temperature, the difference $\Delta x = x'' - x'$ diminishes; this should be accompanied by a transition of the block from one phase to another.

Table 1. The influence of temperature on the parameters of the SMS of the block copolymers.

No.	Primary structure (10^{-3} MW)	x_2/P	SMS	Method	Type of temperature singularity	Refs.
1	PS-PI (51-47)	0.48/1.30	lamellae	SAXS	weak l/p maximum at 383 K and its marked growth in the range 453-523 K, after which it disappears	[53]
2	PS-PI (187-33)	0.15	PCP, PI spheres	SAXS	there are no singularities in the range 293-453 K	[52]
3	PS-PI			SAXS, EM	l/p disappears at 463 K; growth of l/p above 473 K	[55]
	(13.5-13.5)	0.5/1.25				
	(25.5-25.5)	0.5/1.20				
	(36-36)	0.5/1.15	lamellae			
	(49-49)	0.5/1.30				
4	PS-PB (7-20)	0.75/1.04	PS spheres	SAXS	l/p disappears at ~423 K	[50]
5	PS-PEO (14-20)	0.59/1.15	lamellae	SAXS, PM	l/p disappears at 433 K	[87]
	(22-10)	0.32/1.15	HEX, PEO cylinders		l/p disappears at 403 K	
	(22-53)	0.71/1.15	HEX, PS cylinders		l/p disappears at 308 K	
6	PS-PVTMS (97-89)	0.52/–	–	PE	CPE maximum at 500 K	[166]
7	PS-PI-PS (16-12-16)	0.38/–	lamellae	DMA, SAXS	sharp fall of viscosity and of modulus of elasticity at 498 K, disappearance of l/p at 513 K	[48]
8	PS-PI-PS (8-35-8)	0.68/1.25	FCCP, PS cylinders	SAXS	disappearance of reflections at 426 K	[54]
9	PS-PI-PS			SAXS	marked growth of l/p above 473 K	[55]
	(16-32-16)	0.5/1.30	lamellae			
10	PS-PB-PS (7-43-7)	0.77/–	HEX, PS cylinders	EM, DMA	disappearance of microheterogeneity between 398 and 463 K and fall of dynamic viscosity at 423 K	[49]
11	PS-PB-PS (7-43-7)	0.77/–	ditto	DSC	annealing at 563 K leads to disappearance of vitrification of PB	[51]
12	PS-PB-PS (7-43-7)	0.75/–	BCCP, PS spheres	SAXS	disappearance of l/p at 513 K	[50]
13	PS-PB-PS (10-55-10)	0.73/–	PS cylinders	PE	CPE maximum at 400 K	[50]
14	PS-PB-PS	0.55/–	–	PE	CPE maximum at 393 K	[167]

Notation: P = M_w/M_n = polydispersity coefficient, PS = polystyrene, PI = polyisoprene, PB = polybutadiene, PEO = poly(ethylene oxide), PVTMS = polyvinyltrimethylsiloxane, PCP = primitive cubic packing, FCCP = face-centred cubic packing, BCCP = body-centred cubic packing, SAXS = small-angle X-ray scattering, EM = electron microscopy, PM = polarisation microscopy, DMA = dynamic mechanical analysis, DSC = differential scanning calorimetry, PE = photoelasticity, CPE = coefficient of photoelasticity, l/p = long period observed for small X-ray and thermal neutron scattering angles, HEX = hexagonal packing.

Such transitions can occur via two pathways: (1) as a result of the rotation of the macromolecule by 180° about the junction between the blocks, so that blocks of different kinds change places simultaneously; (2) as a result of the "folding" of the macromolecule, i.e. a transition to another phase of only a block of one kind (in this instance the heterobond need not necessarily remain at the interface).§ The predominance of one mechanism over the other should

§This mechanism has also been proposed and examined in a recent communication.[63]

depend on temperature and on the primary structure of the macromolecule.

With increase in temperature, the amplitude of the elastic waves which have developed on the surfaces of the domains increases owing to the increase in the role of thermal fluctuations and the decrease in surface tension. These excitations can become collective and can lead to fluctuations in the form of the domains and to the fluctuation overlapping of neighbouring domains as a consequence of their relative proximity. The stability of the superlattice can therefore be diminished before the molecular mixing of the components take place. As a consequence of the decrease in stability, the long period disappears before the components are completely mixed. For this reason, it would be premature to combine the concepts of the fusion of the superlattice and mixing, as suggested by Leibler.[33]

The ordered SMS has a characteristic period which depends on the molecular parameters. Theory predicts the following expression for the period which is valid for three structures (spherical, cylindrical, and lamellar):

$$D = z a r^{2/3} \chi^{1/6},$$

where a is the effective radius of the inertia of one unit; $z = 3.5\Phi^{1/3}$ for the spherical domains, and $z = 4(3/\pi^2)^{1/3}$ for the lamellar SMS.[37] The $D \propto r^{2/3}$ relation for the lamellar structure has also been predicted by the scaling method.[64,65] However, the $D \propto r^{0.643}$ and $D \propto r$ relations have been predicted[66] for high and low MW respectively. We may note that the theory[66] is inapplicable at low MW, where the approximation of a thin interfacial layer, on which it is based, may not hold.

Table 2. The parameter β and the thicknesses of their interfacial layer Δ (at T = 293 K).

Notation: SANS = small-angle neutron scattering method; for the remaining notation, see the footnote to Table 1.

The experimental data compiled in Table 2 indicate the stepwise character of the variation of D in the experimental range of MW and an appreciable scatter of the results obtained by different workers. In the range of values of M from 2×10^4 to 2×10^5, the empirical relation $D = 0.024\ M^{2/3}$ has been obtained and is valid for di- and tri-BP[67] (it was assumed that $M_0 = M_A + \frac{1}{2}M_B$ for tri-BP of the ABA type). This relation agrees well with the theory developed by Semenov[37] and Zhulina and Birshtein[64,65] and somewhat less well with that of Helfand and Wasserman.[66]

(b) The Influence of the Molecular Weight Distribution

The studies on the symmetry and period of the SMS examined above refer to BP with a narrow MWD, which can be regarded as monodisperse to a first approximation. The influence of polydispersity on the period of the SMS has been studied theoretically.[34,40] A simple expression for the period has been obtained in the limiting case where the content of the type 1 component is low:[34]

$$D = (2\pi a/3)[3(r_{12}r_{1w} - 1)/2\bar{\nu}^2]^{1/6},$$

where $r_{12} = \overline{r^3}/\overline{r_1^2}$, $r_{1w} = \overline{r_1^2}/\overline{r_1}$, and $\bar{\nu}$ is the average number of neighbours per short block. For di-BP and tri-BP of type 1—2—1, the parameter $\bar{\nu} = 1$ and D is a maximum, while for tri-BP of type 2—1—2, $\bar{\nu} = 2$ and D is a minimum with $D_{max}/D_{min} = 2$. The period diminishes with increase in the number of blocks in polyblock copolymers.

A smooth increase in the period D with increase in the fraction of long chains in the blend of two di-BP having different block lengths but identical intramolecular contents of the components and with increase in the polydispersity coefficient in di-BP having a Schultz—Zimm distribution has been predicted.[40]¶

The influence of polydispersity on the SMS has been studied experimentally in blends of two monodisperse BP with identical intermolecular components differing in the MW or in the number of blocks.[69] If a tri-BP with a cylindrical SMS is added to a di-BP having a lamellar SMS, then, for a low content of the former, the lamellar structure persists, its parameters varying with composition. This indicates the compatibility of blocks of one kind. In the region of average compositions, two macroscopic phases coexist, each being a saturated solution of one BP in the other and the geometrical parameters of the microphases do not change on dissolution. For high contents of the tri-BP, only a cylindrical structure is formed, its parameters depending on the composition.

If a di-BP with a low MW, in which there is no ordered SMS, is added to a tri-BP having a lamellar SMS, then, for a di-BP content up to 50%, the lamellar structure persists, undergoing only a smooth change in its period, and then sudden disordering takes place. This makes it possible to assign this transition to first-order transitions. Studies have also established that the blending takes place at a molecular level and not at the level of the lamellae.[69] It is noteworthy that the components of the blend were not rigorously monodisperse and that the polydispersity varied with composition.

Analysis of experimental data on BP blends having a lamellar SMS[70] has led to the following observations. Since the number of thermodynamic components in such blends is two, macroscopic separation of the liquid—liquid type can occur in them. The parameter of the interaction of BP of type α with BP of type β is defined by the formula[71]

$$\chi_{\alpha\beta} = \chi_{12}(\Phi_{1\alpha} - \Phi_{1\beta})^2 = \chi_{12}(\Phi_{2\alpha} - \Phi_{2\beta})^2,$$

¶ It has been noted[40] that the study of Leibler and Benoit[68] proved to be erroneous because of the use in the latter of number-average molecular weights.

where $\Phi_{1\alpha}$ and $\Phi_{2\alpha}$ are the volume fractions of blocks of the first and second kinds in the BP of the α and β types and χ_{12} is the parameter of the interaction between the polymers 1 and 2. Since $\Phi_{1\alpha} = \Phi_{1\beta}$ and $\Phi_{2\alpha} = \Phi_{2\beta}$ in the blends investigated, it follows that $\chi_{\alpha\beta} \to 0$. Consequently, in the absence of microphase separation, there is also no macrophase separation, which can occur only as a consequence of the microlayer formation in one of the BP. A mixture of substances which are compatible in the melt but separate into layers on crystallisation is a low-molecular-weight analogue of the BP blend.

With decrease in temperature or on evaporation of the solvent, the block copolymer α having a higher MW and hence a higher T_{cr}^{micro} than the copolymer β is the first to begin undergoing a phase separation. The copolymer β then acts as a solvent, reducing T_{cr}^{micro}. Presumably the equilibrium structure comprises either a mixture of lamellar domains with periods D_α and D_β (structure I)[70] or of lamellar domains with a period D_{mix} and $D_\beta < D_{mix} < D_\alpha$ (structure II).[40,70] In the first case domains and in the second molecules have been mixed. It has been suggested that structure I is stable, while structure II is metastable, since the chains in the latter are perturbed to a greater extent the greater the difference between the sizes of the chains, which increases the free energy. Structures I and II have been observed respectively for large and small differences between the MW of the block copolymers α and β.

If the rate of the microphase separation is lower than the rate of the translational diffusion of the block copolymers α and β, then the microlayer formation in α leads immediately to phase separation between α and β. On further cooling, β also undergoes microphase separation, which leads to structure I. On the other hand, if the rate of microphase layer formation is lower than the rate of translational diffusion, then there is insufficient time for β to diffuse and structure II results. In a study[73] where structure II was observed, it was postulated that it can be both metastable and can correspond to equilibrium, provided that the MW of α and β do not differ greatly.

(c) The Influence of the Number of Intramolecular Components

Hitherto we have discussed two-component BP. However, from both theoretical and practical points of view, BP with three and more components are of interest. A large number of three-component BP have been synthesised and partly investigated[74–86] but the structure has been apparently studied only for PS–PVMA†–PI.[83] Each block of this BP is segregated in "its own" domain, which leads to a three-phase periodic structure. Overall, the SMS consists of alternating PS and PVMA lamellae, while the PI domains are distributed regularly within the PVMA lamellae, forming a two-dimensional structure (Fig.5d).

The field of study concerned with the SMS of BP with three and more components separated into microphases, the theoretical and experimental investigation of all possible types of symmetry of the SMS, and of the forms of the domains is of current interest; the MSB in them has not been investigated at all.

3. The Size of the Domains

The size of the domains should depend primarily on the MW of the blocks and their temperature. The influence of temperature has not so far been investigated either theoretically or experimentally.

† Poly(vinyl methacrylate) (Editor of Translation).

The influence of the MW has been studied only under conditions remote from the MSB, but the domains have a narrow interfacial layer. Theories concerned with the calculation of parameters of the micro-domain structure such as the size of the domains and the thickness of the interfacial layer as well as their dependence on the MW are based on the reasonable assumption of a thin interfacial layer. These theories predict the sizes of the domains in di- and triblock BP, postulating the symmetry of the SMS: cubic with spherical domains,[47] hexagonal with cylindrical domains,[87] and lamellar.[66] The size of the domains has been recently calculated from first principles.[37] A critical survey of the dependences of the size of the domains on MW for $\chi r \gg 2$, i.e. far from the MSB, has been published[70] for di-BP.

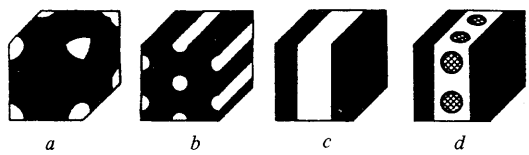

Figure 5. Types of symmetry of the ordered SMS of two- (a, b, and c) and three-component (type ABC) (d) BP:[18] (a) body-centred cubic packing of spheres of phase II in matrix of phase I; (b) hexagonal packing of cylinders of phase II in matrix of phase I; (c) alternating lamellae of phases I and II; (d) alternating lamellae of phases I (A blocks) and III (C blocks) with spherical domains of phase II (B blocks) within phase III.[83]

For spherical domains, the radius of the nucleus of the micelle in the ordered structure is described by the formula[37]

$$R = 2.18\, a r^{1/3} \Phi^{-1/3} \chi^{1/6}.$$

The predicted power dependence of R on the MW with a power exponent of 2/3 agrees with the dependence for lamellar domains,[64,65] the agreement with the conclusions reached by Helfand and Wasserman[66] is less satisfactory, and it differs markedly from the exponent 1/2 predicted by Meier.[96]

In a binary blend of binary BP with blocks having different MW, the thickness of the lamellae, formed by blocks of one kind mixed at the molecular level, is equal to the thickness of the lamellae formed in a BP having the number-average MW of the polymers α and β: $M_n = x_\alpha M_\alpha + x_\beta M_\beta$ (x_i is the number-average fraction of the polymer i). The power exponent in the relation between R and M_n is then 2/3.[70] Thus the size of the domains in BP blends is described by a power relation with the same exponent as in the pure BP. However, a different power exponent, namely 4/5, has also been obtained[69] for BP blends, so that it is necessary to revise these exponents taking into account the non-equilibrium nature of the SMS and the supercooling of the system relative to the MSB.

The degree of homogeneity of the lamellar domains with respect to size proved to be much greater than the homogeneity of the BP with respect to the MW. The degree of polydispersity with respect to the size of the domains is $D_w/D_n = 1.001$, whereas with respect to the MW it amounts to $M_w/M_n = 1.1$, which shows that the macromolecules are packed in domains and that the distribution of the latter with respect to size is much narrower than the MWD.[88]

It is noteworthy that structures with spherical and cylindrical domains have been less thoroughly investigated than the lamellar structures.

4. The Interfacial Layer

It is natural to suppose that, under conditions remote from the MSB, the thickness of the interfacial region is much smaller than the size of the domain. The theories developed in a number of studies[37,47,66,86,96] have been constructed on the basis of this hypothesis, which has been shown experimentally[105] to hold satisfactorily. These theories do not, however, yield an explicit analytical relation for the concentration profile of the block copolymer $\psi(r)$ in the form of a periodic function. We may note that for homopolymer blends, this relation has a form of the Kahn–Hilliard type:[102,103]

$$\psi(r) = \tanh(2r/a_1), \tag{2}$$

in which the thickness Δ of the interfacial layer can be defined as follows:

$$\Delta \equiv \left(\frac{\mathrm{d}\psi}{\mathrm{d}r}\bigg|_{r=0}\right)^{-1} = a_1 = 2a_K/(6\chi)^{1/2} \tag{3}$$

where r is the distance from the interface and a_K the length of the Kuhn segment. Despite the fact that these expressions have been obtained for polymer blends, they have been frequently used also for the analysis of BP.

An expression for the concentration profile under conditions remote from the MSB, valid for lamellar BP and blends, has been obtained recently in an explicit form:[104]

$$\psi(r) = \frac{1-h}{2} F,$$

where $h(r) = k\,\mathrm{sn}(2r/a_1, k)$ is an elliptical Jacobi function with a modulus $k > 0$, a_1 the thickness of the interfacial layer specified by Eqn.(3), and F a complex function of elliptical integrals of the first and second kinds and of the Jacobi function which is independent of r. For $k \neq 1$, the function $h(r)$ is periodic with a period $4(2a_1)^{-1}D$, and, when $k = 1$, i.e. when $D \to \infty$, it is converted into the function (2).

To a first approximation, the thickness of the interface is

$$\Delta(k)/\Delta(1) = [1+2\varepsilon S_1(k)]/k, \tag{4}$$

where $S_1(k)$ is a function whose values lie in the range (0,1), which depends on χr, and ε is a small quantity. For blends, $\varepsilon = 0$ and $\Delta(1) = a_1$, i.e. Eqn.(3) is obtained. Block copolymers have a finite period ($k < 1$) and it follows from Eqn.(4) that they have a thicker interfacial layer.

The thickness of the interfacial layer under conditions remote from the MSB, measured in different studies (see Table 2, and also Henderson and Williams[98] and Shilov et al.[105]) is in the range from 4.4 to 30 Å. The scatter of its values is fairly large and may be associated both with the different ways of calculating the thicknesses from low-angle X-ray and neutron scattering data and with the non-equilibrium nature of the specimens. Various adjustable functions have been used[105] for the electron density profile, but the most realistic equation (4) has not so far been used for analysis.

The influence of this equilibrium on the thickness of the interface has been investigated in relation to BP with spherical domains.[106] The thickness of the interface in a specimen prepared under non-equilibrium conditions (at a temperature below the glass point of one of the components) and then heated above the glass point diminishes exponentially, tending to the limiting values 7.5 Å (the relaxation time is ~60 h). The diameter of the domains then changes little.

The equilibrium thickness determined from experiments on annealed specimens is more than twice smaller than the value calculated by Eqn.(3). The following possible causes of this discrepancy have been quoted:[106] (1) systematic errors in the calculation from low-angle X-ray scattering data to which the greatest contribution may come from the density fluctuations within the domains which has not been taken into account; (2) the inadequate accuracy of the determination of the quantities χ and a in Eqn.(3); (3) the unsuitability of Eqn.(3) at temperatures where one of the components has been converted into a glass. In our view, we may note yet another cause, namely the lack of validity of the application of Eqn.(3), obtained for blends, to BP.

Comparison of the thicknesses of the interfacial layer with the sizes of the domains shows that their ratio does not usually exceed 0.1, which indicates the validity of this intervening layer approximation under conditions remote from the MSB. Nevertheless, the volume fraction of the substance in the interfacial layer can reach considerable values (up to 30%).

Henderson and Williams[99,100] put forward and developed the hypothesis of the asymmetry of the concentration profile in the interface. However, since this hypothesis was based on the temperature variations of viscoelastic quantities, it may reflect the temperature asymmetry and not the spatial asymmetry. At any rate, the hypothesis requires experimental confirmation.

Hitherto we have considered the behaviour of the concentration profile under conditions remote from the MSB. The distribution of concentration in the form of a periodic profile has been obtained on the basis of Landau's theory near the consolute point:[107]

$$\psi(r) = \psi_m(t, k)\sin[r/\delta(t, k)], \tag{5}$$

which is similar to that illustrated in Fig.2. The parameters of this function are defined by the relation

$$\psi_m(t, k) = \psi_0[|t|k^2/(1+k^2)]^{1/2},$$
$$\delta(t, k) = \Delta_0[(1+k^2)/|t|]^{1/2},$$

where $t = T - T_{cr}$, while ψ_0 and Δ_0 are expressed in terms of the coefficients of the Landau expansion. The modulus k is determined by specifying the period $D = 4K(k)$, where $K(k)$ is the total elliptical integral of the first kind.

According to Eqn.(3), the thickness of the interfacial layer is given by

$$\Delta(k, t) = \Delta_0(1+k^2)/|t|k.$$

For a fixed period D, the amplitude of the profile $\psi_m(t) \propto |t|^{1/2}$ and the thickness $\Delta(t) \propto |t|^{-1}$ as the consolute point is approached. For a specified t, the increase in the period ($k \to 1$) converts Eqn.(5) into an expression analogous to Eqn.(2), while the decrease in the period ($k \to 0$) leads to the expression

$$\psi(r) = \psi_0 k|t|\sin(r/\delta).$$

The relation

$$\Delta(k)/\Delta_{min} = (1+k^2)/2k,$$

where $\Delta_{min} = 2\Delta_0|t|$ predicts an increase in the thickness of the interfacial layer with decrease in the period (on passing from a blend to the BP) and the amplitude ratio

$$\psi_m/\psi_m^{max} = [2k^2/(1+k^2)]^{1/2}$$

indicates a decrease in the miscibility of the components in the bulk of the phases on passing from the BP to the blend. This theory is applicable to the range of not unduly low MW of the blocks, which entails an increase in the upper consolute temperature (UCT) and hence is responsible for the difficulty of the experimental test.

The influence of temperature on the thickness of the interfacial layer has been investigated for BP in which the disappearance of the periodic SMS was observed.[50] An increase in temperature did not alter the thickness of the interfacial layer. Such qualitative discrepancy with the theory can be explained either by the fact that the composition differs from the critical composition or by the appearance of a cooperative surface instability (see above), which was not taken into account in the theory.

5. The Chain Conformations in the Domains

The interface should exclude some of the possible conformations of the block and the radius of inertia of the blocks should therefore differ from the radius of inertia of chains of the same length in the absence of an interface. So far only a small number of studies have been devoted to the elucidation of these differences and also of the degree of overlap of neighbouring coils. There are contradictions between ideas concerning the degree of interpenetration of coils of one kind in the direction normal to the surface of the lamella. Some workers conclude that there is slight interpenetration of the coils, so that double layers are produced (Fig.6),[62] while others conclude that they overlap to a marked extent.[70] In the direction parallel to the surface of the lamella, neighbouring coils overlap markedly[67] and are compressed. This compression is accompanied by the swelling of the coils along the normal to the surface, so that the overall radius of inertia remains virtually unchanged.[90]

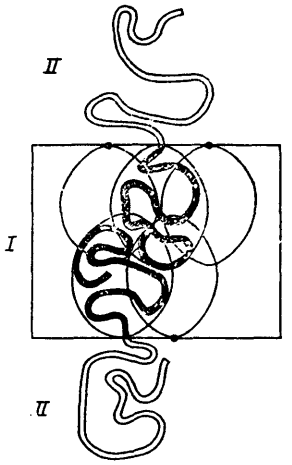

Figure 6. The relative disposition of coils of different blocks in a di-BP within the lamellae: (I) lamellae comprising type I blocks; (II) lamellae comprising type II blocks.

A change in the radius of inertia of the chains relative to the radius of inertia of the corresponding homopolymers have not been observed in the spherical domains.[91] The radius of the domains and their packing are then approximately the same as predicted by Vallance and Cooper.[86] Under non-equilibrium conditions, which frequently obtain in BP with a high MW obtained from a solvent, the macromolecules have significantly greater radii of inertia and the size of the domains at high BP concentrations and/or low temperatures diminishes in accordance with the law $D \propto \Phi_{BP}^{-\gamma}$, where γ = 1/3 for spherical domains, 1/2 for cylindrical domains, and 1 for lamellae.

The average area of the interface per chain (between neighbouring chemical cross-links joining the blocks along the interface), S/N, where N is the number of chains passing through the interface, is described by the following empirical scaling law for both narrowly dispersed BP and their blends:

$$S/N \propto M_n^{1-\beta}, \tag{6}$$

where the exponent β = 2/3. We may note that, among all the types of average molecular weights (M_n, M_w, M_z), M_n leads to the best adjustment of the relation. A relation of type (6) with an exponent of 1/3 is applicable to both lamellar[70] and spherical[91] domains.

6. The Grain Size

An ordered inter-domain structure is limited by the grain size, which is of the order of several microns. The grain boundaries are two-dimensional defects analogous to the boundaries of a crystallite in polycrystalline substances and of magnetic or electrical domains in ferromagnetic and ferroelectric materials. Rod-shaped grains have been observed in BP with lamellar and cylindrical domains, the grains being distributed at random relative to one another.[110,111] These anisotropic grains are strained and are surrounded by cavities and inclusions. It has been suggested that the stresses arise during the evaporation of the solvent.

The optical axis of the grain is parallel to the axis of the cylindrical domains and can be directed either parallel or at an angle to the axis of the rod-shaped grain. Single supercrystals exhibit double refraction associated with the difference between the refractive indices of the microphases.[112,113] If the optical axis is at an angle to the rod, then, on heating, it becomes parallel to the latter owing to the relaxation of the elastomer phase and the rotation of the cylinders.[112] The size and shape of the grains have been investigated by the low-angle scattering of depolarised light, which depends on the anisotropy of the shape and boundaries of the grains.[110,114] The domains do not contribute to the scattering, since their size (300 to 500 Å) is much smaller than the wavelength. The scattering by mechanical stresses is negligible. Apart from the defects of the type of grain boundaries, defects of the type of dislocations have also been observed.

