Oxidation of Sulphur Dioxide in Aqueous Solutions

V.A.Golodov and L.V.Kashnikova

The sulphur dioxide oxidation reactions in aqueous solutions under mild conditions are examined. The kinetics of the oxidation of SO_2 to H_2SO_4 by various oxidants are described, the reaction mechanism is discussed, and its possible practical applications are indicated.
The bibliography includes 96 references.

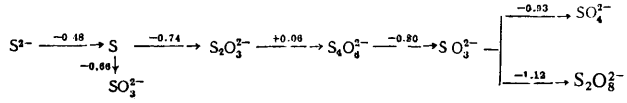
IV. Conclusion 1037

I. INTRODUCTION



The SO_2 oxidation reactions under mild conditions are of interest from the theoretical point of view for the study of the detailed mechanism of the inner-sphere transformations of the substrate molecules. The study of such processes is important also from the practical point of view because they can be used to develop methods for the elimination of the highly toxic component (sulphur dioxide) from the waste gases generated in metallurgical and other industries. (The discharged sulphur dioxide is known to cause considerable damage in nature, to spoil buildings and equipment, and to cause their breakdown.) Although the SO_2 concentration in waste gases is usually low, its overall release throughout the world can be measured in hundreds of millions of tonnes. Therefore, together with the solution of the ecological problems, the utilisation of waste gases makes it also possible to obtain large amounts of sulphuric acid. The use of liquid-phase catalysts is desirable precisely in the oxidation of gas mixtures with a low SO_2 content where heterogeneous catalysts are ineffective.

Three types of reactions are characteristic of sulphur dioxide: reactions occurring without change (a), with decrease (b), and with increase (c) in the valence of sulphur. The oxidation state of sulphur in compounds varies from -2 to +6. In the schemes below, the oxidation-reduction potentials of the corresponding transitions between different sulphur compounds are indicated above the arrows (in V):[1]

(1) Acid solutions:

(2) Alkaline solutions:

The dissolution of SO_2 in water with formation of hydrates and sulphurous acid may serve as an example of reactions in which there is no change in the valence of sulphur:

$$H_2O + SO_2 \rightleftharpoons H_2SO_3 \overset{K_1}{\rightleftharpoons} H^+ + HSO_3^- \overset{K_2}{\rightleftharpoons} 2H^+ + SO_3^{2-}, \qquad (1)$$

where $pK_1 = 1.92$ and $pK_2 = 7.2$.[1] The interaction of sulphur dioxide with bases and the salts of weak acids leads to salts of sulphurous acid.[2]

There is no direct proportionality between the total absorption of SO_2 and its partial pressure (above 1 atm), i.e. Henry's law is not applicable to the dissolution of SO_2 in water.[2] On the other hand, it has been established that the dependence of the solubility of SO_2 in water on pressure (up to 1 atm) is close to linearity. The solubility of SO_2 in sulphuric acid at pressures up to 1 atm obeys Henry's law. With increase in the H_2SO_4 concentration from 0 to 85%, the solubility of SO_2 gradually falls, while in more concentrated acid solutions it increases.[3]

The dissolution of SO_2 in water and sulphuric acid is widely used in chemical industry. The dependence of the solubility of sulphur dioxide on its partial pressure and also on temperature and acidity has been studied in detail,[3] which is important for the solution of practical problems in the manufacture of sulphuric acid. According to equilibrium (1), the solubility of SO_2 in water can be increased by lowering the H^+ concentration or by removing sulphite ions by oxidising them to sulphate ions. However, in the latter case the concentration of H^+ ions increases somewhat, since the H_2SO_4 formed is more ionised than sulphurous acid: this partly weakens the influence of the decrease in the sulphite concentration on the solubility of SO_2.[4]

The physicochemical principles of the sulphur dioxide extraction and concentration processes have been examined in greatest detail by Rozenknop,[2] who quotes the solubilities of SO_2 in water, in solutions of strong acids and bases as well as salts, and in heterogeneous systems and provides equations from which it is possible to calculate the temperature dependence of the vapour pressures of sulphur dioxide solutions.

The heats of the reactions occurring during the absorption of SO_2 have the following values:[2]

$$SO_2 + H_2O \rightleftharpoons H_2SO_3 + 26 \text{ kJ},$$
$$H_2SO_3 \rightleftharpoons H^+ + HSO_3^- + 16 \text{ kJ}.$$

If the absorber is a base, then

$$H^+ + OH^- \rightleftharpoons H_2O + 56 \text{ kJ}.$$

If the absorber is the salt of a weak acid, then the heat of absorption of SO_2 is equal to the heat of ionisation of this acid.

The most suitable absorbers for sulphur dioxide are the following buffer solutions at fairly high pH:[5] (1) solutions of salts of a weak acid and a strong base (for example, sodium sulphite and bisulphite); (2) solutions of salts of a strong acid and a weak base (for example, basic aluminium sulphite); (3) solutions of salts of a weak acid and a weak base (for example, ammonium sulphite and bisulphite); (4) solutions of salts of weak acids in the presence of the free acid (sulphites and bisulphites in the presence of organic acids). Water is used to absorb SO_2 from gases when its concentration is $\geqslant 7$ vol.%; for more dilute gases, this method is uneconomical because of the large consumption of water and the expenditure of heat on desorption.[5]

The kinetics of the absorption of sulphur dioxide by solutions of ammonia and ammonium sulphite-bisulphite have been investigated[6] at 298 K and it has been established that, when SO_2 is absorbed by NH_3 solutions, the following rapid two-stage reaction takes place:

$$SO_2 + 2NH_3 \xrightarrow{H_2O} (NH_4)_2 SO_3,$$

while in solutions of ammonium sulphite an irreversible interaction of SO_2 with SO_3^{2-} ions occurs. The study of the kinetics of the absorption of sulphur dioxide by NH_4OH, NaOH, KOH, Na_2CO_3, and Na_2SO_3 solutions showed[7] that, with decrease in their concentration, the rate of absorption of SO_2 increases for all the absorbers except sodium sulphite. In this case the chemisorption process is limited by the diffusion of SO_2 in the liquid phase and the viscosity of these solutions increases linearly with their concentration. The order of the reaction with respect to SO_2 is close to zero.

The absorbers can be arranged in the following sequence in terms of decreasing SO_2 absorption rate constants (at 293 K):

$$NH_4OH\ (8.99) > KOH\ (5.126) > NaOH\ (5.078) > Na_2CO_3\ (4.931) > > Na_2SO_3\ (4.217\ m^3\ kmol^{-1}\ h^{-1}).$$

The equation for the rate of reaction for different compounds can be written in the general form

$$w = Ae^{-B\tau},$$

where τ is the time in min and A and B are constants which depend on the nature of the absorber and have the following values: 5.8521 and 0.0469 for Na_2SO_3; 6.314 and 0.0254 for Na_2CO_3; 6.6205 and 0.0173 for KOH; 7.3205 and 0.0151 for NaOH; 9.9144 and 0.0048 for NH_4OH.

Few chemical processes are accompanied by a decrease in the valence of sulphur. The reactions of SO_2 with hydrogen sulphide and carbon monoxide may serve as examples:[2]

$$SO_2 + 2H_2S \rightarrow 2H_2O + 3S,$$
$$SO_2 + CO \rightarrow 2CO_2 + S.$$

Reactions occurring with increase in the valence of sulphur are most characteristic of sulphur dioxide. Thus sulphur dioxide combines with chlorine even in sunlight. The interaction of SO_2 with oxygen proceeds as a rule at a high temperature and in the presence of catalysts:[2]

$$2SO_2 + O_2 \xrightarrow{\text{catalyst}} 2SO_3.$$

In an aqueous medium, the oxidation of sulphur dioxide by compounds (ions) with a high oxidation-reduction potential is fairly rapid. In most cases, the process then proceeds with formation of sulphuric acid via a mechanism which we believe to involve the oxidative sulphonation of water[8] and subsequent regeneration of the reduced species Red by molecular oxygen:

$$SO_2 + 2H_2O + Ox \rightarrow H_2SO_4 + Red + 2H^+,$$
$$Red + O_2 + 4H^+ \rightarrow Ox + 2H_2O,$$
$$SO_2 + O_2 + 2H^+ \rightarrow H_2SO_4.$$

The oxidation of SO_2 in aqueous solutions to sulphuric acid is very important for the extraction of sulphur dioxide from gases, but it has still been inadequately investigated.[9]

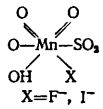
Numerous studies have been devoted to the high-temperature heterogeneous processes involving the oxidation of SO_2 to SO_3—the main method of synthesis of sulphuric acid.[10–15] On the other hand, the oxidation of SO_2 under mild conditions has been described in the literature to a much lesser extent, although it is attractive from the standpoint of economising on energy resources and leads to new possibilities for the investigation of the mechanism of catalysis by complex compounds and solutions.

II. CATALYTIC AND NON-CATALYTIC REACTIONS INVOLVING THE OXIDATION OF SO_2 BY VARIOUS COMPOUNDS

In aqueous media, the oxidation of sulphur dioxide by complex metal anions and molecular oxygen under the influence of homogeneous catalysts is fairly rapid with the formation of H_2SO_4. Table 1 indicates the metal ions (M^{n+}) which oxidise SO_2 to H_2SO_4 in aqueous solutions and also the energetic and kinetic characteristics of oxidation-reduction reactions of the type:

$$2M^n + SO_2 + 2H_2O \rightarrow 2M^{n-1} + H_2SO_4 + 2H^+.$$

Table 1. Kinetic and energetic characteristics of the processes leading to the oxidation of SO_2 to H_2SO_4 in aqueous solutions.



Ion	Active form of complex ion	T, K	Rate constant	E_a, kJ mol^{-1}	ΔS^*, J mol^{-1} K^{-1}	Refs.

Notation. T is the temperature, E_a the activation energy, and ΔS^* the activation entropy.

The oxidation of sulphur dioxide by manganese(VII), chromium(VI), and selenium(IV) compounds and $S_2O_8^{2-}$ has been studied in detail.[16–18,24,25] Thus potassium permanganate is readily reduced by sulphur dioxide in the presence of the F^-, I^-, or OH^- ions in accordance with the stoichiometric equation[16]

$$2MnO_4^- + 5SO_2 + 2H_2O \rightarrow 2Mn^{2+} + 5SO_4^{2-} + 4H^+.$$

The reaction is of first order with respect to the oxidant, the reductant, and H^+ ions. It is believed that the rate-limiting stage of the process is inner-sphere redox decomposition of the intermediate complex incorporating all the reaction components:

Depending on the nature of the ligand-catalyst (OH^-, F^-, I^-), which effects electron transfer between the oxidant and the reductant, the rate of the process varies significantly: the activity of the ligands increases in the sequence $F^- < OH^- < I^-$. It is believed that the high activity of the I^- ion is due to the fact that it is a stronger nucleophile than the F^- and OH^- ions.[16]

Sulphur dioxide is oxidised by chromium(VI) in accordance with the equation

$$2CrO_4^{2-} + 3SO_2 + 4H^+ \rightarrow 2Cr^{3+} + 3SO_4^{2-} + 2H_2O.$$

In the range of $HClO_4$ concentrations up to 10 M, the reaction is of first order with respect to Cr^{3+}, SO_2, and H_3O^+.[17,18] The proposed reaction mechanism includes the formation of the protonated form of chromium(VI) with subsequent addition to the latter of a SO_2 molecule. The stage in which the chromium(VI) complex of sulphur dioxide $CrO_3(OH)SO_2^-$(aq.) decomposes is rate-limiting:

$$\begin{gathered} SO_2 \overset{H_2O}{\rightleftharpoons} SO_2\,(aq), \\ CrO_4^{2-} + H_3O^+ \rightleftharpoons CrO_3\,(OH)^-\,(aq) + H_2O, \\ CrO_3\,(OH)^-\,(aq) + SO_2 \rightleftharpoons CrO_3\,(OH)\,SO_2^-\,(aq) + H_2O, \\ CrO_3\,(OH)\,SO_2^-\,(aq) \rightarrow CrO_3^- + HSO_3, \\ 2HSO_3 \rightarrow H_2SO_4 + SO_2. \end{gathered}$$

The rate of reaction is described by the equation

$$w = k \cdot [CrO_3\,(OH)\,SO_2^-\,(aq)].$$

The oxidation of sulphur dioxide by selenous acid[18]

$$H_2SeO_3 + 2SO_2 + H_2O \rightarrow Se + 2H_2SO_4$$

is greatly accelerated in the presence of proton-ligand catalysts. In the $H_2SeO_3 - HClO_4 - KI - H_2O$ system, the reaction is of first order with respect to Se^{4+}, SO_2, and KI; the order with respect to hydrogen ions is close to two. According to the reaction mechanism proposed,[18] hydrogen ions protonate the oxygen atoms in the SeO_3^{2-} anion after which the protonated forms form complexes with the dissolved sulphur dioxide and I^- ions:

$$\begin{gathered} SeO_3^{2-}\,(aq) + j\,H_3O^+ \rightleftharpoons SeO_m\,(OH)_n^{4-2m-n}\,(aq) + j\,H_2O, \\ SeO_m\,(OH)_n^{4-2m-n}\,(aq) + I^- \rightleftharpoons SeO_m\,I^{3-2m-n}\,(OH)_n\,(aq), \\ SeO_m I\,(OH)_n^{3-2m-n}\,(aq) + SO_2\,(aq) \rightleftharpoons SeO_m\,(OH)_n\,I\,(SO_2)^{3-2m-n}\,(aq). \end{gathered}$$

The redox reaction of the complexes $SeO_m(OH)_nISO_2^{3-2m-n}$(aq.) in stage (2) limits the rate of the process. The subsequent reduction of selenium(III) is rapid and is not reflected in the reaction kinetics:

$$\begin{gathered} SeO_m\,(OH)_n\,I\,(SO_2)^{3-2m-n}\,(aq) \rightarrow SeO_m\,(OH)_n\,(I^0)\,SO_2^{3-2m-n}\,(aq), \\ SeO_m\,(OH)_n\,(I^0)\,SO_2^{3-2m-n}\,(aq) \rightarrow Se^{3+} + I^- + HSO_3, \\ Se^{3+} + HSO_3 \rightarrow H_2SO_4 + Se^0. \end{gathered} \qquad (2)$$

The rate of reaction depends on the relative contents of the protonated forms $Se(IV) - SeO^{2+}$(aq.) and $SeOH^{3+}$(aq.) (κ_1 and κ_2 respectively) which exhibit the highest activity in the oxidation of sulphur dioxide:

$$w = (k_1\kappa_1 + k_2\kappa_2)\,[I^-]\,[SO_2],$$

where k_1 and k_2 are the partial rate constants.

It has been observed that sulphur dioxide is rapidly oxidised by mercury(II) to sulphuric acid in the presence of $HClO_4$ (at a concentration of 2–8 M) with formation of metallic mercury.[19] The reaction orders with respect to Hg^{2+} and SO_2 are close to unity. According to Golodov and Panov,[19] the process includes the following stages:

$$\begin{gathered} HgX_n^{2-n}\,(aq) + SO_2\,(aq) \rightleftharpoons HgX_nSO_3^{2-n}\,(aq) + H_2O, \\ HgX_nSO_3^{2-n}\,(aq) \xrightarrow{2H_2O} Hg^0 + SO_4^{2-} + 4H^+ + n\,X, \\ X^- = Ac^-,\ NO_3^-. \end{gathered}$$

The oxidation of SO_2 by hydrogen peroxide in aqueous solution (ionic strength 1.0; pH 4–8) is of interest.[26,27] For example, it has been established that the reaction orders with respect to SO_2 and H_2O_2 are unity and that with respect to hydrogen ions varies from 1 in the pH range 4.5–6.5 to 2 in the pH range 6.5–8.0. The reaction is accelerated in the presence of proton donors (HA) in conformity with the mechanism of general acid catalysis. It is believed that the process mechanism includes the following stages:

$$\begin{gathered} HSO_3^- \overset{K}{\rightleftharpoons} SO_3^{2-} + H^+, \\ HSO_3^- + H_2O_2 \rightleftharpoons H_2O + HOOSO^-, \\ HOOSO^- + HA \rightarrow H_2SO_4 + A^- \end{gathered}$$

($HOOSO^-$ is the monopersulphurous acid anion).

The rate of reaction is described by the equation

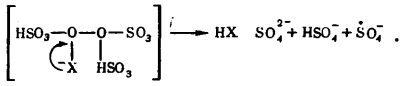
$$w = [H_2O_2]\,[SO_2]\,\{[H^+]/([H^+] + K)\}\,(k_1[H^+] + k_2[HA]),$$

where $k_1 = 58$ and $k_2 = 720$ litre^2 mol^{-2} s^{-1} at $T = 285$ K. The activation energy of the process is 37 ± 2 kJ mol^{-1} and the activation entropy is ~4 J mol^{-1} K^{-1}.

The oxidation of sulphur dioxide by sodium persulphate in the absence of catalysts,

$$Na_2S_2O_8 + SO_2 + 2H_2O \rightarrow Na_2SO_4 + 2H_2SO_4,$$

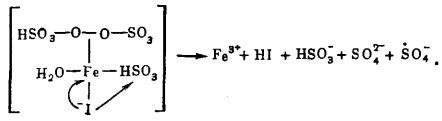
proceeds at low rates.[24,25] The reaction takes place vigorously when acted upon jointly by protic and ligand catalysts. It is believed that sulphur dioxide reacts in the form of HSO_3^- anions in the $Na_2S_2O_8 - HClO_4 - KI - SO_2 - H_2O$ and $Na_2S_2O_8 - HClO_4 - LiBr - SO_2 - H_2O$ systems, because it is known that the addition of the OH^- anion to SO_2 intensifies the reducing properties of the latter as a result of the increase in electron density in the donor orbital of the S atom.[28]



It has been suggested[28] that HSO_3^- anions are oxidised in the following way. The protonated form of the persulphate anion interacts initially with the halide ion X^-, i.e.

$$S_2O_7OH^-\,(aq) + X^- \rightleftharpoons [S_2O_7\,(OH)\,X]^{2-}\,(aq),$$

and the complex $[S_2O_7(OH)X]^{2-}$(aq.) then reacts with HSO_3^-:



$$[S_2O_7\,(OH)\,X]^{2-}\,(aq) + HSO_3^- \rightleftharpoons [S_2O_7\,(OH)\,XHSO_3]^{3-}\,(aq).$$

In the rate-limiting stage, the active complex undergoes a redox reaction via the following mechanism:

It is believed[28] that the ligand (halide ion) gives up its electron to the peroxide linkage in the persulphate ion and then in the form X^0 oxidises HSO_3^-, being itself reconverted into X^-. Such electron redistribution takes place within the limits of the inner sphere of the complex.

The rate-limiting stage in the oxidation of HSO_3^- anions by persulphate anions in the presence of iron(III) is the reaction[25]

The iodide ion gives up its electron to the central atom of the complex, attacks the coordinated donor in the inner sphere, and is reduced to I. In its turn, Fe^{3+} transfers an electron to the peroxide linkage of the persulphate ion, as a result of which the latter is ruptured with subsequent decomposition of the complex. The reaction mechanism in the presence of iron(III) ions differs from that examined above in the fact that the metal in the complex facilitates the electron transfer from the iodide ion to the persulphate ion.

The oxidation of sulphite anions by the individual Fe^{3+} hexacyanoferrate(III) complex has also been investigated at 298 K.[20] The authors believe that the process proceeds as follows:

$$SO_3^{2-} + Fe(CN)_6^{3-} \rightleftharpoons Fe(CN)_6^{4-} + \dot{S}O_3^-,$$
$$Fe(CN)_6^{3-} + \dot{S}O_3^- \rightarrow Fe(CN)_5(CN\dot{S}O_3)^{4-},$$
$$Fe(CN)_5(CN\dot{S}O_3)^{4-} + H_2O \rightarrow Fe(CN)_6^{4-} + SO_4^{2-} + 2H^+.$$

The rate of reaction is described by the equation

$$\omega = k_M[M][SO_3^{2-}][Fe(CN)_6^{3-}],$$

where M is the Na^+ or K^+ ion, $k_{Na^+} = 0.52 \pm 0.02$ litre^2 mol^{-2} s^{-1}, and $k_{K^+} = 1.15 \pm 0.04$ litre^2 mol^{-2} s^{-1}. The oxidation of sulphite anions by hexacyanoferrate is weakly inhibited by molecular oxygen.

The liquid-phase oxidation of SO_2 by iron salts has been studied in acid solutions.[29] The increase in the $HClO_4$ concentration from 0.1 to 2.5 M leads to the formation in solution of the $SO_2.H_2O$ species, whose reactivity is low, as a result of which the rate of the process falls. The reaction orders with respect to SO_2 and Fe^{3+} are close to unity. The reaction mechanism presupposes the formation of the thionate radical HSO_3, which reacts with Fe^{3+} to form sulphate anions.

It has been observed[30] that Co^{3+} salts are more effective catalysts of the oxidation of sulphite ions than Fe^{3+} and Fe^{2+} salts. In the presence of cobalt nitrate, the concentration of sulphite ions at room temperature decreases by a factor of 7 in 3 h. A similar catalytic solution may be used to purify gases with a low SO_2 content.

The oxidation of sulphur dioxide by copper halides in the $CuCl_2-HCl-KI-H_2O$, $CuBr_2-HBr-KI-H_2O$, and $CuBr_2-LiBr-H_2O$ systems has been studied in greatest detail.[18,21,31] It takes place in accordance with the equation

$$2CuX_2 + SO_2 + 2H_2O \rightarrow 2CuX + H_2SO_4 + 2HX. \quad (3)$$

The reaction orders with respect to copper(II) and SO_2 were shown to be close to unity. Univalent copper increases the initial rate of the process by activating HSO_3^- anions (Figs.1 and 2).

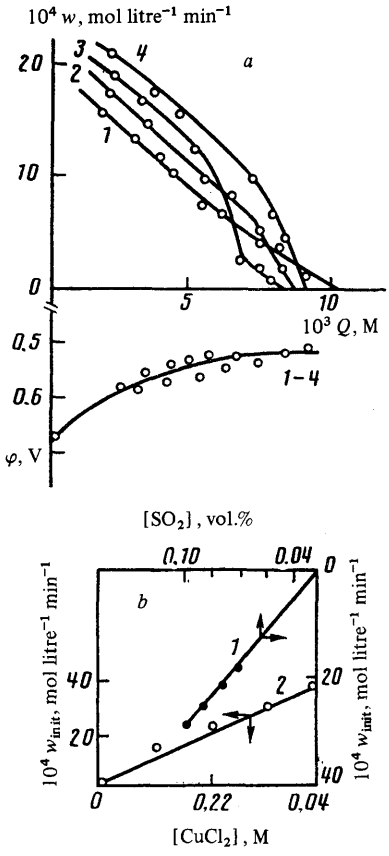


Figure 1. Oxidation of SO_2 by copper(II) chloride at 293 K, [HCl] = 4.8 M, and [KI] = 8 × 10^{-4} M: (a) dependence of the rate of oxidation w and of the potential of the system φ (calculated with respect to the hydrogen electrode potential) on the amount of SO_2 which has reacted for $[CuCl_2]$ = 0.02 M and different initial SO_2 concentrations (vol.%) [(1) 0.062; (2) 0.076; (3) 0.086; (4) 0.103]; (b) dependence of the initial rate of oxidation on $[SO_2]$ (line 1) for $[CuCl_2]$ = 0.02 M and on $[CuCl_2]$ (line 2) for $[SO_2]$ = 0.086 vol.%.[18]

The reduction of Cu^{2+} to Cu^+ takes place in the inner-sphere redox decomposition of Cu^{2+} complexes with HSO_3^- anions via two parallel pathways:

(a) first pathway (X^- = halide ion):

$$CuX_mHSO_3^{1-m}(aq) \rightarrow HSO_3 + CuX_n^{1-n}(aq),$$
$$CuX_m^{2-m}(aq) + HSO_3 + H_2O \rightarrow H_2SO_4 + CuX_n^{1-n}(aq) + H^+;$$

(b) second pathway [associated with the activation of HSO_3^- anions by copper(I)]:

$$Cu_2X_{(n+m)}HSO_3^{2-m-n}(aq) \rightarrow 2CuX_n^{1-n}(aq) + HSO_3.$$

In the reduction of copper(II) by sulphur dioxide in the presence of iodide ions, there is a possibility of electron transfer to the central atom and the formation in the inner sphere of the ligand I^0, which oxidises the HSO_3^- anion to HSO_3:

(a) first pathway:

$$CuX_mI(HSO_3)^{m-}(aq) \rightleftharpoons CuX_m(I^0)(HSO_3)^{m-}(aq),$$
$$CuX_m(I^0)(HSO_3)^{m-}(aq) \rightarrow HSO_3 + CuX_n^{1-n}(aq) + I^-;$$

(b) second pathway [associated with the activation of HSO_3^- anions by copper(I)]:

$$Cu_2X_{(m+n)}I(HSO_3)^{1-m-n}(aq) \rightleftharpoons Cu_2X_{(m+n)}(I^0)(HSO_3)^{1-m-n}(aq),$$
$$Cu_2X_{(m+n)}(I^0)(HSO_3)^{1-m-n}(aq) \rightarrow HSO_3 + 2CuX_n^{1-n}(aq) + I^-.$$

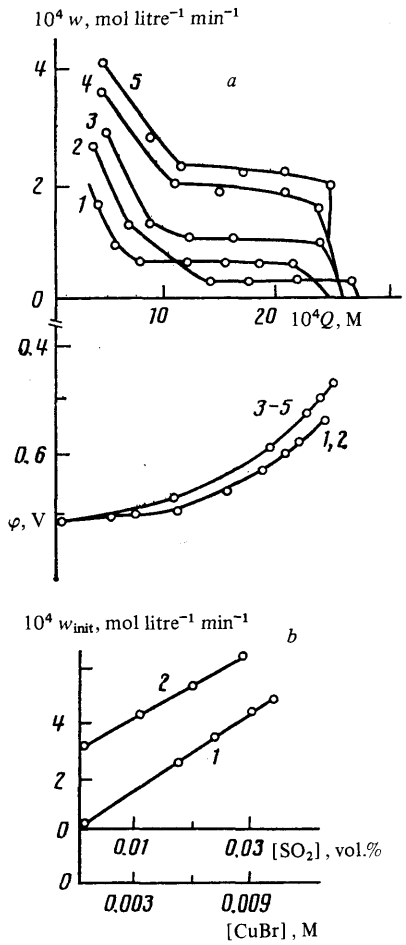

Figure 2. Oxidation of SO_2 by copper(II) bromide at 293 K, [HBr] = 6.0 M, and [KI] = 0.5 × 10^{-3} M: (a) dependence of the rate of oxidation w and of the potential of the system φ on the amount of SO_2 which has reacted for [$CuBr_2$] = 0.005 M and different initial SO_2 concentrations (vol.%) [(1) 0.017; (2) 0.023; (3) 0.028; (4) 0.032; (5) 0.035]; (b) dependence of the initial rate of oxidation on [SO_2] (line 1) for [$CuBr_2$] = 0.005 M and on [CuBr] (line 2) for [$CuBr_2$] = 0.003 M and [SO_2] = 0.028 vol.%.[18]

This scheme explains the catalytic action of the I^- ion (first order with respect to I^-), which served as a "mediator" in the electron transfer from SO_2 to Cu^{2+}. Bearing in mind that the reduction of copper(II) by sulphur dioxide in the $CuBr_2-LiBr-H_2O$ system in the presence of bromide ions alone, takes place at high concentrations of the latter, [Br^-] = 2–8 M and [Cu^{2+}] ≪ [Br^-], we suggest that homoligand copper(II) bromide complexes are the catalysts in this process. The activity of the chloride complexes in the SO_2 oxidation reactions has been observed only at a high sulphur dioxide concentration (100 vol.%).[32]

The rate of reduction of Cu^{2+} depends on the nature of the catalyst. The rate equation is[21]

$$w = (k_1 + k_2[Cu^+])[Cu^{2+}][SO_2],$$

where k_1 and k_2 are the rate constants for the first and second pathways respectively. Since the dependence of the rate of reduction of copper(II) by sulphur dioxide on the current copper(I) concentration is described by descending curves (Fig.1) of a non-autocatalytic character (the decrease in the rate of reaction as a result of the loss of Cu^{2+} is not compensated by its catalytic acceleration by the Cu^+ formed), one may conclude that the first pathway, unrelated to the activation of HSO_3^- anions by copper(I), makes the greatest contribution to the overall rate of the process. However, as a result of the existence of the second pathway, the kinetic curves do not obey a first-order equation with respect to CuX_2, while in the reduction of copper(II) bromide-iodide complexes, a "zero order" is observed over a large extent of the kinetic curves (Fig.2).[31]

Table 2. The activities of copper(II) halide complexes in the SO_2 oxidation reaction.[18,21,31]

Complex; system	k_1, litre mol^{-1} min^{-1}	k_2, litre^2 mol^{-2} min^{-1}	E_1, kJ mol^{-1}	E_2, kJ mol^{-1}	ΔS_1^*, J mol^{-1} K^{-1}	ΔS_2^*, J mol^{-1} K^{-1}
$CuBr_2I^-$ (aq); $CuBr_2$—HBr—KI—H_2O	$5.2\cdot10^2$	$7.7\cdot10^5$	28.8	46.0	—101	0.4
$CuCl_2I^-$ (aq); $CuCl_2$—HCl—KI—H_2O	$3.9\cdot10^2$	$1.7\cdot10^4$	32.6	24.7	—105	—90
$CuBr_3^-$ (aq)	$0.5\cdot10^{-2}$	4.5	44.0	40.0	—52	—5
$CuBr_2$ (aq); $CuBr_2$—LiBr—H_2O	$0.1\cdot10^{-2}$	0.5	—	—	—	—

Notation. k_1 and k_2 are the partial rate constants for the reaction, E_1 and E_2 are the apparent activation energies, and ΔS_1^* and ΔS_2^* are the activation entropies for the first and second pathways respectively.

Calculations and experimental results have shown that complexes with a definite composition of the inner sphere exhibit the highest activity in the reduction of copper(II) by sulphur dioxide. It follows from Table 2 that copper(II) halide complexes can be arranged in the following sequence in terms of their activities:

$$CuBr_2I^-(aq) > CuCl_2I^-(aq) > CuBr_3^-(aq) > CuBr_2(aq).$$

The activation energy for the first stage, which makes the greatest contribution to the overall rate of the process, increases on passing from the bromide-iodide complexes to the chloride complexes and further to the bromide complexes, which is consistent with the reaction rate constants.

The highest activation entropy ($\Delta S_2^* = 0.4$ J mol^{-1} K^{-1}) has been observed for the most active complex $CuBr_2I^-$(aq.) in the $CuBr_2-HBr-KI-H_2O$ system, indicating a high probability of the optimum orientation of the species at the instant of collision.

An appreciable catalytic acceleration of the oxidation of SO_2 by Cl^- and Br^- anions has been observed in a study[33] where the effect of certain anions and cations (Na^+, K^+, NH_4^+, Ca^{2+}, SO_4^{2-}, HCO_3^-, NO_3^-, F^-, Cl^-, Br^-) on the rate of oxidation of sodium sulphite was investigated. A significant cationic effect was not observed and Cl^- and Br^- ions showed an activity at concentrations above 1×10^{-3} M. The insignificant influence of the nature of the cation (Na^+, K^+, NH_4^+) on the oxidation of sulphite anions has also been noted in another study.[34]

It has been observed that the addition of iron chloride to the $CuCl_2-HCl-KI-H_2O$ system significantly increases the rate of oxidation of sulphur dioxide.[22,23] Kinetic and spectroscopic data have led to the conclusion that in the presence of chloride and iodide ions copper(II) and iron(III) form the heteronuclear complexes $CuFeCl_mI^{4-m}$(aq.), which are more active in the reaction with sulphur dioxide than the individual copper and iron complexes. The calculated stability constant of the heteronuclear complex is $\alpha = [Cu^{2+}-Fe^{3+}]/[Cu^{2+}][Fe^{3+}] = 10$.

The reduction of heteronuclear copper(II) and iron(III) complexes by sulphur dioxide also proceeds via two pathways. The reaction by the first pathway, which makes a greater contribution to the overall rate of the process, involves the inner-sphere oxidation-reduction decomposition of these complexes with the HSO_3^- anion in accordance with the equation[22,23]

$$CuFeCl_mIHSO_3^{3-m}(aq) + H_2O \rightarrow CuFeCl_n^{1-n}(aq) + H_2SO_4 + I^- + H^+. \quad (4)$$

The reaction via the second pathway is accelerated as a result of the activation of HSO_3^- anions by copper(I).

The kinetic equation describing the reduction of heteronuclear complexes is

$$w = [Cu^{2+}][Fe^{3+}]^{0.5}[SO_2](k_1 + k_2[Cu^+]),$$

where k_1 and k_2 are the rate constants for the first and second pathways respectively.

An attempt has been made to establish the composition of the heteronuclear complexes corresponding to the formula $CuFeCl_nI^{4-n}$ by the method of isomolar series [continuous variations (Editor of Translation)] (Fig.3).[22,23] The fact that the rate of reaction is a maximum for the ratio $[CuCl_2]:[FeCl_3] = 1:1$ suggested that one Cu^{2+} ion is bound to one Fe^{3+} ion in the active complex.

The existence of heteronuclear complexes in the $CuCl_2-FeCl_3-HCl-KI-H_2O$ system has been confirmed by calorimetric molar ratios and relative yield methods.[23] The formation of heteronuclear complexes is also indicated by the decrease in the intensity of the EPR signal of the $CuCl_2-HCl-KI-H_2O$ solution after the addition of $FeCl_3$ to the latter, demonstrating a decrease in the concentration of the $CuCl_2$ salt as a result of the formation of a heteronuclear complex which does not generate an EPR signal.[23]

In reaction (4), two individual complexes (copper and iron halides) exhibit a synergistic effect. A similar effect has also been observed in the oxidation of sulphur dioxide in aqueous solution by mixtures of manganese and iron salts. The most pronounced effect has been attained in a solution containing 1×10^{-4} M manganese acetate and 1×10^{-6} M iron chloride.[35]

The reason for the acceleration of the S(IV)–S(VI) oxidation is apparently the replacement of the two-stage electronic oxidation of SO_2 by the individual complexes under these conditions by a two-electron single-stage reaction, i.e. the redox process becomes synchronous.

Analysis of the experimental and literature data[18,21-25,31] leads to the conclusion that the reduction of metal complexes by sulphur dioxide proceeds via the formation of an intermediate–the metal complex with the hydrogen sulphite anion, in which the inner-sphere electron transfer from S^{4+} to M^{n+} takes place. It has been established that the components of systems incorporating metal complexes, sulphur dioxide, water, and ligands react in stoichiometric proportions, which rules out a chain mechanism of the reaction.[18,21-25,31]

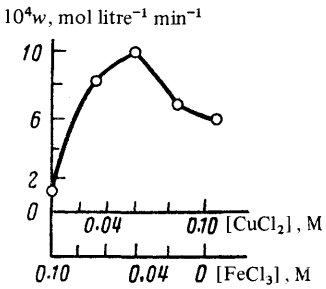

Figure 3. Dependence of the initial rate of reaction on the ratio $[CuCl_2]$: $[FeCl_3]$ at 293 K; [HCl] = 4.8 M; [KI] = 8×10^{-4} M; $[SO_2]$ = 0.58 vol.%.[23]

The electrochemical oxidation reactions of sulphites and SO_2, which readily occur on platinum and graphite anodes, are also of theoretical and practical importance. Thus the study of the anodic oxidation of H_2SO_3 on a platinum electrode showed that the overall rate of the process is determined by the oxidation of the reductant by oxygen from the water adsorbed electrochemically on platinum.[36] The process mechanism can be described by the following scheme:

$$Pt + H_2O - 2e \rightarrow PtO + 2H^+,$$
$$PtO + SO_3^{2-} \rightarrow Pt + SO_4^{2-},$$
$$PtO + SO_2 + H_2O \rightarrow Pt + H_2SO_4.$$

The rate of oxidation of sulphite anions falls appreciably as the bond between oxygen and the surface is strengthened.[37]

In order to increase the rate of reaction, the activation of the surface of the platinum is essential. It has been observed that the electrocatalytic activity of platinum in the presence of potassium iodide is several times higher than that of platinum merely coated by the SO_2H species.[38] It is assumed that the I_{ads} species on the surface participate in electron transfer across the interface. Apparently, both in the homogeneous systems described before and on the surface of electrode-catalysts, the mechanism of catalysis by the $I^0 + I^-$ pair is similar.

The adsorption of H_2SO_3 on electrodes used as electrocatalysts has also been studied in detail.[39-43] The electrochemical oxidation of sulphur dioxide on platinum–gold alloys and on organic metal complexes deposited on pyrographite or carbon black has been described.[44-46] One of the interesting applications of the electrochemical oxidation reaction involves its use in the thermoelectrochemical sulphuric acid method of preparation of hydrogen.

Studies in recent years have shown that not only platinum and platinum–carbon electrodes but also metalloporphyrin electrodes can be used as electrode-catalysts.[47–49]

The electrochemical oxidation of sulphur dioxide, which does not require oxidants, is apparently of interest for the elimination of SO_2 from gases.[50]

III. CATALYTIC REACTIONS INVOLVING THE OXIDATION OF SO_2 BY MOLECULAR OXYGEN

Studies on processes involving the oxidation of sulphur dioxide by molecular oxygen in the presence of homogeneous catalysts and water are of practical interest.

$$SO_2 + {}^1/_2O_2 + H_2O \xrightarrow{\text{catalyst}} H_2SO_4.$$

This reaction has been used since the past century for the preparation of H_2SO_4 by the familiar chamber method which has been described in many publications (see, for example, Amelin and Yashke[51]). However, a mechanism fundamentally different from the classical mechanism has been proposed comparatively recently.[52] All the versions of the traditional mechanism of the chamber process postulate the involvement of sulphuric acid in the form of nitrosylsulphuric acid in the sulphur dioxide oxidation step,[51] although under the experimental conditions the maximum rate of reaction in acid solutions is observed in the absence of H_2SO_4, an increase in the H_2SO_4 concentration inhibiting the reaction.[52]

The $SO_2-H_2O-HNO_3-O_2$ system has been investigated at 363–448 K and SO_2 pressures from 2×10^5 to 8×10^4 Pa.[52] The authors believe that the active oxidising species (oxygen transferring agent) is the nitronium ion NO^+ and it is postulated that the oxygen transfer to sulphurous acid molecules is effected not by the free nitronium ions but by their complexes with sulphite ions. The sulphur dioxide oxidation mechanism is described by the scheme:

$$SO_2 + H_2O \rightleftharpoons H_2SO_3 \rightleftharpoons H^+ + HSO_3^-,$$
$$HNO_3 + H^+ \rightleftharpoons H_2NO_3^+ \rightleftharpoons NO_2^+ + H_2O,$$
$$HSO_3^- + NO_2^+ \rightleftharpoons HSNO_5,$$
$$HSNO_5 + H^+ \rightarrow H_2SN^{\text{V}}O_5 \rightarrow (H_2SO_4)N^{\text{V}}O,$$
$$(H_2SO_4)N^{\text{V}}O \xrightarrow{HSO_3^-;\ O_2} H_2SO_4 + (HSO_3^-)N^{\text{V}}O \rightarrow HSNO_5.$$

Sulphur dioxide is oxidised by molecular oxygen under similar conditions in an aqueous medium using particles of activated charcoal as the catalyst, although it is assumed that in this case the process proceeds via a mechanism different from that of the oxidation of SO_2 in the presence of metal complexes.[53] The reaction is of first order with respect to the catalyst suspended in solution and with respect to molecular oxygen. The order with respect to SO_2 varies from 0 to 2 and the rate of the process is independent of the pH of the solution.[54]

In a study of the kinetics of the oxidation of sulphur dioxide by molecular oxygen in aqueous solutions containing vanadium salts, it has been established that in this case V^{5+} ions initiate the chain reaction:[55]

$$VO_2^+ + SO_3^{2-} + 2H^+ \rightleftharpoons VO^{2+} + \dot{S}O_3^- + H_2O.$$

The process then develops in accordance with the scheme

$$\dot{S}O_3^- + O_2 \rightarrow \dot{S}O_5^-,$$
$$\dot{S}O_5^- + SO_3^{2-} \rightarrow SO_5^{2-} + \dot{S}O_3^-,$$
$$SO_5^{2-} + SO_3^{2-} \rightarrow 2SO_4^{2-}.$$

Chain termination takes place as a result of radical recombination. The equation describing the rate of formation of sulphuric acid is

$$w = k([O_2][SO_2][V]^{1/4})/[H_2SO_4]^2.$$

The oxidation of sulphur dioxide by molecular oxygen in aqueous solutions containing $Fe_2(SO_4)_3$ has been investigated in the absence and presence of V^{4+}.[56] In the former case, a chain reaction mechanism is also postulated:

$$Fe^{3+} + SO_3^{2-} \rightarrow Fe^{2+} + \dot{S}O_3^-,$$
$$\dot{S}O_3^- + O_2 \rightarrow \dot{S}O_5^-,$$
$$Fe^{2+} + \dot{S}O_5^- \rightarrow Fe^{3+} + SO_5^{2-},$$
$$SO_3^{2-} + SO_5^{2-} \rightarrow 2SO_4^{2-}.$$

The rate of reaction is expressed by the equation

$$w = 4.32 \times 10^7 \exp(9625/RT)[SO_2].$$

V^{4+} ions lower the rate of reaction because they interact with the $\dot{S}O_5^-$ radical-ions, diminishing their concentration.

The oxidation of sulphur dioxide by molecular oxygen in the presence of iron salts has also been studied by Freiberg,[57] who established that the reaction order with respect to Fe^{3+} increases from 0 to 1 with decrease in $[Fe^{3+}]$. The oxidation of sulphur dioxide by Fe^{3+} ions competes with its catalytic oxidation by molecular oxygen at $[Fe^{3+}] > 2 \times 10^{-3}$ M. The author quotes two equations describing the variation of the overall rate of reaction with increase in pH and in the sulphur dioxide concentration.

In contrast to Bronikowski,[56] Freiberg[57] postulates a non-radical mechanism of the oxidation of sulphur dioxide:

$$H_2SO_3 \rightleftharpoons H^+ + HSO_3^- \rightleftharpoons 2H^+ + SO_3^{2-},$$
$$Fe(OH)^{2+} + H^+ \rightleftharpoons Fe^{3+} + H_2O,$$
$$Fe^{3+} + HSO_3^- \rightleftharpoons Fe(HSO_3)^{2+},$$
$$Fe(HSO_3)^{2+} + SO_3^{2-} \rightleftharpoons Fe(HSO_3)(SO_3),$$
$$Fe(HSO_3)(SO_3) + O_2 + H_2O \rightarrow Fe(OH)^{2+} + 2HSO_4^-,$$
$$Fe(HSO_3)(SO_3) + Fe^{3+} + H_2O \rightarrow 2Fe^{2+} + HSO_4^- + HSO_3^- + H^+.$$

Lunak et al.[58] likewise adhere to the view that the oxidation of sulphur dioxide by molecular oxygen in the presence of copper(II), iron(III), cobalt(III), nickel(II), and manganese(II), salts cannot be described by a radical-chain mechanism and propose an associative mechanism, according to which relatively stable complexes are formed between sulphite anions and the catalyst. The possibility of the formation of complexes between S(IV) and M^{x+} in the oxidation of SO_2 by molecular oxygen has also been indicated by Beilke and Gravenhorst.[59]

It has been established[58] that the oxidation of sulphur dioxide by molecular oxygen is of first order with respect to SO_2 over a wide range of concentrations of the latter. The catalytic action of transition metal ions on the reaction decreases in the sequence

$$Fe^{2+} \simeq Co^{2+} > Mn^{2+} \simeq Cu^+,\ Cu^{2+} \gg Fe^{3+} \simeq Co^{3+} \gg Ni^{2+}.$$

In the oxidation of SO_2 by molecular oxygen in the presence of Fe^{2+} in the pH range 0.8–5.0 in solutions, the reaction has an induction period whose duration increases with increase in the acidity of the medium.[60] It has been observed that, in the oxidation of sulphur dioxide by molecular oxygen, the addition of Mn^{2+} and Fe^{3+} has a comparatively small influence on the rate of the process.[61] On the other hand, other investigators regard manganese(II), iron(III), and also cobalt(II) compounds as promising catalysts of this reaction.[62–66] It has been established that iron and

manganese salts are active in a comparatively acid medium, while cobalt salts are active only in an alkaline medium. The maximum activity is observed at pH ~3.4 (Fe), 4.1 (Mn), and 9.0 (Co).[62,63] A radical-chain mechanism of the catalytic oxidation of SO_2 has been proposed in the above studies. In the oxidation of sulphur dioxide in acid solutions, the chains are short (n = 1, 2) and the reaction order with respect to SO_2 is close to or greater than unity and that with respect to the catalyst is less than unity. In alkaline solutions, the chains are lengthened and the reaction order is 1.5 with respect to SO_2 and 0.5 with respect to the catalyst.

It has been suggested[64] that the oxidation of SO_2 by molecular oxygen in the presence of $MnSO_4$ proceeds in accordance with the scheme

$$SO_2 + H_2O \rightleftharpoons H_2SO_3 \rightleftharpoons H^+ + HSO_3^- \rightleftharpoons 2H^+ + SO_3^{2-},$$

$$\left.\begin{aligned} Mn^{3+} + HSO_3^- &\rightarrow Mn^{2+} + \dot{H}SO_3 \\ Mn^{3+} + HSO_3^- &\rightarrow Mn^{2+} + \dot{H}SO_3 \end{aligned}\right\} \text{initiation},$$

$$\left.\begin{aligned} \dot{H}SO_3 + O_2 &\rightarrow \dot{H}SO_5 \\ \dot{H}SO_5 + HSO_3^- &\rightarrow HSO_5^- + \dot{H}SO_3 \end{aligned}\right\} \text{chain propagation},$$

$$\left.\begin{aligned} \dot{H}SO_5 + \dot{H}SO_3 &\rightarrow; \quad 2\dot{H}SO_5 \rightarrow; \quad 2\dot{H}SO_3 \rightarrow \\ \dot{H}SO_3 + Mn^{3+} &\xrightarrow{H_2O} H_2SO_4 + Mn^{2+} + H^+ \end{aligned}\right\} \text{chain termination},$$

$$\left.\begin{aligned} \dot{H}SO_5 + Mn^{2+} &\rightarrow HSO_5^- + Mn^{3+} \\ 2Mn^{2+} + HSO_5^- &\xrightarrow{2H^+} 2Mn^{3+} + HSO_4^- + H_2O \end{aligned}\right\} \text{regeneration of } Mn^{3+} \text{ ions},$$

$$Mn^{2+} \rightarrow Mn^{3+} \quad \text{autoxidation}.$$

The scheme also includes other reactions, for example:

$$HSO_5^- + HSO_3^- \rightarrow 2HSO_4^-.$$

A radical-chain mechanism of the oxidation of SO_2 by molecular oxygen has been likewise proposed for catalysis by Co^{2+} [67] and Fe^{2+} [68] ions. The reaction catalysed by Fe^{2+} has an induction period whose duration increases with increasing acidity of the medium.[69] In aqueous solutions at pH 8.5, the catalytic action of Co^{2+} ions is 12 times stronger than that of Cu^{2+} ions.[67] The reaction orders with respect to O_2, Co^{2+}, and SO_2 are respectively 0, 0.5, and 1.5, while in another study[70] a reaction order with respect to O_2 equal to unity has been quoted for analogous conditions.

The oxidation of sulphur dioxide by molecular oxygen in the presence of copper(I, II) halides has been studied in the $CuCl_2-HCl-KI-H_2O$ and $CuBr_2-KI-H_2O$ systems.[71,72] It was found that the process consists of two stages: the reaction involving the reduction of copper(II) by sulphur dioxide in accordance with Eqn.(3) and the reaction in which copper(I) is oxidised by molecular oxygen:

$$4CuX + O_2 + 4HX \rightarrow 4CuX_2 + 2H_2O. \qquad (5)$$

The rate of oxidation of sulphur dioxide by molecular oxygen can in general depend on the ratio of the rate constants for reaction (3) and (5), while under the conditions of the experiments of Golodov et al.[72] it is described by reaction (5).

Fig.4[71,72] presents typical kinetic and potentiometric curves for the oxidation of SO_2 by molecular oxygen. There are two sections on these curves: non-stationary and stationary. Along the non-stationary section, Cu^{2+} is reduced via reaction (3). Under stationary conditions, equilibrium is established between the reactions involving the reduction of Cu^{2+} by sulphur dioxide [reaction (3)] and the oxidation of Cu^+ by molecular oxygen [reaction (5)]. In order to increase the overall rate of oxidation of sulphur dioxide by molecular oxygen, it is necessary to use factors accelerating the oxidation of Cu^+ to Cu^{2+}, which is then rapidly reduced to Cu^+. Calculations have shown[71,72] that the $CuCl_3^{2-}$(aq.) complex in the $CuCl_2-HCl-KI-H_2O$ system and the $CuBr_3^{2-}$(aq.) complex in the $CuBr_2-HBr-KI-H_2O$ system have the highest activity in the reactions where Cu^+ is oxidised by molecular oxygen.

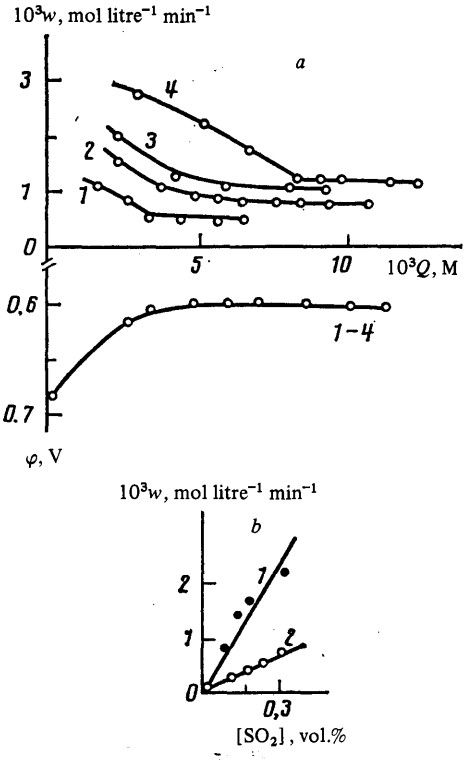

Figure 4. Oxidation of SO_2 by molecular oxygen at 293 K, $[CuCl_2]$ = 0.02 M, [HCl] = 4.8 M, [KI] = 8×10^{-4} M, and $[O_2]$ = 20 vol.%: (a) dependence of the rate of reaction and of the oxidation-reduction potential of the system on the amount of SO_2 which has reacted at different SO_2 concentrations (vol.%) [(1) 0.06; (2) 0.14; (3) 0.17; (4) 0.26]; (b) dependence of the initial (line 1) and stationary (line 2) rates of reaction on $[SO_2]$.[71]

The rate of oxidation of Cu^+ by molecular oxygen is described by the equation

$$w = k_{st}[Cu^+]_{st}[SO_2][O_2],$$

where k_{st} and $[Cu^+]_{st}$ are respectively the rate constant and the concentration of Cu^+ in the stationary region.

Iodide ions do not influence the oxidation of Cu^+. Thus the highest activity in the oxidation of sulphur dioxide by molecular oxygen is shown by copper chloride-iodide complexes. Along the non-stationary section, the reaction is of first order with respect to Cu^{2+}, SO_2, and I^-, while along the stationary section it is of first order with respect to Cu^+, SO_2, and O_2.[71,72] The addition of iron chloride to the $CuCl_2-HCl-KI-H_2O$ system greatly increases the rate of reaction along the non-stationary and stationary sections.[23]

The results of the study by Hegg and Hobbs[73] also show that catalysis by mixtures of iron, copper, and manganese salts leads to a tenfold increase in the rate of oxidation of sulphur dioxide by molecular oxygen compared with the rate of oxidation in the presence of a one-component catalyst alone. The oxidation of SO_2 by molecular oxygen in the presence of copper(I, II) halides and variable-valence metal salts (Mn, Fe) is inhibited by phenolic antioxidants and chelating additives[74] and also by surfactants.[75]

Studies on sulphur dioxide oxidation processes in air are of great theoretical and practical interest.[61,76,77] It has been observed that SO_2 is oxidised in air via several pathways:[61] (a) non-catalytic oxidation by molecular oxygen; (b) oxidation by molecular oxygen in the presence of metallic catalyst particles; (c) oxidation by O_3, H_2O_2, and SO_2; (d) oxidation in the presence of NH_3 acting as a neutralising agent.

The contributions of the principal mechanisms of the oxidation of SO_2 in air to the overall conversion of sulphur dioxide have been examined.[77] The overall contribution of the photochemical formation of excited sulphur dioxide molecules and of their interaction with O_2, O_3, and H_2O_2 as well as the reaction of SO_2 with the $\dot{O}H$, $\dot{R}O_2$, and $\dot{H}O_2$ radicals reaches 9%. The liquid-phase oxidation in the water droplets in clouds reaches 35%. The rate of this process is influenced by the pH of the drops, by the presence of metal ions (Fe and Mn), and by the presence of oxidants other than O_2 (O_3, H_2O_2). The contribution by the gas-phase oxidation of SO_2 with subsequent removal of sulphates from the atmosphere in the form of aqueous solutions is 50% of the overall balance. The remaining SO_2 is removed in the form of solid deposits.

The mechanism of the oxidation of sulphur dioxide in the atmosphere in the presence of metal ions includes the following stages:[78]

$$SO_3^{2-} + M^{+} \rightleftharpoons \dot{S}O_3^{-} + M \quad \text{initiation},$$

$$\left.\begin{aligned} &\dot{S}O_3^{-} + O_2 \rightleftharpoons \dot{S}O_5^{-},\\ &\dot{S}O_5^{-} + HSO_3^{-} \rightleftharpoons HSO_5^{-} + \dot{S}O_3^{-} \quad (pH \lesssim 7)\\ &\dot{S}O_5^{-} + SO_3^{2-} \rightleftharpoons SO_5^{2-} + \dot{S}O_3^{-} \quad (pH \gtrsim 7) \end{aligned}\right\} \text{chain propagation},$$

$$\left.\begin{aligned} SO_3^{2-} + HSO_5^{-} &\rightleftharpoons HSO_4^{-} + SO_4^{2-} \quad (pH \lesssim 7)\\ SO_3^{2-} + SO_5^{2-} &\rightleftharpoons 2SO_4^{2-} \quad (pH \gtrsim 7) \end{aligned}\right\} \text{oxidation},$$

$$\left.\begin{aligned} &\dot{S}O_3^{-} + \dot{S}O_5^{-} \rightleftharpoons S_2O_8^{2-} + O_2\\ &\dot{S}O_5^{-} + \text{inhibitor} \rightleftharpoons \text{inactive product} \end{aligned}\right\} \text{destruction of radicals}.$$

In conclusion, we shall consider the photochemical oxidation of sulphite anions. This reaction in the absence and presence of molecular oxygen has been described in detail.[79] Sulphates are formed in the absence of O_2 as a result of the oxidation of monothionic acid HSO_3, which is the primary product in the irradiation of the sulphite products by visible light,

$$SO_3^{2-} + H_2O \xrightarrow{h\nu} SO_3^{-} + H + OH^{-},$$
$$SO_3^{-} + H^{+} \rightarrow HSO_3 \ (H^{+}\text{—from water}),$$
$$HSO_3 + H + H_2O \rightarrow H_2 + H_2SO_4.$$

In the presence of molecular oxygen, sulphates are formed in accordance with the equation

$$HSO_3 + O_2 + SO_3^{2-} \rightarrow 2SO_4^{2-} + H.$$

Thus the photochemical activation of SO_2 leads to the formation of sulphuric acid vapour in the atmosphere.[80] The acid is then removed from air with rain drops—this is the main pathway leading to the natural elimination of SO_2 from the atmosphere.[81]

It follows from the present review that at the present time there is no unanimous view concerning the mechanism of the oxidation of SO_2 in aqueous solutions; radical-chain and associative mechanisms have been proposed. The adherents of the radical-chain mechanism believe that radicals may be formed in the interaction of sulphite anions with metal ions in accordance with the equation

$$SO_3^{2-} + M^{n+} \rightleftharpoons \dot{S}O_3^{-} + M^{n-1}$$

or as a result of the reactions[55,56,83]

$$2HSO_3^{-} \rightleftharpoons S_2O_5^{2-} + H_2O,$$
$$S_2O_5^{2-} \rightleftharpoons \dot{S}O_3^{-} + \dot{S}O_2^{-}.$$

The associative mechanism includes the formation of relatively stable complexes between sulphite anions and the catalyst.[58,84]

Analysis of the literature data shows that the stoichiometry of the oxidation of sulphur dioxide by metal complexes, i.e.

$$SO_2 + 2M^{n+} + 2H_2O \rightarrow H_2SO_4 + 2M^{n-1} + 2H^{+}$$

is satisfied, which rules out the chain reaction pathway.

It is most likely that the oxidation of sulphur dioxide by metal complexes proceeds via the formation of an intermediate compound of M^{n+} with the hydrogen sulphite anion formed via reaction (6), because the HSO_3^{-} anion is a more active electron donor than SO_2:[82,85]

$$SO_2 + H_2O \rightleftharpoons H_2SO_3 \rightleftharpoons HSO_3^{-} + H^{+}. \qquad (6)$$

The subsequent reactions in the system can be represented by the following scheme:

$$HSO_3^{-} + M^{n+}(aq) \rightleftharpoons MHSO_3^{n-1}(aq) + H_2O, \qquad (7)$$

$$MHSO_3^{n-1}(aq) \rightleftharpoons M^{n-1}(aq) + HSO_3, \qquad (8)$$

$$M^{n+}(aq) + HSO_3 + H_2O \rightarrow H_2SO_4 + M^{n-1}(aq) + H^{+}. \qquad (9)$$

The HSO_3^{-} anion interacts via reaction (7) with the metal complex, whereupon the intermediate $MHSO_3^{n-1}$(aq.) appears and then undergoes the inner-sphere redox reaction (8) with the formation of monothionic acid HSO_3. The possibility of the formation of HSO_3 during the reaction has also been pointed out in other studies.[86,87] In the next stage [reaction (9)], monothionic acid is oxidised rapidly to H_2SO_4.

The oxidation of SO_2 via a chain mechanism is also possible in processes with photochemical and radiochemical activation of the molecules of sulphur dioxide and molecular oxygen.[88-90]

IV. CONCLUSION

The problem of the search for and study of effective catalysts of the oxidation of sulphur dioxide to sulphuric acid, including liquid-phase oxidation, continues to be of interest. Special interest attaches to the elucidation of the process mechanism and of the influence of a number of factors on the kinetics of individual stages of the complex reaction, which promotes the development of promising and economical catalysts.

According to Dorfman,[82] the optimum system for the liquid-phase oxidation of sulphur dioxide by molecular oxygen should contain

the following components: (1) electron donors capable of intensifying the electron-donating function of the sulphur dioxide molecule; (2) halogens which interact with the donor orbital of the SO_2 molecule; (3) a polar solvent and a metal ion which give rise to stable compounds together with a halogen cation or halide anion and increase thereby the dipole moment of the halogen molecule; (4) a variable-valence metal ion, which reacts rapidly with molecular oxygen. The $CuCl_2-HCl-KI-H_2O$ and $CuCl_2-FeCl_3-HCl-KI-H_2O$ systems satisfy these features.[21,23]

The liquid-phase oxidation of SO_2 to H_2SO_4 has already found a practical application: the use of homogeneous catalysts for the elimination of the sulphur dioxide impurity from waste gases in various industries has been described.[91,92] Tests on catalysts based on copper and iron halide salts have shown that, for a high space velocity of the effluent gas (12 000 h^{-1}), the degree of conversion reaches 98% and the residual content of sulphur dioxide is 0.003 to 0.01 vol.%.[92] The 50% acid obtained, containing copper and iron complexes, can be used for the treatment of oxidised copper ores, which makes it possible to reduce the consumption of commercial sulphuric acid. Furthermore, the elimination of toxic sulphur dioxide from the effluent gas greatly improves the ecological position.

The choice of the method for the extraction and processing of sulphur dioxide is determined mainly by its concentration in the gas. Comparatively concentrated, with $[SO_2] > 4\%$, effluent gases in the non-ferrous metallurgy—roasting, converter and water jacket gases—can be used to manufacture sulphuric acid by the chamber or contact (in the presence of vanadium catalysts) method. Data have been published recently concerning the possibility of using heterogeneous catalysts also for gases at low concentrations.[2,93]

The temperature range of the operation of vanadium catalysts is in the region of high temperatures (400–600 °C). Practice has shown that their activity falls during use as a function of the nature of the sulphur-containing raw material, the degree of purification and variations in the concentration of sulphur dioxide, and the temperature range and the presence of catalyst poisons—arsenic and fluorine.[94,95] Gases with a low sulphur content (from 1 vol.% SO_2 upwards) have been utilised in recent years by employing non-stationary conditions.[96]

As shown above, the catalytic oxidation of SO_2 to H_2SO_4 in aqueous solutions takes place successfully also at a much lower SO_2 concentration in the effluent gases and under these conditions the method becomes economically viable. On comparing the liquid-phase homogeneous and heterogeneous catalytic methods for the oxidation of SO_2, it is possible to note the following advantages of the former: (1) homogeneous oxidation of SO_2 proceeds under mild conditions and does not require additional energy expenditures; (2) certain catalysts, for example, solutions of copper(II) halide salts, do not require additional elimination of arsenic and fluorine from the gas: F^- ions increase the rate of oxidation of SO_2 and As^{3+} is readily oxidised by copper(II); (3) waste water, containing active metal ions (Cu^{2+}, Fe^{3+}, Mn^{4+}, Mn^{7+}), can be used for the sanitary purification of gases.

Among the disadvantages of the method, one should include the corrosion activity of the catalytic solutions, the high concentration of halides in certain systems, the need to eliminate metal ions from the H_2SO_4 obtained, and the low final concentration of this acid (50 wt.%).

Thus the study of the processes leading to the oxidation of SO_2 to sulphuric acid in aqueous solutions is not only of theoretical interest but also helps to solve the problem of the purification of effluent gases.

The Synthesis and Properties of Covalent Organic Perchlorates

N.S.Zefirov, V.V.Zhdankin, and A.S.Koz'min

The review is devoted to the chemistry of perchloric acid esters—a relatively little investigated class of compounds with exceptionally interesting properties. Data on the methods of synthesis and reactivities of covalent organic perchlorates are described systematically and surveyed.
The bibliography includes 141 references.

I. INTRODUCTION

During the last 30 years, there has been a sharp increase of interest in perchloric acid and its derivatives. Inorganic and organic compositions based on perchlorates have found extensive applications as rocket fuel and explosives, industrial catalysts, drying agents, accumulator electrolytes, etc.[1] Perchloric acid and perchlorates have come to be widely used in scientific research in analytical, physical, and organic chemistry. The growing interest in perchlorates has been expressed in a fairly large number of publications appearing annually in the periodical literature. However, the vast majority of these studies are concerned with perchlorates having ionic structures—inorganic and organic salts of perchloric acid. Although the first covalent perchorate, ethyl perchlorate, was obtained as early as 1841,[2] the chemistry of compounds of this class has developed very slowly until recently; thus at best 1–2 pages have been devoted to them in the two existing reviews[3,4] and monographs.[1,5]

The reason for this is evident—perchloric acid esters are mostly relatively unstable and extremely explosive substances, which makes working with them very difficult. However, spectroscopic identification methods which have been developed during the last 20 years as well as the technique involving experiments at low temperatures with microamounts of substances have made it possible to reduce the risk in studies in this field to a minimum. Furthermore, there has been a growth of interest in the possible practical applications of covalent organic perchlorates as alkylating agents[6] and polymerisation catalysts.[7-10] These factors as well as the evident theoretical interest which the highly reactive covalent perchlorates represent has led many investigators in recent years to search for new ways of synthesising perchloric acid esters. Among the advances in this field, we may mention the discovery of the phenomenon of the competitive binding of nucleofugitive anions, including ClO_4^-, in carbonium ion processes which have made it possible to extend sharply the range of perchlorates synthesised.

The synthesis of a large set of relatively stable covalent perchlorates, namely arenesulphonylmethyl perchlorates,[11] perfluoroalkyl perchlorates,[12,13] certain skeletal perchlorates,[14-17] as well as silyl perchlorates,[18] may be mentioned as a considerable advance in the chemistry of perchlorates during the last 10–15 years, which has allowed a more thorough investigation of the reactivity of compounds of this interesting class. Furthermore, the development of kinetic measurement techniques made it possible to investigate the detailed mechanisms of the reactions of a series of highly reactive unstable perchlorates.[19-22] All these factors have made it urgently necessary to carry out an exhaustive survey of the literature data on covalent perchlorates and to analyse in detail both the results obtained and the prospects for the development of this branch of organic chemistry. The present review is devoted to this problem; it covers the entire available literature on the synthesis and properties of covalent perchlorates up to 1986 and is the first exhaustive survey of this field.

II. METHODS OF SYNTHESIS

1. General Principles of the Synthesis of Perchloric Acid Esters

One of the simplest covalent perchlorates—ethyl perchlorate—has been obtained by distillation from a concentrated solution of the barium salts of ethylsulphuric and perchloric acid:

$$Ba(RSO_4)_2 + Ba(ClO_4)_2 \rightarrow 2ROClO_3 + 2BaSO_4,$$
$$R = CH_3,\ C_2H_5,\ n\text{-}C_3H_7.$$

The possibilities of this method for the synthesis of methyl, ethyl, and propyl perchlorates were later investigated;[23] in particular, the optimum temperature range for these reactions was discovered (170–200 °C). Despite the appreciable danger involved,[3,23] this method was until 1936 virtually the only procedure for the preparation of lower alkyl perchlorates.[23,24]

Progress in the synthesis of perchloric acid esters has been associated both with the introduction into practical organic synthesis of new inorganic reagents such as perchloric acid, chlorine pentoxide, silver perchlorate, and halogen perchlorates, and with a deeper understanding of the problem of nucleophilic reactivity as a whole.

Any ester of an inorganic acid ROX can be obtained, in principle, in two general ways. The first is based on the reaction of alcohols or their derivatives with the anhydride or halide of the given inorganic acid. In this method of synthesis of the inorganic acid ester, an oxygen–element bond is formed. When applied to covalent perchlorates, the method reduces to the reaction of alcohols and their derivatives with chlorine pentoxide or perchloryl fluoride:

$$ROH + Cl_2O_7 \rightarrow ROClO_3 + HClO_4,$$
$$ROH + FClO_3 \rightarrow ROClO_3 + HF.$$

At the present time, these reactions have been investigated in fair detail and will be examined below. On the whole, this is a fairly acceptable synthetic method, limited solely by the explosive properties of the reagents used, in particular, chlorine pentoxide.

The second general method of synthesis of esters of the type ROX is based on reactions in which the OX^- anion plays the role of the nucleophile attacking the electrophilic carbon atom; an oxygen–carbon bond is formed in this method of synthesis. When applied to the synthesis of covalent perchlorates, this means the use of the perchlorate anion ClO_4^- as the nucleophile:

$$\rangle C^+ + ClO_4^- \rightarrow \rangle C-OClO_3,$$

$$\rangle C-Y + ClO_4^- \rightarrow O_3ClO-C\langle .$$

The development of this approach was significantly restricted by the idea which arose at the beginning of the 1970s that the perchlorate anion has no nucleophilic properties. Indeed, attempts to measure the parameters of the nucleophilicity of ClO_4^- within the framework of the generally employed Swain–Scott[25] and Ritchie[26,27] scales were unsuccessful and estimates in terms of the two-parameter Edwards scale[28] provided grounds for the assumption that this anion is an ultra-weak nucleophile. This view is well reflected in the familiar textbook of Roberts and Caserio,[29] in which lithium perchlorate, a source of the perchlorate anion, is defined as a "non-nucleophilic substance". It is not fortuitous that perchloric acid salts, such as lithium perchlorate, are usually employed in connection with the study of salt effects, because these salts do not affect the course of the reaction by binding to the intermediate carbonium ion.[30–33]

It was believed previously that the covalent binding of the perchlorate anion, leading to covalent perchlorates, is possible only under specially created conditions: in the complete absence of other nucleophilic species and in media with a low polarity. On this basis, a number of methods were developed for the synthesis of covalent perchlorates, for example, by the reaction of alkyl halides with silver perchlorate or by the addition of halogen perchlorate to perfluoro-olefins (see below). A limitation of all these methods was the necessity to use exceptionally explosive or expensive reagents such as halogen perchlorates and silver perchlorate.

However, in recent years the authors of the present review found unexpectedly that the perchlorate ion can manifest nucleophilic properties also in the presence of extraneous nucleophiles (halide ions, AcO^-, AcOH, etc.).[14,15,34–36] This discovery (which applies also to other nucleofugitive anions as well as ClO_4^-—triflate, fluorosulphate, toluene-*p*-sulphonate, methanesulphonate, etc.[36]) made it possible to devise a series of new convenient methods of synthesis of covalent perchlorates having different structures. The methods developed are based on a wide range of carbonium ion processes such as electrophilic addition to olefins,[14,15,34–36] opening of epoxide rings,[36–40] deamination of amines,[34,41] chlorination of sulphides,[42] deoxygenation of alcohols by treatment with sulphur and chlorine,[43] oxidative substitution of iodine in alkyl iodides,[44,45] and the interaction of aryliodoso-derivatives with olefins.[46–48] Alkali metal perchlorates, which are safe to handle and are readily available, are used as the reagents in all these cases.

In conclusion of this Section, we may note that in the description below the data will be grouped in terms of the types of initial compounds rather than the reaction mechanisms; this arrangement of the material is dictated both by the synthetic bias of the present review and by the extremely scanty experimental data on the kinetics and mechanisms of the synthesis of covalent perchlorates.

2. Synthesis From Alcohols and Ethers

The synthetic possibilities of the reactions of alcohols with perchloric acid have been investigated in fair detail. The explosive character of the interaction of anhydrous perchloric acid with absolute ethanol was reported as early as 1936.[23] However, the reactions of polyhydric alcohols with perchloric acid take place more quietly and can be used for the preparative synthesis of perchloric acid mono- and poly-esters. Thus the esters of perchloric acid with ethylene glycol, glycerol, and pentaerythritol have been obtained by the direct interaction of the hydroxy-compounds with anhydrous perchloric acid, which plays the role of a powerful dehydrating agent in this reaction, forming a monohydrate.[49] The esterification was carried out by the cautious addition of the alcohol to an excess of perchloric acid at −78 °C, the mixture being subsequently maintained at 60–80 °C for 20–40 min. The isolation of the esterification products presented a special problem. It has been reported[49] that, when the reaction mixture is diluted directly with water, "enormously powerful explosions" take place, which are apparently a consequence of the very rapid heating on hydration of perchloric acid. This risk was avoided by diluting the reaction mixture initially with 70% perchloric acid. The subsequent addition of a large amount of water causes the precipitation of a deposit of the organic perchlorate in the form of a heavy oil (density in excess of 1.7) or flakes (in the case of pentaerythritol). The authors[49] had to design a special apparatus for the extraction of the perchlorates with ether because powerful explosions occurred in the usual separating funnel when the ethereal solution entered the ground joints.

A modification of the esterification of alcohols with perchloric acid was subsequently developed.[50] Here the reagent employed was a mixture comprising 70% of perchloric acid, concentrated sulphuric acid, and oleum or a solution of an alkali metal perchlorate in 96% sulphuric acid. The alcohol is added slowly to a vigorously stirred emulsion of the acid reagents with an inert organic solvent at a temperature between −10° and 25 °C. The rapidly formed covalent perchlorate is concentrated in the organic phase. The method[50] is suitable only for the synthesis of secondary perchlorates from the corresponding alcohols (yield 70–90%), whilst primary alcohols react very slowly with formation of isomeric secondary perchlorates. The reaction mechanism apparently involves the preliminary formation of alkyl sulphates, the generation of a carbonium ion, possible isomersiation, and binding to the perchlorate anion. The carbonium ion character of the process has been confirmed, in particular, by the formation of an identical 1:1 mixture of 2- and 3-hexyl perchlorates when the reaction was carried out with both 2-hexanol and 3-hexanol.

A convenient method of synthesis of covalent perchlorates by the interaction of alcohols with chlorine heptoxide has been proposed:[51]

$$ROH + O_3ClOClO_3 \rightarrow ROClO_3 + HClO_4.$$

Chlorine heptoxide was used in the form of a relatively safe solution in carbon tetrachloride[52] and the perchloric acid produced in the reaction was bound with sodium sulphate.

One of the attractive features of this reaction is the formation of perchlorates exclusively with a non-rearranged structure, on the basis of which it has been concluded[51] that the C–O bond is really not involved in this reaction. The method yields best results for primary alcohols and diols, while in the reactions with secondary alcohols the corresponding ketones are formed as side products (8–9%) together with the perchlorates. The wide variety of structures and

the yields of the covalent perchlorates in the reactions investigated are demonstrated by the data in Table 1. Baum and Beard[51] noted that they were unable to obtain t-butyl perchlorate, apparently because of the instability of this product. On the other hand, perfluoro-t-butyl perchlorate proved to be entirely stable and was obtained in 33% yield by the reaction of sodium alkoxide with chlorine pentoxide:[51]

$$(CF_3)_3CONa + Cl_2O_7 \rightarrow (CF_3)_3COClO_3 + NaClO_4.$$

Apart from the alcohols themselves, their alkoxides can also be used as starting materials, the role of the reagent being usually assumed in this instance by perchloryl fluoride:[53]

$$RO^-M^+ + FClO_3 \rightarrow ROClO_3 + MF,$$
$$M = Na,\ (NH_2)_3C.$$

Table 1. The yields of covalent perchlorates in the reactions of alcohols with chlorine heptoxide in carbon tetrachloride (according to Baum and Beard's data[51]).

Initial alcohol	Perchlorate obtained	Yield, %
CH_3OH	CH_3OClO_3	42
C_2H_5OH	$C_2H_5OClO_3$	56
$n\text{-}C_3H_7OH$	$n\text{-}C_3H_7OClO_3$	73
$n\text{-}C_4H_9OH$	$n\text{-}C_4H_9OClO_3$	71
$n\text{-}C_5H_{11}OH$	$n\text{-}C_5H_{11}OClO_3$	63
$n\text{-}C_6H_{13}OH$	$n\text{-}C_6H_{13}OClO_3$	58
$HOCH_2CH_2OH$	$O_3ClOCH_2OClO_3$	60
$HOCH_2(CH_2)_2CH_2OH$	$O_3ClOCH_2(CH_2)_2CH_2OClO_3$	38
CF_3CH_2OH	$CF_3CH_2OClO_3$	55
$CH_3C(NO_2)_2CH_2OH$	$CH_3C(NO_2)_2CH_2OClO_3$	67
$FC(NO_2)_2CH_2OH$	$FC(NO_2)_2CH_2OClO_3$	60
$FC(NO_2)_2CH_2OCH_2CH_2OH$	$FC(NO_2)_2CH_2OCH_2CH_2OClO_3$	43
$CH_2{=}CHCH_2OH$	$CH_2{=}CHCH_2OClO_3$	48
$HC{\equiv}CCH_2OH$	$HC{\equiv}CCH_2OClO_3$	43
$CH_3CHOHCH_3$	$CH_3CH(OClO_3)CH_3$	48
$CH_3CHOH(CH_2)_3CH_3$	$CH_3CH(OClO_3)(CH_2)_3CH_3$	62
$CH_3CH_2CHOH(CH_2)_2CH_3$	$CH_3CH_2CH(OClO_3)(CH_2)_2CH_3$	53

Alcohols can serve as the starting materials in the synthesis of covalent perchlorates in yet another reaction, which is a deoxygenation process. In this reaction, developed by the authors of the present review,[43] sulphur, chlorine, pyridine, and lithium perchlorate were used as the reagents. The possibility of the formation of covalent perchlorates is because the alcohols are intially converted into chlorosulphenates by the sulphur dichloride arising as an intermediate and these then generate dichloroalkoxysulphonium ions, which undergo nucleophilic substitution by the perchlorate anion:

$$ROH \xrightarrow[SCl_2]{S+Cl_2} [ROSCl] \xrightarrow{Cl_2} [ROSCl_2^+Cl^-] \xrightarrow{ClO_4^-} ROClO_3,$$

$R = C_8H_{17}$, 2-chlorocyclohexyl.

The reactions of ethers with chlorine heptoxide and acyl perchlorates have been investigated.[54] Acyl perchlorates, obtained by the reaction of acyl chlorides with silver perchlorates (see below) in carbon tetrachloride, cleave secondary ethers with formation of a mixture of secondary alkyl perchlorates and alkyl acetates:

$$(CH_3)_2CHOCH(CH_3)_2 + CH_3\overset{\overset{O}{\|}}{C}OClO_3 \rightarrow (CH_3)_2CHOClO_3 + (CH_3)_2CHOCOCH_3.$$

Primary ethers do not enter into this reaction. Like acetyl perchlorate, benzoyl and *NN*-diethylcarbamoyl perchlorates react with ethers.[54]

In contrast to acyl perchlorates, chlorine heptoxide is capable of cleaving not only secondary but also primary ethers.[54] For example, diethyl ether reacts slowly with chlorine heptoxide, forming ethyl perchlorate.[54]

The main product of the reaction of diisopropyl ether with chlorine heptoxide is the geminal diperchlorate (I),[54] which can also be obtained by the reaction of acetone with chlorine heptoxide[55] or with anhydrous perchloric acid:[56]

$$(CH_3)_2CHOCH(CH_3)_2 + Cl_2O_7 \longrightarrow \left.\begin{array}{l} \\ \\ CH_3\overset{\overset{O}{\|}}{C}CH_3 + 2HClO_4\ (\text{or } Cl_2O_7) \end{array}\right\} \rightarrow CH_3\overset{\overset{OClO_3}{|}}{\underset{\underset{OClO_3}{|}}{C}}CH_3 \quad (I)$$

Esters can apparently also be cleaved by chlorine heptoxide with formation of covalent perchlorates. A single reaction of this type, resulting in the formation of ethyl perchlorate, has been described in the literature[57] (in relation to ethyl carbamate):

$$3NH_2\overset{\overset{O}{\|}}{C}OC_2H_5 + Cl_2O_7 \rightarrow C_2H_5OClO_3 + [H_2NC(OH)OC_2H_5]^+ClO_4^- + H_2N\overset{\overset{O}{\|}}{C}NH\overset{\overset{O}{\|}}{C}OC_2H_5.$$

Cyclic ethers, including epoxides, can also be used as the starting compounds for the synthesis of organic perchlorates. It has been suggested that[54] they be cleaved with acyl perchlorates and chlorine heptoxide. For example, the reactions of acetyl perchlorate with tetrahydrofuran and epoxyethane take place at 0 °C with formation of the corresponding αω-acetoxyperchlorates:

$$\underset{n=2,4}{\overset{(CH_2)_n}{\underset{O}{\bigcirc}}} + CH_3\overset{\overset{O}{\|}}{C}OClO_3 \longrightarrow CH_3\overset{\overset{O}{\|}}{C}O(CH_2)_nOClO_3 \quad (78\text{–}89\%).$$

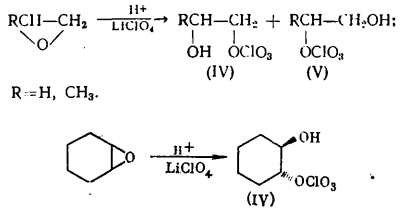
Analogous reactions with chlorine heptoxide[47] lead to αω-diperchlorates:

$$\bigcirc\!\!\!\!\!O + Cl_2O_7 \rightarrow O_3ClO(CH_2)_4OClO_3, \quad 83\%$$

$$\bigcirc\!\!\!\!\!O + Cl_2O_7 \rightarrow O_3ClO(CH_2)_3OClO_3, \quad 55\%$$

$$CH_3\text{—}\underset{\diagdown O \diagup}{CH}\text{—}CH\text{—}CH_3 + Cl_2O_7 \rightarrow CH_3\text{—}\underset{O_3ClO}{CH}\text{—}\underset{OClO_3}{CH}\text{—}CH_3 \quad 30\%.$$

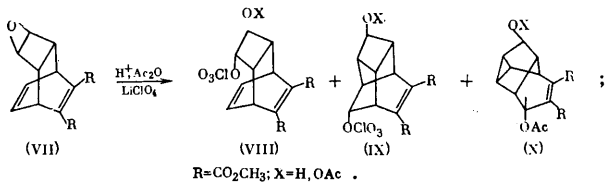
Acid cleavage of epoxides can also be used for the synthesis of covalent perchlorates. As early as the beginning of the XXth century, Hofmann et al.[58] investigated the reactions of epoxyethane and epichlorohydrin with concentrated (70%) perchloric acid and obtained the explosive compounds (II) and (III):



$$2CH_2\text{—}\underset{\diagdown O \diagup}{CH_2} + HClO_4 \rightarrow \underset{\underset{OH}{|}}{CH_2}\text{—}CH_2\text{—}O\text{—}CH_2\text{—}CH_2OClO_3, \quad (II)$$

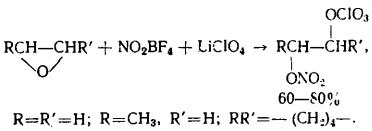
$$CH_2\text{—}\underset{\diagdown O \diagup}{CH}CH_2Cl + HClO_4 \rightarrow CH_2\text{—}\underset{\underset{OClO_3}{|}}{\overset{\overset{OH}{|}}{CH}}\text{—}CH_2Cl. \quad (III)$$

The kinetics of the opening of the epoxide rings with perchloric acid[59] or other acids in the presence of lithium perchlorate[60] have been investigated in detail. Strong evidence has been obtained in support of the carbonium ion character of the intermediates in these



processes,[59] but the formation of covalent perchlorates was not detected in the above studies.[59,60]

The authors of the present review developed a preparative method for the synthesis of covalent perchlorates in reactions involving coupled acid opening of epoxide rings in the presence of perchloric acid salts.[37,40] Epoxyethane, epoxypropane, epoxycyclohexane, and also the epoxy-derivative (VII) of tricyclo[4.2.2.0^{2,5}]decane were chosen as the objects of study. Covalent perchlorates were obtained in all cases by treating these compounds with an acid (acetic, sulphuric, or perchloric) in the presence of lithium perchlorate in ether or ethyl acetate. The β-hydroxy-perchlorates (IV)–(VI) are formed under these conditions from the epoxy-derivatives obtained from alkenes and cyclohexene:[37,40]



R=H, CH_3.

The acid cleavage of the skeletal epoxide (VII) in the presence of lithium perchlorate resulted in the formation of a complex mixture of products including the covalent perchlorates (VIII) and (IX):[38,39]

R=CO_2CH_3; X=H, OAc .

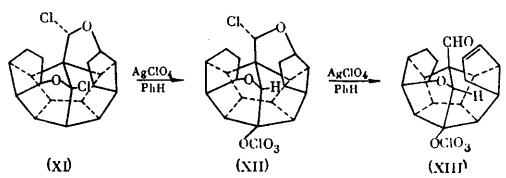
When the epoxide rings are opened not with an acid but with nitronium fluoroborate in the presence of lithium perchlorate in an inert solvent, the formation of β-nitratoalkyl perchlorate in high yields is observed:[37]

R=R′=H; R=CH_3, R′=H; RR′=—$(CH_2)_4$—.

3. Synthesis From Alkyl Halides

During recent years, the method of synthesis of alkyl perchlorates by the exchange reaction of alkyl halides with silver perchlorate in an organic solvent has come to be most widely used:

Anhydrous silver perchlorate is readily soluble in many organic solvents (the solubility of $AgClO_4$ in 100 g of the solvent is 5.3 g in benzene and 101 g in toluene[1]); when an equivalent amount of an alkyl halide is added to such a solution, the rapid formation of a silver halide precipitate is observed, and its rapid removal can produce a solution containing only the alkyl perchlorate. Dilute solutions of alkyl perchlorates are usually safe to handle.



The reactions of alkyl halides with silver perchlorate in a wide variety of solvents have been investigated. It has been shown that ethanol,[24] acetonitrile,[61] and anisole[62] are relatively unsuitable for the synthesis of alkyl perchlorates, which are excellent alkylating agents[4] and readily react with these solvents. The use of chlorohydrocarbon solvents, for example, carbon tetrachloride, which may react with silver perchlorate to form the explosive trichloromethyl perchlorate,[63] is not recommended either. In practice, diethyl ether,[23] dioxan,[64] nitromethane,[65,66] pentane,[67] and benzene[68] are used for the preparative synthesis of alkyl perchlorates.

Alkyl perchlorates are usually obtained from alkyl iodides,[6,67,69,70] although the reactions of alkyl bromides with silver perchlorate have also been studied.[23,68] A series of n-alkyl perchlorates have been prepared by the reaction of C_5–C_8 alkyl iodides with silver perchlorate in pentane in 90–95% yields.[67] However, recent studies[6,51] have cast doubt on the result of this reaction. It was found that, when the reaction of alkyl iodides is carried out in the majority of solvents, with the exception of benzene, a mixture of primary and secondary perchlorates is formed:

For example, this reaction in carbon tetrachloride affords a 1:1 mixture of primary and secondary perchlorates;[6] on the other hand, the reaction of primary alkyl iodides with silver perchlorate in benzene gives a 90% yield of primary alkyl perchlorates exclusively.[6]

The reaction of halogeno-derivatives with silver perchlorate has also uses other than the synthesis of alkyl perchlorates. It has been shown by indirect chemical methods[69,71] and also by ^{1}H NMR [51] that allyl and benzyl perchlorates, as well as acyl perchlorates,[54] can be obtained analogously from acyl chlorides and silver perchlorate:

Covalent silyl perchlorates[72,73] and certain skeletal perchlorates of the norbornane[74] and adamantane[19,20] series have been synthesised by the reactions of the corresponding halides with silver perchlorate. The skeletal covalent perchlorates (XII) and (XIII) have been synthesised by treating the dichloride (XI) (heterocyclic analogue of trisecododecahedrane) with silver perchlorate in benzene:[16,17]

It has been noted[16] that compound (XIII) is the first example of a stable tertiary covalent perchlorate.

The mechanism of the reaction of alkyl halides with silver perchlorate has been investigated quite vigorously. As early as 1940, the kinetics of the reaction of methyl iodide with silver perchlorate were studied in acetic acid, acetone, ethanol, benzene, ethyl acetate, and 50% aqueous ethanol.[70] It was found that the order of this reaction depends on the initial concentration of the reactants and is on average 2.5; the activation energy is 11–13 kcal. The authors[70] established that the rate of reaction is influenced by the excess colloidal silver iodide, which is not removed from the solution for a long time. Further studies[65,66,68,75] showed that the reaction of alkyl iodides with silver perchlorates proceeds via the formation of the ion-pair complex (XIV), which slowly decomposes in a solvent

with a low dielectric constant to a covalent perchlorate and silver halide:

$$RX + AgClO_4 \rightleftarrows [ClO_4^-R^+X^-Ag^+] \rightarrow \text{products.}$$
(XIV)

The reaction of 2-octyl bromide with silver perchlorate in nucleophilic (acetonitrile)[61] and non-nucleophilic (benzene)[68] solvents has been investigated. In both solvents, the reaction is of first order with respect to alkyl bromide and of variable order with respect to silver perchlorate. In acetonitrile, the reaction order with respect to silver perchlorate varies from 1 (at very low concentrations of the salt) to 2 (for 0.3 M $AgClO_4$); in benzene, the order with respect to silver perchlorate varies from 1.5 to 2. These results are consistent with earlier data.[70] It has also been observed[61,68] that, at low silver perchlorate concentrations, small amounts of added tetrabutylammonium perchlorate have a considerable catalytic effect; furthermore, the formation of olefins as side products is reduced in the presence of the ionic perchlorate. The catalytic action of the salt has been explained[61] by the nucleophilic involvement of the perchlorate anion in the rate-limiting stage of the reaction. The reaction with the optically active 2-octyl bromide in benzene leads to the formation of a 2:3 mixture of the enantiomeric 2-octyl perchlorates, the product with the inverted configuration predominating.[68] This result is independent of the silver perchlorate concentration and the addition of tetrabutylammonium perchlorate. It has been noted[68] that the reaction of 2-octyl bromide with silver perchlorate in benzene is much faster than in acetonitrile as a consequence of the formation of a strong complex between the Ag^+ cation and acetonitrile.

Since the ion-pair association and the tendency towards the formation of ionic aggregates by silver perchlorate greatly complicate the study of the kinetics of the reactions with alkyl halides in benzene, a solvent with a high dielectric constant (nitromethane), in which silver perchlorate is almost wholly ionised, was used.[65,66] The reaction of methyl iodide with silver perchlorate in nitromethane takes place with formation of 80% of methyl perchlorate and 20% of a side product of unknown composition, which precipitates together with silver iodide as a red amorphous deposit.[66] As for the other solvents, the complex (XIV) is formed in the first stage of the process and then decomposes rapidly, in several stages, into the final reaction products. The same mechanism has been proposed[65] for the reaction of neopentyl iodide with silver perchlorate in nitromethane, but the rate of this reaction is 33 times greater than that of the analogous reaction of methyl iodide.

The reaction of alkyl halides with silver perchlorate has found a practical application, mainly for the synthesis of methyl perchlorate, which is a powerful methylating agent.[76–78] A disadvantage of this method of synthesis of covalent perchlorates is the necessity to use the expensive and explosive anhydrous silver perchlorate.[1] The possibility of a rearrangement when primary alkyl iodides are used also diminishes the synthetic value of the reaction.[6]

The methods of synthesis of covalent perchlorates from alkyl iodides based on the oxidative iodine elimination reactions are partly free from these disadvantages. The central feature of these processes consists in the oxidation of the iodine atom in alkyl iodides to the tervalent state by various reagents (halogens,[79–81] peracids,[82] and a wide range of inorganic oxidants[83–85]) with formation of intermediates of type (XV). The iodine atom in the +3 oxidation state exhibits the properties of an exceptionally effective leaving group and can be readily substituted by the nucleophiles present,[79,82] including perchlorate anions:[36,44,45,86,87]

$$\text{>C–I} \xrightarrow{\text{oxidant}} \left[\text{>C–I<}\right] \xrightarrow{ClO_4^-} O_3ClO\text{–C<}.$$
(XV)

Inorganic reagents can be represented in this reaction by a pair of substances, namely the oxidant–perchlorate anion-donor pair,[36,44,45] or by a single substance such as chlorine heptoxide,[87] a halogen perchlorate,[12,86,77] or μ-oxodiiodosodiphenyl diperchlorate.[89]

Chlorine[90] and bromine[91] perchlorates have been used[12,86,88] to synthesise perfluorinated alkyl perchlorates. These reagents were first obtained at the beginning of the 1970s in 70–95% yield by keeping caesium perchlorate or nitronium perchlorate with the fluorosulphate of the corresponding halogen for a long time at –45 °C:[90,91]

$$MClO_4 + XSO_3F \rightarrow MSO_3F + XOClO_3,$$
$$M{=}Cs,\ NO_2;\ X{=}Cl,\ Br.$$

The reactions of lower perfluorinated alkyl iodides with chlorine perchlorate take place smoothly at temperatures between –200° and –45 °C with formation of stable covalent perfluoroalkyl perchlorates (XVII) in 95–99% yield:[12,86,88]

$$C_nF_{2n+1}I + 2ClOClO_3 \xrightarrow[-Cl_2]{} \underset{\text{(XVI)}}{C_nF_{2n+1}I(ClO_4)_2} \rightarrow \underset{\text{(XVII)}}{C_nF_{2n+1}OClO_3} + [IClO_4].$$

Compound (XVI), formed in the first stage of the reaction of trifluoromethyl iodide or pentafluoroethyl iodide with fluorine perchlorate, cannot be isolated and the final products of the reaction are gaseous perfluoroalkyl perchlorates, chlorine, and the products of the decomposition of the unstable iodine perchlorate. However, in other cases it is possible to obtain crystalline intermediates stable at room temperature, for example, $(CF_3)_2CFI(ClO_4)_2$ (m.p. 71 to 73 °C) and $C_7F_{15}I(ClO_4)_2$ (m.p. 56–78 °C), which decompose on moderate heating (below 100 °C) with formation of the corresponding covalent perchlorate.[12]

Bromine perchlorate reacts analogously with perfluoroalkyl iodide, but the yields of perfluoroalkyl perchlorates are somewhat lower in this case.[12] The replacement of perfluoroalkyl iodides by the bromides also entails a decrease in the yields of covalent perchlorates. The most stable halogen perchlorate, namely fluorine perchlorate, gives rise to only trace amounts of covalent perchlorates in its reaction with perfluoroalkyl iodides.[13] We may note that halogen perchlorates are extremely explosive even at temperatures of about –200 °C and rapidly decompose at room temperature.[90,91]

The studies of Schack and co-workers[86,88] stimulated the investigation of the reactions of alkyl iodides with chlorine heptoxide. Thus it has been found[87] that the main products of these reactions are covalent perchlorates and the formation of the intermediate (XVIII) with tervalent iodine was postulated:

$$R{-}I + Cl_2O_7 \rightarrow \underset{\text{(XVIII)}}{\left[R{-}I\begin{matrix}ClO_3\\OClO_3\end{matrix}\right]} \rightarrow ROClO_3 + \underset{\text{(XIX)}}{[IClO_3]}.$$

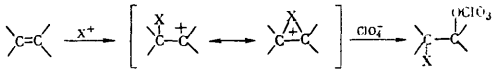
The unstable iodine chlorate (XIX) formed decomposes with formation of I_2O_5 and Cl_2O. The presence of halogen oxides and mixed iodine and chlorine oxides in the reaction mixture leads to the formation of esters and ethers as side products. For example, 22% of ethyl acetate and trace amounts of diethyl ether are obtained together with ethyl perchlorate (63%) in the reaction of ethyl iodide with an excess of chlorine heptoxide at 0 °C:

$$C_2H_5I + Cl_2O_7 \rightarrow I_2O_5 + C_2H_5OClO_3 + CH_3\underset{\underset{O}{\|}}{C}OC_2H_5 + C_2H_5OC_2H_5.$$

The use of an equivalent amount of chlorine heptoxide lowers the yield of ethyl perchlorate and leads to a sharp increase in the content of diethylether in the reaction mixture (more than 20%).

In the course of the study of the phenomenon of the competitive binding of ultraweak nucleophiles in carbonium ion processes, the present authors investigated the possibility of the formation of covalent perchlorates in the oxidative decomposition of alkyl iodides.[44,45,89] The methods of synthesis of alkyl perchlorates developed are based on the oxidation of alkyl iodides in the presence of perchloric acid salts which in this case play the role of a reagent—a source of perchlorate anions:

$$CH_3(CH_2)_nI + M^+ClO_4^- \xrightarrow{[Ox]} CH_2(CH_2)_nOClO_3,$$
$$n = 0-5;\ M = Li,\ Bu_4N;\ [Ox] = m\text{-}ClC_6H_4COOOH,\ H_5IO_6,\ Cl_2,\ NO_2BF_4.$$



The reactions were performed by adding an oxidant [Ox], for example, chlorine, *m*-chloroperbenzoic acid, or iodic acid, to a solution of alkyl iodide in an aprotic solvent (ether, ethyl acetate, or chloroform) in the presence of 1–5 equivalents of lithium perchlorate or tetrabutylammonium perchlorate. Alkyl perchlorates were isolated in 50–70% yield by distillation or chromatography on a silica gel column. The geminal methylene diperchlorate (XX) was obtained for the first time by the oxidative deiodination of methylene iodide:[45]

$$CH_2I_2 + 2LiClO_4 + 2NO_2BF_4 \rightarrow \underset{(XX)}{CH_2(OClO_3)_2}.$$

The oxidation of organic iodides in the presence of sources of perchlorate anions is in our view one of the safest and most convenient methods of synthesis of covalent perchlorates of different types.

4. Synthesis From Olefins

The possibility of obtaining covalent perchlorates from olefins is associated with a two-stage mechanism of the electrophilic addition and generation of carbonium ion intermediates:

The addition of perchloric acid, chlorine heptoxide, and halogen perchlorate has been studied in special detail.[13,50,55,92–95] The studies of the reaction of but-2-ene with anhydrous perchloric acid in methylene chloride were some of the first in this field.[92] The organic perchlorate could not be isolated from the reaction mixture after treatment with water, but identification of 2-butanol and diisobutyl ether confirmed indirectly the formation of 2-butyl perchlorate in this reaction. The authors[92] also reported powerful explosions, which occurred when the butene was introduced into the perchloric acid solution.

The study of the reaction of *cis*-octadec-9-ene with 70% perchloric acid at 100 °C showed[93] that rapid migration of the double bond in the molecule is observed under these conditions. Octadecyl esters of perchloric acid are formed in the above reaction only in trace amounts (2%), while an olefin with a terminal double bond affords 14% of the perchlorate under the same conditions. The reaction of unsubstituted olefins with perchloric acid in the presence of oleum and an inert organic solvent (hexane, chlorobenzenes, etc.) has been studied in greater detail.[50,94] Higher yields of perchlorate (up to 100%) were obtained at reduced temperatuers (–10 °C); the increase to room temperature leads to a sharp reduction of the yields.[50]

Table 2. The yields of secondary alkyl perchlorates in the reactions of olefins with perchloric acid in the presence of a acid catalyst (H_2SO_4 + SO_3).[50]

Olefin	Reaction product	Yield, %
Propene	$CH_3CH(OClO_3)CH_3$	96
Pent-1-ene	$CH_3CH(OClO_3)(CH_2)_2CH_3$	98
Hex-1-ene	$CH_3CH(OClO_3)(CH_2)_3CH_3$	99
Cyclohexene	$(CH_2)_5CHOClO_3$	89
Dec-1-ene	$CH_3CH(OClO_3)(CH_2)_7CH_3$	100
Octadec-1-ene	$CH_3CH(OClO_3)(CH_2)_{15}CH_3$	100
4-Phenylbut-1-ene	$PhCH_2CH_2CH(OClO_3)CH_3$	85
5-Methylhex-1-ene	$CH_3CH(CH_3)CH_2CH_2CH(OClO_3)CH_3$	76
Octa-1,7-diene	$CH_3CH(OClO_3)(CH_2)_4CH(OClO_3)CH_3$	85

In a study of the reactions of olefins with chlorine heptoxide in carbon tetrachloride, it was shown that they usually proceed with formation of a mixture of perchlorates, whose composition is determined by the structure of the olefin.[55] Thus the reaction of propene with chlorine heptoxide affords a mixture of 2-propyl and 1-chloropropyl perchlorates:

$$CH_2{=}CHCH_3 + Cl_2O_7 \rightarrow \underset{\substack{|\\OClO_3\\32\%}}{CH_3CHCH_3} + \underset{\substack{|\\OClO_3\\17\%}}{ClCH_2CHCH_3}.$$

Under these conditions, but-2-ene gives rise to the more complex mixture of products (XXI)–(XXIII), which is the same for the *cis*- and *trans*-olefins:

$$CH_3CH{=}CHCH_3 + Cl_2O_7 \rightarrow \underset{\substack{|\\OClO_3\\(XXI)}}{CH_3CH(OClO_3){-}CHCH_3} + \underset{\substack{|\\Cl\\(XXII)}}{CH_3CH(OClO_3){-}CHCH_3} + \underset{\substack{\|\\O\\|\\OClO_3\\(XXIII)}}{CH_3CCHCH_3}.$$

The reaction of tetramethylethylene with chlorine heptoxide leads to the formation of a mixture of the geminal diperchlorates (I) and (XXIV), which are insoluble in carbon tetrachloride:

$$\underset{\substack{CH_3\quad CH_3\\ \diagdown\ \diagup\\ C{=}C\\ \diagup\ \diagdown\\ CH_3\quad CH_3}}{} + Cl_2O_7 \rightarrow \underset{\substack{|\\OClO_3\\(I)}}{CH_3{-}C(OClO_3){-}CH_3} + \underset{\substack{|\\OClO_3\\(XXIV)}}{CH_3{-}C(OClO_3){-}C(CH_3)_3}.$$

Olefins with electron-accepting substituents (1,1-difluoroethylene, allyl chloride) and ethylene virtually do not react with chlorine heptoxide, but the addition of small amounts of water catalyses the reaction and leads to acceptable yields of perchlorates, which are in this case the products of the addition of perchloric acid to the double bond:

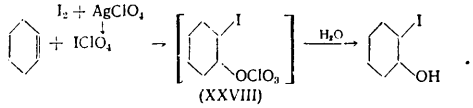
$$CF_2{=}CH_2 + Cl_2O_7 \xrightarrow[CCl_4]{H_2O} \underset{76\%}{CH_3CF_2OClO_3},$$

The wide variety of products in the reactions of olefins with chlorine heptoxide is apparently due to the combination of oxidation-reduction processes and a series of secondary reactions.[55] For example, the formation of the diperchlorate (XXI) can be explained by the interaction of chlorine heptoxide with the epoxide formed when but-2-ene is oxidised.

The additon of halogen perchlorates to the double bond has been studied in relation to perfluorinated olefins.[13,95] The reactions of chlorine and bromine perchlorates with tetrafluoroethylene, perfluoropropene, chlorotrifluoroethylene, and other perhalogeno-olefins take place rapidly at temperatures below -70 °C and lead to perhalogenoalkyl perchlorates in high yields (90–100%).[95] Chlorine and bromine perchlorates add to perfluoropropene strictly regiospecifically with formation of products of only kind—the perchlorates (XXV), in accordance with the Markovnikov rule, which is strong evidence in support of a polar addition mechanism:

$$CF_3CF{=}CF_2 + XOClO_3 \rightarrow CF_3CFXCF_2OClO_3. \quad (XXV)$$

X=Cl, Br.



On the other hand, a mixture of isomers having the normal structure [compound (XXVI)] and the iso-structure [compound (XXVII)] is formed in the reaction of fluorine perchlorate with perfluoropropene:[13]

$$CF_3CF{=}CF_2 + FOClO_3 \rightarrow CF_3CF_2CF_2OClO_3 + CF_3\underset{\underset{OClO_3}{|}}{C}FCF_3.$$

(XXVI), 68% (XXVII), 32%

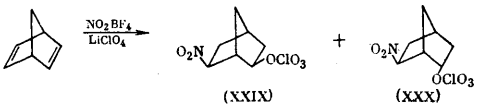
For this reaction, the authors[13] also proposed an ionic addition mechanism; the formation of the secondary perchlorate (XXVII) can be accounted for by the initial electrophilic attack by the oxygen atom on the carbon atom in the 2-position (the polarity of the F–O bond is probably the opposite of that of the Cl–O and Br–O bonds).

The addition of halogen perchlorates to unsaturated hydrocarbons has not been investigated. The only study on these lines[96] is at present only of historical interest. The authors[96] suggested that an ethereal solution of silver perchlorate and iodine contains iodine perchlorate and attempted to obtain 2-iodocyclohexyl perchlorate by treating cyclohexene with this solution:

(XXVIII)

However, the reaction product (XXVIII) proved to be unstable and the authors were able to isolate only 2-iodocyclohexanol after treating the reaction mixture with water. Here we may note that, according to the latest data,[12,97] iodine perchlorate is unstable and decomposes with formation of compounds of iodine in higher oxidation states even at temperatures below -50 °C. We therefore think that the explanation of the formation of compound (XXVIII) by the addition of ClO_4 to cyclohexene[96] is unlikely. An alternative mechanism may involve the coupled addition of iodine and the perchlorate anion to the double bond (see below).

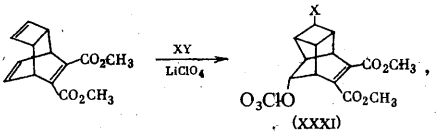
In the course of a study of the competitive binding of the perchlorate anion in carbonium ion processes, we studied in detail the reactions involving the coupled electrophilic addition of perchlorate to olefins.[14,15,35,98–100] A whole series of such reactions can be used for the preparative synthesis of covalent perchlorates. For example, the reactions of unsubstituted olefins (ethylene, hept-1-ene, and cyclohexene) with halogens or nitronium fluoroborate in the presence of a (2–10)-fold excess of lithium perchlorate take place smoothly in an aprotic organic solvent (ether, ethyl acetate, methylene chloride) with formation of β-halogeno- or β-nitro-perchlorates.[35] The addition takes place in accordance with the Markovnikov rule:



$$RCH{=}CHR' + XY + LiClO_4 \rightarrow RCH(X){-}CHR'(OClO_3),$$

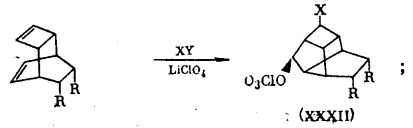
30–70%

R=R'=H; R=C_6H_{11}, R'=H;
RR'=$(CH_2)_4$; XY=Cl_2, Br_2, NO_2BF_4.



The reaction with cyclohexene leads to a mixture of the *cis*- and *trans*-substituted perchlorates.

The electrophilic perchlorate addition reactions have been investigated also for a series of skeletal olefins.[14,15,35] Thus norbornadiene reacts with nitronium fluoroborate and lithium perchlorate in ethyl acetate to form a mixture of the isomeric nitroperchlorates (XXIX) and (XXX) of the nortricyclene series (overall yield 72%):



(XXIX) (XXX)

The reactions of skeletal olefins of the tricyclo[4.2.2.$0^{2,5}$]decane series with electrophiles and lithium perchlorate afford, together with other rearranged products, stable skeletal perchlorates,[14,15] for example:

(XXXI)

(XXXII)

R=CH_3,CO_2CH_3.

The yields of the skeletal perchlorates (XXXI) and (XXXII) in these reactions reach 80%.

5. Synthesis of Covalent Perchlorates by Fragmentation Reactions

The next group of methods of synthesis of covalent perchlorates combines reactions involving the elimination of an electrically neutral species (N_2, CO_2, etc.) in the first stage. The reaction of alkyl chloroformates with silver perchlorate in benzene can be included among reactions of this type.[101] This reaction proceeds via a stage involving the elimination of a CO_2 molecule and leads to alkyl perchlorates together with benzene alkylation side products. In the course of the reaction, primary alkyl derivatives isomerise to secondary alkyl derivatives. The authors[101] proposed the following reaction mechanism:

$$ROCOCl \xrightarrow{Ag^+} \left[ROC^+(=O)\right] \xrightarrow{-CO_2} [R^+] \begin{cases} \xrightarrow{ClO_4^-} ROClO_3 + R'OClO_3, \\ \xrightarrow{-H^+} \text{alkene} + HClO_4 \rightarrow \text{polymer}, \\ \xrightarrow{C_6H_6} RC_6H_5 + R'C_6H_5, \end{cases}$$

where R is a primary alkyl and R' a secondary alkyl.

The yields of the perchlorates and benzene alkylation products in the reaction of chloroformate with a solution of silver perchlorate in benzene at 25 °C are given in Table 3. We may note that the low selectivity of this reaction limits significantly the scope of its use.

Table 3. The yields (%) of the products of the reactions of alkyl formates (ROCOCl) with silver perchlorate in benzene at 25 °C.[101]

R	$ROClO_3$	RC_6H_5	$R'OClO_3$	$R'C_6H_5$
CH_3	86	14	—	—
C_2H_5	47	37	—	—
n-C_3H_7	—	—	70*	10*
iso-C_3H_7	70	10	—	—
iso-C_4H_9	—	—	—	37**

*R′ = iso-C_3H_7; **R′ = t-C_4H_9.

The recently proposed[102,103] method of preparative nucleophilic substitution via "betylates"—salt-like compounds which are capable of readily eliminating the betaine fragment with formation of a covalent nucleophilic substitution product—is of undoubted synthetic value. In particular, the synthesis in 100% yield of 1-hexadecyl perchlorate via the betylate (XXXIII) by heating in toluene has been described:[102,103]

$$ROH \rightarrow ROSO_2(CH_2)_2\overset{+}{N}(CH_3)_3\,ClO_4^- \rightarrow ROClO_3 + {}^-O_3S(CH_2)_2\overset{+}{N}(CH_3)_3,$$
(XXXIII)

R=$C_{16}H_{33}$.

The reactions of aliphatic diazo-compounds with perchloric acid are accompanied by the evolution of nitrogen and also usually lead to covalent perchlorates. A reaction of this type was first carried out in a study[23] where methyl perchlorate was obtained by treating a solution of perchloric acid in ether with diazomethane:

$$CH_2N_2 + HClO_4 \rightarrow CH_3OClO_3 + N_2.$$

The authors[23] noted an extremely high risk of explosion in this method of synthesis of methyl perchlorate.

Dutch workers[11,104] used the reaction of diazosulphones with 70% perchloric acid in dichloroethane to synthesise covalent arenesulphonylmethyl perchlorates (XXXIV), whose yields reached 50%:

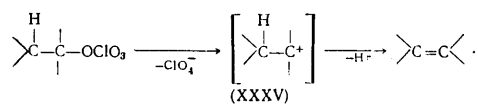
$$ArSO_2CHN_2 + HClO_4 \leftarrow ArSO_2CH_2OClO_3 + N_2,$$
(XXXIV)

Ar = p-$CH_3C_6H_4$, $C_6H_5CH_2$, C_6H_5, p-ClC_6H_4, m-ClC_6H_4, p-$NO_2C_6H_4$.

The present authors[36,105] investigated the deamination of alkylamines with nitrous acid in the presence of lithium perchlorate. These processes, which also proceed via the intermediate formation of diazoalkanes, lead to covalent perchlorates as a result of the nucleophilic substitution of the diazo-group by the perchlorate anion. The reactions were carried out by adding various acids (for example, acetic or hydrochloric) to a mixture of alkylamines, sodium nitrite, and lithium perchlorate in an organic solvent (ether, ethyl acetate) or in water:

$$RNH_2 + NaNO_2 + HX + LiClO_4 \rightarrow ROClO_3,$$
R = n-C_4H_9, n-C_7H_{15}, n-C_9H_{19}; X = Cl, OAc.

Alkyl perchlorates were isolated from the reaction mixture in 30–40% yields.



In conclusion of this Section, we emphasise yet again that all the traditional methods of synthesis of covalent perchlorates involve the risk of explosion to a greater or lesser extent. This risk is largely due to the nature of the inorganic reagents themselves—donors of the perchlorate group. Anhydrous silver perchlorate, which is most often used for this purpose, explodes even on friction.[1] The extremely high danger of the explosion of perchloric acid and chlorine heptoxide, especially on contact with organic solvents, is generally known. Fluorine, chlorine, and bromine perchlorates are unstable and extremely explosive at any temperatures and in any state.[90,91] On the other hand, the methods of synthesis of covalent perchlorates developed by the present authors[14,15,34,48,89,98–100] are more acceptable for practical use, since the reagents in these reactions are the lithium or alkylammonium salts of perchloric acid, which are safe to handle.

III. PROPERTIES

1. Physicochemical Properties and the Problem of Stability

A common property, characteristic of virtually all covalent organic perchlorates is a high risk of their explosion. The first investigators,[2,23] who obtained the simplest alkyl perchlorates, already noted that these highly volatile liquids (the boiling points of ethyl and methyl perchlorates are respectively 52° and 89 °C [23]) are very dangerous to handle. The perchlorates of monohydric alcohols[1,49] and also the lowest β-nitroalkyl[35] and β-nitratoalkyl[37] perchlorates are even more dangerous—these compounds are explosive even in solutions!

Furthermore, a very low thermal stability has been noted for many organic perchlorates: even at room temperature, these compounds char rapidly or polymerise. The low stability of covalent perchlorates is apparently due to the highly nucleofugitive nature of the perchloryloxy-group, i.e. the ease with which it can be expelled from the carbon skeleton with formation of carbonium ion intermediates (XXXV) and elimination products:

(XXXV)

The subsequent interaction of these species with one another leads to polymeric products. Evidently, perchlorates containing substituents capable of stabilising the carbonium ion (XXXV) formed and hence facilitating the heterolytic dissociation of the C–$OClO_3$ bond, will be the least stable. Indeed, according to the available literature data, t-alkyl perchlorates,[51,62] allyl perchlorates,[71] and benzyl perchlorates[106,107] are the least stable; when an attempt is made to obtain them by treating the corresponding halogeno-derivative with silver perchlorate in nitromethane, the mixture chars or a polymeric deposit is formed (molecular weight about 1000 [106,107]).

On the other hand, the presence of electron-accepting substituents in the molecule hinders the heterolysis of the C–$OClO_3$ bond, which usually increases the stability of the perchlorates. Thus perfluoroalkyl perchlorates can be stored at room temperature for years,[12,86]

decomposing only slowly on heating to 200 °C, and are hardly hydrolysed by water. Trifluoromethyl perchlorate decomposes slowly on heating above 100 °C only in the presence of a catalyst—caesium fluoride:[12,88]

$$CF_3OClO_3 \xrightarrow{CsF} COF_2 + FClO_3.$$

The polyperchlorates of polyhydric alcohols[1] and *gem*-diperchlorates[56] are apparently more stable on heating than alkyl perchlorates. 2,2-Diperchloryloxypropane (I), obtained by Baum,[56] can be distilled without decomposition and explodes only on heating to 250 °C; however, *gem*-diperchlorates are exceptionally sensitive to the action of water.

Arenesulphonylmethyl perchlorates (XXXIV) have a high thermal stability.[11,104] These compounds melt without decomposition at temperatures above 100 °C but are extremely explosive.[11] It has been reported[108] that explosions of the single crystals in the diffractometer were observed during the X-ray diffraction analysis of toluene-*p*-sulphonylmethyl perchlorate.

It is interesting to note for comparison that covalent silyl perchlorates exhibit a higher stability than alkyl perchlorates.[18,72,73,109,110] Trialkylsilyl perchlorates $R_3SiOClO_3$ (R = CH_3, C_2H_5, n-C_3H_7, or t-C_4H_9) are oily liquids which fume in air and can be purified by vacuum distillation. The reaction of t-butyl dimethylsilyl perchlorates with alcohols can be used to introduce the trialkylsilyl protecting group.[18,110]

Skeletal perchlorates with a rigid carbon skeleton are more stable than alkyl perchlorates. The stable skeletal perchlorates (XIII), in which the perchlorate group is attached to a tertiary carbon atom, has been obtained.[16,17] Skeletal covalent secondary perchlorates, obtained by the present authors,[15] melt without decomposition at 120—150 °C, are insensitive to impact, and can be stored at room temperature for a long time without appreciable decomposition.

2. Identification

The problem of the identification of perchloric acid ester arose in the first studies on the synthesis of these compounds.[23,24,58] The highly explosive nature of covalent perchlorates precluded elemental analysis by combusting the specimen and hindered the use of chemical identification methods. The explosive decomposition of the lower perchlorates on heating in a capillary was used as a qualitative test for perchlorates.[68] The first quantitative methods for the determination of perchloric acid esters consisted in treating the specimen with an alcoholic solution of KOH with subsequent gravimetric determination of the precipitate of potassium perchlorate, which is insoluble in ethanol.[25] A more modern modification of this method consists in the titrimetric determination of the amount of alkali needed for the complete hydrolysis of the perchloric acid ester.[19,49] It has been found[62,69,71,102,103,111] that covalent perchlorates readily alkylate anisole and toluene in the *para*-position. In its analytical version, this reaction can also be used for the identification of perchlorates. The hydrolysis to alcohols with a known structure has likewise been employed to identify certain perchloric acid esters.[96]

New possibilities for the qualitative and quantitative determination of covalent perchlorates appeared after the development of spectroscopic techniques. The IR spectra of individual alkyl perchlorates were first obtained by Radell et al.[67] and intense absorption bands at 1230 and 1260 cm,$^{-1}$ [$\nu_{as}(ClO_3)$], in the range 1000 to 1100 cm^{-1} [$\nu_s(ClO_3)$], and near 700 cm^{-1} [ν(Cl—O)], characteristic of covalent organic perchlorates, were found. There are no absorption bands in the range 1200—1300 cm^{-1} in the spectra of inorganic perchlorates. Subsequently, it was shown for a large number of perchlorates that intense bands in the range 1200—1300 cm^{-1} are present in the spectra of covalent organic perchlorates of any structure with different substituents[11,13,51] and can be used for the identification of these compounds.

Exceptional possibilities for the identification of perchloric acid esters are provided by NMR.[11,13,50,51,55,104] The presence of an electron-accepting substituent in the molecule (the perchloryloxy-group) results in a pronounced downfield shift of the signal. Thus the chemical shift of the α-proton attached to the perchloryloxy-group (solution in carbon tetrachloride) is 4.2 p.p.m. for methyl perchlorate and from 4.4 to 4.6 p.p.m. for n-alkyl perchlorates.[51] In the presence of a second electron-accepting substituent, the signal of the α-proton at the perchloryloxy-group shifts downfield even further; for example, it is 5.17 p.p.m. for 1-chloro-2-propyl perchlorate,[55] 5.56 p.p.m. for 2-fluoro-2,2-dinitroethyl perchlorate,[51] 6.3 p.p.m. for methylene diperchlorate, and 5.1—5.4 p.p.m. for arenesulphonylmethyl perchlorates.[11] ^{1}H NMR is very convenient for the determination of the yields of perchlorates without isolation from solution by integrating the spectrum of the specimen using a quantitative internal standard.[50,51,54,55,87,101–103]

Mass-spectrometric studies have been carried out only for perfluoroalkyl perchlorates[12,13,88,95] and β-bromoethyl perchlorate.[35] Molecular peaks have been detected in the mass spectra of trifluoromethyl perchlorate[12] and β-bromoethyl perchlorate.[35] Mass spectrometric data for the decomposition of perfluoroalkyl perchlorates with formation of the ClO_3^+, ClO_2^+, and ClO^+ fragments, but not ClO_4^+, have been used[12] to confirm their covalent structure.

Thin-layer[14,15,50,74] and gas—liquid[51,54] chromatographic methods have been employed for the identification and purification of covalent perchlorates. The thin-layer chromatography has proved very useful for the qualitative detection of covalent perchlorates: a characteristic property of these compounds is decomposition with formation of a black spot on moderate heating (100—150 °C) of the plate.[15,35]

Elemental analysis by combustion of the specimen has proved possible for the stable sulphonylmethyl,[11] perhalogenoalkyl,[12] and certain other perchlorates.[14,15,51,55,56]

X-Ray diffraction analysis has been used in recent years to establish the structures of a series of covalent perchlorates.[16,108,113–116] As a result of these investigations, the structures of toluene-*p*-sulphonylmethyl perchlorate[108] the skeletal perchlorate (XIII) of the trisecododecahedrane series,[16] as well as a series of skeletal secondary perchlorates having the tetracyclo[6.1.1.$0^{2,7}$0^{5,10}]-decane (XXXI) [113,114] and tetracyclo[5.3.0.$0^{2,5}$0^{3,8}]decane (XXXI) [115,116] carbon skeletons have been determined unambiguously.

3. Chemical Properties of Covalent Perchlorates

(a) General characteristics of the reactivity of covalent perchlorates. In the first studies on perchloric acid esters, it was already observed that these compounds are extremely reactive and enter especially readily into nucleophilic substitution reactions with water[23,96] and alcohols:[24]

$$Alk\,OClO_3 + ROH \rightarrow Alk\,OR + HClO_4,$$
$$R = H,\ Alk.$$

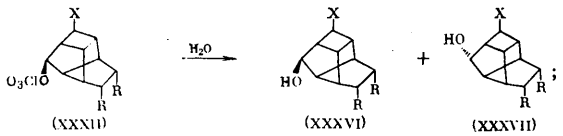
It was shown later that alkyl perchlorates exhibit a strong alkylating activity in relation to aromatic compounds.[65,111,112]

The high reactivity of covalent perchlorates, manifested even in reactions with weak nucleophiles, is due primarily to the fact that the perchlorate anion is a very effective leaving group or, in other words, is highly nucleofugitive. The alkylating capacity of covalent perchlorates varies within very broad limits as a function of the nature of the substituents and the structure of the carbon skeleton. t-Alkylperchlorates[51,62] as well as perchlorates of the allyl[71] and benzyl[106,107] series showed the most striking alkylating activity. The reactions of these perchlorates with nucleophiles apparently proceed via an S_N1 mechanism. Alkyl perchlorates with normal and secondary structures are less reactive and a bimolecular mechanism of the nucleophilic substitution of the perchlorate group is more characteristic of them. The introduction into the molecule of electron-accepting substituents such as a halogen[95,117] and the sulphonyl[10] or carboxy-groups[118] reduces the reactivity of the covalent perchlorate sharply: the abstraction of the ClO_4 group from the carbon atom in these perchlorates is very difficult and processes involving the dissociation of the $O-ClO_3$ bond become preferable.[10,117,118] Certain skeletal perchlorates [for example, compounds (XXXI) and (XXXII)], whose structural features hinder the attack by the nucleophile on the reaction centre, also exhibit a reduced reactivity.[118,119]

The reactions of covalent perchlorates have been studied in greatest detail in relation to methyl perchlorate[19-22,120-128] for a number of reasons. Firstly, methyl perchlorate is capable of undergoing nucleophilic substitution reactions even with very weakly nucleophilic species,[19,78,119,120,129,130] which permits the use of this compound as the substrate for kinetic studies designed to determine the nucleophilicity parameters in S_N2 processes.[121-124] Secondly, the markedly nucleofugitive properties of the perchlorate anion lead to certain anomalies in the kinetics of processes involving the nucleophilic substitution of the perchlorate group, which were initially actually interpreted as evidence in suport of a unimolecular reaction mechanism[123,124] and subsequently stimulated discussion[21,22,64,125] and a more profound study of these processes.[22] Finally, the perchlorate anion has solvation characteristics anomalous for an effective leaving group[126] and this leads to certain characteristic features of the kinetics of the hydrolysis of methyl perchlorate which are of theoretical interest.[19,126]

(b) Solvolysis of covalent perchlorates. Covalent perchlorates frequently enter into nucleophilic substitution reactions even with weakly nucleophilic species such as water and alcohol molecules. The highly nucleofugitive nature of the perchlorate anion leads to certain characteristics of the mechanisms of these processes. The problem of the solvolysis of covalent perchlorates attracted much attention after the publication of the studies[121-124] in 1967–1969 in which it was concluded, from a comparison of the activation entropies for the reactions of methyl perchlorate with certain nucleophiles, that the hydrolysis of this compound has an S_N1 mechanism in contrast to the S_N2 mechanism of methanolysis. This conclusion encountered sharp criticism[21,22,64,131] and gave rise to a number of kinetic studies devoted to a deeper understanding of the mechanism of the solvolysis of methyl perchlorate.[20-22,130,132] The rates of hydrolysis of methyl and ethyl perchlorates have been compared to determine the molecularity of the hydrolysis of methyl perchlorate.[64] In the case of a unimolecular mechanism, one would expect an appreciable acceleration of the hydrolysis after the introduction of the methyl group into the molecule, while for an S_N2 mechanism significant changes in rate in any direction can be usually observed. It was found[64] that the ratio of the rate constants for the hydrolysis of methyl and ethyl perchlorates is 0.8, which is within the limits established for a bimolecular mechanism in relation to a wide variety of leaving groups.

An alternative explanation of the kinetic features of the hydrolysis of methyl perchlorate in terms of Sneen's S_N2C^+ ion-pair mechanism.[133] However, this interpretation appears extremely unconvincing and has been justifiably rejected.[22,130,134] Kinetic data and especially data on the secondary isotope effect, which is observed in the hydrolysis of methyl perchlorate, have been explained within the framework of the traditional S_N2 mechanism and the hypothesis that the transition state in this reaction is looser than usual.[22] A more profound study of the nature of the transition state in the solvolysis of methyl perchlorate has been carried out using isotope effect data.[127] The values of the m constant in the Grunwald–Winstein equation, characterising the nature of the substrate, were used as evidence for the traditional S_N2 mechanism of the hydrolysis.[20,130] For the hydrolysis of methyl perchlorates in the methanol–water system, $m = 0.11$, which is characteristic of a typical S_N2 reaction. On the other hand, in the case of the S_N1 or the S_N2C^+ ion-pair mechanism one would expect $m = 1$.[130] In careful investigation of the kinetics of the solvolysis of covalent perchlorates in solvent systems with different ionising powers Y, a maximum was observed on the plots of the solvolysis rate constant against Y.[20,130] The presence of a region in which the rate of hydrolysis diminishses with increase in the concentration of water in the aprotic solvent (acetone or dioxan) was explained[20,130] by the unusual solvation characteristics of the perchlorate ion, which is more effectively solvated in a dipolar aprotic solvent than in water.[134]

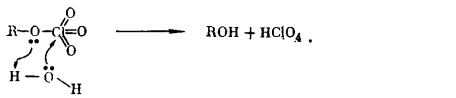


The substitution of a hydrogen atom in methyl perchlorate by an electron-accepting group, such as the sulphonyl[10] and trifluoromethyl[171] groups, leads to other pathways in the solvolytic processes. In such cases, the oxidation-reduction decomposition with elimination of the chlorate anion becomes preferable.

The mechanism of the solvolysis of arenesulphonylmethyl perchlorates has been studied in greatest detail.[11,135-141] The rate of solvolysis of these compounds is determined by the slow stage involving the deprotonation of the methylene group; the carbanion formed decomposes rapidly with formation of the chlorate anion, formic acid (or alkyl formate if the reaction is carried out in alcohol), and arenesulphonic acid.[135-141]

$$ArSO_2CH_2OClO_3 + ROH \rightarrow ArSO_2\bar{C}HOClO_3 + R\overset{+}{O}H_2$$
$$\downarrow ROH$$
$$ArSO_2H + HCOOR + ClO_3^-;$$
$$Ar = p\text{-}NO_2C_6H_4, p\text{-}CH_3C_6H_4;\ R = H, CH_3, C_2H_5, t\text{-}C_4H_9, n\text{-}C_5H_{11}, CF_3CH_2.$$

This pathway is apparently associated with the increased acidity of the methylene protons in arenesulphonylmethyl perchlorates as a consequence of the presence of two strong electron-accepting substituents in the molecule.



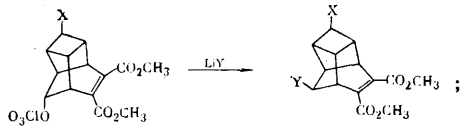
The pathway followed in the solvolysis of secondary perchlorates has been investigated solely in relation to skeletal perchlorates of the type (XXXI) and (XXXII), obtained by reactions involving the coupled electrophilic addition of the perchlorate group to olefins by the authors of the present review.[118] We investigated the reactions of covalent skeletal secondary perchlorates with water and $H_2{}^{18}O$ in acetone and dimethyl sulphoxide (DMSO) under various conditions. In all cases, the stereoisomeric hydroxy-derivatives (XXXVI) and (XXXVII) were isolated as the reaction products, the reaction in acetone proceeding preferentially with retention of configuration of the reaction centre and in DMSO with its inversion:

(XXXII) (XXXVI) (XXXVII)

X=Ar,I; R=CH_3,CO_2CH_3.

The absence of selectivity in the hydrolysis and the results obtained for the distribution of the ^{18}O label can be explained[118] with the aid of a mechanism involving the attack by a water molecule on the chlorine atom in the perchlorate group:

Examples of such reactions in the series of inorganic perchloric acid derivatives are known,[51,53,54] but for covalent organic perchlorates the occurrence of processes determined by the attack on the chlorine atom by the nucleophile were not observed previously.



(c) Nucleophilic substitution reactions. Processes involving nucleophilic substitution in covalent perchlorates are of both theoretical[19,78,120,121,123,124] and practical[4,76,77] interest due to the high reactivity of these compounds. The kinetics of the reactions of methyl perchlorate with more than 20 different nucleophiles have been studied[123,124] in water and methanol in order to test the applicability of the Swain–Scott equation.[25] It was noted[123,124] that the rates of reaction of methyl perchlorate depend relatively slightly on the nature of the nucleophile, which is consistent with the idea that the perchlorate anion is a very effective leaving group. On the whole, it is concluded that these reactions have an S_N2 mechanism and that it is impossible to construct a general series in terms of the strength of the nucleophiles from the processes investigated.

The study of the kinetics of the reactions of methyl perchlorate with amines in water and methanol led to the conclusion[121] that these reactions, carried out with 25 amines, have a bimolecular mechanism. However, in the case of ammonia and butylamine the author put forward the hypothesis that there may be competition between S_N2 and S_N1 mechanisms. This hypothesis is doubtful bearing in mind the results of the polemics on the hydrolysis of methyl perchlorate (see the previous Section).

The kinetics of the reactions of a series of alkyl perchlorates (methyl, ethyl, isopropyl, and 2-adamantyl perchlorates) with *NN*-dimethylaniline in benzene have been studied recently.[19] On the basis of the kinetic parameters and especially the absence of an appreciable H/D isotope effect, it was shown that these reactions proceed via a classical S_N2 mechanism and that the second order rate constants decrease in the sequence Me > Et > iso-Pr $\gg$ 2-Ad.

The high reactivity of the covalent perchlorates is clearly manifested in relation to their reactions with weak nucleophiles such as arenesulphonate anions.[119,120] In a study of the kinetics of the reactions of various tetrabutylammonium arenesulphonates with methyl perchlorate in acetonitrile, the reaction was found to be of second order and it was established that the rate constants are independent of the concentration of the salt.[120] On the other hand, in the bimolecular reaction of silver toluene-*p*-sulphonate with methyl perchlorate, a decrease in the rate constant was observed with increase in the concentration of silver toluene-*p*-sulphonate, which is apparently a consequence of the decrease in the nucleophilicity of the anion as a result of the formation of close ion pairs with the silver cation.

The present authors investigated the stereochemistry of the reactions of skeletal covalent secondary perchlorates with a series of nucleophiles, including arenesulphonate anions (in relation to the toluene-*p*-sulphonate anion.[119] It was shown that the reactions of the perchlorates (XXXI) and (XXXII) with the nucleophiles proceed with complete inversion of the configuration at the reaction centre, which constitutes convincing evidence in support of the S_N2 mechanism:

(XXXI), X=SAr; Y=Cl,Br.

(XXXII). X=SAr,I; R=CH_3,CO_2CH_3; Y=Cl,Br, p-NO_2-$C_6H_4SO_3^-$.

The reactions investigated can serve as a convenient method for introducing various substituents into the molecule of a skeletal compound.

Several studies in which covalent compounds were used for synthetic purposes as alkylating agents have been published in recent years.[76,77] For example, methyl perchlorate can be used to alkylate sugars[77] and certain heterocyclic compounds.[76] Unfortunately, the number of such studies is very limited, but further investigations in this field will undoubtedly lead to the discovery of new synthetic applications of the highly reactive covalent organic perchlorates.

---o0o---

It is seen from the data examined in this review that covalent organic perchlorates have become a class of accessible compounds suitable for various chemical reactions. Although the possibilities for their practical application are held back by the potential and frequently real risk of explosion of perchloric acid esters, nevertheless in most cases this obstacle can be readily eliminated by employing them without intermediate isolation in the form of safe solutions in inert solvents. Furthermore, studies on the reactivity of covalent perchlorates have demonstrated that the perchlorate anion is one of the best leaving groups. The data obtained constitute a basis for the practical utilisation of covalent perchlorates in synthesis as reagents with a stronger alkylating activity than the traditional toluene-*p*-sulphonates and other organic sulphonates. Another distinctive feature is that substitution in perchloric acid esters takes place via an S_N mechanism. Thus a basis has been created for stereospecific syntheses, which also constitutes an advantage of alkyl perchlorates over traditional alkylating agents.

Aryl Derivatives of Thallium(III): Preparation and Use in Organic Synthesis

A.Ya.Usyatinskii and V.I.Bregadze

The review presents new data on the preparation of aryl derivatives of thallium(III) and their application in organic synthesis, which is based on the possibility of the selective introduction of an organic group into an aromatic ring by replacing the thallium atom in arylthallium compounds. Processes involving the modification of aromatic compounds in the presence of thallium salts are also considered. The probable mechanisms of the reactions occurring in such processes are discussed. The bibliography includes 97 references.

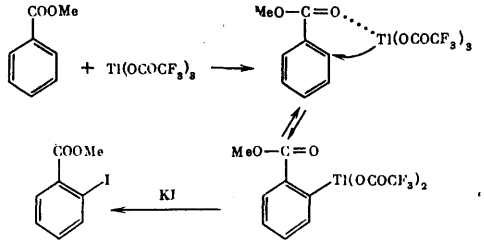
I. SYNTHESIS OF COMPOUNDS OF THE TYPE $ArTlX_2$



1. Reactions Involving Direction Thallation of Arenes

The commonest method of synthesis of compounds of the type $ArTlX_2$ and one which has been investigated in greatest detail is the direct thallation of arenes by trivalent thallium salts. The most convenient system for this purpose comprises thallium trifluoroacetate (TTFA) in trifluoroacetic acid (TFAA).[1-4]

In contrast to arenes activated by electron-donating substituents, which are thallated at room temperature in several minutes, the complete conversion of halogenobenzenes was attained in 48 h at room temperature or in 30 min in boiling TFAA. Substrates with a nucleus deactivated with respect to electrophilic substitution, such as benzoic acid and ααα-trifluorotoluene react with TTFA in boiling TFAA in 21 and 98 h respectively.

The reaction involving the substitution of the thallium atom by an iodine atom can be used to establish the position of substitution in the aromatic ring on thallation. The authors suggest the following methods of synthesis of aryl iodides from the arylthallium bis(trifluoroacetates) obtained depending on the properties of the latter: (a) treatment of the reaction mixture with an aqueous KI solution after the completion of thallation without isolating the products—for arylthallium bis(trifluoroacetates) soluble in CF_3COOH; (b) isolation, drying, and interaction with KI in an aqueous acetone solution—for products crystallising from the reaction mixture; (c) the addition of KI to the reaction mixture in acetonitrile—for aromatic systems sensitive to the action of acids.

The effect of the substituent in the aromatic nucleus on the isomeric composition of the thallation products has been investigated.[3] In the thallation of benzoic acid by treatment with TTFA in TFAA, it was established that substitution takes place mainly in the *ortho*-position in the aromatic ring. It was postulated initially that a mixed thallium(III) carboxylate is formed during the reaction and then donates the thallium atom to the *ortho*-position. However, the thallation of methyl benzoate also affords mainly the *ortho*-products. Bearing this finding in mind, the following reaction mechanism has been suggested:[3]

The isomeric composition of the products formed on thallation of aromatic compounds is presented in Table 1.

Analysis of the data in Table 1 for the thallation-iodination† of the homologous series of phenyl-containing carboxylic acids (compounds 4, 5, 10, and 11 in Table 1) shows that the degree of *ortho*-substitution depends appreciably on the chain length of the carboxyl-containing group, since the carboxy-group is a complex-forming agent in relation to TTFA. In fact, an intermediate is formed in the σ-complex formation stage in which the Tl atom is linked to a carbon atom of the arene and is coordinated to the carbonyl O atom in the side chain of the substitutuent. Such intermediate complexes have been called[3] "chelate intermediates". Thus, whereas benzoic and phenylacetic acids and the corresponding methyl esters afford exclusively *ortho*-derivatives via five- or six-membered "chelate" rings, the *ortho*-thallation of phenylpropionic acid can proceed only via the formation of a seven-membered "chelate" ring, which is less preferable and this in fact entails a decrease in the content of the *ortho*-thallation product (29%).

† By the term thallation-iodination, the authors denote the preliminary thallation of the substrate followed by the treatment of the compounds obtained with KI using one of the methods described by McKillop et al.[2]

The behaviour of a whole series of aromatic compounds containing substituents in the side chain, which are capable of forming complexes with TTFA, has been investigated[3] from the standpoint of the possible supply of the thallium atom to the ring via a "chelate intermediate" formed by the Lewis acid (TTFA) and an oxygen-containing Lewis base. Thus substrates capable of forming five- and six-membered intermediate chelates give rise almost exclusively to *ortho*-substitution products (compounds 15, 17, 22, and 23 in Table 1). The increase in the chain length of the intermediate chelate leads to a sharp fall of the yield of the *ortho*-isomer (compounds 10, 11, 18, and 20 in Table 1). The degree of *ortho*-substitution depends also on the nature of the Lewis base in the side chain of the substrate and decreases in the sequence ester, acid, ether, alcohol. Intramolecular thallation via a "chelate ring" is extremely sensitive to steric factors. Thus the replacement of one α-hydrogen atom in phenylacetic acid by the methyl group results in a decrease in the degree of *ortho*-substitution from 92 to 65%, while the replacement of the second α-hydrogen atom by the methyl group altogether inhibits *ortho*-substitution.

Table 1. The isomeric composition of the products of the thallation of the arenes C_6H_5R at room temperature.[3]

No.	R	Proportions of isomers, %		
		ortho	*meta*	*para*
1	CH_3	9	4	87
2	$CH_2CH_2CH_3$	3	6	91
3	$CH(CH_3)_2$	1	5	94
4	COOH	95	5	0

26	$OCOCH_3$	21	0	79
27	—*	31% thallation in the 6-position		

*2-$CH_3C_6H_4CH_2COOH$.

The intermediate formation of a "chelate" ring is supported by the following results: firstly, the thallation of compounds containing in the side chain activated substituents incapable of forming "chelate complexes" with TTFA takes place in several minutes at room temperature, while the presence of a Lewis base in the side chain appreciably increases the thallation time regardless of the size of the ring which may be formed. Secondly, the degree of *meta*-substitution is highest when there is a possibility of the formation of an eight-membered "chelate" (compounds 8, 16, 18, and 25 in Table 1) and also in those cases where *ortho*-thallation via a "chelate complex" is hindered by steric factors (compounds 6 and 7 in Table 1). The thallation of cumene (compound 3 in Table 1), which has a bulky substitutuent incapable of forming a complex with thallium-(III), affords only 5% of the *meta*-isomer. The authors conclude that thallation is a process much more sensitive to steric factors than mercuration.

Thallation under the conditions of kinetic control leads to the initial preferential formation of *ortho*- and *para*-isomers. Since thallation is reversible, an increase in temperature to 73 °C (boiling CF_3COOH) increases the fraction of the *meta*-isomer, i.e. in this case thermodynamic control plays a significant role.

It is noteworthy that thallation of a substrate containing in the side chain substituents capable of complex formation requires additional time for the attainment of equilibrium. This finding imposes definite synthetic limitations on the *meta*-thallation process, since TTFA decomposes after prolonged heating in TFAA. Thallation of β-phenylethyl acetate (compound 18 in Table 1) under the conditions of kinetic control leads to substitution in the *para*-position of the aromatic ring (84%), which is associated with the increase in ring size in the *ortho*-thallation intermediate from six-membered for β-phenyl-ethanol (compound 17 in Table 1) to eight-membered in its acetate.

Thus variation of the thallation conditions (thermodynamic and kinetic control) makes it possible to introduce a thallium atom selectively in a specific position in the aromatic nucleus.

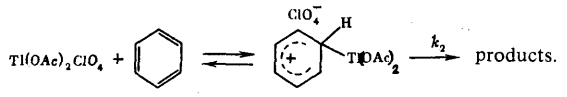
Thallium(III) acetate in acetic acid containing added $HClO_4$ has been used[5] as a thallating agent. In this case, thallation also proceeds smoothly, especially in the case of arenes activated with respect to electrophilic substitution. The products isolated were characterised as the monohydrates of mixed arylthallium acetate perchlorates. The highest yield of the arylthallium compounds is attained at room temperature. An increase in temperature entails a decrease in yield owing to the occurrence of side processes such as the coupling of aromatic radicals and the oxidation of the solvent with formation of a thallium(I) salt.

A series of kinetic studies of the influence of various additives on the course of thallation have been carried out. The thallation of arenes in various acids has been investigated.[6] Heating of thallium-(III) acetate with benzene in 1 M H_2SO_4 leads to the rapid precipitation of a deposit containing $PhTl(HSO_4)_2$, Ph_2TlHSO_4, and $Tl(HSO_4)_3$. Heating of benzene with a thallium(III) salt in perchloric acid affords a mixture of phenylthallium dichloride with diphenylthallium chloride.

It has been established[6] that the rate of thallation increases with increase in temperature to a greater extent for an activated aromatic compound (toluene) than for a non-activated one (benzoic acid). This fact can be associated both with the electronic effects of the substituents and with the possible formation of an intermediate chelate complex.[3] An approximate estimate of the rates of thallation and mercuration in aqueous $HClO_4$ demonstrated that the rate of mercuration under identical conditions is approximately 200–400 times higher than the rate of thallation.

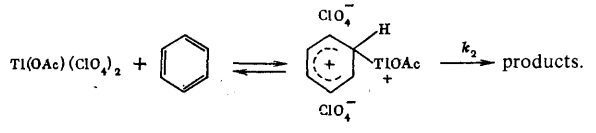
The influence of catalytic strong acid additives on the rate of thallation has been investigated.[7,8] The authors showed that perchloric acid is a more active thallation catalyst than sulphuric acid. The mechanism of the catalysis consists in the formation of polar electrophilic species which are involved in an acid–base

equilibrium:



$$\begin{array}{l} Tl(OAc)_3 \rightleftarrows [Tl^{-}(OAc)_2^{-}OAc] \rightleftarrows Tl^{+}(OAc)_2 + OAc^{-}, \\ K_4\downarrow\uparrow \\ Tl(OAc)_2ClO_4 \rightleftarrows [Tl^{+}(OAc)_2ClO_4^{-}] \rightleftarrows Tl^{+}(OAc)_2 + ClO_4^{-}, \\ K_5\downarrow\uparrow \\ Tl(OAc)(ClO_4)_2 \rightleftarrows [Tl^{2+}(OAc)\,2ClO_4^{-}] \rightleftarrows Tl^{2+}(OAc) + 2ClO_4^{-}, \\ K_6\downarrow\uparrow \\ Tl(ClO_4)_3 \rightleftarrows [Tl^{3-}3ClO_4^{-}] \rightleftarrows Tl^{3+} + 3ClO_4^{-}. \end{array}$$

The values of K_1 were calculated for the *p*-nitroaniline–perchloric acid–thallium(III) acetate system. On the assumption that $Tl(OAc)_2ClO_4$ does not react with the indicator, K_1 = 4.6–5.0 litre mol^{-1}; on the other hand, if $Tl(OAc)_2ClO_4$ does react with the indicator, like $Tl(OAc)_3$, then the constants K_1 are between 6.0 and 8.4 litre mol^{-1}.

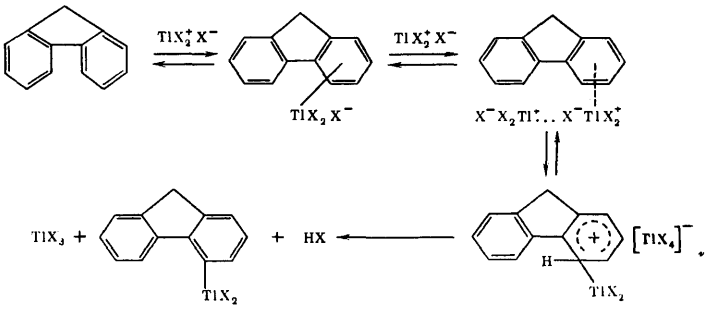


The data obtained show that the constants K_1 and K_2 are important for the determination of the character of the equilibrium in solution and hence of the thallation process itself, since at high catalyst concentrations the content of the $Tl(OAc)_2X$ species increases – the degree of conversion of $Tl(OAc)_3$ into $Tl(OAc)_2X$ is 92% for [HX] = 0.5 M. The data for the conductivities of the solutions permit the conclusion that in pure acetic acid, thallation is effected by the electrophile in the form of an ion pair, while in dilute solutions ionic species are active.

It follows from the activation parameters E_a and $\Delta S^{\neq}$ that more than one electrophilic species is involved in the thallation process. At low catalyst concentrations the process is characterised by high values of E_a and an appreciable positive entropy, while at high concentrations, where the catalyst is most effective, the values of E_a are comparatively low but $\Delta S^{\neq}$ also diminishes appreciably. According to the authors, the rate-limiting stage of the process is the decomposition of Wheland's intermediate, characterised by the constant k_2 (Schemes 1 and 2). The authors describe the process by Scheme 1 at low catalyst concentrations and by Scheme 2 at high concentrations:

Scheme 1

Scheme 2



In their study of the variation of the isomeric composition of the toluene thallation products with time, the authors found that *para*-thallation initially predominates, its extent falling with time and with decrease in the catalyst concentration. Thus thallation for 24 h at an H_2SO_4 concentration of 2 M leads to the following proportions of the isomers: 18.7% *ortho*, 6.4% *meta*, and 75% *para*; when $[H_2SO_4]$ = 0.4 M, the proportions are 37.6, 3.4, and 59% respectively.

The kinetics of the thallation of fluorene by thallium(III) acetate in aqueous acetic acid have been investigated.[9] The authors observed that the reaction is of first order with respect to the substrate and of second with respect to thallium triacetate; its rate is described by the equation

$$v = k_3[Tl(III)]^2[\text{fluorene}].$$

The addition of strong protic acids sharply accelerates thallation; the reaction is of sixth order with respect to sulphuric acid. The reaction mechanism described by Scheme 3 was put forward:

Scheme 3

The second order with respect to the thallating agent agrees with the assumption of the participation of two and more electrophilic species in the thallation process,[8] but the influence of the second electrophile molecule may also be different than that suggested by Narasumnau et al.[9] In principle, there is a possibility of the formation of a dimeric species (Scheme 4) which is a stronger electrophile than the initial thallium(III) salt:

Scheme 4

$$2TlX_3 \rightleftarrows Tl_2X_6 \quad \text{or} \quad [TlX_2]^{+}[TlX_4]^{-}.$$

In a study of the thallation of activated arenes by TTFA in TFAA, the formation of the aromatic radical-cation Ar^{+} in the reaction mixture was detected by EPR.[10] According to the authors, the reaction proceeds via a one-electron transfer stage:

Scheme 5

$$Tl^{III} + ArH \rightleftarrows [ArH\cdot Tl^{III}];\ [ArH\cdot Tl^{III}] \rightleftarrows [ArH^{+\cdot}Tl^{II}],$$

$$[ArH^{+\cdot}Tl^{II}] \begin{cases} \longrightarrow Tl^{II} + ArH^{+} \\ \longrightarrow Ar^{+}{}_{Tl^{III}}{}^{H} \xrightarrow[-H^{+}]{} ArTl^{III} \end{cases}$$

The authors suggest that the electron transfer stage is an obligatory process both for aromatic thallation and for the formation of Ar^{+}.

This concept was developed further in a study[11] where the interaction of the homologous series of methylbenzenes $C_6H_n(Me)_{6-n}$ with TTFA was investigated. It was shown that the active electrophilic species in this process is the cation $[Tl(OCOCF_3)_2]^{+}$, formed as a result of the reversible reaction

$$TTFA \rightleftarrows [Tl(OCOCF_3)_2]^{+} + CF_3COO^{-}\ (K).$$

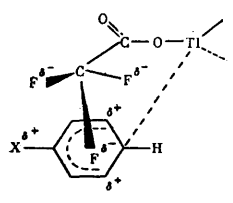
The constant K at 25 °C in TFAA is 1×10^{-3} mol $litre^{-1}$. According to the authors,[11] further reactions are associated with the formation of a π-complex between the arene and $[Tl(OCOCF_3)_2]^{+}$, which decomposes in accordance with Scheme 5. Kinetic data characterising the electrophilic thallation and electron transfer pathways have been published.[11]

The relative rates of thallation of toluene and benzene (k_t/k_b) as well as the partial rates of formation of the isomers in the thallation of toluene with TTFA in TFAA have been determined.[12] The ratios k_t/k_b determined by Kwok et al.[12] and Olah et al.[13] are 43.5 and 33 respectively; the partial rate factors for the thallation of toluene at 25 °C were found to be 12.7, 4.5, and 226 by Kwok et al.[12] and 9.6, 5.7, and 168 by Olah et al.[13] for *ortho*-, *meta*-, and *para*-substitution respectively; this enabled Kwok et al.[12] to conclude that the aromatic thallation reaction proceeds via an aromatic electrophilic substitution mechanism, most probably via a Wheland intermediate, in contrast to the mechanism proposed by Kochi and coworkers.[10,11]

Roberts[14] investigated the kinetics of the thallation of arenes by NMR. He suggests that the data obtained by this method can describe the thallation process more accurately, since in this instance there is no need to treat the reaction mixture with KI and to determine the kinetic parameters of the reaction with respect to the iodoarene formed. It was found that $k_t/k_b = 24$. Roberts[14] explains the increase in k_t/k_b with increase in acid concentration, observed by Briody and Moore,[8] by the influence of the large positive charge on the thallium atom, i.e. in the first stage of the interaction of the electrophile and the substrate, the electrostatic interaction forces should play an appreciable role according to the author.

The kinetic isotope effect, obtained by Roberts, is 5.0 (3.7 according to Briody and Moore[8]). The authors suggest that the rate-limiting stage of the thallation process is proton transfer in a transition complex analogous to a Wheland intermediate.

The time variation of the isomeric composition of the products has also been investigated for toluene. Thus the *ortho*:*meta*:*para* ratios are 28:29:63 after 13 min and 31:38:31 after 5000 min.



The kinetics of the thallation of a wide range of substrates by treatment with TTFA using both NMR and other methods for the detection of products were investigated in detail in a later study.[15] $Tl(OAc)_3.1.5H_2O$ was chosen as the thallating agent, since, according to the authors, it is more stable than TTFA. Furthermore, it was shown[15] that the rates of thallation of arenes by thallium(III) acetate sesquihydrate in TFAA agree with the rates of thallation of the same arenes by treatment with TTFA in TFAA.

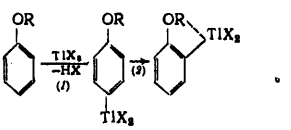
The process mechanism was represented as follows:[15]

$$ArH + TlX_3 \overset{K_1}{\rightleftarrows} \pi\text{-complex} \overset{k_2}{\rightarrow} \text{products}.$$

The values of K_1 and k_2 found in the above study are listed in Table 2.

On the basis of the Hammett and Yukawa-Tsuno parameters, the authors concluded that there is an appreciable charge separation in each phase of the reaction, especially in the π-complex formation stage:

(A)



Analysis of the activation parameters for the reaction showed that, whereas the activation energies for mercuration and thallation are approximately equal, the activation entropy is much higher in absolute magnitude for thallation (−11.9 cal mol^{-1} K^{-1}) than for mercuration (−1.2 cal mol^{-1} K^{-1}). The appreciable, compared with mercuration, charge transfer in the intermediate (A) is responsible for this effect. Ultimately the stability of the complex (A) is higher than the stability of the analogous complex in the mercuration reaction and this contributes to the entropy factor.

Table 2. The values of K_1 and k_2 for the thallation of the arenes C_6H_5R.[15]

No.	R	10^2k_2, s^{-1}	K_1, litre mol^{-1}
1	H	1.04	1.9
2	Me	0.166	2.7
3	Et	10.1	10.7
4	t-Bu	12.3	12.9
5	F	0.176	1.18
6	Cl	0.0733	0.70
7	Br	0.0469	0.89

The thallation of a series of aromatic substrates by TTFA in TFAA, leading to a disubstituted product, has been investigated.[16] Dithalation takes place in the presence of an excess of $Tl(OCOCF_3)_3$; 2,4-bis[(trifluoroacetato)thallio]anisole and 2,4-bis-[(trifluoroacetato)thallio]phenetole were isolated in the case of anisole and phenetole in 70 and 50% yields respectively. The complete dithalation of thiophen has been achieved in acetonitrile; the occurrence of dithallation has been demonstrated by the formation of diiodothiophen. Partial dithallation of benzene, toluene, and *m*-xylene has been observed when they were treated with an excess of TTFA in boiling TFAA.

In the thallation of anisole with an equivalent amount of TTFA, Deacon et al.[16] observed that an appreciable amount of the *para*-substitution product is formed in the first stage of the reaction and that only then is there an increase in the content of the *o*-thallated anisole, which is apparently more stable by virtue of the intramolecular oxygen–thallium coordination with formation of a four-membered chelate ring:

The authors support their view that the thermodynamic stability of *o*-anisylthallium bis(trifluoroacetate) is higher than that of its *p*-isomer by the results of a study[17] in which the interaction of phenylthallium bis(trifluoroacetate) with anisole, leading to the formation of *o*-anisylthallium bis(trifluoroacetate), was described. It is suggested[16] that reaction (2) proceeds via a mechanism different from that of the rearrangement of the *p*-thallated product to the *m*-isomer or of the preferential *ortho*-thallation of substituted arenes via five- and six-membered chelate rings.[3]

It has been suggested that thallium(III) trichloroacetate in trichloroacetic acid be used to thallate benzene and toluene.[18] The reaction takes place smoothly at room temperature, the yields of the

products are about 70%, and the ratios of the isomers for toluene are *ortho : meta : para* = 9 : 5 : 86. However, the synthetic use of the thallium(III) trichloroacetate/trichloroacetic acid system is limited by the electronic influence of the substituents in the aromatic ring. Thus anisole, nitrobenzene, and methyl benzoate do not enter into the thallation reaction under the given conditions.

It has been noted[6,10,11] that the aromatic radicals are coupled to form biaryls in the interaction of arenes, activated by electron-donating substituents, with TTFA and that for many arenes of this kind the above reaction predominates over the electrophilic thallation process (see below). A method has been proposed[19] for the thallation of activated arenes. The suppression of oxidative dimerisation is achieved by using TTFA in an ether/TFAA mixture. The coloured ethereal solution of TTFA and the substrate is usually treated with TFAA before the formation of a colourless solution and the precipitation of a deposit (the thallated arene) or the substrate is added to TTFA in a 2/1 ether/TFAA mixture.

Whereas a whole series of thallating agents in different media can be used for the thallation of arenes activated by electron-donating substituents, the direct thallation of polyfluoroarenes is extremely difficult owing to the inactivity of the aromatic ring with respect to electrophilic substitution. Direct thallation of polyfluoroarenes has been achieved by using a new thalating agent—thallium(III) triflate:[20,21]

$$RH + Tl(O_3SCF_3)_3 \xrightarrow{CF_3COOH} RTl(O_3SCF_3)_2 + CF_3SO_3H,$$
$$R = p\text{-}MeOC_6F_4, p\text{-}MeC_6F_4, m\text{-}HC_6F_4, p\text{-}HC_6F_4, C_6F_5, 3,5\text{-}H_2C_6F_3, 3,6\text{-}H_2C_6F_3.$$

The authors established a qualitative reactivity series for the arenes investigated in the thallation reaction:

$$C_6H_6 > p\text{-}MeOC_6F_4H > 1,2,4\text{-}F_3C_6H_3 \cong 1,3,5\text{-}F_3C_6H_3 > m\text{-}H_2C_6F_4;$$
$$p\text{-}MeC_6F_4H > o\text{-}H_2C_6F_4 > C_6F_5H \geqslant p\text{-}H_2C_6H_4 > m\text{-}O_2NC_6F_4H.$$

They were unable to isolate polyfluorophenylthallium bis(trifluoromethanesulphonates) in a pure form because, after the removal of the solvent, the product remained contaminated by trifluoroacetate impurities and the attempt at crystallisation led to the symmetrisation of the product to bis(pentafluorophenyl)thallium salts. The direct thallation products are therefore characterised by NMR, conversion into the corresponding aryl iodides by treatment with KI, and symmetrisation to bis(pentafluorophenyl)thallium salts.

The highest yield of thallation products was attained in boiling TFAA, but under these conditions *m*-BrC_6F_4H and *m*-$O_2NC_6F_4H$ do not react. The use of trifluoromethanesulphonic acid as the solvent leads to the oxidation of the substrates by the thallium(III) salts to the corresponding phenols. Although, after the conversion of the thallation products by treatment with $Tl(O_3SCF_3)_3$ to aryl iodides the yields of the latter are high, presumably the degree of thallation of polyfluoroarenes is in fact higher still, since a reaction of polyfluorophenylthallium salts with I^-, in which iodine-containing products are not formed, is known.[22]

2. Substitution of the Anion in Arylthallium Bis(trifluoroacetates)

One of the known methods of synthesis of compounds of the type $ArTlX_2$ involves the substitution of the anion in arylthallium bis(trifluoroacetates). The stability of compounds of the type $ArTlX_2$ as a function of the nature of X has been investigated.[23] When X = I, arylthallium compounds are extremely unstable, which had been noted earlier (see, for example, McKillop et al.[2]), so that their decomposition is a preparative method of synthesis of aryl iodides and constitutes a test reaction for the thallation of the aromatic ring. However, one should note the relative stability of $C_6F_5TlI_2$. A stable compound containing the ArTlI fragment has been synthesised.[24] The Ar—Tl—I bond system is stabilised by introducing into the coordination sphere a complex-forming molecule—dibenzo-18-crown-6 ether (DBC):

$$PhTlO + HClO_4 + DBC \xrightarrow{H_2O} [PhTl(DBC)OH]ClO_4 \cdot H_2O \xrightarrow[MeCN]{Na(15\text{-crown-}5)I} [PhTl(DBC)I]ClO_4.$$

The properties of stabilised complexes of the type $[p\text{-}RC_6H_4Tl(L)X]^+$, where R = H or Me, X = Cl, Br, I, SPh, or OH, and L = dibenzo-18-crown-6 ether, have been investigated.[25] For R = H and X = I, the photolysis or pyrolysis of the initial complex leads mainly to iodobenzene, while in the case where X = Br and especially Cl only insignificant amounts of the corresponding halogenobenzenes are produced:

$$[PhTl(L)I]^+ \rightleftarrows [PhTl(L)]^+ \rightarrow PhTl^+$$
$$\downarrow \qquad\qquad \downarrow I^-$$
$$Ph^- \xrightarrow{I^-} PhI$$

The reduction of the complex in which R = Me and X = OH by treatment with $P(OMe)_3$, ascorbic acid, and *N*-benzyl-1,4-dihydronicotinamide affords toluene as the main product, while the analogous reduction of the cation $ArTlX^+$, unstabilised by L, leads to Ar_2TlX.

Arylthallium dibromides are also extremely unstable and readily decompose, affording aryl bromides and small amounts of diarylthallium bromides (15—20%), while arylthallium dichlorides are extremely stable.[23]

A convenient preparative method has been developed for the synthesis of arylthallium dihalides:[26]

$$ArTlCl_2 \xleftarrow{Me_3SiCl} ArTl(OCOMe)_2 \xrightarrow{R_4SnBr_2} ArTlBr_2.$$

The yields of the dihalides obtained by this method are quantitative; the target products, precipitated during the reaction, do not require additional purification.

A method has been proposed[27] for the synthesis of arylthallium diacetates from asymmetric organotin compounds:

$$Ar_2SnR_2 + Tl(OCOMe)_3 \rightarrow ArTl(OCOMe)_2.$$

The alkyl substituent is not split off from the tin atom, the more nucleophilic aryl group being transferred to the thallium atom.

By varying the reactant ratio, it is possible to obtain by this method the acylates of both mono- and di-phenylthallium. The target products crystallise from the reaction mixture and do not require additional purification, but the use of this method is limited by the availability of the organotin compound.

Compounds of the type $ArTlX_2$, where X is a halogen or an organic acid residue, can also be obtained from organomercury, organotin, and organoboron compounds. These methods of synthesis are generally accepted and have been described in detail in a monograph.[28]

II. SYNTHESIS OF COMPOUNDS OF THE TYPE AR_2TlX

1. Synthesis with the Aid of Organometallic Compounds

Compounds of the type Ar_2TlX are the most widely distributed class of organothallium compounds. There exists a whole series of methods of synthesis of these thallium(III) derivatives from organolithium, -magnesium, -zinc, -mercury, -boron, -aluminium, and -tin compounds, the procedures involved in the use of which have been described in detail in a monograph.[28] Methods in which organolithium, -magnesium, -boron, and -mercury compounds are used are the most convenient among them for the preparation of diarylthallium salts:

$$2ArM + TlX_3 \rightarrow Ar_2TlX + 2MX,$$
$$M = Li, MgX, B(OR)_2, HgAr.$$

In recent years, diarylthallium compounds have been synthesised via other organometallic derivatives not so much for the preparation of previously unknown diarlythallium salts as with the aim of creating model compounds for physicochemical studies, e.g. X-ray diffraction. Thus the X-ray diffraction analysis of the complexes of bis(pentafluorophenyl)thallium chlorides and bromides with triphenylphosphine oxide has been carried out.[29,30] Bis(pentafluorophenyl)thallium chlorides and bromides were obtained from thallium(III) salts and the pentafluorophenyl Grignard reagent. The complexes investigated are dimeric compounds with asymmetric chlorine bridges; the thallium atom in these compounds has a coordination number of 5.

The synthesis of diarylthallium trifluoroacetates from TTFA and arylmagnesium halide leads to the target products in satisfactory yields (50–70%), but it takes place in several stages owing to the difficulty of exchanging the Br^- anion for trifluoroacetate:[31]

$$ArMgBr \xrightarrow[Et_2O]{Tl(OCOCF_3)_3} Ar_2TlBr \xrightarrow[EtOH-H_2O]{KOH} Ar_2TlOH \xrightarrow{CF_3COOH} \rightarrow Ar_2Tl(OCOCF_3).$$

The symmetrisation of monoarylthallium derivatives is a more convenient method of synthesis of diarylthallium trifluoroacetates.

2. Symmetrisation of Monoarylthallium Salts

The spontaneous disproportionation of compounds of the type $ArTlX_2$ to Ar_2TlX is widely known,[28] but it had not been used previously as a preparative method. In many cases symmetrisation is a more convenient method than organometallic synthesis. Thus, in order to obtain diarylthallium trifluoroacetates via a Grignard reagent, a three-stage synthesis is required,[31] while refluxing of arylthallium bis(trifluoroacetate) in acetone for 30 min affords diarylthallium trifluoroacetates in 50–90% yields:[31]

$$2ArTlX_2 \rightarrow Ar_2TlX + TlX_3,$$
$$Ar = 4\text{-}MeC_6H_4, 3.4\text{-}Me_2C_6H_3, 2.4\text{-}Me_2C_6H_3, 2,5\text{-}Me_2C_6H_3; X = CF_3COO$$

It has been suggested that trimethyl phosphite, under the influence of which diarylthallium trifluoroacetate is formed from ArTl.$(OCOCF_3)_2$ in several minutes at room temperature in a nearly quantitative yield, be used as the symmetrising agent.[23]

An attempt was made later[32] to investigate the mechanism of the disproportionation of monoarylthallium compounds. It had been suggested earlier[23] that the role of trimethyl phosphite consists in reducing TlX_3 to a thallium(I) compound, which displaces an equilibrium of the type:

$$2ArTlX_2 \rightleftarrows Ar_2TlX + TlX_3.$$

According to the authors,[32] this reaction mechanism is unlikely, because they failed to observe spectroscopic evidence for the spontaneous disproportionation of the starting material. They therefore assumed that the complex $RTlX_2.P(OR)_3$ is formed in the first stage, as a result of which the electron density on the Tl atom increases and the reduction of thalium(III) to thallium(I) is promoted. It is suggested that in this complex the carbon–thallium bond becomes more accessible to electophilic attack by a proton or another thallium atom. However, it is not clear at which stage of the reaction such attack takes place—before reduction, synchronously with reduction, or after it. According to the authors, the electrophilic attack by a proton before the reduction of thallium(III) is unlikely, since the initial complex $RTlX_2.L$ should interact more readily with the electrophile than the product $R_2TlX.L$, and yet it is stable under the protolysis conditions.

The interaction of $RTl(OAc)_2$ with nucleophiles capable of coordination can also lead to the symmetrisation of the starting material instead of the expected nucleophilic substitution of thallium:[32]

$$RTl(OAc)_2 + NaSPh \rightarrow R_2TlX.$$

The authors were unable to determine the nature of X, but they suggest that it is a thiophenoxide.

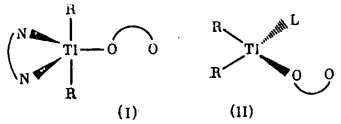
It is noteworthy that phosphorous acid esters are not universal symmetrising agents for arylthallium compounds. Polyfluorophenylthallium bis(trifluoromethanesulphonates) are not symmetrised on refluxing in acetone and on treatment with $P(OR)_3$ but such symmetrisation can be readily achieved by treatment with sodium acetate in boiling water, affording bis(polyfluorophenyl)thallium acetate.[21] $(3,5\text{-}H_2C_6F_3)Tl(O_3SCF_3)_2$, which does not undergo symmetrisation but exchanges the anion and the metal atom, affording as a result the corresponding diacetate, is an exception.

3. Reactions Associated with the Exchange of an Anion at the Thallium Atom

The substitution of an anion at a thallium atom is an extremely convenient preparative method of synthesis of various diarylthallium salts. Of the relatively recent studies, mention should be made of the synthesis of various derivatives of bis(polychlorophenyl)-thallium:[33]

$$(C_6Cl_5)_2TlCl + AgX \rightarrow (C_6Cl_5)_2TlX + AgCl;$$
$$X = MeCOO, ClO_4, 1/2SO_4.$$

Bis(pentachlorophenyl)thallium perchlorate proved to be a convenient starting compound for the substitution of an anion, which cannot be achieved by treating $(C_6Cl_5)_2TlCl$ with silver salts:



$$(C_6Cl_5)_2TlClO_4 + KX \rightarrow (C_6Cl_5)_2TlX + KClO_4;$$
$$X = I, Br, CN.$$

The substitution of an acetate residue by a halogen can be readily carried out by treating diarylthallium acylates with Me_3SiCl or R_2SnBr_2.[26] A new method of synthesis of such acylates has been proposed.[27]

Bis(pentafluorophenyl)thallium compounds $(C_6F_5)_2TlX$ (X = $CF_3COCHCOMe$, $CF_3COCHCOCF_3$, or PhCOCHCOMe) have been obtained by the reaction of $(C_6F_5)_2TlBr$ with the salts of diketones. They form stable complexes with αα-bipyridyl (bipy) and *o*-phenanthroline (phen).[34] The thallium salts of sulphinic acids, obtained as a result of ion exchange, also form stable complexes with bipy and phen:[35]

$$Ar_2TlBr + AgO_2SR \rightarrow Ar_2TlO_2SR + AgBr,$$
$$Ar = C_6H_5, C_6F_5;\ R = C_6H_5,\ 4\text{-}MeC_6H_4.$$
$$Ar_2TlO_2SR + L \rightarrow Ar_2Tl(L)O_2SR,$$
$$L = bipy,\ Ph_3PO,\ Ph_3AsO,\ phen.$$

The structure (I) with a 5-coordinated thallium atom for the complex with a bidentate ligand and the structure (II) for the complex with a monodentate ligand have been proposed from IR and NMR data:[35]

(I) (II)

The authors[35] also synthesised thallium(I) salts of sulphinic acids, but spectroscopic data do not provide a clear idea about their structure.

On heating, the thallium salts of sulphinic acid readily evolve SO_2, which has been used to synthesise bis(polyfluorophenyl)thallium acetates:[36]

$$2C_6F_nH_{5-n}SO_2Li + 3Tl(OCOCF_3)_3 \xrightarrow{MeCO_2H} (C_6F_nH_{5-n})_2TlO_2CMe +$$
$$+ CF_3COOH + 2SO_2 + 2LiOCOCF_3.$$

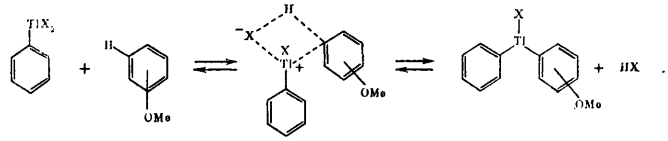
It has been found[35] that the highest yields of the target product are attained when the ratio of the initial reactants is Li : Tl = 2 : 3.

Later the reaction developed in the above study[36] was used to synthesise various dimesitylthallium salts.

Bis(polyfluorophenyl)thallium polyfluorobenzoates have been obtained by substituting an anion at the metal atom:[38]

$$R_2TlX + NaO_2CR \rightarrow R_2TlO_2CR + NaX;$$
$$R = C_6F_5, p\text{-}MeOC_6F_4, p\text{-}HC_6F_4, o\text{-}HC_6F_4, m\text{-}HC_6F_4.$$

4. The Synthesis of "Mixed" Diarylthallium Compounds Ar(Ar')TlX



"Mixed" diarylthallium compounds Ar(Ar')TlX have been obtained by the reaction of monoarylthallium salts with aryl-boronic acids:[39,40]

$$ArTlX_2 + Ar'B(OH)_2 \rightarrow Ar(Ar')TlX.$$

They are less stable than Ar_2TlX and disproportionate after a time:

$$2Ar(Ar')TlX \rightarrow Ar_2TlX + Ar'_2TlX.$$

The thallation of anisole by phenylthallium bis(trifluoroacetate), leading to the formation of a mixed product—phenyl(anisyl)-thallium trifluoroacetate—has been investigated.[41] The formation of the target product was inferred from the amount of phenyl and anisyl iodides after treating the reaction mixture with the I_2/KI system. The authors propose the following process mechanism:

The use of chlorobenzene as the substrate does not lead to a "mixed" phenyl(chlorophenyl)thallium product and only the exchange of the aryl groups at the metal atom is observed:

$$PhCl + PhTlX_2 \rightleftarrows ClC_6H_4TlX_2 + PhH.$$

An analogous exchange of the aryl groups at the thallium atom had been noted earlier.[17]

"Mixed" aryl(*B*-carbaboranyl)thallium salts have been synthesised in accordance with the scheme[42]

$$RC{-}CR + PhMgBr \rightarrow RC{-}CR$$
$$B_{10}H_9Tl(OCOCF_3)_2 \qquad B_{10}H_9Tl(Br)Ph$$

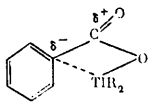
III. SYNTHESIS OF TRIARYLTHALLIUM COMPOUNDS Ar_3Tl

Virtually no new methods of synthesis of compounds of the type Ar_3Tl have been proposed during the last 15 years. This is because the traditional methods of synthesis of such compounds,[28] especially via the organolithium, organosodium, and organomagnesium compounds, are sufficiently convenient and the use of triarylthallium derivatives in synthesis is insignificant. Nevertheless, several recent studies were devoted to the synthesis of compounds of the type Ar_3Tl.

Tris(polyfluorophenyl)thallium compounds have been obtained by the reaction of bis(polyfluorophenyl)thallium salts with metallic compounds:[43]

$$2R_2TlBr + 2Cu + C_4H_8O_2 \rightarrow 2R_3Tl \cdot C_4H_8O_2 + TlBr + 2CuBr.$$

The replacement of the complex-forming solvent (ether, dioxan) by toluene alters significantly the course of the reaction:



$$(C_6F_5)_2TlBr \xrightarrow[PhMe]{Cu} (C_6F_5)_2 + TlBr.$$

The attempts to symmetrise R_2TlBr, where R = *o*-HC_6F_4 or 2,5-$H_2C_6F_3$, were unsuccessful. The authors suggest that R_3Tl is formed via an intermediate organocopper compound. This hypothesis is supported by the formation of $(C_6F_5)_2$ in toluene, since it is known that bis(pentafluorophenyl)thallium bromide does not by itself decompose on refluxing in toluene.[44] In view of the dependence of the symmetrisation on the degree of substitution of the aromatic ring by fluorine atoms, the authors suggest the involvement of carbanionic species in the transition state. In their view, the reaction mechanism involves the coordination of thallium to copper atoms, the subsequent transfer of the polyfluorophenyl group to

copper, and electron transfer from thallium to copper:

$$R_2TlBr + Cu \rightarrow 2RCu + TlBr,$$
$$R_2TlBr + RCu \rightarrow R_3Tl + CuBr.$$

A convenient method of synthesis of tri(polyfluorophenyl)thallium involves the refluxing of bis(polyfluorophenyl)thallium benzoate in pyridine.[38] The rate of decarboxylation diminishes in the following sequence of groups R: $C_6F_5 \simeq p\text{-}MeOC_6F_4 > p\text{-}HC_6F_4 > m\text{-}HC_6F_4 \gg o\text{-}HC_6F_4$, i.e. with decrease in the -I effect of the group. This finding shows that the aryl residue in the transition state is carbanionic:

(III)

Another possible process mechanism involves the participation of the free carbanion, which captures the R_2Tl^+ species faster than it can decompose:

Scheme 6

$$R_2TlO_2CR \rightleftarrows R_2Tl^+ + RCO_2^-;\ RCO_2^- \rightarrow R^- + CO_2;$$
$$R^- + R_2Tl^+ \rightarrow R_3Tl;\ R^- + R_2TlO_2CR \rightarrow R_3Tl + RCO_2^-.$$

The rapid decarboxylation of pentafluorophenylbenzoic acid in pyridine, which apparently proceeds via pyridinium pentafluorophenylbenzoate, supports Scheme 6 according to the authors, although the formation of ion pairs may lead to a transition complex of type (III). Pyrolysis of R_2TlO_2Cr without a solvent leads to a significant yield of R_3Tl only for R = C_6S_5 (40%), while in the remaining cases the reaction products are polyarylenes.

The stability of tris(polychlorophenyl)thallium in air was unexpected.[45] The synthesis of stable compounds containing four pentafluorophenyl groups at the thallium atom has been described:[46]

$$Tl(C_6F_5)_2Br + 2C_6F_5Li \xrightarrow{QX} Q[Tl(C_6F_5)_4],$$
$$X = Cl, Br;\ Q = Et_4N,\ Ph_3PCH_2Ph.$$

The preparation of complexes of the type $R_3Tl(diox)$, where R = C_6F_5 or 2,4,6-$F_3C_6H_2$, has been described.[47] For R = C_6F_5, the reaction of RLi with $TlCl_3$ leads to a mixture of the products $Bu_4N[TlR_4]$ and $(Bu_4N)_3[TlR_6]$, while in the case where R = 2,4,6-$F_3C_6H_2$, the product is exclusively R_3Tl. The complexes $R_3Tl(diox)$ have been obtained either by adding dioxan to R_3Tl in ether (R = 2,4,6-$F_3C_6H_2$) or in accordance with the scheme

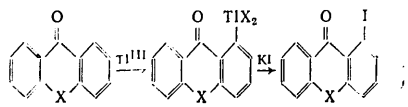
$$Bu_4NTl(C_6F_5)_4 + HBF_4 \xrightarrow{dioxan} Tl(C_6F_5)_3(diox) + Bu_4NBF_4 + C_6F_5H.$$

The reactions involving the substitution of the dioxan ligand lead to:

(a) neutral thallium(III) complexes:

$$R_3Tl(diox) + L \rightarrow R_3Tl(L) + diox;$$
$$L = Ph_3PO,\ Py,\ PPh_3,\ (Ph_2P)_2CH_2;$$

(b) anionic complexes:



$$R_3Tl(diox) + QX \rightarrow Q[TlR_3(X)] + dioxan;$$
$$Q = Bu_4N,\ (PPh_3)_2N;\ X = Cl, CN;$$
$$Q[TlR_3(CN)] + AgX \xrightarrow{-AgCN} \begin{cases} \xrightarrow{X=Cl} QX + TlR_3 \\ \xrightarrow{X=CF_3COO} Q[TlR_3(X)] \end{cases},$$

(c) anionic complexes with a thallium–transition metal bond:

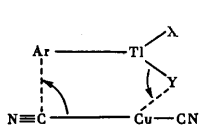
$$R_3Tl(diox) + QM^* \rightarrow Q[R_3Tl{-}M^*] + dioxan$$
$$R = 2,4,6\text{-}F_3C_6H_2,\ M^* = [MoCp(CO)_3]^-,\ [WCp(CO)_3]^-,\ [Mn(CO)_5]^-;$$
$$R = C_6F_5,\ M^* = [MoCp(CO)_3]^-,\ [WCp(CO)_3]^-.$$
$$Tl(C_6F_5)_3 + QM^* \rightarrow Q[(C_6F_5)_3Tl{-}M^*],$$
$$M^* = [Co(CO)_4]^-.$$

IV. APPLICATIONS OF ARYLTHALLIUM(III) COMPOUNDS IN ORGANIC SYNTHESIS

The possibility of substituting the thallium atom in arylthallium derivatives by an organic group has opened a pathway to the selective introduction of a substituent into the aromatic ring, since thallation itself is a selective process. McKillop, Taylor, and coworkers[1] have shown that, when arylthallium bis(trifluoroacetates) are treated with KI, the iodine atom replaces thallium in the aromatic ring. The thallation-iodination reaction has been used successfully for the selective introduction of iodine into the aromatic ring of diaryl ketones:[48]

X=CMe_2, $(CH_2)_2$, S.

The intermediate arylthallium compound formed when an organic substituent is introduced into the aromatic ring is not always isolated. Thus, in the synthesis of phenols,[49] the authors began with the corresponding arenes and TTFA:



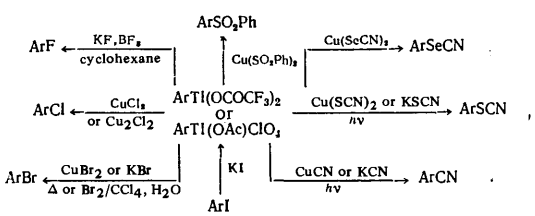
$$PhH \xrightarrow[CF_3COOH]{Tl(OCOCF_3)_3} PhTl(OCOCF_3)_2 \xrightarrow[PPh_3]{Pb(OAc)_4} PhOCOCF_3 \xrightarrow{NaOH} PhOH.$$

The yields of the phenols were 50–80%.

The attempt to obtain aromatic nitriles by the pyrolysis of $[ArTl.(CN)_3]K$ or $ArTl(CN)_2$ ws unsuccessful but the photolysis of a 1% aqueous solution of arylthallium bis(trifluoroacetate) in the presence of 25 equivalents of KCN led to the formation of aromatic nitriles in 50–80% yields. Traces of benzene, cyanobiphenyl, and phenol were detected as side products in the reaction mixture.[49] In order to obtain cyanoarenes, the reaction of $ArTl(OAc)ClO_4H_2O$ with bivalent or monovalent copper cyanides was also used[50] (Scheme 7, see below):

$$ArTlX_2 \xrightarrow[MeCN(pyridine)]{CuCN(Cu(CN)_2)} ArCN.$$

The highest yields of aryl cyanides are obtained when pyridine is used as the solvent. A free radical pathway to the formation of aryl cyanides is thought[50] to be unlikely since neither biphenyl nor benzene were detected in the reaction mixture. Nor were the transfer of the aryl group to acrylonitrile and the polymerisation of acrylonitrile observed. According to the authors, the interaction of the substrate with $Cu(CN)_2$ proceeds via the cyclic transition state



In contrast to the method of Uemura et al.,[50] which is limited by the relatively weak thallating capacity of $Tl(OAc)_2ClO_4$, Taylor et al.[51] obtained the nitriles over a wide range of arenes, both electron-deficient and electron-saturated. An increase in the types of aromatic substrates has been achieved[51] by using a more universal thallating agent—TTFA. The essential feature of the method consists in the refluxing of the thallated substrate with CuCN in acetonitrile for 2–17 h. The proposed reaction mechanism is

$$PhTlX_2 \xrightarrow[-[Cu^{II}CN]^+]{CuCN} [PhTlX \xrightarrow[-TlX]{} Ph^{\cdot}] \xrightarrow[-Cu^+]{^{\cdot}CuCN} PhCN.$$

The intermediate formation of an aryl complex of thallium(II) is postulated; the homolysis of the C–Tl bond in the complex leads to the formation of Ar·—an intermediate in the Rosenmund–von Braun reaction. In those cases where thallation in acetonitrile is impossible, the reaction was carried out in two stages: (1) thallation by treatment with TTFA in TFAA and isolation of the thallated products; (2) reaction with CuCN in acetonitrile; if the thallation is carried out in acetonitrile, the isolation stage is not required and the interaction with CuCN takes place *in situ*. The yields of the nitriles are 60–90% (Scheme 7):

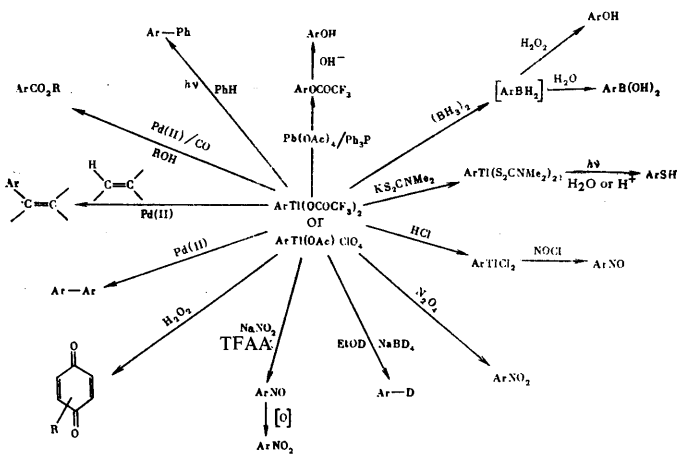
Scheme 7

Aryl thiocyanates have been obtained by the photolysis of a solution of arylthallium bis(trifluoroacetates) in the presence of potassium thiocyanate[52] and on refluxing $ArTl(OAc)ClO_4$ with $Cu(SCN)_2$ in dioxan:[53]

$$\left.\begin{array}{l} ArTl(OCOCF_3)_2 \xrightarrow{h\nu, KSCN} \\ ArTl(OAc)ClO_4 \xrightarrow{Cu(SCN)_2} \end{array}\right\} \rightarrow ArSCN.$$

The yields of aryl thiocyantes are 50–80%.

Phenyl and tolyl selenocyanates have been obtained from phenyl- and tolyl-thallium bis(trifluoroacetates) by treatment with Cu(SeCN) in dioxan.[18]



Arylthallium bis(trifluoroacetates) proved to be convenient initial compounds for the preparation of nitrosoarenes:[54]

$$ArTl(OCOCF_3)_2 \xrightarrow{HCl} ArTlCl_2 \xrightarrow[CHCl_3]{NOCl} ArNO.$$

Since the thallium derivatives of substituted arenes can be isolated comparatively readily in an isomerically pure form, this method is very much more selective than the direct nitrosation of arenes.

Nitroarenes have been obtained for the reaction of arylthallium bis(trifluoroacetates) with NO_2 [55] (yields 50–90%) (Scheme 8, see below). It has been shown in relation to tolylthallium bis(trifluoroacetates) that the main reaction product is *p*-nitrotoluene, but the refluxing of a solution of the thallated substrates before nitration entails some increase in the fraction of the *meta*-isomer. Treatment of the reaction mixture with NO_2 without isolating arylthallium bis(trifluoroacetate) also led to a satisfactory yield of the corresponding nitroarenes in which the *para*-product preominated. Direct nitration of arenes does not involve a selectivity as high as that which can be achieved using arylthallium compounds. Treatment of the products of the thallation of ethylbenzene with NO_2 affords nitroethylbenzenes with the isomers in the proportions $o:m:p$ = 5.3:1.7:93 for an overall yield of 76%, while the direct nitration of ethylbenzene by treatment with NO_2 in CF_3COOH leads to the isomer ratios $o:m:p$ = 42.5:2.0:55.5 for an overall yield of 11%.[55]

Scheme 8

Aromatic nitro-compounds have been obtained by the reaction of an arylthallium substrate with $NaNO_3$, KNO_2, or $AgNO_2$ in trifluoroacetic acid[56,57] (Scheme 8):

$$ArTl(OAc)ClO_4 \xrightarrow[CF_3COOH]{NaNO_2} ArNO_2.$$

It has been established for Ar-*p*-$CH_3C_6H_4$ that the nitro-group replaces the thallium atom and traces of *o*- and *m*-nitrotoluenes were not observed. In contrast to the halogenodethallation[58] and pseudohalogenodethallation[50,53] reactions (Scheme 7), the replacement of thallium by the nitro-group does not occur in organic solvents such as pyridine, dioxan, and dimethylformamide (DMF) even on refluxing. In the case of anisylthallium derivatives, the corresponding nitroarenes were obtained, but the formation of significant amounts of nitroso-derivatives was also noted. The addition of potassium dichromate to the reaction mixture makes it possible to obtain only the nitro-derivatives of anisole. The authors suggest that the action of potassium dichromate does not reduce to simple oxidation of the nitroso-group to the nitro-group; $K_2Cr_2O_7$ probably oxidises the C–Tl bond and then follows attack by NO_2^- in accordance with the scheme proposed for arylpalladium derivatives.[59]

The reaction of arylthallium diacetate with $Me_2CNO_2^-$ on irradiation by the light of a xenon lamp with ordinary glass leads to the formation of 2-arylnitropropanes:[60]

$$ArTl(OAc)_2 + Me_2CNO_2^- \rightarrow ArCMe_2NO_2.$$

The formation of the radical $C_6HMe_4NO^{\cdot}$ has been detected by EPR in the presence of nitrosodurene, which indicates a radical process mechanism:

$$ArTl(OAc)_2 + R_2CNO_2^- \rightarrow ArTlOAc + OAc^- + R_2CNO_2^{\cdot},$$
$$ArTlOAc \rightarrow Ar^{\cdot} + TlOAc,$$
$$Ar^{\cdot} + R_2CNO_2^{\cdot} \rightarrow ArCMe_2NO_2.$$

The product yields are 60–70%. In the absence of irradiation, up to 20% of arylthallium diacetate is formed.

The radical cleavage of the C–Tl bond on UV irradiation is a characteristic feature of arylthallium compounds. Thus irradiation of a suspension of arylthallium bis(trifluoroacetates) in aqueous ammonia results in the formation of aromatic amines.[61] A method of synthesis of aniline and phenol has been proposed.[62] Its essential feature consists in the reaction of the thallated arene in an aqueous or organic medium with a nucleophile (NH_3, H_2O), which results in the formation of the products of the nucleophilic substitution of thallium. The reaction was carried out at relatively low temperatures (200 °C) in steel reactors in the presence of promoting additives such as CuCl, $FeCl_2.4H_2O$, etc. When the reaction is carried out in an aqueous medium, the main products are phenols, while in methane or benzene, in the presence of a suitable promoting agent, for example, $CuCl_2$, the main product proved to be aniline.

The photolysis of arylthallium bis(*NN*-dimethyldithiocarbamates)[61] leads to thiophenols, while arylthallium difluorides are stable under the photolysis and pyrolysis conditions.[63] Fluoroarenes have been synthesised (in 40–90% yield) by refluxing arylthallium difluorides with dry BF_3 in cyclohexane (Scheme 7):[63]

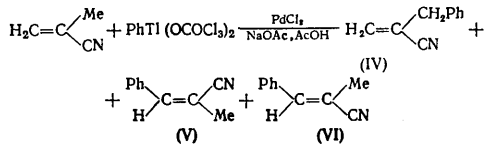
$$ArTlF_2 \xrightarrow{BF_3} ArF.$$

The reaction of arylthallium substrates with palladium salts has come to be widely used in organic synthesis recently.

The interaction of monoarylthallium salts with palladium(II) chloride leads to the formation of biaryls in 40–60% yields:

$$ArTlX_2 \xrightarrow[NaOAc,AcOH]{PdCl_2} Ar{-}Ar + Pd^0 + Tl^I.$$

Apart from biaryls, ArH and ArX were detected as side products.



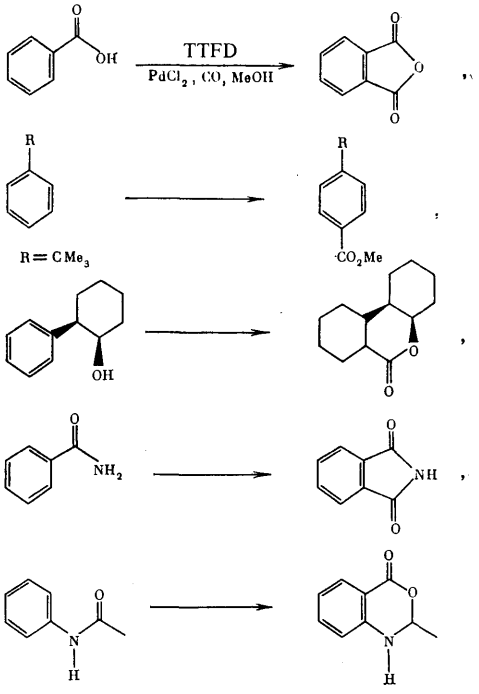
The authors showed that the nature of X does not have a significant influence on the yield of biaryls except in the case where X = Cl and Ar = Ph, where the yield of chlorobenzene is 30%.

The aryl group is transferred from arylthallium salts of olefins:[65]

$$ArTlX_2 + RCH{=}CHR' \xrightarrow[CuCl]{Li_2PdCl_4} ArCR{=}CHR';$$
Ar = Ph, *n*-MeC_6H_4, 1,3,5-$Me_3C_6H_2$; R = H, Ph;
R′ = CO_2Me, H; X = O_2CCF_3, O_2CMe, Cl, CN.

The authors showed that palladium(II) can be used in both catalytic and equimolecular amounts in relation to $ArTlX_2$. The olefins obtained have the *trans*-configuration.

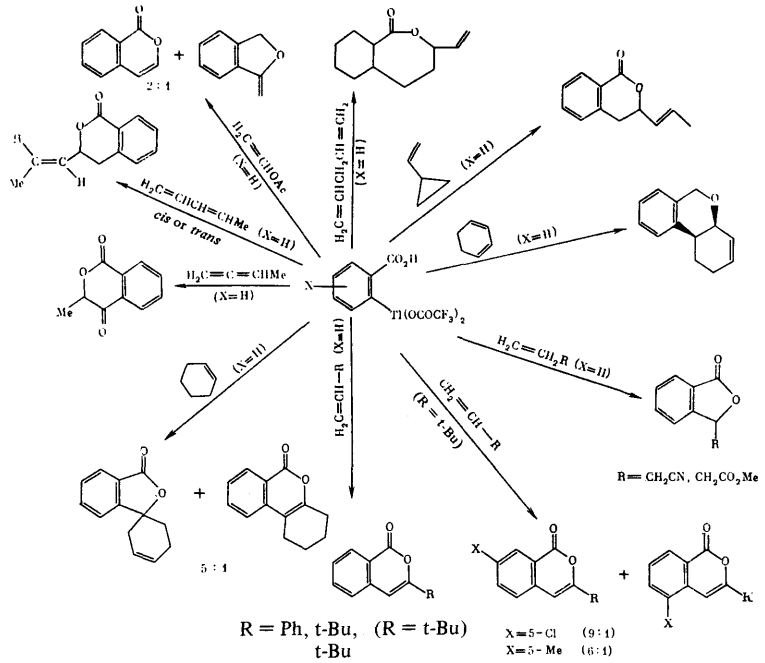
The reaction of phenylthallium bis(trichloroacetates) with $PdCl_2$ in acetic acid in the presence of styrene affords exclusively *trans*-stilbene, while the analogous reaction with methacrylonitrile is not so selective:[18]



The ratios (IV):(V):(VI) = 55:26:19 are obtained. Analogous products have been prepared using metallic palladium as the catalyst.

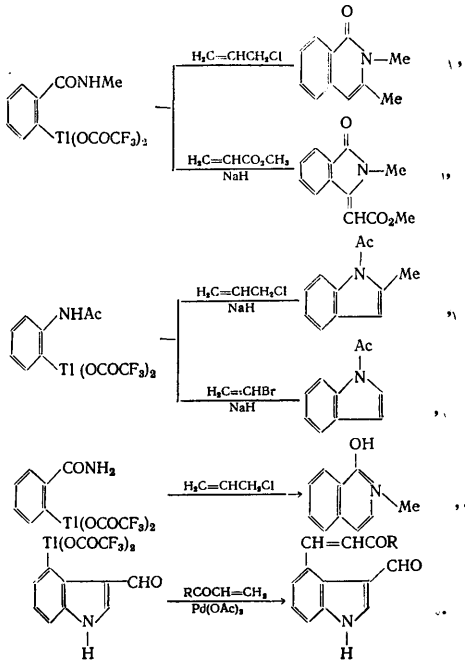
The high selectivity of aromatic thallation and the ease of the exchange of thallium for palladium lead to extensive synthetic prospects for the use of the thallium(III)–palladium(II) system. A method has been proposed[66] for the synthesis of arenecarboxylic acids, consisting in the interaction of the arene with thallium(III) trifluoroacetate in the presence of catalytic amounts of palladium acetate under a CO pressure of 4–7 atm, but the selectivity of the method is low. The use of the analogous reaction under a CO pressure of 1 atm[67,68] made it possible to obtain a series of esters, lactones, and heterocyclic compounds, the reactions exhibiting high regio- and stereo-selectivities in many cases. In contrast to the study of Spencer and Thorpe,[65] the authors do not introduce an oxidant into the reaction mixture assuming that the zero-valent palladium formed is oxidised by the thallium(III) salt generated during the transmetallation of arylthallium bis(trifluoroacetate):

$$ArTlX_2 + PdX_4^{-2} \rightarrow ArPdX_3^{-2} + TlX_3,$$
$$ArPdX_3^{-2} + CO \rightarrow ArC(O)PdX_3^{-2},$$
$$ArC(O)PdX_3^{-2} + ROH \rightarrow ArC(O)OR + HX + Pd^0 + 2X^-,$$
$$Pd^0 + TlX_3 \rightarrow PdX_2 + TlX.$$



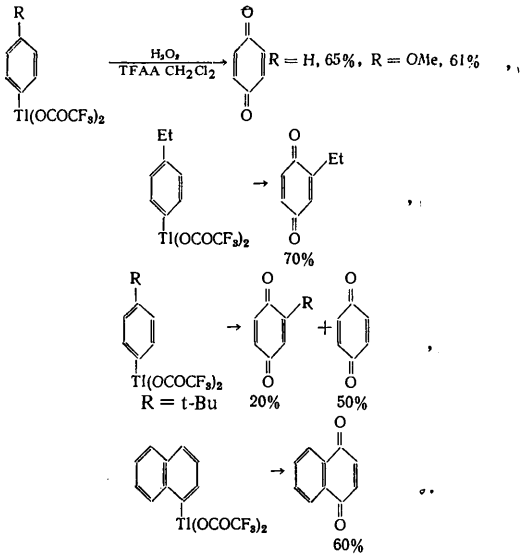
Biphenyl is a side product in this reaction, its formation being suppressed by the addition of LiCl and MgO. It has been found that the use of 0.1 of an equivalent of $PdCl_2$, 2 equivalents of LiCl, and one equivalent of MgO ensures product yields in excess of 90% (Scheme 9).

Scheme 9



A method has also been developed for the synthesis of isocoumarins and 3,4-dihydrocoumarins from thallated benzoic acid, palladium(II) salts, and substituted olefins or cyclopropanes[69] (Scheme 10):

Scheme 10



The reactions were usually carried out in acetonitrile with the ratio substrate: Li_2PdCl_4 = 1:1. In the successful synthetic procedure, the addition of 2 equivalents of Et_3N and Na_2CO_3 to the reaction mixture after the start of the reaction between the thallated substrate and the olefin makes it possible to cyclise the *o*-vinylbenzoic acids formed as side products to isocoumarin (Scheme 10). using an analogous method, isoquinolines and indoles have been obtained[70] (Scheme 11); the synthesis of substituted indoles containing a carbonyl group linked to the heterocyclic fragment has been described.[71]

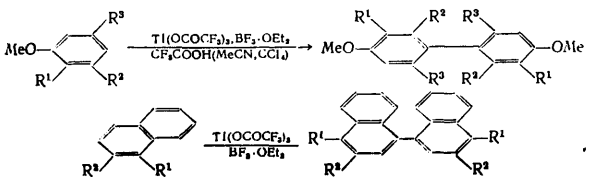
Scheme 11

The oxidation of thallated arenes by H_2O_2 [72] is a fairly convenient method of synthesis of *p*-benzoquinones and in the course of the oxidation the alkyl substituent is either eliminated or migrates (Scheme 12).

Scheme 12

The presence of TTFA is known to ensure the selective bromination of aromatic compounds, while the oxidation of phenols by TTFA makes it possible to obtain a wide range of quinones. However, it has been shown that arylthallium derivatives were not formed in the course of these processes. The data on the bromination of arenes and the oxidation of phenols with particiption of TTFA have been surveyed.[4,73]

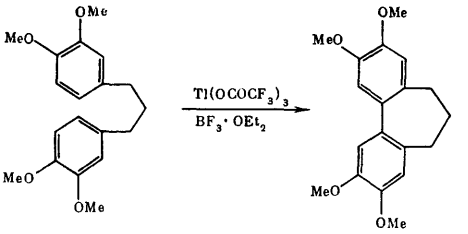
Ryabov et al.[74] were able to synthesise 4,4′-substituted biaryls by adding catalytic amounts of palladium(II) in the interaction of substituted arenes with TTFA:



$$PhX + Tl(OCOCF_3)_3 \xrightarrow{10\%Pd(OAc)_2} XC_6H_4C_6H_4X,$$
$$X = Me, MeO, Cl, F, H.$$

The reaction takes place under mild conditions and the initial arene is used as the solvent. The proportions of the isomers in the arene coupling reaction under the influence of the TTFA/$Pd(OAc)_2$ system were investigated later[75,76] and the partial rate factors f_o, f_m, and f_p were determined in relation to the formation of bitolyl. The yield of 4,4′-bitolyl in the coupling of toluene on treatment with the Tl(III)/Pd(II) system is higher than in the presence of palladium(II) acetate or thallium(III) trifluoroacetate alone. It has been shown[76] that rapid thallation of the aromatic substrate takes place in the first stage, this being followed by the rate-limiting stage—the interaction of $ArTl(OCOCF_3)_2$ with the monomeric palladium diacetate [the $Pd_3(OAc)_6$ depolymerisation product]. The subsequent reactions of the arylpalladium intermediate lead to the observed reaction products. The thallation and transmetallation stages are characterised by rate constants which are respectively $-5.6(\sigma^+)$ and $-3.0(\sigma)$:

$$ArH + TlX_3 \rightarrow ArTlX_2 + HX,$$
$$Pd_3(OAc)_6 \rightleftarrows 3Pd(OAc)_2,$$
$$ArTlX_2 + Pd(OAc)_2 \xrightarrow{slow} ArPd(OAc) + TlX_2(OAc),$$
$$2ArPd(OAc) \xrightarrow{fast} Ar-Ar + Pd^0 + Pd(OAc)_2,$$
$$Pd^0 + Tl^{III} \xrightarrow{fast} Pd^{II} + Tl^{I}.$$

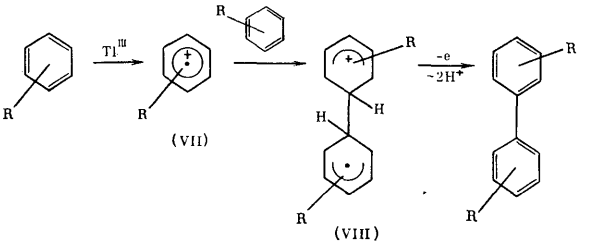


A whole series of studies have been devoted to the coupling of arenes to biaryls on treatment with arylthallium or thallium(III) salts. Thus the photolysis of arylthallium bis(trifluoroacetate) in benzene leads to asymmetric biaryls in 50–98% yields.[77] The reaction of an aromatic Grignard reagent with thallium monobromide in the tetrahydrofuran (THF)–benzene mixture affords biaryls in 70–90% yields.[78] The best reaction condition involves the addition of ArMgBr to a suspension of TlBr in the boiling solvent with the ratio ArMgBr : TlBr = 1 : 1.15. The reaction is complicated when an *o*-substituted organomagnesium compound is used; in this case, dehalogenation or the formation of diarylthallium bromide are observed. The cross-coupling of aryl groups can be achieved by this method. Thus the interaction of a mixture of phenyl- and *p*-anisyl-magnesium bromides with TlBr leads to a mixture of all the possible biaryls: 4-$MeOC_6H_4Ph$ (46%), PhPh (36%), and $(4\text{-}MeOC_6H_4)_2$ (18%).

It has been noted[6] that, when toluene is refluxed with thallium(III) acetate, a small amount of coupling products—isomeric bitolyls—is formed together with the main product—*p*-tolylthallium diacetate. The reaction of arenes containing strong electron-donating substituents with TTFA in TFAA, CCl_4, or acetonitrile with added boron trifluoride etherate leads to arene coupling products in 80–100% yields:[79]

The authors showed that the presence of electron-accepting substituents in the aromatic ring (COOR, CN, NO_2) fully suppresses the coupling reaction.

The possibility of the intramolecular coupling of aryl radicals has also been observed:

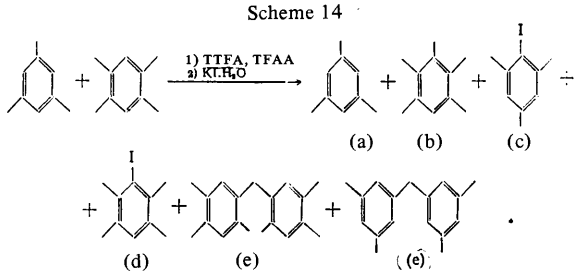


The authors put forward the hypothesis that the coupling of the aryl fragments proceeds via the intermediate formation of an aromatic radical-cation Ar^+. Data[10,11] indicating the intermediate formation of radical-cations in aromatic thallation reactions and also the formation of heptamethyldiphenylmethane (15%) in the interaction of TTFA with durene were quoted in support of this hypothesis. It is known that heptamethyldiphenylmethane is the product of the electrochemical oxidation of durene which proceeds via the intermediate formation of an aromatic radical-cation.[80]

The mechanism of the coupling of arenes on treatment with TTFA and the subsequent synthetic use of this method have been investigated in a study[81] in which five main procedures for the coupling of arenes are proposed: (1) $Tl(OCOCF_3)_3$, CCl_4, $BF_3.OEt_2$, room temperature; (2) $Tl(OCOCF_3)_3$, CCl_4, $BF_3.OEt_2$, −40–60 °C; (3) $Tl(OCOCF_3)_3$, CH_3CN, $BF_3.OEt_2$, room temperature; (4) $Tl(OCOCF_3)_3$, CF_3COOH, room temperature; (5) Tl.$(OCOCF_3)_3$, CF_3COOH, $BF_3.OEt$, room temperature. The addition of boron trifluoride etherate influences significantly the reactions in organic solvents such as CCl_4 and acetonitrile, since in their absence the coupling cannot be achieved in solvents of this kind.

The authors propose the following reaction mechanism: in the first stage an electron is transferred from the arene to TTFA with formation of the aromatic radical-cation (VII), which is followed by the electrophilic attack on the aromatic substrate by the radical-cation with formation of the intermediate (VIII), the oxidative aromatisation of which affords the biaryl (Scheme 13):

Scheme 13

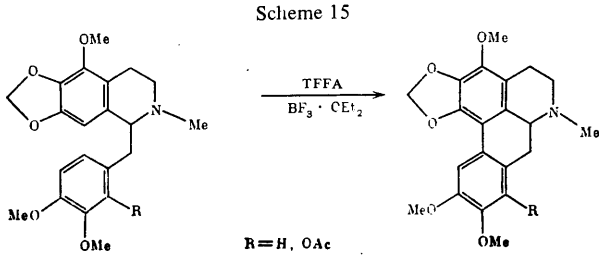


An an alternative, one can postulate that the coupling proceeds via the intermediate formation of an arylthallium compound.

The authors quote the following convincing arguments in support of the proposed mechanism:[81] (1) mesitylene and durene interact with TTFA in CF_3COOH both in the presence of added $BF_3.OEt_2$

and in its absence, but in the former case the aromatic ring is thallated while in the latter coupling leading to biaryl occurs; (2) if the biarylthallium bis(trifluoroacetate) is an intermediate in the biaryl formation reaction, one would expect that the reactivity of the arene in relation to $Tl(OCOCF_3)_3$ is determined by its basicity, whereas if the formation of the biaryl involves a one-electron transfer stage, then the factor determining the interaction of the substrate with the metal salt should be its ionisation potential. Mesitylene is a 200 times stronger base than durene but, in the competitive interaction of mesitylene and durene with TTFA, mainly the durene coupling products are formed (Scheme 14). The data in Scheme 14 are consistent with the difference between the ionisation potentials (8.4 and 8.03 eV) and also between the half-wave polarographic reduction potentials (1.85 and 1.59 eV) for durene and mesitylene respectively.