Using special methods, it is possible to obtain macroscopically anisotropic specimens,[21] which are sometimes called single supercrystals by analogy with single crystals. There exist three methods for obtaining them: (1) by the shear flow of the melt,[21,115] (2) by extrusion,[116] and (3) by casting from a solution with a high boiling point of the solvent.[117]

7. Kinetics of Microlayer Formation

The kinetics of separation into microphases (in the abrupt transition from the single-phase state to the region where two-phase states are stable) in BP should be in general analogous to the kinetics of

the separation into macrophase layers in mixtures, although it should have its characteristic features. However, despite the vigorous studies on the kinetics of separation of blends (as regards homopolymer blends, see, for example, Refs.118–131), the separation of BP melts into layers has been little investigated.

The early stages of the spinodal decomposition have been investigated theoretically in a study[34] where it was shown that periodic (with a period $L_0 = 2\pi/k_0$) inhomogeneities form a train with a length l ($l \gg L_0$), which increases in accordance with the diffusion law

$$l^2(t) \propto l_0^2(t)/\tau(k_0, \Delta T),$$

where l_0 is the length of the train under the conditions of slight supercooling, while the amplitude of the inhomogeneity increases exponentially. The period L approaches L_0 after a time. These theoretical predictions have not so far been confirmed experimentally.

The experimental study of the kinetics of the appearance of the structure is complicated by the need to use powerful sources of X-ray (including synchrotron) radiation or neutron radiation, which make it possible to reduce significantly the exposure time.

There exists the possibility, in principle, of studying the kinetics of microlayer formation by simpler methods, when the components are capable of vitrifying. Such systems can be quenched at various stages of the phase separation and a change in the phase state can be investigated from vitrification parameters, which depend on the amplitude and size of the fluctuations. The increase in the heat capacity jump on vitrification with increase in the phase separation time has been observed by this method.[10,24] In the first instant, there was no jump, which is most probably due to the large scatter of the period and the low amplitudes of the fluctuations. After the appearance of the jump, its width changes insignificantly, which shows that fluctuations with a small scatter of the period contribute to the vitrification jump. The heat capacity jump, corresponding to the second phase, has not been observed either because of the small amount of the phase (it has not been recorded also in the phase separation of blends of homopolymers)[131] or owing to the small size of the phase (it has been shown[163] that, when the size of the particles of the phase is less than 60–70 Å, its vitrification is not recorded). However, in other experiments cooling in the postulated single-phase state leads to the observation of the two vitrifications, although one of them is highly diffuse.[51]

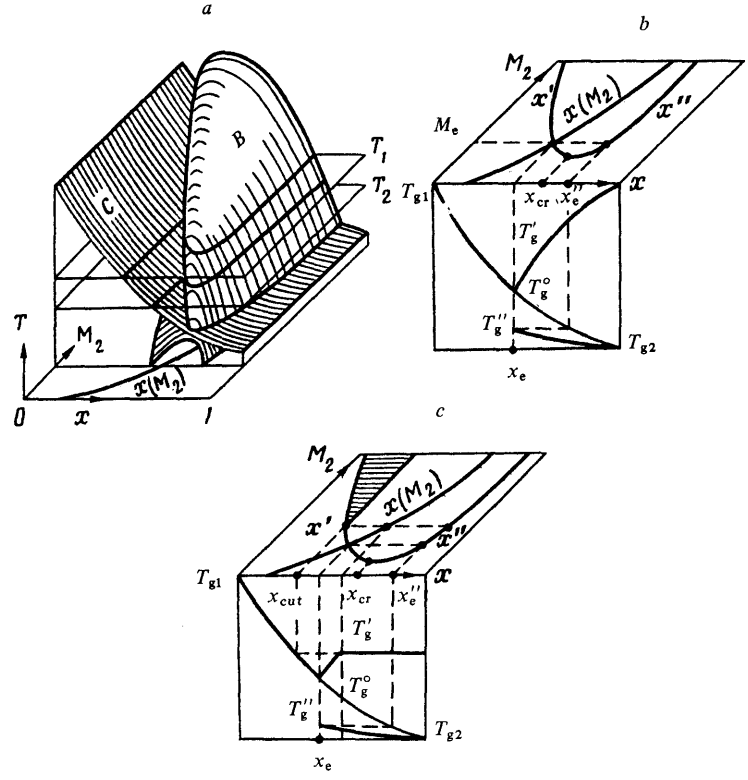

Figure 7. Construction of the vitrification diagrams for BP with M_1 = const. by the surface intersection method:[10] (a) three-dimensional representation of the surfaces in terms of the coordinates $T-x-M_2$ [B— binodal surface; C— vitrification surface for a single phase system (VSSS); $x(M_2)$—overall composition curve; T_1 and T_2—planes corresponding to the temperatures T_1 and T_2]; (b) section through the surfaces by the T_1 plane and the corresponding VD (x' and x''—compositions of the coexisting phases; x_{cr}—critical composition; x_e, M_e—the point at which the composition curve enters the region under the binodal surface; x_e''—the composition of the second phase at the point of entry; T_{g1} and T_{g2}—glass points of the pure components; T_g^0—VCSS; T_g' and T_g''—glass points of phases I and II respectively); (c) section through the surfaces by the T_2 plane ($T_2 < T_1$) and the VD corresponding to the section (x_{cut}—cut-off composition).

The kinetics of the disappearance of the SMS after a sharp increase in temperature have been investigated for PS–BP di-BP with $M_n = 5.2 \times 10^4$ and $\chi_{PS} = 0.30$ (to reduce the temperature of the transition to the BP, 60% of solvent was introduced).[132,133] Microdissolution occurred rapidly (after ~30 s) and accelerated on raising the final temperature. The scattering curve in the final stage corresponded to scattering by a homogeneous BP melt with a broad and weak maximum due to the effect of the correlation hole.

III. MUTUAL INFLUENCE OF MICROLAYER AND GLASS FORMATION

Separation into microlayers and glass formation exert a mutual influence on one another. On the one hand, microlayer formation determines the vitrification of the system if the phase state of the material does not change on cooling to the vitreous state. On the other hand, vitrification can be influenced in microlayer formation if during its occurrence one of the phases can vitrify, which leads to the deviation of the phase state from equilibrium.

The vitrification of BP is determined by parameters of the concentration profile (in the more general case, the density profile) such as the amplitude of the profile, the size of the domains, and the width of the intermediate layer. For different coefficients of the thermal expansion of the phases, the SMS should play a role. The commonest method of investigation of vitrification involves the construction of plots of T_g against the MW of a fixed composition or the construction of plots of T_g against composition for a fixed length of one of the blocks (usually the rigid block, i.e. one with a higher glass point T_{g1}). In relations of this kind, not one but several of the above parameters of the concentration profile contribute to T_g. The estimation of the contributions of different parameters requires special consideration in each case. The direct problem involves in this instance the study of vitrification in systems with a known concentration profile and is still at the beginning of its solution. The converse problem is usually solved: conclusions concerning the different parameters of the profile are reached from the vitrification investigated.

1. Vitrification in Block Copolymers which have Undergone Microphase Separation at Temperatures above the Glass Points of the Components

We shall assume that the systems have a binodal curve with a UCT which lies above the T_g of both components. On transition of the system from the single-phase state to the region of stable two-phase states, at temperatures above the T_g of both components, vitrification does not influence the phase separation and the system can, in principle, reach the state of equilibrium. Subsequent quenching from the phase separation temperature (annealing temperature) freezes (as a consequence of vitrification) the structure of the liquid corrsponding to a definite temperature. By quenching the melt from a specific point in the phase diagram, it is possible to compare the vitrification parameters at the given point on the $T-x$ phase diagram.

(a) Vitrification Diagrams (VD)

As already mentioned, the influence of phase composition on the temperatures of the transitions to the BP can be conveniently represented in terms of the $T-x-M_2$ variables for a fixed M_1. We shall consider initially the behaviour of the glass points on varying the composition of the BP annealed at a temperature T_1 (to which corresponds the T_1 plane in Fig.7a). Before the composition curve enters the region underneath the binodal surface, the system remains in the single-phase state and its single glass point should obey the relations characteristic of T_g for single-phase systems comprising two components. The glass point T_g in this composition range may be described by different semiempirical formulae obtained for SP and homopolymer blends,[135–138] which are also suitable for single-phase BP.[139]

When the composition curve enters the region under the binodal surface, a second phase appears, to which corresponds a second glass point. Depending on whether the composition curve enters from the left or from the right relative to the consolute point, either low-temperature or high-temperature vitrification will occur abruptly on the T_g–composition diagram (VD) (Fig.7b). On further increase in the length of the flexible component, the glass points of both phases should move away from one another, since the separation range $x''-x'$ increases. For this reason, a dip should be observed in the upper branch, whose minimum should be located at the point corresponding to the onset of phase separation. The first and second derivatives should change abruptly at this point.[10,24] For very large lengths of the flexible blocks, the composition curve can emerge from the region underneath the binodal surface and the upper T_g' branch then terminates.

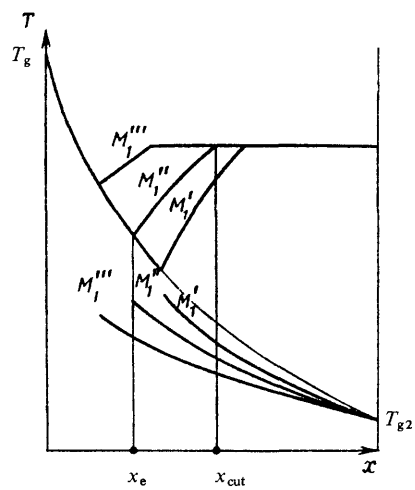

Figure 8. The influence of M_1 on the form of the vitrification diagram (the increase in the number of primes in the designations of the curves denotes an increase in M_1); x_{cut}—cut-off composition; x—content of the second component.[10]

With decrease in the phase separation temperature, the branches on the VD should move apart and the bifurcation point should shift towards lower contents of the flexible component. The increase in M_1 for a fixed phase separation temperature is analogous to a decrease in temperature for a fixed M_1 (Fig.8).

The type of VD predicted by the methods of topological thermodynamics has been observed experimentally for polyblock[39,84,140] (Figs.9a and 9b) and di- and tri-block[141] (Fig.9c) BP. For a low

content of the flexible component, a single vitrification is observed and the T_g of the BP varies in accordance with the same law as that governing SP (this has been tested both by measurements on SP and by calculations using the corresponding formulae). Thus, in the above composition region, the BP considered can be regarded as single-phase. The decrease in T_g depends not only on the content of the flexible component but also on the MW and the primary structure of the BP (di- or tri-block or star-shaped).[141] In BP with specific intermolecular bonds, an increase in M_1 for the same composition entails a decrease in T_g.[39,140] The decrease in T_g to the MSB amounts to several tens of degrees according to some data[141] and reaches 130 K according to others.[140]

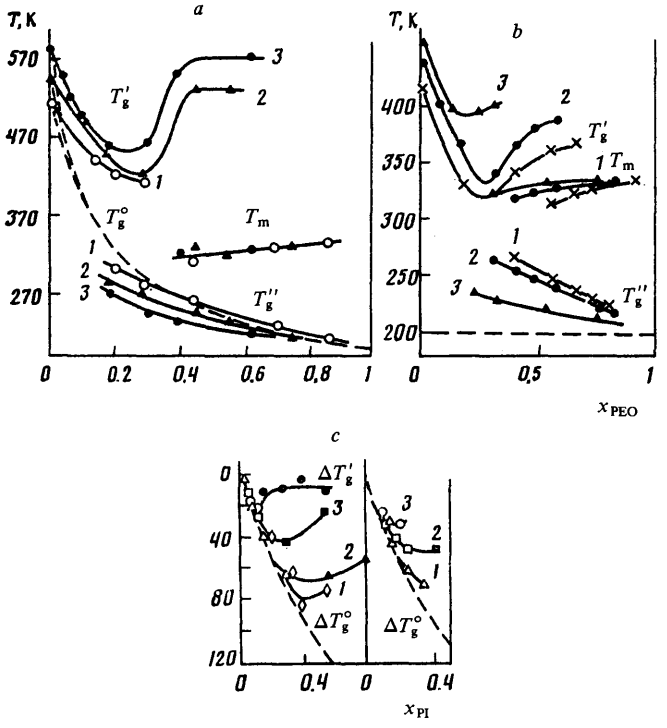

Figure 9. Experimental vitrification diagrams for BP (the increase in the number of the curve corresponds to an increase in M_1): (a) $(PA-PEO)_n$[39] (T_m—melting point); (b) $(PASO-PEO)_n$;[84] (c) PS–PI (on the left), PS–PI–PS (on the right);[141] $\Delta T_g' = T_{g1} - T_g'$; $\Delta T_g^0 = T_{g1} - T_g^0$ (the open and filled symbols denote single-phase and two-phase states respectively); x—the weight content of the component with a low glass point.

The second region—the region before the onset of phase separation—is characterised by a deviation of T_g' from the T_g of SP and by the appearance of a second transition to a vitreous state (T_g''). In some cases, the onset of the deviation coincides approximately with the appearance of the second transition,[39,84] while in others the second transition appears after the start of the deviation.[141,143] An attempt has been made to explain the latter finding by the presence of a large fraction of interfacial layers, which is unlikely. The increments in the compositions of the components were not always sufficiently small. For this reason, one cannot determine exactly the start of the appearance of the second vitrification and the form of the dip in the upper branch, although there is no doubt about the existence of the dip. A decrease in M_1 shifts the MSB towards higher values of x and increases the depth of the dip in the upper branch, which is consistent with the predictions by the geometrical method. The width of the heat capacity jump then increases.[141] After its abrupt appearance, the temperature T_g'' initially differs markedly from T_{g2}, but approaches the latter as x increases. We may note that for the BP discussed, the vitrification curve for single-phase systems (VCSS) is concave and for this reason the addition of the rigid component to the phase with a high content of the flexible component results in an appreciably smaller change in the T_g for the phase than the introduction of the same amount of the flexible component into the rigid phase. It is therefore difficult to observe the deviation of T_g'' from T_{g2}.

In the third region (with a high content of the flexible component), two T_g, differing from T_g^0, are observed, which indicates the existence of two amorphous phases. In this composition region, T_g' either approaches T_g for the corresponding homopolymers[39,141] or reaches a limiting value without attaining T_{g1}.[84] In the latter case, microphase separation is apparently inhibited by the vitrification of the rigid phase (cf. subsection 2 below).

The close correspondence between the forms of the VD predicted by the method of topological thermodynamics, which is based on the hypothesis that T_g depends solely on the phase composition, and the experimental VD as well as the large difference $T_g' - T_{g1}$ (up to 130 K) permit the conclusion that the change in the glass points of the BP indicated is responsible for the change in the amplitudes of the concentration profile as the composition is varied. The behaviour of T_g on crossing the MSB has been explained[141] by the presence of a large fraction of the interfacial layer, which appears to be inadequately justified.

(b) Vitrification in the Two-Phase Region in the Vicinity of the MSB

In the experimental studies examined above, the composition and MW ranges investigated included the MSB. The behaviour of the glass point as the microlayer formation boundary is approached from the side of the two-phase region has not been more thoroughly investigated, although the proximity to the boundary is not always clear because the position of the boundary itself is frequently unknown. It has been noted in many cases that, as the MSB is approached by reducing the MW of the blocks, T_g' falls and T_g'' increases (Table 3). Under these conditions, T_g' diminishes faster than T_g for the corresponding homopolymer. Extrapolation of T_g' and T_g'' to di-BP[108] and poly-BP[104] for a constant composition (decrease in the MW of the blocks in the former case and with increase in the number of blocks, keeping the overall MW constant, in the latter) leads to the intersection of the branches at the point which coincides with the T_g for the SP having the same composition.

Although the fact that the glass points approach one another is not open to doubt, there is as yet no unambiguous explanation for it. This is because the decrease in the MW of the block entails a decrease in the size of the domain and can lead simultaneously to a change in the phase composition and in the thickness of the interfacial layer and also in the MSB. The displacement of T_g is therefore attributed to a series of phenomena: (1) the increase in the content of the interfacial regions;[141,144,145] (2) the increase in the surface/volume ratio owing to the change in the SMS;[153] (3) the

intensification of the dynamic interaction of the flexible and rigid blocks which leads to joint segmental motion;[108] (4) the effect of interfacial tension between the microphases;[161,162] (5) the increase in the average free volume of the vitreous phase under the influence of the mixing near the interface;[153] (6) the change in phase composition.[39,84] We believe that the mechanisms (3) and (6) are the most probable.

In the study of vitrification and of the influence on the latter of the parameters of the concentration profile, it is essential to know the phase state of the melt, since BP are frequently obtained by cooling the melt, which is accompanied by the freezing of its structure. In most studies on vitrification in BP, the phase state of the melt at temperatures above T_{g1} remained unknown. The investigation[134] in which the transition of the BP, tentatively from a two-phase state to a single-phase state,[49] was observed from the change in the viscosity of the melt and electron microscope data is important for this reason. After annealing above the temperature of the postulated transition to the single-phase state and subsequent quenching, very diffuse vitrification of the rigid phase is observed, so that it proved impossible to determine where this process begins. On the other hand, the vitrification of the flexible phase occurred at the same temperature as in the slowly cooled specimens. The values of ΔC_{p1} and the width of the vitrification range of the rigid phase decrease with decrease in the cooling rate, although the heat capacity jump remains more than a factor of two greater than in the corresponding homopolymer. These data apparently indicate a higher content of the flexible sigments in the rigid phase, although, despite the higher degree of mixing, the BP nevertheless remain in the two-phase state after annealing above the transition temperature and subsequent quenching. The existence of a two-phase structure can be associated both with the higher rate of layer formation on cooling in the single-phase state and with the existence of a microheterogeneity at temperatures above the rheological transition temperature (see the discussion of the cooperative capillary instability of the SMS with retention of the two-phase structure in subsection 2 of Section I above). Nor can one rule out also that the diffuse nature of the vitrification is associated with the influence of vitrification on the phase separation (see below).

(c) Vitrification in the Far Two-Phase Region

Apart from the increase in T_g'' with increase in the length of the flexible block, its decrease has also been observed in the two-phase region[155–160] (Table 3). Depending on the nature of the blocks, the decrements in the glass point $T_g'' = T_g'' - T_g^{homo}$ reached 19 K,[155] 15 K,[158] 13 K,[156,157] and 10 K.[160,161] The study of the SMS showed that such decrease is observed only for compositions such that the flexible phase constitutes closed inclusions in a vitreous matrix.[155,157] This led to the reasonable conclusion that the decrease in T_g'' is associated with the difference between the thermal expansion coefficients of the inclusions and the matrix. As a result of the covalent bonds between the flexible chains and the skeleton, the volume of the flexible inclusions cannot diminish on cooling the melt to the extent that they would have decreased in the absence of the skeleton (matrix). This should lead to a "negative pressure", extending the flexible domain. Estimates carried out for a spherical BP domain within a PS matrix from the formula[155]

$$\sigma_i = 2(\alpha_i - \alpha_m)E_iE_m\Delta T/[6E_m(1-2\mu_i) + 3E_i(1-\mu_m)]$$

* The supermolecular structure was not investigated.

(subscript i refers to the inclusion and m to the matrix; σ_i is the thermal stress developed within the highly elastic domain, α the thermal expansion coefficient, E the modulus of elongation, and μ the Poisson coefficient) lead to a negative pressure of 78 MPa. The decrease in T_g, calculated from the relation $dT_g/dp = 0.24$ K MPa^{-1} and equal to 18.7 K, agrees well with the experimental value.

After a time, the free volume should be lost from the inclusion as a result of the relaxation of the vitreous matrix (the compaction of the specimen), which diminishes the hydrostatic extension of the flexible inclusion with which the observed decrease $\Delta T_g''$ is apparently associated. However, one should note that thermal stresses should apparently act not only on the spherical flexible domains but also always when the rigid phase forms a monoconnected region, i.e. the matrix. In particular, they should act also on cylindrical flexible domains. It may be that a decrease in T_g'', which begins already when the content of the rigid block is $\sim 50\%$, is associated with this factor.[156,158] The relaxation time of the free volume owing to the rearrangement of the matrix should decrease with increase in the content of the flexible block.

It is remarkable that T_g'' depends on the MW of the flexible block and not on the size of the domains, the decrease in MW resulting in a fall of $\Delta T_g''$.[155] Although this has been explained[155] by the decomposition of the flexible blocks, which tends to lower the thermal strain, this hypothesis requires proof.

Generally speaking, thermal stresses should alter T_g'' not only far from the phase separation boundary (where a rigid matrix still persists) but also in its vicinity, provided that the composition curve enters the region under the binodal surface far from the consolute point. The phase compositions and hence the thermal expansion coefficients will then differ greatly, which will lead to an effect by the rigid matrix on the flexible inclusions.

The behaviour of T_g'' in the remote two-phase region permits the following conclusions. The identity of T_g'' for the BP with a long rigid block and T_g'' for the homopolymer having the same MW in the range of MW where T_g of the homopolymer still depends on the MW is not consistent with the concept of the free volume of the terminal units, since the free volumes of the BP and the homopolymer should differ significantly.[148,155,164] This permitted the logical hypothesis[164] that the flexible segments attached to the end of the rigid block are so mobile that they can transmit their mobility to the rigid block, which should thus behave as if it had a free end. This idea agrees with the conclusion[108] that the disposition of the rigid block in the tri-BP macromolecule (at the centre or at the ends) does not influence T_g.[108,152] However, we may note that, in contrast to Kanbur's study,[164] where the decrease in M_2 for x = const. did not alter T_g', the decrease in M_2 from M_1 = const. in the study of Levin et al.[157] lead to a decrease in T_g'.

Comparison of the behaviour of T_g' in a series of BP, where the rigid block was the same and different components were selected as the flexible block, showed that, at a remove from the phase separation boundary, T_g' is independent of the chemical nature of the flexible block and of the BP composition.[148-152] The chemical nature and the MW of the flexible block influenced T_g' only when the MW and the composition were close to the MSB.[152] From this, one may conclude that, since the compatibility of different oligomers with the rigid oligomer varies, under conditions remote from the phase separation boundary there is no blending whatever of unlike segments in the vitreous microphase.

The width of the jumps in the BP thermal conductivity is greater than for the corresponding homopolymers and only the upper part of the vitrification region with T_g'' broadens in the direction of higher temperatures (up to 32 K) and only the lower part of the vitrification region with T_g' broadens towards lower temperatures (down to 26 K). A decrease in the content of the rigid block, accompanied by a decrease in the size of the inclusions of the rigid phase, led to the broadening of the vitrification region on the low-temperature side as far as 43 K.[154] The width of the vitrification region of the flexible phase as a function of the specific surface of the interface fits on a single curve for all the systems investigated regardless of the nature of the interface (i.e. for both BP and latexes), which has led to the conclusion that the width is determined solely by the area of the interface. The widening becomes appreciable for a specific surface of $\sim 10^4$ m^2 kg^{-1}, which corresponds to a microphase whose size is 0.5 μm. From this it follows, in particular, that in homogeneous BP the vitrification range should be the same as in homopolymers. It has been suggested[154] that an increase in the temperature of the upper boundary of the vitrification region is caused by the fact that the two vitreous phases are separated by a solid interface. It was not appropriate to take into consideration the thickness of the interfacial layer, which should be very small in the remote two-phase region, for the explanation of the broadening of the vitrification region.

Thus the above analysis of the data and ideas available at the present time on the vitrification of BP undergoing microphase separation at temperatures above T_{g1} permit the following conclusions. In the region of the single-phase state, T_g obeys the relations valid for SP. In the region of the transition through the MSB, the glass point of one of the phases deviates from the relation describing SP and a second transition to a vitreous state appears. In the two-phase region near MSB, the T_g of the rigid phase is usually below the T_g of the corresponding homopolymer and the T_g of the flexible phase is above it. Both these effects can be explained either by an increase in the similarity of the phase compositions as the phase separation boundary is approached or by the dynamic interaction of the linked blocks. As the boundary is approached, $\Delta C_p'$ decreases while $\Delta C_p''$ increases, the width of the vitrification region in the rigid phase increasing. However, the treatment of the changes in the intensity and width of the transitions is not unambiguous and requires further study.