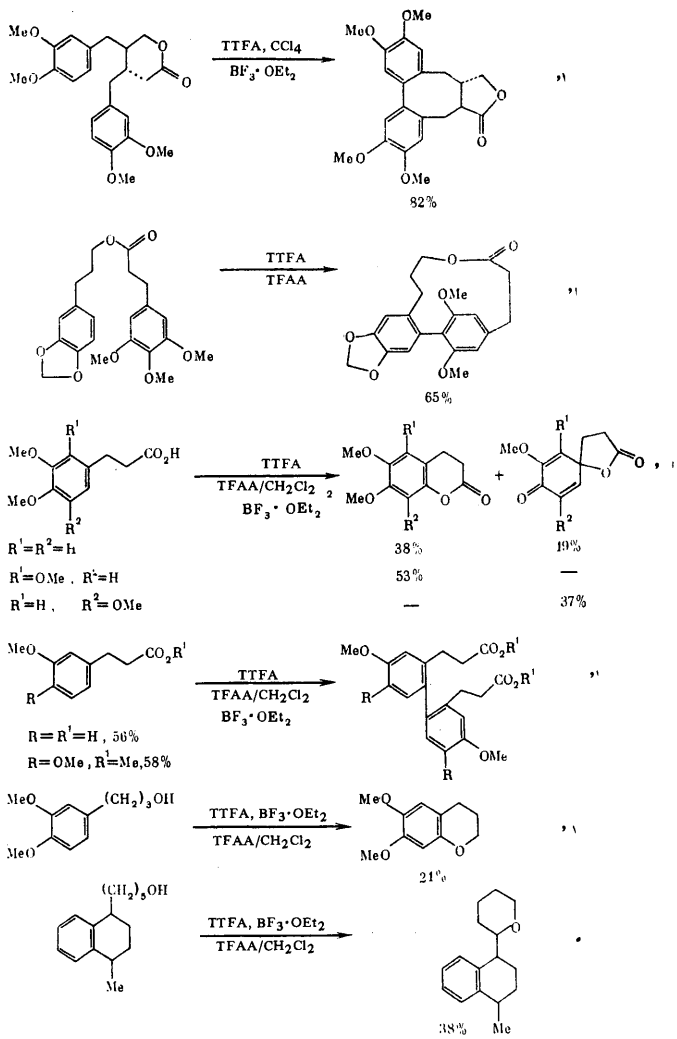
Scheme 14



Reaction time	Yield of products, % a	b	c	d	e	f
1 h*	25.0	33.5	19.0	8.4	13.5	0.3
1 min**	38.1	52.0	0.3	0	8.5	0.1
1 h**	36.1	52.0	0	0	11.5	0.1

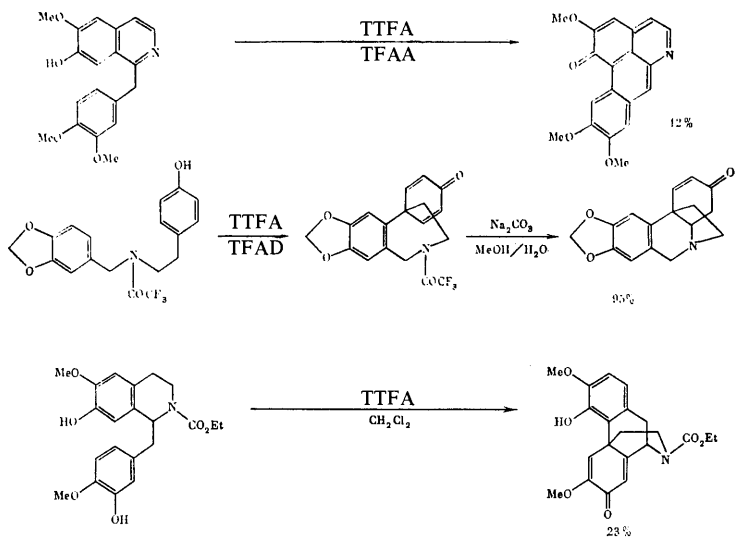
*Without $BF_3.OEt$. **With added $BF_3.OEt_2$.

The salts of other metals capable of accepting an electron, such as mercury(II) trifluoroacetate, iron(III) chloride, lead tetra-acetate, and $CoCF_3$, have been investigated in arene coupling reactions,[81] but the yields of biaryls obtained using them are lower than in the case where thallium(III) trifluoroacetate is employed.



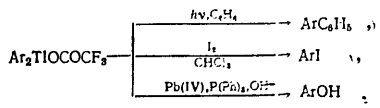
Although a C—Tl bond is in all probability not formed in the reactions involving the coupling of aryl groups on treatment with TTFA in the presence of boron trifluoride etherate, we believe it is essential to consider them briefly bearing in mind the extensive synthetic possibilities arising when this system is used. Thus, a whole series of alkaloids of the aporphine and homoaporphine series have been synthesised using the method developed by McKillop et al.:[79] (±)-ocoteine, (±)-*N*-acetyl-3-methoxynornantenine, (±)-kreysigine, (±)-*O*-methylkreysigine, and (±)-multifloramine.[82] The reactions were carried out in CH_2Cl_2 containing added $BF_3.OEt_2$: the product yields were about 50%. Scheme 15 illustrates the synthesis of (±)-ocoteine (R = H) and (±)-acetoxyocoxylonine (R = OAc) in 46 and 35% yields respectively.

Scheme 15



The single step synthesis of (±)-ocoteine developed by Taylor et al.[82] is simpler and the product yields are higher than in the method used previously.[83] Intramolecular cyclisation on treatment with TTFA has been used successfully for the synthesis of tetracyclic dibenzocyclo-octadiene systems[84] and also 11-and 13-membered cyclic lactones[85] (Scheme 16).

Scheme 16



In those cases where the intramolecular coupling of the aryl fragments is impossible, the radical-cation intermediate is stabilised by the side chain or as a result of the reaction with another substrate molecule (Scheme 16). The intramolecular coupling of aromatic substrates on treatment with TTFA makes it possible to synthesise a whole series of polyarylene and spirocyclic compounds,[88–92] including certain alkaloids of the morphine series[93–95] (Scheme 17).

Scheme 17

Diarylthallium compounds can be used in organic synthesis for the preparation of asymmetric biaryls, aryl iodides, and phenols:[31]

The yields of the products are high, but the use of monoarylthallium compounds for the synthesis of biaryls, aryl iodides, and phenols appears more convenient.

Derivatives of monoarylthallium $ArTlX_2$ are the most promising and convenient starting compounds for organic synthesis. The use of diaryl- and triaryl-thallium compounds is evidently more useful in organometallic synthesis, as has been described, for example, in a monograph[28] and in two communications.[96,97]

The Anomalies of the Increase in Viscosity in Binary Polymer Systems

S.M.Mezhikovskii, E.I.Vasil'chenko, and Sh.A.Shaginyan

The literature data on the anomalies in the rheological properties of binary polymer systems, expressed as the increase in their viscosity characteristics, are examined and surveyed in the present review. The known hypotheses and theories of the anomalous changes in viscosity are analysed and an attempt is made to relate the concentration and temperature variations of the viscosities of binary polymer blends to their phase organisation.
The bibliography includes 94 references.

I. INTRODUCTION

The deviation of the characteristic features of the flow of solutions and melts from the behaviour of Newtonian liquids has come to be called an anomaly in viscosity.[1] However, according to Frenkel'[2] and Bartenev,[3] the natural manifestation in polymer systems of the strong intermolecular interaction, which determines the dependence of viscosity η on the stress τ and the rate of shear $\dot{\gamma}$, should hardly be classified as an anomalous phenomenon.

In the present review by "anomalies" we understand experimental manifestations of the viscosity-dependent properties which cannot be explained on the basis of the generally accepted theories of the flow of polymers and their blends.[1-13] From this point of view, the abrupt decrease or increase in the viscosity of polymers in the presence of low-molecular-weight, oligomeric, and polymeric additives should be classified as anomalies in the first place (see, for example, Refs.14-19). Cases where the viscosity of the mixture can prove to be lower or higher than the viscosity of the least or most viscous component of the system are of special interest.

The anomalous decrease in the viscosity of binary polymer systems† (BPS) has been discussed in detail in recent years in the review literature,[7,8,12,13] whereas virtually no attention has been devoted to the anomalous increase in viscosity (AIV). The illogicality of the phenomenon itself, namely the increase in the viscosity of the mixture after the introduction of a less viscous component,‡ and the absence of clear grounds for its theoretical justification have aroused a certain scepticism among investigators.

This review gives a systematic account of the experimental and theoretical results concerning the anomalous increase in the viscosity characteristics of BPS.

II. EXPERIMENTAL OBSERVATIONS OF THE ANOMALOUS INCREASE IN VISCOSITY

Publications concerning special studies of the AIV in BPS began to appear comparatively recently[14,15,17] although experimental observations of this phenomenon date back to studies as early as the 1960s.[16,18,20] The anomalies associated with the increase in the viscosity of the mixture compared with that of the highly viscous component itself are known not only for polymeric but also for low-molecular-weight organic[24,25] and metallic[26,27] liquids.

1. Mixtures of Low-molecular-weight Liquids

The increase in shear viscosity in a definite concentration range in a water-benzene mixture was observed as early as the beginning of the century. The dynamic properties[28-31] and anomalies in the viscosities[24,25] of a whole series of binary liquids systems have now been investigated. We may note two factors. Firstly, the increase in the viscosity of low-molecular-weight mixtures has usually been observed within a comparatively narrow range of compositions at temperatures close to the critical point. Secondly, the specific viscosity increments

$$\Delta\eta = \eta_m - \eta_v, \quad (1)$$

where η_m is the viscosity of the mixture and η_v the viscosity of the most viscous component, quoted in different studies, frequently do not agree since $\Delta\eta$ depends greatly on the experimental conditions.[30,31]

2. Mixtures of Metallic Liquids

The characteristic features of the dynamic properties of melts of metallic mixtures have been analysed in detail.[26] The extrema observed[26,27,32-36] on the viscosity isotherms for iron-nickel melts

† Unless specially stipulated, here and henceforth the binary polymer systems are understood as polymer-solvent mixtures, where the solvent can be a low-molecular-weight, oligomeric, or a high-molecular-weight compound.

‡ In terms of formal characteristics (but by no means in terms of the essential physical features), the effect discussed is close to the antiplasticisation phenomenon: the increase in the modulus and strength of polymers after the introduction of small amounts of plasticisers into the latter[21]—a phenomenon which aroused vigorous discussion in its time.[22,23]

as well as the anomalous effects consisting in the fact that, on heating in the temperature range from 1400° to 1800 °C, the viscosity η initially diminishes steadily as the temperature rises and then increases abruptly within a comparatively narrow temperature range (at 1500–1550 °C or at 1700–1750 °C [27,36]) only to fall again on raising the temperature still further are of greatest interest. According to Baum,[26] the previous history of the melt not only influences the intensity of the extrema but also determines the very fact of their existence.

3. Polymeric Liquids

The anomalous increase in viscosity has been observed in BPS of different types: mixtures of polymers with low-molecular-weight liquids[18,37] or with oligomers[15,38] and in blends of high-molecular-weight components.[5–8,14,16,17,39–42] In the last case the AIV effect has been observed for blends of two elastomers,[14,16,17,41] two plastics,[39,40,42] a plastic–raw rubber blend,[7,8,12,41] and also for block copolymers.[43,44] An extremum in the dependence of the viscosity on composition has been discovered both for binary polymer melts and for their solutions in a common solvent.[12]

The range of compositions in which AIV can be manifested is unusually broad. An increase in viscosity has been observed at both low concentrations (0.05–3%) of any of the components added to the system[7,11,12,15] and in the range of average compositions.[6,8,14,39] The range of concentrations in which the anomaly is manifested in the viscosity increment can be very narrow (fractions per cent) [15,18] or fairly broad (tens per cent).[14,39] Viscosity isotherms with a single extremum are characteristic of some systems,[12,16,38,39] while others have isotherms with two extrema[8,11,40] and in some instances there may be several extrema.[8]

It is so far impossible to compare quantitatively the published data on the AIV even for isotypical systems, since in most studies the viscosity parameters of the BPS have been determined on apparatus of different types and have been expressed in terms of different characteristics (effective viscosity, initial Newtonian viscosity, Mooney viscosity, torsional moment on the plastograph roller, the melt index, etc.).[12,14–17,37–42]

Analysis of the published experimental data shows that the sign of the extremum on the concentration variations of the viscosity, its absolute magnitude, and its position on the "viscosity–composition" curve depend on the molecular characteristics of the components, the temperature of the test,§ the deformation conditions ($\dot{\gamma}$ and τ), the method of preparation of the specimens, etc. A change in the parameters enumerated can lead not only to a displacement of the positions of the extrema or to a change in their absolute magnitude but can actually result in a transformation of a minimum into a maximum and conversely.

As an example, Fig.1 presents thermograms of the viscosity characteristic F (the force required to drive a melt through a capillary) obtained for a mixture of natural rubber (NR) and polybutadiene (PB) over the entire range of compositions at different shear velocities.[17] In the range of $\dot{\gamma}$ from 0.3 to 3 s^{-1}, the usual deviation of the viscosity[3,4,7] from additive values is observed but at higher shear velocities anomalies appear on the curves (the anomalies are shown shaded in the figure). In the given experiment, the character of the variation of F with mixture composition changes several times as $\dot{\gamma}$ is varied by five orders of magnitude.

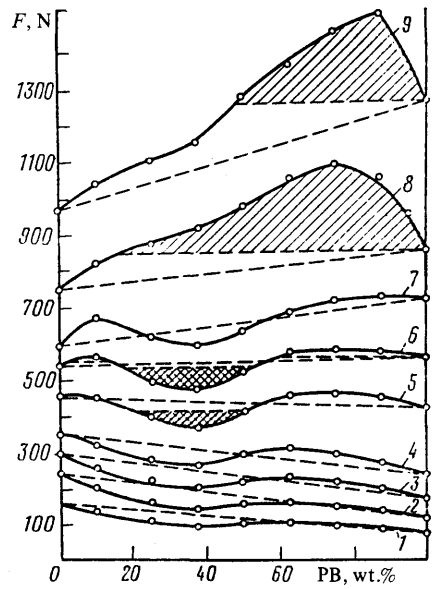

Figure 1. Dependence of the quantity F for the melt of a mixture of a natural rubber and PB on composition for different shear velocities ($\dot{\gamma}$, s^{-1}):[17] 1) 0.3; 2) 0.75; 3) 1.5; 4) 3.0; 5) 7.5; 6) 15; 7) 30; 8) 300; 9) 3000; T = 126 °C.

In the study quoted, it is emphasised that other measured viscosity parameters (for example, the Mooney viscosity at 100 °C and the twisting moment on the roller of the Brabender plastograph at 94 °C) do not exhibit significant anomalous deviations. Nevertheless, it follows from two investigations[14,16] that the AIV effect is not associated with any specific way of measuring viscosity.¶ Indeed, the viscosity maximum has been observed for the same mixture of NR and PB in a study[16] of the dependence of the parameter of the

§ In this case we are concerned not with the trivial influence of temperature, whose alteration can lead to fusion, devitrification, and the corresponding abrupt alteration of the properties of the system (such cases have been examined[45]), but with more complex mechanism of the effect of temperature on viscosity.

¶ Cases are known[6] where a change in the method of specifying the shear deformation or the design of the capillary in the rheological apparatus leads to the degeneration of the maximum to a minimum on the viscosity–concentration curve. As will be clear from the subsequent exposition, if the AIV is an objective property of a given system, then, regardless of the apparatus used, this effect can be observed by selecting the necessary experimental conditions for this purpose. Furthermore, the experimentally observed increase in viscosity can be a result of hydrodynamic flow effects determined by the design of the apparatus.

twisting moment on mixture composition. However, it is noteworthy that the experimental conditions in the study by Hess et al.[16] were different from those used by Folt and Smith.[17]

Using a capillary viscometer for the study of blends of polyethylene (HPPE) and polystyrene (PS), Han and Kim[14] observed, in particular, that, although at all the temperatures investigated (200°, 220°, and 240 °C) the viscosity thermograms have the form of curves with an extremum, nevertheless anomalies (in the sense adopted in the present review) are manifested at different temperatures and for different shear stresses in different ways.

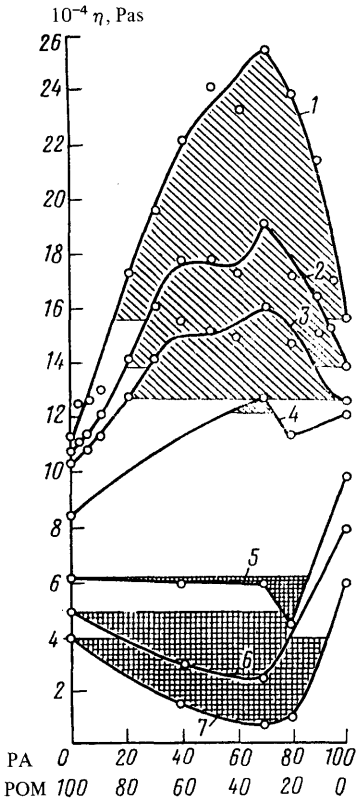

Figure 2. Dependence of the viscosities of POM–PA melts on composition at 190 °C and different shear stresses (10^4 τ, Pa):[47] 1) 1.27; 2) 3.93; 3) 5.44; 4) 6.30; 5) 12.59; 6) 19.25; 7) 31.62.

The influence of the shear stess on the AIV was also observed by Vinogradov and co-workers[39,40,46,47] in a study of the rheological properties of blends of polyoxymethylene (POM) and polyamide (PA) at 190 °C (Fig.2). With increase in τ from 0.6 to 3.5 × 10^4 Pa, Δη gradually diminishes in the range of compositions where a viscosity increment is manifested. Furthermore, after the attainment of a specific value of τ, the increase in η is replaced by its anomalous decrease, which progresses with increasing shear stress.

The examples presented show that the very fact of the anomalous variation of the viscosity of polymer blends compared with the viscosities of the components and the sign of this variation depend on the deformation conditions. The influence of the temperature of the test is just as complex. Apart from the study already mentioned,[14] this is indicated also by Lipatov's experimental data.[8] From the latter, it follows, in particular, that, when the composition of the polyethylene (HPPE)–polypropylene (PP) blend is altered, the viscosity of the melts, measured at 190–210 °C, passes twice through a maximum. An increase in the temperature of the test to 230–270 °C results in the disappearance of these maxima. In contrast to the case considered, in the cellulose acetobutyrate (CAB)–POM system (Ref.8, p.250) the AIV disappears on reducing the temperature and not on raising it.

In discussing the influence of temperature on the AIV, one should note several further unusual examples of an extremum in the variation of the viscosity.[7,12,13,16,18,21,41,42,45–50] A maximum has been observed[18] on the curve characterising the temperature variation of the viscosity of a solution of polystyrene in cyclohexane. This maximum can be recorded experimentally only when the temperature is varied in steps not greater than 0.2 K.

Data have been presented in a monograph[13] from which it follows that, after a monotonic decrease of the relative viscosity of an aqueous methylcellulose solution with increase in temperature, there is an abrupt increase in the range 50–55 °C.

It was shown in a recently published study[50] that η of a poly(vinyl chloride) (PVC)–trioxyethylene dimethacrylate mixture increases by a factor of two when the temperature is raised from 60° to 100 °C and then falls, reaching its initial value at 140 °C.

The maximum in the concentration variation of the effective activation energy for the viscous flow of BPS has been noted in several studies.[7,22,48,49]

Many investigators point out the role of the previous history of the system, which determines in many instances the character of the viscosity-dependent properties of BPS.[5–8,22,23,40,41,46] It has been specially emphasised[40] that, when POM is blended with PA in an alcoholic suspension (with subsequent removal of alcohol), there are two maxima on the "viscosity–composition" curve, but after the "dry blending" of the powders there is only maximum.

It has been shown[41] that a specimen prepared from PB–polyisoprene (PI) solutions is characterised by a viscosity maximum, which is converted into a minimum if the specimens are obtained by blending these raw rubbers on rollers.

The role of the previous history of the system as regards temperature has been noted.[7] If a mixture of PI and PS solutions is prepared and tested at a constant temperature (20 °C), then there is a viscosity maximum on the "property–composition" curve, but, when the system is first heated to 80 °C and then cooled to the temperature of the test (20 °C), a viscosity minimum is observed in the same composition range. This difference in behaviour is characteristic only of systems with a narrow molecular weight distribution (MWD) of the components. If the polymers constituting the blend were polydisperse, only a viscosity minimum was observed experimentally regardless of the previous heat treatment.

Some of the results discussed above indicate indirectly the kinetic nature of the anomalies discussed, but the communications quoted present facts indicating the thermodynamic nature of the anomalous

properties. Naturally, the hydrodynamic flow effects, associated with the structure of the blend, the design of the apparatus, and the deformation conditions, may mask or, on the contrary, can reveal anomalies which are objectively characteristic of specific systems.

4. Raw Rubber–Oligomer Mixtures

In the study of raw rubber oligoacrylate ester (OAE) systems,[15,28,51-58] the AIV was observed only in the range of low concentrations of the oligomers. It follows from the inspection of the flow curves for polydisperse SKI-3 raw rubber and its blends with two types of OAE—linear and branched[53]—that the AIV is manifested only in BPS with microamounts (< 0.5%) of the added linear oligomer. An increase in the OAE concentration to 1% restricts the range of τ values in which the anomalous effect is manifested and, on further increase in the oligomer content, the anomalies disappear over the entire range of τ.

It has been shown[51-53] that the AIV in binary raw rubber–OAE blends is not associated with the methodological characteristic features of the experiment and the chemical interaction of the components but is determined by the very structure of these systems, which depends on the nature of the components and their ratio.

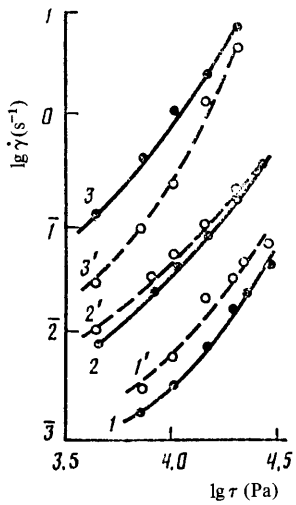

Figure 3. Flow curves for *cis*-polyisoprenes with MW = 6.2×10^5, 2.7×10^5, and 5×10^4 (curves 1–3 respectively) and their mixtures with 0.1 wt.% of TGM-3 (curves 1′–3′) at 70 °C.[54]

The relation between the anomalies in the viscosity-dependent properties of BPS on the molecular characteristics of the polymer component has been investigated.[54] Fig.3 presents the flow curves for *cis*-polyisoprene specimens differing in the molecular weight (MW) and their blends with trioxyethylene $\alpha\omega$-dimethacrylate (TGM-3), while Fig.4 presents the dependence of $\Delta \lg \eta$ for these blends on the MW of the polymer at different temperatures and shear stresses. It follows from these data that under the conditions selected for the test, the AIV effect is manifested only for blends of the low-molecular-weight raw rubber and OAE. With increase in the MW of the raw rubber, the relative magnitude of this effect diminishes and OAE has only a plasticising effect on high-molecular-weight raw rubbers.

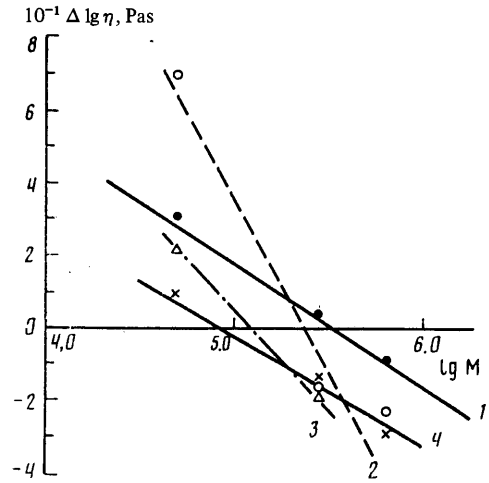

Figure 4. Dependence of $\Delta \lg \eta$ on the MW of *cis*-polyisoprene and its mixture with 0.1% of TGM-3 at 50 °C (curves 1, 3, and 4) and 70 °C (curve 2); $\lg \tau$ (Pa): 1) and 2) 4.0; 3) 3 and 6; 4) 4.26.[54]

It has been shown[54] that the influence of the shear stress in experiments with a low-molecular-weight raw rubber is analogous to that observed[52] for blends of industrial high-molecular-weight raw rubbers with OAE: an increase in τ lowers the relative magnitude of the viscosity increment. On the other hand, the effect of temperature proved to be different. In contrast to experiments with industrial SKI-3 and SKD raw rubbers,[38,51,52] where the viscosity increment was totally eliminated with increase in temperature, in the given instance the relative magnitude of the AIV effect depends not only on the tendency towards a change in temperature and τ but also on their ratio: for some shear stresses, $\Delta\eta$ increases with increase in temperature whilst for others it diminishes. Nor can a distinct $\Delta\eta = f(c)$ relation be traced for blends of low-molecular-weight raw rubbers with OAE. It has been shown[54] that this is a consequence of the random variation of the MWD of raw rubbers in different syntheses.

An analogous conclusion has also been reached in a study[59] where it was shown in relation to blends of two polydisperse polymers (HPPE and POM) that the AIV depends in many respects on the MWD of the components and that the extremum is gradually abolished as the low-molecular-weight fractions are removed.

In the analysis of the influence of the polymeric component on the character of the manifestation of viscosity anomalies in raw rubber–OAE systems, attention should be drawn to two factors. (1) The viscosity anomaly is manifested most clearly and logically only in BPS based on polydisperse raw rubbers;[52] (2) even a slight difference between the MW and MWD of industrial batches of raw

rubbers may result in a situation where the AIV, which is consistently reproduced in specimens prepared from the same batch of raw rubber, cannot be observed in specimens obtained from another batch.[51-54]

The ambiguity of the entire set of experimental observations of the anomalous variation of the viscosity of BPS of different types considered above indicates the existence of parameters of the system (the actual system and not its components) which were not taken into account by the investigators and which can in fact be responsible for the extrema on plots reflecting the dependence of the viscosity of the BPS on concentration and temperature.

III. HYPOTHESES AND THEORIES OF THE ANOMALOUS CHANGES IN VISCOSITY

1. Low-molecular-weight Liquids

Ostwald[60] was apparently the first to suggest a relation between the increase in viscosity through an extremum and the phase transition in the vicinity of the critical point. This hypothesis was based on the modelling of the structure of the system in the critical state by "particles" constituting small-scale inhomogeneities, which led to an analogy with highly disperse colloids whose viscosity is higher than that of the solutions. This "colloidal" model was used for a comparatively long time to interpret many experimental observations at a qualitative level (see, for example, Refs.24, 25, and 28–31).

Quantitative schemes relating the shear viscosities of liquid systems to the appearance of large-scale fluctuations near the critical point began to appear in the 1960s. A theoretical justification of the anomalous variation of viscosity and other transport coefficients in mixtures of low-molecular-weight liquids in the critical state was initially provided by Fixman's studies,[61,62] concerned with the hydrodynamic description of the macroscopic properties of these mixtures within the framework of the approximation of interacting modes, and later by studies[63-65] in which this idea was examined within the framework of the decoupled-mode and the dynamic renorm group approximation.

The physical significance of all these approaches is that, when the system exists in the critical range of compositions and temperatures (c_{cr} and T_{cr}), then part of the mechanical energy (for example, in the deformation of the mixture) is dissipated on long-wavelength concentration fluctuations at a consequence of the interaction of the latter with the velocity gradient and their diffusion-dependent dissipation. Hence it follows naturally that the viscosity of the mixture in the critical state should increase, because in this case the entire shear energy is not consumed on the displacement of the molecules.

Thus, for systems in the vicinity of the critical point, the experimental viscosity η_m consists of the regular ("non critical") component η_r, which has been identified with the viscosity of the homogeneous solution, and the excess ("critical") correction ($\Delta\eta_{cr}$), whose value depends on the closeness of the experimental conditions to the critical conditions for the given system:

$$\eta_m = \eta_r + \Delta\eta_{cr}, \quad (2)$$

$$\Delta\eta_{cr} = f(r^{\Phi}), \quad (3)$$

where $r = (T - T_{cr})/T_{cr}$ is the critical parameter of the shear viscosity.

Solutions of the hydrodynamic equations within the framework of the approximations mentioned above yield in some cases[61-63] identical values of the parameter Φ, whilst in others[63-66] they lead to non-concordant results.

The ideology of large-scale fluctuations is applicable to systems which are both at the critical point and in the region of metastable states near the spinodal curve. The long-wavelength fluctuations arising under these conditions have the same influence on the shear viscosity.

Comparison of the experimental and calculated (within the framework of dynamic scaling) data[67,68] shows that Φ varies within broad limits: from −0.37 to 0.5 not only for different systems but even for isotypical systems.

2. Metallic Liquids

Virtually all the explanations of the concentration-dependent anomalies in the viscosities of metallic liquids are based on the use of the cybotactic model of the structure of liquids.[26,27]

Two versions of the possible explanation have been considered.[26] In one of them, it is assumed that the introduction of an additive or an increase in temperature lead to the decomposition of the initial large cybotaxes and to the formation of new ones having a smaller store of internal energy than the initial ones, which in fact causes an increase in the viscosity of the system. In the other version, the rearrangement of the structure of the cybotaxes is associated with the change in composition or temperature regarded as an activated process with a transition state, whose appearance requires an expenditure of additional energy. The entropy of the transition state is higher than that of the initial or final state and the change in the entropy of activation for viscous flow in the transition state accordingly proves to be smaller, while the activation energy and the viscosity are higher.

Unfortunately all the treatments of the anomalies in the viscosity-dependent properties of metallic melts are qualitative.

3. Polymeric Liquids

The AIV effect has been hardly considered in the reviews published in recent years on studies of the viscosities of dilute and concentrated solutions of polymers and polymer melts.[69,70] In the original studies the most varied ideas and approaches have been invoked to account for the anomalous variation of the viscosity-dependent properties of BPS, but all of them (with some exceptions—for example in Refs.5, 40, and 56) had as their aim the explanation of the causes of the abrupt decrease in viscosity. Ideas involving structural plasticisation,[23,46,71] a change in the free volume of the system after the introduction of the second component,[4,8,42] a decrease in the energy of the intermolecular interaction in the presence of the additive,[7,12] the separation into layers comprising different phases,[5-8] critical[7] and metastable[8,11] states of the system, etc. were invoked for this purpose. The development of these ideas has been reflected in reviews and monographs[7,8,11,12] and they will therefore not be considered in the present communication. We shall only mention that, from our point of view, the approaches based on the search for correlations between the anomalies in the rheological properties and the system thermodynamics proved most fruitful and most general.[7,8]

Judging from the number and wide variety of the experimental facts (see Section II), the AIV effect in BPS is a fairly common phenomenon. However, a reasonable explanation, providing for a single treatment of all the characteristics of its manifestation, has not so far been found. In many instances the causes of the increase in the viscosity of BPS are so evident that the absence of this effect would have to be regarded as anomalous and not its experimental manifestation. Thus, the increase in the viscosity of the blend of powdered PVC with liquid OAE mentioned above[50] with increase in temperature must inevitably occur as a consequence of the conversion of the mixture into a monolithic form and the transition from the flow of a dispersion to the flow of a plastisol. Gel formation in a solution of methylcellulose, occurring at a specific concentration of the solution in a specific temperature range, should also entail an increase in viscosity, which has in fact been observed in the experiment discussed above.[13] On the other hand, the disappearance of one of the two viscosity maxima, noted in a study[40] of the POM–PA system on raising the temperature, should have occurred without the fusion of the crystallising component.

It is just as evident that the phase transitions in BPS causing the transformation of the flow of single-phase solutions into the flow of dispersions can lead to an increase in viscosity, for example, in conformity with the familiar Einstein equation:†

$$\eta_m = \eta_0(1+2{,}5\varphi), \qquad (4)$$

where η_0 is the viscosity of the dispersion medium and φ the volume fraction of the disperse phase. However, from this it does not follow by any means that the viscosity of the mixture must be higher than the viscosity of the disperse phase.

(a) Single-phase BPS

A large group of studies,[2,4,7,13,73] devoted to the characteristics of the flow of polymer solutions, were confined to the elucidation of the possible causes of the deviation of the viscosities of the BPS from additivity without concentrating attention on the anomalously high values of these deviations. For this purpose, the idea that the free volume of the system changes (increases or decreases) on mixing the initial components were resorted to; the idea of a fluctuating network of entanglements, which can be more or less stable in BPS than the initial polymers, has also been used. In some cases, the concept of the supermolecular structure of polymers in solutions has likewise been employed.[4]

Virtually all the experimental features observed for polymer solutions can be ultimately accounted for qualitatively within the framework of the kinetic theory of Frenkel' or its modifications.[10]

Application of the scaling hypothesis to the analysis of the dynamic properties of polymer solutions made it possible to[74,75] impart to the idea of entanglements the form of quantitative relations. In particular, the viscosity of solutions of flexible-chain polymers is described by the expression[74]

$$\eta_m \simeq \eta_s N_e^{-2} N^3 \varphi^{\frac{3}{3\nu-1}} = \eta_s N_e N^3 \varphi^{11/4}, \qquad (5)$$

where η_s is the viscosity of the solvent, N the number of monomer units in the polymer chain, N_e the average length of the chain between entanglements in the polymer melt, φ the volume fraction of the polymer, and $\nu = 3/5$ the swelling index of the coils in semidilute solutions.

This approach is being vigorously developed at the present time. For example, different scaling expressions have been obtained recently[76] for the viscosities of systems of polymer solutions in each of the six regions of a dynamic phase diagram (Fig.5) as a function of the solution concentration φ, the length of the polymer chain N, and its flexibility P.

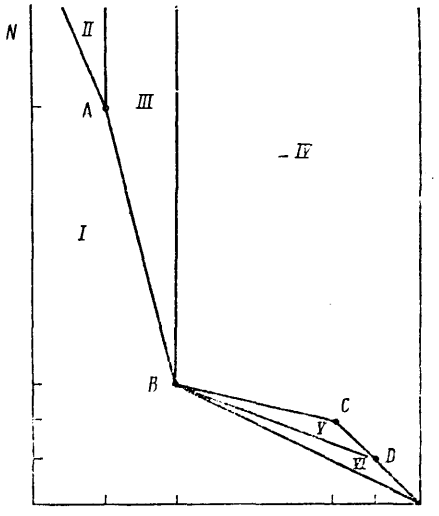

Figure 5. Dynamic phase diagram for a BPS solution;[76] φ = volume fraction of the polymer; points A, B, C, and D correspond to P^3, P, $P^{3/4}$ and $P^{1/2}$ respectively.

In region I, the entanglements between the macromolecular coils are insignificant and the viscosities of the solution in the solvent are identical. With increase in φ, the swollen coils begin to overlap and the system passes to region II, and there is a corresponding change in the laws governing viscous flow. The subsequent differentiation of the regions in the diagram is associated with allowance for N and P. For example, if $P = 1$, then the differences between the properties of the solutions corresponding to regions II–VI disappear, these regions "merge", and only two zones remain on the diagram—with overlapping and non-overlapping coils. On the other hand, if $P = 1$, then (and this is important for the problem discussed here) in each of the differentiated regions of the diagram the viscosity depends in different ways on φ. For example, at high dilutions ($\varphi_m \simeq \varphi^{3.8}$), the power exponent increases to 6 in the region of semidilute solutions and on passing to region V it diminishes to 1.4. This makes it possible to explain the presence of extrema on the $\eta_{sol} = f(\varphi)$ curves. Furthermore, the different power relations beween η_m and P, noted[76] for different regions of the diagram, and the temperature dependence of the flexibility of the molecule explain the non-linearity of η_m as a function of T. Analysis of the expressions quoted[76] shows that in region II the viscosity of the solution

† Subject to the condition that this equation, which was derived for dispersions of hard spheres, is applicable to BPS.[72]

should diminish on heating, while in region IV it should increase. Consequently, depending on the BPS concentration, an increase in temperature can lead to both an increase and a decrease in viscosity.

(b) Two-phase BPS

In order to account for viscosity-dependent properties of BPS known to be heterogeneous, two approaches are mainly used. In one of them the viscosity of the BPS is considered from the standpoint of the flow of colloidal dispersions for which the increase in viscosity with increasing fraction of the disperse phase is reasonable, and this is why a number of workers[5,7,11,22,23] have been surprised by the appearance of minima and not maxima on the $\eta_m = f(\varphi)$ curves.

For heterogeneous BPS, which can be regarded as dispersions with particles deformed under the influence of a load applied to the system (i.e. the shape of the particle is a function of τ and $\dot{\gamma}$), the applicability of Eqn.(4) is problematic (see the preceding footnote). There is as yet no universal theory of the flow of dispersions, although there are many empirical equations and models taking into account the influence of individual factors (the nature and shape of the particles, the state of aggregation of the disperse and dispersion phases, etc.). We may note, for example, the equation proposed by Lipatov,[11] which takes into account the molecular weight of the polymer, and the Schowalter–Taylor model[79] in which the viscosity of the mixture is related to the viscosity of each phase.

Thus the increase in viscosity is inherent in the very nature of the flow of colloidally disperse systems, although none of the known models lead to the conclusion that η_m should be greater than the viscosity of the most viscous component.

The second approach is based on the ideas concerning the structural transformations introduced by the BPS flow process itself, for example, the formation of a vibrous structure of the stream as a result of one of the components being stretched in the direction of the deformation or as a result of the formation of alternating annular layers when emulsions flow in a capillary,[7,14,39,40,77,78] etc. When the composition of the initial mixture, the deformation conditions, or the design of the apparatus are altered, the diameter of the fibres, the radius of curvature of the layers, the order in which they alternate, etc. can change. As a result of hydrodynamic effects, this can induce in its turn a decrease of an increase in the translational mobility of the macroscopic system as a whole.

(c) Binary Polymer Systems with Limited Compatibility of the Components

For systems of this type, the change in the character of the flow and all the non-linear effects in the concentration and temperature dependences of the viscosity are attributed to phase transitions, while anomalous deviations are usually attributed to the characteristic features of the structures formed under these conditions.

Thus the increase in viscosity has been explained[80] by the possibility of the formation of "strongly interlinked mosaic-like structures" during spinodal separation. In other studies,[51–55] the anomalous variations of the viscosity-dependent properties of rubber–oligomer systems are interpreted by analogy with the antiplasticisation effect.

Having compared the experimental $\eta = f(\varphi)$ curves with phase diagrams, Lipatov[8] proposed a modified Mooney's equation with a description of the viscosity of BPS in the region of a homogeneous state (before the attainment of the binodal curve):

$$\eta_m = K(1-\varphi_1)^{\alpha} M^{3,4}, \tag{6}$$

where K and α are empirical constants and φ_1 is the concentration of one of the polymers; in the region of the two-phase state (within the spinodal curve), Einstein's Equation (4) holds, while the viscosity of the system in the metastable zone (between the binodal and spinodal curves) can be calculated by means of the equation

$$\eta_m = K(1-\varphi_1')M^{3,4}(1+2{,}5\varphi_1''), \tag{7}$$

where $\varphi_1' + \varphi_1'' = \varphi_1$ represents the concentrations of the added polymer in the continuous and disperse phases and its overall content in the system.

Thus the section corresponding to a decrease in the viscosity on the $\eta = f(\varphi)$ curve is described by Eqn.(6), while the increase in viscosity is described initially by Eqn.(4) and then, after the interaction with the spinodal curve, by Eqn.(7).

Although the scheme considered does not yield quantitative agreement with experiment (as was pointed out by the author himself), nevertheless it permits a qualitative explanation of the possibility of the appearance of a viscosity minimum on the $\eta_m = f(\alpha)$ curves and the subsequent increase in viscosity. However, a whole series of other experimental facts (in particular the multiplicity of extrema) can in no way be accounted for by this scheme.

(d) Theory of the Viscosity of BPS in the Critical State

The work of Manevich and co-workers[81] is based on the fundamental idea of the approximation of interacting modes. However, in contrast to earlier studies,[61,62] they took into account additionally the non-Newtonian character of the flow of polymeric liquids and the asymmetry of the phase diagrams of polymer blends. As a result, the following expression was obtained for positive critical corrections to the viscosity:

$$\Delta\eta_{cr} = ac_2^2 \frac{1}{q} M^3 \left(1 + \frac{b}{q^4}\right), \tag{8}$$

where $q \simeq [(T - T_{cr})/T_{cr}]^{1/2}$, c_2 is the concentration of the polymer, M its molecular weight, and a and b are numerical coefficients. The parameter q is related in its turn to the chemical potential of the system μ_1 by the expression

$$\frac{4\pi a}{q^2} = \frac{V_1}{c_2}\left[KT \Big/ \left(\frac{\partial \mu_1}{\partial c_2}\right)_{P,T} + m\right], \tag{9}$$

where $m = V_2/V_1$ is the ratio of the molecular volumes of the components. The change in the chemical potential is calculated here in accordance with the Flory–Huggins theory.

It follows from the theory of the viscosity of BPS in the critical state, that, in order to record the increase in viscosity, it is necessary to select the temperature-concentration conditions in such a way that the temperature and concentration are either identical or approach T_{cr} and c_{cr}.

Unfortunately in the form presented by Manevich et al.,[81] this theory does not establish quantitative criteria which would make it possible to estimate the difference between the experimental parameters of state and the critical values for which the contribution of the critical corrections is comparable to the experimental accuracy. It is

qualitatively clear that, if $\Delta c = c_{cr} - c \to 0$ and $\Delta T = T_{cr} - T \to 0$, then $\eta_{cr} \to$ max. But for each specific polymer–solvent pair, the Δc and ΔT for which $\Delta\eta_{cr}$ is comparable to η_m apparently have values characteristic of the given system. This apparently also explains the finding that, in the study mentioned above,[18] the AIV could be observed only under conditions where the temperature was varied in steps $\Delta T \leqslant 0.2$ K.

We emphasise that, if the current values of c and T are less than the critical values, then their increase brings the system closer to the consolute temperature (CT), whereupon $\Delta\eta_{cr}$ increases, which means that η_m will also increase. On the other hand, if c and T are greater than the critical values, then the subsequent increase in these parameters will entail a decrease in $\Delta\eta_{cr}$. As already mentioned in the previous Section, significant changes in the character of the concentration and temperature dependence of the viscosity have indeed been observed for BPS investigated under different conditions. It also follows from the theory examined that, with increase in the shear stress, the large-scale concentration fluctuations, which determine the increase in viscosity, are gradually disrupted‡ with a corresponding decrease also in $\Delta\eta_{cr}$.

(e) Theory of the Viscosity of BPS Near the Limit of Thermodynamic Stability

The character of the variation of the viscosity of BPS as the spinodal curve is approached, where large-scale concentration fluctuations also arise spontaneously, has been examined.[82,83] When a shear deformation is superimposed, part of the energy of the hydrodynamic flow is dissipated at these fluctuations which in fact entails an increase in the viscosity of the blend. The addition ("spinodal") correction to the viscosity has the form

$$\Delta\eta_{sp} = \frac{3\sqrt{2}\pi^3}{20}\frac{\rho f^2 k_B T\,(N_A(1-c)\,\tau_M^A + N_B c\tau_M^B\,(N_A N_B)^{1/2}}{N_e[N_A c + N_B(1-c) - 2\chi c\,(1-c)\,N_A N_B]^{1/2}}, \qquad (10)$$

where c is the concentration of component A expressed in terms of the number of monomer units, N_A and N_B are the degrees of polymerisation of the components, τ_M^A and τ_M^B are the microscopic relaxation times of the components, N_e is the number of monomers between entanglements in the reptation diffusion model along the "tube" formed by the entanglements, f is the Onsager coefficient characterising the degree of the intermode relation between the viscous and diffusion modes, k_B is the Boltzmann constant, and χ is the Huggins constant.

Eqn.(10) reflects the dependence of $\Delta\eta_{sp}$ on the length of the molecular chains of the components, their relaxation characteristics, the degree of the intermode relation, and the composition, temperature, and density of the mixture. However, the applicability of this formula is limited to monodisperse systems. In order to account for the polydispersity of the macromolecules, an additional function of the distribution density with respect to the degrees of polymerisation of each component (Π_A and Π_B) was introduced[82] into Eqn.(10).

‡ A qualitative dependence of the microstructure of the blend on the shear stress has been described[2,84] and it has been shown that, with increase in τ, the dimensions of the microparticles and the formations produced by association diminish. The influence on τ on the orientational effects of concentration fluctuations, which induces the anisotropy of the dynamic properties of BPS, has been noted.[85]

Analysis of the integral form of the expression for $\Delta\eta_{sp}$ with allowance for Π_A and Π_B shows that, for a specified mixture composition and the total number of molecules in the system $N_A c + N_B(1-c)$, only those molecules contribute to $\Delta\eta_{sp}$ whose N_A and N_B for specified c and χ fall within the region adjoining the thermodynamic stability limit of the BPS. The same A and B molecules (for example, molecules with low degrees of polymerisation) which for a given T form true solutions with one another and those (for example, molecules with large N_A and N_B) which form heterogeneous mixtures under these conditions do not contribute to $\Delta\eta_{sp}$ and influence the macroscopic viscosity of the system only additively or in accordance with other laws.

Thus, if a "polydisperse" system with specified experimental c and T falls within the region adjoining the spinodal curve, then and only then do some of the molecules participate in the formation of large-scale fluctuations and only that fraction of them determines the agreement between the experimental viscosity and the value calculated by Eqn.(10). The remaining molecules, for which the elementary flow steps take place in accordance with other laws, will mask the flow in accordance with Eqn.(10).

The reliability of the experimental observation of the AIV has also been estimated.[82] For $\Pi_A \to 0$ and $\Pi_B \to 0$, the possibility of observing the effect is determined by the relation

$$\delta\eta/\Delta\eta_{sp} = \delta T/2\Delta T, \qquad (11)$$

where $\delta\eta$ is the accuracy of the measurement of $\Delta\eta_{sp}$ and δT is the accuracy of the thermostatic temperature control. Hence it follows that the possibility of obtaining a reliable value of $\Delta\eta_{sp}$ appears only if $\Delta T \geqslant \delta T$. It was found that, for a monodisperse BPS characterised by $N_A = N_B \simeq 10^4$, $N_e \simeq 10^2$, $\tau_M^A = \tau_M^B = 10^{-9}$ s, $f \simeq 1$, and $\rho \simeq 1000$ kg m^{-3}, an increase in viscosity by a factor of 2 (i.e. when $\Delta\eta_{sp} = \eta_r$) can be observed near the spinodal curve for $\delta T \simeq 1$ K.

The "critical" and "spinodal" corrections to viscosity have been revised[83] in connection with allowance for osmotic forces whose interaction with viscous friction forces is believed[74] to determine in many respects the mechanism of the dynamics of polymer solutions and melts.

The inclusion of the osmotic pressure of components A and B in the rheological equation for BPS leads to an expression in which, apart from positive corrections inducing an increase in viscosity, there is also another correction $\Delta\eta_{os}$ whose sign is negative (reducing the viscosity). This is due to the fact that osmotic forces facilitate the "dissipation" of the concentration fluctuations themselves and hence less of the energy supplied to the system from outside is expended on this process.

Yet another important conclusion has been made,[83] namely that the more significant the difference beween N_A and N_B, the greater the contribution by the above negative correction to the overall $\Delta\eta$. In other words, the greater the difference between the MW of the components of the BPS, the greater the probability of a decrease and not an increase in viscosity.

IV. COMPARISON OF THEORY WITH EXPERIMENT

The above analysis of experimental and theoretical data indicates a wide variety of possible causes leading to the AIV and the absence of a single view concerning the mechanism of this phenomenon. However, it is evident that the increase in the viscosity of BPS is always associated with structural features characteristic of them as mixed systems.

1. The Phase Diagram of BPS

Fig.6 presents a conventional phase diagram of BPS in terms of the variables $\varphi_A - T$, where φ_A is the concentration of the polymeric component. Regions have been differentiated in the diagram in which the laws governing flow are apparently different. The phase diagrams of BPS have been analysed in detail in a number of studies.[13,86–88] Here we shall note only the most general postulates necessary for further logical exposition. Fig.6 illustrates the θ-line for the solutions shown by a dashed curve. In the zone above the θ-line, only three regions are shown: with non-overlapping (V) and overlapping (V') coils as well as the region of swollen gels (V''), although in principle this zone can be differentiated in greater detail (as was done, for example, by Semenov[76]).

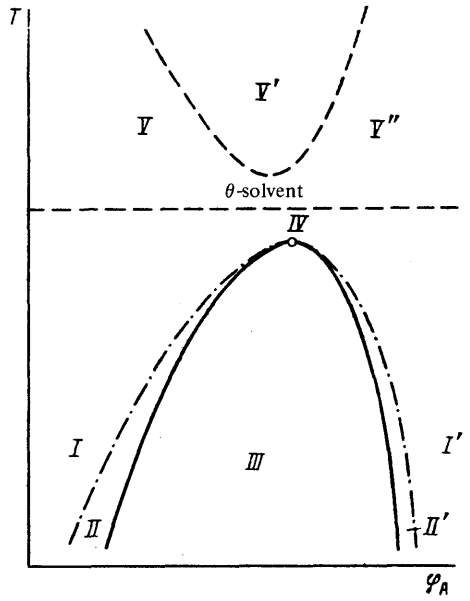

Figure 6. Conventional phase diagram for a BPS.[54]

In the zone of "poor" solvents (below the dashed line), six regions have been differentiated: two regions of true solutions—with an excess of the solvent (I) and with an excess of the polymer (I'); two regions of a metastable state (between the binodal and spinodal curves)—to the left (II) and to the right (II') of the spinodal curve; the region of two-phase states (III) located within the spinodal curve; the region of the critical state (IV) adjoining the upper consolute temperature (UCT).§ The positions of the branches of the binodal and spinodal curves depend on the affinity of the components (χ) and on their molecular-weight characteristics. For example, if N_B is large (the BPS consists of two polymers), then the branches are usually close to the coordinate axis and region (III) predominates in the diagram. If the MW of the solvent diminishes (transition to oligomeric and low-molecular-weight liquids), then the solution zone (especially to the left of the binodal curve as virtually all known phase diagrams of BPS are asymmetric) as a rule becomes broader.

Thus above the θ-line BPS form two solutions over the entire composition range regardless of temperature. Below the θ-line, two solutions are formed for any values of φ only at $T >$ UCT. On the other hand if $T <$ UCT, then BPS are by definition systems with limited compatibility, and when $\varphi < (\varphi'_A)_B$ (where the subscript B denotes the position of the point on the binodal curve) they form true solutions (region I) which correspond to traditional ideas about polymer solutions[4] whereas in the case where $\varphi > (\varphi''_A)_B$ they form solutions corresponding to molecularly plasticised systems.[22,23] Here $(\varphi'_A)_B$ and $(\varphi''_A)_B$ are the polymer concentrations along different branches of the binodal curve at a specified T.

Unfortunately few studies of the anomalies in the viscosity-dependent properties of systems with known phase diagrams have so far been published.[11,52,59,80] It is therefore difficult to compare experimental rheological data with thermodynamic features of the BPS. This is especially significant for systems with limited compatibility of the components for which the position of the CT and the regions of the metastable state are unknown in the vast majority of cases. As regards solutions and heterogeneous mixtures, there are usually sufficient indirect data confirming whether or not they belong to a particular phase organisation.

2. Solution Regions

The explanations of the causes of the non-linear effects of the AIV observed in polymer solutions and in single-phase BPS melts have not been adequately supported by arguments at the present time. The scaling approaches to the analysis of the dynamics of dilute and concentrated polymer solutions in "good" solvents (regions $V - V''$ in the diagram), which have been developing vigorously, undoubtedly contain new ideas capable of providing in the future a clear-cut physical interpretation of the entire set of effects which have been discovered. Examples of the fruitfulness of these approaches have been published.[74,76] However, in the present state of the development of these views, statistical physics has not yet provided a general picture of the relation between the viscosity and the parameters of state of BPS, the system thermodynamics, and the conditions of the rheological experiment. Nevertheless, it has yielded the very significant conclusion that the fundamental laws do not prohibit the possibility, in principle, of an increase in viscosity in polymer–solvent systems both in the region of dilute and semi-dilute solutions and in the region of polymer gels.

The scaling approaches being developed should undoubtedly influence also the development of the theory of polymer solutions in solvents with different thermodynamic affinities (regions I and I').

In our view, the approach based on the cybotactic (by analogy with metallic liquids) or anisotropic (by analogy with liquid crystal systems) models is undoubtedly promising. However, virtually no examples of the interpretation of the experimentally observed anomalies in the viscosity-dependent properties of BPS from these standpoints are encountered in the literature.

§ For systems with a lower consolute temperature (LCT), the above reasoning does not change fundamentally.

3. The Region of Two-phase BPS

The heterophase nature of BPS is as a rule due to the following causes: (1) the components are entirely thermodynamically incompatible; (2) the compatibility of the components is limited but at the experimental temperature the compositions of the systems investigated correspond to the two-phase state; (3) the components are potentially miscible but, by virtue of kinetic causes, the system has not attained equilibrium by the beginning of the rheological experiments and is therefore characterised by a definite level of heterogeneity; (4) phase separation takes place during the flow process. We shall examine further two main groups of factors which can lead to an anomalous variation of the viscosity-dependent properties regardless of the cause which has induced the heterophase nature of the BPS. One of them is associated with the intrinsic heterogeneity of the initial mixtures, which determines the characteristic features of their flow as disperse systems. The other is associated with the morphology of the extruded materials, arising solely during the flow process, which can alter the mechanism of mass transfer during the rheological experiment. It is more accurate to say that the structural changes accompanying the flow of BPS can mask the manifestation of features characteristic of classical dispersions.

As mentioned above, there is as yet no universal theory of the flow of polymer dispersions and the Einstein, Goot, Wand, Andrade-de Gusman, Mooney, Schowalter–Taylor, etc. equations are used to account for the experimental observations (depending on the form of the particles of the disperse phase and the range of concentrations of the dispersions). Within the framework of these ideas, the increase in the viscosity of BPS as a function of concentration is evident. However, a satisfactory explanation of the anomalously high values of $\Delta\eta$ observed experimentally has not yet been found.

As regards the factors inducing the increase in viscosity (or diminishing it) as a consequence of the change in the structure of the extruded material during the flow of BPS, at the present time they are considered only at the qualitative level. Examples were quoted above (see, for example, Refs.7, 39, 40, 47, 80) in which typical approaches to the interpretation of the anomalies in the increase and decrease in viscosity as the morphology of the extruded material varies are described.

We may note that it is precisely in two-phase BPS that the influence of the design of rheological apparatus on the results of the rheological experiment is manifested to the greatest extent. This is apparently associated with the fact that the method used to establish a given shear deformation, the design of the capillary, and hence the flow regimes in many respects determine the structure of the BPS formed during the flow process. For example, the transformation of the viscosity minimum into a maximum on the $\eta = f(c)$ curves, which has been observed[6] for a heterogeneous system as the length of the capillary was varied, is apparently induced by the increase in the viscosity of the wall layer, which is caused in its turn by a change in the hydrodynamics of the flow.

4. The Regions of the Metastable and Critical States

A distinctive feature of BPS with limited compatibility of the components is the fact that the structure of these systems, arising in the metastable and critical states itself, induces the manifestation of anomalies in dynamic properties. The large-scale fluctuations arising spontaneously in the critical region and in the vicinity of the spinodal curve, dissipate "non-productively" part of the energy of the shear deformation of the system, which leads ultimately to an increase in the macroscopic viscosity of such BPS.

Manevich and co-workers[81–83] were able to impart (in relation to BPS) the form of mathematically complete physical series to the idea of the dissipation of energy by large-scale fluctuations. The viscosity η_m, manifested in regions II, II′, and IV (Fig.6), consists of the viscosity of the regular solution (η_r) and the additional positive corrections $\Delta\eta_{sp}$ (regions II and II′) and $\Delta\eta_{cr}$ (region IV). Furthermore, it follows from the study of Mitlin and Manevich[83] that the "osmotic" correction, whose sign is negative, contributes to η_m. Each correction is defined by the corresponding equations, relating its value to the molecular characteristics of the components, the thermodynamic parameters of the system, the state parameters, and the deformation regimes.

Comparison of the conclusions derived from these theories with experiment yields a satisfactory qualitative agreement in some cases,[8,59,80] whilst in others[51–55] it does not. The physical clarity of the theories of Manevich and co-workers[81–83] is so attractive that it has stimulated the desire to account (at least formally) for the causes of the disagreement between experiment and theory in the latter cases. If it is assumed that the increase in viscosity for BPS of the rubber–OAE type is indeed induced by large-scale concentration fluctuations, then in the most general case the above discrepancy may be caused by the molecular polydispersity of the polymer, which leads to the "smearing" of the limits of the thermodynamic stability of the BPS in the vicinity of which these fluctuations are in fact generated. Since this approach may prove useful in the analysis of the dynamic properties of any polydisperse systems,¶ we shall deal in greater detail with certain causes of the discrepancies between theory and experiment. The following fact may be regarded as established:

1. A polydisperse polymer is in fact a solution of fractions with different MW. It has been demonstrated[8,11,89–92] that, under certain conditions (the role of the MWD is of primary importance), there is even a possibility of microphase separation in mixtures of polymeric homologues.

2. The dissolution of a mixture of polymeric homologues in an organic solvent should lead to the establishment of equilibrium between the solutions of fractions with different MW.[13] One of the technological procedures for the fractionation of polymers is based on this precise factor. There is a possibility of at least two thermodynamically non-equivalent cases: (a) the solvent forms a molecular solution with all the fractions of the polymer; (b) for a specified composition and temperature, certain fractions of the polymer are insoluble.

3. Theoretical calculations[93] have shown that, when the blended polymers have similar MWD, then the CT for the blend is independent of composition; otherwise the CT shifts to the region of extreme compositions. Bearing in mind the previous conclusion, one may conclude that in a blend of two polydisperse polymers there is a range of CT determined by the CT of different fractions. The claim that there exists a region of consolute concentrations whose width should depend on the width of the MWD of the components is also valid.

¶ We may recall the anomalies in the viscoelastic properties of a series of other BPS have also been attributed[59] to the polydispersity of the components.

4. It follows from the study of Vinogradov and Malkin[1] that, in a flow of polydisperse polymers, the low-molecular-weight fractions can be regarded as plasticisers of the high-molecular-weight fractions. The converse claim that the high-molecular-weight fractions thicken the low-molecular-weight fractions should also be valid.

5. A decrease in the proportion of low-molecular-weight fractions in a polydisperse polymer should lead to an increase in the viscosity of the mixture.[1]

6. Allowance for the polydispersity of the components in the theory of the viscosity of BPS near the thermodynamic stability limit[82] leads to the conclusion that only some of the total number of molecules in the system participate in the generation of large-scale fluctuations. Consequently, only some of the molecules ensure the increase in the viscosity of the system. The laws governing the translational movement of the remaining BPS molecules determine their "entry" into a particular region of the phase diagram.

When applied to blends of a polydisperse rubber with OEA, the postulates formulated above mean that structural inhomogeneities should exist in such systems. The inhomogeneities are characterised by different local concentrations of the oligomer corresponding to the limits of its solubility in fractions with different MW: the low-molecular-weight fractions contain a relatively larger amount of the dissolved oligomer than the high-molecular-weight fractions; furthermore, the CT of the solutions of the low-molecular-weight fractions are lower than those of the high-molecular-weight fractions.

Overall, this implies that, when the polymeric component of the BPS has a fairly wide MW distribution, then the system always contains molecules "belonging" to different parts of the phase diagram. Consequently even insignificant changes in the MWD, the composition, or the temperature should entail a shift of the thermodynamic equilibrium established between solutions of different fractions and a redistribution of the molecules between different regions. This should inevitably lead to a change in the macroscopic viscosity of the system, which is made up of the viscosity of the regular solution and the corresponding corrections for the increase in viscosity due to the molecules "present" in regions II and IV (Fig.6). Furthermore yet another factor becomes significant: after the introduction of the oligomer, the molecules of the low-molecular-weight fractions of the polymer, which serve as plasticisers of the high-molecular-weight fractions in the absence of the solvent, cease to exert a plasticising effect and are therefore forced to enter a metastable or critical state participating in the generation of the large-scale fluctuations. The experimental "resultant" viscosity is in fact determined by the competition between all these factors.†

Thus the macroscopic viscosity of the mixture of a polydisperse polymer and the solvent can be represented as follows:

$$\eta_m = \eta_r + \Delta\eta_{cr}\varphi_{cr} + \Delta\eta_{sp}\varphi_{sp} + \Delta\eta_a\varphi_a - \Delta\eta_p\varphi_p, \qquad (12)$$

where η_r is the viscosity of the regular solution, $\Delta\eta_{cr}$ the positive "critical" correction taking into account the increase in the viscosity of the fraction of macromolecules (η_{cr}) in the critical region, $\Delta\eta_{sp}$ the positive (spinodal) correction determined by the appearance of large-scale fluctuations among the fraction of the macromolecules (φ_{sp}) near the spinodal curve, $\Delta\eta_a$ a positive correction (for "anti-plasticisation") determined by the fact that a proportion (φ_a) of the molecules of the low-molecular-weight fractions cease to plasticise the system, $\Delta\eta_p$ the correction (the "plasticising" correction) determined by the plasticising effect of the solvent and a proportion (φ_p) of the polymer molecules.

Evidently, $\Delta\eta_{cr}$, $\Delta\eta_{sp}$, and $\Delta\eta_a$ lead to an increase in the viscosity of the blend, while $\Delta\eta_p$ leads to its decrease. On this basis, a structural organisation of solutions of the individual fractions of the "polydisperse system" such that, according to Eqn.(12), the positive viscosity corrections predominate is presumably established under the experimental conditions selected[51-55] at low OAE concentrations. Other conditions being equal, an increase in the oligomer content increases φ_p and hence $\Delta\eta_p\varphi_p$ and therefore entails a decrease in η_m. After an increase in viscosity, its decrease is therefore observed on the "viscosity–composition" curve.

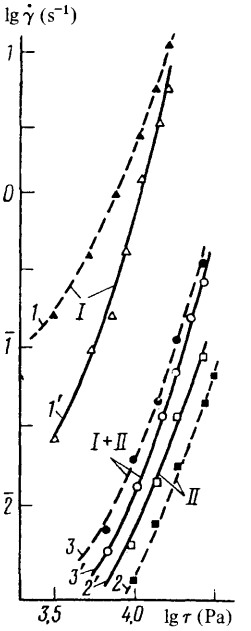

Figure 7. Flow curves for *cis*-polyisoprenes with MW = 5×10^4 (curves 1 and 1′) and 6.2×10^5 (curves 2 and 2′) and for their equimolar blend (curves 3 and 3′): 1)–3) without TGM-3; 1′)–3′) with 0.1 wt.% of TGM-3.[54]

† The contribution of the negative "osmotic" correction to the viscosity proposed by Mitlin and Manevich[83] is not taken into account below, because its quantitative relation with the "plasticising" viscosity correction ($\Delta\eta_p$) is not clear. It is suggested that the latter includes the "osmotic" correction.

The above schematic considerations make it possible to explain also why the position of the maximum on the experimental "viscosity–composition" curve is inconsistent with the theoretical prediction.[81-83] The cause of the discrepancy is the "diffuseness" of

the phase states of the individual fractions of the solutions of polydisperse BPS. This hypothesis has so far been confirmed only by indirect experiments.[54]

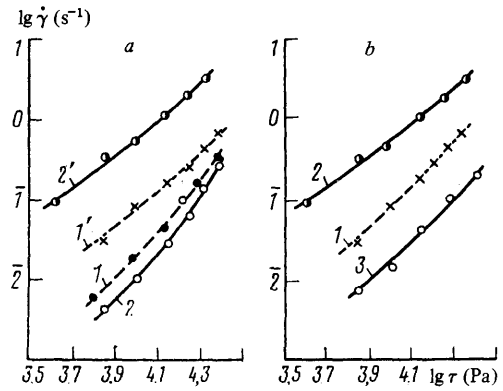

Figure 8. Flow curves for blends of *cis*-polyisoprenes with MW = 5×10^4 and 6.2×10^5: (a): 1) and 2) 1:1 concentration ratio; 1′) and 2′) 2:1 concentration ratio; 1) and 1′) without TGM-3; 2) and 2′) with 0.05 wt.% of TGM-3; (b): 1) without TGM-3; 2) with 0.05 wt.% of TGM-3; 3) with 0.05 wt.% of TGM-3; 2:1 concentration ratio.

It follows from Fig.7 that the increase in viscosity in the raw rubber–OAE system based on a high-molecular-weight raw rubber is manifested only when the system is "diluted" by the low-molecular-weight fraction of the same rubber. Since the relative increase in the viscosity is a maximum for BPS based on low-molecular-weight raw rubbers (Fig.3), it was to be expected that, in complex systems consisting of OAE and a blend of high- and low-molecular-weight raw rubbers, an increase in proportion of the low-molecular-weight fraction of the rubber component in the latter should increase the relative AIV. However, it follows from Fig.8 that, for the same OAE concentration, an increase in the proportion of the low-molecular-weight fraction in the raw rubber (the ratio of the low- and high-molecular-weight fractions is 2:1) not only does not intensify the effect but actually leads to a monotonic decrease in viscosity. This unexpected result is reasonable, provided that the hypothesis discussed above is valid. Indeed, the low-molecular-weight fraction is "responsible" not only for $\Delta\eta_{cr}$ and $\Delta\eta_{sp}$ but also for $\Delta\eta_p$. In the given instance, an increase in its concentration entails an increase in φ_p and an increase in the contribution to η_m by the negative viscosity correction. This results in a decrease in the experimental value.

---o0o---

The anomalous dependence of the viscosity-dependent properties of BPS on concentration and temperature is a consequence of the characteristic features of their structural organisation for different parameters of state (in different regions of the phase diagram).

Although the true mechanism of the anomalous viscosity effect is still far from being understood, the studies in recent years have provided a physical foundation (the relation between the viscosity and the structural parameters of the BPS determined from its phase organisation) for the correct formulation of experimental and theoretical investigations of this phenomenon and have also extended the possibilities for its practical application.

The decrease in the viscosity of BPS (regardless of whether it is manifested in a traditional or anomalous manner) has a favourable effect on the processing of polymers and there are no fundamental problems as regards its practical use. The situation is much more complex with the practical application of the AIV. This is a many-sided problem. On the one hand, in many instances it is essential to increase the viscosity of compositions, for example, of paint and varnish systems, deposited on vertical and inclined surfaces. A fairly wide range of viscosities is inherent in the requirements which must be met by adhesive compositions, hermetic seals, etc. The regulation of viscosity (including its increase) is therefore an important technological procedure for the preparation of polymeric materials with specified properties. Another aspect of this problem consists in the fact that the understanding of the mechanisms of the increase in viscosity permits its prevention in those cases where it is undesirable.

As mentioned above, in BPS based on industrial polymers, which means polydisperse polymers, there are always microregions with a locally increased viscosity regardless of the macroscopic viscosity of the system as a whole. This property of BPS has made it possible to discover yet another application of the AIV phenomenon.[94] By increasing the viscosity in individual mixing stages, it has become possible to improve the dispersion of the filler in raw rubbers. The use of solvents with different solvent powers (the corresponding compositions with OEA) has made it possible to diminish simultaneously the energy expenditure on the processing.

The search for new practical applications of the increased viscosity effect is undoubtedly an interesting task in polymer materials science, but it can be solved successfully only if the true mechanisms of the rheological anomalies in binary polymer systems are clearly understood.

Kinetics and Mechanism of the Inhibited Polymerisation of Vinyl Monomers

M.D.Gol'dfein and G.P.Gladyshev

New data on the kinetics and mechanism of reactions involving the inhibition of the radical polymerisation of vinyl monomers obtained during the last 10-15 years are described systematically and discussed. Equations describing the kinetics of the inhibited polymerisation, accompanied by side and secondary reactions such as additional initiation, chain regeneration, secondary inhibition, and inhibitor regeneration reactions are examined and analysed. The principal kinetic features associated with the structure of the monomer and the inhibitor, the type of initiation, and the influence of the medium are noted. Data are presented on the inhibiting activities of the compounds considered and the advantages of the latter relative to known stabilisers are demonstrated.
The bibliography includes 127 references.

I. INTRODUCTION

One of the main criteria of a radical-chain polymerisation mechanism is the presence of inhibitors—substances whose addition in insignificant amounts to the reaction system can lower the rate of the process until its complete arrest.[1] The fundamental importance of inhibitors consists in the fact that they can be used as a kind of probe for the investigation of the polymerisation mechanism and as counters of active centres.

The practical value of inhibitors is determined by their application for the prevention of the undesirable formation of high-molecular-weight products under the conditions of the synthesis, purification, and storage of monomers.

The commonest inhibitors of the radical polymerisation of vinyl monomers are oxygen, quinones, phenols, aromatic amines, nitro-compounds, transition metal salts, and certain systems manifesting an increase in the reactivity of chemical compounds when they are mixed (synergism). In each specific case, the inhibiting activity of compounds of the above classes is different and depends significantly on particular physicochemical factors.

The retardation of polymerisation is associated with the interaction of active radicals with a relatively ineffective (weak) inhibitor, which results either in a decrease in the concentration of the active centres or in the formation of species incapable of propagating the kinetic and molecular chains.

In the presence of highly effective (powerful) inhibitors, the reaction is accompanied by an induction period during which there is no polymerisation. At the end of the induction period, steady-state kinetics are usually established and the rate of the process can be identical with the rate of the inhibited polymerisation or can be lower than the latter. The character of the dependence of the induction period τ on the intial inhibitor concentration $[X]_0$ is determined by the structures of the inhibitor and the monomer, the method and mechanism of initiation (thermal, material, etc), the nature of the initiator (azo-compound, peroxide, etc) and certain other physicochemical conditions in polymerisation.[2-6] A linear dependence of the induction period in polymerisation on the inhibitor concentration is usually encountered. In many cases, the induction periods increase faster or more slowly with increasing inhibitor concentration, which is usually due to the regeneration of the inhibitor or the additional initiation (or regeneration) of the chain.[6] During these reactions, the relation between the kinetic parameters and the concentrations of the reaction system components is various.

For different mechanisms of the interaction of the inhibitor with the active radicals, the stoichiometric inhibition coefficient μ may lie within a fairly wide range.

II. EQUATIONS FOR THE INHIBITION REACTION RATE CONSTANT

1. The Bagdasar'yan–Bamford Equation

The time variation of the rate of inhibited polymerisation makes it possible to find the inhibition reaction rate constant.[3,6] The mechanism of the radical-chain polymerisation in the presence of a highly effective inhibitor may be formulated in the following simplest form:

$$\begin{aligned} I &\xrightarrow{K_{cons}} 2R_0, \\ R_0 + M &\xrightarrow{K_i} R, \\ R + M &\xrightarrow{K_p} R, \\ R + R &\xrightarrow{K_t} \text{polymer}, \\ R + X &\xrightarrow{K_X} \text{polymer}, \end{aligned}$$

where I, M, and X are the initiator, monomer, and inhibitor molecules, R_0 and R are the primary and polymeric radicals, and K_{cons}, K_i, K_p, K_t, K_x are the rate constants for the corresponding elementary reactions.

Using the steady-state relations for any instant during the induction period,

$$W_i = K_t[R]^2 + K_x[R][X], \quad (1)$$

(W_i is the rate of initiation), and for the rate of consumption of the inhibitor,

$$-\frac{d[X]}{dt} = K_x[R][X], \quad (2)$$

it is possible to obtain the Bagdasar'yan–Bamford equation:

$$F_1 \equiv -\frac{1}{\varphi} + \ln\frac{1+\varphi}{1-\varphi} = \frac{K_x W_{max}}{K_p[M]}t + A, \quad (3)$$

in which the reduced rate φ is equal to the ratio of the rate of reaction at any instant to the steady state rate of polymerisation W/W_{max} and A is the constant of integration.

Eqn.(3) describes the polymerisation kinetics in the presence of an "ideal" inhibitor.[2,7] The Bagdasar'yan–Bamford equation is applicable only to inhibited polymerisation in which side reactions take place without the participation of the inhibitor itself and their contribution to the overall process kinetics does not vary with time. It is also valid in the presence of a chain regeneration reaction. In all these cases, the dependence of the duration of the induction period in the polymerisation reaction on the initial inhibitor concentration is usually linear.

The fundamental importance of Eqn.(3) is determined by two factors. Firstly, the plot of the function against time is linear and the inhibition constant can be found from its slope.[6] Secondly, the relation

$$W_i = \frac{\mu[X]_0}{\tau}, \quad (4)$$

which is the theoretical basis of the universal inhibition methods for the rigorous determination of the rate of initiation, can be obtained from it.

2. The Equation Describing the Kinetics of Inhibited Polymerisation Taking into Account Chain Initiation by the Inhibitor Molecules

The time variation of the rate of polymerisation can be influenced by the reaction involving the additional initiation by inhibitor molecules, which is characteristic of certain substances of both radical and non-radical nature. In such cases, special relations must be used to find the inhibition constants.[8,9]

In the interaction of the inhibitor with the monomer, leading to the formation of active centres, the steady-state relation (1) changes:

$$W_i + K_i[X][M] = K_x[R][X] + K_t[R^2], \quad (5)$$

(K_i is the rate constant for the additional initiation reaction) and the consumption of the inhibitor obeys the equation

$$-\frac{d[X]}{dt} = K_i[X][M] + K_x[R][X]. \quad (6)$$

At the end of the induction period, the reaction takes place at a steady-state rate W_∞ and

$$W_i = K_t[R]_\infty^2. \quad (7)$$

Ultimately, the kinetics of the inhibited polymerisation are described in this instance by the equation

$$F_2 \equiv -2\theta\ln(\varphi+\theta) - (1-\theta)\ln(1-\varphi) + (1+\theta)\ln(1+\varphi) + \frac{1/\theta-\theta}{2}\ln\left|\frac{\varphi-\theta}{\varphi+\theta}\right| = \frac{K_x W_\infty}{K_p[M]}(1-\theta^2)t + B, \quad (8)$$

from which it is possible to find the inhibition constant K_x/K_p, provided that the parameter $\theta = K_i[M]/K_x[R]_\infty$ is known. The quantity θ can be found in its turn from the reduced rate φ at the point of inflection (φ_b) in the S-shaped relation between the rate of inhibited polymerisation and time. If φ obeys Eqn.(8), then it follows from the condition for the point of inflection that

$$\theta^3 + \frac{2\varphi_b}{1+\varphi_b^2}\theta^2 - \frac{2\varphi_b^4-\varphi_b^2}{1+\varphi_b^2}\theta + \frac{\varphi_b^5+2\varphi_b^3-\varphi_b}{1+\varphi_b^2} = 0. \quad (9)$$

If the kinetics of the inhibited polymerisation are described by the Bagdasar'yan–Bamford equation, then $\theta_b = 0.643$. In the presence of additional initiation, φ_b varies from 0.643 to 1.0. Fig.1 illustrates the dependence of θ on φ_b calculated by Eqn.(9).

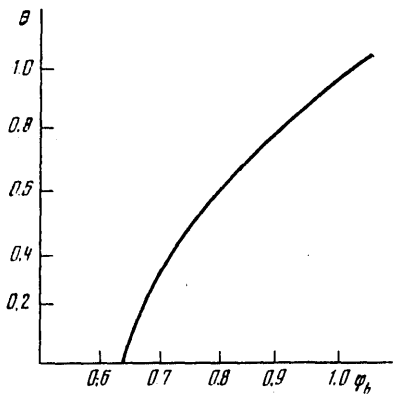

Figure 1. Dependence of the parameter θ on φ_b according to Eqn.(9).[9]

Eqn.(8) can be transformed into

$$F_2 \equiv K_i[M]\left(\frac{1}{\theta}-\theta\right)t + B,$$

which makes it possible to find the additional initiation rate constant K_i.

3. Kinetic Equation Taking into Account the Effects of the Secondary Inhibition (Retardation) of Polymerisation

The effect of a highly efficient inhibitor on polymerisation can produce not only an induction period but can also lower the rate of reaction with increasing inhibitor concentration.[6,10] The decrease in the concentration of growing chains is usually associated with their interaction with the primary inhibition products Y:

$$R + X \xrightarrow{K_X} Y;$$
$$R + Y \xrightarrow{K_Y} \text{polymer}.$$

In a steady-state process, we have during the induction period

$$W_i = K_X[R][X] + K_Y[R][Y] + K_t[R]^2.$$

The consumption of the inhibitor is described by Eqn.(2) in this case also. When account is taken of the material balance relation $[Y] = [X]_0-[X]$ and the steady-state equations for the non-inhibited polymerisation

$$W_i = K_t[R]^2 \tag{10}$$

and at the end of the induction period

$$W_i = K_t[R]_\infty^2 + \alpha K_Y[R]_\infty[X]_0 \tag{11}$$

(α is the stoichiometric secondary inhibition coefficient), we obtain

$$F_3 \equiv -\frac{1}{\varphi} - \ln(1-\varphi) + (1-\varphi_\infty^2)\ln\varphi + \varphi_\infty^2 \ln\left(\varphi + \frac{1}{\varphi_\infty^2}\right) = \frac{K_X W_\infty}{K_p[M]} t + C. \tag{12}$$

In the last equation, φ is the ratio of the rate of polymerisation at any instant W_t to the steady-state rate of the inhibited reaction W_∞ and φ_∞ is the ratio of W_∞ to the steady-state rate of the non-inhibited process W.

Thus the primary inhibition constant K_X/K_p is determined from the slope of the linear time variation of F_3. Evidently, if the inhibition products Y do not have a retarding influence on the subsequent polymerisation ($W\infty = W$ and $F_\infty = 1$), then Eqn. (12) becomes identical with Eqn.(3).

The secondary inhibition (retardation) rate constant K_Y is calculated from the relation obtained from a calculation for the polymerisation scheme in the presence of a relatively ineffective inhibitor[3,6] and the analysis of the non-steady state equation (11):

$$K_Y = \frac{(1-\varphi^2)K_t W}{\alpha\varphi K_p[M][X]_0}$$

4. Refinement of the Conditions Governing the Applicability of the Kice Equation to the Solution of the Converse Kinetic Problem in Inhibited Polymerisation

Studies have been published comparatively recently[11-13] in which, on the one hand, a new approach was described to the analysis of the Kice equation[14] and, on the other, the conditions governing its application were defined more rigorously.

Kice's fundamental assumptions concerned two factors: the inhibitor does not participate in the chain initiation stage and the quadratic chain termination rate constant is independent of the presence of the inhibitor.

Smirnov and Karapetyan[11] suggested that only one evident simplifying condition be used—the quasi-steady-state nature of the active and inactive radicals. As before, in this instance the reduced rate φ is determined by the ratio of the concentrations of the growing chains in the presence and absence of the inhibitor, namely $[R]_X$ and [R] respectively:

$$\varphi = \frac{W_X}{[M]_X} \Big/ \frac{W}{[M]} = [R]_X/[R].$$

The usual mechanism of radical polymerisation in the presence of a molecular inhibitor was supplemented by reactions involving initiation by the inhibitor

$$R_0 + X \xrightarrow{K_{iX}} R_X,$$

chain regeneration

$$R_X + M \xrightarrow{K_r} R$$

and chain cross-termination

$$R + R_X \xrightarrow{K_{tX}} \text{inactive product}.$$

(K_{iX}, K_r, and K_{tX} are the rate constants for the corresponding reactions).

If $\varphi^2/(1-\varphi^2) \gg K_rK_t/K_pK_{tX}$, which is always valid for typical inhibitors ($K_r/K_p \gg 1$, $\varphi \gg 0.1$), then the kinetics of the inhibited polymerisation are described by the equation

$$A\left(\varkappa + \frac{2\epsilon}{\varphi}\right) = C + B, \tag{13}$$

where

$$\varkappa = K_X[X]/\{K_{cons}f[I](K_t)_{X=0}\}^{0.5},$$
$$C = K_rK_tK_X[M][X]/K_{tX}\varkappa,$$
$$\epsilon = K_{iX}[X]/(K_{iX}[X] + K_{iM}[M]).$$

(K_{iM} is the rate constant for the reaction $R_0 + M \rightarrow R$).

$$A = \frac{\theta}{2}\left(\frac{B}{\varphi} - 1\right),$$
$$B = \varphi\left(1 + \theta\frac{1-\gamma\varphi^2}{\varphi^2}\right)^{0.5},$$
$$\gamma = (K_t)_X/(K_t)_{X=0},$$
$$\theta = 4(K_t)_{X=0}K_{tXX}/K_{iX}^2.$$

(K_{tXX} is the rate constant for the reaction $R_X + R_X \rightarrow$).

When $\epsilon = 0$ and $\gamma = 1$, Eqn.(13) becomes identical with the Kice equation:

$$A\varkappa = C + B.$$

in which A and B depend only on φ and θ. Under the usual inhibition conditions, the reduced rate φ is a function of κ, C, and θ. The deviations from the kinetics described by Eqn.(13) are observed for low values of φ and unduly high rates of chain regeneration.

The relation $\theta \ll 1$ holds for the inhibited polymerisation. Here $B < 1$ for any φ and the chain regeneration parameter C can assume any values, including $C \gg B$. When the latter inequality holds, the reduced rate and the expressions for the rates of inhibited polymerisation are determined by the mechanism of the inhibition reaction.

When the active radical R interacts with the inhibition product, we have

$$\varphi = (C/\varkappa)^{0.5}$$
$$W_X = K_p (K_{cons} f K_r / K_X K_{tX})^{0.5} [M]^{1.5} [I]^{0.5} [X]^{-0.5}.$$

If chain termination takes place via the interaction of inhibitor radicals with one another, then

$$\varphi = 2C/\varkappa\theta^{0.5},$$
$$W_X = \{K_p K_r (K_{cons} f / K_{tXX})^{0.5} / K_X\} [M]^2 [I]^{0.5} [X]^{-1}.$$

Both expressions for the rate of the inhibited polymerisation show that the very fact of inhibition does not in any way imply an increase in the kinetic order with respect to the initiator.

In the presence of stable radicals and transition metal ions not involved in the initiation of the reaction and not promoting the chain regeneration, the inhibition mechanism changes. The inhibition steps are expressed in the form

$$R + X \xrightarrow{K_X} \text{inactive products},$$
$$R + M^{2+}L_2^- \xrightarrow{K_X} M^{3+}L_2^-R^-,$$
$$R + M^{3+}L_3^- \xrightarrow{K_X} M^{2+}L_2^- + RL\,(L = \text{ligand}).$$

In such cases the inhibition reaction rate constant can be found from the equation

$$K_X = \frac{2(1-\varphi^2)(K_{cons} f [I] K_t)^{0.5}}{\varphi [X]}$$

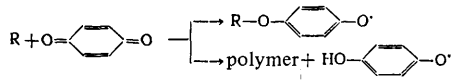
This equation is identical with the relation presented previously and obtained for the rate constant for the interaction of the inhibitor with the polymeric radical K_Y under weak inhibition conditions where there are no induction periods and only a decrease in the rate of polymerisation is observed. However, stable radicals and transition metal salts are usually effective inhibitors of radical polymerisation. In their presence, the rate of polymerisation and hence also φ vary with time and are virtually zero during the induction period, which reduces significantly the possibility of employing the last equation for finding the rate constant for relatively ineffective inhibition.

III. INHIBITORS AND MECHANISMS OF THE INHIBITION REACTIONS UNDER THE CONDITIONS OF RADICAL POLYMERISATION

Fairly extensive experience has now accumulated concerning, on the one hand, the search for effective stabilisers of vinyl monomers and, on the other hand, the determination of the kinetic features and mechanisms of the inhibiting action of different classes of substances. In general, one should note that the problem of the chemistry of the inhibition of radical polymerisation had not received due attention for a long time. At the same time, these questions are always of current interest, especially in connection with the selectivity of the action of inhibitors. Depending on the reactivity of the monomer (or its polymeric radical), temperature, the presence of various kinds of admixtures in the medium, the structure of the inhibitor itself, etc., the mechanism of the interaction of the inhibitor with the active radical can in many instances be ambiguous.

The first more or less systematic data concerning these questions have been published in monographs.[2-5] Subsequently, in the course of one and a half decades, only isolated studies appeared in the scientific literature. The most interesting of the latest reviews in which a wide range of inhibitors and the mcehanisms of their action are considered are those of Lazareva and Sidorov[15] and Barabashina et al.[16] The principal value of these reviews consists in the fact that they deal not only with the methods for the stabilisation of pure monomers but attention has been given to information about the most probable mechanisms of the inhibition of polymerisation occurring in individual stages of the synthesis of the monomers and for different ways of isolating, purifying, fractionating, and processing such monomers.

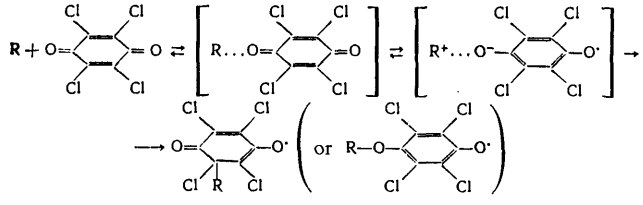
A chapter in the monograph of Gladyshev and Popov is devoted to questions of the regulation of the gel-effect in radical polymerisation with the aid of relatively ineffective inhibitors.[17]



Apart from the previously known classes of stabilisers enumerated above, many inhibitors and inhibiting systems have been described in the patent literature. For example divinylacetylene,[18] hexamethylenetetramine,[19] salts of dibutyldithiocarbamic acid,[20] the composition containing phosphoric acids and (or) phosphoryl oxide, cresol, benzaldehyde,[21] aromatic amines with different structures,[22-27] *p*-methoxyphenol[28] and other phenols,[29] combinations of inhibitors of the amine and phenolic types,[30] compounds containing the nitroso-group linked to a carbon atom of the aromatic ring,[31] etc., have been proposed for the inhibition of the polymerisation of acrylates and methacrylates.

There have been comparatively few studies devoted to the relation between the structure of polycondensed aromatic hydrocarbons and their ability to inhibit the polymerisation of vinyl monomers. These questions were raised for the first time and in several studies.[32-35] It has been shown[36] that condensed aromatic hydrocarbons do not influence the chemically initiated polymerisation of methyl methacrylate but do inhibit the photosensitised reaction, reducing its rate without inducing an induction period. The inhibiting activity increases in the sequence naphthalene < phenanthrene < anthracene < chrysene. The inhibiting effect of the above substances is associated with their transition to the triplet state under the influence of light.

In their study of the polymerisation of vinyl acetate initiated by azobisisobutyronitrile in the presence of aniline and its derivatives,[37] Simonyi and Tudos[37] suggested that, when the substituent is changed, the stoichiometry of the inhibition reaction does not change but a decrease in the inhibition rate constant has been observed. Thus the constants K_X for aniline, *N*-methylaniline, and *NN'*-dimethylaniline are respectively 17, 6, and 0.7. After the introduction of a substituent into the benzene ring in the *para*- and *meta*-positions, the activity of the inhibitor is described by the Hammett equation. *ortho*- and poly-substituted anilines exhibit a reduced reactivity.

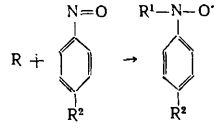


Many quinonoid compounds and their derivatives effectively inhibit radical polymerisation. The inhibiting activity of quinones is determined not only by their chemical structure and oxidation-reduction potential but also by the electron-donating capacity of the

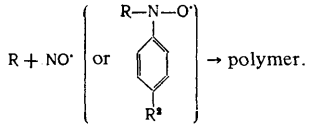
macroradical and the polarity of the medium (usually the monomer itself).[38] Depending on these factors and the physicochemical conditions in the reaction, there is a possibility of recombination and disproportionation:[3]

or the formation of an inactive radical via an intermediate charge-transfer complex (CTC).[39,40]

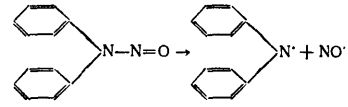
Further studies showed[41] that the rate-limiting stage in the interaction of the active radical with quinones is the conversion of the CTC into the inhibitor radical. The reaction involving methacrylates and acrylates is slow but can be accelerated by the addition of certain electron-donating compounds, for example, phenothiazine. The mechanism of the inhibition by quinones has been represented as follows in the case of the polymerisation of methyl methacrylate in the presence of chloranil:



Regardless of the mechanism of the interaction of the quinone with the growing radical, the stoichiometric inhibition coefficient is in all cases close to two.



Polymerisation in the presence of nitro- and nitroso-derivatives is usually accompanied by an induction period and retardation of the reaction.[16] Compared with quinones, nitro-compounds reduce the rate of the process to a lesser extent, since their interaction with macroradicals is more difficult. Their inhibiting capacity is determined by the nature of the monomer, the type of polymerisation (in bulk or in solution), increasing with increase in the number of nitro-groups. From the mechanism of the inhibition of polymerisation by substances in this class,[16,42-45] it also follows that $\mu \simeq 2$:



or

and further

Nitro-compounds can interact with growing chains but also with primary initiator radicals.[46] In certain cases, the nitroso-compound can decompose with formation of nitric oxide and a product having the properties of a stable radical:[47]

The stoichiometric inhibition coefficients of dimethyl-*p*-nitrosoaniline and *p*-nitrosodiphenylamine in the polymerisation of styrene, acrylonitrile, and methyl acrylate depend on the monomer concentration.[48] For example, the decrease in the mole fraction of the monomer from 1 to 0.3 in the acrylonitrile–DMF–*p*-nitrosodiphenylamine system entails an increse in μ from 0.86 to 1.8, while in the methyl acrylate–DMF–*p*-nitrosodiphenylamine system μ increases from 1.54 to 1.94 as the mole fraction of the monomer is reduced from 1 to 0.5. Tudos and co-workers[48] explained the changes in the stoichiometric coefficient on the basis of the hot radical theory.[48]

The results of studies on the inhibiting capacity of nitroso-compounds under radical polymerisation conditions proved to be closely related to the problem of the removal of the stabiliser from the monomer before its conversion into the polymer. This is usually achieved by fractionation with preliminary extraction of the inhibitor. The optimum solution of this problem is achieved by the monomer stabilisation method in which the inhibitor is effective during the storage of the monomer but does not affect its polymerisation.

One of the versions of the solution of this problem consists in the use of inhibitors interacting with the components of the reaction medium (for example, with the initiator) and then losing their activity. The radical-anion complexes of tetracyanoquinodimethane may serve as an example of inhibitors of this kind.[49,50]

Another version involves the use of inhibitors which are sparingly soluble in the monomers. During the storage of the latter, when the rate of the initiation of the polymerisation is low, there is sufficient dissolved inhibitor for effective stabilisation. However, this concentration of the inhibitor does not have a significant influence on the polymerisation under the properties of the high-molecular-weight products formed. The results obtained in the study of polymerisation in the presence of added cupferronates (ammonium salts of *N*-nitroso-*N*-phenylhydroxylamine and its derivatives) in fact correspond to this particular version.[51] Sodium, potassium, ammonium, and copper cupferronates inhibit effectively the polymerisation of acrylates and methacrylates in solution in DMF. The duration of the induction period increases linearly with increasing concentration of the additives. In contrast to the polymerisation of styrene, for which the stoichiometric inhibition coefficient is two[16] (analogously to the mechanism adopted for inhibition by nitro- and nitroso-compounds), in the polymerisation of acrylates and methacrylates, μ = 1.5. In these cases, an interaction has been observed between the cupferronates and the monomers with formation of free radicals and a decrease in μ.

In the polymerisation of methyl acrylate, butyl acrylate, and methyl methacrylate, the dependence of the induction period on the concentrations of the cupferronates is non-linear and the steady-state rate of the inhibited reaction is less than that of the non-inhibited reaction.

One of the features of the above salts of practical importance is that they inhibit polymerisation not only in air but also under oxygen-free conditions.

The differences in the influence of various cupferronates on polymerisation are caused by their different solubilities. Copper and sodium cupferronates exhibit the highest and lowest solubilities respectively in acrylic monomers. The results of Gol'dfein et al.[51] make it possible to plot calibration relations for the polymerisation inhibition periods observed in saturated solutions of cupferronates in monomers as a function of the concentration of the salts.

The interaction of cupferronates with acrylates and methacrylates leads to their deactivation and is one of the causes of the non-linearity of the concentration variation of the induction period. After a time, the cupferonates gradually decompose. In terms of stability, they can be arranged in the following sequence: copper > sodium > potassium > ammonium cupferronates. Furthermore, the degree of their deactivation depends on the chemical structure of the monomer: it is highest in methyl methacrylate and lowest in methyl acrylate.

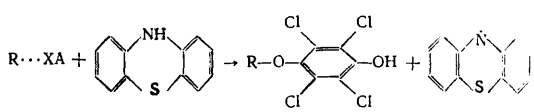
At certain stages in the synthesis of the monomers, the reaction mixtures contain fairly large amounts of water. The presence of water in the monomers influences also the solubility of the cupferronates and hence their inhibiting activity. The presence of water in the monomer has a greater effect on the induction period in polymerisation the higher the solubilities of the cupferronate and water in the monomer.

Metal salts have different effects on the kinetics and mechanism of the radical polymerisation of vinyl monomers.[2-4] Thus a concentration-dependent inversion of the catalytic properties is characteristic of iron and copper chlorides.[52,53] The inhibiting effect of aliphatic acid salts depends on the nature of the metal in the salt and also on the medium in which the reaction takes place (in bulk or in solution) and on the size of the anion.[54] The inhibiting influence of zinc, cobalt, and lead stearates on the polyerisation of styrene and methyl methacrylate, initiated by the inhibition in such cases consists in the interaction of the active radical with the intermediate complex formed between the stearate and the peroxide. Transition metal chlorides and aliphatic acid salts have not found extensive practical applications.

The influence of the medium on the kinetic parameters of the inhibition of the polymerisation of vinyl monomers in the presence of iron and copper chlorides has been analysed.[57] For example, in the inhibition of the polymerisation of acrylonitrile in aqueous sodium thiocyanate solution, the inhibition constant increases by 2–3 orders of magnitude compared with the polymerisation in solution in DMF.[58]

Metal salts of dialkyldithiocarbamic acid have come to be recommended as effective inhibitors of the polymerisation of acrylic monomers. These compounds readily accept peroxy- and alkyl radicals. The mechanism of the inhibiting effect is complicated in the presence of hydroperoxides, because the interaction of the salt with the active radical or hydroperoxide results in the formation of a paramagnetic compound with an enhanced inhibiting capacity.[59] The efficiency of the inhibition then depends on the ratio of the concentrations of the components of the reaction system and on the nature of the metal salts,[60] increasing in the sequence

$$Zn(S_2CNR_2) < Ni(S_2CNR_2)_2 \ll Cu(S_2CNR_2).$$



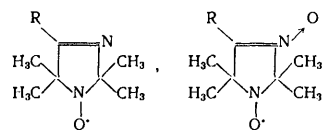
The mechanism of the inhibition of polymerisation by dialkyldithiocarbamates cannot be regarded as established at the present time. Some workers[61] believe that the site in the salt molecules most vulnerable to attack by active radicals is at the sulphur atoms. Others[62,63] postulate interaction with the metal ion and that this is responsible for the transfer of electrons from the ligand to the radical, which is feasible in view of the presence of a covalent bond between the metal and sulphur atoms.[64]

Copper diethyldithiocarbamate (CDTC) exhibits effective inhibiting activity in the polymerisation of acrylic acid in aqueous solution and in solutions in acetic acid and isopropyl acetate.[65] In all cases, the dependence of the induction period on the salt concentration is linear and the stoichiometric inhibition coefficients are greater than unity and depend on the type of solvent. The highest inhibiting capacity of CDTC has been observed in aqueous solution and the lowest in acetic acid. The values of μ obtained in the polymerisation of acrylic acid in air and under oxygen-free conditions are virtually identical, which indicates the same stoichiometry of the interaction of CDTC with alkyl and peroxy-radicals. The mechanism of the inhibition in these cases is apparently analogous to the mechanism of the inhibition of oxidation reactions by phosphorodithioates[66] accompanied by electron transfer to the active radical. The increase in μ (in excess of 2) can be associated with the interaction of the radicals with two sulphur atoms.

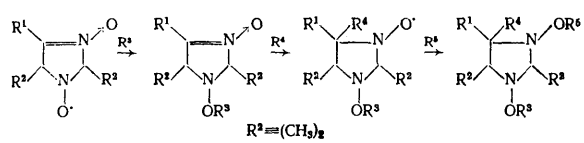
The rate of polymerisation of acrylic acid in organic media is fairly considerably reduced compared with the rate in aqueous solution. This is due to the formation of complexes by acetic acid and isopropyl acetate with the polymeric radicals[67,68] and the reduction of the reactivity of the latter. The interaction of these solvents with the growing chains is also responsible for the decrease in μ in the polymerisation of acrylic acid in solutions in acetic acid and isopropyl acetate compared with the reaction in water. The primary (K_X/K_p) and secondary (K_Y/K_p) inhibition constants have been found for the systems indicated by Eqns.(14) and (15) respectively.

A mixture of chloranil (CA) and phenothiazine (PT) proved to be an effective inhibiting system.[69] In contrast to the polymerisation of styrene, where chloranil is a powerful inhibitor,[70] in methyl acrylate only a slight inhibition is observed and CA has no influence on the polymerisation of methyl methacrylate. On the other hand, when PT or the oligomeric product of its oxidative condensation (OPT) was added, a synergistic effect with a distinct induction period was observed.[71,72] It has been shown[69] that the rate-limiting stage of the inhibition process involves the interaction of the growing chain with a CA molecule and not with the PT...CA complex. The sharp increase in K_X, approximately by two orders of magnitude in the presence of PT or OPT, can be satisfactorily accounted for by the mechanism above.[41]

The interaction of PT with CTC leads to the formation of the PT· radical:



The PT· radical can interact with R, M, and XA to form a new radical capable of terminating yet another chain. However, the stoichiometric inhibition coefficient proved to be less than two which is due to the regeneration of the chain in the interaction of PT· with a methyl methacrylate molecule. In the polymerisation of methyl acrylate, the inhibiting effect of the CA–PT system is appreciably smaller. In this case not only the active radicals but also the CTC enter into the reaction with CA. Thus the structure of the monomers and the donor–acceptor properties of the monomers and the growing radicals play a decisive role in the inhibition mechanism.



The study of the kinetics of the inhibition of the polymerisation of vinyl monomers in the presence of binary systems has been suggested.[73,74] It has been shown that mixtures of CA with triethylamine and also of anthracene with phenothiazine and oligophenothiazine effectively inhibit the radical polymerisation of methyl methacrylate. The existence of critical inhibitor and initiator concentrations is associated, according to the authors, with the inhibiting effect of *NN*-diethylaminovinyltrichloro-*p*-benzoquinone, formed as a result of the conversion of the CTC into a radical pair. The observed synergistic effect can be explained by the radical-chain reactions involving the consumption of the inhibitors.

Stable radicals incapable of recombining are effective inhibitors of the polymerisation of vinyl monomers. Data concerning the use of hydrazyl, verdazyl, iminoxy-, and arylnitroxy-radicals in addition to certain radical-anions as spin-trapping agents as well as polymerisation in the presence of these substances, indicating the complexity of the inhibition mechanism, have been quoted in a recently published review.[50]

Nitroxy-radicals of the type of imidazoline and imidazolidine proved to be extremely interesting from both theoretical and experimental standpoints.[75,76] They belong to the class of five-membered nitrogen-containing heterocyclic free radicals:

Compared with the types of stable radicals listed above, the nitroxy-radicals based on imidazoline and imidazolidine have a number of advantages. The additional nitrogen atom of the *N*-oxide group combined with the functional group in the 4-position in the heterocycle makes it possible to achieve complex formation and cyclometallation without the involvement of the radical centre. The presence of the imine or imine *N*-oxide (nitrone) group in the imidazoline molecule leads to a much greater stability of the nitroxy-radical in an acid medium, which is an important factor in the practical employment of such radicals as inhibitors of polymerisation, occurring, for example, under the conditions of the synthesis of methacrylates. Imidazoline *N*-oxides, as agents interrupting oxidation chains and as trapping agents for short-lived radicals of various types, should manifest the highest inhibiting activity under these conditions:

According to the scheme formulated above, the stoichiometric inhibition coefficient should be greater than unity.

It has been shown[77,78] that the 2,2,5,5-tetramethyl-3-oxo-4-phenylimidazolin-1-yloxy-radical (TMPIZ) effectively inhibits the polymerisation of styrene and methyl methacrylate. It was of interest that the form of the dependence of the duration of the induction period on the initial concentration of the stable (linear) radical and the stoichiometric inhibition coefficients (μ = 1.5 for styrene and μ = 1.25 for methyl methacrylate) are independent of the nature of the initiator (an azo-compound or a peroxide), as has been observed, for example, for iminoxy-radicals and especially for arylnitroxy-radicals.[50]

TMPIZ has a weak inhibiting effect on the polymerisation of methyl methacrylate in the presence of both concentrated and dilute sulphuric acid. At the same time, the form of the dependence of the steady-state rate on the TMPIZ concentration is determined by the concentration of sulphuric acid in water. The inhibition constants K_X/K_p are therefore found by taking into account the kinetics of the polymerisation at the end of the induction period—using Eqns.(3) and (12) respectively in the presence of concentrated and dilute acid.

The inhibiting activity of TMPIZ, a nitroxy-radical derived from imidazoline, in an acid medium made it possible to use it for the determination of the rate of initiation of the polymerisation by sulphuric acid and also of the rate constants for the chain propagation and termination reactions corresponding to different contents of the acid in water and in the reaction system.[78]

In the inhibition of the thermal polymerisation of methyl methacrylate in the presence of sulphuric acid, the dependence of the induction period on the TMPIZ concentration is markedly more non-linear than might have been expected in the presence of an additional initiation reaction. It is most likely that this is associated with the characteristics of the mechanism of the thermal initiation. Some workers[79,80] suggest that the thermal polymerisation is initiated by triplet radicals and that all the radicals interact with the inhibitor. Others draw attention to the possibility of the interaction of the inhibitor with the monomer[81-83] and of reactions between the inhibitor and an intermediate formed at a rate exceeding the rate of initiation.[84] The kinetics of the inhibited polymerisation have been analysed in greatest detail taking into account these reactions in relation to styrene,[85] where the inhibitors were divided by the author into two groups—interacting and not interacting with the intermediate, which is a biradical in thermal initiation.

IV. POLYMER STABILISERS—EFFECTIVE INHIBITORS OF RADICAL POLYMERISATION

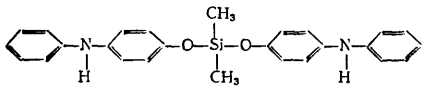
1. Polymerisation in Bulk and Certain Features of the Inhibition of Thermo-oxidative Polymerisation

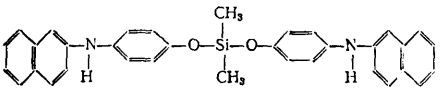
Despite the fundamental difference between their structures, aromatic amines and phenols are often combined in a single group of inhibitors.[86] In the presence of oxygen, these compounds inhibit effectively radical polymerisation, but in its absence they manifest only the properties of weak inhibitors.[17] Furthermore, both amines and phenols tend to form hydrogen bonds with peroxy-radicals, which tends to increase the rate of the inhibition reaction.

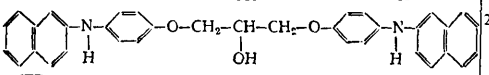
In many cases the abstraction of a hydrogen atom from the reagent by an active radical is the decisive elementary step in the initiation stage, for example:

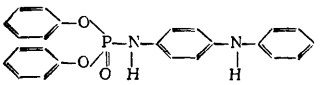
$$RO_2 + R^1—NH—R^2 \rightarrow ROOH + R^1—\dot{N}—R^2,$$

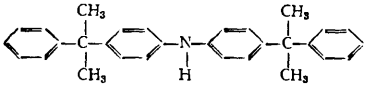
$$R \text{ (or } RO_2) + R^1—\dot{N}—R^2 \rightarrow \text{polymer},$$

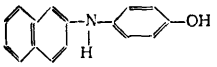


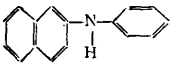


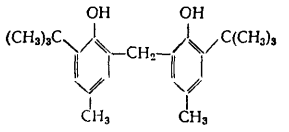












$$R^1—\dot{N}—R^2 + R^1—\dot{N}—R^2 \rightarrow \text{inactive product}.$$

The high rate of interaction of RO_2 with the amine molecule is then caused by the formation of polar activated complexes $ROO^-...H^+$

...N⁻< and not by the low energy of the N–H bond. The inhibiting activity of aromatic amines depends on the polarity of the substituents in the benzene ring: electropositive substituents increase and electronegative substituents diminish the inhibiting effect.

During the last decade, new highly effective inhibitors of the polymerisation of vinyl monomers in the presence of oxygen have been found in the class of aromatic amines,[87-94] which had been synthesised previously as additives to polymeric materials for their stabilisation. These compounds, some of which are listed in Table 1, are readily soluble in many organic solvents, acrylic and methacrylic monomers, and concentrated sulphuric acid.

Table 1. New effective inhibitors of the polymerisation of vinyl monomers.[87-94]

Structural formula	Chemical name	Technical name
	dimethyldi-(*p*-phenylamino-phenoxy)silane	S-1
	dimethyl(β-naphthylamino-*p*-phenoxy)silane	S-41
	2-hydroxy-1,3-di-(*p*-phenylamino-phenoxy)propane	S-47
	2-hydroxy-1,3-di-(β-naphthylamino-*p*-phenoxy)propane	S-49
	*N*-(C_7–C_9)-alkyl-*N'*-phenyl-*p*-phenylene diamine	S-789
	(*p*-phenylamino-phenyl) amide of diphenylphosphoric acid	S-875
	4,4'-bis(αα'-dimethyl benzyl)-diphenylamine	S-933
	*p*-hydroxyphenyl-β-naphthylamine (hydroxyneozone)	HN
	phenyl-β-naphthyl-amine	neozone D
	phenyl-*p*-isopropyl-amino phenyl-amine	diaphen FP
	2,2'-methylenebis-(6-t-butyl-4-methyl)phenol	22-46

In the presence of the above amines, the oxidative polymerisation of styrene and acrylic and methacrylic acids and their esters, initiated by azobisisobutyronitrile (ABIN), is preceded by induction periods whose duration increases linearly with increase in the concentration of the additive. As can be seen from Fig.2, if the induction period is adopted as the criterion of the inhibiting activity, all the substances presented are found to be superior to hydroquinone—the most widely used stabiliser at the present time. The width of the transitional region between the non-steady-state and steady-state kinetics depends little on the inhibitor structure. Under oxygen-free conditions, the test substances have almost no inhibiting influence on the polymerisation of acrylates and methacrylates in bulk for the initial degrees of conversion.

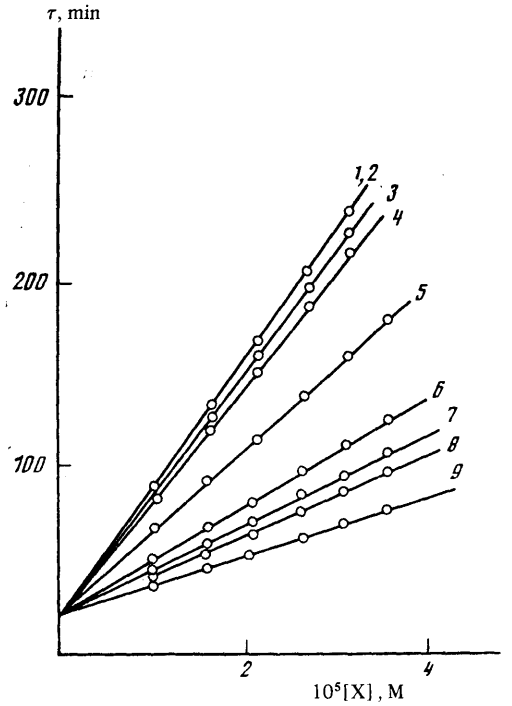


Figure 2. Dependence of the induction period in the polymerisation of methyl methacrylate (τ) on the concentration of inhibitors (60 °C); [ABIN] = 10^{-3} M: (1) S-1; (2) S-47; (3) S-49; (4) S-41; (5) S-789; (6) S-875; (7) HN; (8) HQ; (9) PT.[94]

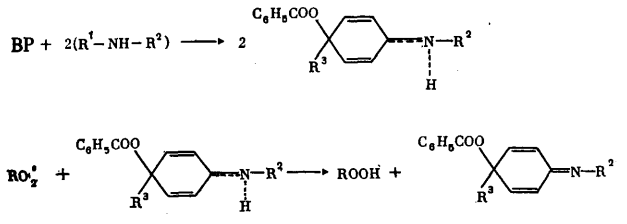
Another extremely important and objective characteristic of the efficiency of the inhibitor is the stoichiometric coefficient μ. For bifunctional inhibitors such as the S-1, S-41, S-47, and S-49 products, one may expect that in each case μ = 4. However, it was found that in all instances the values of μ found by Eqn.(1) are greater than four. This difference from the theoretical value of μ is associated with the regeneration of the amines as a consequence of the interaction of the inactive inhibitor radical with the growing chain not only via recombination but also via disproportionation. The ratio of these two types of chain termination depends on the structures of both the monomer and the inhibitor. Thus, as a consequence of steric hindrance, the contribution of the recombination reaction in the polymerisation of butyl acrylate is smaller than in the polymerisation of methyl acrylate. This leads to higher values of μ in the inhibition of the polyermisation of butyl acrylate by the above compounds (approximately by a factor of two). Furthermore, the



stoichiometric coefficients in the case of both acrylate and methacrylate are greater for S-1 and S-47 than for S-41 and S-49 respectively. The differences between the structures of the amines in each of these pairs are due to the replacement of the benzene ring, linked to the NH group, by the naphthalene ring. In the latter case, the delocalisation of the unpaired electron in the aminyl radical is more significant. This increases the probability of the addition of active radicals not to the nitrogen atom (a process which is sterically hindered) but to one of the carbon atoms of the naphthalene rings, which increases in its turn the contribution of recombination to the overall chain termination.

When the polymerisation process is acted upon by other aromatic amines, also of the polyfunctional type (S-789, S-875, S-933, etc), μ is almost independent of the structure of the inhibiting additive but is determined to a significant extent by the structure of the monomer and the nature of the initiator.[92] In such cases, the active radicals interact with only one NH group, located between two benzene rings. At the same time $\mu \geqslant 2$ also indicates the regeneration of the inhibitor.

The aromatic amines investigated can be arranged in series in terms of their inhibiting activity. For the inhibited oxidative block polymerisation of methyl methacrylate, this series assumes the following form in relation to hydroquinone and phenothiazine:

S-1 > S-41 > S-47 > S-49 > S-789 > S-875 > S-933 > HN > HQ > PT.

In the initiation of the polymerisation of vinyl monomers by benzoyl peroxide (BP), the inhibiting activity of the compounds enumerated above diminishes appreciably. This is caused by the interaction of the peroxide initiator with an amine molecule, which is indicated by the sharp change in the colour of the BP solutions in the monomers when amines are introduced into them. By analogy with the mechanism of the interaction of BP with an arylnitroxyradical,[95] it is assumed[92] that the following reactions occur under the conditions investigated:

Under the real conditions of the synthesis, purification, and storage of acrylic and methacrylic monomers, spontaneous polymerisation frequently occurs and leads to the formation of undesirable high-molecular-wight products. Such polymerisation usually proceeds at elevated temperatures (80–150 °C) in air (naturally in the absence of special initiators) and is thus thermo-oxidative in character. The ballast polymers formed block the industrial apparatus and put it out of order. Furthermore, all this entails considerable losses of the monomers. The search for thermal polymerisation inhibitors in the study of the mechanism of inhibition under these conditions therefore assumes special importance.

The main characteristic feature of the inhibition of the thermal polymerisation of acrylates and methacrylates, in contrast to the initiated polymerisation, is the presence of a break in the dependence of the induction period (at high temperatures) on the inhibitor concentration (Fig.3). From this it follows that there is a critical inhibitor concentration $[X]_{cr}$ above which a sharp increase in the duration of the induction period is observed. The quantity $[X]_{cr}$ then depends significantly not only on temperature but also on the structure of the monomer and the inhibitor.

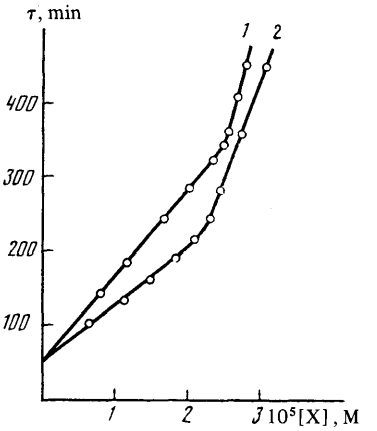


Figure 3. Dependence of the induction period in the thermal polymerisation of methyl methacrylate in air on the concentrations of S-1 (curve *1*) and S-47 (curve *2*) at 100 °C.[94]

For many branched chain reactions, especially for the oxidation of organic compounds, the presence of critical phenomena has been established, including the critical inhibitor concentration.[96,97]

Analogous effects may be observed also in the inhibition of the thermo-oxidative polymerisation of vinyl monomers. The decomposition of polymeric peroxides, leading to the initiation of new reaction centres, occurs also during the induction period and can be regarded as degenerate chain branching. It is noteworthy that degenerate chain branching[98] was not taken into account in any of the previous studies concerned with the inhibition of thermo-oxidative polymerisation.[99–103] These ideas were first put forward in studies[91,92] of the inhibiting capacity of the aromatic amines indicated above.

Kinetic analysis of the radical-chain mechanism of oxidative polymerisation in the presence of inhibitors leads to an equation for the variation of the concentration of polyperoxides (P):

$$\frac{d[P]}{dt} = \nu W_i + \varphi[P], \qquad (14)$$

where $\nu = K_p[M]/\mu K_X[X]$ is the length of the kinetic chain in the presence of the inhibitor, $\varphi = K_3(\nu\alpha - 1)$ the self-acceleration factor, and α the efficiency of the inhibition by polyperoxides.

The condition $\varphi = 0$ is attained at the critical inhibitor concentration $[X]_{cr}$ determined by the rates of chain propagation and decomposition of the polymeric peroxides and also by the occurrence of secondary reactions (for example, the regeneration of the inhibitor):

$$[X]_{cr} = \alpha K_p[M]/\mu K_X. \qquad (15)$$

For $[X] \leqslant [X]_{cr}$, the inhibitor is consumed fairly rapidly inducing only very short induction periods. For $[X] > [X]_{cr}$, the inhibitor concentration diminishes slowly, which leads to a sharp increase in the induction period. The abruptness with which the dependence of τ on [X] passes through $[X]_{cr}$ is determined by the ratio of the rates of initiation and decomposition of polyperoxides (K_i/K_d).

Equations have been obtained[103] for the induction period and for the rate of oxidative polymerisation in the presence of an antioxidant and the lower and upper limits to the inhibitor concentration, the critical rate of initiation, and the critical monomer concentration were established. At inhibitor concentrations below the lower limit, the antioxidant hardly influences the kinetics of the oxidative polymerisation and can be regarded as an inert admixture. Under these conditions, the concept of the induction period is valid only for a reaction taking place in a closed system, while its duration is determined solely by the concentration of oxygen and the rate of its consumption. At inhibitor concentrations greater than the upper limit, the antioxidant acts as an oxidant in relation to the monomer and the polymerisation inhibitor and the concept of the induction period is valid for both closed and open systems. A system passes from the non-inhibited oxidative polymerisation regime to the inhibited reaction regime precisely in the region between the lower and upper limits of the antioxidant concentration.

Extremely interesting phenomena have been observed in the study of the oxidative polymerisation of styrene inhibited by 2,6-di-t-butylphenols.[104,105] The polymerisation kinetics have in these instances a stepwise character, being accompanied by primary (τ_1) and secondary (τ_i) induction periods. The observed kinetics are associated with the period of formation of a secondary inhibitor X^2, whose concentration oscillates as a function of time, i.e. with an auto-oscillatory regime. Since the studies were performed in a closed system, the oscillations in the concentration of the secondary inhibitor are caused, according to the authors, by the involvement of the intermediates in the reaction and are non-decaying in the observed time interval. During the secondary induction periods, the rate of polymerisation decreases sharply with increase in the antioxidant concentration. According to the expression for the induction period in polymerisation in the presence of oxygen,[106,107]

$$\tau = \frac{\mu K_X [O_2]_0 [X]_0}{(K_p [M] + K_X [X]_0) W_i}$$

the latter should be absent at the end of the primary induction period. The role of oxygen in the formation of X^2 should then be indirect and should be shown by the products of the oxidative reaction of phenols. In a general form, the proposed mechanism of the auto-oscillatory regime in the inhibition of the radical polymerisation of styrene includes three main reactions leading to the formation of the secondary products Y and the intermediate Q and to the regeneration of the inhibitor X^2:

$$RO_2^{\cdot} + X^1 \rightarrow Y,$$
$$R + Y \rightarrow Q \rightarrow \text{inactive product},$$
$$Q + X^1 \rightarrow X^2.$$

An attempt has been made[108] to model mathematically the auto-oscillatory polymerisation in the presence of phenols. The main postulate was the idea that polymerisation is then an unbranched radical-chain process (this is in fact achieved at the end of the primary induction period).

2. Inhibition of the Polymerisation of Acrylates and Methacrylates in the Presence of Sulphuric Acid

Sulphuric acid is one of the main components in the synthesis of acrylic and methacrylic monomers. The problem of the inhibition of polymerisation in the presence of sulphuric acid is of particular current interest since the acid is capable of intensifying the formation of polymers and can deactivate many of the known stabilisers.

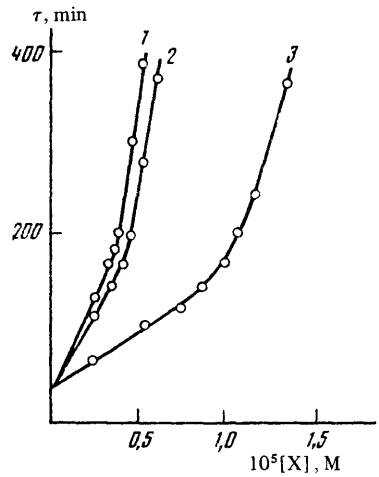

Figure 4. Dependence of the induction period in the polymerisation of methyl acrylate in air in the presence of 5 vol.% of H_2SO_4 on the concentrations of inhibitors at 75 °C: (1) S-1; (2) S-41; (3) HN.[51]

In order to understand the mechanism of inhibition in the presence of sulphuric acid, it is essential to know the specific features of the influence of the acid itself on the elementary polymerisation stages. In the study of the influence of sulphuric acid on the photopolymerisation of methyl methacrylate under oxygen-free conditions,[109–111] the formation of a complex between the acid and the monomer was observed. The increase in the rate and in the degree of polymerisation was explained by the increase in the reactivity of the monomer (or the macroradical) and also by the increase in the macroscopic viscosity and the change in the conformation and in the effective rigidity of the growing chains. The influence of sulphuric acid on the kinetics and mechanism of the polymerisation of acrylic monomers has been investigated[112] at elevated temperatures in the presence of oxygen. The introduction of sulphuric acid decreases sharply the induction period induced by the inhibiting effect of oxygen, and increases the rate of polymerisation. The dependence of the rate and of the induction period on the sulphuric acid concentration has a fairly complex character involving an extremum. The data obtained indicate the formation of complexes between the monomer and acid having different quantitative compositions. The formation of the complex accelerates the decomposition of the peroxide as a result of its protonation by the acid with subsequent homolysis of the -O—O- bond, analogously to the mechanism of the induced decomposition of hydroperoxides in the presence of certain acids.[113]

The compounds listed in Table 1 inhibit effectively the polymerisation of acrylic monomers also in the presence of sulphuric acid.[51,114] With increase in its content in solution, the induction period is sharply reduced, which is associated both with the increase in the rate of initiation and with the interaction of the inhibitor with the acid, lowering its efficiency. In contrast to polymerisation in bulk, where critical phenomena were manifested at fairly high temperatures, in polymerisation in the presence of sulphuric acid they are observed also at relatively low temperatures (Figs.4 and 5).

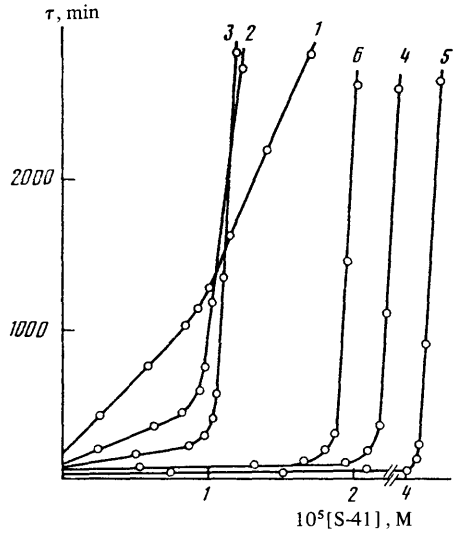

Figure 5. Dependence of the induction period in the polymerisation of methyl methacrylate in air on the S-41 concentration at 60 °C and different initial sulphuric acid concentrations (Vol.%): (1) 2; (2) 5; (3) 10; (4) 20; (5) 30; (6) 41.[51]

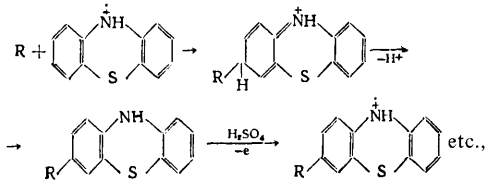
Table 2. The critical concentrations of inhibitors in the polymerisation of acrylates and methacrylates in the presence of sulphuric acid.[51]

Inhibitor	$10^5[X]_{cr}$, M, 100 °C	
	methyl acrylate (5 vol.% H_2SO_4)	methyl methacrylate (30 vol.% H_2SO_4)
S-1	0.7	0.8
S-41	0.9	1.3
S-47	—	1.3
S-49	—	1.1
HN	3.0	2.0
HQ	90.0	8.0



Eqns.(14) and (15) are likewise applicable to the inhibited polymerisation of acrylates and methacrylates in the presence of sulphuric acid. Since the latter accelerates the decomposition of polyperoxides, the observed effects are manifested more strikingly under these conditions. This justifies the view that the critical concentration of the inhibitor can be regarded in such cases as the main parameter characterising the efficiency of the inhibitor. Table 2 presents the values of $[X]_{cr}$ for certain new polymerisation inhibitors and compares them with hydroquinone.

The critical inhibitor concentration, the abruptness with which the dependence of τ on [X] passes through it, and the stoichiometric inhibition coefficient depend on the concentration of the acid in the system. The decrease in μ with increasing concentration of the acid is possible when, as a result of the interaction with it, the substances S-1, S-41, etc. are converted into compounds which either do not inhibit polymerisation or are characterised by a much lower value of μ. A dynamic equilibrium is established between both forms of the substance and an increase in the content of sulphuric acid shifts it towards the less effective inhibitor, which in fact reduces the stoichiometric coefficient.

The EPR spectra of the systems investigated do indeed indicate the interaction of the unpaired electron with the nitrogen and hydrogen atoms, as a result of which the amine (X) is converted into a radical-cation:[51]

$$2X + 3H_2SO_4 \leftarrow 2X^{\dot{+}} + 2HSO_4^- + H_2O + H_2SO_3.$$

Such a reaction had been proposed earlier in a study[115] where an intensification of the inhibiting effect of phenothiazine was observed in the presence of sulphuric acid. The increase in μ was explained by the following inhibition mechanism:

The dependence of the efficiency of the inhibiting effect of the phenothiazine–sulphuric acid system on the acid concentration at a constant phenothiazine concentration passes through an extremum. According to the authors, this is associated with the dual function of sulphuric acid, in the presence of a high concentration of which in the system the initiating effect begins to predominate over the inhibiting effect.

The magnitude of the EPR signal and hence the amount of the radical-cation also vary with the composition of the reaction medium. In sulphuric acid and also in the presence of its excess, the EPR signal is smaller than, for example, in a methyl methacrylate–sulphuric acid solution.

As shown previously,[86] phenols and aromatic amines are used as a rule as antioxidants. On the other hand, in the presence of sulphuric acid the conversion of aromatic amines into stable radical-cations imparts to them the ability to inhibit polymerisation also in the absence of oxygen. At the end of the induction period, polymerisation under oxygen-free conditions proceeds at a steady-state rate, diminishing with increase in the initial inhibitor concentration. This is associated with the retardation of the reaction by the products of the interaction of the active radicals with the amine radical-cations. The kinetic data obtained are consistent with Eqn.(15), which is indicated by the linearity of the relation between $(1-\varphi^2)/\varphi$ and the inhibitor concentration (Fig.6).

The dependence of the steady-state rate of polymerisation on the inhibitor concentration in the presence of atmospheric oxygen has a completely different character. The rate initially increases, but,

having reached a maximum at $[X]_{cr}$, it begins to fall. An increase in the concentration of sulphuric acid in the solution intensifies these effects. The increase in the rate of the process is due to the accumulation of inhibition products—hydroperoxides, the rate of decomposition of which increases in its turn with increasing concentration of the acid. This in fact promotes a more striking manifestation of the extremum in the relation between W and [X] at high acid concentrations. The decrease in the steady-state rate is caused by the consumption of the polymerisation-initiating peroxides and hydroperoxides during the induction period, whose duration increases sharply in the region of $[X]_{cr}$.

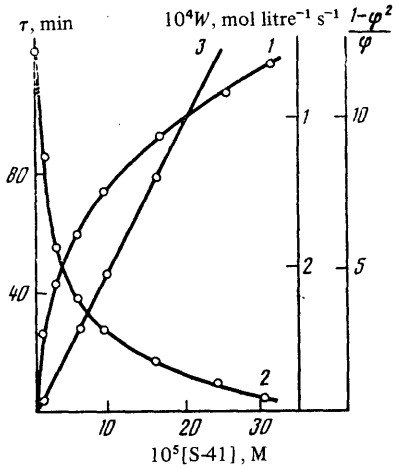


Figure 6. Dependence of the induction period (curve *1*), the steady-state rate of polymerisation of methyl methacrylate (curve *2*), and the ratio $(1-\varphi^2)/\varphi$ (curve *3*) on the concentration of S-41 under oxygen-free conditions and in the presence of 20 vol.% of H_2SO_4; 60 °C; [ABIN] = 2×10^{-4} M.[51]

If initiating products are formed in the inhibition reactions, then this is reflected in the form of the dependence of the induction period on the inhibitor concentration. Indeed, at fairly high concentrations of sulphuric acid, the above dependence deviates from linearity for $[X] < [X]_{cr}$. With increase in the inhibitor concentration, the induction period increases to an increasingly smaller extent and rises sharply only when $[X]_{cr}$ is attained.

V. CHARACTERISTIC FEATURES OF THE INHIBITION OF BULK AND HETEROPHASE POLYMERISATION

The study of inhibition in viscous media makes it possible to simplify greatly the kinetic schemes and to determine in many instances the reactivities of weakly reactive compounds in radical reactions.[17] The principal effect distorting the kinetic picture in polymerisation at relatively high conversions is the gel-effect. In order to control this effect (in order to displace the instant of its appearance to the region of higher conversions or to suppress it completely), one can introduce a relatively ineffective inhibitor into the reaction medium.

In polymerisation in highly viscous media (at high conversions and in systems containing a polymer), quadratic chain termination becomes diffusion-controlled and the constant K_t decreases sharply. In such cases, termination even by a weak inhibitor may become rate-determining and it follows from the expression obtained for the reduced rate

$$\varphi = \frac{W_X}{W} = \frac{(K_t W_i)^{0.5}}{K_X [X]}$$

that the inhibiting effect increases with decrease in K_t and W_i (or with increase in the degree of reaction). Having taken into account the temperature dependence of K_t and K_X, we have

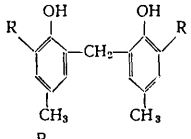
$$\varphi = A \exp[(E_X - 0.5E_o)/RT], \text{ where } A = \frac{A_t W_i^{0.5}}{A_X [X]}$$

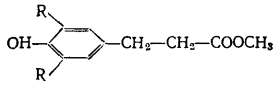
Usually $E_X > E_t$ and φ should diminish with increasing temperature, which reduces the gel-effect. Here one should bear in mind that the decrease in φ may be somewhat compensated by the decrease in the inhibition efficiency associated with the increase in K_t as a result of the decrease in the viscosity of the medium as the temperature rises. However, this is observed only when fairly inert products are formed as a result of inhibition.

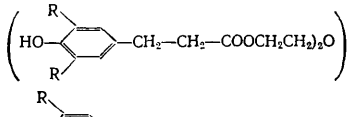
The decrease in the gel-effect and hence in all the consequences of a high degree of polymerisation can be achieved by introducing oxygen into the reaction system at a specified conversion. At the same time, the most effective inhibition of homopolymerisation at high conversions or under the conditions of a heterophase reaction is observed when oxygen and a weak inhibitor act simultaneously. Calculations for the corresponding radical-chain mechanisms lead in such cases to relations from which it follows that

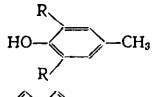
$$\varphi = W_{O_2}/W = 10^{-3} - 10^{-2},$$
$$\varphi = W_{O_2,X}/W_X = 10^{-6} - 10^{-5}.$$

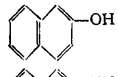
It is seen from a comparison of these data that oxygen increases the activity of the weak inhibitor. In the presence of oxygen, the intensification of the inhibiting effect of phenols, amines, and nitro-derivatives is associated not only with the formation of their oxidised forms (such as quinones, quinone imines, etc.) but also with the increase in the reactivity of these compounds in reactions with peroxy-radicals compared with the reactions with alkyl radicals.[116]

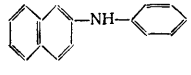












The use of weak inhibitors together with a monomer relatively inactive in relation to copolymerisation is of definite practical concentration interest. If the concentration and reactivity of one monomer are significantly lower than those of the other, then the efficiency of the weak inhibitor increases the degree of conversion more markedly than in the absence of the relatively inactive monomer.

The method of weak inhibition has been used to demonstrate the high activity of certain monomers in copolymerisation reactions.[117]

The characteristic features of the heterophase polymerisation are associated with the low mobility of the macroradicals in the solid phase and with the sharp retardation of the rate of their mutual termination. Under these conditions, the processes involving chain termination by the weak inhibitor may also be significant in the initial stages of the reaction. Therefore in certain cases heterophase polymerisation is a more convenient model for the study of weak inhibition reactions than extensive polymerisation. The efficiency of weak inhibitors in the class of aromatic amines, nitro-derivatives, and phenols increases sharply in the polymerisation of acrylonitrile in bulk compared with the reaction in solution in DMF.[118]

The same effect has been observed in the polymerisation of vinyl chloride and methacrylic acid in bulk and also of methyl methacrylate in the methanol–water precipitating mixture when acted upon by diphenylamine, *m*-dinitrobenzene, and other inhibitors.[119-121] The study of the heterophase polymerisation of various monomers in precipitating media made it possible to obtain data on the reactivites of a large number of inhibitors.[17]

Table 3. The apparent rate constants for the reactions of alkyl (K_X) and peroxy-radicals (K_{XO}) with inhibitors determined during tests (60 °C).[124,126,127]

Inhibitor	Structural formula	10^2K_X; $10^{-4}K_{XO}$, litre mol^{-1} s^{-1}
Hydroquinone		1.8; 21.4
α-Naphthol		1.6; 18.6
22-46		2.1; 39.8
Phenosane 1		0.7; 2.1
Phenosane 28		0.46; 1.7
Ionol		0.7; 2.2
β-Naphthol		0.8; 2.4
Neozone D		0.75; 6.7

Note: R = $C(CH_3)_3$.

The efficiency of weak inhibitors increases in polymerisation emulsion and depends both on their solubility in the chain propagation reaction zone, the topochemistry of the elementary steps, the rate of generation of free radicals, and the number of polymer-monomer species.[122,123]

A series of methods for testing weak radical polymerisation inhibitors, which are strong inhibitors of the oxidative polymerisation and degradation of polymers have been proposed in recent years.[124-127] One of the methods is based on the use of the model reaction involving the heterophase radical polymerisation of acrylonitrile. It is easy to show that the estimation of the apparent inhibition constant K_X in the reaction

$$R + X \rightarrow RH + \dot{X}$$

requires that the following criterion should be satisfied:

$$\frac{W_X}{W} = \frac{(K_i W_i)^{0.5}}{K_X [X]} = \varphi \ll 1.$$

Comparison of data on the inhibition of the polymerisation of acrylonitrile and the inhibition of the oxidative polymerisation and oxidation of hydrocarbons reveal a correlation between the inhibition constants in polymerisation (K_X) and oxidation (K_{XO}) reactions for a series of substituted phenols (Table 3). The correlation makes it possible to predict the reactivities of antioxidants by testing them (in relation to alkyl radicals) with the aid of the model heterophase polymerisation reaction.

Methods for the Separation and Quantitative Determination of Nucleotides, Nucleosides, and Bases

S.N.Zagrebel'nyi, V.I.Pupkova, and Yu.L.Khripin

The results from the methods for the separation and quantitative determination of nucleotides, nucleosides, and bases† have been classified and discussed. Special consideration has been given to those methods used the most in the last decade—thin-layer chromatography and different types of high-performance liquid chromatography such as ion-exchange, reversed-phase and ion-pair methods, as well as spectrophotometric and titrimetric methods.
The bibliography includes 180 references.

CONTENTS

I. Introduction 1098
II. Thin-layer chromatography 1098
III. High-performance liquid chromatography 1100
IV. Other methods for determining the components of nucleic acids 1105

I. INTRODUCTION

At the present time the separation of the components of nucleic acids is mainly carried out using liquid chromatographic methods such as thin-layer chromatography (TLC) and high-performance liquid chromatography (HPLC); and the number of published studies using these techniques accounts for more than 80% of all the methods used for this purpose.[1,2]

The separation and quantitative determination of components of nucleic acids are very important in different fields of biochemical research and medicine. Components of nucleic acids are to be found in physiological liquids, cells, and tissues.

The presence of these components, their metabolites, as well as modified bases, nucleosides, and nucleotides is used to assess the catabolism of nucleic acids, their fermentative breakdown, and different functional and oncological diseases. No less important is the determination of trace components in commercial preparations of nucleosides and nucleotides. Their use in molecular biology for the synthesis of genetic structures as well as in enzymology as substrates imposes strict requirements for the chromatographic homogeneity of the preparations. Nucleotide analysis is necessary for confirmation of the structure and determination of the quality of chemically synthesised oligonucleotides. A new area in which the analysis of components of nucleic acids is being used is the food industry. Recently, a method for the analysis (using HPLC) of purines and pyrimidines in milk to determine its quality has been posed.[3]

All this indicates that the choice of method and conditions for separation and quantitative determination of the components of nucleic acids are of vital importance at the present time.

In this review we have classified those studies we consider the most interesting during the last ten years on methods for separating bases, nucleosides, and nucleotides such as TLC and HPLC, have indicated the conditions that permit their separation in complex mixtures, focussed attention on their quantitative determination, especially using TLC, and have briefly discussed other analytical methods. The length of this review does not permit a discussion on the problems connected with the preparation of samples for analysis, but they have been reported in detail in two reviews[4,5] and in the literature cited.

II. THIN-LAYER CHROMATOGRAPHY

During the last ten years TLC has become a highly effective analytical method that has been successfully used to solve many problems in different branches of biochemistry, bioorganic chemistry, and molecular biology. The use of modern instruments for quantitative detection and elution, batching systems together with an improved plate quality and development of high-performance thin-layer chromatography (HPTLC) and continuous thin-layer chromatography (CTLC) methods have converted TLC from a qualitative to a quantitative method and have placed it on the same level as HPLC.[6-13]

At the present time TLC has gained universal recognition as a result of the speed of conducting analyses, the relative simplicity of the equipment, its economy and versatility; and with the development of HPTLC, which has considerable advantages over conventional TLC, it has become highly efficient, rapid, sensitive, and reproducible.[14-16] These advantages are achieved with the use of a thin layer of sorbent (silica gel) with uniform particle diameter of about 5 μm, and with new methods for feeding the eluent, the use of special U-chambers for chromatography, an improved method of applying samples, and the use of efficient systems for processing data. The standard deviation of the results in the determination of nanogram quantities of a compound using this method does not exceed 1.5–2.3%. With all these advantages of HPTLC it is possible to separate up to 20 compounds simultaneously over a period of a few minutes and to detect femtogram quantities (10^{-15} g) of compounds.[17]

During the last 5–7 years a new method, CTLC, has been developed, combining the analytical possibilities of TLC and column liquid chromatography.[18] In CTLC the solvent is fed continuously to a thin layer of sorbent with sample previously applied. During separation of the compounds the solvent and compound being

† Referred to as components of nucleic acids in the text.

analysed are continuously removed from the chromatographic system, and at the same time a continuous detection method is carried out. With repeated use of the same plate, constant conditions for separation, complete saturation in the CTLC separation chambers, and a uniform soaking of the sorbent layer it is possible to obtain results with a reproducibility that is better than traditional TLC almost by a factor of 10. Using the continuous method it is possible to separate complex mixtures of compounds (which are separated with difficulty or not separated at all by other methods), and it is a versatile liquid chromatographic method with a very extensive potential for analysis.

A new stage has appeared in the development of TLC—the extensive use of instrumental methods for the quantitative determination of results of separation on a thin layer of adsorbent as well as automation of the whole chromatographic process have started.[17-21] Quantitative analysis in TLC is composed of several stages: introduction of the sample, separation of the components on a thin layer of sorbent, and quantitative determination of the results of analysis. After separation of the compounds on the plate they can be extracted by one of the following methods: removal of the compounds together with the adsorbent layer followed by their extraction; direct extraction from the adsorbent layer bonded to a support with elution by the pumping of an appropriate solvent system through it; extraction of the compounds by addition to the adsorbent layer of a porous material into which they pass together with the solvent; and direct transfer of the compounds being analysed into the detection systems. The methods for quantitative determination of separated compounds can be subdivided into direct and indirect ones. The first group contains all methods that involve the extraction of compounds prior to their quantitative determination. The different methods for analysing extracts and the ranges of detectable quantities of the compounds are shown in Table 1.[22]

Table 1. Methods for the quantitative determination of compounds after their extraction from thin layers of adsorbent.[22]

Quantities determined	1–100 mg	10–100 mg	10–100 ng
Methods of determination	gravimetry, titration, polarimetry	spectrometry, (UV, IR, NMR), mass spectrometry, isotopic methods, GLC refractometry	fluorescence, phosphorescence, biological methods

Extraction of the compounds being analysed together with removal of the adsorbent is carried out manually or by means of automated systems. The adsorbent zone is removed by suction into a suitable tank, from which the compound to be analysed is extracted. For the determination of microquantities of compounds, the adsorbent that is withdrawn into a microtube with solvent is separated by centrifuging or filtration through suitable filters, after which the eluate can be used directly for detection. The volume of eluate usually amounts to 50 – 100 μl and the degree of extraction to more than 90%.[23]

Direct extraction of the compounds being analysed from the adsorbent layer is carried out by preserving the integrity of the layer in the zone itself. The simplest version of this method is one which involves cutting of chromatograms on a flexible support into strips, which are placed in vessels with a solvent to extract the compounds being analysed.[24] A more complete solution to this method consists of the construction of an airtight apparatus and pumping suitable solvent systems through the strips around the zone containing the compound to be analysed. The eluate is then passed to a detection system. The total quantity of solvent passed through varies from 1 to 2 ml and the standard deviation of the results of analysis vary from 0.2 to 1.3% depending on the quantity of compound being analysed.[25] The use of this method is limited by the need for efficient separation of the compounds being analysed.

Simple methods for the direct elution of the separated compounds into microvolumes of solvent (40 – 100 μl) involve the pumping of a solvent through the adsorbent layer containing compound, injecting it on to strips with adsorbent bonded to filter paper, and preliminary concentration followed by elution.[26,27]

When the latter version is used the standard deviation of the results amounts to 0.005 – 0.01 μg.[27] The compounds extracted are detected using spectrophotometric, fluorometric, or radiochemical methods.

The direct quantitative determination of compounds on a chromatogram can be carried out by measuring the area of a spot or its colour intensity. However, this type of determination is associated with significant errors and is only suitable for reference measurements. More accurate methods require the use of special instruments. All the methods of this group are based on the principle of photometry, densitometry being used most frequently followed by spectrophotometric, fluorometric, and radiochemical methods, which have high sensitivity and made identification and quantitative determination possible for a large number of different compounds.[28-32] A comparison of optical methods for the quantitative determination of results from the separation of mixtures is presented in Table 2.[22] Other instrumental methods for the quantitative determination of the results have similar features to the optical methods.

Table 2. Comparison of optical methods for the quantitative determination of results.[22]

Method	Standard deviation, %	Required quantity of compound, μg	Time of analysis, min
Visual comparison	10—30	1—10	0.1
Extraction from layer followed by optical determination	2—5	10—100	20
Optical scanning based on measurements of:			
absorption of radiation	1.5—2.5	0.1—10	2
fluorescence	1—2	10^{-4}—10^{-1}	2

At the present time special equipment used for optical scanning in TLC is still not easy to obtain, as a result of which its widespread application in the laboratory has been somewhat restricted. The most widely used methods of optical scanning have certain limitations—they have insufficiently high chemical selectivity and a restricted area of application. There is a linear dependence of the signal on the content of compound in the zone over a narrow region

of measurement. For this reason the use of these methods for determining impurities at levels of less than 1–2% in preparations of nucleic acid components is virtually impossible.

In optical scanning the nature of sample application, the volume applied, separation, the shape of the spot, and the flow length are decisive factors in obtaining quantitative results. In order to reduce the detection limits, measurements should be made in a transmission system and not a reflection system. With strict adherence to specific conditions the standard deviation of the results of analysis is 1%.

In this connection it is demonstrated that TLC under pressure is a promising method for separating multicomponent mixtures of compounds with similar properties by quantitative scanning.

Radiochemical methods of detection in TLC are characterised by high sensitivity and good reproducibility. Radiochromatograms are evaluated by different methods—directly on the adsorbent layer as well as after extraction of the compound from the layer or by preliminary removal of sections of adsorbent together with the compound being separated. The removal of adsorbent for the analysis of radioactive compounds is carried out using mechanised and automated equipment. The equipment is based on the mechanical scraping off of sorbent and its transfer to the extraction chamber, where desorption of the compounds being determined takes place. The eluate passes through a filter system to collectors and for measurement. The equipment is suitable for the simultaneous analysis of several samples. This method can be used for chromatograms on which the zones of compounds are separated from each other by 2–6 mm.

The detection limit using a radiochemical method is $10^{-7}-10^{-4}$ Ci and depends on the energy of the elementary particles formed by decay of nuclei, the conditions of chromatographic analysis, and the features of the detection system. The standard deviation of the results is 1%. When the samples are analysed there is a linear relationship between the quantity of compound being analysed and the signal of the detection system over a wide range of measurements.[17]

The choice of stationary phase in TLC is decisive in achieving the required selectivity in the separation of mixtures to be analysed. The necessity for highly efficient chromatographic separation presents specific requirements for the choice of adsorbent. Cellulose modified with polyethyleneimine and silica gel have been widely used for the separation of complex mixtures of nucleic acid components. The use of plates with a sorbent layer applied in advance leads to a considerable simplification in the TLC method. Commercial plates provide a better reproducibility of results than with plates prepared in the laboratory because of the high degree of uniformity in composition and thickness of the sorbent. Several firms produce silica gel and polyethyleneimine (PEI)-cellulose plates that are suitable for separation of the components of nucleic acids.[33] The most convenient material as a support is aluminium foil, which can be bent, cut, and made into plates of the required shape. The efficiency of separation depends on the grain size, specific surface area, pore size, and moisture content.[12]

Good separation of compounds occurs on PEI-cellulose when the content of PEI is 0.5–1% and with low pH values of the eluent.[34] The mobility of each product is determined by the magnitude of negative charge, which depends on the pH of the eluent. Boric acid systems are used to separate deoxyribo- and ribo- derivatives. Borate complexes of ribonucleotides have an additional negative charge and have lower mobility than deoxyribo- derivatives. Multistep or gradient elution with salt solutions of varying concentration is used to separate compounds according to the number of their phosphate groups.[35–39] The separation of uncharged compounds—purine and pyrimidine bases and nucleosides—is carried out on unmodified cellulose or silica gel.

Silica gel is used to separate different mixtures of components of nucleic acids. The selection of suitable solvent systems permits separation with respect to both the type of nitrogenous base and the type of carbon residue.[40–44] Good separation of complex mixtures containing 5′- and 5′-poly-phosphates of purine nucleosides occurs with the use of systems containing ammonia as a strong base, which prevents the formation of hydrogen bonds between the amino groups of the compounds being analysed and silica gel. For the separation of nucleoside 5′-polyphosphates, acidic systems containing isobutyric acid are the most suitable; for nucleosides the most suitable are "reversed-phase" systems having a high concentration of salts such as $(NH_4)_2SO_4$ and NaCl.

For the separation of components of nucleic acids silica gel has been successfully used in recent years in HPTLC, which is characterised by highly efficient separation and a low detection limit for compounds. With the use of adsorbents such as aminopropylated silica gel, which has anion-exchange properties, and silica gel modified with hydrocarbon radicals, a number of studies have been carried out on the separation of components of nucleic acids.[45–53]

The best results on the separation of complex mixtures of nucleic acid components that differ according to the type of nitrogenous base, hydrocarbon residue, and number of phosphate groups have been obtained using two-dimensional chromatography and mainly on PEI-cellulose.[54–57] Some data on the separation of different mixtures of components of nucleic acids are presented in Table 3.

III. HIGH-PERFORMANCE LIQUID CHROMATOGRAPHY

The progress made using HPLC is due to its high resolving power, mild conditions for separation, and efficient design of apparatus. The use of high-pressure chromatographs with high-sensitivity detectors, new types of sorbent, and also the design of spectrophotometers that permit ultramicroanalysis to be carried out have contributed towards providing HPLC with a lead over all other methods in its use for the separation of components of nucleic acids and has made it possible to separate effectively microgram and nanogram quantities of compounds in a short time.[61–68]

A general tendency in HPLC is the change-over to the use of chemically modified silica gels as sorbents with particle diameter of 5–10 μm and even 3μm. Detection is carried out using fluorescence, UV-photometric, electrochemical, or atomic emission detectors,[68–77] while identification of the components can be carried out using a combination of HPLC and mass spectrometry.[78–80]

For the separation of components of nucleic acids, those forms of HPLC such as ion-exchange chromatography, reversed-phase chromatography and ion-pair reversed-phase chromatography are used almost exclusively. Adsorption ("direct-phase") HPLC is used at the present time only in isolated cases.[81]

1. Ion-exchange High-performance Liquid Chromatography

Ion-exchange chromatography (IEC) is a traditional method for separating the components of nucleic acids.[34,65,82] In ion-exchange chromatography, separation of the compounds is based on the difference in charges on their molecules; hydrophobic interactions also play a definite part. At the present time a large number of different ion exchangers for HPLC are produced. Generally, these

Table 3. Separation of the components of nucleic acids by thin layer chromatography.

Components separated	Adsorbent	Solvent systems	Note	Refs.
Bases, deoxyribonucleotides deoxyribonucleosides	silufol (Kavalier, Czechoslovakia)	dioxan–isopropanol–2 M ammonia–1 M ammonium acetate (3:2:4.7:0.3); dioxan–isopropanol–5 M ammonia–1 M ammonium acetate (3:1.8:4.9:0.3)	–	[44]
Bases, deoxyribonucleosides	silufol (Kavalier, Czechoslovakia)	dioxan–ammonia (7:3); isopropanol–ammonia (8:2); dioxan–isopropanol–ammonia (4:4:2)	radiochemical detection	[44]
	RP-silica gel C_{12} (Kodak, USA)	1.5 mM TBA + 5% methanol; 0.4 M ammonium phosphate, pH 3.5; 0.1 M ammonium acetate, pH 6.9 + 5% acetonitrile		[51]
Ribonucleotides	NH_2-silufol	1 M acetic acid–ethanol (10:1), pH 3.2	–	[52]
Bases, ribo- and deoxyribo-nucleosides and nucleotides	silica gel GF-254 (HPTLC), (Merck, FRG); PEI-cellulose (Merck, FRG)	Chloroform–methanol–acetic acid (3:2:1); chloroform–methanol–water (81:15:4)	nucleotides remain at start	[58]
		Chloroform–methanol–acetic acid (3:2:1) in 0.1 M boric acid		[58]
Ribo- and deoxyribo-nucleotides	PEI-cellulose (Merck, FRG)	0.25 M acetic acid (9 cm), 0.8 M formic acid (4 cm)–direction 1; 0.22 M Tris-HCl, pH 8.0, in methanol (10 min), methanol (10 min)–direction 2	two-dimensional chromatography	[59]
Ribonucleotides	PEI-cellulose (Merck, FRG)	direction 1–0.2 M LiCl (2 min), 1 M LiCl (6 min) 1.6 M LiCl (75 min); 0.5 M sodium formate, pH 3.4 (0.5 min) 2 M sodium formate, pH 3.4 (2 min), 4 M sodium formate, pH 3.4 (60 min)–direction 2	two-dimensional chromatography	[59]
Ribonucleoside 5′-mono-, 5′-di-, and 5′-tri-phosphates	silufol (Kavalier, Czechoslovakia)	dioxan–isopropanol–water–ammonia (4:2:4:1); dioxan–water–ammonia (6:4:1)	radiochemical detector	[43]
		dioxan–isopropanol–ammonia–1 M ammonium acetate (3:2:4.7:0.3)		[44]
	NH_2-silica gel (HPTLC), (Merck, FRG)	0.2 M NaCl in a mixture of: methanol–water (3:7); 0.2 M NaCl mixed with methanol, ethanol, and chloroform		[47]
Deoxynucleoside 5′-mono-5′-di- and 5′-tri-phosphates	NH_2-silufol	1 M acetic acid–ethanol (10:1), pH 6.5	radiochemical detector; two-dimensional chromatography	[52]
	NH_2-silufol	1 M acetic acid–ethanol (10:1), pH 6.5		
Ribo- and deoxyribo-nucleoside 5′-triphosphates	PEI-cellulose (Merck, FRG)	direction 1—1 M LiCl with 5% boric acid, pH 7.0, washing with methanol, 2 M sodium formate (pH 3.4)–1.6 M LiCl (1:1) at 4 °C; 0.85 M potassium phosphate, pH 3.4—direction 2	"	[60]
Ribo- and deoxyribo-nucleosides	cellulose (Merck, FRG)	0.2 M; 2 M; saturated solution of $(NH_4)_2SO_4$	"	[35]

are either modified copolymers of styrene with divinylbenzene containing a relatively high proportion of the latter or supports based on microporous silica gels.[83] Anion exchangers usually contain quaternary ammonium groups (Partisil-10 SAX, Ultrasil-10 AX, Lichrosorb AN, etc.), less often they contain tertiary amino groups (Nucleogen DEAE). Quite often aminopropylated silica gel (APS-Hypersil, Lichrosorb-NH_2) is used as an anion exchanger. The advantage of ion exchangers based on silica gel is the highly effective separation and short analysis time achieved by high rates of mass exchange, although the stability of these sorbents is not high and the operating pH range for the mobile phase is from 2 to 7.5.[59–63,83–85] Cation exchangers most frequently contain alkylsulphonate groups (Partisil-10 SCX, Ultrasil-10 CX). In recent years ion-exchange derivatives of rigid hydrophilic resins such as Spherone, TSK-Gel-PW,[84] and others have been used quite frequently.

Anion-exchange chromatography is widely used for the analysis of nucleotides, in particular, nucleoside polyphosphates.[86–97] Gradient elution is more frequently used. Although this permits separation of more than 20 compounds over a short period of time, much time is spent in regenerating the column after analysis. Moreover, the salt concentration gradient leads to a drift in the base line of the UV detector. The drift can be compensated by the addition of a calculated quantity of acetone to the initial buffer or by partial replacement of phosphate by chloride, inclusion of which in the mobile phase can, however, lead to corrosion of the chromatographic equipment.[98–100]

An isocratic system of separation does not impose such high requirements of purity for the reagents being used and gives better reproducibility of results than with gradient elution. A disadvantage of isocratic chromatography is the appreciable width of peaks with large K' values for retention of the chromatographic zone, which reduces the sensitivity and accuracy of analysis.[101,102]

The order of elution of nucleotides during anion-exchange HPLC is not always easy to interpret. Perhaps the only rule that has no exceptions is the order of elution of nucleoside polyphosphates: NMP, NDP, NTP.‡ It is a more complex problem with isomeric nucleoside monophosphates and with the separation of ribo- and deoxyribo-nucleotides. Thus, Nguyen and co-authors[102] observed the following orders of elution (column with Partisil-10 SAX sorbent, 3% MeOH in 0.08 M phosphate buffer as eluent, pH 4.15):

1) CMP, UMP, AMP, GMP
2) dCMP, TMP, dAMP, dGMP
3) 2′-UMP, 2′-AMP, 2′-CMP, 2′-GMP,
4) 3′-UMP, 3′-CMP, 3′-AMP, 3′-GMP
5) dCMP, CMP, 3′-CMP, 2′-CMP
6) UMP, 2′-UMP, 3′-UMP
7) AMP, dAMP, 3′-dAMP, 2′-AMP, 3′-AMP
8) 3′-dGMP, GMP, dGMP, 3′-GMP, 2′GMP.

‡ Abbreviations for the components of nucleic acids are given in accordance with the IUPAC–IUB recommendations (Molekulyar. Biolog., 1972, **6**(1), 167–171).

As can be seen, the pattern is very complex. It is clear that hydrophobic interactions do not play a conclusive role. Although adenine is protonated to a considerable degree at pH 4.15, adenine nucleotides are eluted after UMP and TMP. At lower pH values, however, AMP "overtakes" UMP, but the order of UMP and GMP is retained.

Bases and nucleosides are separated on anion exchangers as a result of hydrophobic interactions. Non-ionic interactions with the support are partly suppressed by an increase in temperature and the addition of organic solvents to the mobile phase.[103,104] With an isocratic system it is possible to separate bases, nucleosides, and nucleotides simultaneously.

Recently, the need to speed up and simplify analyses and also the necessity for analysing very complex samples containing bases, nucleosides, and their mono- and poly-phosphates as well as UDPG, NAD, NADP, and related compounds have led to a certain decline in interest in anion-exchange chromatography and have stimulated research in the field of ion-pair RPC (see below). Combined chromatographic systems that consist of two anion-exchange and reversed-phase columns are also capable of separating such mixtures effectively, but the method of analysis in this case is considerably more complex.[105,106]

As regards cation-exchange chromatography, this method has been used traditionally for the analysis of bases. Taking into account the fact that at low pH values the charge of bases differs by no more than one, separation can readily be carried out in an isocratic system. Examples of the separation of components of nucleic acids are given in Table 4.

2. Reversed-Phase Chromatography

Chromatography in which the eluent is more polar than the stationary phase is known as reversed-phase. Usually the stationary phase is in the form of a silylalkyl ether, while aqueous buffer solutions and/or their mixtures with polar organic solvents are used as the mobile phase.[108] The widespread use of RPC is due to a whole number of advantages:[108,109] a) compounds of very diverse classes can be separated, and compounds that have marked differences in polarity and structure can be separated in one chromatographic cycle (for example, a mixture of nucleosides and their phosphates); b) the method has high efficiency and selectivity; c) the columns are rapidly regenerated; d) the method can be used to analyse very dilute samples with a large volume; e) the supports are commercially available.

The following disadvantages of the RPC method should be mentioned:[108] a) the stationary phases are only stable over the pH range 2–7.5; b) interaction of the molecules being separated with the stationary phase has a composite mechanism because of the presence of residual silanol groups (Si–OH) on the surface of the stationary phase; c) the retention mechanism of compounds in RPC has been insufficiently studied. Evidently these shortcomings are not fundamental problems and it is nearly always possible to select the optimum combination of stationary and mobile phases for the resolution of any given task.

Microporous silica gels with chemically bonded hydrocarbon groups, most frequently n-octadecyl (C_{18} or ODS) or n-octyl groups (C_8), are used in RPC as stationary phases.[109] In order to obtain them, silica gels are usually treated with alkylsilyl halides. However, because of steric hindrance, up to 30% of the silanol groups present on the surface of the silica gel remain unmodified; a limited portion of them can be removed by repeated treatment, with trimethylsilylating agents, and by "capping".[109–111] The properties of the stationary phases depend on the type of grafted ligand, the concentration of alkyl and available silanol groups on the surface, the characteristics of the initial silica gel, the specific surface area, the specific pore volume, etc.[110–120]

In one review[108] there is a list of more than 70 supports, which were being produced by over 50 firms. It may be assumed that by now the number of supports being produced has increased even further.

Table 4. Examples of the separation of components of nucleic acids by ion-exchange HPLC.

Sample No.	Type of sample	Support*; column dimensions, mm	Composition of mobile phase and type of elution	Order of elution of sample components	Complete analysis time, min	Refs.
1	synthetic mixture	TSK gel K-anion-BW (9 μm); 0.19×450	80 μM $(NH_4)HPO_4$, pH 7.15	Cyd < Urd < Cyt < Ura < Guo < Ado < Gua < Ade < CMP < UMP < 2′-CMP < 3-CMP < 2′UMP < 3′-UMP < GMP < AMP < 2′-GMP < 2-AMP < 3′-GMP < 3′-AMP	60	[87]
2	synthetic mixture	Partisil 10-SAX (10 μm); 4.6×250	Gradient up to 0.3 M KH_2PO_4 and 0.3 M KCl, pH 3.3 → 4.9	CMP < AMP < UMP < IMP < GMP < UDP < CDP < ITP < CTP < ATP < GTP < NADH < NADPH < UDPG	~40	[94]
3	cellular extracts	APS-Hypersil (5 μm); 5.0×100	Gradient up to 0.5 M KH_2PO_4 and 0.8 M KCl, pH 2.9	XMP < CMP < AMP < NAD^+ < TMP < IMP < GMP < CDP < UDPG < ADP < dADP < TDP < GDP < CTP < ATP < dATP < GTP	~15	[95]
4	rat liver extract	Lichrosorb-NH_2 (5 μm); 4.6×150	0.1 M K_2HPO_4, 0.1 M NH_4Cl, 20% MeCN, pH 6.5	AMP < GMP < $NADP^+$ < ADP NADPH < GDP < ATP < GTP	20–25	[106]
5	DNA hydrolysates from fibroblast cultures	Ultrasil-10CX (10 μm); 4.6×250	0.02 M $(NH_4)H_2PO_4$, pH 2.3	Thy < Gua < Cyt < Ade < m^5Cyt	~15	[107]

* Particle diameter given in brackets.

The lack of information on their method of synthesis and properties produces a certain difficulty in operating with commercial supports. It is therefore not surprising that a comparative study of the chromatographic properties of commercial supports has been the subject of a large number of studies, the results of which can be reduced to the following principles:[121-129]

1. In the RPC of nonpolar compounds the selectivity of separation does not depend very much on the type of support and the efficiency also does not vary significantly.

2. The separation of compounds containing polar groups is affected not only by the type of support but also by the difference in batches of supports of a single type. In this case asymmetry and/or broadening of the chromatographic peaks often occur, which is usually due to the presence of available silanols on the surface and its contamination with heavy metals.

3. Supports with a high content of residual silanols (Nucleosil-C_8, Partisil-ODS2, Partisil-ODS3) have inferior stability in aqueous salt mobile phases compared to capped supports (Nucleosil-C_{18}, Partisil-CDS_3, CCS-C_8, Ultrasil-ODS, and others) because of the more rapid dissolving of the silica gel matrix and the possible irreversible adsorption of different compounds.

Reversed-phase chromatography is a most important and widely used method for separating the components of nucleic acids that is based on the high selectivity of nonpolar supports with respect to heterocyclic bases.[130-140] In studies on the effect of RPC parameters on the separation of components of nucleic acids it was found that the content of the organic solvent in the mobile phase does not alter the selectivity of separation but only affects the retention; the pH and ionic strength can affect the selectivity of separation.[129-131]

Bases and nucleosides can be separated using RPC with low concentrations of organic solvents. In order to suppress nonspecific interactions a buffer (usually phosphate, pH 4–6) is added in low concentration (10–50 mM) to the eluent. As can be seen from Table 5, bases are eluted first, then the corresponding nucleosides, and finally deoxynucleosides, with purines usually being retained to a greater extent than pyrimidines. In solving frequent problems the analytical method can be simplified by varying the composition of the mobile phase. Thus, Fraser and Pearson[141] carried out the separation of a mixture at pH 2.5. In this case dU and T were effectively separated, while dA, dG, and dC, which were not of interest to the authors, were hardly retained at all on a reversed-phase column.

Clinical samples and also hydrolysates of tRNA can contain up to 20 minor nucleosides, so analysis of such complex samples requires the use of gradient elution (Nos.1–3, Table 5). The problems associated with the analysis of minor nucleosides in the clinic have been examined in detail in two reviews[4,5] and in one study[133] where the authors succeeded in separating and determining quantitatively more than 20 nucleosides in samples of physiological origin. Elution was carried out in a multistage MeOH gradient and the analysis time amounted to over 100 min. For the analysis of a less complex sample the same authors used isocratic elution; the analysis time was reduced by a factor of nearly 15. Examples of the separation of bases and nucleosides are given in Table 5.

The presence of a negatively charged phosphate group makes nucleotide molecules more hydrophilic than molecules of nucleosides and bases, so that nucleotides are retained to a lesser degree on reversed-phase columns. Mobile phases without organic solvents are used for the separation of nucleotides; the pH is most frequently about 4–5, which suppresses the ionisation of a second phosphate group, and the concentration of buffer is increased considerably in comparison to the RPC of nucleosides.

An increase in the ionic strength of the mobile phase leads to an increase in retention time of nucleotides to acceptable values during RPC (this effect has been studied in detail[97,129,130]), while at the same time because of the increase in inherent UV absorption of the mobile phase the sensitivity of the detector is reduced.

Nucleoside polyphosphate molecules are even more hydrophilic. The order of elution for polyphosphates (NTP < NDP < NMP) in RPC is the reverse of that in anion-exchange chromatography.

When the simultaneous separation of nucleotides and nucleosides in the mobile phase is required, methanol must be added and gradient elution carried out.[147-150]

Examples of the separation of nucleotides are given in Table 6.

Table 5. Examples of the separation of bases and nucleosides by reversed-phase HPLC.

Sample No.	Type of sample	Support; column dimensions, mm	Composition of mobile phase and type of elution	Order of elution of sample components	Complete analysis time, min	Refs.
1	clinical analyses	Ultrasphera-ODS (5 μm); 4.6 × 150	MeOH gradient, 10 mM KH_2PO_4, pH 4.9	Hx < dCyd < Ado < Ino < dGuo < Thd < Ade < dAdo	25	[142]
2	clinical analyses	Hypersil-ODS (3 μm); 4.6 × 50 + 4.6 × 150	MeOH gradient, phosphate buffer, pH 6.0	Cyt < Ura < Cyd < Hx < Xan < Urd < Ade < Ino <	~20	[143]
3	tRNA hydrolysates or tissue extracts	μ-Bondapak C_{18} (10 μm); 4.0 × 300	MeOH gradient, phosphate buffer, pH 5.1 (36 °C)	Guo < dUrd < dCyd < Thd < Ado < dAdo Cyd < Urd < m^1Ado < m^5Cyd < m^7Guo—about 15 nucleosides in all	35-40	[144]
4	DNA and RNA hydrolysates	Supelcosil C_{18}-DB (5 μm); 4.6 × 150	8% MeOH in 0.05 M KH_2PO_4, pH 4.0	Cyd < dUrd < dUrd < m^5dCyd < Ino < Guo < dIno < dGuo < dThd < Ado < dAdo	7	[145]
5	human placental extract	Micropak CH-10 (10 μm); 4.0 × 300	MeOH gradient, phosphate buffer, pH 6.5	Xam < Hx < NAD^+ < Ino < Ado < Ade	~20	[146]

3. Ion-Pair Reversed-Phase Chromatography

Ion-pair (IP) reversed-phase chromatography (RPC) is a form of RPC used to separate compounds that dissociate in aqueous organic solvents. Compounds containing lipophilic groups capable of forming ion pairs with ions of the opposite charge from the components of the sample being analysed are added to the mobile phase; the compounds are sodium dodecylsulphate, quaternary ammonium bases or zwitterions.[152–154]

As has already been stated, nucleotides, in particular nucleoside polyphosphates, are only weakly retained on reversed-phase sorbents because of their low hydrophobic capacity. There are two methods of increasing the retention of ionised molecules during RPC. Firstly, chromatography can be conducted with that pH of eluent at which the acid (or basic) dissociation of the molecules of compound being separated is insignificant. This method, often called "ion suppression",[155] in relation to nucleotides is to a certain extent used in those studies that were discussed in the previous section. Secondly, nucleotides are suitable candidates for IP RPC; in this case an increase in retention of the ions is achieved by introduction of hydrophobic ions of the opposite charge into the mobile phase.

A number of studies[155-157] have been devoted to studying the mechanism of IP RPC. We can list here the main conclusions of these investigations:

1. The presence of hydrophobic ions in the mobile phase strengthens the adsorption of ions of the opposite charge. The more hydrophobic the ion, the greater is the increase in K' for the counter-ion. Consequently, the effect occurs at lower concentrtions for a more hydrophobic ion. Thus, addition of 2.5 mM TBA to the mobile phase increases K' for the nucleotides to a greater extent than addition of 5 mM TEA or 20 mM TMA.[158]

2. The dependence of K' on the concentration of hydrophobic counter-ion for ionic components of a mixture most frequently follows a bell-shaped curve; nucleotides are no exception to this rule.[159] The position of the K' maxima varies somewhat for different compounds under the same conditions. As a rule, the concentration of ion-pair agent is selected in the region of K' maxima of the components of the mixture being separated.

3. The presence of hydrophobic ions in the mobile phase slightly reduces the retention of nonionic compounds; for example, addition of TBA to the eluent reduces the K' values of nucleosides.[159]

4. As in conventional RPC, an increase in the concentration of organic solvent decreases the retention time of both ionic and nonionic components in IP RPC.

5. An increase in the concentration of salts reduces the retention time of ionic components in IP RPC.

6. The relationship between retention times and pH in IP RPC is the reverse of that with ion suppression; the retention time is longer if the eluate molecules are ionised and capable of forming an ion air. Thus, at pH 3.0 addition of TBA increases K' for TMP and UMP and has no effect on K' for CMP and AMP, which at pH 3.0 are zwitterions; at pH 5.7 TBA increases K' for all nucleotides.[160–162]

We should mention that the actual mechanism of IP RPC has not so far been established. Hypothetical "ion-pair", "dynamic ion-exchange", and "ionic-interaction" mechanisms have been discussed in one review.[155]

Some examples of the analysis of components of nucleic acids using IP RPC are given in Table 7. We have restricted ourselves here to five examples but the number of studies on the IP RPC of nucleotides is very considerable.[152,163–169]

The order of elution of nucleoside polyphosphates is the same as that in anion-exchange chromatography. It is interesting to note that in 2.5 mM TBA the order of elution of mononucleotides also corresponds to the order of elution in anion-exchange chromatography at low pH. In 20 mM TMA, UMP is eluted after CMP, as in normal RPC.

In all of the examples in Table 7 apart from No.4, an isocratic system of elution was used, although in some cases nucleoside polyphosphates with considerable different molecular charges were separated, in other cases nucleotides and nucleosides were separated. On the whole, gradient elution is used less often in IP RPC than in ion-exchange chromatography or in RPC for mixtures of nucleosides and nucleotides, which is a definite advantage.

As was mentioned above, for the analysis of very complex samples either quite elaborate systems combining IEC and RPC are used or IP RPC is used, and this is illustrated by example No.4 in Table 7.

Table 7. Examples of the separation of components of nucleic acids by IP RPC.

Sample No.	Type of sample	Support; column dimensions, mm	Composition of mobile phase and type of elution	Order of elution of sample components	Complete analysis time, min	Refs.
1	Various tissue extracts	Lichrosorb RP-8 (RP-18); 4,0×250	0.3% TBA; 0.65 KH_2PO_4, pH 5.8; 240 ml MeCN, water up to 1100 ml	AMP < ADP < GTP < UTP < ATP	~10	[155]
2	Various tissue extracts	Ultrasphere ODS (5 μm); 4,6×250	2,5 мМ TBA; 12% MeCN pH 2,5 (HCOOH)	CMP < AMP < GMP < UMP < IMP < XMP	~30	[158]
3	Hydrolysates of chemically synthesised oligonucleotides	Partisil-5C_8; 5 (μm) 4,6×250	2.0 мМ TBP; 0.005 М KH_2PO_4, pH 4,9; 7% MeOH	dCyd < dCMP < dGuo < Thd < dGMP < TMP < dAdo < dAMP <	~60	[159]
4	Various mixtures	Servachrom ODS-S: 100; 4,6×250	5.0 mM TBA; phosphate buffer, pH 6.0; gradient up to 10% MeCN	Cyd < Urd < CMP < Guo < UMP < GMP < Ado < CDP < AMP < UDP < GDP < CTP < ADP < UTP < GTP < ATP	~60	[170]
5	DNA hydrolysate	Ultrasphere-C_8 (5 μm); —	10 mM hexanesulphonate; 5% MeCN; 10 mM phosphate buffer, pH 2.9	Ura < Hx < Guo < Cyt < m^5Cyt < Ade	10	[171]

Although the separation in example No.4 is not so impressive as in two studies,[105,106] it was obtained in a considerably simpler system, and it may be assumed that separation of a 16-component mixture is within the limits of IP RPC, especially when gradient elution is used.

Finally, nucleic bases can also be separated at low pH values under conditions of IP RPC by introduction of suitable components to the mobile phase (see, examples No.5, Table 7 and No.5, Table 4).

Thus, ion-pair chromatography is the most promising method of HPLC for the analysis of nucleotides or their mixtures with nucleosides.

IV. OTHER METHODS FOR DETERMINING THE COMPONENTS OF NUCLEIC ACIDS

In the last 8–10 years there has been a development of methods for potentiometric titration of components of nucleic acids based on the acid-base properties of purine and pyrimidine bases, methods based on the selective oxidation of the *cis*-1,2-glycol group of the ribose part of ribonucleosides and their phosphates, and methods based on colour reactions of purine bases and the carbon part of the nucleosides.

For the separate analysis of multicomponent mixtures of nucleic acid components, differential alkalimetric or acidimetric titration in the medium of organic solvents is used without requiring preliminary separation of the different purine and pyrimidine derivatives.[172-174]

Potentiometric titration methods are specific and accurate. The disadvantages in using them relate to the large consumption of samples (20–200 mg) and the impossibility of determining impurities that constitute less than 10%.

In order to make a selective determination of ribonucleosides and their phosphates, methods for the oxidation of the *cis*-1,2-glycol group with periodate are used with subsequent titrimetric or colorimetric analysis of the iodate formed by oxidation of the compounds being analysed.[175-176]

The colour reactions used to determine the components of nucleic acids are based on the following properties: adenine is diazotised to give azo compounds with α-naphthylamine; guanine is reacted with Folin's reagent; purine nucleotides form coloured ribose compounds with orcein and deoxyribose compounds with diphenylamine.[177-180]

Methods for oxidation of the *cis*-1,2-glycol group in ribose and the colour reactions which are used to determine the components of nucleic acids are selective and sensitive and are used for the analysis of a specific class of compounds, but they are not suitable for the differentiated determination of nucleic acid components within this class.

Modern Ideas About the Mechanisms of Homogeneous and Heterogeneous Acid Catalysis: Similarities and Differences

V.B.Kazanskii

The modern ideas about the nature of the protonated states in aqueous solutions in non-polar solvents and on the surfaces of heterogeneous oxide catalysts of the acid type are examined. It is concluded that in heterogeneous systems mechanisms analogous to the mechanism of homogeneous acid catalysis in aqueous solutions operate only in catalytic reactions of polar molecules. Owing to the absence of solvation effects, the catalytic reactions of hydrocarbons take place, contrary to the widely held view, via intermediate covalent and not ionic structures. On the other hand, the properties of carbenium ions are characteristic of transition states, which in many instances also possess features resembling those of adsorbed carbenes of surface ylides. The role of synchronous or concerted mechanisms in heterogeneous acid catalysis is discussed.
The bibliography includes 108 references.

I. INTRODUCTION

The phenomenon of acid catalysis consists in the acceleration of chemical reactions in the presence of liquid (homogeneous acid catalysis) or solid (heterogeneous acid catalysis) acids. Individual examples of acid catalysis were known very long ago, as early as the end of the XVIIIth century. They include, for example, the esterification of alcohols, the hydration of olefins, etc.

Heterogeneous acid catalysis, with the aid of which the majority of the reactions in petrochemistry and petroleum processing (cracking and skeletal isomerisation of paraffins and olefins, the migration of the double bond in olefins, their oligomerisation, the alkylation of aromatic compounds, etc.) are nowadays carried out, has found the widest practical applications. The explanation is that heterogeneous acid catalytic reactions can be carried out over a wide temperature range, up to 700–800 K, which naturally extends the range of thermodynamically feasible catalytic reactions. Furthermore, heterogeneous catalysis is more susceptible to technological formulation, since it is easier to achieve on its basis continuous chemical manufacturing processes in which there is no stage involving the separation of the catalyst from the initial reactants and the final products.

The examples of the practical use of homogeneous acid catalysis are much more modest. Perhaps the most important of these is the alkylation, on a large industrial scale, of isoparaffins by olefins, and the hydration of ethylene in the presence of sulphuric acid. Despite

this, the ideas about the mechanisms of acid catalysis were formulated as early as the late 1920's precisely for homogeneous catalysis. We shall therefore begin the consideration of the mechanism of acid catalytic reactions with homogeneous catalysis.

II. HOMOGENEOUS ACID CATALYSIS

1. Catalysis in Aqueous Solutions. The Brønsted Relation

The theory of homogeneous acid catalysis in aqueous solutions, formulated in 1924 by Brønsted,[1,2] is based on the idea of the intermediate protolytic interaction of the reactants with the undissociated acid molecules (general acid catalysis) or with hydroxonium ions (specific acid catalysis). It is suggested that this entails the transfer of a proton to the substrate molecule with formation of positively charged protonated forms which exhibit an increased reactivity:

$$\begin{aligned} &AH + B \rightarrow BH^+ + A^- \text{ (general acid catalysis),} \\ &H_3O^+ + B \rightarrow BH^+ + H_2O \text{ (specific acid catalysis).} \end{aligned} \quad (1)$$

Their secondary reactions followed by decomposition lead to the regeneration of the catalyst and the formation of the final product. Here it is postulated that the protonated intermediate species have specific chemical properties which determine the selectivity of the acid catalysis. For example, it has come to be assumed that the acid-catalytic reactions of hydrocarbons are based on chemical reactions of the carbenium ions formed on proton transfer. On the other hand, the intermediate formation by secondary reactions of alkoxonium ions, etc. is characteristic of the reactions of alcohols.

If it is assumed, after Brønsted, that the proton transfer stage is rate-limiting, then the familiar correlation, which has come to be known as the Brønsted relation, should hold between the rate constants for the acid-catalytic reactions and the strength of the acids used as catalysts:

$$k = aK^{\alpha}, \quad 0 < \alpha < 1 \quad (2a)$$

or in the logarithmic form

$$\lg k = \alpha \lg K + C. \quad (2b)$$

These equations follow from the analogy between the proton transfer to water molecules, which is characterised by the acid dissociation constant K, and the proton transfer to the substrate molecules.

Eqns.(2) have been tested by Brønsted and his school for various acid-catalytic reactions, for example, for the decomposition of diazocompounds, the hydrolysis of esters, the enolisation of ketones, etc.[5] It was shown, within the limits of chemically similar groups of substances and acids, that the corresponding linear correlations do indeed hold between the logarithms of the equilibrium constants and the reaction rates, the proportionality coefficients C and α varying somewhat on passing from one group of substances to another. On the other hand, when the acid strength is varied within very wide limits, appreciable deviations from Eqns.(2) are usually observed. It must also be emphasised that Brønsted's reasoning is not sufficiently rigorous, because the analogy between the proton transfer to water molecules and the corresponding transfer to substrate molecules actually leads to a linear relation between the logarithms of the corresponding equilibrium constants, and not between the equilibrium acid dissociation constants themselves, and the rate constant for the proton transfer to a substrate molecule. In other words, Eqns.(2) presuppose the existence of a linear relation between the equilibrium constants and the rate of formation of the protonated form of the substrate.

Frequent attempts have been made to justify theoretically the existence of such a relation. Among them, the familiar model of intersecting unperturbed potential curves for the protonated states of the acid and substrate, proposed by Horiuti and Polanyi, merits most attention, its development having led subsequently to the creation of the theory of absolute reaction rates.[3,4] This model is not, however, confirmed by modern spectroscopic data, from which it follows that, for a sufficiently strong interaction beween an acid and a base, the form of the potential energy curve for proton vibrations is significantly perturbed (see Section III, subsection 4). Thus the Brønsted equation must be regarded as an empirical relation applicable to fairly narrow groups of substances and reactions rather than a rigorously theoretically justified relation.

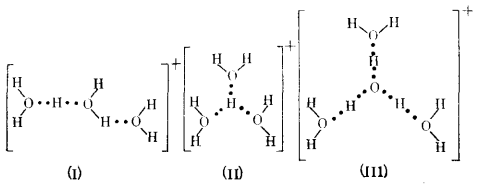
2. Modern Ideas about the State of the Proton in Aqueous Solution

It is generally accepted that electrolytic dissociation in aqueous solutions is possible only as a result of solvation effects. Its contribution to the overall process energetics is decisive. For example, the heterolytic dissociation of the water molecule in the gas phase into the H^+ and OH^- ions is associated with an enormous energy expenditure, which is approximately 17 eV (1630 kJ mol^{-1}). However, in the liquid phase this energy is almost completely compensated by the sum of the hydration energies of the proton and the hydroxide ion. The endothermicity of the heterolytic dissociation of liquid water is therefore characterised by only 0.6 eV (or 60 kJ mol^{-1}), while the dissociation constant of this reaction is 1.8×10^{-16} g-ion litre^{-1}.

We shall consider the make up of the heat of hydration of the proton in liquid water. The affinity of the proton for the first water molecule is 7.4 eV ($\sim$710 kJ mol^{-1}). When the second and subsequent water molecules are added, the solvation energy decreases monotonically in the following sequence (the corresponding heats of hydration are given in brackets):

$$\begin{aligned} &H_3O^+ + H_2O \rightarrow H_5O_2^+ \quad (134 \text{ kJ mol}^{-1}), \\ &H_5O_2^+ + H_2O \rightarrow H_7O_3^+ \quad (96 \text{ kJ mol}^{-1}), \\ &H_7O_3^+ + H_2O \rightarrow H_9O_4^+ \quad (72 \text{ kJ mol}^{-1}), \\ &H_9O_4^+ + nH_2O \rightarrow H_9O_4^+ \cdot nH_2O \quad (79 \text{ kJ mol}^{-1}). \end{aligned} \quad (3)$$

Thus the overall proton hydration energy is 1100 kJ mol^{-1}. On the other hand, the heat of hydration of the hydroxide ion is smaller by approximately a factor of 2 and amounts to $\sim$500 kJ mol^{-1}.[5]



The exceptionally fine energy balance between the electrolytic dissociation processes in liquid water must be specially emphasised. The corresponding heat change represents the difference between two very large quantities—the energy of the heterolytic dissociation of the OH bond and the sum of the heats of solvation of the proton and the acid residues formed in this process. Although each of these quantities is approximately 1600 kJ mol^{-1}, the dissociation process is almost thermally neutral overall. Therefore, even very

slight changes in the energy of the abstraction of a proton from the acid molecule or in the heat of hydration of the proton in the acid residue have a marked influence on the character of the electrolytic dissociation. We shall return to this question below in the discussion of proton transfer to molecules with different basic properties in heterogeneous systems.

The main information about the real structure and geometry of the different hydrated forms of the proton in liquid water has been obtained from IR spectroscopic data, on the basis of quantum-chemical calculations, and with the aid of the results of other physicochemical measurements. Such information reduces to the following findings.[5]

The simplest stable state of the hydrated proton in liquid water is the hydroxonium ion H_3O^+ and the symmetrical very slightly polarised ion $O_2H_5^+$.[6-8] Regardless of the nature of the initial acid, it is characterised by a continuous absorption in the IR in the range $1000-3500$ cm^{-1}. In this structure the proton is not localised in the vicinity of one of the oxygen atoms but oscillates between them; this agrees with the estimated average lifetime of the H_3O^+ ion in liquid water (2×10^{-13} s).[5] For a theoretical interpretation of the continuous absorption, two approaches have been suggested: in one of them account is taken of the inter-relation between the proton transitions and the phonon spectrum of the medium,[9] while in the other account is taken of the inter-relation between the proton transitions and the vibrations of the hydrogen bond.[10,11] In both cases, a satisfactory agreement with experiment is achieved.

Of the two versions of the addition of yet another water molecule to the $O_2H_5^+$ ion that which leads to the linear structure (I) is preferred, because the structure (II), which has C_{3v} symmetry and the trigonal configuration, is less stable owing to the strong electrostatic repulsion between the negatively charged oxygen atoms.

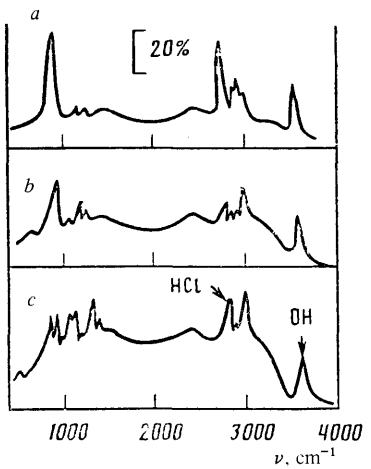
(I) (II) (III)

The linear structure (I) is also very slightly polarised, because even the smallest distortion of the geometry leads to the localisation of a proton on the right- or left-hand side of the chain of water molecules.

As can be seen from Eqns.(3), further hydration of the $O_3H_7^+$ ion also produces a considerable energy gain, which agrees with the finding that the most stable structure and therefore the structure which predominates in aqueous solutions is the symmetrical trigonal $O_4H_9^+$ (III). It can be assumed that the proton in the structure (II) oscillates continuously between two neighbouring oxygen atoms, i.e. it forms part of the composition of the continuously migrating simplest species $O_2H_5^+$. The ease of its formation and decomposition in the oscillations of the water molecules linked by hydrogen bond network does explain the high mobility of the proton in aqueous solutions. In other words, the familiar Grotthus relay mechanism of proton migration in liquid water is a consequence of the high polarisability of the simplest solvated $O_2H_5^+$ fragments.

3. Proton Transfer in Non-aqueous Media

Certain details of the mechanism of proton transfer from acid molecules to solvent or substrate molecules can be more readily traced in non-aqueous solutions, since the IR spectra do not then show the broad lines due to the hydroxy-groups linked by the hydrogen bond network. This makes it possible to investigate the influence of the successive addition of several molecules on the protonation. Such measurements by IR spectroscopy have been carried out recently by ourselves for the interaction of HCl and HBr with the molecules of water, methyl, ethyl, and isopropyl alcohols, and diethyl ether in CCl_4, CH_2Cl_2, and nitromethane.[12,13] The dilute solutions used in these studies contained an acid ($0.02-0.2$ M) and the substrate ($0.01-0.5$ M).



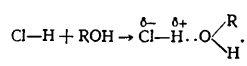


Figure 1. IR absorption spectra of the complexes of methyl alcohol (a), ethyl alcohol (b), and isopropyl alcohol (c) with HCl in CCl_4. Alcohol concentration 5×10^{-2} M; acid concentration 3×10^{-2} to 6×10^{-2} M.[12]

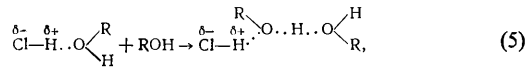
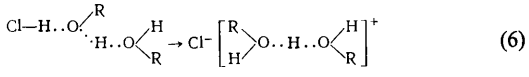
Fig.1 presents typical IR spectra of the complexes of HCl with methyl, ethyl, and isopropyl alcohols in CCl_4. Narrow lines due to the stretching vibrations of the H—Cl, C—H, and O—H bonds are observed against the background of the broad bands due to the HCl molecules perturbed by a hydrogen bond. In addition there is also a continuous absorption analogous to that observed previously for $O_2H_5^+$ ions in aqueous solutions,[6,7] i.e. the absorption induced by the oscillations of protons between two oxygen atoms. The measurements carried out for different ratios of the acid and alcohols showed that the intensity of the broad lines near 2400 cm^{-1}, due to the presence of HCl molecules perturbed by the hydrogen bond, increases linearly with increasing alcohol concentration. On the other hand, the narrow line associated with the free HCl molecules at 2820 cm^{-1} diminishes linearly. This result was explained by the



formation of 1 : 1 complexes between acid and alcohol molecules via a strong hydrogen bond:

(4)



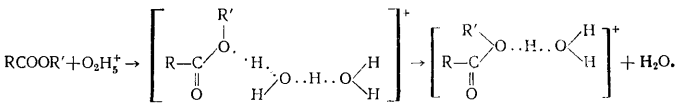
In contrast to this, the intensity of the continuous absorption, measured at 2000 cm^{-1}, increased in proportion to the square of the concentration of the alcohol or water molecules, which made it possible to attribute the composition HCl.2ROH to the alcohol complexes. Apparently, even in the case of a strong acid such as HCl, complete proton transfer occurs immediately to only two alcohol molecules. This entails the formation of complexes, resembling the $O_2H_5^+$ ions in aqueous solutions, in which the proton oscillates between two oxygen atoms. This in fact leads to the appearance of the analogous continuous absorption in the IR spectrum. On the other hand, the proton affinity of one alcohol molecule is sufficient only for the formation of complexes with a strong hydrogen bond.

The mechanism of proton transfer to two alcohol molecules may be analogous to the mechanism of the relay transfer in liquid water. Yet another hydrogen bond is formed initially with participation of a second alcohol molecule:

(5)

and this is followed by the vibrational excitation of such an associated species, which leads to complete proton transfer:

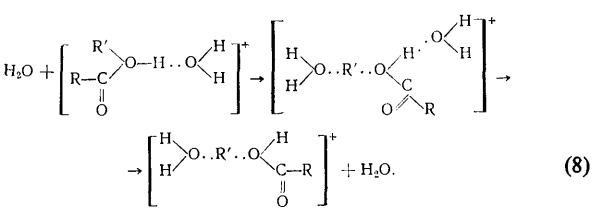
(6)



The proton is also apparently transferred via the same mechanism to two water molecules, while the interaction with one water molecule also results in the formation of a complex with only a moderately strong hydrogen bond. The HCl stretching vibration band then shifts from 2820 and 2500 cm^{-1}. We may also note that the shifts of the vibration frequency of the hydrogen bond-perturbed acid molecules in the 1 : 1 complexes and the intensity of the continuous absorption of the 1 : 2 complexes agree well with the substrate basicity series (H_2O < CH_3OH < C_2H_5OH < C_3H_7OH) and the acid strength series (HBr > HCl). In the case of aqueous solutions, the conclusion that a proton is transferred to two water molecules at once was reached also in relation to films of polyfluorosulphonic acid[6] and sulphuric acid solutions.[14,15]

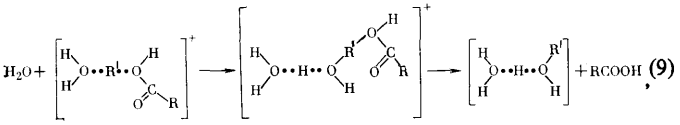
The proton transfer in non-polar solvents from a wide range of weak and strong acids to the molecule of a strong base (pyridine) has been investigated.[16] The protonated forms were detected only after the interaction with very strong acids (HNO_3, HCl, HBr, $HClO_4$). Weaker acids form only hydrogen-bonded complexes whose stability varies within wide limits. These data also evidently indicate only a weak tendency towards proton transfer only in non-polar solvents. The reduced tendency towards proton transfer and the absence of solvation effects have likewise been observed in the gas phase[17] and in inert gas matrices.[18]

4. Modern Ideas about the Mechanism of Homogeneous Acid Catalysis



The results described above indicate a decisive role for the interaction of the acid with several water or substrate molecules in the transfer of a proton to the latter. Therefore, in discussing the mechanism of homogeneous acid catalysis in aqueous solutions, it is evidently insufficient to consider only the interaction of the reacting molecules with hydroxonium ions or with undissociated acid molecules alone and account must be taken also of the possibility of the formation of more complex solvated complexes including several water molecules. This conclusion agrees with the results obtained in a study of the kinetics of the hydrolysis of esters in aqueous solutions of strong acids:[14,15] it was shown that the activated complex involves the $O_2H_5^+$ ion and not the hydroxonium ion H_3O^+. We shall consider the possible mechanism of this reaction in greater detail.

It appears likely that its first stage is proton transfer from the $O_2H_5^+$ ion to the ester molecule, which is analogous to the proton transfer via a chain of hydrogen-bonded water molecules:



(7)

The positively charged ion of the protonated ester is then solvated by yet another water molecule, which results in the localisation of the positive charge on the R′ fragment:

(8)

The decomposition of this complex (also with participation of a water molecule) then leads to the formation of an acid and the protonated alcohol, which loses its proton as a result of yet another reaction involving a water molecule:

(9)

(10)

Thus water participates in all the intermediate stages of the catalytic reaction. Its driving force is the high polarisability of the complexes incorporating a solvated proton, which are readily formed and decomposed under the influence of the vibrations of the solvent molecules surrounding them. This entails a "switchover", as it were, from the dissociating bonds to the newly formed bonds induced by the proton migration along the hydrogen-bonded chain of molecules.

This mechanism differs from that considered in the literature,[14,15] but we believe that it agrees better with modern data concerning the state of the hydrated proton in aqueous solutions and concerning the mechanism of proton transfer in liquid water. It also confirms the idea of "bond redistribution chains" developed for enzyme catalysis[19,20] and the mechanisms of proton transfer in biological systems discussed in a number of studies.[21–23]

III. HETEROGENEOUS ACID CATALYSIS

The ideas about the mechanisms of heteogeneous-catalytic reactions of hydrocarbons were formulated much later than for the the homogeneous acid catalysis—not until the end of the 1940's and the beginning of the 1950's. At that time, a number of workers put forward independently the hypothesis of the carbenium ion mechanism of the reactions in question[24–28] based on purely chemical analogies with low-temperature reactions of hydrocarbons in the presence of strong acids (the higher reactivity of olefins compared with paraffins, the high reactivity of compounds with a tertiary carbon atom, the selective formation of isoparaffins under the catalytic conditions, the occurrence of olefin isomerisation, hydrogen transfer, and hydrogen isotope exchange reactions, etc.).

The next important step was the experimental demonstration of the acidity of amorphous aluminosilicates and certain other oxide catalysts based on the use of the absorption of ammonia and Hammett indicators.[29,30] These studies led to the widespread adoption of the idea that adsorbed carbenium ions exist on the surfaces of oxide catalysts and that they play a decisive role in the mechanisms of the catalytic reactions of hydrocarbons, although this hypothesis was never in fact subsequently confirmed by direct spectroscopic methods.

Multistage schemes, analogous to those for general acid catalysis in solutions, are usually postulated for the mechanisms of heterogeneous-catalytic reactions of hydrocarbons.[31–34] For example, for the catalytic reactions of olefins, it is suggested that the adsorbed molecules are initially linked by strong hydrogen bonds to the acid hydroxyls. Complete proton transfer then takes place with formation of adsorbed carbenium ions. It is also assumed that such protonated intermediate forms exhibit an enhanced specific reactivity, which explains the selectivity of the corresponding heterogeneous-catalytic reactions. For example, the reverse abstraction of a proton from them leads to the migration of the double bond in the olefin molecules. Linear carbenium ions can isomerise to branched ions, which induces the skeletal isomerisation of the hydrocarbons. The occurrence of cracking, etc. is explained by the splitting off of carbenium ions from olefin molecules. In particular, the fairly typical mechanism of the heterogeneous-catalytic reactions of but-1-ene can be represented as follows in accordance with these ideas:

$$\begin{aligned} &CH_2{=}CH{-}CH_2{-}CH_3 + H^+ \rightarrow CH_3{-}\overset{+}{C}H{-}CH_2{-}CH_3 \rightarrow \\ &\rightarrow CH_3{-}CH{=}CH{-}CH_3 + H^+ \text{ (migration of the double bond)}, \\ &\rightarrow CH_3{-}\overset{CH_3}{\overset{|}{\underset{+}{C}}}{-}CH_3 \rightarrow CH_2{=}\overset{CH_3}{\overset{|}{C}}{-}CH_3 + H^+ \text{ (skeletal isomerisation)}, \\ &\rightarrow CH_2{=}CH_2 + C_2H_5^+ \rightarrow 2C_2H_4 + H^+ \text{ (cracking)}. \end{aligned} \qquad (11)$$

Although such schemes have come to be widely adopted in the literature and they describe satisfactorily the composition of the products of heterogeneous-catalytic reactions of hydrocarbons, from our point of view they are no longer consistent with the significance which is nowadays attributed to the concepts of the mechanism of catalytic reactions. Indeed, carbenium ions are not in fact free but are adsorbed on the catalyst surfaces. Therefore, depending on the strength of the acid centres or on the nature of the basic centres to which the carbenium ions are bound during adsorption, their chemical properties can vary within extremely wide limits. For example, it is known that the migration of the double bond in olefins takes place on weaker acid centres than their skeletal isomerisation.[34] This difference is not, however, taken into account by Scheme (11). It also fails to reveal the driving forces of various elementary reactions on the adsorbed carbenium ions. Furthermore, these processes have come to be part of the order of the day by virtue of the results obtained in the study of proton transfer by modern spectroscopic methods and the results of quantum-chemical calculations. Their discussion is the main aim of the present article.

1. Spectroscopic Data on the Protic Acid Centres on the Surfaces of Oxide Catalysts

Among acid catalysts, amorphous and crystalline aluminosilicates (zeolites), alumina, aluminium phosphate, phosphoric acid on silica gel, etc. have come to be most widely used. Their active centres are acid hydroxy-groups, which are formed on the surfaces of the oxides on partial hydrolysis of the metal–oxygen bonds (the so called terminal OH groups) or when the protons compensate the excess local negative charge on the surface fragments (the so called structural OH groups). The number of these groups, determined from the intensity of the proton resonance spectra or by the method involving isotope exchange with molecular deuterium, usually corresponds to only a few per cent of the monolayer coverage. If such hydroxy-groups have fairly pronounced acid properties, then they do play the role of the active centres in heterogeneous acid catalysis.

Brønsted centres of both types have been studied in detail by IR spectroscopy[35,36] and NMR,[37,38] which made it possible to obtain detailed information about their geometry, the energy barriers to the rotation of the $M\diagup^{O}\diagdown H$ fragment, and certain other parameters characterising such centres. In particular, it has been demonstrated by IR spectroscopy that the number of different hydroxy-groups on the zinc oxide surface is three, while on the surface of nickel(II) oxide it is four. There are OH groups of five different types on the surface of alumina. The discrete character of the distribution of the hydroxy-groups is characteristic also of the hydrogen-forms of the zeolites.

A systematic treatment has been proposed[39,40] for the surface hydroxy-groups based on the hypothesis that the frequency of their stretching vibrations depends primarily on the coordination number of the oxygen atoms in relation to the surrounding cations. In other words, it was assumed that the nature of the OH bond is determined mainly by the character of the hybridisation of the orbitals of the oxygen atom. On the other hand, there exists the view that the stretching vibration frequency of the hydroxy-groups depends predominantly on the acid–base properties.[41] This is based on the fact that stretching vibration frequencies of 3839 and 2955 cm^{-1} are characteristic of the free OH^- ion and the OH^+ ion respectively.[42] Thus the lower-frequency hydroxy-groups have acid properties and the higher-frequency groups have basic properties.

However, the stretching vibration frequency of the hydroxy-groups can also be influenced by a number of other factors. It is therefore extremely desirable to measure not only the fundamental frequency

of the stretching vibrations of the OH bond but also other parameters characterising it.

This can be done with the aid of the diffuse scattering IR spectroscopy, the great possibilities of which have been demonstrated in a number of studies.[43-49] This method makes it possible to extend greatly the range of spectroscopic measurements, including the frequencies of the first and second overtones of the stretching vibrations of the surface OH groups, and to calculate from these data the energies of their homolytic dissociation and the parameters of the Morse functions ω_e and x for the OH bond. The results obtained indicate that the vibrations of the OH groups, which virtually do not interact with the vibrations of the oxide lattices, are highly characteristic. It was also found that the frequencies of the deformation vibrations of the surface hydroxy-groups contain most information as regards the nature and geometry of such groups. They are difficult to measure directly owing to the marked absorption of light by the oxide lattice in the range $800-1500$ cm^{-1}, but it is possible to obtain them as differences between the frequencies of the combination stretching-deformation vibrations and the frequencies of the stretching vibrations. The lowest deformation vibration frequency ($\sim 700-800$ cm^{-1}) is that of terminal OH groups. On passing to bridging hydroxy-groups, whose oxygen is linked to two cations of the oxide lattice, the deformation vibration frequency increases to $1000-1100$ cm^{-1}. This can be explained by the increase in the rigidity of the M⟨OH⟩M fragment when oxygen is coordinated to the second cation. For hydroxy-groups with a still higher oxygen coordination number, the combination stretching plus deformation vibrations frequencies are usually not observed at all, so that the number of bands in the fundamental region of their IR spectrum is greater than in the combination region. The results of these measurements make it possible to refine and test the conclusions concerning the nature and geometry of the surface hydroxy-groups reached from the analysis of the fundamental stretching vibrations frequencies alone.

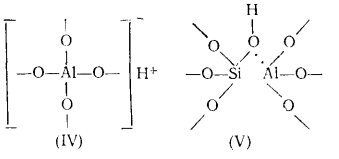
IR spectroscopy is used widely also in quantitative measurements of the acid strength of the surface hydroxy-groups. The bathochromic shifts of the stretching vibration frequencies, induced by the formation of hydrogen bonds with the molecules of different bases, are usually employed for this purpose. These shifts are linearly correlated both the with acidity of the OH groups and with the basicity of the molecules interacting with them:[50,51]

$$\Delta\nu_{OH}/\nu_{OH} = a - b\Delta pK_a, \qquad (12)$$

where $\Delta pK_a = pK_a^{ac} - pK_a^{bas}$, ν_{OH} and $\Delta\nu_{OH}$ are the stretching vibration frequency of the OH group and its shifts induced by interaction with the molecules of bases, pK_a^{ac} is the logarithm of the acid dissociation constant, and pK_a^{bas} the logarithms of the basicity constants of the corresponding bases.

Thus pK_a^{ac} for the OH surface groups on any one oxide can be determined from a series of shifts induced by the adsorption on it of several weak bases characterised by different pK_a^{bas} values. On the other hand, the frequency shifts, induced by the adsorption of the same base, for example, benzene or carbon monoxide, on the surfaces of different oxides, are usually measured to compare the acidities of their hydroxy-groups. Studies involving the use of IR spectroscopy of the acid–base properties of oxides have been surveyed in a review.[52]

2. Quantum-chemical Cluster Models of the Surface Hydroxy-groups and the Nature of Their Acidity



The nature of the acidity of the OH groups can also be analysed with the aid of quantum-chemical calculations performed using the so called "cluster" models.[53-58] The simplest model of an OH acid is the A–O–H molecule, where A is a hydrogen-like atom, whose ionisation potential can be varied within wide limits. If it is equal to 13.6 eV, as for the hydrogen atom, then a structure of this kind models the neutral water molecule. Lower ionisation potentials correspond to alkali metals, whereupon the hydroxy-groups are negatively charged and acquire basic properties. On the other hand, higher ionisation potentials correspond to ions with a high positive charge such as N^{5+}, P^{5+}, S^{6+}, etc. The electron density then shifts to the A atom, imparting acid properties to the hydroxy-groups.

These effects can be described more rigorously using clusters taking into account the real structure of the oxide surfaces. For example, in the case of terminal hydroxy-groups on the silica surface, one frequently considers the $Si(OH)_4$ or $SiOH(OA)_3$ clusters, where A are hydrogen-like atoms, as for the simplest clusters.

It follows from the foregoing that one of the causes of the formation of strongly acid terminal hydroxy-groups on the oxide surfaces is the polarising effect of neighbouring highly charged cations. Accordingly, the surfaces of partly hydrolysed alkali and alkaline earth metal oxides have basic properties, while the terminal groups on the TiO_2, V_2O_5, and MoO_3, or WO_3 surfaces have acid properties. The strength of the centres then increases with increasing positive charge on the cations. With the exception of WO_3, these oxides are not, however, used in heterogeneous acid catalysis because, at a high temperature in the presence of hydrocarbons or other reductants they readily pass to lower valence states.

Mixed oxides, among which crystalline skeletal aluminosilicates (zeolites) and amorphous aluminosilicates are most important, are much more significant for acid catalysis. They are characterised by the presence of structural bridging hydroxo-groups in which the coordination number of oxygen in relation to the cations is two.

The crystal lattice of aluminosilicates is constructed of oxygen tetrahedra at the centres of which are silicon or aluminium atoms. When it is described in terms of the ionic model, the aluminium-occupied tetrahedra carry a single excess negative charge, which is compensated by the charges of the adjoining cations or protons with which the Brønsted acidity of the aluminosilicates [structure (IV)] is in fact associated:

Within the framework of the covalent model (V), the acid centre may consist of a terminal silanol group, whose oxygen is linked by a coordinate bond to an adjoining aluminium atom (a Lewis acid centre). The combination of the Brønsted and Lewis acid centres shifts the electron density from oxygen to aluminium, diminishes the negative charge on the OH group, and enhances its acid properties.

In amorphous aluminosilicates, the number of such bridging acid groups is small and only a small proportion of the entire aluminium content corresponds to them. On the other hand, the vast majority

of the hydroxy-groups formed on hydrolysis of the surfaces are terminal OH groups with weakly acid properties.[36]

The situation is different in the hydrogen-forms of zeolites—aluminosilicates with a strictly regular crystal structure. Ideally the number of acid hydroxy-groups is in this instance identical with the number of aluminium atoms present in the lattice, i.e. it is many times greater than in amorphous aluminosilicates. This in fact explains the high catalytic activity of zeolites.[59,60]

Quantum-chemical cluster models of hydroxy-groups in zeolites have been developed,[61] and the calculations performed have shown that, with increase in the number of neighbouring aluminium atoms, the acidity of the hydroxy-groups diminishes monotonically; this can be inferred from the decrease in the positive charge on the proton and from the increase in the energy of its abstraction from the corresponding clusters. It has also been concluded that a characteristic feature of crystalline aluminosilicates with a definite silicon : aluminium ratio is the presence of hydroxy-groups with a constant number of nearest aluminium atoms. For example, in high-silica zeolites, the bridging hydroxy-groups are surrounded solely by silicon atoms. They are therefore characterised by identical Brønsted acid centres of identical strength.[62] With increase in the number of aluminium atoms in the crystal lattice, for example in the case of faujasites, hydroxy-groups having two or three neighbouring aluminium atoms appear and the character of the Brønsted acidity changes, which has in fact been confirmed experimentally.[34]

Thus quantum-chemical cluster models permit an atomic-molecular description of the structure of the acid centres in zeolites and explains satisfactorily the discrete character of the variation of the acidity in specimens with different aluminium contents in the lattice.[63,64] It is no less significant also that, with their aid, one can carry out fairly well-founded quantitative calculations of the intermediate structures in heterogeneous acid-catalytic reactions, which will be discussed below.

Analogous atomic-molecular models have also been used to treat systematically the hydroxy-groups on the surfaces of other oxides, for example, alumina.[41] There is no doubt that in the future this approach will permit a rational systematic treatment of the surface OH groups on oxides with a wide variety of different acid–base properties.

3. The Nature of the Protonated Intermediate States on the Surfaces of Oxide Catalysts

As already stated above, heterolytic dissociation in solution is possible only in the presence of solvation effects, whose contribution to the process energetics is decisive. Therefore proton transfer on the surfaces of heterogeneous oxide catalysts during high-temperature gas-phase reactions in the absence of polar solvents differs radically from the protonation in aqueous solutions.