In the remote two-phase region, both glass points agree with the T_g of the corresponding homopolymers and the heat capacity jumps correspond to the contents of the components, but the width of the jumps is as a rule greater than for the homopolymers. The widening of the range corresponding to the low-temperature vitrification is directed towards higher temperatures, while the corresponding widening of the high-temperature vitrification is directed towards lower temperatures. This can be explained by the presence of an interface, the widening becoming more pronounced with increase in the specific area of the interface. It may be that this effect contributes also to the widening in the region of the MSB. In the composition range where the flexible phase represents a polyconnected region, a decrease in the T_g of the flexible phase compared with the corresponding homopolymer is observed. This decrease is associated with the stretching hydrostatic pressure, which is exerted by the rigid matrix on the domains comprising flexible covalently bound chains and is associated with the difference between the thermal expansion coefficients of the domain and the matrix.

It appears essential at the present time to investigate quantitatively the vitrification in BP whose phase state and SMS have been characterised not only in the region between the glass points of the components but also in the melt. The study of the vitrification in

the region of MSB taking into account the kinetics of phase separation appears especially important. Furthermore, it is essential to devise a theory of the vitrification of BP in all the regions of the phase diagram.

2. Vitrification in Block Copolymers Undergoing Microlayer Separation at Temperatures between the T_g of the Components (the Influence of Vitrification on Microlayer Formation)

If the phase separation temperature is below the boundary temperature T_b, determined by the intersection of binodal curve with the VCSS (Fig.10), then the fluctuation concentrations develop until their amplitude in the half-period with a large content of the rigid component reaches the cut-off value x_{cut} at which the glass point for this half-period, having increased, becomes equal to the phase separation temperature.[10,24] Thus the microphase with a high content of the rigid component passes to the vitreous state before the attainment of equilibrium as regards composition. This effect should shorten the separation range in the phase diagram and in the VD.

The influence of vitrification on the phase separation has been observed experimentally.[10,24] After the system has passed from the single-phase to the two-phase region, the thermogram does not show initially any anomalies. This is apparently associated with the fact that in the initial instant there are only smooth concentration fluctuations with a large scatter of periods, which leads to the pronounced spreading of the transition to the vitreous state. A small thermal conductivity jump then appears and grows as a function of time, while the temperature corresponding to the point of inflection (T_g) increases monotonically (Fig.11). With decrease in the phase separation temperature (T_{ps}), the glass point, determined after annealing for 1 h, decreases linearly by more than 100 K with a slope close to unity, which corresponds to the predictions of the geometrical method. No other factor, apart from the change in the phase composition can apparently shift T_g by more than 100 K. The analogy between the freezing of the phase separation as a result of vitrification and the self-inhibition of the hardening reaction of network polymers is noteworthy.

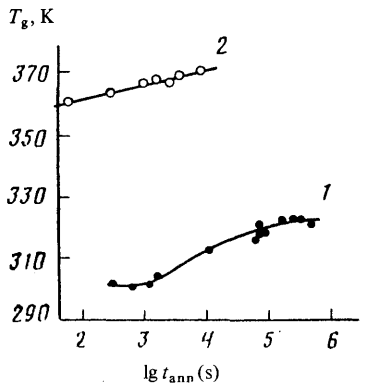

Figure 11. Dependence of T_g' on the annealing time in the PA–PEO BP:[10] (1) T_{ann} = 290 K; T_{ann} = 350 K.

The geometrical analysis based on the consideration of the intersections of the binodal surface, the vitrification surface for a single phase system (VSSS), and the temperature plane (T-plane), permits the construction of all possible types of T_g–composition and T_g–MW relations in the BP in the case where vitrification influences the phase separation.[10,24] This analysis presupposes that T_g depends solely on the phase composition. As an example, Fig.7a illustrates the mutual intersection of the binodal surface, the VSSS, and the T-plane. So long as the composition curve does not intersect the curve of the coexisting compositions, the system remains in the single-phase state. In this region, T_g should vary in accordance with the law for a single-phase system. If the composition x_c at which the composition curve joins the coexisting phases curve is greater than x_{cut}, then, after the start of phase separation, the difference between the phase compositions will increase and the glass points will therefore diverge. However, as soon as the composition of the phase with a high content of the rigid component reaches x_{cut}, it ceases to change on further alteration of the overall composition.

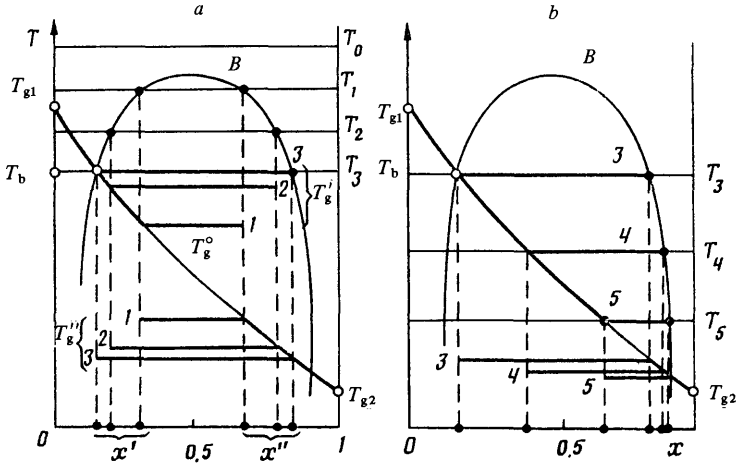

Figure 10. Construction of VD for blends in the case where the binodal curve and the VCSS are superimposed.[10] B—binodal curve; T_g^0—VCSS; T_b—boundary temperature; x' and x''—compositions of the coexisting phases; the numbers of the VD branches correspond to the subscripts of the T_i: (a) $T_i > T_b$; (b) $T_i < T_b$.

The upper branch in the VD beyond the cut-off composition should become horizontal (Fig.7).

The decrease in T_{ps} should reduce x_e and should increase x_{cut}, as a result of which the bifurcation point in the VD should shift towards lower values of x and and the horizontal plateau should be displaced towards lower temperatures. When the temperature falls so much that x_e becomes smaller or equal to x_{cut}, the bifurcation point should shift towards higher values of x and the dip in the upper branch should disappear. The plateau should again be displaced downwards as a linear function of T_{ps}. The increase in M_1 influences the form of the BP analogously to the decrease in temperature. All the possible forms of the VD, reflecting the influence of vitrification on the phase separation in BP, have been published.[10] VD, whose form is analogous to those discussed above, have been observed experimentally.[39,84,140,141] The attainment of a plateau below T_{g1} has been established most reliably by Godovskii et al.[84]

The above discussion shows that in the two-phase region, T_g for the rigid phase can be reduced owing to the presence of an excess of the flexible component in this phase. Since in the study of vitrification the BP was heated only slightly above T_{g1} in the vast majority of instances, the difference between the non-equilibrium and equilibrium compositions should diminish with increase in M_1 because the UCT then shifts towards higher temperatures and the equilibrium compositions approach the vertical axes. The decrease in T_g' with decrease in M_1 is apparently associated with this factor.

The study of the superposition of the layer formation and vitrification processes in BP and polymer blends has only just begun and detailed investigation of this problem is needed because such superposition is frequently encountered in practice.

---o0o---

The above discussion on the microlayer and glass formation in block copolymers shows that in real systems these processes frequently superimpose and influence one another. For this reason, not only a detailed investigation of each separately but also of their mutual superposition and influence is needed. Despite the evident advances in the study of the mechanism of microlayer formation, we are still at the beginning of the path leading to the investigation of processes leading to microheterogeneity in BP. The influence of the MWD and of the number of blocks on microlayer formation, the microlayer formation kinetics, the transitions from one SMS to another, and the superposition of microlayer formation and vitrification have been studied inadequately. The importance of this field follows from the prospect that BP may be employed for technical purposes and also from the fact that BP constitute the simplest synthetic heteropolymers with a more or less ordered primary structure and serve as the first support of the bridge connecting synthetic and biological polymers. Specific synthesis of heteropolymers with an ordered primary structure will undoubtedly lead in the future to the complete construction of this bridge. The phase and microphase transformations in biological objects, which are multicomponent mixtures of heteropolymers and low-molecular-weight substances from the molecular point of view, apparently play an important role in the existence and evolution of living organisms.

Specific Pyrolysis of Polycondensation Polymers

L.G.Gladkova, E.F.Kolpikova, Ya.S.Vygodskii, and A.S.Fialkov

The review discusses processes involving the thermochemical conversion of polymeric materials with a network structure (furfural and phenol-formaldehyde polymers) and polyimides into carbonaceous materials. The structural characteristics and properties of the carbonaceous materials based on the polymers are analysed and their applications are indicated. The bibliography includes 122 references.

I. INTRODUCTION

The successful development of modern technology is to a large extent determined by the creation of materials capable of retaining their operating properties at a high level under extreme conditions. The aromatic polyamides, polyimides, polysulphones, and polybenzoxazoles synthesised hitherto, in which a high thermal stability and heat resistance are combined with effective strength and dielectric parameters and with radiation and chemical stability, have made it possible to solve many problems in modern technology.

However, the possibilities of thermostable polymers are limited, the temperature of their prolonged use in air does not exceed 300 to 400° in most cases, and treatment with strong chemical agents can lead to their dissolution or decomposition. A further increase in the resistance of polymeric materials to the effect of temperature in corrosive media is possible by creating on their basis secondary carbon structures. Such structures are chemically inert, are highly resistant to heating, and in many cases possess a high mechanical strength. They are obtained by the heat treatment of macromolecular compounds under non-oxidative conditions.

The main type of polymers used to prepare carbonaceous materials comprises phenolic polymers in view of their low cost, large-scale production, and the reliability of the sources of the natural raw material. However, the relatively low yield of coke, vigorous gas evolution, and pronounced shrinkage during the pyrolysis of phenolic polymers do not permit the full realisation of the potential possibilities of carbonaceous materials obtained from polymers. The inadequate assortment, the limited thickness, the appreciable brittleness, and the presence of undetectable defects in gas-impermeable articles made from carbonaceous materials based on phenolic polymers narrow their practical applications.

The above factors necessitate the search for new polymeric sources of carbonaceous materials which will make it possible to obtain articles with stable and improved characteristics. Polymers with a heterocyclic structure, among which polyimides occupy an outstanding position, can undoubtedly serve as polymers of this kind. The high coke numbers of polyimides, the small gas evolution during their pyrolysis, and the possibility of processing them in a powder form combined with the ability of certain representatives of the polymers of this type to be converted into a highly elastic and viscofluid state justify the assumption that they are promising materials for the creation of thermostable carbonaceous materials with a valuable set of properties.

The present review is devoted to the analysis of studies concerned with modern ideas about processes involving the carbonisation and graphitisation of polymeric materials.† It appeared useful to survey the results of experimental and theoretical studies on processes involving the specific pyrolysis of phenolic polymers, since these have been studied in greatest detail, and polyimides which are some of the most promising representatives of new polymers as potential sources of carbon.

This approach makes it possible to establish important characteristics of the conversion of the polymeric raw material into carbonaceous materials which influence their physicochemical properties.

II. THE FORMATION OF THE STRUCTURES OF CARBONACEOUS MATERIALS ON THE BASIS OF NETWORK POLYMERS

The preparation of carbonaceous products on the basis of polymeric materials involves several heat treatment stages during which their main properties are established.[1,2] In the general case, the stages in the manufacture of carbonaceous materials from polymers are carbonisation and graphitisation. The first stage consists in the heat treatment of the initial raw material (or articles formed from the initial raw material) up to temperatures in the range 1100 to 1300 °C (carbonisation), which makes it possible to obtain under certain conditions carbonaceous materials with a two-dimensionally ordered structure.[1,3] The second stage involves the heat treatment of these materials up to temperatures in the range 2500 – 3000 °C,[1,4] during which mainly their structural rearrangement takes place.

In many instances, additional operations are introduced—preparation of the initial raw material, the moulding of articles, hardening, etc.[1,4] The required form of the article is imparted to the initial polymer which can be cast in the form of a film or moulded in any of the usual ways—by pressing, casting under pressure, and extrusion.[1,5]

It is known[1,6] that the structure and hence also the properties of carbonaceous materials are determined by the nature of the polymer, the character of the intermediate products formed during pyrolysis,

†The review does not present information about processes leading to the formation of carbon fibres, which constitutes an independent field of study.

and the carbonisation and graphitisation conditions. Factors such as the rate of heating to the maximum temperature and maintenance at this temperature can influence significantly the specificity and extent of the thermochemical transformations of the initial raw material and the qualitative characteristics of the materials formed—the crystal and disperse structures, the carbon content, and the concentration of heteroatoms.[1,2]

1. Characteristic Features of the Carbonisation of Phenolic Polymers

The carbonisation of polymeric materials, i.e. their thermal transformation into carbon, is an important stage determining the properties of the final carbonised product. It is achieved by the slow heating of the polymers with and without catalysts in a reducing or inert atmosphere.[7-10] Inert gases (nitrogen,[3,11,12] argon,[13,14] and helium[15]), a high vacuum,[13,16] a coke charge,[17] and a powdered alumina charge[18] were used for this purpose. A reducing atmosphere (H_2, CO) is more rarely employed.[19,20]

The final temperature of the treatment of the polymer is mainly 800–1200 °C,[20,21] although it can be below (600 °C)[11] or above (1400–1600 °C)[12,22] this range. In the carbonisation stage, low-molecular-weight products of the pyrolysis of the polymers are split off, a coke residue is formed, the geometrical dimensions and density of the specimens are altered, and a porous structure and a contact surface are formed. Qualitatively new properties arise in the carbonised polymeric material as a result of these changes.

The onset of the thermochemical transformations of phenol-formaldehyde (FP) and furfural-phenol-formaldehyde (FPF) polymers is believed to be at 150 °C according to electron paramagnetic resonance data.[23-25] When FP and FPF polymers are heated above 300 °C, they begin to undergo degradative changes accompanied by weight loss.[26-29] The principal decrease in the weight of FPF polymers occurs in the temperature range 300–600 °C,[28-30] while the maximum rate of this process has been noted at 460 °C.[1,26] On heating to 1200 °C, the FP and FPF polymers vigorously evolve low-molecular-weight and volatile products[26,27] and the weight loss is then more than 50%.[1,26]

When network polymers are carbonised in the temperature range 250–450 °C, degradative processes, accompanied by the evolution of volatile pyrolysis products and the formation of condensed aromatic fragments, take place preferentially.[25,31] A sharp increase in the concentration of unpaired electrons,[24,30] reaching an extreme value at temperatures of about 600 °C,[23,24] corresponds to this period. Higher temperatures induce the recombination of the aromatic fragments and the appearance of condensed aromatic formations with higher molecular weights.[25,31] The concentration of paramagnetic centres (PMC) then falls sharply.[24]

It has been shown[31,32] that planar layers with hexagonal packing appear in carbonised FP polymers already in the temperature range 200–350 °C.[31,32] However, the hypothesis that the onset of the formation of the structure of carbonised FP and FPF polymers occurs at 500 °C appears more likely.[33] The most intense structural transformations of individual parts of the carbon skeleton of the pyrolysed FP and FPF polymers occur at 500° and 720 °C.[34]

The principal products of the gas evolution in the pyrolysis of the above types of polymers are CO, CO_2, CH_4, H_2, H_2O, and phenol[13,30,34-36] and up to 600 °C mainly carbon oxides and water are evolved, while at higher temperatures the principal products are methane and hydrogen.[36,37]

It has been established[37-39] that, when PF and FPF polymers are heated, they are dehydrated as a result of the interaction between hydroxy-groups, which can take place with cyclisation, and between hydroxy-groups and methylene bridges.

The low apparent activation energy for the dehydration of PF polymers (25–38 kJ mol^{-1}) shows that this process takes place readily.[40]

The maximum rate of evolution of carbon oxides on pyrolysis of FPF and furfural-acetone (FA) polymers is observed at 380° and 500 °C, to which correspond the maxima in the exothermic effect on the differential-thermal analysis (DTA) curves, while the maximum rates of the endothermic evolution of hydrogen and methane have been noted at 390° and 580 °C.[41]

Carbon oxides are formed in the thermal degradation of the least stable oxygen-containing groups at defective sites of the three-dimensional polymer network.[35,42] It has also been reported that CO_2 may be produced as a result of the decomposition of hydroxy- and hydroperoxy-groups formed with participation of chemisorbed atmospheric oxygen[34] and that CO may be formed on decomposition of benzene rings.[26] It has been established[29] that, even at temperatures around 1000 °C, the volatile products of the pyrolysis of PF polymers contain an appreciable amount of CO, while only traces of CO_2 have been noted above 700 °C. The explanation is that at elevated temperatures the reaction equilibrium

$$2CO + O_2 \rightleftarrows 2CO_2$$

is displaced towards the formation of carbon monoxide.

Heating of network polymers above 500 °C leads to far-reaching chemical transformations, which is indicated by the appearance of appreciable amounts of CH_4 and H_2 in the gaseous pyrolysis products.[26,35] Methane is produced as a result of the degradation of methylene bridges, which proceeds via the formation of the reactive methylene radical.[35] This process takes place most vigorously at about 600 °C, above which processes involving the evolution of CH_4 and H_2 predominate. It is emphasised[37,43] that hydrogen may be formed on pyrolysis of PF polymers and also in lower temperature ranges on decomposition of the methylene bridges. At temperatures above 500 °C, the fraction of H_2 increases in the pyrolysis products of the PF and FPF polymers as a result of the dehydrogenation of aliphatic units and the condensation of aromatic rings.[35] It is known[44] that the energy of the C–H bond in the benzene ring is lower than that of the C–C bond, so that on pyrolysis the former is dissociated first. However, Ouchi and Honda[37] have shown that dehydrogenation of aromatic units at high temperatures can be accompanied by the cleavage of the ring with formation of active thermal degradation products and condensed polyphenylene rings.

The dynamics of the specific pyrolysis of PF and FPF polymers is determined by the ratio of the rates of dissociation of the chemical bonds and of the recombination of the radicals formed.

The chemical structure of the polymers undergoes significant changes during heating: the solid coke formed after the removal of the low-molecular-weight products is gradually enriched in carbon and its content of heteroatoms diminishes.[28,32] In the initial stages of the pyrolysis, these transformations are recorded by spectroscopic analysis. Thus the intensity of the absorption bands referring to the OH, CH_2, and C–O–C groups (at 3400, 1475, and 1100 cm^{-1}) gradually decreases in the IR spectra of the heated PF and FPF

polymers.[26,38] This is accompanied by a gradual increase in the concentration of benzene rings, which can be inferred from the increase in the intensity of the 1500 cm^{-1} band.[26,38]

The FPF polymers heat-treated at temperatures up to 500 to 600 °C contain, together with carbon, still a considerable amount of hydrogen and oxygen.[1,31] The 1100 cm^{-1} absorption bands persist in the IR spectra of such materials, while the 1415 cm^{-1} absorption bands, referring to the residual CH_2 groups, completely disappear. Absorption bands charactersitic of condensed aromatic structures appear and grow at the same time.[26,38] The decrease in the concentration of PMC on heating the polymers above 600 °C also indicates vigorous formation of condensed aromatic systems.[1,35] The changes in the polymers can be inferred from their colour. Deepening of the colour to brown and black in the range 300–600 °C indicates the development of a system of aromatised rings.[5] On raising the temperature, further carbonisation of the solid residues in the polymers takes place. For example, heating of the FPF polymers above 1200 °C increases the carbon content in the coke residue from 68.3 to 97.6 wt.% with a corresponding decrease in the oxygen content from 27.1 to 0.3 wt.%.[30] The residual oxygen forms part of the composition of the hexagonal rings and aliphatic units constituting the final network structure of the carbonised material.[1] The hydrogen and nitrogen contents in the carbonised materials diminish,[30] but nitrogen persists in materials heated to 1200 °C (1.8 wt.%).[1]

The study of the processes involved in the heat treatment of resol PF polymers by EPR showed[24] that, up to 500 °C, the density of the three-dimensional polymer (resite) network does not influence significantly the carbonisation process and the structure of the carbonised residue. The greatest changes in the composition of the heat-treated products are observed[24] in the temperature range 500–700 °C, to which corresponds the maximum PMC concentration of $\sim 10^{19}$ to 10^{20} spins g^{-1}. The changes in the paramagnetic properties at temperatures above 500 °C have been attributed[24] to the fact that at this temperature the density of the three-dimensional network of the polymers begins to influence significantly their carbonisation process. The maximum PMC concentration in the region of 600 °C is determined mainly by localised unpaired electrons, which have been identified with ruptured chemical bonds—free radicals.[45–47]

At temperatures in the range 700–750 °C, parallel networks of hexagons begin to be formed in the carbonised materials.[33] It is believed[38] that isotropic regions comprising tiny "crystallites" consisting of non-ordered accumulations of graphite layers are formed at the temperatures indicated. The initial polymer structure disappears fully and the formation of a two-dimensional structure, characterised by a large amount of non-ordered substance, large dimensions of atomic networks, and their imperfect packing is completed.[30,31,33] The transformation of the aromatic molecular chains of the polymer into carbon with a two-dimensional structure takes place within a relatively narrow temperature range, which in fact explains[48] the sharp change in the properties of the materials at 700 °C.

The diamagnetic susceptibility of the carbonised PF and FPF polymers increases above 700 °C, indicating the onset of the growth of hexagonal carbon layers, which continues without interruption as the temperature is raised.[30] The growth of atomic networks, an increase in the size of the crystallites, and an improvement of order are observed in the range 1000–1300 °C.[31,32,49]

The pyrolysis of PF and FPF polymers in an inert atmosphere can be divided into three stages:[42,50,51] 300–350 °C—a slight weight loss and a slight change in volume; 350–(500–600 °C)—vigorous evolution of gaseous pyrolysis products accompanied by weight loss and a decrease in density as a result of the development of an internal porosity; (500–600)–1200 °C—an appreciable intensification of shrinkage with a comparatively small weight loss and an increase in density and thermal conductivity.