Under the conditions of heterogeneous acid catalysis, the situation approaches more closely to the proton transfer in non-polar solvents discussed above where the solvation effects are minimal and the protonation of the substrate is associated with additional energy expenditure. For the majority of adsorbed molecules, the proton transfer is therefore significantly endothermic. It becomes energetically favourable in the interaction of very acid hydroxy-groups with strong bases such as ammonia, pyridine etc. These molecules are in fact usually employed as indicators for strongly acid surface OH groups. However, in this connection the fact has been overlooked that, even if adsorbed ammonium or pyridinium ions are actually formed from them on the surfaces of acid type catalysts, this by no means implies that analogous ionic intermediate compounds arise also in the adsorption of olefins or even paraffins, whose proton affinity is much smaller than those of ammonia or pyridine. In fact, in the interaction of hydrocarbons even with very strongly acid Brønsted centres, either complexes with a short hydrogen bond or highly polarised covalent structures are produced. Thus the intermediate active forms in heterogeneous acid catalysis differ significantly from the protonated ionic states in aqueous solutions and other polar sovlents and resemble more closely the complexes formed in the interaction of strong acids with weak bases or of weak acids with strong bases in non-polar solvents.

In this connection, it is appropriate to recall that the concept of carbonium ion mechanisms arose in organic chemistry exclusively on the basis of indirect kinetic and stereochemical data and also as a result of studies on the final products of the corresponding reactions. Carbonium ions are then regarded as short-lived species which cannot be observed directly by physical methods.[65] On the other hand, in heterogeneous catalysis the formation of adsorbed carbonium or carbenium ions is frequently understood too literally, as the solid catalysts are not superacids and solvation effects, stabilising the intermediate structures, are absent in the catalytic reactions of hydrocarbons.

Indeed, surface esters and not ion pairs are formed in the interaction of Brønsted acid centres with olefins or alcohols. These are known to be covalent compounds, as is confirmed by their dipole moments and by the comparatively small low-field chemical shifts in the ^{13}C NMR spectra involving the α-carbon atoms of the alkyl substituents, which do not differ from the chemical shifts in the corresponding alcohols and are in the range 50–70 p.p.m.[66] On the other hand, the shifts for stable carbenium ions in superacid solutions, where the positive charge on the carbon is much higher, reach 300–350 p.p.m. For example, the chemical shift for the central atom in the $(CH_3)_3C^+$ is 335.7 p.p.m. and that for the carbon atom in the $(C_2H_5)_3C^+$ ion is 331.8 p.p.m.[70]

The covalent nature of the C–O bond in the surface esters has also been confirmed by quantum-chemical calculations. Thus it has been shown[67] that the interaction of ethylene with the bridging hydroxy-group of a high-silica zeolite leads to the formation of a surface ethoxy-fragment carrying a comparatively low positive charge of +0.26 e, and not a carbenium ion, while the interaction of an ammonia molecule with the same hydroxy-group results in the formation of an ammonium ion, whose charge is +0.71 e.[68] On the other hand, it follows from quantum-chemical calculations that the tendency towards an increase in the amount of ionic character of the C–O bond in esters increases with increase in its length or on vibrational excitiation.[69] Thus the carbenium ion properties of the alkyl substituents are manifested not in the ground states of the corresponding intermediates but in their transition stages.

The complete rejection of the mechanisms involving adsorbed carbenium ions, which are nowadays generally accepted, does not by any means follow from the foregoing. We merely wish to emphasise yet again that the concept of carbenium ions refers more to transition states than to intermediate compounds. On the other hand the very concept of the "adsorbed carbenium ion" may have a completely different significance in each specific case. From our point of view, it should be understood not as the real existence of contact ion pairs on the surfaces of catalysts but rather as implying the presence of intermediate compounds resembling carbenium ions in the liquid phase as regards their reactivity.

4. Spectroscopic Studies on the Elementary Proton Transfer Stage on the Surfaces of Oxide Catalysts

The reduced tendency towards the formation of ionic structures in the proton transfer from acid hydroxy-groups to molecules adsorbed on the surfaces of heterogeneous catalysts has been confirmed also by spectroscopic data. Above it was already stated that the bathochromic shifts of the stretching vibrations of the OH groups, induced by the formation of a hydrogen bond with the adsorbed molecules, are widely used for the measurement of the strength of the Brønsted acid centres on the surfaces of oxides. The possibilities of IR spectroscopy in the study of the proton transfer mechanism are not, however, exhausted by this. It has been suggested[43,48,71–75] that, together with the shifts of the fundamental stretching vibration frequency, one should also measure the bathochromic shifts of the overtones of the stretching vibrations. These data make it possible to reconstruct the lowest sections of the potential curves for the OH bond in the surface complexes preceding the proton transfer and to calculate the height of the potential barrier in this elementary stage.

Indeed it is well known that the potential energy curve for a diatomic molecule can be constructed from the positions of any two of its vibrational levels. It has been shown[43,44] that, as a consequence of the characteristic nature of the stretching vibrations, the surface OH groups can also be regarded as diatomic fragments which hardly interact with the lattice vibrations of the oxide. Therefore the lowest sections of the potential curves for the OH bond in the free hydroxy-groups and in the hydrogen-bonded complexes can be plotted from the fundamental frequencies and overtones of the OH group vibrations. On the other hand, for the reconstruction of the complete potential energy profile of the elementary proton transfer stage, one can assume to a first approximation that the stage corresponds to an increase in the length of the OH bond by approximately 0.05 nm, which follows from the considerations described above.

It is known that the lengths of the strong hydrogen bonds in a wide variety of complexes are in the range 0.24–0.26 nm.[76] On the other hand, the equilibrium O–H distance in the initial hydroxy-groups is approximately 0.1 nm. Similar values are characteristic also of the length of the C–H (0.109 nm), N–H (0.101 nm), and other bonds formed in protonated intermediate compounds. The extension of the O–H bond by approximately 0.05 nm therefore corresponds to proton transfer to adsorbed molecules and a somewhat smaller increase in its length corresponds to the apex of the potential proton transfer barrier. As regards the complete potential energy profile for the elementary proton transfer stage, the latter can be obtained by positioning the potential curve for the OH bond, calculated from spectroscopic data, and the potential curve for the bond newly formed in the protonated compound in such a way that the distance between their minima is 0.05 nm.

Fig.2 presents the potential energy profiles constructed in this way for the exothermic and endothermic proton transfer stages.[73–75] In the former case, the transfer requires virtually no activation energy. On the other hand, for the endothermic stages the formation of the stable intermediate protonated compounds is possible only provided that the energy expenditure on the proton transfer does not exceed approximately 100 kJ mol^{-1}. Otherwise, the local minimum on the potential curve corresponding to the formation of the protonated state is either absent or its depth is so small that the protonated state is metastable and decomposes even after a few vibrations. This is caused by the comparatively large width of the lowest section of the potential curve for the OH bond and the slight increase in its length on complete proton transfer in its surface complexes. In this respect, heterogeneous acid catalysis differs significantly from homogeneous acid catalysis in aqueous solutions, where the proton transfer reaction coordinate does not have the significance of a simple increase in the length of the OH bond and is accompanied by a rearrangement of many solvent molecules, resulting in the separation of cations and anions in space. Therefore, in aqueous solutions protonated states can really exist even if proton transfer is significantly endothermic.

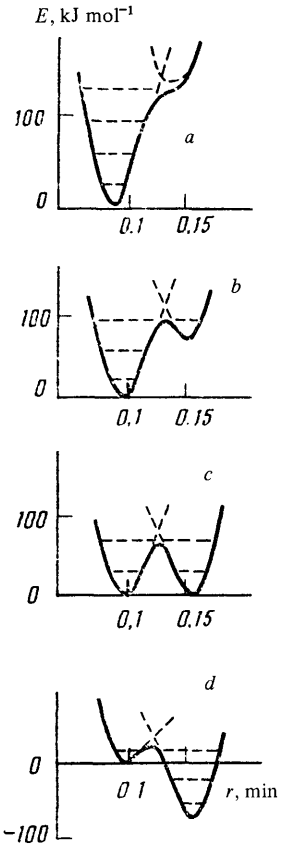


Figure 2. The potential energy profiles for the elementary proton transfer stage constructed on the basis of spectroscopic data:[73,74] (a) process endothermicity 150 kJ mol^{-1}; (b) process endothermicity 100 kJ mol^{-1}; (c) thermally neutral process; (d) process exothermicity 50 kJ mol^{-1}.

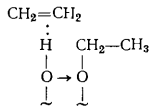
It is possible to formulate several spectroscopic criteria for the determination of the real tendency towards proton transfer to the adsorbed molecules. The most clear-cut of these is the increase in the anharmonicity of the potential curve for the OH bond on formation of surface complexes. To use a picturesque phase, the anharmonicity makes it possible to analyse the response of the acid hydroxy-group to the extension of the OH bond and to the

approach of the adsorbed molecule by the proton. The increase in anharmonicity indicates the attraction of the proton to the substrate and its decrease indicates the repulsion.[77]

The isotope effect, i.e. the ratio of the vibration frequencies of the light and heavy hydroxy-groups perturbed by hydrogen bond formation, may be used as another criterion of the positive tendency towards the formation of protonated states (the ratio diminishes with increase in anharmonicity and in positive tendency towards proton transfer). Furthermore, the tendency towards proton transfer is manifested by the absence of strong perturbation of the first overtone and in the large bathochromic shifts of the stretching vibrations in the spectra of hydrogen-bonded complexes (400–600 cm^{-1} and above).

The application of these criteria to the analysis of the IR spectra of the complexes of hydroxy-groups with various molecules also indicates merely a moderate tendency towards the formation of ionic intermediate structures under the conditions of heterogeneous catalysis. For example, in the benzene complexes with acid hydroxy-groups of the hydrogen-form of the type Y zeolite, the decrease in the fundamental stretching vibration frequency is approximately 350 cm^{-1}. This, however, is insufficient for the complete proton transfer to benzene molecules. The anharmonicity coefficient also increases only up to 4×10^{-2}, i.e. by a factor of approximately two. Approximately the same bathochromic shifts are observed likewise in the interaction of acid hydroxy-groups of the type HY zeolite with ethylene.[78]

The proton affinities of certain molecules.[80]



Molecule	Proton affinity, eV	Molecule	Proton affinity, eV
H_2	4,4	C_4H_8	7,8
CH_4	5,1	CH_3OH	7,8
C_2H_6	5,6	C_3H_8	7,9
C_3H_8	6,1	CH_3CHO	8,0
C_2H_4	6,9	CH_3CN	8,1
H_2O	7,1	C_2H_5OH	8,1–8,4
C_6H_6	7,5	CH_3OCH_3	8,5
cyclo-C_6H_{10}	7,7	NH_3	9
CH_3NO_2	7,7–7,8	CH_3NH_2	9,2

The formation of ion pairs hardly occurs even in the interaction of ethylene with the very highly acid hydroxy-groups of the high-silica zeolites of type ZSM-5. This is indicated both by the moderate shifts of the OH vibration frequencies in the spectra of the hydrogen-bonded complexes and by the linear structure of the ethylene oligomers formed at room temperature, which cannot be explained by steric effects, because the polymerisation of propene on the same catalysts leads to the formation of branched structures in their channels.[79] Apparently, in conformity with the quantum-chemical calculations already discussed above, the interaction of ethylene with such centres entails the formation of highly polarised covalent structures and not ion pairs. Thus spectroscopic data also demonstrate that the concept of carbenium ions is too simplified when applied to heterogeneous systems.

We may note that the transition from the hydrogen-bonded complexes to polarised covalent structures and further to surface contact ion pairs depends very markedly on the energetics of the elementary stage of proton transfer. For example, the benzene is not protonated in its interaction with the acid OH groups of a type Y zeolite (the proton affinity of benzene is 7.5 eV—see Table), but contact ion pairs are undoubtedly formed in the interaction of these groups with ammonia (the proton affinity is 9 eV [80]). Thus the proton transfer and the formation of contact ion pairs require an additional energy of only approximately 1.5 eV. There is nothing surprising in this, because a free energy change of 5.7 kJ mol^{-1} corresponds to one unit on the pK_a scale in aqueous solutions and a free energy change of approximately 120 kJ mol^{-1} or 1.2 eV corresponds to the transition from a weak acid with $pK_a = +10$ to superacids with $pK_a = -10$. Solvation in fact makes good this deficiency in the formation of intermediate ionic states and contributes to the energy balance of the acid–base interaction in aqueous solutions. On the other hand, in the high-temperature catalytic reactions of hydrocarbons, this source of additional energy is absent. It cannot be replaced by the activation energy either, because, as already mentioned above, in the case where the proton transfer stages are insufficiently endothermic minima corresponding to protonated ionic structures are missing from the potential energy surface.

5. The Reaction Coordinate in Heterogeneous Acid Catalysis. Synchronous Mechanisms of Acid Catalytic Reactions

In constructing the energy profiles, discussed in the previous Section, for the elementary proton transfer stage, no account is taken of the additional energy gain associated with the optimisation of the geometry of the protonated state. For example, the conversion of a π-complex of ethylene into the ethoxy-fragment actually involves, apart from the extension of the OH bond as the proton approaches the ethylene molecule, also an increase in the length of the C=C bond when it is converted into a single bond, a change in the hybridisation and in the valence angles in the CH_2 and CH_3 groups, and the orientation of the adsorbed molecule relative to the catalyst surface:

(13)

In other words, the vibrational excitation of the OH bond and the associated increase in length by no means always constitute the optimum coordinate of the elementary protonation stage.

Depending on the relative contributions of various factors, there is a possibility of a wide variety of situations in this instance. For example, the role of relaxation in the formation of the ammonium ion from adsorbed ammonia is minimal. On the other hand, in the example involving the formation of the ethoxy-fragment just discussed, the optimisation of the geometry is extremely significant and the reaction coordinate corresponds to only a very slight extent to an increase in the length of the OH bond. In similar cases we shall henceforth speak of a synchronous mechanism of heterogeneous catalytic reactions involving the simultaneous activation and rearrangement of many chemical bonds in the adsorbed molecules or intermediate complexes.

The advantage of these mechanisms under the conditions of acid–base homogeneous catalysis compared with the multistage consecutive protonation-deprotonation of the substrate molecules was noted as early as the end of the 1950's by Syrkin.[81–83] It was

concluded in this connection that there is a possibility of the formation of cyclic five-, six-, and seven-membered transition states and their role in hydrolytic, esterification, Friedel–Crafts, etc. reactions was discussed.[84–86] In relation to heterogeneous catalysis, the important role of synchronous or joint mechanisms in heterogeneous catalysis has been discussed by Boreskov mainly in relation to catalytic oxidation reactions.[87]

The pre-exponential factors in the rate constants for such complex elementary stages are naturally smaller than the stretching vibration frequency of the OH bond because a concerted change in a large number of different coordinates takes place at once in the transition state or many vibrations are found to be in phase. This more complex reaction pathway is associated, however, with a lower energy barrier to the formation of the intermediate protonated state. This more than makes up for the lower activation entropy for the protonation stage and ensures a high rate of the catalytic reaction.[88]

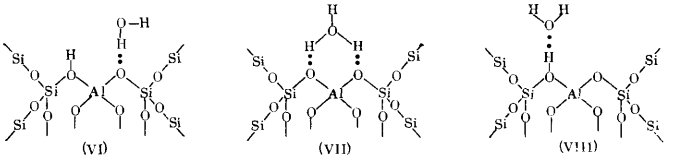
The limiting case in such synchronous mechanisms in acid catalysis involves reactions where the intermediate protonated forms are not formed at all. This is apparently typical of molecules with a low proton affinity, for example, for hydrogen or the paraffins. Since the formation of the intermediate protonated state is unfavourable in this instance, a new bond between the molecule or its fragment and the catalyst surface is formed simultaneously with proton transfer which apparently at least partly compensates for the energy of the abstraction of the proton from the acid centre. For example, in heteroisotope exchange reactions, the proton transfer to the acid centre of the substrate is accompanied by the simultaneous reverse reaction involving the abstraction of another proton from the activated complex. On the other hand, the energy involved in binding the second proton compensates for the difficulty of transferring the first proton to the substrate molecule analogously to the promotion of proton transfer in aqueous solutions by solvation. Specific examples of similar and other synchronous reactions will be discussed below.

6. The Principal Types of Mechanisms of Acid Heterogeneous-catalytic Reactions

Since a great variety of mechanisms of acid heterogeneous-catalytic reactions follows from the foregoing, it is useful to discuss them, having combined them into individual groups, as a function of the presence or absence of solvation effects and as a function of the proton affinity of the reacting molecules. Our aim here is not to provide an exhaustive survey of the literature, because this is impossible within the framework of the present review, and we shall consider only certain most typical examples.

(a) Low-temperature Catalytic Reactions with Participation of Polar Molecules

The mechanism of low-temperature heterogeneous-catalytic reactions involving polar molecules, for example, the hydration of olefins to alcohols, the esterification of alcohols, the hydrolysis of esters, etc., is closest to the mechanism of homogeneous acid catalysis. If the reaction temperature is not too high and there is a possibility of the formation of associated species comprising several molecules, then effects analogous to the solvation effects with participation of polar molecules in solutions come into force and the protonated forms of the substrate play the role of the active intermediates in catalytic reactions. This situation resembles very strongly homogeneous catalysis in aqueous solutions, where solvation effects make a decisive contribution to the formation of protonated states and to proton transfer to the adsorbed molecules. More precisely, this is two-dimensional homogeneous catalysis in a thin liquid film condensed on the surface of the heterogeneous catalyst. In particular, the possibility of the operation of such a mechanism in the olefin hydration reaction has been demonstrated by Chirkov, Vinnik, and co-workers.[89]



Apparently an analogous mechanism also obtains in enzyme catalysis. Here, however, the specificity of the interaction of the water or substrate molecules with the polar groups on the biopolymer surface is manifested. This leads to structure formation in the adsorbed film, which affects both the solvation energy and the proton transfer mechanism.[21–23] This factor does not, however, alter the main features—the real existence of intermediate protonated states in these systems.

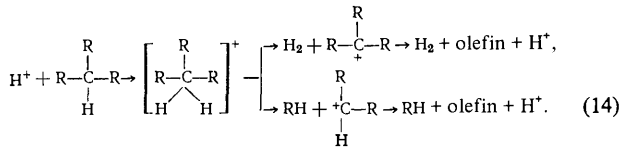
(b) Heteroisotope Deuterium Exchange Reactions

Another limiting case is that of catalytic reactions involving nonpolar molecules having a minimal proton affinity. As can be seen from the Table, these include molecular hydrogen and the paraffins. Since the solvation effects are virtually absent here and the proton affinity is low, the formation of intermediate protonated states is extremely unfavourable. At the same time different versions of synchronous or joint mechanisms operate.

For a series of heteroisotope exchange reactions, their possibility has been confirmed by quantum-chemical calculations carried out using the cluster models of Brønsted acid centres examined above. In particular, synchronous heteroisotope exchange between terminal silanol groups on the silica surface and molecular deuterium can proceed via a symmetrical tetragonal transition state.[54]

The advantage of such synchronous mechanisms in the heteroisotope exchange reaction with water molecules, which have a much higher proton affinity (~7 eV), was more unexpected.[90,91] Quantum-chemical calculations have been performed for the adsorption of water and the mechanism of the heteroisotope exchange between the acid bridging hydroxy-groups in the hydrogen-forms of zeolites and water.[91] Among the three versions of the adsorption of H_2O molecules examined [structures (VI)–(VIII)], the highest heat was obtained for the interaction of water with the basic oxygen of the aluminium–oxygen tetrahedron [70 kJ mol^{-1}, structure (VI)], while the lowest heat was found for its two-point adsorption [40 kJ mol^{-1}, structure (VII)]. The heat of adsorption of water on the proton of the bridging hydroxy-group proved to have an intermediate value [46 kJ mol^{-1}, structure (VIII)].

Bearing in mind that the highest heat of adsorption corresponds to the structure (VI), one may conclude that the rate-limiting stage in the hetero-exchange is most likely to be the desorption of water from the surface. On the other hand, the reaction itself apparently proceeds via a synchronous mechanism, in the transition state (VII)

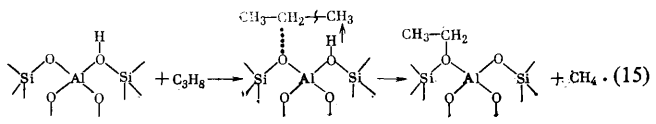


of which there is simultaneous proton transfer from the acid bridging hydroxy-group to the adsorbed water and the abstraction from it of a second proton, which is transferred to a neighbouring basic oxygen atom.

A synchronous mechanism has also been proposed for the heteroisotope exchange between surface hydroxy-groups and acetylene.[92] However, this mechanism is unlikely in the heteroisotope exchange with ethylene, whose rate is much lower.[93,94]

(c) The Cracking of Paraffins

Paraffins constitute another class of compounds in the reactions of which the formation of intermediate protonated states is unlikely because of the low proton affinity. Until recently, it was assumed that their acid-catalytic cracking proceeds via a chain mechanism and that chain transfer is achieved via the transfer of a hydride ion from the paraffin molecule to the adsorbed carbenium ions. It has been suggested that the source of the latter is olefins, which are either present in the starting material as an impurity or are formed in the dehydrogenation of the paraffins.[32]

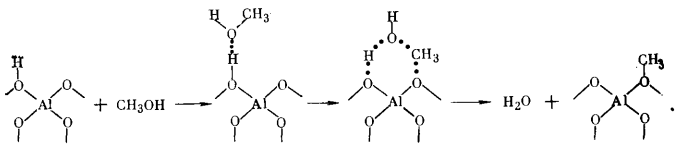


Apart from this classical cracking mechanism, which is valid at relatively low temperatures and high pressures of the hydrocarbons, there is a possibility also of protolytic cracking with participation of non-classical carbenium ions containing pentacoordinate carbon atoms:[95]

(14)

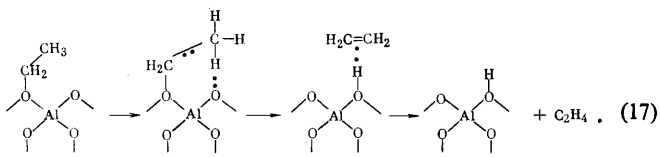
Its distinctive features are the rapid deuterium–hydrogen exchange involving the paraffins without their skeletal isomerisation and the presence of molecular hydrogen and of light C_1 and C_2 paraffins in the cracking products.

However, in conformity with what has been said above, the formation of non-classical carbonium ions as stable intermediates hardly occurs owing to the low proton affinity of the paraffins. It is sufficient to state that non-classical carbonium ions cannot be observed even in the interaction of paraffins with superacids.[70] From our point of view, an alternative synchronous cracking mechanism, involving a six-membered transition state with simultaneous proton transfer to the CH_3 group, the dissociation of a C–C bond in the paraffin molecule, and the formation of a new carbon–oxygen bond is more probable:



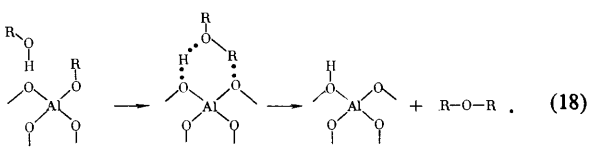
(15)

In this case the activated complex does not indeed resemble the non-classical carbenium ion but it is not a stable intermediate structure which really exists.



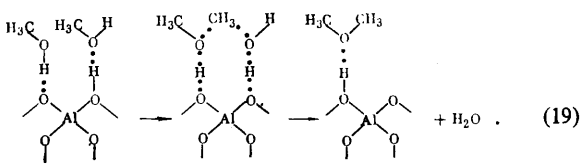
(d) High-temperature Catalytic Reactions of Alcohols

Esterification reactions, dehydration reactions with formation of olefins, alkylation of olefins and aromatic compounds by alcohols, and the synthesis of higher hydrocarbons from alcohols are characteristic high-temperature acid-catalytic reactions of alcohols. There is no doubt that, under the conditions of heteogeneous acid catalysis, the first stage in all these reactions is the formation of surface alkoxy-structures. The mechanism of this elementary stage can be treated, by analogy with heteroisotope exchange reactions between highly acid hydroxy-groups and water molecules, as a synchronous substitution reaction with participation of neighbouring basic centres and involving the inversion of the methyl group in the transition state similarly to what happens in the thoroughly investigated S_N2 nucleophilic substitution reactions



(16)

In the case of higher alcohols, the decomposition of surface alkoxy-fragments leads to the desorption of olefins from the surface:



(17)

and their interaction with a second alcohol molecule results in esterification:

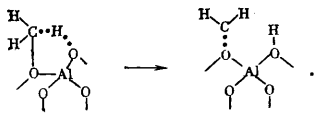
(18)

Another bimolecular synchronous mechanism, involving the formation of an eight-membered cyclic transition state, has also been discussed for this reaction:[90,96]

(19)

The low energy barriers in these elementary stages can be explained by the synchronous nature of the dissociation of old and the formation of new bonds in the activated complexes arising by the interaction of alcohol molecules with the surface acid–base pairs.

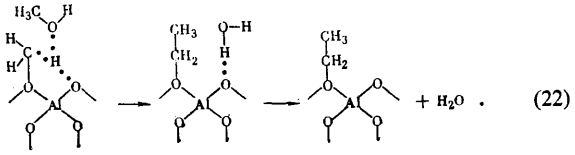
The establishment of the mechanism of the reactions involving the alkylation of olefins and the aromatic compounds by alcohols and also the synthesis of higher hydrocarbons from alcohols constitute a



more complex problem. We shall discuss these questions below in relation to the catalytic reactions of methanol on high-silica type ZSM-5 zeolites.

Much attention has been devoted recently to the synthesis of hydrocarbons from methanol (see, for example, the relevant reviews[97,98]). The most difficult question is that of the mechanism of the formation of ethylene from methanol and of the appearance of the primary C–C bond. A wide variety of schemes involving the formation of oxonium ions, ylides, free radicals, and carbenes have been discussed in the literature,[99] the greatest preference being given to carbenes. For example, it has been suggested[32] that the methanol adsorbed on the zeolite surface loses water with formation of adsorbed carbenoid species, which then polymerise to olefins:

$$HCH_2{-}OH \rightarrow H_2O + {:}CH_2,$$
$$n{:}CH_2 \rightarrow (CH_2)_n. \qquad (20)$$



Similar mechanisms have been examined also in other investigations.[100–102]

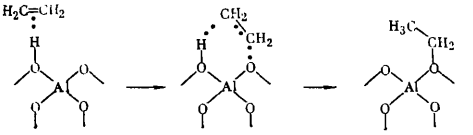
Quantum-chemical calculations have thrown some light on this question.[69,103,104] It has been found that the properties of the surface methoxy-structures themselves are dual to some extent, combining the features of both adsorbed carbenium ions and carbenes. This is caused by the presence of a bond between one of the hydrogen atoms of the methoxy-group and the neighbouring basic oxygen atom, which undoubtedly indicates the possibility of proton transfer to the latter. This tendency increases with increase in the length of the ether bond. Although, according to calculations by the MNDO method and non-empirical calculations in terms of the STO-3G basis set there is a deficiency of approximately 1.5 eV of energy for the complete proton transfer with formation of an adsorbed carbene species and an acid hydroxy-group, i.e.

(21)

the formation of a carbene-like transition state may be significantly facilitated by the interaction with a second methanol molecule, similarly to the situation arising when the interaction with a second water or alcohol molecule favours proton transfer and the formation of ion pairs in homogeneous systems. Such transition state is then converted into a surface ethoxy-group and an adsorbed water molecule:

(22)

The ethoxy-fragment can then be alkylated by further methanol molecules via an analogous mechanism, affording the isopropoxy- or t-butoxy-structure or decomposing with desorption of ethylene.

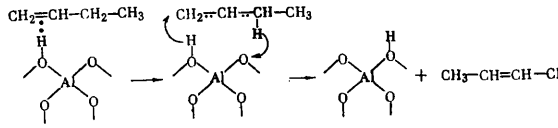


This mechanism is also synchronous, because the abstraction of a proton from the methoxy-group takes place simultaneously with formation of a new bond in the water molecule, while the dissociation of the C–O bond in the methanol molecule is compensated by the formation of a carbon–carbon bond in the alkoxy-fragment. It too has features in common with simultaneous proton transfer to two water or alcohol molecules in homogeneous systems with the sole difference that the additional energy source is in this instance not the heat of solvation of the intermediate protonated state but the energy evolved as a result of the chemical alkylation reaction.

The carbene-like properties of methoxy-groups on the surfaces of high-silica zeolites has been confirmed experimentally.[105] It was found that the interaction of the surfaces of previously methoxylated ZSM-5 zeolites with benzene, ethane, and propane, entails the incorporation of methylcarbene fragments into these molecules, which leads to the formation of toluene, propane, and butane.

(e) Catalytic Reactions of Olefins

Double bond migration, skeletal isomerisation, polymerisation, and cracking reactions are characteristic catalytic reactions of olefins in the presence of heterogeneous catalysts of the acid type. Adsorbed carbenium ions are traditionally considered as the active intermediate structures in all these reactions. In conformity with the foregoing, it is more correct, however, to speak of the formation of surface alkoxy-fragments or esters, whose carbenium ion properties are manifested only in transition states with extended or vibrationally excited C–O bonds.



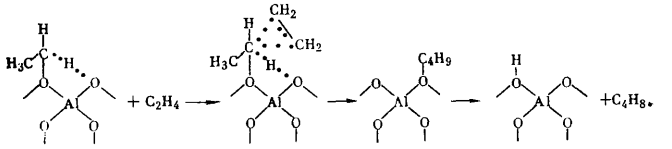
In the interaction of olefins with acid hydroxy-groups, hydrogen-bonded complexes are formed initially. This is followed by the two-point adsorption of the olefin, which, to coin a phrase, "creeps off" to a neighbouring basic centre, being converted into a surface alkoxy-group:

(23)

The reverse process leads to the desorption of olefins. The migration of the double bond in olefins and deuterium exchange involving them can also be explained by the reversibility of reaction (23).

Such multistage (but concerted as regards the elementary proton transfer step) mechanism does not, however, rule out the possibility of the migration of the double bond also via a synchronous mechanism without the formation of stable intermediate protonated states:[62]

(24)

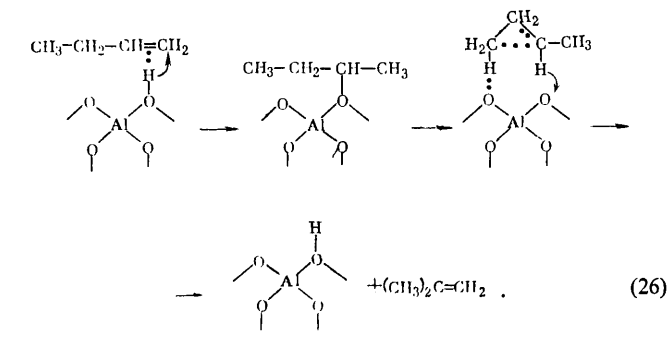


A concerted mechanism of the isomerisation of olefins is more probable for reactions involving moderately acid hydroxy-groups, while the multistage mechanism is preferable in the case of highly acid Brønsted centres.

We shall now discuss the mechanism of the oligomerisation of olefins. It is generally accepted that this reaction proceeds with the participation of adsorbed carbenium ions, which are readily formed from branched olefins but not from ethylene.[34] From our point of

view, this claim must be understood in the sense that the ease of formation of carbenium ion transition states from covalent alkoxy-structures increases with increase in the degree of their branching.

This tendency has been traced[106] with the aid of quantum-chemical calculations for methyl, ethyl, and isopropyl fragments adsorbed on the surfaces of high-silica zeolites. It was found that, although their positive charges are virtually identical, the tendency towards heterolytic dissociation diminishes on passing from the isopropyl to the ethyl substituent. The carbenium ion mechanism, which is characteristic of the oligomerisation of higher olefins, is ineffective in the case of ethylene.



If, on the other hand, account is taken, by analogy with the previously discussed Scheme (21), of the fact that the abstraction of α-protons from the ethyl fragments imparts properties of adsorbed ethylcarbenes to the latter, presumably the oligomerisation of ethylene can also proceed via the "carbene" mechanism in certain cases:[107,108]

(25)

The transition state resembles in this instance cyclopropane or its derivatives. On the other hand, the source of the additional energy compensating for the difficulty forming the carbene-like activated complex is, as in the reactions of methanol discussed above, a chemical reaction, and in this case it is the oligomerisation reaction and not the alkylation reaction. The reverse reaction leads to the cracking of olefins.

It may be that the skeletal isomerisation of olefins proceeds also via an analogous "cyclopropane" transition state formed when γ-protons are split off from the surface alkoxy-groups:

(26)

Thus the generally accepted mechanism of the carbenium ion reactions of olefins under the conditions of heterogeneous acid catalysis can be usefully supplemented by two new elementary reactions which take into account the dual carbenium ion and ylide nature of the transition states formed from covalent alkoxy-structures:

(1) The elimination of a proton from the α-carbon atom, which leads to the possibility of alkylation and oligomerisation reactions via the ylide mechanism, which is an alternative to the carbenium ion mechanism.

(2) The elimination of a proton from the γ-carbon atom, which leads to the skeletal isomerisation and cracking of olefins.

Since the cracking and skeletal isomerisation proceed via the same cyclic cyclopropane transition state, these reactions should take place under similar conditions and on the same active centres.

The conclusions concerning the composition of the products of the corresponding catalytic reactions, made on the basis of the ideas developed above, hardly differ from those which follow from the chemistry of carbenium ions. At the same time, the schemes which we have proposed are much more realistic than those discussed in the literature, because they take into account the interaction of the active intermediate species with the surface. Furthermore, they make it possible to understand what are the driving forces and causes of the selectivity or relative ease of particular elementary stages of heterogeneous acid-catalytic reactions.

IV. CONCLUSION

The results described show that, apart from the analogies between homogeneous and heterogeneous acid catalysis frequently discussed in the literature, there are also significant differences between these types of catalytic action. The main one is the absence of solvation effects in high-temperature catalytic reactions of hydrocarbons. For this reason, many heterogeneous acid-catalytic reactions do not proceed via ionic intermediate compounds, which are energetically unfavourable under these conditions, but via a synchronous mechanism which makes it possible to avoid their formation. Thus the main disadvantage of the modern ideas about the mechanisms of heterogeneous-catalytic reactions is the formal description of these mechanisms within the framework of a single multistage ionic scheme. In fact, depending on the proton affinity of the reacting molecules and also on the presence or absence of solvation effects, a broad range of different mechanisms operate. Their range extends from homogeneous catalysis in thin liquid films condensed on the surfaces of heterogeneous catalysts to a synchronous reaction with the participation of acid-base pairs, where stable intermediate protonated states are not produced.

Another disadvantage of modern theoretical ideas in the field of heterogeneous acid catalysis is the failure to take into account the interaction of protonated intermediate structures with the catalyst surface. The contribution of this factor to the energetics of proton transfer is in fact very significant and in many cases decisive. The interaction of weakly basic organic molecules with Brønsted acid centres therefore leads to the formation in most instances of covalent surface intermediate compounds and not of quasi-free carbenium ions. On the other hand, the properties of carbenium ions are manifested in transition states where the carbon–basic oxygen bond on the catalyst surface is partly dissociated (extended or vibrationally excited).

Finally yet another feature of heterogeneous acid catalysis is the bifunctional nature of its active centres, the acid part of which is a proton donor while the basic part either stabilises the intermediate protonated compounds or promotes the elimination of a proton from the transition states in the synchronous reaction mechanisms. Deprotonation can impart also the features of adsorbed carbenes or ylides to the activated complexes. Allowance for this factor permits a more natural explanation of the mechanisms of the reactions involving the alkylation, cracking, and skeletal isomerisation of olefins. Incidentally, all that has been said applies equally and in general to electrophilic reactions in organic chemistry, while allowance for the interaction of intermediate protonated structures with

counterions is also an essential condition for the correct interpretation of the reaction mechanisms. However, the discussion of these questions is outside the framework of the present review.

The ideas developed above should not be regarded as a criticism of the concept of carbenium and carbonium ions in heterogeneous acid catalysis. The aim is rather to deepen and update this concept. Naturally, many of the mechanisms discussed are so far debatable and their confirmation requires further quantum-chemical calculations for detailed kinetic and spectroscopic studies.

The Phase Boundary Potentials at the Interface between Two Immiscible Electrolyte Solutions

V.S.Markin and A.G.Volkov

The theoretical aspects of the calculation and measurement of the interphase [phase boundary] potential difference at the interface between two immiscible liquids are examined and the non-thermodynamic tetraphenylborate hypothesis, which makes it possible to determine the standard ion distribution potentials, is discussed. The electrochemical properties of charged interfaces are analysed and equations are presented for the interphase potential jumps in the presence of Donnan equilibrium, incomplete dissociation of the salt, two electrolytes with a common ion, complex formation in one of the phases, and an oxidation-reduction equilibrium. The experimental methods for the measurement of the interphase potential difference and for testing the thermodynamic theory of distribution potentials at reversible interfaces are examined
The bibliography includes 93 references.

I. INTRODUCTION

One of the fundamental problems in modern chemistry involves the elucidation of the mechanism of the distribution of charges at the interface between two immiscible liquids. The solution of this problem is essential for the development of phase-transfer and surface catalysis, electrochemistry and colloid chemistry, artificial photosynthesis and biochemistry, improvement of extraction processes, and the creation of ion-selective electrodes.

The electrochemistry of the interface between two immiscible electrolyte solutions developed significantly only in the last century. However, despite major advances, there are many obscure aspects and unsolved problems in this branch of physical chemistry. In the present review, an attempt is made to describe the main properties of charged interfaces between two immiscible electrolyte solutions.

As at any interface, a difference between electrical potentials arises at the interface between two immiscible liquids which in the case of equilibrium systems is called the boundary potential difference or briefly the boundary potential.[1]

The controversy concerning the nature of the potential jumps at the interface between two immiscible electrolyte solutions dates back to the beginning of the century.[2] Despite its apparent simplicity, this problem remains of current interest.[3-6] Some workers[7,8] have transferred, without adequate justification, the Donnan theory,[9] developed for the calculation of the potential differences between electrolyte solutions in two identical solvents α and α', differing only in the ionic composition, to the system of two arbitrary immiscible liquids α and β. The potential difference $\Delta_{\alpha}^{\alpha}\cdot\varphi$ between two identical phases α and α' is a thermodynamically measurable quantity. On the other hand, $\Delta_{\beta}^{\alpha}\varphi$ at an oil-water interface cannot be measured from the standpoint of thermodynamics but it can be estimated on the basis of model considerations.[3,4,10-14] The error associated with it, which was introduced in the above study,[7] led to the derivation of an incomplete formula for the Donnan potential, which is valid only in certain special cases for phases of identical nature. Unfortunately, this inaccuracy spread from the above study[7] to certain reviews[8] and has created the illusion that a purely thermodynamic determination of the Galvani potential difference is possible.

Finally, interphase oxidation-reduction potentials have been examined in the literature solely for certain special systems,[10,12,15] although it is undoubtedly important to give a general definition of this concept.

In the present reivew, an attempt is made to fill these gaps and to arrange systematically the definitions and formulae used to estimate interphase potentials.

II. INTERFACES

1. The Structure of Interfaces

If two pure liquids are placed in a vessel, then, depending on their physicochemical properties, there is a possibility of the formation of several types of structures. If the molecules of each liquid can interpenetrate one another, mixing in any proportions, such liquids can be called ideally miscible. Naturally, it is then impossible to obtain a potential difference between the two phases. An example of such a system is the well known water-ethanol pair. If the molecules of neither liquid can penetrate into the other, then such liquids can be referred to as ideally immiscible. Either a sharp boundary or a transitional layer, in which components from both phases are present, is established between them. An example of two ideally immiscible liquids is the mercury-water system. Sometimes the interface between two liquids is represented arbitrarily by a mathematical surface without thickness. This is an ideal boundary for which the term "interface" is used in the English language literature. However, in reality at the molecular level it is impossible to draw a sharp boundary between two phases. A transitional layer (interphase), whose properties differ from those of the phases in contact, is formed in this region. The thickness of the transitional

layer is $\sim 0.1-10$ nm. In this connection, it must be emphasised that the extremely convenient concept of the ideal boundary is a model one and is therefore outside the framework of thermodynamics.

This review is devoted to the electrochemistry of the interface between two immiscible liquids or more precisely two liquids with limited miscibility, an example of which may be an oil–water system: both phases are sparingly soluble in one another and there is an interface between them, constituting a transitional layer in which the properties of the medium vary from those of one phase to those of the other. The miscibility of the liquids in the most thoroughly investigated oil–water systems is low, being of the order of hundredths per cent (if nitrobenzene, dichloroethane, octane, or decane is used as the organic phase).

2. Polarisable and Non-polarisable Interfaces

The interfaces between two immiscible electrolyte solutions are characterised by polarisabilities of different types depending on the extent to which they are permeable to the charged species present in the system.[16–20] Since formulations which are not completely accurate are frequently encountered in the literature, we shall consider briefly this question.

If the charged species cannot pass through the interface, the latter is referred to as polarisable; otherwise the boundary is called non-polarisable or reversible. We shall begin the discussion with polarisable boundaries. Since any boundary is to some extent permeable to ions, in practice one has to speak only of a particular degree of approximation to the limiting version of polarisable boundaries. This limiting version is frequently referred to in modern literature as an ideally polarisable boundary. In the IUPAC recommendations,[16] a boundary between two phases is called polarisable if the phases contain no components in common or if the exchange of the components is difficult. As will be shown below, this definition is unsatisfactory, because, when the conditions indicated are fulfilled, there is a possibility of situations in which a direct current flows across the interface.

Next it is stated in the above recommendations that the interface can be divided into two components containing respectively charged species from the phases α and β only. This model idea, which constitutes a drastic simplification of the real situation, actually restricts the scope of the investigation of polarisable boundaries, reducing them to a single special case. Other versions, which can be realised in specific systems, escape the investigator's attention. Incidentally, the authors of the recommendations[16] agree that many of their definitions are based on specific models, stipulating this already in the first page of their report.

The use of specific models is not open to objection when this is necessary, but we believe that attempts to define a general thermodynamic property in terms of specific models is illegitimate because this deprives the property described of the necessary generality. However, as pointed out by Frumkin,[21,22] such simplification of the problem is not, in principle, necessary, because in this field a system of definitions not employing specific model concepts has existed for a long time. As early as 1891, Planck[17] introduced the rigorous thermodynamic concept of a completely polarisable boundary. He defined it as the "boundary whose state is fully defined by the charge passed through it starting from a certain instant".

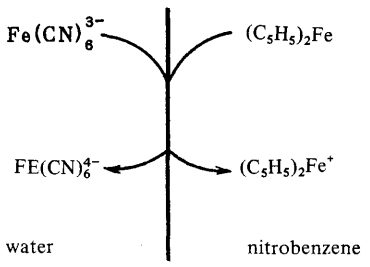
In the first place, it follows from this formulation that the Planck definition fully excludes the possibility of the passage of a direct current through the boundary since otherwise the state of the boundary would no longer depend on the charge passed through it. The current may flow between the phases only in a transient regime. In this definition, nothing is said about the way in which the charged species which have arrived from different phases are distributed in the transitional layer. Their distribution may be of any kind and, in particular, they can overlap (Fig.1). Such a situation can arise on metallic electrodes when there is partial or complete electron transfer to adsorbed ions or from these ions to the metal. However, charge transfer between the bulk phases is impossible in the presence of a completely polarisable boundary.

A special case of a completely polarisable boundary is the ideally polarisable boundary whose underlying concepts have been formulated by Koenig.[18] Fig.1*b* illustrates the structure of Koenig's ideally polarisable boundary. There is a transitional layer between homogeneous phases α and β whose properties vary from those of the phase α to those of the phase β. In the transitional layer, the phases are arbitrarily divided by Koenig's surface which is impermeable to all charged species (both ions and electrons). This surface constitutes an infinitesimally narrow and infinitely high energy barrier for all charged species, which in fact constitutes the difference between ideally polarisable and completely polarisable boundaries. It is in principle unimportant in this case which charged species enter into the composition of each phase. Koenig's definition is outside the framework of thermodynamics, since a definite structure of the interfacial region is postulated in it and non-thermodynamic assumptions concerning the existence of an infinitely high energy barrier for all the charged species are used.

Although the concept of the ideally polarisable electrode was developed by Koenig in 1934, the term ideally polarisable boundary (or electrode) as such was introduced later[19] and Koenig himself[18] used Planck's term. The term "ideally polarisable boundary" has been used in modern literature in a somewhat loose sense starting from Grahame's review.[20] It frequently includes the concepts of both an ideally polarisable boundary and of a completely polarisable boundary. It is sufficient to say that such confusion occurs even in the "electrochemical nomenclature" recommended by IUPAC.[16] Since Grahame[20] did not differentiate the concepts of free and thermodynamic surface charges and did not consider the adsorption or local charge transfer at the interface, he assumed that there is no need to use Koenig's surface in order to introduce the concept of the ideally polarisable electrode. Many investigators repeat this error to the present day, although as early as two decades ago Frumkin and co-workers[21,22] analysed in detail the difference between ideally and completely polarisable electrodes. It was shown that a completely polarisable electrode can include, in contrast to an ideally polarisable electrode, systems with local or adsorption charge transfer. For example, at a platinum electrode, whose potential is more positive than the equilibrium hydrogen potential by up to 300 mV, hydrogen ions are adsorbed from solution, react with the electrons from the metal, and form adsorbed hydrogen atoms:

$$H_{ads} \rightleftarrows H^+ + e^-.$$

This reaction is rapid on platinum and, starting from a certain instant, can be regarded as reversible. Although local charge transfer occurs here and Koenig's surface cannot be introduced,



there is no charge transfer between the phases and the electrode is completely polarisable as defined by Planck but not ideally polarisable as defined by Koenig.

If the phases α and β contain even one common ion, which moves freely across the interface, then such an interface can be referred to as reversible or non-polarisable. Despite the fact that the latter term is generally accepted, it does not reflect quite accurately the state of the system. A reversible (non-polarisable) interface can be partly polarisable or completely non-polarisable. Large currents can flow in either direction across a completely non-polarisable interface between two phases containing at least one common ion without causing a deviation of the interphase potential difference from the equilibrium value. Ideally polarisable and completely non-polarisable interfaces do not exist in nature, although certain electrodes can have properties close to ideality under certain conditions.

A partially polarisable interface corresponds to the intermediate state between ideally (completely) polarisable and non-polarisable interfaces. This difference actually exists and is usually investigated in electrochemistry.

In conclusion, we shall show that the definition proposed by IUPAC,[16] namely that the boundary between phases should be regarded as ideally polarisable when the phases contain no common components or the exchange of the components is difficult and cannot be regarded as satisfactory.

Suppose that a lipophilic reductant and a hydrophilic oxidant have been added to a water–oil system where each phase contains electrolytes (but there are no common ions in the two phases), so that an electron exchange reaction takes place at the interface:

In this case the interface ceases to be ideally polarisable and becomes partly polarisable or non-polarisable depending on the reaction conditions, although the oil and water contain no common ions. One can foresee the objection that electrons can be regarded as a common component in the two phases although they are not present in them in a free form. However, this does not save the IUPAC definition[16] because it vitiates the significance of its first part: "...when the phases contain no common components".

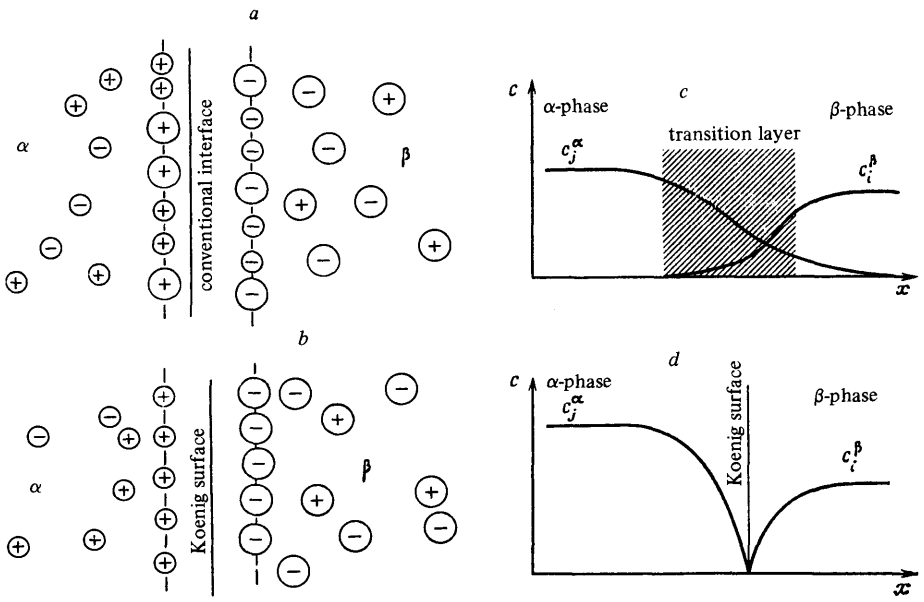


Figure 1. Schematic illustration of the distribution of ions and of the structure of the completely (*a*, *b*, *c*, and *d*) and ideally (*b* and *d*) polarisable interfaces.

III. INTERPHASE POTENTIALS

1. Boundary Potentials

As at any interface, an electrical potential difference is established at equilibrium at the interface between two immiscible liquids, which is referred to as the boundary potential difference or, briefly, the boundary potential. A classification of interphase potential jumps was introduced in 1930.[23] Fig.2 illustrates schematically the interphase potential jumps at the boundary between two immiscible phases, α and β, and also between these phases and the vacuum. The potential Ψ^{α}, measured *in vacuo* in the immediate vicinity of the above surface, is referred to as the Volta potential or the external potential. The potential φ^{α}, in the bulk of the phase, reckoned relative to a point in a vacuum at an infinite distance, is referred to as the Galvani potential or the internal potential. These two potentials differ by the surface potential jump χ^{α}.

In a study of the contact between the phases α and β, the Galvani potential difference

$$\Delta_{\beta}^{\alpha}\varphi=\varphi^{\alpha}-\varphi^{\beta},$$

which is determined by the specific distribution of the charged and polarised dipolar species in the vicinity of the interface, is of principal interest. The dipolar component of the interfacial potential difference $\Delta_{\beta}^{\alpha}\varphi_h$ is sometimes separated from the overall difference between the Galvani potentials; one can then obtain the quantity

$$\Delta_{\beta}^{\alpha}\varphi-\Delta_{\beta}^{\alpha}\varphi_h,$$

which is determined by the distribution of ions. Such separation is of practical value in those cases where the dipolar contribution to the potential jump is independent of the overall interphase potential difference (or depends only slightly on the latter), i.e. is ultimately independent of the ionic potentials and one can assume that all the changes in the interphase potential difference are described solely by the ionic contribution (the measurement and calculation of this contribution constitutes to a large extent the subject of the modern science of the interface between liquid electrolyte solutions). However, there is usually no certainty that the separation of the interphase potential difference into two independent components, due to the ionic and dipolar contributions, is valid and treatment of the results in such terms involves a certain degree of approximation.

One should also bear in mind that, contrary to the claim frequently encountered in the literature,[24] the dipolar potential jump $\Delta_{\beta}^{\alpha}\varphi_h$ at the interface between two immiscible electrolyte solutions is generally speaking not equal to the potential difference at the boundaries of these phases with a vacuum even in the case of specific adsorption:

$$\Delta_{\beta}^{\alpha}\varphi_h\neq\Delta_{\beta}^{\alpha}\chi=\chi^{\alpha}-\chi^{\beta}.$$

The reason is the mutual influence of the phases on the orientation of the dipolar molecules in the boundary layers of the liquid. Table 1 illustrates the thermodynamic feasibility of the experimental measurement of boundary potentials.

The equilibrium potentials at a reversible or non-polarisable interface are divided into three types depending on which species pass from phase to phase:

1. Potentials which arise in an equilibrium system where all the ions are capable of passing from one phase to the other are referred to as *distribution potentials.*

2. If the phases in contact contain ions some of which are capable of crossing the boundary while others are not, *Donnan potentials* or membrane potentials are generated. The transfer of ions may be prevented by either mechanical (as in semipermeable membranes) or chemical (as in ion exchangers) causes. If ions of only one kind can cross the interface, then the membrane potential difference is called the *Nernst potential.*

3. If two immiscible electrolyte solutions exchange electrons and are in equilibrium with respect to electrons, then an *oxidation-reduction potential* is established at the interface.

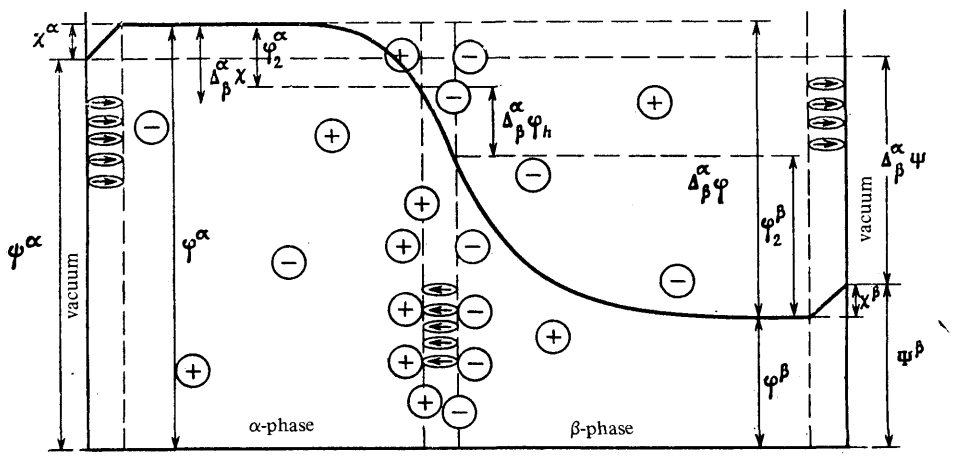

Figure 2. Boundary potentials in an oil–water system: $\psi^{\alpha}(\psi^{\beta})$—external potential or Volta potential; $\varphi^{\alpha}(\varphi^{\beta})$—internal potential of the phase α(β); $\chi^{\alpha}(\chi^{\beta})$—surface potential jump equal to the difference between φ^{α} and ψ^{α} (φ^{β} and ψ^{β}); $\Delta_{\beta}^{\alpha}\varphi$—Galvani potential difference; $\Delta_{\beta}^{\alpha}\psi$—Volta potential difference; $\Delta_{\beta}^{\alpha}\varphi_h$—the dipolar component of the interphase Galvani potential difference; φ_2^{α} and φ_2^{β}—potential jumps in diffuse layers.

Interphase potentials on completely (and ideally) polarisable boundaries can be due to the adsorption of charged or dipolar species at the interface or by the charging of the latter from an external source.

Table 1. Thermodynamic feasibility of the experimental measurement of the boundary potentials in immiscible liquid phases α and β.

Boundary potentials	Feasibility of measurement
External potential of one phase Ψ	Measured
Volta potential $\Delta_\beta^\alpha\Psi$	Measured
Surface potential χ	Not measured
Difference between surface potentials $\Delta_\beta^\alpha\chi$	Not measured, but can be determined when an additional non-thermodynamic hypothesis is used
Internal potential φ	Not measured
Difference between Galvani potentials $\Delta_\beta^\alpha\varphi$	Not measured, but if both phases have the same composition, measurement is possible
Change in $\Delta_\beta^\alpha\varphi$ during any process (adsorption, change in temperature, concentration, etc.)	Measured
Potential difference in the cell between phases of the same composition $E = \Sigma\Delta_\beta^\alpha\varphi$	Measured
Distribution potential of the salt or individual ion—$\Delta_\beta^\alpha\varphi$ or $\Delta_\beta^\alpha\varphi_i^0$	Not measured, but can be determined when an additional non-thermodynamic hypothesis is used
Change in $\Delta_\beta^\alpha\chi$ during any process (adsorption of dipoles, change in temperature, etc.)	Measured

Thermodynamics makes it possible to determine the interfacial potential only at a reversible interface. In the case of an ideally polarisable boundary, the potential is an additional independent variable characterising the state of the boundary and is specified by an external potential source. An electrostatic rather than an electrochemical equilibrium is maintained on an ideally polarisable boundary. It is analogous to the state of a charged condenser.

2. Standard Potentials and Standard Free Energies

Suppose that the phases α and β in contact contain ions I_i with a charge number z_i and an activity a_i. It follows from the condition for electrochemical equilibrium that

$$\Delta_\beta^\alpha\varphi = -\frac{\mu_i^{0,\alpha} - \mu_i^{0,\beta}}{z_iF} + \frac{RT}{z_iF}\ln\frac{a_i^\beta}{a_i^\alpha}, \quad (1)$$

where μ is the chemical potential and F the Faraday. The difference between the standard chemical potentials of the ion i in the two phases

$$\mu_i^{0,\alpha} - \mu_i^{0,\beta} \equiv \Delta_\beta^\alpha G_i^0(i) \quad (2)$$

represents the energy of transolvation or the standard Gibbs free energy $\Delta_\alpha^\beta G_i^0(i)$ of the transfer of the ion i from the phase α to the phase β. We introduce two further definitions: the distribution coefficient of the ions:

$$P_i^{\alpha/\beta} = \exp(-\Delta_\beta^\alpha G_i^0(i)/RT) \quad (3)$$

and the standard potential of the distribution of ions of the given kind:

$$\Delta_\beta^\alpha\varphi_i^0 = -\frac{\Delta_\beta^\alpha G_i^0(i)}{z_iF} \equiv \frac{RT}{z_iF}\ln P_i^{\alpha/\beta}. \quad (4)$$

According to Eqn.(3), it is evident that $P_i^{\alpha/\beta} = 1/P_i^{\beta/\alpha}$.

The interphase potential difference can be represented in the form

$$\Delta_\beta^\alpha\varphi = \Delta_\beta^\alpha\varphi_i^0 + \frac{RT}{z_iF}\ln\frac{a_i^\beta}{a_i^\alpha} \equiv \frac{RT}{z_iF}\ln\left(P_i^{\alpha/\beta}\frac{a_i^\beta}{a_i^\alpha}\right). \quad (5)$$

The equilibrium ratios of the activities of the ions i in two phases is described by the expression

$$\frac{a_i^\alpha}{a_i^\beta} = \frac{\gamma_i^\alpha c_i^\alpha}{\gamma_i^\beta c_i^\beta} = \exp\left[-\frac{z_iF}{RT}(\Delta_\beta^\alpha\varphi - \Delta_\beta^\alpha\varphi_i^0)\right] = P_i^{\alpha/\beta}\exp\left(-\frac{z_iF}{RT}\Delta_\gamma^\alpha\varphi\right), \quad (6)$$

where γ is the activity coefficient and c the concentration.

Hence the physical significance of the concepts introduced becomes clear. The standard distribution potential of the given ion represents the interfacial potential difference which would be established at the interface if the equilibrium activities of this ion in the two phases were identical. The partition coefficient of the ions $P_i^{\alpha/\beta}$ corresponds to the equilibrium ratio of the activities of the ions i in the two phases in the absence of an interphase potential difference.

It follows from the electroneutrality condition for the phases that

$$\sum_i z_ic_i^\alpha = 0; \quad \sum_i z_ic_i^\beta = 0. \quad (7)$$

The relation between the interphase potential $\Delta_\beta^\alpha\varphi$ and the concentration of ions in solutions is described by Eqns.(6) and (7). If there are n types of ions in the system, then the number of equations is $n + 2$ and the number of variables is $2n + 1$, i.e. the number of independent variables in the system is $n - 1$. In other words, it is possible to specify the concentrations of ions of all kinds in a single phase except one. The concentration of the ions of the remaining kind in this phase, the concentrations of all the ions in the other phase, and the interphase potential are then determined by solving a system of equations.

Apart from the activities of individual ions, it is convenient to use the concept of the mean activity of a 1:1 electrolyte BA:

$$a_{BA}^{\pm} = (a_Ba_A)^{1/2}. \quad (8)$$

The mean activity coefficient of the electrolyte is then given by

$$\gamma_{BA} = (\gamma_B\gamma_A)^{1/2}. \quad (9)$$

The partition coefficient of a 1:1 electrolyte can be introduced analogously:

$$P_{BA}^{\alpha/\beta} = (P_B^{\alpha/\beta}P_A^{\alpha/\beta})^{1/2}. \quad (10)$$

It is readily seen that $P_{BA}^{\alpha/\beta}$ is simply equal to the ratio of the mean activities of this electrolyte within the bulk of the phases α and β:

$$P_{BA}^{\alpha/\beta} = a_{BA}^{\pm\alpha}/a_{BA}^{\pm\beta}. \quad (11)$$

It is of interest that this ratio, in contrast ot the analogous ratio for

the individual ions [Eqn.6)], is independent of the interfacial potential. It is also independent of the presence of other ions in the solutions.

3. Distribution Potentials

(a) Fully Dissociated Electrolyte

We shall consider the simplest case where the boundary is non-polarisable and the phases α and β contain a binary 1:1 electrolyte B^+A^-:

$$\alpha,\ B^+A^-|B^+A^-,\ \beta. \tag{12}$$

The interfacial potential can be readily found from Eqn.(5) and the electroneutrality condition:

$$\Delta_\beta^\alpha\varphi = \frac{\Delta_\beta^\alpha\varphi_B^0 + \Delta_\beta^\alpha\varphi_A^0}{2} + \frac{RT}{2F}\ln\frac{\gamma_B^\beta\gamma_A^\alpha}{\gamma_A^\beta\gamma_B^\alpha}. \tag{13}$$

The first term reflects the individual characteristics of the ions in two media in the standard state, while the second depends on the activity coefficients, i.e. reflects the concentration effects. However, in practice the activity coefficients of the cation and anion can be regarded as approximately identical: $\gamma_A^\alpha \simeq \gamma_B^\alpha$ and $\gamma_A^\beta \simeq \gamma_B^\beta$. The expression for the interphase potential difference then assumes the simple form

$$\Delta_\beta^\alpha\varphi = \frac{\Delta_\beta^\alpha\varphi_B^0 + \Delta_\beta^\alpha\varphi_A^0}{2} \equiv \frac{RT}{2F}\ln\frac{P_B^{\alpha/\beta}}{P_A^{\alpha/\beta}}. \tag{14}$$

Thus the interphase potential difference is equal to the arithmetical mean of the standard distribution potentials of the individual ions. This potential difference between the two phases in the presence of a binary electrolyte has been called the distribution potential.[2,25] In this approximation, the distribution potential is independent of the concentration of the electrolyte BA. It is also independent of the structure of the interface, because it is determined solely by the thermodynamic properties of the bulk phases. This rule has been confirmed by experimental studies (see Section 5), although under certain conditions deviations from it occur. At low concentrations of the salt BA, the interphase potential difference depends also on the presence of other ions into which the solvent molecules dissociate and also of HCO_3^- ions if the measurements are performed in air and not in an inert gas.

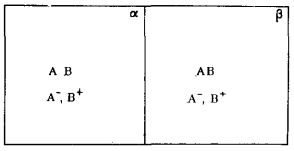
When the number of ions in the system is greater than two, the distribution potential is known to depend on the concentrations of the ionic component of the system. The structure of the interface between two immiscible electrolyte solutions is also determined by the volume properties of the phases in contact. If a monolayer of a surfactant almost insoluble in both phases is adsorbed at the interface, then formally this should not alter the value of $\Delta_\beta^\alpha\varphi$ determined from Eqn.(13). However, the blocking of the surface by the surfactant molecules may disturb the thermodynamic equilibrium, as a result of which the measured potential difference ceases to correspond to the equilibrium value and differs from the distribution potential. The interphase potentials at an interface between two immiscible electrolyte soslutons have been calculated in different specific situations.[11,22,26]

One may consider the general case of an asymmetric electrolyte:

$$\alpha,\ B_p^{k+}A_t^{l-}|B_p^{k+}A_t^{l-},\ \beta. \tag{15}$$

In this case, the interphase potential, determined by the distribution of electrolytes between two phases, is described by the expression

$$\Delta_\beta^\alpha\varphi = \frac{z_B\Delta_\beta^\alpha\varphi_B^0 - z_A\Delta_\beta^\alpha\varphi_A^0}{z_B - z_A} + \frac{RT}{(z_B - z_A)F}\ln\frac{\gamma_B^\beta\gamma_A^\alpha}{\gamma_B^\alpha\gamma_A^\beta}. \tag{16}$$



For an asymmetric electrolyte, the partition potential depends on the salt concentration. The second term on the right-hand side of Eqn.(16) is given by the following expression according to the Debye–Hückel theory:

$$\frac{RT}{(z_B - z_A)F}\ln\frac{\gamma_B^\beta\gamma_A^\alpha}{\gamma_B^\alpha\gamma_A^\beta} \simeq (z_B + z_A)\frac{e_0^3\sqrt{125\,N_A^3}}{2\pi F\varepsilon_0^{3/2}\sqrt{RT}}\left(I_\alpha^{1/2}\varepsilon_\alpha^{-3/2} - I_\beta^{1/2}\varepsilon_\beta^{-3/2}\right),$$

where I_α is the ionic strength of the solution in the phase α, N_α the Avogadro number, ε_0 the electrical constant, and ε_α the dielectric constant of the phase α. In terms of the Debye approximation, the distribution potential is independent of concentration only for a symmetrical electrolyte, where $z_A = -z_B$.

4. Incomplete Dissociation of the Salt

With the aid of the scheme

we shall consider the question of how the incomplete dissociation of the electrolyte can be reflected in the interphase distributions.

Suppose that the reaction

$$B^+ + A^- \overset{K_{BA}^\alpha}{\rightleftarrows} BA, \tag{17}$$

where K_{BA}^α is the dissociation constant of the BA molecule, takes place in the phase α. This means that the equality

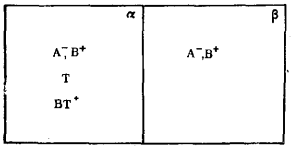
$$a_B^\alpha a_A^\alpha = K_{BA}^\alpha a_{BA}^\alpha. \tag{18}$$

holds at equilibrium. The dissociation constant K_{BA}^α is related to the chemical potentials μ of the corresponding species by the equation

$$RT\ln K_{BA}^\alpha = \mu_{BA}^{0,\alpha} - \mu_{B^+}^{0,\alpha} - \mu_{A^-}^{0,\alpha}, \tag{19}$$

where μ^0 is the standard chemical potential. The same equations can be written for the dissociation in the β-phase.

The undissociated BA molecules can be distributed between the phases and the partition coefficient $P_{BA}^{\alpha/\beta}$ is defined by the equation



$$RT\ln P_{BA}^{\alpha/\beta} = \mu_{BA}^{0,\beta} - \mu_{BA}^{0,\alpha}. \tag{20}$$

The incomplete dissociation of the molecules does not affect the interphase potential. A distribution potential, defined by Eqn.(5), is established at the boundary. The standard distribution potentials of individual ions [Eqn.(4)] also do not change. However, owing to the presence of the dissociation equilibrium and the distribution of the undissociated molecules between the phases, a relation arises between the constants of these processes and the difference between the standard Gibbs free energies of the ions (and hence also the standard potentials):[26]

$$RT \ln \frac{K_{BA}^{\beta}}{K_{BA}^{\alpha} P_{BA}^{\alpha/\beta}} = \Delta_{\beta}^{\alpha} G_{B+}^{0} + \Delta_{\beta}^{\alpha} G_{A-}^{0} = F\Delta_{\beta}^{\alpha}\varphi_{A-}^{0} - F\Delta_{\beta}^{\alpha}\varphi_{B+}^{0}. \quad (21)$$

5. Complex Formation in One of the Phases

Suppose that the binary electrolyte BA is distributed between the phases α and β and that the phase α contains in addition a neutral complexone T which can combine with the cation B^+ to form the charged complex BT^+:

The reaction

$$B^+(\alpha) + T(\alpha) \overset{K_{BT}^{\alpha}}{\rightleftarrows} BT^+(\alpha). \quad (22)$$

takes place in the phase α and the dissociation constant K_{BT}^{α} is defined by the equation

$$RT \ln K_{BT}^{\alpha} = \mu_{BT+}^{0,\alpha} - \mu_{B+}^{0,\alpha} - \mu_{T}^{0,\alpha}. \quad (23)$$

Apart from the homogeneous dissociation constant K_{BT}^{α} of the ocmplex BT^+, it is also possible to introduce the constant of the heterogeneous or surface dissociation $K_{BT}^{\alpha/\beta}$ referring to a process in which the complexone T and the complex BT^+ are in the phase α while the ion B^+ is in the phase β. This constant is defined by the equation

$$RT \ln K_{BT}^{\alpha/\beta} = \mu_{BT+}^{0,\alpha} - \mu_{T}^{0,\alpha} - \mu_{B+}^{0,\beta}. \quad (24)$$

There is a simple relation between the two dissociation constants introduced and the partition coefficient of the ion B^+:

$$K_{BT}^{\alpha/\beta} = K_{BT+}^{\alpha}/P_{B+}^{\alpha\beta}. \quad (25)$$

The equation for the heterogeneous dissociation equilibrium is

$$c_{T}^{\alpha} c_{B}^{\beta} = K_{BT+}^{\alpha/\beta} c_{BT}^{\alpha} \exp(F\Delta_{\beta}^{\alpha}\varphi/RT). \quad (26)$$

The case where the complex BT^+ is very stable (i.e. its homogeneous dissociation constant K_{BT}^{α} is small) while the ion B^+ is only slightly soluble in the α-phase (the partition coefficient $P_{B+}^{\alpha/\beta}$ is small) is of special interest. One can then assume that, apart from the charged complex BT^+, the α-phase contains only one charged species—the counterion A^-. Using the usual procedures, it is possible to find the interphase potential difference for this case:[26]

$$\Delta_{\beta}^{\alpha}\varphi = \frac{RT}{F} \ln \left[\left\{ \left(\frac{c_{B+}^{\beta}}{2K_{B+}^{\alpha/\beta}} \right)^2 + \frac{c_{kom}^{\alpha}}{P_{A-}^{\alpha/\beta} K_{BT+}^{\alpha/\beta}} \right\}^{1/2} - \frac{c_{B+}^{\beta}}{2K_{BT+}^{\alpha/\beta}} \right]. \quad (27)$$

where c_{com}^{α} denotes the overall concentration of the complexone in the free and bound forms in the phase α and the activity coefficients are assumed to be unity for the sake of simplicity.

We shall consider two limiting cases arising from Eqn.(27). Supposing that the concentration of the A^-B^+ electrolyte is low. Then, by expanding Eqn.(27) as a series, we obtain

$$\Delta_{\beta}^{\alpha}\varphi \simeq \frac{RT}{2F} \ln \frac{c_{com}^{\alpha}}{P_{A-}^{\alpha/\beta} K_{BT+}^{\alpha/\beta}}. \quad (28)$$

Eqn.(28) can be given a more usual form by introducing the interphase partition coefficient of the ion B^+ taking into account complex formation:

$$\tilde{P}_{B+}^{\alpha/\beta} = c_{com}^{\alpha}/K_{BT+}^{\alpha/\beta}. \quad (29)$$

The expression for the interfacial potential is then

$$\Delta_{\beta}^{\alpha}\varphi = \frac{RT}{2F} \ln \frac{\tilde{P}_{B+}^{\alpha/\beta}}{P_{A-}^{\alpha/\beta}}. \quad (30)$$

This is a typical expression for the distribution potential which does not include directly the complexone concentration and the form of the relation is determined by the valences of the electrolyte. Eqn.(30) is valid for a 1:1 electrolyte. For arbitrary valences, it assumes the following form:

$$\frac{F}{RT}\Delta_{\beta}^{\alpha}\varphi = \frac{1}{z_B - z_A} \ln \frac{c_{com}^{\alpha}}{P_{A}^{\alpha/\beta} K_{BT}^{\alpha/\beta}}. \quad (31)$$

The dependence of $F\Delta_{\beta}^{\alpha}\varphi/RT$ on $\ln c_{com}^{\alpha}$ is described by a straight line whose slope is 1/2 for a 1:1 electrolyte, 1/3 for a 1:2 electrolyte, and 1/4 for a 2:2 electrolyte.[26]

We shall now proceed to another limiting case. Suppose that the electrolyte concentration is high so that the concentration of the complexone in the phase α is close to saturation. We then obtain for Eqn.(29)

$$\Delta_{\beta}^{\alpha}\varphi = \frac{RT}{F} \ln \frac{c_{com}^{\alpha}}{P_{A-}^{\alpha/\beta} c_{A-}^{\beta}}. \quad (32)$$

Fig.3 illustrates the dependence of $F\Delta_{\alpha}^{\beta}\varphi/RT$ on $\ln c_{A-}^{\beta}$, which consists of two linear sections. The slope of the second section is −1 for a univalent anion A^- or $1/z_{A-}$ in the arbitrary case. The point of intersection M (Fig.3) of the two sections yields $0.5 \ln (c_{com}^{\alpha} K_{BT+}^{\alpha/\beta}/P_{A-}^{\alpha/\beta})$, which makes it possible to determine the heterogeneous dissociation constant of the complex BT^+.

6. The Donnan Potential

The Donnan potential is the name given to the interphase potential difference when some of the ions cannot cross the interface between two immiscible electrolyte solutions while the remaining ions are free to move reversibly from one phase to the other. Suppose, for example, that an ion R with a charge number z_R has

such a high partition coefficient $P_R^{\alpha/\beta}$ that it is almost totally concentrated in the phase α. Apart from the ions R, the system contains a binary electrolyte B^+A^- whose concentration in the β-phase is c_{BA}^{β}

$$\alpha, R^{z_R}, B^+A^- \mid B^+A^-, \beta. \tag{33}$$

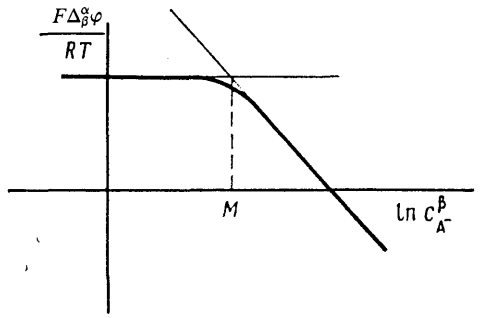


Figure 3. Dependence of the distribution potential on the electrolyte concentration in the phase β during the complex formation reaction in the phase α.

This type of equilibrium was first considered by Donnan[9] for two ideal aqueous ($\alpha \equiv \beta$) electrolyte solutions separated by a semipermeable membrane. The Donnan equilibrium was then investigated also by other workers, but the modifications which they introduced reduced in essence to the replacement in the Donnan equation of the concentrations of ions by their activities, which made it possible to change over from ideal to real solutions. Almost all investigators considered the Donnan equilibrium between two aqueous solutions. However, in the general case the phases α and β can be different and the above equilibrium can be achieved also in the absence of a semipermeable membrane.

The Donnan equilibrium at the interface between two immiscible liquids was first considered in a monograph[1] and then in another study for two ideal electrolyte solutions. Since there are inaccuracies in the study of Joos et al.,[7] we shall present the correct derivation of the Donnan equations for ideal and real immiscible electrolyte solutions in accordance with the study of Markin and Volkov.[26]

By definition, the partition coefficient of the salt is given by

$$P_{AB}^{\alpha/\beta} = a_{AB}^{\alpha}/a_{AB}^{\beta}. \tag{34}$$

Hence follows the equation relating the activities of the ion B^+ and A^- in both phases:

$$a_{B^+}^{\alpha}a_{A^-}^{\alpha} = (P_{AB}^{\alpha/\beta})^2\, a_{A^-}^{\beta}a_{B^+}^{\beta}. \tag{35}$$

From this equation and the two phase electroneutrality conditions

$$z_R c_R^{\alpha} + c_{B^+}^{\alpha} - c_{A^-}^{\alpha} = 0, \tag{36}$$

$$c_B^{\beta} - c_A^{\beta} = 0, \tag{37}$$

it is easy to find the Donnan potential:

$$\Delta_\beta^\alpha\varphi = \frac{RT}{2F}\ln\left(\frac{P_{B^+}^{\alpha/\beta}}{P_{A^-}^{\alpha/\beta}} \times \frac{\gamma_{B^+}^{\beta}\gamma_{A^-}^{\alpha}}{\gamma_{A^-}^{\beta}\gamma_{B^+}^{\alpha}}\right) + \frac{RT}{2F}\ln\left(1 + \frac{z_R^{\alpha}c_R^{\alpha}}{c_{B^+}^{\alpha}}\right). \tag{38}$$

Eqn.(38) resembles Eqn.(14) obtained by Grundwald et al.[28] but differs from it by the distribution potential of the salt defined by the first term on the right-hand side of Eqn.(38).

The Donnan potential can also be formulated as a function of the concentration of the dissolved electrolyte AB:

$$\Delta_\beta^\alpha\varphi = \frac{RT}{2F}\ln\left(\frac{P_{B^+}^{\alpha/\beta}}{P_{A^-}^{\alpha/\beta}}\frac{\gamma_{B^+}^{\beta}\gamma_{A^-}^{\alpha}}{\gamma_{A^-}^{\beta}\gamma_{B^+}^{\alpha}}\right) + \\ + \frac{RT}{F}\ln\left\{\left[1 + \left(\frac{z_R c_R^{\alpha}\gamma_{BA}^{\alpha}}{2P_{BA}^{\alpha/\beta}a_{BA}^{\beta}}\right)^2\right]^{1/2} + \frac{z_R c_R^{\alpha}\gamma_{BA}^{\alpha}}{2P_{BA}^{\alpha/\beta}a_{BA}^{\beta}}\right\}. \tag{39}$$

As can be seen from Eqns.(38) and (39), the Donnan potential is represented by a sum which includes the distribution potential and a term depending on the concentration of the ion R which does not permeate into the electrolyte. If the concentration of the ion R is low, then the second term can be assumed equal to zero and Eqns.(38) and (39) become identical with the expression for the distribution potential. The distribution of ions between phases is then determined by known expressions.

At a high concentration of the ion R, a different expression is obtained for the potential. If we put $z_R > 0$ to make the treatment concrete, we obtain

$$\Delta_\beta^\alpha\varphi = \frac{RT}{F}\ln\frac{z_R c_R^{\alpha}\gamma_{A^-}^{\alpha}}{P_{A^-}^{\alpha/\beta}a_{A^-}^{\beta}}. \tag{40}$$

In this case, the concentration of the counterions A^- in the phase α ceases to depend on the distribution coefficient and the interphase potential and approaches the limiting value

$$c_A^{\alpha} \simeq z_R c_R^{\alpha}. \tag{41}$$

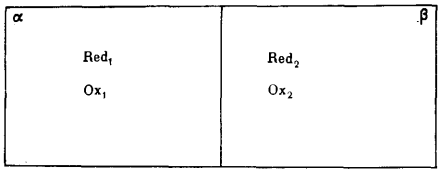
The coions B^+ are then almost fully displaced from the phase α:

$$c_{B^+}^{\alpha} = \frac{1}{z_R c_R^{\alpha}}\left(\frac{P_{BA}^{\alpha/\beta}a_{BA}^{\beta}}{\gamma_{BA}^{\alpha}}\right)^2. \tag{42}$$

7. The Nernst Potential

We shall consider the especially important special case of the Donnan potential when ions of only one type can cross the boundary. Suppose that these are the B^{z_B} ions. The type and number of other ions do not play a significant role. The interphase potential difference arising in such a system is referred to as the Nernst potential:

$$\Delta_\beta^\alpha\varphi = \Delta_\beta^\alpha\varphi_B^0 + (RT/z_BF)\ln(a_B^{\beta}/a_B^{\alpha}). \tag{43}$$



If the phases α and β are identical but are separated by a membrane permeable to the ions B^+, then $\Delta_\beta^\alpha\varphi_B^0 = 0$ and the potential difference is given by

$$\Delta_\beta^\alpha\varphi = (RT/z_BF)\ln(a_B^{\beta}/a_B^{\alpha}). \tag{44}$$

Sometimes the potential difference determined from Eqn.(43) is also referred to as the Nernst–Donnan potential, because, although historically a formula of this type was first obtained by Nernst,[27] it corresponds to a special case of the Donnan equilibrium.

8. The Oxidation-Reduction Interphase Potential

Suppose that each of the two phases, α and β, contains its own oxidation-reduction couple Red/Ox:

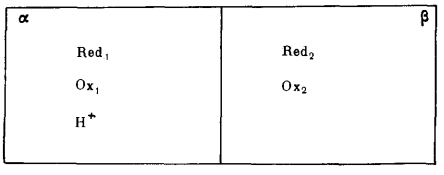
As a result of the exchange of n electrons across the interface, an oxidation-reduction reaction takes place:

$$\nu_1 \mathrm{Red}_1 + \nu_2 \mathrm{Ox}_2 \rightleftarrows \nu_3 \mathrm{Red}_2 + \nu_4 \mathrm{Ox}_1. \tag{45}$$

At equilibrium, the followig equality holds:

$$\nu_1 \bar{\mu}^{\alpha}_{\mathrm{Red}_1} + \nu_2 \bar{\mu}^{\beta}_{\mathrm{Ox}_2} = \nu_3 \bar{\mu}^{\beta}_{\mathrm{Red}_2} + \nu_4 \bar{\mu}^{2}_{\mathrm{Ox}_1}. \tag{46}$$

Hence we find the interphase oxidation-reduction potential:



$$\Delta^{\alpha}_{\beta}\varphi = \Delta^{\alpha}_{\beta}\varphi^{0}_{\mathrm{R/O}} + \frac{RT}{nF} \ln \frac{(a^{\alpha}_{\mathrm{Red}_1})^{\nu_1} (a^{\beta}_{\mathrm{Ox}_2})^{\nu_2}}{(a^{\alpha}_{\mathrm{Ox}_1})^{\nu_4} (a^{\beta}_{\mathrm{Red}_2})^{\nu_3}}. \tag{47}$$

In this case $\Delta^{\alpha}_{\beta}\varphi^{0}_{\mathrm{R/O}}$ denotes the standard interphase oxidation-reduction potential of reaction (45):

$$\Delta^{\alpha}_{\beta}\varphi^{0}_{\mathrm{R/O}} = (\nu_1 \mu^{0,\alpha}_{\mathrm{Red}_1} + \nu_2 \mu^{0,\beta}_{\mathrm{Ox}_2} - \nu_3 \mu^{0,\alpha}_{\mathrm{Ox}_1} - \nu_4 \mu^{0,\beta}_{\mathrm{Red}_2})/nF, \tag{48}$$

where n is the number of electrons transferred from Red_1 to Ox_2. In terms of its physical significance, Eqn.(48) represents the interphase potential for equal activities of the ions of the oxidised and reduced forms in each solvent. We may note that the interphase oxidation-reduction potential is defined by Eqns.(47)–(48) when reaction (45) occurs even when the oxidant or reductant in any of the redox pairs is a neutral species.

If reaction (45) is accompanied by a change in the pH in one of the phases, i.e.

and the reaction

$$\nu_1 \mathrm{Red}_1 + \nu_2 \mathrm{Ox}_2 \rightleftarrows \nu_3 \mathrm{Red}_2 + \nu_4 \mathrm{Ox}_1 + m\,\mathrm{H}^{+}_{\alpha}, \tag{49}$$

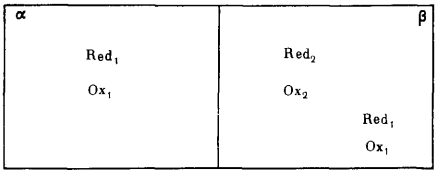
takes place, then from the condition for equilibrium

$$\nu_1 \bar{\mu}^{\alpha}_{\mathrm{Red}_1} + \nu_2 \bar{\mu}^{\beta}_{\mathrm{Ox}_2} = \nu_3 \bar{\mu}^{\beta}_{\mathrm{Red}_2} + \nu_4 \bar{\mu}^{\alpha}_{\mathrm{Ox}_1} + m \bar{\mu}^{\alpha}_{\mathrm{H}^+} \tag{50}$$

it is possible to find the interphase redox potential

$$\Delta^{\alpha}_{\beta}\varphi = \Delta^{\alpha}_{\beta}\varphi^{0}_{\mathrm{R/O}} + \frac{RT}{nF} \ln \frac{(a^{\alpha}_{\mathrm{Red}_1})^{\nu_1} (a^{\beta}_{\mathrm{Ox}_2})^{\nu_2}}{(a^{\alpha}_{\mathrm{Ox}_1})^{\nu_4} (a^{\beta}_{\mathrm{Red}_2})^{\nu_3} (a^{\alpha}_{\mathrm{H}^+})^{m}}, \tag{51}$$

where



$$\Delta^{\alpha}_{\beta}\varphi = (\nu_1 \mu^{0,\alpha}_{\mathrm{Red}_1} + \nu_2 \mu^{0,\beta}_{\mathrm{Ox}_2} - \nu_3 \mu^{0,\alpha}_{\mathrm{Ox}_1} - \nu_4 \mu^{0,\beta}_{\mathrm{Red}_2} - m\mu^{0,\alpha}_{\mathrm{H}^+})/nF. \tag{52}$$

Analysis of the influence of the interface between two liquids on the standard redox potential of an electron-exchange reaction[11-14] has shown that, by selecting the phases α and β, it is possible to displace the standard chemical potential of the oxidants and reductants in the required direction and to achieve at the interface reactions which do not occur at a sufficiently high rate in each phase.

9. The Mixed Potential

If the two immiscible liquids each contain, apart from their own redox couple also common ions or compound redox couples, then a mixed potential is established at the interface to which both the interphase oxidation-reduction potential and the distribution of the ions between the phases contribute.

There is a possibility of various combinations of electron-exchange reactions in the two-phase system. Suppose, for example, that each of the phases α and β has its own redox couple but one of the couples is soluble in both phases:

In this case electron-exchange reactions are possible both at the interface, i.e.

$$\mathrm{Red}^{\alpha}_1 + \mathrm{Ox}^{\beta}_2 \rightleftarrows \mathrm{Ox}^{\alpha}_1 + \mathrm{Red}^{\beta}_2, \tag{53}$$

and in the bulk of the phase β:

$$\mathrm{Red}^{\beta}_1 + \mathrm{Ox}^{\beta}_2 \rightleftarrows \mathrm{Ox}^{\beta}_1 + \mathrm{Red}^{\beta}_2. \tag{54}$$

It follows from the condition for equilibrium that

$$\bar{\mu}^{\beta}_{\mathrm{Red}_1} - \mu^{\alpha}_{\mathrm{Red}_1} = 0, \tag{55}$$

$$\bar{\mu}^{\beta}_{\mathrm{Ox}_1} - \bar{\mu}^{\alpha}_{\mathrm{Ox}_1} = 0, \tag{56}$$

whence

$$\Delta^{\alpha}_{\beta}\varphi = \frac{RT}{nF} \ln \frac{P^{\alpha/\beta}_{\mathrm{Ox}_1}}{P^{\alpha/\beta}_{\mathrm{Red}_1}} + \frac{RT}{nF} \ln \frac{a^{\alpha}_{\mathrm{Red}_1} a^{\beta}_{\mathrm{Ox}_1}}{a^{\beta}_{\mathrm{Red}_1} a^{\alpha}_{\mathrm{Ox}_1}}. \tag{57}$$

The standard potential for reaction (53) is defined by the expression

$$\Delta^{\alpha}_{\beta}\varphi^{0}_{\mathrm{R/O}} = (RT/nF) \ln (P^{\alpha/\beta}_{\mathrm{Ox}_1}/P^{\alpha/\beta}_{\mathrm{Red}_1}). \tag{58}$$

Eqn.(57) is identical with Eqn.(14) for the partition potential only in the case of a two-electron reaction subject to the condition that $z_{\mathrm{Red}_1} = -1$, $z_{\mathrm{Ox}_1} = +1$, and $a^{\beta}_{\mathrm{Red}_1} a^{\alpha}_{\mathrm{Ox}_1} / a^{\alpha}_{\mathrm{Red}_1} a^{\beta}_{\mathrm{Ox}_1} = 1$. The last requirement, concerning the ratio of the concentrations of the redox couple, is artificial in character and may hold only at one point for definite fixed activites of all the ingredients. It does not follow from the phase electroneutrality condition because, apart from the redox couples, there are also other ions in both phases.

Eqn.(57) does not include the second redox couple $\mathrm{Red}_2/\mathrm{Ox}_2$ but the latter does enter implicitly into the second term on the right-hand side of this equation. The second redox couple is forced to become automatically adjusted with respect to the first because, apart from Eqns.(55) and (56), a further two equations, determined by the equilibrium in the system, also hold:

$$\bar{\mu}^{\alpha}_{\mathrm{Red}_1} + \bar{\mu}^{\beta}_{\mathrm{Ox}_2} = \bar{\mu}^{\alpha}_{\mathrm{Ox}_1} + \bar{\mu}^{\alpha}_{\mathrm{Red}_2}, \tag{59}$$

$$\bar{\mu}^{\beta}_{\mathrm{Red}_1} + \bar{\mu}^{\beta}_{\mathrm{Ox}_2} = \bar{\mu}^{\beta}_{\mathrm{Ox}_1} + \bar{\mu}^{\beta}_{\mathrm{Red}_2}. \tag{60}$$

The introduction of a common electrolyte $B_p A_t$ into both phases is not reflected in the form of Eqn.(57) but, by virtue of the electroneutrality of both phases, i.e.

$$\sum_i z_i^{\alpha} c_i^{\alpha} = 0, \quad \sum_j z_j^{\beta} c_j^{\beta} = 0$$

the distribution of the concentrations of the redox components in each phase changes, which makes a considerable contribution to the second term on the right-hand side of Eqn.(57).

The majority of the redox reactions occurring on the liquid water–oil and water–biomembrane interfaces are accompanied by changes in pH, for example:

$$\mathrm{NADH} \rightleftarrows \mathrm{NAD}^+ + 2e^- + \mathrm{H}^+. \tag{61}$$

We shall consider a system of two immiscible liquids α and β:

α	β
Red_1	Red_2
Ox_1	Ox_2
	H^+
	Red_1
	Ox_1

Suppose that each phase has its own redox couple and that one of them is common to both phases:

$$\mathrm{Red}_1^{\alpha} + \mathrm{Ox}_2^{\beta} \rightleftarrows \mathrm{Ox}_1^{\alpha} + \mathrm{Red}_2^{\beta} + m\mathrm{H}^+_{\beta},$$

$$\mathrm{Red}_1^{\beta} + \mathrm{Ox}_2^{\beta} \rightleftarrows \mathrm{Ox}_1^{\alpha} + \mathrm{Red}_2^{\beta} + m\mathrm{H}^+_{\beta}, \tag{62}$$

If n electrons are transferred from Red_1 to Ox_2 in the course of the reactions then, when $m \neq n$, we obtain from the equilibrium condition an expression for the mixed potential:

$$\Delta^{\alpha}_{\beta}\varphi = \Delta^{\alpha}_{\beta}\varphi^0_{\mathrm{R/O}} - \frac{RT}{(n-m)F} \ln \frac{a^{\beta}_{\mathrm{Red}_1} a^{\alpha}_{\mathrm{Ox}_1}}{a^{\alpha}_{\mathrm{Red}_1} a^{\beta}_{\mathrm{Ox}_1}}, \tag{63}$$

in which the standard potential is defined by the formula

$$\Delta^{\alpha}_{\beta}\varphi^0_{\mathrm{R/O}} = \frac{RT}{(n-m)F} \ln \frac{P^{\alpha/\beta}_{\mathrm{Ox}_1}}{P^{\alpha/\beta}_{\mathrm{Red}_1}}. \tag{64}$$

From the condition for thermodynamic equilibrium and the electroneutrality of phases for reaction (61), one can write $4+2=6$ equations for the two redox couples, which exceeds the number of independent variables in the system. If a proton equilibrium is established during reaction (61) between the phases α and β, then the mixed potential can be formulated as follows:[26]

$$\Delta^{\alpha}_{\beta}\varphi = \Delta^{\alpha}_{\beta}\varphi^0_{\mathrm{R/O}} - \frac{RT}{nF} \ln \frac{a^{\beta}_{\mathrm{Red}_1} a^{\alpha}_{\mathrm{Ox}_1}}{a^{\alpha}_{\mathrm{Red}_1} a^{\beta}_{\mathrm{Ox}_1}} + \frac{2{,}3RT}{nF} \Delta^{\alpha}_{\beta}\mathrm{pH}, \tag{65}$$

where

$$\Delta^{\alpha}_{\beta}\varphi^0_{\mathrm{R/O}} = -\frac{RT}{nF} \ln \frac{P^{\alpha/\beta}_{\mathrm{Red}_1}}{P^{\alpha/\beta}_{\mathrm{Ox}_1} P^{\alpha/\beta}_{\mathrm{H}^+}}. \tag{66}$$

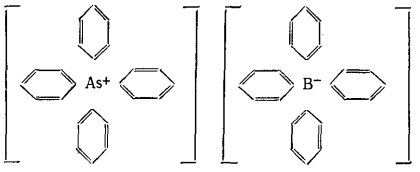
IV. MEASUREMENTS OF INTERPHASE POTENTIAL JUMPS

1. The Tetraphenylborate Hypothesis

It is known from thermodynamics that the absolute difference between electrical potentials can be measured only in conductors of identical composition. For this reason, the difference between the Galvani potentials between a point in an aqueous phase and a point in the bulk of an organic solvent is not susceptible to experimental measurement.

For the determination of the difference between Galvani potentials and surface potential jumps, it is necessary to resort to additional non-thermodynamic hypotheses. It is comparatively easy to measure the relative change in the phase boundary potential difference when the type of dissolved salt is altered, for example, when one of the ions in the salt is changed. One can then measure the partition coefficient of each salt $P^{\alpha/\beta}_{\mathrm{salt}}$. With the aid of Eqn.(5), the phase boundary potential can be expressed in the form

$$\Delta^{\alpha}_{\beta}\varphi = \Delta^{\alpha}_{\beta}\varphi_i - \frac{RT}{z_i F} \ln P^{\alpha/\beta}_{\mathrm{salt}} \tag{67}$$



Thus it is possible to set up a scale of the changes in the potentials when one of the ions is altered, but this scale will include the unknown constant term $\Delta^{\alpha}_{\beta}\varphi^0_i$—the standard partition coefficient of the unchanged ion. The problem reduces to the correct selection of the zero on this scale.

The zero cannot be chosen by thermodynamic methods and requires the invocation of additional hypotheses. The most popular tetraphenylborate hypothesis was formulated in 1960 [28] and then developed in other studies.[29–42] The history of its development has been described in a review.[43]

The essential feature of the tetraphenylborate hypothesis is as follows. If one selects a cation and an anion with identical standard energies of transfer between two solvents, then the interphase distribution potential for such a salt is found to be zero. In this case the partition coefficients of the ions are equal to the partition coefficient of a salt, which can be readily determined experimentally. Having determined it, we find the standard free energy of the transfer and the standard distribution potentials of the individual ions. As can be readily seen, these potentials are identical in absolute magnitude and opposite in sign:

$$\Delta^{\alpha}_{\beta}\varphi^0_{+} = -\Delta^{\alpha}_{\beta}\varphi^0_{-}. \tag{68}$$

It now remains only to select the suitable ions. Preference has been given to different ions in different investigations. For example, Koczorowski[3] used tetraethylammonium picrate $(Et)_4NPi$. In other studies[28–43], preference was given to tetraphenylarsonium tetraphenylborate (TPATPB). The constituent ions of this salt TPB^- and TPA^+, i.e.

are similar, firstly, because they are symmetrical species whose shapes approach those of spheres having identical and fairly large radii, which permits the assumption that the hydrophobic effect is the same for both and, secondly, their charges are equal in absolute magnitude and are located in centres of ionic spheres and are shielded from the solvent, so that the electrostatic contribution to the free energy of transolvation of these ions should be the same. The ions have a comparatively low polarisability and a low surface charge density and hardly enter into specific interactions with the solvent molecules. All these factors permit the hope that the standard energies of the transfer of such ions will be the same for any pair of solvents.

With the aid of the tetraphenylborate hypothesis, it is possible to determine the standard distribution potentials by methods such as cyclic voltammetry, chronopotentiometry, polarography at a dropping electrolyte electrode, chronoammetry, and also solubility and extraction data.[31,35,37,38,40–42,44,45]

Fig.4 illustrates a typical cyclic voltammogram obtained at a scanning rate of 25 mV s^{-1} in the water–nitrobenzene (NB) system containing 10 mM TPATPB in the non-aqueous phase and 10 mM Li_2SO_4 in water.[53] The range of applied potential differences is limited in the negative region by the potential of the transfer of TPA^+ from nitrobenzene to water and in the positive region by the potential of the transfer of TPB^-. Since

$$\Delta^{H_2O}_{NB}\varphi^0_{TPB^-} = -\Delta^{H_2O}_{NB}\varphi^0_{TPA^+},$$

it is possible to select the starting point for the readings on the potential scale and to change over, as in Fig.4, from the applied potential difference scale to the Galvani potential scale or the distribution potential scale.

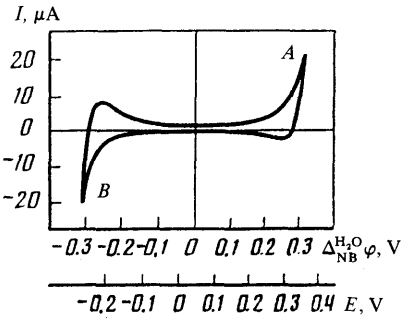


Figure 4. Cyclic voltammetric curve for the water–nitrobenzene system in the presence of TPATPB in nitrobenzene and of Li_2SO_4 in water. Peaks *A* and *B* are due to the transfer of TPA^+ and TPB^- from nitrobenzene to water respectively. The experimental curve has been taken from Hundhammer and Solomon.[31]

The block diagram of the apparatus, on which it is possible to determine the distribution potentials of ions and to investigate the electrochemical properties of the interface between two immiscible

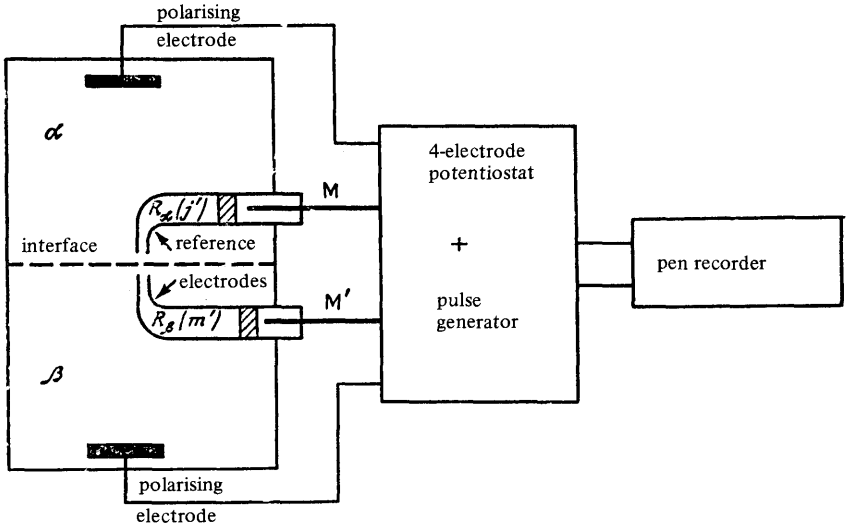

Figure 5. Diagram of the four-electrode apparatus for the measurement of the electrochemical characteristics of the interface between two immiscible electrolyte solutions.

liquids, is illustrated in Fig.5 and the cell and the electrical circuit are presented in Fig.6. The standard distribution potential of an ion depends both on the nature of the solvent (primarily on the optical and static dielectric constant) and on the ionic radius.

Fig.7 presents the dependence of the distribution potentials of ions on their radii for the water–nitrobenzene, water–1,2-dichloroethane, and water–dichloromethane systems plotted on the basis of a series of data[35,37,38,40–42,44–54] and published in a review.[56] The radii of inorganic ions were taken from Gourary and Adrian[57] and those of tetra-alkylammonium salts were taken from Robinson and Stokes.[58]

Figs.7 and 8 show that the distribution potential of an ion decreases sharply with increase in the size of the ion and in the dielectric constant of the non-aqueous solvent. The continuous line in Figs.7*a* and 7*b* represents the theoretical calculation with the aid of non-local electrostatic theory.[13,14] For ions with radii less than 0.3 nm, the main contribution to $\Delta_{\beta}^{\alpha}\varphi_i^0$ comes from the electrostatic component of the free energy of transolvation, while for ions with a radius greater than 0.3 nm the contribution of the solvophobic effect is greatest.[13,14]

2. Methods for the Measurement of the Interphase Potential Difference

The difference between the Volta potentials and the change in the surface or Galvanic potential in a system of two immiscible electrolyte solutions can be measured by the dynamic condenser, radioactive probe, and streaming electrode methods and also with the aid of concentration cells.

The dynamic condenser method, proposed by Kelvin, was subsequently developed in detail in other studies.[59,60] All the experimental methods for the measurement of Volta potentials between the phases α and β are based on the compensation method, which involves the application of a potential difference equal in absolute magnitude but opposite in sign to the Volta potential between the phases α and β.[59–86]

Two types of sensors are normally employed for the periodic measurement of the capacitance of the condenser formed by the surface of the electrode and the interface investigated, namely vibrating and rotating electrodes. The vibrating electrode is less complex than the rotating electrode but its stability is lower.

The block diagram of the apparatus for the measurement of the Volta potential by the dynamic condenser method is presented in Fig.9.[61] The generator of mechanical vibrations causes the vibration of a gold electrode placed at a distance of 0.2–1.0 mm from the surface of the liquid phase investigated. The aqueous solution is connected via a salt bridge filled with a saturated KCl solution (to eliminate the diffusion potential) to a reversible reference electrode. The displacement current arising in the vibration of the gold electrode is compensated by applying to the vibrating electrode a potential equal in magnitude but opposite in sign to the measured Volta potential. The equivalent electrical circuit for the method[62] is presented in Fig.10.

The Volta potential $\Delta\psi$ at the boundary between two immiscible equilibrated (mutually saturated) solutions of electrolytes B^+A^- can be determined experimentally as the compensation potential E_1 in the cell

$$\begin{matrix} M\,|\text{water},\, B^+A^-|\text{gas}|\text{Nitrobenzene},|M. \\ \qquad\qquad\quad B^+A^- \end{matrix} \qquad (I)$$

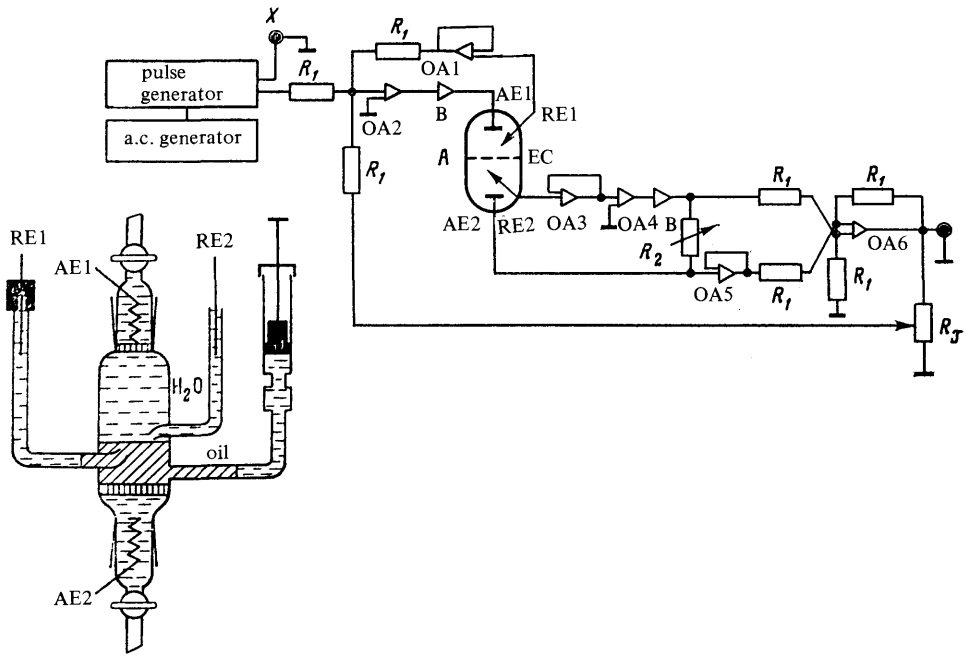

Figure 6. The cell and the electrical circuit of the apparatus for the measurement of the electrochemical properties of the interface between two immiscible electrolyte solutions; EC—electrochemical cell; OA—operational amplifier; AE—auxiliary electrode; RE—reference electrode; A—oil–water interface.[46]

The term gas implies a chemically inert gas phase, i.e. nitrogen, argon, or pure air, M is a metallic electrode, and B^+A^- is the electrolyte.

The Volta potential can be measured by the vibrating electrode method as the difference between the e.m.f.'s E_{II} and E_{III} of cells (II) and (III):

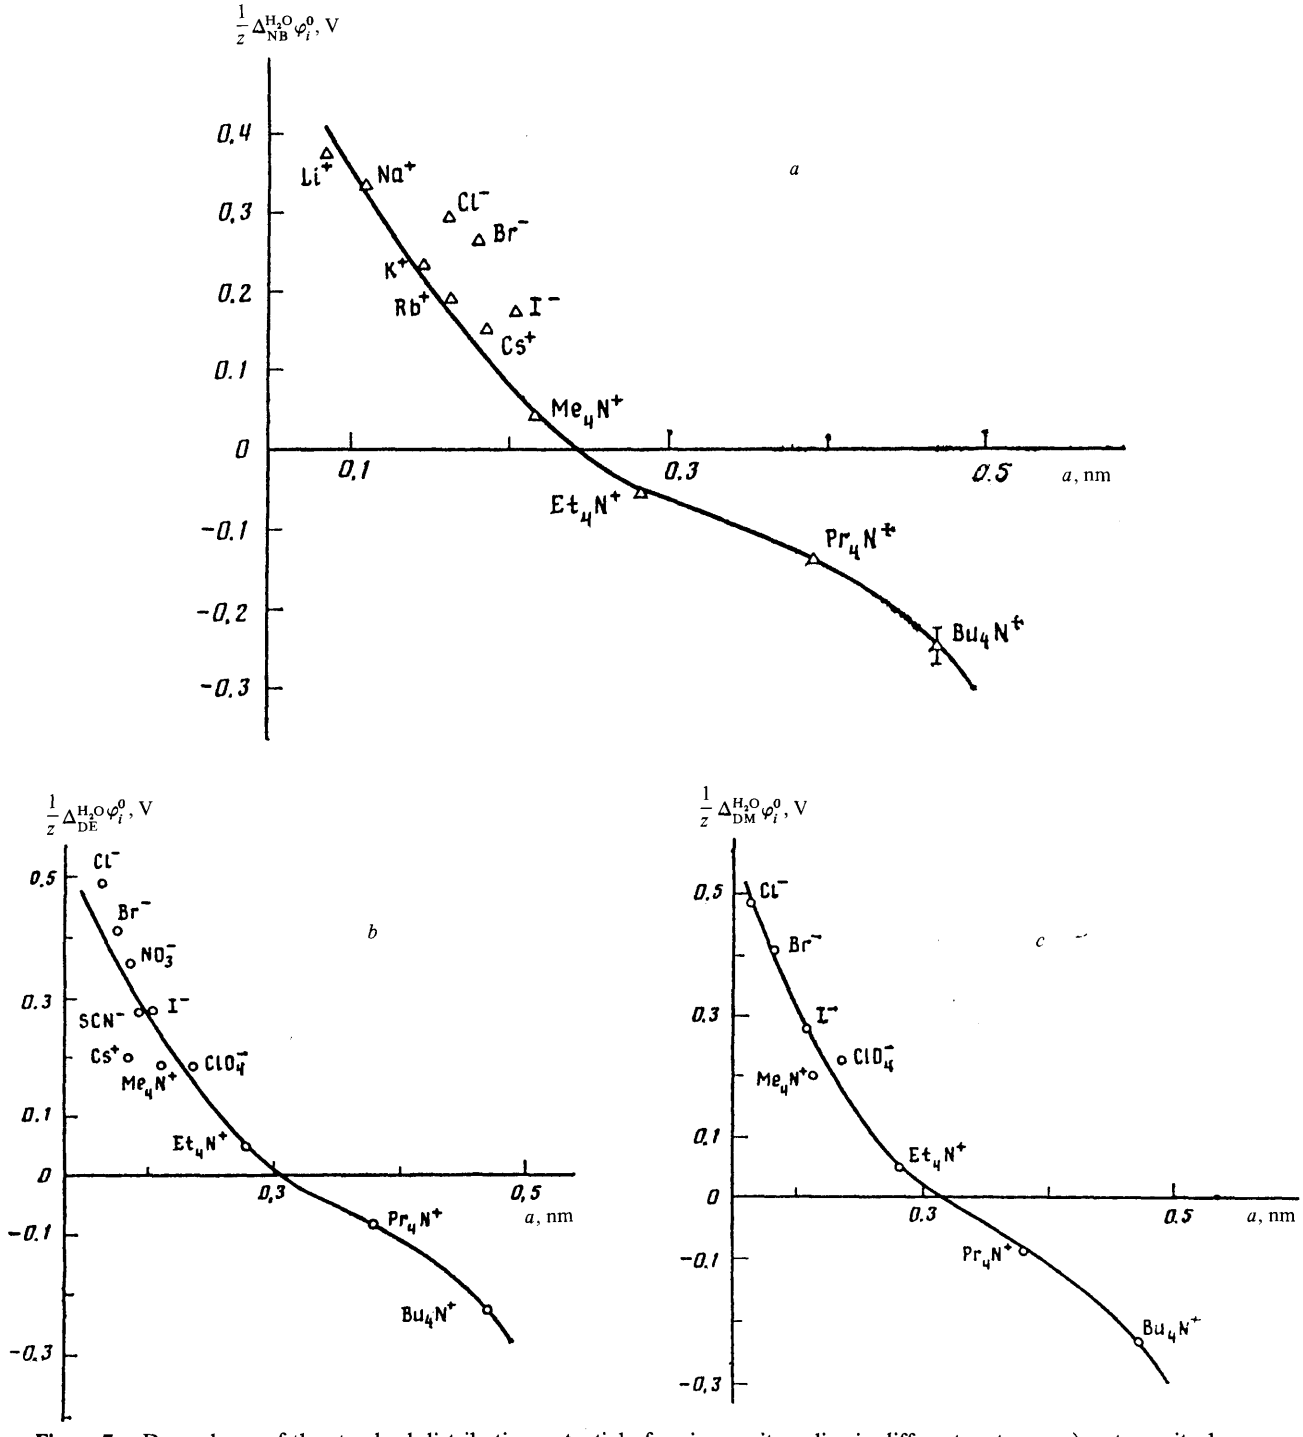

Figure 7. Dependence of the standard distribution potential of an ion on its radius in different systems: *a*) water–nitrobenzene; *b*) water–1,2-dichloroethane (DE); *c*) water–dichloromethane (DM). The experimental data have been taken from a review.[56]

$$M\,|\,\text{vibrating electrode}\,|\,N_2\,|\,\text{nitrobenzene } B^+A^-\,|\,\text{water, } B^+A^-\,|\,\text{saturated calomel electrode}\,|\,M, \quad \text{(II)}$$

$$M\,|\,\text{vibrating electrode}\,|\,N_2\,|\,\text{water, } B^+A^-\,|\,\text{saturated calomel electrode}\,|\,M. \quad \text{(III)}$$

In other words, the relation

$$\Delta^{H_2O}_{org}\psi(MX) = E_I = E_{II} - E_{III}, \quad (69)$$

holds, provided that the following conditions are fulfilled: (a) the constancy of the surface potential of the vibrating electrode: (b) the constancy of the surface potential of the water-saturated nitrobenzene phase; (c) the constancy of the surface potential of the nitrobenzene-saturated aqueous phase; (d) the stability of the calomel electrode and a constant and identical contribution of the diffusion potential between the aqueous phase and the solution in the calomel electrode.

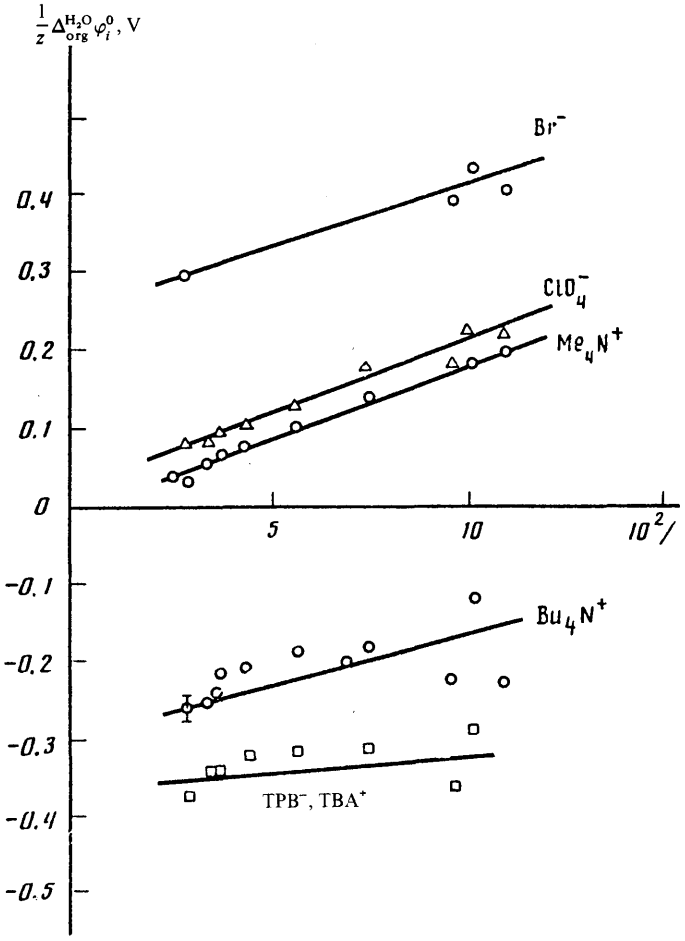

Figure 8. Dependence of the standard distribution potential of the ion on the static dielectric constant ε of the non-aqueous solvent. The experimental data were taken from a review.[56]

The design of the rotating electrode has been described by Dudko[64] and by Freyer and Ohlenbusch.[65] The equivalent circuit is presented in Fig.11. The rotating electrode is placed over a circular cell in such a way that the geometrical centre of the circle which it describes during its rotation coincides with the geometrical centre of the cell. The cell, divided by a partition into identical sections, is filled with the test liquids.

The essential feature of the radioactive probe method is the reduction of the resistance of the air gap between the electrode and the surface of the test liquid when it is bombarded with α-particles from a radioactive source.[66,67] As a result of ionisation, the gap becomes electrically conducting due to the appearance of charged particles. The ^{210}Po, ^{241}Am, and ^{239}Pu isotopes are normally employed.[68,72,73] The ^{241}Am isotope has an advantage over ^{210}Po because of its longer half-life (458 years instead of 138.4 hours); furthermore, ^{241}Am can be used in the form of a foil which has a large surface area and can readily be insulated.[73] The accuracy and reproducibility of the results in the radioactive probe method is lower than in the vibrating electrode method. The equivalent circuit of the method is presented in Fig.12.

An obligatory condition in the measurement of the Volta potential by the radioactive probe method is careful shielding of the measuring chamber and of the electrometer input. An unduly large gap between the electrode and the surface of the solution of the test electrolyte is frequently a source of errors in the measurement of the potential difference as a result of scattering of the radiation and parasitic leakages. If the gap is too small, incorrect values are also obtained owing to the interaction of α-particles with the molecules of the test liquid. The design of the apparatuses whose operation is based on the radioactive probe method and the experimental technique have been described in detail.[69]

In the streaming electrode method,[70,71] a stream of the test liquid flows downwards along the axis of a tube whose inner surface is coated with a down-flowing film of another liquid (Fig.13). The reversible reference electrodes placed in the solutions are connected to the measuring system consisting of a potentiometer and a null instrument with a very large internal resistance. At the instant of compensation, the external potential of this stream is equal to the external potential of the solution flowing along the inner walls of the cylinder. This method is rarely used to investigate the interface between two immiscible electrolyte solutions.[71,73]

All three methods yield identical results in the determination of the Volta potentials of electrolyte solutions.[74-76]

3. The Adsorption Potential

The term adsorption potential is given to the interphase difference between Galvani potentials due to the adsorption of ions or dipoles at the interface.

The problem of the appearance of the adsorption potential, despite its apparent simplicity, has been the subject of a prolonged controversy.[2,4,25,80-86] If two immiscible liquids, α and β, are in equilibrium, the interphase potential difference arises in a transition adsorption layer between them. Formally, it is possible to calculate the electrolyte distribution potential knowning only the solvation energies of the ions in each phase without paying attention to the properties of the interfacial adsorption layer. However, at equilibrium, the properties of the ions in the adsorption layer are unambiguously related to the properties of the ions in the bulk of each of the

phases in contact. The distribution potentials can therefore be calculated in two ways—from the bulk-phase properties of the solvents α and β and from the properties of the adsorption layer.[4]

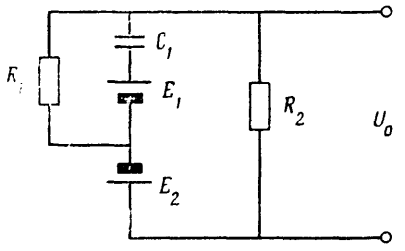

Figure 10. Equivalent electric circuit of the vibrating electrode: R_1—leakage resistance between the electrodes; C_1—capacitance of the vibrating electrode; E_1—potential difference between the vibrating electrode and the surface investigated; E_2—e.m.f. of the source of compensating potential; R_2—resistance in the compensation circuit.

At the beginning of this century, Beutner[87,88] showed that the formal thermodynamic theory of the distribution of ions is sufficient for the determination of the potential difference between two immiscible electrolyte solutions and that no additional hypotheses need be introduced into it.[87,88] However, these views have been criticised.[89,90] Some workers[89,91,92] regarded the adsorption potential as being superimposed on the partition potential jump, while others[2,4,93] assumed that the adsorption potential jump is part of the partition potential.

The partition potential is a purely thermodynamic concept. The calculation of the adsorption potential is outside the framework of thermodynamics. Definite structural ideas are used in it. Nevertheless, both approaches lead to identical results if the hypothesis concerning the structure of the adsorption layer corresponds accurately enough to the real picture. To some extent the adsorption approach appears to be more general: if ionic equilibrium at the interface has been disturbed as a result of the blocking of the interface by a surfactant or if the non-aqueous solvent is non-polar (octane, decane, and heptane), then the theory of distribution potentials cannot be applied to such systems, while adsorption analysis makes it possible to describe them with fair accuracy.[4,68,72,82]

V. TEST OF THE THERMODYNAMIC THEORY OF INTERPHASE POTENTIALS

The following cell has been proposed for the measurement of interfacial potentials:[25]

$$\begin{array}{l}\mathrm{Hg, Hg_2Cl_2}\,|\,\mathrm{H_2O, KCl}\,|\,\mathrm{H_2O, M^+X^-}\,|\,\text{diisopropyl ketone or nitrobenzene, } \mathrm{M^+X^-}\,|\,\text{diisopropyl ketone, } (\mathrm{Et})_4\mathrm{NPi}\,|\,\mathrm{H_2O, Et_4N^+, Pi^-}\,|\,\mathrm{Hg_2Cl_2, Hg;}\end{array} \quad \text{(IV)}$$

$$\Delta^{H_2O}_{RE_1}\varphi = \text{const}\ \Delta^{H_2O}_{H_2O}\varphi \simeq 0\ \Delta^{org}_{H_2O}\varphi_{M^+X^-}\ \Delta^{org}_{org}\varphi = \text{const}\ \Delta^{H_2O}_{org}\varphi_{Et_4NPi} = \text{const}\ \Delta^{RE_2}_{H_2O}\varphi = \text{const}$$

where M^+X^- is the salt investigated, distributed between the two solvents, the distribution corresponding to equilibrium, and RE is the reference electrode. If it is supposed that the diffusion potentials $\Delta^{H_2O}_{H_2O}\varphi$ and $\Delta^{org}_{org}\varphi$ are zero while the distribution potential $\Delta^{H_2O}_{org}\varphi_{Et_4NPi}$ = const., then, by replacing the M^+ or X^- ions by others, it is possible to determine the change in the distribution potential $\Delta^{M_1}_{M_2}\Delta^{org}_{H_2O}\varphi_{MX}$ on passing from one salt (M_1X) to the other (M_2X):

$$\Delta^{M_1}_{M_2}\Delta^{org}_{H_2O}\varphi_{MX} = \frac{RT}{F}\ln\frac{P^{org/H_2O}_{M_1X}}{P^{org/H_2O}_{M_2X}} = \frac{RT}{2F}\ln\frac{P^{org/H_2O}_{M_1}}{P^{org/H_2O}_{M_2}} \quad (70)$$

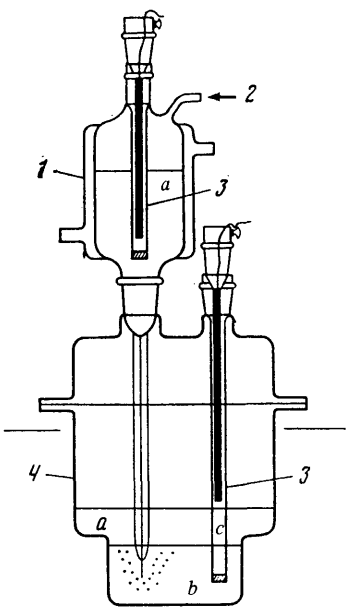

Figure 13. Diagram of apparatus for the measurement of the potential difference at the interface between two immiscible electrolyte solutions by the flow method: *a*) aqueous solution; *b*) oil; *c*) aqueous salt bridge; *1*) water reservoir; *2*) inlet for an inert gas; *3*) reference electrode; *4*) vessel for the streaming electrode.

Eqn.(70) has been tested experimentally for the water–isopropyl ketone,[25] water–acetonitrile, water–quinoline,[86] and water–nitrobenzene[68,81,85] systems.

It has also been suggested that $\Delta^{M_1}_{M_2}\Delta^{org}_{H_2O}\varphi_{MX}$ be measured in the cell[81]

$$\begin{array}{l}\text{Au, vibrating electrode}\,|\,\text{gas}\,|\,\text{nitrobenzene, } \mathrm{M^+X^-}\,|\,\text{water, } \mathrm{M^+X^-}\,|\,\text{water, sat.KCl}\,|\,\mathrm{Hg_2Cl_2, Hg;}\end{array} \quad \text{(V)}$$

$$\Delta^{gas}_{Au}\varphi = \text{const}\ \ \Delta^{org}_{gas}\chi = \text{const}\ \ \Delta^{H_2O}_{org}\varphi\ \ \Delta^{H_2O}_{H_2O}\varphi_{dif} = 0\ \ \ \Delta^{RE}_{H_2O}\varphi = \text{const.}$$

The potential measured in cell (V) is the sum of the potential jumps at all the interfaces. When M_1X is replaced by M_2X in cell (V), it is possible to obtain $\Delta^{M_1}_{M_2}\Delta^{org}_{H_2O}\varphi_{MX}$ as the difference between the potentials of cell (V) in the presence of M_1X and M_2X. The methods of measurement and calculation have been described in detail elsewhere.[81]

Li^+/K^+	Br^-, I^-	−78	—	—	−73
Cl^-/I^-	K^+, Na^+, Et_4N^+, But_4N^+	+98	+102	+100. +92	+95
Br^+/I^-	Li^+, Na^+, K^+, But_4N^+	+79	—	+70. +75	+77
Cl^-/NO_3^-	K^+	+70	—	—	—
Cs^+/K^+	Cl^-	+40	—	—	—
K^+/NH_4^+	I^-	+30	—	—	—
Et_4N^+/K^+	I^-, Cl^-	+128	+126	+120	+124
Me_4N^+/K^+	—	—	—	+65	—

The results of the test of the thermodynamic theory of distribution potentials are presented in Table 2, where it is evident that the experimental changes in the distribution potential of the salt following the replacement of one of the ions agree satisfactorily with the result of the calculation from the partition coefficient of the salt by Eqn.(70).

---o0o---

The interest in the processes occuring at the interface between two immiscible liquids is associated with the fact that we live in essence in a multiphase world. Almost all energy-transforming processes in living systems (respiration, photosynthesis) take place at the interface between two liquid phases.

It may be hoped that the role of the boundary potentials and of the spatial charge separation on the surfaces of biomembranes and their models in bioenergetic mechanisms of respiration, artificial and natural photosynthesis, and the coupling of biochemical reactions will be elucidated in the next few years.

Contemporary Ideas About the Conformations of Eight-membered Cyclic Systems with Planar Fragments

R.P.Arshinova

The results of conformational studies on eight-membered cyclic compounds that contain from one to four planar fragments in exo- or endo-cyclic positions of the molecule have been correlated. By analysing the systematic changes in the torsion angles and folding parameters, which were selected as the main quantitative criteria of the conformational state of the class of compounds being examined, it is possible to present a sufficiently complete and consistent picture of their conformational behaviour, which has a diversity that is determined by the relative configuration and nature of both the planar fragments and the heteroatoms contained in the ring. Special consideration has been given to the basis for the NMR spectroscopic criteria used in identification of the respective conformations.
The bibliography includes 230 references.

I. INTRODUCTION

Molecular carbocyclic and heterocyclic systems that are made up of so-called medium rings containing from 7 to 12 atoms in the ring exhibit many specific properties in comparison with well-studied six-membered rings. During the last ten years there has been a substantial increase in the number of published works devoted to eight-membered cyclic systems, among which rings that contain a planar group of atoms with unsaturated bonds (a carbon group, double bond, aromatic ring) constitute a distinctive group of compounds. They can form the basis for the construction of a variety of systems containing from one to four planar fragments in different positions of the eight-membered ring. The design possibilities are increased with the introduction of different heteroatoms into the ring. Inorganic heterocycles made up of a combination of different heteroatoms have been synthesised as well as mixed molecular systems containing heteroatoms and organic aromatic rings (phenyl and naphthyl) as planar fragments.

The extensive synthetic possibilities have also stimulated interest in the stereochemistry of such systems. The development of conformational studies in this field has occurred irregularly. The elaboration of methods of calculation in molecular mechanics made it possible for the basic principles of the conformational analysis of cyclooctenes and cyclooctadienes to be developed as far back as 1968–1973.[1,2] However, the rules developed for carbocyclic systems did not prove to be very suitable for their heterocyclic analogues, since the points on the potential energy surface which are saddle-shaped for the former are often transformed to global minima for the latter. In order to develop the conformational analysis of heterocyclic systems as a whole, the creation of tests and quantitative criteria for the identification of possible conformers was required. Their development was completed in the 1970's mainly on six-membered rings; the progress achieved was reflected in a number of monographs and reviews.[3-7] However, they also proved inadequate for conversion to eight-membered systems because of the greater conformational mobility and flexibility of the latter and also due to the absence of quantitative selection criteria (and in a number of cases even because of the nomenclature system of the respective conformers).

The basic study of Cremer and Pople[8] concerning the quantitative representation of the conformations of cyclic compounds was published in 1975, and in 1981 these concepts were developed for eight-membered rings,[9-11] which stimulated an increase in the number of published works on eight-membered rings. At the present time it has become necessary to interpret the accumulated material on carbocycles and heterocycles within the framework of a single system of nomenclature and a single approach based on the quantitative representation of conformers.

In this review the main focus of attention has been directed to examining the conformational features of eight-membered heterocyclic compounds. We considered it practicable to introduce into the text of the review information on a number of recently synthesised compounds of this type that have not yet been studied in relation to their conformation and were not included in a recent review.[12] The most fundamental and well verified information is reported for carbocycles. The torsion angles about the cyclic bonds and the folding parameters[7,10,15] have been selected as quantitative criteria in discussing the conformational state of the molecules examined. This together with the standardised nomenclature proposed previously for cyclooctane[13,14] and used by us make it possible to build up a unified pattern of conformational behaviour of eight-membered carbocycles and heterocycles which are so diverse in the conformational sense. The basic conformations and their nomenclature for each series of compounds is given in the respective Sections. The effect of the successive introduction of one, two, three, or four planar fragments into a ring is also examined, and for two average cases the effect of the relative configuration of the planar fragments on the conformation of the compounds is also discussed.

II. EIGHT-MEMBERED RINGS WITH A SINGLE PLANAR FRAGMENT

1. General Concepts of the Conformations of Cyclooctane Systems

In examining the conformations of eight-membered rings with planar fragments we have primarily used the nomenclature systems introduced for cyclooctane itself[13,14] as a basis. An eight-membered ring can adopt ten conformations, which constitute four groups (Fig.1): (a) the boat-chair (BC) group which is simply boat-chair (BC) and skewed or twist-boat-chair (TBC); (b) the crown group which is crown, chair-chair (CC), and skewed or twist-chair-chair (TCC); (c) the boat group which is boat-boat (BB), twist-boat (TB), and boat (B); (d) the chair group which is long chair (LC) and twist-chair (TC). For each conformation, Fig.1 indicates the sequence of torsion angles in the ring (namely, the angles between the planes formed by three neighbouring atoms of the ring: angle φ_1 corresponds to the angle along the C(1)–C(2) bond between the planes containing the atoms in positions 8, 1, 2 and 1, 2, 3; angle φ_2 is the angle between the planes containing the atoms in positions 1, 2, 3 and 2, 3, 4; etc.). The line in Fig.1 corresponds to the symmetry element (axis or plane), ± are the signs for the torsion angle values.

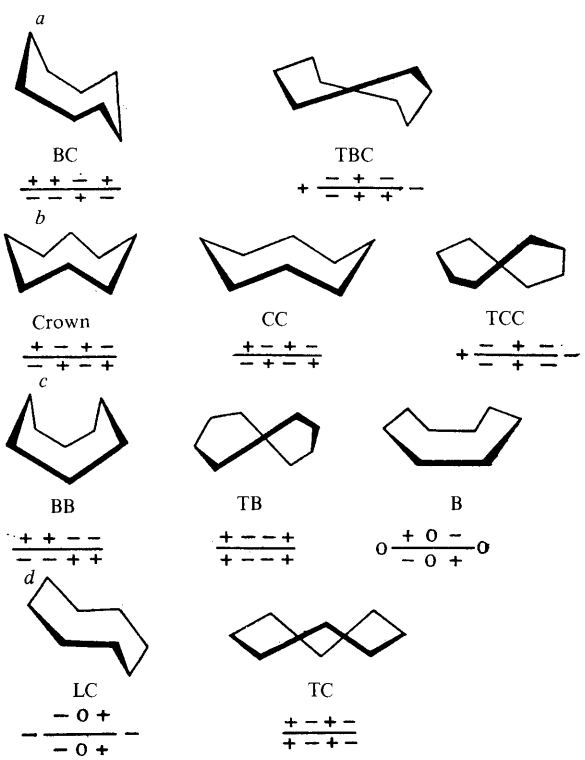

Figure 1. The possible conformations of cyclooctane.[13,14]

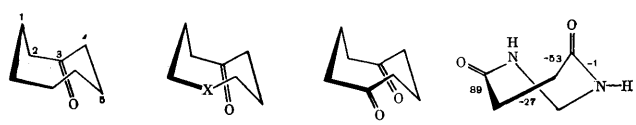
In addition to the chemical numbering of the atoms, differentiation of the conformational system has also been proposed for eight-membered rings. This is due to the existence of nonidentical positions in each conformation, which is caused by the unequal distribution of interactions between the chemically nonbonded atoms. For example, when a heteroatom or carbonyl group (which can be labelled X) is introduced, several forms of BC conformation can be distinguished: BC-1, BC-2, ... BC-8. For heterocycles with a single X, conformations BC-2, BC-3, and BC-4 are enantiomeric to conformations BC-8, BC-7, and BC-6 respectively (in the literature isomers with a mirror plane of reflection are indicated by an asterisk—BC and BC*).

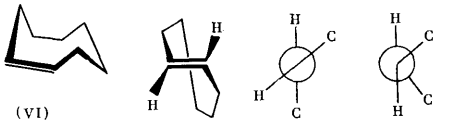


Enantiomeric conformers, like the normal ones, undergo conformational changes as a result of pseudorotation processes (with a partial change in the signs and values of the torsion angles) or inversion (with a partial or complete change in the signs of these angles).[2,14] Sometimes in dynamic NMR spectra it is possible to observe the "freezing-out" of several conformational processes.

The BC form is the preferred conformation of cyclooctane.[2,13,14] Introduction of planar fragments into the *exo* and *endo* positions of the cyclooctane ring affects in different ways the stabilisation of the atoms of the ring in one plane. For *exo* positions (as, for example, in the case of cyclooctanone), as in the saturated rings, three atoms remain in one plane, but in the process the geometrical parameters and torsional configuration about the adjacent bonds change. For *endo* positions, four atoms lie in one plane and one torsion angle is equal to zero. This naturally can assist the stabilisation of conformations with zero torsion angles, as in the B form, especially if two or four planar fragments are introduced into the ring. However, in practice this seemingly indisputable assumption does not always hold. Up to now it remains unclear how the occurrence of planar fragments affects the conformation of eight-membered rings.

2. Mono- and Di-ketones

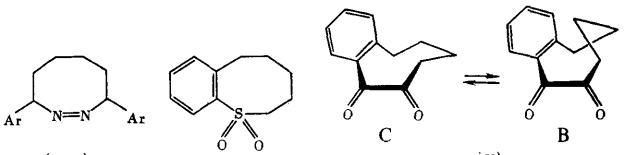
The simplest example of an eight-membered ring with a single planar fragment is cyclooctanone (I), since the carbonyl group in the molecule can be regarded as a planar fragment that introduces a double bond into the exocyclic position of the molecule. According to the calculations (here and subsequently if a method of calculation is not indicated, conformational energy calculations carried out by means of molecular mechanics are implied) and analysis of the temperature dependences of ^{1}H NMR spectra,[2,16] the most favourable conformation for (I) is BC-3 (or BC-7). The stability of this conformer compared to the other BC forms is due to a reduction in the strong transannular repulsions between the pseudoaxial hydrogen atoms on C(3) and C(7) in the cyclooctane ring. An analogous structure BC-3,7 or BC-7,3 is also established for heterosubstituted analogues with X = 0 (II) and X = S (III).[17,18]



From a study of the temperature dependence of the ^1H and ^{13}C NMR spectra it has been possible to detect in this case two types of conformation process, differing from each by 1.2–1.5 kcal mol^{-1} in energy: a low energy process due to pseudorotation of the form BC-3 ⇋ BC-7 ($\Delta G^{\neq}$ for (I) is equal to 6.3 kcal mol^{-1}, for (II) it is equal to 6.7 kcal mol^{-1}, and for (III) it is equal to 7.8 kcal mol^{-1}), and the high-energy process for the inversion BC-3 ⇌ BC-3* via the chair form with $\Delta G^{\neq}$ barriers for (I)–(III) of 7.7, 8.15, and 9.0 kcal mol^{-1} respectively.[18] Both these processes proceed fairly rapidly in the NMR timescale. When substituents are introduced into the ring, the barrier, as a rule, increases. Thus, in 5-t-butyl-substituted cyclooctanone it is 8.0 kcal mol^{-1}.[19] The slight increase in the inversion barriers in (II) is due to a transannular interaction between the oxygen atom and the carbonyl group. Thus, replacement of one methylene group in cyclooctane by a carbonyl group does not produce any substantial changes in the steric structure of the eight-membered ring.

According to IR[20] and NMR spectroscopic data, cyclooctane-1,5-dione has the same structure in the crystalline state as in solution, corresponding to conformation BC-3,7 (IV).[16] Two dynamic processes with $\Delta G^{\neq}$ barriers equal to 6.1 and 7.0 kcal mol^{-1} were found for its deutero-analogue.[16] The two geometrical isomers of 2,4,6,8-tetrabromocyclooctane-1,5-dione also have the BC-3,7 form, and they differ according to the orientation of the C–Br bonds.[21] Ketones in which a heteroatom is situated at the α-position relative to the C=O group should also formally belong to this group of compounds. However, in the case of 2,6-diazocine-1,5-dione (V) it was shown[22] that they comprise systems with an endocyclic planar fragment formed by C=O groups and NH. Thus, compound (V) should be grouped with compounds that contain two endocyclic planar fragments at the 1,5-position relative to each other (see Section V). The torsion angles found for it correspond to those calculated for the TB form of 1,5-cyclooctadiene (LXI).

3. Cyclooctene Derivatives



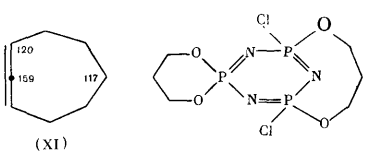
In cyclooctene the ring can be made up in both the *cis*- and *trans*-isomers, and the latter is sufficiently stable to be studied experimentally. It was shown from calculations[23–26] and then also by X-ray diffraction analysis of enantholactam hydrochloride[2] that the most favourable form for the *cis*-isomer is one similar to BC (VI).

(VI) (VII) (a) (b)

In the *trans*-isomer the double bond is highly strained. Calculations predict for it form (VII), namely, twist-chair-chair (TCC) and this has subsequently been confirmed by X-ray diffraction[27,29] and electron diffraction.[30] The double bond is distorted, and the torsion angle is considerably less than 180°: 135.4°,[31] 137.7°,[17] 145.3°,[2,23] 138.0°.[24] This is not a simple twisting of the double bond (*a*) (Newman projection along the double bond), but that in which all six atoms adjacent to this bond are tending to align in one plane (*b*); it has been demonstrated by neutron diffraction that the olefinic hydrogen atoms actually protrude from the plane of the double bond.[2] The torsion angles (φ) along the cyclic bonds in (VII) amount to: 135.4°, –86.5°, 50.7°, and 114.4° (here and subsequently the angle formed by the atoms 8,1,2,3 is given first and that formed by 1,2,3,4 is second, and so on in order).[31] In the case of cyclooctene two conformational processes that occur with barriers of 5.8 and 8.2 kcal mol^{-1} have been found by means of dynamic NMR.[19,32] For the 1-fluoro derivative the barrier is higher according to the ^{19}F NMR spectra and it amounts to 6.1 kcal mol^{-1},[33] while in the *cis*-oxide it increases to 8.0 kcal mol^{-1}.[32]

Among heterocyclic analogues of cyclooctene the *cis*- and *trans*-isomers of 3,8-dialkyl-1,2,-diazocines (VIII) have been discussed,[34] but these results based on a possible equilibrium of *cis*- and *trans*-isomers should be re-examined.[3]

(VIII) (IX) C ⇌ B (X)



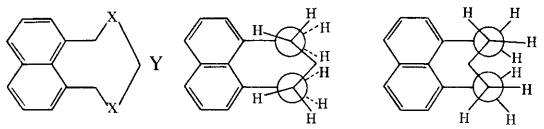
The benzosulphone (IX) has been studied by X-ray diffraction.[35] Introduction of a carbonyl group into the α-position relative to the planar fragment causes them to adopt a coplanar configuration, which has been shown in the case of benzocyclooctene-5,6-dione. In this case five atoms are situated in one plane, and the system becomes analogous to that of cycloocta[d,e]naphthalene (Section III) and its conformational behaviour is such that an equilibrium of C and B forms (X) occurs.

It is evident from the examples given that introduction of a single planar fragment into an eight-membered ring does not lead to substantial changes in its conformational behaviour. For ketones and *cis*-cyclooctenes the most favourable form remains BC as in cyclooctane,[2] and the occurrence of the TCC structure in *trans*-cyclooctene is due solely to steric restrictions that are specific to this case.

III. DERIVATIVES OF 1,2-CYCLOOCTADIENES

1. 1,2-Cyclooctadienes

The calculations made for 1,2-cyclooctadiene (XI)[37] (in the literature there are reports only about attempts to isolate this unstable product in a pure state[38]) revealed two preferred conformers T and TC which have similar energy; their torsion angles and energies are shown in Table 1. The T conformer has a second-order axis of symmetry, and the torsion angles along the cyclic bonds correspond exactly to the T form (see Chapter V). This conformer is defined as TB by the author. The transition barrier between the two forms has been calculated (8.8 kcal mol^{-1}). From the reported values of the bond angles within ring (XI), it is clear that the central allene bond of the molecule is twisted, which produces considerable internal strain in it.

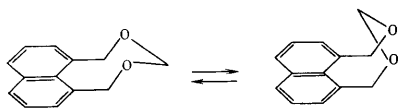


(XI) (XII)

Among heteroanalogues the structure of the inorganic heterocycle (XII) has been studied in the crystalline state.[39] The main structural difference between this molecule and (XI) is determined by the

fact that the central atom in the X–Y–X triad of heteroatoms [see also Chapter VII, compounds (LXXXII) and (LXXXIII)] has a much larger bond angle (about 125°), which is due to the different electronic state of the carbon atom and substituent Y. In the specific case examined, the ring of the *spiro/ansa*-isomer of cyclotriphosphazene (XII) has a BC conformation in which the NP_2O_2 fragment is in the form of a boat.[39] The stability of the BC form is so high that the P(4)N(5)P(6) angle is decreased to 112.7° (this is the smallest of all the values; in a six-membered ring it reaches 124.2°).

2. Derivatives of Cycloocta[d,e]naphthalene



The main feature of compounds of this series [(XIII)–(XVII)] is the occurrence of a *peri* interaction. This dictates the specific type of conformational behaviour that stabilises the B conformation; in it the energy of torsional rotation about the C(1)–C(2) bonds [C(4)–C(5) bonds] is less (skewed conformation) than in the C form.

(XIII)–(XVII) C B

According to the ^{1}H NMR spectroscopic data, the parent carbon compound (XIII) with X = Y = CH_2 and also its deuterated analogue have the B conformation. By studying the temperature dependence it was possible to determine the energy characteristics of the conformational process B ⇌ B*: $\Delta G^{\neq}$ is equal to 14.5 kcal mol^{-1}, $\Delta H^{\neq}$ to 16.1 kcal mol^{-1}, and $\Delta S^{\neq}$ to 5.4 E.u.[40] Introduction of methyl substituents into the X position (X = CMe_2) assists the relative stabilisation of the B form, so that compounds with Y = CH_2 or C=O, even if they have only one *gem*-dimethyl group at the X position, exist exclusively in this conformation. The inversion barriers of the rings increase by 4.8–5.9 kcal mol^{-1} relative to their nonmethylated analogues.[41]

Among the heterocyclic derivatives of this series 1,3-dioxans (XIV) with X = O and Y = CHR have been studied to the greatest extent. For the simplest acetal (R = H), when the energy is minimised with parametrization,[42] two conformations C and B with ΔH_{C-B} of 1.0 kcal mol^{-1} are predicted;[43] according to the ^{1}H NMR data for $CHCl_3$ and $C_2Br_2F_4$ (1 : 1) ΔH is equal to 0.7 kcal mol^{-1}.[44] The existence of a conformational equilibrium follows from the IR spectroscopic data, dipole moments, and ^{13}C NMR spectra of different acetals with R = H, Me, iso-Pr, t-Bu, Ph, *p*-ClC_6H_4, and *p*-$O_2NC_6H_4$.[45]

C (XIV) B

In the 3-t-butyl derivative the value of ΔH increases to 1.4 kcal mol^{-1}; and in the crystalline state, according to the X-ray diffraction data, the C form occurs with an equatorial configuration of the t-butyl group.[46] The C conformation is also typical for sulphate (XV) with X = O and Y = S=O, with the S=O bond exclusively occupying the axial position,[43] as in six-membered sulphates.[5] In acetals the C form is destabilised by the *peri* effect; the increase in nonbonded and torsional strains leads to a relative stabilisation of the B conformation.[46,47]

Replacement of the ring oxygen atoms by sulphur [(XVI) with X = S and Y = CHR] makes this form more favourable in thioacetals, and the proportion of C conformer present is reduced to 7%.[48] In contrast to acetals, ketals (XVI) with X = S, R^1 = R^2 = Me, $(CH_2)_5$ mainly have the C conformation.[48] The subsequent replacement of Y = CR^1R^2 by a sulphur atom gives trithiocines (XVII) with X = S and Y = S, for which dynamic ^{1}H NMR spectroscopy was used to detect an equilibrium of two forms in the ratio 10 : 1 (in pyridine-d_5) which participated in two types of conformational process—a relatively rapid process with $\Delta H^{\neq}$ 15 kcal mol^{-1} and $\Delta S^{\neq}$ −1.1 cal mol^{-1} K^{-1} and a slow process with a higher $\Delta G^{\neq}$ barrier equal to 17.9 kcal mol^{-1}.[49] When calculations were applied to interpret the experimental data it was shown that the B form was more stable than the chair form by 0.6 kcal mol^{-1}. The T conformation is obtained on the energy surface by moving out each $C_{sp^3}-C_{sp^2}$ bond 15° from the plane of the naphthalene ring; this leads to a loss of 13.6 kcal mol^{-1}. The conformational processes detected correspond to the exchange B ⇌ B* via the T form and B ⇌ C.[49]

Thus, the steric structure of an eight-membered ring with two planar fragments in the 1,2-position is determined to a considerable degree by the nature of these fragments. In allene systems twisted forms (T, TC) predominate; replacement of sp^2 carbon atoms by heteroatoms decreases the angle in the ring between the double bonds, which helps to remove strain and the system in terms of its parameters approximates to saturated eight-membered rings (XII). In naphthalene derivatives the *peri* effect together with torsional strain and nonbonded interactions controls the stabilisation of the B and C forms. As was shown above in the case of benzosulphone (IX),[35] these principles are applicable to α-keto derivatives of cyclooctenes.

IV. DERIVATIVES OF 1,3-CYCLOOCTADIENES

Initial calculations of the conformational energies of 1,3-cyclooctadiene (XVIII) identified two preferred conformers, approximately equal in energy and defined as TB.[2,50,51] Subsequent calculations led to more accurate notions of the energetics of these basic conformers and provided a basis for developing their nomenclature.[52] The results of the calculations, the energies, nomenclature, and torsion angles are presented in Table 1. It can be seen from this that two conformers stand out in terms of stability—TBC with C_2 symmetry, which is more stable by 0.5 kcal mol^{-1} than the second form (TB) with C_1 symmetry. The remaining forms are less favourable than TB—the boat by 6.3 kcal mol^{-1}, and the half-chair (HC) and twist form by 8.3 kcal mol^{-1}. The decrease in symmetry of the T form of cyclooctadiene derivatives as compared with the TC conformation depicted in Fig.1 and having C_{2h} symmetry is due to the introduction of planar fragments into the ring. As may be seen from the next chapter, when there is a favourable geometric environment its occurrence is possible [compounds (XLII) and (XLIII)].

* Torsion angle 1 is formed by atoms 8, 1, 2, 3; angle 2 by atoms 1,2, 3, 4; and so on.

** The labels used by the authors for the conformations are given in brackets; D stands for a deformed conformation, HC is a half-chair, TBC ⟷ TB is a form intermediate between TBC and TB.

From a detailed study of the contributions of different types of strain to the total energy it is possible, in our opinion, to distinguish the angle strain, namely, the strain occurring as a result of bond angle deformation (ΔE_θ relative to the TBC form is 3.3 kcal mol^{-1} for TB, 4.3 kcal mol^{-1} for B, 7 kcal mol^{-1} for HC, and 5.2 kcal mol^{-1} for T). These observations, in the opinion of the author of this review, indicate that the conformational situation can change when heteroatoms, which have bond angle values that are different from those of the carbon atoms and often undergo angular deformations more easily, are introduced into the ring. That is why Table 1 also contains data on torsion angles and conformations obtained by X-ray diffraction analysis for the heterocyclic analogues of 1,3-cyclooctadiene and includes the dibenzo derivatives (XIX)–(XXVI).[53-60] The author's labels for the conformations in Table 1 are given in brackets. For two compounds [(XXV) and (XXVI)] we have calculated the torsion angles from atomic coordinates reported in two articles.[59,60]

(XVIII) (XIX)–(XXII) (XXIII)–(XXV) (XXVI)

It is evident from the data in Table 1 that TBC is the principal form; compounds (XX)–(XXII)[54-56] and (XXVI)[60] exist in it (see also the results for rhazinilam.[61]). The TB conformer was not detected in a single case, but the B form is fairly representative [(XIX), (XXIII)–(XXV) with X = Me, Br, Cl[53,54,57-59]].

On the whole it should be noted that the TBC form has quite high values for the dihedral angles about the bonds formed by the ring atoms 4–5, 5–6, 7–8, and 8–1 (about 80–100°) and with alternating signs. In the TB form the angle values are lower, one of those adjacent to the double bonds is positioned almost in the same plane with it while the other is very twisted [5° and 92° in (XVIII)]. A B conformation very similar to that predicted by calculation for carbocycle (XVIII) is found in peroxide (XIX). In it the bond opposite the single bond and situated between the two planar fragments is very twisted (about 120°). In the other compounds the single bonds adjacent to the double bond (4–5 and 1–8) are more twisted in comparison with the remaining ones. This helps to flatten out the 4–5–6–7 and 6–7–8–1 fragments so that the B form in compounds (XXIV)[58] and (XXVI)[59] approximates to the classical cyclooctatetraene structure[62] (Section VII).

1,3-Cyclooctadiene (XVIII) has been studied in solution by means of ^{1}H and ^{13}C NMR.[52,53] An interpretation of the results obtained for its mono- and di-epoxides has been carried out from data calculated on the energies of the conformers. They exist in a primary state as a mixture TBC ⇋ TB, and the proportion of TB falls on changing to the diepoxide. Three conformational processes with barriers of 7.2 kcal mol^{-1} (7.4 for the monoepoxide), 9.0 kcal mol^{-1} (9.9), and about 10 kcal mol^{-1} were detected by temperature measurements. The first corresponds to the conversion TB ⇋ TB* via the B form, the second corresponds to TB ⇋ TBC. From among the heterocyclic compounds, nonempirical quantum-chemical calculations[4] were carried out for the disulphide (XX) on the basis of molecular mechanics[65] and also the temperature dependencies of the ^{1}H NMR spectra were studied.[66] The TBC form is recognised as the most favourable since quite a high inversion barrier was found ($\Delta G^{\neq}$ 28.8 kcal mol^{-1}, $\Delta H^{\neq}$ 26.6 kcal mol^{-1}, and $\Delta S^{\neq}$ -6.0 cal mol^{-1} K^{-1}).[66] Such high barriers have also been determined for dibenzo derivatives of 6,7-dicarboxy-1,2,3,4-dibenzocyclooctane.[66] It is apparent that, as in seven-membered heterocycles,[2] replacement of a double bond by a benzo fragment produces an increase in the barriers for conformational conversions.

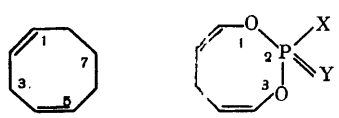
** D stands for a deformed conformation relative to the ideal form.

V. DERIVATIVES OF 1,4-CYCLOOCTADIENES

1. Basic Conformations



Among eight-membered rings with two planar fragments, derivatives of 1,4-cyclooctadiene (XXVII) have been studied in greatest detail. In this chapter we shall examine the possible conformation of this ring on the basis of the X-ray diffraction data and the quantitative properties of the conformers. 1,4-Cyclooctadiene has been the subject of several theoretical studies,[50,67-70] in which three conformations BC, BB, and TB are considered.

BC BB TB B

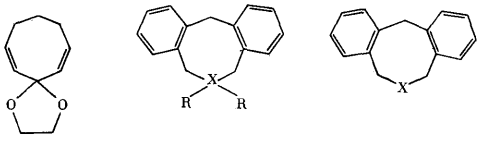
Calculations show that BC is the most stable form; its difference in energy from the TB conformation is 0[67] or 1.1 kcal mol^{-1}.[50] The BB form is the transition state in the process TB $\rightleftharpoons$ TB*.[68] Consequently, for (XXVII) the two forms BC and TB are expected to participate. However, as has already been observed above, the situation can alter on changing to heterocyclic analogues.

The basic conformations of compounds of this type have been studied in the case of 1,3,2-dioxaphosphocines with three- and four-coordinated phosphorus[71] (Y is an unshared electron pair (UEP), or an atom of phosphorus or sulphur) using the method of Cremer and Pople[38] developed for eight-membered rings.[9,10]

(XXVII) **(XXVIII)**

Calculations have been carried out using X-ray diffraction data for 4,5;7,8-dibenzo-1,3,2-dioxaphosphocines[72,73] [compounds (XXXV) and (XXXIX) in Table 3]. Four basic conformations were obtained—the three proposed for (XXVII) and a distorted B form. Table 2 gives the torsion angles about the cyclic bonds in compounds of three- and four-coordinated phosphorus (XXVIII) and the folding parameters. In this case the torsion angles of the different conformations of (XXVII) and their relative energies[68] are listed.

Before going on to discuss actual conformers, let us consider Table 3, where the X-ray diffraction data that is available at the present time for the heterocyclic derivatives of (XXVII) have been collected. The compounds (XXIX)–(XLIX) are listed according to the increase in the number of heteroatoms in the ring.[72-87] These are mainly dibenzo derivatives and only two examples relate to compounds with dinaphtho residues [(XXXVIII) and (XXXIX)].[73,80] On correlating the calculated and experimental data we observe that when compounds have the same conformations, regardless of the nature of the heteroatoms, the torsion angles vary over quite a narrow range, so that dihedral angles can be used, in our opinion, as a quantitative criterion of the conformers. As in the case of (XVIII), the BC form has high values of the torsion angles about the single bonds with alternating signs. This form is fairly typical in compounds with a methylene bridge—(XXIX),[74] (XXXV)–(XXXVII)[72,78,79]—or a sulphur atom [(XLIV)], as well as in thiazocinium salts (LI), 1,5-dithiocines (XLIX),[97-99] and dibenzosilocine.[100] In the BB conformation the fragments enclosing the single bonds that are adjacent to the planar groups are very flattened out (torsion angles constitute 3–8°). In this form the substituents occurring at the flagpole position approach very close to each other, which contributes to a destabilisation of this conformation. The relatively small difference in energy calculated for the BB form of (XXVII)[68] is due to a substantial flattening out of the fragment made up by the atoms 8,1,2,3,4 in comparison with the related BC form. At the same time it is possible to change from the BB to a distorted B conformer by a small rotation. Proposals about the possible existence of such a conformation in heterocycles were also put forward previously.[88,89] However, their quantitative parameters

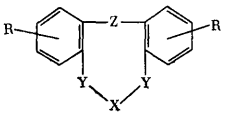


were only obtained recently[71] (Table 2). It was possible to make an unequivocal interpretation of the X-ray diffraction data (Table 3) from a knowledge of the torsion angles. It transpired that this form had been observed by many authors but they had given it arbitrary names. It is typical for azocines (XXX),[75] their sulphur derivatives (XXXI)–(XXXIV),[76,77] 1,3,2-diazaphosphocines (XL),[81–83] and 4,5;7,8-dinaphtho-1,3,2-dioxaphosphocines (XXXVIII) and (XXXIX).[73,80] In some studies this form is also called TB,[76,77] by analogy with a previous study,[88] although it is particularly stressed that this is quite a different conformation from the TB form discussed in the previous studies.[88,89] Thus, only when quantitative criteria were used for the identification of conformers was it possible to avoid ambiguity.

An examination of the T and TB forms deserves particular attention. Even in the basic study of Anet,[68] the dihedral angles for these two forms differed only slightly (Table 2). In the ideal T conformation with the C_2 symmetry, torsion angles 1 and 2 are equal to 60°, and deviations, which are often small (about ±30°) serve to identify the TB form. In the less twisted distorted B conformer these angles have different signs and differ in absolute value by 60–90°. As was predicted in the calculations of Anet[68] and from the folding parameters,[71] this conformation occurs in those cases when the angle at C(6) in the bridge position is readily opened up to 120°. Such a situation must occur in keto derivatives. In fact, the two ketones (XLII) and (XLIII) studied so far[85,86] have a T conformation.

2. Conformational Behaviour in Solution

(a) Derivatives of 1,4-Cyclooctadienes



An analysis of the shielding effect from the C(3) atom in the ^{13}C NMR spectra and also the changes in the ^{1}H and ^{13}C NMR spectra on varying the temperature lead to the conclusion[68] that (XXVII) exists as an equilibrium BC ⇋ T (or TB) with an interconversion barrier of 8 kcal mol^{-1}. As a result of the fact that in their studies the authors have not made a distinction between the T and TB forms, the generalised label [TB] is used subsequently in such cases. According to force-field calculations it is proposed that the pseudorotation T ⇋ T* takes place with a very low barrier of 3.8 kcal mol^{-1}.[68]

(XLV) (XLVI) (XLVII)

The ethyleneketal (XLV) is conformationally pure and exists exclusively in the T form, its barrier for pseudorotation is higher than in (XXVII) by 6.0 kcal mol^{-1}.[18] The conformational behaviour of the dibenzo derivative (XLVI) with R = H is considerably different

Table 3. The conformations of dibenzo derivatives of 1,4-cyclooctadienes with the general formula.

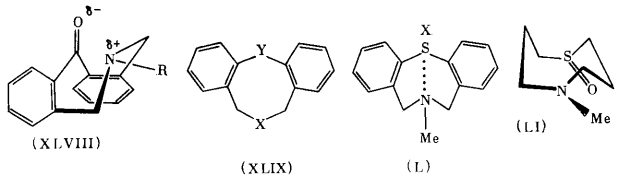
* Numbering of the torsion angles corresponds to that in Table 2.

** Dinaphtho derivatives.

*** *a* indicates an axial orientation of the exocyclic bond, *e* indicates an equatorial orientation.



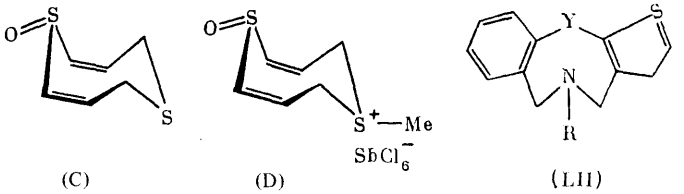
from that of (XXVII);[90,91] the equilibrium BC ⇋ [TB] is displaced 98% towards the first conformer, and the $\Delta G^{\neq}$ inversion barrier between them is much higher (14.9 kcal mol^{-1}), while the barrier for the transition BC ⇋ BC* is even higher (15.3 kcal mol^{-1}).[91] These results are somewhat different from those calculated,[90] according to which the energies of the BC and T forms are equal and the BB form is less favourable than them by 5.3 kcal mol^{-1}. The transition barrier for the process BC → T was also calculated (15.2 kcal mol^{-1}) and its possible pathways indicated.[90]

A change in the nature of the substituents R in (XLVI)—XR_2 = C=O, C=CH_2, CHMe, CHAc, $CMeCH_2OH$, $C(CN)_2$[92]—affects the position of the equilibrium BC ⇋ TB and the inversion barriers to a considerable degree. The population of the TB conformer is essentially small (2–16%). When there is *gem*-substitution it increases to 40–60% [$C(CN)_2$, $CMeCH_2OH$]. As regards the barriers, they increase on changing from a ketone (10.1 kcal mol^{-1}) to a methylene derivative (13–14 kcal mol^{-1}) and then to compounds with XR_2 = CHMe and $C(CN)_2$ (15–16.7 kcal mol^{-1}). The following NMR criteria were proposed for conformational studies on compounds of this class: 1) the flexible T form has a higher entropy than the BC form (ΔS reaches 7 E.u.); 2) the geminal constant ^2J(HH) of the bridge methylene group is determined to a considerable degree by the structure of the ring; for the BC form it is 12–14 Hz, and for the T form it is 19 Hz; 3) in the ^{1}H NMR spectra of the BC form two sets of nonequivalent AB methylene protons occur, and there are two singlets in the exchange T ⇋ T*.[92]

On the whole, it may be stated that replacement of double bonds by aryl residues contributes to an increase in the transition barriers between the BC and T conformers.

(b) 3,4;6,7-Dibenzo-1-azocines and their Heteroanalogues

The first study on dynamic ^{1}H NMR spectra of dibenzoazocines (XLVII) with X = NR_2 and R = H, CN, CH_2Ph appeared back in 1970,[93] but no definite conclusions were then made about the nature of the conformations occurring. This was made possible by a detailed investigation of a series of azocines with R = Me,[94] H, Me, iso-Pr, t-Bu,[95] and CH_2Ph,[88] as well as their carbonyl analogues with a keto group at the bridge position.[96] Dibenzoazocines are conformationally heterogeneous and are characterised by the equilibrium BC ⇋ [TB]. The latter conformation, enclosed in brackets, denotes that its structure has not been established conclusively, and in some studies preference is given to a T conformer with C_2 symmetry[94–96] while in others an asymmetric TB form is preferred. In some cases a BB conformation is considered.[101] The energy factors of the methyl-substituted amine (R = Me) have been obtained (ΔH –3.2 kcal mol^{-1}, ΔS –7 E.u., inversion barrier 15.3 kcal mol^{-1}).[94] The proportion of [TB] conformer increases as the size of the substituent on the N atom increases (in $CDCl_3$—however, the opposite effect was found in CF_3COOH); when R = H the BC conformation occurs with barrier for the transition *e*-BC ⇋ *a*-BC of 16.1 kcal mol^{-1}, when R = t-Bu the barrier is 16.5 kcal mol^{-1},[95] when R = CH_2Ph it is 17.0[88] or 17.4 kcal mol^{-1};[96] on protonation the barriers increase.[95] For aminoketones with R = CH_2Ph and Me, proper consideration was given for the first time in the literature to the distorted B form (XLVIII),[88,96] which is stabilised in these particular examples by a specific transannular interaction between the N atom and the carbonyl group.



The signals from the two methylene groups in this minor form appear as a singlet at –100 °C, so the authors conclude that the compounds have the B form that occurs during the pseudorotation B ⇋ B* with a barrier of ~8 kcal mol^{-1}. Theoretical calculations carried out for *N*-methylazocine[88,96] show that the BC conformation is actually preferred (ΔE ~4.30 kcal mol^{-1}), and then in increasing energy B (5.54 kcal mol^{-1}), T (5.62 kcal mol^{-1}), and BB (5.94 kcal mol^{-1}). Thus, there is still an open question concerning the steric structure of the minor conformer since the energies of the B and T forms are similar. In our opinion, the use of new, recently obtained spectral criteria of the distorted B form will help to resolve this problem also for azocines (see below).

A fairly extensive group of compounds studied is made up by the heteroanalogues of azocines, in particular thiocines (XLVII) with X = S and SO_2. In the ^{1}H NMR temperature spectra of the sulphone X = SO_2, the protons at C(5) and C(7) appear as an AB system, which is an indication that the BC conformation predominates in the equilibrium BC ⇋ [TB][88] with an inversion barrier of 16.2 kcal mol^{-1} [96] and 15.8 kcal mol^{-1}.[88] According to calculations, the BC form is more favourable in the sulphide than in azocine itself. Introduction of heteroatoms into the bridge position (Y = O, S, SO_2) for those compounds with X = S, SO_2 NCH_2Ph already considered has little effect on the conformational behaviour of (XLIX) compounds, which is manifested in the same dependence on temperature for the NMR spectra.[88] It is therefore concluded that they also exist in the equilibrium BC ⇋ [TB]. The values of the barriers in (XLIX) in relation to the nature of X and Y are given in Fig.2.[88] It can be seen very clearly from it that the energy barriers are determined to a greater extent by the nature of the bridging group Y. The lowest values occur for O-derivatives (10.5–14 kcal mol^{-1}), they are somewhat higher for the CH_2 group (14–16 kcal mol^{-1}), and even higher for the SO_2 group (16–18 kcal mol^{-1}), while for sulphides there is a wide range of barrier values from 12.5 to 16.5 kcal mol^{-1}. As regards the effect of the X group, it is shown less clearly, and it can only be stated that in all of the examples studied the barriers for the sulphones are lower than for the sulphides.

The problem concerning the conformation of the minor component can be resolved in the case of dibenzo-1,5-thiazocines by analysing the current literature; because of the lack of conformity in the terminology this is initially difficult to understand. The authors who hold the opinion that the T form occurs define it as TB;[92,94,95] the same label is given in those cases where a distorted B conformation is being considered.[76,77] Let us consider the data in Table 3 once again. Only for one of the azocines listed there [(XXIX)] is the BC conformation observed in the crystalline state,[74] in all of the remaining cases [(XXXI)–(XXXIV)] the B form occurs,[75–77] while in the thiazocinium salts (XXXI)–(XXXIII) of type (L) this conformation can be recognised as constrained by the transannular $R_3N...SX$ interaction, where sulphur has a trigonal bipyramidal structure. In saturated systems this type of interaction also occurs in the BC form of (LI).[97] However, on going to the dibenzo analogues, such a form where opposing N and S atoms are situated on the base

of the boat cannot occur because of the presence of planar fragments. In the two remaining cases—azocine (XXX) and its sulphoxide (XXXIV)[75-77]—stabilisation of the B form is caused for no other reasons than the inherent properties of this system. In solution (benzene-d_6), according to variable temperature ^{1}H NMR spectra, the sulphoxide retains its structure (the protons of the methylene groups appear as an AB system with ^2J(HH) of 15 Hz at 3.18 and 3.42 ppm).[98] In the thiazocinium salts (L) the S...N attraction is high enough for the B form to be retained even in solution,[77,98,99] and it is predominant although in some cases the presence of the BC conformer is detected (up to 45% depending on the experimental conditions[97]). In the opinion of the authors, when the distorted B form occurs the protons of the methylene group appear as a singlet in the region 3.88–4.25 p.p.m. In 1,5-dithiocines the situation is different; there is an AB system in the spectrum with quite a high $\Delta\delta$ value (0.5–0.8 p.p.m.) and geminal constant of 14–15 Hz, which is associated with the BC conformation of compounds (C) and (D):[99]

(C) (D) (LII)

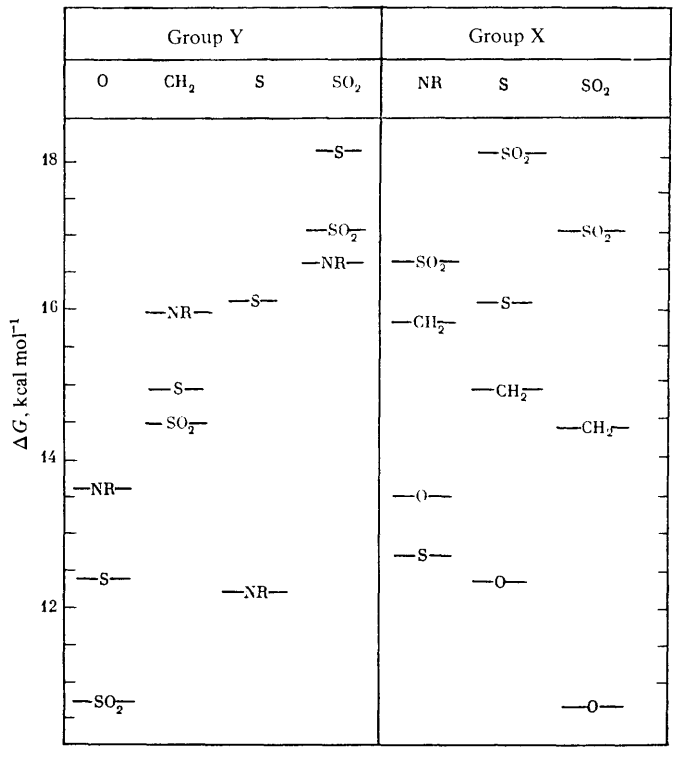


Figure 2. The correlation between the activation barriers $\Delta G^{\neq}$ for the process BC ⇋ B and the nature of groups X and Y;[88] R = CH_2Ph.

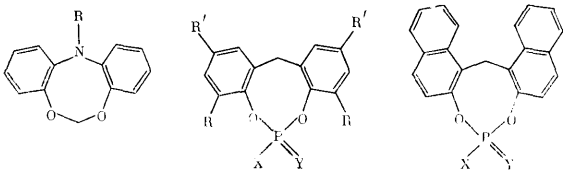

The differences in the conformational behaviour of 1,5-thiazocine and 1,5-dithiocine S-oxides have formed the basis for an explanation of the differences in their reactivity towards electrophiles due to the transannular participation of the amino fragment.[99,102]

There are reports in the literature about the synthesis of benzothienoazocines (LII),[103] 1,5-aza-,[104] and 1,5-oxa(thia)-phosphocines (XLIX) with X = NR, O, S and Y = P(O)R;[105,106] and proposals about their steric structure—whether the BB or TB conformations occur—were deduced by constructing Stewart–Brigleb models. These compounds are very interesting from the point of view of studying the hypervalent bonding of the 1,5-heteroatoms and they will therefore be the subject of future investigations.

On the whole, by examining the conformational behaviour of 3,4;6,7-dibenzoazocines and their 5-heteroanalogues the following conclusion can be made. Despite the discussion which had developed in the literature about the reason for the steric structure of the minor conformer (in certain examples the predominant one), sufficient practical data have so far been accumulated to give preference to a B form that is distorted in one or other direction depending on the geometric parameters of the cyclic fragment. A subsidiary 1,5-transannular interaction helps to stabilise this very conformation. The main competitor to the B form is the BC form, stabilisation of which occurs in compounds that are free of the subsidiary steric interactions.

(c) 4,5;7,8-Dibenzo-1,3,2-dioxaphosphocines and their Heteroanalogues

Compounds of this series have been studied in sufficient detail, which is due to their synthetic asscessibility[101,107] and valuable practical properties.[107-109] Comparatively recently 4,5;7,8-dibenzo-1,3,6-dioxazocines (LIII) were synthesised and their stereochemistry has been studied by means of IR, ^{1}H and ^{13}C NMR, dipole moments, and quantum-chemical calculations using the PPDP/2 method. The latter have also provided the main criterion in selecting the preferred conformer—the BC form. As regards the BB conformation, it has been accepted as not likely to exist[108] because of the strong steric interactions between the methylene and NR groups. It is quite difficult to make definite conformational correlations from the ^{1}H NMR spectra in the compounds examined; a much wider range of possibilities can be admitted in this form of compound with a bridging methylene group, in particular 1,3,2-dioxaphosphocines with different planar fragments (LIV) and (LV).

(LIII) (LIV) (LV)

The spectroscopic characteristics of the CH_2 group [the difference in chemical shift of the protons, geminal ^2J(HH) and long-range ^5J(PH) constants] are closely related to the conformational parameters. Even before the commencement of structural studies, methods had been developed for obtaining compounds of series (LIV) with three-coordinated phosphorus and X = OR,[109] Cl,[110] NR_2[111] and four-coordinated phosphorus with X = H, Y = O,[109,112] X = Cl, Y = S,[113] X = H, Y = S,[114] X = OH, Y = O.[115] The possible steric forms of the cyclic fragment have been examined by means of the folding parameters (Table 2). When these were correlated with the

X-ray diffraction data (Table 3) it was possible to determine the most probable forms—the BC and B conformations. In considering the steric structure of 1,3,2-dioxaphosphocines, one of the main points is also the question concerning the orientation of the exocyclic substituents on the phosphorus atom (we shall take substituent X as a starting point in labelling the conformations). Doubling the number of conformers definitely complicates the solution to the conformational problem, but in many cases, when one form is stable, more reliable conclusions about the steric structure can be made.

Table 4. ^{1}H NMR spectroscopic parameters (δ, p.p.m.; *J*, Hz) of 1,3,2-dioxaphosphocines.[119–121]*

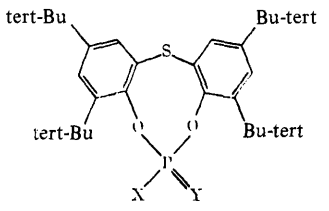
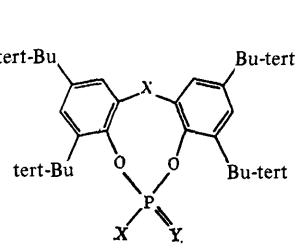
*The chemical shift from Me in the benzene ring varies within the limits 2.24–2.30 p.p.m.; that from t-butyl varies within 1.22 to 1.38 p.p.m.

Some ideas about the preferred conformations were provided by nonempirical quantum-chemical calculations of the conformational energies in derivatives of a series of (XXVIII) in which the dibenzo fragments are replaced by double bonds. Calculations were made for 2-chloro-, 2-methoxy-,[116] and 2-hydro-2-oxo-1,3,2-dioxaphosphocines.[117] They showed that the most favourable form is the *e*-BC conformation. The most unstable is the BB form with *e*-X and to an even greater degree with *a*-X because of the close contact between the C(6), *a*-H on C(6), and P(2) atoms. Destabilisation increases if the substituent on P(2) occupies the *a* position. As regards all the other conformations, the differences in energy between them were not large enough for definite conclusions to be made, especially as the calculations were made for model compounds without optimisation of geometry and calculation of the effect of the medium.

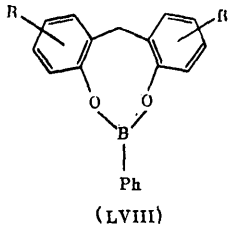


In actual systems studied, the planar fragments are as a rule aryl or naphthyl rings, so it is difficult to expect an absolute convergence of the experimental data and that obtained from calculation.

When we come to consider the spectroscopic characteristics of 1,3,2-dioxaphosphocines, we can turn our attention to the long-range ^5J(PH) constant in azocines. It was originally detected in trivalent phosphorus compounds,[101,118] on the basis of which it was concluded that the BB conformation occurred since the P and H atoms in it are spatially converged. However, as was indicated above,[108,116] the possible occurrence of this structure is very problematic. A single occurrence of this constant cannot yet provide the basis for such a conclusion. Identification of the conformers of 1,3,2-dioxaphosphocines (LIV) and (LV) was made possible from variable temperature ^{1}H NMR spectra.[117,119,122] The spectra of individual conformers were obtained for two of them.[117,122] This assisted the search for spectral criteria of the different conformations. In the ^{1}H NMR spectra the resonance signals from the methylene protons occur in the region 3.24–4.39 p.p.m. for the (LIV) series and at 4.45 to 5.28 p.p.m. for the (LV) series[119–121] (Table 4). They form an AB system, and the low-field doublet in many compounds of the (LIV) series and the high-field doublet in the series of (LV) compounds are split due to long-range interaction with the ^{31}P nucleus. In almost all of the dibenzo derivatives (LIV), with the exception of the phosphorochloridite, a significant (about 1 p.p.m.) nonequivalence (the difference in chemical shifts Δδ) was found in the protons of the methylene group. In addition to the phosphorochloridite, a small Δδ value is also typical for the dinaphtho derivatives (LV). The compounds also differ to a considerable degree with respect to their ^2J(PH) values—12–13 Hz for most of the (LIV) series and 14 to 16 Hz for (LV). Among the P(IV) derivatives of (LIV), ^5J(PH) coupling occurred in one case with X = NEt_2 and Y = S.[122] The spectra of individual conformers were obtained for the phosphorochloridite of (LIV) with R = t-butyl, R′ = Me[117] and the phosphorothioate with X = OEt and Y = S respectively.[122] The energy parameters of the conformational processes of these two compounds were determined: ΔG^0_{195} 0.1 kcal mol^{-1}; $\Delta G^{\neq}_{235}$ 10.85 ± 0.7 kcal mol^{-1} for the first and 0.74 and 12.2 kcal mol^{-1} for the second. In 2-hydro-2-oxo-1,3,2-dioxaphosphocines of (LIV) with R = t-butyl, cyclohexyl, R′ = Me when the temperature was reduced from −40 to −60 °C, there was a sharp increase in Δδ, which corresponds to a slowing down in the intramolecular exchange process with $\Delta G^{\neq}_{220}$ 10.4 ± 0.7 kcal mol^{-1} between the forms,[117] one of which is present in only a small proportion (~10%). In contrast to the dibenzo derivatives, in the (LV) series as the temperature was lowered a regular increase in the difference Δδ was detected, although the spin-spin coupling constant remained virtually constant. This indicates that forms having the same conformation of the cyclic fragment and differing in the orientation of the substituents on the phosphorus atom are taking part in an equilibrium.[120,121] In order to identify the conformers, a quantitative determination of the effect of magnetic anisotropy and electric field of the substituents on the magnitude of Δδ was carried out,[123–125] and also on the contribution from the hyperconjugation effect ΔJ^{π} to the constants ^2J(HH) and ^5J(PH) in the different conformations.[119–121] It was this treatment of the stereospecific nature of the constants in conjunction with dipole moments data that made it possible for the first time to establish spectroscopic criteria for the individual conformers: *e*-BC is characterised by ^2J(HH) of ~12.5 Hz, $^5J(P^{III}H^B)$ and $^5J(P^{IV}H^B)$ are of the order of 3.5–4.0 Hz, Δδ is 1 p.p.m. In the alternative *a*-BC conformation, ^5J(PH) is ~0–2 Hz and the signs for Δδ (H^AH^B) are reversed. Therefore, when there is an equilibrium *e*-BC ⇋ *a*-BC, Δδ is not large (0.2–0.5 p.p.m.), and ^5J(PH) has lower values (1–2 Hz). The *e*-B form has ^2J(HH) of ~14–16 Hz and $^5J(P^{III}H^B)$ of the same order as in the *e*-BC form, but it is less well displayed in P(IV) compounds, Δδ sometimes reaches 1.3 p.p.m.; in the *a*-B conformation ^5J(PH) also cannot be seen. In the equilibrium *e*-B ⇋ *a*-B, as equally in *e*-B ⇋ *e*-BC, Δδ is averaged out and has low values (as a result of the exchange between the *a*, *e*, and *e*′, *a*′ protons). It can be assumed that in the case of compound (LIV) with X = NEt_2, Y = S, R = t-Bu direct evidence has been obtained for the first time for spectroscopic properties of the *e*-BC



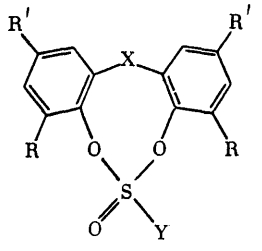
conformer. The compound is conformationally pure in solution, and according to the Raman spectra its steric structure is retained when going from the crystalline form into solution,[126] and its structure in the crystalline state (*e*-BC conformation) has been demonstrated by X-ray diffraction analysis.[79] Similar results have also been obtained for the phenyl phosphite of (LIV) with X = OPh, R = t-Bu, the main conformation of which in solution[119] corresponds to that found in the crystalline state (*e*-BC).[72] An equilibrium of the type *e*-BC ⇋ *a*-BC with a small content of *a*-conformer is also typical for the other dibenzo derivative phosphites with X = NPh_2, NEt_2, OEt, and O-naphthyl. In the phosphorochloridite the population of the second form reaches approximately an equal level (56:44%). In the dinaphtho derivatives of (LV) the BC and BB forms are unlikely to occur because of strong steric repulsions of the α-hydrogen atoms of the neighbouring naphthyl fragments. In the crystalline phase the 2-diethylaminophosphite (XXXVIII) and the diethylaminophosphorothioate (XXXIX) have the *e*-B form.[73,80] The small value of Δδ, ^2J(HH) of ~15.5 Hz, and ^5J(PH) of ~0 Hz must correspond to an equilibrium of the type *e*-B ⇋ *a*-B in the case of P(V) compounds, and similar results have been obtained experimentally. In P(III) compounds the population of the *e*-B conformer is greater with X = NR_2 and less with X = OPh than the *a*-B form.[120,121] If the results obtained for compounds (LIV) with X = H, Y = O[117] are considered in these terms as well as taking into account dipole moment data, a three component equilibrium *e*-B ⇋ *e*-BC ⇋ *a*-BC with population ratio 47:43:10 is acceptable. If the B form is consistent with a geminal constant of 15.6 Hz and the BC form with 12.5 Hz, with the population level of conformers occurring the constant must appear as 14 Hz in the spectra, which is in accord with experiment. The sudden changes in Δδ observed in the variable temperature spectra are due to freezing out of the *a*-BC conformer, which has a Δδ value that is opposite in sign relative to the *e*-B and *e*-BC conformers. The phosphorothioate of (LIV) with X = OEt, Y = S, R = t-butyl exists as an equilibrium mixture of two conformers with population ratio 86:14. In this case the spectral parameters of the minor conformer is consistent with the *a*-BC form (as in the conformationally pure diethylaminophosphorothioate): ^2J(HH) 12.2 Hz, ^5J(PH) 3.5 Hz, Δδ 0.78 p.p.m.; and the predominant conformer is the *a*-B form; 15.5 Hz, 0 Hz, and 1.33 p.p.m. respectively.[122]



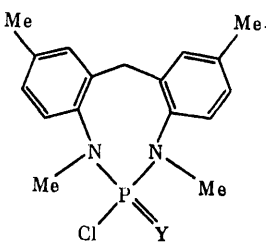
An examination of the spin-spin coupling constants ^nJ(PC) was carried out for the 1,3,2-dioxaphosphocines (LIV) and (LV) considered here in order to establish ^{13}C NMR spectroscopic criteria of use in conformational studies.[121,127] The application of observations reported in the literature concerning the stereospecific nature of the $^2J(P^{III}OC_{sp^2})$ constant[128-130] to the four cyclic conformations led to the conclusion that in the BC form the constant (6.6−6.8 Hz) is greater than in the B conformation (1.5−2.2 Hz).[121,127] The vicinal constants $^3J(POC_{sp^2}C_{sp^2})$ are not large; zero values for (LV) and 2.9−4.4 Hz for (LIV) were obtained with P(III) and somewhat higher values with P(IV). They were correlated with the stereospecific dependences of the $^3J(POCC_{sp^3})$ constants.[131-133] In 1,3,2-dioxaphosphocines the dihedral angle in the POCC fragment is close to 0° in the BB conformation (6°). It is for this type of *cis* orientation that the maximum values for the constant can be expected (of the order of 10−15 Hz). In the *a*-BC conformation a constant close to zero should occur since the dihedral angle has a value of about 90° (80°). In the remaining conformations the order of magnitude of the spin-spin coupling constants is: ^3J(B) > ^3J(TB) > ^3J(*e*-BC). Since from a comparison of the correlations made with the experimentally found values the BB form can be excluded from consideration, it may be assumed that for the first time direct experimental evidence for the absence of the BB conformation has been obtained using ^{13}C NMR spectroscopy.[127] The dihedral angles in the $POCC_{(4)}$ and $POCC_{(2)}$ fragments are related by the equation $\theta(PC_{(4)}) = 180° - \theta(PC_{(2)})$; both angles θ are equal (~90°) in the case of the BC conformation, so the equal value of the two vicinal constants (3.7−4.4 Hz) can serve as a spectroscopic criterion for the BC form. The equality was also found experimentally in dibenzo-1,3,2-dioxaphosphocines (LIV) with P(III).[121,127] As regards the long-range spin-spin coupling constants ^4J(PC) and ^5J(PC), it is difficult at present to make definitive conclusions since the stereochemical relationships have not yet been determined for these constants. In the systems investigated the constant $^4J(PC_{(1)})$ is observed in those cases where ^5J(PH) also has a zero value. However, the reverse does not always occur; the $^5J(PC_{(6)})$ spin-spin coupling constant is as high as 1.5−2.2 Hz in compounds that have a BC conformation.

^{1}H and ^{13}C NMR spectroscopy have been extensively used to study the conformational behaviour of 1,3,2-dioxaphosphocines of the (LIV) series, containing benzene rings into which two t-butyl groups, R = R′ = t-Bu, have been introduced (into the *meta* position relative to the bridging group), and the bridge is an alkylmethylene group CHR (X = OR,[101,134,135] Cl,[119,136] Ph.[136] Bicyclic systems with a POXOP bridge have been reported,[101] and also the corresponding pentaoxyphosphoranes,[134,137] sulphides (LVI) [137-139] with P(III) and X = Cl, Ph, OMe,[139] with P(IV),[139] and with P(V).[137]

(LVI)



(LVIII)



The ^{1}H NMR spectra of the P(III) phosphorus compounds are similar to those reported above for the (LIV) series, and from the existence of a long-range ^5J(PH) constant, the possible occurrence of the BB conformation was proposed.[101,136] In pentaoxyphosphoranes pseudorotation was detected with $\Delta G^{\neq}$ equal to 15.4−15.7 kcal mol^{-1} depending on the nature of the alkoxyl groups at P(V).[135-137] The eight membered ring occupies a diequatorial position in the trigonal bipyramid of the P(V) atom, and pentaoxyphosphoranes with a sulphide bridge have a BC structure.[137] When the temperature is lowered, the doublet of the methylene group (with chemical shift 3.75 p.p.m. and a ^5J(PH) coupling constant equal to 2.7 Hz) from one of the phosphoranes with X = CH_2CF_3 splits into two doublets with chemical shifts 3.52 and 4.11 p.p.m. and ^5J(PH) 1.9 and 2.8 Hz,[135] indicating the presence of a conformational equilibrium.

Recently studies on dibenzo-1,3,2-dioxasilocines (LVII)[139-141] and dibenzo-1,3,2-dioxaborocines[119] were begun. In the methyl derivative of (LVII) with an $SiMe_2$ fragment, the methyl groups are equivalent at room temperature but below 6 °C they become nonequivalent; $\Delta G^{\neq}$ for the process is 13.9 kcal mol^{-1}. The ^{13}C NMR spectra of this compound also change with temperature, and as regards the protons of the methylene group, above T_{coal} they appear as a singlet with δ = 4.12 p.p.m. while below it they appear as a doublet with δ = 3.61 and 4.50 p.p.m., $\Delta\delta$ = 0.89 p.p.m., ^2J(HH) = 14 Hz.[139] The authors came to no definite conclusions about the conformational behaviour (in their opinion there could be BC or BB forms having a plane of symmetry or an equilibrium between identical asymmetric conformations). The inversion barrier in 1,3,2-dioxaborocine (LVIII) is of the same order of magnitude (14.4 kcal mol^{-1}). Since the methylene group in this compound at room temperature appears as a doublet at 3.81 and 4.27 p.p.m. with a geminal constant of 13 Hz, it is suggested that the conformations of (LVII) and (LVIII) are similar.[118] It will be possible to reach definite conclusions about the steric structure of the compounds when detailed variable temperature measurements are carried out, taking into account the spectroscopic criteria (indicating the definite presence of the BC conformer) found in the case of 1,3,2-dioxaphosphocines.

There are also similar spectroscopic parameters for sulphites (LIX) with X = CH_2 and Y = UEP (δ 3.52 and 4.27 p.p.m., ^2J(HH) 12.6 Hz for one of them) existing as equilibrium mixtures given by *a*-BC $\rightleftharpoons$ *e*-BC, and the *e*-BC form predominates when R = Cl, R′ = H and R = t-Bu, R′ = Me, the *a*-BC form predominates when R = R′ = H.[142] In accordance with the spectroscopic criteria found,[120] the dinaphthosulphite with δ 4.64 and 4.84 p.p.m. and ^2J(HH) 16 Hz was assigned the *e*-B form.[142] When the methylene group is replaced by a carbonyl (X = C=O) an equilibrium between the *a*-BC and [TB] forms occurs,[143] whereas the corresponding sulphate with Y = O is conformationally pure and has the BC conformation.[143] These conclusions were based on the IR and ^{13}C NMR spectra. The authors claim that the presence of seven lines in the latter is an indication that the molecule has a plane of symmetry.

(LIX)

(LX)

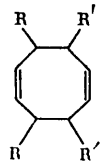
However, since, as was indicated above, such a situation is also possible with a rapid pseudorotation of the type T $\rightleftharpoons$ T* or B $\rightleftharpoons$ B*, it should once again be considered whether the same conformation that was found for the molecule of this sulphate in the crystalline state is retained in solution.[86]

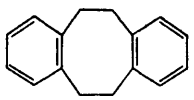
As in the case of 1,3-dioxaphosphocines a reasonable amount of attention has also been given in the literature to diazaphosphocines (LX).[81,144] The phosphorochloridate with Y = O is conformationally heterogeneous; in the ^1H NMR spectra at low temperatures its methyl groups on the two N atoms are nonequivalent. This may be because the compound either retains the distorted boat conformation found in the crystalline state[71,81-83] or in solution a simultaneous inversion of the two nonplanar nitrogen atoms is occurring in it.

In concluding this Section it may be observed that the results obtained made it possible to establish clearly the effect, caused by the nature of the planar fragments, of exocyclic substituents and the electron configuration of three heteroatoms on the conformational behaviour of derivatives of 1,4-cyclooctadienes. The criteria developed in this case can be used to undertake the conformational analysis of other systems of a similar type. In dibenzo derivatives the most favourable conformation in the majority of cases in the BC form, although in some situations a distorted B form also occurs. Less varied in the conformational sense are dinaphtho derivatives; introduction of two bulky planar groups into them destabilises the BC conformation and the distorted B form becomes more typical. Therefore dinaphtho derivatives can be used as specific models for investigation of B conformers of this type.

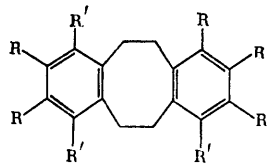
VI. DERIVATIVES OF 1,5-CYCLOOCTADIENES

The stereochemistry of 1,5-cyclooctadiene (LXI) has been examined repeatedly in calculations with several force-fields.[67,70,145-148] The energy minimum here corresponds to the TB conformer with C_2 symmetry. The C conformation with C_{2h} symmetry is less favourable than it by 4.09 kcal mol^{-1} [148] or 1.45 kcal mol^{-1}.[145] The differences in ΔE are due in this case to the different values of the dihedral angle ω_3 (Table 5) obtained by calculations with different force fields and energy minimisation procedures. It is claimed that in such cases the Newton–Raphson method is more accurate in determining the minimum.[2,148] The angle ω_3 calculated for the TB form is 52.5°[148] or 37.9°,[145] and the first value is close to that found by electron diffraction for (LXI) with R = R′ = H[149] and by X-ray diffraction for its *syn*-3,7-dibromo derivative with R = H, R′ = Br (LXI)[157] and 4,8-dimethyl-3,7-dicarboxamide derivative with R = Me, R′ = $OCNH_2$ (LXI).[158]

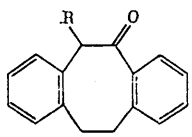




TB B C T



A similar structure was also determined for several organometallic complexes of (LXI),[152,153] dibenzodiazocines,[154-156] and dibenzosilocine.[157] In this conformation there is quite a substantial interaction between the chemically nonbonded H atoms on C(3) and C(7) (distance H...H is 1.992 Å). The energy of the C form is higher because of unfavourable torsional strain along the two types of single C–C bond in comparison with the TB conformer.



When the double bonds are replaced by benzene residues to give (LXII) (so-called 6,8,6-systems), according to the calculations the difference in energy between the TB and C forms decreases to 1.30 kcal mol^{-1} [145] and the boat form is less favourable by only 0.59 kcal mol^{-1}. This difference in conformational behaviour between compounds with double bonds and those with aromatic fragments is due to the difference in torsional interactions along the $C_{sp^2}-C_{sp^3}$ bonds. In diene systems H/H shielding occurs, with an energy estimated at 1.98 kcal mol^{-1}. Since in the dibenzo derivatives the H/C_{sp^2} shielding is less than 0.5 kcal mol^{-1} in energy,[145] in the latter a pseudorotation process readily occurs while in the

dienes inversion occurs. Introduction of methyl groups into the *o*-position of the benzene rings considerably destabilises the TB form, making the C and B conformers more favourable, and moreover, the transition barriers increase substantially.[154]

(LXI)

(LXII)

(LXIII)

(LXIV)

On turning to an examination of the conformational behaviour of these types of compounds in solution, we should note that when variable temperature ^1H and ^{13}C NMR spectra of (LXI) were recorded two processes with low barriers of 4.4 and 4.9 kcal mol^{-1} were detected.[146] On the basis of calculations of potential energy profiles Ermer asserts that the low-energy barrier corresponds here to the exchange TB ⇋ T ⇋ TB (calculated as 4.15 kcal mol^{-1} at 100 K), while two other processes occur, according to the calculations, via an intermediate boat or chair state with similar barriers of 5.73 and 5.91 kcal mol^{-1}. The experimentally determined barrier of 4.9 kcal mol^{-1} [146,148] apparently corresponds to a combination of these processes. *syn*-3,7-Dibromo-1,5-cyclooctadiene (LXI) with R = H, R′ = Br retains the TB form both in solution and the crystalline state.[150]

The first studies of dynamic ^1H NMR spectra of dibenzo derivatives showed that compound (LXII) was conformationally heterogeneous[159] and two processes for it were found with energies of 7.5 and 10.2 kcal mol^{-1}. At a normal temperature a mixture of TB and C conformations is observed in this case with a predominance of the former.[159] The effect of *o*- and *m*-methyl groups[158,160,161] and of tetra- and hexa-methyl substitution[159] on these processes was also studied. For all of them the equilibrium TB ⇋ C was characteristic, and in the *o,o,o′,o′*-tetramethyl derivative (LXIII) with R = H, R′ = Me the population ratio was 88 : 12 and the interconversion barrier proved to be higher (12.1 kcal mol^{-1}) than in the unsubstituted compound. Thus, the presence of *o*-substituents in this case leads to an increase in energy of the transition state. If four methyl groups are introduced into the *m*-position [(LXIII) with R = Me, R′ = H, the inversion barrier is virtually unchanged (10.5 kcal mol^{-1}), while in the conformational equilibrium of the two forms the chair type predominates (40 : 60).[162] Different dibenzo-3-octanols with methyl groups in the 4-, 7-, and 8-positions also, according to the ^1H NMR spectroscopy data, prefer the TB conformation with an *a*-orientation of the hydroxyl group. Compounds that contain one methyl group each at C(4) or C(8) are conformationally heterogeneous and exist as the equilibrium mixture *a*-TB ⇋ *e*-TB (the difference in energy between these conformers is not large—0.33 and 0.44 kcal mol^{-1}.[163]). Similar behaviour is shown by dibenzocyclooctenes containing fragments such as Br and AcO.[163,164] As was indicated above, introduction of a carbonyl group into an eight-membered ring has little effect on its conformational behaviour, which is also confirmed in the case of ketone (LXIV); when R = H the equilibrium TB ⇋ C, which is usual for dibenzo derivatives, occurs, whereas when H is replaced by Me the equilibrium is displaced towards mirror-image TB conformers.[164]

Dynamic spectroscopy has been widely used to study heterocyclic analogues of the type (LXV)–(LXVII), for which the experimental results on inversion barriers have been correlated with those calculations on the transition state energies. Azocines (LXV) with X =

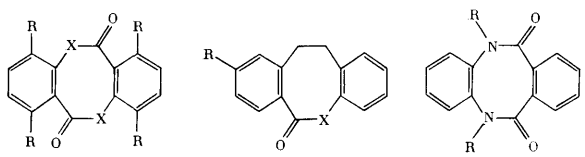
** TS is transition state; symmetry of the conformers is given in brackets.



NAc, NBz, NSO_2, Ar, NCH_2Ph, and NH are characterised by an equilibrium of the C and B forms with transition barrier between them of 10.6–11.1 kcal mol^{-1} (calculated 13.2 kcal mol^{-1}); the barriers for the transitions B ⇋ B* or B ⇋ TB are much higher (14.3–20.1 kcal mol^{-1}).[160]

(LXV) (LXVI) (LXVII)

Diazocines (LXVI) and (LXVII) are also conformationally heterogeneous, but the difference in energy between the alternative C and B forms is low—less than 0.28 kcal mol^{-1} with the exception of diazocine (LXVI) for which the inversion barriers are 12.9 to 14.1 kcal mol^{-1}.[160,165] 3,8-Thiazocine (LXVI) with X = S and Y = NAc also exhibits a temperature dependence in its ^1H NMR spectra, which is due to its conformational heterogeneity. The transition barrier between its forms is substantially higher than in diazocines and amounts to 18.6 kcal mol^{-1}.[165] In contrast to diazocines, in dithiocines (LXVI) and (LXVII) with X = Y = S the conformational equilibrium C ⇋ B is displaced up to 80% towards the B conformer. In the corresponding disulphones (X = Y = SO_2) only one conformer is detected at low temperatures. The barriers for the inversion B → C in compounds (LXVI) (9.0 and 11.9 kcal mol^{-1}) for the sulphide and sulphone are substantially lower than in the corresponding (LXVII) compounds (12.4 and 18.6 kcal mol^{-1}).

When coming to consider the conformations of keto derivatives (LXVIII)–(LXX), we should remember that since the carbonyl group situated in the vicinity of the heteroatom forms a planar fragment, diketone (V) in a conformational sense behaves in a similar manner to 1,5-cyclooctadienes. In this respect diketones (LXVIII) and (LXX) can also be regarded as derivatives of cyclooctatetraene (see next Section). In fact, the conformational properties of diketones (LXVIII) with X = NH, NCH_2Ph,[166] O,[167] S[168] are controlled by a reversible equilibrium inversion of the ring between the B ⇋ B forms. The activation energy of these conformational transitions is high—in diazocines it is 27 kcal mol^{-1},[166] while in dioxocines and dithiocines it is reduced to 17.7–18.4 kcal mol^{-1} [167] and amounts to 24.6 kcal mol^{-1} when R = Me.[168] It has been confirmed by X-ray diffraction analysis of dithiosalicide (LXVIII) with R = H, X = S that the preferred conformation in this case is the boat form with a pseudoplane of symmetry passing through the centre of the S–C(O) bonds.[169]

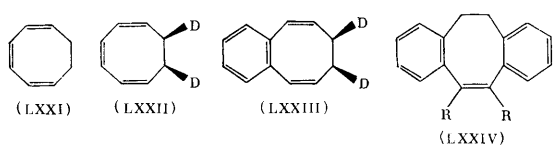
(LXVIII) (LXIX) (LXX)

The barrier in the lactam (LXIX) with R = H, X = NCH_2Ph is also lower (21.4 kcal mol^{-1} [170] (the symmetrically substituted dilactam (LXX) is conformationally pure.[166]) There are indications that the dipole moment of lactone (LXIX) with R = Br (4.09 D) is consistent with the B conformation.

Thus, it may be seen that the conformational behaviour of derivatives of 1,5-cyclooctadienes has as yet been studied insufficiently and to a considerably lesser degree than for 1,4-cyclooctadienes.

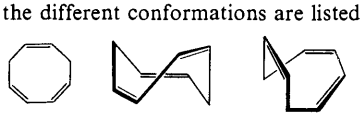
Nevertheless, the results obtained indicate that the remote relative configuration of the two planar fragments helps to stabilise flexible (TB or B) rather than chair-like forms. Introduction of heteroatoms or keto groups into the ring produces an increase in the degree of preference for the B conformer relative to TB, which is due to their occurring in a state analogous to cyclooctatetraene systems.

VII. DERIVATIVES OF CYCLOOCTA-TRIENES AND -TETRAENES



1. 1,3,5- and 1,3,6-Cyclooctatrienes

Since in 1,3,5-cyclooctatriene (LXXI) the alternation of double bonds and single bonds is conducive to conjugation, the theoretical examination of compounds of this type is based on a model of conjugated bonds, assuming a small rotation about the single C_{sp^2}–C_{sp^2} bonds.[31,171,172] It was shown that the most stable form is TB conformer in which the dihedral angle along the CH_2–CH_2 bond is equal to 63°, in contrast to the B form where it has a value of zero. The torsion angles of the three conformers, including the half-chair (HC), are listed in Table 5. The difference in energy between the TB and B forms is due to conjugation effects and torsional interactions. The results of calculations are consistent with dynamic ^1H and ^{13}C NMR spectroscopy data for (LXXI); it was found that the difference in energy between the TB conformer and the B and HC forms is 4.3 and 6.2–6.7 kcal mol^{-1}, and ring inversion occurs with a barrier of 6.6 kcal mol^{-1}.[171]



TB B HC

The introduction of benzene rings in place of double bonds increases the barriers. Thus, on going from (LXXII) to (LXXIII) it increases from 6.7 to 9.2 kcal mol^{-1},[173] and the presence of a second benzene ring contributes to a twofold increase to 18.7 kcal mol^{-1} in the dibenzo derivative, this trend being maintained in the tribenzo analogues.[173] The effect of alkyl substituents on the multiple bond in dibenzo derivatives (LXXIV) on the magnitude of the barrier was studied; in the monomethyl derivative it is higher than in the unsubstituted compound with R = R′ = H and lower than in the disubstituted compound with R = R′ = Me.[158]

(LXXI) (LXXII) (LXXIII) (LXXIV)

For 1,3,6-cyclooctatriene (LXXV) calculations have identified two energy minima, which correspond to the TBC and HC conformers with C_2 and C_s symmetry. The energy difference between them is 1.8 kcal mol^{-1} and the transition barrier 4.10 kcal mol^{-1}.[31,171] The torsion angles in the different conformations are listed in Table 5.

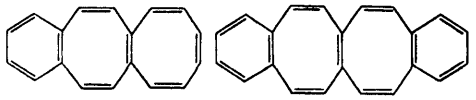
(LXXV) TBC HC

2. Cyclooctatetraenes

Although in 1,3,5,7-cyclooctatetraenes (LXXVI) the alternation of double and single bonds is conducive to conjugation, in a planar system strong angular and torsional interactions occur—and for that reason the B form occurs in this case as a compromise. This has been demonstrated by electron-diffraction data[174] and the results of calculations[1] for (LXXVI) and by X-ray diffraction analysis for its octamethyl derivative.[62] The torsion angles about the cyclic bonds of the B form are given in Table 5. According to the X-ray diffraction studies, introduction of substituents into the ring changes the degree of flattening in the B conformation. It is determined by the magnitude of the so-called external dihedral angles (α). Carboxy-substituted cyclooctatetraene,[175] the 1,4-dinitro derivative,[176] and the 1,3,5,7-tetramethyl derivative[177] have dihedral angles in the range 39–45°.

The proximity of the two pairs of substituents at the 1,4,5,8-positions of the ring (R = $CH_2OC_6H_4Me$-*p*) [178] causes the angle to increase to 48°. The degree of flattening of the octasubstituted compounds is determined by the steric requirements of the substituents. For fluorine atoms which are small in volume the angles are not large (α is 41.0° and 41.7°),[179] on substitution with methyl groups it increases by 8.7–11.0°,[62] and a further increase in substituent volume (phenyl groups) causes the angles to increase to 58.0° and 53.3°.[180,181] In paracyclophane systems no distinctive changes have been found,[182,184] and the conformational state of tetra-annulated systems is determined by the nature of the annulated ring. The tetracyclopentane derivative has the B form (α is 41.4° and 42.3°)[184] and the tetracyclobutane derivative has a planar structure (0.5° and 2.1°).[185]

As regards dynamics, according to the NMR spectroscopic data cyclooctatetraene and its derivatives are characterised by two processes—ring inversion and bond displacement.[186–188] The first of these processes occurs via a planar transition state of D_{4h} symmetry with localised double bonds, and the inversion barrier amounts to about 10 kcal mol^{-1},[189] while for the second process it is higher by 4 kcal mol^{-1}. It is open to question whether a planar structure of D_{8h} symmetry with equivalent C–C bonds[190,191] should also be considered, and in this connection a detailed examination of factors such as resonance destabilisation (antiaromaticity),[192] angle strain, van der Waals repulsion,[193] and related interactions[190] is required. The introduction of alkyl or aryl groups adds a chirality element, with the result that the possibility arises for isolating optically active isomers.[194–198] From the difference between the ^1H NMR spectra of the isomers it is possible to determine the degree of flattening in the ring. Thus, for derivatives with a 1,2-annulated four-six membered ring system it was shown that flattening of the cyclooctatetraene ring increases as the size of the annulated ring decreases.[199]



The boat conformation is preserved in mono- and di-benzo-octalenes (LXXVII) and (LXXVIII).[200,201] Such systems are of interest for studying the inversion barriers between the B and B* conformers using dynamic NMR spectroscopy. In dibenzooctalenes it is quite high (12.3 kcal mol^{-1} for (LXXVIII) with R = CH_2F [202]) and shows little dependence on the nature of R, while in dioctalenes the barrier is even higher (15.3 kcal mol^{-1} [201]). The conformational behaviour of di-, tri- and tetra-benzooctalenes is similar to that of the biphenyl derivative.[199]

The conformational situation can change, as indicated above, when heteroatoms are introduced. In fact, dibenzodiazocine (LXXX) has a distorted B form, the torsion angles of which are also listed in Table 5.