The differences between the structures of the initial polymers and in the hardening conditions are responsible for some specificity in their decomposition and influence the yield of the carbon residues.[25,52] It has been shown[53] that, depending on their chemical structure, the FA polymers afford between 53 and 60 wt.% of coke residue. The properties of the carbonised materials are also determined to a large extent by the structure of the initial polymers. Thus the study of the carbonisation of PF polymers established[42] that the density, the overall and open porosities, and the specific electrical resistance of the carbonaceous materials depend on the ratio of formaldehyde and phenol used to synthesise the initial polymers. It has been noted[42] that the PF polymers obtained using a 1.3–1.6 ratio formaldehyde and phenol and heat-treated at 1250 °C give rise to ~70 wt.% of coke residue, show the smallest shrinkage, have the smallest volume of the open porosity, and have the highest density and ultimate bending strength. The carbonisation of polymers obtained using polymer ratios below the limits indicated gives rise to 60–65 wt.% of coke residues, which has been explained[42] by a decrease in the amount of cross-links, formed via bridging methylene groups. Increased formaldehyde content tends to increase the amount of the low-molecular-weight pyrolysis products evolved as a consequence of the decomposition of the excess hydroxymethyl groups, which leads to an increase in the open porosity of the carbonised materials and an impairment of their strength properties.,

A number of workers have emphasised[50,54,55] that the carbonisation stage should be the slowest part of the overall process involving the formation of carbonaceous materials from polymers. The point is that this stage is accompanied by the vigorous evolution of volatile products, generating an internal pressure in the article, which may increase to such an extent that the article ruptures. During the aromatisation of the heat-treated polymeric structures, an impairment of their strength properties is observed with increase in their electrical conductivity.[5] In order to retain strength, it is necessary to suppress the degradation of polymer chains, which is in most cases initiated by free radicals. The procedures for the preparation of carbonised materials are therefore characterised by low rates of temperature rise (1–5 K h^{-1}).[1] The temperature conditions in the carbonisation of porous articles are characterised by higher heating rates compared with the conditions in the preparation of monolithic articles (20–2000 K h^{-1}).[12,22,56]

2. Graphitisation of Carbonised Phenolic Polymers

The graphitisation process is defined as the temperature-activated continuation of the development of the structure of the substance formed in the preceding stages of the heat treatment.[1] This process, whose name cannot be regarded as especially apt when applied to the coke residues from polymers, is accompanied by slight changes in the weight of the specimens, predominantly as a result of the removal of peripheral atoms and groups, further carbonisation, and ordering of the structure.[1–3]

The practical purpose of graphitisation is a sharp reduction of the electrical resistance, the removal of ash impurities, the reduction of reactivity, and the establishment of the required electrophysical properties of the carbonaceous materials.[57]

Polymers whose hardening takes place without the formation of a mesophase serve[2,4] as the raw material for non-graphitisable or hard types of carbon. Such polymers include, for example, the phenolic and epoxide polymers. This fact has been explained[58-61] by the decrease in the mobility of the structural elements of the substance as a result of the formation of bonds in space during the heat treatment. The non-graphitisability of the products of the carbonisation of certain polymers is also attributed to the influence of the extensive pore system, which bends the graphite layers,[48] and the presence in them of nitrogen above 1200–1500 °C, which prevents the condensation and ordering processes.[30]

The studies on the carbonisation and graphitisation processes involving polymers of the vinyl and furan series, PF and FPF polymers, and oligomeric arylenes established[62] that the graphitisability of the carbonised material can be predicted from the activation energy for the main polymer decomposition process in the range 300–500 °C. Thus the activation energies for the polymers investigated are in the range 70–470 kJ mol^{-1}, while the degrees of graphitisation of the carbonised materials vary from 0 to 90%. Processes in which exothermic polycondensation reactions predominate correspond to activation energies below 125 kJ mol^{-1} and the graphitisability of the cokes is then less than 20%. High activation energies (more than 250 kJ mol^{-1}) are characteristic of endothermic degradation reactions of the main chains of the polymer and the degree of graphitisation of such materials is more than 70%.[62]

On heat treatment of carbonised FPF polymers above 1200 °C, a rapid increase of the diamagnetic susceptibility has been noted, which continued without appreciable saturation up to 3000 °C, showing that the structural ordering processes in the test substance have not reached completion.[30]

In carbonaceous material based on PF polymers, the process leading to the perfection of the structure is inhibited, which in fact explains[47] the slow decrease in the paramagnetism of the test specimens heated to 3000 °C. The symmetrical EPR absorption line, observed up to 3000 °C, reflects the imperfection of the structures of such materials, the retention of small size of the crystallites, their enhanced defectiveness, and the absence of a distinct microtexture.[47]

The X-ray diffraction patterns of carbonised PF polymers show reflections of the (001) and (hk0) types, which are approximately at the angular positions corresponding to the graphite lines.[30,31] The high background level persisting on the diffractometer traces for the heat-treated substances is due to the incoherent X-ray scattering by the aromatically non-organised carbon and the different chemical groups consitituting the amorphous phase.[30,31] With increase in the temperature of the heat treatment of the carbonised PF and FPF polymers, their diffraction pattern changes (the reflections become narrower and more intense)—processes leading to the ordering of the material take place, which involves the orientation of the atomic networks, a decrease in the interplanar spacing, the growth of layers of condensed aromatic carbon, a decrease in the thickness of the packets of planar hexagonal layers, and a decrease in the content of the amorphous phase.[30,31] The structural parameters of the carbonised materials vary as follows: the interplanar spacing d_{002} decreases from 0.370–0.360 to 0.344–0.340 nm for the products heat-treated at 900–1200 and 3000 °C respectively. The sizes of the crystallites L_c and L_a then increase from 3–6 and 1.5–2 nm to 6–12.5 and 4.2–4.6 nm respectively.[30,31]

The character of the change in the X-ray diffraction patterns and the structural parameters as a function of the heat treatment temperature shows that the carbonised PF and FPF polymers are typical non-graphitisable materials with a turbostratic structure.[30] They are characterised by small dimensions of crystallites, are isotropic, have an extensive microporosity and transitional porosity, and their crystal structure remains of the turbostratic type up to high temperatures—as far as 2800–3000 °C.[1,2]

It has been shown[6] that, despite the appreciable changes occurring in the structure of carbonaceous materials based on phenolic polymers during heat treatment, the qualitative character of the globular-cellular structure of the initial polymer is retained up to 3000 °C. The degeneration of the globules to highly oriented regions and the subsequent formation of graphite on the latter proceed with a lag period because this structural rearrangement involves translational processes. It has also been established[6] that the process leading to the imperfection of the structure of the carbonaceous materials based on PF polymers is accompanied by a change in the shape of the globules from spherical to ellipsoidal.

The study of a series of carbonised phenolic polymers—derivatives of phenol, *m*-cresol, and 3,5-xylenol heat-treated at 3000 °C—established[63] that the graphitisability is determined by the structure of the phenolic fragment. The presence of the bulky CH_3 substituents in the phenol improves the graphitisability of the carbonised polymers. Thus non-graphitisable "hard" carbon is obtained from PF polymers, graphitisable or "soft" carbon is obtained from xylenol-formaldehyde polymers, while cresol-formaldehyde polymers give rise to a carbon of an intermediate type.[63] The three-dimensional (112) diffraction line, indicating the appearance of the graphite phase in the test substance, has been noted for carbonised xylenol-formaldehyde polymers at 1800 °C, while for the other two polymers it remained weak even at 3000 °C.[64]

It was established later[65] that mesophase mosaic formations arise in the heat-treated xylenol-formaldehyde polymers at 400–430 °C and promote the formation of large condensed aromatic structures in the test substance, which leads to effective graphitisability of carbonised polymers of this type.

It has been shown[64] that the (002) reflections for carbonaceous materials derived from PF polymers at temperatures above 2800 °C and for materials obtained from cresol-formaldehyde polymers at 2950 °C are compound, while in the case of xylenol-formaldehyde polymers single reflections are obtained. This indicates the presence in the first two specimens of regions differing greatly in the type of structural organisation.

The character of the changes in the compound (002) profile with increase in temperature made it possible to represent the graphitisation process in the following way.[63,64] The distance d_{002} in the initial crystallite of the non-graphitisable carbonaceous material gradually diminishes with increase in the heat-treatment temperature. When d_{002} and L_c reach 0.343–0.344 nm and 2–4 nm respectively, a small proportion of the heat-treated substance changes abruptly. Three components having different structural parameters then appear in the material (see Table).

A further increase in temperature leads to an increase in the amount of the graphite component where d_{002} = 0.336 nm, but even at 3000 °C all three components coexist.[64] It is noteworthy that L_c in the graphitisable carbonaceous material depends on the interplanar spacing, while in the non-graphitisable material it does not. Furthermore, the structural parameters of the graphitisable carbonaceous material vary monotonically and those of the non-graphitisable carbonaceous material vary step-wise.[64]

The study of the processes leading to the formation of the porous structure of the FPF polymers during their heat treatment up to 3000 °C has shown[56] that the pores in such materials can be represented by a honeycomb with a cell size of 10–30 nm and a wall

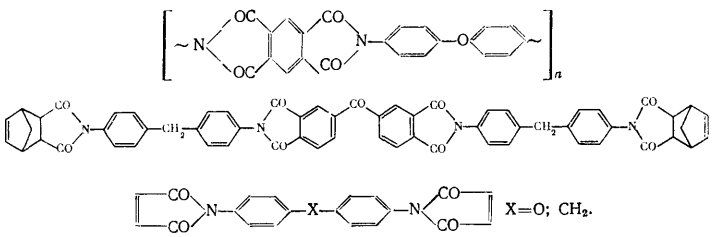
thickness of 5 – 15 nm. The walls of the pores have in their turn much smaller pores.[66]

As the temperature of the heat treatment is reduced, the macroporosity of the carbonaceous materials based on PF and FPF polymers greatly diminishes (from 13% at 1000 °C to 2.3% at 3000 °C).[6] The size of the intraglobular pores and the structural porosity increase under these conditions. The abrupt change in the structural parameters and the character of the distribution of the porosity during the heat treatment of carbonaceous materials suggested[6] that the decrease in porosity takes place not only as a result of the condensation and ordering of the carbonaceous material but also as a result of the generation of crystalline closer-packed graphite-like formations.

Structural parameters of the carbonaceous materials based on phenolic polymers.[64]

Initial polymer	T, °C	d_{002}, nm	L_c, nm
PF polymer	2800	0.3437	2.3
	2800	0.3427	84.0
	2800	0.3863	66.0
	3000	0.3430	3.3
	3000	0.3427	28.0
	3000	0.3370	37.0
Cresol-formaldehyde polymer	2950	0.3448	2.7
	2950	0.3430	8.0
	2950	0.3373	37.0

The graphitisability of carbonised polymers is known to depend on several factors: the rheological properties of the initial polymers, the nitrogen content in the carbonised residues, and the number and energy of the transverse spatial bonds in them[1,48,59] It has been established[67] that the graphitisability of the carbonised materials can be regulated by pressure. However, there is no information in the literature about the influence of each of the above factors on the graphitisability and structure of carbonaceous materials based on polymers.



III. SPECIFIC PYROLYSIS OF POLYIMIDES

Numerous communications devoted to the thermal degradation processes involving aromatic polyimides have now been published.[68–87] Depending on their chemical structure, polyimides are distinguished by a wide variety of properties and there are numerous literature data concerning the influence of their structure on their thermal stability.[70–75] Data concerning the influence of the chemical structure of polyimides on their thermal stability in an inert atmosphere have been surveyed in a monograph.[88] It is believed[85] that the degradation of polyimides begins as a result of the decomposition of the "binding" elements—the imide ring and the bridge structures (atoms and groups of atoms).

The chemical structure of polyimides influences significantly the pathways followed in their thermal decomposition.[68,78,85] The polyimide thermal degradation processes can be determined to a large extent by the presence in them of heterounit fragments: amidoacid and isoimide structures and terminal functional groups.[88,89]

The pyrolysis of polyimides is known[85] to proceed via a series of consecutive-parallel reactions, each of which is associated with the formation of definite products. This process is accompanied by the formation of gaseous, liquid, and solid low-molecular-weight substances and of an infusible high-molecular-weight residue. The main bulk of the low-molecular-weight polyimide degradation products consist of H_2O, CO, CO_2, H_2, phenol, benzene, analine, and benzonitrile.[78,79,82,90] The solid polyimide pyrolysis products consist of aromatic carbocyclic and heterocyclic compounds with a system of conjugated double bonds. At the same time, the processes involved in the specific pyrolysis of polyimides, whose aim is to obtain carbonaceous materials, have been investigated to a much smaller extent.[90–94]

The transformations of polyimide and oligoimides having the following structure have been investigated[90] on heating to 3000 °C:

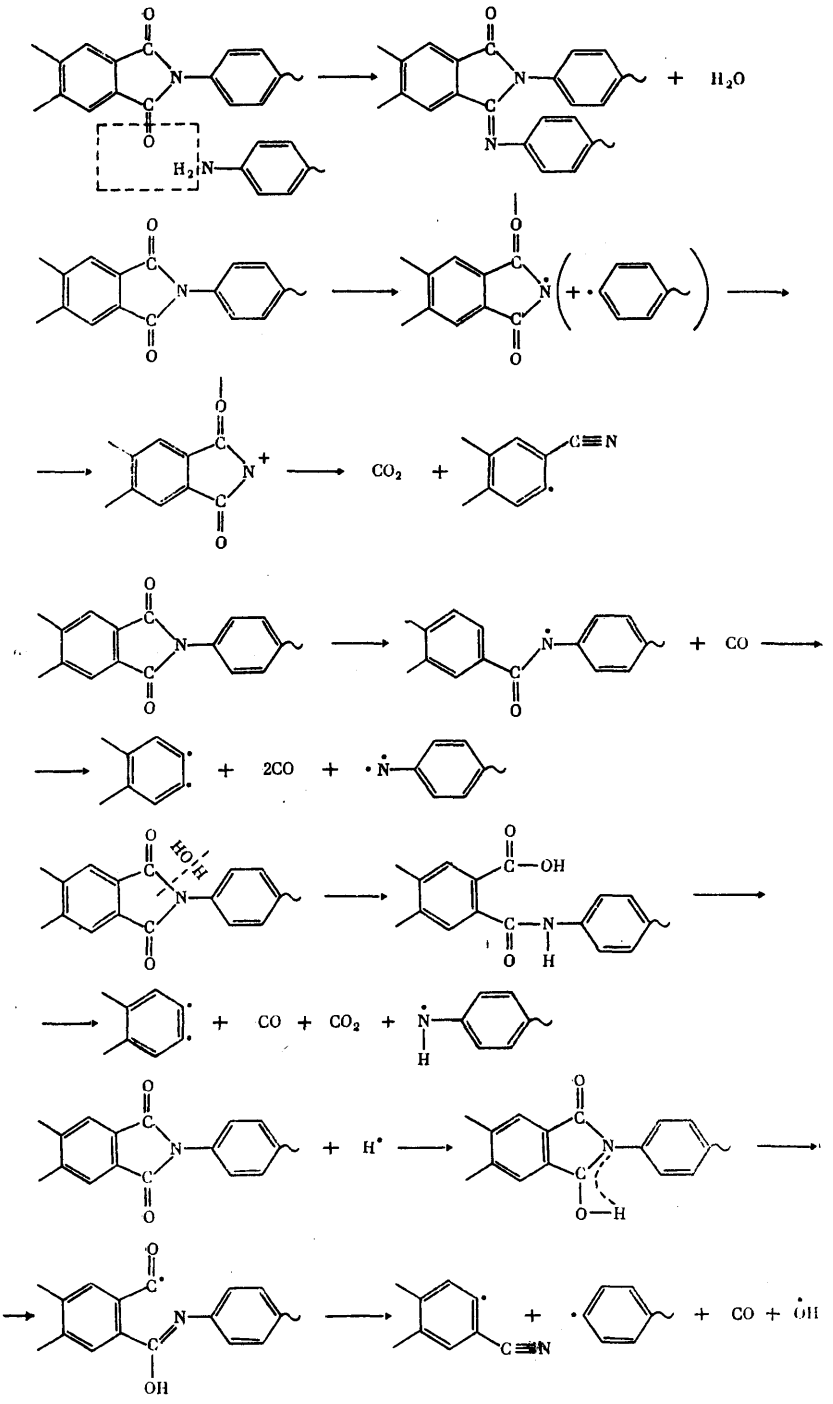
X=O; CH_2.

Carbonaceous materials have been obtained from the polymers and some of their properties have been investigated (hardness, specific surface, and tensile strength). A general scheme for the pyrolysis of polyimides has been published[69] with references to known sources (Fig.1).

In our view, the data on the temperature ranges corresponding to the formation of certain low-molecular-weight pyrolysis products obtained as a result of X-ray diffraction studies and their interpretation are controversial.

The studies on the transformations at temperatures up to 3000 °C in non-oxidising media (argon, coke charge) of polyimides obtained from pyromellitic acid and *p*-phenylenediamine (I), from pyromellitic acid and di(4-aminophenyl) ether (II), from benzophenone-3,3′,4,4′-tetracarboxylic acid and di(4-aminophenyl) ether (III), and from benzophenone-3,3′,4,4′-tetracarboxylic acid and anilinofluorene (IV) have shown[95–97] that the changes in the structure and properties of the polyimides on heating take place at temperatures in the range 300 – 500 °C in a relatively stable mass. Under these conditions, the glass points of the polyimides (III) and (IV) increase gradually and the polyimide (IV) loses it solubility, which may indicate the formation of intermediate three-dimensional structures.

Polyimides may be cross-linked as a result of the interaction of the terminal amino-groups with the imide ring,[83] the interaction of the amide and terminal amino-groups,[88] and the dehydrogenation coupling of two phenyl groups.[85]



Absorption bands at 1650 cm^{-1} (amide), which can be partly attributed to the formation of a three-dimensional network in polyimides, appear in the IR spectra of heat-treated polyimides.[95,97] The fragments formed under these conditions can serve as sources of certain low-molecular-weight pyrolysis products and can influence the course of the subsequent transformations.

The heating of polyimides in argon to 520 – 540 °C and of the polyimide (I) to 580 °C reduces their weight as a result of the removal of low-molecular-weight pyrolysis products, which consist of carbon oxides and water. The formation of the above products in the initial stages of the weight loss process can occur as a result of a series of elementary reactions[98] (see below).

Under real conditions, the pattern in the thermal degradation of polyimides is much more complex even in the initial stages of the weight loss. It is known[85] that, under the conditions of dynamic heating, there is a possibility, in principle, of any bond dissociation reaction with formation of the corresponding products.

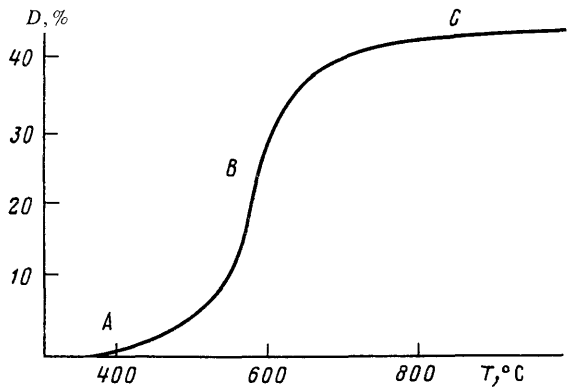
A decrease in the intensity of the 1780 (in a doublet with 1720), 1380, and 725 cm^{-1} absorption bands and an increase in the intensity of the 1650 cm^{-1} band have been observed in the IR spectra of the polyimides (II)–(IV) heat-treated at 540–550 °C.[95-97] These changes indicate the continuation of the reactions in the polyimides.

Heat treatment of the polyimides (II)–(IV) above 550 °C and of the polyimide (I) above 630 °C leads to the development of their thermal degradation processes, which are determined by competing reactions involving the rupture of the spatial cross-links and intramolecular bonds and polycondensation. Under these conditions, the rates of weight loss by the polyimides increase sharply, the

amount of low-molecular-weight pyrolysis products increases, and their composition changes (Fig.2). According to EPR data, the most intense degradative changes, accompanied by the dissociation of chemical bonds and the formation of free radicals, occur in the temperature range 550–650 °C. For the polyimide (I), these processes have been displaced by about 50 °C to the high-temperature region. Most of the weight loss by polyimides occurs in these ranges.[95-97] The degradation of polypyromellitimides, associated with large weight losses, takes place in the narrowest temperature ranges, compared with the polyimides formed from diphenyl ether derivatives and benzophenonetetracarboxylic acid.[95-97]

The rates of decrease in the weight of the polyimides (I) and (III) in the intense degradation region are higher by a factor of 3–4 than those of the polyimides (III) and (IV).

The effective activation energies for the intense polyimide degradation processes in the region of the main weight losses are E_{eff} = 170–300 kJ mol^{-1},[95] E_{eff} for polypyromellitimides being higher by a factor of ~1.5 than E_{eff} for polyimides formed from diphenyl ether derivatives and benzophenonetetracarboxylic acid.



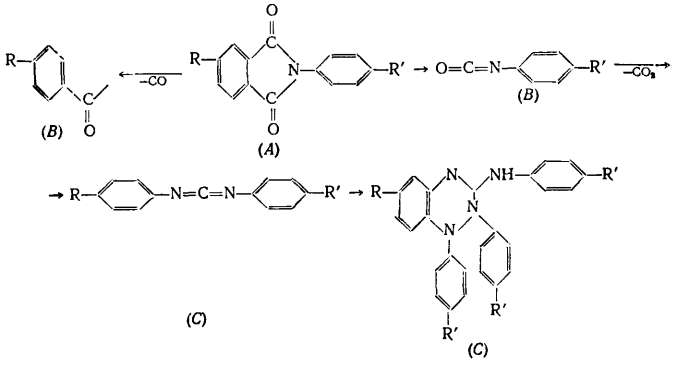


Figure 1. Schematic representation of the pyrolysis of polyimides:[90]

The letters *A*, *B*, and *C* denote regions corresponding to the existence and transformations of the corresponding structures; *D* = weight loss.

Indeed the low activation energy for thermal degradation means that, with increase in temperature, the thermal degradation of polyimides is not accelerated quite so much as that of the polymers with a high activation energy and the advantage of the former will become most apparent at high temperatures. With increase in the mobility of the polyimide macromolecules, the contribution of condensation processes in pyrolysis increases, which may be the cause of the reduced effective activation energies for the thermal degradation processes involving such polymers. Indeed, an increase in chain mobility creates favourable kinetic conditions for the recombination of the fragments produced.

The main bulk of the low-molecular-weight products, whose qualitative composition varies significantly compared with the initial pyrolysis stages, are removed from the polyimides (III) and (IV) at temperatures in the range 550–650 °C. Thus, apart from carbon oxides and water, whose formation was noted already at temperatures corresponding to insignificant weight losses and whose amount increases with increase in temperature, hydrogen, nitrogen, hydrogen cyanide, methane, benzene, phenol, benzonitrile, and diphenyl ether have been identified in the polyimide pyrolysis products (Fig.2). The formation of the above products from the polyimide (I) takes place at higher temperatures (600–700 °C).

The overall amounts of the low-molecular-weight products as well as their composition are comparable for the polymers investigated. Nevertheless, the influence of the chemical composition of the polymers on the character of their thermal degradation can be traced quite distinctly.

The main fraction of the polyimide pyrolysis side products, evolved in the region of vigorous degradation, corresponds to CO and CO_2 (Fig.2); H_2O is also formed in considerable amounts. The maxima of the peaks in the mass spectra of the above products correspond approximately to the temperatures of the highest rates of weight loss.[95-97]

It is noteworthy that the polyimides (I) and (II) evolve larger amounts of CO_2 than CO, while the polyimides (III) and (IV) exhibit the opposite behaviour. The CO_2/CO ratio for the polyimide (I) is greater than for the polyimide (II), which may be due to the high extent of the intramolecular and intermolecular interaction of the donor (diamine) and acceptor (dianhydride) sections in the polyimide macromolecules. It is known[99,100] that such interaction is accompanied by the delocalisation of electrons and the formation of intramolecular and intermolecular charge-transfer complexes. The possibility of an intramolecular rearrangement or of intramolecular oxygen transfer is facilitated in formations of this kind, which promotes the reaction involving the decomposition of the imide ring with formation of CO_2. The bridging heteroatoms or groups of atoms interrupt or greatly weaken the conjugation along the chain.[100] The electron-donating properties of the diamine residues weaken from the polyimide (I) to the polyimide (II), which can explain the changes in the ratio of the carbon monoxide and dioxide formed.

The higher CO content in the pyrolysis products of the benzophenonetetracarboxylic acid polyimides may be caused by the splitting-off of the carbonyl groups from the benzophenone structure.[101] The somewhat smaller, compared with the polyimide (III), amounts of CO formed in the pyrolysis of the polyimide (IV) are probably associated with the influence of the carbo-group.

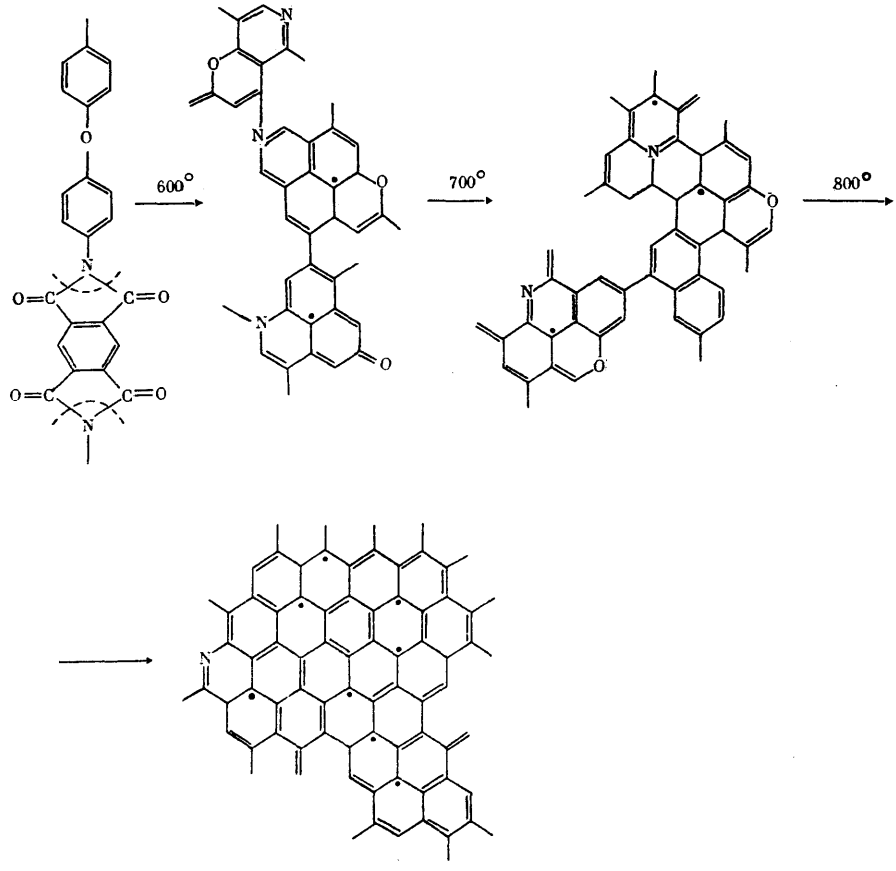
The intensity maxima on the curves describing the formation of the low-molecular-weight liquid products of the pyrolysis of polyimides correspond to the region of high rates of weight loss (Fig.2). The greatest relative amounts of liquid compounds are formed in the thermal degradation of the polyimides (I) and (II).[95-97]

The formation of the products described indicates a far-reaching rearrangement of the chemical structures of the polyimides on heating. The evolution of such compounds by the polyimides under the

conditions of specific pyrolysis should probably be explained, by analogy with the pyrolysis of the network polymers (PF and FPF), by the removal of bulky fragments preventing the molecular condensation of the heat-treated polyimides. Such fragments may be structural elements arising in the initial stages of the pyrolysis and also sections of the macromolecules which were not altered at lower temperatures.

In the heating process, the elemental composition of the coke residues from the polyimides changes, which is particularly notable at the temperatures corresponding to the removal of liquid low-molecular-weight pyrolysis products. At 600–700 °C, the carbon content in the residues increases to 80–86 wt.%, while the fraction of hydrogen and nitrogen diminishes appreciably.[95-97]

Pyrolysis of the polyimides leads to the formation of new products—carbonised polyimides—at temperatures in the range 600 to 700 °C.



X-Ray diffraction data indicate the conversion of the chain structure of the polyimides to a polycyclic condensed structure at temperatures in the range 600–700 °C. The properties‡ of the pyrolysed materials change sharply at these temperatures—they acquire metallic lustre, their electrical resistance decreases to 180–210 Ω cm, and their thermal expansion coefficients and thermal diffusivities increase respectively from 0.2–0.3 (for the unheated polyimides) to 0.5–2.0 $W\ m^{-1}\ K^{-1}$ and from (1.1–1.3) × 10^{-7} to ~4.0 × 10^{-7} $m\ s^{-1}$.[95-97]

It has been shown[102] that the bulk-phase electrical resistance of the Kapton polyimide film decrease by 16–18 orders of magnitude after vacuum heat treatment at 600–800 °C as a result of the formation of carbon–carbon double bonds and free valences in the polymer.

The yield of coke from the polyimides (I)–(IV) at 900 °C in argon is 55–64 wt.%. The greatest amounts of residues are retained by polyimides with bridging atoms in the dianhydride residues.[95-97]

It has been shown[87] that, in polymers having a heterocyclic structure, nitrogen participates in the formation of the coke residue together with carbon. The nitrogen of the phthalimide ring, a considerable proportion of which is retained in the carbonised polyimide at 1000 °C, plays the greatest role in this process.[87]

The study of the vacuum thermal degradation of polyimides with an increased nitrogen content and based on the di- and tri-phenyl derivatives of pyridine and diamines containing pyridine, benzimidazole, and oxadiazole rings has shown[87] that the coke residues from such polymers amount to 60–65 wt.% and that their content is

‡The properties are quoted for specimens in bulk.

independent of the initial structure of the polyimides. The carbonised materials retain on average up to 50–60% of nitrogen relative to its initial amount. It has also been established[87] that, compared with the thermal degradation of polyimides containing nitrogen atoms only in the imide rings, the relative nitrogen content in the coke residue from polyimides with an enhanced [initial] nitrogen content is reduced by 10–15%. It has been suggested that the nitrogen atoms not forming part of the imide ring participate in the formation of volatile thermal degradation products, while the imide ring nitrogen is mainly concentrated in the coke residue.[87] However, the observed characteristics of the pyrolysis of polyimides having different chemical structures[95–97] [(I)–(IV)] suggest that the character of the elimination of nitrogen when they are heated is determined to a large extent by the rheological properties of the initial polymers.

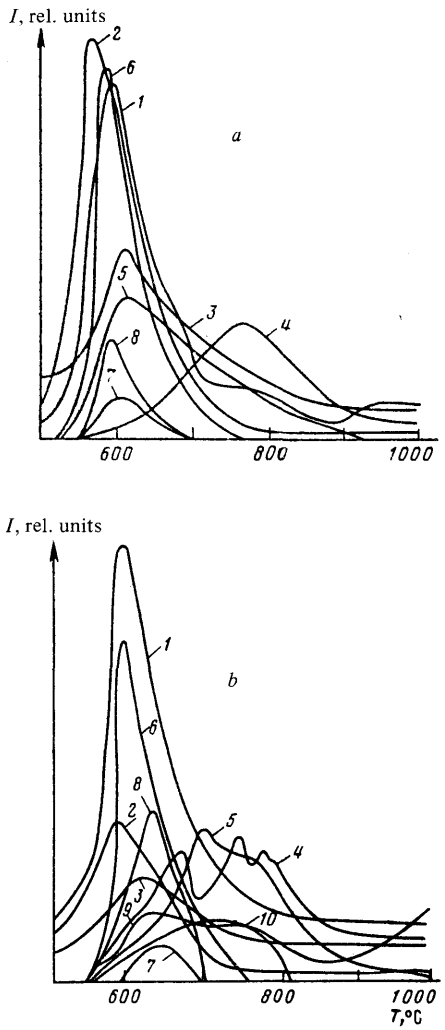


Figure 2. Differential curves for gas evolution in the pyrolysis of polyimides (II) (*a*) and (IV) and (*b*): (1) CO; (2) CO_2; (3) H_2O; (4) H_2; (5) HCN; (6) phenol; (7) benzene; (8) benzonitrile; (9) N_2; (10) CH_4.[96]

Fig.2 shows that the main fraction of the nitrogen-containing pyrolysis products in the thermal degradation of polypyromellitimides is removed before this is observed for polyimides derived from diphenyl ether and benzophenonetetracarboxylic acid.

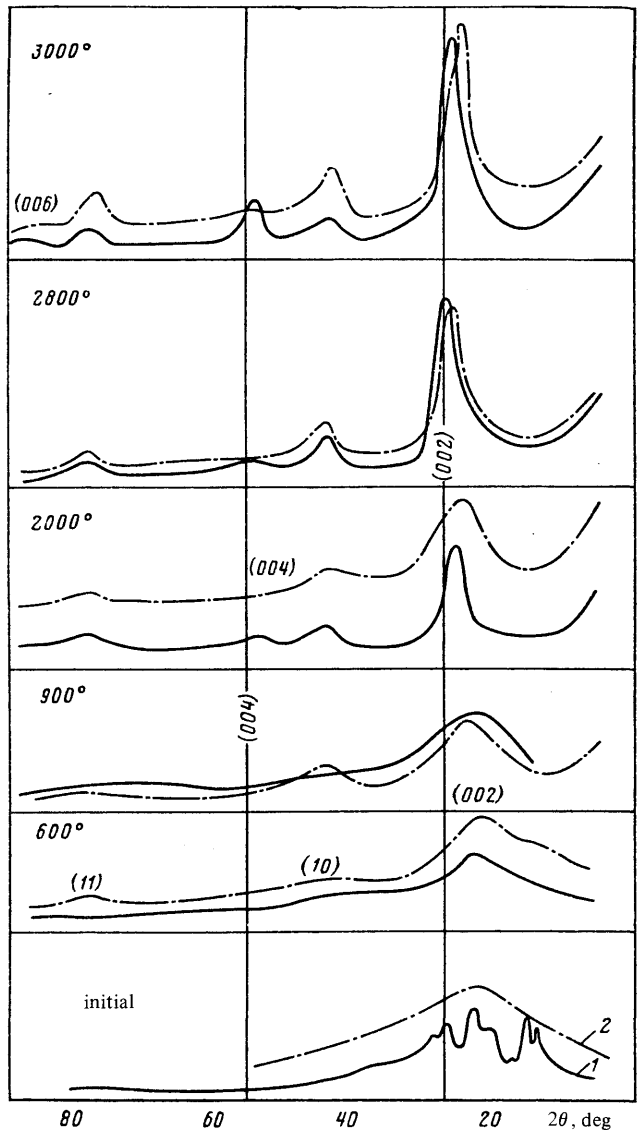

Figure 3. X-Ray diffractometer traces for the initial polyimides (II) (curves *1*) and (IV) (curves *2*) and the carbonaceous materials based on them; heating rate 5–20 K h^{-1}; the vertical lines indicate the angular positions of the principal graphite reflections.[96]

The above factors suggest that the pyrolysis of polyimides with different structures leads to the formation of carbonised materials having different structures. This is manifested particularly strongly when two groups of polymers are considered: polyimides without bridging atoms or groups of atoms in the dianhydride fragments

(polypyromellitimides) and polyimides with the benzene rings in the dianhydride and diamine components separated by such groups—polyimides derived from diphenyl ether and benzophenonetetracarboxylic acid.[95-97] Thus, when the carbonised polyimides (I) and (II) are heated, nitrogen-containing compounds are eliminated initially, which should evidently promote the condensation of these substances, and this is followed by further aromatisation accompanied by the removal of hydrogen, while in the case of the carbonised polyimides (III) and (IV) these processes take place simultaneously.

Heat treatment of the carbonised polyimides in the temperature range 900–3000 °C is accompanied by slight (from 3 to 7%) weight losses and the rates of shrinking processes diminish, approaching zero at 2000 °C. The overall shrinkage is then 16–18%.[95-97] Heat treatment of the materials above 2000 °C leads to the virtually complete elimination of hydrogen from them, the carbon content in the specimens heated to 2500–3000 °C being 99.3–99.9%. It must be emphasised that nitrogen was not detected in the carbonaceous materials based on the polyimides of the first group, obtained at temperatures in the range 1500–1800 °C, while the materials based on the polyimides of the second group retain considerable amounts of nitrogen (0.20–0.33 wt.%) after heating to 3000 °C.[95-97]

During the high-temperature treatment of the carbonised polyimides, the X-ray diffraction patterns change (Fig.3). With increase in the heat-treatment temperature, the intensities of the diffraction profiles of the polyimides increase and the (002) line shifts to the region of larger angles. The improvement of the structure of the carbonised substances is also indicated by the appearance of the (004) line on their diffractometer traces.

The narrowing of the diffraction peaks and the increase in their intensity with increase in the heat treatment temperature and the appearance of the (004) line on the X-ray diffraction patterns indicate the continuing ordering of the structures of the carbonaceous materials.

The form of the X-ray diffraction patterns and the character of the changes in the structural parameters of the carbonised polyimides demonstrate that they are typical non-graphitisable materials with a turbostratic structure.

Materials obtained from polypyromellitimides have the most perfect structure. Their X-ray diffraction patterns show the most intense reflections; after heat treatment at 2950 °C, the (006) lines appear, indicating "long-range order" in the substance (Fig.3). The interplanar spacing in the crystals of the carbonaceous materials obtained from the polyimides (I) and (II) is 0.338 nm, whereas for the remaining materials it is 0.343–0.344 nm. The fraction of the amorphous phase in materials obtained by the heat treatment of polypyromellitimides at 2800 °C is 42% compared with 48–53% for the materials based on the polyimides (III) and (IV).[95-97]

The change in the structural parameters of the crystallites of the carbonaceous materials based on polyimides (Fig.4) is associated with the changes in their chemical composition. The fastest decrease in the interplanar spacing is observed at temperatures such that the processes involving enrichment in carbon and the elimination of nitrogen proceed at high rates; this happens in the range 600 to 1200 °C for the polyimides (I) and (II) and 600–1500 °C for the polyimides (III) and (IV). Above the temperature ranges indicated, the rate of decrease in the interplanar spacing diminishes and the rate of increase in the crystallite diameter appreciably increases. For carbonised materials obtained from the polyimide (IV), this process is particularly vigorous, as a result of which their crystallites have the highest diameter among the materials investigated. Presumably this is associated with the presence in the polyimide (IV) macromolecules of fluorene groups, which, as a result of the thermal transformations in the temperature range 1200–1500 °C, acquire the ability to be located in the planes of different sections of the main chain, having the most ordered structure. The decrease in the diameter of the crystallites in materials based on the polyimide (II) (Fig.4) is due to vigorous processes involving the mutual approach of the hexagonal layers, which may induce their rupture at the most strained bonds.

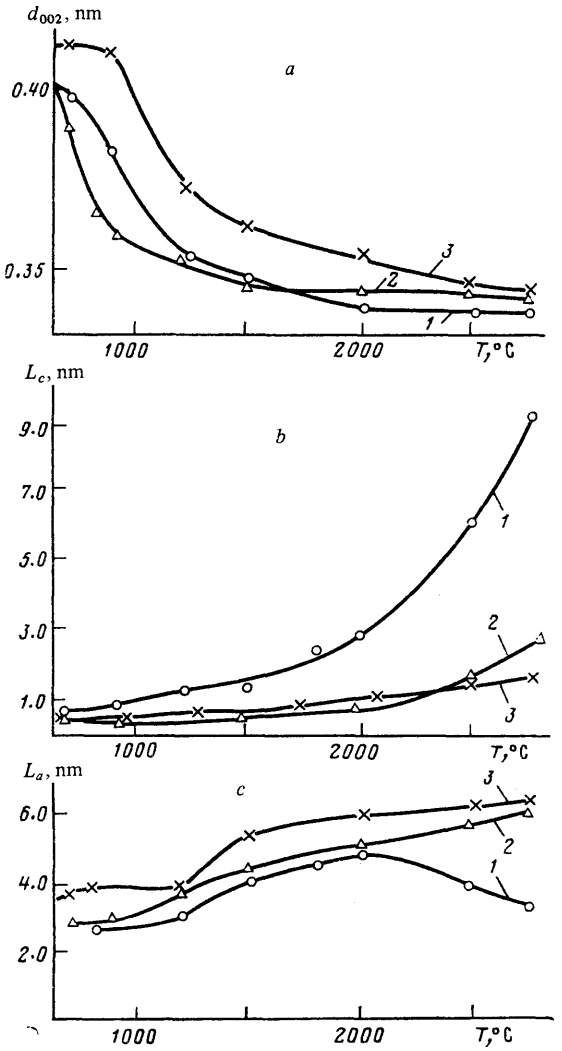

Figure 4. Variation of the interplanar spacing (d_{002}) (*a*), of the thickness of the packets (L_c) (*b*), and of the layer diameter (L_a) (*c*) in the carbonaceous materials based on the polyimides (II) (curves *1*), (III) (curves *2*), and (IV) (curves *3*) as a function of the heat treatment temperature; heating rate 5–20 K h^{-1}.

An increase in the thickness of the crystallites is observed mainly at temperatures where the materials contain the minimum amounts of nitrogen possible for them (Fig.4). Indeed, the growth in thickness of the crystallites in the specimens based on the polyimide (II) is

observed already above 600 °C. The high rates of growth of the height of their crystallites are probably associated with the absence of nitrogen from such materials, heated above 1500 °C.

The data presented show that the structural differences between the carbonaceous materials based on polyimides are mainly associated with the nature of the removal of nitrogen from them. This nitrogen, which has a relatively larger molecular volume than carbon, can prevent the ordering of the structure of the carbonaceous substances.[1,47,103]

It must be emphasised that significant differences between the characteristics of the removal of nitrogen from the polyimides investigated were noted already in the early stages of pyrolysis.

The foregoing suggests that the spatial cross-links, formed in the polyimides in the early stages of the thermal degradation, arise mainly with participation of the nitrogen of the imide ring and prevent its elimination. In carbonaceous materials with a relatively low degree of order [based on the polyimides (III) and (IV)], a considerable nitrogen content has been observed even at 3000 °C, while in the materials based on the polyimides (I) and (II) nitrogen was no longer detected above 1500 °C. One must evidently assume that the spatial cross-linking of polypyromellitimides also takes place, but in such cases it occurs at energetically unfavourable sites. Consequently spatial bonds with different thermal stabilities may arise in the heat-treated polyimides. The weakest of them are ruptured, providing the main source of nitrogen removed from the carbonised materials above 1000 °C, while the strongest are retained up to 3000 °C.

It has been shown[95-97] that the degree of ordering of the structures of the carbonised polyimides is largely determined by the stability of the intra- and inter-molecular cross-links formed in them on heating with participation of the nitrogen of the imide ring. The frequency of such cross-links is known[104] to be capable of varying significantly under the influence of mechanothermal influences, which leads to definite possibilities for regulating the structures of the carbonaceous polyimide-based materials.

The characteristics of the changes in the structural parameters of such materials are determined by the differences between not only their chemical structures but also between their supermolecular structures. Indeed, transient forms of carbon are formed as a result of the reactions in the solid phase, which leads to the possibility of the retention of the initial form of the materials.[4,105]

It has been suggested that the conformation of the skeleton of the polyimide (I) chains can be represented as a planar zig-zag,[106] while for the polyimides (III) and (IV) it can be represented by a greatly extended helix.[88] Sections with different degrees of order can exist in such structures.[107]

The size of the crystallites in the carbonised polyimides is much smaller than that of the crystallites in the carbonised PF and FPF polymers,[30,31] which leads to the expectation that the carbonised polyimides have enhanced strength properties. The wide set of interplanar spacings of the carbonaceous materials obtained from polyimides having different chemical structures provides different possibilities for regulating their physicomechanical characteristics.

The carbonaceous materials obtained from polymers consist of a broad spectrum of molecular structures and supermolecular formations: chain, layer-ribbon, globular, lamellar, diamond-like, and graphite-like formations.[108] The wide variety of structural forms of the artificial carbonaceous materials presuppose a correspondingly wide range of their possible properties.[58,108] By regulating the structure of the material by means of heat treatment or by selecting the initial raw material, it is possible to regulate its characteristics.

Thus vitreous carbon, having many specific properties which are not characteristic of the known modifications of carbon, has been obtained from many types of polymers.[109-117] These properties include an isotropic and monolithic structure, low permeability to liquids and gases, effective strength characteristics, high electrical and thermal conductivities, high thermal stability (in non-oxidising media as a function of the final synthesis temperature—1200 to 3000 °C), high resistance to thermal shock, low density, and resistance to corrosive media which is retained at elevated temperatures.[112-116] Vitreous carbon remains solid up to the sublimation temperature of carbon (3700 °C).[1]

The increase in the chemo-oxidative and thermo-oxidative stabilities and the virtually complete absence of open porosity in vitreous carbon permits its use under conditions where graphite articles break down—in corrosive media and at elevated temperatures and also at an interface between two media. Vitreous carbon articles are used as heat exchangers, components of nuclear reactors and flying vehicles, electrical conductors, electrodes and electric terminals; crucibles, bulb containers, and chemical apparatus for use in specially corrosive media, and implanted components are made from it.[111-117]

The characteristics of the structure and the properties of vitreous carbon have been investigated in detail.[118-122]

The Influence of the Surface on Phase Transitions in Two-component Systems

A.I.Dolinnyi and V.A.Ogarev

The results of theoretical and experimental studies on phase transitions in semi-infinite two-component systems (immiscible liquids and polymer systems) are examined. The conditions for the formation on the substrate surface of a wetting layer of one of the equilibrium phases are discussed in detail within the framework of the average field theory taking into account the small-radius interactions between the substrate and the mixture components. The theoretical conclusions are compared with experimental data. The role of the long-range forces in the wetting transitions and the appearance of anomalously large fluctuations in the wetting films are considered in relation to the simplest models. The results of the study of critical adsorption are briefly described.
The bibliography includes 156 references.

I. INTRODUCTION

The idea, formulated in the 1960's, that fluctuations play a decisive role in the universal behaviour of various systems near the critical point (CP) has been the basis of modern theories of critical phenomena. The scaling theory and the renormalised group method[1-3] have provided a new stimulus to the study of phase transitions (PT).[4-6] Systems whose components are high-molecular compounds (solutions and mixtures of polymers) were added to the traditional objects of study (magnetic substances, alloys, liquids, two-component liquids, etc.).[7-11] The improvement of the experimental technique and the development of novel methods have made it possible to find more accurately the critical parameters characterising the variation of properties in the vicinity of the CP and to conclude that polymer systems belong to the same class, in terms of their universality, as liquids and binary mixtures of liquids.

Together with the continuation of studies on PT in the bulk phase,[12,13] the study of PT in bounded systems is of great interest. Initially the question of the influence of the surface of the substrate on the PT was considered within the framework of Landau's theory[14] applied to the magnetisation of ferromagnetic substances[15,16] and the superfluidity of helium.[17] The transition from limited to complete wettability of the surface near the CP for two-component and pure liquids has been analysed.[18,19] The characteristic features

of the PT in semi-infinite systems discovered in the above studies have attracted the attention of many investigators to this problem and at the present time various questions concerning wetting transitions are being actively elucidated.[20,21] This field of knowledge is going through a period of rapid development, associated with the appearance of an increasing number of new facts. The present review is devoted to the analysis of the behaviour of liquids with limited miscibility and polymer systems in the vicinity of the surface of the substrate. The questions discussed here, concerning the conditions governing the appearance of a wetting layer of one of the equilibrium phases, the order of the transition from complete wetting to limited wetting, and the phenomenon of critical adsorption, are analysed within the framework of the average field (AF) theory.

II. PHENOMENOLOGICAL THEORY OF PHASE TRANSITIONS IN SEMI-INFINITE SYSTEMS

The modifying effect of the substate on PT has been analysed in detail within the framework of the phenomenological theory, whose universal procedures make it possible to consider different phenomena such as surface magnetisation.[15,16,20,22] the superfluidity of helium near the λ-point,[17] and wetting transitions in immiscible liquids.[23]

The fundamental postulates of the phenomenological theory reduce to the following: (1) by analogy with the theory of PT of the second kind,[14,17] it is assumed that in the vicinity of the transition point the free energy density $f(\psi)$ can be expanded in series in terms of the order parameter ψ:

$$f(\psi) = C\psi^2 + D\psi^4 - h\psi, \tag{1}$$

where $C = C_0 t$ and C_0 and D are positive constants. Here and henceforth $t = (T - T_c)/T_c$, T is the temperature, and T_c is the critical temperature. For a two-component system, the deviation of the concentration φ from the critical value φ_c is chosen as ψ, whereupon h characterises the deviation of the difference between the chemical potentials of the components $\Delta\mu$ from the corresponding difference on the coexistence curve $\Delta\mu_c$; $h = (\Delta\mu - \Delta\mu_c)/k_B T$. (2) The wall infringes the spatial invariance of the system and in the boundary layer of the specimen the order parameter is different from its bulk-phase value. The increase in the free energy of the system as a result of the spatial inhomogeneity which has arisen at the boundary is taken into account by introducing a term proportional to the square of the gradient of the order parameter. (3) It is assumed that the forces acting from the sides of the substrate on the system involve only the first layer of molecules, which makes it possible to take into account the contribution to the free energy of the system by the interactions of the substrate with the molecules in the nearest layer with the aid of the term F_s.

Then, neglecting fluctuations and assuming that $\psi(z)$ is the average value of the order parameter in a plane parallel to the surface of the substrate and separated from it by a distance z, the free energy functional of the semi-infinite system can be written in the following form:[20]

$$F[\psi] = F_s + \int_0^\infty dz \left[f(\psi) + \frac{1}{2} k (\nabla\psi)^2 \right], \tag{2}$$

where $k > 0$ is assumed to be constant. The difference between the properties in the surface layer and in the bulk phase promotes the formation of the order parameter profile ensuring a minimum in the free energy of the system. The spatial distribution of $\psi(z)$ is obtained by solving Euler's equation:

$$k \frac{d^2\psi}{dz^2} = \frac{\partial f(\psi)}{\partial \psi} \tag{3}$$

with the following boundary conditions on the surface ($z = 0$) and in the bulk phase:

$$k \frac{d\psi}{dz}\bigg|_{z=0} = \frac{\partial F_s}{\partial \psi}\bigg|_{\psi_s = \psi(z=0)}, \tag{4}$$

$$\lim_{z\to\infty} \psi(z) = \psi_b, \tag{5}$$

where ψ_b and ψ_s are the values of the order parameter in the bulk phase and on the surface respectively.