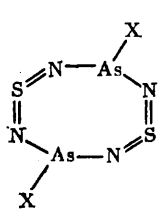
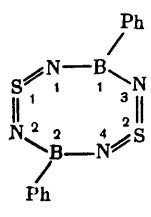
(LXXIX) (LXXX)



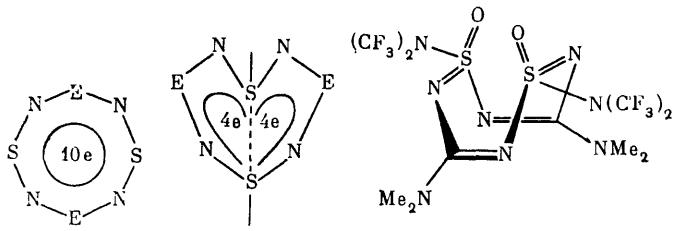
3. Inorganic 8-Membered Heterocycles with Planar Fragments

Extensive opportunities for studying the effect of geometric parameters and intramolecular electronic interactions on conformations are provided by the data on cyclotetraphosphazenes (LXXXI), where by varying the substituents on the phosphorus atom it is possible to obtain a wide variety of compounds, including geometric isomers. X-Ray diffraction studies indicate that the endocyclic PNP and NPN angles are determined to a considerable degree by the nature of the exocyclic substituents on phosphorus and can vary over a very wide range. For F-substituted compounds an almost planar structure of the P_4N_4 ring is characteristic.[204] Some of the compounds studied have a distorted saddle-shaped conformation (BB according to the terminology used in this review); these are $N_4P_4Cl_4Ph_4$,[205] $N_4P_4Cl_2(NMe_2)_6$,[206] $N_4P_4Cl_4(NMe_2)_4$,[207] N_4P_4.$(OMe)_8$.[208,209] A structure similar to the B form was found in $N_4P_4F_4(NMe_2)_4$.[210] A large proportion of the cyclotetraphosphazenes have a CC conformation in which four P atoms are situated in one plane.[211-217] In one case the CC form is stabilised with four coplanar N atoms—this is in the *cis*-isomer of $N_4P_4Cl_4Ph_4$.[217] An increase in the number of F atoms to seven helps to flatten out the ring. In the last of the examples on cyclotetraphosphazene given in Table 6 a nearly planar conformation is present, which is seen very clearly from the values of the dihedral angles.[218]



X-Ray diffraction data have been obtained for compounds that contain two adjacent diplanar fragments. The first of them (LXXXII), as for cyclotetraphosphazene, has a BB conformation in which the As atoms occupy the flagpole position and the t-butyl groups are in equatorial positions.[219] In diborocine (LXXXIII)[220] the boron atom is tending to retain a coplanar configuration for three bonds, so the conformation of the compound changes, being characterised by a bend along the line $N_1...S_2$ and by the presence of two planar groups $N_1B_1N_3S_2$ and $S_2N_4B_2N_2S_1N_1$ (the angle between these two planes is 126°).

(LXXXI)



(LXXXII)

(LXXXIII)

Compounds of the type E(NSN)E with 10 π-electrons (obeying the $4n + 2$ aromaticity rule) can exist, depending on the nature of E, either in a planar form (LXXIV) with E = CPh,[221] S as in $S_4N_4^{2+}$,[222-224] $S_4N_4Cl_2$,[225] $[S_4N_4Cl]^+.X^-$ [X = $FeCl_4$,[226] $ZrCl_{10}$[227]] or in a butterfly conformation (LXXXV) with E = PMe_2,[228] $CNMe_2$ [221] and with a transannular interaction between the two sulphur atoms. At the same time in adducts of type $S_4N_4.AsF_5$ a BB (saddle) form occurs with the four sulphur atoms in one plane.[229] A deformation of the BB form to the B conformation is also possible, as is shown in the case of the dioxide (LXXXVI).[230]

(LXXXIV) (LXXXV) (LXXXVI)

- - - o 0 o - - -

It is possible to draw the following conclusions from what has been stated above. Eight-membered rings with planar fragments are conformationally mobile systems whose behaviour is closely related to the nature of the heteroatoms and the planar fragments and their relative configuration. The main and most clearly expressed trend is the tendency to adopt a chair-type conformation that corresponds the closest possible to the most stable BC form of cyclooctane. This is opposed by purely geometric limitations—the preservation of a planar configuration of the cyclic atoms that form a planar fragment and the two atoms adjacent to them. As a result, the TBC or C form occurs instead of the BC form. However, the introduction into the ring of heteroatoms capable of producing large angular deformations can contribute to inclusion in the ring also occurring in the BC form. An indication of this is the case of 1,2-cyclooctadiene and 1,5,2,4,3-dioxadiphosphazocine corresponding to it—they exist in the TC and BC forms respectively. Since the occurrence of the BC form is extremely difficult in compounds with four planar fragments, the majority of cyclotetraphosphazenes have a CC structure. 1,3-Cyclooctadienes and cyclooctatetraenes have a TBC conformation while 1,5-cyclooctadienes have the C form. The introduction of heteroatoms into the ring can lead to a greater stabilisation of the B conformer relative to the TB form. In all of the examples with diplanar fragments examined it is the B conformation that occurs in a particular proportion. In addition to heteroatoms, the nature and relative configuration of planar fragments also have a substantial effect on conformational behaviour. Changes can be seen clearly on going from rings with double bonds to benzo and naphtho derivatives; the main consequence of this transition is related to the increase in inversion barrier. It will therefore be of particular interest in the future to study heterocycles containing multiple bonds.

It can be seen from the material presented that not all types of compounds have been studied sufficiently. This must mainly concern the initial stage of the studies, when it is still premature to make far-reaching general conclusions. The most complete and interesting results have been obtained for dibenzo and dinaphtho derivatives of 1,4-cyclooctadienes, but many of them still require further tests and checks. It is still necessary to apply much effort in

order to determine all the electronic factors that govern the preference for one or other structures. Matters are much more complex than they appeared to be previously concerning compounds that contain four planar fragments and whose heterocyclic representatives all the time reveal new cases of conformational diversity. While for cyclooctatetraene it would be possible to talk about a single preferred form, namely, the boat form, in heterocyclic derivatives other structures are found that are typical, it would appear, only for saturated systems—structures such as the CC and BB forms. As can be seen, eight-membered rings with planar fragments are promising models for the development of conformational analysis as a whole. The correct analysis of compounds that are so complex in terms of conformation is possible on the basis of quantitative criteria for representing the conformations. The development of principles of conformational analysis for the class of compounds considered here will be a stage in proceeding towards saturated eight-membered rings and large-sized rings that are more complex in terms of conformation.

Reactions of Transition Metal Polyhydride Complexes with Hydrocarbons

V.D.Makhaev and A.P.Borisov

The literature data on the interaction of transition metal polyhydride complexes with hydrocarbons are surveyed and analysed. Attention is concentrated on the examination of reactions with participation of the C-H bonds of hydrocarbons, i.e. on the activation of C-H bonds. The principal features of these reactions—the influence of the central atom of the complex, the nature of the stabilising ligands, the structure of the hydrocarbon, the reaction conditions, the solvent, and thermodynamic and kinetic factors—are examined. The possibility of increasing the catalytic activity of systems based on transition metal polyhydride complexes is discussed.
The bibliography includes 87 references.

I. INTRODUCTION

The term "activation of the C—H bond" in metal complex catalysis denotes processes in which a more reactive carbon—metal bond is formed from a C—H bond at least as an intermediate stage in some kind of process (isomerisation, isotope exchange, dehydrogenation, etc.).[1] In many compounds, the C—H bonds are sufficiently reactive to interact with the active centres of metal complexes. Many examples of reactions with participation of reactive C—H bonds, such as cyclometallation, isomerisation of olefins, isotope exchange in aromatic hydrocarbons, etc. are known.

About two decades ago, Shilov and co-workers[2] showed that in the presence of platinum(II) compounds isotope exchange takes place in solution between saturated hydrocarbons and deuterium. This discovery altered significantly the established ideas about the reactivity of alkanes and influenced greatly the further development of research into the activation of the C-H bond of hydrocarbons. However, for a long time it was impossible to discover new homogeneous systems capable of activating the C—H bonds of unstrained saturated hydrocarbons under mild conditions.

The beginning of the 1980s was marked by considerable advances in this field of research: the first examples of reactions involving the oxidative addition of saturated hydrocarbons to metal complexes with formation of stable alkyl hydride derivatives were discovered and investigated and the possibility of the selective homogeneous catalytic dehydrogenation of alkanes and cycloalkanes was demonstrated. An important step was made on the way to the creation of homogeneous catalytic systems capable of converting saturated hydrocarbons into their functional derivatives under mild conditions. The current interest in this problem is evident—after all, a considerable proportion of the organic raw material resources in fact comprise saturated hydrocarbons, whose low chemical reactivity prevents their widescale employment in chemical industry. The thermal and free-radical reactions used to synthesise functional derivatives of alkanes require a large expenditure of energy and are distinguished by a low selectivity. The need for the creation of new highly selective ways of processing hydrocarbons is the reason for the ever increasing interest in the study of the reactions of alkanes and cycloalkanes with transition metal complexes.[3,4]

Three main types of metal complex systems capable of activating the C—H bond of saturated hydrocarbons under mild homogeneous conditions are known at present—platinum(II) salts in an acid medium, biscyclopentadienyl derivatives of the lanthanides and actinides, and also transition metal polyhydride complexes and their derivatives. There exist a number of reviews on the first two types of activating systems, for example, those of Shilov and Shteinman[5] and Rothwell.[6]

The present review deals with the available literature data at the beginning of 1987 on the interaction of hydrocarbons with transition metal polyhydride complexes (PC)—compounds containing four and more hydride ligands linked to one transition metal atom. The types of PC known at present, the methods for their synthesis, and their chemical and physicochemical properties have been examined in detail in existing reviews.[7,8] The high reactivity of PC with respect to the C—H bonds is explained by the relative ease, characteristic of these compounds, with which they lose some of the ligands (the splitting off of hydrogen or phosphine). This involves the formation of coordination-unsaturated intermediates which tend to fill the coordination sphere by forming metal—hydrogen bonds and which are capable of abstracting a hydrogen atom from the molecules of compounds of different classes—alcohols, ethers, and saturated and unsaturated hydrocarbons.

The studies on the reactions of transition metal PC with hydrocarbons are developing vigorously. We therefore thought it useful to examine initially the available data, in some cases still inadequate, on the reactions of various PC with hydrocarbons and then to discuss the principal features of the processes considered and the factors influencing the reactivity of PC.

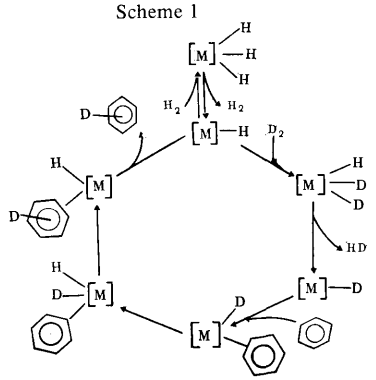
II. INTERACTION OF TRANSITION METAL POLYHYDRIDE COMPLEXES WITH HYDROCARBONS

1. Group VB Metal Complexes

The niobium pentahydride $NbH_5(DMPE)_2$, where DMPE = 1,2-bis(dimethylphosphino)ethane, forms an ethylene complex on interaction with ethylene, whereupon hydrogen and traces of ethane are evolved:

$$NbH_5(DMPE)_2 + C_2H_4 \xrightarrow[16\ h,\ 1\ atm]{pentane,\ 25\ ^\circ C} NbH(C_2H_4)_2(DMPE)_2 + 1{,}8H_2 + C_2H_6 \text{ (traces)}.$$

When the reaction is carried out with deuterioethylene (Nb : C_2D_4 = 1 : 6), isotope exchange of ethylenic and hydride hydrogen atoms is observed; the hydrogen evolved consists of a mixture of isotopes (21% H_2, 44% HD, and 35% D_2). The exchange is slow and does not lead to the broadening of the ^1H NMR signals even at 95 °C in toluene-d_8.[9] The insertion of deuterium in the alkyl groups of the phosphine ligands was not observed.



In contrast to the niobium complex, its tantalum analogue is much less reactive in relation to ethylene.[9] According to patent data, niobium and tantalum pentahydrides catalyse the dimerisation and hydrogenation of ethylene at an elevated temperature and pressure.[10]

The polyhydride complexes of the metals in the third transition row, having an odd number of valence electrons (TaH_5L_4,[11,12] ReH_7L_2,[13] ReH_5L_3, and IrH_5L_2,[14,15] where L is a tertiary organic phosphine), are active catalysts of isotope exchange between molecular hydrogen and aromatic hydrocarbons. $TaH_5(DMPE)_2$ proved to be the most active among these catalysts. The isotope exchange reaction has the following characteristic features:[12] (1) only the aromatic C–H bonds participate in the isotope exchange (in contrast to the exchange catalysed by metallic platinum or $PtCl_4^{2-}$, deuterium does not enter into the methyl groups of toluene or xylene); (2) the exchange takes place in stages—one C–H bond is involved in the exchange in each cycle of the reaction; (3) the reaction is sensitive to the steric effects of the substituents (deuterium exchange in the *ortho*-positions relative to the methyl or trifluoromethyl group takes place to an insignificant extent; the introduction of a second substituent in the *para*-position relative to the first retards the reaction sharply; electron-accepting substituents accelerate the reaction but the differences between the rates of reaction for monosubstituted arenes are small regardless of the type of substituent); (4) the presence of the isotope effect $k_H/k_D = 2-3$ shows that the C–H bond is dissociated in the rate-determining stage.

When triphenylphosphine is added to the reaction mixture, the hydrogen atoms in the *meta*- and *para*-positions in the benzene rings of phosphine participate exclusively in the isotope exchange, while in the presence of the $RuHCl(PPh_3)_2$ catalyst, the hydrogen atoms in the *ortho*-positions are exchanged. It has been suggested that, in the system considered, the phosphorus atom of triphenylphosphine is not coordinated to the tantalum atom and the polyhydride reacts with PPh_3 in the same way as with a substituted benzene having bulky PPh_2 substituents hindering the exchange in the *ortho*-position.

A mechanism has been proposed for the isotope exchange, including alternating stages involving the reductive elimination of H_2, the coordination of the arene, and oxidative addition:

Scheme 1

The weak influence of substituents is explained by the fact that both the oxidative addition and the coordination of the arene influence the rate of the reaction. It has been suggested that substituents exert the opposite influence on the rates of these stages, which in fact leads to the observed variation.

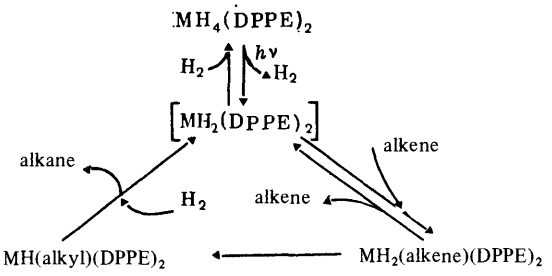
The absence of the deuteriation of the more acid hydrogen atoms in the methyl groups of toluene and anisole shows that only the hydrogen of the double bond coordinated to the metal is exchanged.[12]

The interaction of $Cp^*TaH_4L_2$ ($Cp^* = \eta^5$-C_5Me_5) with ethylene leads to a mixture of tantalum-containing products, ethane, but-1-ene, and free phosphine. Depending on the nature of the ligands L, the rate of reaction diminishes in the sequence $PMe_2Pb > PMe_3 > P(OMe)_3 > Me_2PCH_2CH_2PMe_3$, which is correlated with the decrease in the ease of elimination of the phosphine ligands from the complex. The addition of an excess of the phosphine to the reaction mixture inhibits the reaction. It has been concluded that the interaction of ethylene is preceded by the stage involving the reversible elimination of the phosphine ligand.[16] The complexes $Cp^*TaH_4L_2$, where L are monodentate ligands, form the butadiene complex $Cp^*TaCH_2CH_2CH_2CH_2(C_4H_6)$ in a high yield as a result of the reaction with ethylene. The tetrahydride stabilised by trimethylphosphine catalyses the dimerisation of ethylene to but-1-ene.

The photolysis of the benzene solution of $Cp^*TaH_4(DMPE)$ in an atmosphere of ethylene (2 atm) leads to the complex $Cp^*TaH_2 \cdot (C_2H_4)(DMPE)$ and the stoichiometric amount of ethane. When the ethylene complex is acted upon by hydrogen, the initial tetrahydride and ethane are produced.[16] The photochemical reaction probably proceeds, via a hydrogen elimination stage, in contrast to the thermal reaction.

2. Group VIB Metal Complexes

The interaction of PC of Group VIB metal complexes with hydrocarbons has been studied mainly in relation to the complexes $MH_4 \cdot (DPPE)_2$ [DPPE = 1,2-bis(diphenylphosphino)ethane] and $MH_4 \cdot (PMePh_2)_4$ (M = Mo or W). At 25 °C, the above compounds do not interact with alkenes in solution. Heating of toluene solutions of alk-1-enes and $MH_4(DPPE)_2$ to 100 °C leads to the stoichiometric reduction of the alkenes.[17,18]



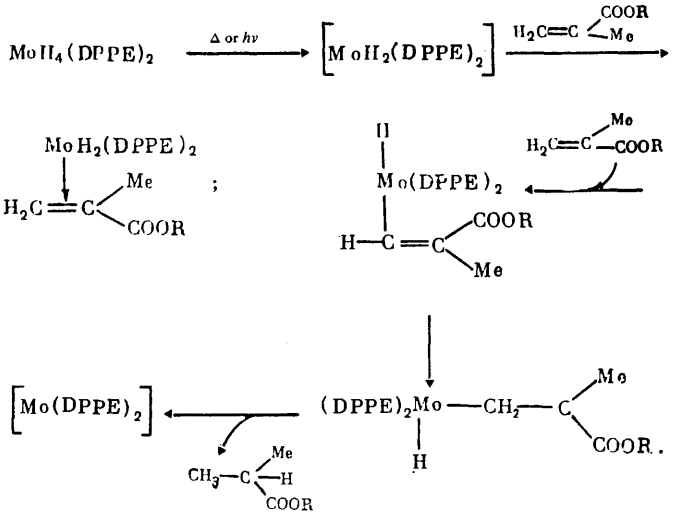
Irradiation of toluene solutions of pent-1-ene and $MH_4(DPPE)_2$ (λ = 355 nm) at room temperature leads to the stoichiometric reduction of the pentene, isomerisation with formation of pent-2-ene not being observed even after prolonged irradiation. Under analogous conditions, *cis*-pent-2-ene, 3,3-dimethylpent-1-ene, and cyclopentene are also reduced.

The photochemical reduction of $MoH_4(DPPE)_2$ with ethylene entails the formation, apart from ethane, of the diethylene complex $Mo(\eta^2$-$C_2H_4)_2(DPPE)_2$, which was isolated from the reaction mixture. The reaction with propene takes place differently and affords the π-allyl complex $MoH(\eta^3$-$C_3H_5)(DPPE)_2$.

It has been suggested that analogous products, containing η^2- or η^3-ligands depending on the structure of the initial olefin, are formed also in the interaction of $MH_4(DPPE)_2$ with other alkenes, but these products could not be isolated. The quantum yield of the pent-1-ene reduction reaction is 0.09 for $MoH_4(DPPE)_2$ and 0.006 for $WH_4(DPPE)_2$. When solutions of molybdenum (or tungsten) tetrahydride and pent-1-ene are irradiated in an atmosphere of hydrogen, the catalytic reduction of the pentene to pentane, unaccompanied by the formation of isomerisation products, is

observed (after 15 h, which corresponds to 150 catalytic cycles, only 1% of pent-2-ene is obtained). Internal olefins and olefins without an allylic hydrogen atom are reduced analogously. Photochemical reduction requires constant irradiation, i.e. long-lived catalytically active species are not formed. When a 0.1 M solution of pent-1-ene is reduced, the quantum yield is approximately equal to the yield in a stoichiometric reaction. On raising the pent-1-ene concentration to 5 M, the quantum yield also increases by an order of magnitude, which agrees with the process mechanism presented below:

Scheme 2

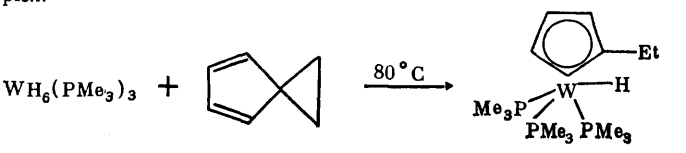


As can be seen from the Scheme, the irradiation of $MH_4(DPPE)_2$ leads to the elimination of a hydrogen molecule with formation of the dihydride, which either interacts with the alkene or again reacts with H_2.

The relative rates of photochemical reduction of alkenes correspond to those expected for reactions with participation of the sterically hindered species $MH_2(DPPE)_2$: pent-1-ene > 3,3-dimethylpent-1-ene > cyclopentene > *cis*-pent-2-ene. The hydrogenation proceeds without the isomerisation of the alkenes, in contrast to many other photocatalytic systems investigated previously.[19] In the reduction of pent-1-ene by deuterium, deuterium atoms add stereospecifically to the double bond and are not distributed statistically among various positions in the molecule, which would have been observed on isomerisation. It is believed[18] that the absence of isomerisation is associated with the steric hindrance due to the two bulky bisphosphine ligands. However, one should note that data concerning the stereospecific addition of deuterium do not agree with the authors' hypothesis of the intermediate formation of π-allyl complexes by alkenes having allylic hydrogen atoms.

The introduction of an aryl substituent into the alkene influences appreciably the composition of the reaction products. The reduction of 4-phenylbut-1-ene under the conditions indicated above also leads to the addition of deuterium in the 1,2-positions. However, this entails the formation of an appreciable amount of isomerisation products; the absence of deuterium from these products shows that structurally different photogenerated species are responsible for reduction and isomerisation.

At 80–100 °C, the complex $MoH_4(DPPE)_2$ interacts with alkyl methacrylates, forming one mole of H_2, one mole of alkyl isobutyrate, and a certain amount of the corresponding hydrido-σ-alkenyl complex $MoH[CH=C(Me)C(O)(OR)](DPPE)_2$ [R = Et, iso-Pr, Bu, or Cy (cyclohexyl); yield 15–80%]. On irradiation, the reaction takes place at room temperature resulting in the insertion of the intermediate coordination-unsaturated species in the C–H bond of the unsaturated compound:[20]

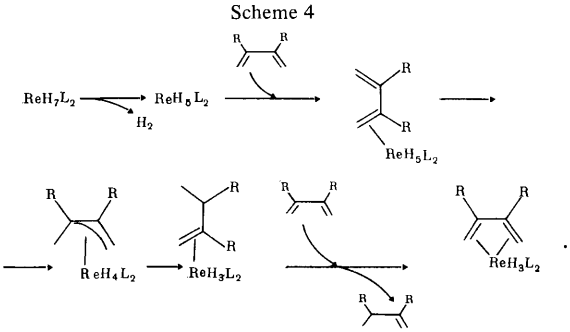


Scheme 3

Under the conditions of the photochemical reaction, molybdenum and tungsten PC are capable of interacting also with benzene and saturated hydrocarbons.[21] When solutions of MH_4L_4 in benzene-d_6 or cyclohexane-d_{12} are irradiated (254 nm), deuterium molecules are present in the gas phase after the reaction and in the case of cyclohexane-d_{12} much more deuterium is evolved than in the reaction in deuteriobenzene. The complex with methyldiphenylphosphine is much more active in this reaction than the complex with bis-(diphenylphosphino)ethane. The composition of the products of the reaction of the metal complexes and hydrocarbons has not been investigated. It has been suggested that the reaction proceeds via a stage involving the oxidative addition of a photogenerated active species to a C–H bond of the hydrocarbon. The cyclometallation reaction is a competing process, which is indicated by the appearance of deuterium in the gas phase on irradiation of $WH_4[P(CD_3)_2Ph_2]_4$ and $WH_4[P(CD_2CD_3)Ph_2]_4$ in benzene or cyclohexane.[22] The dependence of the composition of the gas phase on the irradiation wavelength (deuterium is not observed in the gas phase at λ = 366 nm) and on the nature of the phosphine ligands suggests that, with increase in the irradiation frequency, not only hydrogen but also some of the phosphine ligands are split off (see the reactions with participation of ReH_5L_3).

An interesting feature of the study of Pivovarov et al.[21] is the observation of a higher reactivity of cyclohexane compared with benzene. It may be that a change in the ligand environment and in the reaction conditions will make it possible to devise a system manifesting a still higher activity in relation to alkanes than to arenes.

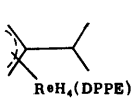
The reactions of the molybdenum and tungsten hexahydrides MH_6L_3 (M = Mo or W) with hydrocarbons have been scarcely investigated. It has been reported that, when a benzene solution of $WH_6(PMe_3)_3$ is refluxed in the presence of cyclopenta-2,4-dienespirocyclopropane, the cyclopropane ring is rapidly opened, which results in the formation of an ethylcyclopentadienyltungsten complex:[23]



3. Rhenium Complexes

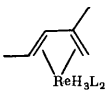
Perhaps the greatest number of different polyhydride complexes are now known for a Group VII metal—rhenium. The interaction of PC with hydrocarbons has in fact been studied in greatest detail in relation to the rhenium complexes. Technetium, an analogue of rhenium, is a radioactive element and studies on the chemical properties of technetium PC have not so far been reported.

The rhenium heptahydrides ReH_7L_2 react under mild conditions with phosphines, amines, and arsines to form the pentahydride ReH_5L_2L'. Further substitution of hydrogen, leading to trihydrides, requires much more severe conditions.[13,24] However, the interaction of ReH_7L_2 with various dienes proceeds readily under mild conditions and is accompanied by the conversion of the heptahydride into the trihydride.[25,26]



The reaction of $ReH_7(PPh_3)_2$ with buta-1,3-diene and its alkyl derivatives in boiling tetrahydrofuran (THF) ends after several minutes. The trihydrodiene complexes $ReH_3(diene)(PPh_3)_2$ are pale-yellow crystalline substances stable in air. The interaction of $ReH_7 \cdot (PPh_3)_2$ with an excess of cyclopentadiene at 25 °C results in the formation of the diene complex $(\eta^4\text{-}C_5H_6)ReH_3(PPh_3)_2$. However, with increase in the amount of the heptahydride, the complex is dehydrogenated catalytically with formation of $CpReH_2L_2$.[27] The interaction of equimolar amounts of ReH_7L_2 and cyclopentadiene in THF at 60 °C leads directly to $CpReH_2L_2$.[25] Cyclohexa-1,3-diene or cyclohexa-1,4-diene afford $(\eta^4\text{-}1,3\text{-}C_6H_8)ReH_3(PPh_3)_2$, the heating of which leads to the arene complex $ReH(\eta^6\text{-}C_6H_6)(PPh_3)_2$. Baudry et al.[26] described the following scheme for the interaction of rhenium heptahydride with dienes:

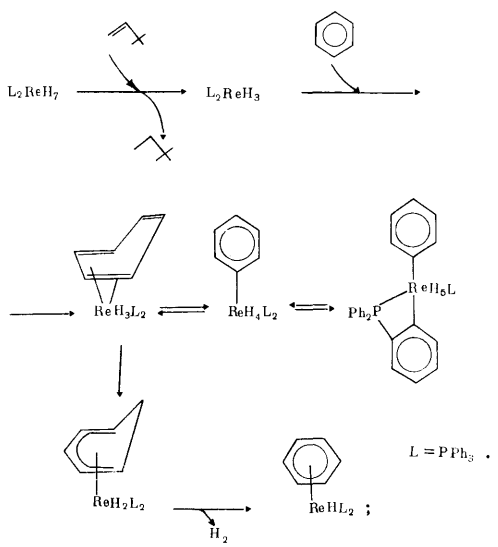
Scheme 4



As a consequence of its low thermal stability in solution, the heptahydride loses a hydrogen molecule and is converted into the pentahydride, which interacts with the diene. The diene ligand promotes further reaction, acting as a hydrogen acceptor, and the complexes $ReH_5(\eta^2\text{-diene})L_2$ are therefore unstable and have not been isolated. The proposed mechanism is supported by the finding that only one mole of hydrogen per mole of the complex is evolved during the reaction and that part of the diene is hydrogenated to a mono-olefin.

The reaction conditions and the composition of the product depend on the properties of the ligands. Thus ReH_7(DPPE), containing the bidentate phosphine ligand, is more thermally stable and does not react with dienes under the conditions indicated. Subsequent treatment of this PC with potassium t-butoxide and dimethyl sulphate in the presence of 2,3-dimethylbutadiene yielded the first example of a PC with an allyl ligand:[28]

On refluxing in THF, the complexes ReH_7L_2 react with propene to form complexes containing the propene dimerisation product—2-methylpenta-1,3-diene—as the ligand:



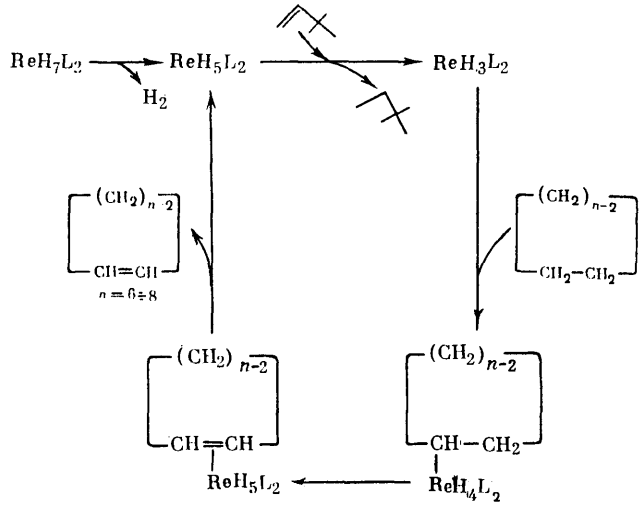
The photochemical reaction of this compound or of the initial heptahydride with an excess of propene affords $(\eta^3\text{-}C_3H_5)_2ReHL_2$, which permits the conclusion that rhenium heptahydride is successively converted initially into the diene complex $ReH_3(\eta^4\text{-}C_6H_{10})L_2$ and then into the π-allyl complex $(\eta^3\text{-}C_3H_5)_2ReHL_2$.[29]

Using the activating effect of olefins on the rhenium PC, a series of unusual reactions have been carried out.[25,26] 3,3-Dimethylbut-1-ene [t-butylethylene (TBE)], which has been shown[30] to be the most convenient dehydrogenating agent in such reactions, was used as the hydrogen acceptor.

In the presence of TBE, rhenium heptahydride reacts with benzene on refluxing, giving rise to $(\eta^5\text{-}C_6H_7)ReH_2(PPh_3)_2$. During the reaction, one mole of H_2 is evolved and 1.1 mole of 2,2-dimethylbutane is formed. When benzene-d_6 is employed, the rhenium complex containing a 50% deuteriated cyclohexadienyl ring, 25% deuteriated hydride ligands, and triphenylphosphine ligands (deuteriated in the *ortho*-position to the extent of 10—15%) is formed. The hydrogen evolved contains hardly any deuterium. Heating of the product *in vacuo* affords the η^6-arene complex:[31]

Scheme 5

The reactions with toluene, *p*-xylene, and mesitylene proceed analogously. This results in the formation of the corresponding dihydrocyclohexadienylrhenium complexes.[32]



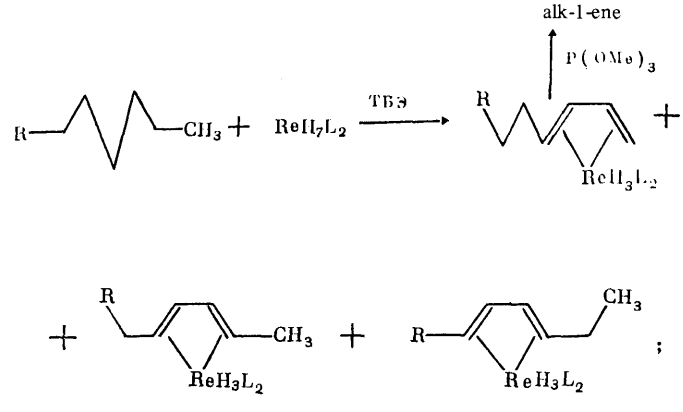
In the presence of TBE, rhenium heptahydride is capable of dehydrogenating saturated hydrocarbons—both cyclic and acyclic.[33-35] The reaction is carried out by refluxing rhenium heptahydride in the corresponding hydrocarbon in the presence of an excess of TBE in an inert atmosphere.

The reaction of ReH_7L_2 (L = PPh_3 or PEt_2Ph) with cyclopentane gives rise to $CpReH_2L_2$. The reaction terminates after 10 min, the entire hydrogen (both from the rhenium hydride and from cyclopentane) being consumed in the hydrogenation of TBE.[33]

The interaction of ReH_7L_2 with higher cycloalkane homologues (cyclohexane, cycloheptane, and cyclo-octane) leads to the corresponding cycloalkenes. It has been noted that the dehydrogenation of cycloalkanes takes place even when air or pure oxygen is passed through the reaction mixture.[34] The yield of the dehydrogenation products increases with enhancement of the electron-donating properties of the phosphine ligands forming part of the composition of the rhenium complex: $P(C_6H_4F\text{-}p)_3 < PPh_3 < P(C_6H_4Me\text{-}p)_3$.

The decrease in the ReH_7L_2 concentration from 5×10^{-2} to 3×10^{-3} M made it possible to achieve the dehydrogenation of cycloalkanes under catalytic conditions. The nature of the PR_3 ligands in ReH_7L_2 has a decisive influence on the course of the catalytic process. Best results have been obtained using $ReH_7.[P(C_6H_4F\text{-}p)_3]_2$, which reacts with cyclo-octane even at 30 °C, giving rise to 1.6 conversion cycles after 10 min. At 80 °C, nine moles of cyclo-octene are formed per mole of the PC. Cyclo-hexene may be used instead of TBE as the hydrogen acceptor in the dehydrogenation of cyclo-octane. The reaction is highly selective: no dehydrogenation products other than cycloalkenes have been observed. Rhenium heptahydrides with more electron-donating triarylphosphine ligands are less active in the catalytic process in contrast to the non-catalytic reaction. Presumably, the electron-donating substituents in the benzene ring of the ligand promote *ortho*-metallation and thereby deactivate the intermediate catalytically active species. Electron-accepting substituents hinder this reaction and therefore promote a higher yield of products. The catalytic process is described by the scheme:

Scheme 6



Under the conditions of this reaction, methylcyclohexane affords a mixture of isomeric olefins,[36] the thermodynamically most stable 1-methylcyclohexene being present only in trace amounts, and the main products are 3- and 4-methylcyclohexenes, which indicates the absence of radical intermediates in the dehydrogenation process. The isomeric composition of the olefins formed depends on the properties of the stabilising phosphine ligands (see Table).

The feasibility of the selective non-radical catalytic conversion of sterically unstrained saturated hydrocarbons into their functional derivatives by treatment with soluble transition metal complexes has been demonstrated[36] in relation to the catalytic dehydrogenation of cycloalkanes in the presence of rhenium hydride complexes.

Composition of the products of the dehydrogenation of methylcyclohexane catalysed by rhenium and iridium PC in the presence of an excess of TBE.[36,37]

Catalyst	Reaction conditions		Number of catalytic cycles	Reaction products, %			
				methylene-cyclohexane	methylcyclohexenes		
	T, °C	t, h			3-Me	4-Me	1-Me
$ReH_7[P(C_6H_4F\text{-}p)_3]_2$	80	1/6	3	6	29	65	1
$ReH_7(PPh_3)_2$	80	1/6	1	9	28	63	1
$ReH_7(PEt_3)_2$	80	2	0.2	28	27	45	1
$IrH_5[P(Pr\text{-}iso)_3]_2$	100	1/4	3	64	10	16	9
	100	1	3.5	55	12	18	15
	150	65	10	1	13	24	62

In the presence of TBE, rhenium heptahydrides are capable of dehydrogenating also normal alkanes.[35] Heating of ReH_7L_2 with an excess of TBE in pentane in a sealed tube (80 °C, 30 min) leads to the pentadiene complex $ReH_3(\eta^4\text{-}C_5H_8)L_2$. The yield of this complex increases on passing from L = PPh_3 to L = $P(C_6H_4Me\text{-}p)_3$. With increase in the rhenium heptahydride concentration, the yield of the complex $ReH_3(\eta^4\text{-}C_5H_8)L_2$ diminishes as a result of the competing formation of $ReH_2(\eta^5\text{-}C_5H_7)L_2$ (cf. with the results of Jones and Maguire[27]). When $ReH_3(\eta^4\text{-}C_5H_8)L_2$ is treated with trimethyl phosphite, pent-1-ene is formed in a high yield and with a high selectivity, while treatment with triethyl or triphenyl phosphite produces a mixture of pentane and pent-1-ene.[38] Treatment of the same compound with benzylisonitrile† leads to the selective formation of *cis*-pent-2-ene. Normal alkanes with 6–8 carbon atoms also react with $ReH_7(PPh_3)_2$ in the presence of TBE. This results in the formation of a mixture of isomeric trihydridodienerhenium complexes, whose treatment with trimethyl phosphite leads to alk-1-enes in a high yield and with a high selectivity:

R = H, Me, Et.

† T.Burchard and H.Felkin, New J. Chem., 1986, **10**(12), 673.

Since the isomeric rhenium complexes are in a dynamic equilibrium under the reaction conditions, the data obtained do not allow one to determine which of the C–H bonds of the alkanes is attacked in the initial stage of the process. It has been suggested that the C–H bonds of the methyl groups are the first to be attacked. In contrast to the reactions with cycloalkanes, which lead to catalytic dehydrogenation products, in the interaction of ReH_7L_2 with n-alkanes, the loss of olefins from the coordination sphere of the complex takes place to an insignificant extent, which makes it impossible to carry out the reaction under catalytic conditions.

The alkanes used in the reaction must be completely free of admixtures of olefins, because even an insignificant amount of such compounds fully inhibits the interaction of rhenium heptahydrides with alkanes.[35]

Rhenium heptahydride stabilised by tricyclohexylphosphine ligands proved to be thermally more stable‡ than the complexes with triarylphosphines, which permitted a more detailed study of certain stages of the activation of C–H bonds by rhenium PC.[39,40] At 60–80 °C, $ReH_7(PCy_3)_2$ reacts with benzene-d_6, deuterium substituting not only the hydride ligands but also the hydrogen atoms at the C(2) and C(3) carbon atoms of the cyclohexyl rings. The regioselectivity of the isotope exchange indicates an intramolecular process mechanism. The higher rate of isotope exchange at the C(3) atom agrees with the intramolecular metallation mechanism, for which the preferential formation of the less strained five-membered ring compared with the four-membered ring should be observed. Acenaphthylene $C_{12}H_8$ is hydrogenated in the inner sphere of the complex with formation of $(\eta^4\text{-}C_{12}H_{10})ReH_3L_2$. The reaction with anthracene does not occur, which indicates the ineffectiveness of the rhenium PC in radical hydrogen transfer processes leading to the hydrogenation of the 9,10-positions in anthracene.

The study of the isotope exchange between ReH_7L_2 and deuterium and of its interactions with acenaphthylene, olefins, and other compounds showed that all these reactions proceed via a stage involving the formation of the intermediate ReH_5L_2 species.

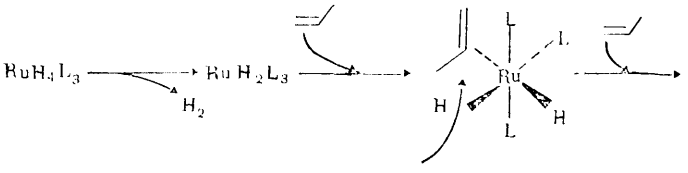
The interaction of rhenium pentahydride $ReH_5(PMe_2Ph)_3$ with hydrocarbons under the conditions of the photochemical reaction has also been investigated.[43–46] Irradiation of a solution of this complex in benzene-d_6 leads to the exchange of the solvent deuterium atoms with the hydrogen atoms in the *meta*- and *para*-positions in the benzene rings of the ligands.[43] the presence of naphthalene in the reaction mixture results in the extensive deuteriation of naphthalene, mainly in the 2,3,6,7-positions.[44]

The photochemical hydrogenation of hex-1-ene by molecular hydrogen has been achieved. The reaction is catalytic with respect to rhenium but requires constant irradiation, as in the case of molybdenum and tungsten PC: when the reaction mixture is kept in the dark for 12 h after irradiation for 10 min, there is no appreciable increase in the yield of hydrogenation products.[44]

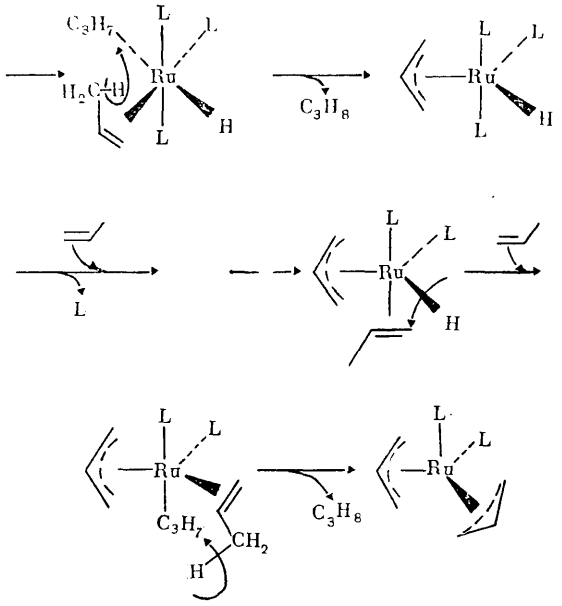
‡ The thermal stability of rhenium heptahydrides increases with enhancement of the electron-donating properties of the ligands. Thus, $ReH_7(PMe_3)_2$, stabilised by trimethylphosphine which is a powerful electron-donating ligand with a small bulk, sublimes *in vacuo* at 40 °C and decomposes at 102 °C.[41] The conversion of ReH_7L_2 into $Re_2H_8L_4$ on heating in solution is retarded on passing from the triphenylphosphine ligand to the more electron-donating ligands PMe_2Ph and PEt_2Ph,[39] although their bulk is in fact smaller.[42] The higher stability of $ReH_7(PCy_3)_2$ can also be explained by the powerful electron-donating properties of tricyclohexylphosphine and not by its small bulk.

Reaction with internal olefins leads to the formation of hydrido-olefinrhenium complexes. When a solution of rhenium pentahydride and cyclopentene in benzene is irradiated, $(\eta^2\text{-}C_5H_8)ReH_3.(PMe_2Ph)_3$ is formed almost quantitatively. The hydrogenation of the olefin is not then observed.[44] Photolysis of the compound obtained leads to coupled hydrogenation-dehydrogenation of the coordinated olefin, which results in the formation of cyclopentane and a mixture of the complexes $CpReH_2L_2$ and $CpReH_4L$.

In the photochemical interaction of ReH_5L_3 with cyclopentadiene, the tetra-hydride complex $CpReH_4L$ (L = PMe_2Ph) was mainly formed, while the thermal interaction afforded the dihydride $CpReH_2L_2$ (L = PPh_3).[25] The interaction of ReH_5L_3 with cyclo-octatetraene under irradiation gives rise to the cyclo-octatriene complex $(\eta^4\text{-}C_8H_{10})ReH_3L_2$.[45] The same compound has been obtained on refluxing $ReH_7(PMe_2Ph)_2$ with cyclo-octa-1,5-diene in hexane, which confirms the hypothesis of the intermediate formation of ReH_5L_2 both in the photochemical activation of ReH_5L_3 and in the thermal activation of ReH_7L_2. On standing for 12 h, the compound $(\eta^4\text{-}C_8H_{10})ReH_3L_2$ is fully converted into the cyclo-octa-1,5-dienyl complex $(\eta^5\text{-}C_8H_{11})ReH_2L_2$. Cyclo-octatetraene is converted into the cyclo-octadienyl ligand regiospecifically: all three hydrogen atoms transferred from rhenium to the hydrocarbon are in the *endo*-positions relative to the rhenium atom, which indicates the intramolecular character of the process.

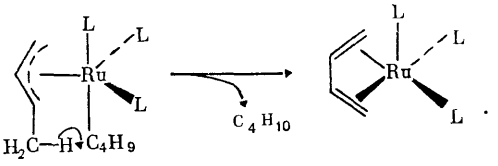


Irradiation of ReH_5L_3 in cyclopentane in the presence of TBE results in the formation of the complex $CpReH_2L_2$ in a low yield, while in the absence of TBE only the dimeric complex $Re_2H_6L_5$—the product of the interaction of ReH_5L_2 with ReH_5L_3—is formed.[47] If ReH_5L_3 (L = PMe_2Ph) is irradiated in the presence of TBE in benzene under nitrogen pressure, a mixture of products is obtained. One of them—the η^6-arene complex—contains the TBE residue, i.e. $(\eta^6\text{-}C_6H_6)ReL_2(CH_2CH_2Bu\text{-}t)$, while the other contains the *ortho*-metallated phosphine and coordinated nitrogen—$\overline{ReL_3(PMe_2C_6H_4\text{-}o)}.(N_2)$.[44]



4. Iron Subgroup Metal Polyhydride Complexes

The iron tetrahydride complex $FeH_4(PEtPh_2)_3$ reacts in THF with cyclohexene, affording $FeH(C_6H_{11})(PEtPh_2)_2$ (THF). It has been suggested that an η^2-olefin iron complex is formed as an intermediate.[48]



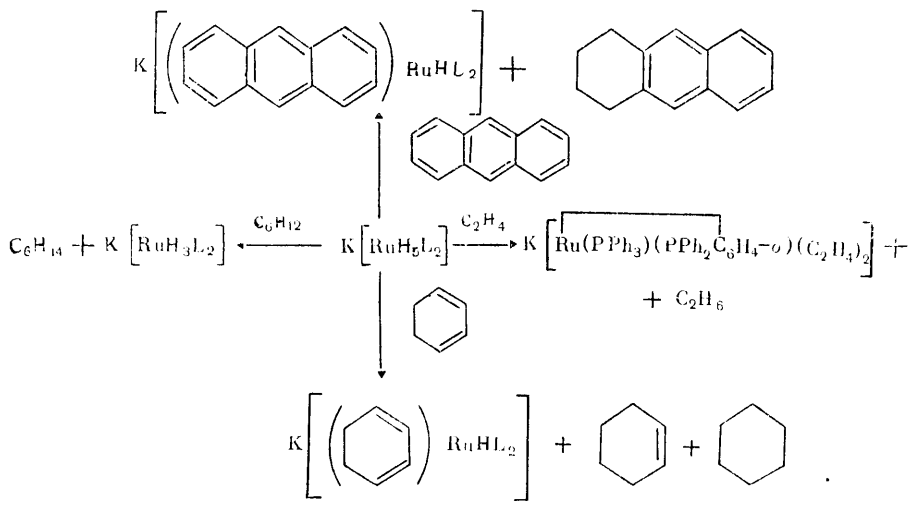
The solid ruthenium tetrahydride $RuH_4(PPh_3)_3$ catalyses the hydrogenation of ethylene but at room temperature the reaction is very slow (ten catalytic cycles in a week[49]). However, if the reaction is carried out in toluene, it is completed after 10 min with formation of $\overline{RuH(PPh_2C_6H_4\text{-}o)}(PPh_3)_2(C_2H_4)$, one mole of hydrogen and one mole of ethane being evolved.[50,51] The reaction of $RuH_4(PPh_3)_3$ with propene at 100 °C takes place in 30 min, affording bis(η^3-allyl)bis(triphenylphosphine)ruthenium:

Scheme 7

The main product of the interaction of $RuH_4(PPh_3)_3$ with an excess of but-1-ene is the butadiene complex $Ru(\eta^4\text{-}C_4H_6)(PPh_3)_3$, the same complex being formed also in the reaction of ruthenium tetrahydride with buta-1,3-diene at room temperature. It is suggested that the butadiene ligand is formed from but-1-ene also via Scheme 7, but in the last stage the hydrogen atom is split off from the methyl group of the 1-methyl-allyl ligand:

Solutions of $RuH_4(PPh_3)_3$ in toluene catalyse the isomerisation of alk-1-enes to alk-2-enes at 25 °C.[52-54] It has been shown in relation to pent-1-ene that *trans*-pent-2-ene is formed preferentially in the isomerisation process in amounts greatly exceeding the equilibrium values for the *cis*-pent-2-ene—*trans*-pent-2-ene system. The reaction is carried out in an argon atmosphere. It takes place initially very rapidly but after a few minutes it begins to slow down and then follows first-order kinetics. The rate of reaction diminishes also when argon is replaced by nitrogen. In the first rapid stage, the isomerisation is accompanied by the hydrogenation of two moles of pent-1-ene per mole of the PC, which corresponds to the utilisation of all the hydride ligands in RuH_4L_3 and, according to the author,[54] indicates the formation of a complex of zerovalent ruthenium with the olefin. The rate of isomerisation is 250 times higher than the rate of hydrogenation. In the second stage of the reaction, only traces of pentane are formed, but, if the reaction mixture is allowed to stand for 24 h or more, yet another mole of pentane per mole of the catalyst is formed. The catalyst then loses its activity, which, however, is restored on treatment with hydrogen. The catalytic activity is apparently lost as a result of the slow *ortho*-metallation reaction.

Subsequent investigations[51] failed to confirm data indicating the formation of alkene complexes in reactions with pentenes. The product of the reaction of RuH_4L_3 with pent-1-ene is RuH_4L_4 for the stoichiometric reactant ratio. The interaction with an excess of pent-1-ene produced the diene complex $Ru(\eta^4\text{-}C_5H_8)L_3$, which is apparently formed from but-1-ene similarly to the butadiene complex. This hypothesis agrees with data demonstrating the formation of two moles of pentane per mole of the catalyst and explains the evolution of one mole of H_2 in the initial stage of the reaction.



The complex $RuH_4(PPh_3)_3$ reacts with the non-conjugated chelating cyclo-octa-1,5-diene (toluene, 100 °C, 5 h) with formation of one mole of cyclo-octane and $Ru(PPh_2C_6H_4\text{-}o)(PPh_3)(\eta^5\text{-}C_8H_{11})$. RuH_4L_3 does not interact with isobutene, cyclohexene and cyclo-octene even at 100 °C.[51]

The complexes RuH_4L_3 [L = P(Pr-iso)$_3$, PCy_3, or $P(NEt_2)_3$] activate the C—H bonds of aromatic hydrocarbons and the alkyl groups in phosphine ligands at room temperature in the dark.[55,56] When the above compounds are dissolved in deuteriobenzene, a rapid disappearance of the signals of the hydride protons and the appearance of signals due to $C_6D_{6-x}H_x$ ($x > 1$) are observed. The products formed catalyse the slower deuterium exchange reaction between the solvent and the phosphine ligand. Triisopropylphosphine is deuteriated to the extent of 70—76%, tricyclohexylphosphine is 25% deuteriated and tris(diethylamino)phosphine is 40% deuteriated. The process mechanism includes stages involving the elimination of the phosphine ligand, the coordination of the arene, and the subsequent activation of the C—H bond of benzene and the phosphine ligand. Analogous reactions take place also in toluene but much more slowly. In the reaction with deuteriotoluene, an increase in temperature to 110 °C results in a sharp acceleration of the process, which indicates a change in the reaction mechanism. According to the authors,[55,56] solutions of ruthenium tetrahydride in aromatic solvents constitute the first example of a system capable of catalysing spontaneously (in the dark without heating or irradiation) the deuterium exchange between the hydrogen atoms of the phosphine ligands and the deuterium atoms of the solvent. Ruthenium polyhydride complexes are apparently much more active catalysts of the activation of the C—H bonds in arenes than the PC of 5*d* metals (tantalum, rhenium, and iridium) investigated previously.[12]

In the presence of TBE, ruthenium tetrahydrides catalyse the dehydrogenation of cyclo-octane. When $RuH_4[P(C_6H_4F\text{-}p)_3]_3$ is heated in cyclo-octane to 150 °C in the presence of TBE, 45—55 moles of cyclo-octene are formed per mole of the catalyst. The complex of ruthenium tetrahydride with triphenylphosphine ligands is less active in this reaction.[57]

The anionic ruthenium complex $K[RuH_5(PPh_3)_2]$ hydrogenates alkenes (ethylene, hex-1-ene), dienes (cyclohexa-1,3-diene), and anthracene (Scheme 8) at room temperature. Two hydride ligands participate in the reaction with hex-1-ene, four hydride ligands are involved in the reaction with cyclohexa-1,3-diene, and six hydride ligands react with ethylene, one of them being formed as a result of the *ortho*-metallation reaction. Anthracene may be hydrogenated under catalytic conditions, whereupon 1,2,3,4-tetra-hydroanthracene is formed with a high selectivity[58,59] (Scheme 8).

Scheme 8

The interaction of $RuH_6(PCy_3)_2$ with ethylene at room temperature leads to $Ru\overline{H[C_6H_{10}PCy_2]}(PCy_3)(C_2H_4)_2$. It has been suggested that the hydride ligands are displaced by the excess ethylene and that intramolecular metallation of one of the cyclohexyl groups takes place in the unstable zerovalent ruthenium complex $Ru(C_2H_4)_2 \cdot (PCy_3)_2$ formed.[56]

The reaction of $RuH_6(PCy_3)_2$ with an excess of cyclopentene in pentane at room temperature affords a mixture of the products $RuH_2(PCy_3)_2(C_5H_6)$ and $RuH(PCy_3)_2Cp$. $RuH(PCy_3)_2Cp$ is formed quantitatively in the presence of TBE. At 120 °C in the presence of TBE, ruthenium hexahydride reacts with cyclopentane to form hydridocyclopentadienyl complexes, which, however, could not be identified.[60]

Osmium tetrahydrides are much less active in relation to olefins than their ruthenium analogues.[61] The interaction of $OsH_4 \cdot (PEt_2Ph)_3$ with four moles of cyclo-octa-1,5-diene (COD) (toluene, 100 °C, 65 h) produces, after treatment with ethanol, cyclo-octene (50 % yield), the unreacted cyclo-octadiene, and $Os(COD)(PEt_2Ph)_3 \cdot EtOH$. The reaction with 12 moles of oct-1-ene under the same conditions gives rise to two moles of octane, a mixture of various octenes (isomerisation products), and an uncharacterised olefin complex of osmium. The catalytic hydrogenation of oct-1-ene, accompanied by the formation of isomerisation products, takes place in the presence of hydrogen. At the end of the reaction, the osmium PC can be regenerated from the reaction mixture. The selectivity of the hydrogenation and isomerisation of olefins has been noted: predominantly terminal alkenes are hydrogenated, while isomerisation leads mainly to internal olefins.

The irradiation of $OsH_4(PMe_2Ph)_3$ in benzene-d_6 leads to isotope exchange. After irradiation for 1 h, the initial tetrahydride is 90% converted into the deuteride $OsD_4(PMe_2Ph)_3$.[62]

It has been noted that the hexahydrides OsH_6L_2 dehydrogenate saturated hydrocarbons in the presence of TBE.[63]

5. Iridium Complexes

Like other PC of metals with an odd number of valence electrons (see subsection 1), the complexes IrH_5L_2 catalyse the deuterium exchange between gaseous deuterium and aromatic hydrocarbons.[14,15]

The iridium pentahydrides IrH_5L_2 interact with alkenes similarly to ruthenium tetrahydride: the reaction with ethylene at 45 °C in benzene affords ethane and complexes with metallated phosphines, while the reaction with propene gives rise to the π-allyl complexes $Ir(\eta^3\text{-}C_3H_5)L_2$.[64]

In the reactions with linear mono-olefins C_nH_{2n} ($n > 3$), iridium pentahydrides catalyse the intermolecular transfer of hydrogen atoms with formation of the corresponding alkane and diene. Ethylene, may be used as the hydrogen acceptor, which is reduced to ethane; a higher olefin is converted to a diene under these conditions:

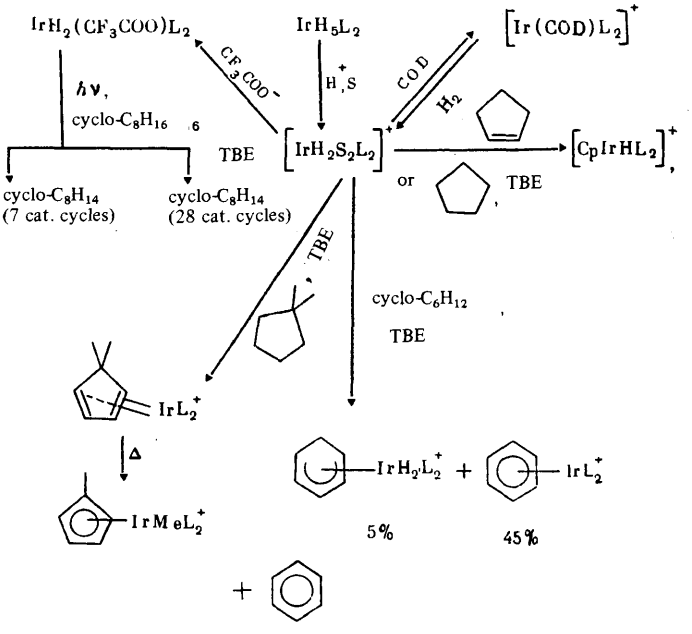
$$\text{Alkene(1)} + \text{alkene(2)} \xrightarrow[2\text{-}25 \text{ cat. cycles}]{25\text{-}130\ ^\circ\text{C},\ 3\text{-}40\ \text{h}} \text{alkane(1)} + \text{diene(2)}.$$

The linear conjugated dienes formed have predominantly the *trans,trans*-configuration. The interaction of IrH_5L_2 with *cis*-but-2-ene at 60 °C yielded the butadiene complexes $IrH(\eta^4\text{-}C_4H_6)L_2$; after the reactions with pent-1-ene, hex-1-ene, and hex-2-ene, it was not possible to isolate any hydride or olefin complexes. A decrease in the catalytic activity of IrH_5L_2 is observed during the reaction. Depending on the nature of the ligands L, the catalytic activity of iridium pentahydride diminishes in the sequence $IrH_5[P(Pr\text{-}iso)_3]_2$ » $IrH_5(PPh_3)_2$ > $IrH_5(PMe_3)_2$ » $IrH_5(PCy_3)_2$.[64] The mechanism of the disproportionation reaction is probably similar to that described above for the interaction of ruthenium tetrahydride with olefins (see Scheme 7). The possibility of carrying out the reaction under catalytic conditions indicates the great lability of the coordination sphere of iridium complexes, because the reactions involving ruthenium stop

at the stage in which stable diene complexes are formed, while in the case of iridium the diene ligand is displaced from the coordination sphere by the alkene.

At 35 °C, $IrH_5[P(Pr\text{-}iso)_3]_2$ catalyses the deuterium exchange between the vinyl hydrogen atoms of TBE and the deuterium atoms of deuteriobenzene.[65] The rate of exchange of hydrogen atoms in the *trans*-positions relative to the t-butyl group is approximately an order of magnitude higher than for the *cis*-atoms. These results show that the activation of the vinyl C–H bonds can occur for certain types of olefins at a higher rate than the reaction involving the addition-elimination of the metal hydride at the double bond. The competition between the processes involving oxidative addition to the C–H bond and the formation of a π-complex has also been observed in the reaction of ethylene with the pentamethylcyclopentadienyliridium complex $[Cp^*Ir(PMe_3)]$.[66]

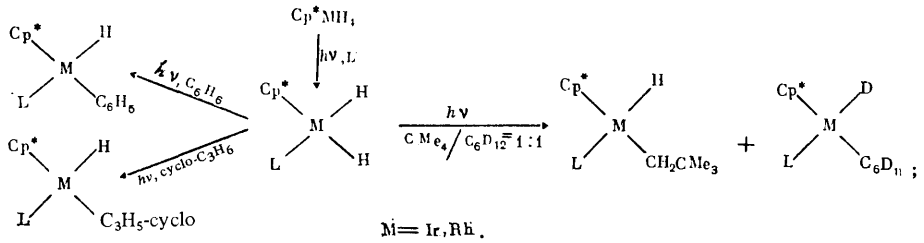
At a higher temperature, $IrH_5[P(Pr\text{-}iso)_3]_2$ catalyses the deuterium exchange between the hydrogen atoms of methane and the deuterium atoms of deuteriobenzene in the presence of two equivalents of TBE. Approximately 13 catalytic cycles take place after 7 days and approximately 40 cycles take place after 53 days at 80 °C. The main reaction product is CH_3D. It has been noted[67] that, in contrast to isotope exchange catalysed by transition metal halides in an acid medium,[5] in the system considered the contribution of multiple exchange is insignificant. In the absence of TBE, the deuterium exchange takes place between deuteriobenzene and the hydride ligands and also the hydrogen atoms of the phosphine ligands. An excess of TBE (> 10 equivalents) prevents the deuterium exchange with methane. In this case, small amounts of ethane, toluene, biphenyl, and propane were detected among the reaction products. It has been suggested that the first three products are formed via the reductive elimination of R–R′ from the intermediate LL′IrRR′ [R = Me, R′ = Ph, L = $P(Pr\text{-}iso)_3$, L′ = $P(Pr\text{-}iso)_2CHMeCH_2$)]. Propane is formed as a result of the degradation of the phosphine ligand.[67]



Iridium pentahydride exhibits a higher catalytic activity in catalytic reactions involving the dehydrogenation of cycloalkanes to cycloalkenes than the rhenium or ruthenium PC. Heating of $IrH_5[P(Pr\text{-}iso)_3]_2$ with an excess of TBE in cyclo-octane at 150 °C for 5 days leads to 70 moles of cyclo-octene per mole of the PC, while the best result for ruthenium tetrahydride was 45–55 moles after 10 days and that for rhenium heptahydride was 9 moles. It has been noted that compounds capable of forming 14-electron intermediates on elimination of two molecules of hydrogen, like the iridium PC, are effective catalysts of processes leading to the activation of C–H bonds in hydrocarbons.[57]

In the dehydrogenation of methylcyclohexane under the influence of $IrH_5(PPr^i_3)_2$, the main primary reaction product is methylenecyclohexane, which gradually isomerises under the reaction conditions, affording the thermodynamically more stable 1-methylcyclohexene (see Table). Iridium pentahydrides are capable of dehydrogenating catalytically not only cycloalkanes but also n-alkanes, in contrast to the rhenium PC, which forms stable diene complexes in their reactions with alkanes. The primary product of the reaction of IrH_5L_2 with n-hexane is hex-1-ene (45 °C, 5 min, 0.3 of a catalytic cycle, selectivity 78%), which isomerises rapidly, giving rise to a mixture of *cis*- and *trans*-hex-2-enes (80 °C, 30 min, 9 catalytic cycles, selectivity 75%).

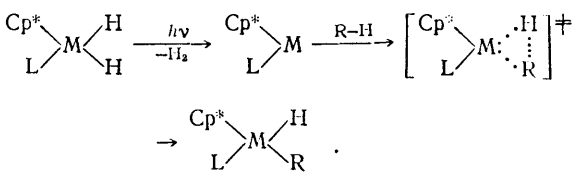
The reactivity of the test systems in relation to different types of C–H bonds has been determined by the method of competing reactions: CH_2 (in cyclohexane) : CH_3 (in methylcyclohexane) : CH_3 (in n-hexane) = 1 : 8 : 60. Despite the fact that the primary C–H bonds are much stronger than the secondary and tertiary bonds, when IrH_5L_2 is used the methyl groups are in fact attacked preferentially probably under the influence of steric factors. Thus the iridium PC catalyse the selective catalytic introduction of functional groups into saturated hydrocarbons. After active and stably operating catalysts have been created, such a process might be useful, for example, for the selective preparation of functional derivatives of higher n-alkanes containing many identical methylene groups but only two methyl groups.[37,63,68]



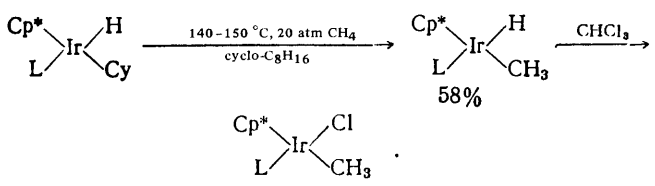
In an acid medium, $IrH_5(PPh_3)_2$ catalyses the ionic hydrogenation of olefins, surpassing in its activity systems such as $PtL_2(CF_3COO)_2$ and $Ru(CF_3COO)_3$ in CF_3COOH.[69,70] On treatment with acids, iridium pentahydrides form the complexes $[IrH_2(Solv)_2L_2]^{x+}$, where Solv is the solvating solvent (acetone, methylene chloride, etc.), an acid anion, H_2 molecule, etc., capable of entering into the C–H bond activation reactions. Like the Cp^*IrH_4 derivatives examined below, these compounds are not polyhydrides but they can be regarded as derivatives of the corresponding PC. In the present review, the properties of these compounds are examined only in terms of the aspects which are necessary for the discussion of the reactivities of the PC. We may note that it was in fact in the study of the interaction of $[IrH_2(Solv)_2L_2]BF_4$ (Solv = acetone, L = PPh_3) with cycloalkanes (cyclopentane, cycloheptane, and cyclooctane) in dichloroethane that the first stable organometallic compounds, with ligands formed as a result of the reactions of a saturated hydrocarbon in the coordination sphere of the complex, were obtained.[71] The results of a study of the reactions of these complexes with hydrocarbons[71–75] are presented in Scheme 9:

Scheme 9

Irradiation of the polyhydride complex Cp^*IrH_4 (Cp^* = C_5Me_5) in the presence of trimethylphosphine leads to the dihydride complex $Cp^*Ir(PMe_3)H_2$ capable of interacting photochemically with a wide variety of hydrocarbons—alkanes, cycloalkanes, alkenes, and arenes—to form the products resulting from insertion in a C–H bond (Scheme 10).[76,78]



Scheme 10



M = Ir, Rh.

The rhodium analogue $Cp^*Rh(PMe_3)H_2$ also has analogous properties. The product of the interaction of the rhodium complex with cyclopropane has been isolated in the form of the bromo-derivative which has been characterised by X-ray diffraction.[78] The study of the selectivities of the iridium and rhodium complexes examined in relation to different types of C–H bonds in saturated hydrocarbons showed that the insertion takes place predominantly in primary C–H bonds. The secondary C–H bonds are less active and the products of insertion in tertiary C–H bonds have not been observed.

Irradiation of the iridium complex in a mixture of neopentane and cyclohexane-d_{12} leads to the formation of the hydridoneopentyl and deuteridocyclohexyl complexes. These data, together with the study of the selectivity of the insertion reaction, led the authors to the conclusion that the reaction proceeds via a mechanism involving direct insertion in a C–H bond and not via a free radical formation stage:

Alkyl hydride complexes with secondary alkyl groups are thermally less stable than those with primary alkyl radicals, regenerating the reactive intermediate on heating, which leads to the possibility of the thermal activation of alkanes. At an elevated temperature, alkyliridium hydrides are capable of entering into the oxidative addition reaction with methane. The methyliridium complex formed under these conditions has been isolated on a preparative scale in the form of the chloro-derivative:[78]

III. FACTORS INFLUENCING THE REACTIVITY OF TRANSITION METAL POLYHYDRIDE COMPLEXES IN REACTIONS WITH HYDROCARBONS

The data examined shows that the transition metal PC are capable of entering into a wide variety of reactions with hydrocarbons: of forming π-complexes with unsaturated compounds, of hydrogenating, dehydrogenating, and isomerising olefins, of catalysing hydrogen isotope exchange, dimerisation, and polymerisation reactions, of dehydrogenating alkanes and cycloalkanes, etc. Involvement in coupled hydrogenation-dehydrogenation reactions is characteristic of transition metal PC, which makes it possible to carry out such reactions under conditions catalytic with respect to the PC. The formation of π-complexes by metal polyhydrides with unsaturated compounds promotes in many instances the occurrence of further reactions of the latter.

In most cases the reactions of metal PC with hydrocarbons proceed via a stage involving the C–H bonds of the hydrocarbons. For olefins, such reactions lead to the isomerisation or dehydrogenation of the initial compound, which results in an increase of the strength of the bond between the hydrocarbon ligand and the metal ($\eta^2 \rightarrow \eta^3 \rightarrow \eta^4$, etc.). It has been shown recently that a C–H bond in olefins can be dissociated via the oxidative addition mechanism and that the formation of a π-complex is in this case a competing process. The activation of the C–H bonds of arenes or alkanes by metal polyhydrides also takes place via the stage involving the oxidative addition of the hydrocarbon to the metal complex. The relative reactivities of the C–H bonds in alkanes in oxidative addition (primary > secondary > tertiary) form a sequence which is the opposite of that for the free-radical reactions. Whereas in radical processes the dissociation of the weakest tertiary bond is energetically preferable, in oxidative addition reactions, thermodynamic and kinetic factors (the stronger the metal–primary alkyl bond, the smaller steric hindrance to attack on the primary carbon atom) favour the insertion of metal polyhydrides in a primary C–H bond. The characteristics of the oxidative addition of the C–H bonds of hydrocarbons to metal complexes are being at present vigorously investigated.

It is noteworthy that metal polyhydride complexes as such are relatively inactive in reactions with hydrocarbons, because the majority of PC are electron-saturated stable compounds obeying the effective atomic number rule.[7,8] In order to involve these compounds in the reaction, a definite influence is necessary—thermal, photochemical, or chemical (for example, by a hydride ligand acceptor—a proton, a carbonium ion, or an olefin), leading to the loss of some of the hydride or phosphine ligands and the formation of highly reactive electron- and coordination-unsaturated intermediates. The molecular hydrogen or the free phosphine formed in this process can inhibit further reaction. Therefore, substitution of some of the hydride ligands in the PC can also increase the reactivity, as shown in relation to the iridium complex Cp^*IrH_4.[78,79]§

§ A series of previously unknown transition metal PC with cyclopentadienyl and alkylcyclopentadienyl ligands $CpMH_mL_n$ (M = Ta, W, Re, or Ir), whose chemical properties have been studied inadequately, have been synthesised in recent years. However, studies by Bergman[78] and Jones[79] have shown that compounds of this type merit very close attention as starting materials for the creation of systems activating C–H bonds.

Compounds formed on protolysis of certain PC are highly reactive in reactions with hydrocarbons. These are complexes in which coordination sites liberated as a result of the loss of hydride ligands are occupied by molecules (acetone, dichloromethane, etc.—solvento-complexes) or anions weakly bound to the central atom.[80]

It is noteworthy that the protolysis of transition metal PC can lead to the formation of compounds with molecular hydrogen as the ligand (hydrogen complexes). For example, on treatment with acids, IrH_5L_2 is converted under certain conditions into $[IrH_2(H_2)_2.$ $.L_2]^+$.[81] Transition metal complexes of molecular hydrogen as the ligand were first described in 1980.[82] It has been suggested that compounds of this type are more common than is known at the present time. One of the most active compounds in C—H bond activation reactions, namely ReH_7L_2, is also a complex of molecular hydrogen—$ReH_5(H_2)L_2$.[83] Molecular hydrogen complexes can probably play an important role in reactions leading to the activation of C—H bonds.[83]

The 16-electron intermediates formed on thermal or photochemical treatment exhibit a high reactivity and rapidly enter into intramolecular and intermolecular reactions. However, the formation of 14-electron intermediates is necessary for the catalytic process, which can be achieved, for example, by specially selecting hydrogen acceptors. An effective hydrogen acceptor in reactions with transition metal PC is TBE.[30] This olefin is fairly reactive, has a high heat of hydrogenation, and the 2,2-dimethylbutane formed when it is reduced is readily split off, liberating a coordination site, as a result of which a 14-electron intermediate is produced. The use of TBE made it possible to carry out the dehydrogenation reactions of cyclic and acyclic alkanes, which are catalytic as regards the PC. The dehydrogenation of an alkane to the alkene with liberation of hydrogen is an endothermic process ($\Delta H \simeq 140$ kJ mol^{-1}). Under normal conditions, the equilibrium is almost wholly displaced towards the formation of the alkane. The coupled TBE hydrogenation reaction compensates for the energy expenditure and the dehydrogenation of the alkane becomes thermodynamically feasible. However, for industrial processes involving the synthesis of functional derivatives from alkanes, reagents more readily available than TBE (for example, oxygen), interaction with which would compensate for the energy expended on the dissociation of the C—H bond, are necessary. It has not yet been possible to achieve such processes. Photochemical dehydrogenation, in which the driving force of the process would be ensured by supplying energy from outside in the form of radiation, is attractive from the technological point of view. The possibility of such a process¶ has been demonstrated in relation to the homogeneous catalytic dehydrogenation of cyclooctane by an iridium complex under irradiation.[75]

The nature of the central atom has a marked influence on the reactivity of PC. The PC of 5*d* metals are the most stable and their involvement in reactions with hydrocarbons requires comparatively severe conditions. The PC of 4*d* metals are much more reactive. Since the PC of 3*d* metals have been studied inadequately, it is impossible to compare their properties with those of other PC.

The results of the investigation of the PC-catalysed isotope exchange of deuterium with arenes have shown that compounds of 5*d* metals, having an odd number of valence electrons, are much more reactive than complexes of metals with an even number of valence electrons. The coordination sphere of the former is probably more labile, its lability increasing along the Period from left to right (cf. the reactions of rhenium and iridium PC with alkenes[35,64] and alkanes[38,68]). According to the data available at the present time, Group VIII metal compounds with an odd number of valence electrons (rhodium and iridium) do in fact have the highest activity in reactions including a stage involving oxidative addition with participation of a C—H bond.

Many transition metal PC contain tertiary organic phosphines as ligands, whose electronic and steric properties have a decisive influence on the reactivity of the PC. An increase in the number of phosphine ligands increases the strength of the metal—hydrogen bond, as a result of which more severe conditions are required for the involvement of the PC in the reaction. The role of steric factors also becomes more pronounced under these conditions. For complexes of a specific type (for example, MH_4L_4), the lability of the metal—phosphorus bond increases with increase in the bulk of the ligands.[85] The use of very bulky ligands such as PCy_3 and P(Pr-iso-)$_3$ ($\theta = 160-180°$ [42]) can be regarded as one of the methods for increasing the reactivity of the complexes. Electron-deficient complexes containing such bulky ligands and exhibiting a high reactivity in reactions with small molecules have been obtained.[86] As the electron-donating properties of the ligand become more pronounced, the thermal stability of the PC increases but so also does the reactivity of the intermediates formed both in reactions with hydrocarbons and in intramolecular processes, leading to their deactivation. One of these processes is cyclometallation for the suppression of which one uses ligands with a comparatively low reactivity in this reaction—trimethylphosphine and the pentamethylcyclopentadienyl anion. However, the best result is not always achieved by using these ligands. Thus the highest reactivity in the catalytic dehydrogenation of cycloalkanes has been observed for the iridium complex with triisopropylphosphine and not with trimethylphosphine.[57] The ratio of the rates of the target and side processes apparently depends not only on the electronic but also on the steric properties of the ligand and on the nature of the complex-forming metal. The data available at the present time are insufficient to make a well-founded choice of the metal, stabilising ligands, and the type of complex for the attainment of the best result in the reactions considered.

The properties of the solvent and the purity of the reactants play an important role in the reactions of transition metal PC with hydrocarbons. For example, the dehydrogenation of n-alkanes by rhenium heptahydrides and of cycloalkanes by solvento-complexes of iridium is suppressed by unsaturated compounds or solvents capable of forming stable complexes with the intermediate. Stable complexes of transition metals with saturated hydrocarbons are at present unknown. Unstable complexes, for example, $Cr(CO)_5.$ $.(C_6H_{12}$-cyclo), have been obtained.[87] An excess of the alkane or perfluorohydrocarbons are therefore used as solvents for the reactions of PC with alkanes. However, the question of which compounds are capable of inhibiting the reactions of PC with alkanes has not yet been solved. In certain cases, the PC interact with saturated hydrocarbons also in the presence of reactive compounds. Thus iridium complexes solvated by the highly reactive acetone dehydrogenate cycloalkanes in solvents such as chlorinated hydrocarbons, while the complexes ReH_7L_2 are capable of dehydrogenating cycloalkanes even in air. All this gives rise to the hope that

¶ In our country, studies on the introduction of functional groups into alkanes in the presence of transition metal complexes under the influence of radiation are being prosecuted by Shilov and co-workers.[84]

further investigations will create catalytic systems for the activation of alkanes which operate successfully in the usual solvents and which do not impose extremely rigorous conditions on the purity of the reactants.

Thus the results of the study of the interaction of transition metal PC with hydrocarbons have made a definite contribution to the investigation of the homogeneous activation of the C–H bonds of hydrocarbons. However, the creation of industrial methods for the selective synthesis of functional derivatives from alkanes still requires a large amount of fundamental research. It may be hoped that further investigations of the reactions of transition metal PC with hydrocarbons will prove useful for the solution of this problem, which is important from both theoretical and practical points of view.

Agostic Hydrogen Atoms in Transition Metal Complexes

A.G.Ginzburg

The methods of formation, the structures in the crystal and in solutions, the properties, and the reactions of complexes with a bridging hydrogen atom and three-centre M...H-C bonds in which the electrons of the C-H bonds play the role of two-electron ligands at the metal atom are examined.
The bibliography includes 221 references.

I. INTRODUCTION

The following types of binding of hydrogen have been known until recently in the chemistry of transition metal hydride complexes (see the relevant reviews[1-7]): (1) terminal hydrido-ligands in the complexes $LnMH_x$ ($x = 1-9$); (2) bridging μ^2-H ligands in the dinuclear and polynuclear complexes $L_nM(\mu^2\text{-}H)_xML_n$ ($x = 1-4$); (3) triply bridging μ^3-H ligands where the μ^3-hydrogen atom is located above the triangular face of the polyhedron (which is characteristic of the chemistry of clusters). In the FeH_6^{4-} anion, the Fe atom is in the centre of an octahedron made up of six H atoms.[8] A whole series of clusters have been obtained where 1-3 hydrogen atoms are located within a skeleton made up of metal atoms [the so called "inner cavity" or "encapsulated" ("interstitial") hydrido-ligands], for example, in the anions $HCo_6(CO)_{15}^-$, $H_2Ni_{12}(CO)_{21}^{2-}$, etc. (see the relevant reviews[6,7]).

The aliphatic C-H bonds in the molecules of CH_4 and other alkanes have been regarded traditionally as chemically inert and incapable of interacting with the metal centre in organometallic complexes. However, during the last 8-10 years fairly numerous examples of the activation of C-H bonds and of the oxidative addition to low-valence rhodium and iridium complexes have been found; numerous instances of the coordination of aliphatic and aromatic C-H bonds to transition metals have been observed and complexes with an H_2 molecules as the η^2-ligand have been obtained. The interest in compounds where the C-H bond is coordinated to a metal is indissolubly linked to the problem of the search for new effective catalysts for the activation of C-H bonds and organic synthesis on the basis of alkanes. This problem has attracted much attention and is being very vigorously investigated (see the relevant reviews[9-11]). Studies on these lines have been stimulated by advances in the field of both stoichiometric organometallic synthesis and in metal complex catalysis. These reviews consider complexes where hydrogen constitutes a bridge between the metal and carbon atoms with formation of two-electron, three-centre (2e, 3c) bonds M...H-C (CHB).† In such complexes, there is a new type of binding of hydrogen to transition metals. CHB of virtually all Group III-VIII transition metals, except vanadium and nickel,‡ have now been obtained and characterised by structural methods in the solid phase or by NMR methods in solutions. The formation of CHB proved to be characteristic not only of electron-deficient complexes of the elements at the beginning of the Periods (Sc, Y; Ti, Zr, Hf; Nb, Ta) but also of the lanthanides (Nd, Sm, Yb) and the elements in the middle of the Periods (Cr, Mo, W; Mn; Fe, Ru, Os; Co, Rh, Ir). Thus the ability to stabilise the electron-deficient centre by means of intramolecular coordination via C-H bonds, leading to the formation of a bridged M...H-C fragment, is a general property characteristic of the majority of transition metals. This phenomenon is apparently more general than was supposed previously. CHB formed with participation of aliphatic, olefinic, alkylidene (carbene), and aromatic C-H bonds are known.

All the CHB known at the present time are electron-deficient complexes whose metal centre formally has 12-16 electrons. The majority of CHB are cationic complexes or neutral molecules. The "driving force" and cause of the coordination of C-H bonds to the metal is the tendency to build up the electronic environment of the metal by means of the electron pair of the C-H bond to 18 electrons, or to decrease the electron deficiency by two electrons by increasing the number of electrons from 12 to 14 or from 14 to 16. The presence of an electron-deficient centre is an essential but not a sufficient condition for the formation of CHB. Apart from the electron deficiency, it is also necessary that the lowest unoccupied molecular orbital (LUMO) of the complex, used for the coordination with the C-H bond, should have the appropriate orientation in space. According to the results of X-ray diffraction analysis (XRD), in the case of the 16-electron complex $(\eta^7\text{-}C_7H_7)Ti(Dmpe).CH_2CH_3$,§ Ti...H-C bonds with the hydrogen of the CH_3 moiety of the ethyl group are not formed.[12] Quantum-chemical calculation has shown that in this case the LUMO consists mainly of the d_{z^2} orbital of titanium and is oriented along the z azis; owing to its unfavourable steric disposition, this orbital is incapable of effective overlap with the α- or β-CH bonds of the ethyl group and a bridge

†Complexes with hydrogen bridges. The corresponding Russian abbreviation is KMB (Translator).

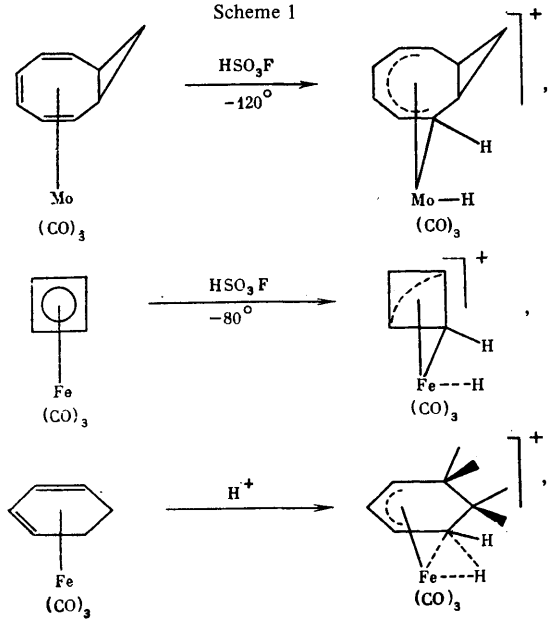
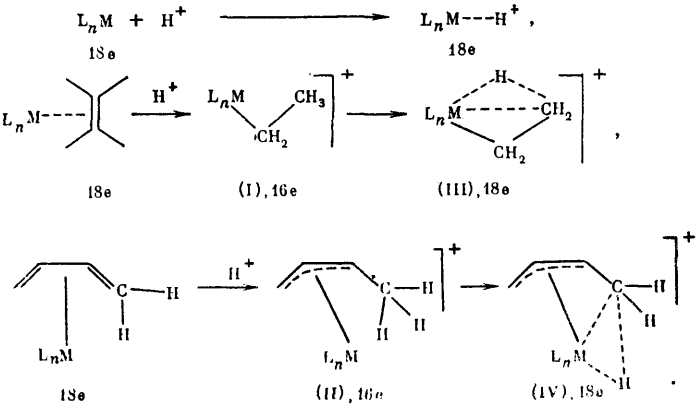
§Dmpe = $Me_2PCH_2CH_2PMe_2$.



bond is not formed despite the presence of the electron-deficient centre. There exists a single brief review devoted to three-centre M...H−C bonds,[13] whose authors proposed a new term for such bonds and hydrogen atoms—"agostic" C−H bonds or hydrogen atoms. This term is frequently used in the foreign literature.



II. EARLY STUDIES

The first information about the possibility of the coordination of C−H bonds to transition metals appeared in 1968−1975. In many cases, the signals of the CH_2 and CH_3 protons in the H NMR spectra of the complexes were observed in the high field region (δ ranging from 0 to −12 p.p.m. and above), which is known to be characteristic of metal hydrides (see the review of Kaesz and Saillant[1]). It was shown on the basis of XRD data that in many cases there is a weak interaction in ruthenium, palladium, and platinum complexes between the metal and the hydrogen in the *ortho*-position in the arylphosphine ligands. On the other hand, owing to the insufficient accuracy of the XRD method, the positions of the hydrogen atoms could not be as a rule located by direct procedures. The conclusion that there is an interaction between the C−H bond and the metal was reached on the basis of the presence of short intramolecular M...H contacts, significantly shorter than the sums of the van der Waals radii of M and H. Interactions of this type have been described for the following complexes: $Ru(PPh_3)_3Cl_2$ (Ru...H distance 2.59 Å);[14] *trans*-$Pd(PPhMe_2)_2I_2$ (Pd...H 2.8 Å);[15] $Rh(PPh_3)_3^+ClO_4^-$ (Rh...H 2.56 Å);[16] $Pd(PPh_3)_2(Br)(CR{=}CR.CR{=}CHR)$, where R = COOMe (Pd...H 2.3 Å);[17] $Ni[Et_2B.(pyrazolyl)_2]_2$;[18] $Mo[Et_2B(pyrazolyl)_2](\eta^3\text{-}CH_2CHPhCH_2)(CO)_2$ [Mo...H 2.27 Å, δ(Mo−H) = 2.4 p.p.m.].[19]

More than 10 years ago, a series of studies were published[20-24] in which π,σ structures with protonation of the metal and the simultaneous formation of M−C σ-bonds were proposed for the protonated forms of the η-complexes solely on the basis of ^1H and ^{13}C NMR data (Scheme 1). Later these results were revised and it was concluded that an M−C σ-bond does not arise in such cases. The formation of the Fe...H−C 2e, 3c-bond was first postulated for the protonated form of the complex $(\eta^4\text{-}C_6H_8)Fe(CO)_3$.[25]

Scheme 1

During the last 8−10 years extensive experimental data have accumulated on the synthesis and properties of CHB both in the crystal (structural methods) and in solutions, a systematic account of which is given below.

III. METHODS OF FORMATION

An exceptionally wide variety of structures are characteristic of the complexes of the type considered. Their general property is that the metal atom is an electron-deficient centre. In the presence of electron-donating ligands or solvents (L), electron-deficient complexes are usually stabilised as a result of the addition of L to an unoccupied coordination site. However, if the system has no electron-donating ligands, then one of the possible ways in which the electron deficiency can be partially or completely made good and a stable 18-electron shell created involves the intramolecular coordination of an unoccupied orbital of the metal (LUMO) to one of the electron pairs of a C−H bond with formation of an M...H−C 2e, 3c-bond. In this case the C−H bond plays the role of a kind of two-electron "ligand". Depending on the geometry of the M...H−C fragment, such bonds can be divided by convention into "open" (M−H−C angle 120−130° and above), and "closed" (with an angle of 70−90°). There is no clear-cut boundary between these types.

Evidently, the formation of CHB is to be expected primarily among electron-deficient complexes of the elements at the beginning of the Periods (Sc, Ti, V, and their analogues), for which a large number of deviations from the 18-electron rule are known. Indeed, among the 12−16-electron complexes of Y, Ti, Zr, and Ta, numerous examples of the formation of M...H−C bridge bonds have been found. The formation of these bonds proved to be characteristic of a large group of 14- and 16-electron alkylidene complexes of Ta (and also Nb and W), typical representatives of which are the structurally characterised complexes $Ta(=CH-CMe_3)(\eta\text{-}C_5Me_5).(C_2H_4)(PMe_3)$, $[Ta(=CH-CMe_3)(PMe_3)Cl_3]_2$, and $W(=CH-CMe_3)(CO)(PMe_3)_2Cl_2$. Since the identification of the M...H−C bridge bonds in the crystal is based exclusively on structural research methods and in solutions mainly on NMR data, the properties and characteristics of the bridge bonds in the solid phase and in solutions will be examined in greater detail below in Sections IV and V.

Several reactions in which there is a possibility of the formation of CHB are known for compounds of the elements in the middle of the Period (Group VI−VIII) elements. The protonation and decarbonylation reactions have been studied in greatest detail.

1. Protonation

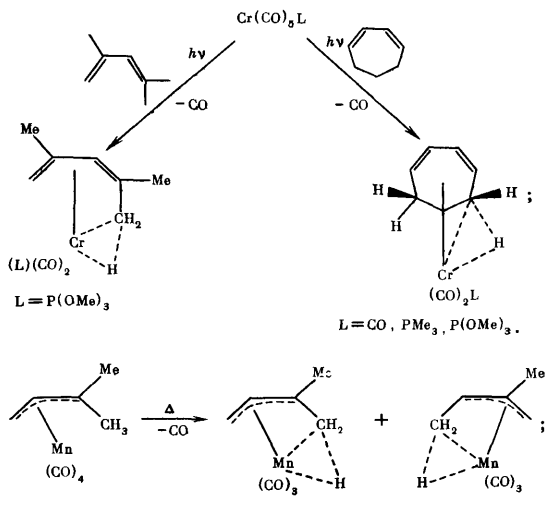
It is well known that the η-complexes and low-valence carbonyl complexes of transition metals constitute a new class of bases—polyfunctional organometallic Lewis bases. They interact readily with various electrophiles (E)—including protic and aprotic acids, the attack by E being as a rule directed to the centre with the highest basicity. In complexes of the type L_nM, there is a possibility of the addition of E both to the metal atom and to the ligands (L). The relative basicities of the different centres and the direction of attack by E depend on the structure of the complex, the nature of the metal, the character and type of the ligand environment, and the nature of E (see the relevant reviews[26-28]). If the 18-electron complex L_nM is protonated at the metal atom, then the product is the cation $[L_nM-H]^+$, where the metal retains the 18-electron environment and there are no grounds to expect the formation of a CHB. However, if the proton adds to the carbon atom of the C=C bond in the coordinated olefin or diene ligand, then the number of electrons supplied by the ligand for binding to the metal diminishes by one. η^2-Olefins or η^4-dienes (donors of two or four electrons) are then converted respectively into η^1-alkyl or η^3-allyl ligands (donors of one and three electrons). Taking into account the positive charge, the formal electronic environment of the metal in the monocationic complexes (I) and (II) arising on protonation can be stabilised as a result of the coordination of the unoccupied orbital of the metal to the electrons of a suitably directed C—H bond with conversion into cationic or neutral (if an anionic complex has been protonated) CHB (III) and (IV). The instances of the formation of CHB on protonation of 18-electron precursors are compiled systematically in Table 1.

The intramolecular isomerisation of hydride complexes, known in relation to the cationic dieneruthenium hydride complexes,[44] bears a close analogy to protonation by acids (HBF_4, HPF_6, CF_3SO_2OH, etc.). The isomerisation of the dienemetal hydride complexes to CHB can be regarded as "intramolecular protonation":

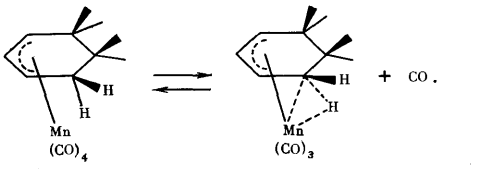
(V) (VI)

The cationic η^4-dieneruthenium hydride complexes (V) have been isolated and characterised; they are stable in solution at temperatures below −10 °C, while in the temperature range 0—60 °C (depending on the size of L and the type of the donor atom), compounds (V) isomerise spontaneously and irreversibly to the η^3-allyl complexes (VI) with a bridging hydrogen atom as a result of the intramolecular proton transfer from the metal to the cyclo-octadiene ligand.[44] From this it follows that in the given case the η^3-allyl

CHB of type (VI) are thermodynamically more favourable than their η^4-dienemetal hydride precursors. The rate of isomerisation (V) → (VI) depends on the size of L and decreases in the following sequence of groups L: $P(OCH_2CMe_3)_3$ > $P(OMe)Ph_2$ ≃ PMe. .Ph_2 > PMe_2Ph > $MeC(CH_2PPh_2)_3$ > $P(OMe)_2Ph$ > PMe_3 ≃ $AsMePh_2$. When L = $P(OMe)_3$, $AsMe_3$, or $AsMe_2Ph$, there is no isomerisation.[44]



An important feature is that in the reactions involving the protonation of the η-complexes by strong acids, unstable olefin- or diene-metal hydride intermediates are formed initially as a result of the kinetically controlled rapid attack by H^+ on the metal atom. As a consequence of the subsequent migration of hydrogen from the metal to a carbon of the olefin or diene ligand, the intermediates are converted into thermodynamically more favourable cationic CHB. The dieneruthenium hydride complexes having the general formula $[(\eta^4\text{-}C_8H_{12})RuL_3H]^+$ proved to be sufficiently stable to be isolated and and characterised, but in the case of other metals they can be kinetically or thermodynamically unstable. In the reaction of the cationic dihydride complex $[Ir(H)_2(PPh_3)_2(Me_3CO)_2]^+$ with 2,3-dimethylbutadiene, the η^3-allyl CHB $[Ir(H)(PPh_3)_2(\eta^3\text{-}CH_2CMeCMe}.$.$CH_2\text{-}\mu\text{-}H)]^+$ (VII) was isolated as the final product. Apparently initially two acetone molecules are substituted by the diene ligand with formation of the thermodynamically unstable dieneiridium hydride complex $[IrH_2(PPh_3)_2(\eta^4\text{-}CH_2 = CMeCMe = CH_2)]^+$, which then affords compound (VII) as a result of the rapid intramolecular proton transfer from iridium to the diene.[55]

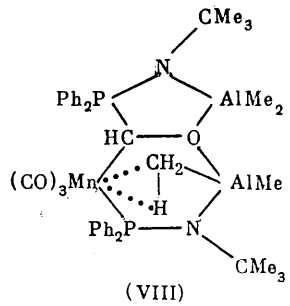


Protonation by strong acids is most characteristic of complexes of metals in the middle of the Periods (Mo, Mn, Fe, Co). Such reactions are unknown for the elements at the beginning and end of the Periods.

2. Decarbonylation

The second type of processes leading to the formation of CHB involves photochemical or thermal decarbonylation of the carbonyl complexes. On irradiation with UV light or on heating, the abstraction of one or several CO groups results in the formation of electron- and coordination-unsaturated intermediates, which can afford CHB in the presence of diene ligands, as shown in Scheme 2 for manganese and chromium complexes.

Scheme 2

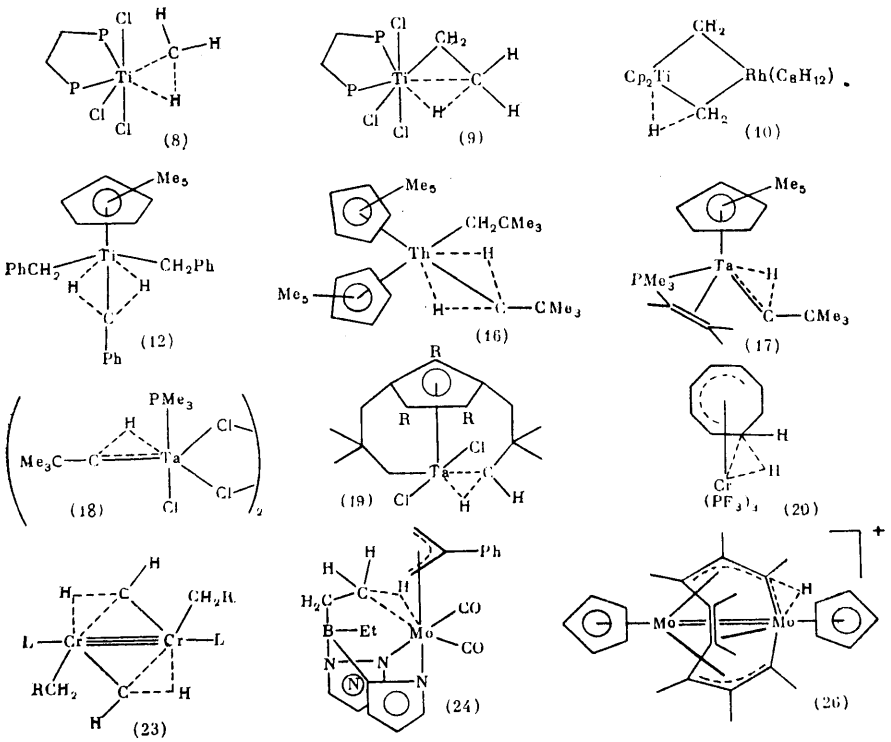


UV irradiation of $Cr(CO)_5L$ [L = P(OMe)] in pentane at 293 K in the presence of 2,4-dimethylpenta-1,3-diene did not yield the expected complex $Cr(CO)_3(L)(\eta^4\text{-}C_7H_{12})$, as in the reactions with other dienes.[56] Instead, the elimination of three CO groups and coordination of the $Cr(CO)_2(L)$ fragment to the diene led to the isolation of a CHB having the structure $Cr(CO)_2(L)(\eta^4\text{-}C_7H_{11}\text{-}\mu\text{-}H)$, in which the diene ligand is linked to chromium via two C=C bonds and the bridging hydrogen atom.[57] The photochemical decarbonylation of $Cr(CO)_5L$, where L = CO, PMe_3, or $P(OMe)_3$, in the presence of cyclohepta-1,3-diene, affording the complexes $Cr(CO)_2(L)(\eta^4\text{-}C_7H_9\text{-}\mu\text{-}H)$, proceeds analogously.[58] In both cases, the CHB isolated were characterised structurally. Thermolysis of the η^3-allyl complex $Mn(CO)_4(\eta^3\text{-}CH_2CHCMe_2)$ in toluene at 110 °C leads to the abstraction of CO with formation of a mixture of isomeric complexes with a bridging hydrogen atom: $Mn(CO)_3$. .$(\eta^3\text{-}CH_2CHCMe\text{-}CH_2\text{-}\mu\text{-}H)$.[59] The thermal decarbonylation of the enyl complex Mn(η^3-cyclohexenyl)$(CO)_3L$, where L = phosphine or phosphite, proceeds analogously[59] (Scheme 2).

3. Ligand Substitution

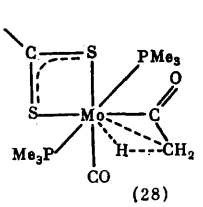
A number of instances of the formation of CHB as a result of ligand substitution are known. One of them involves the displacement of two acetone molecules by 2,3-dimethylbutadiene in an iridium complex, which was already mentioned above. The interaction of salts of the square-planar cation $[Ir(PPh_3)_2(\eta^4\text{-}C_8H_{12})]^+A^-$ (A = PF_6, BF_4, or SbF_6) with gaseous H_2 in the presence of 8-methylquinoline (in CH_2Cl_2 at 0 °C) yielded, as a result of the oxidative addition of H_2 with simultaneous displacement of cyclooctadiene, cationic iridium(III) complexes having the composition $[IrH_2(PPh_3)(\mu\text{-}H\text{-}CH_2C_9H_6N)]^+A^-$ in which 8-methylquinoline is linked to iridium via a nitrogen atom and one bridging H atom in the methyl group.[60]

The substitution of one of the ligands L = PMe_3 and the abstraction of NaCl in the interaction Of $Mo(CO)(CO)(\eta^2\text{-}C,O\text{-}C(O)CH_2SiMe_3)L_3$ with sodium dimethyldithiocarbamate results in the formation of the complex $Mo(CO)(S_2CNMe_2)(L)_2\text{-}C(O)CH_2\text{-}\mu\text{-}H$, where the acetyl group is linked to Mo via a Mo–C σ-bond and a bridging H atom.[61] The above cationic dieneruthenium hydride complexes $[Ru(H)(L)_3(\eta^4\text{-}1,5\text{-}C_8H_{12})]^+$ or the products of their intramolecular isomerisation, namely CHB with the cyclooctenyl fragment $[Ru(\eta^3\text{-}C_8H_{12}\text{-}\mu\text{-}H)L_3]^+$ are converted into the corresponding cationic CHB of the type $[Ru(L)_3(\eta^3\text{-Enyl-}\mu\text{-}H)]^+$, where L = PMe_2Ph, PMe_3, $P(OMe)_2Ph$, or $P(OMe)Ph_2$, in reactions with 1,3-dienes (cyclohepta-1,3-diene, cyclohexa-1,3-diene, butadiene) as a result of the displacement of cyclo-octa-1,3-diene.[62] CHB formed in the following reactions have been obtained and characterised structurally: cocondensation of chromium vapour with cyclo-octa-1,3-diene or cyclo-octa-1,5-diene in the presence of PF_3 leading to the formation of the complex $Cr(\eta^5\text{-}C_8H_{10}\text{-}\mu\text{-}H)(PF_3)_3$;[63] the reaction of $Mn(CO)_5H$ with two moles of the ligand $Ph_3PN(CMe_3)$. .$AlMe_2$ leading to the formation of the bicyclic complex (VIII):[64,65]

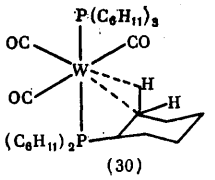


(VIII)

It has been suggested that the 17-electron radical-cations, formed in the one-electron electrochemical oxidation of the 18-electron complexes $(\eta\text{-Cp})_2W(R)(R')$, where R and R′ are an alkyl or an aryl group, can be stabilised via the formation of three-centre three-electron W...H−C bonds with the α- or β-hydrogen atom of the residue R.[66] The formation of cationic or neutral CHB in the protonation reactions is summarised in Table 1. The converse reaction is also known, namely the deprotonation of a neutral cluster with formation of an anionic CHB. It has been shown that the neutral tetrahedral cluster $Fe_3(CO)_9(\mu\text{-H})_3(\mu^3\text{-HC})$, not containing agostic H atoms, exists in solution in equilibrium with a further two isomeric clusters $Fe_3(CO)_9(\mu\text{-H})_2(\mu^3\text{-HC-}\mu\text{-}\textit{H})$ [isomer (A)] and $Fe_3(CO)_9(\mu\text{-H})(\mu^3\text{-HC-}\mu\text{-}\textit{H}_2)$ [isomer (B); the agostic hydrogen atoms are distinguished by being italicised]. In the isomers (A) and (B), there are respectively one and two Fe...H−C 2e, 3c-bonds. Deprotonation of $Fe_3(CO)_9(\mu^3\text{-HC})$ by treatment with an excess of $(PPh_3)_2N^+Cl^-$ leads to the formation of the anionic CHB $Fe_3(CO)_9$. $.(\mu\text{-H})(\mu^3\text{-HC-}\mu\text{-H})^-$.[67]



IV. THE STRUCTURE IN THE CRYSTAL ACCORDING TO DATA OBTAINED BY STRUCTURAL METHODS



The identification of the M...H−C bridge 2e, 3c-bonds in the crystal is based exclusively on data obtained by structural research methods—X-ray diffraction analysis and neutron diffraction (ND). Scheme 3 presents formulae for a series of structurally characterised CHB and Table 2 summarises certain crystal-chemical data for the M...H−C bridged fragments: the M...H, C−H, and M−C distances and the M−H−C angle. It was not until 1979−1981 that it became possible to understand the fine features of the structure of the CHB as a whole class of complexes with a new type of coordination of the hydrogen atom in a C−H bond to the metal in connection with the considerable improvement of the accuracy of the XRD method and the publication of a series of pioneering studies in which the structures of CHB containing tantalum,[84,85] manganese,[35,95] and iron[100,101] were established.