The first integral is

$$\frac{d\psi}{dz} = \pm \{2[f(\psi) - f(\psi_b)]/k\}^{1/2}. \tag{6}$$

The sign of the derivative is determined by the ratio of the values of ψ in the bulk phase and on the boundary: if $\psi > \psi_b$, then $d\psi/dz < 0$ and conversely. It follows from Eqns.(4) and (6) that

$$\frac{\partial F_s}{\partial \psi} = \pm \{2k[f(\psi_s) - f(\psi_b)]\}^{1/2}. \tag{7}$$

Hence one can find the order parameter on the surface ψ_s. If Eqn.(7) has several roots, then each of them leads to a definite spatial distribution of $\psi(z)$. The profile ensuring the minimum surface free energy σ corresponds to the condition for equilibrium:

$$\sigma = F_s + \int_0^\infty dz \left[k \left(\frac{d\psi}{dz} \right)^2 \right]. \tag{8}$$

Having specified a simple expression for F_s, it is possible to obtain a solution to Eqns.(3)–(5) in an analytical form and to analyse the possible situations. In the main, the following form of F_s is investigated:[20,23]

$$F_s = -\frac{1}{2} g \psi_s^2 - h_1 \psi_s. \tag{9}$$

It describes the perturbing influence of the wall on the semi-infinite system as a result of the modification of the chemical potentials of the components (second term) and the changes in the interactions between the molecules at the boundary (first term). The relation between the extrapolation length $\lambda = -k/g$ and the energy of the interaction of the sites in the surface layer J_s has been established with the aid of lattice models. Having characterised the difference between J_s and the energy of the interaction of sites in the bulk phase J by the quantity $\Delta_s = J_s/J - 1$, Mills[24] and Binder and Hohenberg[25] found $\lambda^{-1} = 1 - \Delta_s/\Delta_c$, where Δ_c is the critical value of Δ_s ($\Delta_c = 4$).[26]

We shall now consider the results obtained in the solution of Eqns.(3)–(5) and (9) for the simplest case where $h = h_1 = 0$ (Figs. 1 and 2). For fixed cohesion forces of the molecules in the surface layer Δ_s, it is always possible to differentiate in the phase diagram the temperature range in which the entire specimen is in a non-ordered state: $\psi(z) = 0$ (region V in Fig.1). For $\Delta_s < \Delta_c$ ($\lambda > 0$), this state persists until the attainment of the bulk-phase PT temperature. When non-zero values of the order parameter appear in the bulk phase, the substrate tends to disorder the system (region I), which diminishes $\psi(z)$ in the vicinity of the surface (Fig.2*a*). If the interaction energy of the molecules in the surface layer exceeds the critical value ($\Delta_s > \Delta_c$, $\lambda < 0$), the non-ordered state exists throughout the bulk of the specimen at temperatures $t > t_s > 0$. At t_s, order appears in the boundary layer of molecules (the C^1_{sur} surface transition takes place), but the non-ordered state of the substance persists away from the wall. Region II in the phase diagram (Fig.1) differentiates the states of the system for which the order parameter on the surface differs from the bulk-phase value but approaches

$\psi_b = 0$ on moving away from the boundary (Fig.2*b*). The decrease in temperature to the critical value induces a bulk phase transition (extraordinary C^{∞}_{ext} transition) and the establishment in region III (Fig.1) of the profile illustrated in Fig.2*c*. The boundaries of the ordinary (C^{∞}_{ord}), extraordinary, and surface transitions converge at a single point *Sp*, where $\Delta_s = \Delta_c$ ($\lambda^{-1} = 0$). The condition $\Delta_s = \Delta_c$ means that the presence of the wall does not influence the interaction energy of the molecules, so that, as a result of a special transition (*Sp*), the state of the system changes simultaneously throughout its bulk at the critical temperature. For $t < 0$, the distribution of the order parameter is shown in Fig.2*b*.

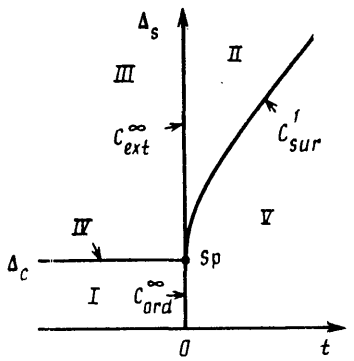

Figure 1. Schematic illustration of the phase transitions occurring in a semi-finite system[22] (for the explanation, see text).

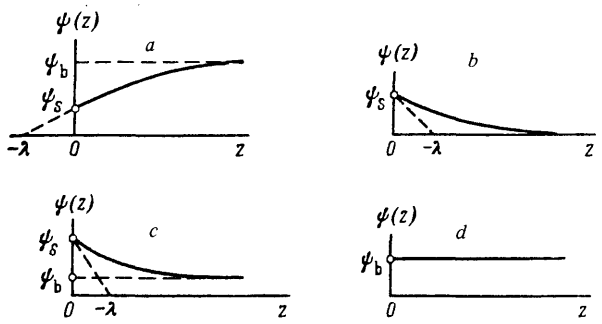

Figure 2. Variation of the order parameter ψ with the distance from the substrate surface for different values of the extrapolation length $\lambda = -k/g$ and temperatures t:[20] (a) $\lambda > 0$, $t < 0$; (b) $\lambda < 0$, $t > 0$; (c) $\lambda < 0$, $t < 0$; (d) $\lambda^{-1} = 0$, $t < 0$ ($h = h_1 = 0$ throughout).

Thus, even in the simplest case, the phenomenological theory makes it possible to discover a significant difference between the properties of the specimen in the bulk phase and in the surface layer. The nature of the transitions near the CP is controlled by the interaction energy of the molecules at the wall: an increase in Δ_s (and hence in g) increases the temperature of the surface transition and an order parameter different from the bulk-phase value appears above the critical temperature. The problem has been investigated in greatest detail in studies;[15,16,22,23] limitations on the values of the parameters h and h_1 were removed, non-classical temperature variations of the coefficients in Eqn.(1) were considered etc. More complex cases of semi-infinite systems with two order parameters have also been analysed.[27]

III. CAHN'S THEORY AND EXPERIMENTAL STUDIES ON WETTING TRANSITIONS

Consider a liquid consisting of components A and B with an upper consolute temperature (UCT). Above T_c, the liquid consists of a homogeneous phase with the composition φ_0 (concentration of component B). Below T_c, the mixture decomposes into the phases α and β, whose compositions φ_α and φ_β depend on temperature. We shall assume that phase β contains an excess of component B ($\varphi_\beta > \varphi_0$), whereupon phase α is enriched in component A ($\varphi_\alpha < \varphi_0$). As T_c is approached, the compositions of the phases coexisting at equilibrium approach one another and the interfacial tension at the $\alpha-\beta$ boundary diminishes. In the vicinity of T_c, simple scaling relations apply:[12,13]

$$\varphi_\beta - \varphi_\alpha \propto t^{\beta}, \tag{10}$$

$$\sigma_{\alpha\beta} \propto t^{\mu}, \tag{11}$$

where $\beta = 0.33$ and $\mu = 1.26$ are critical parameters. We now bring the mixture into contact with the wall, which adsorbs preferentially one of the mixture components (for example B). The behaviour of the two-phase system near the wall S is determined by the interfacial energies $\sigma_{\alpha s}$, $\sigma_{\beta s}$, and $\sigma_{\alpha\beta}$ at the S$-\alpha$, S$-\beta$, and $\alpha-\beta$ boundaries respectively. Under conditions where $\sigma_{\alpha s} - \sigma_{\beta s} - \sigma_{\alpha\beta} < 0$, the equilibrium wetting angle θ arises and Young's law holds:[28]

$$\sigma_{\alpha\beta} \cos\theta = \sigma_{\alpha s} - \sigma_{\beta s}. \tag{12}$$

In his analysis of the temperature variation of θ in the two-component system considered, Cahn[18] suggested that the difference between the interfacial energies ($\sigma_{\alpha s} - \sigma_{\beta s}$) in the vicinity of T_c is determined mainly by the compositions of the equilibrium phases and depends on temperature in the same way as $\varphi_\beta - \varphi_\alpha$. Then, taking into account Eqns.(10) and (11), we have from (12)

$$\cos\theta \propto t^{\beta-\mu}, \quad \beta-\mu = 0.93. \tag{13}$$

According to Eqn.(13), the condition for the complete wetting of the substrate surface by phase β ($\theta = 0$) is attained at a certain temperature T_W, which differs from the critical temperature. Then, when $T_c > T > T_W$, we have $\sigma_{\alpha s} - \sigma_{\beta s} - \sigma_{\alpha\beta} > 0$ and, for liquids with limited miscibility, contact with the wall by the component with the higher interfacial energy (A in the present instance) becomes unfavourable, which leads to the formation on the surface S of a layer of the phase in which the concentration of this component is lower.

The structure of the liquid at the substrate surface has been studied within the framework of the average field theory.[18] Here it is assumed that the microstructure produced in the liquid is controlled by the volume properties of the mixture, the concentration gradients, and the forces acting from the side of the wall only on the layer of molecules of the liquid adjoining it. The initial functional of the interfacial free energy has the form[18]

$$\sigma[\varphi] = F_s + \int_0^{\infty} dz \left[\Delta f(\varphi) + k\left(\frac{d\varphi}{dz}\right)^2 \right], \tag{14}$$

$$\Delta f(\varphi) = f(\varphi) - f(\varphi_0) - (\varphi - \varphi_0)\left(\frac{\partial f}{\partial \varphi}\right)\Big|_{\varphi=\varphi_0}, \tag{15}$$

where $f(\varphi)$ is the local density of the free energy of the homogeneous

liquid. The function $\Delta f(\varphi)$ reaches its minimum values for compositions corresponding to phase equilibrium [$\Delta f(\varphi_\alpha) = \Delta f(\Delta_\beta) = 0$] and has a local maximum at $\varphi_\alpha < \varphi < \varphi_\beta$. As the temperature approaches the critical value, $\Delta f(\varphi)$ at the local maximum diminishes and is very low in the vicinity of T_c.

The solution of the variational problem [Eqns.(14) and (15)] yields the spatial distribution of the concentration at the wall in each of the coexisting phases:

$$z(\varphi) = -\int_{\varphi_s}^{\varphi} [k/\Delta f(\varphi)]^{1/2}\, d\varphi. \qquad (16)$$

An elegant graphical analysis carried out by Cahn[18] established that near T_c the surface concentration φ_s is the same in both equilibrium phases and exceeds φ_β (the bulk phase concentration) for the more concentrated phase. Then, the function $\varphi(z)$ in phase α initially diminishes from φ_s *to* φ_β and at $\varphi = \varphi_\beta$ we have $\Delta f(\varphi_\beta) = 0$ and, according to Eqn.(16), $z \to \infty$, i.e. a macroscopic layer arises between the wall and phase α. Thus, a two-step transition is observed at the S$-\alpha$ interface: initially S$-\beta$ and then $\beta-\alpha$. When the temperature is appreciably below T_c, the adsorption of component B from phase α is slight and the condition $\varphi_s < \varphi_\beta$ holds. Since φ_s determines the lower integration limit in Eqn.(16), the profile of the variation of the concentration between the coexisting bulk phases β and α,[29] cut off at $\varphi = \varphi_s$, can be used to obtain the concentration profile $\varphi(z)$ at the S$-\alpha$ boundary. The transition from limited to complete wetting takes place at a definite temperature T_w and is a transition of the first kind.

The formation of a surface layer in which the concentration is close to φ_β is possible even in a homogeneous system for $\varphi_0 < \varphi_\alpha$ (under the conditions of the instability of the bulk phase having the composition φ_β). The difference from the two-phase system consists in the fact that the thickness of this layer is in this case finite, since $\Delta f(\varphi_\beta) \neq 0$.

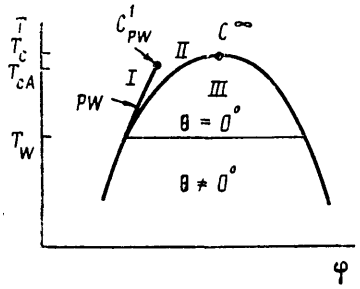

Figure 3. Phase diagram for a two-component semi-infinite system[18] (for explanation, see text).

The influence of the substrate on the two-component system is illustrated in the phase diagram in Fig.3. In the single-phase region I, the degree of adsorption of component B is low ($\varphi_s < \alpha_\beta$) and the composition of the surface layer never reaches φ_β even for $\varphi_0 = \varphi_\alpha$. Region II is one where the surface concentration exceeds the bulk phase concentration of component B in phase β. The appearance of a layer having a finite thickness with composition close to φ_β is characteristic of it. The *PW* line, separating these adsorption regions describes the concentrations of the homogeneous solution at which two profiles with different surface concentrations φ_s correspond to a single minimum in the functional (14). With increase in temperature the difference between these profiles diminishes and vanishes completely at the temperature T_{cA} at the critical point for the C^1_{PW} surface transitions (Fig.3).

Overall thermodynamic analysis[30] and the results of calculations based on different models[31–34] show that the *PW* line has a common tangent with the binodal curve at the point corresponding to the temperature T_W and the transition from the low adsorption region to the high adsorption region for systems having a UCT takes place on cooling. The deviation of T_{cA} from T_W varies from several to tens of degrees according to different estimates.[33–35] In region III (the region corresponding to complete wetting of the substrate), phase α is displaced from the surface of the wall by a macroscopic layer of phase β.

The strategy of the experimental studies of wetting transitions is determined mainly by the results of the theoretical analysis of the problem. The possibility of the appearance of wetting layers has been demonstrated already in the first study[36] of the influence of the substrate on the cyclohexane–methanol two-phase system (with a small amount of added water). The boundary with the non-critical phase (vapour) also played the role of a wall in the experiments.

Subsequent experimental studies of systems with a UCT [35,37–42] and systems with a lower consolute temperature (LCT),[43,44] carried out by various methods (visual observation,[37] capillary rise,[43] ellipsometry,[38–41] and light scattering[44] and reflection[42]), demonstrated convincingly that the formation of wetting layers is a general phenomenon associated with the influence of the surface of the wall. (The pattern arising under these conditions is illustrated schematically in Fig.4). The temperature of the transition from complete to limited wetting (T_W) differs significantly from the critical temperature. For systems with a UCT, it lies below T_c (for example, in the isopropyl alcohol–perfluoromethylcyclohexane system, $T_W = 38.0 \pm 0.1$ °C, while $T_c = 90.5° \pm 0.5$ °C [40]) and, for systems with a LCT, it lies above T_c (in the 2,6-lutidine–water system, $T_W \simeq 48$ °C, while $T_c = 34$ °C [43,44]).

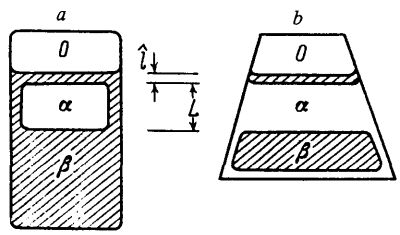

Figure 4. Experimentally observed wetting phenomena:[38] (a) methanol–cyclohexane system with added water in a glass bulb. The denser methanol phase β wets the glass surface and is distributed at the interface with the vapour 0; (b) the perfluoromethylcyclohexane–methylcyclohexane system in a quartz bulb. The lighter phase α with an increased methylcyclohexane contact wets quartz; the layer of phase β (enriched in C_7F_{14}) is distributed at the interface with the vapour.

Before considering experimental data referring to the measurement of the thickness of the wetting layers, we may note that Cahn's theory[18] was constructed without taking into account external fields.

Consequently, in the absence of the gravitational field, the wetting layer might be very thick and might occupy a considerable proportion of the volume of the system. In the gravitational field, the increased potential energy of the layer of the denser phase β at the interface with the vapour (Fig.4*a*) [or of the lighter phase α at the lower wall (Fig.4*b*)] tends to make it thinner. As a result of the balance between the gravitaional and surface forces, the equilibrium thickness of the layer $\hat{l}$ is attained. It follows from the analysis of the surface forces[45] that

$$\Pi(\hat{l}) = \Delta\rho g L, \qquad (17)$$

for $\pi(\hat{l})$ represents the forces acting per unit of each of the phases separated by a film; $\Delta\rho = \rho_\beta - \rho_\alpha$, ρ_α and ρ_β are the densities of phases α and β respectively, g is the acceleration in the free fall, and L is the thickness of the layer of phase α separating the wetting film and the bulk phase β (Fig.4).

If the attenuation of the wetting layer under the influence of the gravitational field is coupled with the rearrangement of the structure of the liquid owing to the overlap of the concentration profiles formed at the boundary of the film with the vapour and phase α, then $\pi(\hat{l})$ is determined by structural repulsion forces $\pi_c(\hat{l})$. Using the expression proposed by Widom,[46]

$$\Pi_c(\hat{l}) = \sigma' \exp(-\hat{l}/\xi), \qquad (18)$$

where ξ is the correlation radius of fluctuations in the bulk phase, we find that the thickness of the wetting film at the boundary with the vapour depends only slightly on the thickness of the layer of phase α but is extremely sensitive to temperature near T_c (by virtue of the temperature dependence of the correlation radius):

$$\hat{l} = \xi \ln\left|\frac{\sigma'}{\Delta\rho g L}\right|. \qquad (19)$$

Under conditions remote from T_c, where structural forces do not exert a decisive influence, the layer may be stabilised by long-range van der Waals forces:[47]

$$\Pi_м(\hat{l}) = W\hat{l}^{-q}, \qquad (20)$$

$$\hat{l} = \left(\frac{W}{\Delta\rho g L}\right)^{1/q}, \qquad (21)$$

where W is a coefficient which depends on the polarisabilities of phases α and β.[45] The exponent q reflects the presence or absence of a lag in the molecular forces: $q = 3$ for non-lagging forces and $q = 4$ for lagging forces.[45] Since the parameter W is proportional to the difference between the polarisabilities of the equilibrium phases, which depends on temperature in the same way as $\Delta\rho$,[47] the thickness of the wetting layers stabilised by molecular forces varies only slightly with temperature. The derivation of Eqn.(21) was based on a model in which the layer is assumed to be homogeneous up to its boundaries. The model inevitably breaks down and the thickness of the zone corresponding to the transition from the layer to the bulk phase is comparable to $\hat{l}$, which may occur when L is large and the thickness of the layer $\hat{l}$ is equal to several molecular diameters or if the width of the transition region, proportional to the correlation radius of the bulk phase fluctuations, increases as the temperature approaches T_c. In such cases there is a possibility of a transition from one stabilisation regime to another.[48] When $W < 0$ (attraction between the phases separated by a layer), only structural forces prevent the attenuation of the film. The final result depends on the balance between molecular, structural, and gravitational forces.

The thickness of wetting layers at the boundary with the vapour in systems having different chemical compositions (see Table) has been investigated by the ellipsometric method.[38–41] The results show that, below the wetting temperature, the thickness of the layer does not exceed 2 nm (in the *iso*-$C_3H_7OH - C_7F_{14}$ system[40,41]). Above T_W, the thickness of the layer reaches several tens of nm.

Studies over a wide temperature range indicate clearly the existence of two different mechanisms of the stabilisation of wetting layers. The role of molecular forces in the formation of wetting layers is manifested under conditions remote from T_c, where $\hat{l} \propto L^{-1/3}$ according to experimental data and small variations in thickness with temperature are observed. However, for large values of L, structural forces are apparently involved in stabilisation, which in fact leads to a weak dependence of the thickness on L (see Table, system 2). Near the critical temperature, where the zones corresponding to the transition from the film to the phases bounding it (the gas phase and phase α in Fig. 4*a*) begin to overlap, this is found

The thicknesses of the wetting layers at the interface with the vapour (experimental data).

to be the decisive factor which regulates the temperature variation of the thickness of the [wetting?] layer[39,42] and ensures the absence of a dependence on the thickness of the layer of phase α. The formation of thick wetting layers of the polar nitromethane from a nitromethane–carbon disulphide mixture on a horizontal glass surface can hardly be accounted for by the stabilising action of dispersion forces. On the other hand, calculations of the Hamaker constant performed[49,50] for this system on the basis of the Dzyaloshinskii–Lifshits–Pitaevskii theory[51] have shown that dispersion forces tend to destabilise the layer of nitromethane on the glass surface. The existence under equilibrium conditions of layers hundreds of nm thick requires the presence of forces acting over long distances. It has been suggested[49,50] that, in the presence of a polar component (nitromethane), having a high dielectric constant, the hydroxy-groups dissociate on the glass surface and the resulting electrostatic forces are involved in the stabilisation of the layer. How correct this model is will be shown by studies with careful monitoring of the surface charge.

The pronounced discrepancies between the thicknesses of the wetting layer measured experimentally and calculated using the theory of dispersion interactions[51] for certain systems[52] require the estimation of the time intervals necessary for the attainment of equilibrium. Such an estimate has been made[52] for two mechanisms of the variation of the thickness of the layer—diffusion of the mixture components to the interface and the leakage of the liquid from the layer via channels formed by the wetting layers on the surface of the vessel walls. If the growth of the layer is regulated by the diffusion of the components, then under conditions remote from T_c, the formation of the equilibrium wetting layer from liquids with limited miscibility on the surface of the substrate takes days and even months. As T_c is approached, the time required for the attainment of equilibrium increases. In a stirred system, this time is shortened but the thickness of the layer increases with increasing rate of stirring, which indicates a quasi-equilibrium state of the layer. If the equilibration mechanism in the attenuating layer is determined by the flow of liquid, then the equilibration time depends on the width of the channel and may amount to years.

A number of facts which cannot be explained within the framework of the above theoretical considerations have been discovered experimentally: a weak dependence of $\hat{l}$ on the thickness of the upper phase in the isopropyl alcohol–perfluoromethylcyclohexane (PFMCH) system (Table, system 4) and the decrease in the thickness of the wetting layer near T_c.[39,42] The results of a study of the phenol–water system are fairly unexpected from the theoretical point of view.[53] Expecting to observe a thick layer of phenol in the two-phase region at the boundary with the vapour, the authors[53] observed instead the appearance of hundreds of tiny drops which exist near the boundary for a long time.

Furthermore, studies on the wetting transitions in different systems have shown that the attainment of the critical temperature is not always accompanied by the formation of wetting layers. There are no layers at the boundary with the vapour in the cyclohexane–methanol two-component system[39] (only the addition of small amounts of water initiates transitions at the suface). This is clearly manifested in experiments on the wetting of solid substrates. Thus the temperature of the wetting transition on the glass surface in the 2,6-lutidine–water system diminishes, approaching T_c, with increase in the concentration of potassium chloride.[54] At the salt concentrations in excess of 0.072 M, the transition is suppressed and there is only limited wetting of the glass by the phase enriched in lutidine.

Glass capillaries whose surface has been methylated to different extents have been used[55,56] to investigate the wetting transitions in the nitromethane–carbon disulphide system. On a weakly methylated surface, the approach to the critical temperature is accompanied by wetting transitions of the first kind. However, when the polarity of the substrate diminishes so much that the preferential adsorption of carbon disulphide begins, the wetting transition vanishes over the entire temperature range below T_c and limited wetting of the capillary surface by the carbon disulphide phase takes place. Measurements of the wetting angle θ on glass in the systems cyclohexane–methanol with small amounts of added water, cyclohexane–aniline, and ethyl salicylate–diethylene glycol[57] have shown that in the vicinity of T_c the angle θ reaches 90°. The experimental data presented show that Cahn's theory[18] does not exhaust the entire wide variety of situations arising in real systems. The restriction of the zone where the substrate exerts an influence to direct wall–liquid contacts is an extremely controversial postulate of the theory.

The question of the existence on the phase diagram of a line separating the regions corresponding to strong and weak adsorption of one of the components also requires careful experimental confirmation (Fig.3). An attempt has been made[35] to observe a jump in the adsorption of PFMCH from an isopropyl alcohol–PFMCH mixture at the boundary with the vapour. When the homogeneous mixture was cooled slowly, the ellipticity coefficient of the light reflected from the liquid–vapour surface increased sharply. It was coupled with the appearance of a PFMCH film. Thick films are formed and persist indefinitely at a temperature higher by 0.18 K than the phase transition temperature in the bulk phase. However, when the cooling of the system was interrupted by vigorous shaking and subsequent standing until equilibration, this effect was absent. Consequently, in this instance there is no abrupt change in the degree of adsorption. The size of monodisperse spherical quartz pellets in the lutidine–water single-phase system has been measured[44] by the light scattering method as a function of the mixture composition and temperature. Having observed an increase in the intensity of the scattered light as the lutidine concentration approaches the value corresponding to the coexistence curve, the authors[44] postulated that this is due to the increase in the thickness of the adsorption layer of lutidine on the surface of the particles of the dispersion phase. It was also established that a decrease in the lutidine concentration in the mixture entails the aggregation of the particles. The curve corresponding to the aggregation of the particles on the phase diagram for this system was identified with the *PW* line.

IV. GENERALISED PHASE DIAGRAMS AND SURFACE SPINODAL CURVES

The place occupied by the phenomena involving wetting and the formation of a layer with a finite thickness in the overall pattern of the influence of the surface on PT is clearly defined by the phenomenological theory.[23] The inclusion of the $h\psi$ and $h_1\psi_s$ terms in Eqns.(1) and (9) for the free energy density and the direct contact energy made it possible to construct diagrams for the transitions in the space of the variables $\{t, h, h_1, g\}$.[23] Fig.5 presents the results obtained for the three previously differentiated regions based on different values of the parameter g. It follows from the functional (2) and Eqns.(1) and (9) that, when the signs of the parameters h and h_1 are changed, the quantities F, $f(\varphi)$, and F_s retain their values when ψ is replaced by $-\psi$. This means that, in the vicinity of the critical temperature, all the effects associated with the influence of

the wall and described previously for one of the equilibrium phases ($h = 0$) should be reproduced also for the other phase when the sign of the parameter h_1 changes, i.e. the wetting of the wall by one of the phases should always be observed in the vicinity of T_c. The principal characteristics of the phase diagrams for semi-infinite systems are illustrated in Fig.5: the wetting transitions for phase β (and correspondingly for phase α) at $h = 0$ are represented by the $W(D)$ lines, the set of points corresponding to the sharp change in the thickness of the adsorption layer in the single-phase system forms the $PW(PD)$ surface bounded by the loci of the critical points $C^1_{PW}(C^1_{PD})$. The character of the variation of the wetting lines for small deviations of the temperature from the critical value is described by the power relation $|t| \propto |h_1|^{1/\Delta_1}$, where $\Delta_1 = 1/2$, 1, and 3/2 [23] for $g < 0$, $g = 0$, and $g > 0$ respectively. For $g > 0$, the C^1_{PW} and C^1_{PD} lines extend to $t > 0$, meeting at the surface transition point C^1_{sur} (Fig.5*c*). The positions of the ordinary (C^∞_{ord}), special (Sp), and extraordinary (C^∞_{ext}) transitions (Fig.1) are illustrated in Fig.5 by multicritical points at which the lines of different PT intersect.

The jump in the thickness of the layer adjoining the substrate (to which the PW line in Fig.3 corresponds) may be regarded as a surface transition of the first kind. Since the existence of metastable and unstable states is associated with such transitions, then, by analogy with the PT in the bulk phase, in describing the sharp change in the thickness of the layer one may introduce the concept of the "surface" spinodal curve. The position of the surface instability curve relative to the PW line and the coexistence curve for the bulk phases has been analysed in detail.[32] It has been shown that the branches of the spinodal curve originate from the critical point C^1_{PW} and their positions on the phase diagram depend significantly on the ratio of the interaction energies of the components in the bulk phase of the system and on the surface of the substrate (Fig.6). For example, for $g < 0$, both branches of the spinodal curve terminate at the coexistence curve, the left branch being located under these conditions very close to the PW line (Fig.6*a*). It has been suggested[32,58] that the line, which is a continuation of the spinodal curve into the two-phase region of the bulk of the system, characterises the boundary of the wetting instability. According to this hypothesis, the substrate is wetted in the metastable region after the intersection of the surface spinodal curve, provided that the system was initially in the weak adsorption region and that the transition from one region in the phase diagram to the other was rapid. (If the initial state corresponds to the region with strong adsorption, wetting is observed under the conditions corresponding to the coexistence curve.) On this basis, the hypothesis was put forward that the surface of the substrate may be wetted in the two-phase region below T_W when the system passes rapidly to the region of surface instability.[32] Thus one should expect in the two-phase region a qualitatively different behaviour of the system in the vicinity of the surface of the substrate depending on the initial state and the rate of cooling. The processes occurring at the wall can compete with the initiation of the new phase in the bulk of the system. This occurs when the state of the system in the bulk phase is metastable, being stable with respect to infinitesimal changes in composition, while near the substrate surface it is unstable, i.e. unstable in relation to infinitesimal fluctuations. One can then observe the segregation of a phase from the metastable state via a barrier-free mechanism.

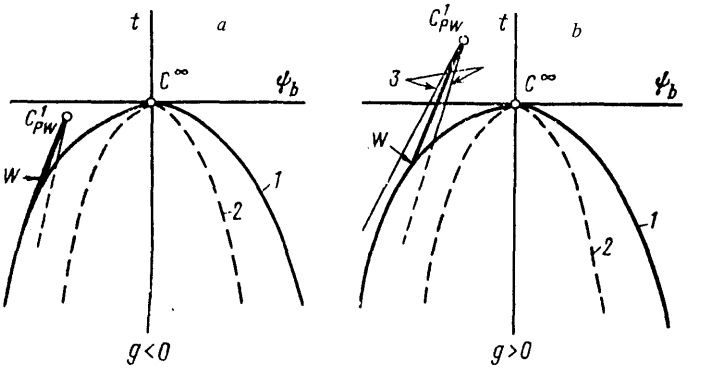

Figure 6. Phase diagram for a semi-infinite system in terms of the coordinates volume order parameter (ψ_b) – temperature (t);[32] 1) coexistence curve; 2) spinodal curve; 3) surface spinodal lines. For the significance of other notation, see the caption to Fig.5.

We shall consider next a generalised phase diagram corresponding to the case where the energy of the interaction between the molecules in the surface layer is smaller than in the bulk phase (Fig.5*a*). Calculations have shown[23] that, for certain values of the parameters h_1 and g, the transition from limited to complete wetting on moving along the coexistence curve may take place continuously and not as a result of an abrupt change in the thickness of the surface layer.

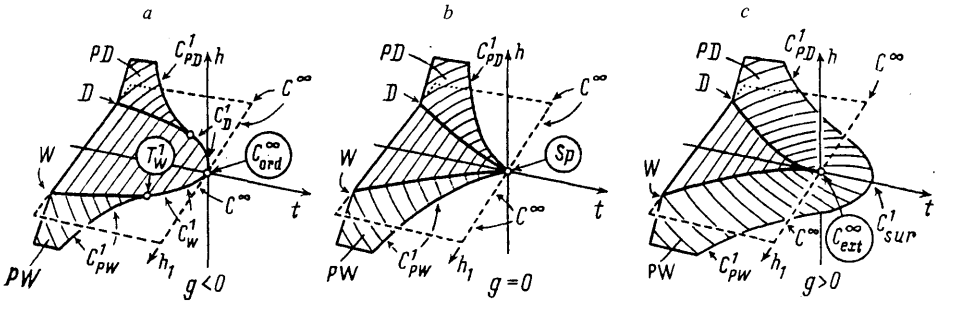

Figure 5. Phase diagram for a semi-infinite system for different values of the parameter g;[23] W, D—wetting lines; C^1_W, C^1_D—critical wetting lines; PW, PD—surfaces separating the regions with weak and strong adsorption; C^1_{PW}, C^1_{PD}—the critical point loci bounding the region; C^1_{sur}—surface transition point; C^∞—line corresponding to the transition in the bulk phase; multicritical effects are indicated within circles.

Such a transition is called a critical wetting transition (the C_W^1 and C_D^1 lines correspond to this transition in Fig.5*a*). The tricritical wetting point T_W^1 separates the W and C_W^1 transitions. The locus of the critical points C_{PW}^1 of the transition associated with the abrupt change in adsorption in single-phase systems (in systems where critical wetting takes place, PW transitions are not observed) terminates at the point T_W^1. Fig. 5*a* shows that the critical wetting occurs when $|h_1| < |h_{1,T_W^1}|$ (with increase in g, $|h_{1,T_W^1}| \to 0$). Consequently, this transition can be observed only in systems with low values of the parameter h_1.

The possibility of the continuous growth of the thickness of the wetting layer under the conditions of coexistence of the bulk phases was first pointed out in studies[59,60] where the wetting transitions were analysed using one-component liquid models. It was shown[59] that, in the critical wetting transitions, the following relation should hold for the interfacial energies:

$$\sigma_{\alpha s} - \sigma_{\beta s} - \sigma_{\alpha\beta} = -C\left(1 - \frac{T}{T_{cW}}\right)^2,$$

which leads to a temperature dependence of the wetting angle differing from the scaling relation (13):

$$\cos\theta = 1 - \frac{C(1 - T/T_{cW})^2}{D(1 - T/T_c)^{1.26}},$$

where C and D are constants and T_{cW} is the critical wetting transition temperature.

The experimental data[35,36,40,41,43,44,54–56] leave no doubt that the first order wetting transition does indeed exist. On moving along the coexistence curve, the degree of adsorption changes abruptly at some instant, becoming (in the absence of external fields) infinite. The possibility of a continuous transition is less evident. Theoretical analysis of specific systems may be of great help in selecting systems in which one should seek critical wetting transitions. As an example, we may refer to a study[61] where wetting transitions were investigated taking into account the orientation of the molecules on the substrate surface. The authors[61] observed an alternation of wetting transitions on moving along the binodal curve towards T_c. Polymer systems must also be included among specific systems: for virtual constancy of the segment–segment and segment–substrate interaction energies in such systems, it is possible to alter significantly the concentration and temperature ranges where wetting transitions may occur by varying the chain length within wide limits.

V. PHASE TRANSITIONS IN SEMI-INFINITE POLYMER SYSTEMS

Numerous theoretical and experimental studies have been devoted to questions of the adsorption of polymers.[62–66] We shall concentrate attention on the investigation of the concentration profile of polymer segments in a poor solvent, following Cahn's ideas[18] and on the basis of the results of a number of studies.[32,67–70] We shall assume that the polymer concentration on the surface is low ($\varphi_s = \lim_{z\to 0}\varphi(z)$, $\varphi_s \ll 1$), which makes it possible to neglect the interaction between the segments of the macromolecules in the first layer and to represent F_s in the form

$$F_s = \sigma_0 + \sigma_1\varphi_s, \qquad (22)$$

where σ_0 is the surface energy at the substrate–solvent interface; $\sigma_1 > 0$ corresponds to an increase in energy with increasing concentration and indicates that the interaction of the macromolecule with the substrate is unfavourable. If the adsorption of the macromolecule reduces the free energy of the system ($\sigma_1 < 0$), then the condition $\varphi_s \ll 1$ holds only for weakly binding substrates: $|\sigma_1| < k_BTa^{-2}$.[69,70]

Under ideal equilibrium conditions, the concentration profile $\varphi(z)$ is determined from the minimum in the functional

$$\sigma - \sigma_0 = -|\sigma_1|\varphi_s + \int_0^\infty dz\left[f(\varphi) - \mu\varphi + \pi + \frac{k_BT}{24a\varphi}\left(\frac{d\varphi}{dz}\right)^2\right], \qquad (23)$$

where

$$f(\varphi) = k_BTa^{-3}(\varphi N^{-1}\ln\varphi - v\varphi^2/2 + w\varphi^3/6)$$

is the local free energy density (in terms of a virial expansion) of the polymer solution,[8] a the size of the site in the Flory lattice,[7] N the number of units in the polymer chain, and v and w are parameters describing the pair and three-particle interactions between segments respectively. For v greater than the critical value v_c, it is possible to differentiate on the phase diagram a concentration range in which the formation of two phases with different polymer concentrations ensures a minimum in the free energy of the system. The functional (23) has been analysed in detail[67,68] in relation to a range of low polymer concentrations in a poor solvent. In this case, the osmotic pressure π of the macromolecules in solution is very low and one can assume that $\pi \simeq 0$ and that the chemical potential is large: $\mu \simeq k_BTa^{-3}N^{-1}\ln\varphi_0$. The introduction of the variables $\gamma = 6|\sigma_1|\cdot a\xi/k_BT$, $y = (\varphi/\varphi_\beta)^{1/2}$, $x = z/\xi$, and $\eta^2 = [\ln(\varphi_0/\varphi_\beta) + 1]/\ln\varphi_\alpha$ makes it possible to represent the functional (23) in the form

$$\frac{\sigma - \sigma_0}{|\sigma_1|\varphi_\beta} = -y_s^2 + \gamma^{-1}\int_0^\infty dx\left[y^6 - 2y^4 + \eta^2y^2 + \left(\frac{dy}{dx}\right)^2\right], \qquad (24)$$

where ξ is the correlation radius of the concentration fluctuations in solution for $\varphi_0 = \varphi_\beta$ and φ_α and φ_β are the equilibrium compositions of the dilute and concentrated phases respectively.

Next we obtain from the scheme described in Section II

$$\left(\frac{dy}{dx}\right)^2 = y^6 - 2y^4 + \eta^2y^2, \qquad (25)$$

$$-2y_s = \frac{2}{\gamma}\left(\frac{dy}{dx}\right)\Big|_{x=0} = -\frac{2}{\gamma}(y_s^6 - 2y_s^4 + \eta^2y_s^2)^{1/2}. \qquad (26)$$

It follows from Eqn.(26) that the real surface concentrations y_s can be obtained if the condition $1 - \eta^2 + \gamma^2 \geqslant 0$ is satisfied. Since η^2 is determined by the concentration of the solution, the length of the polymer chain, and temperature, it follows that, for a specified value of η, one can select substrates for which $\gamma \gg \gamma^* = (\eta^2 - 1)^{1/2}$ and $\varphi_s/\varphi_\beta = y_s^2 \simeq 1 + \gamma$, i.e. near the wall the concentration of the segments corresponds to a semidilute solution of the polymer and the "tail" of the profile extends into the bulk phase where the concentration is low. (For $\gamma < \gamma^*$, the energy of the interaction of the macromolecule where the substrate surface is low and cannot compensate for the energy expenditure on the creation of the concentration gradient, adsorption is an energetically unfavourable process.)

Detailed consideration of the density profile of the segments near the substrate surface[67,68] established that, over small distances $z < \xi$, the distribution of the concentration is determined solely by the energy of adhesion of the segments to the surface and that, for $\gamma \gg \gamma^*$, the concentration of the segments falls rapidly on moving away from the substrate. The distribution of the concentration in the central and "tail" parts of the profile depends significantly on η.

For $\eta^2 < 9/8$, a point of inflexion appears on the concentration profile and a fairly extended plateau is formed. The width of the plateau increases as the bulk-phase concentration of the polymer solution approaches values corresponding to the coexistence curve. For long distances from the substrate surface, the concentration of the segments tends exponentially towards the bulk-phase value. Thus the relations discovered in the study of the influence of the surface on homogeneous systems near the critical temperature[18] were also manifested in polymer solutions.

By expanding the local free energy density near T_c in series in terms of the order parameter $\psi = (\varphi - \varphi_c)/\varphi_c$, the functional of the free energy of the polymer system was transformed[32] into a form which has been investigated in detail within the framework of the phenomenological theory. For a polymer solution, we have

$$F_p[\psi(z)] = D^{-1}N^{-1}\left\{\int_0^D \mathrm{d}z\left[\frac{a^2}{24}N^{1/4}\left(\frac{\mathrm{d}\psi}{\mathrm{d}z}\right)^2 + \right.\right.$$
$$\left.\left. + \frac{1}{2}\left(\frac{\chi_c - \chi}{\chi_c}\right)\psi^2 + \frac{1}{12}N^{-1/4}\psi^4 - h\psi\right] - h_1\psi_s - \frac{1}{2}g\psi_s^2\right\}. \quad (27)$$

In the case of a polymer blend with equal sizes of chains of different kind, we have the expression

$$F_{cm}[\psi(z)] = D^{-1}N^{-1}\left\{\int_0^D \mathrm{d}z\left[\frac{a^2}{24}N\left(\frac{\mathrm{d}\psi}{\mathrm{d}z}\right)^2 + \right.\right.$$
$$\left.\left. + \frac{1}{2}\left(\frac{\chi_c - \chi}{\chi_c}\right)\psi^2 + \frac{1}{12}\psi^4 - h\psi\right] - h_1\psi_s - \frac{1}{2}g\psi_s^2\right\}. \quad (28)$$

In Eqns.(27) and (28), χ is the Flory–Huggins parameter,[7] χ_c is the value of χ at the critical point, and $D \to \infty$.

Thus the results of the study of the influence of the substrate surface on the phase transitions in immiscible liquids can be extended also to polymer systems. The presence of larger multipliers before the gradient terms in Eqns.(27) and (28) ($N^{1/2}$ and N respectively) compared with Eqn.(2) does not alter qualitatively the results presented in Figs.5 and 6. All the features discussed in Sections III and IV are retained on the phase diagrams of semi-infinite polymer systems. They reflect the possibility of wetting, of the transition from weak to strong adsorption in the single-phase region, and of the existence of surface spinodal curves and the associated wetting in the metastable region of the bulk of the system at a temperature below T_W. We may note that, in contrast to binary liquid mixtures for which the metastability limit is hardly attainable experimentally,[71] in polymer systems (and especially in polymer blends[72,73]) a labile state is really observed for large macromolecules ($N \to \infty$). If an analogous systems arises also in wetting polymer films, then there is a possibility of the experimental observation of the metastable and unstable wetting states.

Only the temperature range near the critical value was investigated by Nakanishi and Pincus,[32] but the parameter h_1 selected was too large, which led to the conclusion that critical wetting cannot be observed in polymer systems. The problem of the wetting of the substrate surface by polymer blends has been analysed in detail.[74] We shall consider the conditions for the occurrence of critical wetting. As we have seen above, a wetting transition of the second kind occurs when, on moving along the coexistence curve from the region of low miscibility of the components, the surface concentration increases continuously and reaches the concentration of the wetting phase. Since the region in which critical wetting occurs is bounded by the tricritical wetting point (Section IV and Fig.5*a*), it is possible to determine the concentration of the blend $\varphi_{T_W^1}$ at which the conditions $\partial^2\sigma/\partial\varphi_s^2 = 0$ and $\varphi_s = \varphi_\beta$ hold simultaneously. For a mixture of macromolecules with $N_A = N_B = N$, it was found that[74]

$$\varphi_{T_W^1} \cong -\frac{a}{g(18N)^{1/4}}. \quad (29)$$

The condition $\varphi_s = \varphi_\beta$ indicates a planar concentration profile near the substrate surface ($\mathrm{d}\varphi/\mathrm{d}z|_{z=0} = 0$). Consequently the parameter h_1 at the point T_W^1 can be estimated from Eqns.(4), (9), and (29):

$$h_{1,T_W^1} = -g\varphi_s = -g\varphi_\beta = -g(1 - \varphi_{T_W^1}) \approx -g + a(18N)^{-1/4}.$$

Then, a wetting transition of the first kind always appears for $h_1 > h_{1,T_W^1}$ and $\varphi < \varphi_{T_W^1}$, while a continuous transition is possible for $h_1 < h_{1,T_W^1}$ and $\varphi_{T_W^1} < \varphi < \varphi_c$. By altering the concentration along the branches of the binodal curve, we find the critical wetting condition for a fixed values of $h_1 < h_{1,T_W^1}$:[74]

$$\varphi_{cw} = 1 + h_1/g.$$

Thus polymer blends are good objects for the observation of critical wetting, since, by altering the chain length, it is possible to vary h_{1,T_W^1}.

Despite the considerable progress in the theoretical analysis of the problem, there have been no complete experimental investigations of wetting transitions in polymer systems. There are literature data indicating the appearance of thick adsorption polymer layers in adsorption from a poor solvent.[62,63] The adsorption of poly(methyl methacrylate), polystyrene, and their copolymers from a mixture of carbon tetrachloride (an effective solvent) and heptane (a non-solvent) on quartz particles has been investigated in fair detail.[75] With increase in heptane concentration near the limit of stability of the homogeneous solution, a sharp increase in the adsorption of polystyrene copolymers with a high styrene content was observed. There was a parallel variation also of the volume of the deposit of the disperse phase particles. These factors indicate the formation of extended adsorption layers on the surface of the quartz particles. The influence of temperature on the adsorption of the polymer near the phase transition point in the bulk of the polystyrene–cyclohexane system has been investigated.[76] The appearance of a peak on the temperature variation of the ellipticity coefficient of the light reflected from the solution–vapour boundary at polymer concentrations above the critical value was attributed[76] to the formation of a wetting film of the solvent. The examples quoted confirmed to some extent the results of the theoretical consideration of the problem. At the same time, systematic investigations of the wetting phenomena arising under PT conditions in the bulk of polymer systems have still to be carried out.

An important application of the theory discussed above involved the calculation of the interaction forces between surfaces coated by adsorption layers of macromolecules. An undoubted advantage of the theory consists in the fact that all the data necessary for the calculations (information about the sizes of the unperturbed polymer chains, adsorption, and the concentrations of the equilibrium phases) can be obtained by studying the volume properties of the solution. Such calculations have been performed[68] for the specific polystyrene–cyclohexane system and have been compared to the results of an experimental study of the interaction forces between mica plates coated by adsorption layers of polystyrene in cyclohexane.[77,79] It was found that the calculations reproduce satisfactorily the experimentally observed inhomogeneous character of the variation of the forces and make it possible to estimate the distances over which attraction between the plates begins to be manifested and is then replaced by repulsion. Since the profile of the forces is a reflection of the distribution of the concentration of the chain segments near

the substrate surface, it follows that attraction over a distance exceeding the size of the unperturbed polymer coil arises as a consequence of the increase in the polystyrene concentration in the zone corresponding to the overlap of the concentration profiles up to values in the range $\varphi_\alpha < \varphi < \varphi_\beta$. In this case, strong interactions between segments of the adsorbed chains, characteristic of the two-phase region of the system, take place, and the plates attract one another. When the plates have shifted so much that φ becomes greater than φ_β, the attraction is replaced by repulsion. Although fine details of the forces profile are fairly satisfactorily predicted by the theory, there is no complete agreement between the absolute values of the forces. This is probably because of the neglect of the possibility of the formation of bridges as a result of the binding of the macromolecule to both plates (it has been shown[80] that the formation of a small number of bridges can become the main source of the interaction between the adsorption layers).

The theory of PT in semi-infinite polymer solutions creates a satisfactory basis for the discussion of the extensive experimental data[81] on interfacial adsorption layers whose stability is fairly high, which has in fact been demonstrated.[82] We shall consider the phase diagram of a polymer solution (Fig.7), in which a boundary between regions differing in the degree of adsorption of the polymer (*PW*) and the gel formation region (shaded) was observed. Suppose that the surface activity of the polymer is fairly high so that $\varphi_s > \varphi_g > \varphi_0$ (φ_g is the concentration at which gel formation takes place). If the concentration of the solution is lower than the values corresponding to the *PW* line, the degree of adsorption is low, but as soon as the concentration exceeds these values, the degree of adsorption becomes high ($\varphi_s > \varphi_\beta$) and a plateau appears on the concentration profile [where $\varphi(z) \simeq \varphi_\beta$], whose extent increases as φ_0 approaches φ_α. If the concentration on the plateau exceeds the gel formation concentration, then a film of gel arises at the interface. The thickness of this film corresponds to the width of the plateau and in the vicinity of φ_α greatly exceeds the size of the unperturbed polymer coil.

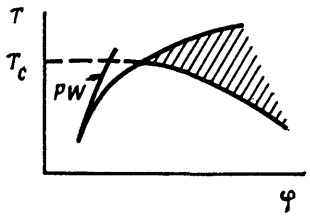

Figure 7. Phase diagram for a semi-infinite polymer solution.[82] The composition region in which gel formation takes place is shown shaded.

VI. THE ROLE OF LONG-RANGE FORCES IN WETTING TRANSITIONS

The theories of the surface transitions in semi-infinite systems considered were constructed taking into account surface forces with a small radius of action. This approach presupposes the existence of a non-specific dependence of the contact energy F_s on the composition of the surface layer and precludes an adequate description of real systems in which the zone of action of surface forces is known[45,83] not to be restricted to a monolayer. The approach to real conditions requires the analysis of the long-range action of the substrate. At the present time, theoretical studies have been carried out on continuous,[33,84–90] lattice,[31,60,91–95] and effective models of the layer.[96–100] Surface transitions in one-component systems and binary liquid mixtures are discussed within the framework of these models. An important aspect of such studies is the search for a relation beween the parameters of the microscopic interactions occurring in the system and the type of the surface transition. The introduction of the potential of the interaction between molecules in the bulk phase makes it possible to remove the limitation associated with the gradient form of the local free energy density and to describe the properties of the inhomogeneous liquid by considering the interaction occurring at the molecular level.

Careful analysis of this question, resorting to different models, showed that the type of the wetting transition is extremely sensitive to the form of the pair interaction potential. When the attraction of the molecule by the wall and by the surrounding molecules is described by potentials which decrease exponentially with increase in the distance between them, one can observe the appearance of wetting transitions of the first and second kind.[84,85] If the attraction between the molecules in the bulk phase operates over distances greater than the surface forces, a transition of the first kind occurs; otherwise we have a transition of the second kind (critical wetting). This model has been investigated in detail.[87] Much attention has been devoted to the modelling of the interactions in the system using the Lennard-Jones potentials.[31,60,85,86,89,90,101] In this case only a wetting transition of the first kind occurs and the features characteristic of it appear. It is noteworthy that the specific features of the microscopic interactions are manifested in the laws according to which the thickness of the layer increases as the system approaches saturation: $\hat{l} \propto |\ln|\Delta\mu||$ for forces with a small radius of action and $\hat{l} \propto |\Delta\mu|^{-1/3}$ for long-range forces.[31]

The interaction potentials between the molecules of the liquid and the substrate $V(z)$ and between the adsorbed molecules and the bulk of the liquid $U(z)$ have been described[89,93–96] by a more general expression

$$V(z) = -\left[\sum_{i=3}^{M} \gamma_{wi}/z^i\right], \quad U(z) = -\left[\sum_{i=3}^{M} \gamma_{fi}/z^i\right].$$

Depending on the coefficients γ_{fi} and γ_{wi}, in these systems it is possible to differentiate critical wetting, a wetting transition of the first kind, and other types of surface transitions. The important role of the terms γ_{f4}/z_4 and γ_{w4}/z^4 in the occurrence of critical wetting has been demonstrated in a study,[96] where an analytical expression was obtained for the separatrix separating the regions of the first- and second-order wetting transitions. The results[89,90,93–96,102] have shown that the fine details of the microscopic interactions are reflected in the macroscopic behaviour of the semi-infinite system: whether or not the wetting layer grows continuously or abruptly with increase in temperature and as the latter approaches T_c depends on the many-particle interactions and the structure of the substrate. Naturally, it follows from some of the above studies[89,94,96] that, in order to be able to predict the type of transition in each specific system, it is essential to have detailed information about it and the determination of such information constitutes an extremely complex problem. In their turn, experimental studies of the wetting transitions can prove an extremely valuable source of information about the microscopic interactions.