It is possible to differentiate the following characteristic features of the bridged M...H–C fragments. The M...H distances involving the bridging hydrogen atoms in the CH_n fragment (n = 2,3) are greater on average by 10–20% compared with the usual ranges of M–H bond lengths for terminal hydrido-ligands (according to data in the review of Teller and Bau[7]). The C–H distances determined from XRD data are known to be always too low by 0.1–0.15 Å by virtue of the characteristics of the method itself. One can therefore compare only the C–H distances obtained by the ND method, from which it follows that the C–H bonds coordinated to the metal are extended (loosened). According to ND data, the C–H distances in CHB are 1.10–1.19 Å, which is approximately 5–10% greater than the average C–H distances involving sp^3-carbon atoms (1.08 to 0.19 Å).

The M...H distances obtained by the ND method are compared in Table 3 with the sum of the covalent radii of the M atoms (according to the data of Andrianov et al.[118] and Churchill[119]) and H atoms (0.37 Å) and the C–H bond lengths derived from ND data are also listed. Except for complexes of Group IV metals (Ti, Th), the M...H distances exceed by less than 10% the sum of the covalent radii of M and H. On this basis, one can apparently conclude that, at least in the cases quoted, the M...H bridge bonds, although extended, do not differ very greatly from the terminal M–H bonds in metal hydride complexes.

A method has been proposed[60] for the estimation of the strength of the interaction of the C–H bond with the metal and of the strength of the bond produced. The distance d_A between the metal atom and the point A, where according to the author's hypothesis the centre of the electron pair of the C–H bond is located and through which coordination to the unoccupied metal orbital takes place, is calculated from the experimental distances d(MH), d(MC), and the dimensionless constant a = 0.28 (the ratio of the covalent radius of the hydrogen atom to the length of the "usual" C–H sp^3-bond).

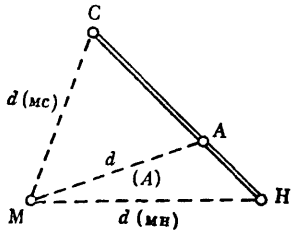

Table 2. Structural data for complexes with a bridging hydrogen atom.

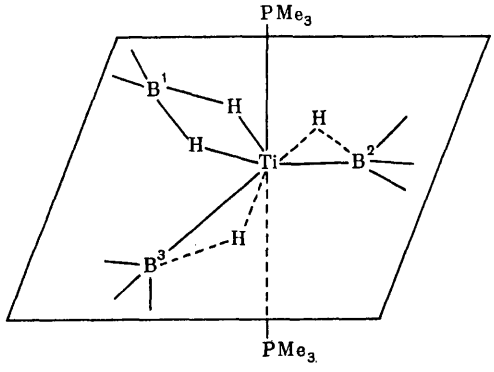
*Pir = pyrazolyl.



In order to be able to compare the complexes of different metals, the difference $r_A = d_A - r_M$, where r_M is the covalent radius of the metal, was adopted as a criterion of the estimate. It has been suggested that r_A be treated as a kind of "covalent radius" of the bonding electron pair. The greater the value of r_A, the weaker the M...H–C interaction. The values of r_A are listed in Table 2. One can differentiate arbitrarily three groups of compounds. Within the framework of the given approach, the bridge bonds are the strongest for Fe_4(μ-CH)(H)$(CO)_{12}$, [Mo_2(η-C_8Me_8-μ-H)(Cp)$_2$]$^+$, [Ta(CH. .CMe_3)(L)Cl_3]$_2$, and Ti(CH_2-μ-H)Cl_3($Me_2PCH_2CH_2PMe_2$) (the values of r_A are in the range 0.59–0.69). The bridging interaction in Mn(η^3-MeC_6H_7-μ-H)$(CO)_3$, [Fe(η^3-C_8H_{12}-μ-H) {P(OMe_3)$_3$}$_3$]$^+$,

$Mo(COCH_2\text{-}\mu\text{-}H)(S_2CNMe_2)(CO)(PMe_3)_2$, $[Ir(PPh_3)_2(H)_2(N,C\text{-}8\text{-}methylquinoline)]^+$, and $Ti(CH_2CH_2\text{-}\mu\text{-}H)Cl_3(Me_2PCH_2CH_2PMe_2)$ are less strong (the values of r_A are in the range 0.75–1.0). The bridge bonds in the complexes $Mo[BEt_2(pyrazolyl)_2](CO)_2(\eta^3\text{-}C_3H_4Ph)$, $Pd(PhCH{=}NMe)_2Cl_2$, and $[M(PPh_2CMe_3)_2]_2$ (M = Pd or Pt), where r_A = 1.0–1.6, are weakest.

Table 3. M...H and C...H distances in complexes with a bridging hydrogen atom according to neutron diffraction data.

Compound	M...H distance, Å	r_M, Å	r_M+r_H, Å	C–H distance, Å	Refs.
$Ti(CH_2\text{-}\mu\text{-}H)(Dmpe)Cl_3$	2.447 (3)	1.56	1.93	1.095 (3)	[75]

$[Fe(\eta^3\text{-}C_9H_{12}\text{-}\mu\text{-}H)(P(OMe)_3)_3]^+$	1.874 (3)	1.34	1.71	1.164 (3)	[100, 101]
$Fe_4(\mu\text{-}CH)(H)(CO)_{12}$	1.753 (4)	1.34	1.71	1.191 (4)	[104]

Note. The average estimate of the covalent radius r_{Th} is based on Th–C bond lengths of 2.543(4) and 2.456(4) Å and the radius r_C = 0.77 Å.

The structure of the complex $(PMe_3)_2Ti(BH_4)_3$.[14]

In 1975–1982, Schrock and co-workers obtained a large number of electron-deficient niobium, tantalum, and tungsten complexes with alkylidene (carbene) ligands, namely :CH–CMe_3, :CH–Ph, etc.; the structurally characterised 14-electron and 16-electron complexes of this type are presented in Table 4, which includes also for comparison data for a series of 18-electron complexes. The following features of the coordination of the alkylidene ligands to the electron-deficient centre have been discovered. The character of the coordination (distances, angles) depends very strongly on whether the complex is of the 16-electron or 18-electron type. Alkylidene ligands contain an sp^2-carbon atom for which a trigonal-planar configuration with valence angles close to 120° is ideal. Deviations from the ideal geometry involving an increase in the $M-C_\alpha-C_\beta$ angles occur in both 16-electron and 18-electron complexes. However, the angles for the 18-electron complexes do not exceed 135 to 150°, whereas in the 16-electron complexes the distortion is significantly greater and the $M-C_\alpha-C_\beta$ angles are 160–170°. The $M-C_\alpha$ distances in the 18-electron complexes are 2.03–2.07 Å, while in the 16-electron complexes they are significantly smaller, amounting to 1.86–1.96 Å. In those cases where the locations of the hydrogen atoms have been determined and the M...H–C bridge fragments (carbene fragments) have been detected, the $M-C_\alpha-H$ angles are sharply diminished–from 90–110° to acute angles in the range 70–80°.

Table 4. Certain structural parameters of the carbene ligands :C(H)–CMe_3 and :C(H)–Ph in the 14-, 16-, and 18-electron tantalum and tungsten complexes.

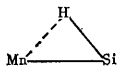
*The locations of the hydrogen atoms have not been determined.

All the distortions in the geometry of the electron-deficient alkylidene complexes mentioned above have the same cause and are induced by the interaction of the α-hydrogen atom and the electrons of the C–H bond with the metal. Yet another parameter, which in the case of the carbene ligands :C(H)R depends greatly on whether the C–H hydrogen bond is of the bridge type, is the spin–spin coupling constant $^1J(^{13}C-H)$ for the ^{13}C NMR spectra. The constants for the C–H sp^3-bond are usually 120–125 Hz, while anomalously low values of the constant J, amounting to 50–110 Hz, are characteristic of the electron-deficient CHB (see below). This indicates a weakening (loosening) of the C–H bond when it is coordinated to the metal. The set of properties enumerated above constitutes characteristic features of the presence of M...H–C bridge 2e,3c-bonds.

An XRD study has been performed on the electron-deficient complexes $Mn_2(C_6H_{11})_4(Me_2PCH_2CH_2PMe_2)$,[129] $(\eta\text{-}C_5Me_5)_2ScCH_2CH_3$,[130] $(\eta^5\text{-}C_5Me_5)_2YCH_3.C_4H_8O$,[131] and also $(\eta^5\text{-}C_5Me_5)_2Th\overline{CH_2\text{-}(\eta^1{:}\eta^5\text{-}C_5R_2H_3)M}$ ($\eta^5\text{-}C_5R_2H_3$)Me, where M = Zr or Hf,[132] but, owing to the structural disorder in the crystal, it was not possible to reach clear-cut conclusions as to the presence or absence of an agostic hydrogen atom. For the same reason, it has not been possible to establish unambiguously whether the Co...H–C or the Co...H–B bond is formed in the complex $Co(\eta\text{-}C_5H_5)(\eta\text{-}Et_4C_2B_2CHMe)$.[133]

The possibility of the simultaneous coordination to the same metal atom of two bridging hydrogen atoms of the $M-CH_2$ fragment has been demonstrated in the complexes $Ti(\eta\text{-}C_5Me_5)(CH_2Ph)_3$ [79] and $Th(\eta\text{-}C_5Me_5)_2(CH_2CMe_3)_2$.[83] In these cases, there exist



in the molecule both bridging and non-bridging CH_2 fragments whose parameters differ sharply. The M—C and C—H distances are significantly shorter precisely for the CH_3 group participating in the bridging interaction compared with the non-bridging CH_2 (Table 5).

Table 5. Structural data for complexes with two bridging hydrogen atoms.

The formation of M...H—E 2e,3c-bonds by transition metals is not restricted to bonds with carbon alone. Whole series of cyclopentadienyl derivatives of manganese of the type $Mn(\eta\text{-}C_5H_5)(CO)_2\cdot(SiR_3)H$, in which there is a bridging hydrogen atom and the fragment

have been obtained and characterised structurally (Table 6). On passing from $SiCl_3$ to Si(Me) (naphthyl)Ph and $SiPh_3$, the Mn—Si and Mn—H distances increase somewhat, while the Si—H distances hardly change. The complexes $Ti(BH_4)_3(PR_2)_2$, where R = Me or Et, have been obtained recently. According to XRD data, the complex with PMe_3 contains two Ti...H...BH_3 2e,3c-bonds.[141] The molecule of this complex has the structure of a trigonal bipyramid with two PMe_3 ligands at the apical positions (see Figure). Of the three BH_4 groups in the equatorial plane, one is coordinated in the usual way, via two bridging H atoms [with the distances Ti—H = 1.90(7) Å, B(1)—H = 1.03(7) Å, and the non-bonding distance Ti...B(1) = 2.40(1) Å]. The other two BH_3 groups are linked to Ti by two three-centre Ti...H—B(2, 3) bonds involving one H atom from each BH_4 group: the distances Ti—B(2, 3) = 2.27(1) Å and Ti...H = 1.73(7) Å are shorter by 0.17 Å than in bonding of the type $Ti(\mu\text{-}H)_2B$. The distances from Ti to the other two H atoms in BH_3 are 2.25(7) and 2.68(7) Å, which exceeds by approximately 0.5 and 0.9 Å the distance to the bridging H atom. The M...H—B (where M = Mo, W, Fe, Ru, or Rh) bridge bonds are present in many transition metal complexes with carbaboranyl ligands of various types, which have been characterised by structural methods.[142-146]

V. THE STRUCTURE IN SOLUTIONS

The ^1H, ^{13}C, and ^{31}P NMR methods and in certain cases IR spectroscopy in the ν(C—H) frequency range are of principal importance for the identification and study of CHB in solutions. The hydrogen atoms of the CH_3, CH_2, and CH fragments involved in the bridge interaction with the metal give rise to ^1H NMR signals in strong fields (δ from 0 to -15 p.p.m.), i.e. in the region where there are signals due to terminal hydrido-ligands. It is therefore impossible to distinguish the two types of hydrogen atoms on the basis of ^1H NMR spectra. For the titanium, tantalum, and niobium complexes, where the metal atom has a small number of *d* electrons, the upfield shift of the signals due to the protons and ^{13}C nuclei in the M...H—CH_n fragments is usually weaker or is not observed at all. Anomalously low ^1J (^{13}D—H) constants for the ^{13}C NMR spectra, amounting to 50—110 Hz, are characteristic of the M...H—CH groups, which probably indicates a smaller strength of the C—H bridge bond compared with the usual bonds.

Table 6. Structural data for silylmetal hydride complexes with three-centre M...H—Si bonds.

It follows from the XRD data (Table 2) that the C—H bonds coordinated to the metal in the CHB are extended and the hydrogen atom is close to the metal. The extension of the C—H bond weakens it and reduces the force constant of the C—H stretching vibration. The ν(C—H) frequencies for the bridging hydrogen in the CHB are 2200—2700 cm^{-1}, which is lower by 100—600 cm^{-1} than the usual value (2800—3000 cm^{-1}). The low constant $J(^{13}C—H)$ and the sharp decrease in the ν(C—H) frequencies indicate fairly reliably a decrease in the C—H bond orders on coordination to the metal. Both these effects are distinct in the NMR and IR spectra of the 14-electron and 16-electron alkylidene complexes of niobium, tantalum, and tungsten with the :CH—CMe_3 and :CH—Ph ligands and also the related angular sandwich complexes of titanium and thorium (Table 7). Several alkylidene complexes of tantalum and tungsten have been characterised structurally (Table 4) and bridging hydrogen atoms have been found in them. On the basis of the similar $J(^{13}C—H)$ constants and ν(C—H) frequencies, presumably the other complexes listed in Table 7 also have a distorted geometry with the α-hydrogen atom inclined relative to the metal and involving the formation of M...H—C bridge bonds.

Table 7. The constants $J(^{13}C-H)$ and the frequencies $\nu(C-H)$ of complexes with M...H−C bridge bonds.

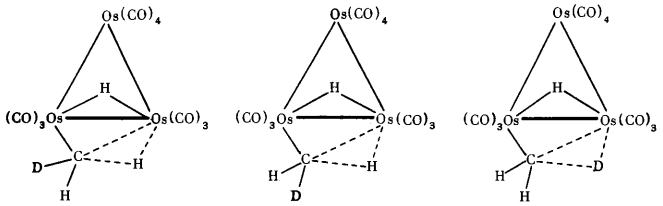
*The structure has been established by structural methods.

On protonation (with CF_3SO_3H or CF_3COOH), the 18-electron carbyne complex $L_4(Cl)W{\equiv}CCMe^3$ is converted into the cationic 16-electron carbene complex $[L_4(Cl)W{=}CH{-}CMe_3]^+$ (IX) (L = PMe_3 throughout), in which the α-hydrogen atom of the carbene ligand interacts with one of the C−P−P faces of the octahedron and the W atom:[157]

(IX)

The spectroscopic data for compound (IX) and the isoelectronic neutral complex $L_4(Cl)Ta{=}CH{-}CMe_3$ (X)[153] are similar:



Compound	δ(CH) at 295 K, p.p.m.	$J(H-^{31}P)$, Hz	$J(^{13}C-H)$, Hz	Refs.
$[L_4(Cl)W{=}CH{-}CMe_3]^+$	−8.4 (quintet)	9	45	[157]
$L_4(Cl)Ta{=}CH{-}CMe_3$	−7.4 (quintet)	6	69	[153]

The complexes (IX) and (X) are stereochemically non-rigid compounds but at 295 K the rapid, in terms of the NMR time scale, migration of H between the four C−P−P faces leads to the apparent equivalence of the four P atoms.

In the 16-electron cations $[L_4(X)W{=}CH_2]^+$, where X = Cl[157] or I,[158] formed on protonation of the carbyne complexes $L_4(X)W{\equiv}CH$, at 298 K both hydrogen atoms of the methylene ligand give rise to a single averaged signal owing to rapid exchange (δ = −0.16 and −0.80 p.p.m.), which is split into a quintet. On cooling to 165 or 153 K, the two H atoms become non-equivalent and give rise to two different signals: the shifts δ are −7.67 and −9.00 p.p.m. for the H atoms interacting with the C−P−P face and the W atom; for the compound with X = Cl, the H atom not interacting with W produces a signal at δ = 7.05 p.p.m., while in the case where X = I the signal of this H atom is masked by the signal of the solvent. The complex with X=I has been studied by XRD, but the locations of the H atoms have not been determined.[159]

The majority of the CHB contain the CH_3 or CH_2 groups and are stereochemically non-rigid complexes (see below), whose NMR spectra exhibit reversible temperature variations (TV). Under the conditions of rapid exchange, the two or three protons of the CH_3 or CH_2 groups are equivalent and give rise to an average signal in the range δ = 0−−3 p.p.m., while the carbon nucleus in the ^{13}C NMR spectra is manifested by a binomial 1:2:1 triplet or a 1:3:3:1 quartet with an average constant J = 120−130 Hz. In slow exchange, the two protons of the CH^aH^b group are non-equivalent, form the AB (or AX) system, and give rise to two doublets with a geminal constant $J(H,H)$ = 15−30 Hz. The three non-equivalent protons in $CH^aH^bH^c$ form the ABC three-spin system and give rise to three multiplets, the signal of the bridging proton (H^a) usually having δ = −10−−15 p.p.m. The resonance signal of the carbon nucleus is split under the conditions of slow exchange respectively into a doublet of doublets (for CH^aH^b) or into a doublet of triplets ($CH^aH^{b,c}$) with different constants: $J(^{13}C-H^a)$ = 50−110 Hz for the bridging H^a atom and J = 130−150 Hz for the non-bridging H^b and H^c atoms. The ^1H and ^{13}C NMR data for CHB under the conditions of both rapid and slow exchange are compiled in Table 8.

When H is replaced by D in the M...H−CH_n (n = 1,2) groups, additional effects appear in the ^1H and also ^2H NMR. Deuteriation leads to an unusual upfield shift of the resonance signals of the CH_2D, CHD_2, and CHD groups relative to CH_3 and CH_2 (Δδ = 0.3−1.2 p.p.m.), although for the usual compounds geminal substitution of H by D in CH_3 or CH_2 is accompanied by only a very slight shift of the signals (Δδ = 0.01−0.3 p.p.m.). An appreciable influence of the H/D substitution on the constants $J(^{13}C-H)$ has been noted. The marked dependence of δ and Δδ on isotope substitution was first observed for the cluster complex $HOs_3(CO)_{10}\cdot(CH_2\text{-}\mu\text{-}H)$ and has been called the "isotope perturbation effect" or the chemical shift effect.[161] Three rotational isomers are possible for this cluster, in which the bridge position is occupied by either H [rotational isomers (XI) and (XII)] or by D [compound (XIII)]:

(XI) (XII) (XIII)

The equilibrium (XI) ⇄ (XII) ⇄ (XIII), whose position depends on temperature, exists in solution; the contributions of the individual rotational isomers are not the same and the distribution differs from the statistical distribution owing to the difference between the properties of H and D (isotope effect). Since the C–H and C–D bridge bonds are extended compared with the non-bridge bonds and also bearing in mind the difference between the zero-point energies of the C–H and C–D bonds, one may conclude that the bridge position is preferred for the light H atom compared with the heavier D atom. Each of the H-bridged forms will therefore contribute more than the D-bridged form.

Since the H atom linked to two M atoms should generate a signal in a stronger field than the non-bridging atom, for unequal amounts of the individual rotational isomers the signal due to the protons in CH_2D is located in a stronger field than the signal from CH_3. The observed strong temperature dependence of δ and Δδ is associated with the shift of the equilibrium between the rotational isomers. Data for the dependence of the chemical shifts on isotope substitution in CHB are presented in Table 9.

*Here q = quartet, dd = doublet of doublets, and dt = doublet of triplets.

**The complex is chiral and exists as a mixture of two diastereoisomers.

***Two isomers with different positions of the bridging H atom.

It has been suggested that there is a possibility of the coordination of the metal centre to the CH_4 molecule, which is isoelectronic with the BH_4^- anion, and also to other alkanes.[141] In a study of the photochemical reactions of the complexes $(\eta\text{-}C_5R_5)M(CO)_2$ (where R = H or Me; M = Co, Rh, or Ir) in matrices at 12 K by IR and UV spectroscopic methods, the formation of products of the oxidative addition of CH_4, and, furthermore, the formation of compounds of yet another type, for which the structure of complexes with an agostic hydrogen atom was proposed, i.e. $(\eta\text{-}C_5R_5)(CO)$. .M...H$-CH_2$, was noted.[162] In a number of investigations, the formation in solutions of CHB of different structure, containing Ta,[163] W,[164] Fe,[165] Mn,[166] Ru,[167,168] and Co,[169] has been observed or postulated on the basis of NMR, IR, and UV spectroscopic data as well as kinetic data.

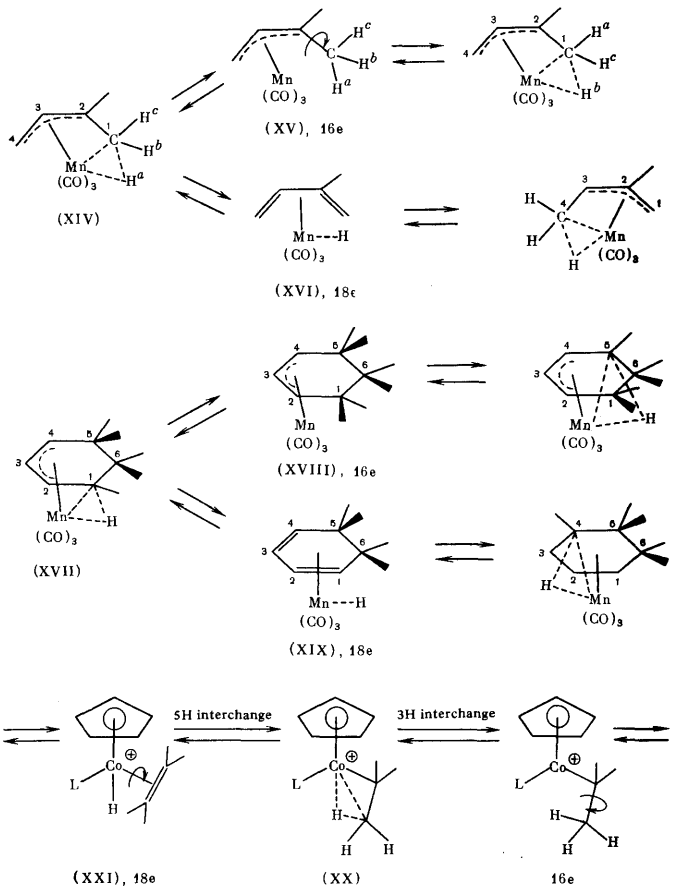
VI. PROPERTIES AND REACTIVITY

1. Stereochemical Non-rigidity

The majority of CHB are stereochemically non-rigid complexes characterised by different intramolecular rearrangements (IAR) associated with the migration of a hydrogen atom and/or ML_n fragments relative to the carbon atom of the skeleton of the η-ligand. These rearrangements can be degenerate (DIAR) or non-degenerate. Several (up to three) different IAR can occur simultaneously, whereupon the ^1H, ^{13}C, and ^{31}P NMR spectra exhibit reversible temperature variations. The following types of rearrangements with participation of the CH_3, CH_2, CH groups and ML_n fragments are typical for CHB.

1. The interchange of the positions of the bridging H^a and non-bridging H^b and H^c atoms in the CH_3 group (rotation about the $C-CH_2-\mu$-H bond) via a 16-electron intermediate—a type "A" rearrangement:



16e

The positions of the C atoms do not then change.

2. Two types of rearrangements, illustrated in relation to manganese compounds[35,59] (Scheme 4), are possible for η^3-allyl CHB.

Scheme 4

After the dissociation of the bridge bond, the μ-H atom can move either to a carbon atom with formation of the 16-electron intermediates (XV) and (XVIII) or to the metal atom with formation of 18-electron dienemetal hydride intermediates (XVI) and (XIX). For the non-cyclic CHB (XIV), the rearrangement via the 16-electron intermediate (XV) belongs to type "A" and leads to the exchange of the three protons H^a, H^b, and H^c. The rearrangement via the 18-electron intermediate (XVI) is non-degenerate owing to the presence of the methyl group at C(2) and leads to the exchange of the bridging hydrogen atom between the C(1) and C(4) atoms in the same ligand (a type "B" rearrangement).

For the cyclic CHB (XVII), rotation about the C−C bond is impossible and, after the formation of the 16-electron compound (XVIII), the bridging H atom is exchanged between C(1) and C(5) without change in the carbon skeleton (IAR) of type "B". The

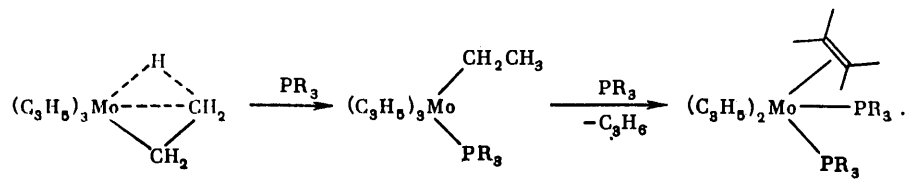
rearrangement of compound (XVII) via the 18-electron intermediate (XIX) also leads to the migration of the bridge, but, in contrast to the rearrangement via the 16-electron intermediate, is accompanied by the 1,2-migration of $Mn(CO)_3$ relative to the carbon skeleton of the η-ligand. In a more general sense, all the IAE associated with the migration of ML_3 relative to the carbon skeleton of the ligand (rearrangements of type "C") can be assigned to this type.

In compounds (XVI) and (XIX) and analogous intermediates, the proton involved in the M—H bond is "acid" and readily enters into an exchange with the acid derived from the solvent. If the CHB are generated by treatment with deuterio-acids (Table 1), then deuterium is inserted under these conditions in the 1,4-positions for the non-cyclic system and in the 1,5-positions for the cyclic system.[41]

3. The cobalt complexes with the η^2-ethylene ligands (η-Cp)Co.(L)(η-CH_2=CHR), where L = phosphine, phosphite, or CH_2 = CH_2, produce on protonation the CHB $[(\eta\text{-Cp})Co(L)(CH_2CHR-\mu\text{-H})]^+$ (XX), where R = H or alkyl.[49–52] In this case, a type "A" rearrangement takes place (exchange of the three protons in $CH_2-\mu$-H) and also an IAR with the exchange of the five protons in $CH_2CH_2-\mu$-H via the intermediate (XXI) (Scheme 4) and rotation about the cobalt—ethylene bond (rearrangement of type "D").

4. Rearrangements associated with the interchange of the positions of the groups L in the ML_3 "tripod" (IAR of type "E") take place in CHB with the groups ML_3 = $Mn(CO)_3$, $Fe(CO)_3$, $Fe(P)_3$, $Ru(P)_3$, etc., where (P) = phosphite or phosphine.

5. In CH_3 having two or more identical structural elements (M atoms, C_2H_4 or C_4H_6 ligands, etc.) rearrangements take place with migration of the bridge between such elements (IAR of type "F"). The migration of μ-CH between two out of the four Fe atoms in $HFe_4(CO)_{12}(CH)$[43,104] as well as the alternate involvement of each of the four carbon atoms of the CH_2= groups of the protonated form $[Mo(PMe_3)_2(CH_2$=$CHCH$=$CH_2)_2H]^+$ in the formation of the Mo...H—C bond via an 18-electron metal hydride intermediate[32] are examples of such rearrangements. The migration of an α-hydrogen atom of the alkylidene ligand between the four C—P—P faces in the octahedral cationic complexes $[W(PMe_3)_4(X)(=CH-R)]^+$, where R = CMe_3 or H, can be assigned to IAR of type "F".[157] Apart from the rearrangement indicated, in the complex with R=H there is also a rearrangement involving the interchange of the positions of the two hydrogen atoms of the CH_2 ligand (type "B").



The rearrangements known for the CHB and the barriers $\Delta G^{\neq}$ obtained from the NMR data are listed in Table 10.

The chemical properties of the CHB have been little investigated. Their characteristic reaction involves the ready dissociation of the bridge bond. The M...H—C interaction is comparatively weak: on treatment with nucleophiles—the 2-electron ligands PR_3, $P(OR)_3$, CO, CNR, etc.—these bonds are readily cleaved with substitution of H by L, as shown below for tris-η^3-allylmolybdenum complexes:[160]

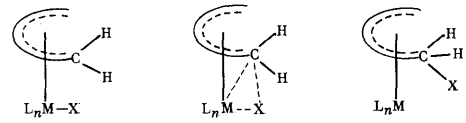
Depending on the type of complex and the nature of M, the ease of the dissociation of the bridge bond can be various. Thus $[Fe(\eta\text{-}C_8H_{12}$-μ-H$)\{P(OMe)_3\}_3]^+$ reacts with CO and $CNCMe_3$ but not with $P(OMe)_3$, the Fe...H—C bond being dissociated and the Fe—C_8H_{11} bond being retained.[41] On the other hand, the complexes $[Ru(C_8H_{12}$-μ-H$)L_3]^+$, where L is a tertiary phosphine or arsine, readily react with L, a process involving the dissociation of the Ru...H—C and Ru—C_8H_{12} bonds and the formation of the $RuHL_5^+$ cations.[44] The complexes (XIV) and (XVII) (Scheme 4) readily enter into a reaction with CO in which the Mn...H—C bond is dissociated, and



are converted into the complexes (η^3-allyl)$Mn(CO)_4$.[35,59] Compounds (XIV) and (XVII) are readily deprotonated on treatment with KH with evolution of H_2 and the formation of the anions (XXII) and (XXIII). When these are alkylated with MeI, the methyl group adds to the diene ligands and not to the Mn atom:[35,59]

(XXII) (XXIII)

The problems of the theoretical analysis of the structure and reactivity of CHB have attracted much attention. Several quantum-mechanical calculations have been made for the CHB both by the extended Hückel method (EHM) and by non-empirical methods. The characteristic features of the structure and of the unusual geometry of the alkylidene ligands in tantalum complexes and the characteristics of the activation of the C–H bond and of the hydrogen α-elimination reactions have been analysed.[170] In other studies by Hoffmann, the quantum-mechanical description of the activation of the C–H and H–H bonds by complexes having the d^n ($n > 0$) and d^0 configurations and also on the surface of the metal has been examined.[171,172] Calculations by the EHM have been performed for the model complexes $MeTiH_3$ and $Me_2TiH_5^{2-}$ and the influence of various factors and of the character of the ligands on the stabilisation of the 2e,3c-interaction in the methyl complexes has been discussed.[173] The electronic structures of the complexes $[Fe(\eta^3\text{-}C_8H_{12}\text{-}\mu\text{-}H)(CO)_3]^+$, $[Fe(\eta\text{-}C_8H_{12}\text{-}\mu\text{-}H)(PH_3)_3]^+$, $[Fe(C_6H_8\text{-}\mu\text{-}H)(CO)_3]^+$, $Mn(\eta\text{-}C_6H_8\text{-}\mu\text{-}H)(CO)_3$, and $Cr(\eta\text{-}C_8H_{10}\text{-}\mu\text{-}H)(PF_3)_3$ have been calculated[174] on the basis of the geometry obtained from XRD data.[35,41,63] The energy profile of the conversion of $[CpCo(PH_3)C_2H_5]^+$ into $[CpCo(PH_3)(C_2H_4)H]^+$ has been calculated and it has been concluded that the intermediate with the Co...H–C 2e,3c-bond is more stable than the ethylenemetal hydride complex.[175] *Ab initio* calculations have led to the optimisation of the geometry of the model complexes $Pd(Et)(H)(PH_3)$ and $Pd(H)_2(C_2H_4)(PH_3)$ and of the transition state between them, involving Pd...H–C 2e,3c-bonding, as well as the complexes $Pd(CH_3CHF_2)(H)(BH_3)$ and $Ni(Et)(H)(PH_3)$, and the role of the three-centre interactions in α-elimination reactions has been considered.[176] Optimisation of the geometry of the complex $Ti(Et)(PH_3)_2(Cl_2)(H)$(*ab initio* calculation) yielded a Ti–H distance of 2.23 Å and a Ti–C_α–C_β angle of 89°,[177] which agrees well with XRD data for Ti(Et)(Dmpe)Cl_3 (2.29 Å and 86° [75]). The most convenient structure of the complexes $Ti(Me)(PH_3)_2(X)_2(Y)$, which yielded a Ti–H distance of 2.51 Å and a Ti–C–H angle of 100° for X = Y = Cl,[178] which agrees well with experiment for Ti(Me)(Dmpe)Cl_3 (2.45 Å and 99° [75]), was calculated analogously. Calculations by the EHM have been performed for complexes containing molyb-denum[30] and cobalt.[52]

The survey of the structures and properties of CHB shows that a large number of complexes (B) (X = H) with M...H–C 2e,3c-bonds have already been obtained and characterised both in the crystal (more than 60 structures) and in solutions. The complexes are thermodynamically more stable than the corresponding alkene-, diene-, or polyenyl-metal hydride complexes (A) (X = H). The equilibrium (A) ⇄ (B) ⇄ (C), leading to the migration of hydrogen between the metal atom and the ligand, exists in solutions:

(A) (B) (C)

It has been suggested that there is an analogy between the complexes (B, X = H) and (B, X = alkyl) as regards structure, properties, and the dynamics of the migration of the group X and that in the complexes (B,X = alkyl) there is a possibility of the ready migration of the alkyl (Me, Et) group from the metal to the ligand.[51] A mechanism has been adopted for the polymerisation of olefins in the presence of Ziegler-Natta catalysts in which the key stage involves the migration of the alkyl group (R) from the metal atom to the olefin ligand and chain propagation via the insertion of R in the C–H bonds.[179] If such migration is possible in the complexes (B, X = alkyl), then they may be expected to manifest catalytic properties. It has been shown that the complexes $[(\eta\text{-}C_5Me_5)Co(L).(CH_2CHR\text{-}\mu\text{-}H)]^+$ do indeed catalyse the polymerisation of ethylene under mild conditions.[51]

In connection with the vigorous investigation of the activation of C–H and C–C bonds in alkanes,[10,11] new data have been obtained recently on the mechanisms of the reactions involving the oxidative addition (OA) of C–H bonds in the alkanes RH to low-valence rhodium, iridium, and rhenium complexes with formation of $R-(ML_n)-H$.[182–184] In the reactions of RH with rhodium compounds, intermediates of the type of CHB with the η^2-coordination of a C–H bond are apparently formed initially and then rapidly undergo intramolecular isomerisation to hydridoalkyl complexes.[184] A three-centre transition state with participation of M, C, and H atoms, preceding the dissociation of the C–H bond, has been proposed for the OA reactions.[185] The trajectories of the interaction of the M, C, and H nuclei in the course of the reactions have also been analysed:[60]

$$M + C\text{—}H \rightarrow C\text{—}(M)\text{—}H.$$

The data considered in the present review permit the conclusion that stable CHB with three-centre M...H–C bonds are apparently good models of the transition states in the OA reactions of alkanes.

It is important to emphasise that CHB can serve as intermediates in the various reactions of organometallic complexes with participation of acids. The H/D exchange reactions involving aromatic η-ligands in ferrocene, i.e. $(\eta\text{-}C_5H_5)M(CO)_{3-n}(P)_n$ [M = Mn or Re; (P) = phosphine; $n = 0-2$] and $(\eta\text{-}C_6H_6)Cr(CO)_2(L)$ (L = CO or phosphines), were studied in detail in 1962–1973 (see the relevant reviews[180,181]). A mechanism with protonation of the metal and the migration of an H atom to the η-ligand has been proposed for these reactions.[181] It is known that the complex $(\eta\text{-}C_4H_4)Fe(CO)_3$ (XXIV) is readily protonated[24] and rapidly exchanges H or D with CF_3COOD.[186] It has been concluded[24] that the Fe atom is protonated, but it is clear on the basis of the set of ^1H and ^{13}C NMR data, presented above in Section V, that the form of these spectra for the protonated form (XXIV) [the chemical shifts δ and the constants $J(^{13}C-H)$] agrees only with the formation of a three-centre Fe...H–C bond and an agostic H atom. The insertion of deuterium in η-ligands on protonation of the complexes (η-Dien)$Fe(P)_3$

by deuterioacids has already been mentioned above;[41] for -Dien = $\eta^4C_8H_{12}$, the CHB formed, with an Fe...H−C bond, was isolated and its structure was demonstrated by a structural method.[100,101] On the basis of the foregoing, it is logical to assume that the H/D exchange between the cyclic ferrocene ligands and the η-complexes of manganese, rhenium, and chromium, on the one hand, and acids, on the other, may also proceed via intermediates with bridging hydrogen.

During the preparation of the manuscript for the press, the following communications, describing the synthesis of complexes with agostic hydrogen atoms or postulating their formation as intermediates, were published. A review[187] deals with the activation of C−H bonds in alkanes by complex hydrides and organometallic compounds and the reactions and transformations of alkanes in the coordination sphere of the metal. The structure of $TiMeCl_3$ in the gas phase has been established by electron diffraction.[188] The following complexes with M...H−C bonds have been characterised by the XRD method; $Ru(SC_6H_2$-2,4,6-isoPr$_3)_4$ [189] and the cyclopalladised complexes $C_6H_4CHMe-NMe(Pr\text{-}iso)-Pd(L, L')$, where L, L′ = $(PPh_3)Cl$[190] or the acetylacetonato-group.[191] The agostic Fe...H−B bond in the complex $(PMe_3)_2(CO)FeCH(SR)S-BH_3$ has been detected by XRD.[192] Several polypyrazolylborate complexes with M...H−B bonds, including $[(Pir\ ¶)_2BH\text{-}\mu\text{-}H]Zr(Cp)Cl_2$,[193] $[(3,5\text{-}Me_2Pir)BH\text{-}\mu\text{-}H]Ru(\eta^4\text{-}C_8H_{12})H$,[194] and the complex $[(Pir)_2BH\text{-}\mu\text{-}H]_3Y$ containing three agostic Y...H−B bonds simultaneously have been characterised structurally.

In the studies quoted below, the conclusion that agostic hydrogen atoms are present was reached from ^1H and ^{13}C NMR spectra. The formation of the Li...H−C and Y...H−C bonds has been postulated for the complexes $Me_3CSC_6H_4Li(THF)_2$ [196] and $(C_5Me_5)_2YCH_2C_6H_3Me_2$.[197] The protonation of anionic ($n = -1$) or neutral ($n = 0$) η^4-diene complexes with acyclic and cyclic dienes of the type $[(\eta^4\text{-Dien})ML_x]^n$ leads to the formation of neutral or cationic η^3-allyl complexes with agostic hydrogen: $[(\eta^3\text{-allyl-}\mu\text{-H})\text{-}ML_x]^{n+1}$. The anionic complexes of manganese[198] and the neutral complexes of iron,[199,200] cobalt, rhodium, and iridium[201] (preliminary communication—see Buchmann and Salzer[54]) are protonated in this way. The Ru...H−C agostic bonds have been discovered in the complexes $[Ru(\eta\text{-}C_5Me_5)(\eta^5\text{-}C_8H_{11}\text{-}\mu H)]^+$ [202] and $Ru(\eta^3\text{-}C_7H_{11}\text{-}\mu\text{-}H)(PPh_3)_2Cl$.[203] The synthesis and reactions of cationic dinuclear derivatives of biscyclopentadienylruthenium, where one of the hydrogen atoms of the bridging CH_3 group is coordinated to ruthenium, have been described.[204,205] The substitution of the agostic hydrogen atom in the dinuclear complex containing molybdenum and manganese by the isolobal fragment $Au(PMe_2Ph)$ has been carried out.[206] It was suggested that the reaction involving the dehydrogenation of alkanes to alkenes in the presence of $IrH_2(O_2.CCF_3)[P(C_6H_4F)_3]_2$ results in the formation of the catalytically active intermediate withan Ir...H−C bond.[207] The pathways leading to the redistribution of hydrogen in the protonated form of the complex $Mo(C_2H_4)_2$(*cis*-$Ph_2PCH=CHPPh_2)_2$ have been discussed[208] and it has been suggested that this process does not necessarily proceed via a 16-electron σ-ethyl intermediate.

The formation of agostic bonds in clusters has been observed in a number of studies. In the aryne complex $H_2Os_3(CO)_9(\mu^2\text{:}\mu^4\text{-}C_6H_4)$, there is rapid proton exchange between the ring and the metal, apparently via an intermediate with agostic hydrogen;[209] analogous intermediates have been proposed for the hydrogen substitution and elimination reactions in $Fe_3(CO)_9(\mu\text{-}H)_3(\mu\text{-}CCH_3)$.[210] It has been shown by ^1H and ^{13}C NMR that the protonation of the heterometallic anionic carbido-clusters $MFe_3(CO)_{13}C^{2-}$ (M = Cr or W), $MnFe_3(CO)_{13}C^-$, and $RhFe_3(CO)_{12}C$ with the "butterfly" skeleton leads to the formation of agostic Fe...H−C bonds between the hydrogen of the methylidyne fragment and the iron atom.[211]

The interaction of CH_4 and CD_4 with organometallic complexes has been investigated by IR spectroscopy in matrices at 12−16 K. The formation of the relatively unstable compounds of the type $L_nM...H-CH_3$ has been postulated for Cp_2Ni, $(C_5Me_5)_2Ni$, $(C_5Me_5)_2Mn$, and (arene)$M(CO)_3$.[212] The quantum-chemical aspects of the electronic structure, the problem of the relative stabilities of the intermediate systems with M−H and M−C bonds, the coordination of methane, and the interaction of C−H bonds with the metal complex centre have been examined in a monograph[213] and in the literature quoted therein. The results of theoretical calculations of the electronic structure, stability, and reactivity of complexes with M...H−C,[214-218] Fe...H−E (E = B or C),[219] and Ti−Si−C[220] bonds have been described in a number of communications. Quantum-chemical calculations for compounds with Mn−H−Si bonds have been carried out.[221] Evidently both the experimental and the theoretical chemistry of complexes with agostic hydrogen atoms continues to develop very vigorously.

Dibenzylideneacetone Complexes of Transition Metals

A.Z.Rubezhov

Information on dibenzylideneacetone complexes of transition metals is reviewed. Their methods of preparation, physicochemical and chemical properties, and also applications as reagents and catalysts are discussed. The bibliography includes 162 references.

I. INTRODUCTION

Immediately after they were first prepared,[1,2] transition metal complexes with dibenzylideneacetone (DBA) (palladium and platinum complexes in the first place) attracted the attention of both organometallic chemists and synthetic chemists because of their high reactivity and ease of preparation, and the debate concerning their structure continued until 1974 when the structure was reliably established by X-ray structure analysis. DBA complexes of palladium and platinum are now firmly established in the armoury of chemists as convenient starting materials for the preparation of organic derivatives of these metals that are difficult to obtain by other methods, and also as homogeneous catalysts in a great variety of reactions (allylation, nucleophilic addition reactions, alkylation, cross-linking, etc.).

The aim of this review was to survey the available material on the preparation of DBA complexes, especially those of the platinum metals, to show how the formation of complexes with a specific structure (monomeric DBA derivatives, dimeric complexes, solvates of dimers) depends on the preparation conditions used and the reagents, to outline the synthetic possibilities of this class of compound, which is highly reactive, and to summarise the very disjoint information on the use of DBA complexes of palladium and platinum as catalysts. However before doing this it is necessary to discuss the properties of free dibenzylideneacetone which characterise it as a potential ligand.

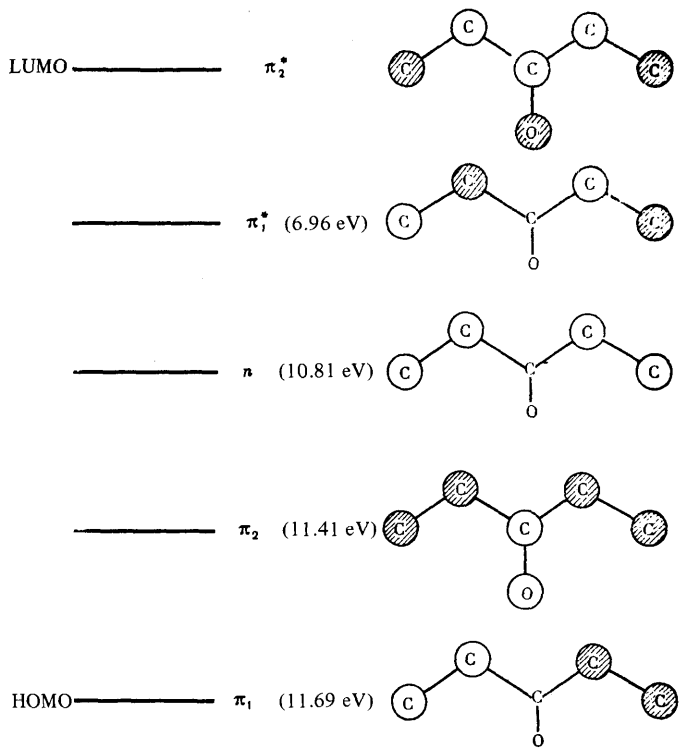

Figure 1. Frontier molecular orbitals of divinyl ketone.

II. DIBENZYLIDENEACETONE AS A LIGAND

To assess DBA as a ligand in complexes with transition metals it is necessary to be aware of its conformational properties and electronic structure because these are controlling factors in coordination. To assess the second factor it is sufficient to have data on the nature of the frontier orbitals, i.e. the highest occupied (HOMO) and lowest unoccupied (LUMO) molecular orbitals of the DBA molecule. Such an assessment has been made;[3] the simplest analogue of DBA, divinyl ketone $CH_2=CHCOCH=CH_2$ in the *s-cis,s-cis* conformation, was considered as the model molecule. The energies of the frontier orbitals of the divinyl ketone molecule[3] are shown in Fig.1.

Analogous data for acrolein $CH_2=CHCHO$ [3] and ethylene† are given in Fig.2 for comparison. The HOMO of divinyl ketone is an oxygen p_y-orbital which is a non-bonding AO of the oxygen in the

†The energy of the HOMO of ethylene was taken to be the ionisation energy I = 10.62 eV;[4] the energy of the LUMO was calculated from u.v. spectroscopic data (the energy of the $\pi \rightarrow \pi^*$ transition is 61 000 cm^{-1}).[5]

carbonyl group (the charge on the oxygen, $q_O = 0.82$, agrees well with results obtained by other authors[6]). Its energy (10.81 eV) is similar to the energy of the corresponding MO in acrolein (10.15 eV) but these orbitals have different symmetries; in the acrolein molecule the non-bonding AO of the oxygen in the carbonyl group is oriented along the x axis, i.e. it is a p_x-orbital.

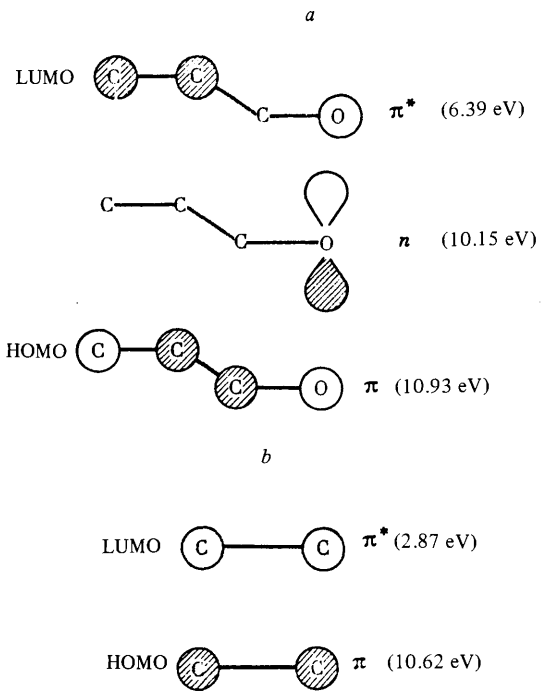

Figure 2. Frontiers molecular orbitals of: *a*) acrolein; *b*) ethylene.

The next occupied MO in the divinyl ketone molecule (and also in acrolein) is the π-bonding MO of the C=C bond with an energy of 11.69 eV (11.76 eV in acrolein); the corresponding antibonding π*-MO's have energies of 6.96 eV for divinyl ketone and 6.39 eV for acrolein. For ethylene the energy of the π-MO is 10.62 eV which is comparable with the energies of the corresponding MO's in divinyl ketone and acrolein; the energy of the lowest π*-MO in ethylene is 2.87 eV which is considerably different from the energy of the corresponding orbitals in divinyl ketone. Hence the formation of a $d \rightarrow \pi^*$ type metal–ligand donor-acceptor back bond, particularly with metals in low oxidation states for which the highest occupied d orbitals have energies in the region of 8 eV,[7] will be energetically more favourable for the two α,β-unsaturated carbnonyl compounds (acrolein and divinyl ketone) than for ethylene. This conclusion agrees with results[8] indicating an increase in the stability of olefinic π-complexes of transition metals in low oxidation state when acceptor substituents are introduced into the olefin molecule.

The most suitable donor orbitals in the divinyl ketone molecule are the n- and π-orbitals and the second are more favourable although their energy is somewhat lower ($\Delta E = 0.9$ eV). As a rule, therefore, in α,β-unsaturated carbonyl compounds the double bond is much more easily coordinated than the carbonyl group. Nevertheless, bidentate coordination, with the α,β-unsaturated ketone forming chelate or bridging complexes, is also possible.[3,8] Hence, *a priori*, for DBA the possibility of both $n \rightarrow d$‡ and $\pi \rightarrow d$ types of coordination cannot be excluded. As will be shown below, both occur.

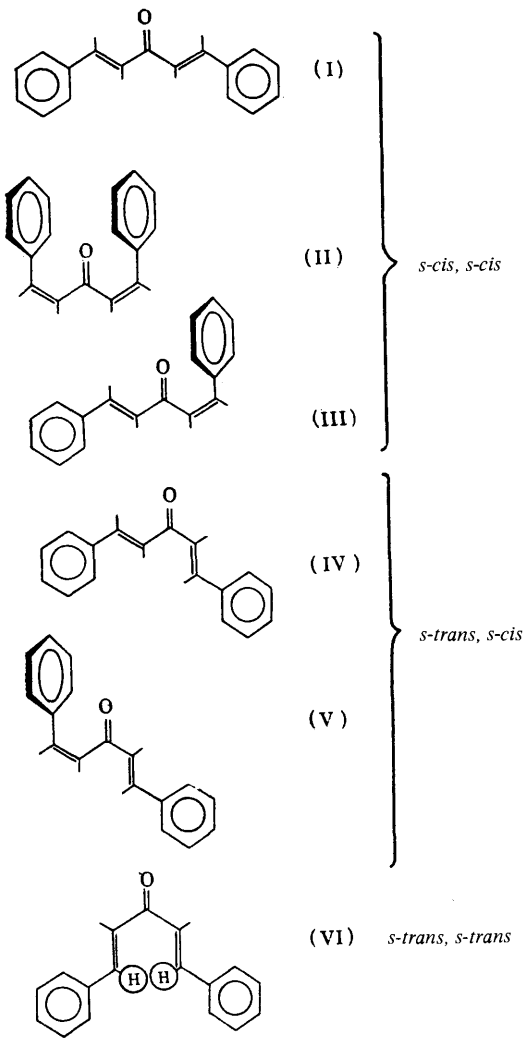

Figure 3. Possible conformations of DBA.

We shall now discuss the conformational properties of DBA. In principle it is possible to have the following alternatives of a planar arrangement of the C=C and C=O bonds relative to each other combined with different configurations of the ethylenic bonds (Fig.3):[9,10] three *s-cis,s-cis* conformations (I, II, and III), two

‡ $n \rightarrow d$-Coordination was assumed for DBA in its complexes with Pd^0 and Pt^0;[2] see also Ref. 3.

s-trans,s-cis (IV and V), and one *s-trans,s-trans* conformation (VI). However, Stuart–Brigleb models and van der Waals diagrams with Stuart–Brigleb radii show that the planar *s-trans,s-trans* structure (VI) is impossible owing to repulsion between the β and β′ hydrogen atoms (the overlap is 1.2 Å); structures I and IV§ are completely planar and hence energetically more favourable [the small overlap (0.21 Å) between the α and β′ hydrogen atoms in structure IV can be disregarded].[12] In structures II, III, and V steric hindrance forces one or both of the phenyl groups out of the plane of the double bonds. U.v.,[12,13] n.m.r.,[14] and i.r. [9] spectroscopic data also indicate that DBA molecules occur in solution only with a *trans* configuration of the two ethylenic bonds. This is also supported by dipole moment data.[14] Thus the conformational characteristics of DBA in solution define it as an olefin in which the two double bonds are unlikely to be coordinated to the same metal atom because they have different symmetries. Coordination of DBA as a 1,4-diene is therefore less favoured and effectively two possibilities remain: DBA acts as a bridging ligand in binuclear complexes or is an ordinary unidentate olefin with somewhat greater potentialities for donor-acceptor back bonding compared to ethylene. How such potentialities are realised will be shown below.

III. THE STRUCTURES OF DBA COMPLEXES OF TRANSITION METALS

As indicated above, in its metal complexes DBA can act as both an *n*- and a π-donor ligand but in the latter case, owing to its conformational characteristics, DBA is less likely to form diene complexes of the chelate type and more likely to act as a uni- or bi-dentate π-olefinic ligand.

The available X-ray structural data indicate that all the possible modes of bonding between DBA and transition metals occur.

However, we shall first discuss the spectroscopic (u.v., i.r., and n.m.r.) properties of DBA complexes.

Table 3. Parameters of the ^{13}C n.m.r. spectra of DBA and $L_2Pt(DBA)$ complexes.[21]

L	C_a	C_b	C_c	C_d	$J(Pt-C_c)$	$J(Pt-C_d)$
PEt_3	124 6	134.8	49.7	61.0	235	180
$AsEt_3$	123.0	135.8	46.3	58.0	275	185
DBA (uncoord.)	135.4	142.7	135.4	142.7	—	—

The u.v. spectra of uncoordinated DBA, the complexes $Pd(DBA)_2$, $Pt(DBA)_2$, and $Pd_2(DBA)_3.CHCl_3$, and also tribenzylideneacetylacetone (TBAA) and $Pd_3(TBAA)_3.CHCl_3$ are compared in Table 1.

It is clear that the bands due to the $n \rightarrow \pi^*$ and $\pi \rightarrow \pi^*$ transitions in DBA show no change in either position or intensity on coordination. In the opinion of the authors of Refs.16 and 17 this indicates that the carbonyl group in DBA is not involved in the coordination.

I.r. spectroscopic data for DBA, $Pd(DBA)_2$, $Pt(DBA)_2$, $Pd_2(DBA)_3.CHCl_3$, $Pd_2[(C_6D_5CH=CH)_2CO]_3.CHCl_3$, TBAA, and $Pd_3(TBAA)_3.CHCl_3$ are compared in Table 2.

The conclusions drawn from the i.r. spectra by different authors are very contradictory. The data in Table 3 [Table 2? (Ed. of Translation)] can provide support for coordination both via the carbonyl group and via the C=C double bonds in DBA.

Next we shall consider the n.m.r. spectroscopic data for DBA and its complexes. The similarity between the ^1H n.m.r. spectral characteristics of uncoordinated DBA and complexes of the type $M(DBA)_2$ (M = Pd, Pt) was noted as far back as 1971.[2] In compounds of the type $M_2(DBA)_3$ (M = Pd, Pt) the signals of the olefinic protons in DBA are shifted to low field on coordination with the metal atom.[18,19] ^1H n.m.r. spectroscopic data indicate that only one of the two C=C bonds in DBA is coordinated to the platinum in $L_2Pt(DBA)$ type complexes.[20] This was also confirmed for the complexes $L_2Pd(DBA)$ (L = PPh_3, PEt_3, PPh_2Me, $AsPh_2$, $AsEt_3$) by ^{13}C n.m.r. spectrosocpy (Table 3).[21]

N.m.r. spectroscopic data thus show that the coordination of the DBA is of the $\pi \rightarrow d$ type and the DBA complexes of Pd and Pt can be regarded as π-olefin derivatives of these metals.

The question of the structure of DBA compounds of palladium, platinum, and rhodium was finally resolved by X-ray structure analysis.

Dibenzylideneacetone forms several types of complex: $M(DBA)_2$ (M = Pd, Pt), $M(DBA)_3$ (M = Pd, Pt), $M_2(DBA)_3.Solv$ (M = Pd, Pt), $MO_2Cl_2(DBA)_2$ (M = U), and $C_5Me_5M(DBA)$ (M = Rh). X-Ray structure determinations have been carried out on all these types except $M(DBA)_2$.

§However, measurements of the molar Kerr constants of DBA can be reconciled with an *s-cis,s-cis* conformation only on condition that the phenyl groups are rotated by 26.5° around the 1,4-axes.

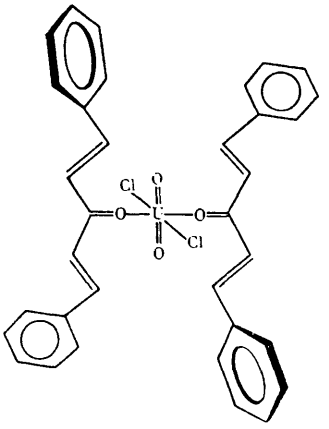

Figure 4. Structure of $UO_2Cl_2(DBA)_2$ in the crystal.

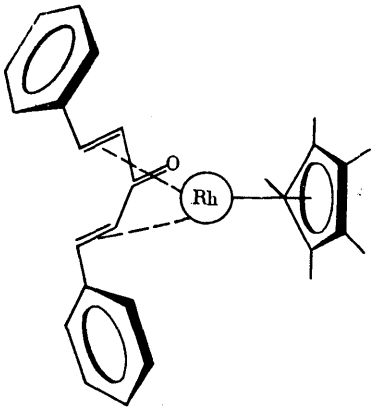

Figure 5. Structure of $C_5Me_5Rh(DBA)$ in the crystal.

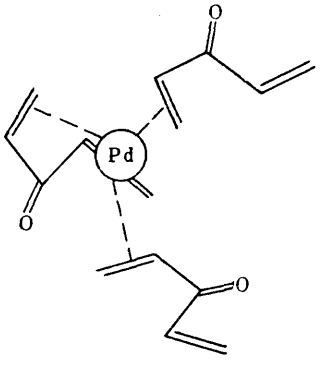

Figure 6. Structure of $Pd(DBA)_3$ in the crystal.

In the uranyl compounds the DBA is coordinated to the uranium atom via the oxygen atom of the carbonyl group (Fig.4);[22-24] the ligand is in the *s-cis,s-cis* conformation and the changes in the C=O and CH=CH bond lengths in DBA owing to coordination are unimportant. The phenyl rings are in the plane formed by the

$$-CH=CH-\overset{\overset{O}{\|}}{C}-CH=CH-,$$

system, i.e. the DBA is in the planar *cis,cis*-form (I) which is energetically the most favourable for uncoordinated DBA.

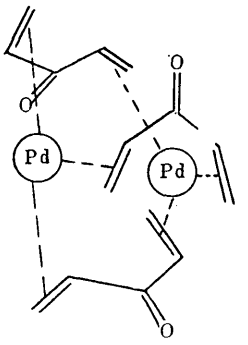

Figure 7. Structure of $Pd_2(DBA)_3.CH_2Cl_2$ in the crystal.

In the rhodium complex (Fig.5) DBA acts as an η^4-dienone ligand.[25,26] The coordinated DBA has the symmetrical *s-trans,s-trans* configuration (VI) which, as has already been mentioned, is impossible for the uncoordinated ligand because of the intramolecular H...H interaction between C(3)H and C(5)H; this distance is 1.2 Å in free DBA and 1.89 Å in the rhodium complex. The DBA molecule in this complex is under considerable strain and this is evidently the reason for the high catalytic activity of $C_5Me_5Rh(DBA)$. Tris(dibenzylideneacetone)palladium (Fig.6) is a tris-olefin complex of Pd^0.[27] Each of the three pentadiene ligands is coordinated by only one C=C bond, the DBA molecule is in the most favourable *s-cis,s-trans* conformation (IV), and the relatively small changes in the DBA bond lengths on coordination reflect the weakness of the metal–ligand bond in these complexes.

In the solvated complexes $Pd_2(DBA)_3.Solv$ the three ligands are bonded to the palladium atoms in different ways depending on the nature of the solvent Solv.[28,29] When Solv = CH_2Cl_2 two of the DBA molecules are in the *s-cis,s-trans* conformation but the third is in the *s-cis,s-cis* form (Fig.7). When Solv = $CHCl_3$ all three DBA ligands are in the *s-cis,s-trans* conformation. The factors determining the conformational properties of the DBA ligands in the $Pd_2(DBA)_3$ complexes are considered[28,29] to include not only the intramolecular contacts in DBA itself but also interligand interactions and, all in all, they will lead to an optimally strong π-bond between the metal and the olefin fragment of the DBA. On these grounds the most favourable DBA conformation will be *s-cis,s-cis*, in which the two C=C fragments are oriented approximately in the trigonal planes of the two Pd atoms. However, this does not provide sufficient separation between the two metal centres. The *s-cis,s-trans* conformation is more suitable from the latter point of view.

The interaction-between-the-metal-atoms factor does not of course apply in "monometallic" complexes but the *s-cis,s-trans* conformation usually still occurs because of the DBA–DBA interligand interactions. However, in (bipy)Pd(DBA), where there are no such interactions, the DBA ligand is in the *s-cis,s-cis* conformation (W-conformation) (Fig.8).[30]

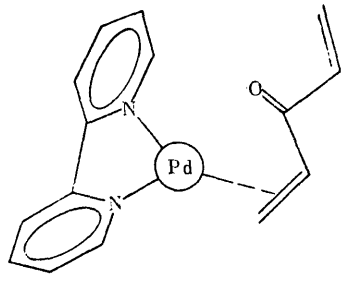

Figure 8. Structure of (bipy)Pd(DBA) in the crystal.

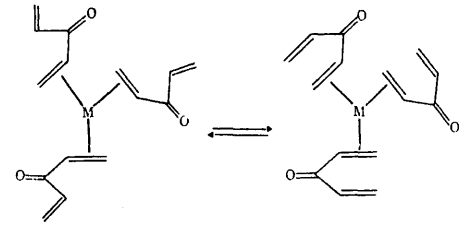
The available experimental data on the strutures of DBA complexes in the crystalline state thus agree fairly well with the preliminary assessments discussed above. The structures of the complexes in solution have been studied by n.m.r. spectroscopy.[31-33]



In a $CDCl_3$ solution the $Pd_2(DBA)_3.CHCl_3$ molecule has the three DBA ligands in the *s-cis,s-trans* conformation,[33] as in the crystal. Similarly, the ^1H n.m.r. spectrum of $Pd_2(DBA)_3.CH_2Cl_2$ in CD_2Cl_2 shows that one of the DBA ligands is in the *s-cis,s-cis* form, also agreeing with the X-ray structural results.[29]

There was found to be a linear correlation between the values of J(AB) and δ(H) for the olefinic protons in the DBA ligands. Hence the spin–spin interaction is determined by the same factors as the chemical shift. In the opinion of Kawazura et al.[31] the ability of the ligand to form a donor-acceptor back bond with the metal (π-back-donation) is one such factor. The capability of olefin ligands for back donation in turn depends on two factors: the geometry of the olefin (*cis* or *trans*) and the distance between the metal atoms and the double bond.

From the results of MO calculations for olefinic complexes of nickel[34] with the metal and the C=C bond located in the same plane, *trans*-olefins are more capable of back donation than *cis*-olefins. In the case where all three DBA ligands are in the *s-cis,s-trans* form (the $CHCl_3$ solvate) the mean distances between the Pd and the C=C bond (2.19–2.22 Å) are shorter than in the CH_2Cl_2 solvate where one ligand is in the *s,cis,s-cis* conformation. The interaction of these two trends evidently also determines the structure of the complexes in solution.

For the analogous platinum complex $Pt_2(DBA)_3.CHCl_3$, whose structure has not been determined by X-ray diffraction, ^1H n.m.r. data for a solution in $CDCl_3$ [32] indicate that two of the DBA ligands have the *s-cis,s-trans* conformation and one is in the *s-cis,s-cis* form, as in Ref.31; the connection between J(Pt–H) and the capability of DBA for back donation is discussed.

Studies have been made of the ^1H n.m.r. spectra of $M(DBA)_3$ complexes (M = Pd, Pt) [23] which will be more dynamic in solution as compared to the binuclear $M_2(DBA)_3$ compounds.[27] In $CDCl_3$ at –60 °C all three coordinated DBA ligands have an *s-cis,s-trans* conformation with the *s-trans* fragment of the ligand bonded to the metal atom. On raising the temperature the following equilibrium occurs:

In the Pt complex the amount of the equilibrium form containing the *s-trans,s-trans* ligand may be fairly large. The authors attribute this to more effective back donation in the Pt derivative than in the Pd complex.

Thus DBA complexes of Pd and Pt have the same structure in the crystalline state and in solution. The conformational and energy characteristics of DBA as a potential ligand which were discussed above apply almost totally in its complexes with the platinum metals. In these derivatives DBA acts as an olefin with an electron-accepting substituent and the compounds discussed can be regarded as π-olefin complexes of platinum metals in low oxidation states.[35]

IV. METHODS OF PREPARING DBA COMPLEXES OF TRANSITION METALS

For the preparation of DBA complexes of transition metals only one method, the reaction of an excess of DBA with a metal salt in the presence of a base, is used.[1,2,16,18,21,28,35-39] The reactions are usually carried out in an alcoholic or aqueous-alcoholic solution, with sodium acetate or carbonate as the base.

A second method, the substitution of other ligands by DBA,[39] has no preparative value and is used only to determine the comparative stability of the complexes of palladium with DBA and TBAA.¶

$Pd(DBA)_2$ was first obtained[1] by adding sodium acetate to a methanol solution of a mixture of Na_2PdCl_4 and DBA (DBA/Pd $\geqslant$ 3) heated to 60 °C. Cooling to room temperature gave a brownish black crystalline complex of composition $Pd(DBA)_2$ which is fairly stable in air in the solid state but slowly decomposes in solution depositing palladium metal. This complex is sparingly soluble in CH_2Cl_2, $CHCl_3$, and benzene forming highly coloured solutions.

$Pd(DBA)_2$ was later obtained[37] by adding a hot aqueous solution of K_2PdCl_4 to an alcoholic solution of a three-fold excess of DBA and an eight-fold excess of NaOAc in alcohol in a nitrogen atmosphere. However, the products had different i.r. spectra, as was noted in Ref.28. If the complex obtained by the latter method[37] is recrystallised from $CHCl_3$ or CH_2Cl_2 the product has an i.r. spectrum similar to that of the specimen obtained by the first method.[1] A detailed investigation of the latter showed[18,21] that its recrystallisation from $CHCl_3$ or any other organic solvent gives complexes with the composition $Pd_2(DBA)_3.Solv$, where Solv represents a molecule of the solvent used. A very convenient method for preparing $Pd(DBA)_2$

¶TBAA, PhCH=CHCOC(COCH=CHPh)=CHPh, (m.p. 112 to 113 °C) has an *s-cis,s-trans* conformation according to i.r., u.v., and n.m.r. spectroscopic data.[39]

is the addition of palladium chloride to a hot (~50 °C) methanol solution of a mixture of DBA and AcONa (Pd/DBA/AcONa ratios = 6/20/50).[18] Ater the reaction mixture has been stirred at 40 °C for 4 h a reddish purple precipitate with m.p. 135 °C and the composition $Pd(DBA)_2$ is formed. This is evidently the complex the authors of Refs.1 and 2 were dealing with. Dissolving it in hot chloroform gives a dark violet solution from which purple acicular crystals with m.p. 122–124 °C and the composition $Pd_2(DBA)_3.CHCl_3$ are deposited when ether is added. If $Pd(DBA)_2$ is dissolved in benzene, toluene, or dichloromethane, the corresponding solvates $Pd_2(DBA)_3$.Solv, where Solv = C_6H_6, C_6H_5Me, or CH_2Cl_2, crystallise out.[28] It is interesting that the complexes formed by *p,p'*-dimethoxydibenzylideneacetone[18,21] and *p,p'*-di-isopropyldibenzylideneacetone[25] contain no solvent molecules but have the composition Pd_2L_3, where L is the corresponding DB derivative. Interconversion of the $Pd_2(DBA)_3$.Solv complexes occurs on recrystallisation from the appropriate solvent.[18] However, in the preparation of $Pd_2(DBA)_3$.Solv the use of chloroform is recommended[28] because recrystallisation from this solvent gives the maximum product yield (~80%). The palladium complex with *p,p'*-di-isopropyldibenzylideneacetone mentioned above was obtained by dissolving the PdL_2 initially formed in THF and then adding methanol. It is interesting that in the preparation of tris(di-isopropyldibenzylideneacetone)dipalladium[36] the reagents were mixed in the "reverse" order: anhydrous sodium acetate was added to a hot mixture of DBA and Na_2PdCl_4 in methanol; the yield of the final product was 75%.

TBAA reacts with $PdCl_2$ and AcONa under the conditions described above[18] to form, after recrystallisation from $CHCl_3$, the purple acicular complex $Pd_3(TBAA)_3.CHCl_3$ in an 84% yield.[39] As with DBA, the precipitate formed initially gives the corresponding solvate $Pd_3(TBAA)_3$.Solv on crystallisation from $CHCl_3$, CH_2Cl_2, or benzene. Unfortunately the composition of the initial precipitate was not determined. Like the $Pd_2(DBA)_3$.Solv complexes, the TBAA complexes can be interconverted on recrystallisation from the appropriate solvent.† When the reaction of $PdCl_2$ with TBAA is carried out in cyclohexanol instead of methanol, the cyclohexanol is oxidised to cyclohexanone in an 81% yield calculated on the basis of the palladium chloride used in the reaction.[39]

Another palladium complex with DBA, mononuclear tris(dibenzylideneacetone)palladium, is also known. $Pd(DBA)_3$ can be obtained in two ways: by adding a four-fold excess of DBA to a benzene solution of $Pd_2(DBA)_3.C_6H_6$ [38] or by the reaction of Na_2PdCl_4 with DBA in aqueous alcohol in the absence of sodium acetate.[37] In the first case a mixture of the complex $Pd(DBA)_3$ with free DBA is formed. Chemical analysis of the complex indicates the presence of one molecule of benzene to each molecule of the compound. $Pd(DBA)_3.C_6H_6$ dissociates readily in solution, giving $Pd(DBA)_2$. Thus, taking account of the results from Ref.28, we may conclude that there is a series of DBA complexes of palladium in equilibrium with each other:

$$Pd_2(DBA)_3 \overset{DBA}{\rightleftharpoons} Pd(DBA)_2 \overset{DBA}{\rightleftharpoons} Pd(DBA)_3.$$

A similar mononuclear tris(dibenzylideneacetone)platinum complex has been obtained.[2] It is prepared by boiling K_2PtCl_4 with a three-fold excess of DBA in methanol in the presence of sodium acetate. Air or oxygen must be present but its role is not clear; chemical anlaysis shows that the product contains no "extra" oxygen. Maitlis et al.[36] mention that $Pt(DBA)_2$ is formed by the reaction of K_2PtCl_4 with DBA in the absence of oxygen; however, in later work[37] these authors, referring to methods for preparing $Pt(DBA)_n$ (n = 2, 3), do not mention anything about the determining effect of oxygen or air. A comparison of methods for preparing $Pt(DBA)_2$ and $Pt(DBA)_3$ shows that the latter is formed in a more prolonged reaction (4 h as against 10 min) and at higher DBA/Pt and AcONa/Pt ratios (17/1.2 and 30/1.2 respectively, as against 10/3.6 and 35/3.6). Furthermore $Pt(DBA)_3$ is formed at 40 °C but $Pt(DBA)_2$ in boiling ethanol (~80 °C). The two complexes are very different in colour: $Pt(DBA)_2$ is purplish black and $Pt(DBA)_3$ is canary yellow. The tris-complex dissociates completely to $Pt(DBA)_2$ and free DBA when dissolved in organic solvents;[2] this is indicated by cryoscopic determinations of the molecular weight in benzene. $Pt(DBA)_2$ forms the solvates $Pt_2(DBA)_3$.Solv when it is dissolved in such solvents as C_6H_6, $CHCl_3$, toluene, etc.[19] These results have been confirmed for the platinum complex with *p,p'*-di-isopropyldibenzylideneacetone.[36] The addition of an aqueous solution of K_2PtCl_4 to a boiling solution of NaOAc and *p,p'*-di-isopropyldibenzylideneacetone in ethanol (K_2PtCl_4/NaOAc/di-isopropyl-DBA ratios = 7.2/73.0/15.7) followed by boiling for 1 h gave a black complex of composition PtL_2, where L = *p,p'*-di-isopropyldibenzylideneacetone, which in THF forms a dark purple solution. After evaporation of the solution and the addition of methanol violet-black crystals of composition Pt_2L_3 slowly crystallised out. The complex obtained in Ref.16 is evidently the solvate $Pt_2(DBA)_3.CH_2Cl_2$ and not $Pt(DBA)_2$,[19] because it was produced by crystallising the crude $Pt(DBA)_2$ from dichloromethane. In the same work[16] the mixed complexes $L_2Pt(DBA)$ (L = PPh_3) were obtained by the reaction of L_4Pt with DBA in toluene; this is another example of the preparation of DBA complexes by ligand substitution. Triphenylphosphine is easily displaced from $Pt(PPh_3)_4$ by other α,β-unsaturated olefins;[16] the complexes $(Ph_3P)_2PtL'$, where L' is 4-phenylbut-3-en-2-one or 1,3-diphenylprop-2-en-1-one, were obtained in this way. The spectroscopic properties of these complexes are similar to those of the DBA complexes. It is interesting, in connection with this, that 4-phenylbut-3-en-2-one (benzylideneacetone) forms complexes with Fe^0 which have an η^2-olefinic or η^{1-4} heterodiene structure[17,40–47] depending on the nature of the other ligands bonded to the iron atom. The formation of η^2-olefinic complexes has also been observed in the reaction of 4-methyl-pent-3-en-2-one with the Pt^{II} derivatives K_2PtCl_4 and $(C_2H_4)_2Pt_2Cl_4$;[48,49] with Pd^{II} π-allylic complexes are formed.[50,51]

Thus the DBA complexes with palladium and platinum which were originally thought to have the composition $M(DBA)_2$ in fact have the more complex structure $M_2(DBA)_3$.Solv; another type of DBA complex, $M(DBA)_3$, is also known for palladium and platinum. Finally, there are reports of DBA complexes of rhodium[25] and uranium[22] containing respectively one and two molecules of the ligand per metal atom. The rhodium derivative $Me_5C_5Rh(DBA)$ was obtained[25] by the reaction of di-μ-chloro-bis(pentamethylcyclopentadienylrhodium) with DBA in alcohol in the presence of Na_2CO_3, i.e. by the usual method of preparing DBA complexes of transition metals. The uranium complex $UO_2Cl_2(DBA)_2$ was isolated in the photodimerisation of DBA in the presence of UO_2Cl_2.[22] It has long been known that DBA is dimerised to 1,3-diphenyl-2,4-dicinnamoylcyclobutane by UO_2Cl_2 [52] and $SnCl_4$ [53] whereas photodimerisation in the absence of metal salts gives 1,2-diphenyl-3,4-dicinnamoylcyclobutane.[54] The reaction of DBA with metal salts has also been mentioned elsewhere.[55–59] For

†Hence the scheme given in Ref.18 is also valid for TBAA complexes.

example, under the action of alkali metal alkoxides the semicarbazone of *trans,trans*-DBA cyclises to *cis*- and *trans*-1,2-diphenylcyclopent-3-enes.[55] Five-membered alicyclic compounds are formed by the reaction of DBA with Os^{IV} salts in the presence of Zn dust;[56] reductive dimerisation gives 1-styryl-2-cinnamoyl-3,4-diphenylcyclopentanol in a quantitative yield. Electrochemical reduction of DBA or the action of such reducing agents as Mg and Zn amalgams also lead to reductive dimerisation but the yield of the cyclopentanol mentioned above is very small.[57-59] Similar reductive dimerisation reactions occur in the $Os^{IV}-Zn$ system with other α,β-unsaturated ketones.[56]

V. CHEMICAL PROPERTIES OF DBA COMPLEXES OF TRANSITION METALS

Two types of reaction are characteristic for DBA complexes of transition metals: substitution of the ligands without changing the oxidation state of the central metal atom and oxidative addition which, as a rule, takes place with substituion of the DBA ligands. The reactivity of the palladium compounds has been studied most thoroughly because these compounds are readily available and stable. Note that the kinetic and thermodynamic stabilities of the DBA complexes of Pd and Pt are diametrically opposed. The DBA ligand is the most labile of the known π-ligands[60] because it is easily displaced even by such ligands as acetylenes; however, the thermodynamic stability of DBA complexes of transition metals is comparable with the stability of such strong complexes as the π-allylic complexes. For example, the dissociation energy of the Pt−DBA bond is 273 kJ mol^{-1} [61] which is greater than the corresponding energy of the Pd−π-allyl bond in bis-π-allylpalladium chloride (237 kJ mol^{-1}).

1. Ligand Substitution Reactions

Even in the earliest work on the chemistry of DBA complexes[1,2] the high tendency for coordinated DBA to be replaced by various ligands was noted. The strength of the reaction depends on the nature of the metal atom and the properties of the substituting ligand. A soft base such as triphenylphosphine reacts with tris(dibenzylideneacetone)dipalladium, replacing all the ligands and forming tetrakis(triphenylphosphine)palladium:[18,21] even a large excess of the harder base bipyridyl (bipy) replaces only two DBA molecules on reaction with $Pd_2(DBA)_3$ in acetone, forming the unstable complex (bipy)Pd(DBA).[18,21] Pyridine (py) and *o*-phenanthroline (phen) react similarly. Complete replacement of DBA from the platinum complex $Pt_2(DBA)_3$ occurs only on reaction with the stronger π-acceptor $AsPh_3$ (reagent ratio $AsPh_3$:$Pt_2(DBA)_3$ = 4);[18] reaction with an excess of R_3P (R = Me, Et, Ph) or a deficiency of $AsPh_3$ [$AsPh_3$: $Pt_2(DBA)_3$ = 2] gives the partially substituted products $L_2Pd(DBA)$ (L = PMe_3, PEt_3, PPh_3, $AsPh_3$).[16] These results indicate that the DBA complexes with platinum are more stable and also that the strength of the metal−DBA bond increases with the degree of substitution. This may be due to the stabilising effect of the *n*-donor ligands; however, the results of a thermogravimetric study[18,21] show that the stepwise detachment of DBA ligands from a palladium complex occurs even in the absence of other ligands.

From a practical point of view the reactions of DBA complexes with olefins are the most interesting because they are at present the only method for preparing olefinic π-complexes of Pd^0 of the type L_2Pd(olefin).[62]

(a) Reactions with olefins. $Pd_2(DBA)_3$ reacts with olefins without *n*-donor ligands being present but the olefinic complexes formed have not been isolated because they decompose to palladium metal and free DBA under the reaction conditions used (acetone, room temperature).[18,63,64] Stable (olefin)PdL_n complexes are formed if ligands such as bipy, phen, or $P(OR)_3$ are present in the reaction mixture together with the olefin.[18,63-65] The stability of the complexes formed is determined by both the nature of the olefin and the basicity of the ligand L. Only olefins with electron-accepting substituents form stable complexes; for stable complexes to be formed the lower the π-accepting ability of the olefin the greater must be the σ-donor properties of the ligands. A table showing the effect of the nature of the olefin and the ligand L on the stability of (olefin)PdL_n type complexes has been published.[18,64]

Table 4. Stability of the palladium olefin π-complexes (olefin)PdL_n.[66]

Olefin	*e*	L					
		bipy	phen	tmeda *	$P(OPh)_3$	$P(OMe)_3$	PPh_3
Maleic anhydride	2.25	++	++	++	++	++	–
Dimethyl fumarate	1.49	++	++	++	++	++	–
Divinylsulphone	1.33	++	+	+	+	+	–
Dimethyl maleate	1.27	++	++	+	–	–	–
Acrylonitrile	1.20	++	++	–	–	–	–

Note. ++) complex stable and can be isolated; +) a complex is formed but decomposes during isolation; –) no complex formed.

*tmeda = tetramethylethylenediamine.

The *e* values given in Table 4 are taken from Ref.66; they characterise the electronic properties of a grouping bonded to a vinyl radical. $e < 0$ for electron-donating, and $e > 0$ for electron-accepting substituents. Syrene (substituent = phenyl), for which $e = -1$, is used as a standard.

Stable complexes are formed only with olefins which have $e \geqslant 1.20$. Olefins with $e < 1.20$ [butyl acrylate (1.06), methacrylonitrile (0.81), acrylic acid (0.77), methyl vinyl ketone (0.68), and ethyl acrylate (0.22)] do not give stable olefinic complexes even when L = bipy; in all cases (bipy)Pd(DBA) compounds are formed. It also follows from Table 4 that stable complexes are formed with such good σ-donating and weak π-accepting ligands as bipy and phen; less powerful σ-donors, e.g. tmeda and $P(OR)_3$, form complexes only with a very strong π-acceptor, such as maleic anhydride. The weak σ-donor PPh_3 does not form stable mixed complexes with any of the olefins listed in Table 4; in all cases $Pd(PPh_3)_n$ is formed.

The reactions of olefins with Pt-complexes of DBA are similar[16,66] but as platinum is more nucleophilic than palladium[67] stable olefinic complexes are formed even with phosphines and arsines. The following complexes have been obtained:[39] $(PPh_3)_2Pt$(olefin) (where olefin = 4-phenylbut-3-en-2-one or 1,3-diphenylprop-2-en-1-one), $(PEt_3)_2Pt(CF_2=CF_2)$, and $(AsPh_3)_2Pt(CCl_2=CCl_2)$. Similar complexes are formed in the reaction of $L_2Pt(DBA)$ with olefins.[39] DBA is thus displaced from its complexes by an olefin such as tetrachloroethylene which is capable of displacing stilbene and diphenylacetylene from $(PPh_3)_2Pt$(olefin) complexes.[68,69] In the

sequence indicating the ease of substitution of ligands[60] DBA is placed next to acetylenes:

$$C_2H_4 < C_2H_2 \approx DBA < (CN)_2C{=}C(CN)_2 < (CO \approx PPh_3) < < O_2NC_6H_4C{\equiv}CC_6H_4NO_2.$$

p-Quinones react with $Pd_2(DBA)_3$ in the presence of neutral ligands similarly to olefins, forming L_2Pd(quinone) type complexes,[28] which can also be obtained by reactions of PdL_4 with the corresponding quinones.[70] However, the preparation of π-quinone complexes of palladium via the DBA complexes is more advantageous and gives products with a higher degree of purity and greater yields.

The reaction of olefins with DBA complexes of palladium in the presence of neutral ligands thus gives previously known[67] Pd^0 derivatives; their stability is governed by the delicate electronic balance between the donor and acceptor properties of the neutral ligands and the olefins. Quite recently, by combining electron-donating and electron-accepting olefins, a group of Japanese authors[71,72] has prepared mixed olefinic complexes of Pd^0 by the reaction of $Pd_2(DBA)_3$ with an electron-accepting olefin in the presence of an excess of an electron-donating olefin or diene. The acceptor olefins used were maleic anhydride, dimethyl fumarate, and tetracyanoethylene, and the donor olefins were cyclo-octadiene, norbornadiene, norbornene, and cyclopentene.

New tri-coordinated complexes of Pd^0 have been obtained by this method. Up to the present only two purely olefinic π-complexes of Pd^0 are known: $(cod)_2Pd$, where cod = cyclo-octa-1,5-diene,[73–76] and $(CH_2{=}CH_2)_3Pd$;[73–75] the method for preparing mixed olefinic derivatives proposed in Refs.71 and 72 offers further prospects for obtaining these practically important compounds. The stabilisation of Pd^0 by a combination of electron-donating and electron-accepting olefins evidently plays an important role in the palladium-catalysed cyclotrimerisation reactions between dimethyl acetylenedicarboxylate (an electron acceptor) and norbornadiene or norbornene (electron donors).[77]

(b) Reactions with acetylenes. Another very interesting aspect of the reactivity of DBA complexes of palladium and platinum is their reaction with acetylenes. The investigation of these reactions has provided many fundamentally important results which are of general significance for the chemistry of organometallic compounds of transition metals.

The ability of DBA complexes of palladium and platinum to react with alkynes has been mentioned in earlier work devoted mainly to the study of reactions with olefins.[16,20,39,64]

The reaction of $(PEt_3)_2Pt$(DBA) with hexafluorobutyne in toluene at room temperature over a period of 48 h gives a quantitative yield of the known complex $(PEt_3)_2Pt(CF_3C{\equiv}CCF_3)$.[16] The same product is formed by the reaction of $(DBA)_2Pt$ with an excess of hexafluorobutyne in the presence of triethylphosphine[18,20] or of tetrakis(triethylphosphine)platinum with $CF_3C{\equiv}CCF_3$.[75]

The reaction of acetylenes with DBA derivatives of palladium has been studied more thoroughly. The reaction of $Pd_2(DBA)_3$ with dimethyl acetylenedicarboxylate (dmad) in the absence of phosphorus-containing or any other stabilising ligands leads to the formation of a polymeric cyclopentadiene-palladium complex which was isolated and characterised by its ^1H n.m.r. spectrum.[64]

A similar metalladiene complex of platinum, platinacyclopenta-2,4-diene, is formed by the reaction of dmad with $Pt(DBA)_2$ or $Pt(DBA)_3$.[76] It was not isolated pure but was characterised by the ^1H n.m.r. spectrum and by conversion to the bis(triphenylphosphine) adduct $\{(PPh_3)_2Pt[C(COOMe)]_4\}_n$. These metallacyclopentadiene complexes are suggested to be intermediates in the cyclotrimerisation of acetylenes catalysed by Pd^0 and Pt^0 compounds.[76]

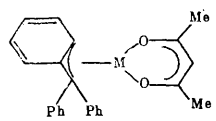
The results of the reaction of $Pd_2(DBA)_3$ with dmad in the presence of *n*-donor ligands depend to a considerable extent on the nature of the ligand used.[64,77] In the case of PPh_3 a bis(triphenylphosphine) complex of Pd^0 with dmad is formed initially; this complex reacts with a second dmad molecule to form palladiacyclopentadiene. $P(OPh)_3$ also reacts with $Pd_2(DBA)_3$ and dmad to give bis(triphenylphosphite)(dmad)palladium(0) in the initial stage but the latter complex is not converted to palladiacyclopentadiene on reaction with excess of the alkyne. However, treatment of the polymeric palladiacyclopentadiene with triphenyl phosphite gives bis(triphenylphosphite)palladiacyclopentadiene as expected. Bidentate *n*-donor ligands (bipy, phen, tmeda, dmg, bte, badn)† react with $Pd_2(DBA)_3$ in the presence of dmad, by-passing the π-acetylene complex stage, and forming the corresponding palladiacyclopentadiene straightaway. It is interesting in this regard that the reaction between bipy, $Pd_2(DBA)_3$, and maleic anhydride takes place with intermediate formation of a π-olefinic complex which is later converted to palladiacyclopentadiene. The stability of the intermediate π-acetylene complex therefore depends on the nature of the *n*-donor ligand, as follows: bipy ≈ phen ≪ PPh_3 < $P(OPh)_3$. In this sequence from left to right there is a marked increase in the π-accepting ability of the ligands which will stabilise the π-acetylenic derivatives of Pd^0.[78]

The palladium complex of TBAA referred to previously reacts with dmad in the presence of bipy to form the bipyridyl complex of palladiacyclopentadiene.[39]

(c) Preparation of enyl type complexes. The ability of DBA derivatives of Pd to form π-allyl complexes by oxidative addition of allyl substrates, which was mentioned in the early work of Japanese authors,[1] is a characteristic property of Pd^0 compounds. μ-Bridging bis-π-allylpalladium halides or cationic π-allyl complexes can be obtained depending on the way the reaction is carried out. For example, the reaction of $Pd_2(DBA)_3$ with methylallyl chloride in benzene gives di-μ-chloro-bis(π-methylallylpalladium);[1] allyl bromide, allyl chloride, but-2-enyl chloride, and cinnamyl chloride react similarly. The rate of oxidative addition varies in the order:[64]

$$C_3H_5Br > C_3H_5Cl > 2\text{-}C_4H_7Cl > 1\text{-}C_4H_7Cl > 3\text{-}PhC_3H_4Cl.$$

For example, the reaction with allyl chloride takes 5 min but with cinnamyl chloride 30 min are required.

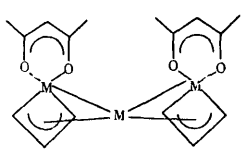


If the complex (bipy)Pd(DBA) is used in the reaction with the allyl halides or $Pd(DBA)_2$ is used in the presence of bipy, then cationic π-allyl complexes of palladium are formed.[64] The reactions of the allyl halides with the complex $(TBAA)_3Pd_3.CHCl_3$ are similar.[39] However, all these reactions are of no practical interest for the preparation of π-allyl complexes of palladium. Unfortunately π-allyl halide compounds of platinum, which are difficult to obtain, cannot be produced by this method. The reaction of DBA complexes of Pt with allyl halides takes place in the presence of donor ligands and gives cationic π-allyl compounds of platinum which are of little interest from a practical point of view.

Allyloxyphosphonium and allylisothiouronium salts react with $Pd_2(DBA)_3$ in a similar way to the allyl halides; in the presence of donor ligands cationic π-allyl complexes of palladium are formed in high yields.[79]

‡dmg = dimethylglyoxime, bte = 1,2-bis(methylthio)ethane, and badn = biacetyldianil.

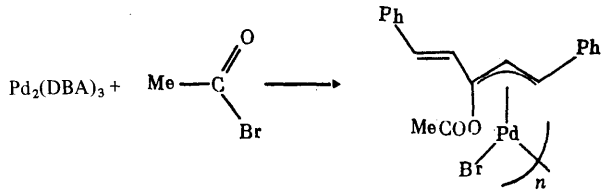
In all the work quoted above in this section[1,39,64,79] the π-allyl complexes are formed from compounds which already contain an allylic system (allyl halides, allyloxyamidophosphonates, allylisothiouronium salts, etc.), so that the production of π-allylic compounds is not unexpected. On the contrary, in view of the clear tendency of palladium to form π-allylic type complexes,[80] the isolation of π-allylic derivatives from these reactions is a normal result.



From this point of view the series of papers on the reaction of DBA complexes of palladium and platinum with triphenylmethyl chloride[81-83] and triarylcyclopropenylium bromide[84-86] form a clear contrast. Although the benzyl group is known to be capable of η^3-type bonding with a transition metal atom,[87-92] the formation of a π-allylic ligand from triphenylmethyl precursors has not been established with a sufficient degree of certainty.[93] Complexes of the $\{M[CPh_2(C_6H_4X)]Cl\}_n$ (M = Pd, Pt; X = H, F, OMe) type have been obtained by the reaction of dibenzylideneacetone derivatives of palladium or platinum with substituted triphenylchloromethanes.[82] For these compounds a dimeric structure with a Pd_2Cl_2 bridging fragment was proposed on the basis of the far infrared spectra [ν(M−Cl) = 288 cm^{-1}] and molecular weight determination. X-Ray structure determinations on acetylacetonate derivatives[83] showed that the Pd and Pt compounds are isostructural and there is η^3-coordination of the CPh_3-ligand with the metal atom, i.e. the structure of the complex in the crystalline state is:

M = Pd, Pt

The importance of this work[81-83] is that the results obtained enable the structure of similar nickel complexes, which were prepared as long ago as 1966,[93] to be described correctly.

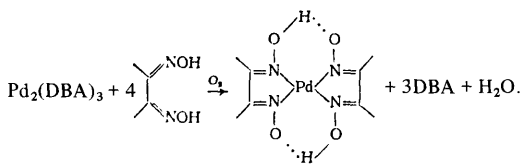


Interesting structure types of η^3-complexes have been reported.[84-86] The reaction of DBA complexes of palladium and platinum with phenyl-substituted cyclopropenylium bromides gives sparingly soluble complexes of the $[M_3(C_3R^1R^2_2)_2Br]$ type which undergo reactions that are typical of complexes with bridging M_2Cl_2 fragments.[86] An X-ray structure determination was carried out on $Pd_3[C_3Ph(p\text{-}MeOC_6H_4)_2]_2(acac)_2$. The structure[85] can be described as two palladiacyclobutenyl "units" $\{(acac)Pd(C_3R^1R^2_2)\}$, with η^3-type bonding of each of them to a third palladium atom:

M = Pd

Thus during the reaction a C−C bond in the cyclopropenyl ring has been broken; in the unsymmetrically substituted phenyldi-(4-methoxyphenyl)cyclopropenylium bromide it is predominantly the $MeOC_6H_4C-CC_6H_4OMe$ bond that is broken.

Another unusual η^3-complex has been obtained by the reaction of $Pd_2(DBA)_3$ with acetyl bromide:[94]



Treatment of this complex with aqueous NaOH regenerates the original $Pd_2(DBA)_3$, reactions with thallium β-diketonates or cyclo-octa-1,5-diene in the presence of $AgPF_6$ lead to cleavage of the μ-bromide bridges and formation of monomeric [(PhCH=CHC(OCOMe)C_2H_2Ph)Pd(acac)] or {[PhCH=CHC(OCOMe).C_2H_2Ph]Pd(cod)]PF_6.

The formation of a π-allylic ligand can be represented as attack by $MeCO^+$ on the oxygen atom of the carbonyl group in DBA; a similar process—the formation of allylic complexes of iron by the reaction of $MeCO^+BF_4^-$ with $Fe[RCH=CHC(O)R^1](CO)_4$—has been reported.[95]

2. Other Reactions of DBA Complexes of Palladium and Platinum

Some of the reactions discussed in this section have been mentioned previously. For example, the total replacement of DBA by phosphines,[16,28] and partial substitution by bipyridyl and phenanthroline[18,21] and also by phosphines and arsines.[16] Below we shall consider reactions of DBA derivatives, mainly those of palladium, which also take place with total or partial replacement of the DBA and lead to the formation of various palladium complexes which are, in a number of instances, difficult or impossible to prepare by other methods. A common feature of the reactions discussed below is oxidation of the metal atom (particularly palladium to form Pd^{II} derivatives), i.e. these processes are essentially reactions in which there is oxidative addition to a complex of palladium in a low-valent state. However, the special properties of DBA complexes lead, in this instance, to unexpected results. For example, the oxidation of triphenylphosphine complexes of zerovalent nickel, palladium, and platinum by oxygen is known to give peroxo-deriva-tives of these metals.[96] The dibenzylideneacetone derivative of palladium does not form peroxo-complexes under these conditions; the oxidation of $Pd_2(DBA)_3$ by oxygen in the presence of bipy gives (bipyridyl)dihydroxopalladium[18,64] and formaldehyde. The forma-tion of formaldehyde in this reaction presupposes the intermediate formation of (bipyridyl)peroxopalladium which is reduced by methanol to the dihydroxo-complex. It is interesting that oxidation of (bipy)Pd(DBA) by the action of 7% H_2O_2 in methanol also gives (bipyridyl)dihydroxopalladium.[64]

The oxidation of $Pd_2(DBA)_3$ by oxygen in the presence of dimethylglyoxime takes place quite differently:[18,64]

All the oxygen is quantitatively used in converting the oxime hydrogen to water; similar reactions are observed with acetylacetone and 8-quinolinol.[64]

In the reaction of (L−L)Pd(DBA), where L−L = bipy or phen, with aroyl- or tosyl azides the DBA ligand is displaced and amide derivatives of palladium(II) are formed:[97]

R=4-MeC_6H_4CO, X=N_3, L—L=bipy;
R=Ts, X=NHTs, L—L=bipy;
R=Ts, X=NHTs, L—L=phen.

(L—L)Pd$(N_3)_2$ type complexes, which were identified by i.r. spectroscopy, are formed as by-products. If the reaction is carried out in methanol instead of ethanol the amount of by-product increases.

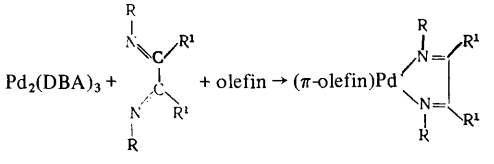
Benzoyl isocyanate reacts with (bipy)Pd(DBA) by a completely different route, forming a metallaoxazoline ring by 1,4-addition of Pd^0 to the heterodiene system:[98]



A similar palladiathiazoline complex is formed by the reaction of (bipy)Pd(DBA) with thiobenzoyl isocyanate.[98] The same compound is obtained in a quantitative yield by the reaction of (bipy)Pd(DBA) with 2-phenylthiazoline-4,5-dione.[98] During the reaction CO is liberated vigorously; it is assumed[98] that a palladiathiazine derivative is formed initially and this is converted to the palladiathiazoline complex with elimination of carbon monoxide. However, under the same conditions the biacetylanil derivative of dibenzylideneacetonepalladium reacts with phenylthiazoline-4,5-dione without elimination of CO, giving a 76% yield of the palladiathiazoline complex. This complex does not eliminate CO even on heating.

The use of dibenzylideneacetone complexes to obtain various σ-derivatives of palladium and platinum is described in a series of papers.[100–106]§ σ-phenyl complexes of palladium with sterically hindered phenoxy groups have been synthesised by the Reutov–Sokolov method (see Ref.108); the preparation of σ-palladiated complexes by using $Pd(DBA)_3$ has been reported.[109–115]

In all the reactions listed above in this section there is oxidative addition of the various substrates to Pd^0 with formation of Pd^{II} derivatives. There are two reports in which DBA compounds of Pd^0 react either without a change in the formal oxidation state of the palladium[114] or with the formation of formally univalent palladium derivatives.[115]

In Ref.114 complexes of palladium with 1,4-diazabutadienes were obtained starting from $Pd_2(DBA)_3$, $Pd_3(TBAA)_3$, and $Pd_3(TTAA)_3$ (TTAA = tritoluylideneacetylacetone) which was synthesised by the authors. However, the anticipated (1,4-diazabutadiene)Pd(DBA) type complexes could not be isolated because they are too unstable. In the opinion of these authors[114] the reason for the instability of such compounds is the imbalance between the electron-donating and electron-accepting properties of 1,4-diazabutadiene and DBA. Whereas the former is a strong σ-donor, the π-accepting properties of DBA are clearly insufficient to reduce the electron density on the metal atom. To stabilise the complexes it is necessary to use either less basic diazabutadienes or ligands which are better π-acceptors than dibenzylideneacetone. Hence the principles governing the choice of ligand will be approximately the same as in the preparation of π-olefinic complexes of Pd^0 starting from $Pd_2(DBA)_3$ (see above). In fact, the introduction of strongly electron-accepting substituents into the 1,4-diphenyldiazabutadiene molecule led to the formation of a stable Pd^0 compound. On the other hand, the use of electron-accepting olefins [tetracyanoethylene (TCNE), maleic anhydride (MA), dimethyl fumarate (DMF), and diethyl fumarate (DEF)] as co-reagents enables olefin-diazabutadiene complexes of Pd^0 with more basic diazabutadienes to be obtained:

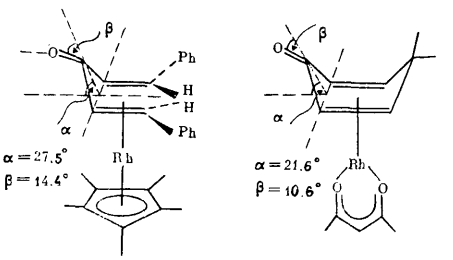
R = Bu^t, R^1 = H, olefin = TCNE; R = Bu^t, R^1 = H, olefin = MA; R = Pr^i, R^1 = H, olefin = MA; R = cyclo-C_6H_{11}, R^1 = H, olefin = MA; R = cyclo-C_3H_5, R^1 = Me, olefin = DMF; R = 4-$MeOC_6H_4$, R^1 = H, olefin = DMF; R = 4-$MeOC_6H_4$, R^1 = H, olefin = DEF; R = Bu^t, R^1 = H, olefin = DMF; R = Bu^t, R^1 = H, olefin = DEF; R = Pr^i_2CH, R^1 = H, olefin = DMF.

§For more detail see the review in Ref.107.

A comparison of these results with those in Table 4 shows that all the diazabutadienes used have σ-donor properties which surpass those of such strong σ-donors as trimethyl and triphenyl phosphite and resemble those of tetramethylethylenediamine.

The reaction of $Pd_2(DBA)_3$ with an excess of MeNC gives solutions which are stable in the absence of air and which react with iodine to give the Pd^{II} derivative $(MeNC)_2PdI_2$. The $Pd_2(DBA)_3$/MeNC system is concluded to be a synthetic equivalent of $Pd(MeNC)_x$ species. The reaction of $Pd_2(DBA)_3$ and methyl isocyanide with $[(MeNC)_4Pd](PF_6)_2$ gives dimeric Pd^I complexes in a good yield.[115]

Similar dimers containing Pd–Pd, Pd–Pt, and Pd–Mn bonds have been obtained.[116,117]



VI. USE OF DBA COMPLEXES OF THE PLATINUM METALS AS HOMOGENEOUS CATALYSTS

DBA complexes, particularly those of palladium, have recently been intensively studied as catalysts of very varied reactions. An attempt to classify this work is made in Table 5.

It appears from the examples given in this table that catalysis by DBA complexes of palladium in essence differs little from catalysis by other Pd^0 complexes[160,161] but the use of DBA catalysts is to be preferred because of their easy accessibility and the simplicity of working with them.

---o0o---

The bulk of the work on the chemistry of DBA complexes of transition metals and determination of their structures was carried out in the period 1971–1974 and subsequent publications relate mainly to their use as reagents, catalysts, etc. DBA derivatives of palladium and platinum are now firmly established in preparative organometallic chemistry as highly reactive starting materials suitable for the synthesis of the most diverse classes of organo-Pd and organo-Pt compounds. However, the DBA molecule may be of interest in organometallic chemistry not only as an olefinic or dienone ligand as such but also as a model structural fragment in a number of more complex organic molecules of other classes. For example, metal complexes with semi-quinonoid π-ligands can be regarded[162] as unusual "closed" analogues of DBA complexes like $(DBA)RhC_5Me_5$,[26] as follows:

The validity of this analogy is confirmed by the considerable similarity observed in the angles α and β, which characterise the conformational changes in the dienone system resulting from π-coordination of the double bonds to the transition metal atom.[162]