Next we shall consider, on the basis of the results of a number of studies,[21,91,92,103,105] what new contributions are made by long-range forces, compared with the forces with a small radius of action, to the

wetting transitions. As we have demonstrated above, in the latter case the presence of the substrate always initiates wetting in the vicinity of the critical temperature. We shall compare the phase diagrams presented in Fig.5 with the diagrams constructed[91,92] on the assumption that weak long-range forces exist, diminishing on moving away from the substrate surface in accordance with the law $h_{LR} \propto z^{-(m+1)}$ (where $m = 2, 3$), and there are short-range interaction forces between the molecules of the liquid (Fig.8). We shall assume that these forces promote the wetting of the substrate by phase β for $h_1 > 0$. The diagrams have many features in common: they reflect the presence of ordinary, special, and extraordinary transitions determined by the effective parameters of the interaction of the molecules of the liquid at the wall g^*; the type of behaviour of the wetting lines near T_c is the same. However, significant differences are also manifested. Fig.8 shows that, near T_c for $h_1^* < 0$ and $g^* = 0$, and $g^* > 0$, the wetting transitions, which in the case of short-range forces of the interaction of the substrate are characterised by the formation of a wetting layer (phase α) of infinite thickness (in the absence of gravitational field), now become transitions accompanied by the appearance of layers having a finite thickness (*PD*). Furthermore, for $g^* < 0$, the critical wetting transitions are transformed into wetting transitions of the first kind and the wetting of the substrate by the second phase is fully suppressed.

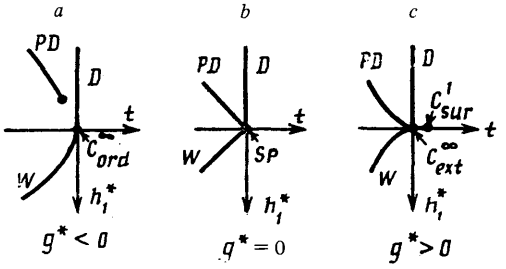

Figure 8. Phase diagram for a semi-infinite system with weak long-range forces in the substrate[92] (the legend is given in the caption to Fig.5 and further explanation can be found in the text).

The breakdown of the symmetry of the phase diagrams, characteristic of short-range potentials of the substrate (Fig.5), can find an explanation within the framework of the phenomenological theory if account is taken of the long-range effect of the substrate by including in Eqn.(2) the term[21,91,92,103–105]

$$\int_0^l [-h_{LR}(z)\,\psi(z)]\,dz, \quad l \to \infty .$$

This leads to an additional change in the interfacial free energy by the amount $\Delta\sigma = Al^{-m}$. Next, if the long-range forces cooperate with the forces of the direct interaction of the liquid molecules with the wall, then, for $h_1 > 0$, $\Delta\sigma$ is positive and the formation of a wetting layer with an infinite thickness ($l = \infty$) ensures a minimum in the free energy of the system. In this situation a macroscopic layer arises only as a result of a transition of the first kind. On the other hand, if the interactions of the substrate with the nearest layer of molecules are favourable for the other phase ($h_1 < 0$), then $\Delta\sigma < 0$ and at $t \neq 0$ the macroscopic layer of this phase never corresponds to the conditions for a minimum in the interfacial free energy, i.e. the long-range forces suppress the wetting transition. In this case critical wetting occurs at T_c.

The inhibition of the wetting transitions by long-range forces makes it possible to understand the results of experimental studies in which there was no wetting in the vicinity of T_c. On the basis of the phase diagram illustrated in Fig.8*a*, Franck and co-workers[55,56] interpreted the results of the study of such transitions in the nitromethane–carbon disulphide system on a chemically modified glass surface. It was assumed that, with increase in the number of methyl groups on the surface, the parameter h_1 diminishes monotonically, while the sign of the long-range potential of the substrate remains unaltered. The experimentally observed increase in the wetting transition temperature and its approach to the critical temperature with decrease in the polarity of the glass can then be accounted for with the aid of the phase diagram in Fig.8*a*. Indeed, when $h_1^* \to 0^+$, then we also have $t_W \to 0$. If the degree of modification of the glass surface increases so much that the preferential adsorption of carbon disulphide begins, the long-range and short-range forces compete with one another, promoting the disposition of different phases near the substrate and there is no wetting.

With increase in long-range forces, new effects appear on the phase diagrams:[92] a sequence of wetting transitions arises near T_c and wetting layers with different concentration profiles are observed in different temperature ranges. The parameter g^* plays a significant role under these conditions.

An important problem in the experimental investigation of wetting transitions is the quality of the substrate surface. In the theoretical study of this question, the wall is assumed to be ideally smooth, so that the interactions between the substrate and the liquid molecule depend solely on the coordination at right angles to the surface. However, the imperfection of the surface or the presence of impurities, both in the material itself and adsorbed on the latter, lead to random variations in the energy of the interaction of the molecules with the substrate in the plane of its surface. A recent analysis of experimental data has shown[106] that the inconstancy of the wetting energy (even when the best of the available substrates are used) influences significantly the adsorption isotherm near the two-dimensional liquid–vapour critical point. The study of this process in relation to wetting transitions[107,108] has shown that the random energy inhomogeneity of the wall does not affect the critical wetting transition and promotes a continuous variation of the degree of adsorption when the system passes from the weak adsorption region to the strong adsorption region (on intersection of the *PW* line on the phase diagrams).

VII. FLUCTUATIONS IN THE WETTING LAYERS AND CRITICAL PARAMETERS OF WETTING TRANSITIONS

In considering the wetting phenomena, we neglected previously the fluctuations in the wetting film. The underestimation of the role of fluctuations in describing the PT in the bulk phase makes the results obtained using classical theories inaccurate in the vicinity of T_c.[1–3,5] Only for systems where there are strong interactions between the molecules over long distances and for polymer blends[109–111] (with the exception of a narrow temperature range near T_c) are the conclusions based on the average field theory reliable. Appreciable interest has arisen recently in the study of fluctuations in wetting layers[30,74,87,88,97–100,112,129] and in the elucidation of their influence on the stability of the layer. Attention has been concentrated on the study of capillary waves arising at the boundaries of the wetting layer. At the same time, the appearance of fluctuations of another kind, capable of preventing the formation of a wetting layer of

the denser phase at the boundary with the vapour, has also been noted.[39,112]

Below we shall consider briefly the fluctuations in the wetting films formed when a gas is adsorbed on a substrate. The presence of the film limits the fluctuations at the film–vapour boundary, but, under the conditions of the continuous increase in the thickness of the film (for critical wetting or for an increase in concentration up to saturation), the influence of the substrate weakens and the adsorption layer terminates as the almost free liquid-vapour interface. Many characteristics of the wetting transitions, including the critical phenomena, can be explained within the framework of the model of the layer with effective interactions between the surfaces bounding the film.[97–100,113–122] In this model, the surface fluctuations are described as the deviations $\delta(x, y)$ of the position of the free boundary of the film, corresponding to its local thickness $l(x, y)$, from the equilibrium thickness $\hat{l}$: $l(x, y) = \hat{l} + \delta(x, y)$, where x and y are coordinates in a plane parallel to the substrate surface. The functional of the free energy of the film assumes the form[113–118]

$$F[l] = \int dx\,dy\left[\frac{1}{2}\sigma_{\alpha\beta}(\nabla l)^2 + V(l)\right] = F[\hat{l}] + \\ + \int dx\,dy\left[\frac{1}{2}\sigma_{\alpha\beta}(\nabla\delta)^2 + \frac{1}{2}\left(\frac{\partial^2 V(l)}{\partial l^2}\right)_{\hat{l}}\delta^2 + O(\delta^3)\right].$$

The first term describes the change in free energy as a result of the increase in the surface area as a result of the fluctations in $l(x, y)$: $V(l)$ is the effective potential of the film (it determines whether or not the attraction or repulsion of the free surface of the film by the well depends on the potentials of the interactions of the molecules with the substrate). If the attraction between the surfaces bounding the film is fairly strong and retains the free film surface at a certain distance l from the wall, then the change in conditions is accompanied by a continuous decrease in this attraction. We shall assume that the substrate is impermeable to the molecules of the liquid. Then the potential $V(l)$ of the wetting films formed from the single-phase systems depends on the extent to which the vapour has failed to reach saturation and in the case of surface forces with small radius of action has the following form:[115–119,123]

$$V(l) = A\exp(-\tau l) + |\Delta\mu|\,l, \tag{30}$$

while in the case of long-range forces we have[115–118]

$$V(l) = Bl^{-m} + |\Delta\mu|\,l, \tag{31}$$

where A, B, and τ are coefficients and $\Delta\mu$ is the deviation of the chemical potential from its value on the coexistence curve. Wetting in model systems whose potential $V(l)$ is described by Eqns.(30) and (31) takes place for positive values of the coefficients A and B, whereupon $\Delta\mu \to 0$.

In the model considered, the dependence of the equilibrium film thickness $\hat{l}$, the correlation radius of the surface fluctuations $\xi_{\|}$, and the interfacial free energy on the degree of unsaturation can be found from the relations

$$\left.\frac{\partial V(l)}{\partial l}\right|_{\hat{l}} = 0;\quad \sigma_{\alpha\beta}(\xi_{\|})^{-2} = \frac{\partial^2 V(l)}{\partial l^2};$$
$$\sigma_s = V(\hat{l}). \tag{32}$$

The character of the variation of these quantities for $\Delta\mu \to 0$ makes it possible to determine the critical parameters of the wetting transition β_s, $\nu_{\|}$, and α_s:

$$\hat{l} \propto |\Delta\mu|^{\beta_s};\quad \xi_{\|} \propto |\Delta\mu|^{-\nu_{\|}};\quad \sigma_s \propto |\Delta\mu|^{2-\alpha_s} \tag{33}$$

For systems where only small-radius interaction forces exist, it follows from Eqns.(30), (32), and (33) that $\beta_s = 0$, $\nu_{\|} = 1/2$, and $\alpha_s = 1$; if the intensity of the interactions between the liquid molecules and the substrate diminishes in accordance with a power law, the critical parameters depend on the parameter m in Eqn.(31):

$$\beta_s = -(m+1)^{-1};\quad \nu_{\|} = (m+2)/(2m+2),$$
$$\alpha_s = (m+2)/(m+1)$$

[for non-lagging van der Waals forces ($m = 2$), we have $\beta_s = -1/3$, $\nu_{\|} = 2/3$, and $\alpha_s = 4/3$ [114–118,123]]. Thus the appearance of a macroscopic wetting layer on the substrate surface as the coexistence curve is approached is accompanied by an increase in fluctuations on the free surface of the layer. This factor indicates the similarity of the behaviour of the systems in the wetting transitions to the behaviour of the bulk-phase systems near the critical point.

The question arises whether the growing fluctuations alter the results obtained within the framework of the average field theory for surface wetting transitions. An answer may be obtained by estimating with the aid of a suitable hyperscaling relation,[116,118] for example:

$$(d-1)\nu_{\|} = 2 - \alpha_s \tag{34}$$

the limiting number of dimensions d^* of the space.[1–3] The character of the variation of the quantities $\hat{l}$, $\xi_{\|}$, and σ_s as a function of $\Delta\mu$ is predicted correctly by the average field theory, provided that the number of dimensions of the space in which the transition is investigated is greater than d^*. By substituting in Eqn.(34) the values of $\nu_{\|}$ and α_s quoted above, it is possible to find d^*. For the modelling of the interactions in the film by means of the potential defined by Eqn.(30), we have $\nu_{\|} = 1/2$ and $\alpha_s = 1$, so that $d^* = 3$. Additional analysis of this case showed[117] that, for a three-dimensional space, the average field theory yields the correct values of the wetting parameters. Under the conditions of long-range action, the quantity d^* is extremely sensitive to the character of the variation of the forces: $d^*(m) = (3m + 2)/(m + 2)$, but, for finite values of m, the quantity $d^*(m) < 3$ (long-range forces diminish d^*, as for the critical phenomena in the bulk phase). Thus the average field theory describes correctly the influence of the substrate surface on total wetting transitions.

Critical wetting is also accompanied by an increase in surface fluctuations. The parameter $\nu_{\|}$ in the temperature variation of the correlation radius, calculated in accordance with the average field theory for models in which the existence of only forces with a small radius of action is postulated, is 1, while $d^* = 3$.[116,124] However, in critical wetting the role of fluctuations is more significant; $\nu_{\|}$ loses its universality and depends on the dimensionless parameter $\omega = k_B T(4\pi\sigma_{\alpha\beta}\xi_{\|}^2)^{-1}$. Three ranges of ω values have been differentiated:[119–122,125] $\omega < 1/2$ with $\nu_{\|} = (1 - \omega)^{-1}$, $1/2 < \omega < 2$ with $\nu_{\|} = (2^{1/2} - \omega^{1/2})^{-2}$, and $\omega > 2$ with $\nu_{\|} = \infty$. It has been suggested[122,128] that, for pure liquids, their binary mixtures, and polymer systems (as well as other systems which belong to this class of universality), the parameters ω near T_c refer to the second region (according to Moldover,[13] $\omega \simeq 0.8$). If the fluctuations in the wetting films are small, then $\nu_{\|} = 1$. The transition from the classical forms of critical conditions, obtained on the basis of the average field theory, to the non-classical form occurs when the correlation radius of the surface fluctuations is equal to to 5–6 molecular diameters.[129] The experimental confirmation of the relations described in real systems, where long-range forces play an important role, is hardly feasible.

Under the conditions of the existence of long-range forces, the critical behaviour of three-dimensional systems is independent of the surface tension and surface fluctuations do not alter the average field

regime.[99,119] For potentials of the type $V(l) = A(T - T_{cW})l^{-n} + Bl^{-m}(A, B > 0, m > n > 0)$, we have $\beta_s = -1/(m-n)$ and $\nu_{||} = (m+2)/2(m-n)$. So far the problem of the experimental confirmation of the theory remains open.

VIII. CRITICAL ADSORPTION

The picture of the influence of the surface on PT in two-component systems must be supplemented by considering the adsorption of the components from a homogeneous mixture having the critical composition. It has been established that in the vicinity of T_c an anomalous increase in the degree of adsorption of one of the mixture components on the surface of the wall is observed. This phenomenon is called critical adsorption. Its essential feature reduces to the following. Under the conditions of the preferential interaction of one of the components with the wall, the composition of a mixture of liquids changes over distances from the wall surface comparable to the correlation radius of the fluctuations in the bulk phase. Since the approach to T_c induces a sharp increase in the fluctuations in the system, within a certain concentration and temperature range near the critical point, an extended region should arise at the substrate surface in which the mixture composition differs from the bulk-phase composition. The closer the system is to the critical point, the wider the layer of liquid in which the composition is modified.

The critical adsorption phenomenon, first observed by Rusanov and co-workers,[130-132] has become the subject of intense theoretical and experimental studies. It is possible to distinguish two theoretical approaches to the consideration of critical adsorption in two-component systems. The first of these is based on the thermodynamic Gibbs relation for adsorption:[133]

$$\Gamma_{B(A)} = -\left(\frac{\partial\sigma}{\partial\mu}\right)_T = -\left(\frac{\partial\sigma}{\partial\varphi}\right)_T\left(\frac{\partial\varphi}{\partial\mu}\right)_T, \tag{35}$$

(where $\Gamma_{B(A)}$ is the relative degree of adsorption) and requires knowledge of the equation of state and of the character of the variation of the surface tension as a function of mixture composition and temperature in the critical region. In modern theories of critical phenomena,[1-3] the dependence of the chemical potential on composition is described by the expression $|\mu - \mu_c| \simeq |\varphi - \varphi_c|^{4.8}$, where μ_c is the critical potential of component B in the mixture at the critical point. The studies by Widom and co-workers[134-138] have led to the conclusion that, in the vicinity of the critical point, the surface tension is a monotonic function of composition, increasing with increase in the concentration of the component with a higher value of σ. At the critical temperature, the form of the function $\sigma(\varphi)$ is analogous to the form of the critical isotherm for a one-component liquid. The form of the dependence of the surface tension on concentration has been established:[133,138]

$$|\sigma - \sigma_c| \propto |\varphi - \varphi_c|^{\mu/\beta}, \mu/\beta \cong 3.9. \tag{36}$$

When the classical values of the critical parameters $\mu = 3/2$ and $\beta = 1/2$ are used, the concentration dependence of the deviation of the surface tension from its value at the critical point σ_c becomes more pronounced:[133,134]

$$|\sigma - \sigma_c| \propto |\varphi - \varphi_c|^3 \ln[|\varphi - \varphi_c|^{-1}]. \tag{37}$$

The experimental data for the nitrobenzene–hexane,[131] nitroethane–3-methylpentane,[137] and isobutytric acid–water[137,138] systems agree with the principal theoretical conclusions concerning the character of the variation of σ with concentration. However, the inadequate accuracy of the methods for the measurement of surface tension and the methodological difficulties arising in measurements in the critical region makes it impossible to determine which of the relations (36) and (37) holds.

The temperature dependence of the degree of adsorption near T_c can be obtained from Eqns.(35)–(37):

$$\Gamma_{B(A)} \propto |t|^{\beta-\nu} = |t|^{-0.3}, \tag{38}$$

$$\Gamma_{B(A)} \propto \ln|t^{-1}|, \tag{39}$$

where ν is the critical exponent in the temperature variation of the correlation ranges of the volume fluctuations. (The classical form of the equation of state $|\mu - \mu_c| \propto |\varphi - \varphi_c|^3$ is used in the derivation of the last relation.)

The second way of investigating critical adsorption is associated with the elucidation of the concentration profile at the interface beween the binary liquids with the critical composition and the wall. This procedure can be used in the analysis of the liquid–vapour and liquid–solid interfaces. A wide variety of theoretical approaches are adopted for the investigation of the form of the concentration profile: the average field theory,[134-136] scaling,[139] the renormalised group method,[140-142] and the method of functional expansions.[143-145] We may note that in the case under consideration an approximation is used according to which the existence of surface forces with a small radius of action is postulated. This approximation is entirely justified, since, with increase in the correlation radius, the wall has no influence over long distances ($z > \xi$).

The average field theory postulates a slow decrease in the concentration of the adsorbed component with increase in the distance from the surface:[133,134,143]

$$\Delta\varphi(z) = \varphi(z) - \varphi_c \propto z^{-1}. \tag{40}$$

More realistic models, constructed either on the basis of the equations of state for two-component liquids, reflecting the real features of the critical systems,[133,135,140,143,144] or using modern theories of critical phenomena,[139-142] yield a different form of the concentration profile. According to a number of workers,[139-142] one of the mixture components is adsorbed preferentially at the boundary with the substrate at the critical point, the decrease in the concentration of this component on moving away from the wall obeying the law

$$\Delta\varphi(z) \propto z^{-\beta/\nu}. \tag{41}$$

If the experimental temperature differs from T_c, then Eqn.(41) holds only within the limits of the correlation radius and is then replaced by another equation according to which the composition changes faster:

$$\Delta\varphi(z) \propto \exp(-z/\xi), \quad z \gg \xi. \tag{42}$$

The excess concentration of the adsorbed component can be determined by analysing the profile

$$\Gamma \propto \int_0^\infty \Delta\varphi(z)\,dz. \tag{43}$$

In order to elucidate the character of the temperature variation of the degree of adsorption, one introduces the hypothesis that, over distances exceeding the molecular size a, Eqns.(41) and (42) hold, while in the range $0 < z < a$ the concentration is constant and $\varphi(z) = \varphi_s$. In this case, the surface excess is described by an expression of the type

$$\Gamma = a\varphi_s\left[\frac{2\nu-\beta}{\nu-\beta}\left(\frac{\xi}{a}\right)^{1-\beta/\nu} - \frac{\beta}{\nu-\beta}\right] \propto |t|^{\beta-\nu}. \tag{44}$$

(For a liquid–vapour interface, a similar discussion has been published elsewhere.[133-136,143-145])

The critical liquid–vapour[130–132,146–150] and critical liquid–solid wall[151–155] interfaces are studied experimentally with the aid of a wide variety of optical methods. In the studies quoted above, an anomalous behaviour of structure-centred parameters in the vicinity of the critical point has been noted. In the study of the surface of the nitrobenzene–hexane binary mixture having a nearly critical composition, a sharp increase in the ellipticity coefficient was observed in the vicinity of T_c.[130,142] Ellipsometric studies of the liquid–vapour interfaces in various critical mixtures have been continued.[150] Rusanov and Pshenitsyn,[130] Peliti and Leibler,[142] and Schmidt and Moldover[150] concluded that the observed anomalies are caused solely by surface phenomena and indicate an increase in the degree of adsorption in the critical region. Critical adsorption of the components of the nitrobenzene–hexane mixture on a glass surface has been investigated by the fluorescence method.[151] The increase in the fluorescence intensity near the critical point is explained by the selective interaction of nitrobenzene with glass. It has been established[152–154] that an increase in the intensity of the reflection of light from the interface between glass and a mixture of nitromethane with carbon disulphide is due to the critical adsorption of nitromethane; the change in the polarity of the glass induced by making it hydrophobic promoted the preferential interaction of carbon disulphide with the substrate and the consequent decrease in the reflection coefficient.

Although there is convincing evidence for the anomalously high degree of adsorption in the critical region, a quantitative interpretation of the experimental results presents certain difficulties. Firstly, it is necessary to establish the relation between the parameters measured experimentally and the degree of adsorption[146,149] and the distribution of concentration in space.[76,148,150,155] Secondly the conclusion about the temperature variation of the degree of adsorption or about the concentration profile must be based on a comparison of relations fairly similar in form: $\Gamma \propto \ln(t^{-1})$ and $\Gamma \propto (t)^{-0.3}$, $\Delta\varphi(z) \propto z^{-1}$ and $\Delta\varphi(z) \propto z^{-1/2}$. These factors are apparently the cause of the ambiguous interpretation of the experimental data. Thus a logarithmic temperature dependence of the degree of adsorption of cyclohexane at the interface with vapour from solutions in aniline has been established.[146,147] It has been found[149] that the critical adsorption parameter is 0.35 ± 0.15, but at the same time there is a temperature range in which the results are described satisfactorily by linear relation between Γ and $\ln(t^{-1})$. On the basis of a study of the temperature variation of the ellipticity coefficient of the light reflected from the interface between the vapour and a solution of polystyrene in cyclohexane, it has been demonstrated[75] that, for the critical adsorption of the solvent, the concentration profile corresponds to Eqns.(41) and (42). The data of Heidel and Findenegg[148] also agree with the model for which Eqns.(41) and (42) are valid, but the $\Delta\varphi(z) \propto z^{-1}$ relation cannot be fully excluded. The application of the methods for the solution of the converse ellipsometric problem developed recently may prove useful for the final elucidation of the question of the distribution of concentration in the adsorption layer under the conditions of critical adsorption, together with an increase in experimental accuracy.[156]

---o0o---

It follows from the data presented that the presence of the wall leads to the appearance of a whole range of transitions near the surface. The study of the physics of phase transitions and of the physical chemistry of surfaces has ensured during the last 5–10 years rapid progress in the theory of transitions induced by the presence of the wall. In a brief review, it is impossible to reflect fully all the fine details of the models used in the consideration of various aspects of wetting transitions and to discuss comprehensively all the theoretical results obtained with their aid. Preference has been given to the clearest data reflecting important aspects of the phenomenon.

The experimental study of the problem requires considerable effort associated both with the preparation of the objects of study and with the careful thermostatic control of the system, on the one hand, and with the long equilibration time, on the other. So far there are no experimental data on wetting transitions in polymer systems, although certain hopes for the attainment of a combination of the interactions between the components which is manifested in the form of critical wetting are in fact associated with precisely these systems. There are scanty data concerning the existence in a homogeneous system of regions characterised by significantly different degrees of adsorption of the mixture components on the substrate. There have been no studies whatever of labile states of the surface layer. These and other questions require comprehensive consideration.
